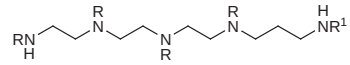
Novel cholesterol-polyamine carbamates have been prepared and their pK_as determined potentiometrically for conjugates substituted with up to five amino functional groups and the binding affinity for calf thymus DNA has also been determined; these polyamine carbamates are models for lipoplex formation with respect to gene delivery (lipofection), a key first step in gene therapy.

Polyamines such as tetra-amine spermine **1** are widely distributed in nature and display a variety of important biological activities.[1,2] Polyamines affect DNA replication and translation, protein synthesis, membrane stabilization and the activity of certain kinases and topoisomerases. Stabilization of specific DNA conformations and charge neutralisation of intracellular polyanions (*e.g.* DNA and RNA) may be among the most important physiological roles of polyamines. Their binding has a profound effect on DNA structure, causing transitions from B to both A and Z forms, and at higher concentrations conformational changes, *e.g.* aggregation and condensation.[2,3] Condensation is caused by alleviation of charge repulsion between neighbouring phosphates on the DNA helix allowing collapse into a more compact structure.[3] Polyamine mediated condensation is a rapidly expanding area of research for non-viral vectors in gene therapy (lipoplexes in lipofection).[4]

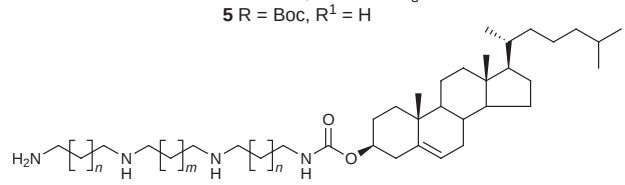
The application of synthetic lipo-polyamines constitutes a safer and more efficient gene transfer strategy which, unlike the use of viral vectors, does not elicit immune responses.[5] Within the prerequisites for delivery of DNA across an intact cytoplasmic membrane are condensation and masking the negative charge of the phosphate backbone; polyammonium ions are therefore suitable for use as gene delivery systems.[6,7] Covalent attachment of a lipid moiety,[8] such as an aliphatic chain[2,7,9] or a steroid,[6,10,11] further enhances polyamine-mediated DNA condensation.[12] The mechanism by which these compounds cause lipofection is poorly understood. Knowledge about the pK_as, especially accurate prediction along a polyamine (polyammonium) chain, will allow protonation states at physiological pH to be determined and therefore DNA binding affinities can be predicted with greater confidence. Such physicochemical properties are important in the design of lipoplexes for efficient lipofection.

Herein we report the design and synthesis of polyamine carbamates of cholesterol (at position 3), using our orthogonal protection stragegy for efficient syntheses of unsymmetrical polyamine amides.[13] Six compounds have been made using polyamines: 1,12-diamino-4,9-diazadodecane **1** (spermine, 3.4.3), 1,11-diamino-4,8-diazaundecane (thermine, norspermine, 3.3.3), 1,10-diamino-4,7-diazadecane (3.2.3), 1,9-diamino-3,7-diazanonane (2.3.2), tetraethylenepentamine **2** (2.2.2.2) and pentaethylenehexamine (2.2.2.2.2) affording **6**–**11** respectively. Our protocol for the synthesis of carbamate **10** is outlined.‡ The pK_a values of these compounds were then measured using a Sirius PCA101 automated pK_a titrator, in 0.15 M KCl ionic strength adjusted water; values obtained for spermine (3.4.3) **1** are comparable with literature values determined both potentiometrically and spectroscopically.[14–16]

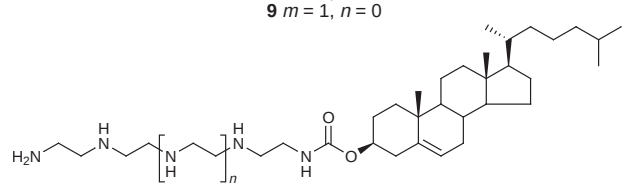
Spermine (3.4.3) **1**



2 R = H, R^1 = H
3 R = H, R^1 = $COCF_3$
4 R = Boc, R^1 = $COCF_3$
5 R = Boc, R^1 = H



6 *m* = 2, *n* = 1
7 *m* = 1, *n* = 1
8 *m* = 0, *n* = 1
9 *m* = 1, *n* = 0



10 *n* = 1
11 *n* = 2

The DNA binding affinities for this series of polyamine conjugates **6**–**11** were determined using calf thymus DNA (6 μg, [DNA base-pair] = 3.0 μM),§ and a fluorescence quenching assay based upon exclusion of ethidium bromide which is effectively present in excess (1.3 μM).[11,12] The binding affinities are critically compared as both the charge ratio[4] and concentration at which 50% of the ethidium bromide fluorescence was quenched (in 20 mM NaCl, see Table 1). These data give support to our hypothesis that binding is a function of charge and that the regiochemical distribution of such charges is also significant for DNA affinity; conjugates 3.4.3 **6**, 3.3.3 **7**, 3.2.3 **8** and 2.3.2 **9** show this trend. Likewise, polyethylene imine conjugates **10** and **11** were (respectively) weaker with only 2.0 charges at pH 7.4 and stronger wtih 2.3 charges distributed along the polyamine. Carbamates **7** and **11** have comparable pK_as across the first three protonation sites, but their structural differences are reflected in their DNA binding affinities (Table 1). These subtle differences in DNA condensation as a function of charge distribution are clearly important for lipoplex formation when compared with the higher charge on unconjugated spermine (3.8 at pH 7.4).

In a recent, comprehensive paper on the role of charge in polyamine analogue recognition, Bergeron *et al.* demonstrated that small structural alterations resulted in substantial differences in biological activities.[15] pK_as are a function of the interamine distance as well as their substituents. It is important to recognise that any charge is shared across several of the basic

Table 1 Polyamine pK_as and ethidium bromide exclusion data

[a] Net positive charge calculated from the Henderson–Hasselbach equation at pH 7.4. [b] Charge ratio[4] at which 50% exclusion of ethidium bromide is effected using calf thymus DNA at pH 7.4. [c] Concentration of polyamine conjugate at which 50% exclusion of ethidium bromide (1.3 μM) is effected using calf thymus DNA (3.0 μM) at pH 7.4.

centres and that it cannot be attributed to a single point. Even when the first charge is introduced principally on the primary amine, it is also distributed on to the secondary amines. This has been shown using unsymmetrical triamine, spermidine.[17]

The four methylene central spacer found in spermine **1** has also been shown to be important for binding affinity, confirming that both the number of positive charges and their distribution has a profound effect on the polyamine's ability to induce DNA conformational changes.[18] The measured pK_as for polyamines containing aminopropyl[16] and aminoethyl[10] units and Transfectam (DOGS)[7,19] add further weight to this hypothesis. These results will be of use in gene therapy studies and should find ready application in the design of lipoplexes with particular reference to spermidine and spermine class alkaloids. This evaluation of pK_a data, the number and regiochemical distribution of charges along the polyamine backbone, may lead to a clearer understanding of lipoplex modes of action.

We thank the EPSRC and Celltech Therapeutics Ltd, for a CASE studentship (to A. J. G.). We acknowledge some preliminary experimental work of Ms Dima Al-Hadithi (University of Bath) and useful discussions with Dr Ian S. Haworth (University of Southern California). I. S. B. and I. S. H. are recipients of a NATO grant (CRG 970290).

‡ An important first step is the ready purification of technical grade (~80%) 2.2.2.2-pentamine **2** by selective protection of one primary amino functional group by reaction with ethyl trifluoroacetate (1.0 equiv., MeOH, −78 °C for 1 h then to 0 °C over 1 h) to form trifluoroacetamide **3**. Immediately, in this solution, the remaining four amino functional groups were Boc protected with di-*tert*-butyl dicarbonate (5 equiv., 0–25 °C over 1 h then 14 h) to afford fully protected polyamine **4**. The trifluoroacetyl protecting group was then cleaved by increasing the pH to 11 with conc. aq. ammonia, stirring (25 °C, 15 h) to afford, after flash chromatography over silica gel (CH_2Cl_2–MeOH–conc. aq. NH_4OH 200 : 10 : 1 to 150 : 10 : 1 v/v/v), tetra-Boc protected polyamine **5** (19%). Reaction of the free primary amine of **5** with 3-cholesteryl chloroformate (1.2 equiv., 3.0 equiv. TEA, CH_2Cl_2, 0 °C for 10 min then to 25 °C for 12 h) afforded, after purification over silica gel (EtOAc–hexane 8 : 2 to 6 : 4 v/v) fully protected carbamate **10** (81%). Deprotection (CH_2Cl_2–TFA 10 : 90 v/v, 0 °C, 2 h) and purification by RP-HPLC over ABZ + Plus (5 μm, Supelcosil) (MeCN–0.1% aq. TFA 1 : 1 v/v, λ = 220 nm) afforded the polytrifluoroacetate salt of polyamine carbamate **10** (50%) HR-FABMS (+ve ion in *m*-NBA) [Found 602.5380 (M + 1). $C_{36}H_{68}N_5O_2$ requires 602.5380].

Chelation-assisted alkylation of benzylamine derivatives by Ru^0 catalyst

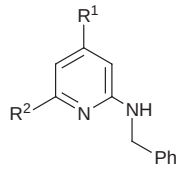
Chul-Ho Jun,*† Duck-Chul Hwang and Sang-Jin Na

Department of Chemistry, Yonsei University, Seoul 120-749, Korea

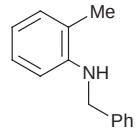
***N*-Benzyl-*N*-(3-methyl-2-pyridyl)amine 1 reacts with various alkenes *via* sp³ C–H bond cleavage by catalytic $Ru_3(CO)_{12}$ to give the corresponding alkylated products.**

C–H bond activation is currently of interest in organometallic chemistry.[1] In particular, its application to organic synthesis has been under intensive development in recent years.[2] One useful method by which to achieve C–H bond activation by transition metal complexes is cyclometallation utilizing nearby heteroatoms.[3] Stoichiometric cleavage of a C–H bond of a methyl group through cyclopalladation has been applied to functionalization of organic molecules.[4] Vinyl,[5] imine,[6] aldehyde[7] and aromatic groups[8] were catalytically alkylated through chelation-assisted C–H bond cleavage by a transition metal catalyst and subsequent cross coupling with an alkene. Many chelation-assisted alkylations are centered on the sp² C–H bond, and not on the sp³ C–H bond, probably due to the better thermodynamic stability of the metal–sp² carbon bond compared to that of the metal–sp³ carbon bond.[9] Here we report the catalytic addition of a benzylic sp³ C–H bond to an alkene to give alkylated products.

N-Benzyl-*N*-(3-methyl-2-pyridyl)amine **1** reacted with 500 mol% of hex-1-ene **2a** in toluene at 130 °C for 6 h under 10 mol% of $Ru_3(CO)_{12}$ **3** based on **1**. After the reaction, the corresponding alkylated product **4a** was isolated in 95% yield by column chromatography (Scheme 1). The reaction mechanism is shown in Scheme 2. The first step is likely to be the oxidative addition of a Ru^0 catalyst to the benzylic C–H bond in **1** to generate **5**, a stable 5-membered ring metallacycle complex. The coordination of **2a** to **5**, hydride-insertion into **2a** and the subsequent reductive elimination of the resulting metal–hexyl complex **7** produces **4a** with the regeneration of catalyst **3**. Alkylations of various amine substrates with **2a** were carried out. In this reaction, it was found that the geometrical structure of **1**, in which the methyl group is placed in the 3-position of the pyridyl group, is prerequisite. When **8–10**, in which the methyl

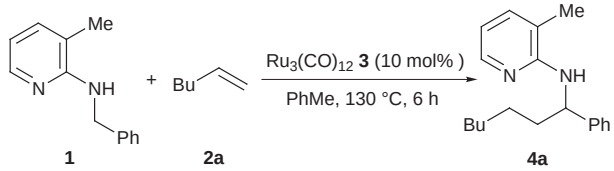


8 R^1 = Me, R^2 = H
9 R^1 = H, R^2 = Me
10 R^1 = R^2 = H



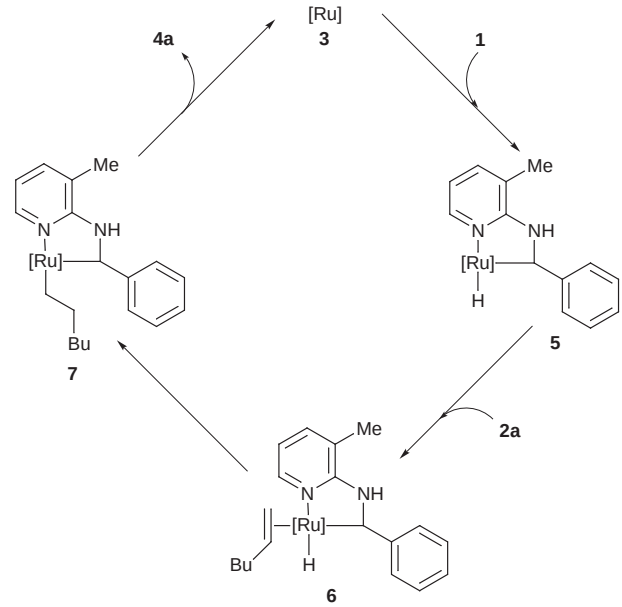
11

group is either placed in the 4- or 6-position or is replaced by hydrogen, trace amounts of alkylated products were obtained under identical reaction conditions (1–2% GC yield). These



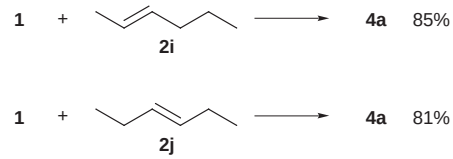
1 **2a** **4a**

Scheme 1



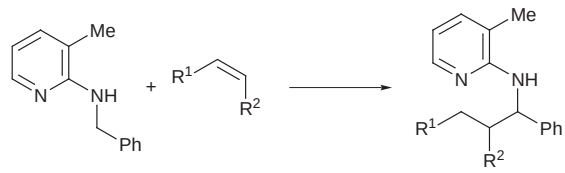
Scheme 2

results demonstrate that the 3-methyl group in **1** may retard the free rotation of the benzyl group around the amine group, and help the benzylic C–H bond to approach the Ru catalyst after the coordination of the nitrogen atom in the pyridyl group to the Ru catalyst. Also, precoordination of the metal complex is a very important requirement for cleaving the C–H bond since **11** bearing no coordination site gave no alkylated product and was fully recovered. The reactions between **1** and various alkenes were examined, and the results are shown in Table 1. For terminal olefins (entries 1–6), linear alkylated products were obtained. Sterically hindered alkenes such as **2c** and **2d** reacted with **1** to give the alkylated products **4c** and **4d** in a lower yield (72 and 75%) than unhindered alkenes such as **2a** and **2b**. Styrene **2e** was also formed in a low yield (70%) due to a side reaction, polymerization (entry 5). When internal olefins such as **2i** and **2j** were used, the linear alkylated product **4a** was isolated in 85 and 81% yield respectively (Scheme 3). No branched alkylated product was detected. The reason must be that the 2- or 3-hexyl–metal complex initially generated from hydride insertion into **2i** or **2j**, may isomerize to the 1-hexyl–metal complex due to the steric congestion of the secondary alkyl group. This type of isomerization has already been studied.[10] However, for cyclic alkenes such as **2g** and **2h**, the corresponding cycloalkyl compounds, **4g** and **4h,** were isolated in 70 and 60% yield, respectively. To examine the effect of phenyl substituents, competitive alkylation between benzyl-



Scheme 3

Table 1 Alkylation of **1** with various alkenes **2**[a] in the presence of **3**

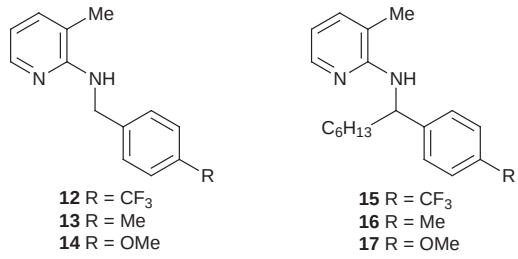


1 **2** **4**

Entry	Alkene	R^1	R^2	Product	Isolated yield (%)
1	**2a**	Bu	H	**4a**	95
2	**2b**	C_8H_{17}	H	**4b**	93
3	**2c**	Bu^t	H	**4c**	72
4	**2d**	Cyclohexyl	H	**4d**	75
5	**2e**	Ph	H	**4e**	70
6	**2f**	Bn	H	**4f**	85
7	**2g**	$-(CH_2)_3-$		**4g**	70
8	**2h**	$-(CH_2)_4$		**4h**	60

[a] 500 mol% based on **1**.

amines bearing electron-donating and electron-withdrawing groups was carried out. When a mixture of **12** and **13** was



12 R = CF_3
13 R = Me
14 R = OMe

15 R = CF_3
16 R = Me
17 R = OMe

allowed to react with **2a** under 20 mol% of catalyst **3** at 130 °C for 1.2 h, 39 and 70% yield of **15** and **16** (**15**:**16** = 1:1.8) were determined by GC, indicating that the electron-donating group activates benzylic C–H bond cleavage better than the electron-withdrawing group. For the competitive reaction of **12** and **14** with **2a**, a mixture of **15** and **17** was obtained in 26 and 60% yield (**15**:**17** = 1:2.3). The higher ratio of 1:2.3 for **15**:**17** compared with that of 1:1.8 for **15**:**16** can be rationalised by a more electron-donating substituent such as the methoxy group in **14** showing higher activity for C–H bond activation than the moderately electron-donating methyl group in **13**.

In conclusion, the sp^3 C–H bond of benzylamine bearing the 3-methyl-2-pyridyl group was readily alkylated with various alkenes *via* cyclometallation by a $Ru_3(CO)_{12}$ catalyst.

This research was supported by the Korean Science and Engineering Foundation (Grant No. 97-05-01-05-01-3). We also thank Mr Dae-Yon Lee for technical assistance.

Supercritical fluid extraction of surfactant template from MCM-41

Sibudjing Kawi*† and Man Wai Lai

Department of Chemical Engineering, National University of Singapore, Kent Ridge Crescent, Republic of Singapore 119260

Supercritical fluid extraction was used to extract and recover >90% of the surfactant template from the pores of as-synthesized pure siliceous MCM-41 and the MCM-41 after supercritical fluid extraction shows more uniform pore size distribution than the calcined MCM-41.

Since the discovery of the M41S family of mesoporous materials by Mobil scientists in 1992,[1,2] intensive research has been undertaken by various researchers on the synthesis mechanism and applications of these new materials. Current synthesis involves the use of liquid surfactant as the liquid-crystal templates and these templates are normally removed by calcination to yield the porous materials.

Removal of the template by calcination destroys the template which constitutes *ca.* 50 mass% of the as-synthesized material.[3] Recently, the use of liquid extraction to remove the templates has been reported.[4–6]

The present work describes a new and alternative method of recovering the surfactant templates from as-synthesized materials using supercritical fluid extraction (SFE). This should result in significant savings as the recovered templates can be reused in future synthesis. The MCM-41 materials and the extracted templates were shown to have retained their structures and properties after SFE. In addition, SFE may be used to remove surfactant templates at much lower temperatures from new mesoporous materials, which mesopores could easily collapse under high temperature calcination.

The pure siliceous MCM-41 material were synthesized using cetyltrimethylammonium hydroxide (CTMAOH) and fumed silica. A gel with a molar composition of 1 CTMAOH : 1.04 SiO_2 : 62.50 H_2O was prepared and loaded into polypropylene bottles. The gel was heated at 96 °C for 48 h after which the as-synthesized materials were washed by centrifugation and recovered by filtration. A small part of the as-synthesized sample was calcined in air at 550 °C for 15 h in order to serve as a comparison to samples that underwent SFE. SFE was performed on the remaining samples under different extraction conditions. Supercritical CO_2 modified with MeOH (which was used to increase the solvating power of the supercritical fluid) was used for extraction. The range of pressures and temperatures investigated in this study span from 150 to 350 bar and from 35 to 125 °C, respectively.

The SFE experiments were carried out using a Jasco SFE system consisting of a HPLC pump for carbon dioxide, a syringe pump for the modifier, a chiller for cooling the pump head, an oven for controlling the extraction temperature, an extraction vessel for holding the sample during extraction and a back pressure regulator for controlling the extraction pressure. Powder X-ray diffraction (XRD), which was performed using a Shimadzu XRD-6000 Spectrometer, and N_2 absorption and desorption, which was performed using Quantachrome Autosorb-1 at 77 K, were used to characterize the MCM-41 materials after calcination and after SFE. FTIR (Shimadzu DR-8001) and GC–MS (Hewlett Packard Model 6890) were used to identify the chemical structures and composition of the extracted surfactants. Using TGA (Shimadzu DTG-50), extraction efficiencies of the SFE process were determined by comparing the mass loss between the as-synthesized sample and the samples after SFE.

Table 1 shows the extraction efficiencies under different conditions. The results show that no surfactant template was extracted when pure CO_2 was used as the supercritical fluid since it does not have sufficient solvating strength at the typical working pressures to quantitatively extract surfactants that are quite polar.[7] However, by adding a small amount of methanol into the supercritical CO_2, substantial extraction of the template was achieved. In fact, the highest extraction efficiency (*i.e.* 93.2%) was achieved using a methanol flow rate of 0.2 ml min^{-1}. The addition of methanol as a modifier dramatically increases the bulk solubility of the analytes (extracted surfactants). The enhanced bulk solubility properties of the supercritical fluid cause a shift in the matrix/fluid distribution of the analyte, resulting in favorable partitioning to the supercritical fluid.[8] Using the methanol-modified supercritical CO_2 an increase in the extraction pressure increases the extraction efficiency due to the increase in the solvating power of the supercritical fluid.[9,10]

The results in Table 1 also indicate that there exists an optimum temperature for maximum extraction efficiency since the extraction efficiency achieved at 85 °C is much higher than that at 45 or 125 °C. It has also been shown that, by increasing the extraction temperatures, the energy barrier of desorption can be overcome, resulting in higher extraction efficiencies.[11,12] Hence, the extraction of the surfactant template from MCM-41 is facilitated by the higher temperature at 85 °C. However, at 125 °C, the increase in temperature results in a lower density of the supercritical fluid, thereby lowering the solvating power of the fluid and hence the extraction efficiency.

Fig. 1 shows the powder X-ray diffraction patterns of the calcined MCM-41 and the MCM-41 after SFE (with extraction efficiency of 93.2%). The results show that both the XRD patterns correspond well with those reported for pure siliceous MCM-41. The 2θ position for the MCM-41 after SFE is lower than that of the calcined MCM-41, indicating a larger unit cell size for the MCM-41 after SFE. In fact, the 2θ position for the MCM-41 after SFE is similar to the as-synthesized sample, indicating that pore contraction did not occur during the removal of the surfactant template by SFE. The narrower XRD pattern for the sample after SFE may also indicate that the sample after SFE possesses better crystallinity than the calcined

Table 1 Extraction efficiencies under various conditions for a CO_2 flow rate of 1 ml min^{-1} for 3 h[a]

Extraction temperature/°C	Extraction pressure/bar	Methanol flow rate/ ml min^{-1}	Extraction efficiency (%)
85	350	0.0	0.0
45	350	0.1	55.6
85	350	0.1	81.0
125	350	0.1	61.7
85	250	0.1	57.3
85	150	0.1	41.5
85	350	0.2	93.2

[a] Flow rate of CO_2 measured at the pump head cooled to −5 °C. Using Peng Robinson equation of state, the variation in the density of CO_2 at −5 °C between 150 and 350 bar is only 3%.

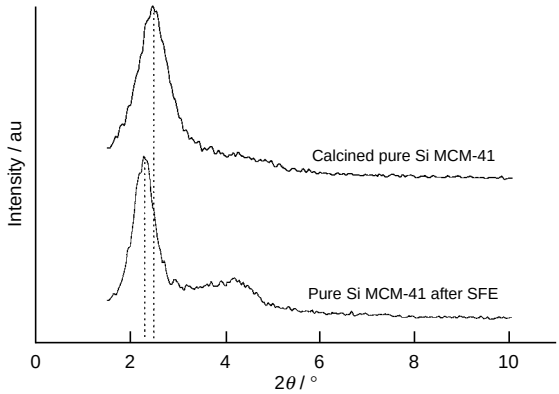

Fig. 1 X-Ray diffraction patterns of the calcined MCM-41 and MCM-41 after SFE

Table 2 Properties of as-synthesized, calcined and SFE samples

Sample	a_o/Å	Pore diameter, d_p/Å	A_{BET}/ $m^2\ g^{-1}$	Pore volume/ $cm^3\ g^{-1}$
As-synthesized	44.7	—	—	—
Calcined	41.5	26.4	1031	0.95
SFE	44.7	29.4	1007	1.08

sample. Assuming hexagonal symmetry, the unit cell sizes of the materials are calculated and tabulated in Table 2.

The N_2 isotherms (not shown) also show no hysteresis in both the calcined and SFE samples. The surface areas were calculated using BET analysis while the pore diameters were calculated from the desorption branch of the isotherms using BJH analysis. The results of these calculations are also collected in Table 2. The surface areas of both the calcined and SFE samples are comparable. In agreement with the XRD results, the pore size of the calcined sample is lower than the SFE sample, indicating again that SFE is able to remove the surfactant template without affecting the pore size and the pore structure of MCM-41. Also, the pore size distribution of the SFE sample is sharper than the calcined sample, indicating that the samples after SFE have slightly more uniform pores than the calcined samples.

GC–MS was performed to identify the constituents of the extracted surfactant and the MS results of the extracted surfactant were compared with the MS results of CTMAOH dissolved in methanol (used as a standard). Fig. 2 shows the MS results obtained and both Fig. 2(*a*) and (*b*) have peaks at the same *m*/*z* values, indicating that the extracted material is CTMAOH.

FTIR (results not shown) was also used to identify the extracted surfactant. The absorbance spectrum of the extracted organic template is similar to that of pure CTMAOH, indicating again that no changes to the structure of the CTMAOH were detected after SFE. The GC–MS and FTIR results show that as the chemical structure and composition of the extracted surfactant remain the same as those of the fresh surfactant, the

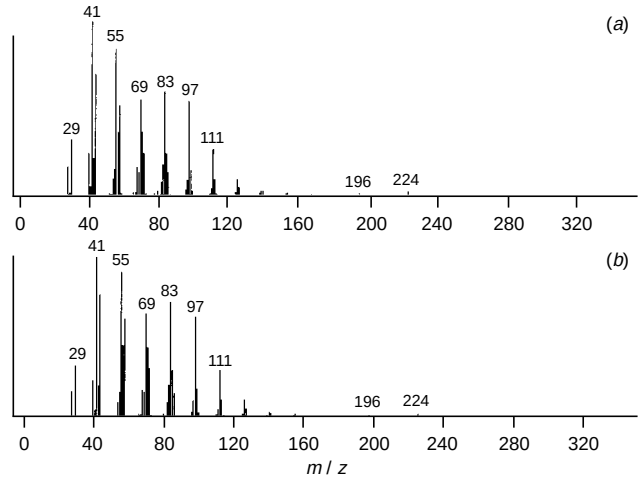

Fig. 2 The mass spectra of (*a*) a standard solution of methanol and CTMAOH and (*b*) extracted surfactant in methanol

extracted surfactant could be recycled and reused as a template in the synthesis of MCM-41 materials.

In conclusion, supercritical fluid extraction is effective in extracting the organic template from the pores of as-synthesized MCM-41. The MCM-41 materials after SFE retained their uniform pore size distribution and high surface areas and in fact have a larger pore size than the calcined MCM-41. The structure of the surfactant extracted by SFE was also unmodified and may be reused in the future synthesis of MCM-41.

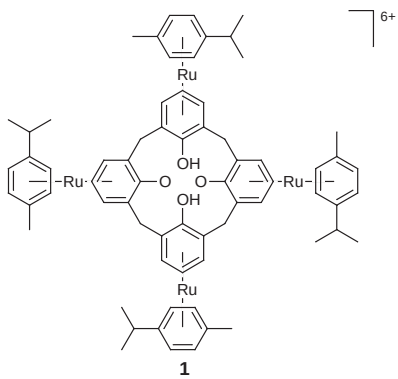
C–H··π hydrogen bonding *vs.* anion complexation in rhodium(I) complexes of cyclotriveratrylene

Kirsty S. B. Hancock and Jonathan W. Steed*†

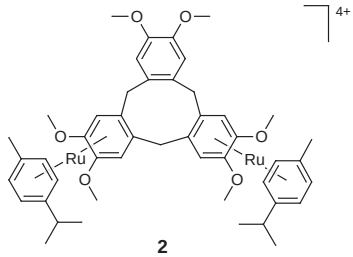
Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS

The bimetallic rhodium(I) complex [{Rh(nbd)}$_2$(CTV)][BF$_4$]$_2$ exists as an infinite self-included chain in the solid state with intracavity CH···π interactions linking the inclusion polymer together; the analogous monometallic complex co-crystallises with the dinuclear species as an inclusion compound with acetone as the guest.

In the past decade the topic of supramolecular anion complexation has received ever increasing attention as a consequence of the relatively challenging and hitherto unexplored nature of the field.[1–5] This culminated last year in the publication of the first book dealing solely with the area.[6] The key to the production of useful anion hosts for applications in areas such as environmental and biochemical sensors, and in bulk waste remediation is the selectivity of the host for a given anionic guest (*e.g. in vivo* sensing of Cl^- [3] or monitoring the environmental levels of nutrients such as phosphates and nitrate[2,6]). Our initial approach to this problem has been based upon a simple consideration of electrostatic attraction of the anion to the site of greatest positive charge density on a host mediated by the steric requirements of this cationic binding pocket. The host is thus selective for anions possessing the most complementary size and symmetry match to the host binding pocket since it is these anions which are able to make the closest approach to the host positive charge. This simple concept has been demonstrated by the synthesis of organometallic hosts **1**[7,8] and **2**[9,10] in which the calix[4]arene[11]



1



2

or cyclotriveratrylene (CTV)[12] cavities have been shown by X-ray crystallography to be occupied by tightly fitting anionic guests. In the case of host **1** the crystallographically demonstrated poor fit of I^- is borne out by ^{1}H NMR titration results in solution which give binding constants in aqueous solution decreasing in the order Cl^- > Br^- > I^-.[7] The selectivity of hosts such as **1** and **2** is reduced however, as a consequence of their multiply charged nature in as much as the host cavity is not the only site available for anion binding. Host **1** in particular binds up to five additional anions outside the host cavity. We now report preliminary results in a programme of research designed to reduce the overall host charge, in the anticipation of thus increasing host selectivity.

The synthesis of monocationic complexes of type '(arene)-Rh(diene)' [arene = benzene, xylenes, hexamethyl benzene *etc.*, diene = norbornadiene (nbd) or cyclooctadiene] was reported by Green and Kue in 1972[13] starting from the [Rh(diene)$_2$]$^+$ **3** cations. Complexes of type **3** are relatively tedious to prepare, however, and we accordingly adopted the simpler procedure of direct reaction of [{Rh(nbd)Cl}$_2$] **4**[14] with CTV in CH_2Cl_2–acetone in the presence of 2 equiv. of Ag[BF$_4$]. After removal of precipitated AgCl this resulted in a clear yellow solution from which the complexes [Rh(η^4-nbd)(η^6-CTV)][BF$_4$] **5** and [{Rh(η^4-nbd)}$_2$(η^6:η^6-CTV)][BF$_4$]$_2$ **6** were obtained upon evaporation of the bulk of the solvent. Compounds were characterised by FABMS and ^{1}H NMR spectroscopy.

Crystals suitable for X-ray crystallography were prepared by slow diffusion of diethyl ether into an acetone solution of complex **6** over a period of *ca.* three weeks. Surprisingly, during the course of the crystal growth, partial solvolysis of **6** to give **5** occurred such that a co-crystallised product of formula [Rh(η^4-nbd)(η^6-CTV)][BF$_4$]·[{Rh(η^4-nbd)}$_2$-(η^6:η^6-CTV)][BF$_4$]$_2$·0.5 Me$_2$CO was eventually isolated. This fortuitous circumstance resulted in structure determinations (at −150 °C) for both **5** and **6** in the same experiment, Fig. 1.‡ Strikingly, the structure reveals that for **6**, in contrast to a wide range of bimetallic complexes related to the tetracation **2**,[10] the CTV cavity in **6** is not occupied by one of the BF_4^- anions. Instead **6** forms an inclusion polymer in which the norbornadiene ligand of one dicationic molecule engages in two short chelating, C–H··π hydrogen bonding interactions with the CTV carbon atoms C(3A) and C(4A) of the ring attached to Rh(1A); distances C(13A)···C(3A) 3.431(14), C(10A)···C(4A) 3.451(14), H(13A)···C(3A), 2.99, H(10A)···C(4A) 3.00 Å (C–H bond lengths normalised to 0.95 Å), Fig. 2. This may be compared to H···C distances in the range 2.73–3.05 Å recently reported for the organic system 2,3,7,8-tetraphenyl-1,9,10-anthyridine·toluene[15] in which there is much less steric hindrance at the arene (enabling a short C–H··π-centroid interaction), and falls well within the range associated with carbon acid hydrogen bonding interactions.[16,17] The observation of short intermolecular contacts alone does not however, necessarily mean an attractive intermolecular interaction. However, in this case the hydrogen bond acid–base complementarity between the donor and acceptor is clearly evident. Increased acidity of alkenes upon coordination to a metal centre arises from delocalisation of the metal positive charge, while it is the carbon atoms adjacent to the electron donating methoxy substituents which are the most electron rich on the CTV framework.

This result may be compared to the inclusion of iron(II) cations of type [Fe(arene)(Cp)]$^{-1}$ by free CTV recently

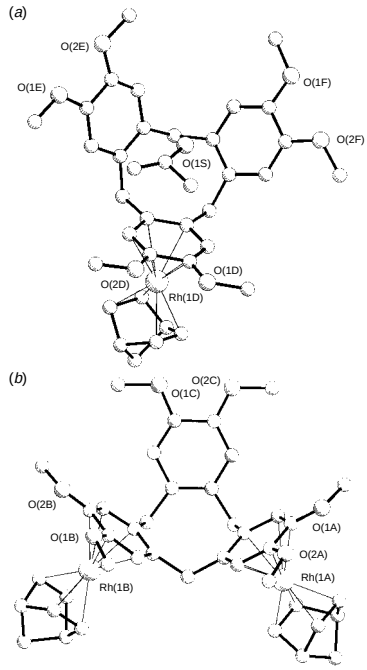


Fig. 1 (*a*) The monometallic and (*b*) bimetallic CTV based host complexes found in the structure of $[Rh(\eta^4\text{-nbd})(\eta^6\text{-CTV})][BF_4]\cdot[\{Rh(\eta^4\text{-nbd})\}_2(\eta^6:\eta^6\text{-CTV})][BF_4]_2\cdot 0.5Me_2CO$

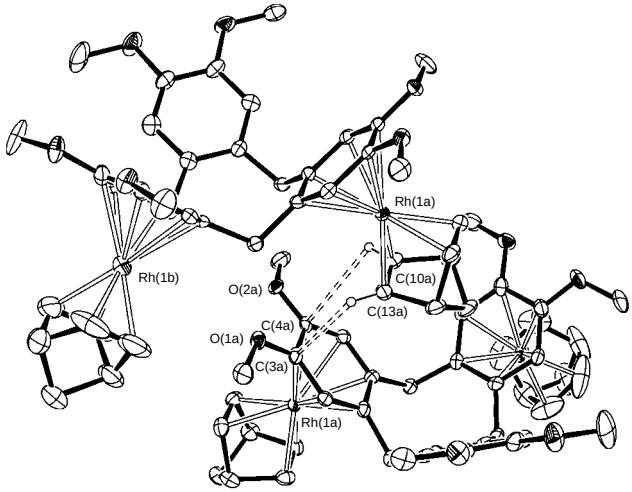

Fig. 2 C–H···π hydrogen bonding in the bimetallic complex **6**

reported by us,[18] in which shortest cyclopentadiene to CTV C···C contacts range from 3.44 to 3.59 Å depending on the identity of the arene. Curiously, however, in **6** it is the metallated ring attached to Rh(1A) which interacts with the C-acid guest. In contrast to compounds such as **2**, back bonding from the Rh^I centre will render the metalated CTV rings relatively electron rich, and it is presumably for this reason that intracavity anion binding is not observed in this case, in contrast to all other such systems with more than one metal centre.[2,7–10,19] However, the metallated ring should not be as electron rich as the free ring C(1C)–C(6C) and it seems that stacking of the anions external to the cavity around the two stacked Rh centres is maximised by the observed inclusion arrangement. This results in a short C(2A)–H···F(1A) contact; C(2A)···F(1A) 3.148(12) Å. Hence, it is clear that the electrostatic forces between cations and anions and the chelating C–H···π hydrogen bonding interactions act synergically.

The structure of the co-crystallised molecule of **5** is of the solvent-inclusion type, with the CTV cavity being occupied by a partial molecule of acetone, the crystals apparently having undergone some desolvation even at the very low temperature of the experiment. The acetone is approximately parallel with the metallated ring C(1D)–C(6D) with guest–host contacts in the range 3.4–4.0 Å.

The fact that no intracavity anion inclusion by even the bimetallic host **6** is observed in the solid state correlates with its anion binding ability in solution. Addition of 10 mol equiv. of $[NBu^n_4]I$ to a sample of **6** in $(CD_3)_2CO$ resulted in no change whatsoever in its ^1H NMR spectrum. This contrasts to the tetracationic ruthenium species **2** in which a similar experiment results in chemical shift changes of 0.89 ppm for the protons of the CTV rings.[20] In an attempt to estimate the strength of the double C–H···π interaction in solution, the ^1H NMR spectrum of **6** was monitored at a variety of concentrations from 0.02 to 0.002 M. This did result in slight downfield shifts (*ca.* 0.1 ppm) for the resonances assigned to the protons of the CTV rings, suggesting some degree of self-association. However, similar changes were also noted upon addition of excess $[NBu^n_4][BF_4]$ and hence this is probably not representative of significant C–H···π interactions in solution.

We thank Johnson Matthey plc for generous loans of rhodium trichloride, the Nuffield Foundation for the provision of computing equipment. We thank King's College London and the EPSRC for provision of the diffractometer system and the EPSRC for a studentship (to K. S. B. H.).

High yield selective synthesis of C_{60} dimers

Y. Iwasa,*[a]† K. Tanoue,[a] T. Mitani,[a] A. Izuoka,[b] T. Sugawara[b] and T. Yagi[c]

[c] *Institute for Solid State Physics, University of Tokyo, Minato-ku, Tokyo, 106, Japan*

Squeezing the organic molecular crystal $(ET)_2C_{60}$ at 5 GPa and 200 °C followed by removing unreacted ET molecules produces C_{60} dimers, with a yield of *ca.* 80%.

Polymeric fullerenes have attracted considerable interest because of their various structures and properties.[1] Both neutral and doped polymers have been synthesized by various techniques. While doped polymers are found to be formed spontaneously by slow cooling to room temperature,[2] polymerization in the neutral state requires activation of C_{60} *via* light irradiation[3] or application of external pressure at high temperature.[4,5] An advantage of high pressure synthesis is that by tuning the temperature and pressure, one can selectively synthesize one- and two-dimensional polymers in bulk. Recently, a new technique, called the mechanochemical method, produced a bulk amount of C_{60} dimers in 25–30% yield.[6] X-Ray crystallographic analysis of the dimer revealed that the dimer is formed *via* a 2 + 2 cycloaddition [Fig. 1 (*b*)].

To control the dimensionality and the degree of polymerization, here we report a novel method of squeezing the crystals of a molecular compound of C_{60} and ET [ET = bis(ethylenedithio)tetrathiafulvalene].[7] In the $(ET)_2C_{60}$ crystal, a novel arrangement of C_{60} is achieved by covering a part of the C_{60} molecules with ET molecules. Fig. 1(*a*) shows the arrangement of C_{60} in a crystal of $(ET)_2C_{60}$, where C_{60} molecules form a one-dimensional closest packing arrangement with a regular triangle lattice framework along the *c*-axis.[7] Interfullerene distances parallel and diagonal to the *c*-axis are 9.923(2) and 9.919(3) Å, respectively. Since they are very close to that of the face-centred cubic lattice of neat C_{60} (10.02 Å), pressure-induced cross-linking of C_{60} molecules in the $(ET)_2C_{60}$ crystals is highly promising. Incidentally, the charge transfer interaction between ET and C_{60} in this crystal is estimated to be small, as judged by the difference between redox potentials of each element.

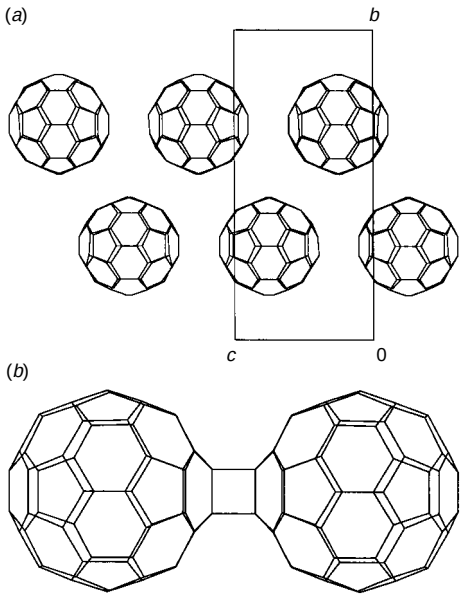

Fig. 1 (*a*) Arrangement of C_{60} in $(ET)_2C_{60}$ crystal; (*b*) C_{60} dimer

The starting $(ET)_2C_{60}$ crystals were obtained by slow evaporation of a CS_2 solution of a stoichiometric amount of C_{60} and ET. High pressure treatment was performed following previously described procedures.[4] Polycrystalline $(ET)_2C_{60}$ (50–100 mg) loaded in a gold capsule was reacted at 5 GPa and 200 °C using a wedge-type cubic anvil high pressure apparatus. After squeezing, the sample was recovered from the reaction capsule, and subjected to characterization under at ambient conditions.

Raman spectra of the pentagonal pinch mode $A_g(2)$ for the I_h of C_{60}, which is a sensitive probe for the occurrence of interfullerene bonds, were obtained.[3] Reflecting the almost neutral nature of the $(ET)_2C_{60}$ complex, the $A_g(2)$ mode was observed at 1469.3 cm^{-1}, which is identical to the position for pure C_{60}. In the as-pressurized $(ET)_2C_{60}$, the corresponding mode appeared at 1462.9 cm^{-1}, displaying a 6.4 cm^{-1} red-shift. This result indicates that interfullerene bonds are formed in the pressurized sample.

Earlier work has proved that infrared spectroscopy is a useful tool to identify the C_{60} polymer phases.[8,9] Fig. 2 shows the infrared absorption spectra of several samples dispersed in KBr pellets. The spectrum of starting $(ET)_2C_{60}$ is shown in Fig. 2(*c*). This spectrum is approximately explained as the sum of those for the constituent molecules, C_{60} [Fig. 2(*a*)] and ET [Fig. 2(*b*)], this being consistent with the absence of charge transfer suggested by the structural analysis. The spectrum of the as-

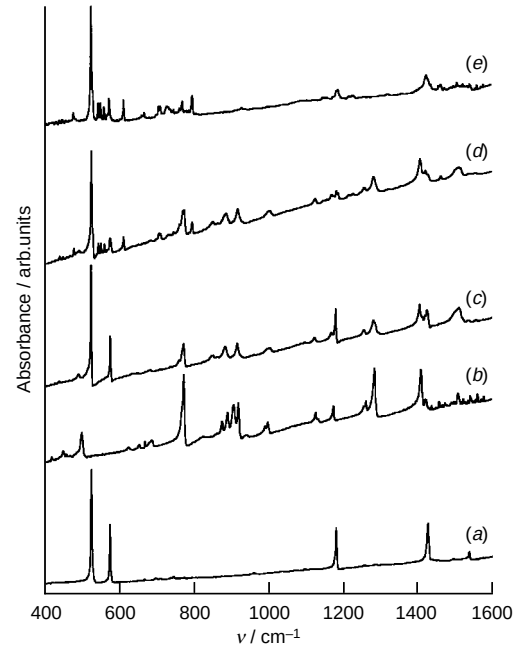

Fig. 2 Infrared absorption spectra for (*a*) C_{60}, (*b*) ET, (*c*) pristine $(ET)_2C_{60}$, (*d*) as-pressurized $(ET)_2C_{60}$, and (*e*) $(ET)_2C_{60}$ washed by CH_2Cl_2. ET molecules were removed in the final product.

pressurized sample is displayed in Fig. 2(*d*), which is remarkably different from the spectrum of the starting $(ET)_2C_{60}$. By a careful comparison between the two spectra, we found that the peaks attributable to ET were not changed by pressurization, while those from C_{60} exhibited notable changes. In order to confirm the change more precisely, the unreacted ET molecules were removed by sonication in CH_2Cl_2. The infrared spectrum [Fig. 2(*e*)] of the washed sample shows no trance of ET and can be ascribed to reacted C_{60}. Since this substance was soluble to *o*-dichlorobenzene, the degree of polymerization is expected to be substantially smaller than those for the one- and two-dimensional polymers, which are insoluble to *o*-dichlorobenzene.

The infrared spectrum [Fig. 2 (*e*)] of the obtained sample differs significantly from those for the polymers reported in previous papers, but is very similar to that for photodimerized C_{60}.[10] Furthermore, the spectrum of the mechanochemically synthesized dimer[6] turned out to be almost identical to Fig. 2(*e*), including the peak positions and intensity distributions. These spectral results strongly indicate that the dominant product of high pressure treatment of $(ET)_2C_{60}$ is the C_{60} dimer [Fig. 1(*b*)].

High performance liquid chromatographic analysis of the obtained sample was performed on a Cosmosil Buckyprep column with toluene as the eluent. The retention volume (14.5 ml) of the main peak was exactly the same as that for the mechanochemically obtained dimer.[6] Although several weak peaks are observed in the chromatogram, no signal derived from unreacted monomer C_{60} was found. The purity of C_{60} dimer was estimated to be about 79% based on the peak area of the chromatogram, detected by monitoring UV light at 326 nm. Since the weight-loss during the pressure treatment and purification is negligible, we can conclude that roughly 80% of the C_{60} monomer is converted to the dimer. This yield is considerably higher than that of the mechanochemical method.

Although most of the product of the above method is soluble in *o*-dichlorobenzene, there remains a small amount of insoluble material. Thus a substantial amount of one-dimensional oligomers or ladder polymers might be synthesized according to the current method by optimizing the reaction conditions. The reaction mechanism in the restricted spaces in such types of molecular compounds could be an interesting issue to be explored in the future.

Authors are grateful to Professor K. Komatsu and Dr Y. Murata, Kyoto University, for their help in sample characterization, and to Mr. T. Uchida, University of Tokyo, for his help in high pressure synthesis. Radical-chain reductive carboxyalkylation of electron-rich alkenes: carbon–carbon bond formation mediated by silanes in the presence of thiols as polarity-reversal catalysts

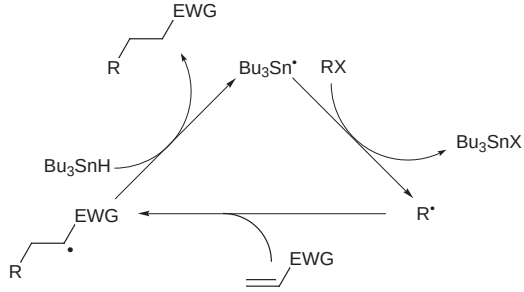
Hai-Shan Dang, Kyoung-Mahn Kim and Brian P. Roberts*†

Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ

The reductive carboxyalkylation of electron-rich alkenes by α-halogenoesters in the presence of triphenylsilane under free-radical conditions is catalysed by thiols: prochiral alkenes give optically-active adducts when the thiol catalyst is homochiral.

The reductive alkylation of electron-poor alkenes, using alkyl halides or psuedohalides in the presence of tributyltin hydride, is a radical-chain reaction of considerable importance for intermolecular C–C bond formation.[1] The propagation stage of this process, which is sometimes referred to as the 'tin method' or the 'Giese reaction', is illustrated in Scheme 1.



Scheme 1

This reaction suffers from certain limitations, notably the use of toxic organotin compounds and the need to keep the tin hydride concentration low in order to avoid trapping the radical R• to form RH before it has time to add to the alkene. The latter problem is more severe when the alkene is electron-rich, because simple alkyl radicals are nucleophilic, and the reaction is not then a practical method for C–C bond formation. Trialkylgermanes[2] and tris(trimethylsilyl)silane[3] have been employed in place of the tin hydride as they are less toxic and also less efficient hydrogen-atom donors. There are also a few examples of the successful use of α-halogenoesters, which yield relatively electrophilic α-alkoxycarbonylalkyl radicals, in conjunction with tributyltin hydride to bring about reductive alkylation of electron-rich alkenes.[4]

We have reported that the principle of polarity-reversal catalysis,[5] in this instance by thiols, may be applied to promote the overall abstraction of electron-rich hydrogen by nucleophilic alkyl radicals from silicon in simple triorganosilanes, through the catalytic cycle of reactions (1) and (2), and we have described how this silane–thiol couple can serve as an effective replacement for trialkyltin hydrides in many radical-chain processes.[6]

$$R^{\bullet} + XSH \rightarrow RH + XS^{\bullet} \quad (1)$$

$$XS^{\bullet} + R_3SiH \rightarrow XSH + R_3Si^{\bullet} \quad (2)$$

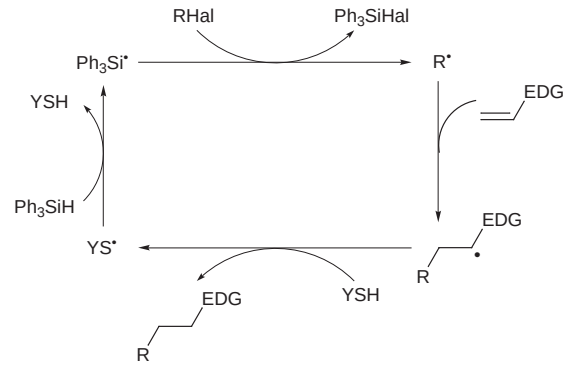
$$Bu^tON{=}NOBu^t \rightarrow 2Bu^tO^{\bullet} + N_2 \quad (3)$$

The SH group of a thiol provides electron-deficient hydrogen, which favours hydrogen-atom transfer to the nucleophilic alkyl radicals that are formed by addition to electron-rich alkenes, while polar effects will discriminate against the abstraction of hydrogen from thiols by electrophilic radicals.[7] With these considerations in mind, we reasoned that reductive alkylation of electron-rich alkenes, mediated by the silane–thiol couple, could be a viable method for C–C bond formation when the alkyl halide provides an electrophilic alkyl radical. In this communication we report the translation of these ideas into practice, along with the results of preliminary attempts to develop asymmetric syntheses based on this new methodology.

Table 1 Reductive carboxyalkylation of alkenes using organic halides in the presence of triphenylsilane, catalysed by thiol and initiated by TBHN in dioxane at 60 °C

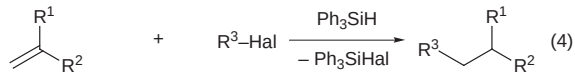
Entry	Alkene	R³Hal	Thiol	Adduct	Adduct yield (%)[a]
1	**1a**	**2a**	MTG	**3aa**	78
2	**1a**	**2a**	TPST	**3aa**	88[b]
3	**1a**	**2b**	MTG	**3ab**	75
4	**1a**	**2b**	TPST	**3ab**	72
5	**1a**	**2c**	TPST	**3ac**	78
6	**1b**	**2a**	TPST	**3ba**	86
7	**1b**	**2b**	TPST	**3bb**	75
8	**1c**	**2a**	TPST	**3ca**	85
9	**1d**	**2a**	TPST	**3da**	78
10	**1e**	**2a**	TPST	**3ea**	60
11	**1f**	**2a**	TPST	**3fa**	63
12	**5**	**2a**	TPST	**6**	76
13	**7**	**2a**	TPST	**8**	63[b]
14	**7**	**2a**	**10**	**8**	63 (24% ee)[c]
15	**7**	**2a**	**11**	**8**	64 (27% ee)[c]
16	**7**	**2b**	**10**	**9**	72 (19% ee)[d,e]

[a] Isolated yields based on alkene; satisfactory spectroscopic and analytical data were obtained for all new compounds. [b] The yield was similar in benzene solvent. Only a trace of adduct was formed in the absence of thiol. [c] The ee was determined by chiral-stationary-phase HPLC analysis (Chiralcel-OD column, eluent: hexane–isopropyl alcohol 99 : 1); the enantiomer in excess was eluted second. [d] The ee was determined by ^{1}H NMR analysis using a homochiral shift reagent [Eu(hfc)$_3$]. [e] The ee was the same when **11** was used as catalyst.



Scheme 2

All reactions were carried out at 60 °C and were initiated by thermal decomposition of di-*tert*-butyl hyponitrite (TBHN, $t_{\frac{1}{2}}$ = *ca.* 55 min),[8] which produces *tert*-butoxyl radicals [eqn. (3)] that go on to abstract hydrogen from the silane and/or the thiol to afford chain-carrying silyl or thiyl radicals. When a dioxane solution containing isopropenyl acetate **1a** (2.50 mmol), triphenylsilane (3.25 mmol), dimethyl chloromalonate **2a** (3.75 mmol) and TBHN (0.125 mmol) was heated under argon for 2 h, examination of the reaction mixture by ^{1}H NMR spectroscopy showed that < 1% of the adduct **3aa**‡ had been formed. However, when the experiment was repeated in the presence of methyl thioglycolate (MeO_2CCH_2SH, MTG, 0.125 mmol, 5 mol% based on alkene) under otherwise identical conditions, the adduct **3aa** was isolated in 78% yield. A somewhat higher yield was obtained in the presence of triphenylsilanethiol (TPST, 5 mol%) as catalyst (Table 1, entries 1 and 2). The reductive carboxyalkylation of **1a** [eqn. (4)] evidently proceeds



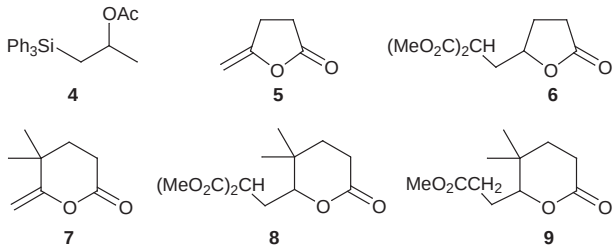
(4)

1a R^1 = OAc, R^2 = Me
b R^1 = OAc, R^2 = Bu^t
c R^1 = $OSiMe_2Bu^t$, R^2 = Me
d R^1 = OBu, R^2 = H
e R^1 = Pentyl, R^2 = Me
f R^1 = CH_2OAc, R^2 = Me

2a $(MeO_2C)_2CH$–Cl
b MeO_2CCH_2–Br
c $(EtO_2C)_2CMe$–Br

3

by a radical-chain mechanism, the propagation stage of which is shown in Scheme 2. A similarly high yield of the adduct **3ab** was obtained when dimethyl chloromalonate was replaced with methyl bromoacetate **2b** in the presence of either MTG or TPST (entries 3 and 4), but with methyl chloroacetate under the same conditions the yield of **3ab** was reduced to 40% and a large amount (50%) of the adduct **4** was also isolated. Evidently, the

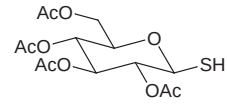


4 **5** **6** **7** **8** **9**

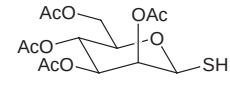
triphenylsilyl radical adds to the C=C bond[6d,e] in **1a** at about the same rate as it abstracts halogen from the chloroacetate, while with the more reactive bromoacetate halogen-atom abstraction is much faster than addition to the alkene. A good yield of the adduct **3ac** was obtained from the reductive carboxyalkylation of isopropenyl acetate with diethyl 2-bromo-2-methylmalonate (entry 5).§

Similar addition reactions were carried out with the alkenes **1b**–**f** and the results are summarised in Table 1:¶ essentially no adduct formation occurred in the absence of thiol catalyst. The methylenelactones **5** and **7** also functioned well as acceptors (entries 12 and 13).‖

The stereogenic centres in the adducts **8** and **9** are formed when the prochiral chain-carrying radicals, produced by addition to these alkenes, abstract hydrogen from the thiol catalyst (Scheme 2). If the thiol is homochiral then the hydrogen-atom transfer will be enantioselective and optically-active adducts should result. Reductive carboxyalkylation of the methylenelactone **7** using the carbohydrate-derived thiols **10** and **11** as catalysts gave the adducts **8** and **9** with an enantiomeric excess (ee) up to 27% (entries 14–16).** Although the optical purities obtained so far are low, the results



10



11

are encouraging because the transfer of chirality is catalytic and the reactions are carried out at relatively high temperatures. Efforts to design more effective homochiral thiol catalysts are underway.

Financial support for this work was provided by the EPSRC.

Notes and References

† E-mail: b.p.roberts@ucl.ac.uk

‡ The adduct **3aa** arises from **1a** and **2a**, the adduct **3ab** arises from **1a** and **2b** and so on.

§ Triphenylbromosilane is formed in reactions involving bromides. This bromosilane is a Lewis acid and is also very sensitive to hydrolysis, so that care must be taken if the reactants or adduct are sensitive to acid.

¶ No adducts could be obtained from the enol acetate $PhC(OAc)=CH_2$. It is likely that the oxygen-conjugated benzylic radicals formed by addition to this alkene do not abstract hydrogen from the thiol catalyst at a sufficient rate to maintain a chain reaction.

‖ *Typical procedure*. A solution in dry dioxane (4 cm^3) containing isopropenyl acetate **1a** (0.250 g, 2.50 mmol), triphenylsilane (0.846 g, 3.25 mmol), dimethyl chloromalonate (0.625 g, 3.75 mmol), TBHN (22 mg) and triphenylsilanethiol (37 mg) was stirred and heated at 60 °C under an atmosphere of dry argon for 2 h. The solvent was removed by evaporation under reduced pressure, the residue was dissolved in Et_2O (10 cm^3) and the solution was washed with 5% aqueous $NaHCO_3$, then with saturated brine and then dried ($MgSO_4$). After evaporation of the ether, light petroleum (bp 40–60 °C) (5 cm^3) was added and the slurry was filtered to remove most of the triphenylsilanol, which was washed on the sinter with a little petroleum. After evaporation of the solvent from the filtrate, the residue was purified by flash-chromatography (eluent: petroleum–Et_2O 95 : 5 to 5 : 1) to give the adduct **3aa** as a clear oil (0.511 g, 88%). δ_H 1.24 (3 H, d, *J* 6.2, Me), 2.00 (3 H, s, Ac), 2.35 (2 H, m, C*H*$_2$CH), 3.46 [1 H, dd, *J* 8.6 and 6.1 $(MeO_2C)_2$C*H*], 3.72(7) (3 H, s, OMe^A), 3.73(2) (3 H, s, OMe^B), 4.89 (1 H, m, C*H*OAc); δ_C 20.1, 21.1, 34.7, 48.4, 52.7 (2C), 68.7, 169.3, 169.5, 170.4.

** Enantioselective reductive carboxylkylation of **7** could also be mediated by tributyltin hydride. When triphenylsilane was replaced by tin hydride (1.3 equiv.), added slowly during 2 h as a dioxane solution also containing TBHN, but otherwise essentially under the conditions of entry 14, the adduct **8** was isolated in 80% yield and showed an ee of 25%. This result also demonstrates that thiols can act as polarity-reversal catalysts for the abstraction of hydrogen from tin hydrides by alkyl radicals.

Amphiphilic core–shell nanospheres obtained by intramicellar shell crosslinking of polymer micelles with poly(ethylene oxide) linkers

Haiyong Huang,[a] Edward E. Remsen[b] and Karen L. Wooley*[a]†

[a] *Department of Chemistry, Washington University, One Brookings Drive, St Louis, MO, 63130, USA*
[b] *Monsanto Company, 800 N. Lindbergh Blvd., St. Louis, MO 63167, USA*

Intramicellar crosslinking of the polymer chains within the shells of polystyrene-*b*-poly(acrylic acid) micelles by reaction with difunctional poly(ethylene oxide) afforded unimolecular amphiphilic core–shell nanospheres (50 nm hydrodynamic radius); the resulting surface hydrogel layer gives an approximate fivefold increase of particle volume from the dry state to aqueous solution.

The concept of shell crosslinked knedel-like structures (SCKs)[1] has been applied to synthesize nanoparticles with core–shell structures, composed of poly(ethylene oxide) (PEO) chains as covalent crosslinks binding together the peripheral layer of polymer micelles. The unique combination of size, structure, stability and composition of these nanospheres renders them great potential for drug delivery systems. Extensive efforts have been undertaken by other researchers to understand the structurally related drug delivery properties of the submicrometer-sized polymeric particles.[2–6] For example, the sub-100 nm diameter of PEO-adsorbed polystyrene nanoparticles allowed for evasion of sequestration by the phagocytosis process,[2] and the hydrophilicity of PEO facilitated the transportation of these particles through the interstitum by aqueous channels.[7] Moreover, the surface PEO blocks of polymer micelles sterically stabilized the nanospheres and prolonged the circulation lifetime in the blood.[3]

The shell-crosslinked nanospheres in this study offer some advantageous features, such as the ability to maintain structural integrity upon infinite dilution and mechanical stresses, the stability of covalently bound PEO within the surface domain, and the potential to attach receptor-recognizing ligands to the residual carboxylate side groups on the PAA block. SCKs have previously been prepared with coupling *via* short difunctional oligomeric crosslinkers,[8] in which the chemical composition of the crosslinkers resulted in differences in the nature of the shell. This report demonstrates that PEO can be incorporated into the SCK shell as a polymeric crosslinker to greatly increase the shell thickness and to modify the surface properties[9] of the SCKs (*e.g.* permeability and flexibility), without the evidence of intermicellar reactions occurring.

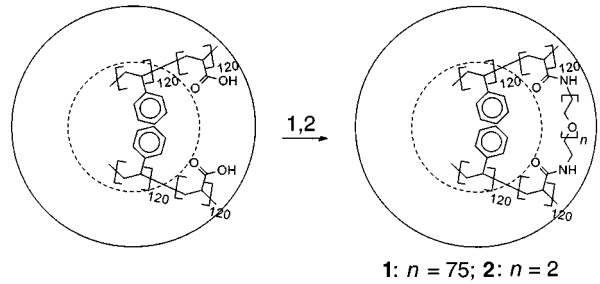
SCKs are essentially unimolecular polymer micelles, which are prepared by stabilization of the basic structure of the spherical micellar assembly through linking together of the hydrophilic portions of the chains within the micelle shell. Therefore, the synthesis of the SCKs involves only three steps: (*i*) preparation of an amphiphilic block copolymer; (*ii*) self-assembly of the amphiphilic block copolymer into polymer micelles; (*iii*) crosslinking through side groups along the blocks occupying the shell of the polymer micelles.

The preparation of the SCKs began from the diblock copolymer, polystyrene-*b*-poly(acrylic acid) (PS-*b*-PAA), which was conveniently synthesized by living free radical polymerization.[10] The living free radical polymerization was accomplished by a stepwise atom transfer radical polymerization technique, similar to the procedures reported by Matyjaszewski and coworkers.[11] Micelles composed of PS-*b*-PAA were formed by addition of water to a solution of the polymer in THF,[12] and an aqueous solution of micelles was obtained by dialyzing against distilled water. The crosslinking was accomplished by condensation reactions of diamino linkers with PAA, facilitated by a carbodiimide coupling agent (Scheme 1).

The carboxylic acid groups on the PAA block were first activated by reaction with the water soluble carbodiimide, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide methiodide (1 equiv. based upon the acrylic acid groups). The crosslinker, poly(ethylene glycol) diamine (M_w = 3400 Da, 0.5 equiv. based upon the acrylic acid groups), was then added to crosslink the PAA domain by formation of amide bonds[13] and yield SCK **1**. For evaluation of the effects of the crosslinker length, SCK **2** was crosslinked *via* a short tri(ethylene oxide) linker in a similar fashion using 2,2′-(ethylenedioxy)bis(ethylamine).[8] In both cases, the urea by-product was removed by dialysis against distilled water.

^{1}H NMR resonance signals could not be detected in D_2O solutions, due to the colloidal nature of **1** and **2**. Therefore, solid samples of the SCKs were obtained by lyophilization, and the compositions of **1** and **2** were characterized by IR spectroscopy. Upon formation of **1**, absorption bands corresponding to free carboxylic acid groups (3600–2500 and 1710 cm^{-1}) of the polymer micelles attenuated to 10–30% of their original intensity, as amide I and II bands appeared at 1650 and 1540 cm^{-1}. Solid-state NMR experiments are in progress to determine the extent of amidation and the effects on the shell permeability. In contrast, upon formation of **2**, the carbonyl stretch of the carboxylic acid band disappeared in the IR spectrum, and only the amide carbonyl bands were observed. Strong absorption from C–O stretching of the ethylene oxide linkers was observed at 1108 cm^{-1} for both **1** and **2**. The compositions of the SCKs were quantitatively confirmed by elemental analysis.

Transmission electron microscopy (TEM) provided further evidence for structural differences between **1** and **2** (Fig. 1). The cores of **1** and **2** appear to be approximately the same diameter, however, the shell thicknesses are very different. SCK **1** has a distinct corona owing to the poly(ethylene oxide) linker [Fig. 1(*a*), the PEO coronas are the gray areas surrounding the brighter center cores], whereas SCK **2** has a sharp edge [Fig. 1(*b*)]. The average diameters of the nanospheres were determined in aqueous solution by dynamic light scattering (DLS)[8]



1: n = 75; **2**: n = 2

Scheme 1 Amidation chemistry used for crosslinking of poly(acrylic acid) groups located in the shell of Ps-*b*-PAA polymer micelles to form the SCK nanospheres. 1, $CH_3CH_2N{=}C{=}N(CH_2)_3N(CH_3)_3I$; 2, $H_2N(CH_2CH_2O)_n$-$CH_2CH_2NH_2$.

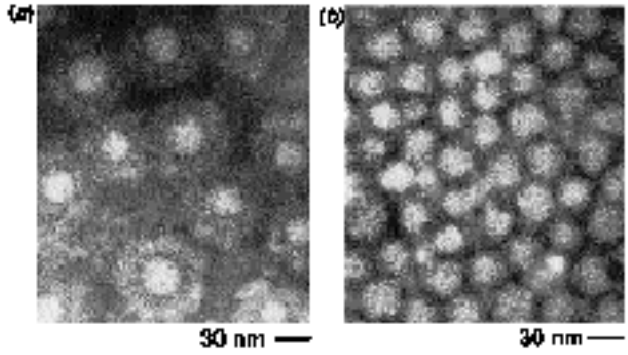


Fig. 1 Negatively stained transmission electron microscopy (TEM) images at 300 K magnification of the SCKs crosslinked by (*a*) PEO linkers to yield a thick hydrogel-like crosslinked shell surrounding and covalently bound to the PS core, and (*b*) tri(ethylene oxide) linkers to yield SCKs possessing a relatively thin shell of oligo(ethylene oxide)-crosslinked polyacrylamide. The TEM samples were prepared by dropping 1 : 1 mixtures of aqueous solutions of the SCK sample and uranyl acetate (2.5% solution), upon a carbon-coated copper grid and allowing to dry.

to be 100 ± 3 nm for **1** and 37 ± 2 nm for **2**. Based on the size of the precursor polymer micelles in the dry state (average diameter is 26 nm, core diameter is 22 nm and shell thickness is 2 nm, determined by TEM and AFM)[8] and the increment of volume added from the linkers, the theoretical[14] diameters of SCKs **1** and **2** in the compact dry state were calculated to be 56 and 29 nm, respectively. Because both **1** and **2** result from the same polymer micelle, with an average core diameter of 22 nm, the shell thicknesses in the compact dry state are calculated as 17 and 3.5 nm, respectively. The extent of swelling of the crosslinked hydrogel peripheral layer when placed within water was determined to be about twofold in thickness, corresponding to an approximate eightfold increase in shell volume. Considering the differences in shell thickness **1** experiences a fivefold increase in overall SCK volume, whereas only a twofold total volume increase occurs for **2**.

Differential scanning calorimetry (DSC) experiments were performed to deduce structural information for the dried samples of **1** and **2**. SCK **1** exhibits a melting transition (T_m) at 45 °C, which corresponds to the T_m of PEO,[15] however no T_g is observable for the PS core. This indicates that PEO in the shell exists as a phase separated crystalline domain, and that the PS content may be too low for detection by our DSC instrumentation. In contrast, a glass transition (T_g) for the PS core at 105 °C is evident for SCK **2**, but no detectable T_m or T_g corresponding to PEO is observed. These results support the compositional and structural differences between **1** and **2**.

The ethylene oxide surface layer covalently attached throughout the SCK shell provides a stable, steric barrier between the hydrophobic core and aqueous media. Poly(ethylene glycol)diamine incorporates a higher degree of ethylene oxide units than 2,2′-(ethylenedioxy)bis(ethylamine), which allows phase separation of the PEO, demonstration of behavior characteristic of pure PEO, formation of a thicker hydrogel-like exterior layer, and greater extents of overall nanoparticle swelling in water. The SCKs thus prepared have many enhanced features that should serve well when applied as artificial drug carriers. Investigations into protein binding for early *in vitro* screening of potential biocompatibility are in progress.

This work was funded by a National Science Foundation National Young Investigator Award (DMR 9458025) and Monsanto Company. The authors are grateful to Mr Michael Veith for TEM experiments.

11 The PS-*b*-PAA was prepared by living atom transfer radical polymerization of styrene and then methyl acrylate, followed by HCl catalyzed hydrolysis of the methyl ester functionalities. The polystyrene block was prepared by polymerization of styrene, using a mixture of copper(I) bromide (0.8 mol%), 4,4′-di(5-nonyl)-2,2-bipyridine (1.5 mol%) and 1-bromoethylbenzene (0.8 mol%). This bromo-terminated polystyrene (0.8 mol%) was isolated by precipitation into methanol. The dried bromo-terminated polystyrene was then used to initiate the polymerization of methyl acrylate, in the presence of copper(I) bromide (0.8 mol%) and 4,4′-di(5-nonyl)-2,2′-bipyridine (1.7 mol%). The diblock copolymer was made amphiphilic by hydrolysis of the methyl ester functionalities along the poly(methyl acrylate) block in HCl–dioxane. The PS block was of M_n = 12 500, determined from GPC calibrated with polystyrene standards. Based on the ratio of integration values for resonances of respective protons in the ^{1}H NMR spectrum, the average numbers of styrene units and acrylic acid units in the PS-*b*-PAA copolymer were determined to both be approximately 120. 12 The SCK syntheses were performed on up to 200 mg scales, with the formation of the polymer micelles following similar procedure to that found in ref 8(*b*) as well as L. Zhang and A. Eisenburg, *Science*, 1995, **268**, 1728; Y. Yu and A. Eisenburg, *J. Am. Chem. Soc.*, 1997, **119**, 8383.
13 The single alkyl bromide located at the chain end of each polymer chain resulting from the ATRP chemistry may also undergo reaction with the diamino crosslinkers.
14 The sizes of SCK particles of **1** shown by TEM cannot be taken as the compact dry-state diameters, owing to distortion of the PEO-containing corona of the nanospheres upon drying on the carbon-coated copper grid substrate. Therefore, the SCK size was predicted by adding the volume of the precursor micelle to the additional volume from the linkers (calculated from the product of moles of linker, linker molecular mass and linker density), followed by conversion to the diameter for a spherical SCK. The 29 nm calculated diameter of **2** agrees with the particle sizes observed in the TEM image.
15 T_m of PEO–$(NH_2)_2$ (M_w = 3400) is 45 °C.

The domino cycloaddition/*N*-acyliminium ion cyclization cascade

Albert Padwa

Department of Chemistry, Emory University, Atlanta, GA 30322, USA

Various applications of the domino cycloaddition/ *N*-acyliminium ion cyclization cascade are reported. The key step in the process involves the generation of a reactive *N*-acyliminium ion by fragmentation of an amino substituted [4 + 2]-cycloadduct. The successful synthesis of a number of alkaloids by this sequence of reactions reveals the usefulness and importance of this unique domino cascade.

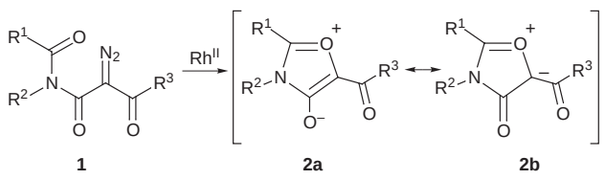
Introduction

Domino processes belong to a growing family of reactions which allow for the regio- and stereo-controlled formation of several carbon–carbon bonds and/or ring systems in a single operation.[1] Cationic reactions that proceed in a domino fashion are featured in the biosynthesis of important natural products, and synthetic applications of both biomimetic and non-biomimetic cationic cyclizations have been widely developed.[2] Important contributions to this area have also been realized utilizing a combination of anionic, radical, carbenoid and transition metal-catalyzed processes.[3] The combination of a sequence of individually powerful methods often has a value significantly greater than the sum of the individual reactions and has become of great interest to the synthetic community. Corey has termed such a sequence as a tactical combination.[4]

In recent years, consecutive pericyclic reactions involving at least one cycloaddition have also been utilized for the synthesis of complex polycyclic ring systems.[5] In the realm of synthesis, in which a premium is put on the rapid construction of polyfunctional, highly bridged carbon and heteroatom networks, the [4 + 2]-cycloaddition has emerged as one of the foremost synthetic methods.[6] Well known and extensively studied for many decades, the Diels–Alder reaction is frequently employed for the construction of six-membered ring systems. The high regio- and stereo-selectivity typically displayed by this pericyclic process and the ease of execution have contributed toward its popularity. Carbon–carbon bond-forming reactions involving *N*-acyliminium ions play an extremely important role in the synthesis of nitrogen heterocycles. Speckamp[7] and Hart,[8] in particular, were the pioneers in this area, showing that *N*-acyliminium ions are valuable intermediates in the synthesis of a broad range of alkaloids. A combination of these two powerful synthetic methods would allow for the rapid, stereocontrolled synthesis of a variety of azapolycyclic products. This feature article describes some of our recent work in this area.

Cycloaddition of 1,3-oxazolium 4-oxides

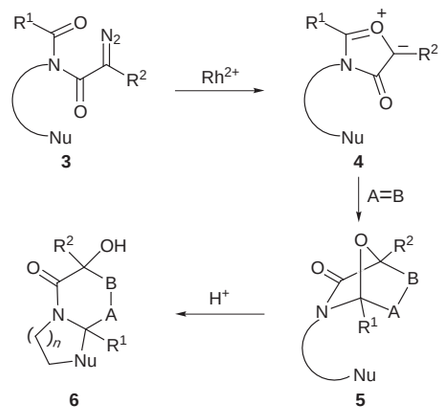
In 1994 we started work in our laboratory to synthesize ring-fused polyheterocycles based on a *sequential cycloaddition/* N-*acyliminium ion cyclization process.*[9] These two types of reaction provide an opportunity for linking two disparate ring-forming reactions in a novel sequential manner. We believed that such a protocol would provide one-pot access to target molecules possessing a high degree of complexity which would otherwise require technically demanding multi-step syntheses. Our early studies showed that 1,3-oxazolium 4-oxides (isomünchnones) **2** can be generated by the rhodium(II)-catalyzed cyclization of a suitable diazo imide **1** (Scheme 1).[10] This type



1 **2a** **2b**

Scheme 1

of mesoionic ylide corresponds to the cyclic equivalent of a carbonyl ylide and was found to readily undergo [4 + 2]-cycloaddition with suitable dipolarophiles.[10] Construction of the prerequisite diazo imides necessary for betaine generation was accomplished by the transformation of the corresponding carboxylic acids to their respective amides. Conversion to the diazo imides was straightforward using established malonylacylation and diazotization procedures.[11] Formation of the isomünchnone ring proceeds by initial generation of a rhodium carbenoid species, followed by an intramolecular cyclization onto the neighboring carbonyl oxygen to form the mesoionic ylide **2**.[10] The resultant isomünchnone may be trapped with electron-rich or electron-deficient dipolarophiles to give the cycloadducts in high yield. These uniquely functionalized cycloadducts (*i.e.* **5**) contain a 'masked' *N*-acyliminium ion which is generated by its treatment with a Lewis acid.[12] By incorporating an internal nucleophile on the tether, annulation of the original cycloadduct **5** allows for the construction of a more complex nitrogen heterocyclic system, particularly B-ring homologues of the erythrinane family of alkaloids. Starting from simple acyclic diazo imides **3**, we established a *domino carbenoid cyclization/[4 + 2]-cycloaddition/cationic* π-cyclization protocol as a method for the construction of complex nitrogen polyheterocycles of type **6** (Scheme 2). This



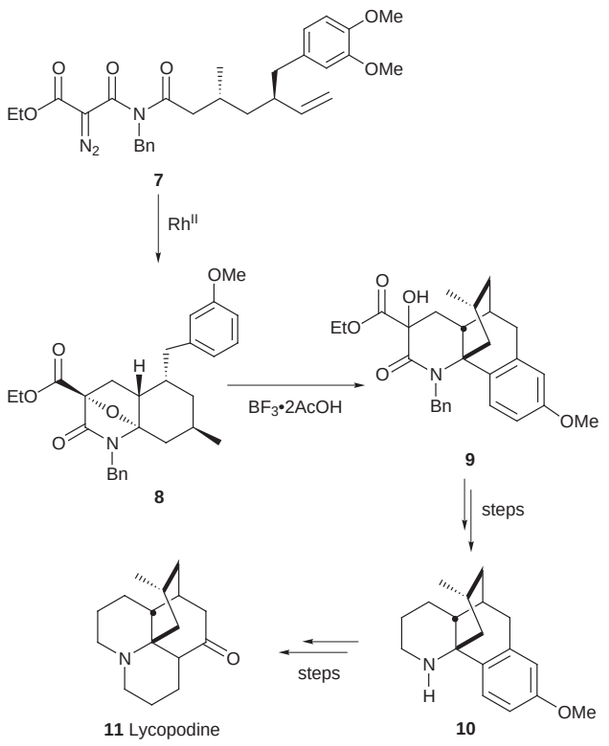
3 **4** **6** **5**

Scheme 2

sequence represents the first example where a [4 + 2]-cycloaddition and *N*-acyliminium ion cyclization are coupled in a one-pot sequence. The novelty of the process lies in the method of *N*-acyliminium ion generation, which to the best of our knowledge is unprecedented. *N*-Acyliminium ions are traditionally generated from the *N*-acylation of imines,[13]

N-protonation[14] and oxidation of amides,[15] electrophilic additions to enamides,[16] and the heterolysis of amides bearing a leaving group adjacent to nitrogen.[7] These reactive intermediates readily react with a wide assortment of nucleophiles to effect an overall α-amido alkylation.

An early application of the domino cascade process toward the construction of alkaloids involved the synthesis of (±)-lycopodine **11** (Scheme 3).[17] The isomünchnone cycloadduct **8** was



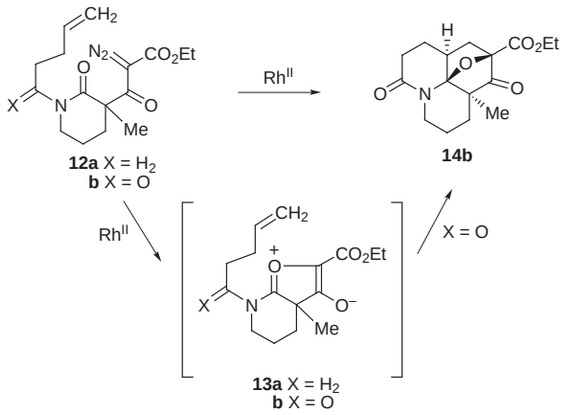
Scheme 3

formed from the Rh^{II}-catalyzed reaction of diazo imide **7** and was found to be the precursor of the key Stork intermediate **10** (*via* 9).[18] Our plan involved formation of **9** by a Pictet–Spengler cyclization of the *N*-acyliminium ion derived from **8**. Central to this strategy was the expectation that the bicyclic iminium ion originating from **8** would exist in a chair-like conformation.[18,19] Indeed, cyclization of the aromatic ring onto the *N*-acyliminium ion center readily occurred from the axial position.[20] The rearranged product **9** was then converted into the key intermediate previously used by Stork for the synthesis of (±)-lycopodine **11**.[18]

Application of the domino cyclization/cycloaddition sequence to the pentacyclic skeleton of the aspidosperma ring system

Prompted by our work dealing with the internal [4 + 2]-cycloaddition reaction of mesoionic oxazolium ylides,[10] we became interested in the rhodium(II)-catalyzed reactions of diazo ketoamides such as **12**. Attack of the amido oxygen at the rhodium carbenoid produced a carbonyl ylide dipole (*i.e.* **13**) that is isomeric with the isomünchnone class of mesoionic betaines **4**. We found that the rhodium(II)-catalyzed formation of carbonyl ylide intermediates derived from cyclic diazo amides furnished tetracycles such as **14b** in good yield, provided that the tether engaged in ring formation carried a carbonyl group (*i.e.* **12b**, X = O) (Scheme 4).[21]

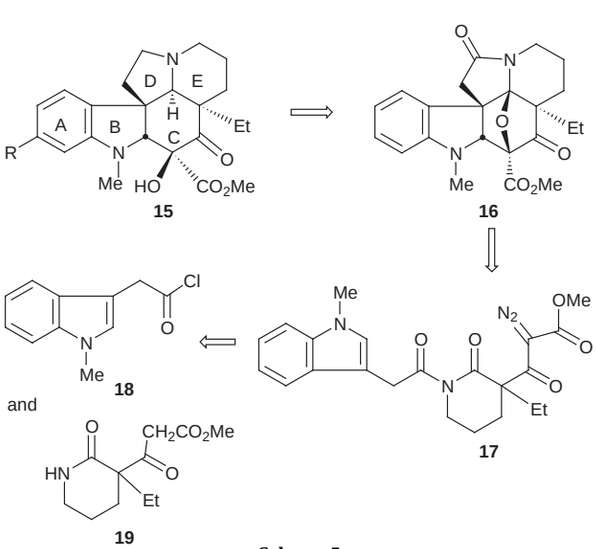
Without the C=O functionality (*i.e.* **12a**, X = H), only decomposition products were observed. By performing *ab initio* transition state geometry optimizations, we learned that a severe



Scheme 4

cross-ring 1,3-diaxial interaction caused by the bridgehead methyl group promoted a boat or twist-boat conformation in the piperidine ring fused to the newly forming one.[21] The presence of a carbonyl group on the tether apparently helps to relieve the steric congestion by favoring a second boat conformation in the latter ring. When the side chain is devoid of a carbonyl group, the calculated reaction barrier is much larger, thereby permitting competing processes to intervene. Thus, the reactivity discrepancy between diazo amido esters **12a** and **12b** can be attributed to steric effects in the transition states.[21]

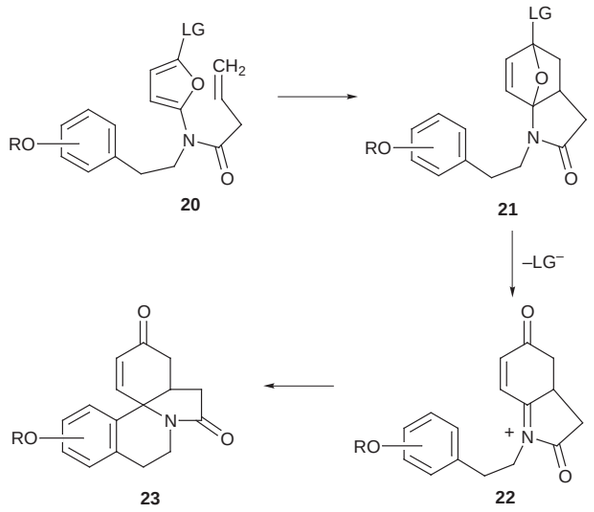
As an extension of these studies, we have developed a fundamentally new approach to the construction of the pentacyclic skeleton of the aspidosperma ring system which involves a related domino cascade sequence.[22] This strategy was successfully applied to the synthesis of desacetoxy-4-oxo-6,7-dihydrovindorosine **15**. The approach used is outlined in Scheme 5 and is centered on the construction of the key oxabicyclic intermediate **16**. We reasoned that **15** should be accessible by reduction of the *N*-acyliminium ion derived from **16**, which, by analogy with our previous work, should be available by the *tandem rhodium*(II)-*catalyzed cyclization/cycloaddition* of α-diazoimide **17**. Cycloaddition of the initially formed dipole across the pendant indole π-system[23] would be expected to result in the simultaneous generation of the CD-rings of the aspidosperma skeleton.[24] The stereospecific nature of the internal cycloaddition reaction should also lead to the correct relative stereochemistry of the four chiral centers about the C-ring. In a recent publication, we described our results which verified the underlying viability of this approach to the aspidosperma skeleton (Scheme 5).[22]



Scheme 5

The 2-aminofuran Diels–Alder strategy

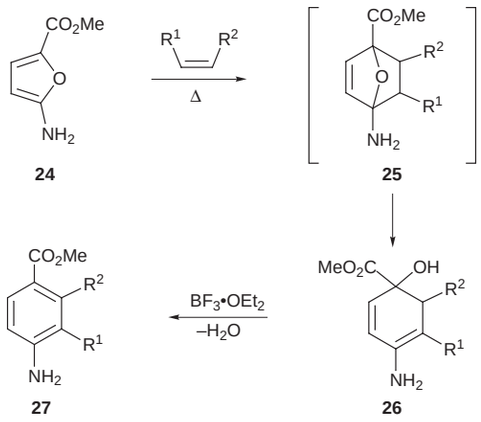
In the next phase of our work, we decided to reconsider some aspects of our domino cascade strategy. It occurred to us that we could also utilize a series of 2-amino-substituted furans for the critical [4 + 2]-cycloaddition step rather than the highly reactive 1,3-dipole, which on occasion was prone to undergo hydrolytic decomposition.[10] Our long-range goal involved using 2-amino-substituted furans such as **20** that contain both a suitable leaving group (LG) and an olefinic tether to allow for an intramolecular Diels–Alder reaction (Scheme 6). The resultant cycloadduct



Scheme 6

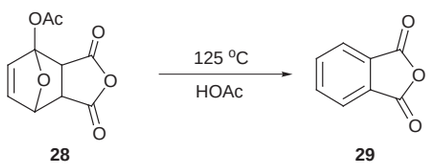
was expected to undergo ring opening to generate a vinylogous *C*-acyliminium ion of type **22**. Our intention was to use this sequence of reactions for a rapid entry into the erythrinane family of alkaloids. With this goal in mind, some model studies were undertaken to determine the facility with which 2-amino-furans would undergo Diels–Alder cycloadditions.[25]

Heterocycles such as furan, thiophene and pyrrole undergo Diels–Alder reactions despite their stabilized 6π-aromatic electronic configuration.[26] By far the most extensively studied heteroaromatic system for Diels–Alder cycloaddition is furan and its substituted derivatives.[26] The resultant 7-oxabicyclo[2.2.1]heptanes are valuable synthetic intermediates that have been further elaborated to substituted arenes, carbohydrate derivatives and various natural products.[26] A crucial synthetic transformation employing these intermediates involves the cleavage of the oxygen bridge to produce functionalized cyclohexene derivatives.[27] In many cases, however, this strategy is not feasible because of the low reactivity of furan toward monoactivated dienophiles. Lewis acid catalysis, interaction with metals, or use of high pressure helps to overcome the sluggishness of furan toward Diels–Alder cycloaddition.[26] MO calculations show that the presence of an electron-donating substituent such as an amino group in the 2-position of the furan nucleus increases its HOMO energy relative to that of furan.[28] A significant increase in the HOMO coefficient at the C-5 position compared to that at the C-2 position also occurs, consistent with an increase in electron density at that position due to resonance interaction with the amino substituent. In this regard, we have recently demonstrated that simple 2-aminofurans such as **24** react with various dienophiles in an intermolecular fashion with high regioselectivity.[28] The initial cycloadducts were not isolated, as they readily undergo ring opening to cyclohexadienols **26**, assisted by the lone pair of electrons on the adjacent nitrogen atom (Scheme 7). The influence of the amino group is evident by the extremely facile cleavage of the oxybridge intermediates under the thermal conditions used in the reaction. This behavior stands in contrast to the related oxabicyclic system **28**, which was reported to undergo ring



Scheme 7

cleavage only when treated with acetic acid at elevated temperatures (125 °C) (Scheme 8).[29]

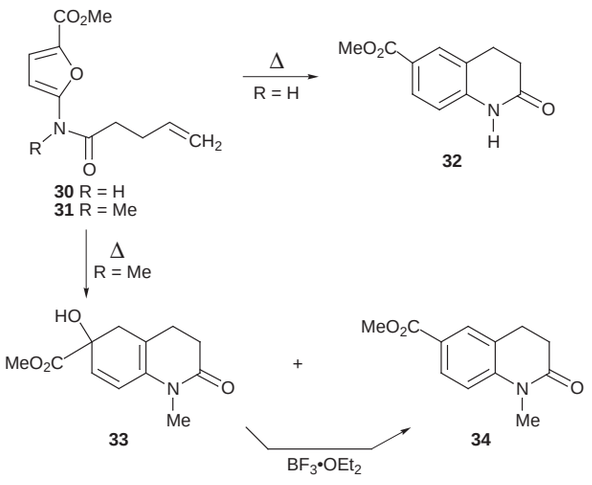


Scheme 8

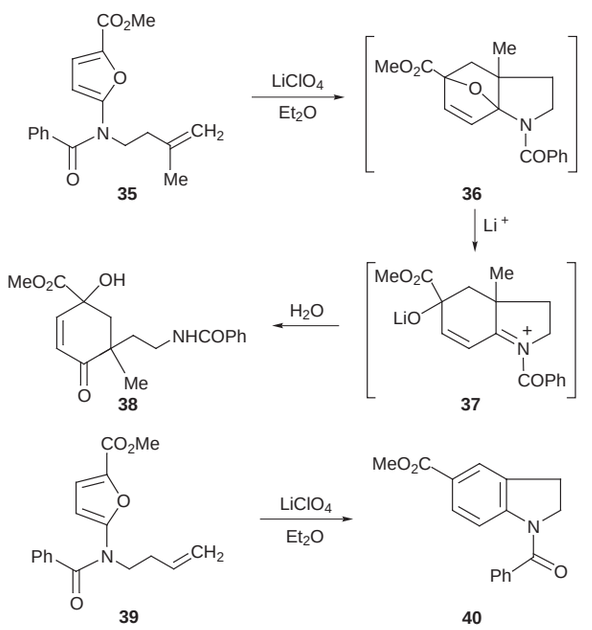
IMDAF Cycloaddition as a method for the preparation of pyrrolophenanthridine alkaloids

The intramolecular Diels–Alder reaction of furans, often designated as IMDAF, helps to overcome the sluggishness of this heteroaromatic ring system toward [4 + 2]-cycloaddition.[26] Not only do IMDAF reactions allow for the preparation of complex oxygenated polycyclic compounds, they often proceed at lower temperatures than their intermolecular counterparts.[30] Even more significantly, unactivated π-bonds are often suitable dienophiles for the internal cycloaddition. While the carbocyclic IMDAF reaction has been the subject of many reports in the literature, much less is known regarding the cycloaddition behavior of furan Diels–Alder systems that contain heteroatoms. Even more rare are examples in which the heteroatom is directly attached to the furan ring.[25] In an effort to investigate the scope of these reactions, a number of new furan substrates were prepared in our laboratory and tested for the *cycloaddition/cyclization* cascade. Tethered amidofurans **30** and **31** were easily synthesized starting from aminofuran **24** and pent-4-enoyl chloride. The thermal reaction of **30** at 200 °C for 24 h afforded tetrahydroquinolinone **32** in 66% yield. Likewise, heating a sample of the *N*-methylated analog **31** at 160 °C furnished a 6 : 1-mixture of cyclohexadienol **33** (77%) and tetrahydroquinoline **34** (13%), the former being easily converted to **34** by treatment with $BF_3 \cdot OEt_2$. In both cases, the initial cycloadducts were not isolated, as they readily underwent ring opening, assisted by the lone pair of electrons on the adjacent nitrogen (Scheme 9).

During the course of our studies we have found that the IMDAF cycloadditions of furanamides such as **35** can also be performed by using 4 M ethereal $LiClO_4$ as solvent.[31] Under these conditions, furanamide **35** underwent cycloaddition at a much lower temperature and in higher yield than under strictly thermal conditions. The major product formed corresponded to cyclohexenone **38**. This reaction presumably involves an initial [4 + 2]-cycloaddition to give **36** followed by a rapid ring opening to afford iminium ion **37** which is subsequently converted to **38** upon reaction with water (Scheme 10). The Grieco conditions[31] were also successfully employed using the unactivated four-carbon tethered furanamide **39** which gave dihydroindole **40** in 73% isolated yield.

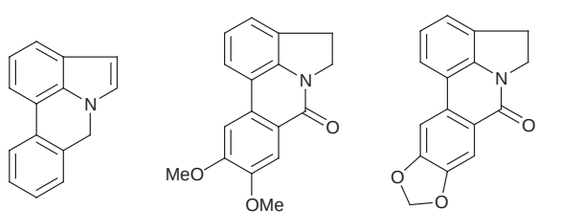


Scheme 9

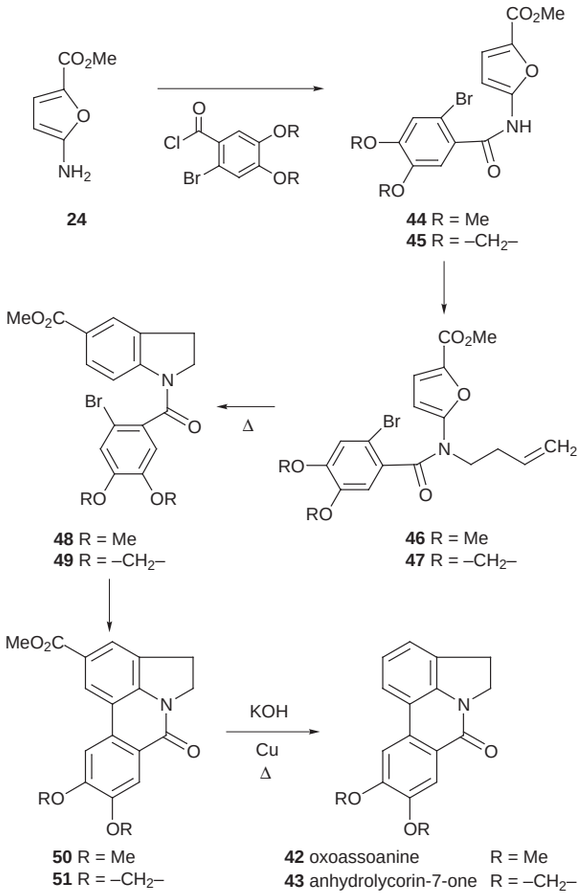


Scheme 10

Having established the suitability of 2-amidofurans to generate dihydroindoles, we turned our attention to the application of the method toward the synthesis of oxoassoanine[32] **42** and anhydrolycorin-7-one **43**.[33] These compounds are



members of the pyrrolophenanthridine class of alkaloids which have been isolated from various species of amaryllidaceae.[34] The 1*H*-pyrrolo[3,2,1-*de*]phenanthridine ring system **41** constitutes the core structural framework of the pyrrolophenanthridine alkaloids. Although a number of synthetic routes are available for this ring system, many of these suffer from low yields and lack generality.[35] A short synthesis of **42** and **43** was carried out as depicted in Scheme 11. This approach is centered

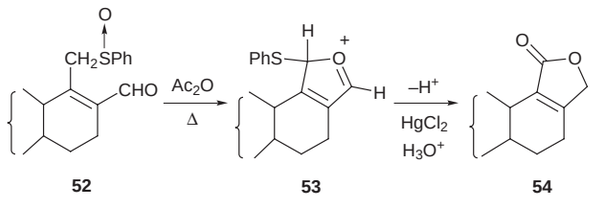


Scheme 11

on the construction of the key dihydroindoles **48** and **49** which are formed by a IMDAF cycloaddition followed by subsequent nitrogen atom lone pair assisted ring opening of the initially formed oxa-bridged cycloadducts. After some experimentation, it was found that using bis(tributyltin) under photochemical conditions afforded the aryl-coupled products **50** and **51** in high yield from the corresponding dihydroindoles **48** and **49**. Both compounds were converted to the natural products by a saponification-decarboxylation protocol.

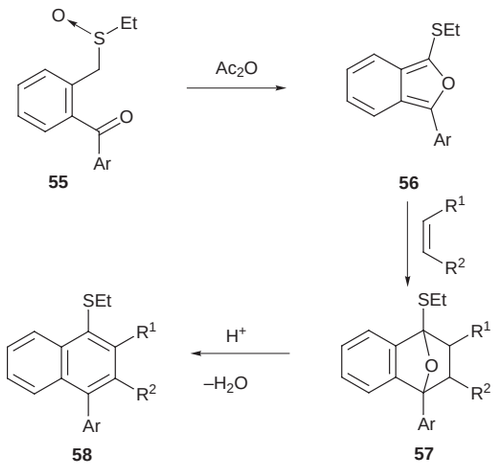
The domino Pummerer Diels–Alder sequence

Much of the chemistry utilized in the two preceding sections relied on our ability to synthesize the requisite 2-aminofurans. One limitation of the method is that sometimes the 2-aminofuran system is not easily accessible. In the context of our studies dealing with *domino cycloaddition/Mannich cyclizations*, we discovered that the Pummerer reaction can be effectively utilized to prepare the required furans.[36] α-Acyl thionium ions generated from α-acyl sulfoxides under Pummerer conditions are powerful electrophiles, reacting efficiently with nucleophilic carbon species.[37] Bimolecular addition of the cation to various carbon–carbon double bonds is well known.[38] In the realm of natural product synthesis, most success has been achieved using intramolecular Friedel–Crafts cyclization of the Pummerer thionium ion intermediate.[39] Far fewer examples exist for heteroatom interception of the Pummerer intermediate.[40] De Groot and co-workers recently developed an efficient procedure for butenolide formation in which the key step involves a Pummerer induced cyclization of aldehydic sulfoxides of type **52** into butenolides **54** (Scheme 12).[41] It was assumed that the neighboring carbonyl group attacks the initially formed thionium ion to give an oxy-stabilized cation **53** which loses a proton to generate a 2-thio-substituted furan



Scheme 12

which is subsequently converted to the butenolide upon hydrolysis. On the basis of this transformation we decided to explore the internal trapping of the Pummerer cation with adjacent carbonyl groups as a method to prepare a variety of substituted furans. The strategy was first tested on keto sulfoxide **55** (Scheme 13). The α-thiocarbocation derived from

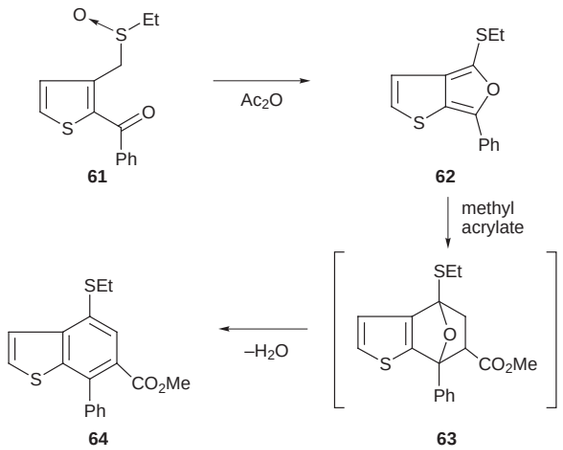


Scheme 13

the Pummerer reaction of **55** was readily intercepted by the adjacent keto group to produce isobenzofuran **56** as a transient intermediate which underwent a subsequent Diels–Alder cycloaddition with an added dienophile. The resulting cycloadduct **57** was readily converted to representatives of several types of arylnaphthalene lignans.[42]

As heteroaromatic isobenzofuran analogs have not been extensively studied in the literature, we focused our attention on the Pummerer reaction of several *o*-heteroaroyl substituted sulfoxides as a method to generate reactive heteroaromatic *o*-xylylenes. Most notable among the heteroaromatic isobenzofurans **60** reported in recent years are the furo[3,4-*b*]furans,

thieno[2,3-*c*]furans, furo[3,4-*d*]isoxazoles and furo[3,4-*b*]indoles.[43] These 10π-systems are isoelectronic with the pentalene dianion and have been of some theoretical interest.[43] MO calculations on these heteroisobenzofurans indicate that they possess little or no aromatic character, and this is reflected in their high chemical reactivity.[43] Using the *domino Pummerer/Diels–Alder sequence* we were able to synthesize several thieno[2,3-*c*]furans and furo[3,4-*b*]indoles.[44] In the presence of a suitable dienophile, the reactive *o*-xylylene underwent [4 + 2]-cycloaddition followed by an acid-catalyzed ring-opening and aromatization to give heteroaromatic naphthalene derivatives (Scheme 14). The *domino Pummerer cyclization/cycloaddition sequence* also occurred intramolecularly using unactivated alkenyl tethers of variable length. The results clearly indicate that the domino cascade process is a powerful method for the construction of complex heteroaromatic *o*-quinodimethanes.

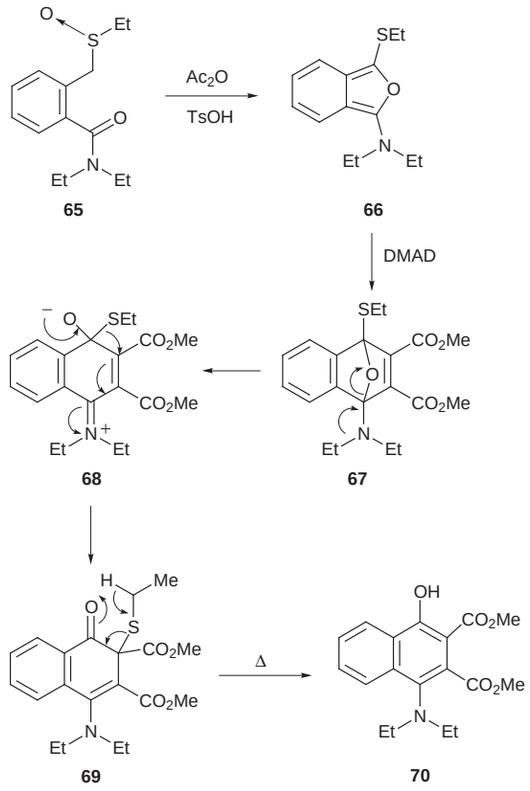


Scheme 14

Cycloaddition/ring opening/elimination sequence of 2-amino substituted isobenzofurans

Prompted by the above results, we became interested in extending the Pummerer-promoted cyclization reaction to *o*-amido-substituted sulfoxides since this would allow for the rapid stereocontrolled synthesis of a variety of azapolycyclic products. Indeed, the *domino Pummerer/Diels–Alder* sequence readily afforded 2-amino-substituted isobenzofurans as transient species which were too labile to isolate but underwent rapid [4 + 2]-cycloaddition with added dienophiles.[45] When dimethyl acetylenedicarboxylate (DMAD) was used as the trapping agent, the initially formed iminium ion **68** could not undergo proton loss (Scheme 15). Instead, **68** rearranged by means of a 1,2-ethylthio shift to afford the tetralone derivative **69**. Compound **69** was converted to naphthol **70** in high yield upon further heating. This process presumably proceeds by elimination of thioacetaldehyde in a hetero-retro-ene fashion, for which there is ample precedence in the literature.[46]

In order to access synthetically more valuable targets, we focused our attention on an intramolecular variation of the *domino amido-Pummerer/Diels–Alder reaction sequence.* The one-pot intramolecular cascade process occurred smoothly when the olefin tether was activated by an ester or when a carbonyl group was located adjacent to the nitrogen atom of the 2-amino-substituted isobenzofuran (Scheme 16).[45] The intramolecular cycloaddition behavior of the incipient isobenzofurans in response to the presence of a C=O group is striking. Five- and six-membered ring precursors **71a** and **71b** delivered cyclized products bearing a carbonyl within the newly formed rings in good to excellent yields. Externalization of the C=O as in **73** likewise led to a facile internal cyclization. Removal of the C=O functionality, however, suppressed intramolecular cycloaddition in favor of the traditional Pummerer reaction. The amine-amide effect is not limited to isobenzofurans. In our previous study of the intramolecular cycloaddition of carbonyl ylide dipoles and tethered alkenyl π-bonds, a similar phenomenon was observed (*i.e.* **12** → **14**).[21] Intermediates with carbonyl groups in the tether provided cycloaddition products; those lacking the C=O group failed to cyclize. The reactivity discrepancy in both cases can be traced to steric effects in the transition states. The incorporation of an amido group is clearly of synthetic advantage as it offers the opportunity to accelerate intramolecular cycloaddition by steric adjustment of ground state and transition state energies either separately or simultaneously. Both examples underscore the unexpected complexity of intramolecular cycloaddition processes that create several fused rings in a domino cascade and simultaneously induce steric effects remote from the reacting centers. Amide tethers have



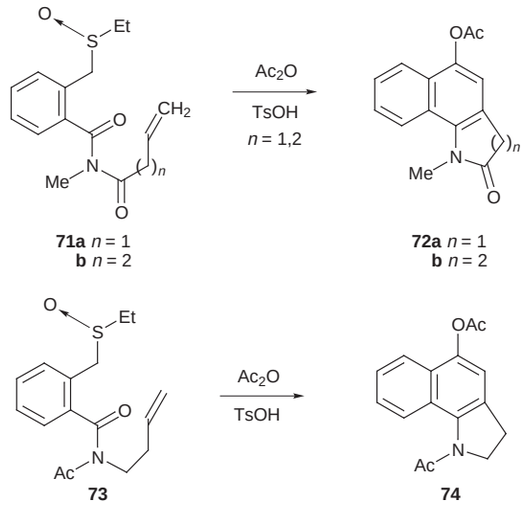
65 **66** **67** **68** **69** **70**

Scheme 15

emerged as remote-site promoters of intramolecular cycloaddition for tandem processes yielding products containing multiple fused rings.

Triple cascade sequence for construction of the erythrinane alkaloid skeleton

Having established the facility with which *N*-acyliminium ions can be formed from the Pummerer reaction of *o*-amido-substituted sulfoxides, we next focused our attention on the final cyclization step of the proposed cascade process (*i.e.* **22** → **23** in Scheme 6).[47] In order to avoid the deprotonation (aromatization) step, we prepared sulfoxides **75** and **76**, each possessing a



71a *n* = 1
b *n* = 2

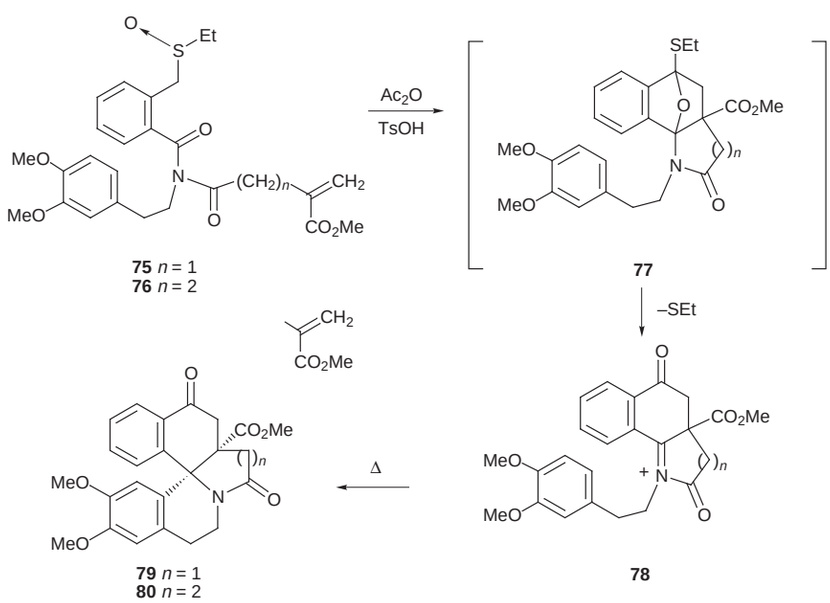
72a *n* = 1
b *n* = 2

73 **74**

Scheme 16

methoxycarbonyl group attached to the olefin tether. This substituent was selected not only to prevent deprotonation, but also because the presence of an electron-withdrawing group on the double bond enhances [4 + 2]-cycloaddition based on FMO considerations. *N*-Acyliminium ion **78** derived from the internal cycloadduct **77** underwent stereoselective spirocyclization to furnish the *cis*-3,4-benzoerythrinane **79** or homoerythrinane derivative **80** in good yield (Scheme 17). The overall triple cascade sequence represents an efficient one-pot approach towards the erythrinane alkaloid skeleton[34] in which the spirocyclic ABC skeleton is assembled in a single operation.

At this point, we decided to undertake a synthesis of (±)-erysotramidine **90** in order to further test the viability of the triple cascade process as an entry into the erythrinane skeleton.[34] The requisite starting imido sulfoxide **81**, possessing both a dienophilic and diactivated aromatic π-tether, was efficiently synthesized from known starting materials. Subjection of **81** to the Pummerer conditions gave compound **87** as a single diastereomer in 83% yield. The *cis* A/B ring fusion present in **87** was unequivocally established by an X-ray crystallographic analysis and is identical to the stereochemical relationship found in the naturally occurring erythrina alkaloids. The conversion of **81** into **87** is believed to follow the pathway



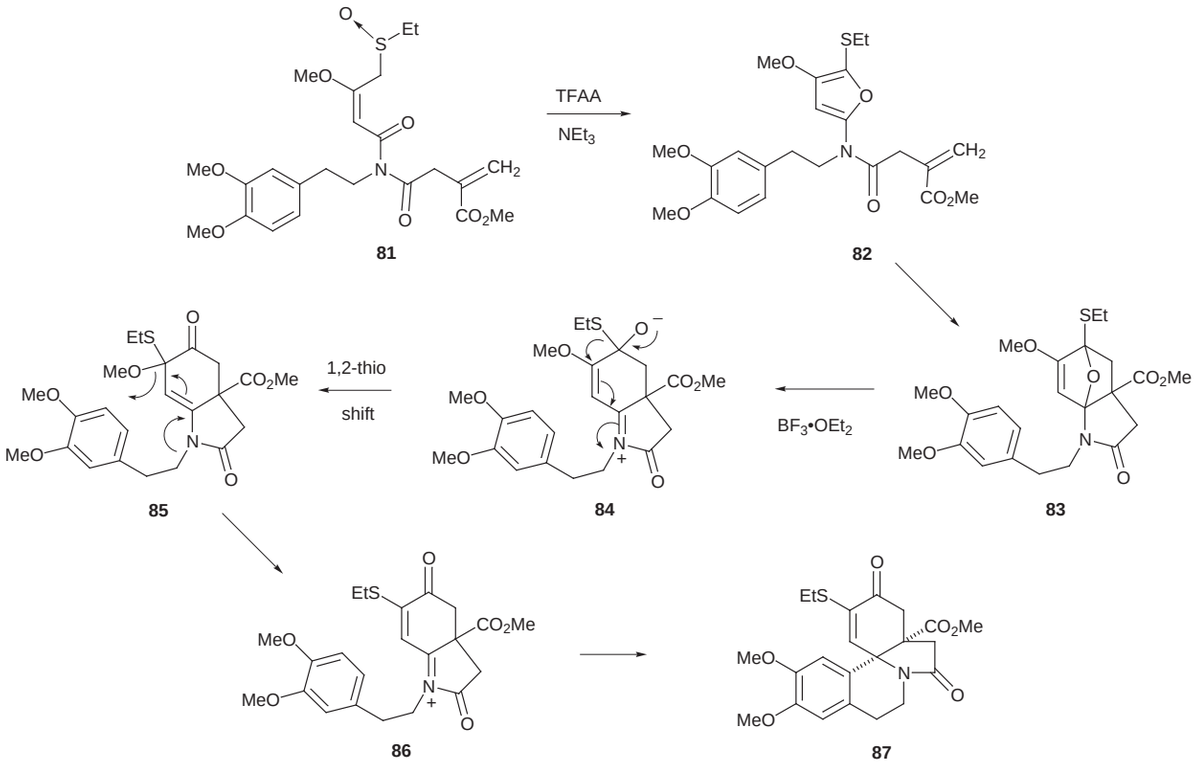
75 *n* = 1
76 *n* = 2

77

78

79 *n* = 1
80 *n* = 2

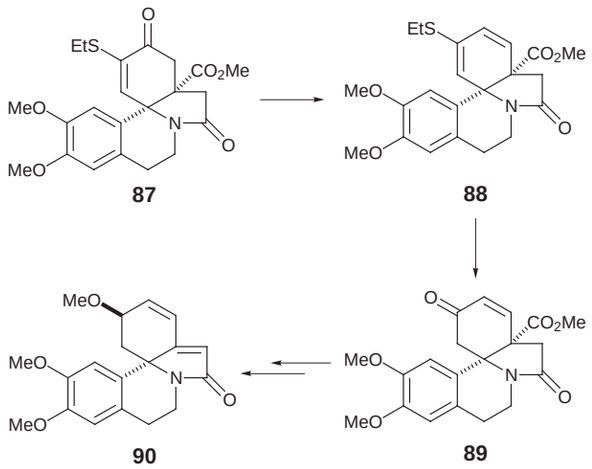
Scheme 17



Scheme 18

outlined below (Scheme 18). The initially formed α-thiocarbocation intermediate generated from the Pummerer reaction of **81** is intercepted by the adjacent imido carbonyl to produce the α-amido substituted furan **82**. This transient intermediate undergoes a subsequent intramolecular Diels–Alder cycloaddition across the tethered π-bond to furnish cycloadduct **83**. Nitrogen-assisted ring opening of the oxabicyclic bridge results in the formation of zwitterionic intermediate **84** which undergoes a 1,2-thioethyl shift followed by methoxide ion ejection. Cyclization of the diactivated aromatic tether onto *N*-acyliminium ion **86** ultimately provides the tetracyclic amide **87**.

With a supply of **87** in hand, this enone was converted into the corresponding vinyl triflate which, in turn, was subjected to a palladium-catalyzed formate reduction to give **88**. The resulting thio-substituted diene was subsequently transformed into ketone **89** *via* a titanium mediated hydrolysis.[48] The present sequence constitutes a formal synthesis of (±)-erysotramidine **90** based on the successful conversion of **89** into **90** by Tsuda.[49]



Scheme 19

Concluding remarks

Over the past four years we have shown that many structurally diverse heterocyclic compounds can be readily accessed *via* the *domino cycloaddition*/N-*acyliminium ion cyclization cascade*. The key step in this process involves the generation of a reactive *N*-acyliminium ion by fragmentation of an amino substituted [4 + 2]-cycloadduct. This triple cascade is applicable toward the preparation of a broad range of alkaloids. It is a reasonable expectation that future years will see a continued evolution of this unique domino cascade toward other synthetic targets.

I thank my enthusiastic and gifted co-workers, whose names appear in the appropriate references, and the National Institute of Health for financial support.

Albert Padwa is the William Patterson Timmie Professor of Chemistry at Emory University. Before that he was on the faculty at Ohio State University (1963–1966) and the State University of New York at Buffalo (1966–1979). He has held visiting positions at University Claude Bernard, France (1978), University of California at Berkeley (1982), the University of Wurzburg, Germany (1985) and Imperial College, UK (1990). Professor Padwa has been the recipient of an Alfred P. Sloan Fellowship (1968–1970), John S. Guggenheim Fellowship (1981–1982), Alexander von Humboldt Senior Scientist Award (1983–1985) and a Fulbright Hays Scholarship (1990). He was elected as the Chairman of the Organic Division of the ACS (1985–1986) and more recently served as president of the International Society of Heterocyclic Chemistry (1994–1996). He has also served as a member of the editorial board of the Journal of the American Chemical Society, Journal of Organic Chemistry, Heterocyclic Communications, Internet Journal of

Chemistry and has been the volume editor of Comprehensive Heterocyclic Chemistry. He is the coauthor of more than 520 publications. His research interests include heterocyclic chemistry, reactive intermediates, dipolar cycloadditions, alkaloid synthesis and transition metal chemistry. Aside from Chemistry, his other passion is mountain climbing in South America.

Nanosized rhodium oxide-containing MCM-41 (Rh-MCM-41) mesoporous molecular sieves are synthesized and characterized by XRD, TEM, N_2 adsorption, NMR, XPS and EXAFS.

The discovery[1,2] of the novel mesoporous silicate based MCM-41 molecular sieve has generated much interest to design hybrid atom-containing MCM-41 by isomorphous substitution of transition metals into the framework or by functionalisation of the silanols in the pore channels for their applications to catalysis and advanced materials.[3–5] Noble metals such as Pt,[6,7] Pd,[8,9] and Ru[10] were supported on MCM-41, and Ag/Ru bimetallic nanoparticles[11] were supported inside the MCM-41 channels and found to be active compared with the corresponding conventional supported catalysts. However there is no study related to the synthesis of noble metal-containing MCM-41 by addition of noble metals to mixed silicate surfactant gels prior to the hydrothermal synthesis. We have systematically studied the formation of hexagonal structure of MCM-41 and the formation of rhodium oxide nanoparticles, while changing the temperature, aging time and Si/Rh ratio during the hydrothermal synthesis. We report here the first synthesis and characterization of Rh-MCM-41.

The synthesis‡ of Rh-MCM-41 was achieved by modifying the recently reported procedure.[12] The Si/Rh ratio in the synthesis was varied in the range 200–70, and the hydrothermal synthesis was carried out *via* two different pathways [route A: 373 K for 10 days (Rh-MCM-41-A) and route B: 423 K for 48 h (Rh-MCM-41-B)] to study the formation of rhodium oxide particles and also the MCM-41 framework. Supporting Rh on MCM-41 (Rh-su-MCM-41) by an impregnated method was also conducted§ for comparison with Rh-MCM-41. The powder XRD patterns of the calcined forms of Rh-MCM-41 are shown and indexed in Fig. 1. The d_{100} spacings and the unit cell parameters (a_0) are listed in Table 1. A highly ordered hexagonal structure was identified for the Rh-MCM-41-A, which resembled pure Si-MCM-41 reported in the literature.[1,12] A shift of the d_{100} peak was noticed for the Rh-MCM-41-B, indicating that the a_0 (5.47–5.71 nm) became larger. The increase in the a_0 implies the promotion of polymerization of the silica precursor by the presence of Rh ions in the gel, and eventually thicker pore walls were produced as compared to the pure Si-MCM-41 (a_0 = 5.00 nm, pore wall thickness: 1.69 nm) prepared under the similar conditions. The increase of a_0 may be due to a catalytic role of rhodium during the construction of the mesoporous framework at 423 K.

The (114) XRD peak of Rh_2O_3 at 2θ = 34.3° was not detected for the Rh-MCM-41-B, indicating that rhodium oxides are highly dispersed and/or amorphous. Rh K-edge EXAFS spectra for Rh-MCM-41-A and Rh-MCM-41-B were measured at 20 K using synchrotron radiation at Photon factory (proposal No. 97G002). The curve fitting analysis using the empirical parameters derived from Rh_2O_3 (Rh–O 0.211 nm, coordination number six), revealed the Rh–O bond distance at 0.205 nm with the coordination number of 4.3–4.5. Preliminary analysis for the second shell also indicated the presence of Rh–Rh bonds at 0.299 nm for Rh-MCM-41-A and at 0.307 nm for Rh-MCM-41-B, the distance being > 0.292 nm for Rh_2O_3. Hence the rhodium oxide particles in the Rh-MCM-41 seem to have different structures from Rh_2O_3.

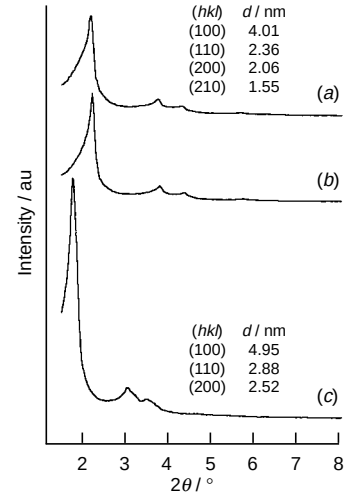

Fig. 1 Powder X-ray diffraction patterns of the calcined forms of Rh-MCM-41; (*a*) Rh-MCM-41-A, (Si/Rh = 200); (*b*) Rh-MCM-41-A(104); (*c*) Rh-MCM-41-B (200)

Table 1 Properties of the Rh-MCM-41 molecular sieves

Sample	Si/Rh ratio[a]	d_{100}[b]/nm	a_0[c]/nm	Pore diameter[d]/nm	S_{BET}/m^2 g^{-1}	Pore volume/ cm^3 g^{-1}	PWT[e]/nm	XPS Si/Rh ratio
Rh-MCM-41-A	200	4.01	4.63	3.02	1016	0.96	1.61	907
Rh-MCM-41-A	70	4.01	4.63	3.02	1028	1.06	1.61	554
Rh-MCM-41-B	200	4.95	5.71	3.40	623	0.80	2.31	415
Rh-MCM-41-B	104	4.74	5.47	3.26	464	0.55	2.21	355
Rh-su-MCM-41	104	4.57	5.27	3.40	1175	0.88	1.87	91

[a] At the synthesis stage. [b] Spacing after calcination. [c] Calculated $a_0 = 2d_{100}\sqrt{3}$. [d] Dollimore–Heal method. [e] PWT (pore wall thickness) = a_0 − pore diameter.

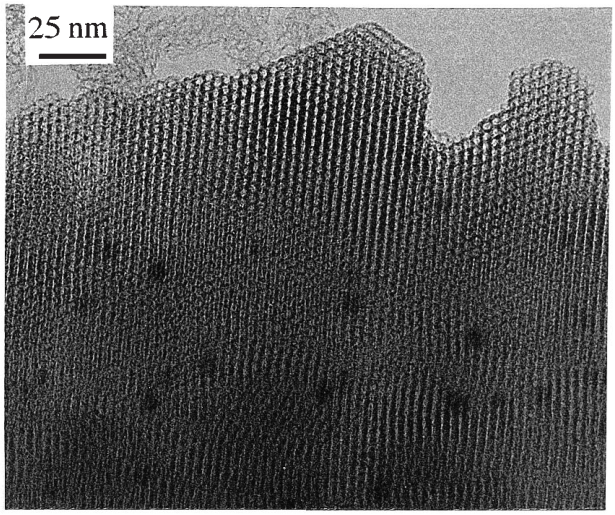

Fig. 2 TEM micrograph (200 kV; ×80 000) of the calcined form of Rh-MCM-41-A with Si/Rh ratio of 200

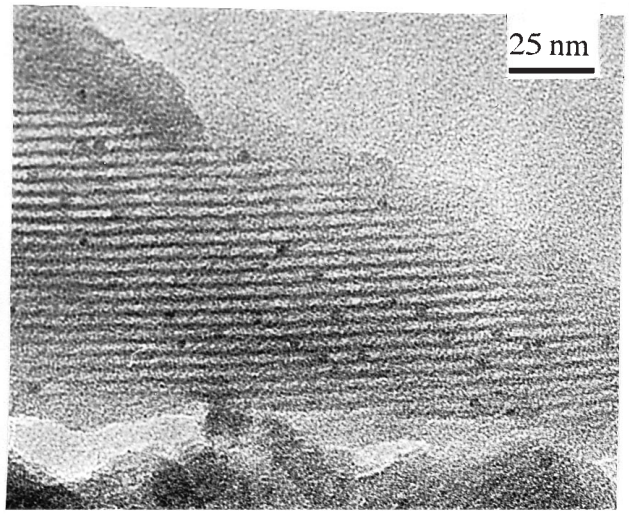

Fig. 3 TEM micrograph viewed perpendicular to the pore axis (200 kV; ×100 000) of the calcined form of Rh-MCM-41-B with Si/Rh ratio of 200

The TEM image of calcined Rh-MCM-41-A is shown in Fig. 2, where the hexagonally packed MCM-41 with dispersed rhodium oxide particles with an average particle size of 6 nm is observed. Fig. 3 is the TEM image viewed perpendicular to the pore axis of the calcined Rh-MCM-41-B, which depicts the uniformly packed channels containing dispersed rhodium oxide nanoparticles (< 3 nm), and the d_{100} value calculated from the TEM image is in agreement with the value from XRD. The thickness of pore walls in TEM is also in agreement with that calculated from XRD in Table 1.

The adsorption–desorption isotherms of N_2 at 77 K were of type IV for Rh-MCM-41 samples which is typical of mesoporous solids and has a narrow pore size distribution. The surface area, pore diameter and pore wall thickness are listed in Table 1. Further characterization of the calcined Rh-MCM-41 samples was performed by ^{29}Si solid state MAS NMR using cross polarization (CP) technique to examine the formation of thicker pore walls in case of Rh-MCM-41-B. The intensity ratio of the two NMR peaks $Q^3 : Q^4$ for Rh-MCM-41-B was 66 : 34, while that for pure Si-MCM-41 was 76 : 24, and this $Q^3 : Q^4$ ratio obtained by CP technique for the Si-MCM-41 is in agreement with that reported by Zhao *et al.*[13] The large increase in the intensity of the Q^4 silicon peak at δ −122 for Rh-MCM-41-B indicates the enhancement of cross-linking by rhodium. The $Q^3 : Q^4$ ratio for Rh-MCM-41-A was identical with that for Si-MCM-41.

The location of rhodium oxide particles in Rh-MCM-41 may be deduced by the Si/Rh ratio in XPS spectra. The Si/Rh XPS ratio for Rh-su-MCM-41 with the Si/Rh bulk ratio of 104 was 91, whereas that for Rh-MCM-41-B with the Si/Rh bulk ratio of 104 was 355. All the Rh-MCM-41 samples in Table 1 showed much larger Si/Rh XPS ratios than the values expected from the bulk composition. These results demonstrate that most of rhodium oxide particles in the Rh-MCM-41-A and Rh-MCM-41-B samples are located in the bulk or the mesopore channel, as imaged in Fig. 2 and 3, respectively, whereas rhodium oxides in Rh-su-MCM-41 are thought to be supported at the external surfaces and near the surfaces.

The comprehensive characterization data demonstrate that the growth of nanosized rhodium oxide particles < 3 nm in the mesopore channel of MCM-41 can be controlled with the appropriate selection of synthesis conditions, and that rhodium plays a catalytic role in the polymeric formation of silica walls of the MCM-41 framework. The application of Rh-MCM-41 to catalysis is in progress.

This work has been supported by CREST (Core Research for Evolutionary Science and Technology) of the Japan Science and Technology Corporation (JST). We thank Dr T. Kogure for assistance with some of the TEM observations which were completed in the Electron Microbeam Analysis Facility of the Mineralogical Institute, The University of Tokyo.

‡ Tetramethylammonium hydroxide pentahydrate (TMAOH) was added to distilled water followed by addition of cetyltrimethylammonium bromide (CTABr) at 303 K. $RhCl_3 \cdot 3H_2O$ (Wako Chemicals) was added to the solution and stirred for 10 min until the solution became clear, then fumed silica obtained from Sigma was slowly added to the solution. The gel composition was 1.0 SiO_2 : 0.19 TMAOH : 0.27 CTABr : 40 H_2O : 0.0049–0.14 $RhCl_3 \cdot 3H_2O$. The gel was aged for 24 h at room temperature and aged at 373 K for 10 days or at 423 K for 48 h. It was filtered, washed with distilled water and dried at 373 K for 12 h, followed by calcination in air at 823 K for 8 h.

§ A methanol solution of $RhCl_3 \cdot 3H_2O$ was added to the calcined pure Si-MCM-41 and the methanol was evaporated with rotary pump and the resultant solid was dried at 373 K for 12 h, followed by calcination at 823 K for 8 h.

Novel unsymmetrical triphenylene discotic liquid crystals: first synthesis of 1,2,3,6,7,10,11-heptaalkoxytriphenylenes

Sandeep Kumar*† and M. Manickam

Centre for Liquid Crystal Research, PO Box 1329, Jalahalli, Bangalore-560 013, India

Oxidation of 2-hydroxy-3,6,7,10,11-pentaalkoxytriphenylene yields the pentaalkoxytriphenylene-1,2-quinone; reductive acetylation of this *o*-quinone furnishes the diacetate that can be directly alkylated to 1,2,3,6,7,10,11-heptaalkoxytriphenylene derivatives showing columnar D_h phases.

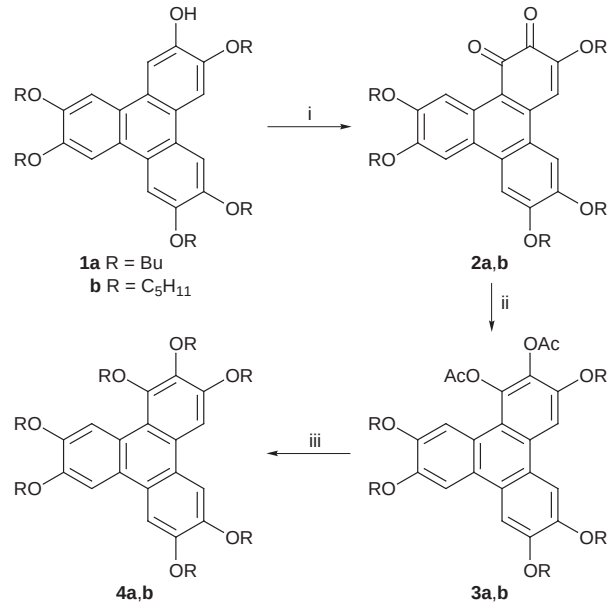
Mesophases formed by discotic liquid crystals (LCs) are now well-recognised to be suitable for many device applications.[1,2] Most of the discogens reported to date consist of a flat, or nearly flat, rigid core surrounded by a number of aliphatic side chains having binary, trigonal, tetragonal or hexagonal symmetries. Symmetrically substituted hexethers of triphenylene are the most widely synthesised and studied discotic mesogens. The potential uses of these materials as one-dimensional conductors,[2,3] photoconductors[4] and light emitting diodes[5] are attracting considerable attention. Several research groups are currently working on the synthesis of symmetrical, unsymmetrical and functionalized triphenylene discotic liquid crystals.[6–14]

Triphenylene derivatives show mesomorphism only when the six peripheral positions are substituted with aliphatic chains. Whereas the synthesis of symmetrical hexalkoxytriphenylenes by oxidative trimerisation of 1,2-dialkoxybenzenes is quite easy, the synthesis of well-defined unsymmetrically substituted derivatives is more complicated. Breaking of symmetry in a hexaalkoxytriphenylene can be achieved by different ways, *e.g.* by changing the chain length of some of the side chains, by changing the nature of one or more side chain or by using lower or higher degrees of substitution. Tinh *et al.* reported the synthesis of several dissymmetrical hexasubstituted triphenylenes by incorporating different alkyl chains into the periphery using a statistical approach and found that introduction of dissymmetric side-chains does not affect the nature of the D_h phase but does result in the reduction of the mesophase stability.[15] An easy route to unsymmetrically-substituted triphenylenes was recently reported using the so-called biphenyl route.[6e,7e] A well-defined synthesis of unsymmetrical and low degree substituted triphenylenes has also been reported recently using organometallic chemistry.[10] When one out of the six ether side chains in hexaalkoxytriphenylenes was replaced by an ester group, the stability of the mesophase was enhanced significantly.[16] A plastic columnar discotic phase is reported in this type of unsymmetric triphenylene derivatives.[17] In an another approach to the preparation of unsymmetrical triphenylenes and to the induction of molecular dipole, colour, *etc.*, nitration and halogenation of hexaalkoxytriphenylenes has been investigated.[6a–d,9] While the nitro or halogen group in these triphenylene derivatives could not be replaced by an alkylthio group by nucleophilic aromatic substitution,[9] reduction of the nitro group followed by acylation with various acid chlorides yielded 'seven tail' triphenylene discotics.[6a] However, because of the presence of the amide group, the clearing temperature of these derivatives are rather high.

We have very recently reported a highly improved synthesis of symmetrical, unsymmetrical and mono-functionalized triphenylene derivatives using $MoCl_5$.[8c] We have also reported the synthesis of various functionalized triphenylene,[7f,8d] mixed tail triphenylene,[7b] low symmetry fluorescent triphenylene[7a] and core functionalized triphenylene discotic LCs.[8b,c]

All the triphenylene derivatives hitherto known have six or less alkoxy chains. While triphenylene derivatives with six alkoxy chains are mesomorphic, triphenylenes having less than six alkoxy chains are nonmesomorphic but can be made mesomorphic by putting other substituents onto the periphery.[7a,b] To the best of our knowledge, there are no examples of triphenylene discotic species having more than six alkoxy chains. Here we report on a novel approach to the synthesis of triphenylene-based discotic liquid crystals containing seven alkoxy chains in the periphery. The synthesis of these novel heptaalkoxytriphenylenes is outlined in Scheme 1.

During the nitration 2-hydroxy-3,6,7,10,11-pentabutoxytriphenylene, we always found a black product in addition to the nitrated and some unreacted starting material.[8e] If the reaction is not monitored carefully, this black material becomes the major product. We suspected that the formation of this black material was due to ring oxidation to an *o*-quinone. Oxidation of 2-hydroxy-3,6,7,10,11-pentabutoxytriphenylene **1a** with other known oxidising agents such as chromium trioxide and cerium(IV) ammonium nitrate yielded the same product. The structure of this compound was assigned as 3,6,7,10,11-petabutyloxytriphenylene-1,2-dione **2a** on the bases of its ^{1}H NMR and mass spectral data. Reductive acetylation of this *o*-quinone resulted in the formation of diacetate **3a**. The diacetate was directly alkylated[8a] with alkyl halide to heptabutoxytriphenylene **4a** in very high yield. Heptapentoxytriphenylene was prepared in the same manner. The ^{1}H NMR data of the products were found to be in perfect agreement with the structure.‡



Scheme 1 *Reagents and conditions*: i, CAN, MeCN, room temp., 2 min, 94%; ii, Ac_2O, Zn, NEt_3, reflux, 0.5 h, 92%; iii, DMSO, KOH, RBr, 60 °C, 1 h, 95%

Both heptaalkoxytriphenylenes **4a** and **4b** are mesogenic. While compound **4a** melted at 65.7 °C and clears at 70.1 °C, compound **4b** exhibited a very broad mesophase from room temperature to 65 °C. The mesophase–isotropic transition temperatures of both heptaalkoxytriphenylenes are very low compared to their hexasubstituted analogues (*ca.* 145 °C for hexabutoxy- and 122 °C for hexapentoxytriphenylene). This could be due to the presence of the extra alkoxy chain and the steric hindrance caused by this chain.

This methodology provides an easy, high-yielding process for the preparation of various unsymmetrical, low clearing temperature, broad mesophase triphenylene discotics. It can also be extended to other discotic cores. The potential of this new method is currently under investigation for the synthesis of various hepta-, octa-, nona- and per-alkoxytriphenylene derivatives.

We are very grateful to Professor S. Chandrasekhar for many helpful discussions. The authors also gratefully acknowledge the technical assistance of Mr Sanjay K. Varshney.

A highly coupled Ru^{III}–Ru^{II} system incorporating sulfur donor ligands

Sue Roche,[a] Lesley J. Yellowlees[b] and Jim A. Thomas*[a]†

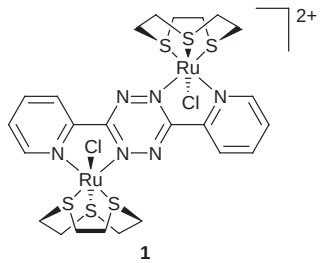
[a] *Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*
[b] *Department of Chemistry, University of Edinburgh, Edinburgh, UK EH9 3JJ*

Bimetallic complex 1, which is based on a Ru^{II} metal centre incorporating sulfur donor ligands, shows strong intermetallic coupling in its mixed valence state comparable to those observed in complexes incorporating conventional nitrogen donors.

Mixed valence coordination chemistry has been dominated for some time by ruthenium(III/II) complexes,[1] most of them being modelled on the Creutz–Taube ion.[2] Theoretical models[3] have been used to understand their spectral properties, especially of the characteristic metal-to-metal charge transfer or intervalence transitions.

Previous research has revealed that the electron transfer properties of such systems are highly dependent on the nature of the metal centres and ligand bridge. Such systems have also played an important part in the development of devices for molecular electronics,[4] where they have formed the basic components of molecular wires and molecular switches. The goal of such research is to develop systems displaying electronic communication between metal centres and thus long range electron transfer and photoinduced charge separation.[5] So far, research has involved changing the bridging ligands[6] and the metal ion.[7] However, all of the metal centres in these complexes contain nitrogen based ligands, such as NH_3 and 2,2′-bipyridine (bpy), coordinated to the metal ion. Our attempt has been to broaden the experimental basis of mixed valence chemistry, by introducing new metal organic fragments incorporating sulfur donor ligands such as the crown ether 1,4,7-trithiacyclononane.

An ideal starting material for these complexes is the previously reported $[Ru(Me_2SO)Cl_2([9]aneS_3)]$.[8] When refluxed overnight with the ligand 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine[9] (bptz) in ethanol–water (1 : 1), a crude product is isolated on the addition of ammonium hexafluorophosphate. After alumina column chromatography, the bimetallic complex cation $\mathbf{1}^{2+}$ was isolated as its PF_6 salt as a blue powder in 48% yield. This compound is air and moisture stable and has been characterised by ^{1}H NMR, UV–VIS and FAB mass spectroscopy.‡



1

The UV–VIS spectrum of $\mathbf{1}^{2+}$ shows two bands (Table 1). The first at 302 nm has a large absorption coefficient (ε = 3497 $dm^3\ mol^{-1}\ cm^{-1}$) and has been assigned to a π–π* transition. The second intense band has ε = 2281 $dm^3\ mol^{-1}\ cm^{-1}$ and occurs at 751 nm. A comparison with structurally similar complexes allows this band to be to assigned metal-to-ligand charge transfer (MLCT).[1b]

Table 1 UV–VIS spectra data for complex **1** in acetonitrile

Complex	λ_{max}/nm	ε/ $dm^3\ mol^{-1}\ cm^{-1}$	Assignment
$\mathbf{1}^{2+}$	302	3497	π–π*
	751	2281	MLCT
$\mathbf{1}^{3+}$	310	3158	π–π*
	678	2312	MLCT
	1852	519	IVCT

In an attempt to quantify the ligand bridge mediated intermetallic interaction, cyclic voltammetry was used. This was carried out in acetonitrile (Table 2). Complex $\mathbf{1}^{2+}$ displays a first oxidation at $E_{1/2}$ 1.36 V. The first oxidations for the related complexes $[\{Ru(NH_3)_4\}_2(bptz)]^{4+}$ ($\mathbf{2}^{4+}$) and $[\{Ru(bpy)_2\}_2(bptz)]^{4+}$ ($\mathbf{3}^{4+}$) occur at 0.72 and 1.52 V respectively. The difference in these values can be explained by considering the nature of the coordination bonding in these complexes. While NH_3 is a purely σ-donor ligand, bpy ligands are also π-acceptors and as such stabilise the Ru^{II} oxidation state producing the observed anodic potential shifts. The electrochemical behaviour of $\mathbf{1}^{2+}$ indicates that the $[RuCl([9]aneS_3)]^+$ metal centre is also appreciably stabilised by π back-donation interactions. Such an observation is consistent with, and confirms, recent findings on the coordination chemistry of thioether ligands.[10]

Complex $\mathbf{1}^{3+}$ displays a strong intermetallic interaction with $\Delta E_{1/2}$ = 0.48 V resulting in a comproportionation constant (K_c) of 1.48×10^8, suggesting that it is a Robin and Day class III system.[12] This value is greater than the previously reported value of $\Delta E_{1/2}$ = 0.39 V for the Creutz–Taube ion,[13] and is similar to complex $\mathbf{3}^{5+}$ ($\Delta E_{1/2}$ = 0.5 V) but less than the value for complex $\mathbf{2}^{5+}$ ($\Delta E_{1/2}$ = 0.84 V). On this evidence, it would appear that $\mathbf{1}^{2+}$ is a less strongly interacting system than $\mathbf{2}^{4+}$. However, a comparison of the optical properties of the mixed valence complexes is more informative.

The intermetallic interaction in $\mathbf{1}^{3+}$ was further investigated using spectroelectrochemistry. The formation of several isosbetic points after the oxidation of $\mathbf{1}^{2+}$ shows a clean conversion taking place, with the MLCT band showing a hypsochromic shift (Table 1). A significant observation is the formation of an new band at 1852 nm (5375 cm^{-1}). This band, which has been assigned to an intervalence charge transfer (IVCT), has an absorption coefficient of ε = 519 $dm^3\ mol^{-1}\ cm^{-1}$. By

Table 2 Electrochemical data[a] for some ruthenium complexes

Complex	$E_{1/2}(1)$/V	$E_{1/2}(2)$/V	$\Delta E_{1/2}$/V	K_c[b]	Ref.
$\mathbf{1}^{2+}$	1.36	1.84	0.48	1.4×10^8	This work
$\mathbf{2}^{4+}$	0.72	1.56	0.84	1×10^{15}	1(*a*)
$\mathbf{3}^{4+}$	1.52	2.02	0.5	3×10^8	11

[a] Cyclic voltammogram of complex cation $\mathbf{1}^{2+}$ was carried out at a scan rate of 200 mV s^{-1} in acetonitrile containing tetrabutylammonium hexafluorophosphate as supporting electrolyte (0.1 M). Potentials were measured *vs.* SCE. All couples were reversible with I_{pc} and I_{pa} equal and ΔE_p < 100 mV. [b] K_c values calculated using $\log K_c = \Delta E_{1/2}/0.059$.

comparison, the IVCT band found for $\mathbf{2}^{5+}$ is observed at 1453 nm with ε = 500 dm^3 mol^{-1} cm^{-1}.[1a]

Application of Hush theory[3b,c] to the IVCT spectral data of $\mathbf{1}^{3+}$ yields a bandwidth at half-height, $\Delta\nu_{1/2}$, which is much higher than the experimental value: $\Delta\nu_{1/2} = (2310\nu)^{1/2}$ cm^{-1}, $\Delta\nu_{1/2}$ ($\mathbf{1}^{3+}$, calc.) = 3524 cm^{-1}, $\Delta\nu_{1/2}$ ($\mathbf{1}^{3+}$, exptl.) ≈ 1375 cm^{-1}.

This discrepancy indicates that, like $\mathbf{2}^{5+}$, $\mathbf{1}^{3+}$ is a delocalised (class III) system, to which the above treatment is not applicable. Accordingly, the degree of electronic coupling, H_{AB}, can be estimated to approximately $1/2\nu$ = 2687.5 cm^{-1}.[3c]

Concluding, not only is this a new structural motif for such studies, it also seems effective in facilitating bridge mediated intermetallic interactions. With an aim to designing functional molecular devices, future studies will concentrate on variations in the metal ion, co-ordination sphere of the metal centre, and the bridging ligand.

We gratefully acknowledge the support of The Royal Society (J. A. T.) and the EPSRC.

Diastereoselective hydrogenation of *o*-toluic acid derivatives over supported rhodium and ruthenium heterogeneous catalysts

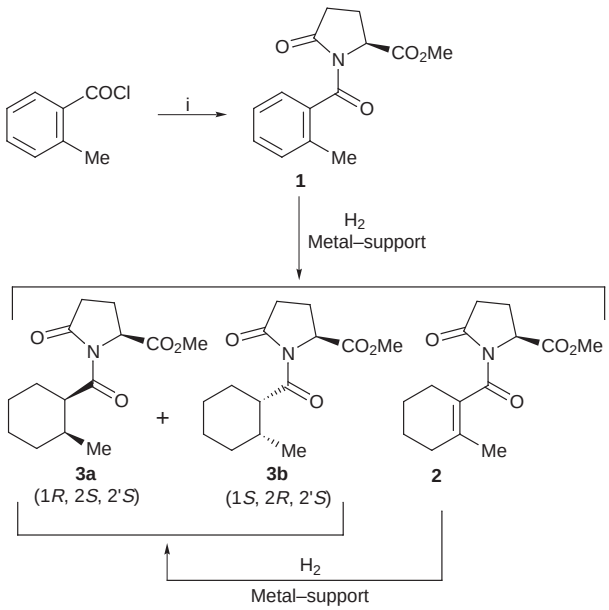
Michèle Besson,*† Pierre Gallezot, Samuel Neto and Catherine Pinel

Institut de Recherches sur la Catalyse-CNRS, 2 avenue Albert Einstein, 69626 Villeurbanne Cedex, France

Asymmetric hydrogenation of an *o*-toluic acid derivative to 2-methylcyclohexanoic acid with high optical selectivity (up to 95%) was performed by using (*S*)-pyroglutamic acid methyl ester as a chiral auxiliary and Rh–Al_2O_3 as the catalyst.

Diastereoselective catalytic hydrogenation with heterogeneous metal catalysts has been applied for the reduction of C=C, C=O or C=N bonds.[1,2] Modest to high diastereoselectivities were obtained, depending on the chiral auxiliary used and the nature of the heterogeneous catalyst. Recently, this method was proposed to hydrogenate aromatic rings.[3,4] Thus, (*S*)-*N*-(2-methylbenzoyl)proline methyl ester was hydrogenated quantitatively on pretreated Rh–Al_2O_3 in the presence of a bulky amine (ethyldicyclohexylamine = EDCA); the *cis* isomer was obtained preferentially (yield > 97%) with diastereoisomeric excess (de) values reaching 67%.[5] We now report on the use of a pyroglutamic acid derivative as a chiral auxiliary which permits the diastereoselective reduction of aromatic moities with higher than 90% de.

Substrate **1** was synthesized with a 82% yield, after purification, by coupling under mild conditions *o*-toluoyl chloride with pyroglutamic acid methyl ester (Scheme 1).[6]‡ The hydrogenation was carried out in a stirred autoclave at a hydrogen pressure of 5 MPa at room temperature. The substrate was dissolved in EtOH and supported rhodium or ruthenium catalysts (2–5 mol%) were added. EDCA (2–3 equiv. with respect to metal) was optionally added. The typical product distribution as a function of time (entry 5) is given in Fig. 1 for a hydrogenation performed over Ru–C catalyst. The aromatic substrate was hydrogenated to **3a** and **b** with a constant de; some



Scheme 1 *Reagents and conditions*: i, (*S*)-pyroglutamic acid methyl ester, toluene, 80 °C, N_2

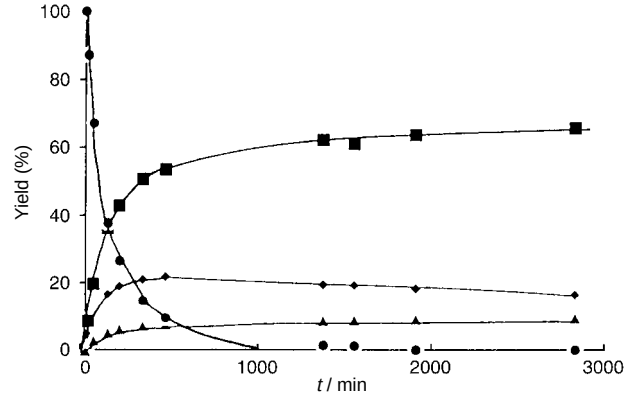


Fig. 1 Distribution of products *versus* time for hydrogenation of **1** over Ru–C (entry 5, Table 1). Reaction conditions: 2.26 mmol **1**, 0.063 mmol Ru, 130 ml EtOH, room temp., 5 MPa H_2. Less than 3% of the *trans* compound was detected. (●) **1**, (◆) **2**, (■) **3a** and (▲) **3b**.

cyclohexenic compound **2** was formed transiently and consecutively hydrogenated to **3**. An overview of the most significant catalytic results is summarized in Table 1.

In all reactions, only small amounts of *trans*-cyclohexane derivative were found (< 3%) and the absolute configuration of the major *cis* product was *(1S,2R,2′S)*. Hydrogenation of (*S*)-*N*-(2-methylbenzoyl) pyroglutamic acid methyl ester **1** in the presence of Rh–C catalyst resulted in 35% de, whereas on Rh–Al_2O_3 the conversion was slightly lower, although the diastereoselectivity was 90%. Addition of a bulky amine (EDCA) to the reaction medium lowered the reaction rate in both cases, but excellent diastereoisomeric excesses were observed, both on carbon (90% de) and on alumina (95% de). Compound **2** was detected in significant amounts only in the case of Rh–C; its hydrogenation gave preferentially **3b** and lowered the de.

In the case of the ruthenium catalyst, high diastereoselectivities were achieved without amine, irrrespective of the support (74 and 85% de on carbon and alumina, respectively). However, it was found that the reaction was slower on the alumina-supported catalyst. The semi-hydrogenated compound **2** was

[a] Molar ratio. [b] Determined by GC analysis (DB 1701). [c] The determination of the major configuration (1*S*,2*R*,2′*S*) was carried out by measuring the optical purity of the hydrolyzed product. [d] The conversion was complete after 100 min reaction. [e] Pretreated under H_2 at 300 °C for 2 h.

present in up to 19%, and due to steric constraints, it was hydrogenated with reduced de. The diastereoselectivity was increased from 74 to 83% when EDCA was added to the Ru–C catalyst.

These results clearly show that (*S*)-pyroglutamic acid methyl ester exerts much stronger chiral induction than (*S*)-proline derivatives since the de increased to 95% from 67%. This is probably due to the presence of the ketone group in the auxiliary, which plays a crucial role by interacting with the catalyst surface and blocking one of the faces of the aromatic ring.

Single stranded DNA-poly(*N*-isopropylacrylamide) conjugate for affinity precipitation separation of oligonucleotides

Daisuke Umeno, Takeshi Mori and Mizuo Maeda*†

Department of Materials Physics and Chemistry, Graduate School of Engineering, Kyushu University, 6-10-1, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan

The conjugate between single-stranded DNA and the temperature-responsive polymer poly(*N*-isopropylacrylamide) was synthesized, and was demonstrated to distinguish its target sequence from mismatch DNAs and separate it from aqueous solution when heated.

Single stranded (ss) DNA has been widely used as an affinity ligand for detection[1] and separation[2] of DNA and RNA having specific sequences because of its high precision in molecular recognition. For affinity separation of a specific sequence, ss DNA-carrying materials such as silica gel,[3] cellulose,[4] and latex particles[5] have been widely applied in the field of molecular and cellular biology. Especially, affinity columns immobilized with poly(dT) or poly(U) are invariably used for the purification of mRNAs from the crude cell extracts.[6] However, the affinity interaction between target sequences and ligand DNA immobilized on the solid materials has been indicated to be weaker and slower than that in homogeneous conditions.[7] Here we describe an alternative system using a conjugate between oligonucleotides and poly(*N*-isopropylacrylamide) (polyNIPAAm) which is known to undergo temperature-directed phase-transition between soluble (< 31 °C) and insoluble (> 31 °C) forms.[8] This conjugate hybridizes with the target sequence in homogeneous solution, and precipitates with the target by the slight change in solution temperature (Fig. 1). The concept of 'thermally-induced affinity precipitation separation' was first proposed by Chen and Hoffman for the separation of IgG using a polyNIPAAm–protein A conjugate.[9]

The vinyl derivative of $(dT)_8$ (**1**) was synthesized by the coupling of 5′-amino-terminated $(dT)_8$ with methacryloyloxy succinimide according to the previous report.[10] **1** (75 μM) and NIPAAm (150 mM) were copolymerized in buffer solution (10 mM Tris–HCl, pH 7.4) at 20 °C using ammonium persulfate (1.3 mM) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (86 mM) as a redox initiator couple in nitrogen atmosphere to give a polyNIPAAm-$(dT)_8$ conjugate with the structure illustrated in Scheme 1. By monitoring the peak area of the monomers on a reversed phase-HPLC, conversions of **1** and NIPAAm were determined to be 71 and 75%, respectively, indicating that the amount of $(dT)_8$ incorporated in the resulting copolymer is almost the same as the feed ratio of **1** to NIPAAm (0.05 mol%) at the polymerization step. The reaction mixture was dialyzed against 10 l of deionized water for a day, followed by lyophilization. The white powder obtained was dissolved in water to 1.0 m/v %. The aqueous solution was then centrifuged at 40 °C. After removal of the supernatant, the precipitated fraction was re-dissolved in water to give a stock solution which was stored at 4 °C. Removal of the unpolymerized constituents (**1** and NIPAAm) was confirmed by disappearance of their peaks on HPLC.

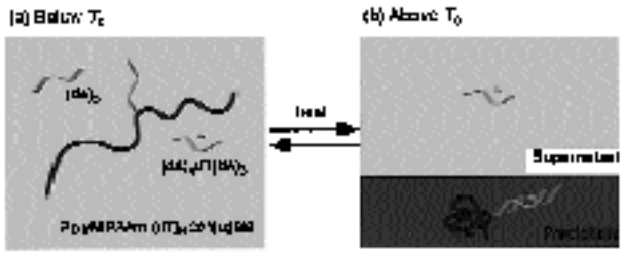

Fig. 1 Schematic illustration of the temperature-directed precipitation of oligonucleotides using polyNIPAAm–$(dT)_8$ conjugate. (*a*) At the temperature below the phase transition point (T_c) of polyNIPAAm, the conjugate is soluble in water and captures its complementary sequence in homogeneous condition. (*b*) At temperatures above T_c, the target sequence is separated to the precipitate with the conjugate. This process is fully reversible.

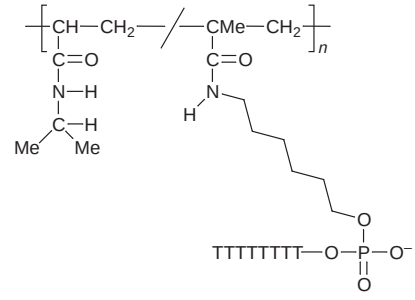
The resultant conjugate between polyNIPAAm and $(dT)_8$ was applied to the one-pot separation of its complementary sequence $(dA)_8$. The conjugate [0.45 m/v %; 20 μM of $(dT)_8$ in strand] was mixed with the target DNA [$(dA)_8$; 10 μM in strand]. Then 1.0 m/v % of polyNIPAAm was added to the mixture because we found that a certain concentration (> 1 m/v %) of homopolymer was required for the reproducible precipitation of polyNIPAAm-$(dT)_8$ conjugate. The concentration of NaCl and $MgCl_2$ was adjusted to be 1.5 and 0.1 M, respectively. The melting curve of the duplex between $(dT)_8$ and $(dA)_8$ and transmittance curve of polyNIPAAm conjugated with $(dT)_8$ under these solution conditions is shown in Fig. 2. From the curves, melting temperature of the duplex between $(dT)_8$ and $(dA)_8$ was determined to be 16.2 °C, while the transition temperature of the conjugate was *ca.* 14 °C.‡ The mixture (150 μl) was incubated at 0 °C for 6 h for hybridization and then heated to 15 °C for desolubilization of the conjugate. The resulting turbid mixture was centrifuged at the temperature, and the supernatant was collected. The amount of $(dA)_8$ in the supernatant was evaluated by the peak area on HPLC. The precipitate fractions were dissolved in 150 μl of water and analyzed similarly.

As is shown in Table 1, 84% of $(dA)_8$ in the system was concentrated into the precipitate fraction in the presence of conjugate. On the other hand, only a small amount of $(dA)_8$ (*ca.* 6%) was distributed to the precipitate when the separation experiment was performed in the absence of the conjugate. The precipitation % of $(dT)_8$ did not depend on the presence of the conjugate, being a small value of *ca.* 5% which should be ascribed to the incompleteness in the collection of the aqueous phase.



Scheme 1 Chemical structure of the polyNIPAAm–$(dT)_8$ conjugate

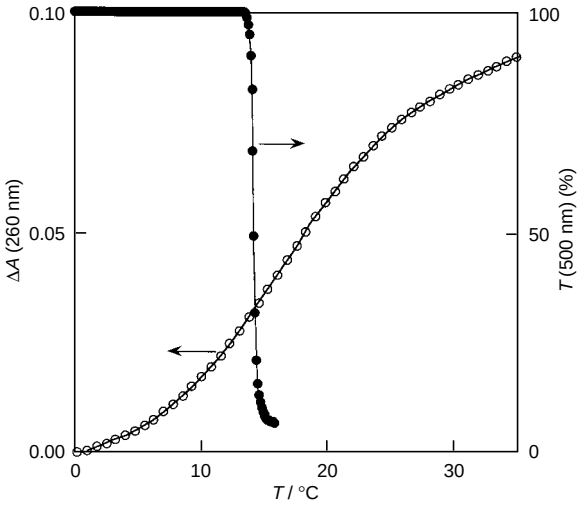


Fig. 2 Melting curve of the $(dA)_8 \cdot (dT)_8$ duplex and transmittance (at 500 nm) curve of the polyNIPAAm–$(dT)_8$ conjugate under the following solution conditions: 1.5 M NaCl, 0.1 M $MgCl_2$ and 10 mM Tris–HCl (pH 7.4). The $(dA)_8 \cdot (dT)_8$ concentration was 3 μM in the strand in the melting temperature measurement, and the concentration of polyNIPAAm–$(dT)_8$ conjugate was 0.068 m/v % [$(dT)_8$ unit, 3 μM in strand] at the transition temperature measurement. Heating rate at both measurements was 0.25 °C min^{-1}.

Table 1 Precipitation efficiency (%) of the oligonucleotides by heating and centrifugation in the presence of the polyNIPAAm–$(dT)_8$ conjugate

	Precipitation %	
Target DNA	+ Conjugate	− Conjugate
$(dA)_8$	83.6 ± 0.8	5.5 ± 0.3
$(dT)_8$	5.3	4.6

An aqueous solution of polyNIPAAm (1 m/v %) and target DNA (10 μM in strand) was heated and centrifuged at 40 °C in the presence (+) or absence (−) of polyNIPAAm–$(dT)_8$ conjugate. Precipitation % was calculated as follows; % = 100 × [DNA found in precipitate fraction]/{[DNA in supernatant] + [DNA in precipitate fraction]}. The precipitation % of $(dA)_8$ is given as mean ± standard error (n = 3).

The applicability of this separation system was further examined for a mixture of $(dA)_8$ and $(dA)_3dT(dA)_4$ (10 μM each). A typical example is shown in Fig. 3: 84.0 ± 1.4 (n = 3) % of $(dA)_8$ was concentrated into the precipitate by the procedure, while 91.7 ± 0.8 (n = 3) % of $(dA)_3dT(dA)_4$ remained in the supernatant. This result clearly indicates that the polyNIPAAm–$(dT)_8$ conjugate distinguished $(dA)_8$ from $(dA)_3dT(dA)_4$, and isolated the complementary DNA selectively from the aqueous solution. In fact, 99% of the precipitated $(dA)_8$ was recovered when the precipitate was resuspended in deionized water and centrifuged at 40 °C.‡

Here we have proposed a simple method for the one-pot separation of ss DNAs with a unique sequence. We have described the separation of $(dA)_8$ using polyNIPAAm–$(dT)_8$ conjugate, because the conjugate having poly(dT) will be useful for the separation of polyadenylated mRNAs which are of great importance in cDNA cloning.

Wolf *et al*. reported that ss DNA attached to latex particles hybridized, in certain conditions, with its complementary oligonucleotide at a comparable rate with free DNA, while it

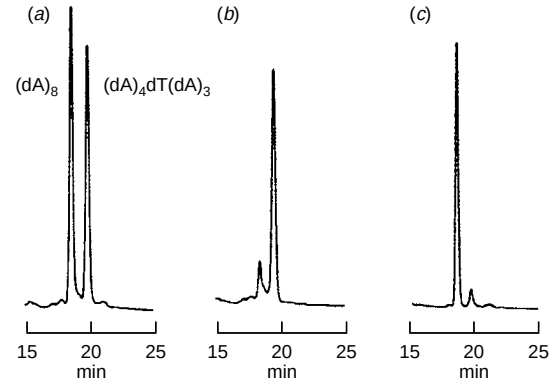

Fig. 3 HPLC chromatograms of $(dA)_8$ and $(dA)_3dT(dA)_4$ before and after the precipitation separation using polyNIPAAm–$(dT)_8$ conjugate. The equimolar mixture of $(dA)_8$ and $(dA)_3dT(dA)_4$ was heated in the presence of polyNIPAAm–$(dT)_8$ conjugate and centrifuged. (*a*) HPLC chromatogram before the process. (*b*) HPLC chromatogram of the supernatant fraction after the process. (*c*) HPLC chromatogram of the precipitated fraction after the process.

hybridized much slower with the larger DNAs,[11] probably because of the steric repulsion due to the latex surface. In this sense, the soluble conjugate described here would be advantageous especially for the larger target molecules such as mRNAs. In addition, this property would be also advantageous even in the post-separation stages. For instance, we hypothesize that cDNA synthesis of the separated mRNA on the polyNIPAAm–poly(dT) conjugate would be much more efficient than that on solid materials such as poly(dT)–silica.[12] These conjectures are under further investigation.

‡ PolyNIPAAm undergoes dehydration (and precipitation) at *ca.* 31 °C in deionized water, as was also the case for the polyNIPAAm–$(dT)_8$ conjugate. However, the addition of salt lowers the transition temperature of polyNIPAAm,[8] which was found to be 14 °C in the present solution conditions for the one-pot separation.

Crystal engineering with tetraarylporphyrins, an exceptionally versatile building block for the design of multidimensional supramolecular structures

R. Krishna Kumar, S. Balasubramanian and Israel Goldberg*†

School of Chemistry, Sackler Faculty of Exact Sciences, Tel-Aviv University, 69978 Ramat-Aviv, Tel-Aviv, Israel

Zinc *meso*-tetra(4-amidophenyl)porphyrin assembles into open two-dimensional arrays parallel to the porphyrin plane by self-complementary hydrogen bonding between the –$CONH_2$ recognition sites of adjacent molecules; manganese *meso*-tetraphenylporphyrin perchlorate and the bidentate 4,4′-bipyridyl ligand afford one-dimensional coordination polymers, which propagate in a direction perpendicular to the porphyrin plane; simultaneous application of these two modules of supramolecular design may lead to porous porphyrin-based materials with enhanced structural integrity.

The design of multiporphyrin architectures has drawn considerable attention in recent years, as such materials have diverse potential for scientific and technological applications as biomimetic models of photosynthetic systems or as functional molecular devices.[1,2] Tetraarylporphyrin molecules have a number of features that make them attractive building blocks for crystal engineering. These molecules are quite rigid, highly symmetric, and easily synthesized, and they exhibit a high degree of thermal and oxidative stability. The porphyrins can be easily 'programmed' by addition of various substituents and recognition sites to either the pyrrole or aryl groups, as well as by varying the nature of the metal atom inserted into the porphyrin core. Several successful attempts to assemble supramolecular porphyrin aggregates, in solution as well as in the solid state, have been reported recently.[3] In this context we have previously described formation of one-, two- and three-dimensional coordination polymers of zinc tetra(4-pyridyl)porphyrin and of zinc tetra(4-cyanophenyl)porphyrin.[4] We have also demonstrated, along with others, the utilization of hydrogen-bonding as an effective means of structural control in the design of homogeneous multiporphyrin architectures.[5,6] As part of this ongoing investigation we now report the structures of new materials based on controlled multiporphyrin aggregation which demonstrate two of the most plausible modes of supramolecular design, utilizing effective synthons for hydrogen-bonding and coordination polymerization.

Zinc *meso*-tetra(4-amidophenyl)porphyrin **1a** is representative of building blocks containing self-complementary recognition sites at the peripheral 4-position of the phenyl rings. The square-shaped tetraamide functionality and its hydrogen bonding capacity can dictate the formation of planar and rigid hollow networks sustained by hydrogen bonds.[7] On the other hand, the use of manganese *meso*-tetraphenylporphyrin **1b** should facilitate the construction of coordination polymers with suitable multidentate ligands, as Mn^{III} reveals high affinity for a six-coordinate environment. In view of the paramagnetic properties of the latter, these materials may also have significant potential as molecular magnets.[8a] Literature survey shows, however, that only a very small number of coordination polymers with metalloporphyrin frameworks have been successfully prepared thus far,[8] while the occurrence of monomeric Mn^{III} complexes is considerably more common. Compounds **1a** and **1b** were prepared by standard procedures of porphyrin synthesis. Single crystals of zinc tetra(4-amidophenyl)porphyrin·$4Me_2SO·H_2O$ **2** suitable for X-ray diffraction analysis were grown by very slow cooling of the solution of **1a** in Me_2SO. Similarly, single crystals of the 1 : 1 complex of MnTPP·ClO_4 with neutral 4,4′-bipyridyl (**3**; crystallizing as a nitrobenzene solvate) were grown from a slowly cooled stoichiometric mixture of these two components in nitrobenzene. The structure and composition of these crystals were determined unequivocally by X-ray diffraction analysis.‡

Fig. 1 illustrates the interporphyrin arrangement in the crystal structure of **2**. As anticipated, the self-assembly process utilizes cooperatively the hydrogen-bonding potential of the amide functions,[7] affording open two-dimensional networks with no inter-penetration between them. Each porphyrin unit is involved in eight hydrogen-bonding interactions at NH···OC distances within 2.984–3.068 Å. The interporphyrin cavities in each layer are *ca.* 5.9–6.8 Å wide and *ca.* 10 Å long (estimated distances between the van der Waals surfaces of the surrounding environment). They are accommodated by two guest molecules of Me_2SO at each of the two crystallographically independent sites. One of the four species axially ligates to the metal center of a porphyrin unit in an adjacent layer at a Zn···O=S coordination distance of 2.151(7) Å. The five-coordinate Zn ion deviates by 0.28 Å from its porphyrin plane towards the axial ligand. The two-dimensional networks relate to each other by crystallographic inversion. They stack in the crystal in an offset manner with a characteristic average spacing of 4.6 Å[4a] to optimize van der Waals stabilization and the fit of the axial ligands from one layer into the interporphyrin cavities of the next layer. As shown earlier, the cavity size characteristics in such layered multiporphyrin motifs depend directly on the functional substituents attached to the porphyrin framework, which allows one to control to a considerable extent the porosity

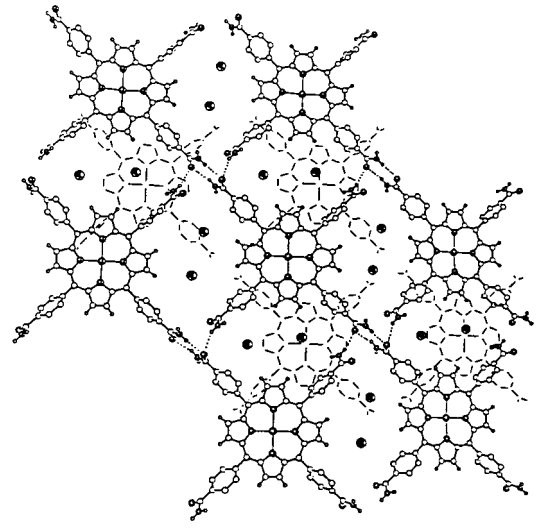

Fig. 1 Assembly of zinc tetra(4-amidophenyl)porphyrin building blocks in the form of two-dimensional open networks sustained by N–H···O=C hydrogen bonds. Each of the oval shaped interporphyrin cavities is occupied by two molecules of Me_2SO. For clarity, the positions of the latter are indicated by large darkened circles. The stick-only frameworks illustrate porphyrin molecules in a neighboring network and indicate the layered nature of the crystal structure.

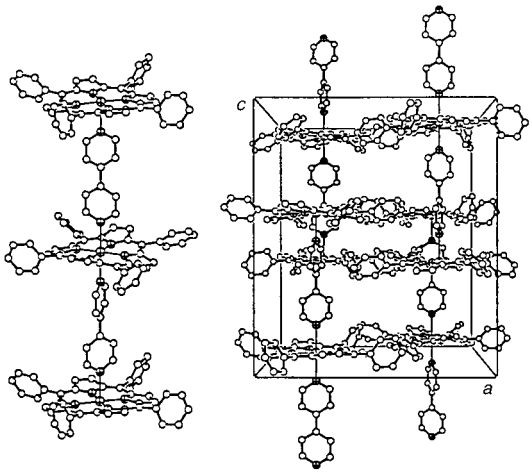

Fig. 2 (Left) Molecular structure of the coordination polymer composed of Mn^{III}–TPP and 4,4′-bipyridyl components. (Right) Perspective view of the crystal structure of this compound down the *b*-axis, showing the 'hollow' lattice of the crystal-packed polymers. The cavities are occupied by the perchlorate counter ions and by disordered solvent (not shown for clarity).

of the porphyrin layers thus formed. In relation to the present observation, the interporphyrin cavity dimensions found in homogeneous layered networks composed of tetra(4-hydroxyphenyl)porphyrin and of tetra(4-carboxyphenyl)porphyrin are 3.5 × 9.5 and 16 × 21 Å, respectively.[5]

The molecular structure of the coordination polymer units which compose **3** is displayed in Fig. 2(left). The linear polymeric strands consist of alternating metalloporphyrin and bipyridyl building blocks linked to each other from both ends by metal–ligand coordination, at Mn···N_{py} distances ranging from 2.321(7) Å to 2.409(7) Å. Along the chains the Mn···Mn separation is 11.79 Å, while between the chains the shortest Mn···Mn distance is 11.05 Å. The polymers are located on axes of twofold rotation at ($\frac{1}{4}$, 0, *z*), and extend along the *c*-axis [Fig. 2(right)]. Their side packing in the *ab* plane is stabilized by dispersive interactions between the TPP frameworks (deformed from planarity to adopt a saddle conformation) as well as by coulombic forces through the anions located in between. The parallel alignment of the polymeric chains in the crystal leads to a nanoporous architecture of the three-dimensional assembly, with tubular shaped voids between the thinner bipyridyl sections of the polymers along the *a* and *b* crystal axes (directions parallel to the porphyrin planes), that are occupied by molecules of the nitrobenzene solvent (near 0.2, $\frac{1}{4}$, $\frac{1}{4}$ and 0.8, $\frac{1}{4}$, $\frac{1}{4}$) and the perchlorate counter ions (centered at 0.50, 0.08, 0.24). The smallest cross-section distance between the van der Waals surfaces of the channel walls is *ca.* 5 Å.

The structural integrity of the multiporphyrin architectures in **2** and **3** can be in principle increased by combination of the coordination polymerization and the lateral hydrogen-bonding features in the same material. Thus, cooperative hydrogen bonding between neighboring polymeric entities in **3** (which in that structure are displaced along the *a* and *b* crystal axes) can be introduced by substituting the TPP building block with suitable recognition groups on the porphyrin periphery (*e.g.* as observed in **2**). The structure of such a designed lattice can be fine-tuned by changing the size and shape of the bridging ligand as well as of the hydrogen-bonding sites on the porphyrin periphery. We are currently exploiting this promising methodology in an effort to construct a new series of structurally robust porous organic crystals and evaluate the potential applications of such molecular-sieve materials in molecular separation, transport and controlled release.

This research was supported in part by the United States-Israel Binational Science Foundation (BSF-grant No. 94-00344), Jerusalem, Israel. The assistance of Dr Leo Straver and Nonius B.V. with diffraction measurements on the KappaCCD diffractometer is gratefully acknowledged.

Molecular riveting: high yield preparation of a [3]-rotaxane

Alexander G. Kolchinski,[a] Nathaniel W. Alcock,[b] Rebecca A. Roesner[a] and Daryle H. Busch*[a]†

An aminothiol axle molecule is so efficient at threading through the macrocycle 24-crown-8 that iodine oxidation produces a [3]-rotaxane in record yield (84%) by literally riveting two rings together.

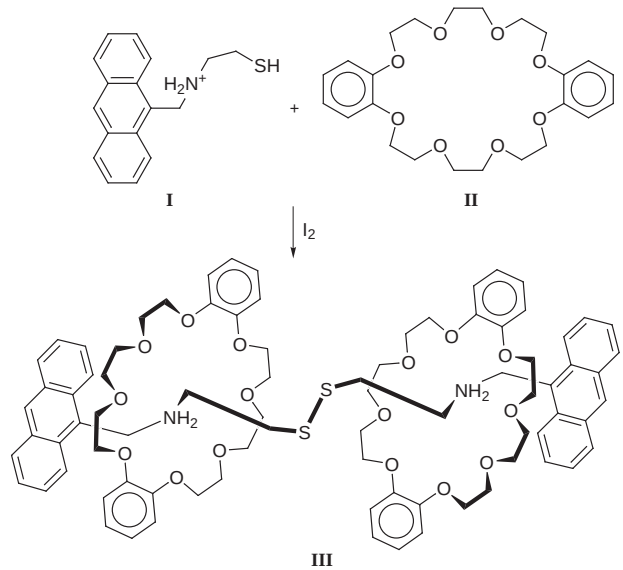
Molecular motifs incorporating mechanically interlocked molecules, such as rotaxanes, catenanes and knots, are harbingers to a virtual molecular macrame of orderly molecular entanglements that will constitute new materials for the 21st century.[1] But the preparation of mechanically interlocked molecules presents a significant challenge,[2] and the probability of success decreases as the number of interlocked molecules increases. For example, only a few [3]- and higher rotaxanes[3] have been prepared and their yields are often low, with the highest reported yield for a [3]-rotaxane being 55%.[3] Reaping the potential of the field will depend on the detailed understanding of template reactions, including such elementary processes as molecular threading, which underlies the work reported here. In on-going studies of the relationships that favor the threading of linear molecules through cyclic molecules, we have found a methodology that produces a [3]-rotaxane in record yield (84%) by literally riveting two rings together. Such high yields open the way to molecularly interlocked polymers based on rotaxane formation.

Having learned from the threading of rings onto polymers[4] that closely positioned coordination sites strongly favor rotaxane formation, we first applied a new methodology to [2]-rotaxane formation.[5] Interaction between a functional group at the terminus of the linear component and its cyclic partner positions the tip of the linear molecule for penetration into the ring and prepays the entropic price of threading. Relaying of the binding site for the cyclic molecule from the terminal to the internal functional group completes the threading process. Closely related syntheses, based on the coordination of secondary ammonium groups to crown ethers were described shortly thereafter.[3b,e,6]

The success of our relay threading and the ease with which secondary amines form pseudo rotaxanes led to the hypothesis that, for maximum threading, the internal function of the axle molecule should bind the cyclic component substantially more strongly than does the terminal function. Further guidance, specifically applicable to [3]-rotaxanes, is provided by the recent work of Stoddart and co-workers,[3e] which relies solely on the crown ether–secondary ammonium ion interaction. For closely related structures, the yields of two [2]-rotaxanes were found to be 24 and 31%, while that for the [3]-rotaxane was only 10%. It may be significant that the fractional yield of the [3]-rotaxane is approximately the square of that for a [2]-rotaxane [$0.1 \approx (0.31)^2$]. These admittedly very limited data correspond to a simple model in which the yield of the blocking reaction may be largely controlled by the preequilibrium concentration of pseudo rotaxane. In such a case, the yield of the [3]-rotaxane is likely to be limited by the product of the yields (preequilibrium concentrations) of the two required threading processes. Therefore we suggest that the preparation of a [3]-rotaxane constitutes a powerful test for the efficiency of a given methodology for molecular threading.

A secondary ammonium group provides the primary binding site in our new axle molecule and the thiol group was selected as the terminal function because (a) it should not compete significantly with the secondary ammonium group for coordination to the crown ether, (b) it should, however, exert a relatively weak, reversible attraction for the crown ether and (c) it is well suited for a number of blocking reactions. To the best of our knowledge, the formation of strong crown ether–thiol complexes has not been reported, while, on the other hand, thiols do form easily detectable hydrogen bonds with a variety of nitrogen and oxygen containing functional groups.[7] The thioammonium salt, **I**Br, was synthesized by Schiff base condensation of 9-anthraldehyde with 2-aminoethanethiol, followed by borohydride reduction.

The oxidative coupling of the thiol groups of two pseudo rotaxane molecules provided a very convenient route for [3]-rotaxane formation (Scheme 1). Complexation of **I** with excess crown ether **II** and subsequent oxidation of the resulting complex with a small excess of iodine gave the [3]-rotaxane triiodide, **III**$(I_3)_2$, in remarkably high yield (84%) (Scheme 1). The high yield synthesis proceeds as follows: 9-anthrylmethyl(2-mercaptoethyl)ammonium bromide (**I**) (0.347 g, 1 mmol) and dibenzo-24-crown-8 (**II**) (1.344 g, 3 mmol) were dissolved at room temperature in the presence of air in a mixture of MeOH (7 ml) and $CHCl_3$ (10 ml). I_2 (0.381 g, 1.5 mmol) in $CHCl_3$ (10 ml) was slowly added over 10 min. Crystallization began after standing for 30 min. After 12 h the reaction mixture was refrigerated for 1 h and then filtered. The resulting brown crystalline product was washed with MeOH and dried in air. Larger iodine concentrations resulted in the formation of a highly crystalline adduct, **III**$(I_3)_2 \cdot 1\frac{1}{2}I_2 \cdot 2$MeOH. The mechanics of this molecular riveting reaction are closely analogous to the familar macroscopic riveting process, *i.e.* the rivet is inserted in



Scheme 1

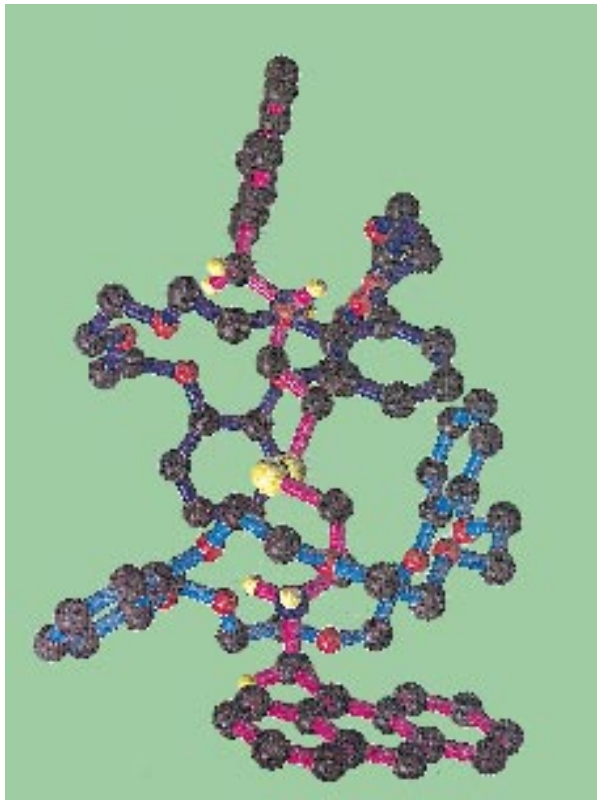


Fig. 1 Structure of the cationic [3]-rotaxane

holes in two parts that are subsequently joined together when the rivet is made complete with massive heads at each end. Referring back to the model described above, if the yield of this reaction were determined by the pseudo rotaxane preequilibrium, the pseudo rotaxane must be present in an equilibrium concentration exceeding 90%.

The crystal structure‡ of the [3]-rotaxane (Fig. 1) confirms the threading of the crown ether and clearly shows the axle–torus interactions. These include H-bonds between the amine nitrogen and the oxygen atoms of the crown, as well as [N^+–C–H···O] interactions between the methylene group adjacent to the anthryl unit and the crown ether oxygens.

The substantially higher yield obtained for **III** compared to all other rotaxanes based on secondary ammonium salt–crown ether partners, as well as the data obtained for polymeric rotaxanes,[4] strongly supports the relay threading hypothesis. Clearly, the close proximity of two binding sites on the axle molecule and the relative coordinating abilities of those two sites play important roles in facilitating these threading reactions. Further, this process of linking two molecules together by a highly efficient reaction gives promise of much new chemistry. For example, we suggest that molecular riveting will ultimately be used to produce new families of polymers and films.

Immobilization of semiconductor nanoparticles formed in reverse micelles into polyurea *via in situ* polymerization of diisocyanates

Susumu Shiojiri,[a] Takayuki Hirai*[a]† and Isao Komasawa[a,b]

[a] *Department of Chemical Science and Engineering, Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8531, Japan*

[b] *Research Center for Photoenergetics of Organic Materials, Osaka University, Toyonaka, Osaka 560-8531, Japan*

Nanoparticles of CdS, ZnS, TiO_2 or AgI, formed in reverse micelles, have been immobilized into polyurea *via in situ* polymerization of hexamethylene diisocyanate; the CdS– or ZnS–polyurea composites obtained were utilized as photocatalysts.

There has been much recent interest in the preparation and processing methods for nanoparticles formed from various materials, including metals,[1,2] metal selenides,[3] sulfides[1,3–8] and oxides,[9] using reverse micellar systems. One of the most powerful methods for recovering the metal sulfide particles is that of particle surface modification using thiols.[3,6–8] The binding of the thiols, however, passivates the surface sulfur vacancies of the sulfide particles, and may substantially change the particle surface characteristics. Moreover, thiol modification cannot be applied to metal oxides; some of which are no less important than sulfides as catalysts and photocatalysts. The present study describes a novel immobilization method for nanoparticles formed in reverse micelles into polymer particles synthesized *in situ*. Addition of a diisocyanate, which reacts with water to form polyurea,[10] to the reverse micellar solution leads to the formation of polyurea fine particles. This polymerization in the presence of nanoparticles formed *in situ* brings about the encapsulation of the nanoparticles into the formed polyurea particles.

A reverse micellar system consisting of sodium bis(2-ethylhexyl) sulfosuccinate (AOT, 0.1 mol l^{-1}), water and isooctane (2,2,4-trimethylpentane) was used for the nanoparticle preparation. CdS or ZnS nanoparticles were prepared by the rapid addition of an AOT–isooctane micellar solution {100 ml, W_0 (= $[H_2O]/[AOT]$) = 6} containing $Cd(NO_3)_2$ or $Zn(NO_3)_2$ to another micellar solution (100 ml, W_0 = 6) containing Na_2S and stirring vigorously with a magnetic stirrer at 298 K. A glass vessel covered with aluminium film and a final composition of $[S^{2-}] = [Cd^{2+}]$ or $[Zn^{2+}] = 6.0 \times 10^{-4}$ mol l^{-1} was used. Hexamethylene diisocyanate [HDI, 0.385 ml (0.0024 mol)] was added rapidly to the nanoparticle-containing reverse micellar solution 2 min after nanoparticle formation.

The broken lines in Fig. 1 represent the absorption spectra for (*a*) CdS and (*b*) ZnS nanoparticles, 1 min after their formation in the reverse micellar systems. The absorption spectra after the HDI addition gradually increased owing to the turbidity of the polyurea (PUA) formation in the solutions. After stirring for 18 h for CdS (19.5 h for ZnS) the nanoparticles were collected together with the formed polymer powder by centrifugation. The precipitate was washed with *n*-hexane and diethyl ether and dried *in vacuo* overnight. The CdS or ZnS nanoparticle–polyurea composites are denoted CdS–PUA or ZnS–PUA, and were yellow and white, respectively, reflecting the colour of the corresponding metal sulfide particles.

Polymerization in a water–acetone homogeneous system produced irregularly shaped PUA particles of *ca.* 1 μm in diameter. Fig. 2(a) shows an FE-SEM image for metal sulfide-free PUA particles formed in the reverse micellar system and in which the PUA has led to a rather ordered morphology consisting of twisted rods. Polymerization in the presence of CdS nanoparticles, however, produced fused rod-like aggregates [Fig. 2(b)]. The presence of nanoparticles or NO_3^- may also influence polymer morphology. The PUA particles showed IR absorption peaks (1260, 1570, 1650 and 3300 cm^{-1}) attributable to urea bonds. Elemental analysis for the CdS-free PUA gave: C, 58.5; H, 10.5; N, 17.5 (calc. C, 59.1; H, 9.92; N 19.7%). The polyurea and PUA composites were slightly soluble in *m*-cresol but insoluble in most organic solvents.

The solid lines in Fig. 1 represent the absorption spectra for CdS (*c*) and ZnS (*d*) nanoparticles in PUA composites (measurement was by diffuse reflectance, owing to the turbid disperison of PUA composites in the photoreaction solution, as described below). The red shifts of the absorption onset compared with spectra (*a*) and (*b*) of Fig. 1 are due to particle growth following HDI addition. The values of the band gap for immobilized CdS and ZnS, as calculated in a previous report[5] were 2.75 and 3.92 eV, respectively, which are larger than the bulk values for CdS (2.5 eV[11]) and ZnS (3.7 eV[11]) owing to the quantum size effect.[12] The diameter of the immobilized CdS and ZnS nanoparticles was estimated using the above obtained values and the Brus' equation,[12] as also in the previous report,[5] to be 4.70 and 4.37 nm, respectively.

The metal content of the PUA composites (total analysis) was determined[8] by decomposing a given quantity of a PUA composite in concentrated H_2SO_4 and measuring the eluted metal ions, using an inductively coupled argon plasma atomic emission spectrophotometer. Since the PUA was not decomposed in HCl (6 mol l^{-1}), only the exposed sulfide particles from the PUA composite were dissolved in the acid and this was also measured. The ratio of the partial dissolved quantity, obtained *via* contact with 6 mol l^{-1} HCl, to that of the total quantity obtained *via* H_2SO_4 decomposition is denoted as particle exposed fraction *F*.[8] Table 1 lists the total metal content and the particle exposed fraction for CdS–PUA and ZnS–PUA.

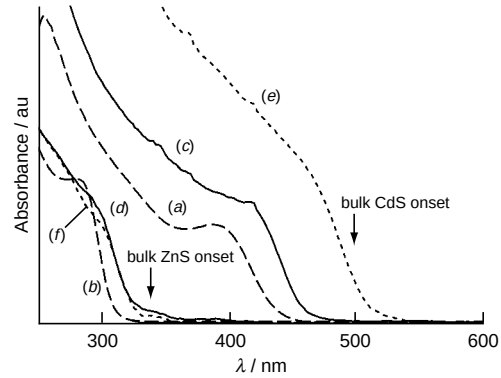

Fig. 1 Broken lines: absorption spectra of metal sulfide nanoparticles in reverse micellar systems 1 min after formation [(*a*) CdS; (*b*) ZnS]. (*c*)–(*f*): absorption spectra of metal sulfide nanoparticles immobilized in PUA composites [(*c*) and (*e*) CdS; (*d*) and (*f*) ZnS] before [solid lines, (*c*) and (*d*)] and after [dotted lines, (*e*) and (*f*)] photoirradiation for 18 h (diffuse reflectance spectra, scattering was subtracted).

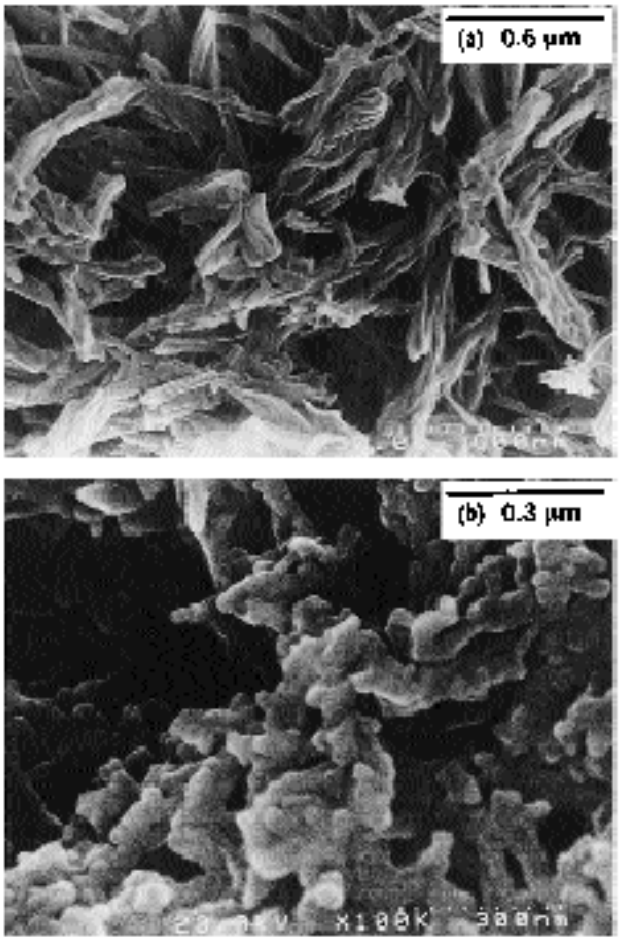

Fig. 2 SEM images for (a) metal sulfide-free PUA particles and (b) CdS–PUA prepared in a reverse micellar system

Table 1 Metal content and particle exposed fraction *F* of CdS–PUA and ZnS–PUA composites and results of photocatalytic H_2 generation

PUA composite	Total Cd or Zn content/ μmol (mg PUA composite)$^{-1}$	*F*	H_2 formed (18 h irradiation)	
			μmol (mg PUA composite)$^{-1}$	μmol (μmol exposed Cd or Zn)$^{-1}$
CdS–PUA	1.71	0.969	2.63	1.59
ZnS–PUA	1.56	0.866	8.56	6.34
CdS–PUA	1.71	0.969	0.0077	0.0047[a]
CdS-free PUA	—	—	0	—

[a] No propan-2-ol present.

The values of *F* obtained for both approach unity, thus indicating almost all sulfide nanoparticles are more or less exposed to the external solution.

Photocatalytic generation of hydrogen on the CdS–PUA or ZnS–PUA composites in a 10 vol% propan-2-ol aqueous solution was demonstrated. Such experiments, *ca.* 4 mg of PUA composite was dispersed in 25 ml of a 10 vol% propan-2-ol aqueous solution by ultrasonication with sodium hexametaphosphate (0.0125 g). 20 ml of this mixture was purged with argon for 1 h, sealed with a septum and photo-irradiated with a 2 kW xenon lamp. Irradiation light with wavelength < 300 nm and light in the IR range was cut off by the Pyrex glass of the tube and by the water filter, respectively. The quantity of H_2 formed in the gas phase in the tube was measured by gas chromatography.

The quantities of H_2 formed during the photo-irradiation of CdS–PUA or ZnS–PUA are also listed in Table 1. The H_2 generation with the PUA composites, probably *via* the reduction of water with propan-2-ol as the sacrificial agent, is very prominent as compared with the results of control experiments. ZnS–PUA is superior to CdS–PUA under the present experimental conditions, owing to the greater reducing ability of the conduction band electrons in ZnS than in CdS.

The dotted lines in Fig. 1 show the absorption spectra (diffuse reflectance spectra) for CdS–PUA (*e*) and ZnS–PUA (*f*) after photo-irradiation. The absorption onset for CdS–PUA shifts towards a longer wavelength and appears to reach that of bulk CdS, thus indicating photo-induced CdS growth *via* the fusion of CdS particles adjacent to each other in the PUA composites. The band gap for the CdS particles, after photo-irradiation, was calculated to be 2.5 eV, the same as that for bulk CdS. On the other hand, a relatively small red shift is seen for ZnS–PUA, with the band gap for the ZnS particles in ZnS–PUA after the photo-irradiation being calculated as 3.86 eV, which is larger than the bulk value of 3.7 eV.

The HDI polymerization method was also applied to nanoparticles of TiO_2 and AgI. These nanoparticles were prepared in AOT–isoocatane systems as described previously.[9,13] The nanoparticles of TiO_2 or AgI were also easily recovered from the micellar system *via in situ* polymerization of HDI and centrifugation, although the method for measuring the particle exposed fraction could not be employed in these cases.

The present study thus describes a novel immobilization method for semiconductor nanoparticles formed in reverse micelles into polyurea *via in situ* polymerization of hexamethylene diisocyanate. This may prove to be a universal method applicable to nanoparticles of any material formed in reverse micellar systems, since the surface properties of the target nanoparticles can be chosen freely. The effect of micellar conditions on PUA morphology and the photocatalytic properties of metal sulfide–PUA materials is worthy of further study.

Reactions of ruthenium cyclopropenyl complexes with trimethylsilyl azide

Ku-Hsien Chang and Ying-Chih Lin*

Department of Chemistry, National Taiwan University Taipei, Taiwan 106, Republic of China

Treatment of three cyclopropenyl complexes [Ru]–C=C(Ph)CHR {[Ru] = (η^5-C_5H_5)(PPh_3)$_2$Ru; R = Ph 1a, CN 1b, CH=CH_2 1c} with Me_3SiN_3 afforded the nitrile complex 3a, the zwitterionic tetrazolate complex 6, and 7, respectively; for 1c, the triazole 8 was also obtained.

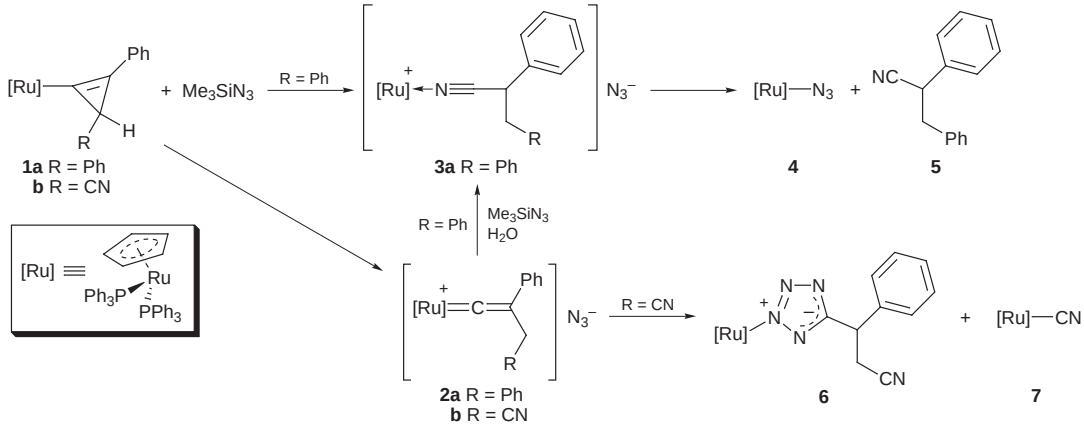
Organic cyclopropene is highly strained and its estimated strain energy is > 50 kcal mol^{-1} (1 cal = 4.184 J).[1] This molecule has played a crucial role in the development of important concepts such as aromaticity and chemical reactivities.[2] A few recent papers focused on applications of various cyclopropenes in organic synthesis.[3] In organometallic systems, deprotonation of a number of vinylidene complexes {[Ru]=C=C(Ph)CH_2R}I {[Ru] = (η^5-C_5H_5)(PPh_3)$_2$Ru; R = CN, Ph, CH=CH_2} readily afforded ruthenium cyclopropenyl complexes.[4] Protonation opens the three-membered rings of these Ru complexes to give back the vinylidene moiety. Nevertheless, in the ruthenium system, the cyclopropenyl and the vinylidene complexes display distinctive reactivities. We carried out reactions of cyclopropenyl complexes with various organic substrates. Herein we report the reaction of Me_3SiN_3 ($TMSN_3$) with a number of ruthenium cyclopropenyl complexes containing different substituents at the cyclopropenyl ring to yield various products.

Upon addition of a fivefold excess of $TMSN_3$ to **1a** in THF at room temperature, the solution displayed color changes during the course of the reaction. The light yellow solution of **1a** turned to deep red at the initial stage then became light orange in *ca.* 3 h and, after 5 h, turned yellow again. We thus carried out the reaction at −10 °C and, while the solution was deep red, isolated **2a**‡ as the major product and the N-coordinated nitrile complex **3a**‡ as the minor product, Scheme 1. From the light orange solution of the same reaction at room temperature, **3a** could be isolated in high yield. Finally with a 5 h reaction time the reaction gave **4**[5] and **5**.[6]‡ As a precursor of **3a**, **2a** is unstable at room temperature.

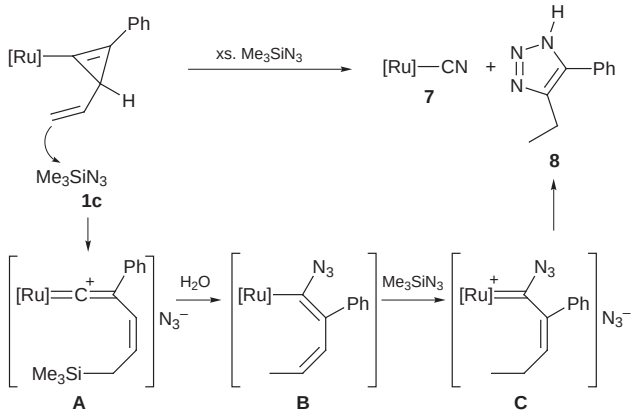
Complex **3a** is also unstable and decomposes to give **4** and **5**. Exchange of the N_3^- counter anion with PF_6^- made **2a** and **3a** more stable. In the ^{1}H NMR spectrum of **2a**, a singlet resonance at δ 3.50 is assigned to the CH_2 group. The ^{31}P NMR spectrum displays a singlet resonance at δ 42.5. However, in the ^{31}P NMR spectrum of **3a** two doublet resonances at δ 41.7 and 41.2 with J_{PP} 35.3 Hz indicate the presence of a diastereotopic center in the N-coordinated nitrile ligand and, in the ^{1}H NMR spectrum, two resonances at 3.15 (J_{HH} 16.6, 6.5 Hz) and 3.00 (J_{HH} 16.6, 10.0 Hz) are assigned to the CH_2 group. The parent peak of the mass spectrum of **3a** clearly indicates addition of one nitrogen atom to **2a**.

Treatment of **1b** with $TMSN_3$ at room temperature caused addition of four nitrogen atoms to **1b** and afforded the yellow tetrazolate complex **6**‡ in high yield and **7**‡ in *ca.* 5% yield, Scheme 1. Complex **6** is stable at room temperature, and in the course of the reaction only a deep red color attributed to a vinylidene intermediate **2b** was observed. The intermediate **2b** could be isolated at 0 °C. In the ^{1}H NMR spectrum of **6**, a dd resonance at δ 4.32 (J_{HH} 7.4, 7.7 Hz) is assigned to the methyne proton and two multiplet resonances displaying doublets of an AB pattern at δ 2.66 (J_{HH} 16.6, 7.4 Hz) and 2.44 (J_{HH} 16.6, 7.7 Hz) are assigned to two methylene protons. In the ^{31}P NMR spectrum of **6**, two doublet resonances at δ 43.8 and 41.7 with J_{PP} 38.0 Hz are assigned to the two PPh_3 ligands owing to the presence of a diastereotopic center. The proton source of the reactions of **1a** and **1b** is believed to come from water in $TMSN_3$ (no attempt was made to dry $TMSN_3$ due to potential hazards) and protons are incorporated into the product through hydrolysis of the TMS substituents. TMSOH was distilled off with THF solvent from the reaction mixture and identified by mass spectrometry. In both reactions, addition of D_2O to THF led to incorporation of two deuterium atoms at two vicinal carbon atoms of both **5** and **6**. No reaction was observed between {[Ru]=C=C(Ph)CH_2CH}PF_6 and $TMSN_3$ possibly owing to the covalent character of the Si–N bond in $TMSN_3$ and weak nucleophilicity of the cationic vinylidene complex to cleave the Si–N bond.

The reaction of **1a** with $TMSN_3$ may proceed by an electrophilic addition of a TMS group followed by hydrolysis to afford **2a**. Further nucleophilic addition of N_3^- at C_α and electrophilic addition of a second TMS group at C_β followed by loss of N_2 gives the N-coordinated nitrile complex **3a**,[5] Scheme 1. In the reaction of **1b** with $TMSN_3$, formation of **6** is



Scheme 1



Scheme 2

rationalized by a [3 + 2] cycloaddition of the CN bond with a second N_3^-.[7] As early as 1958, formation of tetrazolate ring structure has been observed in the [3 + 2] cycloaddition reaction of a nitrile group with azide.[8] Metal-coordinated azide ligands undergo 1,3-dipolar cycloaddition reactions with carbon–carbon and carbon–heteroatom multiple bonds. Among others, this chemistry has been investigated by the group of Beck. The metals involved are most often palladium(II),[9] platinum(II)[10] and cobalt(III)[11] although a whole range of other transition metals[12] has been used. These metal azido complexes react with nitrile to give various tetrazolate complexes.[13] Formation of the tetrazolate ring in **6** is derived from the reaction of nitrile with [Ru]–N_3 since under our mild reaction condition, no such reaction was observed. The reaction of the acetylide complex [Ru]–C≡CPh with an excess of $TMSN_3$ afforded **4** and $PhCH_2CN$, identified by elemental analysis and high resolution mass spectroscopy. Conversion of a vinylidene precursor to N-coordinated nitrile by hydrazine, an organometallic Beckmann rearrangement, has been reported in an iron system.[14]

Interestingly, treatment of **1c** with an excess of $TMSN_3$ afforded **7** and **8**,‡ Scheme 2. The organic product is identified by elemental analysis and high resolution mass spectrometry. Formation of **7** and **8** by cleavage of the C=C double bond of the cyclopropenyl ring and transformation of the vinyl to an ethyl group could be explained as followed. Addition of a TMS group to the terminal carbon atom of the vinyl group accompanied by opening of the three-membered ring resulted in formation of **A**, Scheme 2. We previously reported that the reaction of TCNQ with **1c** gave similar addition at the terminal carbon of the vinyl group.[4] Subsequent nucleophilic addition of N_3^- at C_α followed by hydrolysis gave **B**. Further addition of $TMSN_3$ at C_δ followed by hydrolysis led to the formation of **C**. The single bond character of the C_α–C_β in **C** facilitates its cleavage, which is accompanied by a [3 + 2] cycloaddition of the C_β–C_γ double bond with N_3^- to give the triazole compound **8** and **7**. The fact that **7** is isolated in this reaction as the only organometallic product suggests that it is not likely to have an intermediate with a terminal N-coordinated nitrile ligand. Formation of **7** as a minor product in the reaction of **1b** with $TMSN_3$ could proceed through the same pathway. A detailed mechanism for these processes is currently under investigation.

We are grateful for support of this work by the National Science Council, Taiwan, the Republic of China.

Phosphines exchange in quadruply bonded metal dimers: theoretical proposal for an alternative to the internal flip mechanism

Yves Jean*[a]† and Agusti Lledos*[b]‡

The non-concerted jumping of two phosphine ligands from one metal center to the other in $[Mo_2Cl_4(PH_3)_4]$ is found to be < 30 kcal mol^{-1} (1 cal = 4.184 J) energy costing process (DFT calculations).

Quadruply bonded complexes of $[Mo_2X_4(dpe)_2]$ type (X = halide, dpe = diphosphinoethane) may exist in two isomeric forms:[1] the α isomer with two chelating diphosphines and the β isomer with two bridging diphosphines (Fig. 1). In the former, the $Mo_2X_2P_2$ units are essentially eclipsed while internal rotational angles between 25 and 65° have been found in the latter.[2]

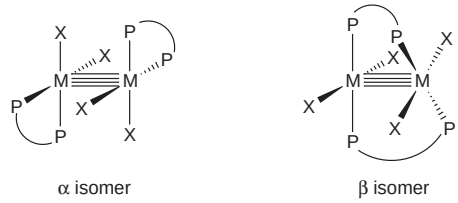

Fig. 1 Schematic structure of α and β isomers in $[Mo_2X_4(P–P)_2]$ complexes

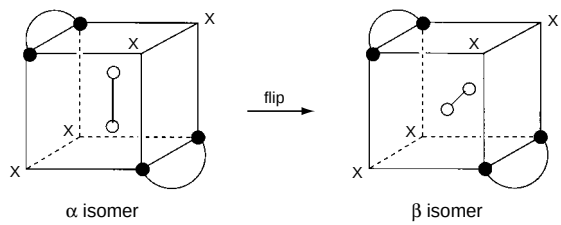
The α → β isomerization has been observed both in solution[3–6] and in the solid state.[5,7] From the experimental data on $[Mo_2Cl_4(dppe)_2]$,[5] two mechanisms are believed to be competitive in solution: (*i*) a dissociative process in which one or both dppe ligands would break one of their M–P bonds; (*ii*) a unimolecular non-dissociative process. In the solid state, only the latter would be at work.[5] A fascinating mechanism has been proposed[4–6] for the non-dissociative process, the so-called internal flip mechanism. It involves as the rate-determining step the internal rotation of the Mo_2 unit inside the cavity formed by the eight ligand atoms (Scheme 1), followed by some internal rotation around the Mo–Mo bond. At the mid-point structure, four ligands (2P, 2X) would bridge the two metal centers. An activation energy of *ca.* 24 kcal mol^{-1} has been estimated for the non-dissociative mechanism in $[Mo_2Br_4(dppe)_2]$ (solution).[4] In the related $[Mo_2Cl_4(dppe)_2]$ complex, a similar activation energy has been measured in solution (28.9 ± 1 kcal mol^{-1}).[3] However, a much higher value (80 ± 7 kcal mol^{-1}) has been found for the solid-state reaction,[7] although the flip mechanism was believed to be at work in both phases. Since 1985 until very recently, this mechanism has been invoked for ligands exchange processes in various bimetallic complexes,[8]

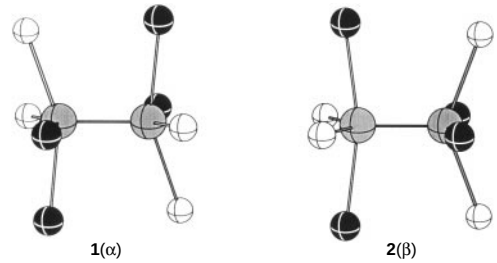


Scheme 1 Schematic picturing of the internal flip mechanism in $[M_2X_4(P–P)_2]$ complexes

the activation energies in solution lying between 20 and 29 kcal mol^{-1}.[8c,e,f]

Cayton and Chisholm have addressed the feasibility of such an intriguing process *via* an orbital symmetry analysis.[9] Fenske–Hall calculations on the $[Mo_2Cl_8]^{4-}$ complex have shown the rigid rotation of the Mo_2 unit to be a symmetry allowed process, but the Walsh diagram revealed that one π bonding MO was destabilized by about 2.5 eV and that the Mo–Mo bond should be elongated in the intermediate structure. These calculations did not however allow the authors to estimate the energy barrier associated to this mechanism.

Here we report the results of DFT calculations on the $[Mo_2Cl_4(PH_3)_4]$ complex used as a model for the real $Mo_2X_4(P–P)_2$ systems. Calculations were performed with the B3LYP functional[10] within both the restricted (RB3LYP) and the unrestricted broken-symmetry (UB3LYP-bs) formalisms.§[11,12] Structures **1** and **2**, with *cis* and *trans* phosphines on each metal center, respectively, were used as models for the α and β isomers. Full geometry optimizations led to structures of C_{2h} and D_{2d} symmetry, respectively.[13] The β isomer (**2**) was found to be the most stable, the energy difference being almost independent of the method of calculation (12.3 and 13.2 kcal mol^{-1} for RB3LYP and UB3LYP-bs methods, respectively).



The mid-point structure associated with the flip mechanism was optimized within C_i constraint and keeping the four bridging ligands in a plane perpendicular to the Mo–Mo bond. The RB3LYP structure was found to be located 86.4 kcal mol^{-1} above the α isomer (**1**) with an Mo–Mo distance elongated to 2.525 Å. Single-point energy-only calculation of this structure using the UB3LYP-bs method led to a very similar result (89.2 kcal mol^{-1}). It is noteworthy that these values are close to the experimental activation energy reported for the α → β conversion of $[Mo_2Cl_4(dppe)_2]$ in the solid state (80 ± 7 kcal mol^{-1}).[7] Although we failed in locating a stationary point in this region of the potential energy surface, the possibility for the flip mechanism to be operative in the solid state is, at least, left open by our calculations. However, it is unlikely on energetic grounds for the reaction in solution (E_a < 30 kcal mol^{-1}). Therefore, we searched for another mechanism for the α → β isomerization reaction.

Exploration of the potential energy surface for phosphine(s) migration processes led to the localization of a stationary point which was further characterized as a transition state (a single imaginary frequency of 124i cm^{-1}). Moving along the reaction coordinate on both sides of the transition state confirmed it

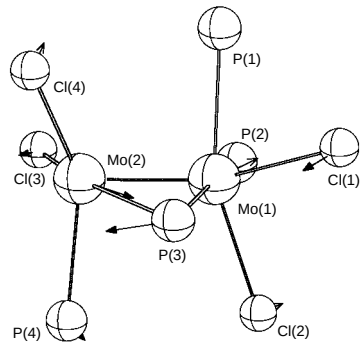


Fig. 2 Optimized geometry of the transition state for the α (**1**) → β (**2**) conversion. Hydrogen atoms of the phosphine ligands are omitted for clarity. The transition vector is also pictured.

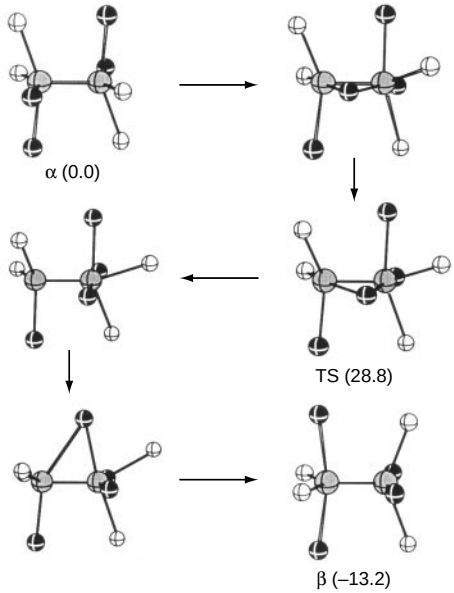
connects the α (**1**) and β (**2**) isomers through a one-step mechanism. The main feature of the transition state structure (Fig. 2) is the presence of a single bridging phosphine (P3, initially bound to Mo2 in the α isomer), with Mo1–P3 2.820 Å and Mo2–P3 3.150 Å (UB3LYP-bs). Although P3 is closer to Mo1 than to Mo2, no Mo–P bond is fully broken at the transition state. Another interesting feature is that the Mo–Mo distance (2.181 and 2.240 Å at the RB3LYP and UB3LYP-bs levels, respectively) is *ca.* 0.3 Å shorter than in the mid-point associated with the flip mechanism and close to that found at the same level of calculations in the quadruply bonded structures **1** and **2**.[13] Last but not least, the computed activation energy (28.4 and 28.8 kcal mol^{-1} at the RB3LYP and UB3LYP-bs levels, respectively) is in good agreement with the experimental estimates for the α → β conversion of quadruply bonded metal dimers in solution.

The whole reaction mechanism is pictured in Scheme 2 (for the atom numbering, see Fig. 2). It involves first the migration of one phosphine (P3) from Mo2 toward Mo1, leading to the bridged transition state. Next P3 binds definitely Mo1, thus creating a vacancy at the Mo2 center and a distorted octahedral arrangement around Mo1. Finally P1, which is more suitably oriented than P2 with respect to the vacant site, migrates from Mo1 to Mo2 to form the β isomer. This mechanism can thus be described as the successive jumping of two phosphine ligands from one metal center to the other.

Although satisfactory in several aspects with respect to the experimental data in solution, there is however one result this mechanism does not account for: in the $[Mo_2Cl_4(dpdbp)_2]$ complex, it has been shown that the α-*syn* and α-*anti* isomers convert to the β-*syn* and β-*anti* isomers, respectively.[6] Such a stereoselectivity would require the migration of P2 instead of that of P1 in the last stage of the reaction path (Scheme 2). Such change might be due to the constraints exerted by the bridging diphosphines in real β-$[Mo_2X_4(P–P)_2]$ systems,[2] the P–Mo–Mo–P dihedral angles being smaller than in our model complex **2** (90°). These constraints should be at work not only at the very end of the reaction (β isomer) but just after the transition state has been reached, when P3 binds Mo1 (one 'bridging diphosphine' involving P4 and P3 atoms). Therefore, the reaction path for $[Mo_2Cl_4(dpe)_2]$ systems should be modified in its last stage by an internal rotation around the Mo–Mo bond which might in turn make P2 more suitably oriented than P1 for migration from Mo1 to Mo2.



Scheme 2 Mechanism for the α (**1**) → β (**2**) conversion going through the transition state given in Fig. 2. Hydrogen atoms of the phosphine ligands are omitted for clarity.

§ Calculations were performed with the GAUSSIAN 94 series of programs[11] with a basis set of valence double-ζ quality on the metal atom[11,12a] and valence double-ζ[11,12b] + d polarization functions[12c] for the P and Cl atoms. Effective core potentials (ECP) were used to represent the 28 innermost electrons of the Mo atom[12a] as well as the electron core of the P and Cl atoms.[12b] 6-31G basis set was used for the H atoms.[12d]

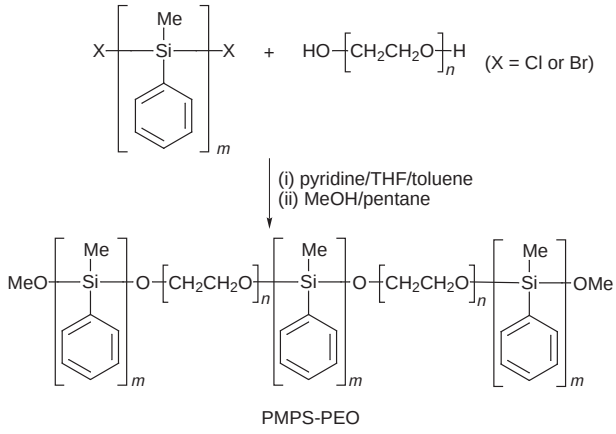
A new amphiphilic multiblock copolymer of polymethylphenylsilane and poly(ethylene oxide) has been synthesised and demonstrated to form well-defined aggregates in water.

Polysilanes have been the subject of extensive research over the past decade due to their remarkable electronic properties that allow for a number of potential applications as conductive, electroluminescent, non-linear optical and lithograpic materials.[1] Many of these properties can be expected to be more fully exploited through the incorporation of polysilanes into copolymer systems[2] which would allow for greater processability but also allow for the manipulation of the macroscopic order of the materials by supramolecular assembly (*e.g.* by microphase separation or aggregation in aqueous dispersions). The majority of amphiphilic block copolymers, none of which are derived from polysilanes, form spherical micellar structures in aqueous dispersions.[3] Recently, further morphologies have been observed in aqueous dispersons such as rodlike, lamellar and vesicular aggregates.[4] However the formation of vesicles by block copolymers remains rare and is confined to copolymers where the component blocks are monodisperse. We report here the formation of vesicles from the multiblock poly(methylphenylsilane)-co-poly(ethylene oxide) (PMPS-PEO), in which the PMPS blocks have a normal size distribution. We believe that this is the first example of vesicle formation by a multiblock copolymer and the first defined aqueous aggregate formed by a polysilane.

The PMPS-PEO copolymer was synthesised according to Scheme 1 utilising Schlenk techniques under a dry argon atmosphere. A solution of 4.78 g of poly(ethylene oxide) (M_n = 7000, 6.8×10^{-4} mol, M_n/M_w = 1.03) in toluene was added to a solution of α,ω-dihalopoly(methylphenylsilane)[5] (M_n = 4400, 6.8×10^{-4} mol, M_n/M_w = 2.00) in THF and toluene. Subsequently pyridine (3 ml, 3.7×10^{-2} mol) was added and the reaction solution was stirred for 30 min. This solution was then added dropwise to MeOH (300 ml) and pentane (400 ml) was slowly added to the resultant mixture. PMPS-PEO was obtained as a yellowish white powder (60% yield, M_n = 27 000, M_w/M_n = 1.6) after filtration and vacuum drying for 72 h. The molecular weights quoted are based upon size-exclusion chromatography (SEC) measurements of THF solutions relative to polystyrene standards using a refractive index (RI) detector. The block structure of the copolymer was confirmed by ^{1}H, ^{13}C and ^{29}Si NMR spectroscopy and also by analysis of the molecular weight determinations of the copolymer and its precursors using both UV and RI detectors in the SEC experiment.[6]



Scheme 1

Although the molecular weights have been determined relative to polystyrene standards it can be assumed that the hydrodynamic properties of the parent homopolymers and the segments in the copolymer structure are very similar. Thus the M_n value of 27 000 for the copolymer corresponds closely to the structure shown in Scheme 1, $[PMPS\text{-}PEO]_2$-PMPS, with a degree of polymerisation (DP) of 2.5.‡ This is merely the most abundant structure and comprises up to 30% of the overall distribution which ranges from PMPS-PEO to $(PMPS\text{-}PEO)_{16}$.

Direct addition of the copolymer to water (1 mg PMPS-PEO/1 ml H_2O) gave poor quality dispersions with most of the PMPS-PEO remaining as bulk solid. However transmission electron microscopic (TEM) analysis of samples of the aqueous portion of the mixture revealed vesicles [Fig. 1(*a*)].

Homogenous dispersions of the copolymer in water could be prepared in two ways. The copolymer was dissolved in THF (100 mg/10 ml THF) and water (3.5 ml) was added dropwise to the stirred solution (the solution became turbid after the addition of *ca.* 1.5 ml water). Subsequently the mixture was subjected to ultrafiltration with continuous concentration and water dilution (3 × 10 ml water). A homogenous white opaque dispersion resulted (concentration = 1.2 g l^{-1}). TEM analysis of freeze fractured samples of this dispersion showed that the copolymer existed as vesicles with remarkably little micellar material [Fig. 1(*b*)]. Both convex and concave hemispheres are clearly visible. The diameters of the vesicles ranged from *ca.* 100 nm to *ca.* 180 nm.

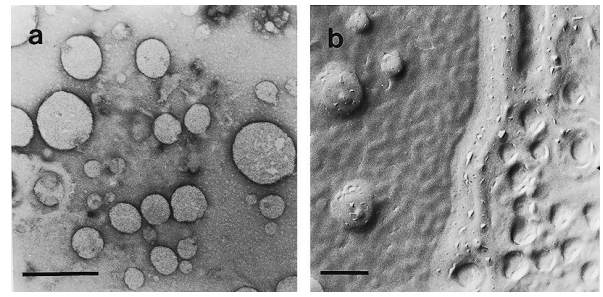


Fig. 1 Transmission electron micrographs of vesicles observed for copolymer dispersions obtained by (*a*) direct addition to water (negative staining), (*b*) ultrafiltration/dilution method (freeze-fracture). Bars represent 300 nm.

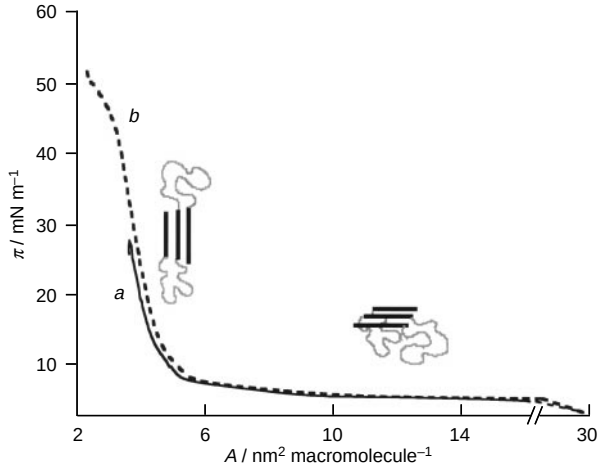

Fig. 2 π–*A* isotherms of PMPS-PEO at (*a*) pure water interface and (*b*) 100 mM $NaCl_{(aq)}$ interface

Vesicle dispersions could also be prepared by the dialysis procedure reported by Zhang and Eisenberg.[7] The copolymer dispersion in water–THF was prepared in a similar manner to the aforementioned procedure (3 ml THF, 1 ml water) and placed in a dialysis bag (exclusion limit = 20 000 Da) and dialysed against pure water (500 ml) for 72 h. EM analysis of negatively stained and platinum shadowed samples of the dispersion after this time again showed vesicles to be the predominant aggregate structure.

To confirm that the observed structures were vesicles an encapsulation experiment was performed utilising the water soluble fluorescent dye 5-carboxyfluorescein in the dialysis procedure.[8] After 72 h the dispersion was eluted (in water) through a Sephadex column (G150, mesh size 40–120 μ). The elution volume of the encapsulated dye (30–110 ml, emission at 519.5 nm) coincided with that of the copolymer (emission 355 nm) indicating that closed vesicles are formed. The elution volume of the free dye was substantially larger (160–190 ml).

To investigate the orientation of the copolymer chains in the vesicle walls surface pressure–area isotherms were recorded for a monolayer of PMS-PEO at the air/water interface.§ The isotherm revealed a very large lift-off area of *ca.* 30 nm^2 $molecule^{-1}$ which would correspond to the approximate area for three PMPS chains orientated parallel to the water surface. The observed plateau from 30 to 5 nm^2 $molecule^{-1}$ (Fig. 2) and the transition to a state characterised by a macromolecular area of 4.7 nm^2 $molecule^{-1}$ indicates a pseudo-first-order transition to a phase in which the PMPS chains become orientated perpendicular to the air/water interface. The collapse point is reached at a pressure of *ca.* 27 mN m^{-1} where the area per polymer chain is 3.7 nm^2, which is in remarkably good agreement with the estimated cross-sectional area for three PMPS rods (*ca.* 3.6 nm^2 based upon models). When PMPS-PEO was spread upon a subphase containing 0.1 M NaCl the monolayer behaviour was essentially the same, the only substantial exception being the higher collapse pressure. This tends to confirm the above model where the limiting area is defined by the PMPS segments.

UV spectroscopic analysis of the dispersion prepared by ultrafiltration revealed a very weak absorption, due to the σ–σ* transition, with a maximum at 342 nm (λ_{max} in THF = 339 nm) superimposed upon the scattering background. This is tentatively attributed to chain straightening and an extension of the effective conjugation length.

The freeze fracture electron micrographs, monolayer studies, structural considerations and UV data support a tentative model

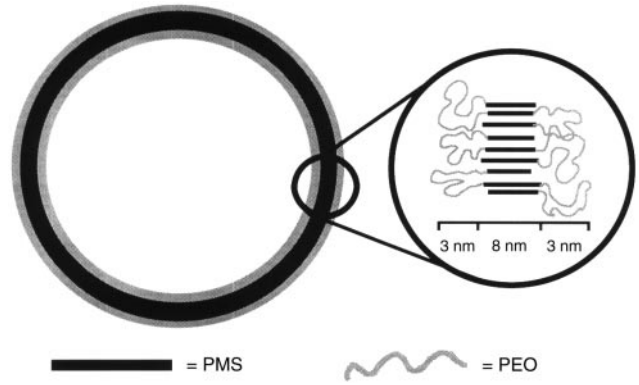

Fig. 3 Proposed model for copolymer organisation in the vesicle walls

of the packing in the vesicle walls as shown in Fig. 3.¶ It is apparent from our results that well-defined and very low polydispersity systems need not necessarily be requirements for the self-assembly of well-defined aggregates. Further work is in progress to study the structures adopted by this remarkable copolymer system.

Notes and References

‡ A polydispersity of 1.6 (recorded by SEC) corresponds to an extent of reaction, *p*, of 0.6 in terms of the kinetics of the linear step-reaction polymerisation involved in the block copolymer formation. This in turn specifies a number average degree of polymerisation (DP) of 2.5 in excellent agreement with the expected Flory distribution.[9]

§ Monolayer experiments were carried out at 20.0 ± 0.1 °C using a double barrier R&K trough of dimensions 6 × 25 cm with a compression speed of 8.8 cm^2 min^{-1}. The copolymer was spread from a solution of $CHCl_3$.

¶ The lengths of the PMPS segments were calculated from literature data;[10] light-scattering experiments have shown a strong correlation between the molecular weights obtained for polystyrene and PMPS in THF solutions by SEC.[11] The lengths of the PEO chains were based upon the molecular weight characteristics supplied by Aldrich; the width of the PEO coronae were calculated assuming repeated folding of the chain parallel to the orientation of the PMPS chains and the value given is therefore the minimum width expected.

A two-step low pressure chemical vapour deposition process for the production of tungsten metal thin films

David V. Baxter, Kenneth G. Caulton, Malcolm H. Chisholm,*† Shiow-Huey Chuang and Coey D. Minear

Departments of Chemistry and Physics, Indiana University, Bloomington, IN 47405 USA

A two-step process for the production of $W_{(m)}$ thin films on Si(100) and SiO_2/Si(100) is described involving the initial low pressure chemical vapour deposition of tungsten carbide from $(Bu^tCH_2)_3W{\equiv}CBu^t$ at 350 °C followed by a post-treatment with H_2 (500–700 °C) or H_2 plasma at 350–700 °C.

Metal films find several industrial applications because of their refractory characteristics. Also applications from wear and corrosion protection to conducting layers and diffusion barriers in electronic devices are of importance. For the latter, the metals of primary interest are W, Al, Cu, Pd, Pt, Au and Ti.[1] The CVD of both $Al_{(m)}$ and $Cu_{(m)}$ have received much attention and a considerable knowledge of the chemistry involved in depositing these metals is now available. Among other things this has allowed the use of surface modification in order to obtain selectivity in deposition.[2] Of the metals noted above tungsten offers certain distinct advantages with respect to its inertness in contact with all major III–V semiconductors even at high temperatures and prolonged contact times.[3] Traditional routes to tungsten films involve reactions between WF_6 and H_2 or SiH_4.[4] These methods are not environmentally friendly because they lead to the formation of the noxious gases, HF and SiF_4. In addition, silane and WF_6 are themselves extremely reactive and require elaborate safety procedures. We describe here the first report of the production of tungsten films by a two-step low pressure chemical vapour deposition (LPCVD) process involving the use a metalloorganic precursor, $(Bu^tCH_2)_3W{\equiv}CBu^t$.

$(Bu^tCH_2)_3W{\equiv}CBu^t$ was prepared by the reacton between $(Bu^tO)_3W{\equiv}CBu^t$ and excess Bu^tCH_2MgCl in diethyl ether.[5] Low-pressure chemical vapour depositions were carried out with a simple hot-walled reactor. The substrates chosen for this study are p-type Si(100) and SiO_2/p-type Si(100) wafers. They were washed with isopropyl alcohol and light petroleum (bp 60 °C) and rinsed with distilled water (in the case of the Si wafers, HF was used) and were stored in isopropyl alcohol. The substrates were placed at the center of the hot zone (350 °C). In the first step, the precursor was transported at 55 ± 2 °C under vacuum to the deposition chamber.[5,6] Highly reflective and smooth tungsten carbide films formed on the substrates and on the wall of the hot chamber. In the second step, the amorphous tungsten carbide films were treated with H_2 (500–700 °C) or H_2 plasma in the temperature range 350–700 °C, for 2 h [eqn. (1)].

$$(Bu^tCH_2)_3W{\equiv}CBu^t \xrightarrow[\text{LPCVD}]{350\ ^\circ C} \text{Tungsten carbide} \xrightarrow[H_2 \text{ or } H_2 \text{ plasma}]{500\text{–}700\ ^\circ C} W_{(m)} \quad (1)$$

The H_2 plasma was inductively coupled at 13.5 MHz with a power density on the order of 5 W cm^{-2}.

The thin films produced after this post-deposition annealing were studied by XRD, XPS, Auger, SEM and four-point sheet resistance probes. Annealing at temperatures below 500 °C leaves amorphous films [broad XRD band centered near 39° (Cu-Kα radiation)]. Annealing at temperatures above 500 °C in an H_2 plasma produced crystalline α-W X-ray patterns but SEM revealed a rough and pitted surface morphology for these films. Films annealed in an H_2 atmosphere retained the high density and surface morphology of the original tungsten carbide films but did not produce pure α-W X-ray patterns at temperatures below 600 °C within 2 h. The XRD of a $W_{(m)}$ film on Si(100) prepared at 700 °C is shown in Fig. 1.

The chemical purity of the films was estimated by Auger spectroscopy (with depth profiling) and XPS. Figs. 2 and 3

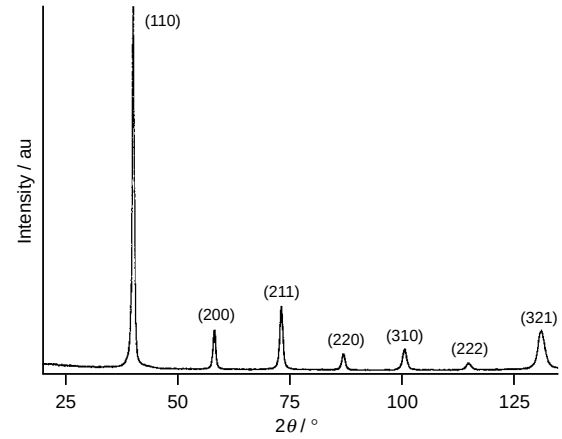

Fig. 1 X-Ray diffraction (Cu-Kα radiation) spectra of W metal film on SiO_2/Si(100) after post processing under H_2, flowing at 10 sccm, at 973 K for 2 h

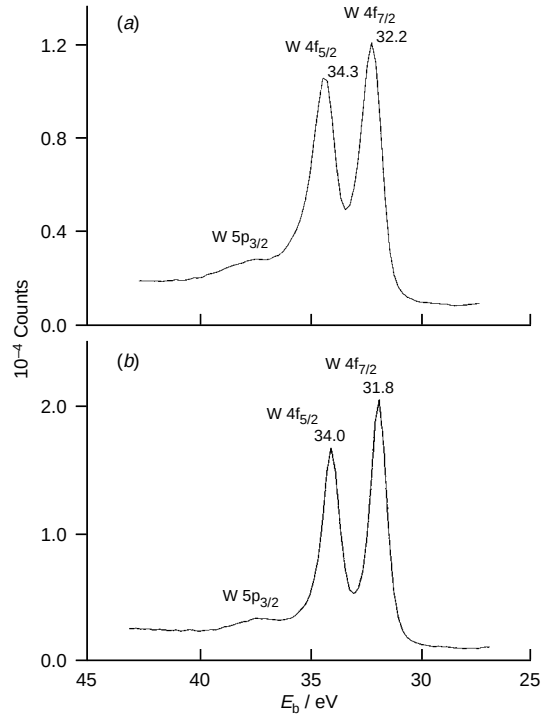

Fig. 2 (*a*) XPS spectra on W 4f region of the tungsten carbide film deposited on Si(100) under vacuum at 623 K for 2 h by $(Bu^tCH_2)_3W{\equiv}CBu^t$. (*b*) XPS spectra on the W 4f region of the tungsten metal film on Si(100) produced after post-treatment with H_2, flowing at 10 sccm, at 973 K for 2 h.

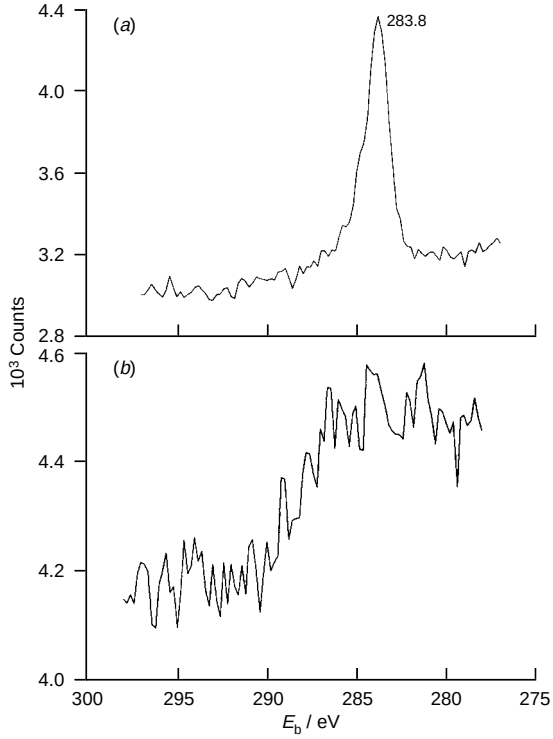

Fig. 3 (*a*) XPS spectra on the C 1s region of tungsten carbide film deposited on Si(100) under vacuum at 623 K for 2 h by $(Bu^tCH_2)_3W{\equiv}CBu^t$. (*b*) XPS spectra on the C 1s region of the tungsten metal film on Si(100) produced after post-treatment with H_2, flowing at 10 sccm, at 973 K for 2 h.

show the XPS data collected near the W 4f and C 1s energies for WC films as originally deposited and after 700 °C, H_2 annealing. These figures demonstrate a carbon content below the detection limit (*ca.* 2%) for this method.

The resistivities for all the films were $> 50\ \mu\Omega$ m, a value too large to be of direct interest for integrated circuit metallization. At least for the plasma annealed films this large resistivity could reflect the poor morphology noted above. It may be that a more gentle remote plasma treatment could produce more conductive films while still removing the carbon impurities. However, the resisitivity of our films of $W_{(m)}$ compare favorably with others produced by CVD.[7]

It should be noted that this two-step process for the production of $W_{(m)}$ films avoids the problems of high carbon content contamination that a one-step process entails when using an organometallic such as $W(CO)_6$, $W(\eta\text{-}C_6H_6)_2$, Cp_2WH_2 or $W(allyl)_4$ in the presence of an H_2 carrier gas.[1d] Indeed, in our studies we find that attempts to prepare $W_{(m)}$ from $(Bu^tCH_2)_3W{\equiv}CBu^t$ by LPCVD in the presence of H_2 results in carbonaceous films.

To conclude, we have discovered a new route for the formation of $W_{(m)}$ films by a two-step LPCVD process. The two step process may be compared with the industrially significant process employing $Ti(NMe_2)_4$ in the synthesis of TiN,[8] wherein Ti(C,N) is first formed by CVD and then in a post treatment with NH_3, converted to pure TiN. The potential advantage of the use of a volatile organometallic tungsten precursor clearly lies in the avoidance of noxious substances such as SiH_4, HF and WF_6. Other organotungsten compounds can be used to prepare tungsten carbide films[9] so one is not limited to the volatile liquid precursor $(Bu^tCH_2)_3W{\equiv}CBu^t$, though this precursor does offer the advantage of minimizing graphite content in the films. Also the present procedure does not require the use of ultrahigh vacuum procedures as has been claimed in the synthesis of $W_{(m)}$ from $W(CO)_6$ at 540 °C.[10] Further investigations of this approach seem justified.

We thank the National Science Foundation for support of this work and Professor H.-T. Chiu at the National Chiao Tung University, Taiwan, for assistance in the XPS characterization.

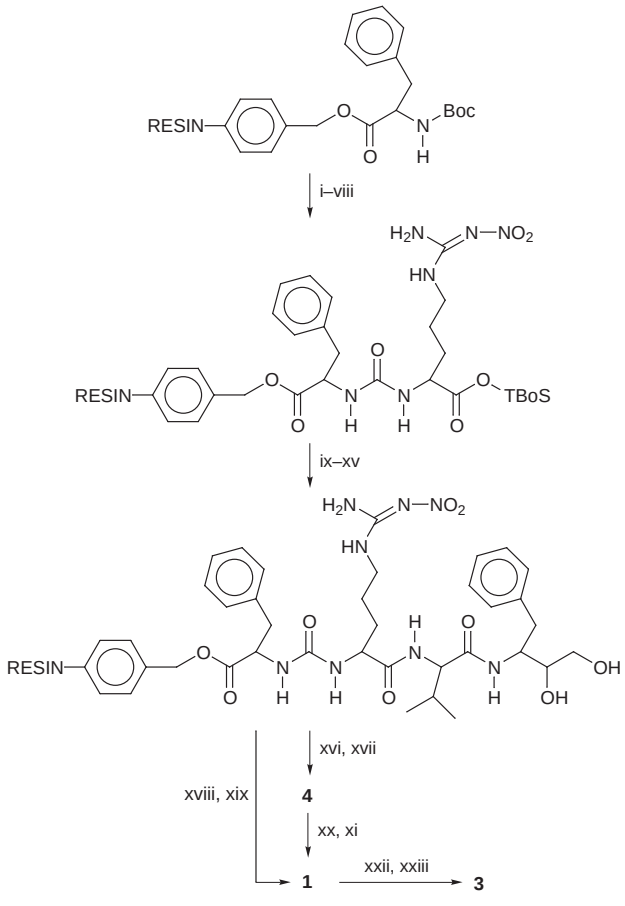
First efficient synthesis of α-MAPI

Robert J. Broadbridge, Ram P. Sharma*† and Muhammad Akhtar

Division of Biochemistry and Molecular Biology, School of Biological Sciences, University of Southampton, Bassett Crescent East, Southampton, UK SO16 7PX

α-MAPI 1 and its analogues have been synthesised using tri-*tert*- butoxysilyl protected amino acids in conjunction with a solid-phase N→C assembly; the terminal aldehyde group of the peptide is generated from a C-modified amino acid containing a *gem*-diol.

MAPI (*microbial alkaline proteinase inhibitor*) is a mixture of three compounds, α-, β- and γ-MAPI possessing similar activity which are produced by *streptomyces nigrescens* WT-27.[1–3] The unique features of these peptides are that they contain terminal carboxy and aldehyde groups and a ureido (–NH–CO–NH–) function. Furthermore, α-MAPI **1** has been shown to inhibit HIV-I protease.[4] Recently, a closely related family of tetrapeptides **3**, **5** and **6** which inhibit HIV-protease has been reported.[5–7] It is hoped that these compounds may ultimately lead to the development of effective anti-proteolytic drugs for the treatment of AIDS. There is no report on the synthesis of **1** and **2**. Therefore, the synthesis of these compounds and their analogues is of paramount importance.



Scheme 1 *Reagents and conditions*: i, CH_2Cl_2 (2 × 1 min); ii, 50% TFA–CH_2Cl_2 (5 and 25 min); iii, CH_2Cl_2 (4 × 1 min); iv, CDI (78 mg, 0.48 mmol), CH_2Cl_2, 30 min; v, repeat iii; vi, remove 2–3 mg resin for ninhydrin assay; vii, Arg–TBos (223 mg, 0.48 mmol), CH_2Cl_2, 120 min; viii, repeat iii; ix, 25% TFA–CH_2Cl_2 (2 × 5 min); x, repeat iii; xi, Val-TBos (172 mg, 0.48 mmol); BOP–HOBt–DIPEA (1 1 : 1 : 3 equiv.), CH_2Cl_2, 120 min; xii, repeat iii, xiii, repeat ix, x; xiv, Phe-diol (87 mg)–BOP–HOBt–DIPEA (1 : 1 : 1 : 3 equiv.), DMF, 120 min; xv, DMF (2 × 1 min), CH_2Cl_2 (2 × 1 min); xvi, HF; xvii, RP-HPLC; xviii, $NaIO_4$, MeOH, 90 min; xix, repeat xv–xvii; xx, $NaIO_4$, MeOH–H_2O (80%, 2 ml), 45 min; xxi, repeat xvii; xxii, $NaBH_4$, MeOH, 30 min, AcOH; xxiii, repeat xvii. The solvent used was 10 ml throughout for 200 mg of resin.

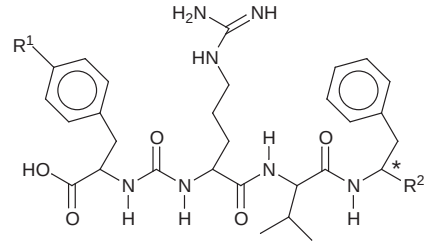


Table 1 Configuration data for **1**–**6**

Compound	R^1	R^2	Config. at *
1 α-MAPI	H	CHO	*S*
2 β-MAPI	H	CHO	*R*
3 Mer-N5075A	H	CH_2OH	*S*
4 α-MAPI-diol	H	$CHOHCH_2OH$	*S*
5 GE20372A	OH	CHO	*S*
6 GE20372B	OH	CHO	*R*

Our recently reported[8] new approach for the assembly of peptides on solid-phase from N→C direction was extended for the synthesis of α-MAPI **1** and its analogues **3** and **4** as illustrated in Scheme 1.

Boc-Phe-Merrifield resin was treated with TFA to remove the Boc group. The resin was thoroughly washed (CH_2Cl_2) and incubated with *N*,*N*′-carbonyldiimidazole (CDI). The reaction was monitored by ninhydrin assay.[9] Arginine-(N^G-NO_2)-tri-*tert*-butoxysilyl ester[8] (TBos)† was added and the mixture was shaken for 2 h. The removal of tri-*tert*-butoxysilyl group was accomplished in quantitative yield with 25% TFA. The peptide chain was further elongated by coupling valine-tri-*tert*-butoxysilyl ester followed by the deprotection of the ester group as before. Finally, the resulting peptidyl-resin was coupled to phenylalanine diol[10] in DMF to give the required peptidyl-resin. The peptide was then cleaved from the resin using liquid HF[11] and after preparative RP-HPLC followed by lyophilisation gave α-MAPI-diol **4** in 75% yield.§ Analytical and spectral data are in agreement with the assigned structure.¶

The diol **4** was smoothly oxidized with $NaIO_4$ to give α-MAPI **1**. The extent of reaction completeness was monitored by RP-HPLC and mass spectrometry. The oxidation was complete in 45 min. RP-HPLC purification afforded α-MAPI **1** in 84% yield§ and gave the expected spectral data.¶ The oxidation of the diol was also carried out on the solid-phase to give the aldehyde **1** in good yield.

α-MAPI **1** was treated with $NaBH_4$ and gave after purification the expected alcohol **3** in 64% yield.¶ Further work in this area is continuing.

‡ All amino acids described in this work are of L-configuration. TBos refers to the tri-*tert*-butoxysilyl group.

§ Analytical and preparative reversed-phase HPLC (RP-HLPC) experiments were performed on a Gilson 715 instrument equipped with a multi-wave length detector (Applied Biosystems 759A) and two slave 306 pumps. Retention times are given for gradient elution using the following conditions: Column, Vydac C_{18} (10 μm, 0.46 and 2.2 × 25 cm); eluent A, 0.1% (v/v) TFA in H_2O; eluent B, 0.1% (v/v) TFA in acetonitrile, gradient, 0% B over 2 min, 0–80% B over 32 min; flow rate 1 ml min^{-1} (analytical) and 10 ml min^{-1} (preparative); absorbance, 216 nm. Molecular weight determinations were carried out by electrospray (ES) Micromass Quattro II mass spectrometer.

¶ All compounds reported herein are white solids and exhibited satisfactory analytical and spectral data. *Selected data* for α-MAPI-diol **4**: single peak, retention time, 16.5 min HPLC; ESMS, *m/z* 628 $[M + H]^+$. *Selected data* for α-MAPI **1**: single peak, retention time, 16.8 min HPLC; mp 211–213 °C (decomp.) (lit.,[2] 204–205 °C); $[\alpha]_D^{24}$ 22.2 (*c* 0.9, AcOH) (lit.,[2] −18); ESMS, *m/z* 596 $[M + H]^+$ and 614 $[M + H_2O]^+$, hemi-acetal; δ_H (360 MHz, $[^2H_7]$DMF) 0.79 (d, 3H, *J* 6.7 CH–C*H*$_3$, Val), 0.81 (d, 3H, *J* 6.9, CH-C*H*$_3$, Val), 1.5–1.75 (m, 4H, CH–C*H*$_2$–C*H*$_2$, Arg), 2.08 (h, 1H, *J* 6.55, C*H*$[CH_3]_2$, Val), 3.0–3.35 (m, 4*H*, 2 × C*H*$_2$, Phe), 3.6 (2H, obscured by solvent, –CH_2–NH, Arg), 4.3–4.6 (m, 4H, 4 × methines), 6.5 (d, 1H, *J* 8), 6.7 (d, 1H, *J* 7.8), 7.2 (m, 10H, 2 × C_6H_5, Phe), 7.55 (br), 7.85 (d, 1H, *J* 8.6), 8.5 (d, 1H, *J* 7.1), 9.58 (s, 1H, C*H*O). *Selected data* for alcohol **3**: single peak, retention time, 16.8 min HPLC; mp 155 °C, softens and 180–182 °C, (decomp. lit.,[5] 182 °C); $[\alpha]_D^{24}$ −24.0 (*c* 0.5, AcOH) (lit.,[5] –24.4); ESMS, *m/z* 598 $[M + H]^+$; ^1H NMR (360 MHz) and ^{13}C NMR (90 MHz) gave expected chemical shift values.

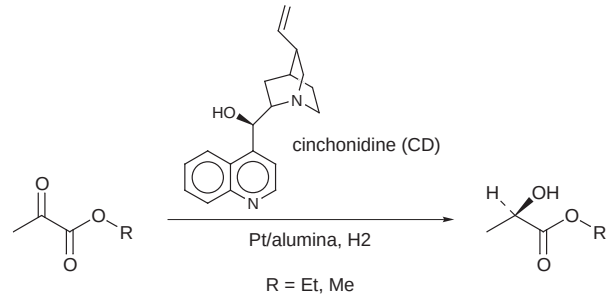
Solvent and substituent effects on the sense of the enantioselective hydrogenation of pyruvate esters catalysed by Pd and Pt in colloidal and supported forms

Paul J. Collier,[a] Tracey J. Hall,[b] Jonathan A. Iggo,*[a]† Peter Johnston,[b]‡ J. Anton Slipszenko,[b] Peter B. Wells*[b] and Robin Whyman*[a]

[a] *Department of Chemistry, University of Liverpool, PO Box 147, Liverpool, UK L69 7ZD*
[b] *Department of Chemistry, University of Hull, Hull, UK HU6 7RX*

The outcome of the enantioselective hydrogenation of pyruvate esters using cinchona alkaloid-modified palladium catalysts is dependent on the choice of solvent/substituent; the sense of the enantioselectivity can be switched from *S* to *R* whilst maintaining the magnitude of the enantiomeric excess.

The enantioselective hydrogenation of methyl pyruvate (MP) and ethyl pyruvate (EP) catalysed by Pt modified by the cinchona alkaloids cinchonidine (CD) and cinchonine (CN) has received much attention over the last decade as one of only a few effective heterogeneous enantioselective systems (Scheme 1).[1–4] It is generally accepted that the adsorption of such modifiers onto a Pt surface *via* the quinoline moiety[5] provides an adjacent site at which *selective enantioface adsorption* of pyruvate occurs and at which subsequent hydrogenation provides lactate product with one enantiomer formed in excess, cinchonidine favouring the *R*- and cinchonine the *S*-enantiomer (Table 1, entries 1 and 2). Concomitant with enantioselectivity is an increase in rate, the enantioselective reaction typically being 20 to 50 times faster than the reaction in the absence of alkaloid. The corresponding Pd-catalysed reactions have been less well studied.[6–9] Two distinctive features of the Pd-catalysed reaction are that (i) the sense of the enantioselectivity is reversed with respect to that of the Pt system (*i.e.* CD directs the reaction to the *S* product and CN to the *R* product), and (ii) there is no rate enhancement.[6–8] Deuterium tracer studies have shown that, over platinum, there is direct addition of two deuterium atoms across the carbon–oxygen double bond but over palladium the main product-forming route is *via* the enolate tautomer and carbon–carbon double bond hydrogenation.[8,10]



Scheme 1

Table 1 The catalytic enantioselective hydrogenation of pyruvate esters

Run	Catalyst	Reactant	Solvent/ substituent	Modifier	Pressure/bar	Initial rate[a]/ mmol s^{-1} mol_{metal}^{-1}	Ee[b] (%)

[a] n/r = not reported. [b] Uncertainty ± 2%. [c] Johnson Matthey type 24C. Experiment performed in Hull. [d] Ref. 6. [e] Englehardt ESCAT14. Experiment performed in Liverpool. [f] Ref. 7.

We now report that the catalysis over palladium surfaces shows a more diverse chemistry than was hitherto suspected and that, depending on the choice of solvent/substituent, *each* alkaloid may give *either* enantiomer in excess.

Pt and Pd colloids stabilized with KD1, a proprietary protecting agent, were prepared by a metal vapour synthesis route[11]§ and used as catalysts in the enantioselective hydrogenation of EP.[12,13]¶ The Pt colloids gave the expected direction of enantioselectivity and rate enhancement on the basis of the known chemistry of supported platinum catalysts, *i.e.* CD and CN modification gave (*R*)- and (*S*)-lactate, respectively (Table 1, entries 3–5). The KD1 stabilizing agent was found to have only a marginal effect on the performance of the catalysts (Table 1, compare entries 3 and 4 with 6 and 7).

Surprisingly however, when modified by addition of a butan-2-one (MEK) solution of CD, the palladium colloids also gave (*R*)-lactate with ees of up to 30% in the hydrogenation of EP (entry 8), *i.e.* in the opposite sense to that previously reported for CD-modified Pd catalysts (*e.g.* entry 24).[6–8] In contrast to reactions using oxide-supported Pd catalysts these reactions also appear to show rate enhancement, the rate of the unmodified reaction being very slow (compare entries 8 and 9). The enantioselectivity induced by CN was more muted, in agreement with previous reports that CN is a less effective modifier than CD, and was in favour of (*S*)-lactate (entry 10). This is the *first* report of palladium emulating platinum in the sense of the enantioselectivity induced in pyruvate ester hydrogenation.

Previous studies of oxide-supported palladium catalysed reactions have used EtOH rather than MEK as the solvent[6,8] or have used the methyl rather than the ethyl ester as reactant.[7] In order to investigate the possibility of unprecedented solvent and/or substituent effects in Orito-type reactions, several oxide-supported palladium catalysts were modified either *in situ* or by the Orito procedure[14]‖ in EtOH, THF and MEK and used as catalysts in the hydrogenation of ethyl and methyl pyruvates. All these catalysts gave the expected[6–8] enantioselectivity, *i.e.* in the opposite sense to that observed for platinum catalysts, CD giving (*S*)- and CN (*R*)- product, and showed a reduced rate in MP hydrogenation, (entries 11–17). However, when used in ethyl pyruvate hydrogenation, CD modified catalysts gave (*R*)-lactate in substantial ee and CN modified catalysts (*S*)-lactate, (entries 18–23), *i.e. in the opposite sense to that previously reported*.[6–8] These results originate in independent studies in Liverpool (entries 18 and 19) and Hull (entries 20–23). Thus, this work is not only the *first* report of Pd following Pt in the sense of the observed enantioselectivity, but is also the *only* report, for *either* platinum or palladium, *of the direction of the enantioselectivity being solvent and/or substituent dependent.*

The mechanistic pathway of the palladium-catalysed reaction is not well-understood. Deuterium labelling experiments have shown that, in contrast to the case with Pt, over Pd the main product forming route is *via* the enol and carbon–carbon double bond hydrogenation.[8] Deuterium tracer experiments are in progress to test whether the palladium catalysed reaction in MEK also follows this mechanistic pathway.

These observations reveal that the palladium catalysed enantioselective hydrogenation of pyruvate esters is a much more complicated system than the analogous platinum-catalysed reaction and that coadsorption of solvent/substituent molecules on the Pd surface both during the modification procedure and thereafter during enantioselective hydrogenation is crucial in determining the stereochemical outcome of the reaction.

The authors thank the Catalysis Initiative of the EPSRC (J. A. I. and R. W.) and Johnson Matthey (P. B. W.) for financial support and the provision of studentships (P. J. C., T. J. H and J. A. S.).

§ Colloidal metal solutions were prepared by metal vapour deposition in a Torrovap reactor. Typically 2.5 g of KD1, a proprietary protecting agent (ICI), was melted and dispersed onto the walls of the 5 l spherical chamber, after which the chamber was evacuated to 10^{-7} Torr and cooled in liquid nitrogen. 11.3 mmol of Pd was then evaporated over 2 h and co-condensed with 145 cm^3 of butan-2-one (MEK) which was simultaneously added to the vessel as vapour. After deposition the chamber was warmed to room temperature during which period a further 2.5 g KD1 in 60 cm^3 of MEK was added. Pt colloids were prepared by an analogous procedure. High resolution transmission electron microscopy showed the Pd colloids typically to have a particle size distribution ranging from 1.75 to 4.75 nm, with a maximum at 2.5 nm. After use in catalysis the particle size had increased to 2 to 9 nm with a maximum at 4 nm.

¶ A solution of the colloid containing 1 mg of Pd, modifier (6 mg, 2.0×10^{-5} mol), freshly distilled ethyl pyruvate (2.7 mg, 0.024 mol) (Aldrich)[15] and solvent/substituent (total reaction volume: 20 ml) was added to a Parr 4592 autoclave. The autoclave was sealed, purged three times with H_2 to 50 bar and then pressurized to 70 bar with H_2 and maintained at 25 ± 1 °C for 1 h.

‖ The reduced catalyst was first immersed in a solution of the alkaloid in the appropriate solvent and the slurry was then stirred in air for about 1 h before the catalyst was loaded into the high pressure reactor.

The novel cyclic oligosaccharides, permethylated cyclofructans MECF, 1b and 2b, discriminate enantiomers of chiral amino acid ester hydrochlorides.

Chiral discrimination of amino acids by cyclodextrins (CD) has been widely investigated in the field of liquid chromatographic and electrophoretic enantioseparations,[1–4] but that by cyclofructans (CF)[5,6] has not as yet been examined. With the application of the FAB mass spectrometry (MS)–enantiomer labelled (EL) guest method,[7–9] one of the rare methods for estimation of the chiral recognition ability of new hosts,[10] we found for the first time that permethylated cyclofructans (MECF) exhibit various degrees of chiral discrimination towards amino acid esters. This is the first successful detection of the chiral amino acid-discriminating ability of cyclic oligosaccharides on a unified scale covering the two series, where various types of complexation mechanism, such as charge-dipole electrostatic, hydrophobic and hydrogen bonding interactions are operative. An oligosaccharide host (H) is complexed with a 1:1 amino acid guest mixture of an unlabelled (*R*)-enantiomer (G_R^+) and a deuterium labelled (*S*)-enantiomer ($G_{S\text{-}Dn}^+$). The enantioselectivity of a given oligosaccharide (host) toward a given racemic amino acid (guest) is quantitatively estimated from the relative peak intensity value $\{I[(H + G_R)^+]/I[(H + G_{S\text{-}Dn})^+] = I_R/I_{S\text{-}Dn}\}$ of the two host–guest diastereomeric complex ion peaks in the FAB mass spectrum.

The cyclic oligosaccharide hosts **1b**–**5b** were permethylated so that their complex ions were sensitively detected by FAB MS. Amino acid 2-propyl ester hydrochlorides[11] were used as guests so that natural abundance correction[7] was unnecessary. All (*S*)-enantiomers were labelled with deuterium (2-propyl ester: n = 6 or 7). A 1:1 racemic mixture solution of enantiomer guests was prepared by mixing an equal amount of a 0.67 M MeOH solution of each enantiomer. A 10 μl aliquot of the guest solution and a 5 μl aliquot of a 0.20 M host $CHCl_3$ solution were added to 15 μl of the 3-nitrobenzyl alcohol (NBA) matrix. A 1 μl sample of the final mixture was used for obtaining FAB mass spectra. A typical FAB mass spectrum is shown in Fig. 1, and the $I_R/I_{S\text{-}Dn}$ values obtained are summarized in Table 1. MECF6 **1b** and MECF7 **2b** showed higher (*R*)-enantioselectivity for $[Trp\text{-}O\text{-}Pr^i]^+$ ($I_R/I_{S\text{-}Dn}$ = 1.38–1.29; $-\Delta\Delta G_{enan}$ = 150–190 cal mol^{-1}) [$-\Delta\Delta G_{enan} = RT\ln(I_R/I_{S\text{-}Dn})$ was employed for interconversion].[7–9] MECF6 **1b** for $[Tle\text{-}O\text{-}Pr^i]^+$ and MECF7 **2b** for $[Ser\text{-}O\text{-}Pr^i]^+$ or $[Pro\text{-}O\text{-}Pr^i]^+$ provided the next best (*R*)-enantioselectivities. On the other hand, MECF7 **2b** for $[Pgly\text{-}O\text{-}Pr^i]^+$ showed an inverse (*S*)-enantioselectivity ($I_R/I_{S\text{-}Dn}$ = 0.76). β-MECD **4b** and γ-MECD **5b** indicated (*R*)-enantioselectivity for $[Ser\text{-}O\text{-}Pr^i]^+$ and $[Pro\text{-}O\text{-}Pr^i]^+$ ($I_R/I_{S\text{-}Dn}$ = *ca.* 1.15; $-\Delta\Delta G_{enan}$ = *ca.* 80 cal mol^{-1}).

Among many thermodynamic chiral discrimination studies, the chiral discrimination of simple amino acids by CDs on the basis of the host–guest (1:1) intermolecular interactions has rarely been reported until now. In one of the reports, Lincoln determined the relative binding constant (K_R/K_S = 0.92 in water at 295.5 K) of α-MECD **3b** with 4-fluorophenylglycine hydrochloride using the ^{19}F NMR titration method.[12,13] The enantioselectivity of α-MECD **3b** for the corresponding $[Pgly\text{-}O\text{-}Pr^i]^+$ under our FAB MS conditions ($I_R/I_{S\text{-}Dn}$ = 0.94) was in a good agreement with the above K_R/K_S value. It is worthwhile to note that this is further experimental evidence for the parallels between the $I_R/I_{S\text{-}Dn}$ and K_R/K_S values which have been described previously.[7–9] The NOE behavior of α-CD **3a** with Trp using ^1H NMR analysis suggested (*R*)-enantioselectivity,[14]

[a] 18-crown-6 (18-C-6) is the typical achiral host employed. Glycine 2-propyl ester $(Gly\text{-}O\text{-}Pr^i)^+$ is the typical achiral guest employed. Averaged value (n = 4) of 10th, 20th, 30th and 40th scan data. Errors of the $I_R/I_{S\text{-}Dn}$ values are estimated within ±0.04. Tle = *tert*-leucine, Pgly = phenylglycine.

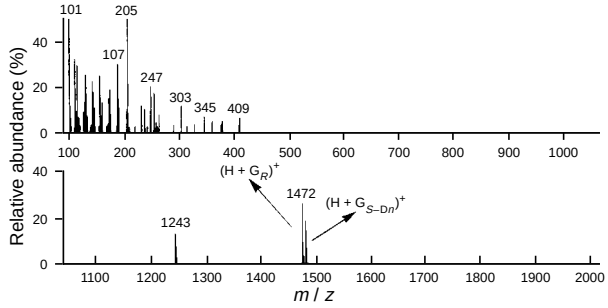

Fig. 1 An example of a FAB mass spectrum from the FABMS/EL guest method. Host: MECF6 **1b**; guest: $[Trp\text{-}O\text{-}Pr^i]^+$. The left peak ($m/z$ 1472) is a complex ion $(H + G_R)^+$ and the right (m/z 1478) is $(H + G_{S\text{-}Dn})^+$.

which was also in line with our results obtained by FAB MS (α-MECD **3b** with $[Trp\text{-}O\text{-}Pr^i]^+$; $I_R/I_{S\text{-}Dn}$ = 1.29).

The crystalline structure of a complex of MECF6 **1b** with Ba^{2+} (counter anion: SCN^-) that was reported previously showed that the cation was coordinated at ten points to the host, four 3-OMe oxygens of the furanose rings and six oxygens in the 18-crown-6 skeleton (Fig. 2).[6] In the case of a complex of MECF6 with amino acid ester hydrochlorides, it is expected that the 3-OMe groups become chiral barriers for the indole or *tert*-butyl groups of the corresponding chiral guest. The difference in the stereochemical complementarity would be origin of the chiral discrimination of MECF6 **1b**.

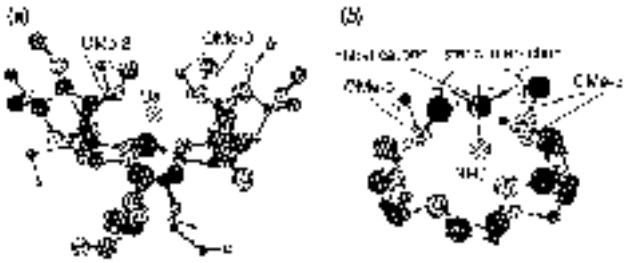

Fig. 2 (*a*) Crystalline complex of **1b** with barium cation (counter anion: SCN^-). Hydrogen atoms are not shown. (*b*) Imaged illustration of a complex of **1b** with an alkylammonium ion. The nitrogen cation of the alkylammonium replaced the barium from (*a*). The α-carbon of the alkylammonium ion was localized at a position of 1.49 Å from the nitrogen, an average C–N distance in amino acids.

We are studying in detail the mechanism of chiral discrimination of the cyclofructans. We hope that cyclofructans and their derivative hosts will be amenable to the further development of new chiral stationary phases and chiral selectors.

We are very grateful to Mitsubishi Chemical Co. for the kind gift of cyclofructans (**1a**, **2a** and the other oligomers).

Importance of intramolecular hydrogen bonding for preorganization and binding of molecular guests by water-soluble calix[6]arene hosts

Julio Alvarez, Yun Wang, Marielle Gómez-Kaifer and Angel E. Kaifer*†

Chemistry Department, University of Miami, Coral Gables, FL 33124-0431, USA

The binding affinity of calix[6]arene hexasulfonate hosts for ferrocene or cobaltocenium guests is highly dependent on the extent of intramolecular hydrogen bonding in the lower rim of the calixarene.

The calixarenes[1] are an interesting and extensively studied class of host molecules characterized by their aromatic character and conformational flexibility. Water-soluble calixarenes are commonly prepared by sulfonation of the aromatic rings, yielding a family of negatively charged hosts.[2] We have previously reported on the binding ability in aqueous solution of sulfonated calixarene hosts with different molecular guests.[3,4] Here, we concentrate our attention on calix[6]arenes **1** and **2** (Fig. 1) and report our findings on the striking differences in the binding affinity exhibited by these two calixarene hosts towards the same guests (ferrocene and cobaltocenium derivatives, Fig. 1). The differences observed can be rationalized on grounds of host preorganization due to intramolecular hydrogen bonding in the calixarene's lower rim.

Calixarene **1** exists in neutral aqueous solution as an octaanion due to the deprotonation of two of its phenolic OH groups. Atwood *et al.* reported the X-ray crystal structure of the sodium salt of $\mathbf{1}^{8-}$.[5] They found that this host exhibits a partial cone conformation with three adjacent sulfonate groups pointing to one side of the cavity and the remaining three sulfonates pointing to the opposite end. The structure is rigidified by hydrogen bonding of each negatively charged phenolate to the two neighboring phenolic OH groups, as shown in Fig. 1. This crystal structure was postulated to be very close to the average solution structure due to the high level of hydration of the crystal.[5]

The accessible electroactivity of the selected guests‡ allowed us to readily examine the binding interactions between each calixarene–guest pair using voltammetric techniques. Relevant electrochemical data are given in Tables 1 and 2. Host **1** forms stable complexes in pH 7.0 aqueous media with all the guests surveyed. This is shown by the decreased current levels observed upon addition of $\mathbf{1}^{8-}$ on the voltammetric waves for the oxidation of the ferrocene guests as well as on those for the reduction of the cobaltocenium guests. This current decrease reveals the association of $\mathbf{1}^{8-}$ with all the guests prior to any electrochemical conversions. In addition to this, the half-wave potential ($E_{1/2}$) for the oxidation of the ferrocene guests shifts to less positive values in the presence of $\mathbf{1}^{8-}$ and the $E_{1/2}$ values for reduction of the cobaltocenium guests shift to more negative values. This is consistent with the octaanionic host binding more strongly to the oxidation states of the guests bearing a higher positive charge.

Similar experiments with $\mathbf{2}^{6-}$, the O-methylated analog of calixarene host $\mathbf{1}^{8-}$, yield very different results. First, addition of this calixarene does not affect the current levels of the voltammetric waves. Secondly the $E_{1/2}$ values also remain

essentially unchanged in the presence of $\mathbf{2}^{6-}$. These data reveal that this hexaanionic calixarene host is ineffective at binding all these guests in any of their two accessible oxidation states. In an attempt to understand the striking binding ability differences between $\mathbf{1}^{8-}$ and $\mathbf{2}^{6-}$, we also performed experiments with $\mathbf{1}^{6-}$, prepared by dissolving the unmethylated calixarene **1** in a solution buffered at pH = 2.6 to insure the full protonation of its phenolic lower rim.[6] The corresponding voltammetric results (Table 2) clearly indicate that this host loses a fraction of its binding ability under these conditions compared to the same host in neutral (pH = 7) media.

It seems dubious that these effects could be rationalized with electrostatic arguments. While calixarene **1** at neutral pH bears eight negative charges, both calixarene **2** at the two pH values surveyed here and calixarene **1** at pH = 2.6 are hexaanions. These less charged hosts still have six negative charges, certainly enough to attract positively charged guests if electrostatic forces were to control the host–guest interactions. To further clarify the observed binding properties we have run a series of molecular modeling calculations§ aimed at finding relevant conformational differences between these hosts. The computational results show that, at neutral pH, the most stable conformation of the octaanionic host $\mathbf{1}^{8-}$ is very similar to the crystal structure reported by Atwood and coworkers [Fig. 2(*a*)]. After full protonation of its lower phenolic rim, the same host (now $\mathbf{1}^{6-}$) adopts a very different, flattened and puckered conformation [Fig. 2(*b*)], which lacks well defined binding pockets in spite of its relative rigid character. This conformational change may be responsible for the diminished binding ability exhibited by this host in acidic media. Finally, the methylated host $\mathbf{2}^{6-}$ exhibits a lot more flexibility since intramolecular hydrogen bonding in the lower rim is no longer possible. In this case, we could not locate a clearly defined energy minimum. The lowest energy conformation found is shown in Fig. 2(*c*), but many other equally disorganized conformations are readily accessible. The flexibility and absence of molecular preorganization are the key factors that determine the poor binding ability demonstrated by this host. Conversely, the octaanionic form of **1** (present at neutral pH) is an excellent host¶ for the guests surveyed here because of its preorganized and rigid character which is determined by the network of hydrogen bonds in its lower rim.

The authors are grateful to the US National Science Foundation for the support of this research work (to A. E. K., CHE-9633434).

‡ The two ferrocene derivatives, Fc–OH and Fc–N^+Me_3, undergo reversible one-electron oxidation to the corresponding ferrocenium forms, Fc^+–OH and Fc^+–N^+Me_3, respectively. We have previously reported on the binding of these two guests by calixarene **1** in unbuffered aqueous media, see ref. 3(*a*). The two cobaltocenium derivatives, Cob^+ and Cob^+–CO_2^-, undergo reversible one-electron reduction to the corresponding cobaltocene forms, Cob and Cob–CO_2^-, respectively, at a potential which is accessible at neutral pH but inaccessible at pH = 2.6. The pK_a of Cob^+–CO_2H is *ca.* 1.3 so that complete ionization is expected in the pH range used in this work.

§ All calculations were run with the Macromodel software package (version 6.0) running on a O2 Silicon Graphics workstation. The energy of each calixarene was minimized, after setting the solvent option to water, using the OPLS force field. Conformtional searches were done using Monte Carlo simulations with an energy range of 100 kJ mol^{-1} (1 cal = 4.184 J). On average, 400–500 unique conformations were identified for each host *en route* to a global minimum. At least two full conformational searches were performed with each host.

¶ ^{1}H NMR spectroscopic experiments indicate that the complexes formed between the guests Fc–N^+Me_3 and Cob^+ with host $\mathbf{1}^{8-}$ have 2 : 1 (guest : host) stoichiometry under these experimental conditions (see the following communication in this issue).

Redox control of host–guest recognition: a case of host selection determined by the oxidation state of the guest

Yun Wang, Julio Alvarez and Angel E. Kaifer*†

Chemistry Department, University of Miami, Coral Gables, FL 33124-0431, USA

In the presence of β-CD, reduction of the strong complex between two cobaltocenium guests and the octaanionic form of calix[6]arene hexasulfonate leads to the formation of 1 : 1 complexes between cobaltocene and β-CD.

Redox conversions have been effectively used to control the strength of host–guest interactions. Typically, changes in the oxidation state of one of the interacting partners (either the host or the guest) lead to substantial modifications in the stability of the host–guest complex. Redox switchable hosts,[1] for instance, contain a redox subunit which can be acted upon (electrochemically or chemically) to alter their binding affinity for certain guests. Here, we extend these ideas to the concept of host selection. We describe a system composed of two redox inactive hosts and one redox active guest in which the oxidation state of the guest determines which of the two hosts is selected for complex formation.[2]

Fig. 1 shows the structures of the host and guest compounds used in this work. The solubilities of hosts and guests permit the investigation of this system in aqueous solution. The two hosts selected are the sulfonated calix[6]arene $\mathbf{1}^{8-}$ and β-cyclodextrin (β-CD). The anionic character and conformational rigidity‡ of host $\mathbf{1}^{8-}$ make it an excellent host for positively charged guests, while β-CD is well known to exhibit a strong binding affinity for suitably sized non-polar guests.[3] The two guests selected are cobaltocenium and carboxycobaltocenium. The cobaltocenium subunit undergoes a fast and reversible one-electron reduction to neutral cobaltocene. Very recently we have reported that, while β-CD does not interact appreciably with the positively charged cobaltocenium (Cob^+), it does form a stable 1 : 1 inclusion complex with the reduced form, cobaltocene (Cob).[4]

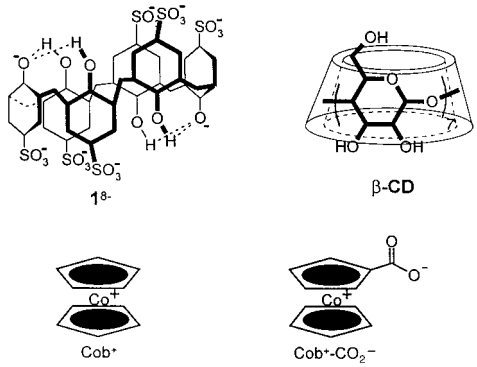

Fig. 1 Structures of calixarene hosts and molecular guests studied in this work

The voltammetric reduction of cobaltocenium yields the hydrophobic Cob form, which precipitates on the electrode surface. These precipitation effects distort the cyclic voltammogram [see Fig. 2(*a*)] from the otherwise anticipated nernstian, reversible shape. Addition of host $\mathbf{1}^{8-}$ shifts the Cob^+–Cob voltammetric wave to more negative potentials but the distortions associated with deposition of the reduced form persist [Fig. 2(*a*)]. These findings are consistent with (*i*) complexation

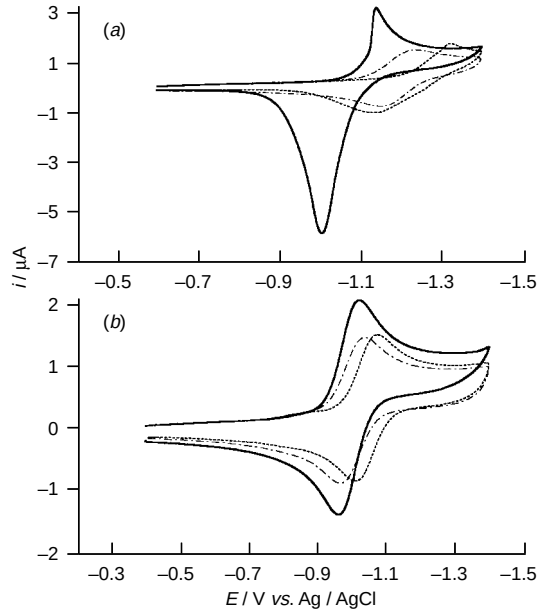

Fig. 2 (*a*) Voltammetric response on a glassy carbon electrode (0.008 cm^2) of a 1.0 mM solution of Cob^+ also containing 0.1 M phosphate buffer (pH = 7) in the absence of any host compound (——), in the presence of 4.0 mM $\mathbf{1}^{8-}$ (------), and in the presence of 4.0 mM $\mathbf{1}^{8-}$ and 4.0 mM β-CD (-·-·-·). Scan rate = 0.1 V s^{-1}. (*b*) Same for 1.0 mM Cob^+–CO_2^- solution.

of Cob^+ by the anionic calixarene host and (*ii*) lack of substantial interaction between $\mathbf{1}^{8-}$ and Cob. NMR titrations (^1H, 400 MHz) of buffered (pD = 7) D_2O solutions of $\mathbf{1}^{8-}$ with increasing concentrations of Cob^+ produce strong evidence for the formation of a stable complex containing two Cob^+ guests bound to the anionic host.[5] The Cob^+-induced splitting patterns of both the aromatic proton and the methylene proton resonances of the calixarene (Fig. 3) constitute strong evidence for the formation of the 2 : 1 complex shown in Scheme 1. In 1992, Atwood *et al.* solved the crystal structure of the hydrated sodium salt of $\mathbf{1}^{8-}$ (crystallized from neutral aqueous solution) and found that the calixarene adopts a double partial cone conformation exhibiting two clearly defined binding pockets.[6] To the best of our knowledge, our NMR data constitute the first unequivocal spectroscopic evidence for the adoption by host $\mathbf{1}^{8-}$ of the same conformation in neutral aqueous solution. In the absence of Cob^+, the aromatic units of the calixarene undergo fast interconversions and, thus, only two proton resonances are observed (one for the methylene protons and another for the aromatic protons). In the presence of more than 2 equiv. of Cob^+, each one of these resonances splits into the patterns shown in Fig. 3. These resonances are consistent with a double partial cone conformation for the calixarene (see assignments in Fig. 3) and can only be rationalized by the formation of a complex in which one Cob^+ guest binds to each of the two cavity openings of the calixarene.§ Complexation of $\mathbf{1}^{8-}$ to two Cob^+ guests slows down the otherwise fast averaging of the

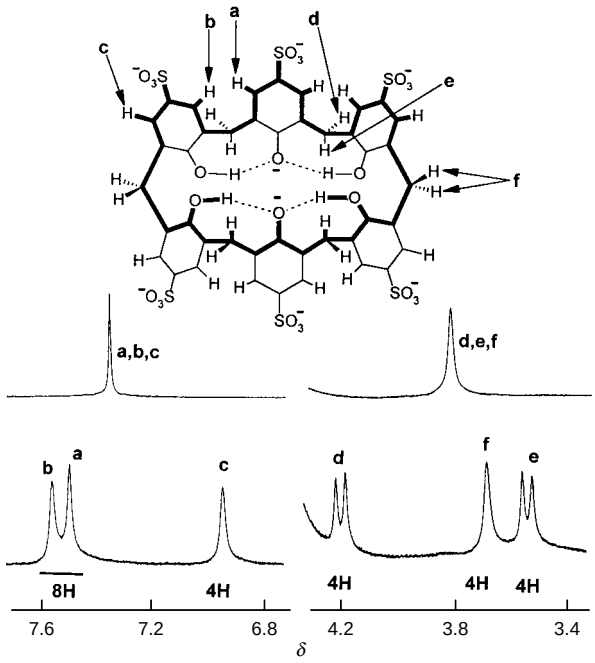

Fig. 3 ^{1}H NMR (400 MHz) of a 2.0 mM solution of $\mathbf{1}^{8-}$ in D_2O also containing 0.1 M phosphate buffer (pD = 7) in the absence (top) and in the presence (bottom) of 6.0 mM Cob^+

host's proton resonances, giving rise to the distinctive splitting patterns shown in Fig. 3.

The $\mathbf{1}^{8-}$–Cob^+ host–guest system is further affected by the addition of β-CD to the medium [Fig. 2(*a*)]. In the presence of this neutral host, the precipitation effects associated with the generation of the hydrophobic Cob form (which is not effectively complexed by $\mathbf{1}^{8-}$) completely disappear, revealing that Cob forms a stable 1 : 1 inclusion complex with the β-CD host, as anticipated from our previous work.[4] Therefore, we must conclude that, while Cob^+ forms a stable 2 : 1 complex with the anionic calixarene host $\mathbf{1}^{8-}$, its reduced form, Cob, is preferentially bound by β-CD. Since the binding interactions between the Cob^+–β-CD and Cob–$\mathbf{1}^{8-}$ pairs are indeed quite weak, the electrochemical reduction of Cob^+ has a profound effect not only on the selection of host by this redox active guest but also on the stoichiometry of the resulting complex as represented in Scheme 1. The voltammetric results obtained with the more water soluble Cob^+–COO^- guest are shown in Fig. 2(*b*). No precipitation of the reduced Cob–CO_2^- form is observed, but the shifts recorded in the $E_{1/2}$ values upon addition of $\mathbf{1}^{8-}$ and β-CD indicate that similar host selection phenomena also take place with this guest.

We have shown here that the redox chemistry of cobaltocenium guests can be used to select the appropriate host between calixarene $\mathbf{1}^{8-}$ and β-CD. These results add to the arsenal of mechanisms and schemes by which redox conversions can be used to control molecular recognition interactions.

Spiro[4.4] and spiro[4.5] lactones from phthaloyl chloride and 1,4- and 1,5-bis-nucleophiles

Mary J. O'Mahony,[a] Charles W. Rees,*[b] Elizabeth A. Saville-Stones,[a] Andrew J. P. White[b] and David J. Williams[b]

[a] *AgrEvo UK Limited, Chesterford Park, Saffron Walden, Essex, UK CB10 1XL*
[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

Phthaloyl chloride reacts with the 1,4-bis-nucleophiles 3 to give spiro[4.4] lactones 7 and 9 and with the 1,5-bis-nucleophiles 10 to give spiro[4.5] lactones 12, as proved by X-ray crystallography, and not the 8- and 9-membered heterocyclic systems previously claimed.

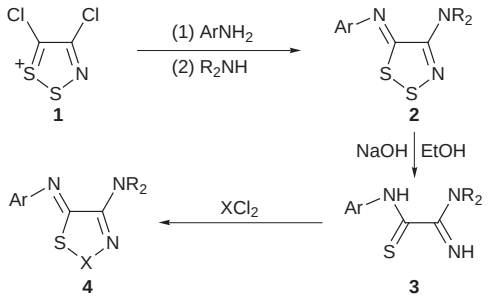
4,5-Dichloro-1,2,3-dithiazolium chloride ('Appel Salt') **1** is a remarkably versatile reagent in organic synthesis.[1–4] When treated with primary aromatic amines followed by secondary aliphatic amines it gives the dithiazoles **2** which can be hydrolysed to the amidino thioamides **3**.[2] As reactive 1,4-bis-nucleophiles compounds **3** are useful in heterocyclic synthesis, particularly when treated with 1,1-bis-electrophiles to give five-membered rings **4** (X = CS, CNPh, SO and SO_2) (Scheme 1),[3] and with 1,2-bis-electrophiles to give six-membered rings.[4] A more unusual application was the reported reaction of compound **3** with the 1,4-bis-electrophile, phthaloyl chloride, in CH_2Cl_2 containing pyridine at room temperature to give the 8-membered ring compounds, 2,5-benzothiazocine-1,6-diones **5** (Scheme 2). Nine examples, selected from R = Pr, Bu and Ar = 4-XC_6H_4 (X = Cl, Br, Me, MeO, NO_2) and 3-$O_2NC_6H_4$, were reported in 45–83% yield.[3]

These unusual 2,5-benzothiazocines were unknown, and if valid, this route would render them readily available. However displacement of the second chlorine in phthaloyl chloride to form a highly unsaturated 8-membered ring seems questionable on mechanistic grounds; furthermore it overlooks the possibility of a lower energy process involving interaction between the two acid chloride groups, typified by the long-known isomerisation of phthaloyl chloride into 3,3-dichlorophthalide.[5] It occurred to us that attack of the second carbonyl group could be through the first, as shown in **6** for example, to give the strain-free spiro[4,4] lactones **7** (or **9**) rather than the 8-membered ring (Scheme 3). This we have now shown to be the case.

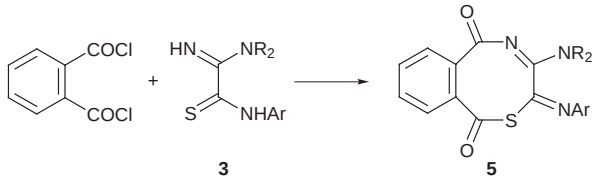
We repeated the preparation of the amidino thioamides **3** (R = Pr, Ar = 4-$O_2NC_6H_4$, 4-$MeOC_6H_4$), and treated them with phthaloyl chloride and pyridine, exactly as reported,[3] to obtain 1 : 1 adducts (44 and 47% yield, respectively). By spectroscopic comparison these were clearly the same products as described in the literature.[3] Careful chromatography and slow crystallisation from Pr^i_2O–hexane gave the 4-nitrophenyl product as yellow crystals, mp 229–231 °C, suitable for X-ray crystallography† which revealed the structure to be the racemic spiro lactone **9** (R = Pr, Ar = 4-$O_2NC_6H_4$). It is clear from their IR, ^1H and ^{13}C NMR and mass spectra that all the claimed benzothiazocines **5** are structurally very similar and thus we deduce that they are all spiro compounds **9**; indeed this structure is in better agreement with the spectroscopic data than the benzothiazocine **5**, which remains unknown.

The X-ray structure of **9** (R = Pr, Ar = 4-$O_2NC_6H_4$) is illustrated in Fig. 1. There are only minor differences in the geometries of the four independent molecules: small changes in the conformations of the NPr_2 groups and in the twist angle between the planes of the imidazole and nitrophenyl ring systems. The only other structural features of note are a pronounced double bond character for N(3)–C(4) and delocalisation within the thioamide [N(1)–C(5)–S(5)].

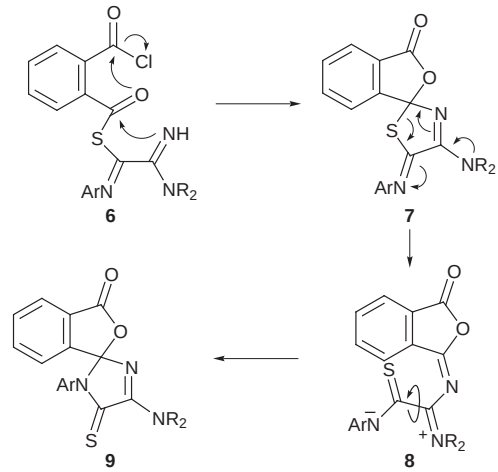
In the reaction of the amidino thioamides **3** with phthaloyl chloride there are various possibilities for the order of nucleophilic attack. Because of the high nucleophilicity of sulfur we consider **6** to be the more likely first intermediate and this would result in the formation of **7** rather than **9**. It is possible that **7** is the kinetic product which then undergoes a Dimroth type rearrangement to the more stable thioamide structure **9**, through the stabilised ring-opened intermediate **8**. This view was strongly supported by studying the reactions of phthaloyl



Scheme 1



Scheme 2



Scheme 3

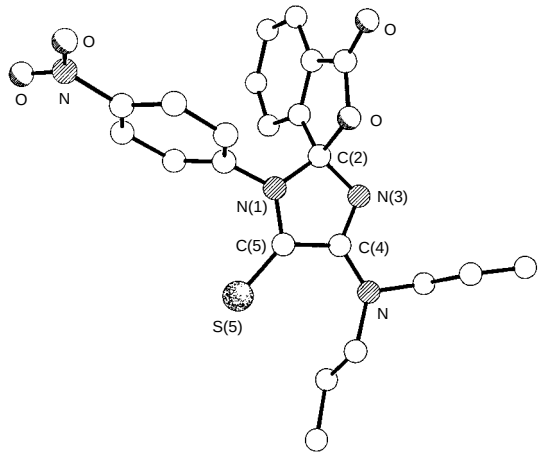


Fig. 1 The structure of one of the four crystallographically independent molecules of **9** (R = Pr, Ar = 4-$O_2NC_6H_4$). Selected bond lengths (Å) [averaged over the four molecules]; N(3)–C(4) 1.29(2), N(1)–C(5) 1.35(2), C(5)–S(5) 1.622(13).

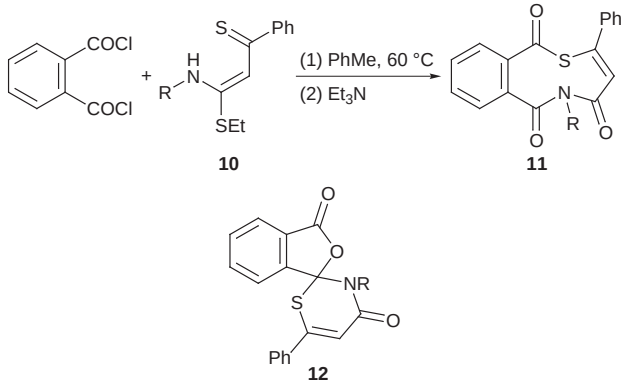
chloride with the amidino thioamides **3** (R = Pr, Ar = 2,6-$Me_2C_6H_3$ and R = Pr, Ar = 2,4,6-$Me_3C_6H_2$) where the bulkier *N*-aryl groups should favour the less congested structure **7** over **9**. From each of these reactions two isomeric products were isolated and shown spectroscopically to be **7** (62%) and **9** (32%) for the dimethyl and **7** (65%) and **9** (28%) for the trimethyl compounds. The products **7** in the dimethyl and trimethyl series are labile and isomerise slowly to **9** on standing in CH_2Cl_2 at room temperature; this rearrangement is markedly catalysed by acid (HCl in $CDCl_3$). In view of the possible formation of structural isomers in the cyclisation of compound **3**, the five-membered ring structures **4**, proposed above,[3] should also be treated with caution and isomeric thioamide structures be considered.

In similar vein the condensation of phthaloyl chloride with the 1,5-bis-nucleophiles **10** has been reported to give the equally striking 9-membered ring system, 2,6-benzothiazonine-1,5,7-trione **11**.[6] Eleven such products (R = Me, Et, allyl, cyclohexyl, Bn, substituted benzyl) were obtained as colourless solids, mostly in very high yields, and all exhibit very similar spectroscopic properties.[6] If correct this would provide an attractive route to this new ring system, but again it seemed likely that the 1,5-bis-nucleophiles **10** could be reacting by the same general mechanism as the 1,4-bis-nucleophiles **3**, to give the analogous spiro[4,5] lactones **12**.



We therefore prepared the thione **10** (R = Et) and treated this with phthaloyl chloride as reported,[6] to give a colourless crystalline product, mp 132–133 °C (61%). X-Ray crystallography reveals a spiro junction between the phthalide and thiazinone ring systems, thus confirming the alternative structure **12** (Fig. 2). The thiazinone ring has a half-chair conformation with the spiro centre C(2) lying 0.64 Å out of the plane of the remaining atoms–which are co-planar to within 0.04 Å.

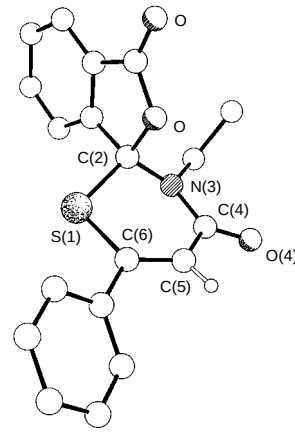


Fig. 2 The molecular structure of **12**, (R = Et). Selected bond lengths (Å); S(1)–C(6) 1.738(3), C(6)–(5) 1.343(4), N(3)–C(4) 1.373(4), C(4)–O(4) 1.226(4), C(4)–C(5) 1.466(4).

The spectroscopic data for **12** (R = Et) agreed well with the spiro structure and with the data reported for the other products, indicating that these too are all spiro compounds, and that the nine-membered ring of **11** is still unknown. A similar spirolactone structure has been assigned to the product from phthaloyl chloride and 2-(dihydroimidazol-2-yl)thiophenol, on the basis of its ^{13}C NMR spectrum which agreed well with that of our product.[7]

It follows from these results that spiro lactone (phthalide) structures should always be considered for the products of condensation of phthaloyl chloride, and related 1,2-bis-carboxylic acid halides, with 1,4 and higher bis-nucleophiles.

We gratefully acknowledge support from AgrEvo UK Limited and Dr P. J. Dudfield and we thank the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

A supramolecular assembly controlled by anions: threading and unthreading of a pseudorotaxane

Marco Montalti and Luca Prodi*†

Dipartimento di Chimica 'G. Ciamician', Università di Bologna, via Selmi 2, Bologna, 40126, Italy

The pseudorotaxane formed in CH_2Cl_2 solution by (9-anthrylmethyl)methylammonium hexafluorophosphate salt and dibenzo-24-crown-8 can be unthreaded by addition of NBu_4Cl through the formation of a strong ammonium chloride ion pair, while pseudorotaxane rethreading can be performed by addition of $NHBu_3PF_6$; all these processes can be followed by pronounced changes in the luminescence spectra, which could allow the use of this system as a fluorescent sensor for chloride ions.

The association between crown ethers and ammonium salts has been widely studied and employed to synthesise self-assembling supramolecular systems.[1–5] In particular, the remarkable capability of the ammonium–crown interaction to be switched on/off through acid–base equilibria has also been exploited to induce mechanical movements in systems such as rotaxanes and pseudorotaxanes.[6–8] In this context, we previously examined the photophysical properties of adducts between fluorescent ammonium ions and aromatic crown ethers, pointing out that the nature of the counteranion of the ammonium cation could influence its association with crown ethers in low polarity solvents where strong ion pairs are formed. Starting from this point, we have conceived a new way, based on anion exchange, of controlling the threading and unthreading of a previously examined pseudorotaxane.[6,8]

All experiments were carried out in CH_2Cl_2 solution at room temperature. The experimental equipment and procedures have been previously described.[6] PF_6^- and Cl^- salts were prepared from commercial (9-anthrylmethyl)methylamine. The other compounds were commercial products. All fluorescence spectra were appropriately corrected.[9]

We have already reported the absorption and fluorescence spectra of (9-anthrylmethyl)methylammonium (**1**H$^+$) hexafluorophosphate and dibenzo-24-crown-8 (**2**), together with the properties of the adduct they origin.[6] Absorption and fluorescence spectra of **1**·HCl present some differences from those of **1**·HPF_6; in particular, the fluorescence intensity is about 35% weaker and the maximum is shifted from 421 to 419 nm. A decrease in the fluorescence lifetime from 8.5 to 5.5 ns is also observed. These findings give clear evidence for the formation of a highly associated ion pair with Cl^-, since the fluorescence of the anthracene moiety is very sensitive to the electronic density on the nearby nitrogen atom, which can be responsible for electron transfer quenching processes.[10] If 1 equiv. NBu_4Cl is added to a 2×10^{-4} M solution of **1**·HPF_6, a decrease in the fluorescence intensity and lifetime is observed as expected for the formation of the **1**H$^+$Cl$^-$ ion pair. On addition of an excess of the $NHBu_3PF_6$ salt, the fluorescence of **1**H$^+$ increases although it does not reach the initial intensity, because of the competition between **1**H$^+$ and $NHBu_3^+$ to form ion pairs with Cl^- [eqn. (1)].

$$\mathbf{1}H^+Cl^- + NHBu_3^+ \overset{K_{exc}}{\rightleftharpoons} NHBu_3^+Cl^- + \mathbf{1}H^+ \qquad (1)$$

An even larger effect of the chloride ion on the fluorescence spectra is observed when **2** is present. If equimolar amounts (2×10^{-4} M) of **1**·HPF_6 and **2** are mixed in a CH_2Cl_2 solution, the adduct **1H2**$^{2+}$ $2PF_6^-$ is formed, where the fluorescence of **2** is completely quenched by an energy transfer process to the anthracene moiety. On the contrary, in a solution of **1**·HCl (2×10^{-4} M) and **2** (2×10^{-4} M) no association is observed, and, as a consequence, no sensitization of the fluorescence of **1**H$^+$ on excitation of **2** is detected. This behaviour in solution can be described on the basis of equilibria (2) and (3)

$$\mathbf{1}H^+ + A^- \overset{K_{ip}}{\rightleftharpoons} \mathbf{1}\cdot HA \qquad (2)$$

$$\mathbf{1}H^+ + \mathbf{2} \overset{K_{as}}{\rightleftharpoons} \mathbf{1}H\mathbf{2}^+ \qquad (3)$$

where A^- is the counteranion. If K_{ip} is very large, as it is for Cl^-, equilibrium (3) cannot compete with equilibrium (2), and the adduct with **2** cannot be formed, while if it is small (as for PF_6^-) the adduct formation is observed. This set of equilibria, together with the different affinity of the chloride ions for the different ammonium ions ($NH_2R_2^+ > NHR_3^+ >> NR_4^+$) can be used for controlling the threading and unthreading of this pseudorotaxane. In a solution of **1**·HPF_6 (2×10^{-4} M) and **2** (2×10^{-4} M) the fluorescence of **2** is, as already observed, completely quenched while sensitised fluorescence of **1**H$^+$ is observed (Fig. 1). On addition of 1 equiv. NBu_4Cl the fluorescence of **2** is completely recovered and the sensitised fluorescence of anthracene disappears (Fig. 1). Simultaneously

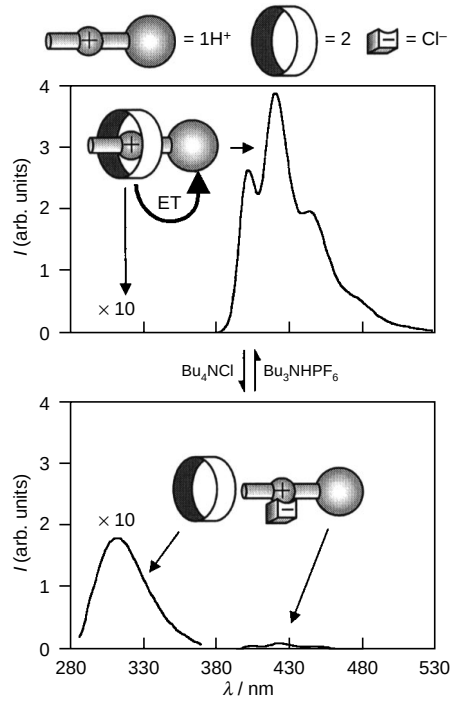

Fig. 1 Changes in the fluorescence spectrum of a CH_2Cl_2 solution of **1**H$^+$ (2×10^{-4} M) and **2** (2×10^{-4} M) upon unthreading and threading of the pseudorotaxane structure caused by addition of NBu_4Cl and $NHBu_3PF_6$, respectively

the anthracene fluorescence (on excitation at λ = 381 nm, where only the anthracene moiety absorbs) decreases to the intensity expected for the **1**H^+Cl^- ion pair formation and the fluorescence lifetime decreases to 5.5 ns. These results indicate that addition of NBu_4Cl leads to the formation of the **1**H^+Cl^- ion pair, preventing the ammonium cation from binding to the crown ether (Fig. 1). Further addition of 1 equiv. $NHBu_3PF_6$ leads again to complete quenching of the fluorescence of **2**, while the **1**H^+ fluorescence intensity and lifetime increase to the initial values, indicating that the pseudorotaxane structure is regenerated. In this case, addition of the $NHBu_3^+$ cation, more strongly bound to Cl^- than to the NBu_4^+ ion, gives rise to equilibrium (1), that, although spontaneously shifted to the left side, can be driven in the presence of **2** to the right side by the occurrence of equilibrium 3, allowing the almost complete formation of the **1**H·**2**$^+$ pseudorotaxane. As can be seen from Fig. 1, dramatic changes in the fluorescence intensities of **1**H^+ and **2** can be observed on every step of the working cycle. This cycle could be repeated several times on the same system, without losing its efficiency, also because tertiary and quaternary ammonium salts cannot compete with **1**H^+ on the association with **2** [equilibrium (3)]. Ion pairing results in a new way of controlling the association of hydrogen bonded supramolecular systems. As a consequence, the pseudorotaxane **1**H**2**$^+$ can be unthreaded and threaded again in three different ways: (i) by adding an acid and then a base, (ii) by adding a base and then an acid or (iii) by adding NBu_4Cl and then $NHBu_3PF_6$. New supramolecular systems could be conceived which, through the combination of these three different modes, would carry out various and complicated logical operations.[11]

Moreover the sensitivity of the ammonium–crown supramolecular systems to the chloride concentration could be usefully employed for the development of new fluorescent chemosensors for chloride ions.[12] Studies in this direction are actually in progress.

We thank Professor V. Balzani and Dr A. Credi for stimulating discussions. This research is being supported by the University of Bologna (Funds for Selected Topics).

Hydroformylation of hex-1-ene in supercritical carbon dioxide catalysed by rhodium trialkylphosphine complexes

Ingrid Bach and David J. Cole-Hamilton*†

School of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland, UK KY16 9ST

Triethylphosphine complexes of rhodium catalyse the hydroformylation of hex-1-ene in supercritical carbon dioxide at rates similar to those obtained in toluene, but with a slightly improved n : i ratio; using trioctylphosphine, much lower rates are observed.

Supercritical carbon dioxide is potentially an excellent solvent for carrying out homogeneous catalytic reactions because it is easily separated from the catalyst and the products and is environmentally benign.[1,2] In addition, the high solubility of gases (totally miscible with $scCO_2$) means that problems associated with transport of gases across interfaces are removed and the gas-like nature of the medium means that diffusion is much faster than in solution reactions.

Extensive studies have been made of hydroformylation of alkenes using $[Co_2(CO)_8]$[3,4] but there have been problems with studying the more active and selective rhodium based species because the triarylphosphine complexes that are usually employed in liquid phase reactions have very low solubility in $scCO_2$.[5] A brief report has appeared in which this problem has been overcome by derivatising the aryl groups with fluorinated chains.[6]

We now report that simple trialkylphosphines such as PEt_3, which are readily available, do not involve the use of costly fluorinated derivatives and have low molecular masses so the relatively small amounts can be employed, can provide highly active catalysts for the hydroformylation of hex-1-ene in $scCO_2$. Trimethylphosphine complexes of ruthenium have been used for the hydrogenation of CO_2[5] and for the formation of DMF from CO_2, hydrogen and dimethylamine in $scCO_2$.[7,8]

Using a catalyst prepared *in situ* from $[Rh_2(OAc)_4]$ and PEt_3, complete conversion to C_7 aldehydes, with a trace of C_7 alcohols [total straight to branched (n : i) ratio = 2.4] is obtained within 2 h at 100 °C.‡ [SAFETY WARNING: All reactions involving $scCO_2$ are carried out at very high pressures (up to 250 bar). They should only be attempted in autoclaves that have been specially designed to withstand such pressures.] Comparison of the pressures within the autoclave during the heating period (10 min), with those obtained during heating an identical solution in the absence of catalyst shows that the onset of reaction occurs at 80 °C, and visual inspection through a sapphire window shows that the mixture becomes homogeneous (monophasic pale yellow solution) at *ca.* 70 °C. Table 1 lists the results of a series of different experiments and shows that the rate is very similar to that obtained with the same catalyst under identical conditions using toluene as the solvent, but the n : i ratio is slightly higher in $scCO_2$. The reaction is retarded by addition of excess of PEt_3, but enhanced by increased p_{CO} or p_{H_2}.

In the solution phase system, we have previously shown[9] that C_7 alcohols can be products of the hydroformylation of hex-1-ene, either formed in a sequential reaction (thf as solvent) or as primary products (alcoholic solvents). In the hydroformylation of hex-1-ene carried out in $scCO_2$, C_7-alcohols are products (*ca.* 8%) after 2 h reaction and become significant (31%) products after longer reaction times. Adding ethanol to the mixture does not increase the amount of alcohol produced, but somewhat reduces the overall rate. We have shown[9] that, in liquid phase reactions, protonation of an acyl intermediate by ethanol is the key step that leads to C_7 alcohol production. It is presumably the inability of $scCO_2$ to solvate the ionic species formed by the protonation, that prevents the direct formation of C_7 alcohols when the reaction is carried out in $scCO_2$ in the presence of ethanol. Interestingly, addition of the fluorinated alcohol, $C_6F_{13}CH_2CH_2OH$, does lead to an increase in the amount of alcohol produced and to a higher reaction rate.

We have also studied other trialkylphosphine ligands. Replacing one ethyl group in PEt_3 with a fluorinated chain ($-CH_2CH_2C_6F_{13}$) increases the reaction rate, presumably because of electron density changes on the rhodium rather than

Table 1 Conditions and yields of products from the hydroformylation of hex-1-ene catalysed by rhodium complexes‡

Solvent	Phosphine	[Rh]/mmol dm^{-3}	p_{CO}/bar	p_{H_2}/bar	t/h	Aldehydes[a] (%)	Heptanol (%)	n : i	TOF/ Rh^{-1} h^{-1}

$scCO_2$	$P(C_8H_{17})_3$	6.56	5	20	2	12	—	3.9	4.2
$scCO_2$	$P(C_8H_{17})_3$	6.69	10	10	2	17	1.5	2.8	6.3
$scCO_2$	$P(C_8H_{17})_3$	6.61	15	10	2	20	2.3	2.8	7.5

[a] Traces of isomerised alkenes are also observed. [b] 0.2 cm^3. [c] 2-Methylhexanol (3%) and hexane are also observed. [d] 2 cm^3. [e] R_f = $C_6F_{13}CH_2CH_2$. [f] 90 °C.

changes in solubility (both reactions are fully homogeneous). Using tri-*n*-octylphosphine, the rate is very much reduced, two phases are apparent in the system and higher n : i ratios (up to 3.9) are obtained with low p_{CO}, although the conversion is low. We have shown that higher n : i ratios can be obtained at low conversion in the solution phase system.[9]

We conclude that hydroformylation of hex-1-ene can be successfully carried out in $scCO_2$ using rhodium based catalysts containing cheap, readily available trialkylphosphine ligands, and that different chemoselectivities can be observed from those observed under some conditions in organic solvents.

We thank the EPSRC and the EC TMR programme for a Fellowship (I. B) and Professor M. Poliakoff for helpful discussion.

Notes and References

‡ Reactions were carried out in a 36 cm^3 Hastelloy autoclave fitted with a mechanical stirrer and a sapphire base for visual observation of the contents. All manipulations were carried out under nitrogen. $[Rh_2(OAc)_4]$ (0.052 g, 0.1176 mmol) was dissolved in PEt_3 (0.1 cm^3, 0.67 mmol) to give a red solution. Degassed hex-1-ene (2 cm^3, 16 mmol) was added and the mixture transferred into the autoclave, pressurised with CO and H_2 and stirred at room temperature for 1 h. Liquid CO_2 was then transferred into the autoclave using a cooled head hplc pump to give a total pressure 65 bar above that of the CO–H_2. The autoclave was then heated for the desired reaction time, with the pressure and temperature being monitored throughout. After the reaction, the autoclave was allowed to cool in dry ice to −50 °C. The CO_2 was vented and the liquid product, typically 1.8 cm^3, was collected and analysed by GLC (quantitative analysis) and GC–MS (identification of products). ^{31}P NMR studies of the final liquid indicated that the major species in solution is $[RhH(CO)_2(PEt_3)_2]$.[9]

For reactions in toluene, the reaction was carried out in the same autoclave using half the amounts of all the reagents, 17 cm^3 of toluene and the same gas pressure. This ensures that all the concentrations are the same as in the $scCO_2$ experiments and that the pressure drop for the same percentage conversion of substrate is also the same.

Remarkable synergy between microwave heating and the addition of seed crystals in zeolite synthesis—a suggestion verified

Colin S. Cundy,*† Richard J. Plaisted and Jing Ping Zhao

Centre for Microporous Materials, Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD

A recent suggestion that there can be a nucleation-related bottleneck in microwave zeolite synthesis has been verified: ZSM-5 has been synthesised very rapidly in seeded systems with and without an organic template.

Microwave dielectric heating is becoming an increasingly important accessory in chemical synthesis.[1–3] Remarkable reductions in synthesis time (by up to a factor of 10^3)[4] are observed and selectivity to particular product isomers has been achieved in naphthalene sulfonation.[5] Following an early study,[6] the microwave-mediated synthesis of micro- and mesoporous materials has been the subject of a number of recent reports, with zeolites,[7,8] $AlPO_4$-type materials[9,10] and MCM-41[11] being successfully prepared. In the microwave synthesis of zeolite Y, crystallisation of undesired phases is suppressed[7] and phase selectivity can be maintained at an unusually high synthesis temperature (150 °C).[12]

The crystallisation of zeotype materials is frequently constrained by limitations at the nucleation stage so that it is common practice to age reaction mixtures or add nucleants to them.[13] There are two potential effects of these procedures on the synthesis reaction: (*a*) reduction of the induction period preceding the detection of crystalline product and (*b*) promotion of a dominant crystalline phase (usually that of the seeding material). Thus, overall synthesis time can be shortened and product purity improved. Different aspects of these two effects have been demonstrated in recent studies on the synthesis of zeolite A with conventional[14] and microwave[8] heating. In one report,[8] microwave heating of zeolite A reaction mixtures which had been aged for various periods led to reaction times as short as 1 min and it was suggested that the rearrangement of the synthesis mixture to yield nuclei was the bottleneck in a microwave synthesis. We demonstrate below using a different zeolite system as a model that this is indeed the case and furthermore that the effects achievable by microwave heating and seeding techniques are strongly synergistic.

The synthesis of zeolite ZSM-5 has been studied using two optimised reaction systems.‡ In the first case, Na, TPA-ZSM-5 was synthesised using the composition:[12] 5.0 Na_2O : 0.2 Al_2O_3 : 60 SiO_2 : 4.0 TPABr : 900 H_2O where the silica source was a silica sol, the alumina source was sodium aluminate and TPA is the templating cation tetrapropylammonium. The second system used similar reagents but contained no organic template:[15] 10.0 Na_2O : 1.0 Al_2O_3 : 60 SiO_2 : 3000 H_2O.

In each case, reactions were carried out in the presence and absence of seed material and using both microwave and traditional heating methods. The seed employed (5% by mass of total silica) was a fully characterised TPA-silicalite (Al-free ZSM-5) sol[16,17] consisting of near-monodisperse nanometre-sized crystalline zeolite particles in water. Reaction temperature was 175 °C throughout and times were recorded from the start of the heating period.

The results are illustrated in Fig. 1. In the unseeded TPA-templated thermal preparation [curve (*e*)], crystalline MFI product was detected (XRD) after 2 h and the synthesis was complete at 5.5 h. Carrying out the reaction at the same indicated temperature using microwave heating reduced the synthesis time to 3 h following the appearance of crystallinity at t = 1 h [curve (*d*)]. The crystallisation of the oven-heated mixture was considerably accelerated by the presence of the nanosized seed material with 15% crystallinity apparent after only 1 h and completion in 2 h [curve (*c*)]. However, the combined effect of nanocrystal seeding and microwave heating produced the remarkable result seen in curve (*a*) where crystallisation was almost complete by the time that the reaction mixture had reached working temperature (3 min).

With no organic template and in the absence of seed crystals, no crystalline product was found after 3 h of microwave heating, whilst only a trace of product was detectable by X-ray diffraction after 7 h of oven heating. The inclusion of colloidal seed material brought reaction rates within the time frame of Fig. 1, although the thermal reaction was the slowest recorded overall [curve (*f*)]. However, the corresponding microwave-mediated synthesis [curve (*b*)] was only a little slower than its templated counterpart [curve (*a*)].

These results may be rationalised by consideration of three factors contributing to the overall reaction time, namely (1) thermal lag, (2) the induction period and (3) crystal growth. The first of these probably accounts for about 0.5 h in the experiments with the oven-heated autoclaves (as determined by separate tests). This is essentially eliminated in the microwave experiments, where the rise to operating temperature of the reactor contents is extremely rapid (≤3 min). It is clear from Fig. 1 that, although the induction period is reduced by the presence of the nanocrystal seed, a notable synergism occurs when microwave heating is additionally employed. Possible reasons for this are discussed in more detail below. The third factor allows for a reaction time adjustment which depends on the pattern of nucleation and crystal growth. The unseeded TPABr-containing compositions produce products of broader particle size range (up to *ca.* 5 μm thermal, 12 μm microwave) than the seeded preparations (≤1 μm), necessitating a longer period of crystal growth for the largest crystals to reach their final size. There are also differences in linear growth rate (templated synthesis > inorganic and microwave > thermal). A more detailed study of crystal growth rates[18] will be reported elsewhere.

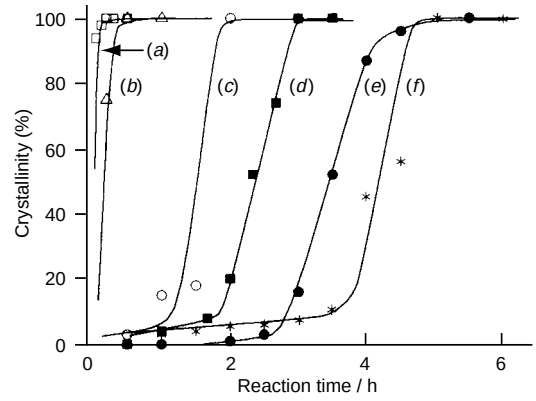

Fig. 1 Growth curves for ZSM-5: (*a*) seeded, TPA, microwave; (*b*) seeded, inorganic, microwave; (*c*) seeded, TPA, thermal; (*d*) unseeded, TPA, microwave; (*e*) unseeded, TPA, thermal; (*f*) seeded, inorganic, thermal

The results above confirm the suggested[8] nucleation-related bottleneck. However, it is useful to make a distinction between the equilibration of the reaction mixture (as evidenced by, for example, changes in pH and silicate anion distribution) and the generation of nuclei, since it can be shown that these are separate, although interlinked, processes.[19] In both the zeolite A and the ZSM-5 cases (but perhaps not universally), the microwave heating rate far outstrips the crystal nucleation rate so that no zeolite product is formed at short heating times in the absence of added seed crystals or sources of nuclei. However, in the earlier work,[8] it was also proposed that the almost instantaneous heat-up allowed the reaction to take place in a synthesis mixture that had hardly changed during the heating process. The very rapid onset of crystal growth which occurs under microwave heating conditions in the presence of added nanocrystalline seed [*e.g.* curve (*a*) *vs.* curve (*d*)] confirms that it is the time to form nuclei rather than the preceding equilibration of the reaction mixture which is the slowest step. However, such rapid and complete crystallisation could not occur unless any slow reagent digestion steps were complete. Hence, the reaction mixture has to be regarded as essentially fully equilibrated rather than hardly changed.

Finally, we consider the differences apparent from Fig. 1 between comparable microwave and thermal reactions. Since both thermal and microwave syntheses are carried out under conditions of controlled and measured temperature, a significant overall temperature difference due to microwave superheating[3] is unlikely. A more probable cause lies in differential microwave heating effects due to the heterogeneity of the dielectric (*i.e.* the reaction mixture) which at all times contains colloidal or particulate material. Local superheating could result from a number of energy-loss mechanisms:[3] (*i*) dipolar polarisation losses varying with local composition, (*ii*) interfacial (Maxwell–Wagner) polarisation losses and (*iii*) conduction losses associated with clusters or arrays of ions. Thus, one component of the enhanced rates observed in the microwave syntheses may derive from an acceleration of reagent digestion and aluminosilicate equilibration processes to produce a medium which is more homogeneous on a molecular scale. However, perhaps an even more significant effect may be occurring at crystal surfaces where microwave energisation of the hydroxylated surface or of associated water molecules in the boundary layer may be linked to specific energy dissipation through modes (*ii*) and (*iii*) above. This could account for the rapid activation of seed crystals under microwave conditions seen in curves (*a*) and (*b*) of Fig. 1.

The authors would like to thank John Dwyer for his interest in this work and the EPSRC for partial support under Grant No. GR/K 06877. The support for the Centre for Microporous Materials provided by BNFL, BOC, Engelhard and ICI is also gratefully acknowledged.

‡ *Experimental details* for the zeolite syntheses: TPA-templated composition: sodium aluminate (0.49 g, BDH, 21.3 mass% Na, 20.8 mass% Al) dissolved in a solution of sodium hydroxide (1.80 g, Prolabo AR) in water (35 g) was added with stirring to a solution of tetrapropylammonium bromide (5.03 g, ABM Chemicals) in 42.5 g of Ludox AS 40 silica sol (40 mass% SiO_2, Dupont). To one half of this mixture was added water (7.5 g) and, to the other, an aqueous colloidal sol of TPA-silicalite (7.5 g, 5.8 mass% solids, mean particle size *ca.* 70 nm). Reaction mixture aliquots were heated in PTFE-lined autoclaves at 175 °C either in a conventional oven or in a CEM MDS-2100 microwave reactor (2.45 GHz).

Inorganic composition: aluminium nitrate nonahydrate (12.75 g, Merck AR) dissolved in water (100 g) was added to a vigorously stirred solution of sodium hydroxide (17.65 g, Prolabo AR) in water (150 g). The resulting clear solution was added to a mixture of Syton X 30 silica sol (203.8 g, 30 mass% SiO_2, Monsanto) and water (456 g). Further water or silicalite sol was added as above to give a seed concentration of 5% by mass (based on total silica) and the comparative syntheses carried out as before.

We report the synthesis and testing of novel macrocyclic organophosphonate retarders which have been proposed using rational molecular design methods based on the selective inhibition of the crystallisation of ettringite, a product of the early stages of cement hydration.

Cementitious materials are among the most widely used by mankind while being among the least well understood. The detailed physicochemical processes involved in the hydration and setting of cement slurries are very complex, and a clearly defined quantitative account is still lacking; indeed, even the precise composition of the cement powder is unknown. Although numerous additives are known and used to retard the cement setting process, little is understood of the mechanism by which they act. Here, we show how it is possible to design and synthesize novel macrocyclic organophosphonate retarders by rational molecular design methods[1] based on the selective inhibition of the crystallisation of ettringite, a product of the early stages of cement hydration. This delays the setting process without altering the setting properties (development of compressive strength, *etc*.) once this process begins.

It is known that phosphonate-based organic compounds, such as **1**, **2** and **3** in Fig. 1, are able to retard the onset of setting in cement slurries under ambient conditions;[1,2] however, the mechanism by which such retarders work has hitherto not been established. Furthermore, some phosphonates (such as **1**) are such powerful cement setting retarders that they also cause the time taken for setting (that is, the compressive strength development, once setting commences) to increase substantially.[1] From the point of view of engineering applications of cement in the oil and construction industries,[3–5] it is usually desirable for cement slurries to set rapidly once the setting process is initiated, thus ensuring the development of the required mechanical properties of the resulting concrete matrix as rapidly as possible. There is, therefore, a need to devise cement setting retarders which not only accurately control the time taken for setting to take place, but also maintain the setting characteristics of neat (untreated) cement once set is initiated. To enable the development of such retarders, however, it is necessary to have an accurate understanding of the processes which control the setting of cement.

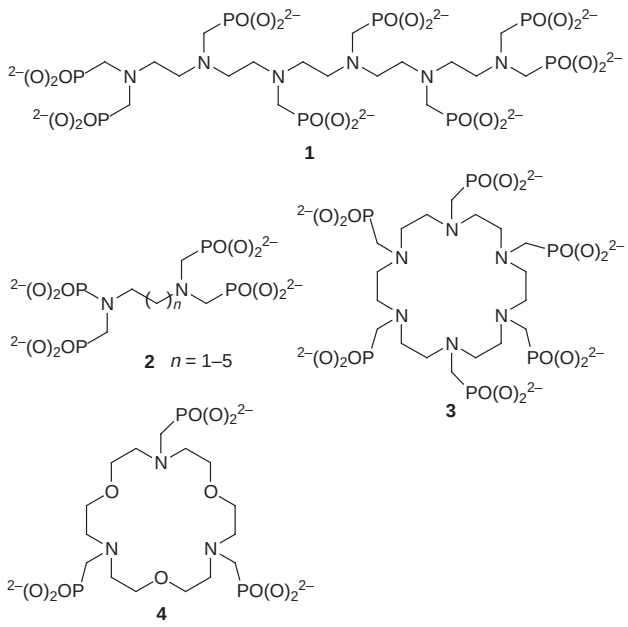

Fig. 1 Some phosphonate cement-setting retarders: **1** and **2**, linear phosphonates; hexaaza-18-crown-6 **3** and trioxotriaza-18-crown-6 **4** macrocyclic phosphonates designed by computer modelling techniques[1]

The work reported here makes use of a recently proposed theoretical model for the setting of cement involving the initial nucleation and growth of crystalline ettringite, $[Ca_3Al(OH)_6]_2[SO_4]_3{\cdot}26H_2O$, from a gelatinous precursor.[1,6,7] An important consequence of this model is that, if retarders can be designed which interfere solely with the process of ettringite nucleation and growth, then cement slurries should set normally once the silicate hydration process is initiated, thus ensuring mechanical integrity of the resulting cured product; a separate mechanism for the retardation of silicate hydration has also recently been proposed.[8] The structural basis for the design of such ettringite-specific retarding agents has been discussed previously[1] and is based on the strategy exemplified earlier by Davey *et al*.[9–12] in which the geometry and functionality of additive molecules are chosen such that they are capable of recognising and binding to the growing surface of nuclei or crystals, thereby accomplishing inhibition of nucleation and/or crystal growth.[1] In turn, if such specific retarding agents designed for an ettringite substrate also exhibit an ability to inhibit the setting of cement, without changing its essential setting properties, then this would be consistent with the nonlinear chemical clock-type hypothesis of Billingham and Coveney[6] in which the autocatalytic formation of crystalline ettringite is the rate determining step.

Although molecular modelling studies have proved useful for the rational design of crystal growth inhibitors for simple inorganic systems,[9–12] the design of crystal growth inhibitors for ettringite is a much more challenging prospect due to the complexity of the inorganic matrix. It was however possible to propose that compounds such as **3** and **4** should be effective agents for inhibiting the crystal growth of ettringite, since they possess the ideal structural motifs for molecular recognition with the most rapidly growing [001] face of the ettringite matrix.[1] In particular, the geometry of the phosphonate functions of **3** and **4** in Fig. 1 are such that they fit into the sulfate binding sites of ettringite ensuring enhanced molecular recognition compared to acyclic phosphonates **1** and **2**.[13] Compound **4** exhibits a greater level of conformational flexibility and is expected to be the more active of the two.[1]

Hexaphosphonate **3** was prepared as reported previously[1,14] and triphosphonate **4** was prepared using analogous methods.[14–17] These two compounds were then used as additives during the formation of ettringite and also in cement samples.

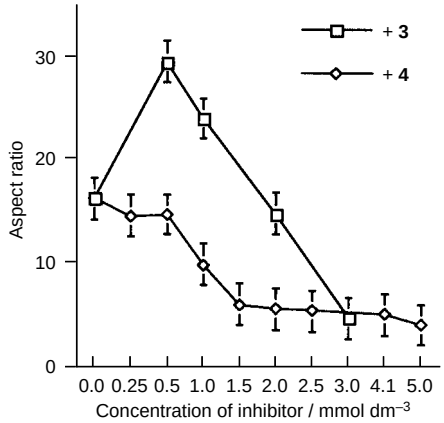

Fig. 2 The influence of additives **3** and **4** on the aspect ratio of ettringite crystals; the data were obtained from SEM images. Note that the trioxygen containing macrocycle **4** is more efficient at limiting ettringite crystal growth at lower concentrations than the macrocycle **3**.

Ettringite crystals,[18] prepared by reacting aqueous $Al_2(SO_4)_3$ with a calcium hydroxide suspension for 30 min at 70 °C, exhibit a prismatic morphology, being elongated about the *c*-axis. Additives **3** and **4** had a profound effect on ettringite crystal morphology, producing a remarkable reduction in the length of the ettringite crystals even at low concentrations: for example at concentrations of **3** and **4** of 1.00 mmol dm^{-3}, there were respectively 45 and 75% reductions in crystal lengths compared to untreated ettringite. Fig. 2 shows the data as the change in measured aspect ratios and indicates clearly the transition from needle to prism. These results are in agreement with the prediction that both compounds **3** and **4** are pre-organised to recognise and bind to the growing {001} faces of ettringite, and that **4** should be a superior inhibitor to **3**.[1]

These results are supported by X-ray powder diffractograms of the solid products of ettringite crystallisations carried out in the absence of additive and in the presence of 4.0 mmol dm^{-3} of additives **3** and **4**. The diffractogram for a pure ettringite sample exhibits the preferred orientation expected for *c*-axis needles, with all {*hkl*} reflections having significantly reduced intensities. This X-ray pattern is entirely consistent with pure, well crystalline ettringite; the relative intensities of diffraction from the (100) and (114) lattice planes at 9 and 22.8° would be 2 : 1 in a powder comprising isometric crystals. The observed enhancement to 4 : 1 is consistent with a product comprising *c*-axis needle shaped crystals. In the presence of additive **3**, this relative intensity is 1 : 1, implying significantly more equant crystal habits; at the same time the pattern indicates the presence of two other crystalline phases, calcium hydroxide and gypsum, not normally seen as a product in these reactions (the relatively intense diffraction peaks at 29.3 and 47.3° are consistent with the existence of gypsum [(111) reflection] and calcium hydroxide [(102) reflection] respectively). In the presence of additive **4** the result is even more extreme, indicating significantly lower levels of ettringite, some gypsum, and calcium hydroxide, together with significant amounts of amorphous material. These data confirm the observed morphological change in the ettringite crystals and also suggest that ettringite nucleation is indeed inhibited by these additives, leading to the production of amorphous material and crystalline gypsum together with a reduction in the overall reaction rate, resulting in unreacted calcium hydroxide. Again molecule **4** is found to be the more active as originally predicted.

The effect of these same additives on the setting of cement slurries was then examined. Rates and extent of setting of samples taken from one batch of class G oilfield cement were measured at additive concentrations of 1.0 mmol dm^{-3} by heat flow calorimetry[1] in which the magnitude and time evolution of the heat of reaction were recorded. It was found that hexaphosphonate **3** doubles the induction time for the onset of setting of cement while triphosphonate **4** extends this period threefold. In addition, however, it is evident that in both cases the setting characteristics, as judged by the profile of the heat flow curves, remain unchanged compared with the case of neat cement, suggesting that these compounds act to inhibit nucleation of ettringite and do not interfere with compressive strength development once that nucleation process has occurred. This is in marked contrast with the general behaviour of acyclic phosphonate cement setting retarders which both delay the onset of setting and inhibit the setting process once it has begun.[1] It is important to note that aged cements, which have been exposed to atmospheric humidity for extended periods, show no delay in the onset of setting and display calorimetric profiles identical to neat cement when treated with these additives. This result is consistent both with the specificity of these additives towards ettringite, which has presumably already formed in these aged materials, and their inability to influence other hydration products such as calcium silicate or hydroxide.

Our results show that additives designed as selective inhibitors for the crystallisation of ettringite can be used to delay the onset of setting of cement slurries without interfering with the eventual setting process itself. This behaviour was discovered on the basis of two central concepts: firstly, that the formation of crystalline ettringite from an amorphous precursor plays a rate determining role in cement setting, and secondly, that it is possible to rationally design compounds which are preorganised for molecular recognition at the surfaces of complex inorganic matrices, such as ettringite, and thus act as powerful crystallisation inhibitors. In the case of cement slurries, the use of such phase-selective retarders should result in the production of cured concrete with very similar mechanical properties to that from the untreated cement.

Jon Griffin is grateful to the EPSRC (GR94007291) and Schlumberger Cambridge Research for the award of a Total Technology grant.

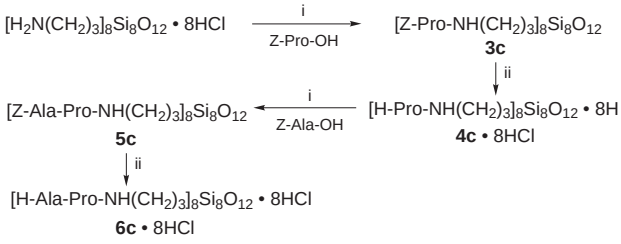
The first use of polyhedral silsesquioxanes to organize ensembles of biologically relevant motifs is described. N-Protected amino acids and peptides can be attached to $[H_2N(CH_2)_3]_8Si_8O_{12}$ 1 and $[p\text{-}HOCH_2C_6H_4]_8Si_8O_{12}$ 2 in either a convergent fashion or a divergent fashion to produce peptidyl silsesquioxanes in excellent yield and purity.

Symmetric core scaffolds possessing multiple reactive functional groups have recently attracted much interest as templates for the presentation of molecular domains of biological relevance. For example, symmetrical tetrafunctional xanthene and cubane have been used as scaffolds to create combinatorial libraries of trypsin inhibitors with moderate activities,[1–3] while porphyrins,[4,5] polyfunctional cyclic peptides[6] and cyclotriphosphazenes[7] have been used as scaffolds for helical bundles of peptides in models for ion channels. Similarly, calixarenes have been used as templates to assist the spatial arrangement of cyclic peptides[8] and sugars.[9] In principle, any polyfunctional molecule may serve as a scaffold to present multiple copies of a biologically relevant pendant group, but the most attractive cores are those which have particular geometrical parameters (*e.g.* size, shape, symmetry) to allow unique ligand presentation. Here, we describe the first use of polyhedral oligosilsesquioxanes as scaffolds for peptides. These robust, readily available Si/O frameworks offer interesting possibilities as cores for ensembles of biologically relevant pendant groups.

A wide range of polyhedral oligosilsesquioxanes can be prepared *via* hydrolytic condensation reactions of trifunctional organosilicon monomers.[10] Two known frameworks that possess terminal protic nucleophilic functionality are octaamine **1** and octaalcohol **2**. Octaamine **1** is readily available as a hydrochloride salt in one step (35% yield) from $H_2N(CH_2)_3Si(OEt)_3$.[11,12] Octaalcohol **2** is prepared in approximately 5% overall yield in three steps from $p\text{-}ClCH_2C_6H_4SiCl_3$.[13]

Octaamine **1** undergoes octafunctionalization with N-protected amino acids and N-protected di- and tri-peptides under standard coupling conditions.[14–16] As outlined in Scheme 1 and Table 1, high yields of coupled products can be obtained by reacting **1** with an excess of an N-protected amino acid (*e.g.* Z-Pro-OH) and *O*-(7-benzotriazol-l-yl)-1,1,3,3-tetramethyluronium (TBTU) in DMF–*N*,*N*′-diisopropylethylamine (DIPEA), and then precipitating the product with aqueous acid.§ The course of these reactions can be conveniently monitored by ^{1}H NMR spectroscopy because the chemical shift for the CH_2N of **1** shifts from δ 2.8 to 3.0 [$(CD_3)_2SO$] upon condensation with the amino acid. The only Si-containing species detectable by ^{1}H, ^{13}C and ^{29}Si NMR spectroscopy in the crude materials are the desired octafunctional derivatives and they are spectroscopically pure. In most cases, the ^{1}H and ^{13}C NMR spectra of peptidyl silsesquioxane are well defined and fully assignable on the basis of COSY, HMQC and DEPT experiments.



Scheme 1 *Reagents and conditions*: i, protected amino acid (1.2–4 equiv. per NH_2), TBTU (2–4 equiv. per NH_2), HOBt + H_2O (4 equiv. per NH_2) and DIPEA (9 equiv. per NH_2) in DMF, 10–24 h, 25 °C; ii, H_2 (100 psi), 10% Pd/C, 1 M HCl–MeOH, 8 h, 25 °C

The syntheses of **3d** and **3e** *via* coupling reactions of **1** with N-protected peptides represent convergent syntheses of peptidyl silsesquioxanes, which are attractive when the desired peptide sequence can be prepared in advance. It is also possible to synthesize peptidyl silsesquioxanes in a divergent fashion by iteratively coupling and deprotecting Z-protected amino acids. For example, removal of the Z-group from **3c** *via* hydrogenolysis over 10% Pd/C in aqueous acidic methanol (100 psi, 25 °C, 8 h)¶ gives **4c**·8HCl in high yield, which can be subsequently coupled with Z-Ala-OH and deprotected to give dipeptidyl silsesquioxane **6c**·8HCl (Scheme 1).

Octaalcohol **2** is also a useful scaffold for peptidyl silsesquioxanes, which may exhibit different properties because of its rigid *para*-phenylene spacer. The synthesis of peptidyl silsesquioxanes derived from **2** is analogous to the preparation of peptidyl silsesquioxanes derived from **1** (Fig. 1 and Table 2). However, the poorer nucleophilicity of the benzylic hydroxyl group requires a much longer reaction time and a generous excess of N-protected amino acid and TBTU for complete coupling to occur. For example, the reaction of **2** with 2 equiv. of Fmoc-Ala-OH and TBTU per OH for 17 h in DMF–DIPEA produces **7c** in only 26% yield. The major product (40%) is the incompletely-substituted product derived from coupling of **2** with seven Fmoc-Ala-OH; small amounts (6%) of incom-

Table 2 Preparation of peptidyl silsesquioxanes derived from **2**

[*p*-$R^1OCH_2C_6H_4]_8Si_8O_{12}$ → [*p*-$R^2OCH_2C_6H_4]_8Si_8O_{12}$

Starting material	R^1	Product	R^2	Isolated yield (%)
2	H	**7a**	Fmoc-Ala	26
2	H	**7b**	Fmoc-Phe	28
2	H	**7c**	Boc-Ala	72
7c	Boc-Ala	**8c**·8TFA	H-Ala	100
8c·8TFA	H-Ala	**9c**	Boc-Phe-Ala	46

See Scheme 1 for reaction conditions. R^1 and R^2 refer to neutral organic substituents on O. Where indicated, starting materials and products were used or isolated as salts containing 8TFA (*i.e.* CF_3CO_2H).

pletely-substituted products containing six Fmoc-Ala groups are also isolated. These compounds can be readily separated by flash chromatography on SiO_2 (20 : 1 CH_2Cl_2–MeOH) and fully characterized by multinuclear NMR spectroscopy and MALDI-TOF mass spectrometry. Complete functionalization of **2** by Boc-Ala-OH was accomplished by using 4 equiv. of the protected amino acid (per CH_2OH), 4 equiv. of TBTU and a reaction time of 7 days. Removal of Boc protecting groups can be efficiently accomplished with TFA in CH_2Cl_2, but the cleavage of Fmoc protecting groups with piperidine (20% in THF, 25 °C) does not occur cleanly, presumably because of base-induced decomposition of the Si_8O_{12} framework.[11]

In summary, we have demonstrated the first use of polyhedral silsesquioxanes to organize ensembles of biologically relevant motifs. Peptides can be attached to octaamine **1** and octaalcohol **2** in either a convergent fashion or a divergent fashion to produce peptidyl silsesquioxanes in excellent yields and purity. In the case of octaalcohol **2**, coupling reactions are more difficult to complete due to the poor nucleophilicity of hydroxy groups, but the octasubstituted compound can be easily separated from less extensively substituted derivatives by column chromatography. These large frameworks can be synthetically manipulated by standard solution methods and characterized by NMR spectroscopy and mass spectroscopy (MALDI-TOF). We have only begun to explore the use of silsesquioxanes as scaffolds for biologically relevant pendant groups, but the ready availability of discrete polyhedral frameworks containing 6–16 silicon atoms offers many interesting possibilities in areas of molecular recognition, biomimetics and drug design. Our work in these and other areas will be reported separately.[17,18]

‡ Contribution No. 7751.
§ Peptidyl silsesquioxane **3c** was prepared by adding DIPEA (0.8 ml, 46 mmol) to a solution of **1**·8HCl (0.074 g, 0.063 mmol), CBZ-Pro-OH (0.501 g, 2.02 mmol), TBTU (642 mg, 2.00 mmol), and 1-hydroxybenzotriazole hydrate (306 mg, 2.00 mmol) in DMF (3 ml). After stirring for 1 day, the crude product was precipitated by dropwise addition of the reaction mixture to ice-cold 0.2 M aqueous citric acid (200 ml). Filtration, extraction with methanol, precipitation with a 0.5 M $NaHCO_3$, washing and drying *in vacuo* (25 °C, 0.01 Torr) afforded **3c** in 44% yield (76 mg). For **3c**, which possesses proline pendants with two rotameric forms (a : b 1.3 : 1): ^{1}H NMR [500.0 MHz, $(CD_3)_2SO$, 25 °C] δ 7.98 (t, NHCO, rotamer a), 7.90 (t, NHCO, rotamer b), 7.35–7.22 (m, C_6H_5), 5.10–4.98 (m, $CH_2C_6H_5$), 4.13 (m, COCH), 3.41 [s, $CH_2(N)CH_2$], 3.35 [s, $CH_2(N)CH_2$], 2.98 (br, $SiCH_2CH_2CH_2$), 2.05 [d, $COCH(N)CH_2$], 1.73 (br, $COCHCH_2CH_2$), 1.42 (br, $SiCH_2CH_2$), 0.53 (br, $SiCH_2$); ^{13}C{^{1}H} [125.7 MHz, $(CD_3)_2SO$, 25 °C] δ 172.06, 153.78, 65.70, 59.63, 47.10, 31.29, 23.07 (rotamer a), 171.75, 154.05, 65.87, 60.12, 46.49, 30.23, 23.95 (rotamer b), 136.95, 128.36, 128.15, 127.75, 127.50, 127.46, 127.00, 41.01, 22.43, 8.75; ^{29}Si NMR [99.3 MHz, $(CD_3)_2SO$, 25 °C) δ −66.2 (s); Elemental analysis for $C_{128}H_{168}O_{36}Si_8N_{16}$. Found (calc.); C, 56.22 (56.28), H, 6.14 (6.20), N, 8.08 (8.20).

¶ Hydrogenolysis of **3c** (250 mg, 0.090 mmol) was performed by using 10% Pd/C (50 mg) in a mixture of methanol (25 ml) and 1 M HCl (10 ml) for 24 h at 25 °C and 100 psig H_2. Filtration and evaporation of the solvent *in vacuo* (25 °C, 0.01 Torr) gave **4c**·8HCl in quantitative yield. For **4c**·8HCl: ^{1}H NMR (500.2 MHz, CD_3OD, 25 °C) δ 9.46, 8.53 (s, NH), 4.26 [s, $CH(N)CH_2$], 3.37 [m, $CH_2N(CH)$], 3.30 [m, $CH_2N(CH)$], 3.18 (br, $SiCH_2CH_2CH_2$), 2.43 (br, $COCHCH_2CH_2$), 2.00 (br, $COCHCH_2CH_2$); ^{13}C{^{1}H} (125.8 MHz, CD_3OD, 25 °C) δ169.32 (CO), 61.04 (COCH), 47.48 ($CHCH_2CH_2CH_2N$), 42.90 ($SiCH_2CH_2$), 31.26, 25.14 (CH_2), 23.64 ($SiCH_2CH_2$), 97.6 ($SiCH_2$). ^{29}Si NMR (99.4 MHz, CD_3OD, 25 °C) δ −66.5 (s); MS (MALDI). Calc. for $C_{64}H_{121}N_{16}O_{20}Si_8$ ($M + H^+$) *m/z* 1658.7, found 1658.7.

Supramolecular assembly of mesostructured tin oxide

Kathryn G. Severin, Tarek M. Abdel-Fattah and Thomas J. Pinnavaia

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, MI 48824, USA

The first example of a mesostructured tin oxide that is stable to surfactant removal has been prepared by hydrolysis of tin isopropoxide in the presence of a neutral amine surfactant (tetradecylamine).

Since the discovery of mesoporous silica molecular sieves in 1992[1,2] several supramolecular assembly pathways have been reported and extended to the synthesis of a variety of mesoporous metal oxide compositions including alumina, titania, niobia and zirconia.[3] Other surfactant metal oxide mesostructures also have been reported, but they have not been stable with respect to surfactant removal. Among them is a tin oxide assembled by the hydrolysis of $SnCl_4$ in the presence of an anionic surfactant.[4] Tin oxide is particularly interesting because it has semiconductive properties and its performance in semiconductor gas sensor applications is highly dependent upon its structure and morphology.[5,6] The structure directing capabilities of a supramolecular assembly pathway may allow for the controlled optimization of a mesostructured form of SnO_2 for chemical sensing.

In this study we use a neutral S^0I^0 assembly pathway‡ to produce the first stable mesostructured tin oxide. The mesostructure is synthesized using a neutral primary amine surfactant as the structure director (S^0) and tin isopropoxide as the inorganic precursor (I^0). We have chosen this pathway because it tends to provide mesostructured materials with thick pore walls.[7] Materials with thick walls may be less susceptible to collapse upon surfactant removal.[8] We have successfully prepared stable mesostructured tin oxide using a range of primary amines including octylamine, dodecylamine, tetradecylamine and hexadecylamine.[9] We report here on mesostructured SnO_2 assembled from tetradecylamine and compare it to the oxide prepared in an analogous manner in the absence of surfactant.

The XRD patterns of the as-synthesized products prepared in the presence and absence of tetradecylamine and that of a commercial SnO_2 sample are presented in Fig. 1. The pattern of tin oxide assembled with tetradecylamine contains the low angle peak (*d*-spacing: ≈ 46 Å) characteristic of mesostructured materials,[1–4,7,8] whereas the tin oxide prepared in the absence of surfactant and the commercial oxide do not exhibit a low angle reflection. However, all three materials exhibit reflections of comparable integral intensity in the region 2θ 20–80° that are characteristic of cassiterite, signifying that the as synthesized materials are largely crystalline in nature. On the basis of the < 110 > line widths, the products obtained by hydrolysis in the presence or absence of surfactant have the same average domain size (15 Å). The hydrolysis and condensation processes are apparently similar in both reaction systems, except that SnO_2 crystallites are assembled into a mesostructure in the presence of tetradecylamine. The presence of a single low angle XRD reflection is consistent with a sponge-like or wormhole channel motif.[7]

XRD patterns of the mesostructured SnO_2 after calcination at different temperatures are shown in Fig. 2. It can be seen that the average *d*-spacing for the mesostructure is largely unchanged by calcination at 300 °C, which indicates that the surfactant has been removed without structural collapse. Also, the average crystallite domain size has increased from 15 to 18 Å. Although low temperature sintering is commonly observed for tin oxide materials,[10] the mesostructured SnO_2 shows a lower tendency toward sintering than the tin oxide prepared in the absence of a surfactant. The domain size of the latter oxide after calcination at 300 °C is 27 Å. Thus, the surfactant acts not only as a structure director, but it also inhibits crystallite growth during calcination.

The mesostructured SnO_2 produced after calcination 300 °C has a BET surface area of 314 $m^2\ g^{-1}$ (Table 1), approximately twice that of the SnO_2 prepared in the absence of surfactant calcined at the same temperature (158 $m^2\ g^{-1}$). In contrast the surface areas reported for SnO_2 gels obtained from aqueous $SnCl_4$ solutions and calcined at 300 °C are only 110–120

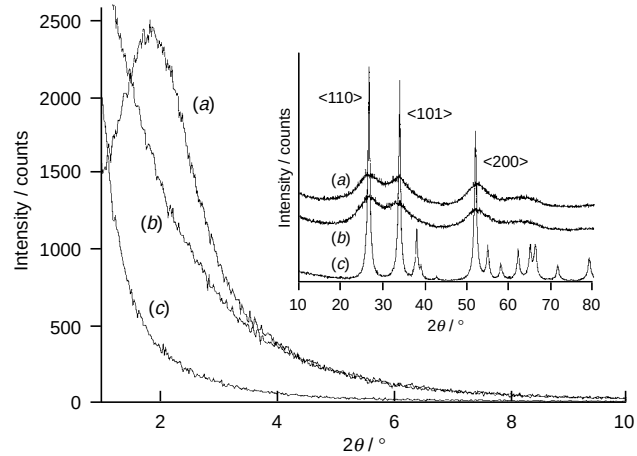

Fig. 1 XRD patterns of tin oxides: (*a*) as-synthesized product obtained by S^0I^0 assembly at ambient temperature, (*b*) as-synthesized product obtained by hydrolysis of tin isopropoxide in the absence of a surfactant, and (*c*) commercial sample of polycrystalline tin(IV) oxide

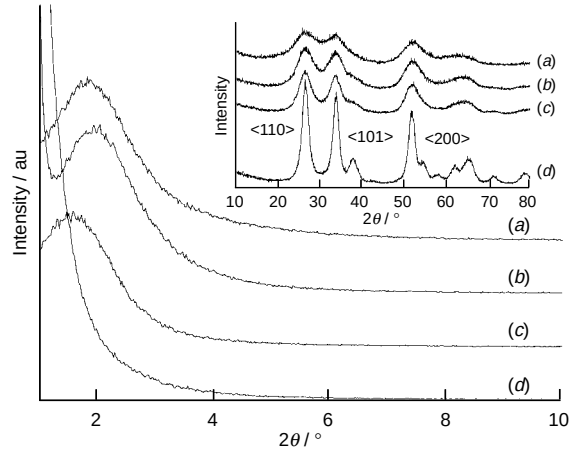

Fig. 2 XRD patterns of tin oxide assembled in the presence of tetradecylamine: (*a*) as-synthesized and after calcination at (*b*) 300, (*c*) 350 and (*d*) 400 °C

Table 1 Characterization of tin oxide prepared from tin isopropoxide in the presence of tetradecylamine surfactant

Calcination temp./°C	*d*-Spacing[a]/Å	Crystallite domain size[b]/Å	BET surface area/m^2 g^{-1}	Average pore diameter[c]/Å
As made	46	15	—	—
300	46	18	314	14
350	56	24	300	18
400	None	44	99	43

[a] As determined from 2θ of the low angle XRD peak. [b] As determined using Scherrer equation from the width of the < 110 > peak at 26.5° (2θ) in the XRD pattern. [c] BJH adsorption average pore diameter.

m^2 g^{-1}.[11,12] Because the density of crystalline tin oxide is more than three times that of amorphous SiO_2, our mesostructured tin oxide has a surface to framework volume ratio comparable to that of mesoporous silicas.[7] No hysteresis is observed in the N_2 isotherms (Fig. 3). Therefore, the pores are relatively free of constrictions and of uniform diameter. The average pore diameter is 14 Å and the pore size distribution is relatively narrow in comparison to the pore distribution observed for the SnO_2 prepared in the absence of surfactant (Fig. 3 inset).

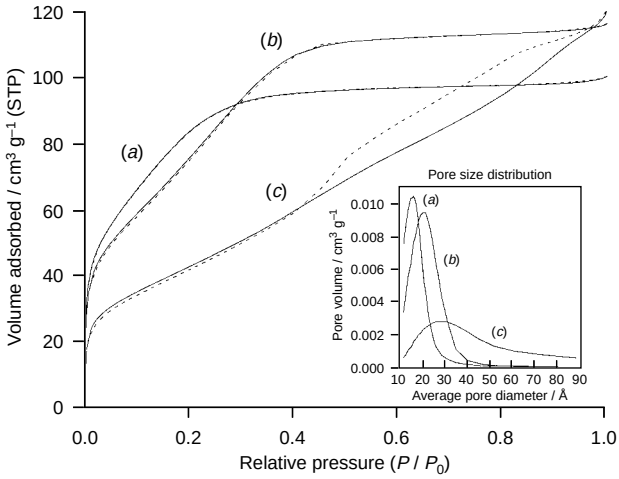

Fig. 3 N_2 adsorption–desorption isotherms of mesostructured SnO_2 synthesized in the presence of tetradecylamine and calcined at (*a*) 300 and (*b*) 350 °C, and (*c*) tin oxide prepared without surfactant and calcined at 300 °C. Inset shows pore size distributions for these materials as determined using the BJH model and the adsorption branch isotherm.

The low angle diffraction peak for the calcined product provides an estimate of the average distance between framework pores (46 Å). Since the average pore size is 14 Å, the pore walls are *ca.* 32 Å thick, almost twice the average crystallite domain size (Table 1). These values are in reasonable agreement with those inferred from TEM micrographs of the as-synthesized mesostructure. We may conclude, therefore, that the walls are comprised largely of aggregates of small crystallites, but we can not preclude the possibility of the crystallites being encapsulated in a matrix of amorphous SnO_2. Small crystalline domains surrounded by amorphous grain boundaries could account for the increase in crystallite domain size without a change in the *d*-spacing of the mesostructure upon calcination.

In contrast to the mesostructured SnO_2 calcined at 300 °C, SnO_2 prepared in the absence of surfactant has an average pore diameter of 28 Å, a value similar to its average crystallite size. The pore size distribution is very broad [Fig. 3(*c*) inset] and consistent with a pore structure resulting from the irregular packing of small crystalline particles. Thus, the role of the surfactant in forming mesostructured SnO_2 is to organize the small oxide crystallites into a structure sufficiently ordered to generate regular pores and a low angle Bragg reflection.

Calcination of the mesostructured tin oxide at 350 °C lowers the BET surface area only slightly to 300 m^2 g^{-1}, but the average crystallite size (24 Å), pore diameter (18 Å), pore volume (0.15 cm^3 g^{-1}) and *d*-spacing (56 Å) are all significantly larger than those measured for the sample calcined at 300 °C (Table 1). As inferred from these measurements, the average pore wall thickness has also increased, to a value of 38 Å. Although more restructuring occurs at 350 °C than at the lower calcination temperature, the lack of hysteresis in the N_2 isotherms (Fig. 3) again indicates that the pore channels remain quite uniform, despite their increased diameters. This thermal dependence of pore size and wall thickness is not typical of a mesostructure formed by micellar assembly and further suggests a mechanism based on the packing of surfactant-decorated crystallites of uniform size.

Upon calcination at 400 °C the mesostructured framework collapses and the surface area is lowered to 99 m^2 g^{-1}. The low 2θ peak is no longer present (Fig. 2) in the XRD pattern and the average crystallite domain size increases to 44 Å (Table 1). In addition, the average pore size has increased to 43 Å, the pore size distribution has broadened and necking has developed in the channels (average diameter *ca.* 37 Å). These results are consistent with a material comprised entirely of cassiterite crystallites. TGA analysis[9] indicates that at this calcination temperature the surface hydroxyl groups condense, and this process may lead to extensive sintering.

Support of this research by NSF CRG grant CHE-9633798 is gratefully acknowledged.

‡ *Experimental methods*: mesostructured SnO_2 was prepared quiescently from a 1 $Sn(OPr^i)_4$: 0.2 tetradecylamine : 60 Pr^iOH mixture under water-saturated air at RT. After 2 days the product was filtered and washed with water and ethanol. The surfactant was removed by a 2 h reflux in ethanol (*ca.* 80% remained) After filtration, the product was calcined (4 h) at the reported temperature (heating rate 1 °C min^{-1}).

Photoactive ruthenium(II) cyclodextrins responsive to guest binding

Steffen Weidner and Zoe Pikramenou*

Department of Chemistry, The University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, UK EH9 3JJ

A terpyridine functionalised cyclodextrin has been synthesised and ruthenium photoactive centres appended to give luminescent metallo-cyclodextrins which respond to guest binding.

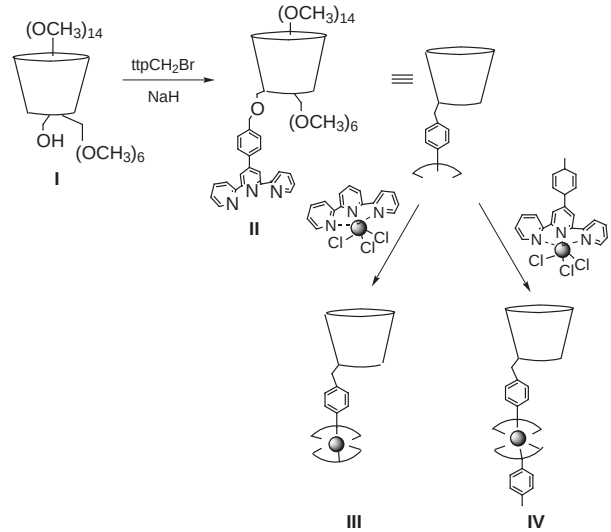
Biology provides many examples of light-sensitive macro- or supra-molecular intelligent systems that are capable of inducing directional motion of electrons and excitation energy. The design of supramolecular systems[1] that perform similar functions is of great interest particularly for their application towards the development of photomolecular devices.[2] Photoactive transition metal systems are very attractive candidates as units for the construction of molecular devices due to their photosensitisation and electrochemical properties.

Research in this area has mainly concentrated on building covalently linked metal complexes.[2] Photophysical studies have shown that the spatial organisation of the photoactive units is important for both energy and electron transfer processes and consequently this has led to the development of rigid polymetallic arrays using appropriate spacer units to covalently link metal centres.[3] High molecular complexity is inevitable in this approach since several features are accumulated in a single molecular component and synthetic challenges limit the choice of photoactive units. In this paper we introduce an alternative approach based on non-covalent links between components. It involves the design of photoactive metal-appended receptors that can act as sensor units upon introduction of a guest molecule in their cavity. When the guest is a metal complex the communication between the appended metal centre and the metallo-guest, brought together in space *via* non-covalent interactions, may then be established. Few examples of the previously reported metallo-receptors[4] have demonstrated their sensor properties.[5] Our design involves a terpyridine functionalised cyclodextrin which can form complexes with photoactive metals. The hydrophobic microenvironment of the cyclodextrin cavity allows the binding of appropriate guest molecules that trigger a change in the luminescence of the appended metal centre. We have synthesised a β-cyclodextrin functionalised with a tolyl-terpyridine unit (β-CD–ttp, **II**) and studied the formation of its luminescent complexes with ruthenium (Scheme 1). When an electron-accepting guest is added to the ruthenium functionalised CD, quenching of the ruthenium emission is observed.

An important precursor for the synthesis is the mono-6-hydroxy permethylated β-CD **I** which allows selective monofunctionalisation of the primary cyclodextrin side and solubility in organic solvents. A recently developed synthetic route for this derivative[6] proposed a convenient method to easily access compound **I** in good yield. Coupling of the cyclodextrin to the terpyridyl fragment was achieved through the reaction of **I** with 4′-[*p*-(bromomethyl)phenyl]-2,2′:6′,2″-terpyridine, ttpCH_2Br, under Williamson ether conditions using an excess of NaH in THF. The reaction was followed by TLC (Al_2O_3; ethyl acetate–methanol 30:1; R_f: β-CD–ttp = 0.7 and β-CDOH = 0.22) and after three days the terpyridine functionalised CD **II** was isolated in 50% yield after extraction by CH_2Cl_2 and size exclusion chromatography.

The 600 MHz ^{1}H NMR spectrum of **II** in $CDCl_3$ shows the fourteen aromatic protons in the range 7.2–8.8 ppm, the seven anomeric protons of the cyclodextrin at 5.0–5.2 and the rest of the cyclodextrin protons in the range 3.0–4.1 ppm. The methylene protons of the tolyl-terpyridine unit are diastereotopic due to the chirality of the CD and appear as two doublets at 4.62 and 4.68 ppm. The connectivities were elucidated by ^{1}H–^{1}H TOCSY spectroscopy. The formula of the compound was also confirmed by FAB-MS and elemental analysis.

Reaction of equimolar quantities of **II** with Ru(tpy)Cl_3 or Ru(ttp)Cl_3 in methanol with addition of *N*-ethyl morpholine afforded [(β-CD–ttp)Ru(tpy)][PF_6]$_2$ **III** and [(β-CD–ttp)Ru(ttp)][PF_6]$_2$ **IV** respectively after precipitation with ammonium hexafluorophosphate and size-exclusion chromatography (BioBeads SX2, DMF–THF 1:1) (tpy = 2,2′:6′,2″-terpyridine, ttp = 4′-(*p*-tolyl)-2,2′:6′,2″-terpyridine). The FAB mass spectra of **III** and **IV** show peaks at *m*/*z* = 2216 and 2306 corresponding to {M − [PF_6]}$^+$ and at *m*/*z* = 2071 and 2161 corresponding to {M − 2[PF_6]}$^{2+}$, respectively. The 600 MHz ^{1}H NMR spectra of **III** and **IV** show the characteristic aromatic proton patterns of terpyridine and tolyl-terpyridine in the region 7.0–9.2 ppm similar to the ones observed for [Ru(ttp)(tpy)]$^{2+}$ and [Ru(ttp)$_2$]$^{2+}$.[7] Complex **III** exhibits an MLCT absorption at 484 nm but it does not emit at room temperature upon excitation at the MLCT band. It is known that [Ru(tpy)$_2$]$^{2+}$ emits only at low temperature at λ_{max} = 598 nm and that [Ru(ttp)$_2$]$^{2+}$ emits at 640 nm at room temperature.[8] Interestingly, [(β-CD–ttp)Ru(tpy)][PF_6]$_2$ **III** emits at 77 K with an emission maximum at 622 nm (Fig. 1) which lies in between the values of the [Ru(tpy)$_2$]$^{2+}$ and [Ru(ttp)$_2$]$^{2+}$ emissions, as expected due to the electronic effects of the ligands. We have independently synthesised [Ru(tpy)(ttp)]$^{2+}$ and it shows the same emission behaviour as **III**.[9] The MLCT absorption of [(β-CD–ttp)Ru(ttp)][PF_6]$_2$ **IV** is centred at 490 nm and leads to room temperature emission with λ_{max} at 635 nm consistent with the expected MLCT emission. The UV-transparent cyclodextrin cavity does not perturb the luminescence properties of the complexes.



Scheme 1

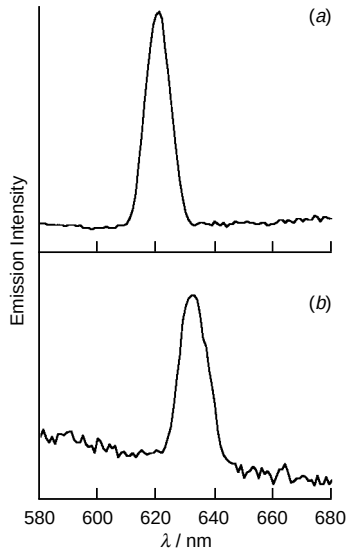


Fig. 1 Emission spectra of (*a*) [(β-CD–ttp)Ru(tpy)][PF_6]$_2$ in acetonitrile at 77 K, λ_{exc} = 480 nm, and (*b*) [(β-CD–ttp)Ru(ttp)][PF_6]$_2$ in acetonitrile at room temperature, λ_{exc} = 490 nm

In order to study the potential of metallo-CDs to participate in energy and electron transfer processes between the appended metal and a guest we initially selected an organic redox active guest, anthraquinone-2-carboxylic acid. The effect on the MLCT emission of the ruthenium centre of complex **IV** upon introduction of an equimolar amount of the guest was examined. Addition of microliter quantities of a 9.8×10^{-4} M solution of the guest in acetonitrile induced partial quenching, up to 20%, of the MLCT emission of complex **IV** (Fig. 2). We attribute this quenching effect to electron transfer between the appended metal and the guest, consistent with previous cases when quinones covalently attached to ligands of ruthenium complexes quench the MLCT emission.[10] In the absence of the cyclodextrin receptor the quenching of the MLCT emission is not observed upon addition of anthraquinone-2-carboxylic acid to a solution of $[Ru(ttp)_2]^{2+}$ under similar conditions. Further photophysical studies of the electron transfer process, and examination of the relation of the guest with the binding constant and the distance of the ruthenium centre, are in progress.

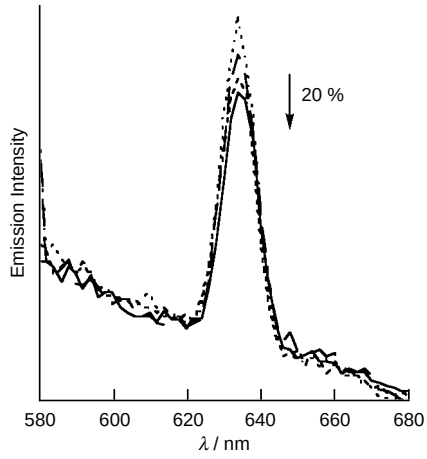

Fig. 2 Emission spectra of 1.9×10^{-5} M [(β-CD–ttp)Ru(ttp)][PF_6]$_2$ in 10% acetonitrile in water upon addition of 0.25, 0.5, 1 molar equivalents of anthraquinone-2-carboxylic acid, λ_{exc} = 490 nm

We have established the formation of photoactive metallocyclodextrins based on a new terpyridine functionalised cyclodextrin and confirmed the communication between guest molecules in the cavity and a ruthenium centre appended to the cyclodextrin cavity. We are currently extending our approach to the inclusion of metallo-guests in the ruthenium cyclodextrins and studying their involvement in energy and electron transfer processes between the appended metal and the metallo-guest.

We are grateful to the Nuffield Foundation for an Award to Newly Appointed Science Lecturers (Z. P.), the ERASMUS exchange scheme for support (S.W.) and the Swansea National Mass Spectrometry Centre for recording the mass spectra. We also thank Dr. Hewage for obtaining the NMR data in the EPSRC/BBSRC supported National Ultra-high Field NMR Centre in Edinburgh.

Self-assembly of a helical dicopper(I) metallophane

Thomas Bark,[a] Thomas Weyhermüller[b] and Fenton Heirtzler*[a]†

[a] *Departement Chemie der Universität, Spitalstrasse 51, CH-4056, Basel Switzerland*

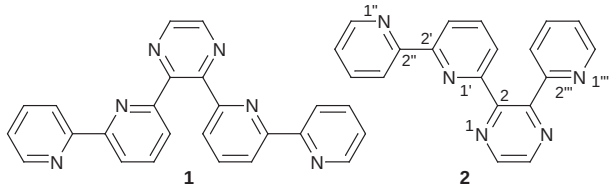
X-Ray crystallographic and ^{1}H NMR spectroscopic studies show that, in the presence of copper(I), an oligopyridyl pyrazine derivative spontaneously forms a single chiral, cyclophane-like dimeric complex and that this is the sole species present in solution and the solid state.

The self-assembly[1,2] of appropriate ligands and labile metal centers to result in double-stranded helicates[1a,c–e] and cyclophane-like structures[2] is well documented. Either linear[1c–e] or knotted [1a] shapes are typical for the former, and a distinguishing characteristic of the latter is frequently the coplanar orientation of aromatic spacer units. In some of these 'metallophanes', this results in a cavity, whilst in others, the non-bonding distances between the spacers are within those values considered to be crucial for π-stacking interactions[3] (*cf.* [2.2]paracyclophane[4]). In several of the latter cases, the spacer directly participates in metal binding.[2a,b]

While helicates are, by definition chiral,[5] this is not so for metallophanes. The majority of such complexes are achiral (*meso*)[2a–d,f] although studies describing a chiral, dizinc(II) metallophane which is stable in dilute solution have also recently appeared.[2e] Chiral metallophanes,whose formation is templated by the inclusion of an aromatic guest molecule, have also been recently described,[2d,e] as have equilibrating mixtures of similar chiral and *meso* complexes.[2d,g,6]

We are interested in the preparation[7] and supramolecular complexation chemistry[2a] of 2,3-bis(2,2′-oligopyridyl)pyrazines. We anticipate that the influences of internitrogen pyrazine base strength within the plane of that ring[8a] and stacking effects perpendicular to it[8b] should together determine the behaviour of this ligand class. Simpler pyrazine-containing ligand systems are known to form cyclic trimeric or tetrameric supramolecular complexes.[8a,9]

Along these lines, we have already shown that the symmetrical 2,3-bis(2,2′-bipyridyl)pyrazine **1** and Co^{II} self-assemble to

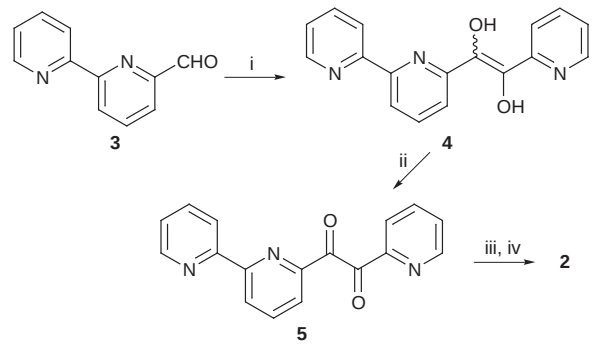


give a dimetallic *meso*-metallophane in which two roughly orthogonal binding domains having different dendicity are generated to geometrically satisfy the metal coordination requirements.[2a] We wished to further test these premises on a 2,3-bis(2,2′-oligopyridyl)pyrazine derivative possessing oligopyridyl groups of explicitly unlike dendicity. The simplest such ligand is the previously unknown 2-(2,2′-bipyridyl)-3-(2-pyridyl)pyrazine **2**. Either tridentate/monodentate or bidentate/bidentate binding modes are conceivable for **2**, and thus we anticipated that it should bind cooperatively with tetrahedral Cu^I.

A crude, but reasonable synthesis of **2** is described in Scheme 1. Thus, condensation of 2,2′-bipyridine-6-carbaldehyde **3**[7] with an excess of pyridine-2-carbaldehyde in the presence of potassium cyanide afforded a mixture of the enediol **4** and 1,2-bis(2′-pyridyl)-1,2-dihydroxyethene. This mixture was directly oxidized with iodine to the corresponding α-diketones, from which the desired product **5** was purified in 14% overall yield. Condensation of **5** with 1,2-diaminoethane, then chloranil-oxidation, afforded **2** in 64% yield.‡

Treatment of **2** with 1 equiv. of [Cu(MeCN)$_4$][BF$_4$] in methanol under reflux and addition of an excess of [NH$_4$][BF$_4$] resulted in the precipitation of a dark red complex which could be recrystallized from nitromethane–diethyl ether. This substance analysed as {[Cu**2**][BF$_4$]}$_n$‡ and in its FABMS spectrum (noba matrix) prominent signals centered at m/z = 750 and 837 were observed, corresponding to [Cu**2**]$_2^+$ and [Cu**2**]$_2$[BF$_4$]$^+$, respectively, and thus we assume a dimeric structure [Cu**2**]$_2$[BF$_4$]$_2$. In its electronic spectrum in acetonitrile, metal–ligand charge-transfer bands centered around 460 (1400) and 570 nm (700 dm^3 mol^{-1} cm^{-1}) were visible, and suggest an N$_4$-environment for Cu^I.[10] The cyclovoltammogram in MeCN indicated a single, reversible Cu^I–Cu^{II} redox process at −0.16 V *vs.* Fc–Fc$^+$. In analogy to literature precedent,[2b,10] we ascribe this to a dimetallic complex containing two identical non-interactive Cu^I centers.

We were, however uncertain of its exact structure, as both *meso*-Λ,Δ and Λ, Λ/Δ,Δ-configured diasteromeric pairs were reasonable structures. The ^{1}H NMR spectrum of [Cu**2**]$_2$[BF$_4$]$_2$ (400 MHz, CD$_3$CN), recorded at 21 °C, displayed a single set of broad resonances, integrating to 13 protons [Fig. 1(*a*)]. This suggested either the ready interconversion of the three diasteromers, like in other dimeric oligopyridine complexes[2d,f,g,6,11] or some type of exchange process with the coordinating solvent, as has been observed for other dicopper(I) bis-N$_4$ systems[2g,10] were occurring. Upon cooling to −40 °C [Fig. 1(*b*)], these absorption sharpened to result in the profile of a single compound, while at 40 °C, a broadening of the same shifts is apparent. As well, the ^{13}C NMR spectrum of the complex, recorded at −40 °C, exhibited 13 C–H correlated resonances displaying NOE enhancement. At no temperature could a decoalescence of signals in the ^{1}H NMR spectra be observed, and the chemical shifts were essentially temperature independent. Since others have already demonstrated that low-temperature



Scheme 1 Preparation of ligand **2**. *Reagents and conditions:* i, 15 equiv. pyridine-2-carbaldehyde, KCN, EtOH–H$_2$O, reflux, 2 h; ii, 1 equiv. I$_2$, CH$_2$Cl$_2$, 25 °C, 15 h; iii, 1 equiv. 1,2-diaminoethane, EtOH, reflux, 2 h; iv, 1 equiv. chloranil, xylenes, reflux, 16 h.

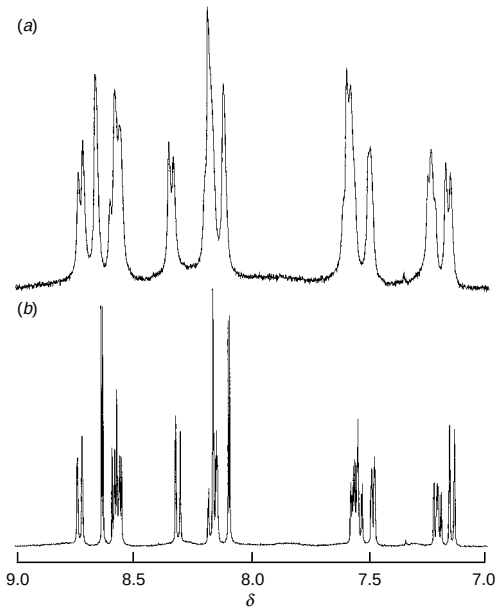


Fig. 1 ^{1}H NMR spectra of $[Cu\mathbf{2}]_2[BF_4]_2$ at (*a*) 21 and (*b*) −40 °C

^{1}H NMR spectroscopy can distinguish equilibrating mixtures of diastereomeric metallophanes[2g] it is evident that $[Cu\mathbf{2}]_2[BF_4]_2$ undergoes no such phenomenon.

In order to determine the stereochemistry of the dinuclear complex, its crystal structure was determined.§ Complex $[Cu\mathbf{2}]_2[BF_4]_2$ crystallizes in a centrosymmetric space group. Consequently, the dication occurs as a racemic mixture of Λ,Λ- and Δ,Δ-configured enantiomers, whereby the equivalent Cu**2** fragments are inter-related by the C_2 axis which runs parallel to the pyridyl pyrazine surfaces and between the bipyridyl flanks.¶ The *P*-helical enantiomer is displayed in Fig. 2. The pyridyl pyrazine copper(I) 'decks' of the metallophane are arranged in a head-to-head fashion. Interdeck non-bonding distances between closest pairs of atoms are 3.47–3.57 Å for the pyrazine rings and 3.42–3.62 Å for the monosubstituted pyridine rings; the pairs of pyrazine and pyridine rings are parallel to within 2.10 and 2.03°, respectively. The bipyridyl and pyridylpyrazine binding domains are twisted by 72.3° with respect to one another, giving the observed rectangular molecular geometry. The intermetallic distance is 5.08 Å. All metal–ligand bonding parameters are within expected values.

Ligand **2** diastereoselectively self-assembles to form a chiral metallophane, which is also stable in solution. That this phenomenon is influenced by stacking of metal-binding pyridyl pyrazine fragments is suggested by molecular models of the Λ,Λ/Δ,Δ-and *meso*-Λ,Δ-disastereomers, which indicate more efficient overlap for the former compound.

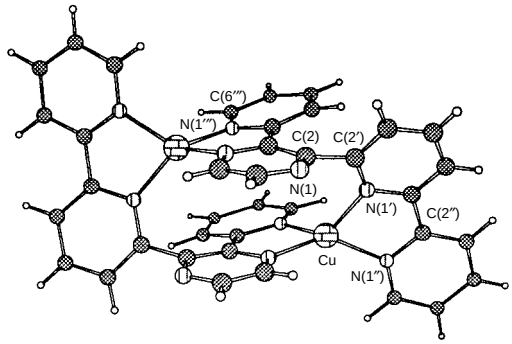

Fig. 2 Crystal structure of the $[Cu\mathbf{2}]_2$-dication. Selected bond angles (°) and lengths (Å): N(4)–Cu–N(1″) 138.46(7), N(1″)–Cu–N(1′) 82.17(7), N(1″)–Cu–N(1‴) 114.39, N(4)–Cu–N(1′) 120.80(7), N(4)–Cu–N(1‴) 80.91(7), N(1′)–Cu–N(1‴) 126.72(7); Cu–N(4) 1.991(2), Cu–N(1′) 2.033(2), Cu–N(1″) 2.005(2), Cu–N(1‴) 2.038(2).

We are currently investigating the extent which stacking interactions control self-assembly in related substances.

We thank the companies Novartis Ag, Biosynth AG and Shell Oil for chemical donations, the Treubel Fond for a stipend (F. H.) and Professors E. C. Constable and K. Wieghardt for encouraging this work.

Organic gels are useful as a template for the preparation of hollow fiber silica

Yoshiyuki Ono,[a] Kazuaki Nakashima,[a] Masahito Sano,[a] Yasumasa Kanekiyo,[a] Kazuhiko Inoue,[a] Junichi Hojo[b] and Seiji Shinkai*[a]†

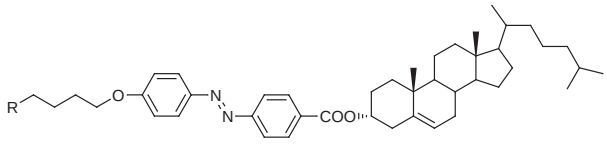
A novel mesoporous silica with a tubular structure has been prepared using organic gel fibers as a template.

Increasing attention has been paid to low molecular-mass compounds that can gelatinize various organic solvents efficiently.[1–11] These phenomena are interesting in that the fibrous aggregates formed by non-covalent interactions are responsible for the gelation. In particular, cholesterol-based gelators, which can form stable gels using only non-hydrogen-bonding interactions, show an excellent gelation ability towards a wide variety of organic solvents at sufficiently low concentrations.[5–9,11] In addition, the resulting gels have chirally oriented structures which are imparted from the characteristic cholesterol skeleton. Through this study we found that even liquid silanol derivatives can be gelatinized by some cholesterol-based gelators.[7,12] It thus occurred to us that if the sol–gel polymerization of the silanol derivatives proceeds in the organic gel state, the gelator fibrils should act as a template which eventually creates a void in the resultant silica. After trial-and-error, we have found that under certain reaction conditions the gelator fibrils survive in the sol–gel process and construct a tubular structure in the fibrous silica.

It is known that compound **1** can gelatinize tetraethoxysilane



R = H **1**, R = $NMe_3^+Br^-$ **2**

(TEOS).[12] First, this gel was polymerized under acidic or basic reaction conditions. SEM observation showed, however, that the structure which might be constructed using this gelator fibrils as a template was not found in the resultant silica. Hence, we newly synthesized compound **2** which contains a quaternary ammonium cation like conventional cationic surfactants generally used as templates for sol–gel polymerization.[13,14] Compound **2** was synthesized according to Scheme 1 and identified by IR and ^{1}H NMR spectral evidence and elemental analysis. Since PPh_3 and azodicarboxylic acid diethyl ester were used for the condensation with cholesterol, the C-3 atom has the unnatural inverted (*R*)-configuration.[7]

The gelation ability was tested using several organic solvents (Table 1). It is seen from Table 1 that **2** is not very soluble in organic solvents but can gelatinize some solvents such as MeOH, EtOH and $MeCO_2H$. As a gelator, therefore, **2** is not so versatile as **1**. Fig. 1 shows a SEM image of a dried gel prepared from $MeCO_2H$ (3.0 mass%). Well grown fibrils with diameters of 50–200 nm are observed in this photograph.

Sol–gel polymerization was carried out as follows: **2** (5.0 mg) was dissolved in CH_2Cl_2 (0.3 g). To this solution were added $MeCO_2H$ (0.32 g), TEOS (0.045 g) and water (0.016 g) in this order. The resultant solution was evaporated *in vacuo* until the CH_2Cl_2 was removed (monitored by the mass decrease) to give a turbid acetic acid gel. This gel was sealed in a glass tube and left at 20 °C for 10 days. We also prepared a reference sample which was treated according to the same procedure in the absence of **2**. After 10 days, both mixtures were totally solidified, indicating that sol–gel polymerization of TEOS proceeded sufficiently. In order to preserve the original organic gel structure and the formed silica structure they must be dried under mild conditions. Thus, the products were dried at room temp. for 2 days to remove $MeCO_2H$ and water. Subsequently,

Benzylamine	—	G[c]
TEOS	G	I
Water	I	I

[a] The solution (5 mass%) was warmed and then cooled to 4 °C to grow the gel: G = stable gel formed at room temperature, S = solution, I = insoluble. [b] Cited from refs. 7 and 12. [c] The gel was formed at 4 °C but turned into a solution at room temp. [d] Super-gelator in which the gel was formed at a concentration of < 1 mass%. [e] Gel formed when cooled in a refrigerator (at −6 °C) and was stable at room temp.

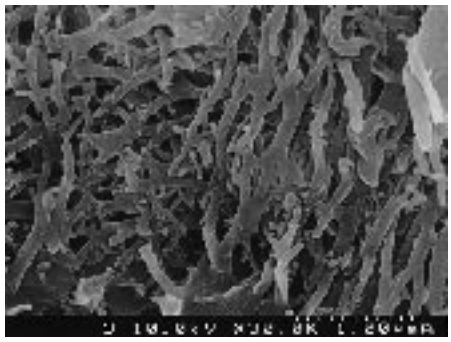

Fig. 1 SEM image for the gel of **2**–$MeCO_2H$: the gel was frozen in liquid N_2 and dried under reduced pressure for 2 h

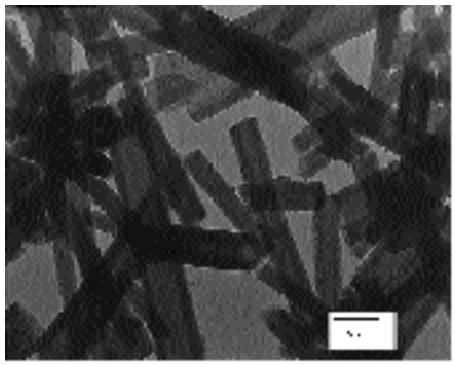

Fig. 2 TEM image for the silica (sample B) with a tubular structure (125 kV Hitachi H7100 TEM)

they were heated at 60 °C for 5 h *in vacuo* in order to entirely remove residual liquid and to accelerate the TEOS polymerization. At this stage a portion of the samples was subjected to SEM observation (sample A). They were further heated at 200 °C for 6 h under an N_2 stream for the polymerization and the removal of the residual stress evolved by shrinkage of the silica network. Finally, they were heated at 500 °C for 2 h under an N_2 stream and for 4 h in air (sample B) for the pyrolytic decomposition of **2**.

The SEM image of sample B is shown in the Graphical Abstract. It is clearly seen that sol–gel polymerization results in well grown fibrous silica and very interestingly, the tube edges contain cavities. In order to view the inside of the strand we obtained a TEM image (Fig. 2). It is clearly seen that these fibers have a tubular structure with inner diameters of 10–200 nm. Although the silica may shrink to some extent during calcination, the size is nearly comparable with that of the organic gelator fibrils (50–200 nm: Fig. 1). On the other hand, sample A obtained after treatment at 60 °C also gave fibrous silica but the tubular structure was not observed in the SEM picture. These results indicate that the organic gelator fibrils of **2** act as a template in the sol–gel process, create the tubular structure and finally are removed by pyrolysis at 500 °C.

Here, we consider why **2** can act as the template while **1** cannot although both gelators aggregate into fibers in the organic solvents. When the sol–gel polymerization is carried out in $MeCO_2H$, the propagation species is considered to be anionic.[15,16] Hence, the oligomeric silica species are adsorbed onto the cationic gelator fibrils and the polymerization further proceeds along these fibrils. This propagation mode can eventually yield fibrous silica with tubular structure. This proposal is further supported by the effect of added alcohol: when the sol–gel polymerization was initiated in **2**–$MeCO_2H$–TEOS–H_2O–EtOH (1 : 63 : 10 : 4 : 22, m/m), the resultant silica had a well developed fibrous network structure but tubular structure was not observed (SEM). Since EtOH facilitates the polymerization, the resultant silica becomes the network structure but cannot construct the isolated silica fibers.[16]‡ In contrast, the organic gelator fibrils of **1** without the cationic charge cannot adsorb the oligomeric silica species even in the absence of EtOH, so that the resultant silica showed only the granular structure (SEM). Similar granular structure was also observed for the silica obtained in the absence of the gelator.

In conclusion, the present paper has demonstrated a novel application of organic gels as a template to prepare a novel porous silica with tubular structure.

We thank Dr P. C. Ewbank for helpful discussions.

Oxonium-ion crown ether complexes from *aqua regia*

Karin Johnson and Jonathan W. Steed*†

Department of Chemistry, King's College London, Stand, London, UK WC2R 2LS

Reaction of an *aqua regia* solution of gold metal with 15-crown-5 and its derivatives results in the formation of the hydrogen bonded aggregates $[H_7O_3][AuCl_4]\cdot$15-crown-5 1 and $[H_5O_2][AuCl_4]\cdot$(benzo-15-crown-5)$_2$ 2; complex 1 exhibits a complex, cross-linked structure in which the $H_7O_3^+$ unit hydrogen bonds to two adjacent crown ethers and a chloride ligand of the anion; the Au^{III} centre also engages in long-range interactions wtih the crown oxygen atoms.

Recent work in acidic liquid clathrate[1,2] media has indicated that the selective crystallisation of various forms of the hydrated proton (H_3O^+, $H_5O_2^+$, *etc.*) may sometimes be achieved by isolation in the presence of a crown ether of the complementary dimensions to the desired oxonium species. A good fit is observed for 18-crown-6 with H_3O^+,[3,4] whereas larger crown ethers such as 21-crown-7 select $H_5O_2^+$.[5,6] Dibenzo-30-crown-10 is able to encapsulate two H_3O^+ ions.[5] In the case of the smaller crown ethers the nature of the oxonium species is variable, and depends considerably on the counter anion.[7] Indeed, $[H_{13}O_6][PtCl_5(H_2O)]\cdot H_2O\cdot$(18-crown-6)$_2$ shows that the oxonium ion species isolated by larger crown ethers may be strikingly influenced by the nature of the anion.[8] For protonated derivatives of 2,6-pyrido-21-crown-7 a water molecule is included within the cavity, while the analogous 2,6-pyrido-24-crown-8 complex encapsulates two water molecules with hydrogen bonding interactions to the protonated nitrogen.[9] We have recently begun a programme of research into host–guest species which exhibit a symmetry or steric mismatch.[10] As an extension of this work we now report the results of our investigations into oxonium ion complexes of tetrachloroaurate(III) containing small and intermediate-sized crown ethers.

Aqua regia [HCl–HNO_3 (3 : 1)] has been known since the thirteenth century as the only reagent capable of dissolving metallic gold.[11] A stock solution containing gold in *aqua regia* was prepared, resulting in oxidation of the gold to $H[AuCl_4]$. To aliquots of this solution were added equimolar amounts (relative to Au) of 15-crown-5 and benzo-15-crown-5 in aqueous ethanol. This resulted in the very rapid formation of bright orange–yellow crystalline products from each solution over periods of 1–4 h in good yields. The products were subjected to analysis by X-ray crystallography at −150 °C,‡ which gave the formulations $[H_7O_3][AuCl_4]\cdot$15-crown-5 **1** and $[H_5O_2][AuCl_4]\cdot$(benzo-15-crown-5)$_2$ **2**. The $H_7O_3^+$ ion in particular is relatively uncommon, though it has been observed in hydrogen bromide tetrahydrate.[12]

Complex **1** consists of an unusual, infinite hydrogen bonded chain containing alternating oxonium ion···crown pairs separated by $AuCl_4^-$ anions. The structure of the repeating unit of the infinite $H_7O_3^+\cdot$15-crown-5 chain is shown in Fig. 1, while the overall crystal packing arrangement is illustrated in Fig. 2.

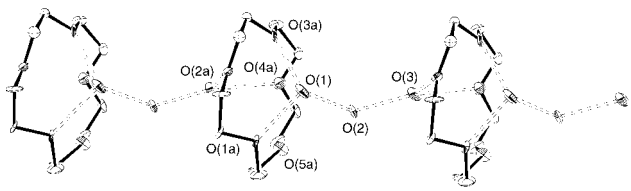

Fig. 1 Structure of the infinite $H_7O_3^+\cdot$15-crown-5 chain repeating unit in **1**

The $H_7O_3^+$ ion exhibits an unsymmetrical conformation with a short O(1)···O(2) distance comparable to that found in $H_5O_2^+$ systems[6,13,14] and a longer O(2)···O(3) interaction, 2.43(2) *vs.* 2.536(18) Å, O(1)–O(2)–O(3) angle 121(2)°. In contrast, a somewhat more symmetrical example is found in $[H_7O_3][H_9O_4]Br_2\cdot H_2O$ in which the inter oxygen separations are 2.465 and 2.498 Å,[12] whereas the hydrogen bonded $H_5O_2^+\cdots H_2O$ pair exhibits very different distances of 2.424 and 2.721 Å.[15] In complex **1** the oxonium ion hydrogen bonds to the crown oxygen atoms O(1a) and O(3a); O···O 2.64(2) and 2.63(3) Å respectively. The opposite end of the $H_7O_3^+$ unit interacts with an adjacent crown *via* longer hydrogen bonds; O(3)···O(2a) 2.75(2), O(3)···O(4a) 2.820(18) Å. This presumably results from the conflicting steric requirements of the $AuCl_4^-$ anion and the oxonium cation, although it may also be influenced by an additional, albeit long hydrogen bond from the central atom of the oxonium ion to one of the chloride ligands of the tetrachloroaurate(III) anion, O(2)···Cl(1) 3.30(2) Å. The gold(III) ion exhibits a square-planar coordination geometry, with Au–Cl distances falling into two groups; Au–Cl(1), –Cl(4) 2.296(7) Å and Au–Cl(2), –Cl(3) 2.267(7) Å (average). Interestingly, the Au^{III} ions also exhibit very long axial interactions with crown oxygen atom O(5a) (which does not take part in a hydrogen bond) and O(3a); Au–O(3a) 3.342(16), Au–O(5a) 3.381(19) Å, resulting in a cross-linked polymeric structure.

Given the polymeric nature of **1**, the structure of the benzo-15-crown-5 derivative **2** is somewhat surprising. Complex **2** contains discrete $H_5O_2^+\cdot$(benzo-15-crown-5)$_2$ units in which a pair of crowns sandwich the oxonium ion (Fig. 3). The syntheses of both **1** and **2** were carried out under identical conditions, in a 1 : 1 ratio of Au : crown. Examination of Fig. 2, however, suggests that the long range Au–O_{crown} interactions seen for **1** as well as the hydrogen bond to O(2), would not be sterically feasible for an analogous benzo-15-crown-5 complex. Indeed, the closest axial approach to the $AuCl_4^-$ anions in **2** is

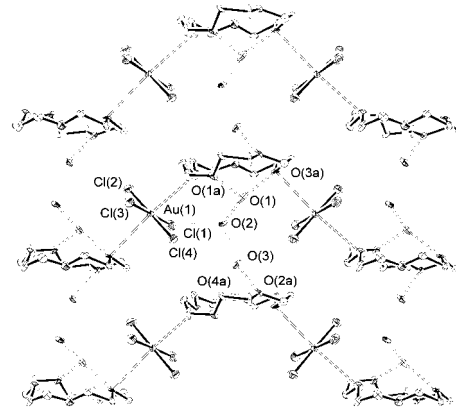

Fig. 2 Crystal packing arrangement in $[H_7O_3^+][AuCl_4]\cdot$15-crown-5 **1** showing long-range axial interactions from the crown ether to the $AuCl_4^-$ anions. Au–Cl(1–4) 2.297(7), 2.268(8), 2.266(7), 2.295(7) Å; Au–O(3a) 3.342(16), Au–O(5a) 3.381(19) Å. Hydrogen bonds: O(1)–O(1a) 2.64(2), O(1)–O(3a) 2.63(3), O(3)–O(2a) 2.75(2), O(3)–O(4a) 2.820(18) Å. Oxonium ion: O(1)–O(2) 2.43(2), O(2)–O(3) 2.536(18) Å.

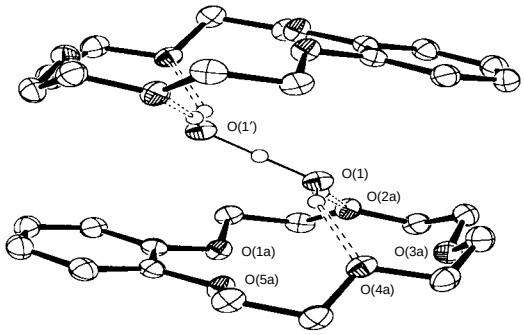

Fig. 3 The discrete H_2O_2'·(benzo-15-crown-5)$_2$ unit in **2**. Hydrogen bonds: O(1)–O(2a) 2.715(4), O(1)–O(4a) 2.642(4) Å. Oxonium ion: O(1)–O(1′) 2.420(6) Å.

by the hydrogen atoms of a crown ethylene moiety, and hence it seems likely that in the absence of these stabilisations a simple ion paired structure results.

Interaction of H[$AuCl_4$] with other crown ethers also results in the formation of oxonium ion–crown ether salts of tetrachloroaurate(III). In particular, reactions with larger crown ethers, namely 18-crown-6 and dibenzo-24-crown-8, give respectively the H_3O^+ and $H_5O_2^+$ containing species [H_5O][$AuCl_4$]·18-crown-6 and [H_5O_2][$AuCl_4$]·dibenzo-24-crown-8. Full details of this work will be reported separately.

We thank the EPSRC and King's College London for funding of the diffractometer system and the Nuffield Foundation for the provision of computing equipment.

A double sandwich silver(I) polymer with 1,1′-bis(diethyldithiocarbamate)-ferrocene

Olga Crespo,[a] M. Concepción Gimeno,[a] Peter G. Jones,[b] Antonio Laguna*[a]† and Cristina Sarroca[a]

[a] *Departamento de Química Inorgánica, Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-CSIC, 50009 Zaragoza, Spain*

[b] *Institut für Anorganische und Analytische Chemie der Technischen Universität, Postfach 3329, D-38023 Braunschweig, Germany*

The polymeric complex $[Ag\{Fc(S_2CNEt_2)_2\}]_n[ClO_4]_n$, in which the silver centres are bonded to two sulfur atoms of different ferrocene moieties and also to the cyclopentadienyl rings in an η^2 fashion, is reported.

In the last few years the chemistry of ferrocene and the design of new compounds containing the ferrocene unit has received much attention, associated with utility in many fields such as organic synthesis, catalysis and material chemistry.[1,2] Numerous derivatives in which the metallocene is bonded to a chelate ligand have been described. Interesting effects such as redox-switched bonding of metal ions within ferrocene crown ethers or investigations into the potential use of such compounds as amperometric sensors for metal ions or protons have been among the highlights of this development.[3–8] It seems that the performance of such molecular devices depends on the efficient electronic communication between the ferrocene and the metal ion coordinated within the chelating ligand.

The compound 1,1′-bis(diethyldithiocarbamate)ferrocene, $Fc(S_2CNEt_2)_2$ [Fc = $Fe(C_5H_4)_2$], although synthesized more than ten years ago,[9] has not been studied as a ligand. Here we report on the reaction of $Fc(S_2CNEt_2)_2$ with $AgClO_4$ to give a polymeric chain with stoichiometry $[Ag\{Fc(S_2CNEt_2)_2\}]_n[ClO_4]_n$, in which the silver centres are bonded to two sulfur atoms of different ferrocene moieties and are also bonded to the cyclopentadienyl rings in an η^2 fashion. Thus the silver atoms can be regarded as being four-coordinate and the molecule as a double sandwich of iron and silver. This is the first example where an η^5-Cp ring of the ferrocene unit is bonded to another metal centre through the π system. Recently Grossel *et al.* suggested the presence of a stabilising interaction between the metallocene π system of ferrocenyl substituted aza crown ethers and the cation bound to the crown moiety.[10] The complex $[Ag\{Fc(S_2CNEt_2)_2\}]_n[ClO_4]_n$ will be interesting in order to study the physical properties, mainly due to the possible existence of the delocalized aromatic conduction electrons.

The reaction of $Fc(S_2CNEt_2)_2$ with $AgClO_4$ (1 : 1 molar ratio) in diethyl ether gives a yellow precipitate from which the complex $[Ag\{Fc(S_2CNEt_2)_2\}]_n[ClO_4]_n$ **1** (Scheme 1) can be isolated.‡ It is stable to air and moisture and behaves as a 1 : 1 electrolyte in acetone. The ^{1}H NMR spectrum is in agreement with the presence of one type of 1,1′-bis(diethyldithiocarbamate)ferrocene ligand. The positive liquid secondary-ion mass spectrum shows the peak $[Ag\{Fc(S_2CNEt_2)_2\}]^+$ at m/z = 589 as the most intense.

The structure of complex **1** has been confirmed by an X-ray diffraction study (Fig. 1).§ The molecule consists of 1,1′-bis(diethyldithiocarbamate)ferrocene units bridged by silver atoms. Each silver centre is coordinated to sulfur atoms of different ferrocene moieties. The silver atom lies on an inversion centre and the iron atom on a twofold axis; consequently only half of the monomeric formula unit represents the asymmetric unit. Of necessity the grouping S–Ag–S^i (i = $-x + 1, -y + 1, -z + 1$) is perfectly linear; additionally, the silver centre is weakly bonded to two carbon atoms of each of two cyclopentadienyl rings. The Ag–C distances, 2.972(8) and 3.027(8) Å, are only slightly longer than the longest found in complexes of silver(I) with aromatic systems (2.47–2.92 Å).[11–20]

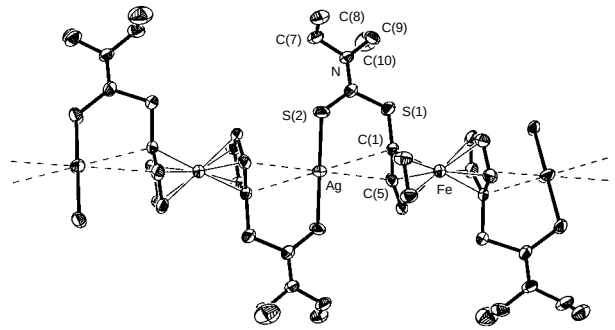

Fig. 1 Part of the polymeric chain of the cation of complex **1** in the crystal showing the atom numbering scheme. Ellipsoids represent 50% probability surfaces. H atoms are omitted for clarity.

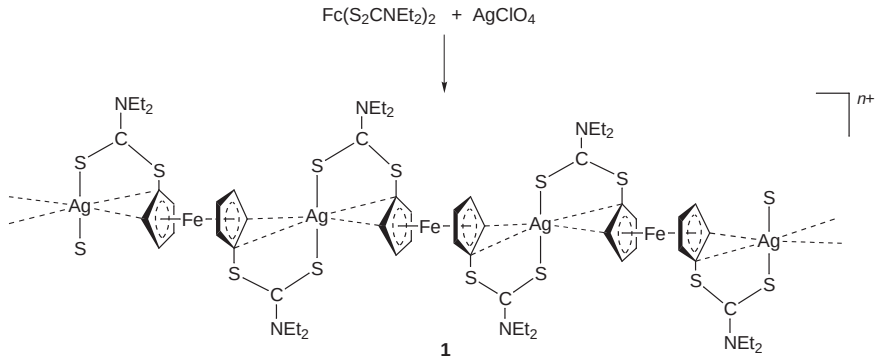

1

Scheme 1

It is also noteworthy that aromatic silver(I) complexes usually show an asymmetry in their Ag–C interactions (as do copper complexes).[21,22] According to Mulliken's model[23] the most favourable position for a silver ion is at the point of highest π-electron density, directly above one of the carbon atoms of the ring. Dewar[24] maintained that silver(I) could act not only as an electron acceptor, but also as a donor of electrons from a filled d orbital to an empty molecular orbital of the aromatic. If this 'back donation' interaction is of importance in the stabilization of the complex, the best overlap is achieved when the silver is located in the π cloud equidistant between the two carbon atoms. This situation has only been observed for naphthalene-tetrakis(silver perchlorate) tetrahydrate (2.59, 2.61 Å).[19] In complex **1** the interaction is weaker, as discussed above.

The interaction of the silver atom with the C(1)–C(5) bond produces only a small effect on the ring geometry, as was previously observed in other silver–aromatic species. However the C(1)–C(5) bond is marginally longer at 1.448(11) Å, although the difference may not be significant, while the C_5 ring remains planar (σ = 0.003 Å).

The Ag–S(2) distance is 2.386(3) Å and compares well with those observed for linear Ag–S bonds in complexes such as $[Ag_2(CH_2PPh_2S)_2]$ [2.382(3) Å].[25]

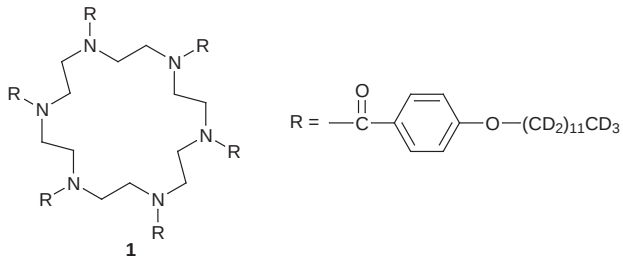
A neutron reflectivity study of a deuterated azacrown [18]N_6 at the air–water interface shows that it forms multilayers upon compression, with monolayers and trilayers being more stable than bilayers.

Typical Langmuir films are composed of a monolayer of amphiphilic molecules at the air–water interface. Upon compression, they are stable up to an irreversible 'collapse point', beyond which three-dimensional droplets are formed and/or the molecules dissolve in the water subphase. Recently, a number of compounds have been shown to form equilibrium multilayers, and in some cases trilayers are more stable than bilayers.[1,2] In other cases,[3] anomalous features in pressure–area isotherms have been associated with structural rearrangements of the molecules themselves.

We have now used neutron reflectivity to study deuterated Langmuir films of 1,4,7,10,13,16-hexakis(4-dodecyloxybenzoyl)-1,4,7,10,13,16-hexazacyclooctadecane **1**.



1

The bulk liquid crystal properties of **1** have excited considerable interest,[4–7] due in part to the potential existence of a hollow channel structure and also to the difficulty in distinguishing between columnar and smectic structures. Langmuir films of **1** are also unusual. Published pressure–area isotherms[5,6,8] measured on compression all show a rise beginning around 200 Å^2 molecule^{-1}, with an inflection point near 160 Å^2 molecule^{-1}, followed by a nonequilibrium 'bump' at slightly higher concentrations. This feature was variously ascribed to intramolecular reorientations, two-dimensional rearrangement of the film or multilayer formation.

To enhance neutron contrast, the alkyl chains were deuterated. Monolayers were spread at 20 °C from 10^{-3} to 10^{-4} M solutions on Millipore purified H_2O (resistivity 18.2 MΩ cm^{-1}). Neutron reflectivity measurements were made on beamline NG-7 of the Center for Neutron Research at the National Institute of Standards and Technology. After each compression, the film was allowed to equilibrate for 30 min before a measurement was made; each measurement took *ca.* 90 min to perform. Typical reflectivity profiles are shown in Fig. 1. The most dramatic feature is the evolution of a minimum at Q = 0.11 Å^{-1}, corresponding to a 60 Å film. This is approximately the thickness expected for a trilayer film. No minimum was ever observed in the vicinity of 0.16 Å^{-1}, as would be expected for a bilayer film.

The reflectivity data were analyzed[9] by modeling the film as a stack of uniform slabs, or boxes, each with a different scattering length density ρ, thickness L and roughness σ. We used in each case the minimum number of adjustable parameters required to obtain an acceptable fit to the data, with at most two slabs being employed. The profiles resulting from these fits are shown in Fig. 2. The general trends are as follows: at low concentrations, the reflectivity profiles are well described by a single flat slab of thickness 21.4 Å and roughness 3 Å. The thickness and scattering length density are close to those expected for a monolayer film with the central cores in contact with the subphase and the alkyl tails projecting away from the interface. As the concentration is increased beyond 1 molecule per 200 Å^2, a second well-defined 22 Å layer is formed. However, this layer does not grow to completion. Well before a concentration of 2 molecules per 200 Å^2 is achieved, the second layer roughens, so that the actual structure consists of a well-defined first layer plus patches of two-layer and three-layer film. At a nominal concentration of 3 molecules per 200 Å^2, the best fit structure is a rough trilayer film, consisting predominantly of a single sharp monolayer with regions of 1, 2 and 3 layers above that, as shown in Fig. 2.

The 'slab' model implicitly assumes that mono- and multilayer regions coexist on short length scales. It is also possible that domains larger than the neutron transverse coherence length are formed, in which case it would be more appropriate to sum reflectivity intensities for the different regions. Our central conclusion, that monolayers and trilayers are more stable than bilayers, still holds in this case, however, since we

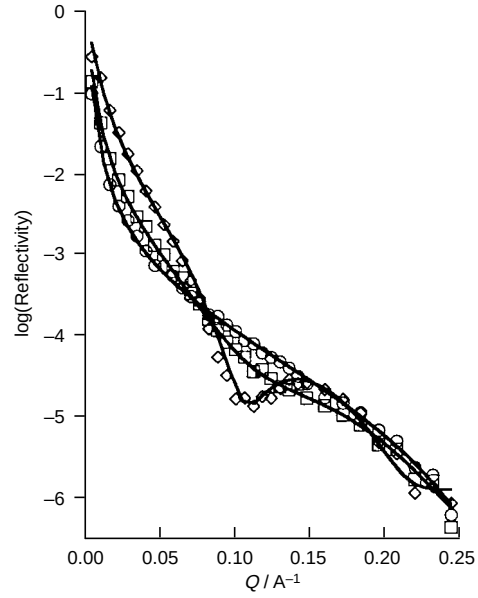


Fig. 1 Log of absolute neutron reflectivity *vs.* momentum transfer perpendicular to surface for three typical film concentrations of **1**: (○) 1.0, (□) 1.5 and (◇) 3.0 molecules per 200 Å^2

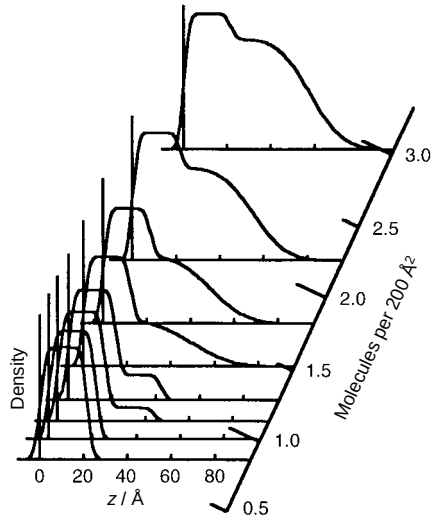

Fig. 2 Density profiles corresponding to 1- and 2-slab fits to the reflectivity data. Scattering length density (arbitrary units) is plotted *vs.* distance from the air–water interface, at a variety of surface concentrations (scaled to a nominal monolayer coverage of 1 molecule per 200 Å^2).

never observe the dip at 0.16 Å^{-1} expected for a bilayer film. We also note that there are systematic uncertainties in the calculated layer thickness, on the order of 15–20%, arising from the assumption of uniform density slabs; models incorporating the possibility of intraslab density variations may yield somewhat different thicknesses.

The relative instability of a bilayer film to trilayer formation most likely arises from the differing character of the hydrophilic amide cores and the hydrophobic hydrocarbon tails. We expect that the molecular orientation should alternate from layer to layer, with the hydrocarbon tails in the first and third tails directed away from the water and those in the second layer directed towards the first layer. The lower interfacial tension between hydrocarbon and air than between hydrated amide groups and air, which is known from X-ray photoelectron spectroscopy of amphiphilic polymers,[10] should then stabilize the third layer relative to the second.

In summary, we have shown that the nonequilibrium maximum observed in pressure–area isotherms of **1** is the result of multilayer formation upon compression. Furthermore, we have found that a bilayer structure is less stable than either a monolayer or a trilayer structure.

Biosynthesis of kelsoene in cultured cells of liverworts *Ptychanthus striatus*

Kensuke Nabeta,[a] Kanae Yamamoto,[a] Makoto Hashimoto,[a] Hiroyuki Koshino,[b] Kenzo Funatsuki[c] and Kenji Katoh[c]

[a] *Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Obihiro 080-8555, Japan*
[b] *The Institute of Physical and Chemical Research, Wako, 351-0198 Japan*
[c] *Shionogi Abrahi Laboratory, Kohga-cho, Shiga- ken 520-3423, Japan*

The most uncommon tricyclic sesquiterpenes, kelsoene 1 and prespatane 2, were isolated from cultured cells of liverwort *Ptychanthus striatus*, and the labelling pattern of kelsoene biosynthesized from exogenous [2-^{13}C]-mevalonate suggested that kelsoene is biosynthesized from germacradienyl cation *via* alloaromadendranyl cation.

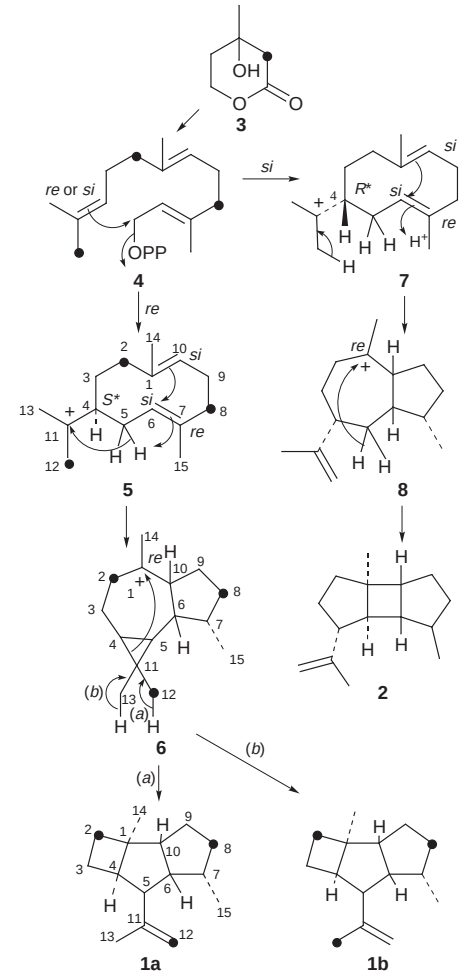
Sesquiterpenes kelsoene **1** and prespatane **2** were isolated for the first time from the tropical marine sponge *Cymbastella hooperi*.[1] Although the formation of an uncommon tricyclo[5.3.0.0^{2,5}]-decane ring system in kelsoene can be explained by the cyclization between C-1 and C-4 in alloaromadendranyl cation **6** with breaking of the C-4/C-11 bond and elimination of one proton from the *gem*-dimethyl groups, there was no experimental evidence provided regarding the biosynthesis of this compound.[1] Here we described the isolation of kelsoene **1** and prespatane **2** from suspension cultured cells of liverwort *Ptychanthus striatus* (Lejeuneaceae), which seems to have almost no phylogenetic relationship with tropical marine sponge, and the biosynthesis of kelsoene. Intact plants of *P. striatus* produce striatane-type sesquiterpenes[2] striatene, striatol and β-monocyclonerolidol.

A callus was induced from the leafy gametophytes of *P. striatus*, transfered on MSK-4 medium with 4% glucose but without 2,4-dichlorophenoxyacetic acid,[3] successively subcultured every four weeks for more than four years, and then used for suspension culture. The suspension culture was propagated routinely in 100 cm^3 of MSK-4 medium under continuous light of 3000 Lux at 25 °C for more than three years. Cells (1200 g fresh weight) were harvested and extracted with EtOAc (6.23 g). Kelsoene **1** (6.6 mg) and prespatane **2** (2.3 mg were isolated from the extract by a judicious combination of liquid chromatography (silica gel and silica gel–$AgNO_3$). Full assignment of the natural abundance ^{1}H and ^{13}C NMR spectra of (+)-kelsoene {[α]$_D$ +77.1 (lit.,[1] +78.1)} was identified by extensive 1D (^{1}H, ^{13}C and differential NOE) and 2D NMR experiments (PFG-DQF-COSY,[4] PFG-HMQC,[5] PFG-HMBC[6]). Prespetane **2** was identified by comparison of ^{1}H and ^{13}C NMR and mass spectral data with those reported previously.[1]

Table 1 ^{13}C enrichment of kelsoene incorporating [2-^{13}C]-mevalonate[a]

Carbon	δ_C	^{13}C Enrichment[b] (atom% excess)	J_{C-H}/Hz[c]
1	45.7	–	–
2	33.0	3.62	136
3	14.6	–	136
4	47.4	–	144
5	48.1	–	131
6	49.9	–	131
7	36.3	–	–
8	33.2	4.52	131
9	26.0	–	131
10	57.8	–	131
11	145.6	–	–
12	109.8	0.98	156
13	24.2	0.90	127
14	23.5	–	124
15	17.7	–	126
Average		3.34	

[a] All assignments are based on extensive 1D and 2D NMR measurements and previously reported data. [b] ^{13}C Enrichment was calculated on the basis of relative peak intensity of ^{13}C enriched peak to non-labelled carbon in biosynthetically labelled compound. [c] C–H coupling constants were determined by gated ^{1}H decoupling ^{13}C NMR analysis.



Scheme 1 Biosynthetic pathway to kelsoene **1** from [2-^{13}C]-mevalonate in cultured cells of *P. striatus*

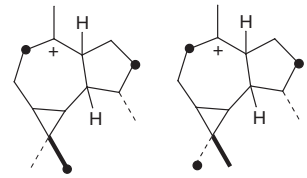
Potassium [2-^{13}C]-mevalonate (MVA, 0.5 mmol) was then fed to the culture (100 cm^3). Cells were harvested after 21 days and extracted with EtOAc. The enriched kelsoene was purified by repeated liquid chromatography as described above.

The ^{13}C{^{1}H} NMR spectrum of kelsoene derived from [2-^{13}C]-mevalonate (average ^{13}C enrichment: 3.34 atom%

excess, Table 1) showed enrichment at the C-2, C-8, C-12 and C-13 positions (4.52, 3.62, 0.98 and 0.90 atom% excess, respectively). Randomization of label between C-12 and C-13 was observed. The level of ^{13}C enrichment in each carbon was determined by comparing the relative intensities of ^{13}C enriched carbons in each carbon with those of the corresponding carbons in the non-labelled compound.

These results may be rationalized by the sequence illustrated in Scheme 1. Cyclization of farnesyl diphosphate **4** to germacradienyl cation **5** *via* the (4*S**)-isopropyl cation would be followed by concomitant intramolecular cyclization between C-6 and C-10 and between C-5 and C-11 of **5** with loss of a proton at C-5 to form a *cis* fused cyclopentane ring and a cyclopropane ring in the resultant alloaromadendranyl cation **6**. Cleavage of the cyclopropane ring and ring closure between C-1 and C-4 with loss of one proton from the *gem*-dimethyl groups generates kelsoene **1**. Observed randomization of label between C-12 and C-13 in kelsoene suggested that the protons of the *gem*-dimethyl groups on the cyclopropane ring in the cation **6** were almost equally eliminated during the conversion of **6** to **1**. Alternatively, the cation at C-11 of **5** might be attacked at both the *re* and *si* faces to form **6a** and **6b**. A proton is then eliminated specifically from a methyl group in either of the two planes of the cyclopropane ring. The co-metabolite, prespatane **2**, might be biosynthesized from a guaianyl cation **8** *via* cation **7** with a (4*R**) isopropyl cation.

Although kelsoene and prospatane were isolated from the marine sponge, they may represent a simple accumulation of constituents from a dietary source such as marine algae, since



6a **6b**

there is a hypothesis that bryophytes originate in green algae.[7]

Simple azetidine *N*-oxides: synthesis, structure and reactivity

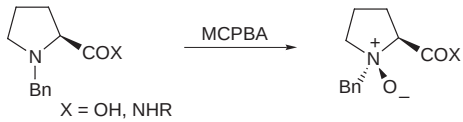
Ian A. O'Neil*† and Andrew J. Potter‡

Robert Robinson Laboratories, Department of Chemistry, University of Liverpool, Crown St, Liverpool, UK L69 7ZD

The preparation of two stable azetidine *N*-oxides is described; one structure was confirmed by X-ray crystallography and the second was found to undergo a quantitative ring expansion to yield a new 6-hydroxy tetrahydro-1,2-oxazine, a potentially useful reagent for further synthetic transformations.

Azetidine *N*-oxides are usually unstable at room temperature, undergoing a [1,2] rearrangement.[1] Only one example of an azetidine *N*-oxide stable at room temperature has been reported.[2] In this case the azetidine ring was fused to a six membered ring. Related compounds include azetidine aminoxyls and nitrones.[3]

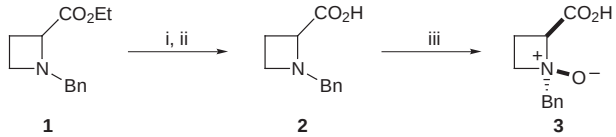
Recent work has shown that tertiary amine oxides derived from proline and pipecolic acid derivatives are stabilised by intramolecular hydrogen bonding if a suitable hydrogen bonding donor group is present in the carboxylic acid side chain. The amine oxides are formed as single diastereoisomers where the amine oxide is *syn* to the carboxylic acid side chain (Scheme 1).[4]



Scheme 1

We were intrigued by the possibility of synthesising the corresponding *N*-benzyl-2-carbonylazetidine *N*-oxides in order to establish if they would be stablised by intramolecular hydrogen bonding. In addition, such compounds should possess novel and useful synthetic potential as a consequence of ring strain.

Racemic ethyl *N*-benzylazetidine-2-carboxylate **1** was prepared according to route of Wasserman.[5] Saponification of the ester with $Ba(OH)_2$ followed by acidification gave the free acid **2**. Oxidation with MCPBA furnished the desired azetidine *N*-oxide **3** in 30% yield as a stable compound (Scheme 2). In contrast, all attempts to form the *N*-oxide of ester **1** led to complex mixtures of products and none of the desired material was ever isolated.



Scheme 2 *Reagents and conditions*: i, $Ba(OH)_2$; ii, H_3O^+; iii, MCPBA, 30% over 3 steps

From spectroscopic data the *N*-oxide **3** had clearly been formed as a single diastereoisomer. Crystals of suitable quality for X-ray analysis were grown and the X-ray structure clearly showed that the amine oxide had been formed *syn* to the carboxylic acid and that there was an intramolecular hydrogen bond between the amine oxide oxygen and the carboxylic acid (Fig. 1). To the best of our knowledge this is the first example of a simple, stable azetidine *N*-oxide characterised by X-ray crystallography.[6]

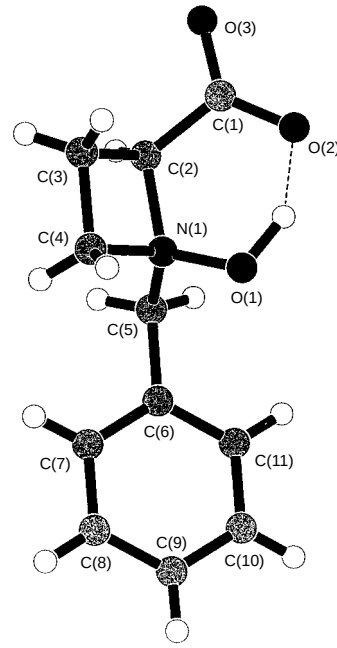


Fig. 1 Crystal structure of **3**

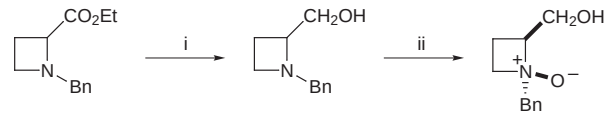
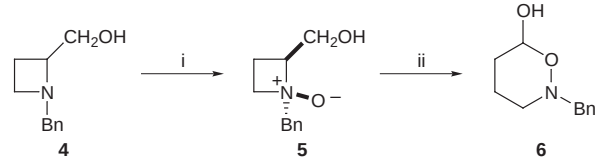
In order to establish if other hydrogen bond donor groups could stabilise azetidine *N*-oxides, the ester **1** was reduced to the primary alcohol **4** with $LiAlH_4$. Oxidation with MCPBA yielded the amine oxide **5** as a single diastereoisomer, in a much higher yield of 63% (Scheme 3). Again this compound was stable at room temperature and full spectroscopic data were obtained.



Scheme 3 *Reagents and conditions*: i, $LiAlH_4$, THF, −78 °C to room temp., 90%; ii, MCPBA, 63%

Upon attempted recrystallisation from hot CH_2Cl_2, the amine oxide underwent a quanitative conversion to a new less polar material (Scheme 4).

The presence of a signal at δ 5.2 in the ^{1}H NMR spectrum suggested that oxazine **6** had been formed. We can rationalise this conversion either as a Cope-type elimination followed by tautomerism of the enol to an aldehyde and lactol formation, or as a [1,2] rearrangement. Such rearrangements have precedent,



Scheme 4 *Reagents and conditions*: i, MCPBA, 63%; ii, CH_2Cl_2, reflux, quant.

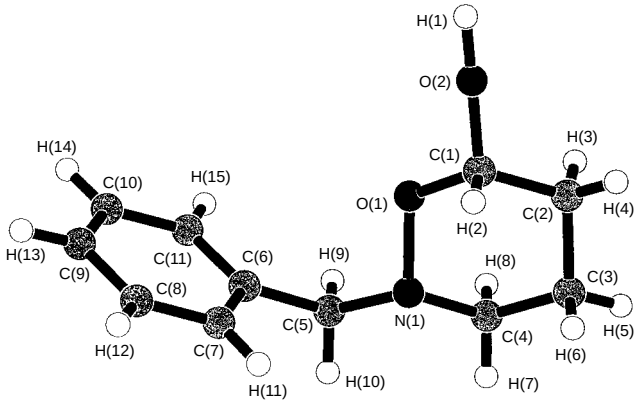


Fig. 2 Crystal structure of **6**

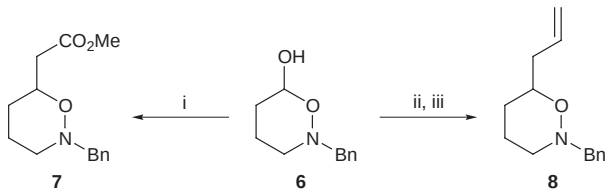
exemplified by the conversion of physostigimine *N*-oxide to geneserine.[7] The structure of tetrahydrooxazine **6** was confirmed by single crystal X-ray analysis of the product (Fig. 2).[6]

This 6-hydroxytetrahydrooxazine in which the nitrogen bears a benzyl group has not been previously prepared. Interestingly, the crystal structure shows that the anomeric hydroxy group is in an equatorial position. We have carried out some preliminary studies on the chemistry of this ring system and have established that it undergoes reactions typical of a lactol. For example, treatment of tetrahydrooxazine **6** with the stabilised ylide shown gave the ester **7** *via* initial alkene formation followed by an intramolecular Michael addition.[8] Conversion of the tetrahydrooxazine **6** to its acetate followed by reaction with allyltrimethylsilane in the presence of BF_3–OEt_2 yielded the allyl adduct **8** (Scheme 5).



7 **6** **8**

Scheme 5 *Reagents and conditions*: i, Ph_3P = $CHCO_2Me$, THF, 68%; ii, AcCl, NEt_3, CH_2Cl_2; iii, $AllylSiMe_3$, $BF_3{\cdot}OEt_2$, 30% over 2 steps

In summary, we have prepared and characterised the first stable simple azetidine *N*-oxide **3** and shown that it is stabilised by intramolecular hydrogen bonding to the carboxylic acid. The corresponding *N*-benzyl-2-hydroxymethylazetidine *N*-oxide **5** undergoes rearrangement in warm CH_2Cl_2 to give a novel tetrahydrooxazine **6**, which shows coupling reactions typical of a lactol.

We thank the EPSRC for their support of this work (grant GR/K50719). I.A.O.N. thanks the James Black Foundation for their continued financial support and Zeneca for a generous unrestricted research grant.

Inhomogeneity in the interaction between methanol molecules and Brønsted acid sites of H-ZSM-5 directly detected by 2D CPMAS ^{13}C NMR spectroscopy

Kei Inumaru,*†‡ Ni Jin, Sayaka Uchida and Makoto Misono

Department of Applied Chemistry, Graduate School of Engineering, The University of Tokyo, 7-3-1, Hongo, Bunkyo-Ku, Tokyo 113-8656, Japan

1D and 2D exchange ^{13}C NMR investigation of the states of methanol adsorbed on H-ZSM-5 at ambient temperature demonstrates the coexistence of methanol strongly interacting with Brønsted acid sites and methanol physisorbed or hydrogen-bonded, and provides the first spectroscopic evidence of a wide distribution in the strength of its interaction with Brønsted acid sites.

In the micropores of zeolites, the electric field induced by the pore walls has often been assumed to assist the activation of molecules, although no direct evidence has been provided. A recent theoretical calculation[1] predicted that the ionic effect of the zeolite framework alters the state of MeOH adsorbed at a Brønsted acid site: a methoxonium ion is preferred in the narrow channel of chabazite, while a hydrogen-bonded neutral complex is stable in the larger cage of sodalite. H-ZSM-5, an important catalyst for chemical processes such as the MTG (methanol to gasoline) reaction,[2] would exhibit interesting characterisitics with respect to the ionic effect on the acid sites because its pore size is intermediate.[1] There are sites in the two kinds of channel and at their intersections in H-ZSM-5, and the local electric field must be reflected in the states of the molecules adsorbed.[3] There have been extensive experimental studies on the state of MeOH using *in situ* IR analysis,[4–7] temperature programmed desorption,[8,9] and solid-state NMR analysis,[5,10–15] as well as theoretical calculations.[1,16–18] High-resolution solid-state ^{1}H NMR spectroscopy has recently shown that MeOH molecules form 'clusters' on the Brønsted acid sites of H-ZSM-5 at high coverages at ambient temperature.[5,12–14] The hydroxy protons of MeOH and the acidic protons rapidly exchanged in these clusters. IR investigations indicated the formation of hydrogen-bonded species on the acid sites.[6,7] Two research groups recently reached different conclusions based on careful NMR studies of the state of adsorbed MeOH, favouring either a resonant structure including adsorbed methoxonium ion[13] or a hydrogen-bonded neutral complex.[14] One of the major differences between the two studies appears in the observed ^{13}C NMR spectra, with peaks of 53.6 *vs.* 50.5 ppm reported. So, the state of MeOH stoichiometrically adsorbed on the acid sites is still controversial. To the best of our knowledge, all NMR studies on this subject were carried out with MeOH/acidic sites ≥ 1.

In this study, by focusing on low coverages of MeOH, we provide spectroscopic (2D exchange ^{13}C NMR) evidence for the co-existence of the two different species and a wide distribution in strength of interaction between the MeOH molecules and the acid sites. These species adsorbed so firmly that they did not exchange their positions at 298 K even on an NMR timescale of 0.5 s. The present results explain the previous results, which are apparently contradictory.

H-ZSM-5 was prepared from Na-ZSM-5 (Si/Al = 11.9, 7.4 Al atoms per unit cell) which was kindly supplied by Toso Co. Ltd. After ion exchange with ammonium nitrate, the zeolite was heated in a dry He stream at a rate of 0.3 K min^{-1} and was finally calcined at 673 K for 10 h. In the ^{27}Al NMR spectrum of the fully hydrated H-ZSM-5, the intensity of the octahedral Al (extraframework Al) resonance at around 0 ppm was less than one twelfth of that of tetrahedral Al in the framework (*ca.* 50 ppm). The samples for ^{13}C NMR analysis were prepared using a glass high vacuum system (*ca.* 100 cm^3). After H-ZSM-5 had been dehydrated at 673 K (heating rate: usually 1 K min^{-1}, *in vacuo*), a calculated amount of $^{13}CH_3OH$ (99 atom% ^{13}C) was introduced at 298 K. The amount of MeOH was varied from 0.5 to 12 molecules per unit cell (MeOH/Al = 0.07–1.6). Then the zeolite was transferred into a small glass cell (*ca.* 0.1 cm^3) and the cell was sealed while the sample was cooled with liquid N_2. The cell was set in a zirconia rotor, and 1D ^{13}C and ^{27}Al NMR spectra were recorded using a JNM-EX270 spectrometer with a cross-polarisation magic angle spinning (CPMAS) probe. 2D ^{13}C NMR exchange experiments (CP excitation)[19] were carried out with a Chemagnetics CMX-300 Infinity spectrometer. 48 1D spectra with 840 scans for each were recorded. All NMR spectra were recorded at 298 K.

Fig. 1 shows the CPMAS ^{13}C NMR spectra for samples having 0.5–12 molecules per unit cell (molecule uc^{-1}) of MeOH adsorbed on H-ZSM-5. The spectra in Fig. 1(*a*) were recorded by single pulse excitation with proton decoupling and the ordinate for each spectrum was normalized by the sample weight. Therefore, the peak intensities are proportional to the number of nuclear spins. The spectra in Fig. 1(*b*) were recorded by CP to improve the signal-to-noise ratio. Similar spectra were obtained using the two methods. This indicates that the CP efficiencies for the signals were similar in these measurements and the relative intensities in each spectrum in Fig. 1(*b*) can be regarded as nearly quantitative. In the case of 12 molecule uc^{-1} (MeOH/Al = 1.6), a broad peak was observed at 51.5 ppm. When the amount of MeOH was decreased to 8 molecule uc^{-1} (MeOH/Al = 1.1), the peak shifted downfield to 52.7 ppm, suggesting an increased interaction of MeOH with the acid sites. A further decrease in the amount of MeOH to 4 molecule uc^{-1} (MeOH/Al = 0.54) caused a splitting of the signal into a narrow peak at 51.5 ppm and a broad shoulder at *ca.* 54 ppm. These two signals were observed more clearly at 2 molecule uc^{-1}. As the

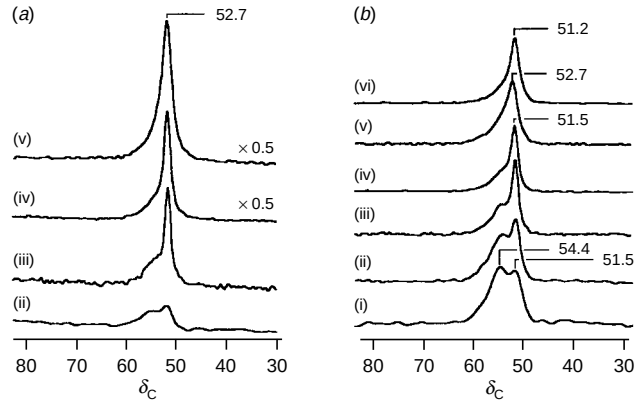

Fig. 1 CPMAS ^{13}C NMR spectra of $^{13}CH_3OH$ adsorbed on H-ZSM-5 at various coverages of MeOH at 298 K; (*a*) single pulse excitation with proton decoupling and (*b*) cross polarization. (i) 0.5 (0.07), (ii) 1 (0.13), (iii) 2 (0.27), (iv) 4 (0.54), (v) 8 (1.1) and (vi) 12 molecule uc^{-1} (MeOH/Al = 1.6). MAS rate = 6 kHz.

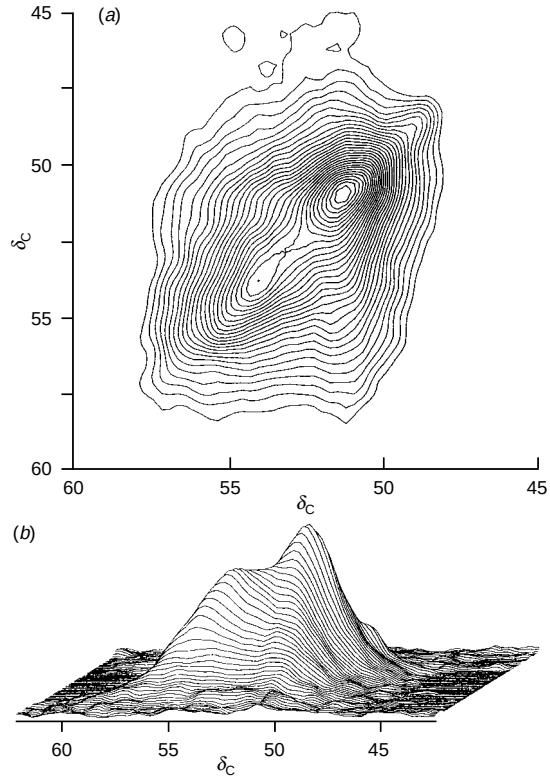

Fig. 2 2D exchange ^{13}C NMR spectrum of $^{13}CH_3OH$ adsorbed on H-ZSM-5 at 298 K; (*a*) contour plot and (*b*) stack plot. Adsorption = 1 molecule uc^{-1}. Mixing time = 0.5 s. MAS rate = 3.5 kHz.

amount of MeOH decreased to 1 molecule uc^{-1} (MeOH/Al = 0.13) and 0.5 molecule uc^{-1} (MeOH/Al = 0.07), the peak at 51.5 ppm decreased and the broad signal at *ca.* 54 ppm became dominant.

The origins of these signals were investigated by the following experiments. First, the ^{13}C NMR spectrum of adsorbed MeOH was measured for H-ZSM-5 with a higher Si/Al ratio (26) at 1 molecule uc^{-1}. The intensity of the broad peak at 54 ppm decreased as compared with H-ZSM-5 with Si/Al = 11.9, while its linewidth was almost unchanged. Next, the degree of dealumination of H-ZSM-5 was increased by accelerating the rate of temperature rise in the pretreatment *in vacuo* from 1 to 3, and then to 10 K min^{-1}. Accordingly, the peak intensity at *ca.* 0 ppm (extraframework Al) relative to that at *ca.* 50 ppm (Al in framework) in the ^{27}Al NMR spectrum (measured after full rehydration) increased from 0.13 to 0.15, and then to 0.17. ^{13}C NMR measurements for these zeolite samples at 1 MeOH molecule uc^{-1} showed that the broad signal at 54 ppm decreased with an increase in the dealumination. On the basis of these two experiments, it may be concluded that the broad signal is not connected with extraframework aluminium sites, but it corresponds to a species strongly interacting with the Brønsted acid sites. In the case of silicalite, the ^{13}C NMR spectrum at 1 MeOH molecule uc^{-1} gave a single sharp peak at 51.0 ppm. This shows that the narrow peak at *ca.* 51 ppm is due to MeOH weakly interacting with the zeolite.

Two research groups recently performed careful studies using temperature-variable ^{1}H, ^{13}C and ^{2}D NMR spectroscopy, and reached different conclusions. Thursfield and Anderson observed a signal at 53.6 ppm and proposed a resonance structure between an adsorbed methoxonium ion and a hydrogen-bonded MeOH molecule.[13] On the other hand, Hunger and Horvath found a peak at 50.5 ppm and assigned it to a hydrogen-bonded neutral complex in which the hydroxy proton of MeOH and the acidic proton of H-ZSM-5 rapidly exchange their positions.[14] These two different results become consistent if the variation of the major species with coverage shown in Fig. 1 is taken into account: the major species at MeOH/Al = 1 gives a peak at 51 ppm, while at low coverage the species strongly interacting with the Brønsted acid sites and hydrogen-bonded MeOH coexist. The two species do not exchange with each other on the NMR timescale.

The broadness of the ^{13}C NMR peak of the strongly bonded species (54 ppm) is notable. In order to elucidate the mechanism of broadening and the exchangeability of the species, a 2D exchange ^{13}C NMR spectrum was measured at 1 molecule uc^{-1} with a mixing time of 0.5 s. As shown in Fig. 2, no cross-peak was observed, so the species observed do not exchange at 298 K at low coverage even on the long timescale of 0.5 s. Fig. 2 provides additional important information. The broad peak for the strongly adsorbed species appears as a long narrow ridge along the diagonal, demonstrating the presence of inhomogeneous broadening. That is, the width of the peak is not due to a short T_2 induced, for example, by strong dipole interactions with other nuclei such as ^{27}Al and neighbouring ^{13}C. The linewidth, which is insensitive to change in the MAS rate, shows that it is not due to residual anisotropy of the chemical shifts or a misadjusted magic angle. Therefore, it was concluded that the broad peak came from several species which have different chemical shifts, reflecting the different strengths of interaction between MeOH and the Brønsted acid sites. This is the first NMR detection of inhomogeneous adsorption states presumably due to the different environments of adsorption in the zeolites. Since the linewidth of the peak is almost unchanged when the Si/Al ratio is varied, this inhomogeneity of adsorbed MeOH is thought to be intrinsic to the H-ZSM-5 structure.

Some of the experimental results in this communication were presented at the Spring Meeting of the Chemical Society of Japan, 1996 (No. 3D538).

Synthesis and characterization of $[NBu_4]_4[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]$, a novel polyoxomolybdate complex with a short $Ag^I\cdots Ag^I$ distance

Richard Villanneau, Anna Proust, Francis Robert‡ and Pierre Gouzerh*†

Laboratoire de Chimie des Métaux de Transition, U.R.A. C.N.R.S. No 419, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris Cedex 05, France

In methanol, the defect nitrosylpolyoxomolybdate $[Mo_5O_{13}(OMe)_4(NO)]^{3-}$ reacts with Ag^+ to give the complex $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ which displays attractive interactions between the two square-planar closed-shell Ag^I cations.

The molecular building block approach, *i.e.* the linking of preorganized units, has proved efficient in the synthesis of polyoxometalates with increasing complexity.[1–6] Whereas the structures of large polyoxomolybdates are mainly based on $\{Mo_7\}$, $\{Mo_8\}$ and $\{Mo_{17}\}$ units, those of polyoxotungstates are mainly based on defect $\{XW_{11}\}$ and $\{XW_9\}$ Keggin subunits but also may include defect $\{W_5\}$ Lindqvist subunits.[1] While the defect anion $\{W_5O_{18}\}^{6-}$ has been characterized in lanthanide[7,8] and actinide[9] complexes and in a palladium complex,[10] complexes of the related $\{Mo_5O_{18}\}^{6-}$ have not yet been reported. However, a derivatized Lindqvist-type $\{Mo_5\}$ unit, $[Mo_5O_{13}(OMe)_4(NO)]^{3-}$, has been characterized,[11] and its coordination chemistry has been investigated. We report herein the synthesis and characterization of $[NBu_4]_4[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]$, the anion of which displays several unusual features.

To the best of our knowledge, silver complexes of polyoxometalates have not been previously reported, with the exception of the cyclic $[As_4W_{40}O_{140}]^{28-}$ anion where each of the four lacunary sites S_2 may be occupied by Ag^I.[12] The compound $[NBu_4]_4[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]$ **2** was obtained by reacting $[NBu_4]_2[Mo_5O_{13}(OMe)_4(NO)\{Na(MeOH)\}]\cdot 3MeOH$ **1**[11] with $AgNO_3$ in methanol.§ Compound **2** was characterized by elemental analysis, spectroscopic methods (IR and UV–VIS)¶ and single-crystal X-ray structure analysis.‖ The structure of **2** consists of discrete centrosymmetrical $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ anions (Fig. 1) and of tetrabutylammonium cations. The silver complex $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ appears to be roughly similar to the palladium complex $[Pd_2\{W_5O_{18}\}_2]^{8-}$.[10] In both cases, each defect polyoxoanion bridges between two cations in slightly distorted square-planar environments. The Ag–O distances range from 2.342 to 2.477 Å (av. 2.381 Å) and the O–Ag–O angles range from 76.1(2) to 102.0(2)°, the larger angles occurring between two oxygen atoms of the same Mo_5 unit. The silver atom is displaced inside by 0.23 Å from the mean plane of its surrounding oxygen atoms. Square-planar coordination is precedented for Ag^I cations, *e.g.* in $[\{(NH_3)_4Pt_2(C_5H_5N_2O_2)_2\}_2Ag]^{5+}$ where Ag^+ is coordinated to four oxygen atoms of 1-methyluracil ligands.[13] The average Ag–O distance of 2.381 Å in $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ is close to the average Ag–O distance of 2.39 Å in the Pt_4Ag complex. In contrast to $[Pd_2\{W_5O_{18}\}_2]^{8-}$ in which the symmetry of the overall anion approaches D_{2h},[10] the Ag···Ag vector deviates by 40.5° from the normal to the mean coordination planes of the silver cations. Another unexpected feature of the molecular structure of $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ is the short distance between the two Ag^I cations. Indeed the Ag···Ag distance of 2.873(2) Å in $[Ag\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ is less than the Ag···Ag distance in the metal, which suggests significant Ag···Ag bonding interaction. Closed-shell interactions in inorganic chemistry are well documented, especially for Au^I which has a strong tendency for metallophilic attraction.[14,15] Although the shortest $Ag^I\cdots Ag^I$ contacts have been observed for ligand-supported metal pairs, *e.g.* in $[Ag_2(PhNNNPh)_2]$,[16a] $[Ag_2(ArNCHNAr)_2]$ (Ar = *p*-tolyl,[16b] *o*-methoxyphenyl[16c]), $[Ag_2(1,8\text{-naphthyridine})_2][ClO_4]_2$,[16d] and in $[Ag_3(1,8\text{-diisocyano-}p\text{-menthane})_2I_3]$,[16e] attractive Ag···Ag interactions do exist in the absence of any bridging ligand.[17] The bridging polyoxoanions most probably play a role in the Ag···Ag separation; however, it is noteworthy that the Ag···Ag distance is significantly shorter than the ligand bite distance of *ca.* 3.15 Å. In contrast, the $Pd^{II}\cdots Pd^{I}$ distance in $[Pd_2\{W_5O_{18}\}_2]^{8-}$ is longer (3.034 Å)[10] than it would be expected in case of a significant direct interaction.[18] Altogether, these features support the view that attractive $Ag^I\cdots Ag^I$ interactions exist in $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$.

The reason for the difference between $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ and $[Pd_2\{W_5O_{18}\}_2]^{8-}$ with respect to metal–metal interaction is not straightforward. It should be pointed out that there are some systematic differences between $[Mo_5O_{13}(OMe)_4(NO)]^{3-}$ and $[W_5O_{18}]^{6-}$, according to the molecular structures of their respective complexes.[7b,8,10,11,19] In particular, the Mo–O distances involving the coordinated axial oxygen atoms (O_a, av. 1.717 Å in **2**) are comparable with those to equatorial oxygen atoms [O_e, av. 1.698(7) Å in **2**), while the W–O_a distances {av. 1.805(5) Å in $[Pd_2\{W_5O_{18}\}_2]^{8-}$}[10] are significantly lengthened by comparison with W–O_e {av. 1.718(6) Å in $[Pd_2\{W_5O_{18}\}_2]^{3-}$}.[10] In addition, the central oxygen atom is much more displaced from the plane of the four basal M atoms toward the apical M atom in the complexes of $[Mo_5O_{13}(OMe)_4(NO)]^{3-}$ (*e.g.* 0.41 Å in **2**) than in those of $[W_5O_{18}]^{6-}$ {*e.g.* 0.14 Å in $[Pd_2\{W_5O_{18}\}_2]^{8-}$}. Therefore the

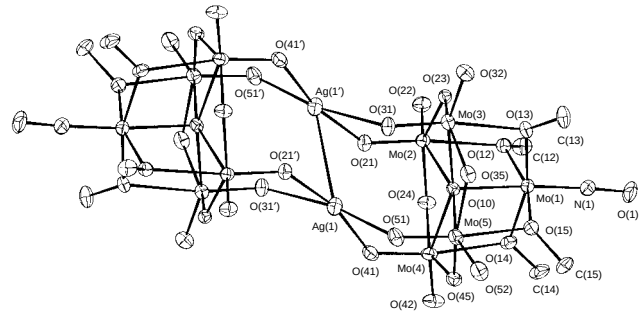

Fig. 1 Molecular drawing of $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ in **2**.[21] Selected bond lengths (Å) and angles (°): Mo(1)–N(1) 1.746(9), N(1)–O(1) 1.22(1), Mo(2)–O(21) 1.720(7), Mo(2)–O(22) 1.698(6), Mo(3)–O(31) 1.716(6), Mo(3)–O(32) 1.704(7), Mo(4)–O(41) 1.717(7), Mo(4)–O(42) 1.700(7), Mo(5)–O(51) 1.717(7), Mo(5)–O(52) 1.692(7), Ag(1)–O(41) 2.342(8), Ag(1)–O(51) 2.346(7), Ag(1′)–O(21) 2.361(7), Ag(1′)–O(31) 2.477(7), Ag(1)–Ag(1′) 2.873(2); O(41)–Ag(1)–O(51) 82.3(3), O(41)–Ag(1)–O(21′) 167.4(2), O(51)–Ag(1)–O(31′) 169.1(2), O(21)–Ag(1′)–O(31) 76.1(2), O(41)–Ag(1)–Ag(1′) 121.4(2), O(51)–Ag(1)–Ag(1′) 126.5(2), O(21′)–Ag(1)–Ag(1′) 65.6(2), O(31′)–Ag(1)–Ag(1′) 62.8(2). The coordinates of the halves of the anion are related *via* the transformation $[x', y', z'] = [-x, -y, -z]$.

comparison of $[Ag_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{4-}$ with $[Pd_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{2-}$ should have been more appropriate. Unfortunately, our efforts to obtain the palladium analogue of **2**, *i.e.* $[NBu_4]_2[Pd_2\{Mo_5O_{13}(OMe)_4(NO)\}_2]$ by reaction of **1** with either $PdCl_2$ or $Na_2[PdCl_4]$ have failed up to now. Only nitrosyl reduced decamolybdates[20] were obtained in these reactions. The behaviour of $[Mo_5O_{13}(OMe)_4(NO)]^{3-}$ towards other main-group cations has been investigated. Both Ba^{2+} and Bi^{3+} form eight-coordinate complexes of the type $[M\{Mo_5O_{13}(OMe)_4(NO)\}_2]^{n-}$ (M = Ba, n = 4; M = Bi, n = 3). However, these complexes differ in the geometry of the coordination polyhedron which is best described as an elongated cube for Ba and a tetragonal antiprism for Bi.[19]

Highly dispersed Fe ions on Nafion membranes are shown to decompose H_2O_2 with similar kinetics as found for homogeneous solutions containing Fe^{3+} ions during the photo-assisted Fenton degradation of Orange II, avoiding the drawbacks of the homogeneous treatment.

Membrane related research has attracted much attention in recent years as a structured medium for a variety of chemical reactions. Nafion perfluorinated membranes have been used during the last decade in a variety of catalytic/electrocatalytical integrated chemical reactions.[1] Polymer membranes have also been used for charge transfer in inorganic and biological systems.[2] Few studies of chemical transformations with CdS or TiO_2 loaded membranes using photochemical activation have been reported until now.[3–6] This study is concerned with the degradation of non-biodegradable azo-dye Orange II by Fenton photo-assisted reactions in Fe-free solutions. This dye does not undergo bacterial degradation in a waste-water treatment plant due to the aromatic and sulfo-aromatic group found the ring structure. Azo dyes, which account for more than 22% of industrial dye production, are commonly found in effluents of the textile industry.[7]

Experiments were conducted with Nafion perfluorinated cation transfer membrane (Dupont 117, 0.007 in, Aldrich #7.467-4) containing hydrophilic sulfonate groups immobilized on the fluorocarbon matrix. Exchange with $FeCl_3 \cdot 6H_2O$ (Fluka) at room temperature was carried out for a few minutes after the Nafion was immersed in HCl. After the ion exchange, the membrane was washed with water followed by immersion in 1 M NaOH to convert Fe^{3+} to its hydrated form. The Fe-ion content of the Nafion was found to be 1.78 mass% after digestion in concentrated HNO_3 (Teflon coated autoclave) under high pressure and temperature. The solution obtained in this way was subsequently diluted and the Fe content measured by AAS (flame detector, Philips 20 M). Photolysis experiments were carried out by means of a Hanau Suntest Lamp with tunable light intensity equipped with an IR filter to remove IR radiation. The short UV radiation ($\lambda \leqslant 305$ nm) was removed by the Pyrex wall of the reaction vessels. Light irradiation reached the Nafion/Fe membrane which was positioned immediately behind the wall of the reaction vessel (60 ml volume containing 40 ml solution) as the only light absorber in this two phase system. The detection of Orange II in solution was carried out *via* an HPLC (Varian 9065 Diode Array) provided with a Phenomenex C-18 inverse phase column. The azo-dye peak was detected at $\lambda = 486$ nm with a retention time of 11.1 min. The solution gradient during the analysis was regulated with a buffer consisting of ammonium acetate and acetonitrile.

The disappearance of Orange II (pH 2.8) under light irradiation on a Fe-loaded Nafion membrane by a Suntest lamp was recorded as a function of time for different concentrations of H_2O_2 in the solution. With increasing concentration of H_2O_2 the Orange II degradation kinetics was accelerated. At H_2O_2 concentrations > 0.8 mM, no further acceleration was observed. This effect is due to the known scavenging effect when using higher H_2O_2 concentration on the further generation of hydroxyl radicals in solution.[8] The concomitant total organic carbon (TOC) decrease was observed to be modest changing from 16 to 11 ppm C after 120 min. Within this time of the azo dye was observed to completely disappear from the solution. Concomitant CO_2 evolution was checked by gas chromatography (GC) confirming that mineralization of the dye proceeds with a much slower kinetics than the Orange II disappearance. This reveals the formation of longer lived intermediates in solution. The decoloration shown in Fig. 1 reflects azo-bond breakage in Orange II.[9,10] During dye abatement where H_2O_2 (0.8 mM) is added, the solution pH was seen to increase from 2.8 to ≈ 3.2. This corresponds to about a fourfould increase in the OH^- concentration in the solution and suggests reaction (1) as the main pathway for

$$\text{Nafion/Fe}^{II} + H_2O_2 \rightarrow \text{Nafion/Fe}^{III} + {}^{\bullet}OH + OH^- \quad (1)$$

Orange II degradation rather than reaction (2).

$$\text{Nafion/Fe}^{III} + H_2O_2 \rightarrow \text{Nafion/Fe}^{II} + HO_2^{\bullet} + H^+ \quad (2)$$

Three experimental observations substantiate further the mechanism suggested in eqn. (1): (*a*) methanol (0.26 M) precluded the abatement of the azo dye due to its $^{\bullet}OH$ radical scavenging properties, (*b*) spectrophotometric results showed that the initial Nafion/Fe^{III} membrane decolored substantially during the photolysis due to the build-up of Nafion/Fe^{II} absorbing at much lower wavelengths. Since the iron has been exchanged at room temperature in aqueous solution the exchanged-hydrated Nafion/Fe^{III} would involve the presence in the Nafion of the Fe-species $Fe(OH)^{2+}$ ($\varepsilon_{366nm} = 275$ dm^3 mol^{-1} cm^{-1}) and $Fe_2(OH)_2^{4+}$ ($\varepsilon_{366nm} = 1000$ dm^3 mol^{-1} cm^{-1}).[18] During the

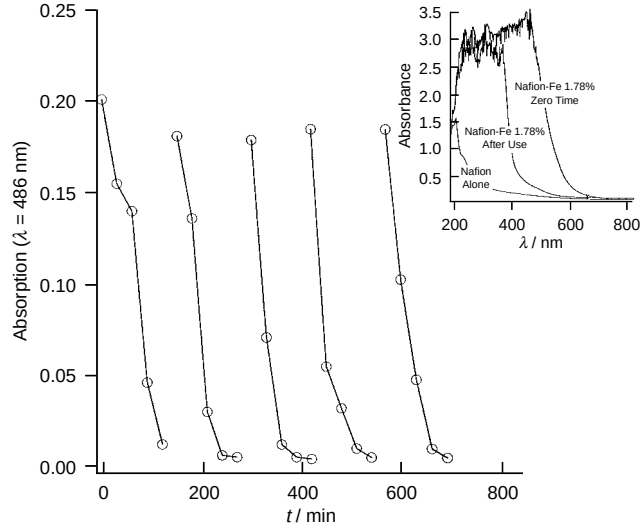

Fig. 1 Nafion/Fe loaded induced degradation of Orange II as a function of time followed by visible spectral observations at the Orange II peak of 486 nm up to the fifth cycle. The inset shows the Fe content in the solution after 26.6 days (1600 min). [Orange II] = 0.05 mM, pH = 2.8, H_2O_2 = 4.85 mM, irradiation intensity = 50 mW cm^{-2}.

dye decoloration (Fig. 1) the orange–brown color of Nafion/Fe^{III} gradually disappears due to the much lower absorption from the charge transfer band of $Fe(H_2O)_6^{2+}$ observed below λ = 265 nm with ε_{254nm} = 20 dm^3 mol^{-1} cm^{-1}.[19] Finally, (*c*) the superoxide radical $HO_2^{\cdot}$ (pK_a = 4.8) photoproduced according to eqn. (2) has a considerably lower one electron standard reduction potential of $E°$ = 0.75 V *vs.* NHE ($HO_2^{\cdot}/O_2^{\cdot -}$) than the $^{\cdot}OH$ radical with $E°$ = 1.90 V *vs.* NHE[20] ($^{\cdot}OH/OH^-$) in eqn. (1). The fast oxidation of the Orange II cannot possibly be explained in terms of this kinetically slower and less energetic $HO_2^{\cdot}$ radical [eqn. (2)].

Fig. 1 shows the repetitive nature of the Orange II photodegradation in the presence of Nafion/Fe-loaded membrane and H_2O_2. After *ca.* 25 cycles, the membrane was regenerated by immersion in 1 M NaOH. The timing of this regeneration was determined by two factors: (*a*) during use, the initial orange–brown coloration with absorption up to λ = 600 nm slowly changed to gray–yellowish with absorption reaching only an upper limit of *ca.* 410 nm. This indicated that during the photolysis the Fe^{III} content in the Nafion membrane decreased leading to the formation of colorless Fe^{II} since the total iron content of the membrane was seen to remain constant (see below). The Nafion without any Fe-loading absorbed only below 300 nm; and (*b*) during the degradation cycles the membrane become more active with time. A faster Orange II degradation of *ca.* 40% was observed compared to the first degradation run. Highly stable Nafion/Fe^{II} species are probably responsible for the observed acceleration as the reaction progresses.

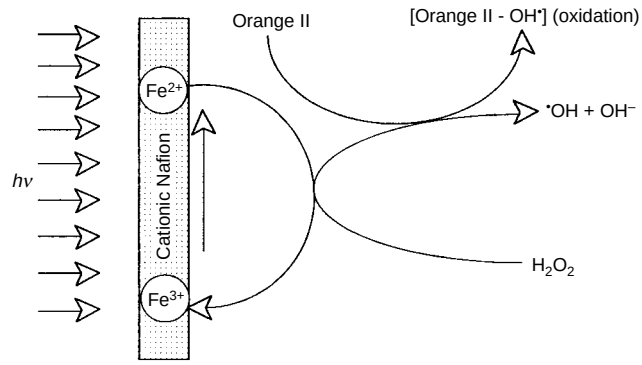
The assessment of the oxidation state of Fe during the reaction was carried out by XPS in a Leybold–Heraeus instrument. Quantitative evaluation of the Fe^{III} and Fe^{II} species revealed 78% Fe^{III} (E_b = 710.0 eV) and 22% Fe^{III}/Fe^{II} (E_b = 713.8 eV) at time zero. The former species appeared mainly as Fe_2O_3 while the latter species consisted mainly of the composite Fe_3O_4 oxide showing the peaks for the constituent oxides. After reaction, the Nafion membrane showed 16% Fe^{III} and 84% Fe^{III}/Fe^{II} oxidation states. The correction for electrostatic charging of the particles during the measurements was carried out by a polynomial fit of the data with a Shirley-type background subtraction. The XPS experimental result further confirms the spectral change in the Fe-Nafion membrane observed during the photocatalysis. The size of the Fe-clusters on the Nafion was determined by TEM to be 37 ± 4 Å (Philips 20 M instrument). The particles were seen to be uniformly deposited on the Nafion and the size distribution was narrowly centered around the median value.

Membranes were regenerated after 500 h irradiation to attain the same Orange II degradation kinetics as observed during the initial cycle. The highly dispersed Fe^{III} ions could be regenerated in the Nafion. In solution the degradation of Orange II proceeded according to eqn. (3).[3,4]

$$^{\cdot}OH + \text{Orange II} \rightarrow [\text{Orange II–OH}^{\cdot}] \rightarrow \text{hydroxylated azo-bond scission intermediates} \quad (3)$$

The inset in Fig. 1 shows the change in absorption of the Nafion membranes with time. After 500 h irradiation a substantial change in absorption of the Nafion/Fe^{III} was seen. A decrease in the absorption of Nafion/Fe^{III} is observed along with concomitant growth of the lower absorbing Nafion/Fe^{II}. This change in absorption is consistent with the molar absorption coefficients and the XPS evidence presented above. The optical absorption of Nafion membranes is shown in the left hand side of the inset. The formation of Q-sized Fe^{III}/Fe^{II} clusters in the Nafion upon irradiation has been confirmed by X-ray diffraction. The exchange procedure used to incorporate Fe ions in the membrane is therefore also a method to produce discrete small sized particles of iron oxides embedded in the polymer structure.

Based on the experimental results a simplified scheme of the reaction is presented (Scheme 1). Scheme 1 shows the photocatalytic degradation of Orange II in acidic solutions due to the photoproduction of oxidative radicals in solution and the build up of Nafion/$Fe^{III}Fe^{II}$ species during the degradation process.



Scheme 1

The redox processes involving H_2O_2 decomposition induce Orange II hydroxylation. Less than 60 min pretreatment were necessary to reach a BOD_5 value of *ca.* 100 mg O_2 1^{-1}. This is indicative for the presence of biodegradable intermediates in solution since no biodegradation was observed for Orange II in the absence of pretreatment. Azo bonds have been reported not to be susceptible to biological degradation.[13]

In conclusion, we have presented the first evidence for a Fenton-like reaction in a Fe-free solution using Orange II as a model compound. Fig. 1 shows a kinetically significant rate of azo dye disappearance in solution. A similar rate is observed in homogeneous Fe ion–H_2O_2 solutions containing ≈100 times higher concentration of Fe^{3+}. This work demonstrates the possibility of degradation of otherwise recalcitrant azo compounds removing the need to dispose of Fe ions after reaction to meet EU directives.[12]

FEATURE ARTICLE

Dynamic anion recognition by macrocyclic polyamines in neutral pH aqueous solution: development from static anion complexes to an enolate complex

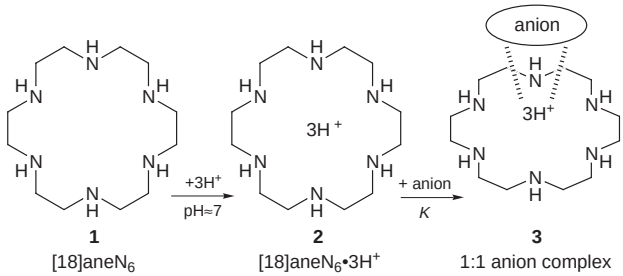
Eiichi Kimura*† and Tohru Koike

Department of Medicinal Chemistry, School of Medicine, Hiroshima University, Kasumi, Minami-ku, Hiroshima, 734-8551, Japan

Multiprotonated macrocyclic polyamines are useful host molecules for anion guests at neutral pH in aqueous solution. An intramolecular uracil anion complex with a diprotonated macrocyclic tetraamine recently provided a unique example of electrostatic stabilization of the uracil N^1 anion at neutral pH, which may be relevant to the facile glycosylation and deglycosylation of uracil at N^1 in DNA. Macrocyclic polyamine complexes with Zn^{2+} possess strong anion affinities and hence can deprotonate weak acids at neutral pH to bind with the resulting conjugate bases: *e.g.* $H_2O \rightarrow HO^-$, $ROH \rightarrow RO^-$, $ArSO_2NH_2 \rightarrow ArSO_2NH^-$, $RCONHR' \rightarrow RCON^-R'$, $RCONHCOR' \rightarrow RCON^-COR'$. The Zn^{2+}–conjugate base complexes act as catalytic nucleophiles (*i.e.* HO^-–Zn^{2+}, RO^-–Zn^{2+}), fluorescence sensors ($ArSO_2NH^-$–Zn^{2+}), and thymine or barbital recognition hosts, which are often found in zinc–enzyme functions. Enolate anion complex formation has recently been observed in intramolecular interaction of carbonyl oxygen with Zn^{2+}.

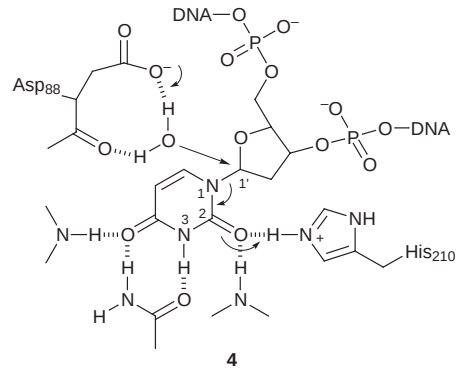
1 Anion complexes with multiprotonated macrocyclic polyamines

Macrocyclic polyamines have long been demonstrated to be good host molecules for polyanions (*e.g.* di- and tri-carboxylates, phosphates, carbonates) and form stable 1 : 1 complexes at neutral pH in aqueous solution, where macrocyclic polyamines are multiprotonated and highly charged.[1–10] For instance, the hexaazamacrocyclic polyamine [18]aneN$_6$ **1** which has pK_a values of 10.2, 9.2, 8.7, 4.1, < 2, and < 2, is mostly present in the [18]aneN$_6$·3H$^+$ form **2** at pH *ca.* 7, which binds with citrate^{3-} (log K = 2.4), AMP^{2-} (log K = 3.3), or ATP^{4-} (log K = 6.4) in 1 : 1 anion complexes **3** (Scheme 1).[2,5] Electrostatic and hydrogen bonding interactions account for the fairly strong complexation.



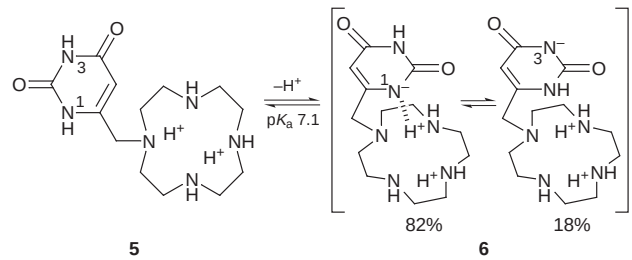
Scheme 1

Enolization of carbonyl compounds is crucial in a wide variety of key reactions in biochemical transformations; enzymes include aldolase, racemase and isomerase. Of special interest is how weak bases of enzymes (*e.g.* imidazole, aspartate or glutamate), with pK_a values < 7, can effectively abstract a proton from carbonyl substrates having much higher pK_a values and there must be some mechanism which lowers pK_a values of the methylene protons adjacent to a carbonyl group.[11] Uracil–DNA glycosylase (UDGase), which disrupts the N(1)–C(1′) bond (see **4**) at neutral pH, is an example of one



of these enzymes.[12,13] The amide carbonyl group C^2=O must be activated (probably by hydrogen bonding with protonated His$_{210}$), so as to lower the electron density of the uracil group to allow a concerted nucleophilic attack by a water molecule (activated by Asp$_{88}$) on the C$^{1'}$ atom. Concerning this mechanism, chemical questions arise: how much is the product uracil anion stabilized by the protonated imidazole or how is uracil N^{1}H selectively deprotonated for activation in the reverse reaction to form the glycosyl bond at neutral pH. These questions are translated into whether the uracil N^{1}H (pK_a *ca.* 9.5) can be rendered more acidic.

In order to address such basic chemical questions, we synthesized a diprotonated cyclen-attached uracil **5**.[14] It is remarkable to find that the uracil N^{1}H group of **5** (Scheme 2) is



Scheme 2

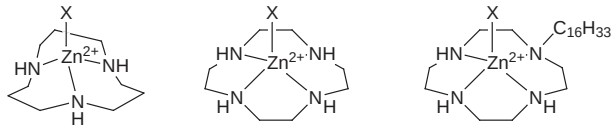
readily deprotonated to the anionic species **6** in aqueous solution [pK_a = 7.14 at 25 °C (I = 0.1)]. The lowered pK_a by more than two units is due to an electrostatic stabilization of the conjugate base (N^1)$^-$ anion by the diprotonated cycle at physiological pH. Furthermore, the negative charge is highly localized at N^1 (82% according to UV and NMR studies), under the strong influence of cyclen NH$^+$. At higher pH where the two protons are removed from the cyclen, the negative charge at N^1 becomes delocalized and the (N^3)$^-$ anionic tautomer becomes more predominant (18% at pH → 63% at pH 12.5).

This simple model may illustrate how easily the uracil N^1H can be deprotonated so as to be a good leaving group in deglycosylation and also to be a good nucleophile for glycosylation at neutral pH. The uracil N^1 site should be especially subject to the electrostatic effect by protonic acids. Thus, uracil may be appropriately chosen for the DNA repair mechanism.

2 Dynamic anion complexes by interaction of macrocyclic polyamine–zinc(II) complexes with water and alcohols

When a strong Lewis acid such as a divalent metal ion replaces protons in macrocyclic polyamine cavities, more acidic macrocyclic molecules are obtained. This is particularly true for Zn^{2+}, which along with Cu^{2+} is one of the strongest Lewis acids, and is characteristically non-directional (no ligand field effect) owing to its d^{10} electronic state (*cf.* the directional d^9 Cu^{2+} ion[15–19]) and Zn^{2+} can be regarded as a condensed multiproton site. The Zn^{2+} ion complexes in four-, five- or six-coordinate structures. Taking full advantage of the properties of Zn^{2+} and rigid macrocyclic configurations, one can design appropriate zinc(II) complexes as host molecules for anions. In this connection, it should be noted that halogen ions X^- or inorganic hydrogen phosphate $HOPO_3^{2-}$ bind to Zn^{2+} at active centers of zinc enzymes to inhibit the enzymatic activities and that zinc enzymes are active towards anionic substrates (*e.g.* $HOCO_2^-$ for carbonic anhydrase, $ROPO_3^{2-}$ for alkaline phosphatase) or neutral molecules (with weak acidity) that are developed into anionic reaction intermediates or transition states [*e.g.* amides for carboxypeptidase, CO_2 (or H_2CO_3) for carbonic anhydrase].[20] Thus, zinc(II) macrocyclic polyamine complexes can be static as well as dynamic receptor molecules for anions, showing more versatile behavior than mere protonated macrocyclic polyamines or other conventional organic anion receptors.[21–23]

The most revealing example is ready deprotonation of water bound to Zn^{2+} in macrocyclic polyamines (**7a** ⇄ **7b** + H^+ and **8a** ⇄ **8b** + H^+), as reflected in the pK_a values (7.3 and 7.9,



7a X = OH_2 **b** X = OH^- Zn^{2+}-[12]aneN_3

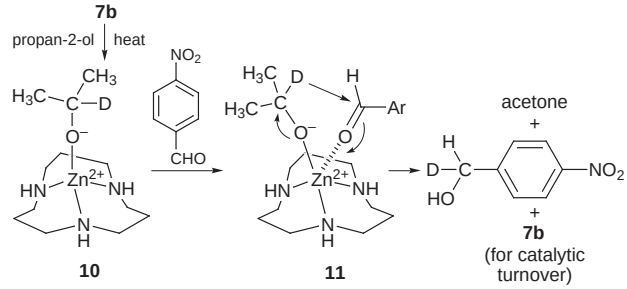
8a X = OH_2 **b** X = OH^- Zn^{2+}-cyclen

9a X = OH_2 **b** X = OH^-

respectively).[24,25] Alternatively, one can view the HO^- anion binding to Zn^{2+}, which is measured in terms of the anion affinity constant K ($10^{6.7}$ and $10^{6.1}$ dm^3 mol^{-1}, respectively). Although HO^-–Zn^{2+} bonds are fairly strong they are characteristically labile. In line with their pK_a values, HO^-–Zn^{2+} complexes are appreciably and rapidly generated at physiological pH, which then act as nucleophiles toward carboxyesters, β-lactam and phosphoesters for catalytic hydrolyses.[24–27] When appended with a hexadecyl group (see **9**), the HO^- anion complex is generated as readily (pK_a = 7.6 for **9a** ⇄ **9b** + H^+) and the resulting anion can migrate into Triton X-100 micelles, whereby the Zn^{2+}-bound OH^- becomes more desolvated and its nucleophilicity towards lipophilic esters such as tris(4-nitrophenyl) phosphate is 290 times stronger than HO^-–Zn^{2+} of **8b**.[28]

It is of interest to point out that the anion affinity of Zn^{2+} is of central importance in the active center of zinc enzymes such as carbonic anhydrase (CA).[17] In the forward (CO_2 hydration) and reverse ($HOCO_2^-$ dehydration) reactions, two anionic reactants OH^- (a good nucleophile toward CO_2) and $HOCO_2^-$ (a substrate) always compete for Zn^{2+}. The successful binding to Zn^{2+} depends on the pH of the medium (*i.e.* concentration of OH^-) and $HOCO_2^-$. This equilibrium then determines the direction of the enzyme reaction: at higher pH hydration of CO_2 and at lower pH dehydration of $HOCO_2^-$ predominate. The 12-membered macrocyclic triamine ([12]aneN_3) zinc(II) complex **7a** (pK_a = 7.3 at 25 °C) has for the first time mimicked such pH-dependent CA behavior of CO_2 hydration and $HOCO_2^-$ dehydration at physiological pH.[29]

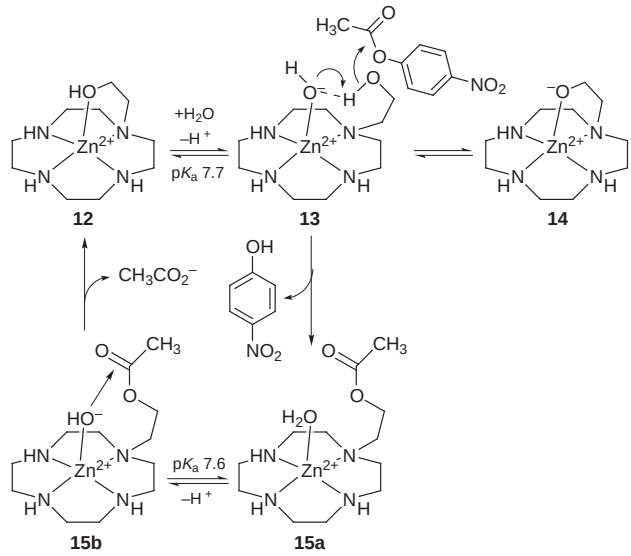
The Zn^{2+}-bound OH^- anion can also behave as a catalytic base. When propan-2-ol was heated with catalytic amounts of **7b** in dimethylformamide in the presence of 4-nitrobenzaldehyde or *N*-methyl nicotinamide, hydride transfer occurred from propan-2-ol to 4-nitrobenzaldehyde (yielding 4-nitrobenzyl alcohol) or *N*-methyl nicotinamide (yielding 1,4-dihydronicotinamide).[30] The reaction mechanism (Scheme 3) was



Scheme 3

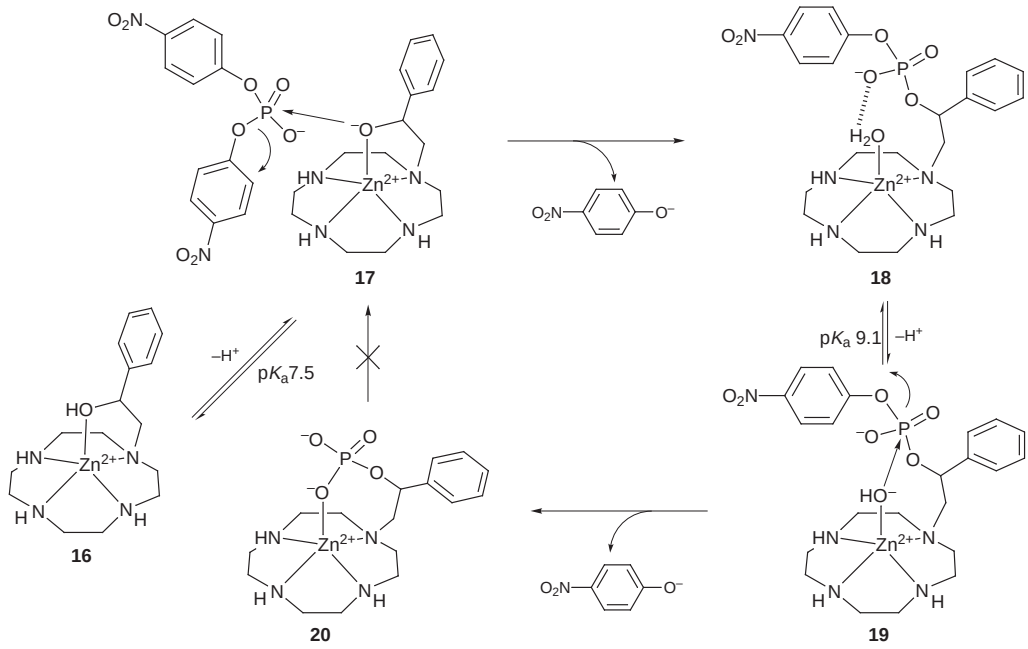
established by using $(CH_3)_2CDOH$. An essential step is generation of an alkoxide at the acidic Zn^{2+} center (**10**), which still leaves the fifth coordination site open for the other reactants coordinating through carbonyl oxygen to permit hydride transfer in the aldehyde-bound complex **11**. This system is a good model for Zn^{2+}-containing alcohol dehydrogenase.

With an alcohol-pendant zinc(II)–cyclen complex **12**, deprotonation occurs with a pK_a value of 7.7 in aqueous solution (Scheme 4).[31] Available evidence supports the HO^-–Zn^{2+}



Scheme 4

structure **13** rather than Zn^{2+}–alkoxide complex **14**. In terms of reactivity, the pendant alcohol in **13** is more nucleophilic than a reference Zn^{2+}-bound OH^- complex **8b**. The product from the reaction of **13** (at pH > 8) with 4-nitrophenyl acetate was exclusively an acetyl-transferred complex **15a**. The pendant acetate in **15a** immediately undergoes hydrolysis by the proximate Zn^{2+}-bound HO^- in **15b** which is immediately generated (pK_a = 7.6). Another alcohol–pendant Zn^{2+} complex **16** is at equilibrium with its monodeprotonated complex **17** in neutral aqueous solution with a pK_a value of 7.5 (Scheme 5).[32] In this case, the alkoxide-bound complex **17** rather than an



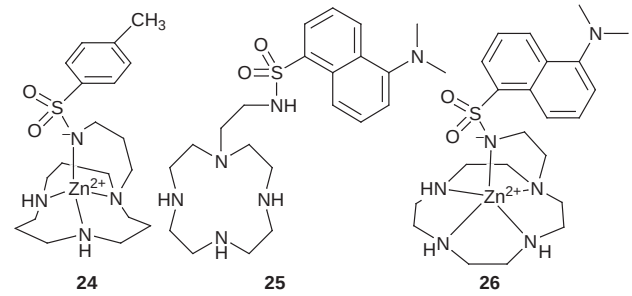
Scheme 5

equivalent **13**-type complex is predominant in alkaline solution. The alkoxide anion complex was isolated and its X-ray crystal structure was determined. The Zn^{2+}-bound alkoxide ion in **17** is again a better nucleophile than HO^-–[zinc(II)–cyclen] **8b**. The alkoxide complex **17** reacted with a phosphodiester to yield an isolable 'phosphate-transfer' product **18**, which is then subject to intramolecular attack by an immediately generated Zn^{2+}-bound OH^- in **19**. The reactions led eventually to a very stable Zn^{2+}-bound phosphomonoester anion complex **20**. Here, we see the appearance of various anions each having different dynamic behaviour in neutral aqueous solution during the reaction processes.

A dinuclear zinc(II) cryptate **21** is a potential receptor of phosphomonoester dianions such as 4-nitrophenyl phosphate (NP^{2-}), although the two Zn^{2+} ions (separated at a distance of 3.42 Å) in the cryptate appear coordinatively saturated in a rigid five-coordinate configuration.[33] However NP^{2-} can transiently bind to **21** at pH *ca.* 6 in aqueous solution to give **22** and cleavage of the P–O ester bond by nucleophilic attack of one of the apically coordinated NH groups yields the phosphoramide product **23** (Scheme 6). The driving force for the recognition by the two Zn^{2+} centres in **22** arises from formation of the stable zinc(II)–phosphate O^- bonds in **23**.

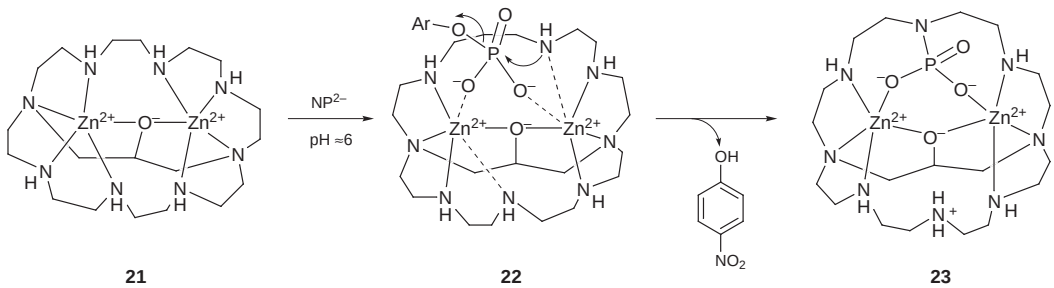
3 Application of anion complexes for recognition of Zn^{2+} and weakly acidic neutral molecules

Just like H_2O and alcohols, other weak acids, *e.g.* aromatic sulfonamides (pK_a *ca.* 10) are deprotonated at physiological pH by macrocyclic polyamine zinc(II) complexes. The recognition



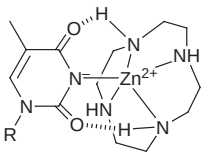
of the deprotonated sulfonamide anion by Zn^{2+} in **24** is a good chemical model designed to explain the inhibition of carbonic anhydrase by aromatic sulfonamides.[34] Attachment of a dansylamide pendant to cyclen **25** has led to a very sensitive and selective fluorescent probe for Zn^{2+} at neutral pH in aqueous solution (owing to formation of **26**).[35] The Zn^{2+}-dependent fluorescence with 5 μM **25** (at pH 7.3) is quantitatively responsive to 0.01–5 μM concentrations of Zn^{2+}, and is unaffected by the presence of mM concentrations of biologically important metal ions such as Na^+, K^+, Ca^{2+} and Mg^{2+}. The zinc fluorophore **25** forms a far more stable 1 : 1 Zn^{2+} complex (K_d = 6×10^{-13} mol dm^{-3} at pH 7.8) than any previously prepared zinc fluorophore[36] and can be regarded as a new prototype of zinc fluorophore.

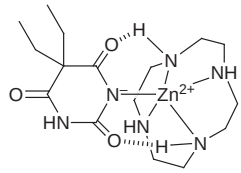
The zinc(II)–cyclen complex **8a** can act as a good anion receptor for imide-containing weakly acidic molecules at neutral pH in aqueous solution. Typical guests are thymidine (or



Scheme 6

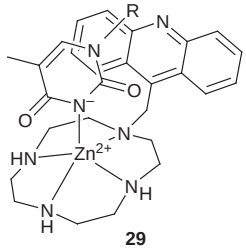
uridine) and barbiturates, which are deprotonated and form 1 : 1 complexes **27a**[37] and **28**[38] upon interaction with **8a**. Complexes **27a** and **28** result from Zn^{2+} deprotonating the imide protons





27a R = 2'-deoxy-1'-ribosyl
b R = 3'-azido-2',3'-dideoxy-1'-ribosyl

28

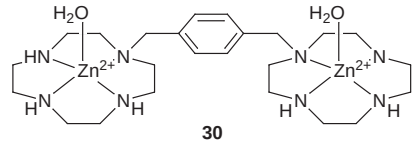


29

and the resulting Zn^{2+}–N^- (imide) bond is reinforced by the two complementary hydrogen bonds between the two imide oxygen atoms and two NH groups of cyclen; K_d values (at 25 °C) are 8×10^{-4} mol dm^{-3} for **27a** at pH 7.4 and 6×10^{-5} mol dm^{-3} for **28** at pH 8. The X-ray crystal structure of the AZT$^-$–[zinc(II)–cyclen] complex **27b** reinforces the stability of these complexes. The major stabilization comes from the Zn^{2+}–N^-(imide) bonding with the two hydrogen bonds providing a supplementary contribution. The zinc(II)–acridinylmethylcyclen complex binds 50 times more strongly with thymine, owing to an additional π–π stacking interaction (see **29**).[39] It is remarkable that zinc(II)–cyclen complexes preferentially recognize neutral thymine or uracil bases over biological anions such as phosphate monoanions in DNA or RNA.

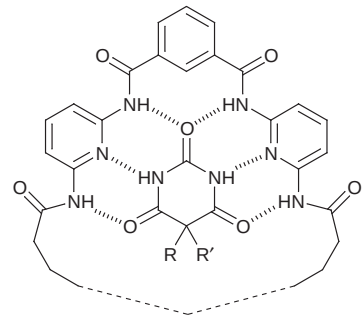
In the light of the fact that zinc(II)–cyclen yielded only the 1 : 1 complex **28** with barbital, although barbital potentially has two imide donor sites, a bis[zinc(II)–cyclen] connected with a *p*-xylene bridge **30** was synthesized to match the dianionic barbital anion.[40] A number of host molecules (*e.g.* **31**[41]) have been synthesized for barbiturates; however, such barbiturate–host complexes are stable only in non-aqueous environments (*e.g.* $K_d = 10^{-2}$–10^{-6} in $CDCl_3$ for **31**): and they dissociate immediately in aqueous solution. Potentiometric pH titration of **30** and barbital (both at 1 mM) led to extremely facile deprotonation of the two imide groups at pH < 7, leading to the formation of the 1 : 1 complex barbital^{2-}–bis[zinc(II)–cyclen] **32**.[40] From an aqueous solution of an equimolar mixture of **30** and barbital at pH 8, a cyclic 2 : 2 complex **33** was isolated and characterized by X-ray crystal analysis. An NMR study of isolated **33** in 10% (v/v) D_2O–H_2O revealed the dissociation of **33** into the original target 1 : 1 complex **32**, establishing a dimerization constant K of $10^{3.4}$ dm^3 mol^{-1} for **32** + **32** ⇄ **33**. Thus, **30** was established to be an excellent host for barbital at neutral pH in aqueous solution.

The acridine-pendant complex, zinc(II)–acridinylmethylcyclen (*cf.* thymidine complex **29**) also acts as a selective host molecule for terephthalic acid by supramolecular self-assembly.[42] In neutral pH aqueous solution, zinc(II)–acridinylmethylcyclen yields a 1 : 1 complex with terephthalate with dissociation constant $K_d = 10^{-2.3}$ mol dm^{-3} at 25 °C. Despite its relatively weak affinity, crystalline **34** [a ternary complex of one terephthalate and two zinc(II)–acridinylmethylcyclen molecules] precipitated almost quantitatively when zinc(II)–acridinylmethylcyclen (10 mM) was mixed with terephthalic acid (5 mM) in an aqueous solution containing excess ClO_4 at pH 8.4. It was found that zinc(II)–acridinylmethylcyclen selectively separates terephthalate as insoluble

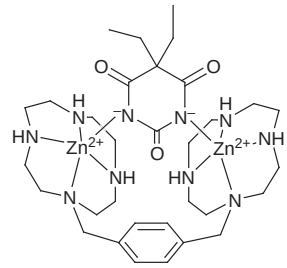


30

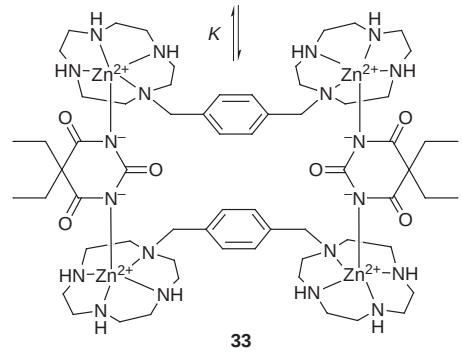
Bis(Zn^{2+}-cyclen)



31



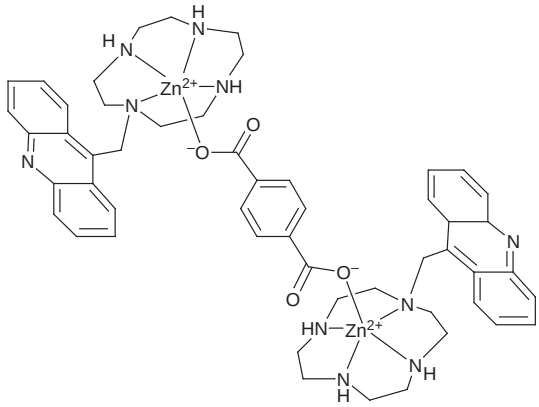
32



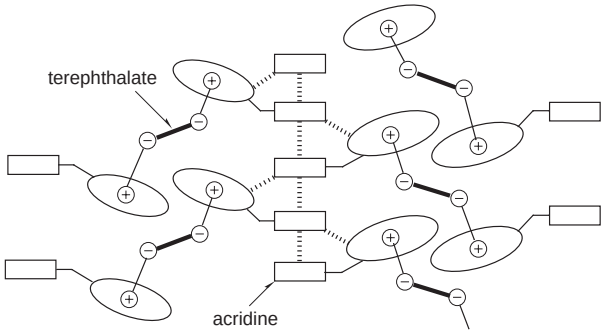
33

crystals of the 2 : 1 complex **34** from a mixture with its isomers (*o*- and *m*-phthalate). This is a consequence of the fact that **34** in the solid state is additionally stabilized by self-assembly in a highly ordered aggregate with π–π stacking (schematic representation **35**), as revealed by X-ray crystal analysis. Metal complexes with aromatic pendants like zinc(II)–acridinylmethylcyclen would be useful for the molecular recognition of other anionic molecules in aqueous media.

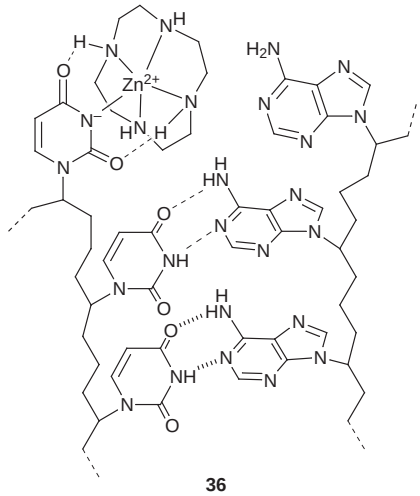
The recognition of thymine (or uracil) by zinc(II)–cyclens has been extended to a single-stranded polynucleotide poly(U) and double-stranded poly(U)–poly(A).[43–46] The affinity constant of zinc(II)–cyclen **8a** for each N^3-deprotonated uracil base in poly(U) is $K = 10^{5.1}$ dm^3 mol^{-1} at 25 °C, which is almost the same ($10^{5.2}$ dm^3 mol^{-1}) for the interaction of zinc(II)–cyclen and N^3-deprotonated uridine. This fact imples that zinc(II)–cyclen shows a negligible interaction with the monoanionic phosphodiester backbone of poly(U). Moreover, zinc(II)–cyclen disrupts U–A hydrogen bonds to unzip the duplex of poly(U)–poly(A) (see **36**), as demonstrated by the decreasing melting temperatures (T_m) of poly(U)–poly(A) in aqueous solution at pH 7.6 (5 mM Tris-HCl, 10 mM NaCl) with an increase in the concentration of zinc(II)–cyclen. A bidentate host molecule, bis[zinc(II)–cyclen] **30**, is a more potent zipper of the poly(U)–poly(A) double strand. Very recently, we have determined an



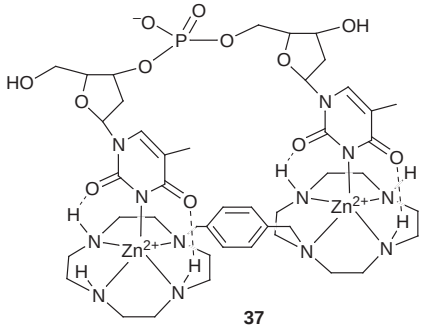
34



35



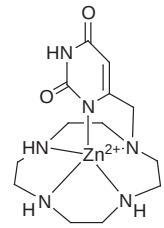
36



37

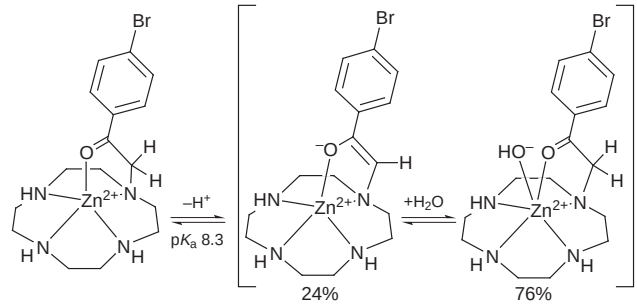
extremely strong interaction of bis[zinc(II)–cyclen] with thymidinylthymidine (TpT) in aqueous solution at pH 7.4 to yield a much more stable complex **37** *cf.* T$^-$–[zinc(II)–cyclen] **27a**.[47] The dissociation constant K_d of 10^{-6} mol dm^{-3} for **37** is almost 10^3 times smaller than that for **27a** ($K_d = 8 \times 10^{-4}$ mol dm^{-3}). This fact, along with the widened T–T plane distance (*ca.* 10 Å) determined by molecular mechanics calculation (MM2) well accounts for the more effective disruption of the poly(U)–poly(A) double strand by **30**. Thus, **30** can act as a useful TpT sequence-selective ligand in biochemical applications.

In section 1, it was stated that uracil N^{1}H is two orders of magnitude more acidic when proximate to a diprotonated macrocyclic tetraamine (see **5** and **6**). When Zn^{2+} is used in place of the two protons in **5**, the acidic Zn^{2+} in the cyclen exerts an even stronger effect on the deprotonation of the uracil N^{1}H to below pH 5.[14] The resulting zinc(II) complex **38** contains a very stable Zn^{2+}–(N^1)$^-$ coordination bond.



38

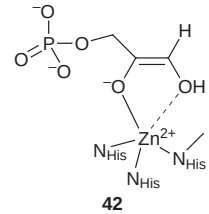
Finally, the acidic Zn^{2+} centre in the substituted cyclen ligand 1-(4-bromophenacyl)-1,4,7,10-tetraazacyclododecane **39** has recently been found to deprotonate a methylene hydrogen adjacent to the carbonyl group to yield an enolate complex **40** in aqueous solution (Scheme 7), which is in equilibrium with an



39 **40** **41**

Scheme 7

equivalent OH$^-$-bound complex **41** (ratio of **40**:**41** = 24:76).[48] Surprisingly, its pK_a value is as low as 8.3 at 25 °C (I = 0.1, $NaNO_3$), which is probably the first successful identification of enolate formation in aqueous solution. It is of interest to note that type II aldolase is a zinc enzyme, which also forms an enolate-bound zinc(II) complex (see **42**).[20]



42

4 Conclusions

This article illustrates that macrocyclic polyamines either in multiprotonated forms or in zinc(II) complexes act as static anion receptors in aqueous solution. The macrocyclic 12-membered N_3– or N_4–Zn^{2+} complexes can, moreover, recognize netural molecules having weak acid protons to yield stable

anion complexes. These anion complexes possess dynamic functions as exemplified by HO^{-}–Zn^{2+} and RO^{-}–Zn^{2+} acting as strong nucleophiles for catalytic hydrolysis of esters or as bases for thymine recognition. This basic principle has been further developed to hydride transfer reactions from Zn^{2+}-bound alkoxides, a Zn^{2+} sensor, DNA base recognition, or stabilization of unusual anions such as enolate in aqueous solution.

Exchanged ligands on the surface of a giant cluster: $[(MoO_3)_{176}(H_2O)_{63}(CH_3OH)_{17}H_n]^{(32-n)-}$

Achim Müller,*† Michael Koop, Hartmut Bögge, Marc Schmidtmann and Christian Beugholt

Fakultät für Chemie der Universität, D-33501 Bielefeld, Germany

The synthesis of 1a·(32 − *n*)Na^+·*ca.* 600 H_2O·*ca.* 30 CH_3OH 1 containing the ring-shaped, mixed-valence (Mo^V/Mo^{VI}) cluster $[(MoO_3)_{176}(H_2O)_{63}(CH_3OH)_{17}H_n]^{(32-n)-}$ 1a as a discrete unit in the crystal lattice is reported, which for the first time yields a compound of this type *via* a facile synthetic method and without amorphous reaction products; remarkably, H_2O ligands can be replaced by CH_3OH on the surface of a giant metal-oxide based cluster which has a nanometer sized cavity and, in contrast to zeolites, reducing properties.

Early reports on the giant reduced ring-shaped, metal-oxide cluster $[Mo_{154}(NO)_{14}O_{420}(\mu_3\text{-}O)_{28}(H_m)_{14}(H_2O)_{70}]^{(42-n)-}$ **2**[1,2] and more recently on the even larger analogue $[(MoO_3)_{176}(H_2O)_{80}H_n]^{(32-n)-}$ **3**[3] (a reduced, protonated giant molecular molybdenum oxide with H_2O ligands), have shown the difficulties associated with the synthesis, isolation, identification and characterization of such systems, especially of the *m* and *n* values which correspond to the different protonations; see below.[1–4] Here we report a facile synthetic method for the pure crystalline blue mixed-valence compound (type III according to the Robin–Day classification)[5] **1a**·(32 − *n*)Na^+·*ca.* 600 H_2O·*ca.* 30 CH_3OH **1** containing the discrete cluster $[(MoO_3)_{176}(H_2O)_{63}(CH_3OH)_{17}H_n]^{(32-n)-}$ **1a** with CH_3OH ligands.‡ In contrast, all previously reported compounds of this type were obtained only under less lucid reaction conditions and not completely in crystalline form.

1 was simply prepared by addition of a methanolic solution of $MoCl_5$ to an acidified solution of molybdate§ and characterized by elemental analysis, single crystal X-ray structure analysis¶ [including bond valence sum (BVS) calculations for determination of the positions of the H atoms and the (formal) number of Mo^V centres], vibrational as well as VIS–NIR spectra, and redox titrations for the (additional) determination of the (formal) number of Mo^V centres.

The single crystal X-ray structure analysis¶ of compound **1** shows eight ring-shaped clusters in the unit cell, the (large) volume of which is comparable to that of protein structures (Fig. 1). The rings are packed only approximately parallel to the *a*,*b* plane, whereby they are tilted slightly relative to one another along the *a* and *b* axes. The cluster **1a** (Fig. 2) consists of sixteen sets of the three characteristic building blocks[2,6] $\{Mo_2\}$, $\{Mo_8\}$ and $\{Mo_1\}$ corresponding to the formula of the hexadecameric cluster $[\{Mo_2\}\{Mo_8\}\{Mo_1\}]_{16}$ ($\equiv[\{Mo^{VI}{}_2O_5(H_2O)_2\}\text{-}\{Mo^{VI/V}{}_8O_{26}(\mu_3\text{-}O)_2(H_m)L_3Mo^{VI/V}\}]_{16}$ with L = H_2O, CH_3OH and *m* = 0, 1 or 2 corresponding to the overall charge related to *n* = 0, 16 or 32).‡ The positions of the CH_3OH ligands in **1a** can be best described by referring to the sixteen characteristic Mo_6O_6 rings which are formed by two adjacent $\{Mo_8\}$-type units and one $\{Mo_2\}$ group. In every such Mo_6O_6 ring but three, a CH_3OH ligand is found coordinated to one or two Mo centres, respectively (for details see Fig. 2; referring to the packing in the crystal structure, the CH_3OH ligands are located at regions in the direct neighbourhood of adjacent rings).

Whereas **1a** is a mixed-valence cluster with an *S* = 0 spin ground state but no metal–metal bonds, the (rather) large diamagnetic mixed-valence $\{Mo_{43}\}$-type cluster[7] $[H_{13}Mo_{43}O_{112}\{(OCH_2)_3CCH_3\}_7]^{9-}$ contains 'dumb-bells' or pairs of covalently bonded Mo^V centres. On the other hand, in the largest reported polyoxotungstate $[Ln_{16}As_{12}W_{148}O_{524}(H_2O)_{36}]^{76-}$ all the W centres exist in completely oxidized W^{VI} form.[8]

The fast formation of cluster **1a** as well as the subsequent crystallization of compound **1**, free from amorphous precipitates, is facilitated not only by the use of aqueous methanol as solvent (with lower solubility than in water, as was used in previous preparation methods) but also by the addition of a solution containing Mo^V centres which become direct constituents of the reaction product **1**. In this context it should be mentioned that generations of chemists have tried to isolate crystals from molybdenum-blue solutions without success.[9,10] Another important result of the present study is that it is in principle possible to substitute ligands on the reducing surface of a giant metal-oxide based cluster with the possible consequence of influencing the activation of the ligands.

We thank F. Peters for his assistance. The financial support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

‡ The cluster charge 32 − *n* corresponds to the difference between the (formal) number of Mo^V centres (32 according to redox titrations and Mo-BVS values) and the number of protonations at the 32 μ_3-O atoms having BVS values of 1.20 ± 0.05. As these are practically constant in *ca.* 20 related structures in the corresponding $(\mu_3\text{-}O)_2O_2$ tetrahedra (see Fig. 2) we have an identical situation in all compounds which have either two, one or no protons in each such tetrahedron corresponding to *n* = 32, 16 or 0; but *n* = 28, 14 or 0 in tetradecameric species like **2**. The determination of the exact formula and the charge of the large investigated protonated mixed-valence cluster by single-crystal X-ray structure analysis therefore presents an almost invincible problem, in particular as charged lattice components like Na^+ located in cavities and channels and large amounts of crystal water molecules or solvent molecules cannot be clearly localized due to disorder phenomena. The analytical data, however, also have only limited accuracy because the concentration of the mentioned charged lattice components is very small (but not the number of ions in the formula unit!) and because the

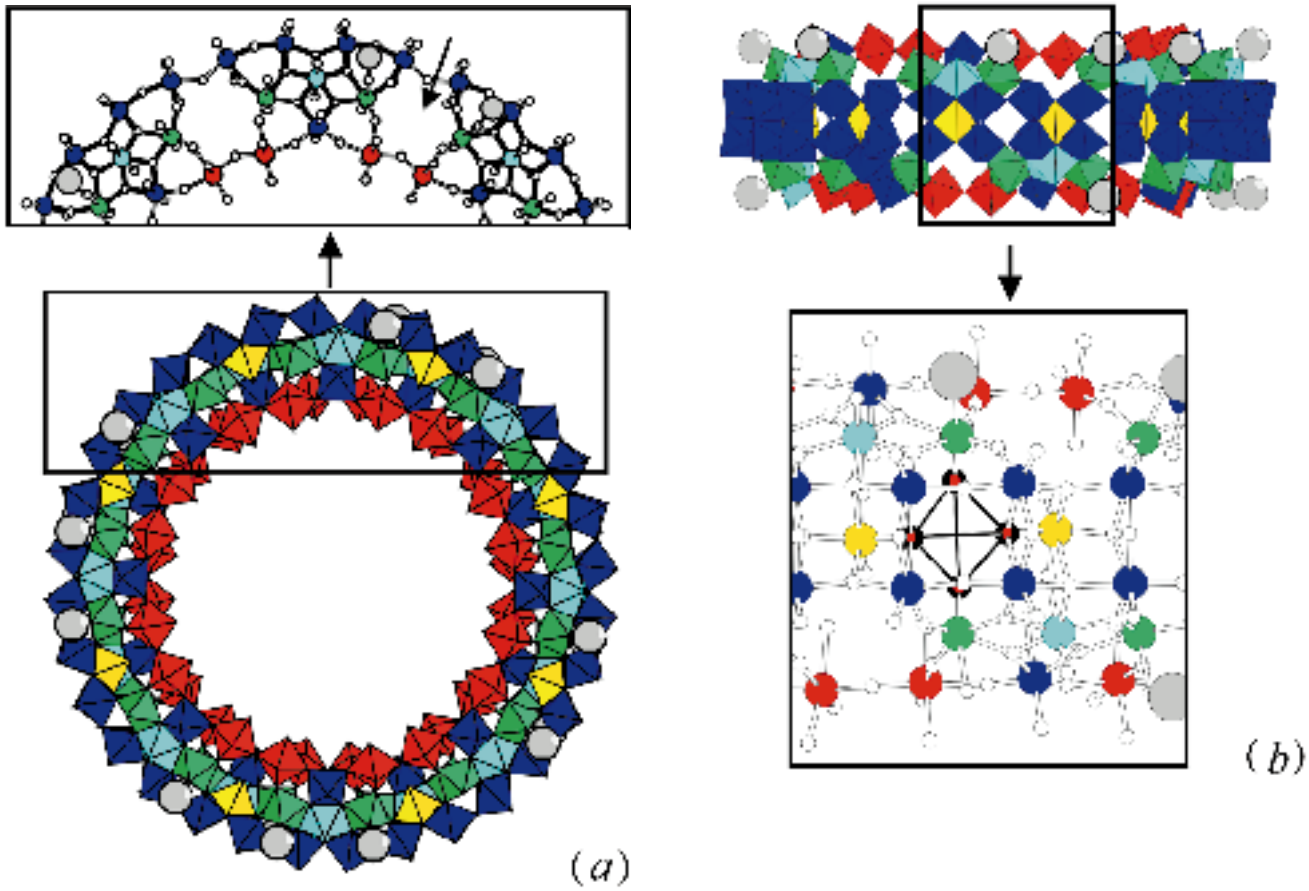

Fig. 2 Polyhedral representations of the structure of **1a** in two perspectives. (*a*) Top view, including an additional enlarged segment in ball-and-stick representation depicting the {Mo_8}-type units and {Mo_2} groups forming the Mo_6O_6 rings (see arrow) on the upper half of the cluster structure, showing the typical positions of the CH_3OH ligands with respect to the {Mo_8} units, as well as the twelve–membered rings. (*b*) Side view including an enlarged segment in ball-and-stick representation showing one of the sixteen $(\mu_3\text{-}O)_2O_2$ tetrahedra (highlighted by black lines) between two incomplete double-cubane-type fragments formed by five Mo and the related six O atoms of the {Mo_8} and {Mo_1} units, whereby the two μ_3-O atoms, highly accessible for protonation, are coordinated to (partly reduced) Mo centres. ({Mo_8} units: blue with the central pentagonal bipyramids (light blue) and the MoO_6 octahedra (green) at the right and left sides of these as (possible) coordination sites for the CH_3OH ligands; {Mo_2} units: red; {Mo_1} units: yellow; C atoms of CH_3OH ligands: grey; O atoms forming the $(\mu_3\text{-}O)_2O_2$ tetrahedron in the enlarged segment of (*b*): red connected by black lines).

large content of solvent molecules in the structure varies due to pronounced weathering. In any event, we consider an *n* value of 16 for the hexadecameric clusters **1a** and **3** (*n* = 14 for tetradecameric species) to be most suitable according to the sodium analysis together with the (only) possible *n* values.

§ A solution of $MoCl_5$ (0.5g; 1.83 mmol in 13.2 ml dry CH_3OH) was added dropwise to a stirred aqueous solution of $Na_2MoO_4{\cdot}2H_2O$ (2.01 g; 8.3 mmol in 18.5 ml H_2O) acidified with 1.0 ml 25% hydrochloric acid. The resulting blue solution was subsequently adjusted with 10% hydrochloric acid to pH 1.4 and stored under exclusion of air. Blue tetragonal-prismatic crystals which precipitated from the filtrate within 4 days were filtered and dried quickly in an argon stream. Yield: 0.64 g, 31.6% based on $MoCl_5$ used. Found: Na, 1.00; C, 1.51; H, 3.85 (Cl, 0.2). Calc.: Na, 0.94 (for 16 Na); C, 1.44; H, 3.94%. Subtraction of the estimated volume of the structurally localized atoms (using increments) from the total volume of the unit cell shows that a maximum of *ca.* 600 crystal water molecules can in principle be present per formula unit. **1**, however, loses a large amount of solvent molecules (about 60%) due to extremely strong and rapid weathering even at room temperature within 2 h. The analytical data which could therefore only be obtained for the partly weathered compound are corrected for this effect (based on time-dependent TG measurements), so that they can be compared to the calculated values which refer to the compound with the maximum crystal water content. Chemically amplified photolithography of a conjugated polymer

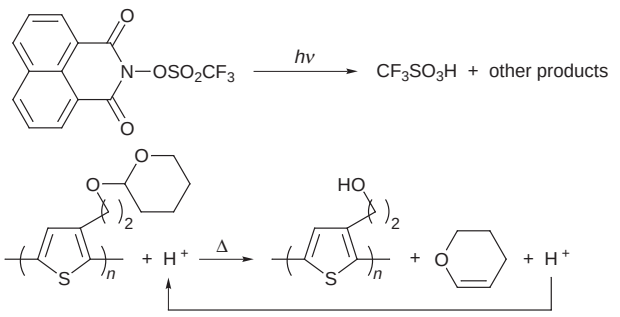
Jianfei Yu, Michael Abley, Cheng Yang and Steven Holdcroft*†

Department of Chemistry, Simon Fraser University, Burnaby, BC, Canada V5A 1S6

The solid state photocatalytic reaction between trifluoromethanesulfonic acid and poly{3-[2-(tetrahydropyran-2-yloxy)ethyl]thiophene} is employed to fabricate polymeric patterns of conjugated polymer.

Microelectronic technologies routinely image polymer films using photolithography. Similar techniques have been employed to deposit conjugated polymers because of their attractive microelectronic and optoelectronic properties.[1] Here we describe a strategy which enhances the photoreactivity of conjugated polymers and facilitates their photolithography. The concept uses chemical amplification which was first demonstrated in photolithography with polystyrene based polymers.[2] The first example of chemical amplification in the photolithography of a conjugated polymer is demonstrated below (Scheme 1) for a polythiophene derivative possessing pendant THP functionality in the presence of a photoacid generator (PAG).

Poly{3-[2-(tetrahydropyran-2-yloxy)ethyl]thiophene} (PTHPET) was synthesized by the following procedure. 2-(3-Thienyl)ethanol was brominated selectively with 1 equiv. of NBS in DMF, and was protected by reacting with 5 equiv. of dihydropyran to afford 2-bromo-3-[2-(tetrahydropyran-2-yloxy)ethyl]thiophene.[3] The regioregular polymer PTHPET was prepared by cross-coupling of the corresponding 5-Grignard reagent.[4] The polymer was precipitated and purified from MeOH. The structure of the polymer was confirmed by NMR spectroscopy: resonance peaks in the ^{1}H NMR spectra centered at 7.12, 4.56 and 3.09 ppm were assigned to the thienyl ring, the methine of the THP moiety, and the α-methylene, respectively.[3a] Eleven resonance peaks were observed in the ^{13}C NMR spectra. Four peaks at 129.5, 132.0, 133.7 and 136.5 ppm were assigned to thienyl ring carbons.[4] The observed peaks at 98.8, 19.5, 25.6, 30.7 and 62.1 ppm are characteristic of the THP group.[5] Peaks at 30.0 and 67.1 ppm were assigned to α- and β-methylene carbons, respectively. The regioregularity of the polymer is evidenced by the fact that only four aromatic carbon signals and only one α-methylene carbon signal were observed. Molecular weight and molecular weight distribution were measured by GPC in THF solution and calibrated against poly(3-hexylthiophene) standards:[6] M_w = 1.15 × 10^4, M_w/M_n = 1.73. The photoacid generator, *N*-(trifluoromethylsulfonyloxy)-1,8-naphthalimide, was a gift from the IBM Research Division, San Jose, CA.



Scheme 1 Reaction scheme for chemically amplified photolithography of PTHPET

PTHPET is thermally stable up to ~220 °C whereupon a 30% weight loss was observed between 220 and 275 °C by TGA. The weight loss is consistent with the deprotection scheme shown in Scheme 1 in the absence of a catalytic proton. When mixed with trifluoromethanesulfonic (triflic) acid (5 mol% based on the thienyl unit), films of PTHPET are chemically stable at room temperature. However, upon heating, the deprotection temperature for the polymer was lowered to 120 °C. Furthermore, deprotection is complete indicating that the reaction is catalyzed by the presence of acid.

Upon thermolysis of PTHPET in the presence of triflic acid, FTIR showed the emergence of a broad signal at ~3400 cm^{-1} due to –OH. This occurred concomittently with the deprotection temperatures determined by TGA. There was also a significant decrease in the signals due to the THP group. Cleavage of THP from PTHPET gave rise to dramatic changes in the absorption spectra. PTHPET alone yielded classical reversible thermochromism between 20 and 210 °C (Fig. 1) but in the presence of 5 mol% triflic acid, λ_{max} dramatically increased at 130 °C upon heating. The red-shift is explained by the sudden release of steric hindrance caused upon elimination of the bulky THP group. The absorption spectra and λ_{max} became independent of temperature upon further heating or subsequent cooling cycles which is consistent with the increase in compactness associated with the shorter side-chain polymer and/or the existence of strong hydrogen bonding between ethanolic side-chains.

PTHPET is completely soluble in common organic solvents, whereas the resultant polymer following cleavage is not. This is the result of a significant change in the length and polarity of the side-chain. This observation, in conjunction with the acid-catalyzed nature of the deprotection process, gave the impetus to examine chemically amplified photolithography of PTHPET in the presence of a photoacid generator (Scheme 1). Films of PTHPET containing 20 mol% of the PAG were cast from THF solution. The PAG exhibited a broad absorption spectrum, λ_{max} 336 nm, and generates triflic acid when irradiated. Films were irradiated with UV–VIS light from a 1000 W Xe lamp through a 361 nm broadband filter with an irradiation intensity of 0.18 mW cm^{-2}. The temperature dependant absorption spectra of

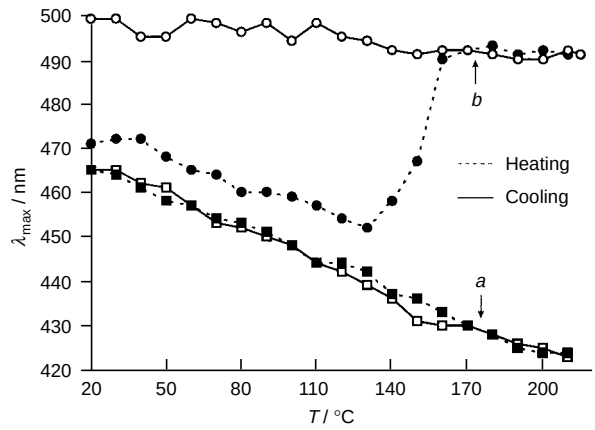


Fig. 1 Temperature dependence of λ_{max} for films of PTHPET (*a*) in the absence, and (*b*) presence of 5 mol% triflic acid

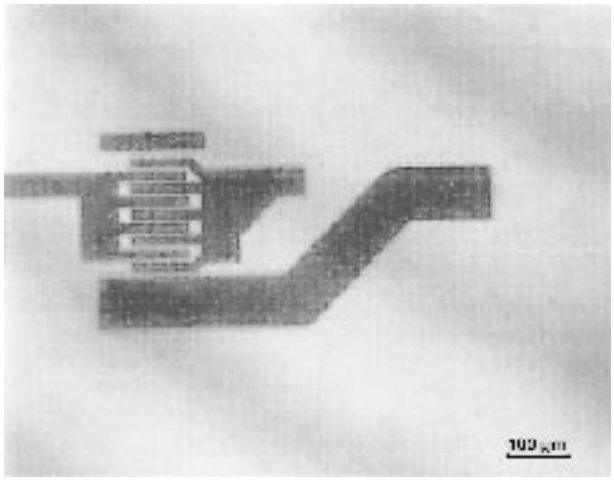

Fig. 2 Micrograph of conjugated polymer obtained by chemically amplified photolithography

photolyzed composite films was recorded following irradiation and showed a dramatic red-shift λ_{max} at 120 °C, *i.e.* similar to that observed for films containing triflic acid (Fig. 1). This is strong evidence for the catalytic cleavage of THP initiated through photogeneration of triflic acid. FTIR confirmed the reaction and the resultant photolyzed films were insoluble in common organic solvents.

Chemically amplified photolithography was demonstrated by irradiating similar composite films (~ 300 nm thick) through a photomask. The films were subsequently heated to 125 °C for 2.5 min and developed with THF, whereupon only the unexposed polymer dissolved. A patterned image of the conjugated polymer is presented in Fig. 2. The resolution of the smallest features is 15 μm and is limited by the optical apparatus. Due to the catalytic nature of this reaction relatively low irradiation doses were required for imaging (65 mJ cm^{-2}). Thus, the degree of photobleaching of the polymer was negligible. Conductivity measurements on the photochemically deprotected polymer doped with a variety of oxidants yielded conductivities very similar (1–4 S cm^{-1}) to the triflic acid deprotected polymer, confirming that π-conjugation was retained.

Spectroscopic, thermogravimetric, solubility and microscopic analyses confirm the reaction presented in Scheme 1. The reaction does not proceed in the solid state at room temperature at an appreciable rate. Upon heating, the reaction rate is increased either through an increase in free volume of the polymer and/or an increase in the rate constant. This is a favourable observation since it infers that the spatial extent of the imaging chemistry can be controlled following irradiation. Studies are underway to determine the electronic, optical and photonic properties of micron-sized polymeric patterns fabricated using this and similar chemical schemes.

We thank the Natural Sciences and Engineering Research Council of Canada for financial support and Dr R. D. Miller, IBM Research Division, San Jose, CA for generously providing photoacid generators.

Radical cyclisation of carbohydrate alkynes: synthesis of highly functionalised cyclohexanes and carbasugars

Elise Maudru,[a] Gurdial Singh*[a]† and Richard H. Wightman*[b]

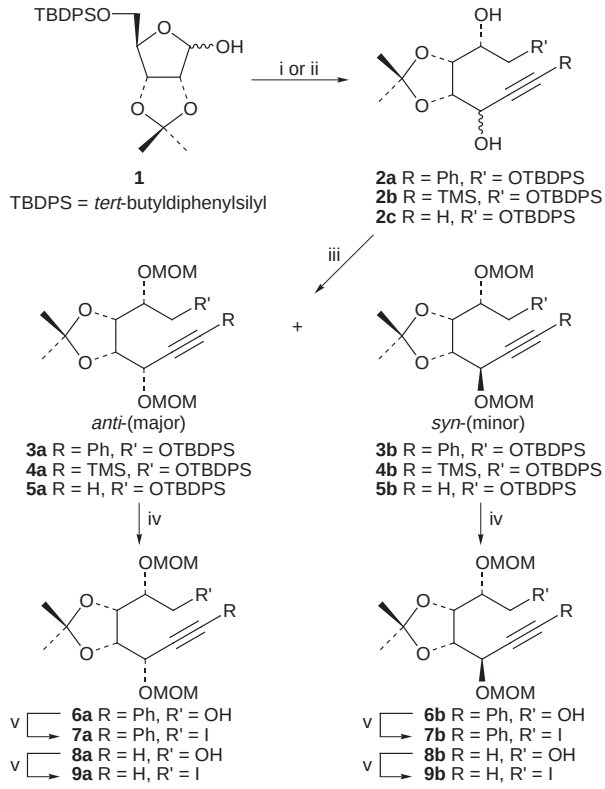
[a] *Department of Chemistry, University of Sunderland, Sunderland, UK SR1 3SD*
[b] *Department of Chemistry, Heriot-Watt University, Edinburgh, UK EH14 4AS*

Carbohydrate alkynes undergo 6-*exo* radical cyclisation to afford cyclohexanes resulting in the synthesis of carbasugars.

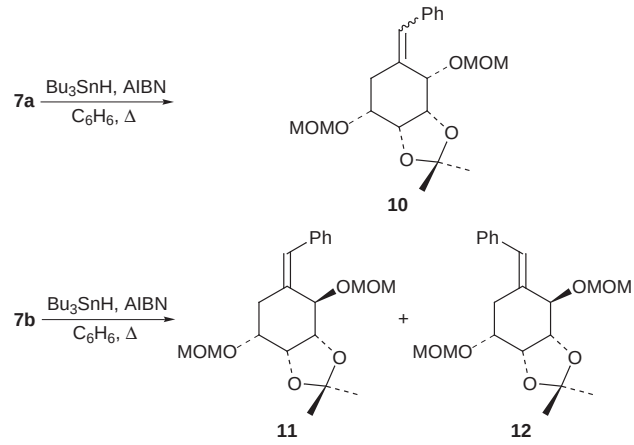
The use of carbohydrates as synthetic precursors of many functionalised carbocyclic compounds is widespread.[1] The first conversion of a sugar to a cyclohexane ring involved the preparation of nitroinositols from 6-deoxy-6-nitrohexose.[2] In the intervening years there have been numerous examples of the use of radical chemistry for the synthesis of cyclopentane derivatives,[3] with notable work in the carbohydrate area coming from the Fraser-Reid group.[4] It is thus surprising that there are few examples of the preparation of six-membered aliphatic rings employing radical cyclisation onto an alkyne.[5] Some reasons for this can be inferred from work on cyclisations of ω-alkenyl radicals. The formation of six-membered rings by radical chain reactions involving 6-*exo* cyclisation is some 40 times slower than that of the hex-5-enyl cyclisation.[6] The consequence of this is that chain transfer by attack of the acyclic radical on the stannane usually present is a much more effective process than with the hex-5-enyl radical. The second problem is that 1,5-hydrogen abstraction leading to a resonance stabilised allyl radical is favourable and in fact this can become synthetically useful.[3b]

We have been interested in the development of 6-*exo* cyclisations of alk-6-ynyl radicals as these would allow the preparation of heavily substituted hydroxycyclohexanes and of carbasugars. In this regard we chose to prepare alkynes derived from D-ribose[7] and to investigate their chemistry. Treatment of the protected silyl-D-ribose derivative **1** with lithium phenylacetylide afforded an inseparable diastereomeric mixture of the diols **2a** in 90% yield (Scheme 1). The protection of both the hydroxy groups as methoxymethyl (MOM) ethers[8] proceeded in a yield of 89% and allowed chromatographic separation of the diastereomers **3a** and **3b** with an *anti*:*syn* ratio of 3 : 2. Alternatively the *syn* isomer **3b** could be prepared almost exclusively using D-ribonolactone as the starting material.[9] Desilylation of **3a** was effected with TBAF in THF in 92% yield and afforded the primary alcohol **6a** which was converted to the corresponding iodide **7a** in 76% yield with triphenylphosphine, imidazole and iodine.[10] Similar chemistry with the isomer **3b** gave the alcohol **6b** and subsequently the iodide **7b** in comparable yields. With both the iodides **7a** and **7b** in hand we investigated their radical cyclisation reactions. Treatment of the iodide **7a** with tri-*n*-butyltin hydride in refluxing benzene in the presence of AIBN effected the 6-*exo* cyclisation affording only the substituted cyclohexanes **10** in 93% yield (Scheme 2) as an inseparable mixture of *E* and *Z* geometric isomers in a ratio of 1 : 1 as determined by ^{1}H NMR analysis. Analogous reaction of the diastereomer **7b** afforded the corresponding cyclohexanes **11** and **12** in 70% yield. In this case we were able to separate the *E* and *Z* stereoisomers by chromatography, in a ratio of 2 : 3. The major isomer **11** was assigned the *Z* geometry about the double bond on the basis of NOE experiments.

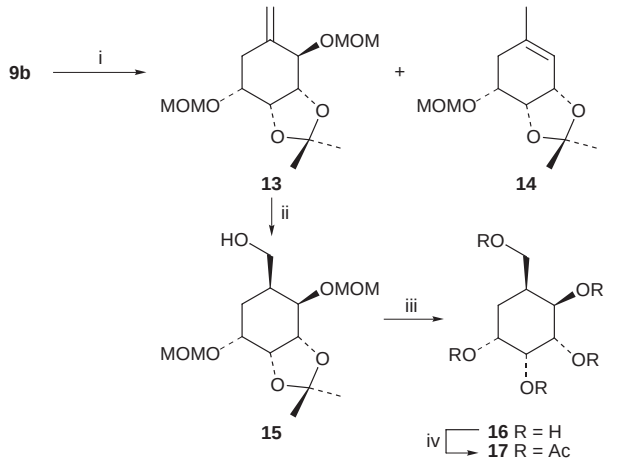
Having been successful in our initial goal we turned our attention to the syntheses of compounds with an unsubstituted *exo*-methylene group. Thus the protected ribose **1** was treated with lithium trimethylsilylacetylide in THF and afforded the diols **2b**, in a combined yield of 45% along with the alkynes **2c**, in 28% yield. The diastereomeric mixture **2b** was converted to



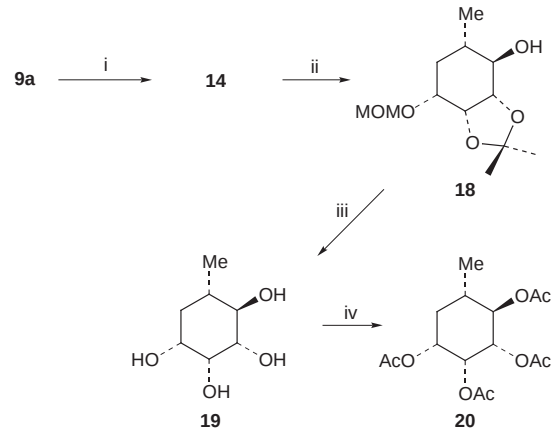
Scheme 1 *Reagents and conditions:* i, LiC≡CPh, THF, −78 °C; ii, LiC≡CTMS, THF, −78 °C; iii, MOMCl, NEt_2Pr^i, CH_2Cl_2, RT; iv, Bu_4NF, THF, RT; v, I_2, PPh_3, Im, PhMe, Δ



Scheme 2



Scheme 3 *Reagents and conditions:* i, Bu_3SnH, AIBN, PhH, Δ; ii, BH_3–Me_2S, THF; 0 °C, H_2O_2, NaOH; iii, 6 M HCl, MeOH; iv, Ac_2O, Py, RT



Scheme 4 *Reagents and conditions:* i, Bu_3SnH, PhH, AIBN, Δ; ii, BH_3–Me_2S, THF; 0 °C, H_2O_2, NaOH; iii, 6 M HCl, MeOH; iv, Ac_2O, Py, RT

the MOM ethers **4a** and **4b** that could be separated in a combined yield of 71% with an *anti*:*syn* ratio of 3.5 : 1. Both of these diastereomers were processed separately. Desilylation of **4a** and **4b** gave the corresponding primary alcohols **8a** and **8b** in 91 and 96% yields respectively. These compounds were identical to those obtained from **2c** after the diastereoisomers had been subjected to protection by MOM chloride to afford **5a**, **5b** and desilylation, the *anti*:*syn* ratio being 3 : 1. The *syn*-product was correlated with material prepared from the pure *syn*-isomer **2c**, which we have described in our earlier report.[9] The alcohols **8a** and **8b** were converted smoothly to the corresponding iodides **9a** and **9b** in 71 and 78% yields respectively. At this juncture we were in a position to study the 6-*exo* radical cyclisation of these iodides. Thus (Scheme 3) the *syn* isomer **9b** was treated with tri-*n*-butyltin hydride and AIBN in refluxing benzene and afforded the expected *exo*-methylene-cyclohexane **13** in 49% yield along with the cyclohexene **14** in 39% yield where the MOM group had been lost. The structure of **14** was clearly evident from the ^{1}H NMR spectrum which had resonances due to only one MOM group and in addition there was a resonance at δ 5.33 due to the vinylic proton and a resonance at δ 1.75 due to a methyl group. We next subjected the iodide **9a** to these conditions (Scheme 4) and we observed that in this case the cyclisation reaction was appreciably slower, taking 24 h to reach completion, but much cleaner in that only **14** was obtained in 99% yield. The formation of **14** can be rationalised by cyclisation of a primary radical in a 6-*exo* mode onto the alkyne, resulting in the formation of a vinyl radical which then abstracts a hydrogen from the methylene carbon of the MOM group followed by β-scission[11] resulting in an allylic radical which subsequently affords the observed product. The formation of **14** is a reflection of the geometry of the vinyl radical in that these are bent with a bond angle of *ca*. 135° whilst the α-phenyl substituted vinyl radical is linear.[12]

The *exo*-methylenecyclohexane **13** (Scheme 3) was hydroborated and gave after oxidation the primary alcohol **15** in 94% yield. Removal of the protecting groups of **15** with 6 M HCl gave carba-α-L-gulopyranose **16** whose spectral properties were in accord with those reported in the literature.[13] Additional structural proof was obtained by acetylation of **16** with excess acetic anhydride and pyridine which afforded the pentaacetate **17** in 100% yield. The cyclohexene **14** underwent hydroboration/oxidation (Scheme 4) with BH_3–Me_2S and afforded the protected carba-β-D-rhamnose derivative **18** in 77% yield. The stereochemistry of the newly formed chiral centres was *anti* with the C-4 hydroxy group β as a result of hydroboration occurring from the opposite face from the *O*-isopropylidene group, and this was confirmed by NOE experiments. Removal of the MOM and isopropylidene protection proceeded uneventfully with 6 M HCl and afforded the fully deprotected carba-β-D-rhamnose **19** in 99% yield. Further structural integrity of **19** was established by acetylation with excess acetic anhydride and pyridine which resulted in formation of the tetraacetate **20** in 99% yield.

We thank the EPSRC for access to central facilities for high resolution mass spectrometric data at the University of Wales, Swansea (Director, Dr J. A. Ballantine) and Professor W. T. Borden (University of Washington) for enlightening discussions regarding vinyl radicals. We thank Dr K. M. Morgan (Heriot-Watt University) for Monte Carlo Calculations.

Preparation and catalytic properties of single phase Ni–Sn intermetallic compound particles by CVD of $Sn(CH_3)_4$ onto Ni/silica

Ayumu Onda, Takayuki Komatsu*† and Tatsuaki Yashima

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152-8551, Japan

Particles of each of the single phase Ni–Sn intermetallic compounds Ni_3Sn, Ni_3Sn_2 and Ni_3Sn_4 have been formed on silica by chemical vapor deposition (CVD) of $Sn(CH_3)_4$ onto Ni/SiO_2 and used as catalysts for cyclohexane dehydrogenation.

We have previously reported unique catalytic selectivities of Co or Pt containing intermetallic compounds (IMCs) for the partial hydrogenation of acetylene[1] or buta-1,3-diene;[2] however, their catalytic activities suffered from low specific surface areas. It was reported that Sn–M (M = Rh, Pt, Pd or Ni) bimetallic catalysts were prepared by CVD of organotin complexes on M/SiO_2.[3–5] Tin species are deposited by the CVD method preferentially onto the particles of these noble metals. In this study, we applied the CVD method to prepare fine particles of single phase Ni–Sn IMCs on SiO_2, which were found to have unique catalytic selectivities in the dehydrogenation of cyclohexane.

Ni (5 wt%)/SiO_2 was first prepared by an incipient wetness method using $Ni(NO_3)_2$ and silica gel (Fuji-Silysia, Caliact 6), followed by reduction at 723 K in H_2. The average diameter of the Ni particles measured by TEM, XRD and chemisorption of H_2 was about 7 nm. CVD of $Sn(CH_3)_4$ (Soekawa Chemicals) onto Ni/SiO_2 was carried out at 373–523 K with flowing H_2 containing 33 Torr of $Sn(CH_3)_4$, followed by hydrogen treatment at 873–1173 K. The samples were dissolved in hydrochloric acid and the amounts of Ni and Sn were determined by ICP. Unsupported Ni–Sn IMCs were prepared by melting a mixture of Ni and Sn powders in an electric furnace at 1730 K under flowing argon, and the resulting ingot was crushed into 25–38 μm particles. A glass circulation system was used for the pretreatment of catalysts with H_2 and subsequent catalytic reactions.

CVD of $Sn(CH_3)_4$ was carried out at various temperatures for 1 h to prepare each Ni–Sn IMC (Ni_3Sn, Ni_3Sn_2 and Ni_3Sn_4). Fig. 1 shows the amount of deposited Sn as a function of CVD temperature on Ni/SiO_2 (*a*) or SiO_2 (*b*). The amounts of deposited Sn increased with CVD temperature on both supports.

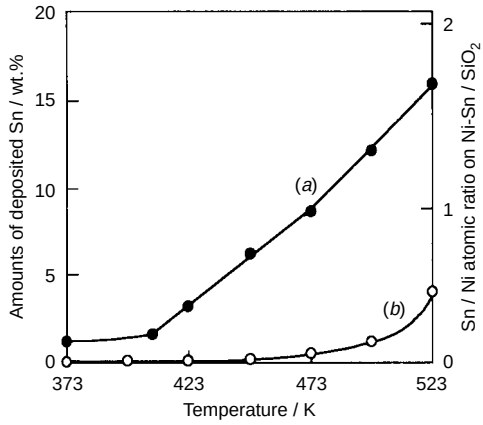

Fig. 1 Effect of CVD temperature on the amount of Sn supported by $Sn(CH_3)_4$ on Ni/SiO_2 (*a*) or on SiO_2 (*b*)

However, the amounts of deposited Sn on Ni/SiO_2 were much larger than those on SiO_2. In particular, no appreciable deposition of Sn was observed on SiO_2 below 423 K. $Sn(CH_3)_4$ was selectively decomposed on Ni particles owing to the high activity of Ni for the hydrogenolysis of $Sn(CH_3)_4$. When CVD of $Sn(CH_3)_4$ was carried out onto Ni/SiO_2 at 423, 448 and 498 K, the Ni/Sn atomic ratios of the samples became very close to 3/1, 3/2 and 3/4, respectively. If Sn atoms are deposited on the surface of Ni particles to form a few Sn layers, the Ni/Sn ratio must be much higher than unity. Therefore, during the CVD treatment, some of the deposited Sn atoms will enter into the bulk of the Ni particles after the hydrogenation of $Sn(CH_3)_4$ with the evolution of methane. In fact, the X-ray diffraction pattern of Ni–Sn/SiO_2 samples just after CVD included weak peaks of Ni–Sn IMCs in addition to those of Ni metal. Hydrogen treatment after CVD was then performed in order to form single phase Ni_3Sn, Ni_3Sn_2 and Ni_3Sn_4 particles.

Fig. 2 shows the X-ray diffraction patterns of the silica-supported Ni–Sn IMC (Ni/Sn = 3/1) after hydrogen treatment at 1173 K for 1 h (*a*) and of the unsupported Ni_3Sn powder (*b*). The supported sample did not show the same diffraction peaks as those of pure Ni supported on SiO_2 (*c*) and pure Sn supported on SiO_2 (*d*), but showed almost exclusively peaks at the same positions as those of unsupported Ni_3Sn. This result confirmed that single phase Ni_3Sn particles were formed on SiO_2 by the CVD and subsequent hydrogen treatment. Generally, Ni_3Sn is formed above 1730 K, because the melting points of Ni and Sn are 1730 K and 505 K, respectively. In this study, we succeeded in the formation of single phase Ni_3Sn particles by hydrogen treatment at much lower temperature after the CVD process.

The XRD measurements showed that single phase Ni_3Sn_2 and Ni_3Sn_4 particles were also formed on SiO_2 by hydrogen treatment at 873 and 723 K after CVD at 448 and 498 K, respectively. It is revealed that the lower the Ni/Sn ratio, the

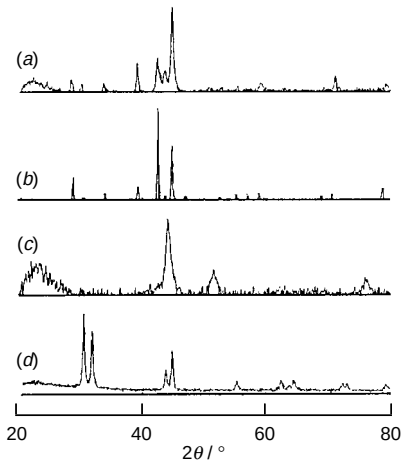

Fig. 2 XRD patterns of supported Ni–Sn IMCs (Ni/Sn = 3/1) on SiO_2 prepared by CVD after hydrogen treatment at 1173 K for 1 h (*a*), unsupported Ni_3Sn (*b*), Ni/SiO_2 prepared by the incipient wetness method after reduction (*c*) and Sn/SiO_2 prepared by CVD of $Sn(CH_3)_4$ on SiO_2 (*d*)

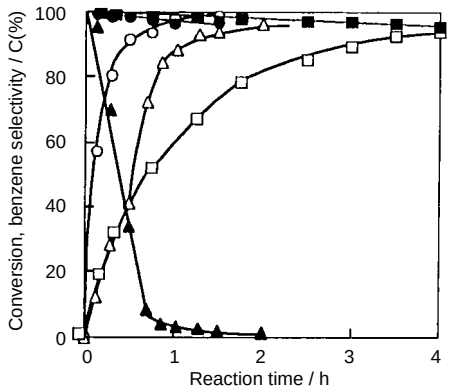

Fig. 3 Conversion of cyclohexane (open symbols) and selectivity to benzene (closed symbols) at 823 K on 0.05 g of Ni_3Sn/SiO_2 (○,●), 0.5 g of unsupported Ni_3Sn (■,□) and 0.5 g of unsupported Ni (△,▲)

lower the temperature of hydrogen treatment necessary for the formation of single phase Ni–Sn IMCs. The broad diffraction peaks of supported Ni_3Sn [Fig. 2(*a*)] suggest that the Ni_3Sn particles have much smaller diameters than those of unsupported Ni_3Sn. The particle sizes of Ni_3Sn, Ni_3Sn_2 and Ni_3Sn_4 determined by XRD were about 18, 12 and 12 nm, respectively. These values correspond roughly with the diameters estimated by TEM. Ni_3Sn particles had the largest diameter as these were formed at the highest temperature in the hydrogen treatment. The use of Ni/SiO_2 with smaller Ni particles would lead to Ni–Sn IMCs with smaller particles. It is concluded that all kinds of single phase Ni–Sn intermetallic compounds are obtained on silica by the CVD of $Sn(CH_3)_4$ and subsequent hydrogen treatment at temperatures much lower than the melting point of Ni.

The reaction profiles of cyclohexane in hydrogen at 823 K on silica-supported and unsupported Ni_3Sn IMCs and pure Ni catalysts are shown in Fig. 3. The initial molar ratio of hydrogen to cyclohexane was 6. On the unsupported Ni, benzene was formed as an initial product and was then converted completely into methane in 2 h. On the other hand, the unsupported Ni_3Sn catalyst scarcely converted the initially produced benzene into methane even at higher cyclohexane conversions, though the activity was lower than Ni. The high selectivity to benzene was revealed to be the characteristic catalysis of Ni_3Sn IMC, which would be due to the weaker adsorption of benzene on Ni_3Sn than on Ni. Silica-supported Ni_3Sn showed almost the same selectivity as the unsupported Ni_3Sn. This implies that no pure Ni particles that are too small to be detected by XRD exist on the silica-supported catalyst. Ni_3Sn has the composition richest in Ni among the Ni–Sn IMCs studied. Therefore, it is also indicated that there would be few Ni_3Sn_2, Ni_3Sn_4 or Sn small particles on the silica gel because the Ni/Sn atomic ratio of this sample (3.1/1) was very close to the stoichiometry of Ni_3Sn. Comparing the activity per weight of Ni_3Sn, the supported Ni_3Sn was 500 times more active than the unsupported Ni_3Sn, though the activities of both catalysts per surface area of Ni_3Sn were almost the same. It is clear that the CVD method has resulted in the preparation of silica-supported Ni–Sn IMC catalysts with higher activities than the unsupported ones, owing to the much higher specific surface areas, with retention of the high selectivity to benzene.

Palladium-catalyzed amination of aromatic halides in water-containing solvent systems: a two-phase protocol

Guido Wüllner, Helge Jänsch, Sven Kannenberg, Frank Schubert and Gernot Boche*†

Fachbereich Chemie, Philipps-Universität, Marburg, D-35032, Germany

The use of the six-fold sulfonated ligand BINAS-6 1 permits the Pd⁰-catalyzed amination of aromatic halides in water containing single- or two-phase systems.

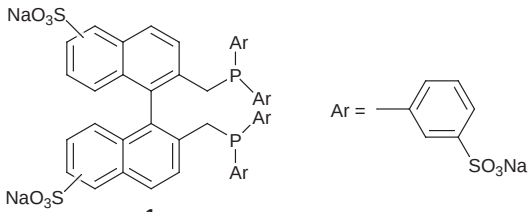
Following the initial investigations of Kosugi *et al.*,[1] both Buchwald[2] and Hartwig[3] and their co-workers have developed in recent years a new methodology for the amination of aromatic halides and triflates (ArX: X = Cl, Br, I, OSO_2CF_3) with amines RR^1NH to yield aromatic amines of the type $ArNRR^1$.[4] ArX and RR^1NH were reacted with (di)phosphine-complexed palladium [Pd^0L, 1–5 mol%] and sodium *tert*-butoxide (1.4 equiv.) in PhMe at 80–100°C under homogeneous reaction conditions [eqn. (1)].

$$ArX + HNRR^1 \xrightarrow[\text{toluene, 80–100 °C}]{Pd^0L,\ NaOBu^t} ArNRR^1 \qquad (1)$$

X = Cl, Br, I, OSO_2CF_3 R = H, alkyl, aryl R^1 = aryl

Under such conditions reapplication of the Pd^0 catalyst would be difficult as is reuse of the relatively expensive (di)phosphine ligand L. In contrast, by using a two-phase protocol, the separation of products (and unreacted starting material) from the catalyst and subsequent reapplication of the catalyst in further reactions is made facile.[5] For this reason there is increasing interest in two-phase catalysis both in the laboratory[6,7] and for industrial applications.[8] Here we report on a two-phase protocol of the aforementioned Pd^0-catalyzed amination reaction.

The ligand used here is the six-fold sulfonated 2,2′-bis(diphenylphosphinomethyl)-1,1′-binaphthyl **1** (BINAS-6) dissolved in water.[9]

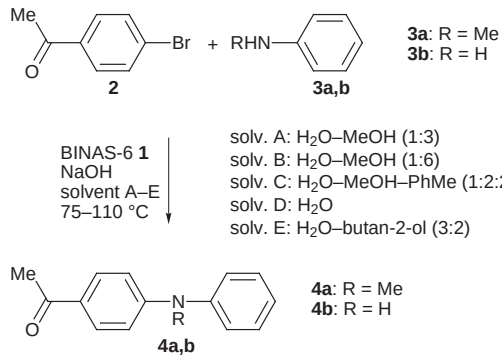


1

The reaction of 4-bromoacetophenone **2** with *N*-methylaniline **3a** in water–MeOH (1:3; solvent A) using NaOH as the base and the aforementioned catalyst Pd^0–**1** afforded 1-[4-(*N*-methylanilino)phenyl]ethan-1-one **4a** in 88% yield [eqn. (2); Table 1, entry 1].

Reacting **2** with **3b** in the presence of Pd^0–**1** and NaOH as the base in water–MeOH (1 : 6; solvent B) resulted in the formation of 1-(4-anilinophenyl)ethan-1-one **4b** in 91% yield [eqn. (2); Table 1, entry 2]. The Pd^0–**1** catalyst, which is dissolved in the aqueous phase, can be reused after separation of the products. The reaction was repeated under similar conditions. The following yields were achieved: second reaction 85% **4b**, (5 h); third reaction 53% **4b**, (7 h); fourth reaction 36% **4b**, (7 h).

The use of a two-phase H_2O–MeOH–PhMe system (1 : 2 : 2; solvent C) in the reaction of **2** with **3a** afforded only low yields



(2)

(36%) of **4a** [eqn. (2); Table 1, entry 3]. The use of emulsifying agents like tetradecyltrimethylammoniumbromide did not increase the yield of **4a**, but resulted in considerable problems during product recovery. With only water as the solvent (solvent D) **4a** was obtained in 36% yield [eqn. (2); Table 1, entry 4].

Butan-2-ol and water form a biphasic system with good miscibility of the two solvents. Thus in the reaction of **2** with **3b** in the presence of Pd^0–**1** and water–butan-2-ol (3 : 2, solvent E) the product **4b** was obtained in 89% yield [eqn. (2); Table 1, entry 5]. NaOH was found to give the best results as compared to other group I hydroxides. The catalyst Pd^0–**1** remains in the aqueous phase while the products can be collected conveniently by separation of the organic layer. Only small amounts of

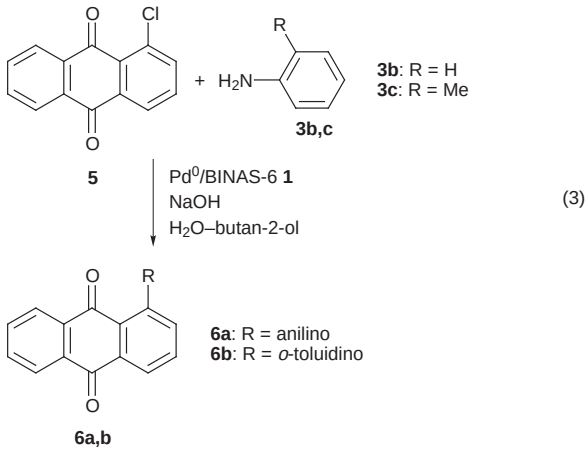
Table 1 Pd^0–**1** catalysed aminations of ArX in water-containing solvent systems. All reactions were carried out under argon with degassed solvents and starting materials. **1** was applied in an aqueous solution (140 mmol l^{-1}). Physical and spectroscopic data of the products were consistent with those reported previously in the literature.

Entry[a]	Halide	Amine	Solvent	Reaction time/h	Product	Yield (%)
1	**2**	**3a**	A	2	**4a**	88
2	**2**	**3b**	B	3	**4b**	91
3	**2**	**3a**	C	32	**4a**	36
4	**2**	**3a**	D	25	**4a**	36
5	**2**	**3b**	E	6	**4b**	89
6	**5**	**3b**	E	6	**6a**	81
7	**5**	**3c**	E	8	**6b**	71

[a] Details of entries 1–7. 1: 160 μmol **1**, 20 μmol $Pd(OAc)_2$, 3 ml MeOH, 1 mmol ArX, 1.3 mmol amine, 1.3 mmol NaOH, 75 °C; products were extracted with Et_2O. 2: 70 μmol **1**, 9 μmol $Pd(OAc)_2$, 6 ml MeOH, 1 mmol ArX, 1.3 mmol amine, 1.4 mmol NaOH, 75 °C; products were extracted with Et_2O. 3: 840 μmol **1**, 100 μmol $Pd(OAc)_2$, 12 ml MeOH, 12 ml PhMe, 6 ml water, 2 mmol ArX, 2.4 mmol amine, 2.8 mmol NaOH, 70 °C; products were collected by separation of the organic layer. 4: 840 μmol **1**, 100 μmol $Pd(OAc)_2$, 12 ml water, 2 mmol ArX, 2.4 mmol amine, 2.8 mmol NaOH, 90 °C; products were extracted with Et_2O. 5–7: 80 μmol **1**, 11 μmol $Pd(OAc)_2$, 3 ml water, 2 ml butan-2-ol, 1 mmol ArX, 1.3 mmol amine, 1.3 mmol NaOH, 110 °C; products were collected by separation of the organic layer.

product (< 5%) remain in the aqueous phase. In this solvent system the catalyst can be reused as well.

Reacting 1-chloroanthraquinone **5** with aniline **3b** in the presence of Pd^0–**1** and NaOH in water–butan-2-ol (3 : 2) allowed amination of **5**, affording 1-anilinoanthraquinone **6a** in 81% yield [eqn. (3); Table 1, entry 6]. The use of *o*-toluidine **3c** under similar conditions gave 1-(*o*-toluidino)anthraquinone **6b** in 71% yield [eqn. (3); Table 1, entry 7].



In conclusion, it has been demonstrated that the Pd^0-catalyzed amination of aromatic halides with amines can be performed by means of a two-phase protocol with NaOH instead of the expensive $NaOBu^t$ as the base. Further advantages are the facile catalyst/product separation and the reusability of the water-soluble Pd^0/BINAS-6 catalyst. The catalyst system is also suitable for the preparation of substituted anthraquinones, which are important in dye stuff production.[10] Further work is being conducted to optimise the reaction conditions and to perform selective single amination reactions of dichloro-substituted anthraquinones.

We are grateful to the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 260 and Graduiertenkolleg Metallorganische Chemie) and the Fonds der Chemischen Industrie for financial support, and Dr H. Bahrmann, Celanese GmbH, Werk Ruhrchemie, for BINAS-6 **1** as well as helpful discussions. The Degussa AG provided us with $Pd(OAc)_2$.

Formation of thermotropic and lyotropic smectic and columnar liquid crystalline phases by a novel type of rigid rod-like amphiphilic molecule

Marius Kölbel,[a] Carsten Tschierske*[a]† and Siegmar Diele[b]

[a] *Institut für Organische Chemie der Martin-Luther-Universität Halle-Wittenberg, D-06120 Halle, Kurt-Mothes-Str. 2, Germany*
[b] *Institut für Physikalische Chemie der Martin-Luther-Universität Halle-Wittenberg, D-06108 Halle, Mühlpforte 1, Germany*

4-Benzyloxy-4′-(2,3-dihydroxypropyloxy)biphenyls with lateral methyl substituents are a novel class of amphiphilic mesogens displaying thermotropic and lyotropic smectic and columnar mesophases due to microsegregation of hydrophilic regions from all-aromatic segments in the absence of a flexible alkyl chain.

The liquid crystalline state which combines order and mobility on a molecular level is of great interest for material science as well as for life science and is found in different classes of compounds. Most are anisometric (rod-shaped or disc-like) molecules and amphiphilic molecules. These molecules consist of an anisometric or a polar basic unit to which one or more flexible chains are grafted. Usually these are alkyl chains and provide the mobility whereas the order is provided by the packing of the anisometric groups or by the attractive forces between the polar groups. Liquid crystalline materials without flexible chains are rare. Examples are *p*-oligophenylenes[1] and high molecular mass condensed polyaromatic compounds (carbonaceous materials).[2] More recently columnar liquid crystalline properties have been found for some polyhalogenated small aromatic compounds such as indene derivatives and pseudoazulenes[3] and for salts of 3-phenyloxyphenyl-2-propionic acid, important non-steroidal antiinflammatory drugs (fenoprofens).[4] Also molecules consisting of aromatic systems with polar groups around their peripheries such as, for example, some drugs, dyes, nucleic acids and antibiotics, can form lyotropic mesophases with protic solvents. In these chromonic liquid crystals[5] the solvent provides the mobility.

Here, we report on a novel type of amphiphiles without flexible alkyl chains, consisting only of a hydrophilic *rac*-2,3-dihydroxypropyl group and a linear array of three *p*-substituted benzene rings providing a rather rigid lipophilic unit.[6] Both the attractive interactions between the rigid aromatic units and the hydrogen bonding provided by the 1,2-diol[7] unit give rise to the very high melting point of **1**. In order to diminish the attractive interactions between the aromatic units a single methyl group was grafted at different positions laterally to the biphenyl unit of **1**. Indeed, a dramatic decrease in the melting temperature was possible and liquid crystalline properties can be observed for all methyl-substituted compounds **2**–**5**.‡ The influence of the position of the lateral substituent on the thermotropic properties is shown in Table 1.

Compounds **2** and **4** show a monotropic phase easily identified as a smectic layer structure (S_A phase) by its typical fan like texture and regions with homeotropic orientation and oily streaks, observed by microscopy between crossed polarisers. For compound **3** one observes a monotropic tilted smectic phase (S_C phase), identified by its typical *schlieren* texture, which on further cooling turns into a highly viscous and optically isotropic (probably cubic) phase. Owing to the monotropic nature of these mesophases, a more detailed investigation by X-ray scattering was however not possible.

An enantiotropic mesophase was found for **5** between 128 and 151 °C. It is characterised by regions with spherulitic as well as broken fan shaped texture (Fig. 1). No homeotropic orientation can be obtained by shearing the sample. Therefore an S_A phase can be ruled out. X-Ray studies provide a diffuse scattering in the wide angle region and three non-equidistant reflections in the small angle region (d_1 = 3.55, d_2 = 1.93, d_3 = 1.27 nm), excluding a smectic layer structure. As there are no references to a hexagonal or a rectangular 2D lattice, we evaluated the pattern under the assumption of a two-dimensional oblique cell, assigning the observed reflections to (10), (01) and (11) with increasing ϕ-values and obtained lattice parameters a = 9.95, c = 5.41 nm and β = 159.1°. In the light of the fact that the aromatic unit should provide a rod-like molecular shape and that the mesophases of **2**–**4** represent layer structures, it seems likely that the columnar phase results from the collapse of smectic layers into band-like segments (ribbons). The collapse can be caused either by an incompatibility of two incommensurate length scales or by a different space filling of microsegregated regions. The first case is found at the transition between smectic bilayer and monolayer structures ($S_{\tilde{C}}$, $S_{\tilde{A}}$ phases).[8] The second type is known from the thermotropic mesophases of pure soaps[9] and has been proposed for columnar mesophases of polycatenar compounds,[10] and several types of calamitic amphiphiles containing oligo(oxyethylene) units.[11,12]

In the crystalline state of **5** in the small angle region three equidistant reflections are observed with a period of d = 3.55

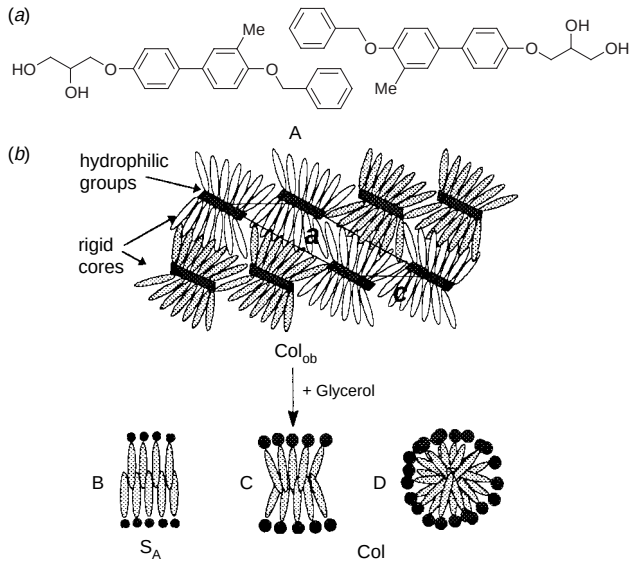

Fig. 2 Schematic presentation of the proposed arrangement of the molecules of **5** in its mesophases. (*a*) Intercalation of two molecules, (*b*) cross-section through a possible thermotropic Col_{ob} phase (A) and through aggregates of possible lyotropic mesophases, formed on addition of glycerol: layer of an S_A-phase (B), ribbon (C) and cylindrical aggregate (D).

nm. The corresponding scattering vector remains on heating the sample whereas the higher orders are significantly shifted at the transition to the liquid crystalline state. Therefore, we assume that the thickness of the ribbons is *ca.* 3.5 nm. The molecular length *L* obtained from CPK models is 2.3 nm. Thus we can conclude on a bilayer arrangement with strongly tilted molecules and/or with a high degree of intercalation. Intercalation of the terminal benzyl groups seems to be likely because the methyl groups provide a partial tapering of the molecules which should facilitate their intercalation [Fig. 2(*a*)]. The shape of the molecules and the intercalation increase the diameter of the aromatic regions with respect to the polar regions of the head groups. Thus, the frustration of the bilayer structure can be explained by the different space filling of the segregated regions of the polar and the aromatic molecular parts.

A possible model which is in accord with the obtained lattice parameter is shown in Fig. 2(*b*), arrangement A. According to this model the oblique lattice results from the organisation of pairs of ribbons (grey and white) consisting of partly intercalated and tilted molecules. Each pair differs from the neighbouring pairs by the average tilt direction of the molecules. The individual ribbons should have a lateral diameter of *ca.* 5 nm and *ca.* ten molecules are arranged side by side an average.

Being amphiphilic, the liquid crystalline properties of **2**–**5** should be influenced by solvents. Their behaviour in the solvent saturated state and in the contact region with the protic solvent glycerol§ was investigated by polarising microscopy. In the contact region between **5** and glycerol the columnar mesophase is destabilised and the formation of an S_A phase with a maximum clearing temperature of 143 °C is observed. In a medium concentration range no columnar mesophase can be found. However, on further increasing the glycerol content a second columnar mesophase appears. This observation confirms the proposed model of the organisation of **5** in the columnar mesophase. The solvent molecules are built in between the polar head groups and increase the diameter of these regions. At a certain solvent content an equivalent space filling of the aromatic and the polar regions is reached, the ribbons fuse and a stable layer structure is found (S_A phase). On further increased solvent content the size of the polar regions could exceed that of the aromatic regions and again the layers break up with formation of a columnar phase. Thus, with respect to the space filling of the different regions the two columnar phases should be inverted to each other. The second columnar phase could again represent a ribbon phase [Fig. 2(*b*), arrangement C], but a columnar phase consisting of cylindrical aggregates [Fig. 2(*b*), arrangement D], cannot be excluded. Columnar phases can also be induced on addition of glycerol to **3** and **4** (Table 1). These induced columnar phases have the same optical texture as that induced in the system **5**–glycerol and should be related to it.

In summary, it was found that rigid all-aromatic amphiphiles represent novel amphotropic liquid crystals.[13] They show the same diversity of different mesophases as thermotropic and lyotropic systems of classical flexible amphiphiles. However, the hydrophobic interactions between flexible alkyl chains are replaced by interactions of rigid aromatic units and therefore ribbon structures are formed. Moreover, a tilted S_C phase was detected which has never been found in the mesophase sequence of conventional flexible amphiphiles and also its appearance is related to the rigid molecular structure.

The 2 : 1 reaction between $Zn(O_2CMe)_2\cdot 2H_2O$ and 1-Meim in refluxing MeCN gives $[Zn_7O_2(O_2CMe)_{10}(1\text{-Meim})_2]$ 1 which comprises two vertex-sharing tetranuclear $Zn_4(\mu_4\text{-O})(\eta^1:\eta^1:\mu_2\text{-}O_2CMe)_5(1\text{-Meim})$ units; solid-state ^{13}C and ^{15}N NMR spectra reveal structural details of the complex.

We have recently become interested in the synthesis of mono- and di-/tri-nuclear zinc complexes containing carboxylate and imidazole ligands which would be satisfactory models for the carboxylate–histidine–metal triad catalytic centres in hydrolytic zinc enzymes.[1–4] This area of Zn chemistry has been poorly explored. Two groups have reported[5,6] the preparation and X-ray structures of the mononuclear, four-coordinate complexes $[Zn(O_2CR)_2L_2]$, where R = Me, Et and L = imidazole, 2-ethylimidazole.

For the better investigation of the Zn^{II}–RCO_2^-–L systems (L = various monodentate imidazoles), we have systematically varied the nature of R, L and solvent, and both the Zn^{II} : L and Zn^{II} : RCO_2^- ratios. We have found all these parameters to have an important effect on the chemical and structural identity of obtained products. We herein report that the 2 : 1 and 3.5 : 1 reactions of $Zn(O_2CMe)_2\cdot 2H_2O$ with 1-methylimidazole (1-Meim) in MeCN lead to the assembly of the remarkable high-nuclearity product $[Zn_7O_2(O_2CMe)_{10}(1\text{-Meim})_2]$ **1**.

$Zn(O_2CMe)_2\cdot 2H_2O$ (4.0 mmol) and 1-Meim (2.0 mmol) were refluxed for 30 min in MeCN (30 ml) to form a colourless solution. Layering this solution with an equal volume of Et_2O afforded colourless crystals of $[Zn_7O_2(O_2CMe)_{10}(1\text{-Meim})_2]\cdot$ 2MeCN, **1**·2MeCN in typical yields of *ca.* 45%; the dried solid analysed as **1**.‡ Employing a Zn^{II} : 1-Meim ratio of 3.5 : 1 in either MeCN or MeOH complex **1** again results. The same procedure in EtOH can be employed for the 1,2-dimethylimidazole (1,2-diMeim) analogue of **1** ($[Zn_7O_2(O_2CMe)_{10}(1,2\text{-diMeim})_2]$ **2**).§

The structrure of **1**¶ (Fig. 1) is extremely unusual and consists of a $[Zn_7(\mu_4\text{-O})_2]^{10+}$ core. The central Zn site [Zn(1)] lies on a crystallographic inversion centre and is the shared vertex of two $Zn_4(\mu_4\text{-O})$ units; this unit is well established in Zn chemistry.[7] The peripheral ligation is provided by ten $\eta^1:\eta^1:\mu_2$-acetate groups and two 1-Meim ligands bonded to Zn(4) atoms; each of the five crystallographically independent acetates spans one edge of the Zn_4 tetrahedron. The Zn_4O tetrahedron is slightly irregular, the Zn···Zn distances being between 3.081(1) and 3.199(1) Å and the Zn–O–Zn angles varying from 103.5 to 112.5(1)°. The shortest Zn···Zn distance between the tetrahedral subunits is the Zn(2)···Zn(4) one [5.333(1) Å]. The geometry at the central Zn is distorted octahedral, while that at the peripheral metal ions can be described as distorted tetrahedral with the distortion at Zn(4) being more severe. Bond distances to Zn(1) are distinctly longer [1.979(2)–2.203(2) Å] as expected for a higher coordination number. There appear to be stacking interactions between the centrosymmetrically parallel 1-Meim ligands that belong to neighbouring heptanuclear molecules [closest interatomic separation, N(1)···C(3) = C(3)···N(1), between opposite ligands is 3.340(5) Å]; these interactions create a form of 'chains' along the *b* axis and aid in stabilizing the crystal structure.

Complex **1** joins a small family of discrete heptanuclear zinc(II) clusters,[8–11] the first reported example being $[Zn_7Me_6(OMe)_8]$.[8] Complex **1** becomes the second member of a homometallic molecular complex containing the $[M_7(\mu_4\text{-O})_2]$ double tetrahedral unit, the only other known example[10] being also a zinc(II) cluster.

The compound is practically insoluble in all organic solvents; its high-resolution solid-state ^{13}C NMR spectrum (recorded[12] at 75.5 MHz) indicates a 2 : 1 : 1 : 1 splitting of the carboxylate carbons[13,14] (δ 181.4–179.4) and 1 : 2 : 1 : 1 splitting of the methyl carbons (δ 24.2–22.2). Evidently, polynuclear zinc(II) complexes are excellent candidates for a comparative study of X-ray structure with solid-state NMR properties because of the

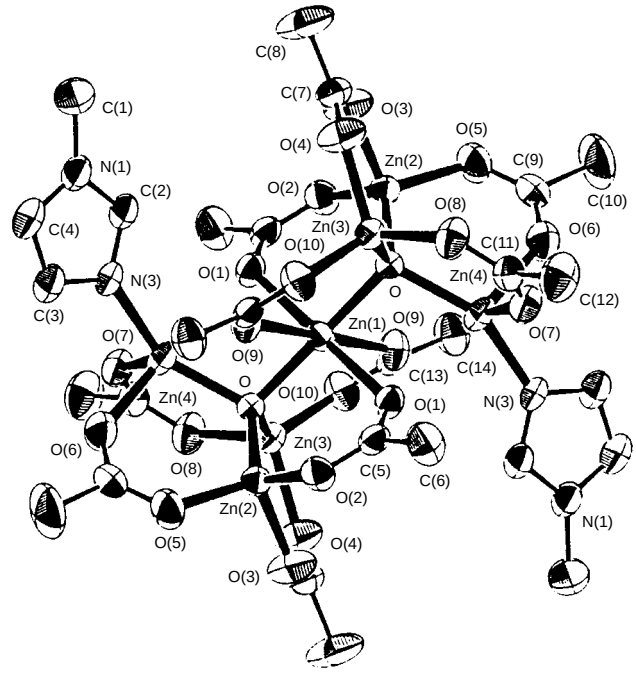

Fig. 1 ORTEP representation of $[Zn_7O_2(O_2CMe)_{10}(1\text{-Meim})_2]$ **1**. Some symmetry equivalent atoms are not labelled. Selected interatomic distance ranges (Å): Zn–O(oxo) 1.914(2)–1.979(2), Zn–O(acetate) 1.944(3)–2.203(2), Zn(4)–N(3) 2.004(3), Zn···Zn 3.081–6.375(1). Selected bond angle ranges (°): *trans* at Zn(1), 180.0; *cis* at Zn(1), 81.3(1)–98.7(1); around Zn(2), 102.4(1)–120.6(1); around Zn(3), 101.5(1)–120.4(1); around Zn(4), 93.0(1)–146.2(1); Zn–O(oxo)–Zn 103.5(1)–112.5(1).

very high quality ^{13}C CP MAS spectra produced and the fact that shieldings of both CO_2^- and acetate CH_3 groups are very sensitive to the precise crystallographic environment. In the present complex, two of the five crystallographically inequivalent acetate ligands present in the unit cell have degenerate ^{13}C chemical shifts for both methyl and carboxylate groups. The solid-state ^{15}N CP MAS NMR spectrum of complex **1** indicates the presence of two resonances at δ −163.6 [N(3)] and δ −212.7 [N(1)] for the bound 1-Meim. Both resonances are significantly shifted to those of the free ligand (δ −120.3 [N(3)] and δ −219.9 [N(1)], neat liquid at 300 K, relative to CH_3NO_2 as reference).

From a synthetic inorganic viewpoint, the preparation of **1** and **2** shows that it is possible to generate polynuclear zinc carboxylate complexes with unusual structures and nuclearities significantly greater than those known to date by relatively minor perturbations to the Zn^{II}–RCO_2^-–L system, in this case, the use of a high Zn^{II} to L ratio. We are currently investigating the reactivity chemistry of **1** and **2** and seeking access to additional structural types.

We thank University of London Intercollegiate Research Service for the provision of solid-state NMR facilities.

Energy gap dependence of electron transfer rates in porphyrin–imide supramolecular assemblies

Joe Otsuki,*[a]† Kenkichi Harada,[a] Koji Toyama,[b] Yoshio Hirose,[b] Koji Araki,[a] Manabu Seno,[b] Kikuo Takatera[a] and Tadashi Watanabe[a]

[b] *College of Science and Technology, Nihon University, 1-8-14 Kanda Surugadai, Chiyoda-ku, Tokyo 101-8308, Japan*

The energy gap dependence of the rate of electron transfer has been revealed for donor–acceptor supramolecular assemblies composed of zinc–tetraphenylporphyrin and a series of spacer–acceptor conjugate molecules which are structurally similar but with varying redox potentials.

Artificial photosynthetic devices rely on spatially organised units with suitable photochemical and electrochemical properties.[1] An increasing number of reports use non-covalent interactions, such as metal–ligand coordinate bonds, hydrogen bonding and so on, to construct a donor–acceptor supramolecular architecture.[2] We noticed, however, that there have been very few cases dealing with systematic variations in supramolecular donor–acceptor assemblies. As such little is known about the energy gap dependence of electron transfer rates through non-covalent interactions in well defined synthetic systems, while several systematic studies have been conducted for covalent donor–acceptor conjugates.[3–7]

Hunter and coworkers reported on a very simple way to assemble donor–[spacer–acceptor] supermolecules, *i.e.* to use axial ligation of pyridine ligands to zinc–porphyrin (*e.g.* Fig. 1 with **1**).[8] We reasoned that systematic variations on the redox potential of the imide unit would be made possible by this strategy and synthesised a series of pyridine–imide conjugates, **2–7**, which were structurally similar but with varying redox potentials (Table 1). Two ethoxy groups were introduced in the pyridine spacer to impart enough solubility to be used in excess, in order to ensure nearly complete complexation of Zn–tetraphenylporphyrin (ZnTPP). The key intermediate, 3,5-diethoxy-4-aminomethylpyridine, was prepared according to a literature method.[9] Once this material was obtained in a fair amount, a variety of commercially available phthalic anhydride derivatives were reacted with it to prepare **2–7**.‡

Upon addition of pyridine–imide conjugates to a solution of ZnTPP in CH_2Cl_2, the Q bands exhibit a red-shift of *ca.* 15 nm, which is characteristic of the axial coordination to the metal centre of ZnTPP. From the change in the electronic spectra, binding constants were determined, as shown in Table 1, which are virtually constant (log K 4.0 ± 0.2, 25 °C, CH_2Cl_2) for the whole series of pyridine–imide conjugates employed.§ Owing to the intense ring-current effect of the porphyrin macrocycle, ^{1}H NMR spectroscopy is a powerful tool to probe the complexation.[11,12] For example, in the limit of complete complexation, protons at pyridine-H2, pyridine-H3, and methylene of **1** experience upfield shifts of 6.29, 1.91 and 1.25 ppm, respectively, which are in accord with the axial coordination of the pyridine ligand. The minimum energy conformation of pyridine–imide conjugates was systematically searched with a molecular mechanics calculation by incrementally rotating C(pyridine)–CH_2 and CH_2–N bonds. The result suggests that, in the most stable conformation, the imide ring lies more or less in a face-to-face orientation with the porphyrin plane, assuming that the pyridine moiety coordinates perpendicular to the porphyrin plane.[13] All this evidence indicates that a supermolecule as depicted schematically in Fig. 1 is formed exclusively.

Fluorescence from the singlet excited state of ZnTPP is quenched upon addition of pyridine–imide conjugates due to electron transfer to the imide[14,15] as shown in Fig. 2. The degree of quenching is in proportion to the amount of complex formed and in quantitative accordance with the curve obtained from the binding constant determined as above. A slight increase in fluorescence intensity (5%) is noted upon complexation with 4-picoline which is used to serve as a model compound to differentiate the effect of axial coordination from that of electron transfer. Quenching by dihexylpyromellitic diimide, which is a model compound for **1** and **7** and lacks coordination capability, is also noted. However, this collisional quenching rate is more than two orders of magnitude smaller than that of **1** or **7** in the concentration range studied and can be safely neglected. Thus the collisional quenching is assumed negligible also for the other acceptors.

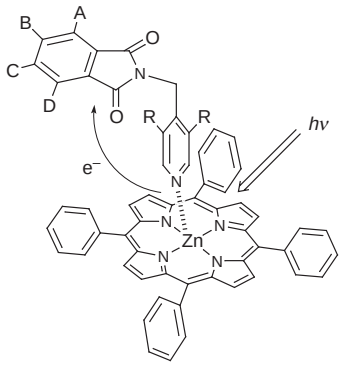

Fig. 1 A supramolecular assembly from ZnTPP and [spacer–acceptor] conjugates with various redox potentials

[a] One-electron reduction potentials. The cyclic voltammetry was conducted with glassy C, Pt and Ag/Ag$^+$ as working, counter and reference electrodes, respectively, under a N_2 atmosphere. Millimolar amount of samples were used in CH_2Cl_2 containing 0.1 M Bu_4NClO_4. [b] Binding constants in CH_2Cl_2 at 25 °C. [c] The quantum yields of intrasupramolecular electron transfer. Repeated runs agreed within ±2% with respect to the initial fluorescent intensity. [d] See footnote ¶. The propagated errors are indicated in Fig. 3.

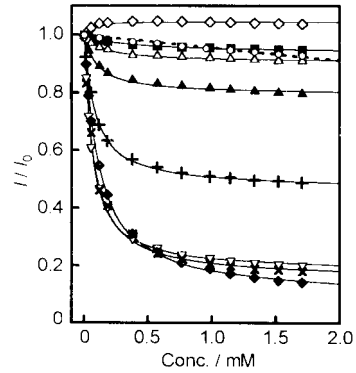

Fig. 2 Quenching of ZnTPP fluorescence upon addition of coordinating acceptors and model compounds (ZnTPP 10 μM in CH_2Cl_2 at 25 °C in air). 4-Picoline (◇), **2** (■), **3** (△), **4** (▲), **5** (+), **6** (▽), **7** (×), **1** (◆) and dihexylpyromellitic diimide (dotted line).

In the limit of complexation, the quantum yields of the intrasupramolecular electron transfer, ϕ_{eT}, are obtained and listed in Table 1. For the studied acceptors with redox potentials varying in the range of 0.8 V, the electron transfer yield varies from 0.11 for **2** to as high as 0.91 for **1**. The rates of electron transfer obtained from these data¶ are plotted against the free energy gap ($\Delta G°$)‖ between the singlet excited state of ZnTPP and acceptors. Increasing energy gap results in increasing electron transfer rate, which is apparently 'normal' behaviour.

In the classical Marcus theory for nonadiabatic electron transfer for the case of weak coupling, the rate of electron transfer, k_{eT}, is given by

$$k_{eT} = (\pi/\hbar^2\lambda k_B T)^{1/2}|V|^2\exp[-(\Delta G° + \lambda)^2/4\lambda k_B T]$$

where $\hbar$ is Planck's constant divided by 2π, λ is the reorganisation energy, k_B is the Boltzmann constant, T is the temperature (298 K), and V is the coupling matrix element.[3,16] Here the two parameters, λ and V, are to be determined by experiment. Assuming that these parameters are constant throughout the series of acceptors, which may be justified on account of their chemical and structural similarity, possible curves from some combinations of these parameters are shown in Fig. 3. It is impossible to single out parameter values to fit all the observed data, especially when the data point for **2** is included. This system awaits further detailed photophysical scrutiny, including transient absorption measurements, to reveal the nature of electron transfer through space or intermolecular bonds.

We have shown that the supramolecular approach is powerful in constructing donor–acceptor architecture with relative ease that can be systematically addressed. In addition, the data presented herein may provide a guide to acceptors to be used in more elaborate donor–acceptor assemblies to obtain desired

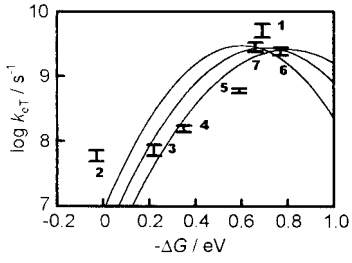

Fig. 3 The dependence of intrasupramolecular electron transfer rate on the energy gap. Curves are also shown according to the Marcus equation with V = 3 cm^{-1} and λ = 0.6, 0.7, 0.8 eV from left to right.

electron transfer rates. This work was supported by Nissan Science Foundation and Foundation Advanced Technology Institute.

‡ Typically, separate solutions of 3,5-diethoxy-4-aminomethylpyridine and substituted phthalic anhydride in MeOH were mixed and heated on a hot plate, letting MeOH evaporate. The reaction mixture was purified by PLC. All compounds obtained had the expected ^{1}H NMR, IR spectra, and HRMS or elemental analyses and purity checked by TLC.

§ The Q bands obey Beer's Law around the concentration (10 μM) used in the absorption and fluorescence measurements and no broadening or splitting of the Soret band[10] is observed, indicating that ZnTPP exists as monomers before complexation. Clear isosbectic points upon addition of the pyridine-containing compounds indicate that only the 1 : 1 complex forms.

¶ The electron transfer rates were determined from $k_{eT} = k_P\Phi_{eT}/(1 - \Phi_{eT})$, where k_P is the decay rate constant of ZnTPP in the absence of quenching ligand, which is 4.9×10^8 s^{-1}. Some of the values (due to our instrumental limit) were independently confirmed by measurement of fluorescence decays, which were single exponential.

‖ The redox potential of the lowest excited state of ZnTPP ($E_P°$) was estimated to be −1.84 V *vs.* Fc/Fc^+ from the ground state redox potential (0.22 V) and the energy of the Q(0,0) band (2.06 eV) of pyridine-complexed ZnTPP. The energy gap, $\Delta G°$, was obtained according to the equation

$$\Delta G° = E° - E_P° + e^2/\varepsilon r$$

where the last term is the Coulomb correction in which ε is the relative permittivity of CH_2Cl_2 and r is the donor–acceptor distance. This term was set to be 0.20 eV based upon the estimated value of r (9.5 Å) from the molecular mechanics calculation described in the text and the known geometry of a pyridine–porphyrin complex.[13]

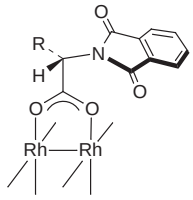
Highly enantioselective construction of the key azetidin-2-ones for the synthesis of carbapenem antibiotics *via* intramolecular C–H insertion reactions of α-methoxycarbonyl-α-diazoacetamides catalysed by chiral dirhodium(II) carboxylates

Masahiro Anada, Nobuhide Watanabe and Shun-ichi Hashimoto*†

Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060-0812, Japan

A highly enantioselective construction of 3-oxa-1-azabicyclo[4.2.0]octanes (up to 96% ee) has been achieved by intramolecular C–H insertion of α-methoxycarbonyl-α-diazoacetamides catalysed by dirhodium(II) complexes incorporating *N*-phthaloyl-(*S*)-amino acids as chiral bridging ligands, which provides a new, catalytic asymmetric route to key intermediates for carbapenem antibiotics.

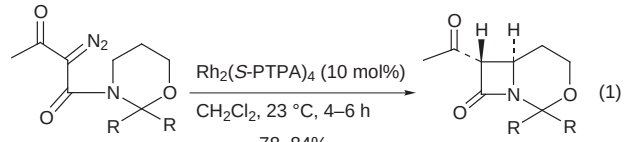
Among a variety of transition metal complexes used to catalyse a broad spectrum of transformations of α-diazo carbonyl



Rh_2(*S*-PTPA)$_4$ R = Bn
Rh_2(*S*-PTA)$_4$ R = Me
Rh_2(*S*-PTV)$_4$ R = Pr^i
Rh_2(*S*-PTPG)$_4$ R = Ph
Rh_2(*S*-PTTL)$_4$ R = Bu^t

compounds, dirhodium(II) complexes have distinguished themselves by their superiority in C–H insertion reactions.[1] Consequently, a great deal of effort is being devoted to the design, synthesis and evaluation of chiral dirhodium(II) catalysts which make it possible to construct both carbocyclic and hetereocyclic systems with high enantioselectivities.[1,2] Our efforts in this area have led to the development of dirhodium(II) carboxylates incorporating *N*-phthaloyl-(*S*)-amino acids as the bridging ligands, which catalyse intramolecular C–H insertion reactions of α-diazo carbonyl compounds to give optically active cyclopentanone and indan-2-one derivatives in high yields and with up to 80 and 98% ee, respectively.[3,4] Herein we report the highly enantioselective construction of 3-oxa-1-azabicyclo-[4.2.0]octanes, which lead to the key azetidin-2-ones for the synthesis of 1-unsubstituted and 1β-methyl carbapenem antibiotics.[5]

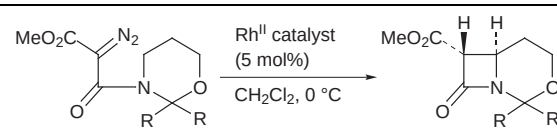
We previously demonstrated that cyclisation of *N*-alkyl-*N*-*tert*-butyl-α-methoxycarbonyl-α-diazoacetamides catalysed by dirhodium(II) tetrakis[*N*-phthaloyl-(*S*)-phenylalaninate], Rh_2(*S*-PTPA)$_4$, led to the exclusive formation of azetidin-2-one derivatives of up to 74% ee,[6] wherein installation of a *tert*-butyl group as an *N*-substituent proved to be crucial to enantiocontrol as well as regiocontrol; however, the inability to remove the *tert*-butyl group precluded its application to the synthesis of carbapenem antibiotics. In this respect, of particular interest is the pioneering work of Ponsford and Southgate dating back to 1979.[7] They developed a racemic route to the thienamycin key intermediate *via* the $Rh_2(OAc)_4$-catalysed C–H insertion reaction of α-diazoacetoacetamides **1a** and **1b** tethered to a tetrahydro-1,3-oxazine system. Following the suggestion that the *N*,*O*-acetal moiety could function as a substitute for the *tert*-butyl group, we then examined cyclisation of **1a** and **1b** with the aid of 10 mol% of Rh_2(*S*-PTPA)$_4$. Cyclisation proceeded smoothly to give the 3,4-*trans*-azetidin-2-one derivatives **2a** and **2b**, but we were disappointed to find that there was no asymmetric induction in either case [eqn. (1)].



(1)

Although the steric and electronic differences between the acetyl and methoxycarbonyl groups as the α-substituent of the diazo carbon was thought to be small, we next explored the feasibility of asymmetric induction with α-methoxycarbonyl-α-diazoacetamide **3a**. To our surprise, cyclisation of **3a** under the influence of 5 mol% of Rh_2(*S*-PTPA)$_4$ afforded the 3,4-*trans*-azetidin-2-one derivative **4a** as the sole product in 89% yield and with 90% ee (Table 1, entry 1). While the mechanistic profile is not clear at present, the beneficial effect of the ester group in this system should be underscored.‡ To further enhance the enantioselectivity, we then screened other chiral dirhodium(II) carboxylates, Rh_2(*S*-PTA)$_4$, Rh_2(*S*-PTV)$_4$, Rh_2(*S*-PTPG)$_4$ and Rh_2(*S*-PTTL)$_4$, derived from *N*-phthaloyl-(*S*)-alanine, -valine, -phenylglycine and -*tert*-leucine, respectively. While the catalysis of **3a** provided **4a** with a consistent sense of enantioselection at the insertion site and in more than

Table 1 Enantioselective C–H insertion reaction of **3** catalysed by chiral Rh^{II} complexes[a]



3a–c **4a–c**

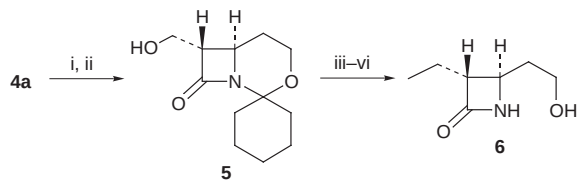
7	**3c**	Et,Et	Rh_2(*S*-PTA)$_4$	8	**4c**	89	83

[a] Reactions were carried out as follows: 5 mol% of the catalyst was added to a stirred solution of the α-diazo amide **3** (1 mmol) in anhydrous CH_2Cl_2 (2 ml) at 0 °C under argon. [b] Isolated yield. [c] Determined by a chiral stationary phase column (Daicel Chiralcel OJ) after reduction with $LiBH_4$ and subsequent benzoylation.

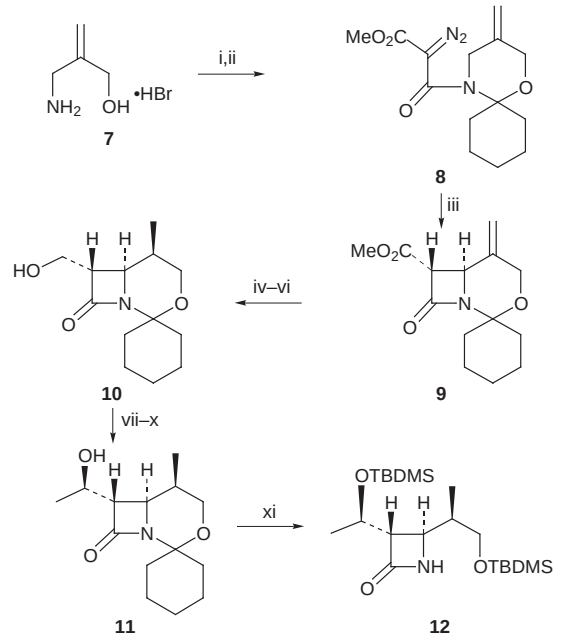


Scheme 1 *Reagents and conditions*: i, $LiBH_4$, THF, 0 °C, 2 h, 94%; ii, recrystallisation from Pr^i_2O–hexane, 90%; iii, Dess–Martin periodinane, CH_2Cl_2, 0 °C, 3 h, 94%; iv, CH_2I_2, Zn, Me_3Al, THF, 0 °C, 2 h, 89%; v, H_2, Pd–C, EtOH, 23 °C, 2 h, 96%; vi, aq. AcOH, 70 °C, 2 h, 97%

92% ee in all cases (entries 2–5), Rh_2(*S*-PTA)$_4$ proved to be the catalyst of choice for displaying the highest degree of enantioselectivity (96% ee, entry 5). With regard to the *N*,*O*-acetal protection, the isopropylidene acetal **3b** exhibited almost the same enantioselectivity as **3a** (entry 6), whereas a dramatic drop in enantioselectivity was observed with the pentylidene acetal **3c** (entry 7). It should be emphasised here that **3a** has distinct advantages over **3b** from the standpoint of its preparative yield.

The azetidin-2-one **4a** {96% ee, $[\alpha]_D^{25}$ +57.7 (*c* 1.02, $CHCl_3$)} thus obtained was then transformed to the key synthetic intermediate **6** for PS-5, which also determined the preferred absolute configuration at the insertion site (Scheme 1). Reduction of **4a** with $LiBH_4$ gave the alcohol **5**, which, upon one recrystallisation from Pr^i_2O–hexane, produced an optically pure sample {mp 89–90 °C, $[\alpha]_D^{25}$ +17.7 (*c* 1.03, $CHCl_3$)}. Oxidation of **5** with the Dess–Martin periodinane followed by sequential methylenation,[8] hydrogenation and hydrolysis afforded the PS-5 intermediate **6** {$[\alpha]_D^{25}$ +25.0 (*c* 1.16, CH_2Cl_2); lit.,[9] +24.3 (*c* 1.33, CH_2Cl_2)}.

Finally, we extended the present protocol to the synthesis of the pivotal intermediate for 1β-methylcarbapenems (Scheme 2).



Scheme 2 *Reagents and conditions*: i, cyclohexanone, $NaHCO_3$, benzene, reflux, azeotropic distillation, 6 h, then methyl malonyl chloride, $PhNMe_2$, CH_2Cl_2, 0 °C, 1 h, 68%; ii, *p*-$AcNHC_6H_4SO_2N_3$, DBU, MeCN, 0 °C, 2 h, 91%; iii, Rh_2(*S*-PTA)$_4$, CH_2Cl_2, 23 °C, 13 h, 83%, 88% ee; iv, $LiBH_4$, THF, 0 °C, 2 h, 91; v, H_2, Raney-Ni (W2), EtOH–EtOAc, 0 °C, 6 h, 96%; vi, recrystallisation from AcOEt–hexane, 82%; vii, Dess–Martin periodinane, CH_2Cl_2, 0 °C, 3 h, 94%; viii, Me_3Al, CH_2Cl_2, 0 °C, 2.5 h, 87%; ix, DMSO, $(COCl)_2$, Et_3N, CH_2Cl_2, −60 °C, 1 h, 95%; x, K-Selectride®, Et_2O, −20 °C, 2 h, 90%; xi, aq. AcOH, 70 °C, 2 h, then TBDMSCl, imidazole, CH_2Cl_2, 0 °C, 4 h, 94%

Toward this end, α-methoxycarbonyl-α-diazoacetamide **8** bearing an exocyclic olefin was prepared from **7**§ by condensation with cyclohexanone followed by *N*-acylation with methyl malonyl chloride and subsequent diazo transfer. Cyclisation of **8** with the aid of 5 mol% of Rh_2(*S*-PTA)$_4$ proceeded uneventfully to afford the desired azetidin-2-one **9** {$[\alpha]_D^{25}$ +0.90 (*c* 1.05, $CHCl_3$)} in 83% yield and with 88% ee.¶ Reduction of **9** with $LiBH_4$ followed by stereocontrolled hydrogenation[11] furnished the alcohol **10**, which, upon one recrystallisation from AcOEt–hexane, produced an optically pure sample {mp 159–160 °C, $[\alpha]_D^{25}$ +16.9 (*c* 1.06, $CHCl_3$)}. Treatment of **10** with the Dess–Martin periodinane followed by alkylation with Me_3Al,[12] oxidation under standard Swern conditions and stereocontrolled reduction with K-Selectride®[13] produced the alcohol **11**. Hydrolysis and subsequent silylation provided the known intermediate **12** {mp 96–98 °C, $[\alpha]_D^{25}$ −7.93 (*c* 0.98, $CHCl_3$); lit.,[14] −7.88 (*c* 1.03, $CHCl_3$)}. The above transformation also established that the preferred absolute configuration at the insertion site in this cyclisation was the same as that with **4a**, suggesting a common stereochemical reaction course in both series.

The present protocol provides a new, efficient and general method for the catalytic asymmetric synthesis of carbapenems.[15] Further extension of the present method to trinem antibiotics as well as mechanistic and stereochemical studies are currently in progress.

Zinc-promoted direct amination of nitropyridines with methoxyamine *via* vicarious nucleophilic substitution

Shinzo Seko*† and Kunihito Miyake

Organic Synthesis Research Laboratory, Sumitomo Chemical Co., Ltd, Tsukahara, Takatsuki, Osaka 569-1093, Japan

Direct amination of nitropyridines with methoxyamine in the presence of a stoichiometric amount of zinc(II) chloride under basic conditions proceeds to give aminonitropyridines.

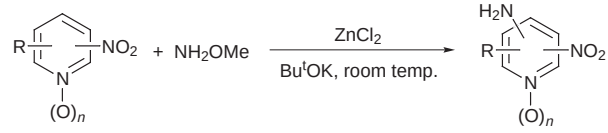
Direct amination of nitropyridine is a simple synthetic approach to aminonitropyridines, which are of great importance as intermediates of various biologically active compounds containing imidazopyridine, triazolopyridine *etc*.[1] The well-known Chichibabin amination,[2] in which the α-position of the pyridine ring is aminated by an alkali metal amide, fails to aminate nitropyridines.[3] Although oxidative direct amination of 3-nitropyridines using liquid ammonia/potassium permanganate has been reported,[4] 2- and 4-nitropyridines do not react in this system. On the other hand, alkylation of nitropyridines[5] and amination of nitrobenzenes[6] *via* vicarious nucleophilic substitution (VNS),[7] which has been extensively studied by Makosza, has been reported. However, little attention has been given to the VNS amination of nitropyridines.[8] Recently, we have found that alkoxyamines, in particular methoxyamine,[9] efficiently aminate nitrobenzenes in the presence of a copper catalyst *via* VNS.[10] As part of our investigations to develop new amination, we report here the direct amination of nitropyridines with methoxyamine in the presence of a stoichiometric amount of a zinc salt.

Treatment of 6-methoxy-3-nitropyridine with methoxyamine in the presence of a stoichiometric amount of zinc(II) chloride under strongly basic conditions in DMSO at room temperature gave 2-amino-6-methoxy-3-nitropyridine in 87% yield (Table 1, entry 1). The yield of the amination was strongly influenced by the combination of substrates and solvents used. In diethoxymethane (DEM), THF, DME, toluene and DMF, yields of 2-amino-6-methoxy-3-nitropyridine were 62, 59, 43, 19 and 0%, respectively (entries 2, 3, 4, 5 and 6). In DMF, the reaction with 2-chloro-3-nitropyridine also did not give the aminated products (entry 12). However, with 4-nitropyridine or 2-amino-3-nitropyridine, DMF was a good solvent (entries 7, 8 and 15). In general, DMSO was relatively favored in this reaction. DMSO may play a significant role in the activation of a Meisenheimer intermediate,[11] which result from nucleophilic attack of methoxyamine *ortho* or *para* to the nitro group.

4-Nitropyridine and 4-nitropyridine *N*-oxide were aminated with methoxyamine to afford 3-amino-4-nitropyridine and 3-amino-4-nitropyridine *N*-oxide, respectively (entries 7 and 8). The *N*-oxide provided the better result. The product is a precursor of 3,4-diaminopyridine, an important intermediate of many pharmaceuticals, which is presently synthesized from pyridin-4-ol *via* a tedious reaction sequence.[1c] Our methodology provides a new efficient route to 3,4-diaminopyridine from 4-nitropyridine *N*-oxide, which is cheaper than pyridin-4-ol. The use of other metallic halides as a promoter of the reaction with 4-nitropyridine *N*-oxide was examined. In the presence of titanium(IV) chloride, manganese(II) chloride, cobalt(II) chloride, nickel(II) chloride, copper(I) chloride or aluminum(III) chloride instead of zinc(II) chloride, the reaction gave 3-amino-4-nitropyridine *N*-oxide in 2, 8, 17, 0, 35 and 0% yields, respectively. The result with copper(I) chloride lacked reproducibility although it was similar to that with zinc(II) chloride. Thus zinc(II) chloride was found to be the best promoter of this amination. In the absence of zinc catalyst, the reaction did not proceed and starting material was recovered. The zinc(II) salt may act as an acceptor of an unshared electron pair from the nitrogen in pyridine ring or the oxygen of the *N*-oxide, and thus activates the substrate. A catalytic amount of zinc salt is insufficient to promote the amination since zinc also forms a coordination complex with the product as well as the substrate. This differs from the previously reported copper-catalyzed amination of nitrobenzenes with methoxyamine, in which interaction between the copper catalyst and methoxyamine was observed.[10]

An *ortho* selectivity with respect to the nitro group was observed in the case of 2-chloro-3-nitropyridine (entries 10 and 11). This selectivity is in good agreement with those observed in the amination of nitrobenzenes with methoxyamine.[10] We presume that in both cases (Scheme 1, X = C,N), *ortho* selectivity was observed because the neighboring nitro group in the σ-adduct **3**, derived from the *ortho* attack of methoxyamine on the nitroarene, assists in the elimination of the methoxy anion *via* a five-membered intermediate **4**.[6b] In contrast, Wozniak has reported that the same substrate was aminated by liquid ammonia/potassium permanganate with *para* selectivity to give mainly 6-amino-2-chloro-3-nitropyridine in 40% yield.

Table 1 Direct amination of nitropyridines **1** with methoxyamine[a]



1 **2**

Entry	R	*n*	Position of NO_2	Solvent	Position of amination	Yields[b] (%) of **2**
1	6-MeO	0	3	DMSO	2	87
2	6-MeO	0	3	DEM	2	62 (70)[c]

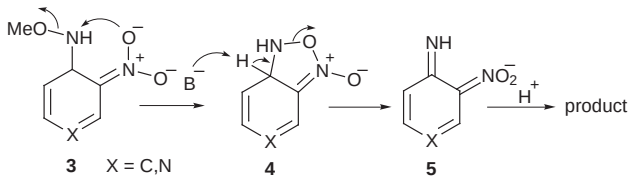
15[d]	2-NH_2	0	3	DMF	6	53
16[d]	2-NH_2	0	5	DEM	6	17 (26)[c]
17[d]	2-OH	0	5	DEM	6	9 (17)[c]

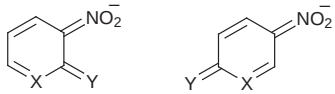
[a] Unless otherwise noted, the amination of **1** was carried out with methoxyamine (1.5 equiv.), zinc(II) chloride (1 equiv.) and potassium *tert*-butoxide (3 equiv.) in solvent at room temperature for 1–10 h. [b] Isolated yields. [c] Yields in parentheses are based on the conversion of **1**. [d] 4 equiv. of potassium *tert*-butoxide was used.



Scheme 1

He explained that the orientation of this reaction was controlled by the charge distribution.[4] However, neither charge control nor orbital control obtained by molecular calculations could explain our results.

It is noteworthy that the amination of 2-amino-3-nitropyridine, 2-amino-5-nitropyridine and 5-nitropyridin-2-ol in the presence of excess base (4 equiv.) proceeded (entries 14, 15, 16 and 17), despite no previous reports of VNS reactions of *o*- or *p*-nitroaniline and *o*- or *p*-nitrophenol. Under strongly basic conditions, *o*- or *p*-nitroaniline, *o*- or *p*-nitrophenol, 2-amino-3-nitropyridine, 2-amino-5-nitropyridine, 3-nitropyridin-2-ol and 5-nitropyridin-2-ol are easily deprotonated to form **6** or **7**. A

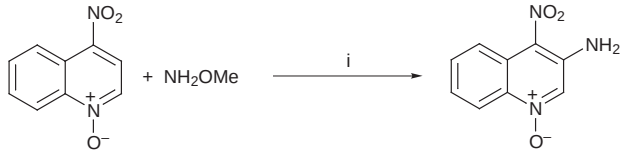


a X = C, Y = NH, O
b X = N, Y = NH, O

nucleophile cannot attack **6a** and **7a** because of the lack of an electrophilic carbon center. However nitropyridine derivatives **6b** and **7b** are susceptible to addition of a nucleophile at the α-position of the pyridine ring as well as to the Chichibabin reaction. Therefore, the amination of 2-amino-3-nitropyridine did not proceed with *ortho* selectivity but proceeded with *para* selectivity to give 2,6-diamino-3-nitropyridine (entries 14 and 15).

Similarly 4-nitroquinoline *N*-oxide was aminated, although in low yield (Scheme 2). This is important because, in spite of many reports of direct amination of bicyclic nitroarenes[12] with hydroxylamine or liquid ammonia/potassium permanganate, direct amination of 4-nitroquinoline derivatives has not been previously reported.

A typical experimental procedure is as follows. To a suspension of $ZnCl_2$ (1 mmol) and Bu^{t}OK (3 mmol) in DMSO



Scheme 2 *Reagents and conditions:* i, $ZnCl_2$, Bu^{t}OK, DMF, room temp., 21%.

(3 ml) was added dropwise a solution of the nitropyridine (1 mmol) and NH_2OMe (1.5 mmol) in DMSO (2 ml), and the mixture was stirred at room temperature. After 1–10 h, the reaction was quenched in saturated aq. NH_4Cl and the products were extracted with EtOAc. The combined organic layers were washed with water, dried, filtered and concentrated. The crude products were purified by silica gel thin layer chromatography to afford the pure aminonitropyridine.

In conclusion, we have developed a new direct amination of nitropyridines with methoxyamine in the presence of a stoichiometric amount of zinc salt. An *ortho* selectivity to the nitro group was observed, which is useful for the synthesis of many pharmaceuticals containing imidazopyridine, triazolopyridine and so on. The general, industrially practical method for direct amination of aromatic compounds has yet to be achieved, especially from the viewpoint of environmental protection. Further studies in this field are in progress in our laboratory.

We thank Professor Z. Yoshida and Professor M. Tokuda for helpful discussions.

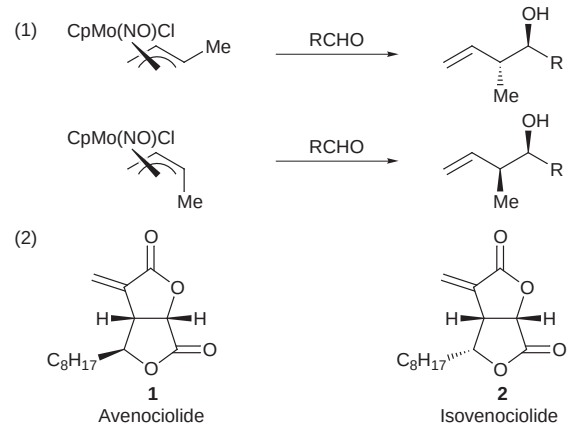
An efficient method for total syntheses of avenaciolide and isoavenaciolide *via* tungsten-π-allyl complexes

Kesavaram Narkunan and Rai-Shung Liu*†

Department of Chemistry, National Tsing-Hua University, Hsinchu, 30043, Taiwan, ROC

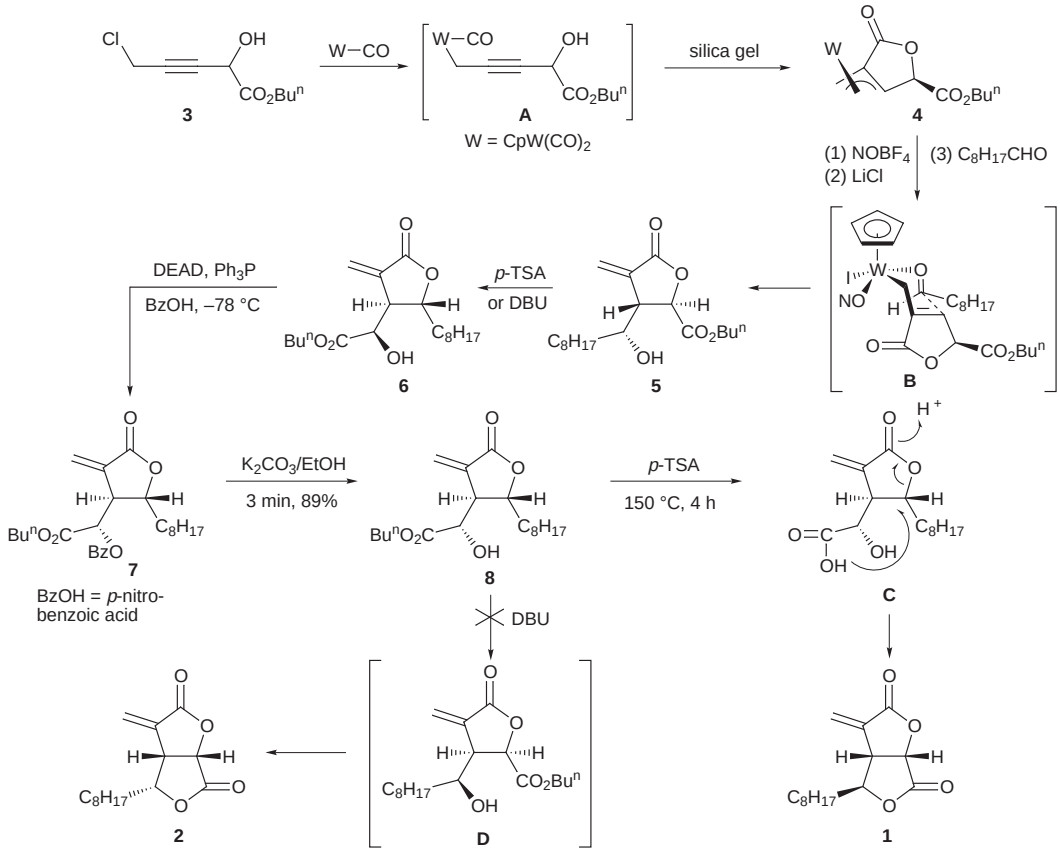
Total syntheses of avenaciolide and isoavenaciolide were achieved in six and three steps respectively based on starting chloropropargyl derivatives; the key step in such syntheses involves intramolecular alkoxycarbonylation of tungsten-η¹-propargyl complexes.

There has been increasing interest in the utilization of molybdenum- or tungsten-π-allyl compounds for organic syntheses.[1,2] Faller *et al.* reported[3] that CpMo(NO)Cl(η³-allyl)[3] condensed with aldehydes *via* a chairlike transition state, yielding homoallylic alcohols with excellent diastereoselectivities (Scheme 1). We applied this method to the syntheses of acyclic 1,3-diols, 1,3,5-triols and other oxygen heterocycles.[4] Despite numerous studies on these π-allyl species, there is no precedent for the synthesis of natural products based on these organometallics. Avenaciolide **1** and isoavenaciolide **2** are secondary metabolites isolated from *Aspergillus* and *Penicillium*; total syntheses of these two compounds have attracted considerable attention[4,5] because of their diverse and potent biological activities. In this paper, we report total syntheses of these two bislactones based on tungsten-π-allyl complexes; this synthetic protocol is highly efficient because only a few steps are required from the starting chloropropargyl derivatives **3** and **9**.

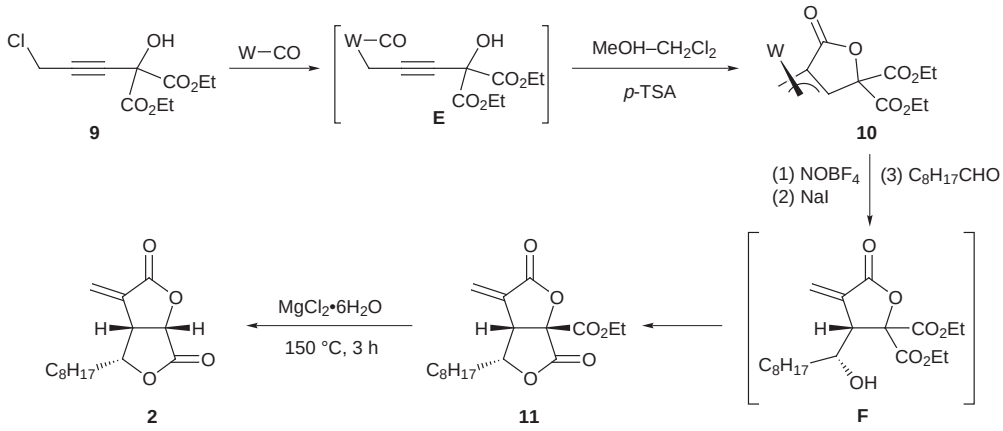


Scheme 1

The starting compound **3** is readily available from propargyl chloride and *n*-butylglyoxalate.[6] As shown in Scheme 2, treatment of **3** with $CpW(CO)_3Na$ (1.3 equiv.) yielded tungsten-η¹-propargyl complex **A** which was not isolated due to its high reactivity. Elution of this tungsten species through a silica



Scheme 2



Scheme 3

column induced intramolecular alkoxycarbonylation[4a,b] to yield tungsten-*syn*-π-allyl complex **4** in 70% yield. The *syn*-configuration of **4** is indicated by the coupling constant J_{34} = 3.1 Hz.[4a,b] Sequential treatment of **4** with $NOBF_4$ (1.0 equiv.) and LiCl (2.0 equiv.) in CH_3CN generated an allyl anion equivalent[3] that reacted with $C_8H_{17}CHO$ to yield α-methylene butyrolactone **5** in 62% isolated yield. The *trans*-configuration of **5** was confirmed by a proton NOE experiment. Determination of the remaining $CH(OH)C_8H_{18}$ configuration relies on its transacylation product **6**. The stereochemistry of **5** can be rationalized based on a chairlike transition structure **B** in which the new carbon–carbon bond is formed opposite the CO_2Bu^n substituent. Although compound **5** has a structural skeleton like those for avenaciolide **1** and isoavenaciolide **2**, inversions of configuration of the C(5) and C(1′) carbons and at the C(5) carbon of **5** are required to produce bislactones **1** and **2** respectively. Notably, epimerization at the C(5) carbon of **5** is expected to give isoavenaciolide **2**. Toward this direction, compound **5** was heated in toluene for 7 hours with the DBU catalyst (0.30 equiv.), however transacylation occurred to yield a new α-methylene butyrolactone **6** in 86% yield that also has a *trans*-configuration. Under the same conditions, the *p*-TSA (*p*-toluenesulfonic acid) catalyst (0.20 equiv.) also gave compound **6** in 91% yield. Hence, we sought to invert the configuration at the CH(OH) carbon of **6**; this was achieved by the Mitsunobu reaction,[7] sequentially giving **7** and **8** in 90% and 89% yields respectively. Heating **8** with excess *p*-TSA·H_2O (2.0 equiv.) in toluene in a sealed tube (150 °C, 4 h) produced the desired avenaciolide **1** in 62% yield together with isoavenaciolide **2** in 5% yield. The generation of **1** can be envisaged to proceed from intramolecular attack of the acid group of **8** at its C(5) carbon to invert its stereoconfiguration,[5c,d] ultimately yielding avenaciolide **1**. Attempts to synthesise isoavenaciolide **2** *via* base-catalyzed transacylation of compound **8** were unsuccessful. Heating a mixture of DBU (0.2–2.0 equiv.) and **8** in toluene at reflux for 72 h did not show any sign of chemical reaction, and the starting material **8** was recovered exclusively.

We sought to develop an alternative approach to the synthesis of isoavenaciolide **2** *via* tungsten-π-allyl complexes; the whole synthesis requires only a few steps from chloropropargyl species **9**.[8] As shown in Scheme 3, treatment of **9** with $CpW(CO)_3Na$ (2.0 equiv.) in THF at 23 °C gave the expected tungsten-η^1-propargyl species **E** which was subsequently treated with *p*-TSA·H_2O (1.0 equiv.) in a MeOH–CH_2Cl_2 mixture (volume ratio = 1 : 10) to induce alkoxycarbonylation to yield tungsten-π-allyl complex **10** in 65% yield. Further conversion of **10** produced a π-allyl anion equivalent *via* sequential treatment with $NOBF_4$ (1.0 equiv.) and NaI (2.0 equiv.), which then reacted with $C_8H_{17}CHO$ to yield a 62% yield of bislactone species **11** which was presumably produced *via* lactonization of the primary species **F**. Decarboxylation of **11** proceeded smoothly through heating its dimethylacetamide solution (150 °C, 3 h) containing $MgCl_2·6H_2O$ (5.0 equiv.)[9] to afford the desired isoavenaciolide **2** in 59% yield.

In summary, we report here the first example of the use of tungsten-π-allyl complexes for the efficient syntheses of naturally occurring compounds such as avenaciolide and isoavenaciolide. The overall synthetic scheme‡ is considered to be the most efficient of the known methods. This demonstration highlights the use of tungsten-allyl complexes in the syntheses of natural products.

Hydroxylation of alkanes by molecular oxygen with dinuclear Fe^{II} macrocyclic complexes as catalysts

Zheng Wang, Arthur E. Martell*† and R. J. Motekaitis

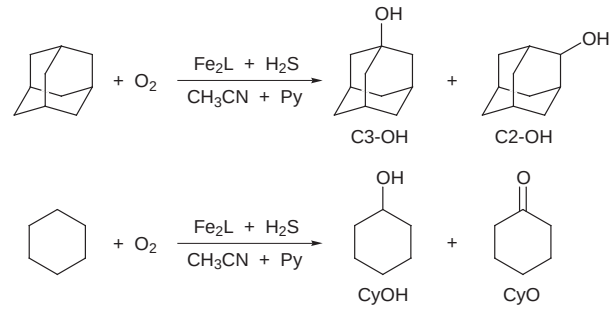
Department of Chemistry, Texas A&M University, College Station, Texas TX77843-3255, USA

The iron(II) complexes of two new macrocyclic ligands: [24]RBPyBC (L24), a 24-membered macrocycle containing phenol, pyridine and amino donor groups, and [30]RBBPyBC (L30), a 30-membered macrocycle containing phenol, bipyridine, and amino donor groups, were found to be effective for the hydroxylation of alkanes, including cyclohexane and adamantane, with H_2S as a two-electron reductant.

The synthesis, characterization, and metal-binding properties of two new macrocyclic ligands [24]RBPyBC (L24) and [30]RBBPyBC (L30) have been reported,[1–3] and the stabilities of their mixed-valence dinuclear iron(II,III) chelates were described. It has now been discovered that the dinuclear iron(II) complexes of these ligands catalyze the hydroxylation of the hydrocarbons cyclohexane and adamantane in the presence of a two-electron reductant (H_2S) and thus may serve as functional models of methane monooxygenase.

Methane monooxygenase is known to contain a binuclear iron active center[4] and has been mimicked by a number of dinuclear model complexes,[5] but in most cases an oxidant such as H_2O_2 or ROOH was used. Descriptions of model systems containing porphyrin ligands in which the oxidant was molecular oxygen have been published.[6] Of the model systems that have molecular oxygen as an oxidant and do not contain porphyrin ligands are the GIF systems of Barton *et al.*,[7] an O_2/Zn/HOAc system of Christou *et al.*[5] and of Kitajima *et al.*,[8] and the present work.

The new dinuclear iron(II) complexes of the macrocyclic ligands designated above, L24 and L30, are indicated below by **1** and **2**, respectively. These dinuclear Fe^{II} complexes are believed to react with oxygen to form a diiron–peroxide intermediate. The active species may decay to a dinuclear Fe^{III} complex with an oxo bridge, releasing an oxygen atom for insertion (hydroxylation) of a hydrocarbon. In the presence of a two-electron reductant the dinuclear Fe^{III} species may revert back to the dinuclear Fe^{II} complex to complete the catalytic cycle.



Scheme 1 Oxidation of adamantane and cyclohexane by molecular dioxygen with diiron complexes as catalysts

The overall oxidation reactions are shown in Scheme 1, which shows the organic substrates and reaction products. The results obtained for the hydroxylation of adamantane and cyclohexane are summarized in Tables 1 and 2. Typical oxidation reaction procedures were as follows: at room temperature and atmospheric pressure, 0.10 mmol of free macrocyclic ligand L24 or L30 was dissolved in 40 ml of CH_3CN. $FeCl_2{\cdot}4H_2O$ (0.20 mmol) was added to initiate iron complex formation. After the mixture was stirred for 10 min, the solution turned dark violet signifying the formation of the dinuclear iron complexes Fe_2L24, **1**, or Fe_2L30, **2**. While stirring was continued, 20 mmol cyclohexane or adamantane was added, then 1.0 ml pyridine was added. Hydrogen sulfide (2 ml min^{-1}) and dioxygen (20 ml min^{-1}) were simultaneously passed through the solution. After successive 2 h periods, the reaction mixture was filtered from the deposited sulfur and the solution was analyzed.

An aliquot (1.0 ml) was taken from the reaction solution and added to an aqueous NaOH solution (5%, 2 ml) at 0 °C. The products were extracted with diethyl ether (3 × 5 ml) and dried over $MgSO_4$. A naphthalene solution (1.0 ml, 0.080 M in diethyl ether) was added as an internal standard. The organic products were quantitatively analyzed by gas chromatography.

Table 1 Oxidation of adamantane by molecular oxygen with diiron complexes as catalysts and hydrogen sulfide as reductant[a]

Catalyst	Time/h	C3-OH/ mmol	C2-OH/ mmol	C3-OH/ C2-OH	Turnover
Fe_2L24	2	0.099	0.29	0.37	3.7
	4	0.867	0.749	1.16	16.2
	6	1.13	0.882	1.28	20.1
	8	1.27	1.05	1.21	23.2
	10	1.51	1.22	1.24	27.3
	20	2.38	2.13	1.12	45.1
Fe_2L30	2	0.360	0.355	1.01	7.2
	4	0.502	0.400	1.26	9.0
	6	0.621	0.492	1.26	11.1
	8	0.782	0.574	1.36	13.6
	10	0.79	0.642	1.24	14.4
	12	0.850	0.719	1.18	15.7

[a] Reaction conditions: $FeCl_2$ (0.20 mmol), ligand (0.10 mmol), adamantane (20 mmol), pyridine (1.0 ml), and CH_3CN (40 ml) at 25 °C. Oxygen and hydrogen sulfide were purged through the solution. Turnover is based on mmols of the products per mmol of the catalyst used.

Table 2 Oxidation of cyclohexane by molecular oxygen with diiron complexes as catalysts and hydrogen sulfide as reductant[a]

Catalyst	Time/h	CyOH/ mmol	CyO/ mmol	CyOH/ CyO	Turnover
Fe_2L24	2	0.96	0.50	1.92	14.6
	4	1.38	0.70	1.97	20.8
	6	1.61	0.73	1.94	24.4
	8	1.85	0.99	1.87	28.4
	10	2.06	1.04	1.98	31.0
	12	2.33	1.26	1.85	35.9
Fe_2L30	2	0.64	0.60	1.07	12.4
	4	0.89	0.83	1.07	17.2
	6	1.10	1.04	1.06	21.4

[a] Reaction conditions: $FeCl_2$ (0.20 mmol), ligand (0.10 mmol), cyclohexane (20 mmol), pyridine (1.0 ml), and CH_3CN (40 ml) at 25 °C. Oxygen and hydrogen sulfide were purged through the solution. Turnover is based on mmols of the products per mmol of the catalyst used.

The mmols of products = $P_{product}/P_{naphthalene} \times 40$ ml $\times$ 0.080 M. The turnovers = the sum of mmols of products/mmol of catalyst. The turnover numbers show that these macrocyclic iron complexes are several times more effective as hydroxylating catalysts for cyclohexane than are the μ-oxo dinuclear iron complexes containing a tris(pyrazol-1-yl)borate ligand described by Kitajima *et al.*[8b] The effectiveness in the catalytic oxidation of adamantane is approximately at the same level as Kitajima's catalyst.[8b] Thus the dinuclear macrocyclic iron(II) complexes described in this paper are among the most effective functional models of methane monooxygenase reported thus far.

The oxidation of cyclohexane gives cyclohexanol and cyclohexanone. The turnovers are 24.4 after 6 h for the 24-membered macrocyclic diiron complex as a catalyst, or 21.4 after 6 h with the 30-membered macrocyclic complex. The ratios of cyclohexanol to cyclohexanone are 1.9 and 1.1 for **1** and **2**, respectively, during the whole period of time of the oxidation reactions. This result shows that the mechanisms of oxidation are similar but slightly different for the two catalysts.

The recent stability studies of dinuclear and mononuclear Fe^{II} and Fe^{III} complexes of the ligand indicate the dinuclearity of the complexes under reaction conditions. Accordingly, the electronic spectra of the reaction mixture before and after the reactions show the same characteristic absorption bands that are attributed to hydroxo dinuclear iron complexes. Thus, we suggest that the active center is a diiron species and the reaction mechanism probably resembles that of MMO.

H_2S serves as both an electron and a proton donor, the equivalent of NADH in MMO systems. The diiron(II) complex can be regenerated from the oxidized diiron(III) complex with H_2S as a two electron reductant to produce a sulfur precipitate which was analyzed quantitatively after the experiment.

In the control experiments for the oxidation of cyclohexane, the turnover is 1.1 in 8 h with Fe^{II} as a catalyst and is 1.7 in 8 h with pyridine as a ligand. Significantly, the turnover is 28.4 in 8 h with the use of the macrocyclic ligand. Autoxidation is clearly ruled out by comparison with these turnover numbers.

It is interesting that the oxidation of adamantane produces only hydroxylation products. The ratio of tertiary adamantanol to secondary adamantanol is around 1.2 for both catalysts. No ketonization product is observed even when the turnover is 45.1 after 20 h. A similar result was obtained by Kitajima *et al.*,[8b] who reported only a trace of ketonization product. This result seems to imply a difference in the mechanisms of oxidation of cyclohexane and adamantane.

The turnover numbers show that the iron complex of the 24-membered macrocycle is a better catalyst for these oxidation reactions than that of the 30-membered macrocycle.

This research was supported by The Robert A. Welch Foundation under Grant No. A-0259. The authors thank Dr Li Tingsheng for assistance with gas chromatography.

Large aligned-nanotube bundles from ferrocene pyrolysis

C. N. R. Rao,*† Rahul Sen, B. C. Satishkumar and A. Govindaraj

CSIR Centre of Excellence in Chemistry, Solid State and Structural Chemistry Unit and Materials Research Centre, Indian Institute of Science, Bangalore, 560012, India

Aligned-nanotube bundles have been obtained in copious quantities by the pyrolysis of ferrocene or ferrocene–acetylene mixtures.

Aligned carbon nanotubes have aroused much interest because of their mechanical properties[1,2] as well as their interesting anisotropic optical and other properties.[2] Aligned carbon nanotube films have also been considered to be good candidates as electron field emitters.[3] One of the procedures employed to prepare nanotube films is to pass a dispersion of arc-produced carbon nanotubes in ethanol through an alumina micropore filter and then press the nanotube-covered filter onto a polymer sheet.[4] Under pressure, the nanotubes are printed onto the sheet in an aligned manner. Aligned nanotubes have also been obtained by the chemical vapor deposition of acetylene catalyzed by iron nanoparticles embedded in mesoporous silica,[5] the pores of the silica controlling the growth direction of the nanotubes. Recently, aligned-nanotube bundles have been prepared by the pyrolysis of 2-amino-4,6-dichloro-*s*-triazine over thin films of a cobalt catalyst, patterned on a silica substrate by laser etching.[6] We have been interested in finding a simple means of producing aligned nanotubes in large quantities and were encouraged in this direction by the discovery that the pyrolysis of hydrocarbons in the presence of organometallic precursor molecules gives good yields of carbon nanotubes.[7] Realizing that a precursor such as ferrocene not only gives rise to small catalytic metal particles but also acts as a carbon source, we carried out systematic experiments on the pyrolysis of ferrocene. Initial experiments showed that aligned nanotubes are produced under certain conditions. We have varied the conditions of the pyrolysis of ferrocene and also carried out the pyrolysis in the presence of acetylene which acts as an additional carbon source, and have found these methods to yield large quantities of aligned-nanotube bundles. In this communication, we report this rather impressive result obtained by a very simple technique.

The procedure employed for the pyrolysis of ferrocene was as follows. A known quantity (100 mg) of ferrocene (presublimed, *ca*. 99.99% purity) was placed in a quartz boat located at one end of a narrow quartz tube (10 mm i.d.), which in turn was placed in a dual furnace system. The part of the quartz tube containing the ferrocene was in the first furnace and the ferrocene was sublimed by raising the temperature of this furnace to 620 K at a controlled heating rate. Argon gas was passed through the quartz tube at a desired rate. The ferrocene vapour was carried by the Ar gas into the second furnace, maintained at 1370 K, where pyrolysis occurred. The main variables in the experiments were the heating rate of ferrocene, the flow rate of the argon gas and the pyrolysis temperature. Large quantities of deposits accumulated at the inlet of the second furnace. These carbon deposits, mainly containing carbon nanotubes, were examined by a LEICA S440i scanning electron microscope (SEM) and a JEOL 3010 transmission electron microscope (TEM).

In Fig. 1(*a*) and (*b*), we show the SEM images of the nanotubes obtained by carrying out the pyrolysis of ferrocene at 1370 K with a fast heating rate of ferrocene (100 °C min^{-1}) and a high flow rate of Ar (1000 sccm; sccm = standard cubic cm per min). The images in Fig. 1(*a*) and (*b*), which are recorded in two different directions with respect to the axis of the nanotubes, clearly reveal the extraordinary alignment. TEM images of these nanotubes revealed that they were multi-walled, some of them partially filled with metallic iron. Pyrolysis of ferrocene at 1170 K under vacuum (10^{-5} Torr) also yielded good quantities of aligned-nanotube bundles. In Fig. 1(*c*) we

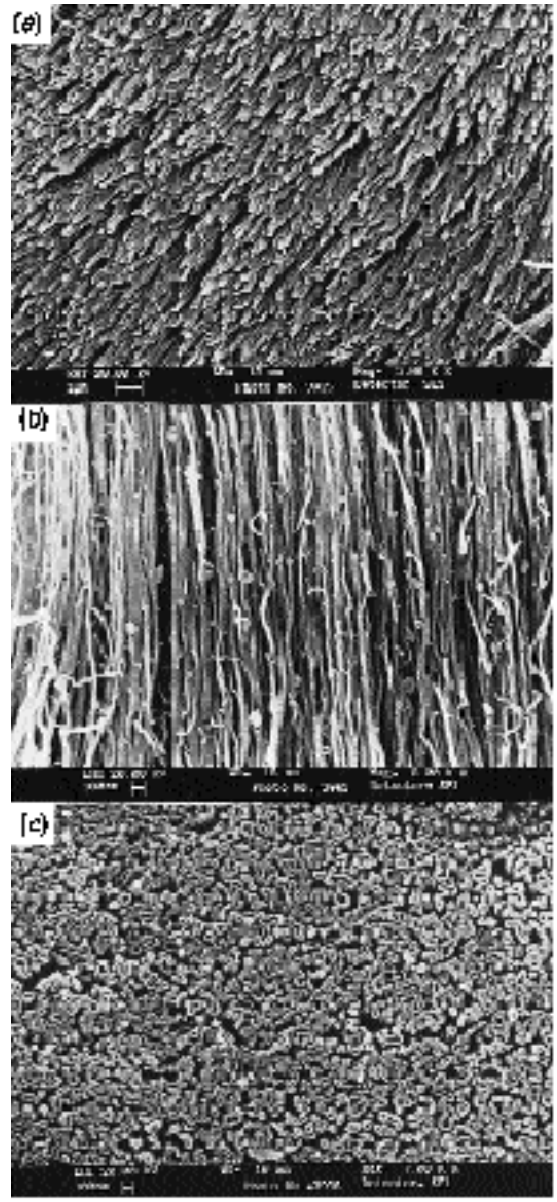

Fig. 1 SEM images of aligned carbon nanotubes obtained by the pyrolysis of ferrocene: (*a*) and (*b*) show views of the aligned nanotubes along and perpendicular to the axis of the nanotubes, (*c*) shows a top view of aligned nanotubes obtained by the pyrolysis of ferrocene under vacuum (10^{-5} Torr) at a slow heating rate (1 °C min^{-1})

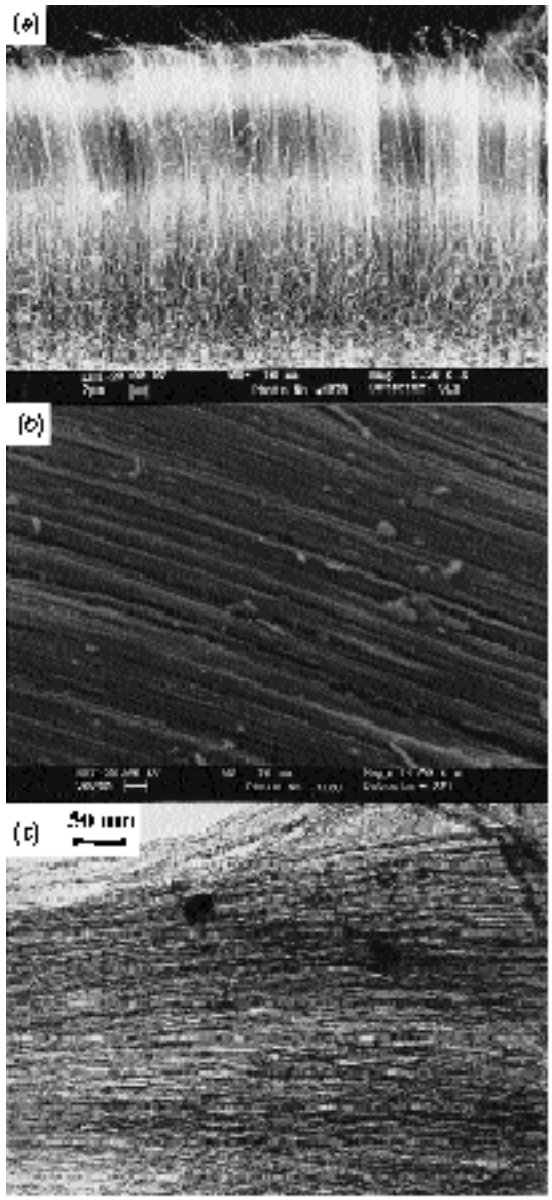

Fig. 2 (*a*) An SEM image of aligned nanotubes obtained by the pyrolysis of ferrocene at 1370 K under a flow of C_2H_2 (5 sccm) and Ar (1000 sccm). In (*b*) and (*c*), we show SEM and TEM images of densely packed aligned nanotubes obtained by the pyrolysis of ferrocene at 1370 K in the presence of a higher proportion of C_2H_2 [flow of C_2H_2 (85 sccm) and Ar (1000 sccm)].

show a top view of such nanotubes. When the rate of heating of ferrocene (1 °C min^{-1}) and the flow rate of argon (10 sccm) were low, fewer aligned nanotubes were obtained at a pyrolysis temperature of 1370 K.

We carried out the pyrolysis of ferrocene with acetylene, by passing a mixture of argon and acetylene through the quartz tube. In Fig. 2(*a*), we show an SEM image of the aligned nanotubes obtained by the pyrolysis of a mixture of ferrocene and acetylene (5 sccm) at 1370 K in flowing Ar (1000 sccm). The alignment could be further improved by increasing the flow rate of C_2H_2. The SEM image in Fig. 2(*b*) obtained in this manner shows densely packed aligned nanotubes. The TEM image in Fig. 2(*c*) reveals how well aligned these nanotubes are. The nanotubes in the bundles were generally closed and were 5–10 μm in length.

Pyrolysis of ferrocene was carried out at a heating rate of 50 °C min^{-1} under a vacuum (10^{-5} Torr). Here, the ferrocene sublimed under vacuum and the vapour was drawn into the pyrolysis zone. In these experiments we mainly obtained

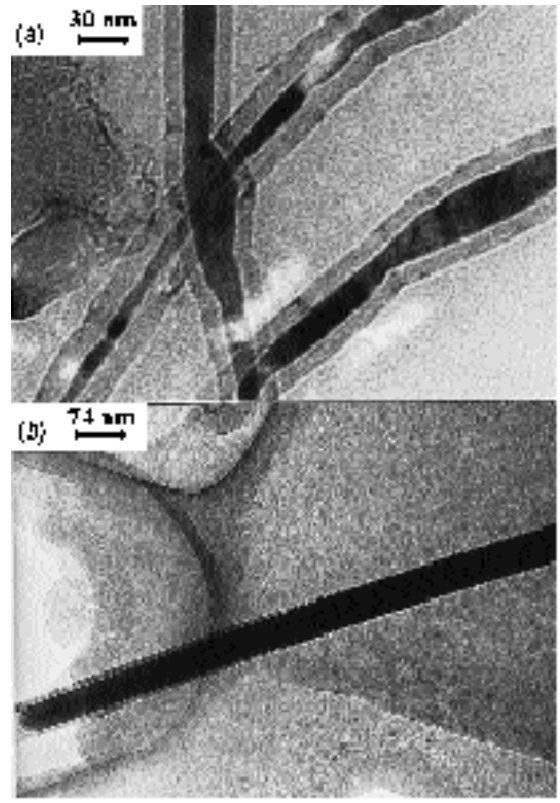

Fig. 3 TEM images of carbon-coated iron nanorods obtained by the pyrolysis of ferrocene (*a*) at 1170 K under vacuum (10^{-5} Torr) and (*b*) at 1370 K under a flow of Ar (10 sccm)

carbon-coated iron nanorods (yield ≥60%). In Fig. 3(*a*), we show a TEM image of metal nanorods with a thick carbon coating, obtained by the pyrolysis of ferrocene at 1170 K under vacuum. We also obtained a fair proportion of nanorods when the flow rate of Ar was low (10 sccm). In Fig. 3(*b*) we show a TEM image of a nanorod obtained by the pyrolysis of ferrocene at 1370 K under an Ar flow of 10 sccm. Note that such nanorods have been reported in the literature, produced by the reaction of carbon nanotubes with volatile oxide or halide species.[8] The present method of producing nanorods is much simpler. The formation of metallic iron in the form of particles or rods in the pyrolysis of ferrocene suggests that the mechanism of alignment of the nanotubes may be related to the magnetic nature of the nanorods or particles of iron.

Synthesis and structure of $[\{Bu^tP)_2H\}K\cdot pmdeta]_2$, containing an organo diphosphido ligand [pmdeta = $(Me_2NCH_2CH_2)_2NMe$]

Reduction of $[Bu^tP]_4$ with K metal (1 : 5 equiv.) followed by the addition of pmdeta and stoichiometric hydrolysis gives $[\{(Bu^tP)_2H\}K\cdot pmdeta]_2$, a unique complex containing a $[Bu^tP(H)PBu^t]^-$ anion ligand homologous with a phosphido anion (R_2P^-).

Early investigations showed that the reduction of $[RP]_4$ by alkali metals leads to fragmentation of the cyclic P_4 rings, giving species containing various anions {such as $[RP]_4^{2-}$, $[RP]_3^{2-}$, $[RP]_2^{2-}$ and $[(RP)_2(H)]^-$} depending on the reaction stoichiometries.[1] However, the solids isolated were mainly characterised by elemental analysis and NMR spectroscopic studies on these and related systems indicated later that mixtures of anions are produced in solution.[2] Owing to the lack of X-ray structural data on the alkali metal complexes and the difficulty in isolating the pure components there have been few systematic investigations of the coordination chemistry of the organopolyphosphido anions and their reactivity with other metal centres is poorly understood.[3] Our emerging interest in the potential use of these anions as ligands to main group elements has lead us to reinvestigate the reduction of $[Bu^tP]_4$ with alkali metals, with the aim of developing well defined reagents for transmetallation.

We report here that the reaction of $[Bu^tP]_4$ with potassium metal (1 : 5 equiv.) in thf followed by the addition of pmdeta and stoichiometric hydrolysis gives the crystalline complex $[\{(Bu^tP)_2H\}K\cdot pmdeta]_2$ **1** (Scheme 1).‡ This complex is the first representative of this type of alkali metal complex to be fully characterised in pure form. Evidence for the presence of the H atom in the anion of **1** is obtained from the IR spectrum (ν_{P-H} 2005 cm^{-1}). In addition, the room-temperature ^{31}P NMR spectrum is similar to that previously reported for $[\{(Bu^tP)_2H\}K]$ in thf (produced in trace amounts in the reaction of K metal with $[Bu^tP]_4$),[2a] although with a markedly larger $^1J_{PH}$ coupling constant in **1** (*ca.* 201 Hz;[5] *cf. ca.* 137 Hz[2a]). The ^{31}P NMR spectrum illustrates that the anion has a rigid structure in solution in which the proton is bonded solely to one P centre (with no intra- or inter-molecular exchange occurring).

The low-temperature X-ray structure of **1**§ shows that it exists as dimeric molecules in the solid state in which two $[(Bu^tP)_2H]^-$ anions are associated into a ring structure by two pmdeta-solvated K^+ cations [Fig. 1(*a*)]. Although a number of lithium organophosphides (containing R_2P^-) have been structurally characterised in recent years,[6] very few complexes of the heavier alkali metals have been reported.[7] Complex **1** is the first containing an organodiphosphide anion, the second homologue of a potential series of organo polyphosphide chain anions of the type $[R_{2x+1}P_x]^-$. The closest analogues of **1** are phosphoramides[8] such as the dimer $[\{Ph_2PN(Ph)\}Li\cdot Et_2O]_2$, containing a $[\{Ph_2PN(Ph)\}]^-$ anion.[8a] The only other alkali metal organo polyphosphide to be reported is $[\{(Bu^t_2P)_2P\}Li\cdot 2thf]$, containing a 'branched' $[(Bu^tP)_2P]^-$ anion.[9]

The anionic P centres of the $[(Bu^tP)_2H]^-$ ligands form the central K_2P_2 ring of the dimeric structure of **1** [K(1)–P(1) 3.340(3), K(1)–P(1a) 3.251(2) Å]. Secondary coordinative interactions occur with the neutral P centres of each $[(Bu^tP)_2H]^-$ anion [P(2)–K(1) 3.658(3) Å]. The bidentate

Scheme 1

coordination mode of the $[(Bu^tP)_2H]^-$ ligands in **1** is similar to that found in dimeric alkali metal phosphoramides[8] and hydrazides,[10] in which P,N and N,N chelation of the alkali metals by the $[R_2PNR]^-$ and $[R_2NNR]^-$ anions occurs. However, one significant difference with the latter is the unusual *cis* orientation of the $[(Bu^tP)_2H]^-$ ligands with respect to the K_2P_2 dimer ring of **1** [giving a 'boat-like' rather than 'chair-like' core, Fig. 1(*b*)]. This orientation seems most likely to be steric in origin. A noteworthy feature in **1** is the presence of a relatively short P–P bond [2.135(3) Å] which is well below distances normally anticipated for single bonds (*ca*. 2.20 Å) and similar to those found in transition metal complexes containing η^2-RP=PR ligands (*ca*. 2.1 Å).[3] In dimeric complexes containing isoelectronic $[R_2NNR]^-$ anions the N–N bonds are generally longer than in neutral hydrazines, as a result of enhanced lone pair repulsion.[10] The shortening of the P–N bonds in complexes containing $[R_2PNR]^-$ ligands may partly be a result of $p_\pi(N)$–$d_\pi(P)$ bonding. However, although the possibility of such bonding cannot be discounted in the $[(Bu^tP)_2H]^-$ anion the principal reason for the short P–P bond length probably stems from compression arising from the chelation of the K^+ cations.

The isolation and full characterisation of **1** provides a well defined and readily accessible source of the $[(Bu^tP)_2H]^-$ anion for application as a ligand to a range of metals. In addition, the presence of a reactive proton also furnishes the potential for further metallation. In this regard preliminary ^{31}P studies indicate that the major product formed by the reaction of **1** with Bu^nLi is not the expected $[Bu^tP]_2^{2-}$ dianion but the $[Bu^tP]_3^{2-}$ dianion.‡

‡ *Synthesis* of **1**; to a solution of $[Bu^tP]_4$ (1.0 g, 2.84 mmol)[1a] in thf (40 ml) was added K metal (0.56 g, 14.2 mmol) and the mixture brought to reflux for 24 h. After this period all the K had reacted (if 8 equiv. are used then only 5 equiv. is consumed even after reflux for 48 h). The mixture was filtered while hot (Celite) and pmdeta (2.1 ml, 10 mmol, distilled over Na) was added. The orange–yellow solution was cooled (−78 °C) and a standard solution of H_2O in thf was added dropwise (10.2 ml, 0.56 mol dm^{-3}, 5.68 mmol). The mixture was allowed to warm to room temperature and stirred (12 h), resulting in a yellow solution and the precipitation of KOH. Filtration (Celite) followed by concentration to *ca*. 8 ml gave a light yellow precipitate which was heated into solution. Storage at 25 °C (12 h) gave large light yellow crystalline needles of **1**; yield 0.33 g (15%) (the low yield reflects the high solubility of the complex in thf); decomp. > 115 °C to orange oil; IR (Nujol), 2205m (P–H str.), other major bands at 1345m, 1309m, 1162s, 1023s, 945m, 900m, 809m, 784m; ^1H NMR (250 MHz, +25 °C, $[^2H_8]$thf), δ 2.75 (1 H, br d, P–H, $J_{^1H^{31}P}$ *ca.* 200 Hz), 2.34 (8 H, m, CH_2CH_2 of pmdeta), 2.21 (3 H, s., NMe of pmdeta), 2.13 (12 H, s., NMe_2 of pmdeta), 1.15 (9 H, br s, Bu^t), 0.99 (9 H, br s, Bu^t); ^{31}P NMR (101.256 MHz, +25 °C, $[^2H_8]$thf, rel. to 85% H_3PO_4), δ −8.90 (dd, Bu^tPH, $J_{^1H^{31}P}$ 201.4 ± 1.1, $J_{^{31}P^{31}P}$ 321.5 Hz), −57.37 (d Bu^tP, $J_{^{31}P^{31}P}$ 321.5 Hz), the ^1H decoupled spectrum gave $J_{^{31}P^{31}P}$ 321.6 ± 0.6 Hz; Anal., Calc. for $[C_{17}H_{42}\}P_2N_3K]_n$: C, 52.4; H, 10.8; N, 10.8; P, 15.9. Found: C, 50.2; H, 10.5; N, 10.5; P 15.3%. The reaction of **1** with Bu^nLi (*ca*. 1 equiv.) in thf was monitored by ^{31}P NMR spectroscopy (+25 °C). This preliminary study reveals that the major product contains the $[Bu^tP]_3^{2-}$ dianion, with a triplet (δ 4.74) and a doublet (δ −44.96) being observed (ratio 1 : 2 respectively, $J_{^{31}P^{31}P}$ *ca* 170 Hz).

§ *Crystal data* for **1**; $C_{34}H_{84}K_2N_6P_4$, M = 779.15, orthorhombic, space group *Pnn*2, a = 14.457(7), b = 16.255(8), c = 10.502(5) Å, U = 2468(2) Å^3, Z = 2, D_c = 1.048 g cm^{-3}. Data were collected on a Siemens-Stoe AED diffractometer (2θ–ω scans) using an oil-coated[11] rapidly cooled crystal of dimensions 0.30 × 0.30 × 0.25 mm (3.64 < θ < 22.48°). Of a total of 3410 reflections collected, 3052 were independent (R_{int} = 0.036). An absorption correction based on ψ-scans was applied (max.,min. transmission = 0.978,0.618). The structure was solved by direct methods and refined by full-matrix least squares on F^2 using all data to final values of $R1$ [$F > 4\sigma(F)$] = 0.058 and $wR2$ = 0.140;[12] largest peak, hole in the final difference map = 0.30, −0.32 e Å^{-3}. All non-hydrogen atoms were refined anisotropically and H-positions were set geometrically. C-atoms of the pmdeta ligand were disordered and were split into two positions using restraints. Transylidation of a transiently formed nitrilium phosphane ylide complex

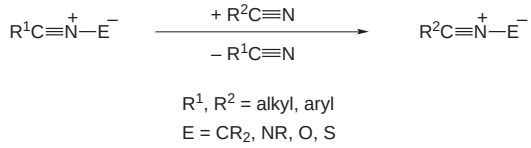
Hendrik Wilkens, Frank Ruthe, Peter G. Jones and Rainer Streubel*†

Institut für Anorganische und Analytische Chemie der Technischen Universität Braunschweig, D-38106 Postfach 3329, Braunschweig, State, Germany

Thermal decomposition of the 3-phenyl-substituted 2*H*-azaphosphirene complex 1 in the presence of dimethyl cyanamide and dimethyl acetylenedicarboxylate (DMAD) yielded dimethylamino-substituted products, the 2*H*-1,2-azaphosphole complex 4b and the diastereoisomeric Δ³-1,3,2-oxazaphospholene complexes 5a,b; this represents the first example of 1,3-dipolar cycloaddition reactions of a nitrilium phosphane ylide complex that is generated *in situ* by transylidation.

Recently, we reported the first evidence for transiently formed nitrilium phosphane ylide complexes by two different trapping experiments. Thermal ring opening of the 2*H*-azaphosphirene complex **1** in toluene in the presence of dimethyl acetylenedicarboxylate (DMAD) yielded a product mixture consisting of the 1*H*-phosphirene complex **3** and the 2*H*-1,2-azaphosphole complex **4a**.[1,2] With dimethyl cyanamide in benzonitrile the trapping resulted in the formation of a 2*H*-1,3,2-diazaphosphole complex;[3] based on the observed selectivity and non-formation of a 4,5-diphenyl-substituted 2*H*-1,3,2-diazaphosphole complex, we assumed a transylidation during the reaction course. To the best of our knowledge transylidation processes among nitrilium betaines have been reported so far only for nitrile sulfides[4] (Scheme 1); neither is their mechanism known nor has this methodology been synthetically exploited. With respect to the enormous potential of 1,3-dipoles such as nitrilium betaines in [3 + 2] cycloaddition reactions and, therefore, in heterocyclic chemistry,[5] we decided to examine this aspect more thoroughly for the case of nitrilium phosphane ylide complexes and performed a trapping experiment with two suitable, but different trapping reagents, DMAD and dimethyl cyanamide.

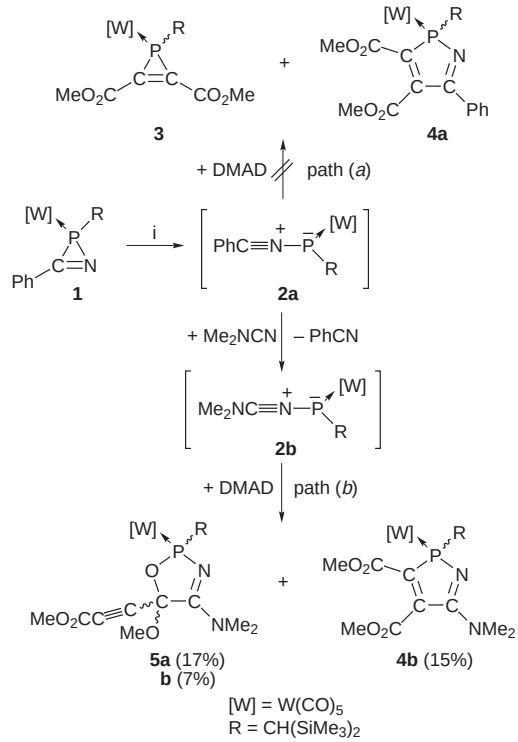


Scheme 1

Thermal decomposition of the 2*H*-azaphosphirene tungsten complex **1** in the presence of 2 equiv. of DMAD and 2 equiv. of dimethyl cyanamide yielded the 2*H*-1,2-azaphosphole complex **4b** and the two diastereoisomeric Δ³-1,3,2-oxazaphospholene complexes **5a,b** (*meso* and racemate) in an estimated ratio of 1 : 1 : 1 (³¹P NMR integration). The formation of both five-membered heterocycles is rationalized by 1,3-dipolar cycloaddition reactions of the *in situ* generated nitrilium phosphane ylide complex **2b** to the C≡C triple bond and the C=O double bond of dimethyl acetylenedicarboxylate [Scheme 2, path (*b*)].

This result has several noteworthy aspects. It is a rare example of a dual reactivity of DMAD towards a 1,3-dipole and it is remarkable that neither the 1*H*-phosphirene complex **3** nor the phenyl-substituted five-membered heterocycle complex **4a** was detected [path *a*)]. Furthermore, during the reaction course a transylidation must have taken place, such that the benzonitrile unit in **2a** was substituted, at least formally, by dimethyl cyanamide, thus forming the nitrilium phosphane ylide complex **2b**. We performed additionally control experiments to check this interpretation. Firstly, we heated a solution of 1*H*-phosphirene complex **3** and dimethylcyanamide to exclude a subsequent ring enlargement reaction, but up to 85 °C no reaction was observed. Secondly, we examined the possible reaction sequence: DMAD gives initially an azete derivative with dimethyl cyanamide, which then could yield 2*H*-1,2-azaphosphole complex **4b** by insertion of transiently formed terminal phosphanediyl complex [$(OC)_5$WPCH-$(SiMe_3)_2$] (*cf.* ref. 2) into a C–N bond of the azete ring; but azete formation could not be detected upon heating a solution of DMAD and dimethyl cyanamide for 2 h at 85 °C.

The composition of the 2*H*-1,2-azaphosphole complex **4b** and the Δ³-1,3,2-oxazaphospholene complexes **5a,b** are confirmed by elemental analysis and mass spectrometry;‡ the structural formulation is based on their characteristic NMR spectral data‡ in solution and that of **5a** was confirmed by X-ray structure analysis.§ The phosphorus nucleus of **4b** displays a resonance at δ 85.6, which is significantly high-field shifted compared to other 2*H*-1,2-azaphosphole complexes (δ 102–105[2]) with a markedly increased phosphorus–tungsten coupling constant of 249.7 Hz (*vs.* 236–238 Hz[2]). The ³¹P NMR parameters of the diastereoisomeric Δ³-1,3,2-oxazaphospholene complexes are δ 191.6 [$^1J_{PW}$ 303.1 Hz (**5a**)] and δ 198.6 [$^1J_{PW}$ 305.9 Hz (**5b**)]. In view of the strong influence of the phosphorus-bonded oxygen atom on the



Scheme 2 *Reagents and conditions*: i, DMAD (2 equiv.), Me_2NCN (2 equiv.), toluene (3 ml), 75 °C, 1.5 h.

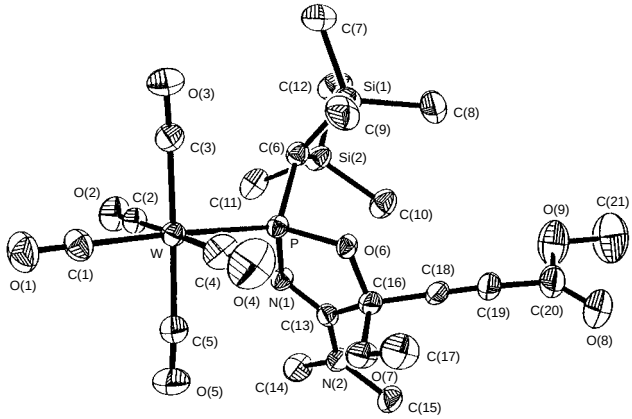


Fig. 1 Molecular structure of complex **5a** in the crystal. Radii are arbitrary. Selected bond lengths (Å) and angles (°): P–W 2.4748(9), P–N(1) 1.677(3), N(2)–C(13) 1.337(4), O(6)-C(16) 1.413(4), C(13)–C(16) 1.552(4), C(18)–C(19) 1.180(5), P–O(6) 1.683(2), N(1)–C(13) 1.301(4); N(1)–C(13)–N(2) 1.242(3), N(1)–P–O(6) 95.23(12), C(13)–N(1)–P 111.5(2), C(16)–O–P 111.9(2), N(1)–C(13)–C(16) 114.8(3), O(6)–C(16)–C(13) 105.3(2).

phosphorus resonances, the almost constant imino carbon resonances of **4b** and **5a,b** (δ 158.0–158.4) are surprising. All these carbon resonances display small carbon–phosphorus coupling constants (1.1-5.3 Hz), which seems to be characteristic for such heterocyclic ring systems; these magnitudes most probably derive from ^2J and ^3J scalar couplings.

The five-membered ring system of the Δ^3-1,3,2-oxazaphospholene complex **5a**, which is the first to be reported, is almost planar; the best plane is given by P–N(1)–C(13)–C(16) (deviation: 0.005 Å) and the oxygen atom lies 0.17 Å out of this plane. The N(1)–C(13) distance [1.301(4) Å] is in the typical range of nitrogen–carbon double bonds, while the coordination sphere of the phosphorus atom is distorted tetrahedral with a phosphorus–tungsten bond length of 2.4748(9) Å.

We are currently investigating the synthetic potential of nitrilium phosphane ylide complexes that are generated *in situ* by transylidations.

Nickel-catalyzed generation of 2-methylhex-5-enyl ethers from allyl ethers with trimethylaluminium

Takahiko Taniguchi and Kunio Ogasawara*†

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578, Japan

Allyl ethers have been converted into the corresponding 2-methylhex-5-enyl ethers in one step on treatment with trimethylaluminium in the presence of a catalytic amount of (dppp)$NiCl_2$.

We recently found that allyl ethers **1** are cleaved facilely and selectively to give the alcohols **2** with expulsion of propene on treatment with DIBAL-H in the presence of a catalytic amount of dichloro[bis(diphenylphosphino)propane] nickel [(dppp)$NiCl_2$] in an aprotic solvent[1] (Scheme 1). The reaction may be applied to allyl acetals, such as **1a**,**b**, using triethylaluminium in place of DIBAL-H to give the same hemiacetal mixture **2a**/**b**, in good yield, without causing reduction of the hemiacetal functionality, although the fate of the allyl functionality was uncertain[1] (Scheme 2). We report here an unprecedented type of C–C bond formation reaction which was observed during the examination of the reaction of the allyl acetals **1a**,**b** with trimethylaluminium in place of triethylaluminium in the presence of the same nickel catalyst.

Thus, when the α-H allyl acetal **1a** was treated with trimethylaluminium (1.3 equiv.) in the presence of (dppp)$NiCl_2$ (2 mol%) in toluene at 0 °C to room temperature for 0.5 h, an inseparable mixture of **3a**‡ consisting of two diastereomers was generated in a substantial yield as well as the expected hemiacetal mixture **2a**/**b**. On the same treatment, the β-H epimer **1b** gave the diastereoisomeric mixture **3b** consisting of two diastereomers and the same hemiacetal mixture **2a**/**b** above. The sugar moiety, including the hemiacetal stereochemistry, of the products was recognized to be unchanged during the reaction by examination of ^1H NMR and mass spectra which indicated that the change occurred in the allyl moiety of **1** with an increment of 56 mass numbers attributed to one Me on a tertiary stereogenic center and one allyl unit. It was also concluded that the reaction that occurred was essentially a dimerization and, therefore, the yields of **3a**,**b** were calculated as 61 and 60%, respectively. The same reaction occurred with another sugar derivative **4** having a bis-allyl ether moiety in the molecule to give the bis(2-methylhex-5-enyl) ether **5** and the mono-2-methylhex-5-enyl ether **6** both as diastereomeric mixtures in yields of 10 and 40% as well as 34% of the double deallylated diol in the presence of 2.6 equiv. of trimethylaluminium (Scheme 3).

The other simple allyl ethers **1c**–**l**, those that gave the corresponding alcohols **2c**–**l** with DIBAL-H and (dppp)$NiCl_2$, were, therefore, subjected to the same reaction with trimethylaluminium in the presence of (dppp)$NiCl_2$ and it was found that all but the aryl ether gave the corresponding products having the same ether moiety in addition to the corresponding deallylated products. The aryl ether gave the phenol quantitatively as the sole product. Most importantly, neither the coupling reaction nor the cleavage reaction occurred at all in the absence of

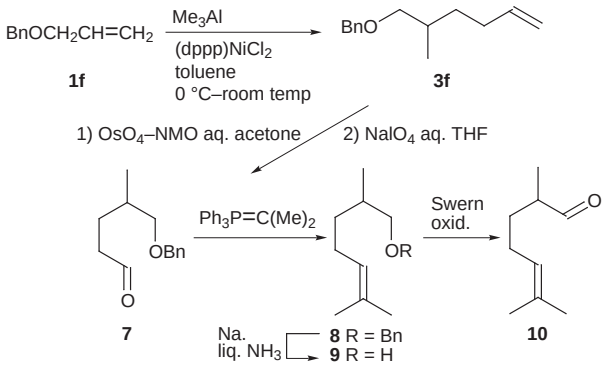
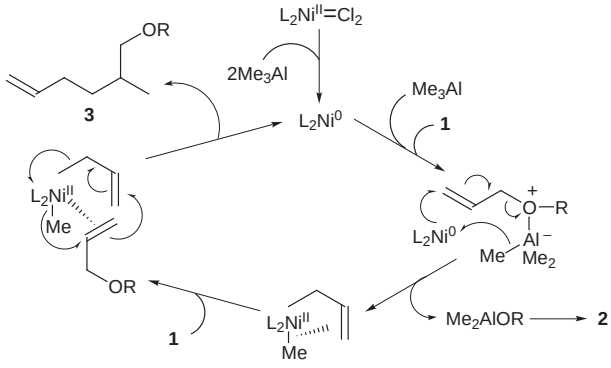


Scheme 4



Scheme 5

(dppp)$NiCl_2$ and only the cleavage reaction occurred when triethylaluminium in place of trimethylaluminium was used under the same catalytic conditions (Table 1).

To confirm the structure of the products **3a–l**, the benzyl ether **3f** generated from allyl benzyl ether **1f** was transformed into the known compound (±)-norcitronellal[2] **10** in 69% overall yield *via* sequential olefin cleavage, Wittig condensation, reductive debenzylation and oxidation through the aldehyde **7**, the ether **8** and the alcohol **9**. This confirmed unambiguously the structure of the common ether half as a 2-methylhex-5-enyl functionality (Scheme 4).

Formation of the 2-methylhex-5-enyl functionality indicated that a concurrent regioselective addition of a methyl moiety from trimethylaluminium and of the allyl moiety from the substrate allyl ether to the allyl double bond of another molecule of the substrate occurred under the conditions used. It is plausible that the reaction was initiated by generation of a Ni^0 complex[3] which led to formation of an allyl–methyl–Ni^{II} complex by reaction with trimethylaluminium and an allyl ether to induce the ether cleavage at the first stage. The complex then interacted with another molecule of allyl ether to allow the regioselective addition[4] of the methyl and allyl functionalities from Ni^{II} to the allyl ether double bond *via* a reductive elimination pathway that reformed the Ni^0 complex (Scheme 5).

Reaction field for efficient porphyrin metallation catalysis produced by self-assembly of a short DNA oligonucleotide

Naoki Sugimoto,*† Takeshi Toda and Tatsuo Ohmichi

Department of Chemistry, Faculty of Science, Konan University, 8-9-1 Okamoto, Higashinada-ku, Kobe 658-8501, Japan

The G-wire structure, which is formed by dGTGGGTTGGGTGGGTTGG in the presence of 50 mM K^+, becomes a catalytic reaction field for porphyrin metallation, inserting Zn^{2+} into porphyrin efficiently.

Many protein enzymes provide a reaction field for their substrates. RNA or DNA can catalyze the cleavage or ligation reaction of nucleic acids, and then has the potential to provide a reaction field for its substrate.[1–4] The catalytic RNA– or DNA–substrate complexes consist of many unpaired regions such as internal loops, hairpin loops and bulges, and the catalysis reactions occur in these unpaired regions.[1–4] Thus, catalytic RNA or DNA produces the reaction fields. If these reaction fields can be made by designing specific sequences of catalytic RNA or DNA, it would be an important development for ribozyme engineering. Recently, a DNA enzyme that can catalyze insertion of Zn^{2+} into mesoporphyrin IX (MPIX) was isolated from a DNA library using *in vitro* selection.[5,6] This minimum DNA enzyme is a 24-mer oligonucleotide and consists of a G-rich sequence that is able to form a G-quartet structure.[6] Although this reaction mechanism was investigated,[7] little is known about the detailed active structure of this DNA enzyme except for the G-quartet that produces the reaction field to catalyze the metallation reaction. Here, in order to develop the chemical engineering of nucleic acids, we have investigated the active structure of the DNA enzyme with catalytic activity for the porphyrin metallation by using an 18-mer DNA sequence, dGTGGGTTGGGTGGGTTGG. This oligonucleotide was designed to contain the G-rich sequence that forms the G-quartet structure and to be shorter than the previous minimum DNA enzyme isolated by Li and Sen.[5,6]

The ability of this 18-mer DNA to catalyze the insertion of Zn^{2+} into MPIX was investigated by HPLC. The reaction yields of the porphyrin metallation were calculated by the ratio of the peak areas at 400 nm between the reactant and the product (ZnMPIX). The metallation reactions were performed in the presence of 50 mM K^+ or Na^+, because the formation of the G-quartet structure is easier in the presence of K^+ than Na^+.[8–12] At the single turnover condition,‡ the reaction yield in the presence of 50 mM K^+ was 91% after 8 h. On the other hand, the reaction yield in the presence of 50 mM Na^+ was 46%. The reaction yields in the absence of K^+ or Na^+ were 20 or 17%, respectively. Further, the k_{cat} values of the 18-mer DNA in the presence of 50 mM Na^+ and K^+ were 8.0×10^{-3} and 1.0 min^{-1}, respectively.§ This value in the presence of K^+ is of the same order as that for ferrochlatase.[13] Thus, the 18-mer DNA was able to catalyze efficiently the porphyrin metallation and played a role as an enzyme in the presence of K^+. The result also suggests that the active structure of this novel DNA enzyme consists of the G-quartets. In order to investigate the effect of DNA sequences other than the G-rich sequence, the activity of 16-mer DNA, dGTGGGTGGGTGGGTGG (which lacks the sixth and fifteenth T residues of the 18-mer DNA oligonucleotide), was also measured in the presence of K^+. Under the single turnover condition, the reaction yield was 55% after 8 h, which is much smaller than that for the 18-mer DNA. The k_{cat} value was 5.6×10^{-3} min^{-1}. Thus, the sequence that joins the G-rich sequence is also important for the formation of the active structure.

The CD spectra of the DNA oligonucleotides were measured to determine the active structure, since CD spectra of nucleic acids are very sensitive to their overall structure.[14] Fig. 1 shows the CD spectrum of the 18-mer DNA oligonucleotide in 50 mM Tris-OAc (pH 7.4) solution containing 50 mM K^+ and 1 mM spermidine at 25 °C. The spectrum has a positive peak around 265 nm and a relatively weak and negative peak around 240 nm. On the other hand, the spectra of the 18-mer DNA in the presence of Na^+ and the 16-mer DNA in the presence of K^+ have two positive peaks around 265 and 295 nm and a relatively weak and negative peak around 230 nm. The intensity at 265 nm of the 18-mer DNA in the presence of K^+ was about 15-fold higher than those of the 18-mer DNA in the presence of Na^+ and the 16-mer DNA in the presence of K^+. The difference in metallation activities between the DNA species corresponds to the difference in the intensity values at 265 nm. Thus, the structural component that produces the positive peak around 265 nm in the CD spectrum must be the active structure for the metallation catalysis. The G-rich DNA species form a parallel or antiparallel G-quartet structure.[8–12,15,16] Previous studies indicated that the CD spectrum of the antiparallel G-quartet structure had 295 nm positive and 265 nm negative bands, while a parallel G-quartet structure with four or more strands exhibits a strong positive band at 260 nm and negative band at 240 nm.[15,16] Since the CD spectrum of the active structure of the DNA enzyme showed a strong positive band at 260 nm, the structure with the catalytic activity for the metallation should have mainly a parallel G-quartet structure with four or more strands. The structures of these DNA species were also investigated by nondenaturing gel electrophoresis. The mobility of the 18-mer DNA in the presence of 50 mM K^+ at 25 °C was demonstrated by the smearing of the band. This suggests that

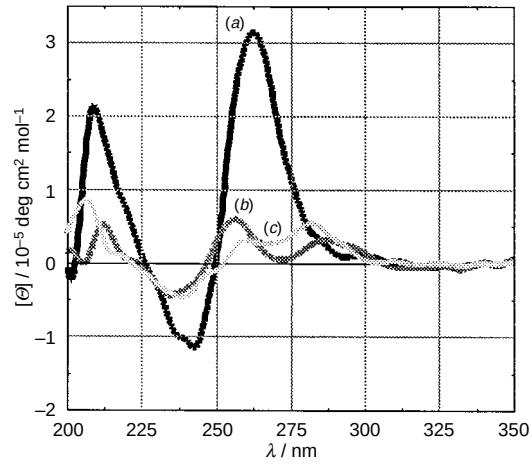

Fig. 1 CD spectra of dGTGGGTTGGGTGGGTTGG in the presence of (*a*) 50 mM K^+ and (*b*) 50 mM Na^+, and (*c*) dGTGGGTGGGTGGGTGG in the presence of 50 mM K^+ at 25 °C. Buffer contains 50 mM Tris-OAc (pH 7.4) and 1 mM spermidine. Concentration of each oligonucleotide was 20 μM.

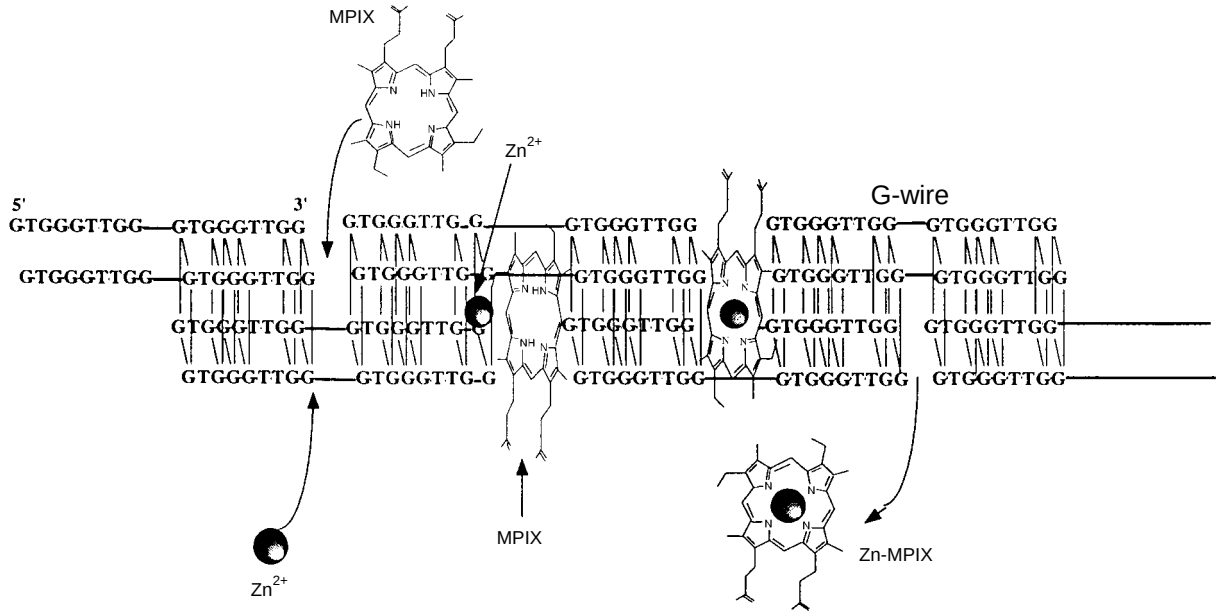

Fig. 2 Schematic illustration of the reaction mechanism between Zn^{2+} and MPIX in the G-wire of the 18-mer DNA species

the structure of the G-wire consists of a slipped tetraplex structure.[17,18] Thus, the results of the CD spectra and gel bands indicate that the active structure of the DNA enzyme is a G-wire structure stabilized by K^+.[17–19]

Fig. 2 shows our proposed reaction field for the porphyrin metallation. In the G-wire field, the porphyrin intercalates into the pocket formed by the junction between the G-quartet domains. Zn^{2+} also inserts into the cavity between two G-quartet planes near the pocket formed by the junction between the G-quartet domains. Following these intercalations, the porphyrin is close to Zn^{2+} so that the metallation occurs easily. The K_m value of the 18-mer DNA in the presence of K^+ was about two orders larger than the others. This value would suggest the possibility that G-wire DNA enzymes are easily able to release the complex between the porphyrin and Zn^{2+} as a product. Furthermore, the G-wire structure has many pockets into which the porphyrins may enter. Thus, this structure produces a good reaction field for the catalytic reaction. In this G-wire structure, the two T residues removed from the 18-mer DNA enzyme locate in the junction site between continuing G-quartet domains. If this region is shortened, the G-wire structure is destabilized by repulsion between the G-quartet domains. Thus, the difference in G-wire formation between the 18-mer and 16-mer DNA species is due to this repulsion between the junctions.

In summary, it was found that a novel 18-mer DNA enzyme, which was shorter than a previously reported DNA enzyme, catalyzed porphyrin metallation. This DNA enzyme formed a G-wire structure as the reaction field to catalyze the insertion of Zn^{2+} into mesoporphyrin IX. This G-wire structure shows promise as a reaction field for other catalytic reactions. Thus, our results in the present study indicate the possibility of DNA usage as materials and reaction fields in chemical nanotechnology.

† E-mail: sugimoto@konan-u.ac.jp

‡ The metallation reaction was carried out in 50 mM Tris-OAc (pH 7.4) solution containing 5 μM DNA, 1 mM Zn^{2+}, 33 μM MPIX, 50 mM KOAc, 1 mM spermidine, 5% DMSO and 0.5% Triton X-100 at 25 °C for 8 h. Before the reaction was initiated, the DNA was reannealed by heating to 90 °C for 2 min, cooled to 25 °C, and incubated for 24 h in the reaction buffer without MPIX and Zn^{2+}. Then, the DNA was preincubated with MPIX for 10 min, and combined with appropriate volumes of the same solution containing $Zn(OAc)_2$. The reactions were stopped by the addition of a solution containing 200 mM Tris (pH 9.0) and 15 mM EDTA. The reactions were monitored by HPLC. The column used was a C18 column, and the mobile phase was 85% methanol and 15% 1 M ammonium acetate, pH 5.2.

§ The rates of metallation in the presence of the 18-mer or 16-mer DNA species were assayed for the concentration range of MPIX from 30 to 500 μM at a fixed concentration of 1 mM Zn^{2+} and 5 μM DNA. For initial rate measurements, good linear relationships between product formation and time were found in each case. The K_m and k_{cat} values were calculated form Lineweaver–Burk plots of $1/(V_{obs}-V_{background})$ *vs.* 1/[MPIX]. Each data point represents the average of at least two sets of independent measurement.

Experimental charge density study of the Mn–Mn bond in $Mn_2(CO)_{10}$ at 120 K

R. Bianchi,[a] G. Gervasio[b]† and D. Marabello[b]

[a] *Centro CNR per lo Studio delle Relazioni tra Struttura e Reattività Chimica, Milano, Italy*
[b] *Dipartimento di Chimica I.F.M. dell'Università, Torino, Italy*

This paper presents an analysis of the charge density, $\rho(r)$, for the Mn–Mn bond in $Mn_2(CO)_{10}$, determined by a multipole model from accurate X-ray data measured at 120 K.

The experimental deformation charge densities of some binuclear metal carbonyls, $[CpFe(CO)_2]_2$, $(\mu\text{-}CH_2)[CpMn(CO)_2]_2$ and $Mn_2(CO)_{10}$, were determined by X-ray diffraction some years ago.[1–3] The theoretical deformation densities for other similar complexes, $Fe_2(CO)_9$ and $Co_2(CO)_8$, and for $Mn_2(CO)_{10}$ were also reported in refs. 4 and 5.

In all the three complexes examined by X-ray diffraction, the deformation maps showed no evidence of significant density accumulation in the metal–metal bonding region. This result was justified by the presence of bridging groups (CH_2 or CO), which join the two metallic fragments to form the entire molecule. This explanation was also supported by the theoretical calculations made for $Fe_2(CO)_9$ and $Co_2(CO)_8$. However, in the case of $Mn_2(CO)_{10}$, which has only terminal carbonyl groups, two Mn–Mn bonding hypotheses were considered: the first is a direct metal–metal bond and the second is an interaction between the d_{xz} or d_{yz} orbitals of one manganese and the π^* orbital of the equatorial carbonyls of the other manganese.[3,6,7] The last hypothesis could be also supported by the bending of equatorial carbonyls towards the opposite Mn atom. Note that the above two hypotheses are not supported by experimental evidence, but a theoretical study, based on Bader's quantum theory of atoms in molecules (QTAM),[8] proved the existence of the Mn–Mn bond in $Mn_2(CO)_{10}$.[9]

Here we report the experimental charge density of the title compound, determined by accurate X-ray data, measured at 120 K and interpreted by the aspherical-atom formalism developed by Stewart.[10] Further, the results of the Bader analysis on the experimental charge density are reported, in order to confirm the existence of the Mn–Mn bond. This is the first topological analysis of the experimental charge density in binuclear metal complexes.

A crystal of $Mn_2(CO)_{10}$ recrystallized from a light petroleum solution was made spherical to a diameter of 0.51 mm and put in a Lindemann glass capillary. The intensity data were collected on a Siemens P4 diffractometer equipped with a low temperature device using liquid nitrogen. 20507 reflections were collected at 120 K, up to $2\theta = 110°$, with Mo-Kα radiation (λ = 0.71073 Å) and with the θ–2θ scan method. Other experimental data are summarized in Table 1. Further information on data collection will be given in the full paper. However, our data collection is not better than that of ref. 3, because they measured the low-order reflections ($\sin\theta/\lambda < 0.76$ Å^{-1}) with the same crystal but two different X-ray wavelengths, Ag-Kα and Mo-Kα.

The quantity minimized in the multipole refinement was $\Sigma w(|F_o|^2 - k^2|F_c|^2)^2$ based on 6217 independent reflections with $I > 2\sigma(I)$ and weights $w = 1/\sigma^2(|F_o|^2)$. The data were corrected for absorption effects, extinction corrections were not introduced and the anomalous dispersion was considered only for the Mn atom. The final aspherical fit to X-ray data was obtained with the following multipole model (POP). Each pseudoatom is assigned a small finite multipole expansion of the atomic form factor. The multipole expansion included two monopoles for C and O atoms and three monopoles for Mn atom and the higher terms were up to the octupole level, except for Mn (up to hexadecapole level). The monopoles consist of shells constructed from the canonical SCF s-, p- and d-orbitals.[11] For the higher multipoles, Slater-type radial functions with fixed standard molecular exponents were used for all carbons and oxygens[12] and the radial exponents of Mn atom were determined in the refinement procedure. All calculations were performed using a modified version of the VALRAY program.[13] The final agreement factors and some other refinement information are listed in Table 1.

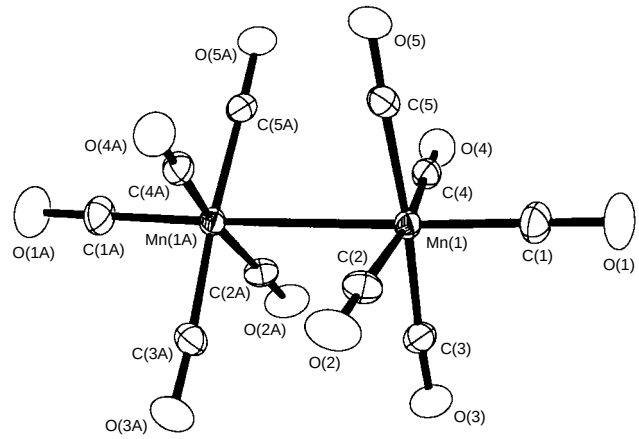

Fig. 1 An ORTEP plot (30% probability) of the entire molecule of $Mn_2(CO)_{10}$.[16] The molecule has crystallographic C_2 symmetry with the two-fold axis passing through the middle of the Mn–Mn bond. Each Mn atom links four equatorial and one axial CO groups in a pseudo-octahedral environment. The equatorial CO groups of the two Mn atoms are staggered [51° between the CO(1)–Mn(1)–CO(2) and CO(1A)–Mn(1A)–CO(2A) planes]. The Mn–Mn bond distance is 2.9042(8) Å; this value is in keeping with the observed dependence on the temperature [2.923(3) Å r.t., 2.9042(8) Å 120 K, 2.8950(6) Å 74 K].[3]

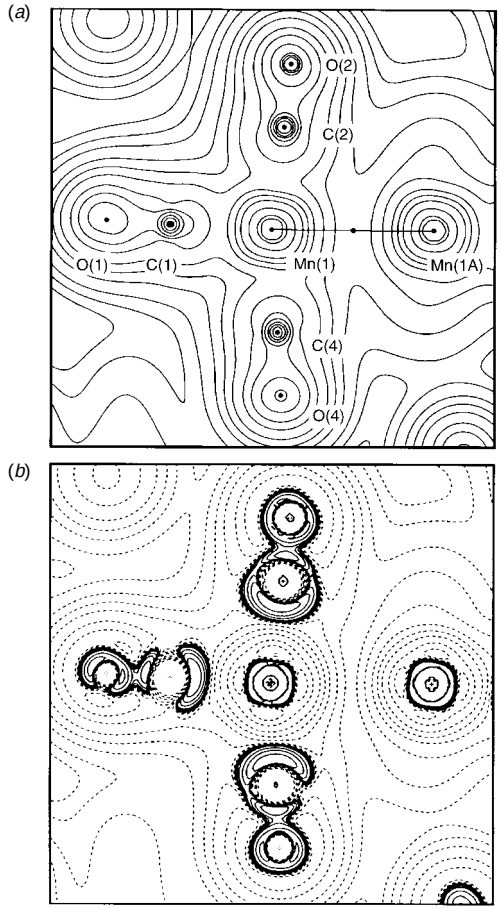

Fig. 2 Experimental charge density, $\nabla\rho(\boldsymbol{r})$ (*a*), and its Laplacian, $\nabla^2\rho(\boldsymbol{r})$ (*b*), on the plane defined by Mn(1), Mn(1A) and C(2). The absolute values of the contours (atomic units) increase from the outermost one inwards in steps of 2×10^n, 4×10^n and 8×10^n with n beginning at -3 and increasing in steps of 1. It has been shown that a necessary and sufficient condition for two atoms to be involved in a bonding interaction is the existence in $\nabla\rho(\boldsymbol{r})$ of a line linking the nuclei along which the charge density is at a maximum with respect to any lateral displacement. Such a line is called a bond path, and the interatomic critical point $\boldsymbol{r}_c$ [where $\nabla\rho(\boldsymbol{r}_c) = 0$] occurring on it is a bond critical point (bcp). At the bcp, there are two negative curvatures (λ_1 and λ_2) that determine the contraction of ρ towards $\boldsymbol{r}_c$ in the directions perpendicular to the bond path, and one positive curvature, λ_3, parallel to the interaction line. The values of $\rho(\boldsymbol{r}_c)$ and of $\nabla^2\rho(\boldsymbol{r}_c) = \lambda_1 + \lambda_2 + \lambda_3$ characterize the atomic interaction. In (*a*) the bond paths of $\nabla\rho(\boldsymbol{r})$ which originate at bcp are superimposed on the same map and the bcp position is denoted by a black dot. In (*b*) positive values are denoted by dashed contours, negative values are denoted by solid contours.

The total electron density, $\rho(\boldsymbol{r})$, based on the multipole model, the gradient and Hessian of $\rho(\boldsymbol{r})$ were calculated with a direct space lattice sum. The topological analysis of $\rho(\boldsymbol{r})$ (search of critical points and bond paths[14]) was carried out using the TOPOND program,[15] interfaced to VALRAY. The topology of $\rho(\boldsymbol{r})$ has been fully described by Bader in the QTAM.

The molecular structure, with the atomic labeling, is shown in Fig. 1. The largest peak in the residual density (based on $F_{obs} - F_{multipole}$) is 0.33 e Å^{-3} and it is close to the Mn position. We observe a slightly positive and not significant deformation density of 0.1(1) e Å^{-3} (total density minus free spherical atoms) at the midpoint of the Mn–Mn bond. On the other hand a very small deformation density has also been observed between the two metal atoms in previous works.[1,3]

Fig. 2 shows the total electron density map and its Laplacian, derived from the multipole POP model, in the plane containing the axial [C(1)–O(1)], the two equatorial carbonyl groups [C(2)–O(2) and C(4)–O(4)] and the two Mn atoms. The number of bcps we found in the experimental electron density corresponds to the expected number of bonds for $Mn_2(CO)_{10}$, including the interaction between the two Mn atoms as illustrated in Fig. 2(*a*). The density at the bcp between the two heavy atoms is 0.190(4) e Å^{-3}. No bcps were found for any cross interaction between one metal and the equatorial COs linked to the other metal atom. The positive value of $\nabla^2\rho(\boldsymbol{r})$ at the Mn—Mn bcp [0.815(8) e Å^{-5}; Fig. 2(*b*)] indicates an unshared interaction[14] between the two Mn atoms: the density is contracted towards each Mn nucleus. Indeed, one finds that $\lambda_3 = 1.209(3)$ e Å^{-5} is here dominant with respect to $\lambda_1 = \lambda_2 = -0.199(3)$ e Å^{-5}. This behaviour is similar to that found in the ionic and van der Waals interactions and clearly indicates a totally different nature with respect to a typical covalent interaction.

In conclusion, an accurate description of the total electron density has been obtained from a multipole analysis of the X-ray data. The low temperature (120 K) at which the diffraction experiment was performed allowed us to obtain a significant total electron density in the metal–metal region and the Bader analysis of this density was a useful tool to characterize the nature of their interaction.

Synthesis and coordination chemistry of 1,3,5-triphosphabicyclo[2.1.0]-pent-2-ene

Vinicius Caliman, Peter B. Hitchcock and John F. Nixon*†

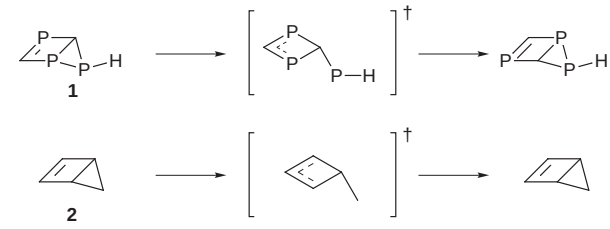
School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK, BN1 9QJ

Room temperature electrocyclisation of the 1,2,4-triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$ affords the new 1,3,5-triphosphabicyclo[2.1.0]pent-2-ene which undergoes a very rapid [1,3]-phosphorus migration which can be stopped by coordination of $[W(CO)_5]$; the two isomeric phosphorus compounds react differently with $[PtCl_2(PEt_3)]_2$, the latter *via* an insertion of the metal into the P–P bond and a chlorine migration reaction to afford *trans*-$[PtCl(PEt_3)P_2C_2Bu^t_2PClCH(SiMe_3)_2]$, the molecular structure of which has been determined by a single crystal X-ray diffraction study.

We recently showed[1] that the activation barrier for the [1,3]-phosphorus migration in the hypothetical 1,3,5-triphosphabicyclo[2.1.0]pent-2-ene $P_3C_2H_3$ **1** is estimated (MP4SDTQ/6-31G*//MP2/6-31G*+ZPE) to be only 11.62 kcal mol^{-1}, which is considerably smaller than the barrier (31.13 kcal mol^{-1}) for the corresponding [1,3]-carbon migration in the structurally related hydrocarbon C_5H_6 **2**. We attributed the much more facile migration within the phosphorus system to favourable cleavage of the weak P–P bond in **1** compared to the strong C–C bond in **2** and to the suprafacial pathway in both systems, which requires the migrating atom to become planar, and is therefore much more favourable for phosphorus than carbon (see Scheme 1). We now present the first experimental support for these proposals with the synthesis of 1-bis-(trimethylsilylmethyl)-1,3,5-triphosphabicyclo[2.1.0]-pent-2-ene **3** and a study of its dynamic behaviour and ligating properties.

The recently described[2] 1,2,4-triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$ **4** readily undergoes a slow electrocyclisation reaction on long standing in sunlight at room temperature, to afford the new isomeric 1,3,5-triphosphabicyclo[2.1.0]pent-2-ene **3** (Fig. 1). The reaction, which is accelerated by irradiation with a tungsten lamp (100 W), is about 60% complete after one week.

When the electrocyclisation reaction is monitored by $^{31}P\{^1H\}$ NMR spectroscopy , the original three doublet-of-doublets resonances (δ_P 244.4 $P_{(A)}$, 180.0 $P_{(B)}$ and 112.0 $P_{(X)}$) of **4** steadily disappear and are replaced by two new resonances attributed to **3** (a doublet δ_P 166.6 and a triplet δ_P 24.1). The simplicity of the $^{31}P\{^1H\}$ NMR spectrum of **3** shows that two phosphorus atoms $P_{(A)}$ and $P_{(B)}$ become magnetically equivalent because of the fast [1,3]-sigmatropic rearrangement of **3**. On cooling the sample the doublet resonance broadens but the dynamic proces is still evident even at −110 °C.



Scheme 1

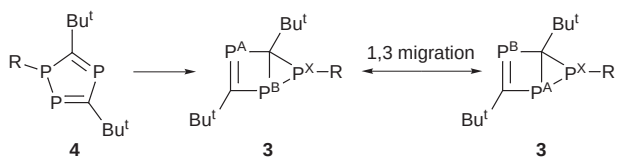


Fig. 1 R = $CH(SiMe_3)_2$

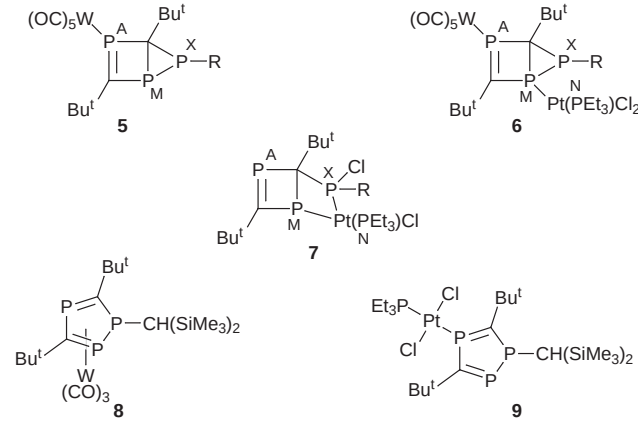
The migration process of $P_{(X)}$ from $P_{(A)}$ to $P_{(B)}$ can however be stopped completely by ligation of a $[W(CO)_5]$ fragment to **3**. Thus $[W(CO)_5(THF)]$ readily reacts with **3** in THF at room temperature to afford the red η^1-complex $[W(CO)_5P_3C_2Bu^t_2CH(SiMe_3)_2]$ **5** in 70% yield. The mode of attachment of the $[W(CO)_5]$ fragment was established as being *via* the unique sp^2-hybridised phosphorus $P_{(A)}$, by its $^1P\{^1H\}$ NMR spectrum which shows three resonances (δ_P 270.7 $P_{(A)}$, 33.8 $P_{(M)}$ and −78.8 $P_{(X)}$), each occurring as a doublet of doublets. The high field shifts of $P_{(M)}$ and $P_{(X)}$ are typical for sp^3-hybridised phosphorus atoms and each exhibits the expected large direct one-bond coupling ($^1J_{P(M)P(X)}$ = 151.3 Hz). The low field $P_{(A)}$ resonance, which is typical of an sp^2-hybridised phosphorus, also shows two additional two-bond couplings ($^2J_{P(A)P(M)}$ = 83.8 Hz and $^2J_{P(A)P(X)}$ = 21.7 Hz) and the characteristic ^{183}W satellites ($^1J_{PW}$ = 229.3 Hz). Isomers **3** and **4** thus behave quite differently towards zerovalent tungsten, the latter giving only the η^5-complex $[W(CO)_3P_3C_2Bu^t_2CH(SiMe_3)_2]$ **8** under a variety of reaction conditions.[3]



$[PtCl_2(PEt_3)]_2$ reacts with **5** in THF at room temperature to afford the yellow bimetallic complex *trans*-$[PtCl_2(PEt_3)W(CO)_5P_3C_2Bu^t_2CH(SiMe_3)_2]$ **6** (79% yield) with a similar structure to **5**, in which the additional $[PtCl_2(PEt_3)]$ fragment becomes attached to the sp^3-hybridised phosphorus at the junction of the 3- and 4-membered rings, as was established spectroscopically.‡

The identity of the 1,3,5-triphosphabicyclo[2.1.0]pent-2-ene, **3**, was confirmed by its unusual reaction with $[PtCl_2(PEt_3)]_2$ at room temperature, to give the yellow air-stable complex *trans*-$[PtCl(PEt_3)P_2C_2Bu^t_2PClCH(SiMe_3)_2]$ **7** (77% yield), the molecular structure of which was confirmed spectroscopically‡ and by a single crystal X-ray diffraction study. The reaction

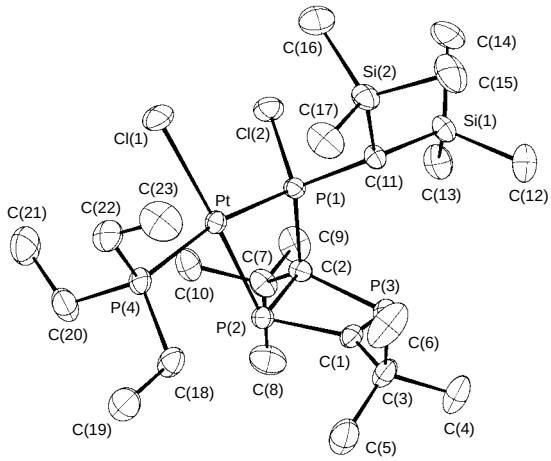


Fig. 2 Molecular structure of *trans*-[PtCl(PEt_3)$P_2C_2Bu^t_2PClCH(SiMe_3)_2$] **7** together with the atomic numbering scheme and some selected bond lengths (Å) and angles (°): Pt–P(1) 2.263(1), Pt–P(2) 2.299(1), Pt–P(4) 2.322(2), Pt–Cl(1) 2.381(2), P(1)–C(11) 1.826(5), P(1)–C(2) 1.877(5), P(1)–Cl(2) 2.062(2), P(2)–C(1) 1.820(5), P(2)–C(2) 1.907(5), P(3)–C(1) 1.698(5), P(3)–C(2) 1.876(5), P(1)–Pt–P(2) 71.90(5), P(1)–Pt–P(4) 167.25(5), P(2)–Pt–P(4) 95.42(5), P(1)–Pt–Cl(1) 100.38(6), P(2)–Pt–Cl(1) 164.50(6), P(4)–Pt–Cl(1) 91.63(6)

involves both an insertion of the metal–ligand fragment into the weak P–P bond of the three-membered ring of **3** and a chlorine migration from platinum to phosphorus. Clearly the dynamic behaviour of **3**, involving rapid breaking and remaking of the P–P bond, facilitates the insertion step.

We previously reported[4] a similar ring opening and chlorine transfer from Pt^{II} to phosphorus in the reaction of [$PtCl_2(CNR)_2$] (R = Bu^t, *p*-$MeOC_6H_4$) with the three-membered phosphirene ring PPhCPh=CPh to form the dimeric chlorophosphane complex [PtCl(PClPhCPh=CPh)($CNBu^t$)]$_2$.

The mass spectrum of compound **7** exhibits a molecular ion peak at *m*/*z* 774 and the expected fragmentation pattern and the $^{31}P\{^1H\}$ NMR spectrum exhibits the anticipated pattern of lines arising from an [AMNX] spin system.§ The molecular structure of **7**, shown in Fig. 2, was established by a single crystal X-ray diffraction study¶ and is in full accord with the NMR spectroscopic data. The symmetry around the Pt^{II} atom is close to idealised square planar geometry, and the Pt–P distances and the P=C double bond length [P(3)–C(1) 1.698(5) Å] are typical.[5,6] Isomers **3** and **4** thus also behave quite differently towards divalent platinum, the latter giving the η^1-complex *trans*-[$PtCl_2(PEt_3)P_3C_2Bu^t_2CH(SiMe_3)_2$] **9** in which the platinum is attached to the unsaturated phosphorus lying between the two ring carbon atoms.[7]

We thank the Brazilian Government (CNPq) for a scholarship (to V. C.).

Coordination control of intramolecular electron transfer in boronate ester-bridged donor–acceptor molecules

Hideo Shiratori,[a] Takeshi Ohno,[b] Koichi Nozaki,[b] Iwao Yamazaki,[c] Yoshinobu Nishimura[c] and Atsuhiro Osuka*[a]†

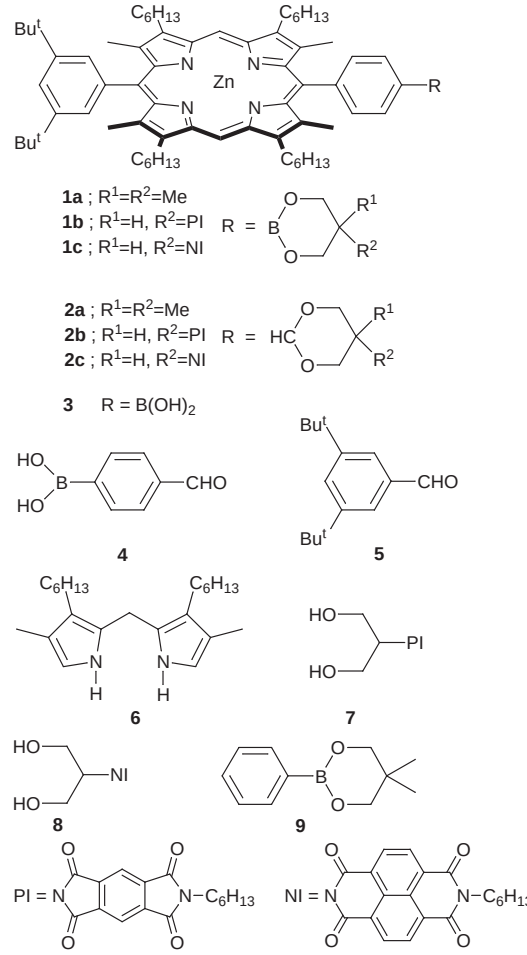
Acid–base reaction at the bridge in a donor–acceptor molecule can influence intramolecular electron-transfer reactions; this has been demonstrated in boronate ester bridged zinc porphyrin–diimide dyads in which intramolecular electron transfer reaction has been completely suppressed by coordination of F^- on the bridge boron.

Intramolecular electron transfer (ET) is the subject of many studies that are aimed at elucidating the role of the various parameters which govern the ET rate.[1] Among these, the chemical identity and nature of the bridge that connects donor and acceptor are important, since ET reactions can be facilitated by appropriate molecular orbitals provided by the bridge.[2] When a donor–acceptor molecule undergoes ET with a rate tunable by external physical and/or chemical input, it may constitute a switching ET molecular system. We report here intramolecular photoinduced electron transfer in boronate ester bridged zinc porphyrin–pyromellitimide (ZP–PI, **1b**) and zinc porphyrin–1,8:4,5-naphthalenetetracarboxylic diimide (ZP–NI, **1c**) (Scheme 1) in which the Lewis acidic boronate ester may enable alteration of the ET rate upon base coordination. This has indeed been demonstrated by addition of fluoride anion (F^-) which suppresses the ET.

Porphyrin **1a** was prepared according to the method reported by Toi *et al.*[3] Attempted hydrolysis of **1a** was unsuccessful in our hands under both basic[3] and acidic conditions.[4] Thus, boronic acid **3** was prepared by the cross-condensation of 4-formylphenylboronic acid **4** and 3,5-di-*tert*-butylbenzaldehyde **5** with dipyrrylmethane **6** followed by oxidation with *p*-chloranil under mild conditions (0 °C, 30 min) in 35% yield. Boron-bridged dyads **1b** and **1c** were prepared by refluxing a toluene solution of **3** in the presence of diol **7** or **8** with 84% and 90% isolated yields, respectively.

In benzene, the fluorescence of ^{1}ZP* in **2b** and **2c** is quenched by the attached PI or NI; the relative fluorescence intensities of **2b** and **2c** to **2a** are 0.89 and 0.36, respectively, and the fluorescence decays of **2b** and **2c** measured by the time-correlated single photon counting technique have been found to obey a single exponential function with lifetimes of 1.21 ns and 0.49 ns, respectively, which are shorter than the lifetime (1.39 ns) of **2a**. The observed fluorescence quenching suggests charge separation (CS) between ^{1}ZP* and PI or NI. The ET quenching has been confirmed by picosecond time resolved transient absorption spectroscopy. The transient absorption spectra taken for excitation with a 17 ps laser pulse at 532 nm revealed the appearance of a 715 nm absorption band due to PI^- for **2b** (not shown) and of 480 nm and 610 nm bands due to NI^- for **2c** [Fig. 1(*b*)],[5] respectively, clearly indicating ion-pair formation. Charge recombination kinetics of the ion pair to the ground state in **2b** measured by monitoring the 715 nm absorbance change follows a single exponential decay with $\tau = 84 \pm 6$ ns, while the similar kinetic trace at 480 nm in **2c** follows a biphasic decay with $\tau_1 = 77 \pm 16$ ns (66%) and $\tau_2 = 380 \pm 100$ ns (34%).[6] The boronate ester-bridged models, **1b** and **1c**, undergo essentially the same ET reactions as those of **2b** and **2c**; the relative fluorescence intensities of **1b** and **1c** to **1a** are 0.70 and 0.36, and the fluorescence lifetimes of **1b** and **1c** are 1.18 ns and 0.57 ns, respectively, which are both shorter than the lifetime (1.40 ns) of **1a**. Transient absorption spectroscopy also revealed the formation of the ion-pair state, and the lifetimes of the ion-pair state are 40 ± 5 ns for **1b** (not shown) and 13 ± 1 ns (60%) and 290 ± 10 ns (40%) for **1c** [Fig. 1(*a*), solid line].

The ET dynamics were also examined in the presence of tetra-*n*-butylammonium fluoride (TBAF). In the ^{11}B NMR spectra taken in benzene, a broad boron signal of **1a** appearing at around 10 ppm with respect to a trimethylborate internal standard was shifted to −14 ppm upon an addition of 1 equiv. of TBAF, indicating the complete coordination of F^- on the



Scheme 1 Structures of models studied

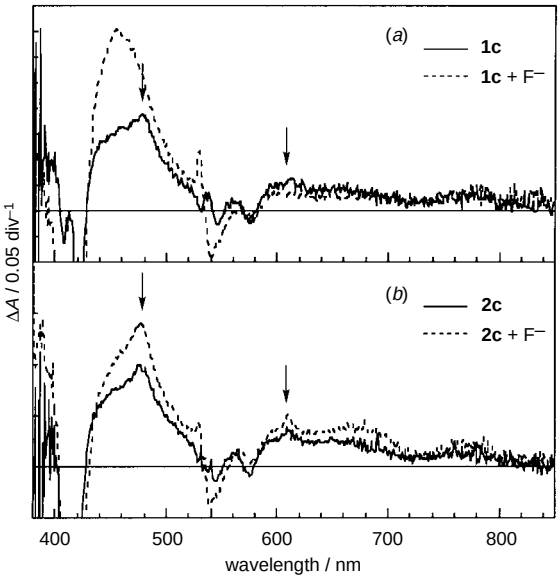


Fig. 1 Transient absorption spectra of **1c** (*a*) and **2c** (*b*) in benzene, at a delay time of 6 ns. Solid lines: in the absence of F^-; dotted lines: in the presence of 1.2 equiv. F^-.

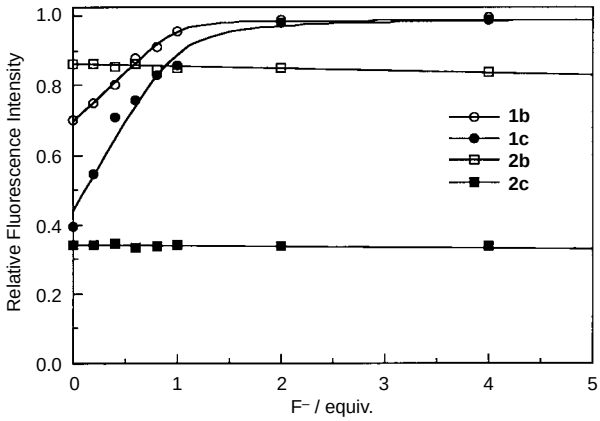

Fig. 2 Change of fluorescence intensities of diimide-linked models upon addition of F^-. Data for **1b**,**c** and **2b**,**c** were recorded relative to **1a** and **2a**, respectively. Concentrations of models were 1 μM.

boron atom. Similar shifts were observed for **1b** and **1c**. Fig. 2 shows the effects of TBAF addition on the fluorescence intensities of **1b**,**c** and **2b**,**c**. It is evident that the fluorescence intensity of **1c** increased with increasing amount of TBAF and returned to the original unquenched level with *ca*. 1 equiv. of TBAF, while the fluorescence intensity of **2c** remained quenched to a constant level up to 5 equiv. of TBAF added. Essentially the same trend was observed for **1b** and **2b**. Upon addition of 5 equiv. TBAF, the short fluorescence lifetimes of free **1b** and **1c** were restored to the unquenched levels (1.56 and 1.57 ns, respectively), which are almost the same as that (1.58 ns) of the acceptor-free reference compound **1a** under the same conditions. In contrast to the ET reactions of **2b** and **2c**, which are rather independent of TBAF [Fig. 1(*b*)], the transient absorption spectra of **1b** and **1c** in the presence of 1.2 equiv. TBAF are practically the same as those of the acceptor-free **1c** with no indication of ion-pair formation [Fig. 1(*a*), dotted line].[7] Therefore it is concluded that the CS reactions in **1b** and **1c** are completely blocked by F^- coordination. Since restoring the initial ET activities of **1b** and **1c** after the addition of F^- is important for constructing a real ON/OFF system, the addition of a large amount of **9** to solutions of F^--complexed **1b** and **1c** was examined but did not lead to the recovery of the ET activities. Finally, note that the CS reactions in **1b** and **1c** are also completely blocked in solvents with high donor numbers such as DMF and triethylamine but such solvent effects are not observed for **2b** and **2c**.

At the present stage, it seems difficult to identify the main reason for this CS inhibition by F^- coordination. The energy levels of the ion-pair states, geometrical parameters, and electronic coupling should be changed upon F^- coordination. Since the addition of TBAF had almost no effect on the redox potentials of these models,[8] the energy levels of the ion-pair states do not change significantly, at least in polar DMF solution, but are more difficult to estimate in nonpolar benzene solution. Since the center-to-center distance between ZP and the boron is estimated to be longer than that between the boron and the diimide,[9] the negative charge at the boron may raise the energy level of the ion-pair state, thereby decreasing the k_{CS} value. A change from a neutral trigonal boron to a tetrahedral 'ate' anion induces a slight shortening of the donor–acceptor distance by 0.4 Å as well as changes in the molecular orbitals of the bridge that will alter the electronic coupling between ZP and the diimide acceptor, relevant for CS. The former structural change seems to be unimportant since comparable k_{CS} rates were observed for the structural analogues, **2b** and **2c**. The latter effect, which may be evaluated by considering the molecular orbitals of the phenylboronate **9**, causes a considerable increase in the LUMO energy of the bridge upon F^- coordination,[10] suggesting the decreased electronic coupling due to the high LUMO energy to be critical in the observed CS inhibition.

Coordination on a neutral bridging boron may provide a convenient method of controlling the intramolecular ET. The generality of this method will be tested in other ET systems and also in triplet–triplet energy transfer systems. Studies in this direction are ongoing and will be reported soon elsewhere.

Mechanistic studies on the photogeneration of *o*- and *p*-xylylenes from α,α′-dichloroxylenes

Miguel A. Miranda,*[a]† Julia Pérez-Prieto,*[b] Enrique Font-Sanchis,[a] and J. C. Scaiano*[c]

Two-colour two-laser techniques have unambiguously proved that photolysis of the *o*-/*p*-(chloromethyl)benzyl radical leads to the sequential two-photon generation of *o*-/*p*-xylylene from α,α′-dichloro-*o*-/*p*-xylene.

Xylylenes are molecules of considerable theoretical and synthetic interest, which have been detected and characterized by different spectroscopic methods.[1] Although benzylic dichlorides have been used as very simple and readily accessible precursors, the involved mechanisms are not completely understood.[2] It has been recently reported[3] that 266 nm laser irradiation of α,α′-dichloro-*o*-xylene (**1a**) produces the dissociation of both C–X bonds *via* a two-photon process; however, the nature of the intermediate species which absorbs the second photon is uncertain. Three possibilities have been considered: the S_1 and T_1 states of **1a** and the *o*-(chloromethyl)benzyl radical (**2a**). Based on the short lifetime of the singlet state of the dichloride and the apparent relative yields of the observed transients, the undetected T_1 state of the dichloride has been suggested as the photochemical precursor of *o*-xylylene.

Our aim was to explore the photochemistry of the benzyl radical **2a** produced after dissociation of one C–X bond of α,α′-dichloro-*o*-xylene, using two-laser two-colour techniques, in order to obtain new data to support or reject the intermediacy of **2a** in the formation of *o*-xylylene. We report here our findings and compare them with those obtained in the photolysis of α,α′-dichloro-*p*-xylene. Based on the obtained results, a mechanism for the formation of *o*- and *p*-xylylenes from their corresponding dichloro precursors is presented.

Laser flash photolysis of deaerated 1.5 mM solutions of **1a** in cyclohexane at 266 nm (Nd: YAG laser, fourth harmonic, < 10 ns, ⩽20 mJ pulse^{-1}) yielded the transient absorption spectra shown in Fig. 1. Two transients with different lifetimes were obtained. According to the literature,[3] they were assigned to **2a** (with a maximum at 330 nm) and *o*-xylylene (**3a**) (maximum at 360 nm, $\varepsilon_{max} = 3 \times 10^3$ dm^3 mol^{-1} cm^{-1}),[4] generated through one- and two-photon processes, respectively.

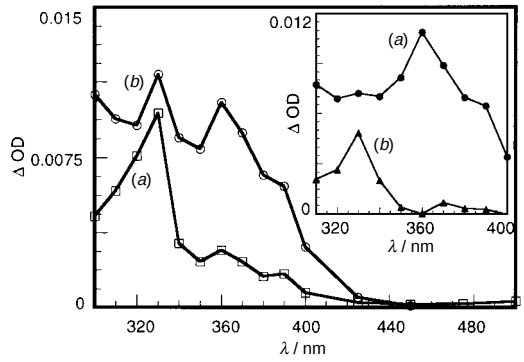

Fig. 1 Transient absorption spectra recorded following laser excitation (266 nm) of **1a** under nitrogen 2 μs after laser pulse (*a*) with diffuser and (*b*) without diffuser. Insert: (*a*) spectrum of *o*-xylylene obtained 2.32 μs after irradiation in the presence of oxygen without diffuser; (*b*) spectrum of **2a** obtained by normalizing and subtracting the spectrum of *o*-xylylene from the spectrum obtained in the absence of oxygen.

When irradiating with a 266 nm laser it is useful to place a beam diffuser (which eliminates 'hot' spots in the laser beam) close to the sample in order to get a better observation of monophotonic transients.[5] Actually, a new spectrum obtained under these conditions showed a higher ratio of radical **2a** to the two photon intermediate, **3a** (Fig. 1).

To confirm the radical nature of the transient at 330 nm, oxygenated samples were examined, showing that, while the band at 330 nm was quenched at close to the diffusion controlled limit (see insert Fig. 1), the lifetime of the transient at 360 nm appeared insensitive to the presence or absence of oxygen (data not shown).

Furthermore, to study the photobehaviour of **2a**, two-colour two-laser flash photolysis experiments[6] were carried out using 266 nm laser pulses (20 mJ pulse^{-1}) to photolyze **1a** and a 308 nm excimer laser (90 mJ pulse^{-1}) to irradiate **2a**. The two pulses were typically separated by *ca.* 2.5 μs, a time sufficiently long that the irradiation of excited states of **1a** by the 308 nm laser is impossible. We note that **1a** is transparent at 308 nm. That the benzyl radical **2a** can be the precursor of *o*-xylylene is clearly demonstrated by comparing the spectra obtained upon irradiation with the first and the second laser (Fig. 2). The permanent and irreversible bleaching of the transient with a maximum at 330 nm was concurrent with the jump of the band with a maximum at 360 nm.

Thus, it seems clear that **2a** photolyzes to *o*-xylylene, and a mechanism for the photogeneration of *o*-xylylene from α,α′-dichloro-*o*-xylene is shown in Scheme 1; while triplet **1a** may or may not produce *o*-xylylene, it is clear that there is no need to invoke this undetected process.

On the other hand, laser flash photolysis of deaerated 1.5 mM solutions of α,α′-dichloro-*p*-xylene (**1b**) in cyclohexane at 266 nm (with a beam diffuser) yielded the transient absorption spectrum shown in Fig. 3. Irradiation of oxygenated samples showed that the band at 320 nm was quenched at close to the diffusion controlled limit, but the lifetime of the transient at 290 nm appeared to be insensitive to the presence of oxygen. Thus, the band at 320 nm can be assigned to the *p*-(chloromethyl)benzyl radical (**2b**) by comparison with the band of the *p*-methylbenzyl radical in solution.[7] On the other hand, the band at 290 nm is assigned to *p*-xylylene in accordance with literature data.[8] At first glimpse, the formation of *p*-xylylene from **1b** appeared to be more efficient than the generation of *o*-xylylene from **1a**, even if both dihalides were photolyzed under the same conditions [compare curve (*b*) in Fig. 1 and the transient in Fig. 3]. However, this could also reflect a different molar extinction coefficient of both xylylenes. Although ε_{max} of **3b** has not been reported, electronic spectra calculated for xylylenes[9] indicate that a much higher intensity should be expected for the absorption of the *para* than for the *ortho* derivative.

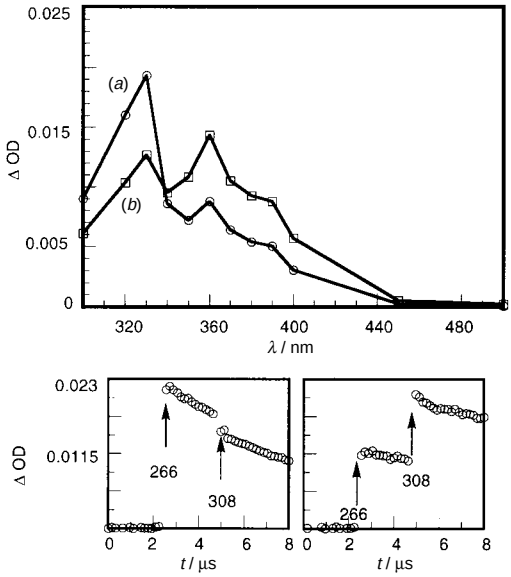

Fig. 2 Top: (*a*) Transient absorption spectrum recorded following laser excitation (266 nm) of **1a** under nitrogen 1.12 μs after laser pulse. (*b*) Transient absorption spectrum obtained upon two laser-two colour excitation of **1a**. The intermediate generated by means of a 266 nm laser pulse is photolyzed after 2 μs by a second laser at 308 nm. Bottom: Kinetic trace at 330 (left) and 360 nm (right); the bleaching at 330 nm corresponds to the disappearance of **2a** and the jump at 360 nm corresponds to the formation of **3b**.

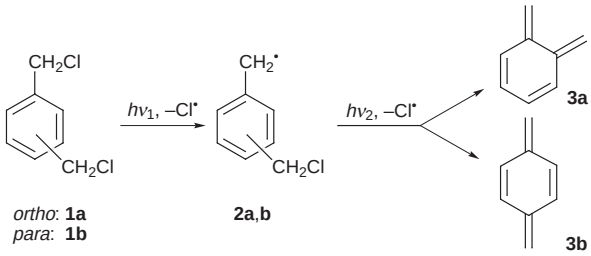

Scheme 1

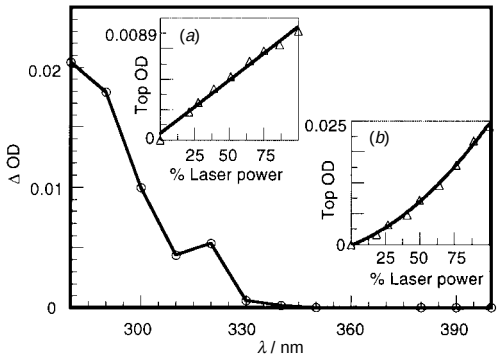

Fig. 3 Transient absorption spectrum recorded following laser excitation (266 nm) of **1b** under nitrogen 0.8 μs after laser pulse. Inserts (*a*) and (*b*) show the effect of the laser power on signal intensities monitored at 320 and 290 nm, respectively.

To establish the nature of the process leading to radical **2b** and *p*-xylylene, an investigation of the effects of light intensity on the relative intensity of their signals was carried out by attenuating the laser beam with a set of calibrated neutral density filters. Inserts (*a*) and (*b*) in Fig. 3 show that there is a linear relationship between the formation of **2b** and the laser power, while a parabola is obtained in the case of **3b**; thus, the evidence supports a one-photon process for the benzylic radical and a two-photon process for *p*-xylylene.

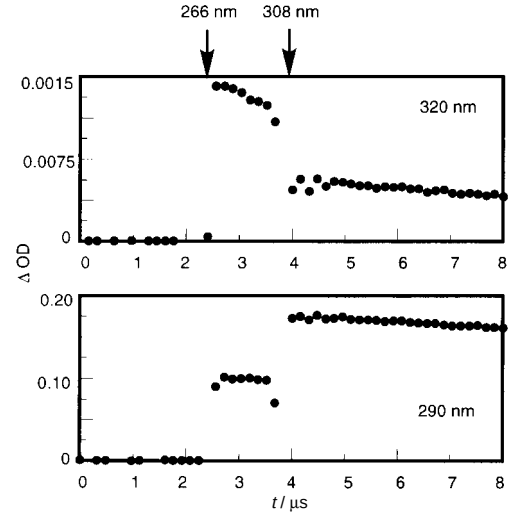

Fig. 4 Two laser-two colour photolysis of **1b**. Top: kinetic trace at 320 nm; the bleaching corresponds to the disappearance of **2b**. Bottom: kinetic trace at 290 nm; the jump corresponds to the formatio of **3b**.

The photobehaviour of radical **2b** was studied by using two-colour two-laser experiments; the 266 nm laser was used to generate this radical, which was further irradiated with pulses from the 308 nm laser. That **2b** can be the precursor of **3b** is clearly demonstrated by comparing traces obtained for both transients (Fig. 4). Thus, the bleaching at 320 nm was coincident with the jump at 290 nm. Based on this evidence the mechanism for the photogeneration of *p*-xylylene from α,α′-dichloro-*p*-xylene is also that of Scheme 1.

In summary, this work has demonstrated that benzyl radicals are the key light absorbing transients in the two-photon generation of *o*- and *p*-xylylenes from the corresponding dichloroxylenes.

Photoinduced reduction of thymine and uracil derivatives by hypophosphite: unusual high quantum yield of chromophore loss

Kongjiang Wang,*† and Zhifang Chai

Institute of High Energy Physics, The Chinese Academy of Sciences, PO Box 2732, Beijing 100080, PR China

The quantum yield of chromophore loss of thymine, uracil and their corresponding nucleosides and nucleoside-5′-monophosphates undergoing irradiation with 254 nm UV light was found to be sharply enhanced by hypophosphite; thymine and uracil were reduced by hypophosphite to give 5,6-dihydrothymine and 5,6-dihydrouracil respectively.

In the photochemistry of nucleic acids, there has been much interest in oxidative damage to DNA and its biological consequences in living cells.[1,2] Here we report the photoinduced reduction (hydrogenation) of thymine (**1a**), uracil (**1b**) and their derivatives by hypophosphite, which was initially found in our tentative simulation of the photochemistry of the primitive sea, by irradiation with a medium pressure mercury lamp.[3] Contrary to the wavelength dependence of the enhancement of the photolysis of nucleic acid monomers by orthophosphates and pyrophosphate on UV light for photoionization of phosphates (< 210 nm),[3,4] no obvious wavelength dependence has been observed in photoinduced reduction by hypophosphite. We present the results obtained by the irradiation with 254 nm UV light.

For actinometry of the low pressure mercury lamp, we repeatedly used the chromophore loss of uridine in areated aqueous solution at pH 6.[5] A 20% $MeCO_2H$ solution of 1 cm pathlength was employed to filter off the photochemically significant quantities of 184.9, 194.2 and 222.4 nm UV light. The quantum yield of chromophore loss (ϕ^{cl}) was determined from the decrease of absorbance at λ_{max} of the substrates. Fig. 1 shows the concentration dependence of ϕ^{cl} of thymine, uracil and their corresponding nucleosides and nucleoside-5′-monophosphates. It is clear from this figure that ϕ^{cl} of thymine, uracil and their derivatives increases when the concentration of sodium hypophosphite is about 3×10^{-3} M or higher. ϕ^{cl} for uracil and thymidine is higher than for the other derivatives. Note that ϕ^{cl} for thymine, thymidine and thymidine-5′-monophosphate increases so sharply that at 1 M sodium hypophosphite ϕ^{cl} for thymine, thymidine and thymidine-5′-monophosphate is 0.016, 0.046 and 0.029, ϕ^{cl} being 0.064, 0.16 and 0.11 for uracil and its derivatives under the same conditions. However, no significant ϕ^{cl} change for uracil and thymine has been observed in the presence of 0.1 M concentrations of other anions (SO_4^{2-}, Cl^-, CO_3^{2-}, citrate, acetate, arsenate, cacodylate, orthophosphates, pyrophosphate), 0.1 M urea and 0.004 M metaphosphate under irradiation with 254 nm UV light. In contrast to the enhancement of the photolysis of nucleic acid monomers by orthophosphates and pyrophosphate,[4] no obvious ϕ^{cl} increase has been observed for cytosine, cytidine and cytidine-5′-monophosphate in the range 10^{-5}–1 M hypophosphite. For adenine, guanine and their derivatives, ϕ^{cl} was observed to increase when the concentration rises to more than 0.01 M, but the relative ϕ^{cl} value is < 5.

Hydrate formation of uracil, uridine and uridine-5-monophosphate was quantified using both HPLC[6] and the method introduced by Moore and Thomson[7] because the latter method has been demonstrated to bring about total dehydration.[6] HPLC elution demonstrates that hydrate formation of uracil and uridine in the concentration range corresponding to photoinduced reduction by hypophosphite ($> 3 \times 10^{-3}$ M) decreases sharply. The low reversibility or irreversibility of the irradiated samples of uracil, uridine and uridine-5-monophosphate in the concentration range corresponding to photoinduced reduction by hypophosphite also indicates that hydrates are not the main products. In dilute solution, dimers of pyrimidine bases and their derivatives arise through the triplet state.[1] ϕ for thymine dimer formation is small (< 0.1), while the reversal quantum yield is about 1.[8] This, combined with the reported limiting concentrations for uracil dimerization (> 0.1 mM)[9] and the aerated aqueous media (O_2 as triplet quencher) in the current system eliminates the possibility of forming the dimers in large quantity.

Fig. 2 indicates that major photoproducts have been formed in aqueous solutions of uracil and thymine containing sodium hypophosphite, which have been purified‡ and characterized.§ Using the authentic samples (Sigma) as internal standard, the retention time of the purified products was found to be the same to 5,6-dihydrothymine (**2a**) and 5,6-dihydrouracil (**2b**). The corresponding peaks were found to disappear by HPLC analysis after incubating the photoproducts in 0.2 M KOH for 1 h at room temperature. This is in agreement with the alkaline lability of dihydrouracil and dihydrothymine.[10] However, after heating the aqueous solution of the photoproducts with or without 0.1 M HCl in a boiling water bath for 10 min, no obvious change was observed *via* HPLC. Both IR and NMR spectra of the purified samples were found to be the same as those of the authentic samples. Overall these data indicate that the major product of

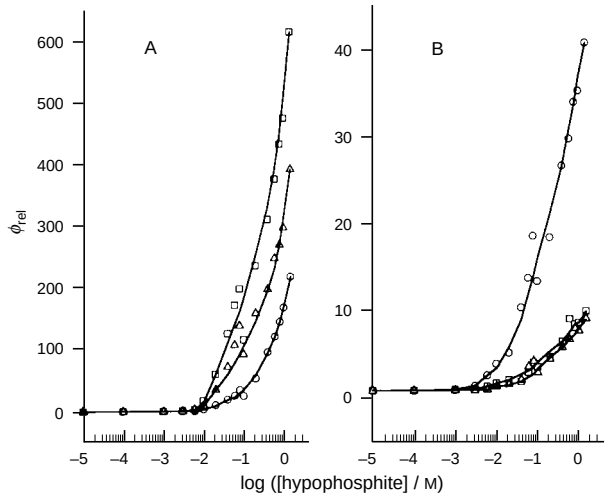

Fig. 1 ϕ^{cl} for thymine (A), uracil (B) and their derivatives as a function of the molar concentration of sodium hypophosphite undergoing the irradiation with 254 nm UV light (6.05×10^{-4} Einstein min^{-1}): (○) the base, (□) the corresponding nucleoside and (△) nucleoside-5′-monophosphate. Generally, 1×10^{-4} M aerated pyrimidines or their mixed solutions with sodium hypophosphite (pH 7 ± 0.3) were irradiated so as to facilitate UV absorbance and spectrum assay. ϕ^{cl} for thymine, thymidine and thymidine-5'-monophosphate in the absence of hypophosphite is 9.7×10^{-5}, ϕ^{cl} for uracil, uridine and uridine-5′-monophosphate in the absence of hypophosphite is 1.8×10^{-3}, 0.018 and 0.014. ϕ^{cl} in the presence of hypophosphite has been normalized to ϕ^{cl} in the absence of hypophosphite.

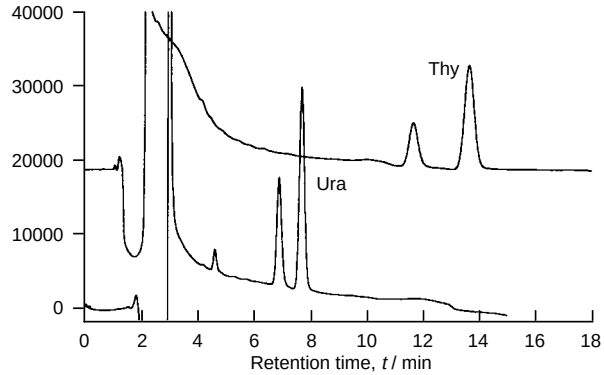

Fig. 2. HPLC elution profiles of products from irradiated 1×10^{-4} M thymine (Thy) and uracil (Ura) containing 0.2 M hypophosphite. The products were eluted from the μBondapak C_{18} column (Waters, 3.9×300 mm) at a flow rate of 1.4 ml min^{-1} (Thy) and 1 ml min^{-1} (Ura). The chromatograms were monitored at 210 nm.

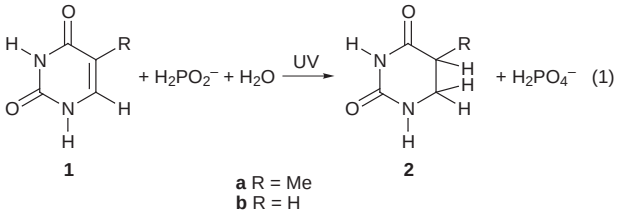
thymine and uracil containing hypophosphite is 5,6-dihydrothymine (**2a**) and 5,6-dihydrouracil (**2b**). UV absorbance at 254 nm of 1 M sodium hypophosphite is 0.009, eliminating complications in the reaction mechanism owing to the competitive UV absorbance of hypophosphite. This, combined with detection of the quantitative oxidated hypophosphite (600 MHz, ^{13}P NMR spectrum), indicates that the enhancement of the chromophore loss by hypophosphite is indeed the photoinduced reduction by hypophosphite [eqn. (1)].



The fact that no obvious difference in the quantum yield has been found between the aerated and nitrogen-saturated samples favors the singlet pathway as the reaction mechanism.

This work was supported by the Presidential Foundation and is a major project of the Chinese Academy of Sciences.

‡ The major photoproducts were prepared by 254 nm irradiation of 1×10^{-3} M aerated thymine or uracil aqueous solution containing 1 M sodium hypophosphite (pH 7 ± 0.3). The photoproducts were extracted using ethyl acetate (for photoproducts of thymine) and a mixed solution of butanone and ethyl acetate (80 : 20, v/v) (for photoproducts of uracil). The collected samples were concentrated on a rotary evaporator. The residue was taken up in water, the products were purified by reversed-phase HPLC (Waters 600, Waters μBondapak C_{18} 19 × 300) with aqueous solution (uracil) or 2% MeOH aqueous solution (thymine). The collected samples were lyophilized to dryness.

Dynamic *cis*/*trans* isomerisation in a porphyrin–fullerene conjugate

Jean-François Nierengarten,*† Laurence Oswald and Jean-François Nicoud

Groupe des Matériaux Organiques, Institut de Physique et Chimie des Matériaux de Strasbourg, Université Louis Pasteur and CNRS, 23 rue du Loess, F-67037 Strasbourg, France

A porphyrin with two fullerene substituents is prepared by condensation of a C_{60} aldehyde derivative and dipyrrol-2-yl methane and by reaction of a preconstructed porphyrin with C_{60} itself; it is obtained as a mixture of two conformers in slow equilibrium, as shown by a variable temperature NMR study.

Since the first reported preparation of a C_{60}-linked porphyrin by Gust,[1] several other fullerene–porphyrin hybrids have been described.[2] Intramolecular processes such as electron and energy transfer have been observed in some of these compounds and C_{60} appears as a particularly interesting electron acceptor in photochemical molecular devices because of its symmetrical shape, large size and the properties of its π-electron system.[3] Concerning their synthesis, all the previously reported porphyrin–C_{60} hybrids have been prepared by reaction of a preconstructed porphyrin with C_{60} itself or a C_{60} acid derivative.[2] We have recently shown that a porphyrin could be constructed starting from a C_{60} aldehyde derivative and pyrrole.[4] As a part of this research, we now report the synthesis of the novel porphyrin **1** with two C_{60} groups directly attached to the core using our methodology. Furthermore, the corresponding Zn^{II}–porphyrin **2** has been prepared by metalation of **1**, but also by reaction of a preconstructed Zn^{II}–porphyrin with C_{60} itself. Interestingly, both **1** and **2** have been obtained as a mixture of two conformers and an NMR study reveals a previously unreported type of dynamic *cis*/*trans* isomerisation.

The synthesis of porphyrin **1** and its Zn^{II} complex **2** is depicted in Scheme 1. Aldehyde **3**,[4] compound **4**[4] and dipyrrol-2-yl methane **5**[5] were prepared according to previously reported methods. The condensation of **3** and **5** was performed in $CHCl_3$ at room temperature in the presence of $BF_3{\cdot}Et_2O$. After 12 h, *p*-chloranil was added to irreversibly convert the porphyrinogen to the porphyrin. The desired porphyrin **1** was isolated in 38% yield and subsequent metalation with $Zn(OAc)_2$ gave **2** in 97% yield. Compound **2** could also be prepared starting from **4**: deprotection (TFA, CH_2Cl_2, H_2O), subsequent condensation of the resulting aldehyde **6** with **5** in $CHCl_3$ with $BF_3{\cdot}Et_2O$ as catalyst and *p*-chloranil oxidation yielded porphyrin **7**, which was metalated with $Zn(OAc)_2$ to give **8**. Fullerene incorporation was based on the regioselective macrocyclisation reaction of the carbon sphere with bismalonate derivatives developed by Diederich and co-workers.[6] Treatment of C_{60} with **8**, I_2 and DBU in toluene at room temperature afforded a mixture of compounds from which the desired Zn^{II}–porphyrin **2** could be subsequently isolated in 2% yield by tedious chromatographic separations. This poor yield could be easily explained by a low selectivity of the intramolecular addition to C_{60} due to competition between the different available reactive malonic units on the porphyrin core after its first intermolecular reaction with C_{60}.

All of the spectroscopic studies and elemental analysis results were consistent with the proposed molecular structures.‡ The ^1H NMR spectrum of **1** at room temperature showed the presence of two conformers in a 1 : 1 ratio (Fig. 1). Molecular modelling studies on compound **1** revealed that each fullerene group is located to one side of the plane of its bridging phenyl ring. Therefore due to the high barrier to rotation of the phenyl substituents on the porphyrin, two conformers are possible for **1**. The two carbon spheres in **1** can be in either a *cis* or *trans* relative orientation (Fig. 1). Whereas the two porphyrin *meso*-

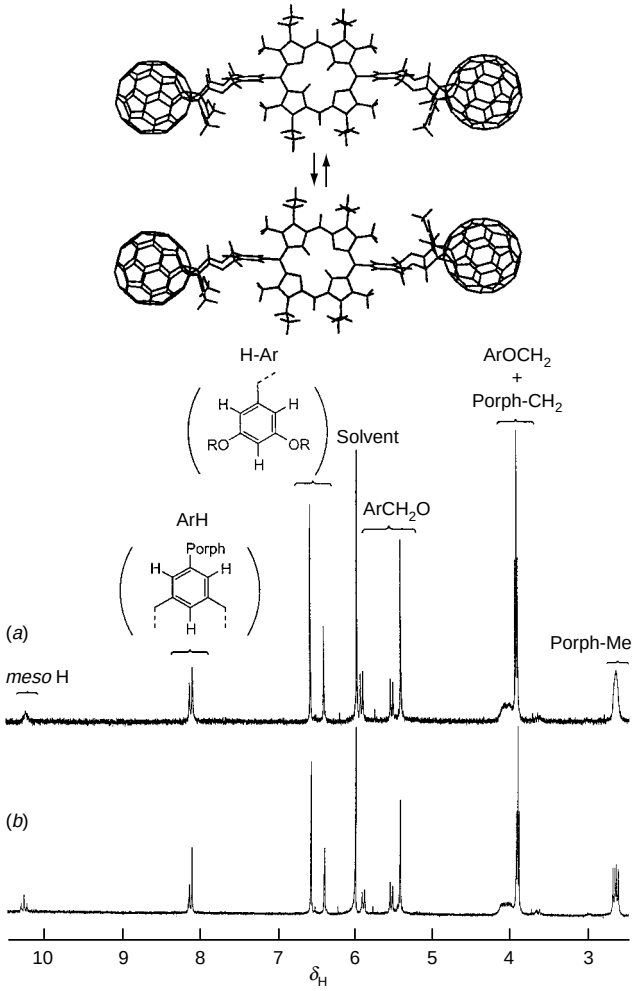

Fig. 1 ^{1}H NMR spectra of **1** ($CDCl_2CDCl_2$, 400 MHz) at (a) 125 and (*b*) 25 °C, and molecular models of the two conformers of compound **1** (the four didodecyloxyphenyl groups have been omitted for clarity)

Hs are equivalent in the *trans* conformer, they are non-equivalent in the *cis* one. As expected, three singlets in a 1 : 2 : 1 ratio are observed at δ 10.20, 10.23 and 10.27, respectively, for the *meso*-Hs in the 1 : 1 mixture of conformers. Furthermore, the four methyl groups on the porphyrin form equivalent pairs in both conformers and the expected four singlets are clearly observed (δ 2.60, 2.63, 2.64 and 2.67) in the ^{1}H NMR spectrum. A variable-temperature NMR study showed a clear coalescence at 125 °C (Fig. 1). By monitoring the coalescence of the porphyrin *meso*-Hs, the free energy barrier for the conformational equilibrium was calculated as $\Delta G^{\ddagger}$ = 85 kJ mol^{-1}.[7] A sharp symmetric spectrum could not be obtained below the limit of heating, however the observed reversible narrowing of all the peaks unambiguously shows that a dynamic effect does occur. This *cis*/*trans* isomerism has also been seen for compound **2** and can be related to the diastereoisomerism observed for some terphenyl systems.[8] Whereas atropisomerism in bis(*o*-substituted phenyl) porphyrins is well known, the conformational isomerism observed for **1** and **2** is, to the best of our knowledge, the first example of a bis(*m*-substituted phenyl) porphyrin for which the barrier to free rotation is high enough at room temperature to be able to distinguish the *cis* and *trans* conformers.

Preliminary luminescence measurements show a strong quenching of the porphyrin emission in **1** and **2** and their photophysical properties are currently under investigation.

We thank the CNRS for financial support, C. Bourgogne for his help with the molecular modelling, Hoechst AG for samples of C_{60} and Professor F. Diederich (Zürich, Swiss) for his interest in our work and his support.

Non-covalent control of site-selective incorporation of the pyridoxal phosphate cofactor into a folded polypeptide motif—mimicking a key step in enzymatic transamination

Malin Allert, Martin Kjellstrand, Klas Broo, Åke Nilsson and Lars Baltzer*†

Department of Chemistry, Göteborg University, S-412 96, Göteborg, Sweden

The site-selective incorporation of the pyridoxal phosphate cofactor into a designed polypeptide motif has been achieved and shown to be controlled by the non-covalent interactions between the phosphate group of the cofactor and a single arginine residue on the surface of the folded polypeptide.

The *de novo* design of functionalized proteins is an attractive alternative in the construction of new catalysts because of the inherent capacity of polypeptides for folding into complex three-dimensional structures determined by non-covalent bonds. Folded polypeptide catalysts, with reactive sites formed by naturally occurring amino acids, are now emerging that catalyse multistep reactions with rate enhancements that rival those of typical catalytic antibodies.[1–3] Coenzyme-based catalysts have, perhaps, an even greater potential because of their intrinsic reactivities, provided that efficient strategies can be found to embed the cofactors into reactive sites in template peptides. The site-selective incorporation of residues for which no codons exist has so far been accomplished by the cumbersome synthesis of artificial amino acids[4,5] or by the site-selective functionalization of lysine, ornithine, diaminobutyric acid[6–8] and cysteine residues.[9,10] Here we report that for the first time non-covalent interactions have been used to control the incorporation of a complex cofactor into a folded polypeptide. Understanding the principles that govern the recognition of functional groups by folded polypeptides opens up efficient routes for the engineering of new proteins with tailor-made specificities.

PP-42, a polypeptide with 42 residues, was designed to fold into a helix-loop-helix motif and dimerise in aqueous solution to form a four-helix bundle protein (Fig. 1). Its design was based on the sequence and solution structure of SA-42[11,12] with the objective of engineering a template polypeptide into which a pyridoxal cofactor could be introduced. PP-42 was synthesised by solid-phase peptide synthesis using Fmoc chemistry, purified by reversed-phase HPLC and identified from the electrospray mass spectrum (calc. 4532.1; found 4531.5).‡ The mean residue ellipticity of PP-42 at a concentration of 0.60 mM is -24500 ± 1000 deg cm^2 dmol^{-1} in aqueous solution at pH 7.0 and ambient temperature, which is comparable to those of other designed helix-loop-helix dimers.[13] The helical content of amphiphilic helix-loop-helix dimers is known to decrease substantially upon dissociation, therefore the measured mean residue ellipticity of PP-42 provides strong evidence that it folds into the designed four-helix bundle motif.

The mechanism of transamination in native enzymes includes the formation of an aldimine from the pyridoxal phosphate cofactor **I** and the side chain of a lysine residue in the active site. Upon introduction of the amino acid substrate into the active site, the lysine side chain is replaced by the amino group of the amino acid, which is transformed to an α-keto acid in a multistep reaction.[14] In order to incorporate the cofactor into the folded helix-loop-helix motif, to mimic the initial step of the enzymatic reaction, a lysine residue was targeted for aldimine formation by placing an arginine side chain in a position to interact with the phosphate group of the cofactor. In the computer modelled structure the guanidino group of Arg-19 is ideally positioned to bind the phosphate group upon aldimine formation at the side chain of Lys-30. Two more lysine residues were introduced into PP-42 to probe whether the phosphate-arginine interaction would be strong enough to make the incorporation site-selective. The sequence of PP-42 contains three lysine and four arginine residues, Lys-11, Lys-15, Lys-30, Arg-10, Arg-19, Arg-33 and Arg-40 (Fig. 1).

The reaction between **I** and PP-42 to form the aldimine was followed by the increase in absorbance at 390 nm, using an extinction coefficient for the aldimine of 4000 M^{-1} cm^{-1} (Fig. 2).§ The degree of aldimine formation was determined from the 400 MHz ^{1}H NMR spectrum recorded in D_2O at pH 4.4 by measuring the reduction of the intensity of the aldehyde proton of **I** at δ 10.43 upon addition of PP-42 under these conditions. More than 95% of the monofunctionalised peptide was obtained using approximately 0.6 mM PP-42 and a five-fold excess of **I**. At pH 4.4 the reaction is rapid and equilibrium is established within a few minutes. The UV spectrum of a solution of 0.6 mM PP-42 and 3.1 mM of **I** at 25 °C and pH 4.4 is shown in Fig. 2 and shows that more than 95% of the PP-42 is bound. In contrast, under identical reaction conditions, the equilibrium

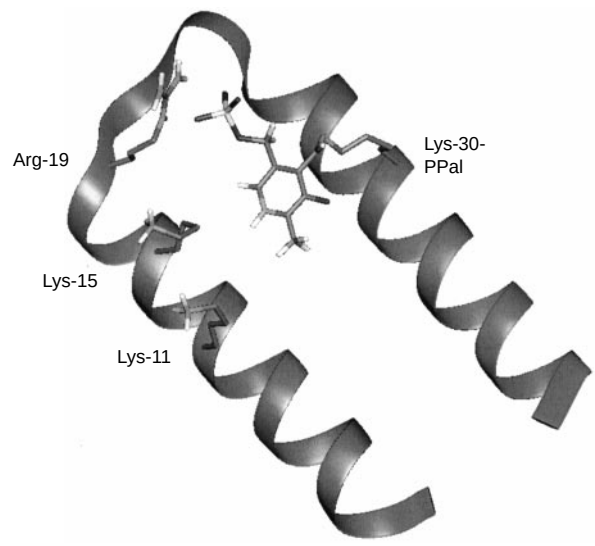

Fig. 1 The amino acid sequence and the modelled structure of PP-42 showing the positions of arginine and lysine side chains on the surface of the folded motif. The amino acid residues are given in the one-letter code where Nle is the artificial amino acid norleucine. Only the monomer is shown for simplicity.

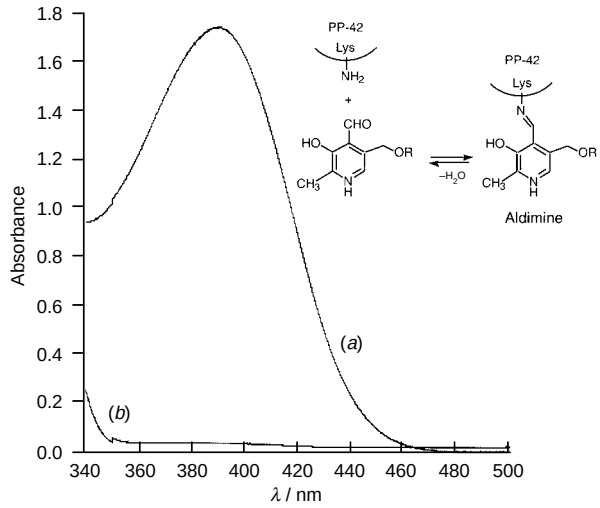

Fig. 2 The UV spectrum recorded in aqueous solution, at 25 °C and pH 4.4, of 0.6 mM PP-42 in the presence of (*a*) 3.1 mM pyridoxal phosphate **I** (R = PO_3^{2-}) and (*b*) 3.1 mM pyridoxal II (R = H). The aldimine formation was followed at 390 nm.

concentration of aldimine upon reaction between PP-42 and pyridoxal **II**, that has no phosphate residue, is insignificant. It can be estimated from the ratio of the absorbances of the two aldimines that the equilibrium constants differ by more than two orders of magnitude, although the absorbance of the pyridoxal-containing mixture is too weak to permit an accurate determination. A strong interaction between the negatively charged phosphate residue and the peptide is thus demonstrated.

The site of incorporation of pyridoxal phosphate into PP-42 was determined by $NaBH_4$ reduction of the aldimine in aqueous solution to form the corresponding secondary amine, followed by trypsin cleavage of the functionalised peptide. The site of functionalization was determined by LC-ESMS of the polypeptide digest. Trypsin cleaves polypeptides on the C-terminal side of basic residues. No cleavage was expected at the lysine side chain that had been functionalized.

A fragment from the reduced form of the functionalized peptide (dication 835.91 and trication 557.61), which corresponded to the molecular mass of the sequence from Gly-20 to Arg-33 (1438.64) plus the mass of pyridoxal phosphate (247.2) and 2H (2.02), less the weight of water (18.02) amounting to approximately 85% of the total amount of reduced functionalized peptide, were found in the LC-ESMS spectrum. The dominant site of aldimine formation was therefore the side chain of Lys-30. A minor amount of aldimine formation at the side chain of Lys-11 was also observed, whereas no aldimine formation involving the side chain of Lys-15 could be detected.

Arg-19 is apparently in a good position relative to Lys-30 to control the functionalization of its side chain, but the proximity of Arg-10 to Lys-11 in a helical conformation appears to give rise to small amounts of aldimine, too, under conditions of excess **I** over peptide. The absence of detectable amounts of aldimine at the side chain of Lys-15 shows that a lysine side chain that is not flanked by an arginine in PP-42 does not form an aldimine with **I** to a measurable extent.

Arg-19 and Lys-30 thus form a two-residue site that competes favourably with other lysine residues in PP-42, and the aldimine formation with **I** is controlled by the binding of phosphate by arginine. The engineering of a Lys-Arg two-residue site is therefore sufficient to ensure the incorporation of the cofactor provided that the arginine side chain has a similar orientation towards the lysine side chain as that of Arg-19 towards Lys-30. The incorporation of **I** can thus be made site-selective in the presence of other lysine residues. To enhance the selectivity further Arg-(*i*)-Lys-(*i*+1) configurations in helical segments should be avoided. In the second step of the catalytic cycle the amino group of an amino acid will replace the lysine side chain in an exchange reaction. Further design of the polypeptide motif is now under way so that the second intermediate, too, will be bound to the peptide catalyst. It can for example be envisioned that the trianion formed in the reaction between **I** and Asp will be bound by arginine residues.

The demonstration of non-covalent control of the incorporation of **I** shows that the interaction between the phosphate group and an arginine side chain in aqueous solution at pH 4.4 is strong enough to ensure the site-selectivite funtionalization of the folded polypeptide. A well-defined two-residue site on the surface of the folded polypeptide can therefore be used to create a molecule of high complexity in a one-step reaction in aqueous solution. The use of the arginine–phosphate bond should be of general interest in a wide range of applications involving phosphates and phospho esters. The results suggest that understanding the interplay between functional amino acid side chains, organised in three-dimensional space by polypeptide templates, is a key element in the rational design of functionalised polypeptides with tailor-made specificities.

Financial support from the Swedish Natural Science Research Council and from Carl Tryggers Stiftelse is gratefully acknowledged. We are indebted to Dr Gunnar Stenhagen for mass spectrometric determinations.

Novel application of chiral micellar media to the Diels–Alder reaction

Michael J. Diego-Castro and Helen C. Hailes*†

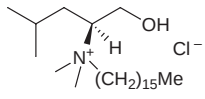
Department of Chemistry, University College London, London, UK WC1H 0AJ

A novel chiral surfactant has been used in the first reported aqueous chiral micellar catalysis of a Diels–Alder reaction and enantioselectivities have been observed.

The chemical industry is undergoing an important transition period in which they are reacting to ever increasing governmental and public pressure to reduce the use of volatile organic solvents. In the context of Diels–Alder reactions, there is also an urgent need to seek alternatives to Lewis acids, since they are typically dumped when spent.

There is good reason to believe that chiral micellar media offer a viable clean alternative to more traditional methods of accomplishing many organic reactions. In particular, aqueous micellar media have the potential to confer special properties on reactions due to their ability to, for example, solubilise substrates and concentrate and preorientate reactants within the micellar core.[1] Furthermore, they are recyclable; there is the potential for enantioselection; they can be prepared at low cost, particularly when using synthons from the chiral pool; they can be applied to a range of different reactions; they are more versatile than other chiral aqueous systems such as cyclodextrins due to the potential number of structural variations; and they are more robust than enzymes. Whilst this field exhibits considerable promise, it is at an early stage in its development. Consequently, there are relatively few currently reported applications of chiral micellar media[2] and, until now, none at all for their application to Diels–Alder reactions.

Here we outline our initial investigations into a methodology, which enabled us to perform a Diels–Alder reaction using chiral micellar media, with enantioselectivities comparable with the best obtained for cyclodextrin based aqueous Diels–Alder reactions.[3] The reaction in question was performed using a novel (*S*)-leucine-derived surfactant **1**[4] to catalyse the reaction between cyclopentadiene and nonyl acrylate, under a variety of conditions.

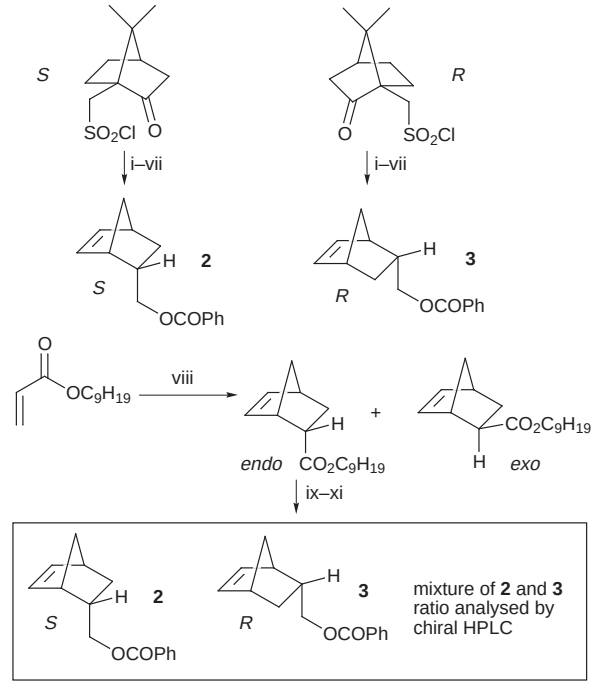


1

In a previous paper,[5] we demonstrated that a variety of factors influence the overall efficiency of the cycloaddition and the diastereoselective *endo* : *exo* (*N*/*X*) ratio. Amongst these are the chain length of the acrylate, the selection of the surfactant concentration and the pH of the solution. In view of the first of these factors, we chose to use nonyl acrylate as the test substrate to explore the feasability of the methodology, both because its long alkyl chain increases the pre-orientation effects within the micellar structure, and because the cycloadduct is stable to chiral HPLC analysis.

In order to ascertain the concentration at which micelles or micellar-like aggregates will be present and some enantioselective induction could be expected, we initially utilised a dye method which gave a value of *ca.* 0.011 g l^{-1} (0.027 mM).[6] Whilst it is well known that the critical micellar concentration (cmc) for a particular surfactant can vary depending on the method that is used,[7] and indeed, surface tension experiments indicated a higher value,[4,6] we felt that in our synthetic applications a dye method gave an appropriate starting point. This is because, in the micellar reaction system with nonyl acrylate present mixed micellar aggregates will be generated, as is also likely when the indicator dye is present.

Analysis of our initial experiments in the presence of the chiral surfactant **1** indicated some chiral induction in the *endo* adduct but negligible induction in the *exo* isomer. It was therefore necessary to assess whether the *R* or the *S endo* adduct was formed preferentially. To this end, we correlated our products using Oppolzer's sultam auxiliary methodology.[8] As outlined in Scheme 1, (*S*)-camphorsulfonyl chloride was treated with aq. NH_3, heated in the presence of Amberlyst-15, then reduced to a cyclic amine which was coupled with acryloyl chloride. The subsequent Diels–Alder cycloaddition reaction with cylopentadiene and the Lewis acid $TiCl_4$, followed by reduction and reaction with benzoyl chloride generated the *endo-S* isomer **2**. An analogous route using (*R*)-camphorsulfonyl chloride was used to synthesise the *R endo* ester **3**. The Diels–Alder *endo* cycloadducts generated in the reaction between nonyl acrylate and cyclopentadiene with **1** present were then isolated from the *endo–exo* mixture using chromatographic techniques. These were converted into a mixture of **2** and **3** *via* reduction and ester formation. Finally, HPLC analysis revealed that the *R* isomer was formed preferentially.‡



Scheme 1 *Reagents and conditions*: i, NH_4OH, THF, 83%; ii, Amberlyst-15, toluene, 110 °C, 18 h, 99%; iii, $LiAlH_4$, THF, 69%; iv, NaH, acryloyl chloride, 65%; v, $TiCl_4$, Et_2O, cyclopentadiene, −78 °C, 20 h, 55%; vi, $LiAlH_4$, Et_2O, 99%, vii, BzCl, CH_2Cl_2, 54%, viii, cyclopentadiene, 20 h, surfactant **1**, 55%; ix, only *endo* isomer was carried through subsequent steps (SiO_2, 4% Et_2O in hexane); x, $LiAlH_4$, Et_2O, 99%; xi, BzCl, CH_2Cl_2, 55%

Table 1 Addition of cyclopentadiene to nonyl acrylate in water containing surfactant **1**

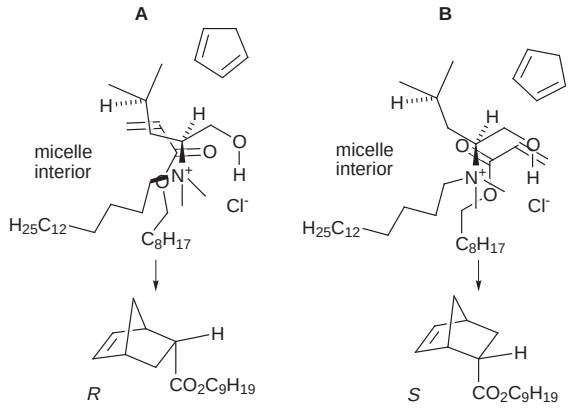
Entry	[Surfactant]/g l^{-1}	Yield[a] (%)	*N*/*X*	Ee[b] (%) (*R*)
1	0.011	55	2.1	10
2	0.022	72	2.1	12
3	0.006	43	2.0	7
4	0.011[c]	29	2.1	13
5	0.011[d]	75	2.2	15

[a] Isolated yields. [b] Determined by chiral HPLC. [c] pH 3. [d] pH 3 with LiCl.

In view of the initial uncertainty in the optimum surfactant concentration for use in such applications, the concentration of **1** was varied and the effects on enantioselectivities and yield were noted,§ see summarised results in Table 1. For comparison purposes, the reaction in water alone under identical conditions, gave a yield of 70% and an *N*/*X* selectivity of 1.7.

At the starting point, an ee of 10% was observed (entry 1), rising slightly (entry 2) as surfactant concentration was increased then falling as the concentration was decreased (entry 3) together with a lowering of the yield, which could be due to the presence of non-micellar aggregates. Previously, we had seen the greatest yields and *N*/*X* selectivities in acrylate systems in the absence of surfactant when operating at pH 3.[5] In this instance, we found that when the solution was at pH 3 the enantioselectivity increased, although the yield of cycloadduct that was isolated was poor (entry 4). In determining how to increase the yield in this system, we reasoned that a salting-out agent would tend to remove the reactants from the aqueous pseudo-phase, increasing the complexation of the substrates to the micelles. Further, it is known that an increased concentration of chloride counterions can cause a shrinkage in the Stern layer, leading to a concentration of reactants[1] which, in our system, could translate to greater pre-orientation and enhanced yield and ees. In view of these factors, we added lithium chloride (4.86 M) to the reaction at pH 3, thence obtaining both the highest yield (75%) and the greatest ee (15%). This result compares well with the results quoted for Diels–Alder reactions in cyclodextrins in which maximum enantioselectivities of 21% are reported.[3]

A number of conformations of the surfactant **1** could be considered (since surfactants are dynamic in nature) and a representative one, consistent with NOE difference experiments is shown below in Scheme 2, in an attempt to provide a tentative simplistic model which nevertheless helps to visualise the observed preferences. All possible conformations have the common feature of a more hindered top face of the molecule as drawn due to the chirality present. Alignment of nonyl acrylate with the underside of **1** results in the cyclopentadiene having to approach from below the acrylate. As shown in Scheme 2 (for the reaction under neutral conditions), the carbonyl moiety can complex to the nitrogen and hydrogen bond to the O–H group with the alkene beneath the isopropyl group in **A**, with subsequent approach of cyclopentadiene beneath the complex leading to the formation of the *R*-isomer. However, in **B**, reaction with the diene would generate the *S*-isomer. Since **A** is complexed more favourably (with possible hydrogen bonding and carbonyl complexation) as well as having the polar carbonyl moiety directed towards the Stern layer, the *R*-isomer would be expected to be more prevalent. Future work will shed more light on this model.



Scheme 2 Positioning of the acrylate with respect to the surfactant head group

In summary, we have performed the first Diels–Alder reaction in aqueous chiral micellar media, obtaining selectivities comparable with the best reported for other non-enzymic aqueous Diels–Alder reactions. We established that the *R* enantiomer in the *endo* isomer was formed preferentially in this system and have rationalised these results.

Subsidiary results include a further confirmation of the fact that the selection of the surfactant concentration is an important but elusive parameter in organic synthesis and that the pH is significant in chiral micellar catalysis. Finally, we have seen that lithium chloride may prove to be useful in such systems.

This work is part of a series of ongoing projects. We are aiming at further enhancing selectivity in Diels–Alder reactions by investigating a range of substrates with the aim of reducing the effects of the competing reaction in the water phase. We are also investigating the use of chiral surfactants in other classes of reaction as well as exploring the effect of more conformationally constrained surfactants.

We are grateful to University College London (Access Funds for M. J. D.-C.), Bush Boake Allen, Central Research Fund University of London, The Royal Society, and The Nuffield Foundation for funding. We thank Dr P. Sandor for running NOE experiments.

Construction of two- and three-dimensional supramolecular networks with an encapsulated lanthanide(III) complex as building block and hydrogen-bonded 4,4′-bipyridyl as spacer

Cheng-Yong Su,[a,b] Bei-Sheng Kang,[b] Han-Qin Liu,[b] Qi-Guang Wang[a] and Thomas C. W. Mak[a]*†

Reaction of the tripodal ligand tris(2-benzimidazolylmethyl)amine (ntb) with hydrated lanthanide(III) perchlorates in methanol affords the complexes $[Ln(ntb)_2]^{3+}$ (Ln = Pr, Eu and Tb) in which the central Ln^{3+} ion is well encapsulated in a cubic coordination environment; *in situ* co-crystallization of the complexes in the presence of 4,4′-bipyridyl produces either a double salt containing the bipyridinium(1+) cation or adducts with two to three bipyridyl molecules, the latter adducts forming doubly interpenetrating two- or three-dimensional cationic networks.

The control of molecular assembly using supramolecular interactions represents a new area of considerable general and topical interest.[1] In particular, strong, selective and directional hydrogen bonding has been exploited for molecular recognition associated with biological activity, and for crystal engineering of molecular solids.[2] Much progress has been made in the construction of organic building blocks into one-, two- or three-dimensional hydrogen-bonded architectures;[2,3] however, the use of metal complexes for assembly or self-assembly by hydrogen bonding has attracted little attention until recently,[4] although the resulting products are often expected to exhibit certain desirable electronic, magnetic, or inclusion behavior.[1b]

The specific spectroscopic and magnetic properties of lanthanide(III) ions have made them essential components in the preparation of new materials and ideal probes in studies of biological systems.[5] The incorporation of trivalent lanthanide ions into supramolecular complexes that act as molecular photonic devices is currently of great interest in supramolecular chemistry.[6] Probes based on Eu^{III} and Tb^{III} are of special relevance because of their long-lived $^5D_0$ and $^5D_4$ excited states and their large Stokes' shift. However, the design of a good lanthanide luminescent probe has to overcome difficulties arising from the low oscillator strengths of the f–f transitions and from the easy de-excitation of the Ln^{III} excited state.[6a,c]

Current research has mainly focused on the encapsulation of the Ln^{III} ions using pre-organized ligands such as coronands, cryptands, podands, calixarenes or Schiff bases.[5c,6d] We now report the syntheses and crystal structures of new lanthanide complexes with the tripodal ligand tris(2-benzimidazolylmethyl)amine (ntb), in which the central Ln^{III} ion displays a rarely found cubic coordination environment and is well encapsulated from interaction with its surroundings by the rigid heterocyclic rings of ntb. Employing the linear difunctional H-bond acceptor 4,4′-bipyridyl as a spacer, the bipyridinium(1+) double salt $[Eu(ntb)_2](ClO_4)_3\cdot(bipyH)ClO_4\cdot 3H_2O$ **1** and two types of bipyridyl adducts bearing different lanthanide/bipy molar ratios, namely $[Pr(ntb)_2](ClO_4)_3\cdot 2bipy\cdot 1.5H_2O$ **2** and $[Ln(ntb)_2](ClO_4)_3\cdot 3bipy\cdot nH_2O$ (**3,** Ln = Eu, n = 2; **4**, Ln = Tb, n = 1) were obtained. Doubly interpenetrating two- or three-dimensional extended networks are formed in complexes **2–4**.

In the presence of 4,4′-bipyridyl, reaction of ntb with hydrated lanthanide(III) perchlorates afforded complexes **1–4.**‡ The nature of the products isolated is evidently sensitive to the presence of a trace amount of acid[8] and different equivalents of 4,4′-bipyridyl. Single crystals suitable for X-ray analyses were obtained by slow diffusion of diethyl ether into a dilute reaction mixture.§

The main structural feature common to all four complexes is the presence of the $[Ln(ntb)_2]^{3+}$ motif, in which the Ln^{III} ion is coordinated by eight nitrogen atoms from the two ntb ligands to give a slightly distorted cubic environment (Fig. 1). Both ntb ligands display a tripod-type tetradentate coordination mode in wrapping around the central lanthanide ion. This kind of coordination geometry is seldom found for eight-coordinated Ln^{III} ions, although Wood *et al*.[9] suggested long ago that the cube should not be energetically unfavorable relative to either the square antiprism (D_{4d}) or the triangular dodecahedron (D_{2d}). The ability of two ntb tripods to shield completely a Ln^{III} ion with N-donor sites without additional bound solvent molecules, especially water or alcohol, is important for the design of lanthanide(III) supramolecular photonic devices since such coordinated solvent molecules are frequently efficient quenchers of Ln^{III} luminescence.[6d]

Since each ntb ligand possesses three NH groups that are potential hydrogen-bond donors (see Fig. 1), the possibility of controlling the assembly of $[Ln(ntb)_2]^{3+}$ moieties by employing the linear difunctional hydrogen-bond acceptor 4,4'-bipyridyl as a spacer component was explored. X-Ray crystal structure analysis showed that in complex **1**, one nitrogen atom of ($bipyH^+$) forms an acceptor hydrogen bond to $[Eu(ntb)_2]^{3+}$ (N···N, 2.900 Å) while the protonated nitrogen atom is connected to one oxygen atom of a perchlorate anion (N···O,

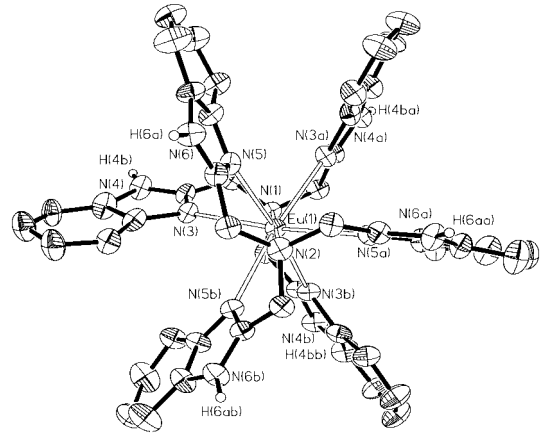

Fig. 1 Perspective view of the $[Eu(ntb)_2]^{3+}$ cation in **3** showing atoms as thermal ellipsoids at the 30% probability level. All H atoms have been omitted, except those of the NH groups that are shown as small spheres.

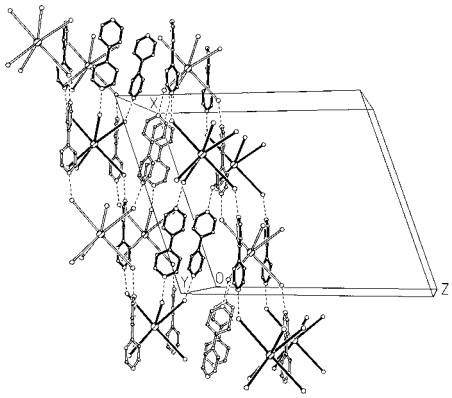

Fig. 2 Interlocking two-dimensional cationic frameworks constituting a layer matching the (001) plane in the crystal structure of **2**. For clarity, each 2-benzimidazolylmethyl arm of the ntb ligand is represented by a long rod joining each NH group to the lanthanide atom, so that each $[Pr(ntb)_2]^{3+}$ cation takes the appearance of an octahedron. All hydrogen atoms, water molecules and perchlorate ions have been omitted. The independent interlocking frameworks are differentiated by solid and open shading.

2.942 Å), thus precluding the formation of the linear chain $\cdots[Eu(ntb)_2]^{3+}\cdots bipy\cdots[Eu(ntb)_2]^{3+}\cdots bipy\cdots$. In complex **2**, each bipy forms a pair of acceptor hydrogen bonds with two different $[Pr(ntb)_2]^{3+}$ cations (N⋯N distances lie in the range 2.783–2.852 Å), thereby generating an open, two-dimensional cationic framework with each $[Pr(ntb)_2]^{3+}$ cation alternately connected to one and three bipy molecules in the *a* direction. Moreover, two independent frameworks of this type interpenetrate each other to form an extended layer corresponding to the (001) plane (Fig. 2), with the perchlorate ions and water molecules located in the inter-layer region. In complex **4** the NH groups of both independent ntb ligands in the $[Tb(ntb)_2]^{3+}$ ion and the bipy molecule are involved in the supramolecular hydrogen-bonding scheme (N⋯N range 2.818–2.871 Å). Linkage between each $[Tb(ntb)_2]^{3+}$ cation and six neighbouring bipy units leads to an open, three-dimensional cationic network, leaving large voids to be filled by another identical, interlocking network (Fig. 3), and the perchlorate ions and water molecules are located in the residual interstices. Compound **3**, in which the $[Eu(ntb)_2]^{3+}$ ion lies on a three-fold symmetry axis (Fig. 1), exhibits the same type of supramolecular structure as **4**, although the two adducts crystallize in different space groups.

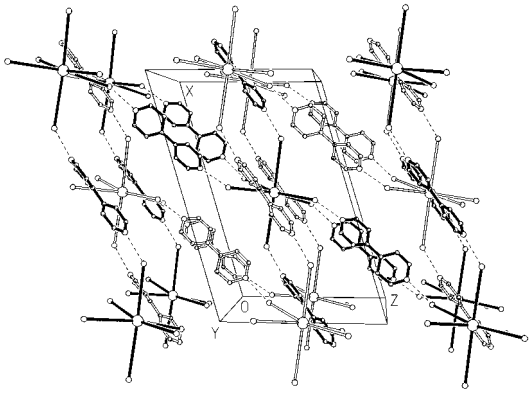

Fig. 3 Three-dimensional doubly interpenetrating networks in the crystal structure of **4**. Representation of the supramolecular structure is simplified in the same manner as in Fig. 2.

In summary, the present study has demonstrated that the intrinsic steric constraints of the tripodal ligand ntb facilitate complete encapsulation of a lanthanide(III) ion in a rare cubic coordination geometry. Assembly of $[Ln(ntb)_2]^{3+}$ building blocks with bipy spacers using supramolecular NH⋯bipy⋯HN hydrogen bonds results in two- or three-dimensional two-fold interpenetrating networks, which may be profoundly influenced by the presence of acid and different equivalents of the spacer component.

Bipyridine functionalized molecular clips. Self-assembly of their ruthenium complexes in water

Johannes A. A. W. Elemans,[a] René de Gelder,[b] Alan E. Rowan[a] and Roeland J. M. Nolte*[a]†

[a] *Department of Organic Chemistry, NSR Center, University of Nijmegen, Toernooiveld, 6525 ED, The Netherlands*
[b] *Crystallography Laboratory, NSR Center, University of Nijmegen, Toernooiveld, 6525 ED, The Netherlands*

Ruthenium-bipyridine complexes of molecular clips self-assemble in water to form scroll- and cigar-like nanostructures.

The development of artificial self-assembled structures with specific shape and size is a topic of fundamental importance.[1,2] Incorporation of metal centers into these structures is of great interest as it may eventually lead to functional nanosized devices, for which many applications can be foreseen.

In our work to construct well defined nanosized assemblies by means of molecular recognition, we recently reported the formation of 'razorblade-like' aggregates in water, which were built up from diphenylglycoluril (DPG) derived molecular clips with water-soluble groups on their convex side.[3] Dimerization of these clips, in which the cavity of one clip is filled by the sidewall of its neighbour and *vice versa*, was found to play a major role in the assembly process. In order to be able to incorporate metal centers in these assemblies, a new type of molecular clip was developed having a bipyridine ligand on its convex side. Here the synthesis and properties of two of these clips are presented, as well as the self-assembling behaviour of their ruthenium-bipyridine complexes in water.

Bipyridine-glycoluril **1** was prepared in 81% yield by acid catalyzed condensation of 1,10-phenanthroline-5,6-quinone[4] and urea in toluene. Clip molecules **2** and **3** were synthesized in 32% and 16% yields, respectively, from **1** and 1,2-bis-(bromomethyl)benzene and from **1** and 2,3-bis(bromomethyl)naphthalene according to a standard procedure.[3]‡

Single crystals of **2** were grown by slow diffusion of methanol into a chloroform solution of this compound.§ The crystal structure [Fig. 1(*a*)] reveals that a large steric interaction exists between the γ-bipyridine and methylene protons of **2** resulting in a more squeezed cavity compared to cavities of other DPG-derived clips. This is reflected in the smaller distance between the aromatic side-walls of **2** (6.18 Å, as compared to 6.67 Å in the crystal structure of **4b**[5]). To investigate the consequences of this narrower cavity on the binding properties of **2** and **3** in $CDCl_3$, ^1H NMR binding studies with various 5-substituted 1,3-dihydroxybenzenes were carried out. It can clearly be seen in Table 1 that binding of guests in **2** is significantly weaker than in the reference compound **4a**, which is in agreement with the observed squeezed cavity of **2**. The host–guest binding properties of **3** in $CDCl_3$ are even weaker than those of **2**, as was observed before in DPG-derived clips containing 2,3-connected naphthalene walls.[6]

Clips **2** and **3** were then complexed with $[Ru(bipy)_2]Cl_2{\cdot}2H_2O$[7] to give water-soluble metalloclips **5** and **6** in 56% and 42% yields, respectively.‡ ^1H NMR experiments indicated that when a solution of **5** in D_2O was diluted, the resonances of the wall protons H_a and H_b and the bipyridine protons H_4 and H_5 shifted downfield, whereas the resonances of all the other protons of **5** did not undergo significant shifts. From an NMR dilution titration (500 MHz) in D_2O, the self-association constant of two molecules of **5** was determined to be $K_{dimer} = 50 \pm 10$ dm^3 mol^{-1}; the same value was calculated for each shifting proton. A 2D NOESY experiment of **5** in D_2O revealed several NOE contacts between the sidewall protons of one molecule of **5** and the bipyridine protons of its neighbour. Combining these results, we propose that **5** forms head-to-tail associates in water, clipping the sterically least hindered side of one of the bipyridine ligands of its neighbour between its cavity walls. From the calculated complexation induced shift values for the shifting protons (H_a: −0.85 ppm; H_b: −0.45 ppm; H_4: −1.41 ppm; H_5: −0.58 ppm), the geometry of the self-associated complex can be predicted, see Fig. 1(*b*). Because of steric hindrance it is not possible for **5** to bind simultaneously two neighbours at both bipyridines.¶

A ^1H NMR dilution titration of complex **6** in D_2O (0.1–2 mM) showed downfield shifts of the resonances of H_4, H_5, H_c and H_d. At concentrations above 2 mM the solutions of **6** became turbid and severe line broadening occurred, which was attributed to the

formation of larger aggregates (*vide infra*). The calculated K_{dimer} using H_c or H_d as a probe (21000 ± 5000 $dm^3\ mol^{-1}$) was much larger than the calculated K_{dimer} using H_4 or H_5 as a probe (2500 ± 500 $dm^3\ mol^{-1}$). These values indicate that **6**, in contrast to **5**, can self-associate in two competing geometries, *viz*. head-to-head and head-to-tail, in which the interaction between the large hydrophobic cavities of **6** in the former geometry is stronger than the clipping of a bipyridine ligand between the cavity side-walls in the latter. The existence of both head-to-head and head-to-tail geometries has been observed before in the case of naphthalene-walled pyridinium-functionalized clips.[3] The self-association of **6** in D_2O is much stronger than the self-association of **5**, which is in contrast with the binding of guests in $CDCl_3$ solution, where **2** is a better host than **3**. In aqueous solution, however, the self-association geometry is dominated by hydrophobic interactions, and since **6** has a much larger hydrophobic cavity than **5** it is expected that **6** forms stronger self-associated complexes.

To further study the aggregates formed, samples of **5** and **6** in D_2O were investigated by electron microscopy (TEM). For **5**, rather undefined scroll-like structures were observed with lengths up to 10 μm [Fig. 2(*a*)]. In contrast, for **6**, well defined 'cigar-like' aggregates were found [Fig. 2(*b*),(*c*)] which displayed a very high monodispersity in size [aspect ratio (length/width) = 11 ± 2]. X-Ray powder diffraction on samples of **5** and **6** revealed no clear reflections, implying that the aggregates are built up from molecular units that interact in a very diverse way or assemble in a variety of geometries. Since the complexes are racemic mixtures of Λ and Δ enantiomers, and in the head-to-tail self-association geometry one molecule of **5** or **6** has the possibility to choose between different bipyridine ligands of a neighbouring clip molecule for binding in its cleft and, additionally, has the option to use each of its own bipyridines to hold another clip molecule, such diversity in binding can be easily envisaged.

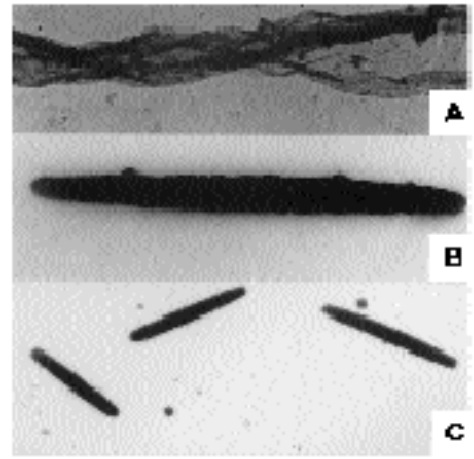

Fig. 2 Electron microscopic pictures of aggregates formed by **5** and **6** in water: (*a*) TEM picture of a scroll formed by **5**, 1 cm = 100 nm; (*b*),(*c*) TEM pictures of 'cigar-like' aggregates formed by **6**, 1 cm = 500 nm (*b*), 1 cm = 1750 nm (*c*). No shadowing or staining techniques were applied.

The observation that **6** assembles into a better defined supramolecular structure than **5** is attributed to the stronger self-association behaviour of **6**. We propose that the molecules of **6** self-assemble in a similar fashion to that reported before for the 'razorblade-like' nanostructures formed by molecular clips with pyridinium functions.[3] With their large hydrophobic cavities, molecules of **6** initially form head-to-head dimers, to which monomers of **6** can be further attached in a head-to-tail fashion. In this way, assemblies are formed that always have a hydrophilic outer surface. What is unique about these assemblies is that they grow until they reach a finite size. Apparently, at a certain point further growth is no longer energetically favoured.

Preliminary fluorescence experiments on solutions of both **5** and **6** in water indicate that upon excitation of the CT band the emission is quenched at higher concentrations due to aggregate formation. Further studies aimed at understanding the mechanism of assembly and the photophysical and electrochemical properties of the 'cigar-like' aggregates are in progress and will be reported in a forthcoming full paper.

A bridging coordination mode of urea and carbamate at a dinuclear nickel(II) centre

Franc Meyer*† and Hans Pritzkow

Anorganisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany

Starting from an active O_2H_3-bridged bimetallic complex, a bridging coordination mode of both urea and carbamate—the substrate and its first hydrolytic product in urease activity—at a dinickel(II) centre relevant to the active site of the metalloenzyme has been characterised structurally.

The nickel containing enzyme urease—which is present in a variety of plants, fungi and bacterial species—catalyses the hydrolysis of urea to form ammonia and carbamate, with the latter decomposing further to yield carbonic acid and another molecule of ammonia.[1] The X-ray crystal structure[2] of the microbial urease from *Klebsiella aerogenes* revealed two nickel ions 3.5 Å apart within the dinuclear active site and corroborated previously suggested models for its hydrolytic activity.[3] It is assumed that urea is activated by coordination to one nickel(II) ion in conjunction with extensive hydrogen bonding within the active site pocket of the protein and is subsequently attacked by a nucleophilic hydroxide bound to the opposite nickel centre.[3,4] However, the exact binding mode of the substrate as well as details of the operative mechanism are not yet unambiguously resolved, however. Considerable effort has therefore been devoted to the search of model complexes featuring a dinickel(II) core with accessible co-ordination sites at the metal centres[5–8] in order to elucidate the possible binding modes of urea at such urease-like systems and finally mimic the enzymatic reactivity. Nevertheless, only in a few cases has co-ordination of urea[7] (generally O-coordination) or even its hydrolytic cleavage[7b] hitherto been observed.

We recently described a class of pyrazolate-based dinuclear complexes, where appropriate chelating side arms attached to the heterocycle enforce metal–metal separations large enough to prevent small monoatomic units like HO^- from spanning both metal centres, thus favouring the formation of intramolecular O_2H_3 secondary bridges like in **1**.[9,10] For a related FHO(H)-bridged dicobalt(II) complex experimental evidence suggested that H_2O can reversibly be extruded from these moieties.[9b] Such a process in the case of **1** would generate an open coordination site for potential substrate binding adjacent to a hydroxide bound to the proximate second nickel ion, thus explaining the hydrolytic activity of **1** towards, for example, nitriles.[11] The similarity of this assumption with the proposed mechanism of urease activity prompted us to investigate the reaction of **1** with urea, especially because urea has been found to exhibit a greater affinity than water for binding to certain metal ions.[12]

Treatment of an acetone solution of **1** with urea or *N*,*N*-bis(trimethylsilyl)urea (Scheme 1) caused a slight change in its UV–VIS spectrum, and the resulting green complex **2**$(ClO_4)_2$‡ could be isolated from the reaction mixture. Single crystals were obtained by layering an acetone solution of the product with light petroleum. A crystallographic study (Fig. 1; two independent molecular entities with similar molecular dimensions were found in the unit cell)§ revealed that a tetraatomic trigonal planar moiety is situated within the coordination pocket created by the basic bimetallic framework, this being identified as a N,O-bridging deprotonated urea on the basis of the combined analytical data.‡ In particular, FAB mass spectrometry showed signals for $LNi_2[NH(O)CNH_2](ClO_4)^+$ and $LNi_2[NH(O)CNH_2]^+$ with the expected isotopic distribution pattern as the most intense peaks. The protons attached to the terminal nitrogen atoms N(9) were located as hydrogen bridges to oxygen atoms of the perchlorate counter anions [*d*(N···O) in the range 3.08–3.21 Å], while the Ni-bound O and N atoms of the bridging urea could not be distinguished crystallographically and are presumably disordered over both positions.

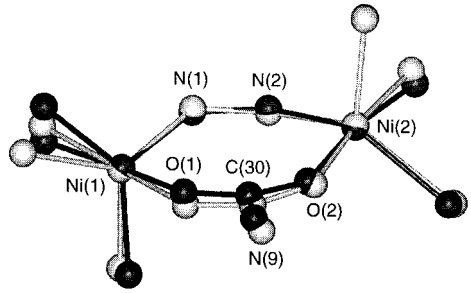

Fig. 2 Overlay of the crystallographically determined dinuclear sites of **2** (light) and **3** (dark). Selected atom distances (Å) and bond angles (°) for **3**: Ni(1)–O(1) 1.971(3), Ni(1)–N(1) 1.979(4), Ni(2)–O(2) 1.982(4), Ni(2)–N(2) 1.987(4), Ni(1)···Ni(2) 4.229(1), O(1)–C(30)–O(2) 127.3(5).

Formation of **2** from urea and *N*,*N*-bis(trimethylsilyl)urea implies the cleavage of the N–$SiMe_3$ bonds in the latter case, which is in accord with the known facility of N–Si bond hydrolysis in N-silylated amides.[13] The resulting trimethylsilanol was identified by GC–MS and ^{29}Si NMR spectroscopy among the volatile products of the present reaction. The observed deprotonation of parent urea by nickel-bound hydroxide to form **2** is understandable in the light of the drastic increase in substrate acidity upon its co-ordination to metal ions.[14] Thereby ureas are several orders of magnitude more acidic when N-bonded (pK_A < 6) then when O-bonded (pK_A > 11), and in the former case may even be more acidic than co-ordinated water.[14] It has thus been noted that isomerisation of the urea substrate from initial O-bonding to N-bonding can be thermally driven at intermediate pH, with the resulting deprotonated urea being kinetically inert and providing a thermodynamic sink for the linkage isomerisation.[14] A decisive driving force for the present reaction to form **2** certainly stems from the exceedingly strong tendency of these pyrazolate-based bimetallic complexes to incorporate secondary bridging ligands at the inner co-ordination site.[9,15]

In order to definitely exclude the presence of an O,O-bridging carbamate in **2**, complex **3** was synthesised independently for comparison (Scheme 1). At the same time this provides further insight into the possible coordination mode of this latter moiety—assumed to be the primary hydrolytic product of urease activity—at a dinickel(II) centre.[6] The IR absorptions of **3** assigned to the coordinating carbamate unit‡ clearly differ from those of the urea bridge in **2**, and mass spectrometry afforded a dominant signal with the expected isotopic distribution pattern for the molecular ion $LNi_2(O_2CNH_2)^+$. This is one mass unit higher than those observed for **2** and thus allows an unambiguous distinction between the two complexes and further corroborates the presence of a bridging urea in **2**.

As shown by an X-ray single crystal analysis of **3**$(BPh_4)_2$ the overall molecular geometry of the bimetallic cation is quite similar to that of **2** (Fig. 2), however the Ni···Ni separation is slightly shortened [**2**: 4.255(2) Å; **3**: 4.229(1) Å], as are the C(30)–O/NH bond lengths {**2**: *d*[C(30)–O/NH] = 1.28(1)–1.31(1) Å *vs.* **3**: *d*[C(30)–O] = 1.249(6)/1.242(6) Å] in accordance with the difference in covalent radii of either a bridging O–C–O (**3**) or disordered O–C–NH (**2**) moiety spanning the metal centres. Two acetonitrile solvent molecules included in the crystal lattice of **3**$(BPh_4)_2$ are positioned suitably for weak hydrogen bonding with the protons attached to N(9) {*d*[N(9)···N(10)] = 3.190 Å; *d*[N(9)···N(11)] = 3.423 Å}, although the latter could not be located in the crystallographic analysis.

2 and **3** thus represent first structurally characterised examples of a bridging coordination mode of both deprotonated urea and carbamate at a dinickel(II) core. These molecular arrangements obviously have considerable thermal stability as both DSC and TGA measurements of **2**$(ClO_4)_2$ and **3**$(BPh_4)_2$ indicate no degradation or loss of weight until above 200 °C, and consequently the corresponding coordination modes should be taken into consideration when studying the interaction and reactivity of urea with urease-mimetic dinickel model systems. The findings furthermore underline that a bridging carbamate ligand, which is present in the form of a carbamylated lysine residue in the urease active site itself, is a reasonable alternative to the ubiquitous carboxylate bridges in dinuclear metal arrangements.

Acknowledgement is made to Professor Dr G. Huttner for his generous and continuous support of our work as well as to the Deutsche Forschungsgemeinschaft (Habilitandenstipendium for F. M.) and the Fonds der Chemischen Industrie. We thank Dr F. Rominger and Professor Dr P. Hofmann for collecting the X-ray data of complex **3**$(BPh_4)_2$.

Catalytic asymmetric imidation of selenides into selenimides

Hiroya Takada, Masamitsu Oda, Yoshihiro Miyake, Kouichi Ohe and Sakae Uemura*†

Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan

The direct catalytic imidation of various prochiral selenides with TsN=IPh in the presence of CuOTf using chiral 4,4′-disubstituted 2,2′-bis(oxazoline) ligand afforded the corresponding chiral selenimides (~ 36% ee).

The synthesis and the synthetic application of optically active organosulfur compounds have been widely studied.[1] Recently, we succeeded in developing direct catalytic sulfimidation of prochiral sulfides to chiral sulfimides with *N*-(*p*-tolylsulfonyl)-imino(phenyl)-λ³-iodane (TsN=IPh)[2] in the presence of CuOTf and the chiral ligands, 4,4′-disubstituted bis(oxazoline).[3] In contrast, the asymmetric synthesis of analogous organoselenium compounds, selenimides, has been much less studied.[4–6] In 1981, Krasnov *et al.* reported the first synthesis of the optically active selenimides by starting from dialkyl- and diaryl-selenium dichlorides,[4] but the scope of this reaction has not been fully developed probably because of low yields of the products as well as their quite low optical activity. Recently, Kamigata and co-workers have shown an example of conversion of a chiral selenoxide obtained by optical resolution of a diastereomeric mixture[7] into the corresponding enantiomerically pure selenimide, ascertaining the detailed stereochemistry of the compound.[6] We have already demonstrated the diastereoselective imidation of chiral allylic selenides using TsN=IPh or chloramine-T (TsNClNa) as an imidation reagent.[8] We report here a first example of the direct catalytic enantioselective imidation of simple selenides into the corresponding selenimides (Scheme 1).

As described above, a direct catalytic imidation of prochiral sulfides to chiral sulfimides proceeded with TsN=IPh in the presence of CuOTf and bis(oxazoline) in various solvents. We first looked for the solvent in which imidation of prochiral

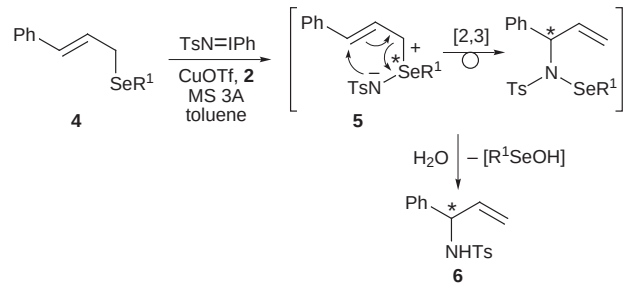
[a] All the reactions were performed in toluene (0.02 M) in the presence of 12 mol% chiral ligand **2** and 10 mol% CuOTf for 24 h unless otherwise noted. [b] Enantiometric excesses were determined by HPLC using suitable chiral columns. [c] The reaction was performed without MS 3A. [d] MS 4A, for 48 h. [e] See footnote §.

Scheme 2

selenide **1** with TsN=IPh did not proceed in the absence of CuOTf. Treatment of benzyl phenyl selenide with TsN=IPh in MeCN and CH_2Cl_2 at 25 °C for 24 h afforded benzyl phenyl selenimide in 46% and in a trace amount, respectively, but in toluene no reaction occurred. Therefore, we chose toluene as solvent[9] and carried out imidation of benzyl phenyl selenide with TsN=IPh in the presence of CuOTf (10 mol%) and the optically active bis(oxazoline) **2** (12 mol%) at 25 °C for 24 h under N_2 (Scheme 1).[10] Benzyl phenyl selenimide was formed in 40% yield, but no asymmetric induction occurred. Fortunately, further studies revealed that the reaction proceeded enantioselectively when molecular sieves were added (compare entry 1 in Table 1). This is probably due to the interference of the rapid selenimide–selenoxide equilibrium[11] (Scheme 2) by removal of water present in the reaction mixture. A rapid racemization of the selenoxide is well known.[12] At a lower temperature the reaction was slower (entry 3). The reaction also proceeded with several other aryl benzyl selenides, but the selenide having bulky substitutents on an aryl ring such as benzyl 2,4,6-tri-*tert*-butylphenyl selenide (**1e**) did not react at all. Typical results are shown in Table 1. The desired product was isolated in moderate yield without racemization by removal of the precipitate through Celite and purification of the residue by column chromatography (SiO_2). When this reaction was applied to various aryl cinnamyl selenides **4**, the expected chiral allylic amides (~ 30% ee) were obtained selectively in moderate to good yield *via* [2,3] sigmatropic rearrangement of the



Scheme 3

Table 2 Catalytic asymmetric imidation of cinnamyl selenides **4**[a]

Entry	R^1	Product	Yield (%)	Ee (%)[b]
1	Ph	**6a**	63	20

5	2-$NO_2C_6H_4$	**6e**	Trace	—

[a] All the reactions were performed in toluene (0.02 M) in the presence of 12 mol% chiral ligand **2** and 10 mol% CuOTf for 24 h. [b] Enantiomeric excesses were determined by HPLC using suitable chiral columns.

intermediate chiral allylic selenimide (Scheme 3, Table 2), clearly showing that the chirality transfer occurred at the rearrangement step.

Although the enantioselectivity obtained here is not yet satisfactory (~ 36% ee) and lower than the corresponding sulfur case,[3] the finding presented here is the first example of the direct catalytic enantioselective imidation of organic selenides into the corresponding selenimides.

‡ Representative procedure for the imidation of selenide: to a solution of MS 3A (*ca.* 300 mg), CuOTf (0.010 mmol, 0.10 equiv.) and chiral 2,2′-bis(oxazoline) **2** (0.012 mmol, 0.12 equiv., Aldrich) in 5.0 ml of toluene were added first TsN=IPh (0.10 mmol, 1.0 equiv.) and then the selenide (0.20 mmol, 2.0 equiv.)[10] and the resulting mixture was stirred under nitrogen at 25 °C for 24 h. Removal of the precipitate through Celite and evaporation of the solvent gave a crude product. Purification by silica gel column chromatography gave a pure chiral selenimide.

The 'valence tautomers' of *o*-iodosobenzoic acid: the case of 4-pentyl-2-iodosobenzoic acid

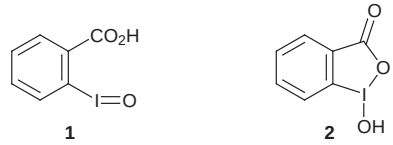
Robert A. Moss,*† Saketh Vijayaraghavan and T. J. Emge

Department of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, New Jersey 08903, USA

Contrary to a previous report, only the closed (iodoxolone) form of 4-pentyl-2-iodosobenzoic acid (3a) can be isolated; the previously assigned open (iodoso) form (3b) is actually 4-pentanoyl-2-iodobenzoic acid.

o-Iodosobenzoic acid (IBA, **1**) has long been known[1] to exist in the cyclic 1-hydroxy-1,2-benziodoxol-3(1*H*)-one form (**2**).[2,3] X-Ray crystal structure[4] and theoretical studies[5] agree that the cyclic form is the better representation, although the internal I–O bond is longer than a 'normal' single I–O bond, indicating significant 'open' character.[4b,c,5]

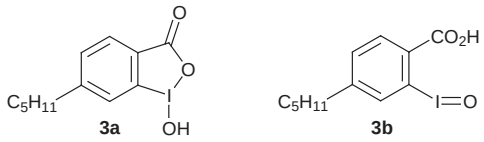
A valence tautomeric representation of IBA (**1** ⇌ **2**) suggests that both **1** and **2** can exist as separate entities. Such



1 **2**

representations have often appeared,[6] even if they were not intended to imply the simultaneous presence of interconverting open ('iodoso') and closed (iodoxolone) forms. Thus, in 1990, Panetta *et al*. reported the *separate isolation* of the iodoxolone and iodoso valence tautomers of 4-propyl- as well as 4-pentyl-2-iodosobenzoic acids.[7] These extraordinary results have been reiterated in a recent authoritative review,[3b] so that it becomes imperative to verify them, particularly because of the importance of IBA and its analogues as decontamination agents for toxic phosphonates and phosphates.[4b,c,5–8]

We have now reinvestigated the case of the 4-pentyl 'tautomers' (**3a** and **3b**), and report here that the previously described[7] compounds were misassigned; in fact, only a single 4-pentyl-2-iodosobenzoic acid can be isolated, and it is best represented as the 'closed' iodoxolone compound, **3a**.

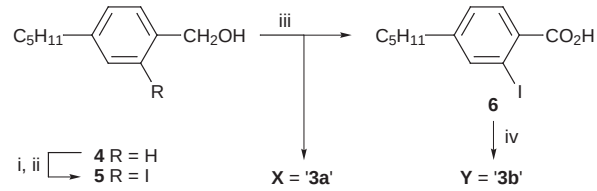


3a **3b**

The origin of the misassignments in ref. 7 lies in the synthetic sequence, which we summarize in Scheme 1. 4-Pentylbenzyl alcohol (**4**) was first regiospecifically iodinated to **5**.[7,9]

In the following and key step, iodo alcohol **5** was oxidized to 4-pentyl-2-iodobenzoic acid (**6**) using phase transfer catalysis in a $KMnO_4$–water–benzene system.[7,10] This reaction led not only to the desired **6**, in 63% yield, but also to a second, chromatographically-separated product, **X** (25%, mp 115–116 °C), assigned[7] as 4-pentyl-2-iodosobenzoic acid in its cyclic (iodoxolone) form, **3a**. A separate H_2O_2/Ac_2O oxidation[7,11] of **6** afforded 4-pentyl-2-iodosobenzoic acid **Y** (mp 188.5–189.5 °C) assigned[7] as the open (iodoso) valence tautomer, **3b**.

The assignments[7] of **X** and **Y** rest on acceptable elemental analyses for $C_{12}H_{15}IO_3$, suggestive of isomerism, as well as IR



Scheme 1 *Reagents and conditions*: i, BuLi, $Me_2NCH_2CH_2NMe_2$; ii, I_2; iii, $KMnO_4$–H_2O, C_6H_6, cat. $Bu_4P^+Cl^-$; iv, 30% H_2O_2, Ac_2O, 40 °C, 20 h

carbonyl bands for **X** at 1710 cm^{-1} and **Y** at 1650 cm^{-1}. The higher frequency C=O band of **X** was considered indicative of a 'lactone' structure as in **3a**.[7] However, it is known[2] that the carbonyl band of IBA, in its iodoxolone form, is at 1633 cm^{-1} (Nujol), so that the reported IR band of **X** at 1710 cm^{-1} is inconsistent with structure **3a**; it is **Y** (1650 cm^{-1}) that is more likely to merit this assignment.

We repeated the synthetic sequence of Scheme 1.[7] In particular, the permanganate oxidation of **5**, after chromatography of the product on silica gel (hexanes–EtOAc–HOAc, 79 : 20 : 1 to 28 : 70 : 2) afforded **6** (48%, mp 67.5–68.5 °C, lit.[7] 68.0–69.0 °C) and **X** (10%, mp 115–116 °C, lit.[7] 115–116 °C).

Our sample of **X** displayed the same mp, an experimentally comparable elemental analysis, and a similar IR C=O band (1707 cm^{-1}) relative to those reported[7] for '**3a**'. Nevertheless, several observations indicated that **X** was not **3a**. (1) The NMR spectrum of **X**‡ revealed only four sets of alkyl protons rather than the anticipated five. (2) The pentyl benzylic resonance of **5** (a triplet at δ 2.55) was missing in **X**, while a more deshielded triplet appeared at δ 3.1. (3) The IR spectrum (KBr) of **X** revealed two intense C=O absorptions at 1707 and 1686 cm^{-1}. The Supplementary Material for ref. 7 reports this band at 1685 cm^{-1}; it can be assigned to an aromatic CO_2H. The former band was assigned[7] to the carbonyl of **3a**, but the 'lactone' carbonyl group of (*e.g.*) **2** is known to absorb at 1633 cm^{-1} (Nujol).[2] (4) Compound **X** was kinetically inactive toward *p*-nitrophenyl diphenyl phosphate (PNPDPP) in aqueous micellar cetyltrimethylammonium chloride (CTACl) at pH 8 (see Table 1), whereas authentic benziodoxolones (*e.g.* **2**) rapidly cleave PNPDPP under these conditions.[8a,b] (5) Additionally, **X** did not oxidize iodide to iodine, a common property of iodosobenzoates.[8b]

Accordingly, an X-ray crystal structure determination was carried out for **X**,§ revealing it to be not an iodoso compound at all, but 4-pentanoyl-2-iodobenzoic acid (**7**) (Fig. 1). Clearly, the $KMnO_4$ oxidation of **5** to **6** must have been accompanied by overoxidation[12] at the benzylic position of the pentyl chain, affording (both) ketone **7** (and iodoterphthalic acid). Structure **7** immediately accounts for the spectral characteristics of **X** itemized above in points (1)–(3),¶ and, of course, **7** should also be inactive in the hydrolysis of PNPDPP or the oxidation of iodide [points (4) and (5)].

Compound **Y**, which we obtained from the peroxide oxidation of **6** (Scheme 1) had a mp identical to the compound previously obtained,[7] and is actually 4-pentyl-2-iodosobenzoic

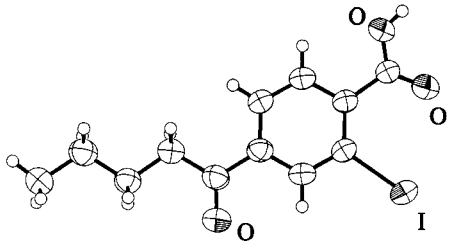


Fig. 1 ORTEP diagram of **X** (4-pentanoyl-2-iodobenzoic acid, **7**)

acid, best represented as **3a** (not **3b**[7]). Thus, **Y** (**3a**) gave both an appropriate elemental analysis [C, 43.l; H, 4.53; I, 38.0%) and NMR spectrum.‖ The IR (KBr) spectrum of **3a** displayed its C=O band at 1602 cm^{-1}, considerably lower than the reported[7] 1650 cm^{-1}. However, benziodoxolone carbonyl bands are very sensitive to conditions of their determination; the C=O absorption of **2** has been variously reported at 1633,[2] 1612,[6b] and 1605[6b] cm^{-1}. Additionally, **3a** showed the expected[2] (I)OH absorptions at 2928 and 2444 cm^{-1}. A standard iodometric titration[13] of **3a** gave 93% of I=O oxidative activity.

Most importantly, **3a** was very reactive toward PNPDPP. Its kinetic properties were assessed from a rate constant–[surfactant] profile for the cleavage of PNPDPP in micellar CTACl;[8b] conditions and results appear in Table 1. Not only is **Y** (**3a**) highly reactive toward PNPDPP, where **X** (**7**) is inactive (entry 2), but **3a** affords an acceleration of 1460 relative to micellar CTACl alone (entry 1), 4.6 times greater than the acceleration provided by the parent IBA (**2**) (entry 3). This reactivity advantage is an expected consequence of the hydrophobic pentyl group of **3a**, which affords better binding of **3a** to the micellar phase in which the phosphorolytic reaction occurs.[8b,c]

Table 1 Rate constants for the cleavage of PNPDPP[a]

Entry	Catalyst	$k_\psi/10^{-4}$ s^{-1}	k_{rel}
1	None[b]	2.05[c]	1.00
2	**X** (**7**)	2.00	0.98
3	**2**	640[d]	312
4	**Y** (**3a**)[e]	3000[f]	1460
5[g]	**2**	18.3	8.9
6[g]	**Y** (**3a**)	63.3	30.9

[a] For background, see ref. 8(*b*). Conditions for entries 1–4: [CTACl] = 1.0×10^{-3} M, [PNPDPP] = 1.0×10^{-5} M, [catalyst] = 1.0×10^{-4} M, pH 8, 0.02 M phosphate buffer, μ = 0.08 (NaCl), 25 °C. Rate constants were determined by monitoring the time dependent absorbance of the released *p*-nitrophenylate ion at 400 nm. [b] CTACl alone. [c] Given as 1.8×10^{-4} s^{-1} in ref. 6(*a*). [d] Ref. 8(*b*). [e] [PNPDPP] = 3.0×10^{-5} M, [Y] = 3.0×10^{-4} M. [f] Stopped-flow determination. [g] Microemulsion conditions:[7] 8% (w/w) CTABr, 8% *N*-methylpyrrolidinone, 4% toluene, 80% 0.03 M aqueous $Na_2B_4O_7 \cdot 10H_2O$ buffer, pH 9.4, 25 °C; [PNPDPP] = 3×10^{-5} M, [catalyst] = 3×10^{-4} M.

Although we could not obtain crystals of **3a** suitable for X-ray analysis, its closed, 'lactone' structure follows from the IR spectrum,[2] and from its kinetic properties toward PNPDPP (which link **3a** to other phosphorolytically reactive iodosobenzoates for which the closed structure has been established).[4–6,8] True 'iodoso' compounds, such as *m*-iodosobenzoic acid, show little esterolytic reactivity.[8a] Additionally, we determined the pK_a of **3a** as 6.8 from a pH–rate constant profile[4c,5,8b] for the cleavage of PNPDPP by **3a** in 0.02 M micellar CTACl and 0.02 M phosphate buffer over the pH range 5.35–7.68. A pK_a ~7 is appropriate for an *o*-iodosobenzoate in the iodoxolone form.[2,8]

Finally, **3a** was reported to be 477 times *less* reactive than IBA itself toward PNPDPP in a CTABr–*N*-methylpyrollidinone–toluene–aqueous borate microemulsion, a phenomenon attributed to incorporation of the more hydrophobic catalyst into the oily interior of the microemulsion.[7] However, we find **3a** to be quite reactive toward PNPDPP under these conditions (Table 1, entry 6); indeed, it is actually ~3.5 times more reactive than IBA (entry 5), paralleling the results in micellar CTACl (see above, and entries 3 and 4). Note (Table 1) that both IBA and **3a** are less reactive toward PNPDPP in the microemulsion than in micellar CTACl, an expected consequence of lessened mutual catalyst/substrate concentration in the microemulsion.[14]

In conclusion, only one 4-pentyl-2-iodosobenzoic acid can be isolated, and it is best represented as iodoxolone **3a**. A similar situation is likely to hold for 4-propyl-2-iodosobenzoic acid[7] as well.

We are grateful to the US Army Research Office for financial support.

A three-dimensional open-framework tin(II) phosphate exhibiting reversible dehydration and ion-exchange properties

Srinivasan Natarajan,[a] M. Eswaramoorthy,[a] Anthony K. Cheetham[b] and C. N. R. Rao[a]†

[a] *Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research Jakkur P.O., Bangalore 560 064, India*

[b] *Materials Research Laboratory, University of California, Santa Barbara, CA 93106, USA*

A three-dimensional open-framework tin(II) phosphate, prepared hydrothermally with 1,3-diaminopentane as the template, is shown to exhibit reversible dehydration and ion-exchange properties.

The synthesis of microporous solids with different connectivities and pore chemistry from those obtained in zeolitic materials is of considerable interest because of the potential applications of these materials as catalysts, molecular sieves and ion exchangers.[1,2] Investigations in this direction have led to the discovery of many materials with interesting structures. Recently, open-framework tin(II) phosphates with novel building motifs, such as vertex-sharing trigonal pyramidal SnO_3 units and truncated square-pyramidal SnO_4 units, have been synthesized.[3–5] It would be most desirable to design a more open, three-dimensional network with channels running along the crystallographic axes and to facilitate the formation of such a structure, we have employed a branched diamine as a structure-directing agent, in place of the linear diamines. With 1,3-diaminopentane, we have been able to obtain a tin phosphate with three different channel systems. The structure possesses two molecules of water which can be reversibly intercalated and, more significantly, exhibits remarkable ion-exchange properties reminiscent of aluminosilicate zeolites. Here we describe the synthesis, structure and characterization of this unique open-framework material.

The structure of the new Sn^{II} phosphate‡ involves networking of strictly alternating SnO_3 and PO_4 units in which all the vertices are shared. The SnO_3 and PO_4 units form a framework with the formula $[Sn_4P_3O_{12}]^-$. Charge neutrality is achieved by the incorporation of the diprotonated organic cation $[NH_3CH_2CH_2CH(NH_3)CH_2CH_3]^{2+}$. There is half a unit of the organic cation per formula unit and the structure contains two molecules of water. Thus, the composition of the material is $[Sn_4P_3O_{12}]^-\{[NH_3CH_2CH_2CH(NH_3)CH_2CH_3]^{2+}\}_{0.5}\cdot 2H_2O$. The asymmetric unit (Fig. 1) contains 27 independent non-hydrogen atoms.

The entire framework structure can be considered to be made from a networking of four-, six-, eight- and twelve-membered rings formed by T atoms (T = Sn, P). The four-, six- and twelve-membered rings are connected to each other in such a way that they form a uniform 8-ring channels bound by 8 T atoms (T = Sn and P) along the *a* and *b* axes [Fig. 2(*a*) and (*b*)]. The widths of these channels are 7.0 × 6.1 Å along the *a* axis and 8.3 × 8.8 Å along the *b* axis (longest and shortest atom–atom contact distances, not including van der Waals radii). The widths of the channels suggest that the eight-membered channels along the *b* axis are more regular [Fig. 2(*b*)]; the amine molecules sit in the middle of these channels. When viewed along the *a* axis, the two water molecules occupy the distorted six- and twelve-membered channels [Fig. 2(*a*)]. The lone pair of electrons of the Sn^{II} protrude into the twelve-membered channel rendering it ineffective for sorption of a guest molecule. Along the *c* axis, the 4-, 6- and 8-rings are connected to form a twelve-membered ring channel which has the appearance of a six-membered channel due to distortion. The amine and the water molecules are both present in this channel. Most of the distortions in the channels arise due to the three coordination of the tin(II) with the oxygens in this structure. The Sn atoms coordinated to three oxygens occupy the vertex of a trigonal pyramid; the lone pair presumably occupies the fourth vertex of the tetrahedron. The M–O bond lengths and O–M–O bond angles (M = Sn, P) are similar to those observed for other tin phosphate materials.

Since the synthesis involved the use of two different optical isomers of the branched organic diamine, we expected the isomers to be resolved and form different channels. We find, however, that the two amine isomers are located at the crystallographic center of inversion in the structure creating a new type of disorder (Fig. 1). A low-temperature single crystal X-ray diffraction study ($T \approx 100$ K) showed no change in the disorder, indicating it to be static rather than dynamic.

Thermogravimetric analysis (TGA) in an oxygen atmosphere showed a mass loss of *ca.* 3.9% at 125 °C due to the removal of two molecules of water present in the channels (calc. 4.1%). Careful experiments showed that the material (heated to 125 °C) reabsorbs the water on cooling and storage for a few hours under atmospheric conditions (typically 4 h). This feature is indeed noteworthy as this is the first time such a complete reversible dehydration–hydration process has been observed in an open-framework tin phosphate material. TGA studies also reveal that the protonated 1,3-diaminopentane is removed at 350 °C. The crystal structure collapsed after the removal of the amine.

In our effort to remove the template molecule from the open-framework structure by other methods, we employed soft chemical routes, including ion-exchange. Since the structure is open and the framework is anionic, we used an NaCl (1.0 M) solution for the ion-exchange with the expectation that the Na^+ cations might exchange for the protonated diamine. After 4 days of continuous stirring at room temperature (the solution was

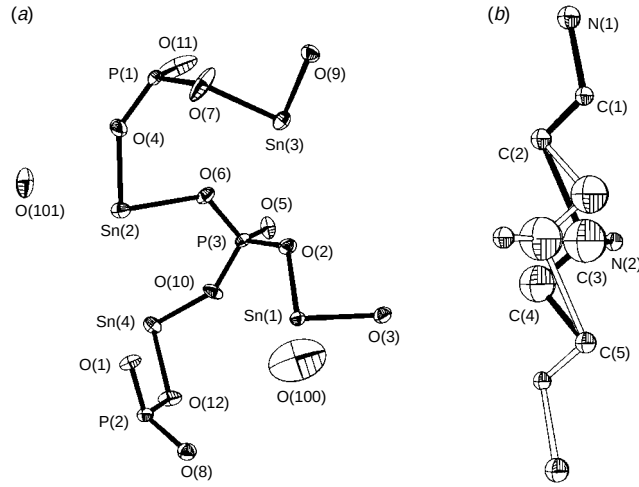

Fig. 1 ORTEP plots of (*a*) the framework along with the water molecule and (*b*) the organic template molecule showing the disorder

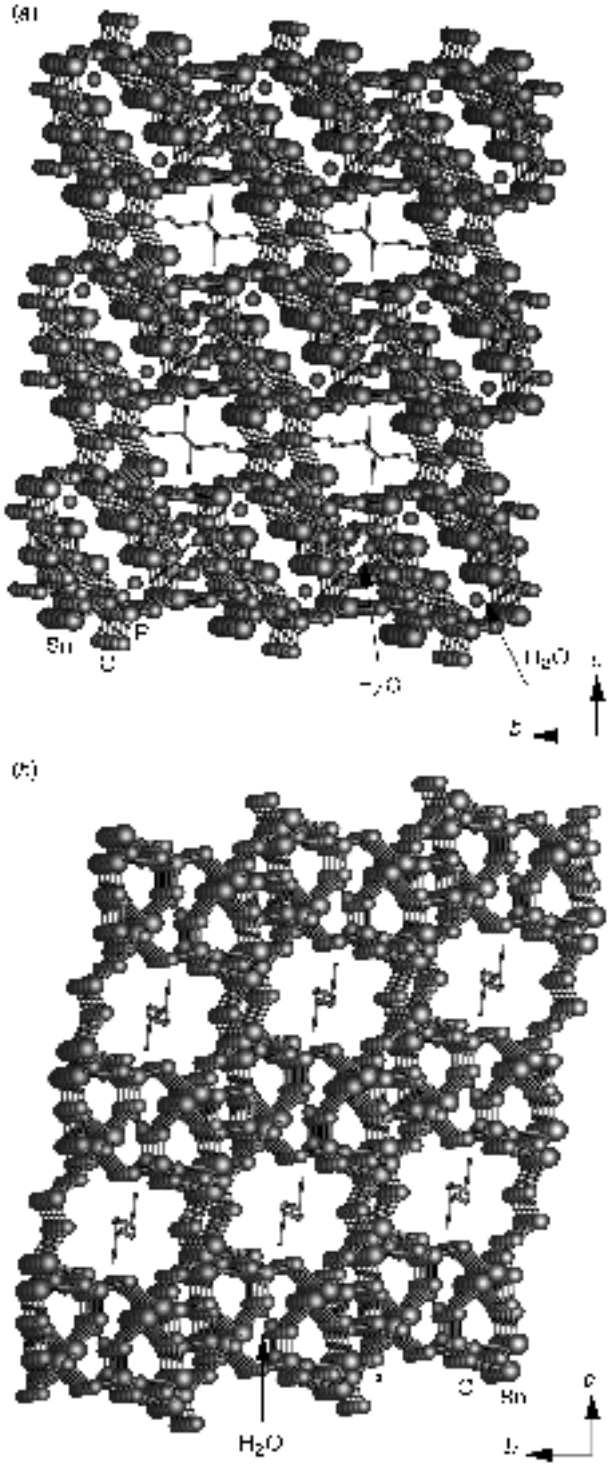

Fig. 2 Structures of $[Sn_4P_3O_{12}]^-\{[NH_3CH_2CH_2CH(NH_3)CH_2CH_3]^{2+}\}_{0.5}\cdot 2H_2O$ viewed down the *a* axis (*a*) and *b* axis (*b*). Note that the amine and the water molecule occupy different channels in both cases.

replenished every 24 h), *ca*. 50% of the amine was exchanged, as indicated by FTIR and TGA studies. The powder XRD pattern of the ion-exchanged sample was consistent with that of the parent material. Gravimetric adsorption studies were carried out on the parent material and the Na^+-exchanged sample after dehydration at 175 °C, by employing N_2 and MeOH as adsorbants. Methanol exhibits a Langmuir type I isotherm corresponding to about 1 molecule per unit cell (at higher pressures, $p/p_o \geqslant 0.8$, the results indicate some type II component as well) and N_2 shows a type IV isotherm for the dehydrated Na^+-exchanged sample (Fig. 3). The parent material, however, showed no significant adsorption of these molecules. This study suggests that there is considerably greater free volume in the dehydrated Na^+-exchanged sample. Further experiments on the ion-exchange properties of this novel three dimensional tin(II) phosphate material and its catalytic properties are currently in progress and the results will be reported elsewhere.

‡ The title compound was synthesized from a starting tin phosphate gel containing a mixture of the two optical isomers of 1,3-diaminopentane as the structure directing agent. Tin(II) oxalate (Aldrich), phosphoric acid (85 wt%, Merck), 1,3-diaminopentane (DYTEK, Aldrich) and water in the ratio SnC_2O_4 : 0.5 P_2O_5 : 1.0 1,3-diaminopentane : 55 H_2O were mixed, sealed and heated at 170 °C for 3 days under autogeneous pressure. The resulting product, containing a mixture of white powder and a few colorless single crystals, was filtered and washed thoroughly with deionised water. The single crystals were separated easily under a polarizing microscope. The powder X-ray diffraction patterns taken independently on both the white powder and the single crystals were found to be identical indicating that the product was a new material. A suitable, needle-like single crystal (0.06 × 0.05 × 0.04 mm) was selected and mounted at the tip of a glass fiber using cyanoacrylate adhesive. Crystal structure determination by X-ray diffraction was performed on a Siemens Smart-CCD diffractometer (Mo-Kα radiation, λ = 0.71073 Å). A hemisphere of intensity data was collected at room temperature in 1321 frames with ω scans (width of 0.30° and exposure time of 30 s per frame).

Crystal data for the title compound: triclinic, space group $P\bar{1}$ (no. 2), a = 9.417(1), b = 9.754(1), c = 11.002(1) Å; α = 80.51(1), β = 71.64(2), γ = 61.68(1)°, U = 844.2(2) Å^3, Z = 2, M = 861.85(1) and ρ_{calc} = 3.39(1) g cm^{-3}. A total of 3352 reflections were collected in the range $-8 \leqslant h \leqslant 10$, $-8 \leqslant k \leqslant 10$, $-12 \leqslant l \leqslant 11$. These were merged to give 2383 unique data (R_{merg} = 2.3). The absorption correction was based on symmetry equivalent reflections using the SADABS[6] program. Because of the heavy disorder on the carbon and nitrogen atoms of the amine molecule, hydrogen atoms though found on the Fourier map were not used for refinement purposes. The last cycles of refinement included atomic positions, anisotropic thermal parameters for all the atoms. Final R = 0.0397, R_w = 0.0937 and S = 1.04 were obtained for 215 parameters. The final Fourier map minimum and maximum: −1.26 and 1.68 e Å^{-3}. The structure was solved and refined using the SHELXSTL-PLUS[7,8] package of programs. CCDC 182/895.

Self-assembled thin films from lamellar metal disulfides and organic polymers

Patricia J. Ollivier,[a] Nina I. Kovtyukhova,[b] Steven W. Keller[c] and Thomas E. Mallouk*[a]†

The intercalation/exfoliation reactions of MoS_2 and SnS_2 yield lamellar colloids, which may be grown layer-by-layer on cationic surfaces by alternate adsorption of cationic clusters or polymers.

Over the past several years, self-assembly has become increasingly useful as a simple and inexpensive method for making functional thin films.[1] While much of this work has focused on organic monolayers, inorganic surface heterostructures are also interesting because of the structural,[2] magnetic,[3] electrochemical[4] and other properties associated with inorganic compounds. Unfortunately, to date, the building blocks of these thin films have been electronic insulators: clays, metal phosphates and lamellar oxides.[5] Here, we report the successful extension of this technique to lamellar chalcogenides, which in bulk form are semiconductors, semimetals, and metals. These materials have been used previously to prepare interesting bulk nanocomposites.[6]

Lamellar metal disulfides (MoS_2, SnS_2) were reductively intercalated by reaction with excess Bu^nLi in hexane, then added to water to make exfoliated suspensions that were approximatley 5 mass% MS_2.[7] As prepared, these suspensions were basic, but upon dilution to 1 mass%, the pH decreased to 8–9. Attempts to lower the pH further resulted in flocculation. These 1% suspensions were stable for periods of days (orange–brown SnS_2) to weeks (brown–black MoS_2), and transmission electron microscopy (Fig. 1) revealed intact single- and multiple-sheet aggregates ranging in lateral dimensions from *ca.* 20–500 nm.

Growth of the metal disulfide films was initiated by first priming polished silicon wafers with a cationic monolayer. This was accomplished by hydroxylating the surface, by 30 min sonication in 'piranha' solution (4 : 1 conc. H_2SO_4–30% H_2O_2), and then adsorbing a monolayer of aluminium Keggin ions [$Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$], (5 min adsorption from an 80 °C solution of the chloride salt[8]), or poly(allylamine hydrochloride), PAH (15 min adsorption from a 0.01 M aqueous solution at pH 8 and ambient temperature). Both surface priming procedures create a high charge density surface, which binds the anionic MS_2 sheets. The first monolayer of MS_2 sheets was adsorbed by immersing the primed silicon into the appropriate colloidal suspension for 15 min, and rinsing with water. These MS_2 monolayers tile the surface incompletely, as shown in tapping-mode atomic force microscopy (AFM) images, Fig. 2. The adsorption process appears to select relatively small sheets from the broad distribution of sizes present in the colloid (Fig. 1). Surface coverage was estimated at about 75% for MoS_2 on the Al-Keggin-primed surface, and about 50% on the PAH-primed surface. While it was not possible to resolve the lattice structure of the MS_2 sheets, AFM line scans over the terraces of sheets showed mean roughness of the order of 1–2 Å, consistent with exposure of the basal planes. The step height from the primed substrate to the top of the sheets was typically 13–15 Å, which corresponds roughly to the thickness of a single layer of MoS_2 sheets (6 Å) plus a layer of hydrated Li^+ cations.

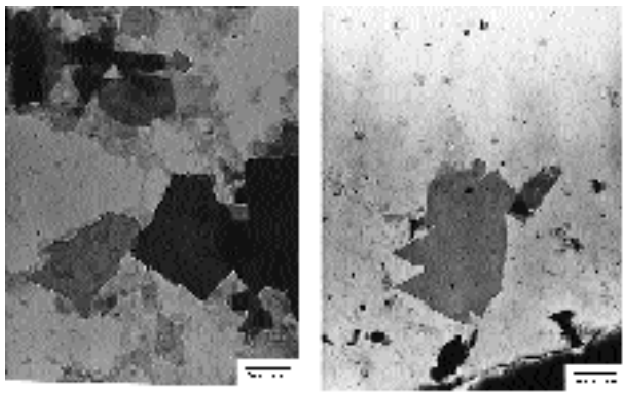

Fig. 1 Transmission electron micrographs of (left) colloidal MoS_2 and (right) SnS_2 particles

Multilayer films were grown by sequentially adsorbing the MS_2 colloids and polymeric PAH cations in 15 min cycles, with intermediate washing steps. The layer growth was monitored by ellipsometry, transmission UV–VIS spectroscopy (using quartz substrates), and AFM. The observed change in average layer thickness per adsorption cycle, Fig. 3, was consistently 14.8(3) Å per layer pair for MoS_2/PAH and 23.8(3) Å for SnS_2/PAH. UV–VIS spectra confirmed the regular stepwise growth of film thickness. In the case of MoS_2, the layer pair thickness is approximately that expected for a monolayer of PAH plus a single sheet of MoS_2, whereas for SnS_2 it is apparent that more than one monolayer is deposited in each adsorption cycle. Consistent with this observation, TEM studies of the SnS_2 colloid show that it is not completely exfoliated. For both MoS_2 and SnS_2, the layer pair thickness was quite insensitive to the adsorption time, up to several hours. This observation is consistent with the model of electrostatic self-assembly as a self-limiting process in which film growth ceases once the layer charge is inverted by adsorption of poly-anions or -cations.[9]

In contrast to the more regularly tiled surfaces observed with zirconium phosphate/polymer multilayers,[10] AFM images of the MoS_2 multilayer films reveal a 'spongy' morphology, in which sheets and polymer appear randomly oriented. The rms roughness of a four layer pair film of MoS_2/PAH was 16 Å on the PAH-anchored substrate, and 8 Å on the Al-Keggin derivatized surface. This is consistent with the model proposed by Kleinfeld and Ferguson for multilayer growth on islands, which eventually coalesce into smoother films.[11] The more densely tiled first monolayer that grows on the Keggin-primed surface yields a smoother film after a few layers are grown. XPS analysis of Si–SiO_x–Al Keggin–$(MoS_2\text{-PAH})_n$–MoS_2 (n = 0, 3; Table 1) films confirms that the sheets are intact and cover the surface relatively well after deposition of four layers. In the monolayer spectra, the surface coverage is low and the XPS spectrum is dominated by adventitious carbon and signals from the Si/SiO_x substrate. Both Mo and S are present in the film, but their ratio cannot be determined accurately because of counting errors. With multilayer films, the Si, Al and O signals from the buried substrate and primer layer are attenuated relative to Mo and S, which are present in the expected 1 : 2 ratio.

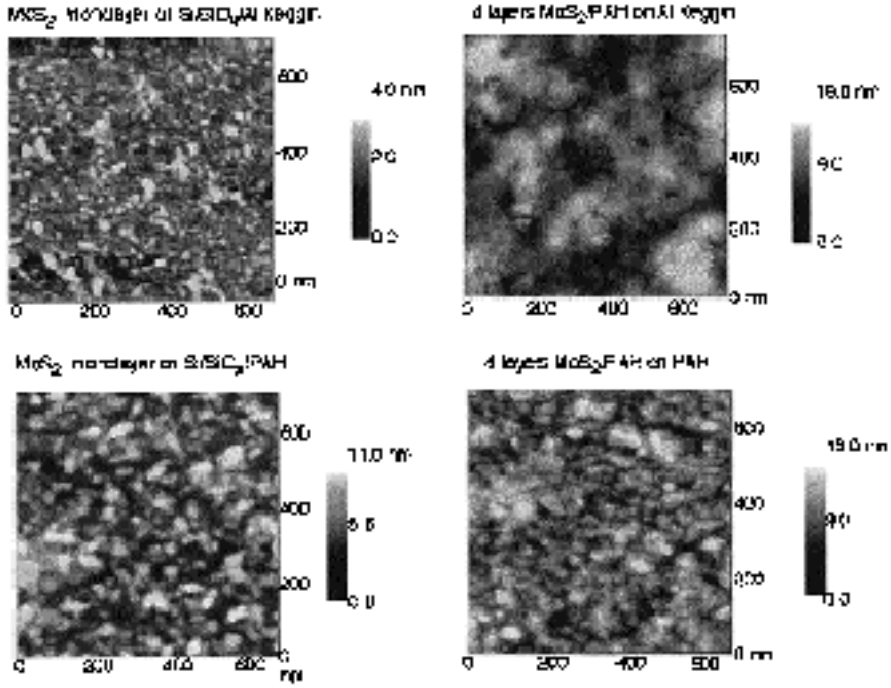

Fig. 2 Tapping-mode AFM images of monolayer MoS_2 and $(MoS_2/PAH)_3MoS_2$ films on Si/SiO_x/PAH and Si/SiO_x/Al Keggin substrates

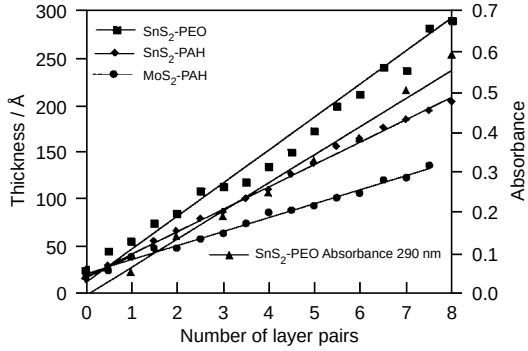

Fig. 3 Ellipsometric and UV absorbance data showing the thickness and change in absorbance of MS_2/polymer films *vs.* number of layer pairs. The thickness of 'zero' layers corresponds to the SiO_x and primer (PAH or Al-Keggin). Half-integer abscissa values refer to films terminated by an MS_2 layer, and integer values by a PAH or PEO layer.

Table 1 Relative integrated peak areas, corrected for atomic sensitivity, for $Si–SiO_x$–Al Keggin–$(MoS_2\text{-}PAH)_n$–MoS_2 (n = 0, 3) films

	n = 0	n = 3
Si	21.3	4.4
Al	3.4	0.2
Mo	0.7	1.9
S	0.7	3.7
C	44.0	72.9
O	29.9	16.9

The basal plane surface of MS_2 colloids is relatively non-polar, relative to previously studied clay, metal oxide and metal phosphate lamellar colloids. MoS_2 and SnS_2 exfoliated colloids can be re-stacked by neutral polymers, such as poly(ethylene oxide), PEO.[12] Accordingly, the cationic PAH polymer was replaced by a solution of neutral PEO, and multilayer films were grown by the same method. The film growth, monitored by ellipsometry and UV–VIS spectroscopy, is regular and the trend is similar to that found with PAH, 15 Å per layer pair with MoS_2 and 35 Å per layer pair with SnS_2. Apparently, PEO complexes the Li^+ ions that charge-compensate the colloid sheets, much as it does in the bulk intercalation compounds.[12b] This interaction is sufficiently strong to persistently bind sequentially adsorbed layers.

This work was supported by a grants from the National Science Foundation (CHE-9529202) and Civilian Research and Development Foundation. Instrumentation for AFM experiments was provided by National Science Foundation grant CHE-9626326.

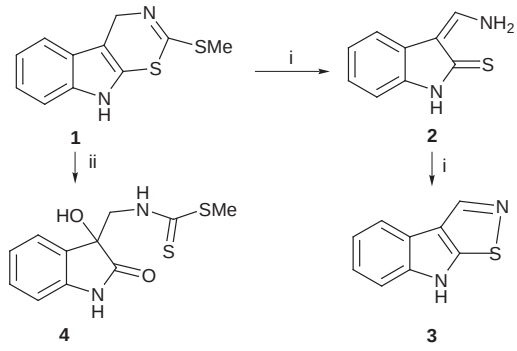
A convenient synthesis of the cruciferous phytoalexins brassicanal A and brassilexin by mimicry of a fungal detoxification pathway

M. Soledade C. Pedras*† and Francis I. Okanga

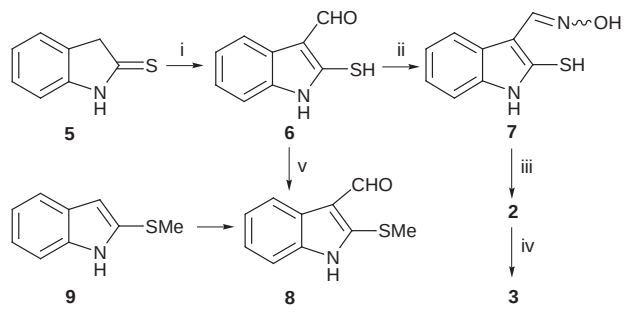
Department of Chemistry, University of Saskatchewan, 110 Science Place, Saskatoon, SK, Canada S7N 5C9

The cruciferous phytoalexin brassilexin 3 has been synthesized in four steps from indoline-2-thione *via* 3-(aminomethylene)indole-2-thione 2, a metabolic intermediate of the detoxification pathway of the phytoalexin cyclobrassinin 1; in addition, the phytoalexin brassicanal A 8 has been synthesized in two steps from 2-indolinethione.

It is now well-recognized that the blackleg fungus [*Phoma lingam* (Tode ex Fr.) Desm., perfect stage *Leptosphaeria maculans* (Desm.) Ces. et de Not.], one of the most destructive fungal pathogens of rapeseed (*Brassica napus, B. rapa*), can overcome the plant's induced chemical defenses, *i.e.* phytoalexins, by enzymatic detoxification.[1–6] Recently, we reported[6] an unprecedented detoxification of the cruciferous phytoalexin cyclobrassinin **1**[7] *via* the phytoalexins brassilexin **3**[8] and dioxibrassinin **4**[9,10] by isolates of *P. lingam*‡ (Scheme 1). A detailed analysis of the metabolites involved in that fungal biotransformation of cyclobrassinin **1** indicated that 3-(aminomethylene)indole-2-thione **2**, or its thiol tautomer(s), was a precursor of brassilexin **3** (Scheme 1).[6] In continuation of that work we have now accomplished the synthesis of brassilexin **3** by mimicry of that detoxification pathway, utilizing the key intermediate **2** (Scheme 2). This route provides a very convenient process for preparation of both compounds **2** and **3**,



Scheme 1 Transformation of cyclobrassinin by the phytopathogenic fungus *Phoma lingam*: i, 'avirulent' isolate Unity; ii, 'virulent' isolate BJ −125



Scheme 2 *Reagents and conditions*: i, NaH, HCO_2Et, 25 °C, 92%; ii, $NH_2OH·HCl$, AcONa, EtOH, reflux, quant.; iii, $TiCl_3$, $NaBH_3CN$, MeOH, 25 °C, 85%; iv, activated charcoal, 25 °C, 82%; v, CH_2N_2, Et_2O, 25 °C, quant.

offering also the possibility of introducing carbon and/or nitrogen isotopes into the indol-3-yl substituents in good yield. Previous syntheses of brassilexin **3** from indole-3-carbaldehyde *via* cyclobrassinin **1** (11% overall yield),[11–13] or directly from indole-3-carbaldehyde (11–30% overall yield),[14] have been reported. However, our route affords the best overall yield to date while following the simplest process in terms of purification and reaction conditions. Utilizing the route shown on Scheme 2, brassilexin **3** was obtained from indolinethione **5**[15] in four steps (typically 50 mg scale reactions) in *ca.* 64% overall yield. In addition, this route provided aldehyde **6**, which on reaction with CH_2N_2 quantitatively yielded brassicanal A **8**, another cruciferous phytoalexin,[16] in *ca.* 92% yield. This synthesis of brassicanal A **8** also presents a great improvement to the previously reported procedure, which employed methylation of indolinethione **5** followed by Vilsmeier formylation of the corresponding 2-thiomethyl ether **9** (Scheme 2, 39% overall yield from **5**).[4]

During previous biotransformation studies,[6] we observed that brassilexin **3** could be obtained from metabolite **2** after standing in solution or on silica gel TLC plates. Interestingly, this transformation was catalyzed by activated charcoal to afford brassilexin almost quantitatively, demonstrating that metabolite **2** would be a synthetically useful brassilexin precursor if available in reasonable yields. One apparent method for the preparation of **2** was the reduction of amino derivatives of 3-(hydroxymethylene)indole-2-thione (or equivalent tautomer, *e.g.* **6**) similar to the preparation of 3-hydroxymethylene-2-oxoindole derivatives.[17] Thus, formylation of thione **5**[15] with EtO_2CH afforded aldehyde **6**, whose ^1H and ^{13}C NMR spectroscopic data§ indicated that only the thiol tautomeric form was present. Oximination of **6** under standard conditions[18] yielded quantitatively oxime **7**, which was readily reduced to the desired intermediate **2** with $NaBH_3CN$ in the presence of $TiCl_3$.[19] Finally, treatment of **2** with activated charcoal afforded brassilexin in excellent yield.¶

It is worth noting that thione **2** was hypothesized to be a biogenetic precursor of brassilexin **3** *in planta*.[6] In addition, although thiol **6** does not appear to have been prepared previously, it was proposed as a precursor of brassicanal A *in planta*.[20] Our facile synthesis of intermediates **2** and **6** offers the possibility of isotopic labelling and should facilitate future biosynthetic studies on brassilexin **3** and brassicanal A **8**. Particularly because brassilexin **3** appears to be involved in the blackleg disease resistance of several agriculturally important cruciferous oilseeds (*e.g. B. juncea*, *B. carinata*),[21] its biosynthesis has tremendous potential application and is presently under investigation in our laboratory.

We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and the University of Saskatchewan.

Electron-transfer reactions in an H-bonded assembly composed of a diacylaminopyridine bearing zinc porphyrin and 1,8 : 4,5-naphthalenetetracarboxylic diimide (K_a = 2.8 × 10² dm³ mol⁻¹) in benzene occur with k_{CS} = 4.1 × 10¹⁰ s⁻¹ and k_{CR} = 3.7 × 10⁹ s⁻¹, while the corresponding covalently linked model with a comparable distance and energy gap undergoes electron transfer with k_{CS} = 9.9 × 10¹⁰ s⁻¹ and k_{CR} = 6.7 × 10⁸ s⁻¹.

In recent years there has been a considerable upsurge in the development of hydrogen (H)-bonded assemblies that can undergo efficient electron-transfer (ET) reactions,[1–6] since most biological electron transfers take place in non-covalently assembled arrays of several chromophores where the overall electronic coupling between the donor and acceptor seems to depend on the electronic interaction at a non-covalent H-bonded motif. Although several synthetic models have been presented to display ET within H-bonded assemblies, key aspects of ET dynamics still remain unclarified. In particular, ion-pair states have been only scarcely identified by transient absorption spectroscopy, leaving behavior of photogenerated ion pairs across H-bonds unknown except for a limited number of examples.[3,6,7]

Here, we study an H-bonded assembly of a photoexcitable electron-donor zinc porphyrin **9** and electron-acceptor 1,8 : 4,5-naphthalenetetracarboxylic diimide **10** and ET dynamics within the assembly. Porphyrin **9** bears a *meso*-substituted 2,6-diacylaminopyridyl group that is expected to form a strong H bond to the diimide **10**.[8] The radical anion of **10** possesses sharp and characteristic absorption bands that have proven to be particularly useful for analysis of electron-transfer kinetics.[9] Aldehyde **5** was prepared in six steps from citrazinic acid (Scheme 1). The cross-condensation of 3,5-di-*tert*-butylbenzaldehyde, aldehyde **5** and 4,4′-diethyl-3,3′-dimethyldipyrrylmethane gave porphyrin **6** in 62% yield (on the basis of **5**), which was converted to a 2,6-diaminopyridyl-substituted porphyrin **7** in 67% yield by hydrolysis under acidic conditions (HBr–phenol–acetic acid). Porphyrin **9** was prepared by the reaction of **7** with hexanoyl chloride and subsequent insertion of Zn.‡ Diimides **10** and **11** were prepared by the cross-condensation of 1,8 : 4,5-naphthalenetetracarboxylic dianhydride with urea and 2-aminopropane-1,3-diol followed by silylation with *tert*-butyldimethylsilyl chloride in *ca.* 30 and 13% yields, respectively. The siloxyl substituents were introduced in order to increase the solubilities of these diimides in non-polar organic solvents.

To confirm the complexation *via* H-bonding, the ^{1}H NMR spectra of **9** in the absence and presence of increasing amounts of **10** were examined in C_6D_6, $CDCl_3$ and CD_2Cl_2. Typical chemical shift changes upon complexation of **9** and **10** in $CDCl_3$ are summarized in Scheme 2. Most prominently the imide H_a proton and the amide H_b protons were downfield shifted, while the other protons were essentially unperturbed. The fact that no particular upfield shift was observed for the aromatic protons of **10** precludes the coordination of **10** to the zinc centre in **9**. Similar shifts were observed in C_6D_6 and CD_2Cl_2, while no such shifts were detected in [$^2H_8$]THF or [$^2H_6$]DMF. The observed chemical shift changes are consistent with a complexation by three-points H-bonding as depicted in Scheme 2. From the ^{1}H NMR titration, the binding constants were determined using a standard non-linear least-square curve fitting method: 2.8 × 10² dm³ mol⁻¹ in benzene, 1.0 × 10² dm³ mol⁻¹ in $CDCl_3$ and 79 dm³ mol⁻¹ in CD_2Cl_2. Further, the continuous variation method (Job's plot) was used to determine the complexation stoichiometry as 1 : 1.

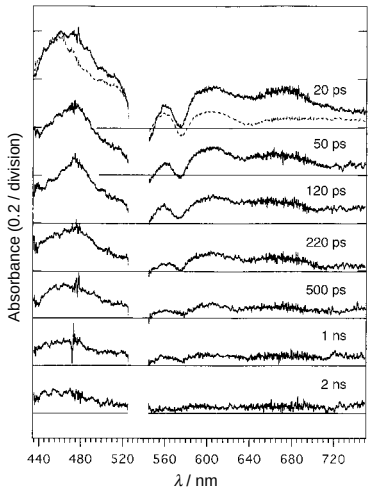

Fig. 1 Transient absorption spectra of a benzene solution of **9** (2.0×10^{-4} M) and **10** (1×10^{-2} M) at λ_{ex} = 532 nm. The dotted line shows the spectrum at a 20 ps delay time for **9** alone.

M) revealed substantial fluorescence quenching (70%) compared with the fluorescence of **9** alone. Such fluorescence quenching was not observed in THF and DMF nor for a solution of **9** and **11**, indicating that a complexation *via* H-bonding was crucial for fluorescence quenching, rather than diffusional encounters.

To provide further support for ET *via* H-bonding, time-resolved transient absorption studies were carried out. Fig. 1 shows the picosecond transient absorption spectra of **9** alone and in the presence of **10** at λ_{ex} = 532 nm in benzene. Under the conditions used, > 95% of **9** was complexed with **10** and the fluorescence of **9** was completely quenched. The transient spectrum of **9** alone (shown by dotted line at a delay time of 20 ps) is a typical transient absorption spectrum of a 5,15-diaryl-octaalkyl zinc porphyrin, in which the absorption band at 458 nm is due to $S_n \leftarrow S_1$ absorption and the bleaching at 640 nm is due to stimulated emission of the S_1 state and these two bands decay with τ = 1.6 ns. The transient absorption spectra of the complex **9**–**10** provided clear evidence for the formation of a diimide anion radical (474 nm) and a zinc porphyrin cation radical (655 nm), both of which were observed early at 20 ps delay time and decayed with τ = 270 ps. Thus, the rate of charge recombination within the complex **9**–**10** is 3.7×10^9 s^{-1}. By analyzing the time profile at 458 nm where the main absorbing species is the S_1 state of the zinc porphyrin, the rate of charge separation has been determined to be 4.1×10^{10} s^{-1}. These ET rates across an H-bond were compared with those in a related covalently linked model **13**, which has a similar energy diagram and a slightly shorter center-to-center distance, to characterize ET across an H-bond bridge.§¶ The transient absorption studies revealed that the rates of charge separation and recombination in **13** are 9.9×10^{10} and 6.7×10^8 s^{-1}, respectively. Thus it may be concluded that (1) electronic coupling across an H-bond interface necessary for charge separation is comparable to that across two C–C single bonds, in line with recent results reported by Therien and coworkers,[5] and (2) an ion-pair across H-bonds is considerably shorter-lived in comparison to a covalently linked ion-pair. The latter aspect that can account for difficulty in detecting an ion-pair across H-bonds may be understood in terms of stabilization of the ion pair, thus the decrease in $-\Delta G$ in the inverted region, by H-bond reorganization which is accompanied by the charge separation.[7] The assembly **9**–**12** has been also studied by transient absorption spectroscopy and found to undergo ET-reaction with $k_{CS} = 2.9 \times 10^{10}$ s^{-1} and $k_{CR} = 2.4 \times 10^9$ s^{-1}, revealing that the isotope effect k_H/k_D is 1.4 and 1.5 for charge separation and recombination, respectively, roughly in line with results reported by Nocera and coworkers.[3a] Our next target will be the development of a H-bonded asembly of donor–acceptor triads and tetrads which can realize long-lived charge separation in spite of inherently shorter-lived ion-pairs across H-bonds. Our attempts in this direction will be reported elsewhere.

Determination of enantiomeric excess for amino acid ester salts using FAB mass spectrometry

Masami Sawada,*[a]† Hiroshi Yamaoka,*[b] Yoshio Takai,[a] Yorito Kawai,[c] Hitoshi Yamada,[a] Tomoko Azuma,[b] Tamaki Fujioka[b] and Toshikazu Tanaka[c]

[a] *Materials Analysis Center, the Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka, 567, Japan*

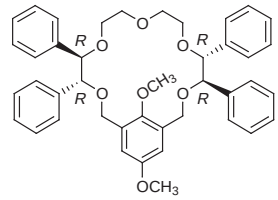
[c] *Faculty of Engineering, Osaka Institute of Technology, Asahi-ku, Osaka, 535, Japan*

The enantiomeric excess of α-amino acid ester hydrochlorides is determined for the first time using FAB mass spectrometry coupled with enantiomer-labelled host method.

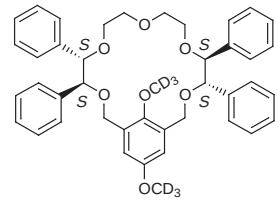
The simple determination of enantiomeric excess using FAB mass spectrometry, without chromatographic separation of the enantiomers,[1,2] has been demonstrated for the first time using *R*/*S* mixtures of α-amino acid esters or, more generally, organic primary amine hydrochlorides. The principle of this method is based on the FAB mass spectrometric detection (nitrobenzyl alcohol matrix)[3–6] of enantiomeric recognition of primary amines by chiral macrocyclic host compounds.[7,8] This method uses a 1:1 mixture [for example, (*R*)-nonlabelled/(*S*)-deuterium-labelled] of chiral crown ethers [for example, (*RRRR*)-**1** and [$^2H_6$]-(*SSSS*)-**1**], and is known as the enantiomer-labelled (EL) host method. In other words, the hosts are utilized as a pair of specific reagents for determining the ee of organic primary amines.

The relative peak intensity of the diastereomeric host–guest complex ions, which are produced from the complexation between a 1:1 mixture of the enantiomeric hosts (H_{RRRR}):[^2H_n]-(H_{SSSS}) and the primary amine salt guest (G^+), is taken as a quantitative measure; *n* is the number of deuterium labels [eqn. (1)].

$$I[(H_{RRRR} + G)^+]/I[[^2H_n]\text{-}(H_{SSSS} + G)^+] = I_R/I_S = IRIS \text{ (abbreviation)} \quad (1)$$



(*RRRR*)-**1**



[$^2H_6$]-(*SSSS*)-**1**

The fundamental concept of this methodology is schematically shown in Fig. 1, where the diastereomeric host–guest complex ion peaks are given. For the conceptual data shown in Fig. 1, the (*R*)-guest complexes the (*RRRR*)-host by an arbitrary factor of 2.0 better than the (*SSSS*)-host (run 1, *IRIS* = 2.0). Accordingly, the (*S*)-guest should complex the (*SSSS*)-host by a factor of 2.0 better than the (*RRRR*)-host (run 2, *IRIS* = 0.50) because of the mirror image relationship between the host–guest complex ions produced. Furthermore, the racemic (*RS*)-guest should provide a pair of equal peak intensities (run 3, *IRIS* = 1.0) because of the net compensation of a racemic host–racemic guest combination. Therefore, in the case of a given guest with unknown ee, one can expect to determine the percent enantiomeric excess from the relationship between the *IRIS* and the ee values.

The (*RRRR*)-**1** host was prepared by a route previously reported by Kaneda, Hirose and Misumi.[9,10] The corresponding

Run	Host	Guest	Pattern of H–G diastereomeric complex ion peaks	I_R/I_S
A:	**FABMS/EL host method**			
1	*RRRR* / [^2H_n]-*SSSS*	*R* (*R*)100% ee		2.0
2	*RRRR* / [^2H_n]-*SSSS*	*S* (*S*)100% ee		0.5
3	*RRRR* / [^2H_n]-*SSSS*	*R* / *S* 1:1 racemic	^2H_n	1.0
4	*RRRR* / [^2H_n]-*SSSS*	*R/S* unknown	Various	Various
B:	**FABMS/EL guest method**			
5	*RRRR*	*R* / [^2H_n]-*S* 1:1 racemic		2.0
6	*SSSS*	*R* / [^2H_n]-*S* 1:1 racemic	^2H_n	0.5

Fig. 1 FAB mass spectrometry with the enantiomer-labelled host and guest methods

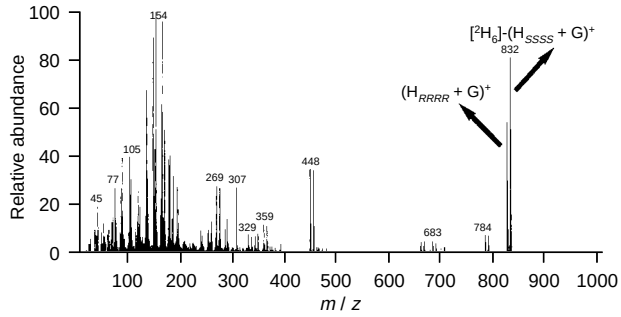


Fig. 2 A typical FAB mass spectrum (nitrobenzyl alcohol matrix) using the enantiomer-labelled host method [host: (*RRRR*)-**1** and [$^2H_6$]-(*SSSS*)-**1**; guest: (*S*)-PglyOMe•HCl (80% ee)]

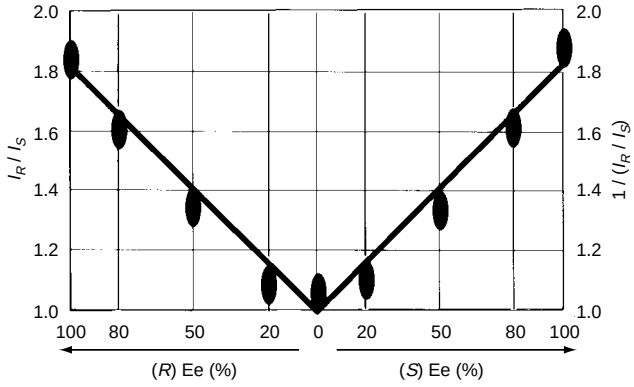

Fig. 3 A plot of $I[(H_{RRRR} + G)^+]/I[[^2H_6]\text{-}(H_{SSSS} + G)^+]$ *vs.* ee

enantiomer-labelled [$^2H_6$]-(*SSSS*)-**1** was similarly prepared *via* 2,6-bis(bromomethyl)hydroquinone [$^2H_6$]dimethyl ether.

A FABMS solution was prepared by mixing the following three solutions: (i) 5 μl of a 1:1 mixture of a 0.16 mmol dm^{-3} $CHCl_3$ solution (25 μl) of (*RRRR*)-**1** and a 0.16 mmol dm^{-3} $CHCl_3$ solution (25 μl) of [$^2H_6$]-(*SSSS*)-**1**, (ii) 5 μl of a 0.08 mmol dm^{-3} MeOH solution of a given guest, and (iii) 30 μl of NBA matrix. After evaporation of MeOH and $CHCl_3$ in the ion source, the concentrations in NBA were calculated to $[H_{RRRR}] = [H_{SSSS}] = [G] = 0.0133$ mmol dm^{-3}. Several guest solutions with different ees were prepared by appropriate mixing of solutions of both the (*R*)- and (*S*)-phenylglycine methyl ester (PglyOMe) hydrochloride salts, and the *IRIS* values were determined by FAB mass spectrometry (Table 1). A typical FAB mass spectrum is shown in Fig. 2. In order to see the characteristic relationship, the *IRIS* value is plotted on the ordinate when the (*R*)-guest is in excess, and the reciprocal of the *IRIS* value is plotted when the (*S*)-guest is in excess (Fig. 3). The *IRIS* value varies in a linear fashion with the ee quantity and produces a symmetric V-shaped plot. Therefore, it is clear that the ee value of a given guest with unknown ee can be determined from the *IRIS* values obtained for both the guests with unknown and known (100%) ee. As mentioned previously,[5] there exist, in general, weak concentration effects of the host and guest solutions upon the *IRIS* values, so it is necessary to measure the FAB mass spectra under fixed sample concentration conditions.

The *IRIS* value of run 1 (or run 2) (the EL host method) should be equivalent to the *IRIS* value of run 5 (or run 6) (the EL guest method)[5] for the mirror image relationship between the complex ions. Therefore, using the EL host method with a series of enantiomerically pure guests (run 1 or run 2), we can determine the chiral recognition abilities of this host toward a series of guests using the same *IRIS* scale derived from the EL guest method (run 5 or run 6). Table 1 shows several *IRIS* values

Table 1 The $I[(H_{RRRR} + G)^+]/I[[^2H_6]\text{-}(H_{SSSS} + G)^+]$ values toward various primary amine hydrochlorides

Amine	*IRIS* values[a]
GlyOMe	1.00

(*S*)-AsnOMe	0.51
(*S*)-PheOMe	0.51
(*S*)-ValOEt	0.35
(*R*)-1-Phenylethylamine	0.95
(*R*)-1-Phenyl-2-hydroxyethylamine	0.62
(*R*)-1-(*p*-Nitrophenyl)ethylamine	1.03

[a] Averaged values of 10th, 20th, 30th and 40th scans ($n = 4$). The standard deviations were within ±5%. [b] (*S*)-Aspartic acid dimethyl ester hydrochloride.

obtained experimentally using the EL host method with a series of hydrochloride salts of enantiomerically pure amino acid esters and organic primary amines. These data have shown which type of guest is suitable to the ee determination. Since the *IRIS* values of the PglyOR$^+$, AspOR$^+$, AsnOR$^+$ and ValOR$^+$ guests show relatively high degrees of chiral recognition character [*IRIS* $\geqslant$ *ca.* 2.0 for (*RRRR*)-host preference or *IRIS* $\leqslant$ 0.5 for (*SSSS*)-host preference], these guests are applicable to determine the ee quantities. On the other hand, the *IRIS* values of the 1-phenylethylamine hydrochloride guests are close to unity, so these are not appropriate for such a purpose. These differences strongly suggest the importance of the COOR function in the guest part for higher chiral recognition ability in the present system.

We have described a conceptually novel method for ee determination of amino acid ester salts using FAB mass spectrometry (positive mode). The methodology is potentially applicable to other host–guest systems with relatively high degrees of chiral recognition.

The authors thank Professor T. Kaneda and Dr K. Hirose for their kind instruction of the synthesis of the chiral crown hosts.

An efficient synthesis of analogues of unsymmetrical archaeal tetraether glycolipids

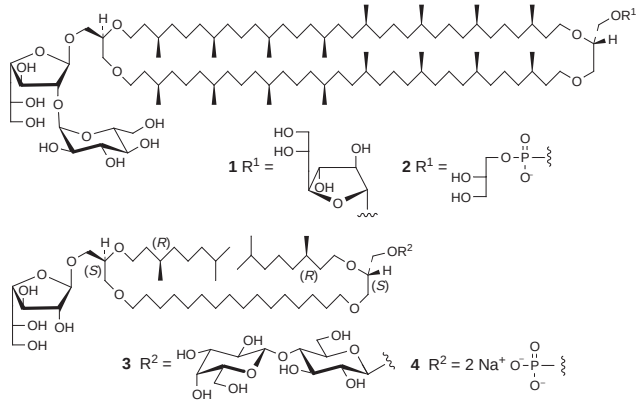
Unsymmetrical tetraether analogues of glycolipids found in archaebacteria, possessing either two different carbohydrate units or a saccharidic moiety and a phosphate group as polar heads and a quasi-macrocyclic lipid core, are efficiently synthesized from versatile chiral building blocks.

The Archaea domain, composed of a variety of extremophilic microorganisms, belongs to a third kingdom of life which is clearly distinct from the well-known Bacteria and Eucarya domains.[1–3] Preservation of the membrane function under extreme conditions such as high temperatures and strong acidity lies with the unique structure of archaebacterial lipids, which fundamentally differ from those of their bacterial and eucaryotic counterparts.[4] Of particular interest is the unusual molecular architecture of the macrocyclic tetraether lipids found in methanogenic and thermoacidophilic species.[5] These lipids are characterized by a bipolar structure with two head groups linked together by two C40 polyisoprenoid chains. Recently, Gräther and Arigoni demonstrated that several natural lipids were in fact nearly statistical mixtures of regioisomers differing in the relative orientation of their glycerol units.[6] The dimensions of the tetraether lipids are therefore sufficient to form monolayered membranes[5] and the presence of two head groups with different sizes at opposite sides of the monolayer is expected to induce membrane curvature.[4b] The presence of galactofuranose units in some glycolipids is puzzling since hexoses appear only in the pyranose form in mammalian glycoconjugates. The unique chemical design of these archaeal lipids represents an interesting opportunity to build exceptionally thermal stable vesicles which might be suitable for nano-scale technologies and for drug-delivery applications.[7]

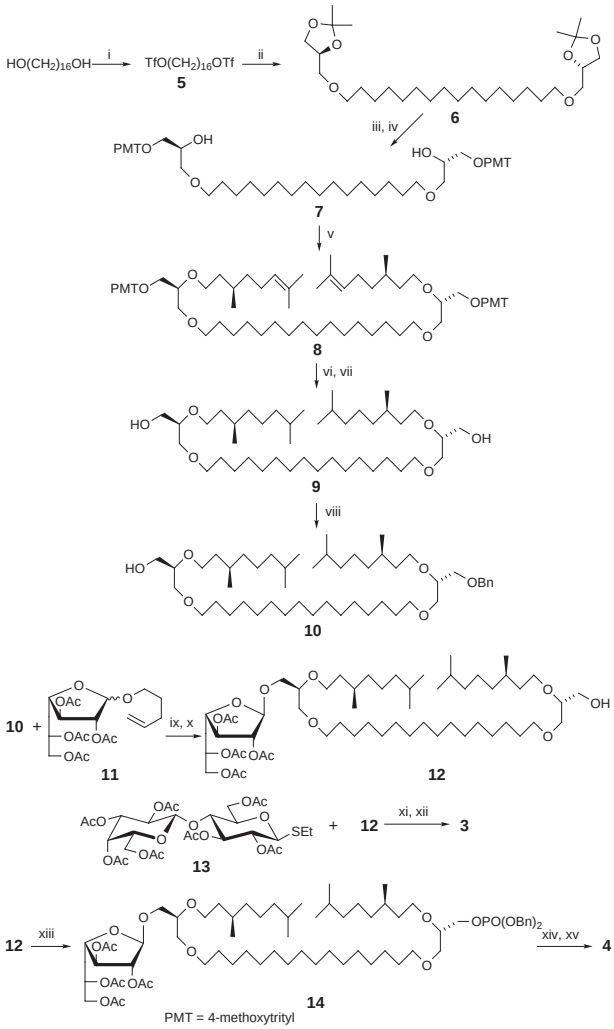
We report here the first synthesis of the chiral unsymmetrical quasi-macrocyclic tetraethers **3** and **4** as models of the natural



lipids **1** and **2** isolated from *Methanospirillum hungatei*, which is a methanogenic species.[5] The most characteristic structural features of the target molecules lies with (i) a lipid core consisting in a linear hexadecanemethylene spacer and two (*R*)-dihydrocitronellyl chains having a combined length equal to that of the bridging unit, attached to glycerol respectively at *sn*-3 and *sn*-2 positions, (ii) either a D-galactofuranose and a phosphate group or the former and a lactosyl unit as polar head groups at opposite ends of the lipid core, and (iii) an *S* stereogenic center at each glycerol backbone similar to that of the corresponding natural glycolipids **1** and **2**.[5] These synthetic bolaamphiphiles might show similar behaviour to cyclic lipids when aggregated or inserted into membranes.[8]

The general synthetic pathway for **3** and **4** (Scheme 1) involved the preparation of the key diol intermediate **9**, subsequent monoprotection of one of the hydroxy groups and sequential introduction of the polar heads. The crucial glycosylation or phosphorylation step of the monoglycosylated compound **12** should be performed under extremely mild conditions in order to preserve the highly hydrolysable β-D-galactofuranosidic linkage. Hemimacrocyclic diol **9** was obtained from (*S*)-(+)-2,2-dimethyl-1,3-dioxolan-4-ylmethanol [(*S*)-(+)-solketal],‡ hexadecane-1,16-diyl ditriflate **5**, and (*R*)-(−)-citronellyl bromide as the starting materials. After experimentation, we found that reaction of hexadecane-1,16-diol with Tf_2O in the presence of the hindered base 2,6-lutidine resulted in the efficient formation of the expected ditriflate **5**. Separation of the ditriflate from the base was easily accomplished by flash chromatography, thus affording compound **5** in 80% yield. Alkylation of two (*S*)-solketal units by **5** proceeded efficiently (83%) in refluxing CH_2Cl_2 for 24 h using 1,8-bis(dimethylamino)naphthalene (proton sponge: PS) as a base. Removal of the isopropylidene groups in the presence of a Dowex acidic resin in refluxing MeOH gave the tetraol (73%) which was selectively protected by *p*-methoxytritylation of the primary hydroxy groups. Williamson coupling of the remaining secondary hydroxy groups using commercially available (*R*)-(−)-citronellyl bromide provided the unsaturated tetraether **8** (80% yield). Palladium-catalyzed hydrogenation of **8** led to the formation of byproducts due to the unexpected cleavage of the ether linkages at the *sn*-2 glycerol sites. Addition of 1 equiv. of triethylamine in the hydrogenation media avoided this side reaction and furnished quasi-quantitatively the corresponding saturated lipid. Finally, the key diol **9** was readily prepared by removal of the trityl groups under acidic conditions.[9]

At this stage, the next challenging problem involved the selective protection of **9** so as to introduce two different polar head groups at opposite ends. After experimentation, we found that the protocol reported by Bouzide and Sauvé[10] was the most efficient methodology for the monoprotection of the diol. Treatment of **9** with Ag_2O and BnBr in CH_2Cl_2 led to the formation of the monobenzylated product **10** (50% yield) in addition to the dibenzylated derivative (10% yield) and the unreacted recyclable diol (36%). The introduction of the β-D-galactofuranoside unit was performed stereospecifically by way of *n*-pentenyl glycoside (NPG) glycosylation[11] from the key galactofuranosyl donor **11**.[12] After hydrogenolysis of the benzyloxy group, we envisaged either the glycosylation or the



Scheme 1 *Reagents and conditions*: i, Tf_2O, 2,6-lutidine, CH_2Cl_2, 0 °C, then room temp., 80%; ii, (*S*)-solketal, PS, CH_2Cl_2, reflux, 83%; iii, Dowex H^+ resin, MeOH, reflux; iv, 4-methoxytrityl chloride, pyridine, DMAP, THF, reflux, 60% over two steps; v, (*R*)-citronellyl bromide, NaH, 130 °C, 80%; vi, H_2, Pd/C, Et_3N, AcOEt; vii, HCO_2H, Et_2O, 70% over two steps; viii, Ag_2O, BnBr, CH_2Cl_2, 50%; ix, NIS, Et_3SiOTf, CH_2Cl_2; x, H_2, Pd/C, EtOH, 73% over two steps; xi, NIS, TESOTf, 4 Å molecular sieves, CH_2Cl_2; xii, MeONa, MeOH, 65% over two steps; xiii, 1*H*-tetrazole, $(BnO)_2PNPr^i_2$, CH_2Cl_2, then MCPBA, CH_2Cl_2, −40 to 0 °C, 80%; xiv, MeONa, MeOH; xv, H_2, Pd/C, MeOH, acetate buffer (pH 5) (3:1 v/v), then Amberlite® IR-120 (Na^+), MeOH, then gel-filtration on Sephadex LH-20 (1:2 CH_2Cl_2–MeOH), 85% over two steps

phosphorylation of the free alcohol under mild conditions in order to prevent any hydrolysis of the former β-D-galactofuranosidic bond. The glycosylation of **12** using lactosyl thioglycoside **13** as a donor[13] was carried out under NIS–Et_3SiOTf conditions and provided the desired β-D-glycoside in 70% yield. Deacetylation of the glycosyl hydroxy groups under standard conditions gave the totally deprotected bipolar lipid **3** in 93% yield.§

Having successfully prepared the bis-glycoside **3**, we turned our attention towards the introduction of a phosphate group onto intermediate **12**. Alkyl dibenzyl phosphate **14** was prepared by reacting alcohol **12** with dibenzyl *N*,*N*-diisopropylphosphoramidite and 1*H*-tetrazole followed by *in situ* mild oxidation of the resultant alkyl dibenzyl phosphite with MCPBA (80% yield).[14] The transformation of **14** into the phosphate salt **4** was performed by sequential deacetylation of the galactosyl unit, catalytic hydrogenolysis (Pd/C) in a buffered solvent mixture (MeOH–AcOH–NaOAc, pH 5) avoiding the glycoside hydrolysis and treatment with Amberlite® IR-120 (Na^+ form, water).

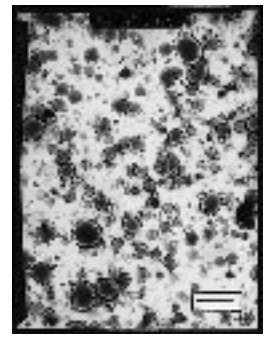


Fig. 1 Transmission electron micrograph of compound **4** vesicles negatively stained with uranyl acetate. The bar is 1500 nm.

Purification by gel filtration chromatography with Sephadex LH-20 furnished the targeted unsymmetrical glycolipid analogue **4** in 85% yield.

Aqueous dispersions of glycolipids **3** and **4** were sonicated at 60 °C for 20 min. Transmission electron microscopy revealed that phosphate **4** furnished spherical vesicles of 100–1000 nm diameter stable for several weeks at ambient temperature as shown in a representative micrograph (Fig. 1). Compound **3** provided myelin-type aggregates (not shown).

Further physicochemical measurements are under investigation.

We are grateful to the CNRS and the Région Bretagne for grants to R. A.-V. and G. L., respectively, to M. Lefeuvre for assistance with NMR experiments, and to P. Guenot for mass spectrometry measurements.

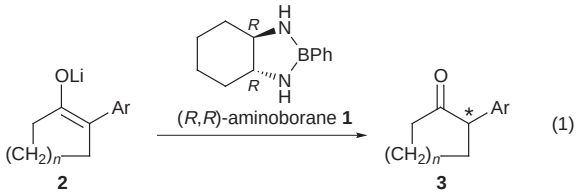
Chiral aminoborane as a chiral proton source for asymmetric protonation of lithium enolates derived from 2-arylcycloalkanones

Akira Yanagisawa, Hiroshi Inanami and Hisashi Yamamoto*†

Graduate School of Engineering, Nagoya University, CREST, Japan Science and Technology Corporation (JST), Chikusa, Nagoya, 464-8603, Japan

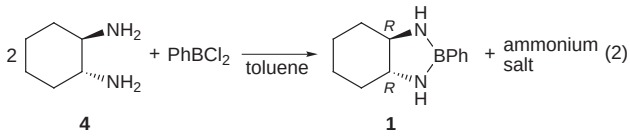
Reaction of lithium enolates of 2-arylcycloalkanones 2 with (*R*,*R*)-aminoborane 1, prepared from (1*R*,2*R*)-1,2-diaminocyclohexane 4 and $PhBCl_2$, gives the corresponding optically active ketones 3 with up to 93% ee; this is the first example of enantioselective protonation using a metal-containing chiral proton source.

Asymmetric protonation of prochiral metal enolates has proved to be an efficient method for the synthesis of chiral carbonyl compounds.[1] The success of this process depends on the structure and acidity of the chiral proton source. Several chiral acids have been developed so far, and have been applied to enantioselective protonations.[2–4] However, as far as we know, there are no reports on a proton source containing metal atoms. We describe here a new enantioselective protonation of lithium enolates **2** with chiral aminoborane **1** [eqn. (1)].

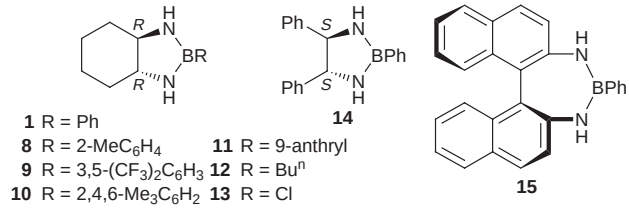


Heteroatom-substituted chiral boron compounds such as oxazaborolidines and acyloxyboranes are well-known as chiral Lewis acid catalysts for various asymmetric reactions.[5] High levels of asymmetric induction are obtained in Diels–Alder reactions or Mukaiyama aldol reactions, and the formation of a stable complex of a boron catalyst with a carbonyl compound is regarded as the key to success. We considered that if a chiral aminoborane could form a rigid cyclic transition state structure with a lithium enolate, and if the amide proton is acidic enough, a highly enantioselective protonation might occur.

Chiral aminoborane **1** was synthesized from (1*R*,2*R*)-1,2-diaminocyclohexane **4** (2 equiv.) and $PhBCl_2$ (1 equiv.) in toluene [eqn. (2)].[6] The resulting ammonium salt was filtered



off. Treatment of lithium enolate **6**, generated from silyl enol ether **5** and Bu^nLi/hexane (1.1 equiv.) in THF at 0 °C,[7] with a solution of (*R*,*R*)-aminoborane **1** (1.5 equiv.) in toluene–THF (1:1) at −78 °C for 2 h followed by quenching with Me_3SiCl (to remove unreacted **6**) at −78 °C gave (*S*)-enriched 2-phenylcyclohexanone **7** in 94% yield and 84% ee (Table 1, entry 1).‡ Using various chiral aminoboranes, we studied the enantioselectivity of this protonation; yields and enantiomeric excesses of the product **7** obtained by reactions with other chiral aminoboranes **8**–**15** in THF at −78 °C are shown in Table 1. Substitution of the phenyl group of **1** by a chlorine atom resulted in a lower



enantioselectivity, while the chemical yield increased (entry 7). As a consequence, (*R*,*R*)-aminoborane **1** was the most effective chiral proton source for the protonation of **6**.

This asymmetric protonation was applied to a variety of lithium enolates of ketones **17**, and the results with (*R*,*R*)-aminoborane **1** are summarized in Table 2. These reactions have the following characteristics: (i) all of the reactions proceeded to give a satisfactory yield at −78 °C for 2 h, except for the lithium enolate of 2-methylindanone **22**, which gave a low yield due to concomitant side reactions (entry 5); (ii) moderate to high asymmetric induction occurred in the protonation of lithium enolates **6**, **19**–**21** and **29**, which possess an aryl group at the C-2 position (entries 1–4 and 12). The highest enantioselectivity (93% ee) was obtained with the enolate of 2-(2-naphthyl)cyclohexanone **21** (entry 4). The enolates **22**, **23**, **27** and **28** derived from 2-methylindanone, 2-methyltetralone and their derivatives also gave good optical purities (entries 5, 6, 10, and 11). However, the use of simple substrates bearing no aromatic

‡ Procedure for protonation of lithium enolate **6** with (*R*,*R*)-aminoborane **1**: To a solution of (1*R*,2*R*)-1,2-diaminocyclohexane (172 mg, 1.5 mmol) in dry toluene (4 ml) was added $PhBCl_2$ (97 µl, 0.75 mmol) at −78 °C. The mixture was warmed to room temperature and again stirred for 2.5 h at this temperature. The resulting ammonium salt was filtered off under an argon atmosphere and washed with dry THF (2 ml). To the filtrate was added at −78 °C a solution of lithium enolate **6**, prepared from trimethylsilyl enol ether **5** (123 mg, 0.5 mmol) and BunLi (1.67 M hexane solution, 0.33 ml, 0.55 mmol) in dry THF (2.3 ml) at 0 °C, through a stainless steel cannula under an argon stream. After being stirred for 2 h at −78 °C, TMSCl (65 µl, 0.5 mmol) was added, and stirring continued for another 30 min at this temperature. The reaction mixture was treated with saturated aqueous NH_4Cl, extracted with Et_2O , dried (Na_2SO_4), and finally purified by column chromatography on silica gel to give (*S*)-enriched 2-phenylcyclohexanone [(*S*)-**7**, 94% yield] with 84% ee. The enantiomeric ratio was determined by HPLC analysis using a chiral column (Chiralcel OD-H, Daicel Chemical Industries, Ltd.). The absolute configuration was determined by comparison of its optical rotation with published data; (*S*)-isomer (87% ee): $[\alpha]_D^{29}$ −88.9 (*c* 1.0, $CHCl_3$) [ref. 3(*c*)]. Observed value of (*S*)-isomer (84% ee): $[\alpha]_D^{28}$ −94.1 (*c* 1.1, $CHCl_3$).

Electrochemical reduction of halogenosugars on silver: a new approach to *C*-disaccharide-like mimics

Marco Guerrini,[a] Patrizia Mussini,[b] Sandra Rondinini,[b] Giangiacomo Torri[a] and Elena Vismara*[c]†

[a] *Istituto di Chimica e Biochimica 'Giuliana Ronzoni', via G. Colombo 81, 20133 Milano Italy*
[b] *Dipartimento di Chimica Fisica ed Elettrochimica, Università degli Studi di Milano, via Golgi 19, 20133 Milano, Italy*
[c] *Dipartimento di Chimica del Politecnico di Milano, via Mancinelli 7, 20131 Milano, Italy*

Electrochemical reduction on silver of tri-*O*-acetyl-α-D-fucopyranosyl bromide 3 affords (1 → 1′)-linked *C*-disaccharide-like mimics 6–8; reduction of 1,2 : 3,4-di-*O*-isopropylidene-6-deoxy-6-iodo-α-D-galactopyranose 5 provides 1,2:3,4-di-*O*-isopropylidene-6-deoxy-6-(1′,2′ : 3′,4′-di-O-isopropylidene-6′-deoxy-α-D-galactopyranos-6′-yl)-α-D-galactopyranose 9; simultaneous reduction of 5 and tetra-*O*-acetyl-α-D-glucopyranosyl bromide 1 or tri-*O*-acetyl-α-L-fucopyranosyl bromide 4 gives 9 and methylene-bridged *C*-disaccharide-like mimics 11, 12 or 13, 14, respectively.

C-Glycosides are of interest as molecules of potential biological activity and are also useful for enzymatic and metabolic studies.[1] Some *C*-disaccharides have also been investigated.[2]

Here we describe an electrochemical approach to *C*-disaccharide-like mimics, the reduction of halogenosugars in MeCN at a silver electrode, a method already extensively applied to glycosides syntheses.[3,4] This approach was confirmed by the electroreduction using the above conditions of tetra-*O*-acetyl-α-D-glucopyranosyl bromide **1** which mainly provides 1,3,4,5,8,9,10,12-octa-*O*-acetyl-D-gluco-L-altro-L-erythro-2,6 : 7,11-dianhydrododecitol,[8] 1,3,4,5,8,9,10,12-octa-*O*-acetyl-D-gluco-D-galacto-L-erythro-2,6 : 7,11-dianhydrododecitol and 1,3,4,5,8,9,10,12-octa-*O*-acetyl-D-gluco-L-ido-L-erythro-2,6 : 7,11-dianhydrododecitol[8] with an overall yield of 50%, the ratio being *ca.* 2 : 1 : 1.[5] We can account for the formation of these biglucosyl derivatives *via* a radical pathway, *i.e.* the dimerisation of tetra-*O*-acetyl-D-glucopyranosyl radical **2**.[3,4]

The *O*-glucosides themselves formed in the electrolyses of **1** on silver in the presence of phenols can be accounted for by coupling of an anomeric radical and a phenoxyl radical.[3,5] These electrolyses were carried out in MeCN *via* cyclic voltammetry of **1** at a silver electrode which displays one irreversible peak at E_p = −1.3 V (*vs.* aq. SCE). Electrochemical reduction of **1** at a mercury electrode in DMF or MeCN was proposed by Vianello and co-workers as a new approach to 3,4,6-tri-*O*-acetyl-D-glucal, the cyclic voltammetry of **1** displaying one irreversible peak at E_p = −1.9 V (*vs.* SCE).[6] No dimers were observed. Different mechanisms are no doubt involved in electrolyses of **1** using mercury or silver electrodes. On mercury, the overall electrode process of **1** was interpreted as a two electron C–Br bond cleavage coupled to a very fast elimination of the acetate anion, which leads to 3,4,6-tri-*O*-acetyl-D-glucal. 1,2,3,4,6-Penta-*O*-acetyl-β-D-glucopyranose was also isolated, *via* nucleophilic substitution.[6] The electrode process on the silver cathode appears more complex. Compound **1** undergoes a single electron-transfer reduction; the following elimination of the bromide anion leads to the intermediate radical **2**, which affords dimers (50%); 3,4,6-tri-*O*-acetyl-D-glucal (20%) and 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose (15%) are also isolated, thus indicating that a further reduction of **2** occurs.

On the basis of these results, we have investigated whether silver cathodic reduction of halogenosugars could be suitable to generate carbohydrate radicals, with the aim of developing new synthetic methods. The voltammetric behaviour of **1**, tri-*O*-acetyl-α-D-fucopyranosyl bromide **3**,[7] tri-*O*-acetyl-α-L-fucopyranosyl bromide **4**[7] and 1,2 : 3,4-di-*O*-isopropylidene-6-deoxy-6-iodo-α-D-galactopyranose **5**[8] were studied both at silver and mercury electrodes in MeCN (Table 1).

Table 1 Reduction peak potentials

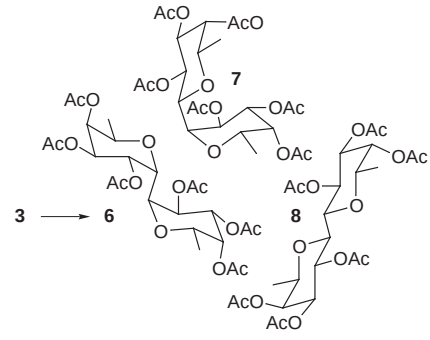
Halogenosugar	E_p (Ag)/V (*vs.* SCE)	E_p (Hg)/V (*vs.* SCE)
1	−1.30	−1.95
3[a]	−1.20	−1.95
5	−1.23	−1.81

[a] Compound **4** is reduced at the same E_p as **3**.

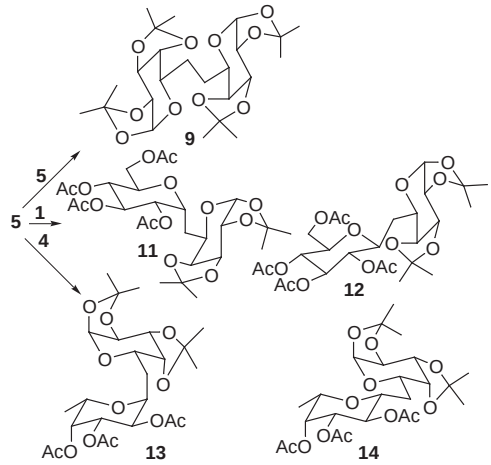
Data in Table 1 confirm the remarkable electrocatalytic activity of silver with respect to mercury. Compounds **1**,**3**–**5** were submitted to preparative electrolyses on a silver cathode in MeCN. Tri-*O*-acetyl-α-D-fucopyranosyl bromide **3** was electrolysed at −1.5 V. 3,4,5,8,9,10-Hexa-*O*-acetyl-D-galacto-L-ido-D-threo-1,12-deoxy-2,6 : 7,11-dianhydrododecitol **6**‡ (15%), 3,4,5,8,9,10-hexa-*O*-acetyl-D-galacto-L-altro-D-threo-1,12-deoxy-2,6 : 7,11-dianhydrododecitol **7**‡ (15%) and 3,4,5,8,9,10-hexa-*O*-acetyl-D-galacto-D-galacto-D-threo-1,12-deoxy-2,6 : 7,1-dianhydrododecitol **8**‡ (4%) (Scheme 1) were recovered, together with 3,4-di-*O*-acetyl-D-fucal (11%) and fucose tetraacetate (10%).

The product distribution of **3** appears similar to that of **1**, except for the dimer ratio. 1,2 : 3,4-Di-*O*-isopropylidene-6-deoxy-6-iodo-α-D-galactopyranose **5** is suitable for generating a non-anomeric radical and for derivatisation to occur at the other end of the sugar skeleton. The reduction of **5** at −1.7 V provides 1,2 : 3,4-di-*O*-isopropylidene-6-deoxy-6-(1′,2′ : 3′,4′-di-*O*-isopropylidene-6′-deoxy-α-D-galactopyranos-6′-yl)-α-D-galactopyranose **9**[4,9] as the only product (Scheme 2). Once again its formation can be explained by the presence of an intermediate radical like 1,2 : 3,4-di-*O*-isopropylidene-6-deoxy-α-D-galactopyranos-6-yl radical **10**.

On the basis of these results and of the similar redox potentials of the investigated substrates (Table 1), we asked



Scheme 1



Scheme 2

ourselves if it was possible to couple two different radicals generated at the same stage. Our goal was the synthesis of non-symmetrical *C*-disaccharides-like mimics. Radical **2** is a secondary radical, to some extent stabilised by an O atom in the α-position, while **10** is an unstabilized primary radical. So could the so-called anomeric radical **2** behave as a persistent radical[10] and act as a scavenger of the more reactive **10**? Compounds **1** and **5** were simultaneously reduced at −1.5 V in the ratio 1.5 : 1. 1,2 : 3,4-Di-*O*-isopropylidene-6-deoxy-6-(2′,3′,4′,6′-tetra-*O*-acetyl-α-D-glucopyranosyl)-α-D-galactopyranose **11**§ (9%) and 1,2 : 3,4-di-*O*-isopropylidene-6-deoxy-6-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-α-D-galacto-pyranose **12**§ (9%) were isolated (Scheme 2) together with **9** (17%), with only a very small amount of glucosyl dimers (> 3%).

Compounds **4**[7] and **5** in the ratio 2 : 1 were also simultaneously reduced at −1.5 V. 1,2 : 3,4-Di-*O*-isopropylidene-6-deoxy-6-(2′,3′,4′-tri-*O*-acetyl-α-L-fucopyranosyl)-α-D-galactopyranose **13**¶ (11%) and 1,2:3,4-di-*O*-isopropylidene-6-deoxy-6-(2′,3′,4′-tri-*O*-acetyl-β-L-fucopyranosyl)-α-D-galactopyranose **14**¶ (11%) were isolated together with **9** (34%) (Scheme 2).

In both cases glycals and penta- or tetra-acetyl derivatives were also isolated. The product distributions show that dimerisation of **10** competes well with its trapping by glycosyl radicals, but also that there is no dimerisation of glycosyl radicals in the presence of **10** or that it is significantly reduced.

The mechanism of these reductions is very intriguing as we could argue that not only are carbohydrate radicals involved as intermediates, but also that dimerisation is the only termination reaction, which would be very unusual. The glucopyranosyl radical **2**, for instance, has been extensively studied especially by Giese. In the absence of a radical scavenger, it mainly undergoes migration of the acetate group from position 2 to 1.[11] In the electroreduction we did not actually observe any migration at all! We extensively studied the chemical behaviour of **10**.[8] Although it acts as a good hydrogen abstractor even from MeCN, in the electroreduction we did not observe any hydrogen abstraction at all! Some coupling of **10** was observed, but only in the presence of Fe^{II}[12] and, in that particular case, the effect of Fe^{II} was interpreted using Kochi's hypothesis as being due to 'metal ion–free radical complexes of relatively longer life than a simple alkyl radical'.[13]

In conclusion, we have provided evidence for the ability of a silver cathode to generate carbohydrate radicals and perhaps to induce their dimerisation, but, for the moment, we are not able to give any satisfactory interpretation of the mechanism. Indeed, even if yields are lowered by the presence of glycals and acetate derivatives, this peculiar electroreduction affords different kinds of *C*-disaccharide-like mimics, and in this sense it could be proposed as a mild, clean, one-pot method with which to form stable interglycosidic bonds.

We gratefully acknowledge MURST and CNR for the financial support, the student Daniela Beccati for the experimental work.

The activation of carbon disulfide by a cluster. The reaction of the μ_3-CS complex $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)_2PPh_3\}(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ with CS_2

Anthony R. Manning,[a]† Anthony J. Palmer,[a] John McAdam,[b] Brian H. Robinson[b] and Jim Simpson[b]†

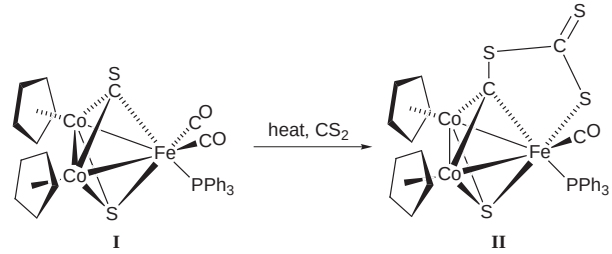
[b] *Department of Chemistry, University of Otago, Dunedin, New Zealand*

When $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)_2PPh_3\}(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ is refluxed in CS_2 solution, it is converted to $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)PPh_3\}(\mu_3\text{-}S)\{\mu_3\text{-}CSC(S)S\}]$ which contains an unusual C_2S_3 bridging ligand.

$[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)_2PPh_3\}(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ **I** is formed when the η^2-CS_2 ligand in $[Fe(PPh_3)_2(CO)_2(\eta^2\text{-}CS_2)]$ is cleaved by $[Co(\eta\text{-}C_5H_5)(PPh_3)_2]$.[1,2] When a solution of this compound in carbon disulfide is heated to reflux for 12 hours, a further molecule of CS_2 is taken up and CO is lost. The product, **II**, is obtained in 75% yield. It is a brown crystalline solid which, when crystallized from carbon disulfide solution, analyses as $Co_2(\eta\text{-}C_5H_5)_2Fe(CO)(PPh_3)(S)(CS)\cdot 2CS_2$. This is consistent with NMR and IR spectroscopic data,‡ but does not define the actual structure of **II** which was determined by X-ray crystallography on a crystal grown from benzene solution which analyzed as $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)PPh_3\}(\mu_3\text{-}S)\{\mu_3\text{-}CSC(S)S\}]\cdot 2C_6H_6$.§ It is illustrated in Fig. 1.

The molecular structure of **II** is closely related to that of **I**[1,2] and is based on an $FeCo_2$ triangle capped on one face by a μ_3-S ligand and on the other by a μ_3-C atom. The coordination about each of the two Co atoms is completed by a η^5-C_5H_5 group whilst that about Fe is completed by a CO and a Ph_3P ligand and the S* atom of a S*C(S)S moiety which is also bonded to the μ_3-C atom. The coordination about Fe is severely distorted from that found in **I** where the $Fe(L)_3$ fragment is more or less symmetrical with respect to an axis from Fe to the midpoint of the Co–Co bond. Furthermore the $FeCo_2$ triangle is no longer an isosceles triangle as it is in **I** [Fe–Co = 2.5099(6), 2.5061(6) Å] as Fe(1)–Co(1) at 2.642(3) Å is very much longer than Fe(1)–Co(2) at 2.502(4) Å.

The C_2S_3 ligand has no precedent. The various C–S bond lengths lie between those for a C=S (*ca.* 1.62 Å in thioketones)[3] and a C–S (*ca.* 1.82 Å in thioethers)[3] which is indicative of delocalised bonding. In particular the μ_3-C–S distance in **II** [1.774(11) Å] is very long compared with that in **I** [1.638(3) Å] or its S-methylated derivative, $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)_2PPh_3\}(\mu_3\text{-}S)(\mu_3\text{-}CSMe)]I$, [**III**]I,[2] [1.728(7) Å]. The C–S distances are all longer than the comparable ones in $[Co(\eta\text{-}C_5H_5)(CNBu^t)(S_2C{=}S)]$.[4] The overall reaction which gives rise to **II** is shown in Scheme 1. It is reminiscent of that of a thiolate anion, RS^-, which with CS_2 forms a thioxanthate anion $[RSCS_2]^-$[5] and is a reflection of the nucleophilicity of the μ_3-CS ligand which has been illustrated by the ease with which **I** is alkylated to **III**$^+$ salts. The related complex $[\{Co(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ is also readily alkylated at S to give $[\{Co(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}S)(\mu_3\text{-}CSMe)]I$, but it does not react with CS_2. This implies that the conversion of **I** to **II** takes place because the first-formed $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)_2PPh_3\}(\mu_3\text{-}S)(\mu_3\text{-}CS{\rightarrow}CS_2]$ intermediate can undergo CO loss with the formation of an Fe–S bond which stabilizes the C_2S_3 ligand.



Scheme 1

Analogues of **II** are obtained when Ph_3P in **I** is replaced by $(PhO)_3P$ or $Bu^n{}_3P$, but not when it is replaced by $(MeO)_3P$. The extent of this reaction is being investigated at present.

The exocyclic S atom in **II** is nucleophilic and with electrophiles E such as $Me^+(I^-)$ or $HgCl_2$ gives $[\{Co(\eta\text{-}C_5H_5)\}_2\{Fe(CO)PPh_3\}(\mu_3\text{-}S)\{\mu_3\text{-}CSC(S{\rightarrow}E)S\}]$ adducts. These have been characterized by elemental analysis and spectroscopy.

Attempts to use **I** to activate other cumulenes such as CO_2, COS and MeNCS have not, as yet, been successful. The only isolable product has been $[\{Co(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$,[6] which is a thermal decomposition product of **I**.

We thank Professor W.T. Robinson, University of Christchurch, Christchurch, New Zealand for collecting the X-ray data, and Labkem Ltd. (Dublin) for financial assistance to A. J. P.

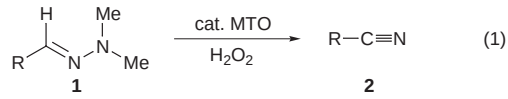
The MTO-catalyzed oxidative conversion of *N*,*N*-dimethylhydrazones to nitriles

Saša Stanković and James H. Espenson*†

Ames Laboratory and Department of Chemistry, Iowa State University, Ames, Iowa, 50011, USA,

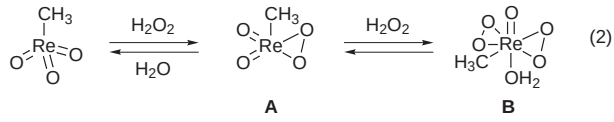
Methyltrioxorhenium catalyzes the fast and efficient oxidation of aldehyde *N*,*N*-dimethylhydrazones to the corresponding nitriles in high yield.

N,*N*-Dimethylhydrazones derived from aldehydes (**1**) can be oxidatively transformed into nitriles (**2**) using hydrogen peroxide as the oxidizing agent and methyltrioxorhenium (CH_3ReO_3, abbreviated as MTO) as the catalyst, usually at the 1% level, as shown in eqn. (1). Ten specific examples are



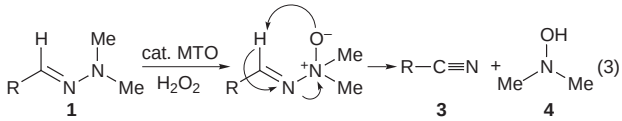
presented in Table 1.

MTO is a well established catalyst for oxidations utilizing hydrogen peroxide,[1,2] including oxidations of various nitrogen-containing compounds.[3–7] The reactions were best carried out in acetonitrile–acetic acid–pyridine solvent, 94.5 : 5 : 0.5. The use of acetic acid was mandatory since the hydrazones are sufficiently basic to deactivate MTO to the inactive perrhenate.[8] Without pyridine, however, the reaction was accompanied by 5–10% hydrolysis to the parent aldehyde. Hydrolysis can effectively be suppressed by a small amount of pyridine, to reduce the Lewis acidity of MTO and its peroxo adducts. This procedure prevents the hydrolysis of epoxides formed by the oxidation of alkenes by MTO–hydrogen peroxide.[9] Pyridine also accelerates the formation of the catalytically active peroxorhenium complexes as in eqn. (2).



Under the described conditions the hydrazones **1** were completely transformed into the corresponding nitriles after several minutes as indicated by GC–MS analysis. The reaction is quite general: *N*,*N*-dimethylhydrazones of aliphatic, unsaturated, aromatic and heterocyclic aldehydes were successfully oxidized to the corresponding nitriles. Other present oxidizable functionalities did not interfere (see Table 1, entry 8 where the hydrazone was oxidized without the pyridine *N*-oxide being formed). In this particular example pyridine was not used, since the starting hydrazone itself functions in this regard. Also in entry 10, as expected, the double bond was not epoxidized during the reaction, indicating far greater reactivity of the hydrazone moiety compared to the double bond.

The oxidation of **1** presumably goes through the oxide **2**, which undergoes a Cope-type elimination[10] to yield the nitrile **3** and dimethylhydroxylamine **4**, eqn. (3). *N*,*N*-Dialkylhydroxylamines are known to undergo oxidation to nitrones with H_2O_2–MTO.[7] No attempts were made to detect either dimethylhydroxylamine or its oxidation product.



N,*N*-Dialkylhydrazones are versatile and useful intermediates in organic synthesis, especially in carbon–carbon bond forming[11] reactions, which has led to considerable interest in the development of mild methods for their transformation into nitriles. Non-oxidative procedures *via N*,*N*,*N*-trimethylhydrazonium salts or directly, in hyperbasic media,[12,13] have been used, but they require high temperatures and strong bases. Several mild oxidative procedures for the use of hydrogen peroxide, using 3-chloroperbenzoic acid and magnesium monoperoxyphthalate, have been reported.[10,14,15] These reactions, however, are rather slow; for example, the 3-chloroperbenzoic acid reactions require several hours.

Hydrogen peroxide is a desirable reagent on several counts. Selenium dioxide and 2-nitrobenzeneselenic acid catalyze its reactions, giving good yields of nitriles from aromatic and

[a] With 10 mM substrate, 300 mM H_2O_2, 25 mM pyridine and 1 mM MTO in acetonitrile, acetic acid, pyridine (94.5:5:0.5) for 15 min. [b] Isolated yield. [c] Without pyridine.

unsaturated *N*,*N*-dimethylhydrazones, but hours, even days, are required. Moreover, these catalysts give poor results with aliphatic *N*,*N*-dimethylhydrazones which are largely hydrolyzed. Phosphomolybdic acid, $H_3PO_4 \cdot 12MoO_3 \cdot 12H_2O$, performs better with aliphatic hydrazones but it gives by-products such as the corresponding acids. Compared to these catalysts, MTO is clearly superior. MTO also catalyzes the oxidative cleavage of ketone hydrazones to the parent carbonyl compounds; these reactions are now being investigated.

A typical experimental procedure is as follows: **1** (100 mmol) was added to a rapidly stirred solution of MTO (1 mM), hydrogen peroxide (0.3 M, added as 30% solution in water), pyridine (25 mM) in 100 ml of acetonitrile containing 5 vol% HOAc. After 15 min, most of the acetonitrile was removed by rotary evaporation, and the residue poured into 300 ml of diethyl ether, washed successively with 0.1 M HCl and saturated sodium hydrogen carbonate. (In the case of 4-cyanopyridine, entry 8, the ether solution was washed only once with saturated sodium hydrogen carbonate.) The ethereal solution was then dried over anhydrous sodium sulfate, and the product obtained after evaporation. The crude nitriles were purified by column chromatography (*n*-hexane–acetone).

Dithioamide metal ion receptors on fluorescent lipid bilayers for the selective optical detection of mercuric ion

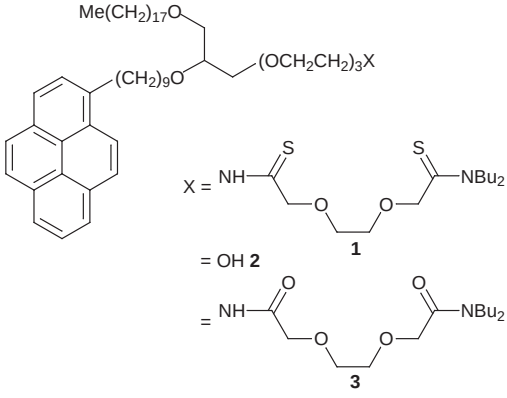
Darryl Y. Sasaki*† and Benjamin E. Padilla

Sandia National Laboratories, Albuquerque, NM 87185, USA

Functionalized lipid bilayers with dithioamide receptors at the surface and pyrene labels in the hydrophobic interior showed a selective fluorescence response to mercuric ion with sensitivity limits at the ppb level.

The release of mercury into the environment originates from a variety of man-made and natural sources, including fossil fuel combustion and the electronics industry.[1] As many mercurial compounds are highly toxic, the monitoring of mercurials in the environment and in industrial waste streams is highly desirable. The development of optically responsive sensor materials for the detection of heavy metal ions has received much attention in recent years offering an inexpensive and robust sensor platform with remote detection capability. Often the sensor material employs the use of ion recognition sites to selectively bind specific analytes from solution. In particular, sensors that can detect mercuric ion have been prepared using porphyrins,[2] bioreceptors,[3] borates[4] and polyamines[5] as the ion recognition ligands. Typically the recognition group operates in conjunction with a neighboring chromophore that produces a change in spectral properties upon binding. We describe here a novel sensor material that uses a molecular assembly as a platform for ion recognition as well as a reversible and sensitive optical transducer to the binding event.

Previously[6] we showed that a distearylphosphatidylcholine (DSPC) bilayer doped with a synthetic lipid having an iminodiacetic acid headgroup and a pyrene label in the tail could detect sub-ppb levels of Cu^{2+} selectively. The selectivity was determined to be a function of the ion binding headgroup, however, the mechanism of the fluorescence response and generality of the detection approach was uncertain. Herein, we describe a new sensor tailored for the binding and detection of 'soft' metal ions previously not recognized by the iminodiacetic acid group. As the recognition ligand we chose the thioamide functional group for selective detection of mercuric ion.[7,8] Lipid **1**,‡ which contains the dithioamide headgroup, was prepared by a series of steps starting from compound **2**.[9] The alcohol headgroup of **2** was converted to the primary amine by mesylation of the alcohol, followed by azide substitution with sodium azide in DMF, and then LAH reduction. The reaction of this amine with 8-(4-nitrophenyl)-3,6-dioxaoctanoate-1-dibutylamide, prepared through two steps from 3,6-dioxaoctanedioic acid, yielded the diamide product **3** in 83% yield. The dithioamide **1** was obtained as a light yellow–green viscous liquid in 75% yield through the reaction of **3** with P_2S_5 in pyridine at elevated temperature for 24 h followed by flash column chromatography.



Lipid bilayer preparation is briefly described below; a more detailed description can be found elsewhere.[10] Films of 5% **1** in DSPC were prepared by evaporation of a chloroform solution of the lipids on the inside of a conical tube. The films were then hydrated in a MOPS buffer solution (pH 7.4, 0.02 M morpholinopropanesulfonic acid–0.10 M NaCl) at 65 °C with vortex mixing. The solution temperature was maintained near room temperature while being probe sonicated for 12 min using a 2 mm tip at a power of 25 W under a nitrogen atmosphere. Following sonication the solution was centrifuged and the supernatant passed through a 0.2 μm filter. Total lipid incorporated into the bilayers was 50% as determined by phosphate analysis.[11] The **1**/DSPC aggregates imaged with transmission electron microscopy (not shown here), using a 1% ammonium molybdate stain, formed disc-like structures with no apparent inner volume unlike the typical spherical structures found with DSPC liposomes. Although the structural geometry and headgroup polarity of the lipid components determine the packing geometry of the bilayer,[11] it is interesting to find that incorporation of small amounts of **1** can significantly alter the DSPC bilayer geometry. Details of these and related results will be described elsewhere.

The fluorescence spectrum of the 5% **1**/DSPC lipid bilayers in buffered solution shows emission maxima from both the pyrene monomer at 376 nm and the excimer at near 470 nm [Fig. 1(*a*)]. With a total lipid concentration of 0.05 mM the observed excimer to monomer intensity ratio (*E*/*M*) is 2.2. Addition of certain metal ions (chloride salts) into solution causes a decrease in the fluorescence intensity of the pyrene excimer with a concomitant increase in the monomer emission. A highly selective response was found for mercuric ion with a limit of detection at 100 nM (20 μg l^{-1}). Fig. 1(*b*) shows an example of the fluorescence response from the 5% **1**/DSPC bilayers to the presence of 1.0 mM Hg^{2+}. The *E*/*M* response for Hg^{2+} was linear from a concentration of 10^{-7} to 10^{-4} M on a semilogarithmic plot shown in Fig. 2. Against the heavy metal

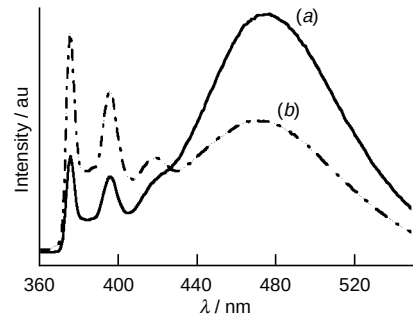


Fig. 1 Fluorescence spectra of 5% **1**/DSPC lipid bilayers in MOPS buffer solution (pH 7.4) in the absence (*a*) and presence of 1.0 mM $HgCl_2$ (*b*)

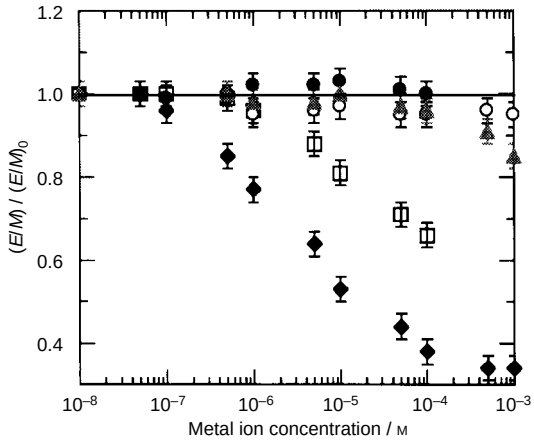

Fig. 2 Plot of the normalized ratio of fluorescence intensities from pyrene excimer to monomer (*E/M*) *vs.* metal ion concentration, showing metal ion selectivity of the 5% **1**/DSPC bilayers. Selectivity was in the order Hg^{2+} (◆) > Cu^{2+} (□) ≫ Cd^{2+} (▲) > Pb^{2+} (●) and Mn^{2+} (○). Equilibration of response took only moments following addition of metal ion and slight stirring.

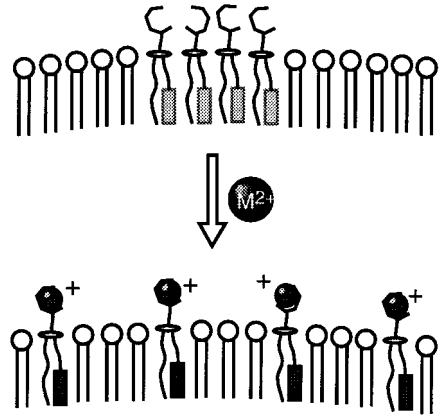

Fig. 3 Illustration of lipid molecule aggregational changes upon metal ion binding to receptor sites. Initially the receptor **1** is phase separated from the DSPC matrix. Metal ion complexation with the receptor and formation of charged headgroups causes static repulsion of the pyrene labeled molecules and loss of local aggregation.

ions Mn^{2+}, Ni^{2+}, Ca^{2+}, Cr^{3+}, Co^{2+} and Pb^{2+}, the bilayers were unresponsive up to mM concentrations. Of the metals evaluated only Cu^{2+} and Cd^{2+} gave responses with 10- and 1000-fold lower sensitivity, respectively, compared to Hg^{2+}. The material was also insensitive to high concentrations (100 mM) of monovalent alkali metals (*i.e.* Na^+, Li^+, K^+). Response times were rapid, limited only by the rate of mixing of the solution. To regenerate the material an excess of EDTA was added to solution to remove metal ions bound to the recognition sites. Complete fluorescence recovery was realized in a few minutes and the material could be reused. As a control, compound **3**, which has a poor metal chelating headgroup, when prepared as a bilayer with DSPC and tested for metal sensitivity showed no response to any of the above mentioned metal ions.

The observed fluorescence response to selected metal ions is due to a change in aggregational properties of the pyrene labeled lipid in the DSPC matrix. In the absence of metal ion, molecules of lipid **1** tend to aggregate into pools within the bilayer due to differences between the physical state of the two membrane components. At room temperature, DSPC (T_c = 55 °C) forms crystalline domains causing a partitioning from the liquid phase of lipid **1** (T_c < room temperature). This creates high local concentrations of pyrene which increases the collision rate of the fluorophores subsequently producing a large population of pyrene excimers compared to monomers.[12] Metal ion binding to the dithioamide headgroup induces a reorganization of molecules in the molecular assembly. Aggregates of **1** are dispersed into the DSPC matrix reducing the local concentration of pyrene resulting in a population shift in the excited state species and the observed loss in intensity of excimer emission and gain in monomer emission. Of the changes that could result from metal ion complexation, formation of a charged headgroup on **1** producing static repulsion between **1**–M^{2+} chelates would lead to the observed changes in molecular organization in the bilayer. Fig. 3 illustrates the molecular aggregate state before and after metal complexation. Initially, when **1** is neutrally charged, lipid organization is controlled by differences in the crystalline and liquid behavior of the components. Following metal ion binding and formation of charged headgroups on **1** electrostatic repulsion overcomes the separation of physical phases resulting in a dispersal of **1** in the matrix.

Although dithioamides have been used as ionophores for 'soft' metals, such as Hg^{2+}, Pb^{2+} and Cd^{2+}, the present sensor shows almost exclusive selectivity for Hg^{2+}. Some slight structural differences that exist between those in literature[7,8] and that on **1**, and the use of a lipid bilayer as the site of recognition, may account for the differences in selectivity. We are continuing to pursue new metal chelating headgroups to increase the range of metal ion selectivities for eventual configuration into a sensor array system for evaluation of mixed wastes.

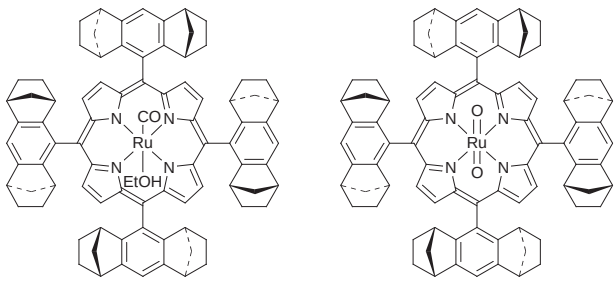
Aerobic enantioselective alkene epoxidation by a chiral *trans*-dioxo(D_4-porphyrinato)ruthenium(VI) complex

Tat-Shing Lai,[a] Rui Zhang,[a] Kung-Kai Cheung,[a] Hoi-Lun Kwong[b] and Chi-Ming Che*[a]†

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China*
[b] *Department of Biology and Chemistry, City University of Hong Kong, Tat Chee Avenue, Kowloon Tong, Hong Kong, PR China*

A dioxoruthenium(VI) complex with a D_4-chiral porphyrin ligand has been prepared and characterized by spectroscopic methods and X-ray crystal analysis; the complex exhibits catalytic activity towards aerobic enantioselective epoxidation of prochiral alkenes with enantioselectivity up to 73% ee at an oxygen pressure of 8 atm.

Among various terminal oxidants used in metalloporphyrin-catalysed organic oxidations,[1] dioxygen is the most appealing since it is both economical and environmental friendly,[2,3] but reports on the use of dioxygen in enantioselective alkene epoxidations are sparse. Chiral Mn(β-ketoiminato) complexes were reported to catalyse asymmetric aerobic alkene epoxidations but aldehyde is required as a sacrificial reducing agent.[4] We herein report the first example of aerobic enantioselective epoxidation of alkenes that does not rely on the use of a co-reductant. The D_4-porphyrin was synthesized according to the literature procedure.[5] The catalyst precursor is [Ru^{II}(por*)(CO)(EtOH)] **1**[6,7] which has been characterized by X-ray crystallography.[7] Oxidation of complex **1** with



1 **2**

m-chloroperoxybenzoic acid in CH_2Cl_2 afforded [Ru^{VI}(por*)O_2] **2** in 60–70% yield after purification by column chromatography.‡ Complex **2** is diamagnetic. Its FAB spectrum shows peaks attributed to M^+, [$M^+ - O$] and [$M^+ - 2O$]. The $\nu_{as}(RuO_2)$ stretch and the oxidation marker band are positioned at 822 and 1019 cm^{-1} respectively. These spectroscopic data agree with the *trans*-dioxoruthenium(VI) formulation.[8,9] The structure with a high R_w value was established by an X-ray diffraction study (Fig. 1).§ The Ru=O distances average 1.74 Å, as expected for a Ru=O bond.[10] Unlike other reported [Ru^{VI}(por)O_2] (por = porphyrinato dianion) complexes,[2,8,9] complex **2** is stable in solid state for months and in purified MeCN or CH_2Cl_2 for more than 24 h. However in the presence of pyrazole, it reacts with alkenes to give the corresponding epoxides with moderate to good enantioselectivities and a paramagnetic ruthenium product that was formulated to be [Ru^{IV}(por*)$(pz)_2$] [pz = pyrazolate, μ_{eff} = 2.94 μ_B (solid sample) at room temp., FABMS *m/z* = 1375] (Scheme 1). The results are summarized in Table 1. For the five alkenes studied, the ee ranged from 20 to 72%. The 65% ee of styrene oxide (entry 1) is among the highest obtained with chiral porphyrin catalysts.[11,12] However, the ee obtained for *cis*-disubstituted alkenes are not as high as those obtained with chiral Mn–Schiff base catalytic system.[13] The absolute configurations of the major enantiomers of styrene oxide and *cis*-β-methylstyrene oxide were determined to be (*R*) and (1*R*, 2*S*) respectively. The epoxidation of *cis*-β-methylstyrene (entry 2) proceeded with high retention of configuration. Epoxidation of *trans*-β-methylstyrene gave only 20% ee and complete retention of configuration (entry 3).

Interestingly, the dioxoruthenium complex catalysed enantioselective aerobic oxidation of alkenes with moderate to good ee (Scheme 2). The results are listed in Table 1. Catalytic oxygenation of styrene using air at 1 atm pressure in CH_2Cl_2 gave very low turnover. However, under 8 atm pressure of oxygen, styrene oxide was obtained with 10 turnovers and 70% ee (entry 1). With *cis*-β-methylstyrene as the substrate, *cis*-β-methylstyrene oxide was observed with 20 turnovers and 69% ee and the ee increased to 73% if toluene was used as the solvent. The *cis*/*trans* ratio was 10 (entry 2), a value similar to that obtained in the stoichiometric reaction. Prolonged reaction time from one to two days did not increase the total turnovers. At the end of the reaction, UV–VIS spectrophotometric analysis of the reaction mixture revealed that the ruthenium–porphyrinato moiety remained intact (Soret band was at 411 nm). A brown diamagnetic complex, which showed no ν(C=O) IR band, was isolated after silica gel-column chromatography using ethyl acetate as the eluent. Its FABMS spectrum revealed

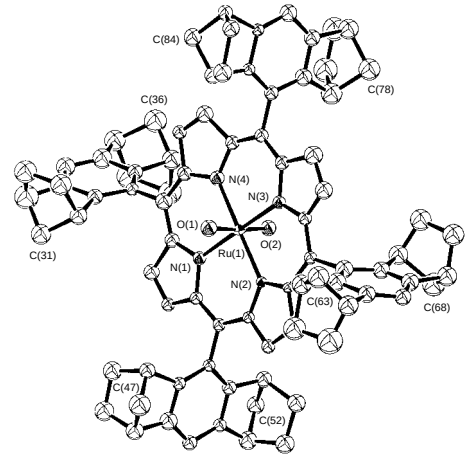


Fig. 1 Perspective drawing of **2**. Selected bond lengths (Å) and angles (°): Ru–O(1) 1.73(1), Ru–O(2) 1.75(1), Ru–N(1) 2.08(1), Ru–N(2) 2.069(10), Ru–N(3) 2.05(1), Ru–N(4) 2.05(1); O(1)–Ru–O(2) 175.4(5), O(1)–Ru–N(1) 91.1(5), N(1)–Ru–N(2) 90.3(4), N(1)–Ru–N(3) 178.3(5).

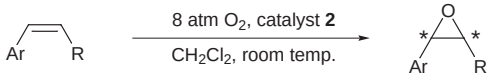
[a] Stoichiometric reactions were conducted at room temperature for 12 h; oxidant 4 mg, substrate 200 mg, pyrazole 50 mg in 5 ml CH_2Cl_2 unless otherwise stated. [b] Reactions were performed at room temp. at *ca.* 8 atm for 22–24 h; catalyst 4 mg and substrate 40 mg in 4 ml CH_2Cl_2 unless otherwise stated. [c] Yield were calculated based on the amount of ruthenium complex. [d] Enantiomeric excesses were determined by chiral GC (J&W Scientific Cyclodex B; length 30 m for entries 1, 2, 4 and 5, chiraldex G-TA, 30 m for entry 3). [e] The product yields for the calculation of turnover no. were determined by GC with *p*-dichlorobenzene or *p*-bromochlorobenzene as internal standards. [f] In benzene. [g] Absolute configuration was determined by comparison with an authentic sample. [h] Absolute configuration was determined by matching the order of elution of the two enantiomers on a Cyclodex-B column. [i] In toluene. [j] Absolute configuration was determined by comparing its ^{1}H NMR spectrum in the presence of $Eu(hfc)_3$ with that of a sample of known enantiomeric composition, J. T. Groves and R. S. Myres, *J. Am. Chem. Soc.*, 1983, **105**, 5791.



Scheme 2

a $[Ru(por^*)(C_9H_{10}O)]$ ion peak [*m/z* = 1377 (20%)]. The dioxoruthenium(VI) complex is likely to be the active intermediate of the reaction, since with the exception of 1,2-dihydronaphthalene, both the catalytic and stoichiometric reactions produced similar ee for the same substrate, and thus the mechanism of this reaction could be similar to that of the $[Ru(tmp)O_2]$ (H_2tmp = tetramesitylporphyrin) system reported by Groves and Quinn.[2] As the Ru–D_4-porphyrin moiety has survived the oxidation, we envisage that high catalytic turnovers can be achieved through optimizing the reaction conditions. Thus this work has provided a starting point for designing future catalysts for efficient aerobic enantioselective epoxidation without the need of a sacrificial reducing agent.

‘Phospha-Wittig’ reactions using isolable phosphoranylidenephosphines ArP=PR$_3$ (Ar = 2,6-Mes$_2$C$_6$H$_3$ or 2,4,6-But$_3$C$_6$H$_2$)

Shashin Shah and John D. Protasiewicz*†

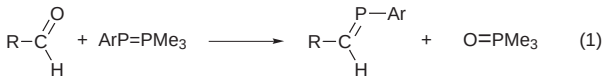
Department of Chemistry, Case Western Reserve University, Cleveland, OH 44106-7708, USA

Phosphoranylidenephosphines DmpP=PMe$_3$ (1a, Dmp = 2,6-Mes$_2$C$_6$H$_3$) and Mes*P=PMe$_3$ (1b, Mes* = 2,4,6-But$_3$C$_6$H$_2$) act as ‘Phospha-Wittig’ reagents with aldehydes providing phosphaalkenes [ArP=C(H)R] in high yields.

The successful synthesis of a ‘true phosphobenzene’, Mes*P=PMes* (Mes* = 2,4,6-But$_3$C$_6$H$_2$),[1] signaled a new era in the study of phosphorus–phosphorus double bonds.[2] We have recently uncovered reactions of [Cp$_2$Zr=PDmp(PR$_3$)] (Dmp = 2,6-Mes$_2$C$_6$H$_3$) which produce phosphoranylidenephosphines DmpP=PR$_3$ (R = Me or Bu).[3] Phosphoranylidenephosphines are formally the products of phosphinidene transfer to phosphines.[4] These novel materials contain PP multiple bonding of a very differing nature, as exemplified by the following resonance forms:

$$\mathrm{ArP{=}PR_3 \leftrightarrow Ar\bar{P}{-}\overset{+}{P}R_3}$$

Similar resonance forms are commonly drawn for Wittig reagents R$_2$C=PR$_3$, and the nature of the bonding between the P and C atoms in these species has been reviewed.[5] Bearing such a close kinship to Wittig reagents, it was anticipated that phosphoranylidenephosphines could act as potential ‘phospha-Wittig’ reagents by reacting with aldehydes to generate phosphaalkenes RP=C(H)R [eqn. (1)]. Several transition metal containing systems have been reported that accomplish similar transformations.[6–8] Herein we present the reactivity of the phosphoranylidenephosphines DmpP=PMe$_3$ **1a** and Mes*P=PMe$_3$ **1b** with aldehydes to generate phosphaalkenes.



(1)

Compounds **1a** and **1b** are conveniently prepared by reduction of either DmpPCl$_2$ or Mes*PCl$_2$ with Zn dust in the presence of excess PMe$_3$ in 88–95% yields [**1a**: ^{31}P NMR (C$_6$D$_6$), δ −2.8, −114.7 (J_{PP} 582 Hz); **1b**: ^{31}P NMR (C$_6$D$_6$), δ 4.7, −134.0 (J_{PP} 581 Hz)].[3]‡ In the absence of air and water, compounds **1a**, **b** are stable yellow crystalline solids. Both **1a** and **1b** slowly decompose in solution to lose PMe$_3$ and form DmpP=PDmp and Mes*P=PMes*, respectively (days to weeks).[9]

Reactions of **1a** and **1b** with C=O containing molecules were thus examined. A series of *para*-substituted benzaldehydes reacted with **1a**, **b** in THF to produce the desired phosphaalkenes in excellent isolated yields (Table 1). Work-up involves removal of THF and extraction of the phosphaalkene into hexanes to remove the relatively insoluble O=PMe$_3$. Reaction times, as well as product yields, varied with the nature of the substituent; the most electron releasing substituents required the longest reactions times (2–24 h) and provided the lowest yields. Each reaction produced a single isomer of the phosphaalkene, and the $^2J_{PH}$ coupling constants (24–25 Hz) are consistent with an assignment of *E*-isomers for the products.[10]§

Our new protocol can be contrasted to multistep procedures utilizing sterically hindered primary phosphines such as Mes*PH$_2$. For example, compound **2b** has been prepared in 80% yield after purification by chromatography [eqn. (2)].[10] The primary phosphine Mes*PH$_2$ is obtained by LiAlH$_4$ reduction of Mes*PCl$_2$ and isolated in 80% yield after recrystallization.[11] Our procedure thus represents not only a saving in time but also of material due to phosphaalkene access from the more readily available dichlorophosphine precursors. A more dramatic advance in the utility of the current reaction was realized by the discovery that compounds **1a** and **1b** can be generated and used *in situ*. For example, reaction of DmpPCl$_2$, benzaldehyde, zinc dust and excess PMe$_3$ gives an isolated yield of 95% of DmpP=C(H)Ph. Likewise, Mes*P=C(H)Ph is obtained in 87% yield from Mes*PCl$_2$ under the same conditions.

(2)

The scope of the phosphaalkene forming reactions using **1a** was also investigated. Pentafluorobenzaldehyde, ferrocenecarboxaldehyde and pivaldehyde provided phosphaalkenes **7a**–**9a** in good yields, demonstrating the remarkable tolerance of the phosphoranylidenephosphines to varying functional groups. Reactions of **1a** with ketones proved more problematic,

Table 1 Reactions of aldehydes to give phosphaalkenes

Aldehyde R(H)C=O		Phosphaalkene R(H)C=PAr	Yield (%)	^{31}P{^{1}H} (C$_6$D$_6$)§ δ
	X = H	**2a**	94	240.9
		2b	93	258.5[10]
	Cl	**3a**	90	243.8
		3b	90	261.4
	NO_2	**4a**	92	265.6
		4b	92	284.6
	OMe	**5a**	97	225.4
		5b	87	245.1[15]
	NMe_2	**6a**	78	210.4
		**7a**	96	286.8 (t, J_{PF} 98Hz)
		7b	97	304.3 (t, J_{PF} 93Hz)
		**8a**	61	222.1
		**9a**	91	221.2

however. Acetophenone, benzophenone and cyclohexanone showed no evidence of phosphaalkene formation and yielded extensive amounts of DmpP=PDmp over time.

Effords to extend the reactivity of phosphoranylidenephosphines to systems having less steric hindrance than Dmp or Mes* have been partially successful. Attempts to isolate TripP=PMe_3 (Trip = 2,4,6-$Pr^i_3C_6H_2$) by reduction of $TripPCl_2$ with Zn dust in the presence of PMe_3 resulted in rapid formation of $(TripP)_3$.[12] Addition of benzaldehyde, however, to such reactions results in mixtures of $(TripP)_3$ and TripP=C(H)Ph {$^{31}P\{^1H\}$ (C_6D_6), δ 254.7; ^1H NMR, δ 8.99 [TripP=C(*H*)Ph, d, J_{HP} 25.6 Hz]}, suggesting the presence of a transient TripP=PMe_3 capable of effecting phosphaalkene formation.

Reactions of phosphoranylidenephosphines with aldehydes would be of greater synthetic value if the more readily handled (and cheaper) PPh_3 could replace PMe_3 in these reactions. Unfortunately, efforts to prepare DmpP=PPh_3 by reduction of $DmpPCl_2$ with Zn in the presence of PPh_3 resulted in isolation of DmpP=PDmp. Attempts to generate DmpP=PPh_3 *in situ* for reaction with benzaldehyde also failed. Exchange of the PMe_3 unit in **1a** with added PPh_3 also proved futile. The PMe_3 groups in **1a** and **1b** do undergo exchange with certain non-hindered trialkylphosphines in solution. For example, **1a** and **1b** react quickly with PBu_3 to produce mixtures of **1a**, PMe_3 and DmpP=PBu_3 [**1c**, ^{31}P NMR(C_6D_6), δ 24.1, −151.3 (J_{PP} 589 Hz)] and mixtures of **1b**, PMe_3 and Mes*P=PBu_3 [**1d**, ^{31}P NMR(C_6D_6), δ 19.9, −153.7 (J_{PP} 612 Hz)], respectively.[13,14] Compound **1c** can also be generated *in situ* (as above) from PBu_3 and $DmpPCl_2$, which in the presence of benzaldehyde yields the phosphaalkene DmpP=C(H)Ph and O=PBu_3 in good yields. Work-up, however, requires more effort than the PMe_3 system due to the decreased volatility of PBu_3.

In conclusion, we have demonstrated that readily prepared and isolable phosphoranylidenephosphines are apt phosphinidene carriers in phospha-Wittig reactions. Our procedure represents a significant advance for the synthesis of phosphaalkenes as it utilizes dichlorophosphines directly, rather than derived primary phosphines. High yields and functional group tolerance are further highlights of this phospha-Wittig approach. Further studies of the phosphinidene and atom transfer reactions of these conveniently prepared phosphinidene-carriers are underway.

We thank the National Science Foundation (CHE-9733412) and the Department of Chemistry (CWRU) for support of this research.

Unique cationic, neutral and anionic copper(II) nitrite species in a single compound

Alexander J. Blake, Stuart J. Hill and Peter Hubberstey*†

Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD

Crystallisation from an aqueous/acetonitrile solution of copper(II) nitrite containing bdmppy {bdmppy = 2,6-bis[(3,5-dimethyl)pyrazol-1-yl]pyridine} affords a compound with a unique arrangement of cationic [{Cu(bdmppy)(NO_2)}$_2$(μ-NO_2-κ*O*:κ*N*)]$^+$, neutral [Cu(bdmppy)(NO_2)$_2$] and anionic [Cu(NO_2)$_4$]$^{2-}$ copper(II) nitrite species, which feature diverse copper–nitrite coordination modes.

Copper nitrite complexes with ancillary *N*-donor ligands are of current interest[1–4] following the elucidation of the structures of several copper-containing nitrite reductase enzymes, such as *Achromobacter Cycloclastes*[5] or *Alicaligenes Xylosoxidans.*[6] The nitrite anion is a versatile ligand to copper(II)[7,8] exhibiting nitro (*via* the nitrogen),[9] nitrito (*via* an oxygen),[10] chelating (*via* both oxygens),[8] or bridging (*via* the nitrogen and an oxygen)[11] coordination modes. This versatility is displayed in the complex [Cu(L)(NO_2)][PF_6] {L = tris[(2-pyridyl)methyl]-amine}, where two structural isomers have been determined, differing only in nitro or nitrito co-ordination.[2b] In nitrite reductases the site of nitrite binding has been shown to involve three histidine donors;[5,6] the mode of nitrite coordination, although still to be confirmed, is thought to be asymmetric bidentate (*cis*-monodentate).[6]

Using the tridentate *N*-donor ligands 2,6-bis(pyrazol-1-yl)-pyridine (bppy) and its tetramethyl analogue 2,6-bis[(3,5-dimethyl)pyrazol-1-yl]pyridine (bdmppy) to mimic the three histidine donors of the enzymes, we have investigated the chemistry of Cu(bppy) and Cu(bdmppy) moieties with the nitrite anion. As part of this work we have synthesised and structurally characterisated the unique complex [{Cu-(bdmppy)(NO_2)}$_2$(μ-NO_2-κ*O*:κ*N*)]$_2$[Cu(bdmppy)(NO_2)$_2$]$_2$[Cu-(NO_2)$_4$]·MeCN **1**, which we describe herein.

The stoichiometric addition of an aqueous solution of 'copper nitrite' [prepared by the addition of an aqueous solution of $CuSO_4$·5H_2O to a stoichiometric amount of Ba(NO_2)$_2$] to a solution of bdmppy resulted in a green solution, slow evaporation of which in air gave a green crystalline product **1**. Single crystal IR spectroscopy confirmed the presence of ligand and nitrite **1**.‡

The structure of complex **1** (Fig. 1) was determined by single crystal X-ray diffraction.§ Its unit cell consists of seven copper centres; two dimeric cationic [{Cu(bdmppy)(NO_2)}$_2$(μ-NO_2-κ*O*:κ*N*)]$^+$ units, two neutral [Cu(bdmppy)(NO_2)$_2$] units, a [Cu(NO_2)$_4$]$^{2-}$ anion and an acetonitrile solvent molecule. Three distinct copper–nitrite coordination modes occur (Scheme 1). Following precedence[7] these are defined as (i) *cis*-monodentate, (ii) *trans*-monodentate and (iii) bridging. For all *cis*-monodentate nitrites, the second oxygen atom is remotely located (> 2.50 Å) in an axial coordination position. This contact is ignored, however, in describing the nitrite coordination mode and the copper(II) coordination geometry owing to the fact that it is a consequence of constraints imposed by the anion geometry.[7]

The [{Cu(bdmppy)(NO_2)}$_2$(μ-NO_2-κ*O*:κ*N*)]$^+$ units [Fig. 1(*a*)] are dimeric [Cu··Cu 5.304(1) Å] and represent the first fully structurally characterised example of the κ*O*:κ*N* bridging motif in copper(II) chemistry. Previously, a disordered example has been described in [{Cu(dien)}$_2$(μ-bimpydz)][NO_2]-[BF_4]$_3$·MeCN [dien = diethylenetriamine; bimpydz = 3,6-bis-(imidazol-1-yl)pyridazine].[11] Each of the two independent copper atoms has all three nitrogen atoms from the bdmppy ligand and an oxygen atom from a *cis*-monodentate nitrite in the basal positions of a square pyramidal geometry [Cu(2)–N 1.964(3), 1.997(3), 2.010(3); Cu(2)–O(31) 1.962(3); Cu(3)–N 1.968(3), 2.006(4), 2.011(4); Cu(3)–O(51) 1.957(3) Å]. The bridging nitrite occupies the apical position of both copper co-ordination spheres [Cu(2)–N(4) 2.307(4), Cu(3)–O(41) 2.267(3) Å]. The second oxygen atoms of each of the *cis*-

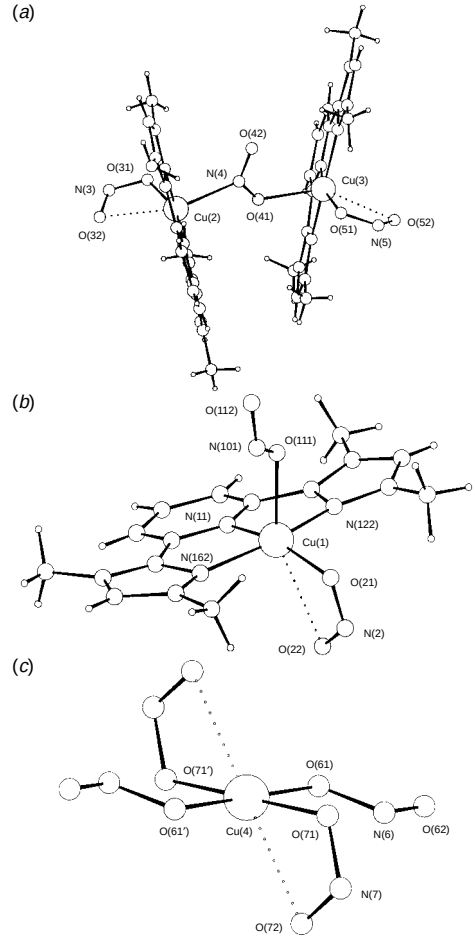

Fig. 1 The molecular structures of the three unique copper nitrite species in **1**: (*a*) the dinuclear [{Cu(bdmppy)(NO_2)}$_2$(μ-NO_2-κ*O*:κ*N*)]$^+$ cation, (*b*) the neutral [Cu(bdmppy)(NO_2)$_2$] species and (*c*) the [Cu(NO_2)$_4$]$^{2-}$ anion

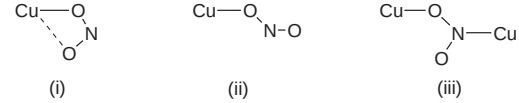

Scheme 1 Copper–nitrite coordination modes: (i) *cis*-monodentate (asymmetric bidentate); (ii) *trans*-monodentate; (iii) bridging

monodentate nitrites are weakly bound in axial positions [Cu(2)–O(32) 2.577(3), Cu(3)–O(52) 2.576(3) Å].

In the neutral [Cu(bdmppy)$(NO_2)_2$] species [Fig. 1(*b*)], the copper atom has a coordination geometry based on a square pyramid, with the three nitrogen atoms of the bdmppy ligand occupying three of the basal positions [Cu(1)–N(11) 1.978(4), Cu(1)–N(122) 1.990(5), Cu(1)–N(162) 1.984(4) Å]. The remaining basal site is occupied by a *cis*-monodentate nitrite [Cu(1)–O(21) 1.958(4) Å]. The apical position is occupied by a weakly bound disordered nitrite which adopts either a *trans*-monodentate [67%; Cu(1)–O(111) 2.168(8) Å] or *cis*-monodentate [33%; Cu(1)–O(121) 2.15(3), Cu(1)–O(122) 2.90(3) Å] co-ordination mode. Overall the copper atom adopts an N_3O_2 donor set. Again the second oxygen atom of the basally located *cis*-monodentate nitrite is weakly bound in the remaining axial position [Cu(1)–O(22) 2.655(4) Å].

The $[Cu(NO_2)_4]^{2-}$ anion [Fig. 1(*c*)] is situated on a centre of inversion, and comprises two symmetry related *cis*-monodentate [Cu(4)–O(71) 2.039(5) Å] and two symmetry related *trans*-monodentate nitrites [Cu(4)–O(61) 1.955(4) Å], resulting in a square planar CuO_4 coordination sphere. The second oxygen atoms of the *cis*-monodentate nitrites are weakly bound in the two remaining axial positions [Cu(4)–O(72) 2.518(5) Å]. Although the anions $[Cu(NO_2)_5]^{3-}$ and $[Cu(NO_2)_6]^{4-}$ are well documented in the literature as salts of the form $M^I_3[Cu(NO_2)_5]$ (M^I = K, Cs),[12] and $M^I_2M^{II}[Cu(NO_2)_6]$ (M^I = Tl, K, Rb, Cs; M^{II} = Ca, Sr, Ba, Pb)[13] or $M^I_5M^{III}[Cu(NO_2)_6]_2$ (M^I = Tl, K, Rb, Cs; M^{III} = Ce)[14] there is only one previous report of the $[Cu(NO_2)_4]^{2-}$ anion, as the structurally uncharacterised 1,2-xylylenebis(triphenylphosphonium) salt.[15] Hence this is the first reported structure containing the tetranitritocuprate(II) anion.

The only other copper(II) nitrite in the literature containing a *mer*-directed tridentate N-donor ligand is [Cu(terpy)(NO_2)-$(H_2O)][NO_2]\cdot H_2O$, **2** (terpy = 2,2′:6′,2″-terpyridyl). Despite the similarity of the tridentate ligands, the two complexes show very different formulations. Complex **2** has a square based pyramidal geometry and is ligated by the three N-donors of the terpy ligand, a monodentate nitrite anion and an axially located water molecule.[9]

We thank the EPSRC for a maintenance grant (to S. J. H.) and for the provision of a four-circle diffractometer.

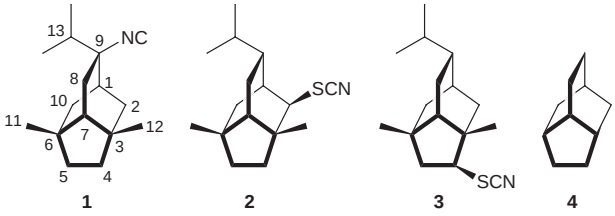
An intramolecular rhodium carbenoid C–H insertion approach to chiral isotwistanes. Synthesis of (−)-neopupukean-4,10-dione and (−)-neopupukean-10-one

A. Srikrishna*† and Santosh J. Gharpure

Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India

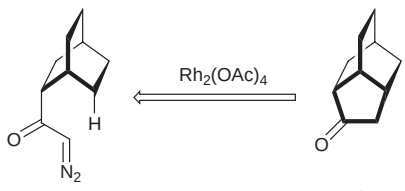
The first synthesis of a chiral neopupukeanane starting, from (*R*)-carvone and employing a double Michael reaction and a regioselective intramolecular rhodium carbenoid C–H insertion reaction as key steps, is described.

Recently, Scheuer and co-workers, during their biosynthetic experiments directed towards discovering the origin of the isocyano group in marine sponges, isolated[1] a new rearranged tricyclic sesquiterpene, 9-isocyanoneopupukeanane **1**, from the sponge *Ciocalypta* sp. whose relative stereostructure was established with the help of extensive 2D NMR spectroscopy. Subsequently, the research groups of Scheuer and Higa reported[2] the isolation of two thiocyanato derivatives of this new class of sesquiterpenes, 2-thiocyanatoneopupukeanane **2** from the sponge *Phycopsis terpnis* from Okinawa and 4-thiocyanatoneopupukeanane **3** from an unidentified species from Pohnpei. A characteristic of the structures of these neopupukeananes is the presence of a unique 9-isopropyl-3,6-dimethyltricyclo[4.3.1.0^{3,7}]decane carbon framework incorporating two quaternary carbon atoms besides the presence of the isocyano and thiocyanato functionalities, making them challenging synthetic targets. In continuation of our interest in the synthesis of chiral pupukeanones from (*R*)-carvone,[3] we herein report the first total synthesis of a chiral neopupukeanane[4] employing a regioselective intramolecular rhodium carbenoid C–H insertion reaction[5] as the key step for the generation of the isotwistane **4** carbon framework.



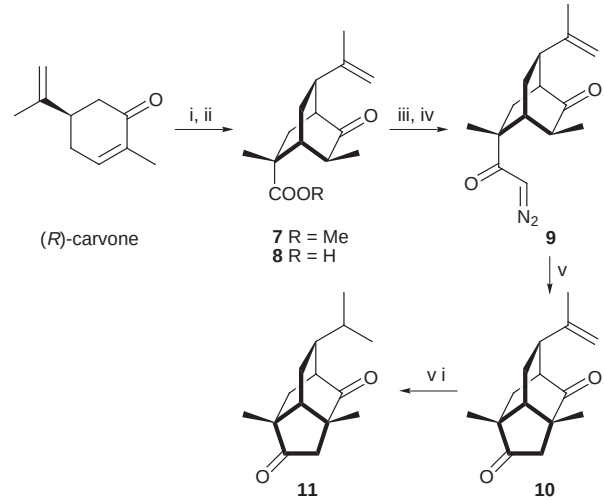
1 **2** **3** **4**

It was envisaged that the rhodium catalysed decomposition of the bicyclic diazo ketone **5** will generate the isotwistane **6** (Scheme 1) in a regioselective manner *via* the preferential formation of a five-membered ring by the insertion of the intermediate rhodium carbenoid into the only available C–H bond. A double Michael reaction on carvone[6] was chosen for the generation of an appropriate bicyclic precursor of an analogue of the diazo ketone **5**, which could be suitable for



5 **6**

Scheme 1

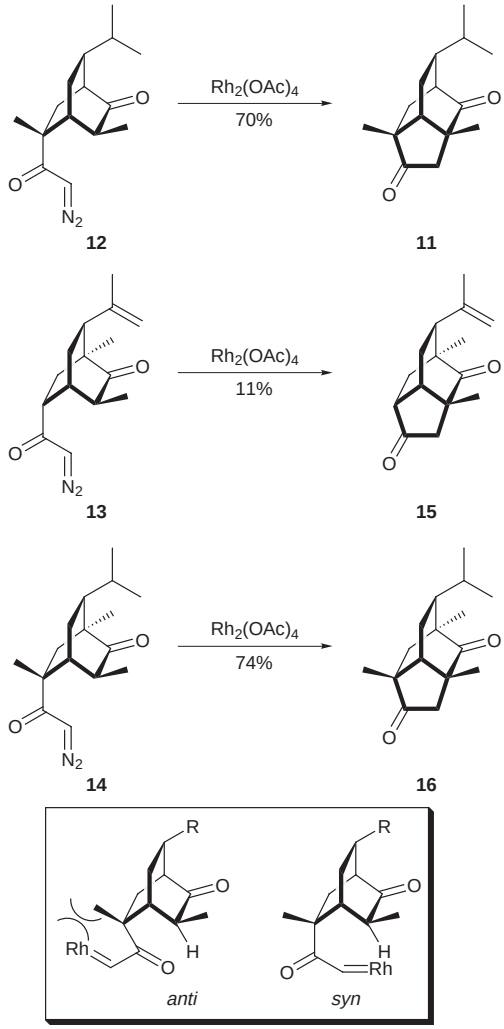


(*R*)-carvone **7** R = Me **8** R = H **9** **11** **10**

Scheme 2 *Reagents and conditions*: i, LiHMDS, $H_2C{=}CMeCO_2Me$, hexane–Et_2O (9 : 1), −78 °C → room temp., 50%; ii, 10% aq. NaOH, MeOH, reflux, 8 h, 92%; iii, $(COCl)_2$, C_6H_6, 2 h; iv, CH_2N_2, Et_2O, 0 °C → room temp., 2 h 90% (2 steps); v, $Rh_2(OAc)_4$ (cat.), CH_2Cl_2, reflux, 2 h, 90%; vi, H_2 (1 atm), 10% Pt/C, EtOH, 4 h, 96%

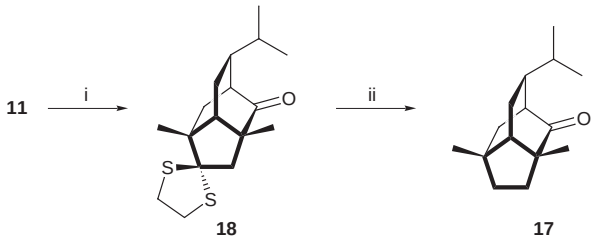
further elaboration into chiral neopupukeananes. Thus, double Michael reaction of (*R*)-carvone with LiHMDS and methyl methacrylate furnished the bicyclic keto ester **7** in a regio- and stereo-selective manner (Scheme 2) which, on base-catalysed hydrolysis, furnished the keto acid **8**. It is worth mentioning that in the keto acid **8**, the stereochemistry of the secondary methyl group at the carbon α to the keto group is *anti* with respect to the acid group, which was perfectly suited for the projected C–H insertion reaction for the generation of the tricyclic system. Reaction of the acid **8** with oxalyl chloride followed by treatment of the resulting acid chloride with an excess of ethereal CH_2N_2 furnished the diazo ketone **9**. Treatment of the diazo ketone **9** with a catalytic amount of rhodium acetate in refluxing CH_2Cl_2 led to the formation of the isotwistane dione **10** containing the complete carbon framework of neopupukeananes, *via* the regioselective C–H insertion of the intermediate keto carbenoid. The structure of neopupukean-13-en-4,10-dione **10** was established from its spectral data.‡ Catalytic hydrogenation in EtOH using 10% Pt/C transformed the dione **10** into neopupukean-4,10-dione **11**.‡ To test the generality of the C–H insertion, the reaction was carried out with three other bicyclic diazo ketones **12**–**14** to generate the isotwistanes **11**,**15** and **16** (Scheme 3). It is interesting to note that the reaction was not so facile when there is no tertiary methyl group at the α′-position of the diazo ketone, *cf.* **13**; perhaps the steric crowding due to the tertiary methyl group forces the rhodium carbenoid to occupy the *syn* orientation.

The difference in the steric crowding of the two ketones in dione **11** was exploited for the conversion of neopupukean-4,10-dione into neopupukean-10-one **17** (or 9-epineopupukean-2-one). Thus, treatment of dione **11** with $HS(CH_2)_2SH$



Scheme 3

(1 equiv.) in the presence of $BF_3{\cdot}OEt_2$ in benzene at room temperature generated the thioketal **18** (Scheme 4), which on desulfurisation with Raney nickel furnished neopupukean-10-one **17**.‡



Scheme 4 *Reagents and conditions*: i, $HS(CH_2)_2SH$, $BF_3{\cdot}OEt_2$, C_6H_6, room temp., 8 h, 82%; ii, Raney Ni, EtOH, reflux, 9 h, 85%

In conclusion, we have developed a rapid methodology for the generation of chiral isotwistanes, containing the neopupukeanane carbon framework, employing a regioselective intramolecular rhodium carbenoid C–H insertion reaction. In addition to being the first synthesis of neopupukeanones, the generation of the chiral compounds, brevity and simplicity are the highlights of the present strategy. Currently, we are investigating the extension of this methodology for the synthesis of other neopupukeananes to establish the absolute stereochemistry of the natural products.

We thank the Department of Science and Technology, New Delhi, for financial support and the Council of Scientific and Industrial Research for the award of a research fellowship to S. J. G.

Further evidence that the polycyclization reaction by oxidosqualene-lanosterol cyclase proceeds *via* a ring expansion of the 5-membered C-ring formed by Markovnikov closure. On the enzymic products of the oxidosqualene analogue having an ethyl residue at the 15-position

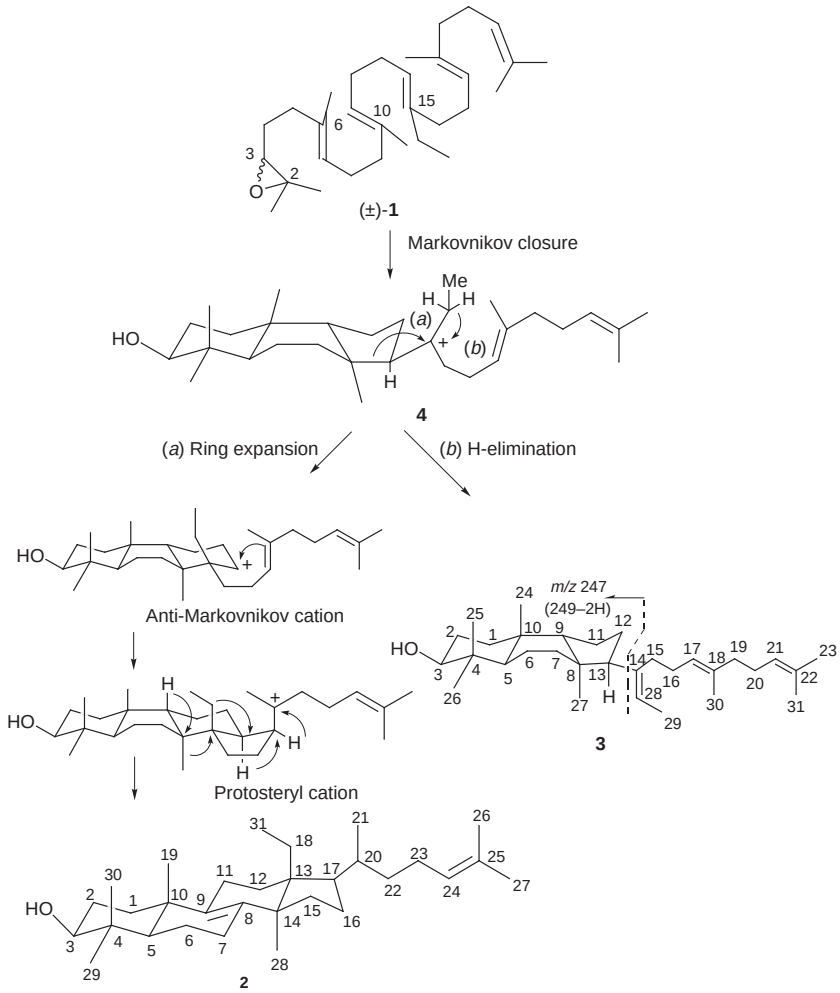
The incubation of the substrate analogue, (3*S*)-(6*E*,10*E*,14*E*,18*E*)-15-ethyl-2,6,19,23-tetramethyl-2,3-epoxytetracosa-6,10,14,18,22-pentaene (-)-1 with 2,3-oxidosqualene-lanosterol cyclase from pig liver gave products 2 (a lanosterol homologue) and 3 (a tricyclic product), definitively demonstrating that the cyclization of oxidosqualene proceeds *via* the expansion reaction from a 5- to a 6-membered ring for the C-ring formation of lanosterol.

In a preceding paper,[1] we reported the unprecedented cyclization products given by 2,3-oxidosqualene cyclase: substitution of the ethyl groups with methyl groups at both C-10 and C-15 of oxidosqualene halts the enzymic reaction at the monocyclic ring stage. This demonstrated that the cyclizing reaction to the protosterol cation proceeds *via* discrete carbocation intermediates, although usually this reaction has been assumed to be concerted, and gives the first example of the cyclase reaction being stopped at the stage of the initial A-ring formation. To gain more insight into the fine control of the polyolefin cyclization, we have now examined the enzymic reaction of the analogue **1**, in which only the methyl group at C-15 in the squalene backbone has been replaced by an ethyl group. Here, we report the tricyclic and tetracyclic formed products by the cyclase and give further evidence for the involvement of a C-ring expansion process in the formation of lanosterol.

The synthesis of (±)-**1** was essentially the same as previous papers.[1,2] The coupling reaction of (2*E*,6*E*)-1,10-dibromo-3,7,11-trimethyldodeca-2,6-diene-11-ol with (2*E*,6*E*)-1-bromo-



Scheme 1

3,7,11-trimethyldodeca-2,6,10-triene, by treatment of cuprous iodide with lithium pyrrolidide,[3] afforded the desired **1**, the squalene derivative having ethyl groups at C-10 and C-15, and 2,3:22,23-dioxidosqualene in the yields of 36, 29 and 6%, respectively, which could be easily separated by SiO_2 column chromatography due to remarkable differences of the products' polarity. Enzyme preparation from the microsomal fractions of pig liver was carried out according to the literature.[1,4] A sample of (±) **1** (38 mg) was anaerobically incubated for 24 h at 37 °C and lyophilized. Extraction of the reaction residues with hexane gave two new peaks (**2** and **3**) *via* GLC. The behavior of **2** and **3** on SiO_2 TLC was the same, irrespective of solvent system. By using an argentation SiO_2 column (10%), the metabolites **2** (solid) and **3** (oil) were isolated in yields of 5.8 and 2.2 mg, respectively. The total conversion was 42% based on one enantiomer of (±)-**1**. The specific rotations of **2**, **3** and the recovered **1** were +21.58 (*c* 0.417, $CHCl_3$), +13.25 (*c* 0.083, $CHCl_3$) and +1.93 (*c* 0.497, EtOH), respectively, indicating that the 3*S* form, (-)-**1**, was selectively transformed. The molecular composition of **2** was determined to be $C_{31}H_{52}O$ from EI-HRMS (*m/z* 440.4043; requires 440.4018) and the following characteristic mass fragments were observed: *m/z* 440 (M^+, 56%), 425 (M^+-Me, 100%), 407 (M^+-Me-H_2O, 21%); the fission patterns and peak intensities were the same as authentic lanosterol (*m/z* 426, 411, 393). The molecular composition of **3** was also determined to be $C_{31}H_{52}O$ from EI-HRMS (*m/z* 440.4035); *m/z* 440 (M^+), 247 (249-2H; tricyclic moiety). The hydroxy groups of **2** and **3** were confirmed to be equatorial from the coupling constants of H-3 (dd, *J* 4.5, 12 Hz). Detailed analyses of NMR spectra including ^1H–^1H COSY 45, HOHAHA, NOESY, DEPT, HMQC and HMBC experiments unambiguously verified the structures of **2** and **3** to be a lanosterol homologue and a tricyclic compound, respectively. In the HMBC spectrum of **2**, the crosspeak of 19-Me with the sp^2 quaternary C-9 and that of 28-Me with C-8 confirmed the position of the double bond, and the correlations of 28-Me and 31-Me to C-13 also proved the ethyl position. The clear NOEs of 31-Me with 21-Me and of 19-Me with 31-Me indicated that all the stereo-orientations of **2** were identical to those of lanosterol. The stereochemistry at C-20 has yet to be established, but it should have the same *R* configuration as natural lanosterol; the chemical shift (δ_C 35.1) of C-20 was homogenous. On the other hand, **3** had a partially cyclized 6/6/5 fused-ring system possessing a chair/boat geometry. The boat geometry of the B-ring was confirmed by the apparent correlation of H-5 with 27-Me and that of H-9 with 24-Me in the NOESY spectrum. The NOE correlation of 27-Me with H-13 indicated the α-orientation of H-13. The ethylidene moiety was also inferred from the HMBC data.

Formation of the two products **2** and **3** suggests that a common precursor **4**, the tricyclic cation having a 6/6/5-fused system, should be produced before the subsequent reactions occur (Scheme 1). The carbocation intermediate **4**, a thermodynamically favored product by Markovnikov closure, undergoes ring expansion toward the anti-Markovnikov cation of the 6-membered C-ring to form the protosterol cation, which is then subjected to four sequential antiparallel 1,2-shifts of two hydrogens, the ethyl group and the methyl group, followed by deprotonation leading to double bond formation [path (*a*)], just as does the natural substrate. It is noticeable that the *ethyl* group also underwent the migration reaction. If a proton is eliminated from the ethyl group, the tricyclic **3** is formed [path (*b*)]. The ring expansion competes with the deprotonation process from the ethyl group. The tricyclic fused-A/B/C ring system has also been isolated from the enzyme products of the $\Delta^{18,19}$ double bond *Z*-isomer,[5] the truncated substrate[6] and the 20-oxa analogue.[6] Recently, Corey proposed the idea, on the basis of the enzyme reactions of the truncated C_{20} and 20-oxa analogues, that the 6-membered C-ring of lanosterol is formed *via* ring expansion of the 5-membered cation, previously produced by Markovnikov closure. However, the enzyme reactions were halted at the intermediate stage without completion of the cyclase reaction, thus, the ring expansion process remained unclear. In contrast, analogue **1** afforded the complete lanosterol skeleton **2** along with capture of the intermediate **3**; therefore, this finding provides strong evidence for the involvement of a ring expansion process. The intermediate **4** would have been formed in a Markovnikov fashion and as a result of the longer lifetime of **4** due to the enhanced steric repulsion between the methyl at C-10 and the ethyl at C-15, compared to that between the two methyl groups of natural squalene, the detailed mechanism of which has been discussed.[6b] Kyler and co-workers have assumed that substitution on the β-side of the folded conformation interferes with the normal cyclization.[7] A good conversion of **1** to **2**, despite the ethyl moiety being situated on the β-face, was a contrast to this hypothesis inferred from Bakers' yeast. This inconsistency may originate from the difference in the biological source used. Indeed, no reaction was detectable for **1** or the diethylated oxidosqualene with the yeast cyclase.[1] The binding site and/or cavity size for the methyl group at C-15 may be different for the yeast and mammal enzymes. In the case of the diethylated analogue, only the initially cyclized A-ring was formed,[1] while the monoethylated **1** gave the subsequent tricyclic and tetracyclic reaction products. These results also imply that the 10-methyl group plays a critical role in the normal polycyclizaton reaction by the mammalian cyclase, which is consistent with a previous report.[8]

Weak intermolecular interactions in sulfonamide salts: structure of 1-ethyl-2-methyl-3-benzyl imidazolium bis[(trifluoromethyl)sulfonyl]amide

Jacob J. Golding,*[a] Douglas R. MacFarlane,[a] Leone Spiccia,[a] Maria Forsyth,[b] Brian W. Skelton[c] and Alan H. White[c]

The crystal structure of a 1,2,3-trisubstituted imidazolium salt of the bis[(trifluoromethyl)sulfonyl)]amide ion is presented; this salt is a prototype for similar, room temperature liquid, imidazolium salts; the structure shows that the anion and cation interact weakly, with little if any hydrogen bonding present.

The use of molten organic salts as electrolytes in a variety of electrochemical devices, such as photo-electrochemical cells,[1] is becoming more widespread. As these applications become more varied,[2] the need for a variety of new, low melting point, fluid, ionic liquids is apparent. In the investigation of novel ionic liquids, interactions between the anion and cation are of great interest, as are the conformational states of each component of the salt, since the key transport properties (conductivity and diffusivity) are determined to a significant extent by these interactions. The relationship between structure and physical characteristics of many ionic liquids is yet to be fully quantified. The direct insight into the spatial relationship between cation and anion afforded by the elucidation of crystal structures provides a basis from which features of the ionic liquid itself can be understood, since the short range order and interactions of related, non-crystalline compounds may be similar to those of the crystalline form.

It is becoming clear[1–3] that anions (and cations) with diffuse charges and negligible hydrogen bonding yield the lowest melting points and hence have the greatest potential to produce ionic compounds that are liquid at room temperature. For example, the bis[(trifluoromethyl)sulfonyl]amide ion, $(CF_3SO_2)_2N^-$, has been found to produce low melting point (sub-room temperature in some cases, and completely non-crystalline in others) salts which are also characterized by their high fluidity and high ionic conductivity relative to other molten salts.[3] Owing to a lack of structural information on these types of complexes, the origins of these two important effects (low mp and high fluidity) are not well understood. In this work we present crystal structure data for a low melting (mp ≈ 50 °C) organic salt, 1-ethyl-2-methyl-3-benzyl imidazolium bis[(trifluoromethyl]sulfonyl)amide **1**.‡§

In the only previously reported crystal structure[4] determination of a salt of this anion {magnesium hexaaquobis[(trifluoromethyl)sulfonyl]amide dihydrate}, the anion was subject to molecular distortions[4] due to hydrogen bonding to the water molecules coordinated to the $[Mg(H_2O)_6]^{2+}$ cation. The structure presented here allows a clearer picture of the geometric features of this anion to be observed, in the absence of the hydrogen-bonding interactions which are present in the previous structure.

Fig. 1 shows the crystal structure of **1**. The imidazolium ring lies above the amide nitrogen, with the $-SO_2CF_3$ groups positioned away from the benzyl group. The distances between oxygen, nitrogen or fluorine and the closest hydrogen atoms approximate to van der Waals separations (*ca*. 2.6, 2.7 and 2.55 Å, respectively) indicating no evidence of the presence of strong hydrogen bonding in the crystal lattice.[5] The large degree of thermal motion evident in both ions is also consistent with the absence of any strong interaction between the anion and cation. This implies that ionic, rather than covalent, interactions hold the salt in a low melting point crystalline form.

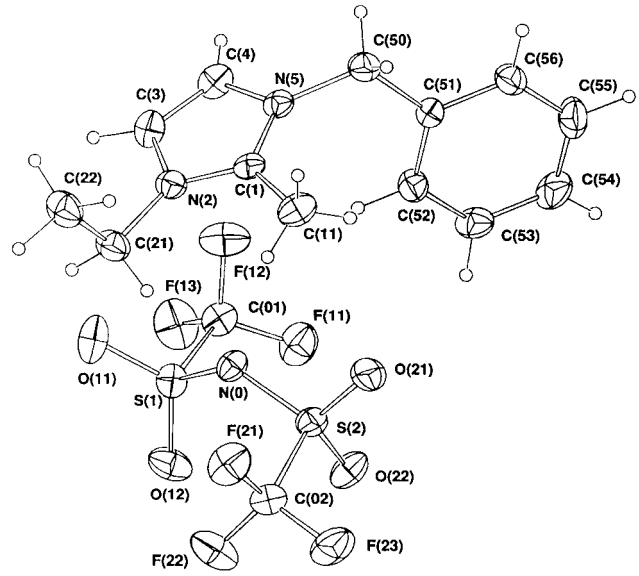

Fig. 1 Projection of the salt **1**. 20% Thermal ellipsoids are shown for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å.

Bond length and angle data for the 1-ethyl-2-methyl-3-benzyl imidazolium cation in this salt (Fig. 2), agree with previously reported imidazolium cations[5–7] (the majority of which are unsubstituted in the 2-position). The imidazole ring remains planar and the bond lengths in the imidazolium ring show strong residual double bond character at C(3)–C(4) with only partial delocalization of the positive charge, as previously reported.[5–7] It is perhaps not surprising that this and related trisubstituted imidazolium salts (*i.e.* 1-alkyl-2-methyl-3-benzyl imidazolium salts) do not easily form salts which are liquid at

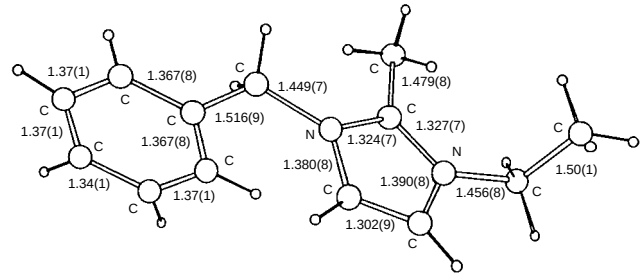

Fig. 2 Ball and stick representation of imidazolium cation including bond lengths (Å)

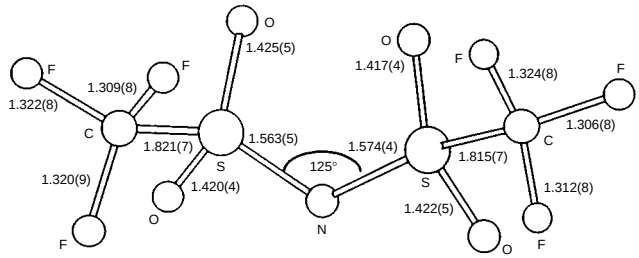

Fig. 3 Ball and stick representation of the bis[(trifluoromethyl)sulfonyl]amide anion including bond lengths (Å)

room temperature, when the influence of the size and orientation of the benzyl group, perpendicular to the plane of the imidazole ring [dihedral angle 86.7(3)°], are taken into account.

Fig. 3 shows the bond lengths and spatial arrangement of the anion. The anion as a whole has near C_2 symmetry, and the sulfonyl moieties have distorted tetrahedral symmetry with bond angles ranging from 102 to 115°.

Previous investigations of sulfonyl amide anions[4,8] have supported Cruickshank's[9] description, which proposed d_π–p_π interaction between neighbouring sulfur and nitrogen atoms. This interaction effectively delocalizes the negative charge across the S–N–S moiety but not necessarily onto the sulfonyl oxygens, as might have been expected on the basis of simpler models. The structure determined in this work supports this model, the S–O bond lengths all being quite characteristic of the S–O double bond in SO_2 (1.43 Å) and showing no evidence of lengthening due to charge delocalization onto the sulfonyl oxygens. The lengthening of the S–O bonds (0.07 Å) observed by Haas *et al.*[4] when the sulfonyl amine was converted to the amide can be partially explained by the increased charge density across the S–N–S moiety. Given the strong hydrogen bonding present in their compound, no conclusive evidence of charge delocalization onto the sulfonyl oxygens can be deduced from that structure. On the other hand, the S–N bond lengths shown in Fig. 3 (1.56–1.57 Å) are significantly shorter than typical S–N single bonds ($\approx$1.75 Å) as a result of the S–N–S charge delocalization, hence charge delocalization onto the sulfurs is clearly indicated.

The key features of this anion in promoting a low melting point in its compounds, concomitant with high fluidity, would therefore appear to be this charge delocalization coupled with the lack of hydrogen bonding. The slightly larger than trigonal S–N–S angle (125°) will also, combined with the bulk of the $–SO_2CF_3$ groups, provide steric impediments to close interactions with neighbouring cations.

The crystal structure presented here provides a contrasting view of the interaction of organic cations, *vs.* solvated inorganic cations, *e.g.* aquo ions, with this anion. In the case of $[Mg(H_2O)_6][N(SO_2CF_3)_2]_2$, the intermolecular hydrogen bonding distorted the geometric features of the anion. In the structure presented here, however, the relatively unperturbed intramolecular features of the anion have been elucidated. This has been possible because only weak electrostatic interactions are evident between the sulfonamide anion and the imidazolium cation.

The support of the Australian Research Council is gratefully acknowledged.

First example of a sixteen membered Jäger macrocycle having a 'Z' conformation

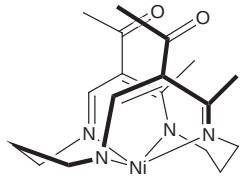
James H. Cameron,*† Duncan P. Nicol and Georgina M. Rosair

Chemistry Department, Heriot-Watt University, Riccarton, Edinburgh, UK EH14 4AS

The crystal structure of the first sixteen membered Jäger type macrocycle having a Z conformation rather than the expected saddle shaped geometry has been determined.

The family of tetraaza macrocycles first reported by Jäger[1] displays a fascinating interplay of structure–reactivity relationships and this has been exploited to interesting effect, in particular by Busch and Cairns, in the production of the so-called 'cyclidene' macrocyclic complexes[2] where examples have been used in reversible oxygen binding,[3] as models for cytochrome P-450,[4] and in supramolecular chemistry.[5]

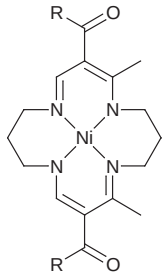
The solid state structure of the Jäger macrocycles varies widely with ring size.[6] The fourteen membered rings are planar, the fifteen membered rings adopt one of two possible geometries (either 'saddle shaped' or a Z conformation) while the sixteen membered ring, until now, has been found exclusively in the saddle shaped geometry (**I**). The saddle shape of the



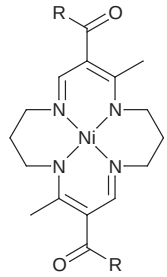
I

sixteen membered species arises due to the conformations adopted by the two saturated six membered metallochelate rings present in the structure.[6]

As part of a study into the steric control of reactions of superstructured macrocycles[7] we prepared a new example of a sixteen membered Jäger type complex, **1**, with neopentyl



1a R = Bu^t
2a R = Me



1b R = Bu^t
2b R = Me

substitutents,‡ and found that it exists as a 1 : 1 ratio of two isomers: the conventional species, with *cis* related ring methyl groups (**1a**) and an unusual *trans* isomer (**1b**). The complex was prepared by the general scheme described in the literature, except using neopentanoyl chloride as the acylation reagent.[8] The isomers were separated using preparative TLC on neutral alumina, with $CHCl_3$–MeCN (10 : 1) as eluent and the isomeric nature of the two fractions was confirmed by mass spectrometry and by microanalysis. The slower moving isomer had a ^{1}H NMR spectrum consistent with those of saddle shaped (*cis*) Jäger complexes, while both the ^{1}H and ^{13}C NMR spectra of the other isomer indicated that it possessed higher symmetry.

Single crystals of each isomer were grown from $CHCl_3$–MeCN and the structures of **1a** (Fig. 1) and **1b** (Fig. 2) were determined.§ Complex **1a** has the expected saddle shape and the most interesting feature of the structure is the disorder in the position of C(10), arising from the presence of both boat (22%) and chair (78%) conformations for the metallochelate ring containing this carbon atom. In **1b**, the ring methyl groups appear in a *trans* relationship, rather than the usual *cis*, and this causes the keto oxygen atoms also to adopt a *trans* relationship, to minimise steric repulsion between ring and acyl methyl groups. Further, also to avoid steric interaction with the ring methyls, both saturated metallochelate rings adopt a skewed conformation, forcing the molecule to adopt a structure that has one unsaturated chelate ring above and one below the Ni–N_4 plane, producing the unprecedented (for a sixteen membered ring) Z isomer. Notably this structure possesses a centre of inversion at the nickel centre and the NiN_4 unit is exactly planar. In both molecules there are intermolecular contacts between the keto oxygens and hydrogen atoms on the saturated portion of the macrocycle [in **1b**: O(1)···H(4) 2.534(3), in **1a**: O(1)···H(10B) 2.581(5), O(2)···H(3B) 2.589(4) and O(2)···H(5A) 2.359(4) Å].

Identification of the existence of **1b** opens the way for the production of new sixteen membered Jäger macrocyclic ligands with a radically different supramolecular structural motif from that of the *cis* isomer. For example the extended Z structure could be used as the basis for new polymeric systems, by bridging across the keto functions. Our work in this interesting area is continuing.

Initially we believed that the new type of structural isomer was being formed during the addition of the neopentyl group,

Selected bond lengths (Å) and angles (°) for **1b**: Ni(1)–N(2) 1.874(2), Ni(1)–N(2A) 1.874(2), Ni(1)–N(1) 1.895(2), Ni(1)–N(1A) 1.895(2), N(1)–C(2) 1.308(3), N(1)–C(3) 1.479(3), N(2)–C(6) 1.296(4), N(2)–C(5) 1.469(3); N(2)–Ni(1)–N(2A) 180.0, N(2)–Ni(1)–N(1) 91.08(10), N(2A)–Ni(1)–N(1) 88.92(10), N(2)–Ni(1)–N(1A) 88.92(10), N(2A)–Ni(1)–N(1A) 91.08(10), N(1)–Ni(1)–N(1A) 180.0, C(2)–N(1)–C(3) 121.2(2), C(2)–N(1)–Ni(1) 126.6(2), C(3)–N(1)–Ni(1) 112.2(2), C(6)–N(2)–C(5) 118.1(2), C(6)–N(2)–Ni(1) 122.9(2), C(5)–N(2)–Ni(1) 118.7(2). Symmetry transformations used to generate equivalent atoms: A $-x, -y, -z + 1$. (*b*) Side view of **1b**, emphasising the *Z* conformation.

but this required a major rearrangement of the parent macrocycle which mechanistically seemed unlikely. Careful scrutiny of the reactions revealed that in fact both *cis* (**2a**) and *trans* (**2b**) forms of the parent sixteen membered complex were produced in the Schiff's base condensation reaction used to form this Jäger macrocycle from its acyclic precursor, and both **2a** and **2b** have now been structurally characterised.[9] Prior to this work, the *trans* form had not been recognised as a product of the cyclisation reaction, and we believe that this is because it is usually the minor isomer and also it is rather more soluble than the *cis* isomer, hence previously only the *cis* form had been isolated and characterised. We have now carried out a detailed study of the conditions of the ring closure reaction and have found that it is possible to favour the formation of the *trans* isomer relative to the *cis*, and the details of this work, and the X-ray structures of **2a** and **2b**, will be reported in a separate publication.[9]

We thank Professor D. H. Busch and Dr N. W. Alcock for helpful discussion, and EPSRC for the award of a Postgraduate Studentship (to D. P. N.).

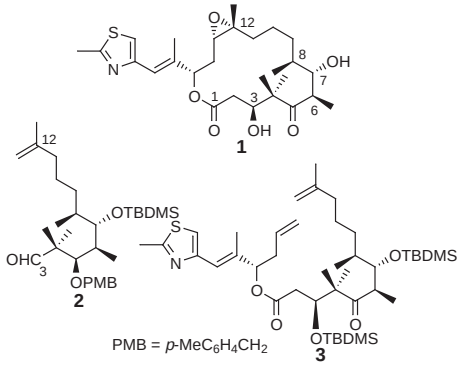
Total synthesis of (−)-epothilone B

Scott A. May and Paul A. Grieco*†

Department of Chemistry and Biochemistry, Montana State Univeristy, Bozeman, Montana 59717, USA

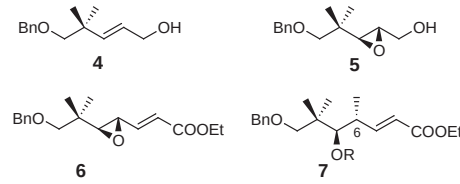
The sixteen-membered ring macrolide (−)-epothilone B 1 has been synthesized by a route which features stereospecific methylation of an (*E*)-γ,δ-epoxy acrylate, the use of a double asymmetric reaction employing (*R*,*R*)-diisopropyltartrate and (*E*)-crotylboronate, and ring closure by means of an olefin metathesis reaction.

(–)-Epothilone B **1**, isolated by Höfle and co-workers[1] from the myxobacteria *Sorangium cellulosum* strain 90, has been the object of intense synthetic activity.[2,3] The excitement surrounding the epothilones stems, in part, from research conducted at the Merck Research Laboratories by Bollag[4] and co-workers who demonstrated that the epothilones function *via* a paclitaxel-like mode of action by binding to and stabilizing cell microtubule assemblies. Particularly significant has been the finding[4] that (−)-epothilone B appears to be effective against a number of drug-resistant tumor cell lines. We detail below an intramolecular olefin metathesis strategy for the construction of (−)-epothilone B which features preparation of the C(3)-C(12) fragment **2** and its elaboration into **3**, and subsequent conversion of **3** into **1**.

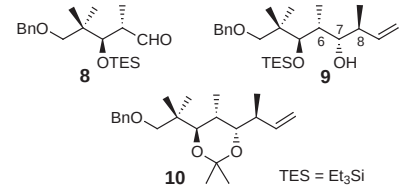


Synthesis of the chiral C(3)-C(12) fragment **2** commenced with the optically active epoxide **5**, $[\alpha]_D^{25}$ −10.1 (*c* 2.5, $CHCl_3$), which was prepared from allylic alcohol **4**[5] *via* a Sharpless epoxidation[6] [diethyl L-tartrate (0.26 equiv.), $Ti(O\text{-}Pr^i)_4$ (0.2 equiv.), Bu^tOOH (3.0 equiv.), CH_2Cl_2, 4 Å mol sieves, −40 °C (8 h) → −10 °C (8 h)]. With the ready availability of **5**, efforts were focused on introduction of the C(6) methyl group. Toward this end, **5** was transformed, in 87% overall yield, into the (*E*)-γ,δ-epoxy acrylate **6** *via* a Swern oxidation [DMSO, $(COCl)_2$, CH_2Cl_2, −78 °C, 1 h, then Et_3N, 0 °C, 1 h] and an (*E*)-selective Horner–Wadsworth–Emmons reaction [NaH, THF, $(EtO)_2POCH_2CO_2Et$, 0 °C, 1 h, then RCHO, THF, 0 °C, 30 min]. Treatment of a 0.07 M solution of **6** in 1,2-dichloroethane in the presence of 6.0 equiv. of water cooled to −30 °C with 10.0 equiv. of Me_3Al (2.0 M in hexane) gave rise to **7** (R = H), $[\alpha]_D^{25}$ +11.7 (*c* 2.5, $CHCl_3$), as the sole product in 87% yield.[7] The methylation of **6** is stereospecific, proceeding with net inversion of configuration about C(6). Note that, in the absence of water, the transformation of **6** into **7** (R = H) does not proceed to any appreciable extent.

Elaboration of the remaining two stereocenters at C(7) and C(8) necessitated conversion of substrate **7** into aldehyde **8** which was realized (95% overall yield) *via* a three step protocol

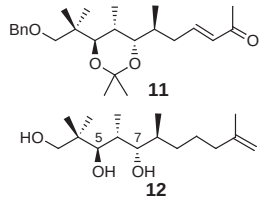


[TESOTf, 2,6-lutidine, CH_2Cl_2, 45 min, then OsO_4 (catalytic), NMO, acetone–water–Bu^tOH (2:5:1), 7 h, followed by $NaHSO_3$, 14 h, then $Pb(OAc)_4$, C_6H_6, 15 min]. Exposure of **8** to (*R*,*R*)-diisopropyltartrate and (*E*)-crotylboronate[8] in toluene [−78 °C (3 h) → room temp. (12 h)] in the presence of 4 Å molecular sieves gave rise to **9**, $[\alpha]_D^{25}$ −8.6 (*c* 2.1, $CHCl_3$), as the sole product in 93% yield, thus establishing the required *syn*,*anti* arrangement about C(6)–C(7) and C(7)–C(8). Prior to functionalization of the $\Delta^{9,10}$ terminal olefin, the triethylsilyl ether was cleaved (TBAF, THF, 30 min) and the resulting 1,3-*anti* diol was converted, upon exposure (15 min) to 2,2-dimethoxypropane and catalytic TsOH, into the 1,3-*anti* acetonide **10**, $[\alpha]_D^{25}$ +11.6 (*c* 1.7, $CHCl_3$), in 93% overall yield. The stereochemical assignment for the *anti* acetonide follows from the ^{13}C NMR spectrum of **10**. The observed chemical shifts for the acetonide carbons (δ 23.4, 25.7 and 100.1) in **10** are in excellent agreement with previous data from independent studies on 1,3-*anti* acetonides by Rychnovsky[9] and Evans.[10]

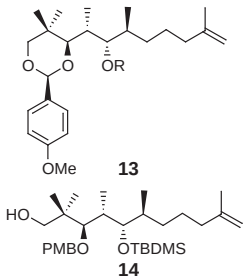


Completion of the synthesis of the C(3)-C(12) fragment **2** was realized as follows. Hydroboration [catecholborane, $(PPh_3)_3RhCl$ (catalytic), THF, 45 min; NaOH, H_2O_2][11] of **10** followed by oxidation (Swern conditions) and subsequent Horner–Wadsworth–Emmons condensation (THF, 4 h) of the resulting aldehyde with the sodium anion derived from diethyl (2-oxopropyl)phosphonate gave rise, in 55% overall yield, to **11**, $[\alpha]_D^{25}$ +26.0 (*c* 1.05, $CHCl_3$). Enone **11** was transformed (77% overall) into triol **12** *via* a three step sequence [H_2, 10% Pd/C, EtOH–EtOAc (1:1), 5 h, then $Ph_3P{=}CH_2$, THF, 3 h, then 1.0 M HCl–THF (1:1), 50 °C, 3 h] which set the stage for selective protection of the C(5) and C(7) hydroxy groups, which proved critical for completion of the total synthesis of epothilone B since the 1,3-diol acetonide present in **11** was not compatible with the olefin metathesis reaction in the late stages of the synthesis.

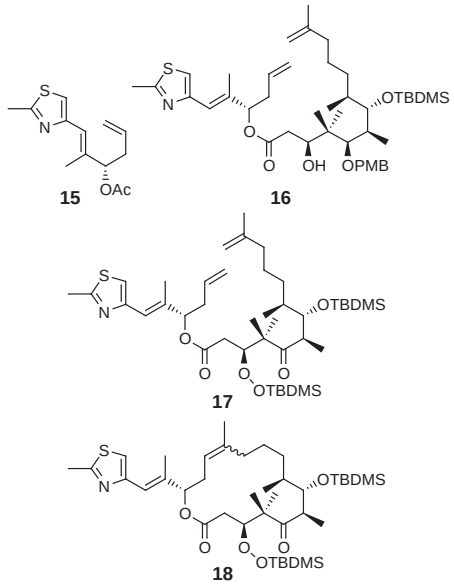
Exposure (30 min) of **12** to *p*-anisaldehyde dimethylacetal in benzene containing catalytic TsOH gave rise (90%) to **13** (R = H) which, upon silylation [TBDMSOTf, 2,6-lutidine, CH_2Cl_2, −78 °C, 4 h], provided (94%) **13** (R = TBDMS), $[\alpha]_D^{25}$ +19.7 (*c* 3.9, $CHCl_3$). Protection of the C(5) hydroxy group as its 4-methoxybenzyl (PMB) ether was realized *via* regioselective



reductive ring cleavage[12] of the 1,3-dioxane ring of the 4-methoxybenzylidene acetal **13** (R = TBDMS). Thus, a 0.04 M solution of **13** (R = TBDMS) in CH_2Cl_2 , cooled to −78 °C, was treated with 10.0 equiv. of a 1.0 M solution of DIBAL-H in CH_2Cl_2. After warming to −15 °C (1.5 h), a 75% yield of primary alcohol **14** was isolated. Oxidation (Swern conditions) of **14** provided the intact C(3)-C(12) fragment **2**, $[\alpha]_D^{25}$ −7.6 (*c* 4.6, $CHCl_3$), in 98% yield.



In order to complete the total synthesis of **1**, the ester enolate derived (LDA, THF, −78 °C) from the known acetate **15**[2] was condensed with **2** giving rise (83%) to a readily separable mixture (1.7 : 1) of diastereomers favoring **16**, $[\alpha]_D^{25}$ −28.6 (*c* 1.4, $CHCl_3$), possessing the correct configuration at C(3). Protection [TBDMSOTf, 2,6-lutidine, CH_2Cl_2, −50 °C, 4 h] of the C(3) hydroxy group, followed by cleavage [DDQ, CH_2Cl_2–H_2O (18 : 1), 0 °C, 3 h] of the C(5) 4-methoxybenzyl ether and subsequent Dess–Martin oxidation gave rise to **17**, $[\alpha]_D^{25}$ −44.0 (*c* 2.4, $CHCl_3$), in 65% overall yield.



Ring closure to complete the formation of the sixteen-membered ring of **1** was realized by an intramolecular olefin metathesis reaction.[13,14] Exposure (4 h) of a 0.001 M solution of **17** in benzene (heated to 55 °C) to 20 mol% of the molybdenum-based catalyst [$Mo(CHMe_2Ph)\{N(2,6\text{-}Pr^i_2C_6H_3)\}\{OCMe(CF_3)_2\}_2$] of Schrock[13] afforded in 55% yield a 1 : 1 mixture of *Z* and *E* isomers (*cf.* **18**) which could be separated by preparative TLC. Upon treatment of the enantiomerically pure *Z*-isomer with HF·pyridine (THF, 3 h), a 60% yield of pre-epothilone B **19** was obtained. Epoxidation (dimethyldioxirane,[15] CH_2Cl_2, −50 °C, 4 h) of **19** provided crystalline **1**, mp 93–94 °C (lit.,[2] 93.6–94.7 °C), $[\alpha]_D^{25}$ −32.2 (*c* 0.09, $CHCl_3$) [lit.,[2] −31.0 (*c* 0.045, $CHCl_3$)] in 86% yield. The ^{1}H NMR spectrum of synthetic **1** was identical in all respects with a spectrum of natural (-)-epothilone B.

We thank Professor S. Danishefsky for helpful discussions and the ^{1}H NMR spectra of natural (−)-**1** and synthetic (−)-**17**. This research was supported by a grant from the U.S. NIH (CA 28865).

Crystal structure of a chiral nitrido-manganese salen complex. The nitrogen analogue to the intermediate in the Jacobsen epoxidation reaction

Aase Sejr Jepsen, Mark Roberson, Rita G. Hazell and Karl Anker Jørgensen*†

Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, Aarhus C, DK-8000, Denmark

A chiral nitrido-manganese salen complex has been synthesised and characterised by X-ray diffraction; the geometrical and electronic structure of the complex are discussed in relation to the intermediate in asymmetric reactions.

The transfer of an oxygen atom(s) from high-valent oxo-metal complexes to alkenes in an enantioselective manner has been developed to be highly successful using asymmetric catalysis.[1] For the epoxidation of alkenes the use of chiral manganese salen complexes as the catalyst is among the most useful and widely applicable as it has proven effective for a variety of different alkenes.[1a,2]

The intermediate in reactions using chiral manganese(III) salen complexes as the catalyst has been postulated to be an oxo-manganese(V) salen complex.[1a,3] There are a number of indirect proofs for the oxo-manganese(V) salen intermediate, and recently direct proof by application of electrospray tandem MS appeared.[4] A further aspect of reactions catalyzed by chiral manganese salen complexes, which also relates to the intermediate in the reaction, is the mechanism for the oxygen transfer process. The majority of the experimental results for the epoxidation reaction point to a mechanism starting with addition of the alkene to the oxygen atom in the oxo-manganese salen intermediate and the epoxide is formed by collapse involving a rotation of the carbon–carbon bond.[1a,5] An alternative mechanism is based on the concept of metallaoxetanes as intermediates in oxygen-transfer reactions[6] and assumes that the alkene adds to the oxo–manganese bond in a [2 + 2] fashion followed by collapse giving the epoxide.[7]

Although much attention has been devoted to the intermediate in reactions catalyzed by chiral manganese(III) salen complexes no direct structural evidence for the intermediate is available. One way to obtain structural information about the intermediate could be to turn attention to the corresponding nitrogen analogue of the chiral oxo-manganese(V) salen complex as the structural difference between an O=Mn^V and a N≡Mn^V bond is small (*vide infra*). Here we present the preparation, characterisation and electronic structure analysis of the nitrogen analogue to the intermediate in the Jacobsen epoxidation reaction.

The dark brown chiral manganese(III) salen complex **1** reacts with NH_3 in CH_2Cl_2 at −50 °C using NBS as the oxidant to yield a deep green complex **2** isolated in 89% yield [reaction (1)].[8]‡

^{1}H NMR spectroscopic investigations of **2** give the following resonances in $CDCl_3$: δ_H 1.47 (s, 9H), 1.50 (s, 9H), 2.14 (s, 3H), 2.15 (s, 3H), 4.70 (d, *J* 11 Hz, 1H), 5.14 (d, *J* 11 Hz, 1H), 6.57 (s, 2H), 7.09–7.37 (m, 14 H), 7.55 (s, 1H), 7.62 (s, 1H). The ^{1}H NMR data show that the Bu^t, Me, CH=N and CH(Ph)CH(Ph) hydrogen atoms are non-equivalent. The ^{13}C NMR spectrum for **2** shows the following resonances: δ_C 20.4, 29.7, 35.6, 81.2, 81.4, 119.4, 120.5, 124.0, 128.8, 129.1, 129.4, 129.5, 131.3, 131.7, 134.7, 134.9, 135.6, 137.9, 141.1, 166.0, 166.2, 167.3, 167.5. These data for **2** show also the non-equivalence of several signals, most notably the signal for the chiral carbon and imine carbon atoms. The IR spectrum for **2** shows a N≡Mn stretch at 1049 cm^{-1}. Recrystallisation of the green complex gave crystals from MeOH (mp 206–208 °C) which were useable for X-ray analysis.

The structure of **2** is depicted in Fig. 1§ and shows the presence of the N≡Mn bond. The N≡Mn bond length is found to be 1.537 Å and similar to other N≡Mn bonds characterized.[8,9] Other selected bond distances and angles are in the legend to Fig. 1. If one compares the N≡Mn^V bond length in **2** with, according to our knowledge, the only two other characterised O=Mn^V bonds (1.548 and 1.558 Å) in related types of complexes,[10] the structural similarity between the N≡Mn^V and O=Mn^V fragments is obvious. It is also notable for the structure of **2** that the oxidation of the manganese atom causes a displacement of this atom by 0.49 Å out of the plane consisting of the four atoms coordinating to manganese. The displacement of the manganese atom when forming the N≡Mn^V complex probably causes the change in electronic environment at the chiral ligand which accounts for the non-equivalent resonances observed in the NMR spectra of **2**. The reactivity of **2** has also been briefly investigated under various reaction conditions, but compared with the corresponding chiral oxo-manganese(V) salen complex it is much less reactive.[11]

In an attempt to obtain further insight into the structure and the chemical properties of the chiral nitrido-manganese(V) salen complex **2** the electronic structure has been investigated. A

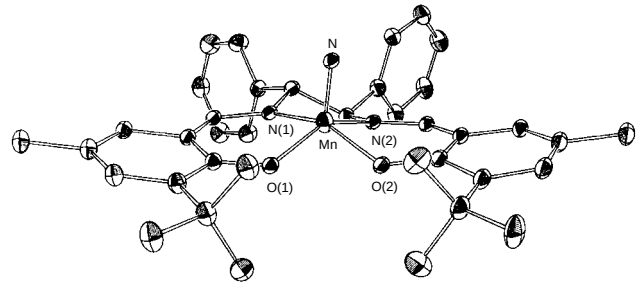

Fig. 1 Molecular structure of **2**. C–H hydrogen atoms are not shown (the other molecule is similar except that 12% have Mn and N on the other side of the salen plane). Selected distances (Å) and angles (°) for **2**: Mn–N 1.537(6), Mn–N(1) 1.949(6), Mn–N(2) 1.968(6), Mn–O(1) 1.903(6), Mn–O(2) 1.915(6), O(1)–Mn–N 109.8(3), O(2)–Mn–N 103.2(3), N(1)–Mn–N 101.6(3), N(2)–Mn–N 104.0(3).

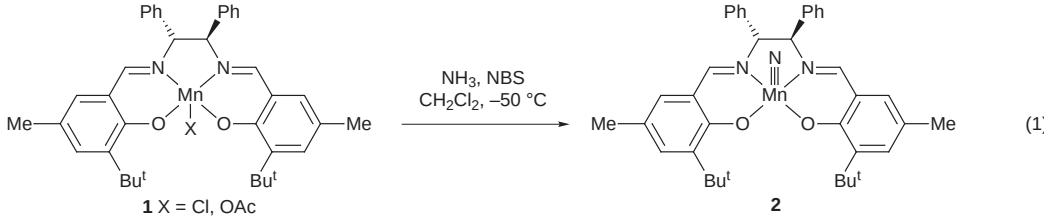

(1)

model compound (**3**) for **2** was optimised using *ab initio* DFT calculations applying a B3LYP/6-31G* basis set and a TZV basis set for manganese.[12] For the singlet state of **3** the optimised structure is shown below with the calculated bond lengths at the manganese atom and it is notable that the N≡Mn, Mn–N and Mn–O bond lengths for **3** are similar to the same bonds in **2**. Furthermore, the displacement of the manganese atom (0.45 Å) out of the plane consisting of the four heteroatoms coordinating to manganese in **3** is also similar to the displacement in **2**. The simple model **3** seems thus to be a reliable model for **2**.

Mn≡N: 1.497 Å
Mn–N: 1.970 Å
Mn–O: 1.965 Å

The calculations give a N≡Mn bond order of 2.8 indicating a bond with triple bond character. The charges on the nitrogen and manganese atoms are −0.15 and 0.87, respectively. The frontier orbitals calculated for the N≡Mn bond in **3** give the HOMO at −5.71 eV and with only a minor contribution of the bonding combination of N p_x–Mn $d_{x^2-y^2}$, but this orbital is mainly located on the ligand. The second HOMO is at −6.00 eV and is mainly on the manganese atom as $d_{x^2-y^2}$; while the fourth HOMO at −7.62 eV is the bonding combination of N p_y–Mn d_{yz}. The LUMO and the third LUMO, at −1.60 eV and −0.95 eV, respectively, are the antibonding combination of N p_y–Mn d_{yz} and N p_x–Mn d_{xz} orbitals, respectively. The antibonding combination of N p_z–Mn d_{z^2}, the σ^*_{N-Mn} orbital, is at −0.20 eV.

It is interesting to compare the structure of the nitrido-manganese(v) salen complex **3** with the closely related oxo-manganese(v) salen complex. The structure of the latter is unknown, but the similarity in $N{\equiv}Mn^{V}$ and $O{=}Mn^{V}$ bond lengths (*vide supra*) is striking; however, the structural similarity does not account for the difference in reactivity. A comparison of the electronic structure for both the $O{=}Mn^{V+}$ and $O{=}Mn^{V}$–Cl (optimised structures) obtained by *ab initio* DFT calculations[12] gives important information. The results for the two oxo-manganese complexes are alike, so only the former will be discussed here. The O=Mn bond length is optimised to be 1.546 Å which is similar to the two characterised $O{=}Mn^{V}$ bonds (1.548 and 1.558 Å) in related types of complexes.[10] The charges at oxygen and manganese are −0.20 and 1.18, respectively. The bond length and charge considerations of the $N{\equiv}Mn^{V}$ and $O{=}Mn^{V}$ complexes are thus not that different. However, the O=Mn bond order is calculated to be 2.3, showing a much weaker bond than the N≡Mn bond, and, furthermore, the $O{=}Mn^{V}$ complex also shows a different frontier orbital picture compared with the $N{\equiv}Mn^{V}$ complex, as the related frontier orbitals of the former are found at lower energies, the HOMO at −10.65 eV, while the LUMO is at −7.92 eV. The lowering of the LUMO in $O{=}Mn^{V}$ by 6.3 eV points to a significant difference in reactivity, when reacting with electron-rich alkenes. The more reactive chiral oxo-manganese(v) salen complex compared with the closely related chiral nitrido-manganese(v) salen complex is thus probably due to a much weaker O=Mn bond and lower lying unoccupied MOs in the former complex.

With the structural knowledge of the chiral nitrido-manganese(v) salen complex the remarkable enantioselectivity of the related oxo-manganese(v) salen complex might begin to be understood in detail as the present results allow one to analyse the approach of *e.g.* alkenes to the intermediate.

The work presented here was made possible by a grant from The Danish National Science Foundation.

‡ Reaction conditions for the preparation of **2**. A solution of [(*R*,*R*)-diphenyl-*tert*-butylmethylsalen]Mn(Cl) (360 mg, 0.56 mmol) in 30 ml CH_2Cl_2 was cooled to −50 °C. NBS was added (470 mg, 2.8 mmol). Gaseous NH_3 was fed through the reaction mixture for 5–10 min and a colour change to green was observed. The reaction mixture was warmed and the contents transferred to a separator funnel with 25 ml H_2O added. The dark green organic phase was isolated and the aqueous layer extracted with 25 ml CH_2Cl_2. The combined organic phases were washed with 4 × 25 ml H_2O and the solvent removed. The solid material was re-dissolved in CH_2Cl_2 and purified by chromatography (Al_2O_3, 4 × 18 cm) with CH_2Cl_2 as the eluent. A dark green band was collected and recrystallized in MeOH.

Copper-exchanged zeolite Y is a highly active catalyst for the aziridination of alkenes; modification using bis(oxazolines) leads to preparation of the first heterogeneous enantioselective aziridination catalyst.

The design of asymmetric catalysts is of intense current interest,[1] and procedures making use of chiral transition metal complexes have been described for epoxidation, cyclopropanation, aziridination and hydrogenation of alkenes in homogeneous solution.[2–6] There is increasing recognition that heterogeneous catalysts have practical advantages over homogeneous ones.[6–8] We describe here a generic approach to the design of heterogeneous transition-metal catalysts by making use of the well-known ability of zeolites to undergo metal cation exchange,[9] together with their acid–base properties.[10] By constructing transition-metal complexes within the spatially restricted environment of the zeolite pores, enantioselective organic transformations can be catalysed with comparable or even greater efficiency than in the corresponding homogeneous process. We exemplify this approach with the first heterogeneous catalyst for asymmetric aziridination of alkenes.

We have found that CuHY zeolite is successful in catalysing the aziridination of a range of alkenes employing [*N*-(tolyl-*p*-sulfonyl)imino]phenyliodinane (PhI = NTs) as the nitrogen source. The results are shown in Table 1. The Cu-exchanged zeolite (CuHY) was prepared by conventional ion-exchange methods with aqueous $Cu(OAc)_2$ solution, the concentration of which was chosen so as to obtain the required exchange level (*ca*. 50–60% of available H^+). The cation-exchanged zeolite was then washed with distilled water and dried at 110 °C in air. CuHY was initially screened in the aziridination of styrene (Table 1, entries 1–3), since this alkene affords good yields of aziridine when copper triflate is used as a homogeneous catalyst.[4] Using a five-fold molar excess of styrene, the desired *N*-tosylaziridine was obtained in 90% yield (entry 1). These initial results confirmed our contention that cations within zeolites could be used as heterogeneous counterparts of known homogeneous catalysts, and, to the best of our knowledge, this is the first example of an aziridination reaction catalysed heterogeneously.

Table 1 CuHY-catalysed aziridination of representative alkenes

Entry	Alkene[a]	Cu (mol%)	Yield (%)[b]
1	Styrene	25	90 (92)
2	Styrene[c]	25	87 (35)
3	Styrene	5	62
4	α-Methylstyrene	25	33
5	*p*-Chlorostyrene	25	76
6	*p*-Methylstyrene	25	66
7	Cyclohexene	25	50 (60)
8	Methyl cinnamate	25	84 (73)
9	*trans*-Stilbene	25	0 (52)
10	*trans*-Hex-2-ene	25	44

[a] Unless otherwise specified reaction conditions were: MeCN, 25 °C, styrene : PhI=NTs = 5 : 1. [b] Isolated yield of aziridine based on PhI=NTs. Values in parentheses indicate yields obtained from homogeneous reactions. [c] styrene : PhI=NTs = 1 : 1 molar ratio.

In order to confirm the absence of homogeneously catalysed reaction, following reaction the zeolite catalyst was recovered by filtration and another aliquot of reactants (styrene: PhI=NTs = 5 : 1 molar ratio) was added to the recovered filtrate; no further product was observed. Further, the removed catalyst was reused with fresh reagents and solvent, and the zeolite demonstrated similar activity to when it was used initially.

It was noted in earlier studies that, in the homogeneously catalysed reaction,[4] the yield of aziridine decreased to 37% when the molar ratio of styrene : PhI=NTs = 1 : 1 was employed, due to the competing breakdown of the PhI=NTs reagent. This decrease was found to be less significant using our heterogeneous catalyst, where 87% yield was obtained when a styrene : PhI=NTs = 1 : 1 molar ratio was used (Table 1, entry 2) as compared to a yield of 90% when a styrene : PhI=NTs = 1 : 1 molar ratio was used (Table 1, entry 1).

CuHY was found to be successful in catalysing the aziridination of a range of alkenes (Table 1) in addition to styrene. It is observed that the catalyst gives best results with phenyl-substituted alkenes and lower yields are observed with cyclohexene and *trans*-hex-2-ene. Interestingly, for the aziridination of *trans*-stilbene no product could be observed. This was considered to be the due to the relatively bulky aziridine product being too large to be accommodated within the supercages of CuHY. However, the aziridination of *trans*-methyl cinnamate inside CuHY proceeded in 84% yield, despite being similar in structure type to the *trans*-stilbene product. We used molecular modeling to investigate the ease with which these two aziridines could be placed into the pore structure of zeolite Y. These calculations suggest that the *N*-tosylaziridine formed from *trans*-methyl cinnamate can adopt a conformation which can easily be accommodated in the pores of zeolite Y. The aziridine derived from *trans*-stilbene can be constructed within the supercages but is indeed too bulky to diffuse through the connecting channels of the zeolite. We consider this to be a crucial piece of evidence since it shows that the aziridination reaction with the CuHY catalyst occurs within the intracrystalline space. Furthermore, this exciting result illustrates the potential for a heterogeneous catalyst to possess size-specificity to a precise degree. Such a property could be exploited by constructing zeolites with a range of pore sizes, and could also be developed to achieve regioselectivity in a reagent containing two or more double bonds.

Evans *et al.*[4] have shown that modification of the copper homogeneous catalysts using chiral bis(oxazoline) ligands induces enantioselectivity. We have examined modification of the CuHY catalyst with a range of oxazolines and have observed *N*-tosylaziridine products with up to 61% ee. The optimum conditions for racemic heterogeneous aziridination of alkene, in

the absence of bis(oxazoline), was observed to be at 25 °C using MeCN as solvent. As expected, for the enantioselective reaction, the use of lower reaction temperatures was found to give the highest enantioselectivities. We have found that a temperature of −10 °C provides the highest enantioselectivity of 42% ee without compromising yield when using MeCN solvent and 2,2-bis{2-[(4*R*)-1-phenyl-1,3-oxazolinyl]}propane **1** as the chiral modifier. It would be reasonable to assume that one chiral modifier would be required per zeolite supercage to obtain maximum enantioselectivity. We have, however, found that very low levels of the expensive modifier can be used without resulting in decreases in yield or enantioselectivity. An excess of **1** significantly reduces the yield of aziridine, due to pore-blocking, but both yield and enantioselectivity were maximized with a molar ratio of only PhI=NTs : **1** = 1 : 0.05. This corresponds to a molar ratio of Cu^{2+} : **1** of 2 : 1, indicating that not all the Cu^{2+} cations are modified in our experiments. In a subsequent experiment, an excess of **1** was stirred with CuHY (Cu^{2+} : **1** = 1 : 60) in MeCN. The zeolite was filtered and washed with acetonitrile, then used as the catalyst in fresh solvent and reactants. Both yield and enantioselectivity observed were identical to that obtained when **1** was added directly to the reaction mixture (molar ratio of PhI=NTs : **1** = 1 : 1.05). It is clear that very low levels of the modifier are required to obtain the enantioselectivities reported.

3 R^1 = Ph, R^2 = R^3 = H
4 R^1 = R^2 = Ph, R^3 = H

5

With the optimum conditions established for the enantioselective aziridination of styrene, other bis(oxazolines) and alkenes were screened with CuHY as the catalyst (Table 2). *trans*-β-Methylstyrene was found to show similar degrees of enantioselectivity to styrene. However, *trans*-methyl cinnamate gave a much higher result of 61% ee, albeit in poorer yield. The *tert*-butyl substituted bis(oxazoline) **2**, when used in MeCN, gave racemic aziridine. We suggest this is because MeCN, a ligand for Cu^{2+}, binds more strongly to the active sites than does this bis(oxazoline). Support for this interpretation comes from our observation that, by carrying out the reaction using styrene as the solvent, enantioselectivity was restored, although both yield and ee were then lower than for the homogenous reaction. To provide further evidence that the reaction is proceeding within the supercages of the zeolite, reactions were carried out using a simple phenyl-substituted bis(oxazoline) **3**, which is known to fit inside the zeolite, and using a diphenyl substituted analogue **4**, which was considered as the result of molecular simulations to be too bulky to fit inside the zeolite pores. At 25 °C the smaller bis(oxazoline) **3** gave 10% ee for both the heterogeneous and homogeneous reactions. However, for the heterogeneously catalysed reaction, using CuHY as catalyst, the bulky diphenyl bis(oxazoline) **4** gave racemic product, despite inducing 15% ee for the equivalent homogeneously catalysed reaction. This is again evidence that the reaction is truly heterogeneous and is occurring within the pores of the zeolite. Further modification of the bis(oxazaline) has shown that the pyridine-bridged bis(oxazoline) **5** gives the highest enantioselectivity of 61% ee for the aziridination of styrene (Table 2). We consider that these initial results are encouraging and that careful optimization of the chiral ligand will result in further improvements in ee and yield.

The major advantage of the use of CuHY as a catalyst for this reaction is the ease with which it can be recovered from the reaction mixture by simple filtration if used in a batch reactor (alternatively it can be used in a continuous flow fixed bed reactor). We have carried out the heterogeneous asymmetric aziridination of styrene until completion, filtered and washed the zeolite then added fresh styrene, PhI=NTs and solvent, without further addition of bis(oxazoline) **1**, for several consecutive experiments and have found that both yield and enantioselectivity are retained. After each consecutive experiment a portion of CuHY was retained to determine the concentration of copper still present in the zeolite. For each experiment we found that only traces of the copper were removed from the catalyst (< 0.5% of the total Cu^{2+} is lost from the catalyst). Filtrate containing trace Cu^{2+} has been used in a reaction and was not found to catalyse aziridination. We have noted that adsorbed water can build up within the pores of the zeolite on continued use and this can lead to some loss of activity. However, full enantioselectivity and yield can be recovered if the catalyst is simply dried in air prior to reuse. We are therefore confident that this catalyst system can form the basis of a commercial heterogeneous catalyst for the aziridination of alkenes.

Table 2 Representative bis(oxazolines) for the enantioselective aziridination of alkenes

Oxazoline	Alkene[a]	*T*/°C	Yield (%)[b]	Ee (%)[b,c]
1	*trans*-Methyl cinnamate	−10	8 (21)	61 (70)
1	*trans*-β-Methylstyrene	−10	74	36
1	Styrene	−10	82	44
1	Styrene	25	87	29
2	Styrene	−20	64	0
2	Styrene[d]	−20	15 (89)	18 (63)
3	Styrene	25	78 (75)	10 (10)
4	Styrene	25	73 (74)	0 (15)
5	Styrene	−10	4	61

[a] Unless otherwise specified, reaction conditions were: MeCN, alkene: PhI=NTs = 5 : 1. [b] Values in parentheses indicate yields obtained from homogeneous reactions. [c] Enantioselectivity determined by chiral HPLC. Absolute configurations of major products, determined by optical rotation, are (*S*) for *trans*-β-methylstyrene and *trans*-β-methyl cinnamate, (*R*) for styrene. [d] Styrene was used as solvent.

$Tl_2Au_4S_3$: $x = 4/3$ member of the series $A_{2-x}Au_xQ$. Preparation and an analysis of its gold–gold bonding

Sandra Löken, Claudia Felser and Wolfgang Tremel*†

Institut für Anorganische Chemie und Analytische Chemie, Universität Mainz, Becher Weg 24, Mainz D-55099, Germany

$Tl_2Au_4S_3$ was synthesized by reacting gold with reactive fluxes of Tl_2S and S; its crystal structure is characterised by sheets of buckled 16-membered rings of Au and S with short Au–Au contacts between the sheets; the Au–Au bonding has been analysed through high-level band structure calculations.

The chemistry of ternary gold chalcogenides continues to attract interest because of the richness of structures displayed by them. Thus even in the simple formulation AAuQ, the anionic species found include linear, molecular AuQ_2 units in KAuQ (Q = S, Se),[1] AuQ chains in AAuQ (A = Rb, Cs and Q = S, Se, Te),[2] planar hexagonal Au–Te networks in AAuTe (A = Na, K),[2] *etc.* The unique feature of many of these compounds is the presence of short Au–Au distances arising from mixing of gold 5d, 6s and 6p levels; these are usually described in terms of d^{10}–d^{10} interactions. Computational difficulties abound in handling an element such as gold whose electronic structure is influenced by relativistic effects, and there seem to be few high-level band structure calculations detailing the nature of bonding between gold atoms in extended solids. Much of the previous theoretical work on d^{10}–d^{10} interactions has focussed on molecular systems with the exception of some alkali-metal aurides.[3]

We have noted short Au–Au distances in many quaternary gold chalcogenides from the A–Au–X–Q systems where X (= Ge, Sn, P, As) is a main group element that forms chalcogeno anions.[4] Gold chalcogenides and related systems have been studied extensively during the past few years.[4–9] In the course of these investigations we have found the first ternary gold chalcogenide with thallium (replacing the alkali metal).‡ The compound $Tl_2Au_4S_3$ turns out to be the $x = 4/3$ member of the series $A_{2-x}Au_xQ$. With A = alkali metal and Q = chalcogen, the members with $x = 1/2$,[6] 5/6,[7] 1,[2] 6/5,[8] and 3/2[9] have been previously characterised. To understand the nature of the short Au–Au contacts in the title compound, we have used scalar-relativistic TB-LMTO band-structure calculations in conjunction with an analysis of the crystal orbital hamiltonian population (COHP) which we present here. Apart from the bonding situation, these compounds are of interest because they display direct band gaps suggesting uses such as in infrared detection.

The crystal structure of $Tl_2Au_4S_3$ is shown in Fig. 1.§ It is characterised by buckled sheets comprising 16-membered rings of Au and S arranged in an alternating manner. The confirmation of the rings are boat-like. The S–Au–S units in the ring are linear or nearly so. Acute Au(1)–S(1)–Au(2) angles [91.8(3)°] at the corners of the rings lead to an Au–Au distance of 3.350(1) Å within the rings. However, the stacking of the sheets along *c* results in an intersheet Au–Au distance of 3.010(1) Å. These distances are emphasised in the [100] projection by light grey lines. The Tl atoms are in a distorted trigonal prismatic S coordination and sit in the boats defined by the buckling of the Au–S sheets. They are moved off the prism centers; as a result, there are short Tl–Tl contacts of 3.307(3) Å (*cf.* Tl metal where it is about 3.36 Å[10]). The presence of 16-membered rings in the structure is to be contrasted to previous $A_{2-x}Au_xQ$ structures which have (so far) been reported as having 6 ($x = 1$),[2a] 8 ($x = 1$),[2b] 12 ($x = 3/2$),[9] and 24 ($x = 6/5$)[8b]-membered rings.

Fig. 2(*a*) and (*b*) display the decomposed LMTO densities of state (DOS) of the $Tl_2Au_4S_3$ near the Fermi energy. It is clear from Fig. 2(*a*) that there is strong mixing of the s, p and d states of gold. Interestingly, despite short Au–Au contacts, the states closest to E_F are actually derived from a mixing of Tl 6s and S 3p [Fig. 2(*b*)]. Thus Tl acts not only as an inert countercation, in contrast to the other ternaries described earlier, where K^+, Rb^+, *etc.* serve only to balance charge. This is also seen from the COHP plots displayed in Fig. 2(*c*). Strong Au–Au interaction leads to bonding and antibonding states below E_F, with the bonding states being much greater in number. Above E_F, the COHP is flat but slightly bonding. This is because the Au 6s and 6p states are mixed in with the 5d states. This behaviour has been previously remarked in some silver oxides.[11] The principle Au–Au bonding interaction around 5 eV below E_F arise due to Au d states as seen from the DOS. The Au–S interactions lead to well separated bonding and antibonding states below and above the E_F. However, the occupied states closest to E_F are associated with the (shorter) Tl–S distance of 2.978(1) Å. The gap between filled and empty states in the LMTO DOS is in agreement with the measured optical band gap of 1.5 eV obtained from the diffuse-reflectance spectra [Fig. 2(*d*)]. From the preceding discussion, the transition that causes this direct band gap is from filled Tl 6s–6p to the empty, hybridised Tl 6p–S 3p states.

This research has been suppported by the Fonds der Chemischen Industrie. The donation of quartz tubes from

New symmetry-breaking deprotonation reactions of cyclic imides using a chiral lithium amide base

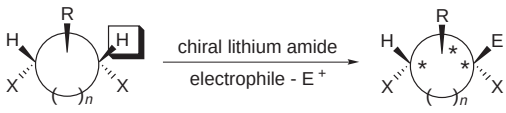
David J. Adams, Nigel S. Simpkins*† and Torben J. N. Smith

Department of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD

Treatment of various *N*-substituted succinimides, possessing additional three-, four- or five-membered ring-fusion, with a mixture of chiral lithium amide base and Me_3SiCl, enables enantioselective silylation to give products in up to 95% ee.

During the past few years there have been great developments in the application of chiral lithium amide base reactions to asymmetric synthesis.[1] Most of the enantioselective deprotonation reactions of these chiral bases described to date involve discrimination between enantiotopic hydrogens activated by a single common functional group. The best developed chemistry of this type is the asymmetric enolisation of cyclic ketones, although somewhat analogous situations involving metallation of sulfoxides and prochiral organometallics have also been described.[2]

We considered that a considerable broadening in the scope for applications of chiral lithium amides would be possible if *multifunctional* substrates could be employed. In a general sense this could involve desymmetrisation of a prochiral molecule having a number of functional groups deployed on a suitable conformationally constrained template (most likely a carbocyclic or saturated heterocyclic or polycyclic system). In this type of chiral base reaction the key step would involve kinetically controlled discrimination between hydrogens which are activated by *separate* functional groups. For a situation in which just two functional groups are involved (as the activating groups for two enantiotopic methine hydrogens), the transformation can be illustrated as the conversion of **1** into **2** (Scheme 1).[3]



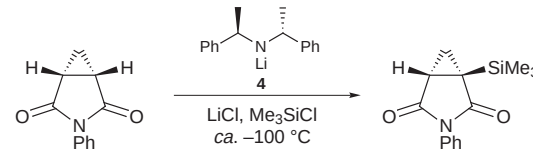
1 **2**

Scheme 1

The two activating groups X could be typical carbonyl types, including ketone, ester or amide, or other types such as sulfone. These two functions could be close together or somewhat remote (variation in *n*) and the overall framework could bear substituents R as long as the overall symmetry is retained in substrate **1**. As can be seen, the chiral base transformation, involving selective substitution at one activated position would be expected to generate chiral products having a number of asymmetric centres (marked *).

Herein we describe our initial results in this new area of chiral lithium amide base chemistry in which we have examined the desymmetrisation of a number of ring–fused imides, *i.e.* $n = 0$ and X = amide (X groups linked to form a five-membered ring imide).

Initial work showed that treatment of cyclopropane derivative **3** with chiral base **4** at low temperature in the presence of Me_3SiCl resulted in the formation of the desired product **5** in 80% yield and 95% ee (Scheme 2).[4]‡

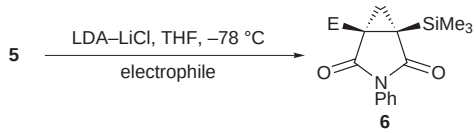


3 **5** 80% (95% ee)

Scheme 2

Imide **5** proved to be crystalline, which enabled us to determine the absolute configuration shown by single crystal X-ray structure determination.§ Our delight at this excellent result was tempered by the observation that only the use of Me_3SiCl as an *in situ* electrophile appears to enable clean substitution, with the attempted reaction with alkylating agents such as MeI resulting only in the destruction of starting material. Although this is a drawback, we were able to circumvent this apparent limitation by substitution of the remaining acidic hydrogen by conventional means (Table 1).

Table 1 Substitution of **5** using LDA

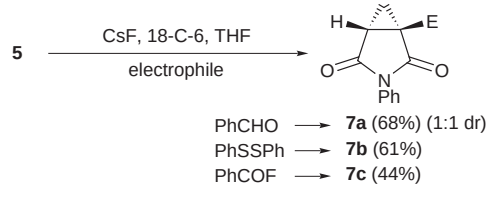


6

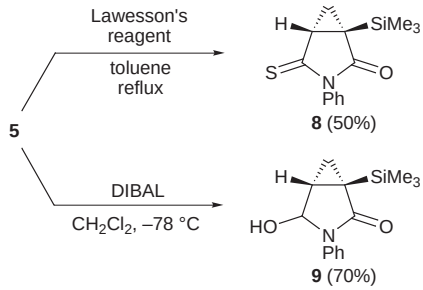
Compound	Electrophile	Yield of **6** (%)
6a	MeI	93
6b	AllylBr	73
6c	BnBr	67
6d	PhSSPh	71
6e	PhCHO[a]	61
6f	PhCOCl	57

[a] Formed as a *ca.* 1 : 1 ratio of diastereoisomers.

Thus, introduction of a range of different substituents was possible in good to excellent yield by use of LDA–LiCl as the base.[5] In the case of **6a** we have confirmed that removal of the silicon group is possible, to give the expected methylated imide. As an alternative approach to the problem we have found that fluoride-mediated substitution of the Me_3Si group of **5** is possible by a narrow range of electrophiles (PhCHO, PhSSPh and PhCOF), to give directly the imide products **7** (Scheme 3).[6] We expect that no loss of ee takes place in this process, although this has not been confirmed to date.



Scheme 3

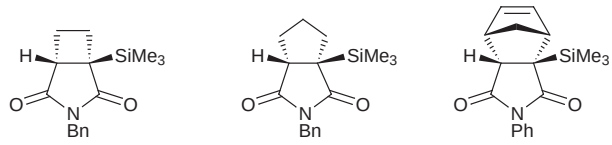


Scheme 4

Since one of the main objectives of this new chiral base chemistry is to enable the synthesis of varied enantiomerically enriched products, it was important to establish if the initial enantioselective substitution to give **5** enabled subsequent regiocontrolled reactions of the imide. In line with our expectations, imide **5** undergoes highly regioselective thionation and reduction reactions, to give **8** and **9** respectively (Scheme 4).[7,8]

Taken in combination with the highly enantioselective access to compounds of type **6** and **7**, this chemistry begins to indicate some of the potential of our new approach for the synthesis of lactams, lactones, pyrrolidines, *etc*.

Finally, we were able to extend this new asymmetric process to several other imide systems, the silylated products **10**–**12**



being isolated in excellent levels of ee from reaction of the appropriate symmetrical imide starting material with a mixture of **4** and Me_3SiCl at low temperature.[9]¶

These results show that the concept outlined in Scheme 1 can be realised, and the products clearly have some potential for target synthesis. However, these asymmetric transformations of ring-fused imides form but a small sub-group of the chemistry implicit in Scheme 1, and efforts to realise further examples of this diverse group of reactions are underway.

We are grateful to the EPSRC and Chiroscience Limited (Cambridge Science Park, Milton Road, Cambridge, UK CB4 4WE) for support of T. J. N. S under the CASE scheme. We are also very grateful to Professor H. Hiemstra of the University of Amsterdam for samples of certain ring-fused imides.

Notes and References

† E-mail: nigel.simpkins@nottingham.ac.uk

‡ In a typical asymmetric silylation, a solution of the chiral lithium amide base **4** mixed with LiCl was added dropwise to a mixture of starting imide and Me_3SiCl (excess) in THF at *ca.* −100 °C (internal temperature). The mixture was then allowed to warm slowly (4 h) to ambient temperature before standard aqueous work-up and chromatography on silica gel. All products have been fully characterised by spectroscopic methods and give satisfactory elemental analysis and/or HRMS results. Enantiomeric excess values were established by HPLC (UV detection) using Pr^iOH–hexane as eluent, using a Chiralcel OD column for **5**, **11** and **12**, and a Chiralcel OJ column for **10**.

§ The absolute configuration of **5** was established by the collection of low temperature data, including Friedel equivalents, and by refinement of a Flack parameter, value 0.05(19), see H. D. Flack, *Acta Crystallogr., Sect. A*, 1983, **39**, 876. The absolute stereochemistry of product **12** was likewise established; Flack parameter −0.12(14). We thank Dr A. J. Blake of this Department for these determinations; full details will be published elsewhere.

¶ These reactions have not been optimised; the absolute configurations shown for **10** and **11** are based on analogy with **5** and **12**.

1 For reviews, see P. O'Brien, *J. Chem. Soc., Perkin Trans. 1*, 1998, 1439; P. J. Cox and N. S. Simpkins, *Tetrahedron: Asymmetry*, 1991, **2**, 1; N. S. Simpkins, *Advances in Asymmetric Synthesis*, ed. G. R. Stephenson, Blackie Academic, 1996; K. Koga, *Pure Appl. Chem*., 1994, **66**, 1487.

2 For leading references in these two areas, see A. J. Blake, S. M. Westaway and N. S. Simpkins, *Synlett*, 1997, 919 (sulfoxides); R. A. Ewin, D. A. Price, N. S. Simpkins, A. M. MacLeod and A. P. Watt, *J. Chem. Soc., Perkin Trans. 1*, 1997, 401 (organometallics).

3 We have recently described an enantioselective elimination reaction akin to the process outlined in Scheme 1, see C. D. Jones, N. S. Simpkins and G. M. P. Giblin, *Tetrahedron Lett*., 1998, **39**, 1023.

4 The starting imide **5** was prepared *via* reaction of the corresponding anhydride (J. J. Tufariello, A. S. Milowsky, M. Al-Nuri and S. Goldstein, *Tetrahedron Lett*., 1987, **28**, 267) with aniline, see A. L. J. Beckwith and D. R. Boate, *J. Org. Chem.*, 1988, **53**, 4339. See also A. Mustafa, S. M. A. D. Zayed and S. Khattab, *J. Am. Chem. Soc*., 1956, **78**, 145 for an alternative synthesis, and ref. 9.

5 In the past we have observed increased rates of metallation by addition of LiCl to lithium amides, see for example D. A. Price, N. S. Simpkins, A. M. MacLeod and A. P. Watt, *Tetrahedron Lett*., 1994, **35**, 6159; B. J. Bunn, N. S. Simpkins, Z. Spavold and M. J. Crimmin, *J. Chem. Soc., Perkin Trans. 1*, 1993, 3113. Recently, little effect of LiCl on the rate of deprotonation of a simple ketone by LDA was observed, see M. Majewski and P. Nowak, *Tetrahedron Lett*., 1998, **39**, 1661.

6 These reactions were modelled on analogous substitutions of episulfones that we examined previously, see A. P. Dishington, R. E. Douthwaite, A. Mortlock, A. B. Muccioli and N. S. Simpkins, *J. Chem. Soc., Perkin Trans. 1*, 1997, 323.

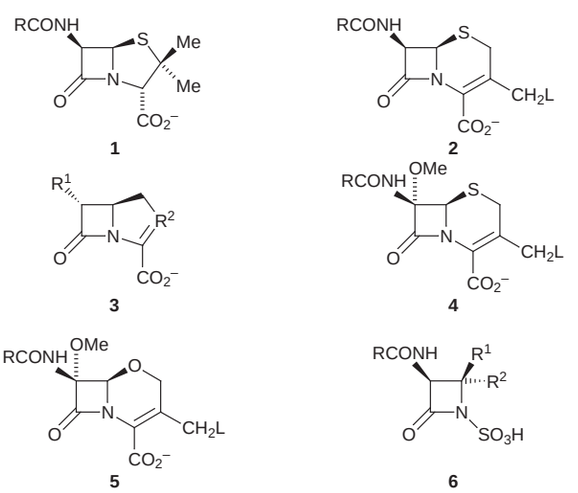
The mechanism of catalysis and the inhibition of β-lactamases

Michael I. Page*† and Andrew P. Laws

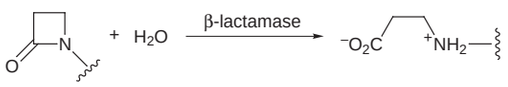
Department of Chemical and Biological Sciences, The University of Huddersfield, Queensgate, Huddersfield, UK HD1 3DH

Formation of a tetrahedral intermediate by nucleophilic attack on the β-lactam carbonyl carbon of penicillins generates a lone pair on the β-lactam nitrogen which is *syn* to the incoming nucleophile, in contrast to the normal *anti* arrangement found in peptides. Ring opening of the β-lactam requires protonation of the β-lactam nitrogen by a general acid catalyst. The general acid/base catalyst in β-lactamases is probably a glutamate and a tyrosine residue in class A and C enzymes, respectively. Phosphonamidates inactivate class C β-lactamases by phosphonylation of the active site serine, the rate of which is enhanced by a factor of at least 10^6. The enzyme's catalytic machinery used for hydrolysis is also used for phosphonylation. The rate enhancement may be greater than 10^9 if the mechanism occurs by an inhibitor assisted reaction involving intramolecular general acid catalysis. Class B metallo-β-lactamases are inhibited by thiol derivatives with K_i as low as 10 μM. The mechanism of hydrolysis of the metallo-β-lactamase involves a dianionic tetrahedral intermediate stabilised by zinc(II).

β-Lactam antibiotics account for 50% of the world's total antibiotic market. They have high anti-bacterial activity and low toxicity.[1] In addition to the traditional families of penicillins and



cephalosporins—the penams **1** and cephems **2**, respectively—there are the carbapenems **3**, the cephamycins **4**, the oxacephamycins **5** and the monobactams **6**.[2] This battalion of structures differ in their spectrum of antibacterial activity—from narrow anti-*Staphylococcal* agents to broad spectrum β-lactams capable of killing a wide variety of Gram positive and negative bacteria—and in their ability not to be susceptible to the β-lactamase hydrolytic enzymes which are the most common, and growing, form of bacterial resistance to their normally lethal action. β-Lactamases catalyse the hydrolysis of the β-lactam to give the ring opened and bacterially inert β-amino acid (Scheme 1).[3]



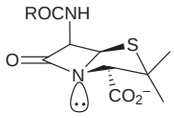
Scheme 1

Two main therapeutic strategies have been adopted to counteract bacterial resistance to β-lactam antibiotics. One involves the design of antibiotics which are not susceptible to β-lactamase catalysed hydrolysis. The other is to use an inhibitor or inactivator of β-lactamase together with a normal β-lactam antibiotic. Unfortunately, bacteria seem to be able to produce new β-lactamases which catalyse the hydrolysis of previously poor substrates and which are no longer susceptible to previous inhibitors. For example, when the carbapenems **3**, such as imipenem, were first introduced in the 1970s they were seen as versatile broad-spectrum antibacterials resistant to hydrolysis by most β-lactamases. However, now 'carbapenamases' are increasingly produced by a variety of bacteria.[4] There are two distinct types of β-lactamase production in bacteria and so far about 200 different enzymes have been identified.[5] Inducible enzymes may be chromosomal or plasmid encoded but the more common constitutive β-lactamase production is predominantly plasmid mediated. Constitutive mutants of Gram-negative strains produce enormous amounts of enzyme so that periplasmic β-lactamase concentrations[6] may be up to 1 mM—about 10^4-fold greater than that used in most laboratory kinetic experiments. Such high concentrations of catalyst combined with their high efficiency means that there is little chance of β-lactam antibiotics reaching their targets without being hydrolysed.

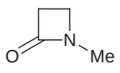
Chemical reactivity of β-lactams

Four membered β-lactams occur relatively rarely in nature, therefore it is not surprising that the biological activity of these compounds should be attributed to the chemical reactivity of the β-lactam ring. Shortly after the introduction of penicillin to the medical world it was suggested that the antibiotic's activity was due to the inherent strain of the four-membered ring or to reduced amide resonance.[7] The non-planar butterfly shape of the penicillin molecule **7** could reduce amide resonance and thus increase the susceptibility of the carbonyl group to nucleophilic attack, compared with planar amides. However, there is little evidence to suggest that the kinetic reactivity of β-lactams in penicillins and cephalosporins is due to an unusually strained or an amide-resonance inhibited β-lactam.[2] Interestingly, although the rate of alkaline hydrolysis of the simple β-lactam **8** is only three-fold greater than that of **9**,[2] the corresponding 4-membered β-sultams[8] and β-phospholactams[9] are 10^7–10^9 fold more reactive than the corresponding acyclic sulfonamides and phosphonamidates, respectively.

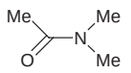
Nucleophilic substitution at the carbonyl of β-lactams is an acyl transfer process involving covalent bond formation between the carbonyl carbon and the nucleophile and C–N bond fission of the β-lactam (Scheme 2). In these types of reactions the mechanism involves, at least, a two-step process.[2,7] Covalent bond formation to the incoming nucleophile occurs before C–N bond fission, resulting in the reversible formation of



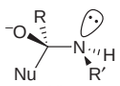
7



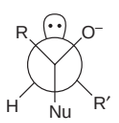
8



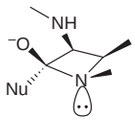
9



10



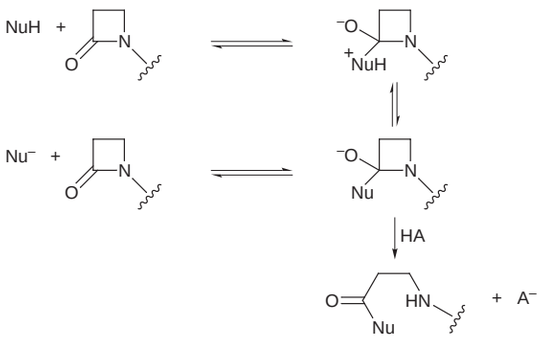
11



12

a tetrahedral intermediate. Contrary to expectations, opening the four-membered ring is not a facile process.[10] In many of these nucleophilic substitution reactions the rate-limiting step is often not the first addition step but a subsequent one which may sometimes even be ring-opening itself.[2]

Those reactions which involve the attack of a neutral nucleophile which has an ionisable hydrogen (Scheme 2) invariably require general base catalysis to remove the proton.[2,7] The requirement for proton removal is paramount—and in extreme cases only the reaction of the anionic nucleophile is observed (Scheme 2). For example, there is no pH-independent



Scheme 2

reaction of water with penicillin, and alcohols react only through their anions.[11] The importance of general base catalysis is a reflection of the fact that contrary to expectations penicillins are not powerful acylating agents.[11] Similarly, C–N bond fission requires protonation of the amine nitrogen.[2,7]

It has been suggested that ring opening does not occur by stretching of the C–N bond but rather by a rotational motion.[10,12] This minimises strain effects and maximises favourable orbital interactions. The unusual mode of C–N bond fission could have interesting consequences in the enzyme-catalysed hydrolysis of β-lactams for the geometrical relationship of the proton donor in the protein and the amine leaving group.

Another interesting difference between nucleophilic substitution in penicillins and peptides/amides is the preferred direction of attack and the geometry of the initially formed tetrahedral intermediate. It is usually assumed that nucleophilic attack on the carbonyl carbon of a planar peptide will generate a tetrahedral intermediate with the lone pair on nitrogen *anti* to the incoming nucleophile, (**10**, **11**). Conversely, nucleophilic attack on β-lactams occurs from the least hindered α-face (*exo*) so that the β-lactam nitrogen lone pair is *syn* to the incoming nucleophile in the tetrahedral intermediate (**12**).[13, 14] This has obvious consequences for the placement of catalytic groups—particularly the general acid donating a proton to the departing amine of the β-lactam.[12]

β-Lactamases

The main mechanistic division of β-lactamases is into serine enzymes and zinc enzymes.[3] The former have an active site serine residue and the catalytic mechanism involves the formation of an acyl–enzyme intermediate. The metallo-enzymes appear to involve only non-covalently bound intermediates. On the basis of their amino acid sequences, the serine β-lactamases are sub-divided into three classes—A, C and D—whereas the class B β-lactamases consist of the zinc enzymes.[3]

Serine β-lactamases

Structure

The class A and class C enzymes are monomeric medium-sized proteins with M_r values of about 29 000 and 39 000, respectively.[3] The structures of four class A[15–17] and two class C[18,19] β-lactamases have been reported. There are two major structural domains—all-α and α/β—with the active site situated in a groove between the two domains. The class C β-lactamases have additional loops and secondary structure on the all-α domain. The active site serine is situated at the N-terminus of the long, relatively hydrophobic, first α-helix of the all α-domain. There are several highly-conserved residues surrounding the active site which may be involved in substrate recognition and the catalytic process of bond making and breaking. Firstly, a lysine residue is always present as the third amino acid and one helix-turn further down the chain from the serine and pointing into the active site. Two other residues forming one side of the catalytic cavity are Ser-Xaa-Asn (class A) or Tyr-Xaa-Asn (classes C and D) with the side chains of the first and third residues pointing into the active site. The Ser130-Asp131-Asn132 (the SDN loop) motif is also almost invariant in class A. The other side of the cavity is formed from the β-sheet of the α/β domain and is generally Lys-Thr-Gly. In class A enzymes there is also a conserved glutamate which, in the static crystal structure, is hydrogen-bonded to a conserved water molecule which in turn is hydrogen-bonded to the active site serine.

Mechanism of hydrolysis

There is very strong evidence for the formation of an acyl enzyme intermediate (Scheme 3)—including electrospray mass

Scheme 3

spectrometry,[20] infra-red measurements,[21] trapping experiments,[22] the determination of the rate constants for their formation and breakdown[23] and even an X-ray crystal structure.[24]

The two experimental kinetic parameters associated with simple systems exhibiting Michaelis–Menten behaviour are the second-order rate constant k_{cat}/K_m determined below saturation and the first order rate constant k_{cat} determined above saturation.[25] The *interpretation* of these experimental macroscopic rate constants as they vary with parameters such as pH, substituents in the substrate[26,27] and amino acid replacement in the enzyme[28] depends upon the model assumed for the reaction pathway. The overall reaction pathway for the serine β-lactamases is given in eqn. (1).

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EA \xrightarrow{k_3} E + P \qquad (1)$$

It is usually assumed that formation of the usually relatively unstable acyl enzyme (EA) is irreversible, *i.e.* $k_{-2} = 0$ and the second-order rate constant k_{cat}/K_m, determined below saturation

conditions, is then given by eqn. (2) and hence always reflects the rate of acylation *irrespective* of the value of k_2 and k_3.

$$\frac{\text{Rate}}{(\mathbf{E})(\mathbf{S})} = \frac{k_{cat}}{K_m} = \frac{k_1 k_2}{k_{-1} + k_2} \quad (2)$$

Under saturation conditions the observed rate constant, k_{cat}, is independent of substrate concentration and is given by eqn. (3) and so simplifies to the rate of acylation k_2, if $k_3 >> k_2$ and the enzyme is essentially present as the enzyme–substrate complex. Conversely, k_{cat} reflects the rate of deacylation, k_3, when $k_2 >> k_3$ and the enzyme is present mainly as the acyl enzyme.

$$k_{cat} = \frac{k_2 k_3}{k_2 + k_3} \quad (3)$$

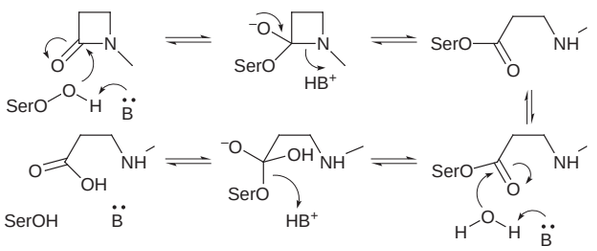
However, if formation of the acyl enzyme is *reversible* then k_{cat}/K_m and k_{cat} are given by eqns. (4) and (5), respectively. For

$$\frac{k_{cat}}{K_m} = \frac{k_1 k_2 k_3}{k_3(k_{-1} + k_2) + k_{-1}k_{-2}} \quad (4)$$

$$k_{cat} = \frac{k_2 k_3}{k_2 + k_{-2} + k_3} \quad (5)$$

serine proteases, k_{-2} represents the 'intermolecular' aminolysis of the acylenzyme to regenerate the peptide substrate. For the hydrolysis of β-lactams catalysed by β-lactamases the k_{-2} step corresponds to 'intramolecular' aminolysis to regenerate the β-lactam substrate (Scheme 3). Although the formation of a strained four-membered β-lactam is likely to have a significant activation energy it is not totally inconceivable that this intramolecular step has an entropic advantage[29] and is competitive with intermolecular hydrolysis of the acylenzyme. For example, we have demonstrated, using esterase enzymes, that lactams can be formed from amino esters in water in preference to the hydrolysis product.[30] The interpretation of the macroscopic rate constant k_{cat}/K_m may then become ambiguous because it reflects all microscopic rate constants up to and including the first effectively irreversible step.

Formation of the acyl enzyme intermediate requires at least two proton transfers—proton removal from the attacking serine and proton donation to the departing β-lactam amine (Scheme 4). Despite the availability of a number of X-ray crystal



Scheme 4

structures of several class A and class C β-lactamases[15–19] and many site-directed mutagenesis studies,[28] the indentity of the catalytic groups involved in these proton transfer steps remain elusive.

In principle, the general base which accepts a proton from the nucleophilic serine is not necessarily the same residue which then acts as a general acid to donate a proton to the departing β-lactam nitrogen. Conceptually this is neater and our prejudices are reinforced by the juxtaposition of the nitrogen lone pair, the serine and the general base/acid being on the same (*exo*) α-face of the substrate in the tetrahedral intermediate **12**. Similarly, the hydrolysis of the acyl enzyme requires two proton transfer steps—from water and to the departing serine—and only our preference for simplicity requires these to be one and the same residue *and* the same as that involved in the acylation step (Scheme 4). This hydrolytic water probably also approaches from the α-face and can be displaced by a 6α- or 7α-substituent in the penicillin or cephalosporin nucleus, respectively, which explains the poor activity of class A β-lactamases against imipenem[31] and cephamycins.[32] Protein stability measurements of covalently-bound phosphonates to a class A β-lactamase also support this hypothesis.[33]

There are therefore at least four transition states corresponding to formation and breakdown of the tetrahedral intermediate to give initially the acyl enzyme followed by its hydrolysis (Scheme 4). The concept of a unique 'transition state analogue' as an inhibitor for an enzyme catalysing a reaction through many steps becomes ambiguous—there could be many analogues corresponding to different transition states.[34] The evolutionarily-perfect enzyme reduces the transition state energies for all steps in the conversion of reactants to products without 'over-stabilising' any intermediates.[35] The maximum second-order rate constant for an enzyme-catalysed reaction is that corresponding to diffusion control (*ca.* 10^8 M^{-1} s^{-1}) and some β-lactamases appear to be near this limit and are 'perfect catalysts'.[36]

In class A β-lactamases there are two serious contenders for the general base/acid—Glu166 and Lys73. The pH-dependence of k_{cat}/K_m indicates two ionising residues are important for catalysis—one of pK_a *ca.* 5 and formally required in its basic form and one of pK_a *ca.* 9 and formally required in its acidic form. If the low pK_a group corresponds to the general base then this is acceptable for the carboxylic acid of Glu166 but is rather low for an ammonium ion of Lys73. Although it has been suggested that Lys73[24,37] may have a reduced pK_a it is difficult to envisage the required reduction of 5.6 pK_a units given the close proximity to Glu166 (2.8 to 3.4 Å).[15–17] A normal pK_a of Lys73 is supported by ^{13}C NMR studies[38] and theoretical calculations.[39] In class A β-lactamases[15–17] the Glu166 carboxylate oxygen distance to Ser70 oxygen is 3.5–4.0 Å whereas the Lys73 nitrogen distance to the Ser70 oxygen is 2.5–2.9 Å. It is possible that the intervening water molecule, seen in the crystal structure, can act as a bridge for proton transfer from Ser70 to Glu166, acting as a general base catalyst. Alternatively, the flexibility of the Ω-loop on which Glu166 resides may allow the distance between the two residues to shorten during the acylation process. The internal structures of proteins are in a state of constant motion at ambient temperature and a degree of flexibility in β-lactamases has been proposed for many years.[40] The ability of β-lactamases to accommodate substrates of diverse structure is indicative of their flexibility.

Site-directed mutagenesis of Glu166 shows that the rates of both acylation and deacylation are affected, although the latter is more so.[28] However, in general base-catalysed reactions the dependence of reactivity upon the basicity of the catalyst and the geometrical relationship between the acid-base pair is not usually strong.[25] It is quite conceivable for mutants to act as reasonable catalysts even when the amino acid residue acting as the general base/acid in the wild type is replaced because another residue, or even the peptide link itself,[14] can take over the role of proton acceptor/donor without significant loss of activity.

On balance it appears that the evidence supports Glu166 (Scheme 4, B = $GluCO_2^-$) acting as the unique proton transfer agent—as a general base and acid in the formation and breakdown of the tetrahedral intermediate, respectively, and in the same role for the hydrolysis of the acyl enzyme intermediate.

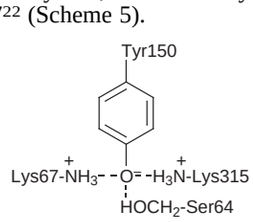
Class C β-lactamases

Historically, class C β-lactamases were often referred to as 'cephalosporinases' because of the characteristic higher turnover numbers, k_{cat}, observed for cephalosporins compared with penicillins. However, the k_{cat}/K_m values for the two classes of enzymes are generally similar and high for both penicillins and

cephalosporins (10^5 to 10^8 M^{-1} s^{-1}).[41] A major difference between the two classes is that for class C β-lactamases deacylation is often rate-limiting, so that the acyl enzyme intermediate may accumulate, giving rise to low values of K_m.[41] Furthermore, class C enzymes are weak catalysts for the hydrolysis of non β-lactam substrates such as esters and thioesters.[42] In class C β-lactamase there is no equivalent glutamate residue but Tyr150 may take its role with Lys67 equivalent to Lys73 in the class A enzyme.[18,19] In addition, it has been suggested that the hydrolytic water involved in deacylation of the acylenzyme approaches from the β-face[43] and that this hydrolysis may be substrate-assisted by the expelled amine, which was the β-lactam nitrogen, acting as a general base catalyst.[44] In class C β-lactamase it has been suggested that the phenol of Tyr150 has a severely reduced pK_a and acts as a general base catalyst for proton removal from Ser64[18,42] although this is not supported by site-directed mutagenesis of Tyr150.[45]

The *E.cloacae* P99 class C β-lactamase catalysed hydrolysis of benzylpenicillin has been shown to yield, in addition to the normal hydrolysis product, the penicilloyl α-methyl ester in the presence of methanol.[22] This is presumably due to the partitioning of the acyl enzyme intermediate between its reaction with water to give the hydrolysis product and its reaction with methanol to produce the penicilloyl ester. At pH 8, with 1 M methanol, up to 30% of the product is the methyl ester. Under saturation conditions the pH-dependence for the second-order rate constant for methanolysis gives two apparent pK_as for the methanolysis reaction which are similar to those observed for hydrolysis, implying that the same catalytically important groups are being used for both reactions.[22]

The absolute values of the pK_a and their shift in D_2O indicate differences between the acidic and basic limbs of the pH–rate profiles. The shift in pK_a^2 in D_2O obtained from k_{cat}/K_m and k_{cat} for hydrolysis is about 0.4 and is that expected from fractionation factors for common acidic groups.[46] However, ΔpK_a^1 is 0.85 from k_{cat}/K_m and k_{cat} for both methanolysis and hydrolysis. This shift and the observed inverse kinetic solvent isotope effect on k_{cat}/K_m is unusual and is indicative of a system with an abnormally low fractionation factor for the basic species formed and/or a high fractionation factor for the protonic state undergoing dissociation.[47] The most likely basic group responsible for the acid limb of the pH–rate profile for both acylation and deacylation is Tyr150, which is hydrogen-bonded to Lys315 and Lys67[22] (Scheme 5).

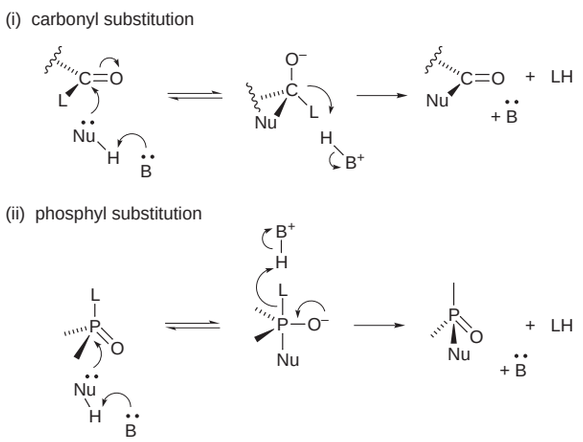


Scheme 5

Because of its relatively positive environment and the strong hydrogen bonding of the phenoxide ion by lysine residues, Tyr150 has a severely reduced pK_a. It appears that the Tyr150 residue is a very strong candidate for the role of a general base catalyst in class C β-lactamases (Scheme 4, B = TyrO$^-$).[22]

Catalytic efficiency of β-lactamase-catalysed acyl and phosphyl transfer

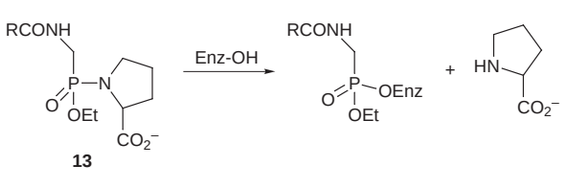
Nucleophilic substitution at acyl centres generally proceeds *via* the formation of an unstable tetrahedral intermediate (TI).[25] The reaction pathway involves a change in geometry as the carbonyl carbon is converted from three- to four-coordination. Furthermore, it is usually assumed that there is some preferential direction of nucleophilic attack such that the incoming nucleophile approaches at approximately the tetrahedral angle to the carbonyl group.[48] By contrast, the associative mechanism for phosphyl group transfer involves a pentacoordinate intermediate with trigonal bipyramidal geometry.[25,49] An initially four-coordinate and tetrahedral phosphorus centre is converted to a five-coordinate one and, in general, it is assumed that the preferential pathway involves the nucleophile taking up the apical position and the leaving group departing from an apical position of the trigonal bipyramidal intermediate (TBPI).[49] Nucleophilic attack at both carbonyl and phosphyl centres is often facilitated by general base catalysis when the nucleophile generates an acidic centre upon covalent bond formation in the intermediate. Similarly if the leaving group is very basic, bond fission and expulsion of the leaving group may be assisted by general acid catalysis. Given the preferential geometrical requirements for incoming nucleophiles and departing leaving groups, there must be a favoured relative positioning of the general base and general acid catalysts (Scheme 6).



Scheme 6

It is often assumed, but with little actual supporting evidence, that enzymes catalyse reactions by an exquisite positioning of the catalytic groups.[50] This is obviously not the case for β-lactamases, which efficiently catalyse the hydrolysis of both penicillins and cephalosporins where there are significant geometrical differences, *e.g.* between the β-lactam carbonyl and nitrogen and the C-3 carboxylic acid in penicillins and that at C4 in cephalosporins. Also if rigid positioning of catalytic groups was so important then it is doubtful if an enzyme with a primary function as a catalyst for acyl transfer could be an effective catalyst for phosphyl transfer because of the geometrical differences in the displacement mechanisms (Scheme 6), although the possibility of pseudorotation in the intermediate may make matters even more complicated.

The class C β-lactamase is, in fact, extremely efficient in enhancing the rate of phosphyl transfer[51] and the pH dependence of the kinetic parameters indicate that similar catalytic machinery is used for both acyl and phosphyl transfer. The class C β-lactamase from *Enterobacter cloacae* P99 is inactivated by the phosphonamidate **13** (R = BnO)[51] by a phosphonylation process analogous to the enzyme-catalysed acylation by the penicillins (Scheme 7).



13

Scheme 7

It is necessary to demonstrate that the enzyme actually *enhances* the rate of the phosphonylation reaction. It is well-known that enzymes can catalyse the same reaction of a variety

of substrates and even different reactions with alternative substrates.[52] However, demonstrating the efficiency of the catalysis when the substrate is modified is not straightforward. Modification of the substrate structure can affect the absolute free energies of both the initial reactant state and the transition state, whereas the observed differences in rate constants for the enzyme catalysed reaction only reflect the *difference* in energies between these two states.[53] Different chemical structures can affect the ease of bond-making and -breaking *via* classical electronic factors such as inductive, resonance and steric effects. However, the free energy of activation of an enzyme-catalysed reaction is also affected by the favourable binding energies between the protein and substrate substituents not directly involved with the reaction site. It is therefore necessary to separate these two effects before conclusions about the efficiency of enzyme catalysis can be made. We have suggested[26] that an 'enzyme rate-enhancement factor' (EREF) can be evaluated by dividing the second-order rate constant for the enzyme catalysed reaction, k_{cat}/K_m, by that for hydrolysis of the same substrate catalysed by hydroxide ion, k_{OH}. These factors 'normalise' substrate reactivity and indicate the true efficiency of catalysis.

Both diastereoisomers of the phosphonamidate **13** (R = BnO) completely and irreversibly inactivate the P99 class C β-lactamase in a time-dependent manner to give apparent first order rate constants, k_{obs}, for inactivation. These in turn show a first-order dependence on the concentration of the phosphonamidate to give the second-order rate constants, k_i, for inactivation. The two diastereoisomers show different rate constants for inactivation (5.10 and 0.14 $dm^3\ mol^{-1}\ s^{-1}$). There is no discernible difference in the chemical reactivity of the two diastereoisomers towards alkaline hydrolysis. The 36-fold difference in reactivity is therefore good evidence of selectivity in the reaction of the enzyme with the two phosphonamidates and indicative of specific interactions between the inactivators and the protein. Further evidence of selectivity is seen from the fact that the phosphonamidate **13** (R = BnO) is not a significant inhibitor of either the class A β-lactamase or the class B zinc-dependent β-lactamase from *B. cereus*. The time-dependent inactivation is indicative of covalent bond formation between the enzyme and the phosphonamidate, which is confirmed by electrospray mass spectrometry (ESMS).[51] For the most reactive diastereoisomer, inactivation of the enzyme occurs by formation of a 1 : 1 covalently bound enzyme–inactivator complex in which a proline residue has been displaced by a nucleophilic group on the enzyme—presumably the active site serine. Conversely, the less reactive diastereoisomer reacts with β-lactamase by displacing ethanol, which can be detected by gas chromatography. The observation that the enzyme reacts with one diastereoisomer by displacing proline and with another by displacing ethanol is again indicative of a stereoselective reaction occurring at the active site.

Phosphonamidates are relatively chemically stable and the fast reaction with the β-lactamase indicates that the catalytic machinery of the enzyme used for hydrolysis is also used for phosphonylation and inactivation. This is confirmed by the enzyme rate enhancement factors. The P99 β-lactamase catalyses the hydrolysis of benzylpenicillin with an EREF of 2.6×10^8. Phosphonylation of β-lactamase by the most reactive diastereoisomer of the phosphonamidate **13** occurs by P–N fission and displacement of proline, but the hydroxide ion-catalysed hydrolysis of the phosphonamidate **13** occurs with P–O fission, so the EREF value for phosphonylation is therefore $> 2 \times 10^6$. Clearly, the enzyme is facilitating P–N fission almost as effectively as it does C–N fission in β-lactams. Despite the differences in geometrical requirements for substitution at acyl and phosphyl centres and the enormous differences in intrinsic chemical reactivities between the β-lactam in penicillin and the phosphonamidate, the β-lactamase enzyme is able to significantly lower the activation energy for reactions of both compounds.

The generation of a formal negative charge on oxygen in the tetrahedral intermediate is accompanied by a large change in the basicity of the oxygen—a change in pK_a of the corresponding conjugate acids of at least 12 pK_a units (Scheme 6). The kinetically important species of the tetrahedral intermediate is its anion even though the thermodynamically more stable form is the neutral conjugate acid at neutral pH. Nonetheless, the anion must be strongly solvated by hydrogen-bonding and many enzymes which catalyse acyl transfer reactions have an 'oxyanion hole' which stabilises the tetrahedral intermediate by hydrogen-bonding from adjacent peptide links. The *difference* in this interaction between the initial state carbonyl oxygen and the tetrahedral intermediate as a result of the change in oxygen basicity makes a major contribution to the lowering of the activation energy compared with the non-enzyme-catalysed reaction.[54] Such an 'oxyanion hole' exists for the serine β-lactamases[55] and, in common with serine proteases, one of the peptide N–H hydrogen-bond donors is that belonging to the serine residue—Ser70 in the class A enzymes and Ser64 in the class C enzymes. The 'intramolecular' hydrogen-bond with the active site serine peptide NH presents a fairly well-defined geometry. In the equivalent pentavalent phosphyl enzyme the negative charge on the oxygen presumably takes up an equatorial position so that it is *ca*. 90° to the newly formed serine O–P bond compared with the approximately tetrahedral angle formed with the β-lactam substrate (Scheme 6). Despite these differences, the enzyme is capable of catalysing the phosphonylation with extreme efficiency.

It is often assumed that the phosphylation of serine enzymes can only occur with organophosphorus compounds with good leaving groups because these do not require proton transfer from general acid catalysts to aid departure.[56] However, the class C β-lactamase is obviously capable of displacing the proline residue from the phosphonamidate **13** despite the poor leaving group and the presumed need for protonation of the amine nitrogen.

There are two ionisations in class C β-lactamase which control hydrolytic catalytic activity (Fig. 1)—corresponding to

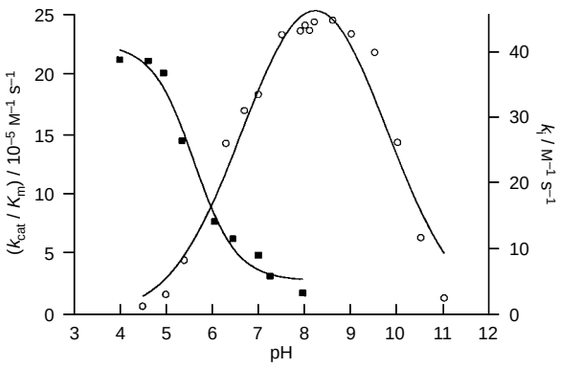


Fig. 1 (○) A plot of k_{cat}/K_m (left hand axis) for the class C *E.cloacae* β-lactamase-catalysed hydrolysis of benzylpenicillin against pH and (■) k_i (right hand axis) against pH for the inactivation of the enzyme by the phosphonamidate **13 (R = BnO)**

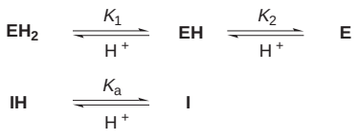
groups of pK_a *ca.* 6.1 and 10.1.[22] The pH-dependence of k_i (Fig. 1) shows that inactivation also depends on a catalytic group of pK_a 6.2, which suggests that the catalytic machinery used for hydrolysis is also used for the phosphonylation of **13**. However, the pH–rate profile for inactivation indicates an additional proton is required, *i.e.* whereas hydrolysis apparently requires the group of pK_a 6 to be in its deprotonated, basic form, phosphonylation apparently requires this group to be in its protonated, acidic form, which is probably the result of kinetic ambiguity. The rate of hydrolysis of the substrate **S** is proportional to [**EH**][**S**] where [**EH**] is the protonic form of the enzyme with the groups of pK_a 6 and 10 in their basic and acidic forms, respectively (Scheme 8). The observed kinetics (Fig. 1)

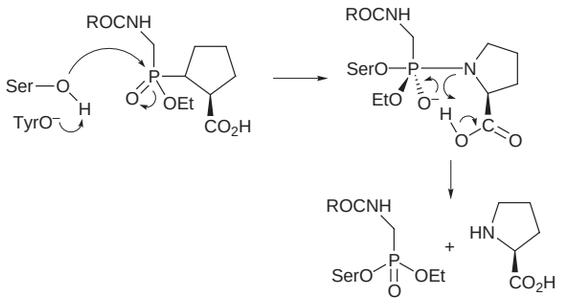


Scheme 8

for inactivation by the inhibitor **I** indicate a rate proportional to [$\mathbf{EH_2}$][**I**], which, for a process of phosphonylation of the active site serine (Scheme 7) is difficult to interpret mechanistically. Of course, the rate law can have various kinetic equivalents [eqn. (6)].

$$\text{Rate} = k_i[\mathbf{EH}_2][\mathbf{I}] = \frac{k_i}{K_1}[\mathbf{EH}][\mathbf{I}][\mathbf{H}^+] = \frac{k_i K_a}{K_1}[\mathbf{EH}][\mathbf{IH}] \quad (6)$$

Phosphonylation could occur through **EH** with the group of pK_a 6 acting as a general base for serine attack as in the hydrolytic reaction (Scheme 9). Breakdown of the trigonal bipyramidal



Scheme 9

intermediate, however, could occur by proton donation to the proline nitrogen from the solvent hydronium ion and not the protein [eqn. (6)]. Only the L-proline phosphonamidate **13** (R = BnO) is an effective inhibitor; the corresponding ester is ineffective and the D-proline isomers are much weaker. This could reflect the normal requirement of a carboxylate anion for molecular recognition. It could, however, indicate that the reaction occurs through **EH** and **IH** [eqn. (6)] where the latter is the conjugate acid of the phosphonamidate **13**, *i.e.* with the carboxylic acid group undissociated. The pK_a of this carboxylic acid is 3.86, so, over the pH range studied for inactivation, the major species present is the carboxylate anion of the phosphonamidate **13**. The pH-dependence for inactivation (Fig. 1) would then be given by eqn. (7). The true second-order rate constant for phosphonylation would then be k_iK_1/K_a =

$$k_{obs}^{inact} = k_i \cdot \frac{K_1}{K_a} \cdot \frac{H^+}{K_1 + H^+} \quad (7)$$

6.43×10^3 dm^3 mol^{-1} s^{-1}, giving an EREF of $> 3\times 10^9$. The class C β-lactamase is indeed very effective at enhancing the rate of phosphonylation. If the mechanism does involve the undissociated carboxylic acid of the phosphonamidate as 'substrate' then this is probably the result of 'substrate'-assisted catalysis, with the carboxylic acid acting as an intramolecular general acid catalyst facilitating P–N fission from the trigonal bipyramidal intermediate (Scheme 9).

Class B metallo-β-lactamases

Class B β-lactamases are metalloproteins which require zinc(II) ions for their activity. The first of these enzymes discovered was called β-lactamase II[57] and is produced by *Bacillus cereus*, which also produces two distinct class A enzymes. In 1985 there were just two species identified as producing metallo-β-lactamases. Now there are at least 20 bacterial sources of the metallo-enzyme including those found in *Pseudomonas maltophilia* (L-1), *Aeromonas hydrophila* (A2) and *Bacteroides fragilis*.[58]

Although these metallo-enzymes were initially thought to be clinically unimportant, some pernicious strains have been shown to owe their antibiotic resistance to their ability to produce zinc-β-lactamases.[59] The mechanism-based inactivators which have been used against the serine enzymes are generally ineffective against the Zn^{II}-dependent enzymes, and, at present, there are no clinically-useful inhibitors known. One of the main characteristics of the zinc-enzyme is its ability to catalyse the hydrolysis of nearly all β-lactams including carbapenems **3**. These β-lactamases are extremely efficient at catalysing the hydrolysis of imipenem with values of k_{cat}/K_m of *ca*. 10^6 M^{-1} s^{-1}, which is at least a 1000-fold greater than that shown by 'classical' class A β-lactamases such as TEM-1. A review of the catalytic properties of the well-characterised class B β-lactamases shows that the *A. hydrophila* enzyme exhibits the most specific substrate profile, while the other enzymes are rather broad-spectrum.[60]

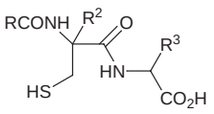
The sequences of the metallo-β-lactamases have been established and they all contain a single peptide chain, composed of 220–230 residues.[61] A sequence comparison indicates that the *P. maltophilia* enzyme is only remotely related to the others, which do appear to constitute a more homogenous group and exhibit 37 strictly conserved residues. Surprisingly, His86, one of the histidine residues which seems to be involved as Zn^{II}-binding ligands in the *Bacillus cereus* enzyme, is replaced by an Asn residue in the *A. hydrophila* β-lactamase.

Of particular ambiguity is the number of zinc ions per molecule of β-lactamase. A low resolution crystal structure of the *B. cereus* (569/H/9) β-lactamase showed 1 mol of Zn^{II} in the active site bound by three histidines and one cysteine.[62] A second metal-binding site was identified, but this only weakly bound Zn^{II}. However, more recently, a second crystal structure of the same enzyme showed only a single metal-binding site, with other significant differences. The zinc ion, in the *B. cereus* (569/H/9) β-lactamase is coordinated by three histidine residues (86, 88 and 149) and, probably, a water molecule in a distorted tetrahedral arrangement.[63] Equilibrium dialysis[64] and ^{1}H NMR analysis[65] indicate that the *B. cereus* II enzyme is capable of binding two zinc ions but computer-assisted molecular modelling indicates there is just one major metal ion binding site.[62] As with many metallo-β-lactamases, the zinc ion of the *B. cereus* II enzyme can be replaced by different metal ions and still retain some β-lactamase activity.[64] Most mechanistic and structural information is derived from the *B. cereus* enzyme. However, there has very recently been a structure reported for the binuclear zinc β-lactamase from *B. fragilis*[66] which tightly binds both Zn^{II} ions, although the loss of a single Zn^{II} is not catastrophic for β-lactamase activity.[67].

The mechanism of action of *B. cereus* II metallo-β-lactamase is generally thought to be similar to that of carboxypeptidase A and to involve a water molecule, bound to the zinc ion of the active site, attacking the carbonyl group of the β-lactam ring. It was originally proposed that glutamate-37 acts as a general base and deprotonates the water molecule with the proton subsequently being donated to the nitrogen atom of the β-lactam ring to cause cleavage.[68] However, glutamate-37 is too far from the zinc ion to perform this function and site-directed mutagenesis studies have shown this glutamate is not essential for the catalytic function of the enzyme.[69] It has been demonstrated that aspartate-90 is essential for enzyme activity and consequently suggested that this residue acts as the general base to assist in the hydrolysis of the amide bond of β-lactam substrates.[63,70] In summary, it is not known whether the hydrolysis of β-lactams catalysed by class B β-lactamases occurs by general base catalysis or whether zinc acts simply as an electrophile or as a provider of zinc-bound hydroxide ion. Furthermore, if there is a second binding site for zinc its exact role is not known.

Inhibition of metallo-β-lactamases

Whatever the detailed mechanism of action of β-lactamase, it is likely that zinc(II) stabilises the tetrahedral intermediate **12** presumed to be formed during the catalytic process. Thiols are well-known inhibitors of metallo-proteases because of their ability to coordinate to the active site zinc.[34] We have synthesised several thiol derivatives with structures containing suitable sites for molecular recognition (**14**) as potential



14

inhibitors of the class B metallo-β-lactamases.[71,72] The thiols are indeed competitive inhibitors of the *B.cereus* class B β-lactamase and values of K_i were determined by the effect of varying concentrations of the thiol on the value of the second-order rate constant k_{cat}/K_m for the hydrolysis of benzylpenicillin and cephaloridine. The inhibition constants vary from 10 to 400 μM and are dependent on the nature of the substituents and the stereochemistry at R^2 and R^3.[71] The antihypertensive drug and ACE thiol inhibitor captopril is also an effective inhibitor with a K_i of 27 μM. Replacing the CH_2SH moiety in **14** by CO_2H gives far less effective inhibitors. As described later, these thiol inhibitors were useful in determining the pK_a of the zinc bound water.[72]

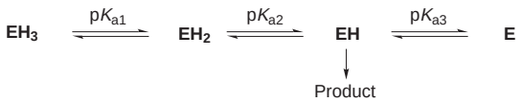
Despite the increasing clinical importance of the metallo-β-lactamases there have been few reports of effective inhibitors.[73]

Mechanism of hydrolysis

The number of binding sites for zinc(II) per molecule of class B β-lactamases appears to be one[63] or two.[66] The crystal structure of the enzyme from *B.cereus* 569/H used in our studies has one tightly bound zinc.[63] The effect of additional zinc(II) in solution on the catalytic activity of the enzyme is minimal. Between pH 5.5 and 7.0 a ten thousand-fold excess of zinc(II) increases k_{cat}/K_m by less than 36%, indicating that for this enzyme, at least, there is no catalytically important second site for zinc(II).[72]

The pH-dependence of the rate of hydrolysis of β-lactams catalysed by the class B metallo-β-lactamase from *B. cereus* is very unusual. The pH-dependence of the logarithm of the rate constants, k_{cat}/K_m and k_{cat}, for the hydrolysis of benzylpenicillin and cephaloridine show characteristic bell-shaped behaviour, but, amazingly, *the slope on the acidic limb is 2.0* and not the usual 1.0. The variations in kinetic constants are the result of reversible ionisation and are not due to acid-catalysed inactivation/degradation of the protein.[72] There is no evidence for rapid and reversible denaturation of the enzyme at pH 4.5 from changes in the CD spectrum.

It therefore appears that the rate is suppressed at lower pH because of *two* protonation processes. Because similar behaviour is observed for the two substrates, a penicillin and a cephalosporin, this unusual behaviour is attributable to protonation of the enzyme. The pK_as corresponding to these two equilibrium processes, *i.e.* pK_{a1} and pK_{a2} in Scheme 10, must be



Scheme 10

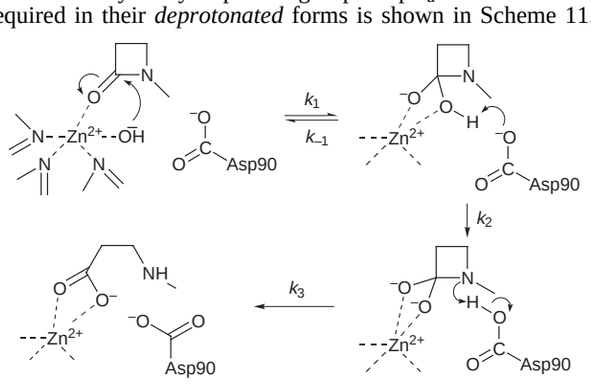
similar, with pK_{a1} = pK_{a2} = 5.60 ± 0.20. Altogether, there are *three* kinetically important ionising groups including one with a pK_a of 9.5 (Scheme 10). The mechanism may not necessarily involve the two groups of pK_a 5.6 and that of pK_a 9.5 in their deprotonated and acidic forms, respectively. The kinetics simply indicate that there are three basic residues and a proton controlling activity. Two of the most likely candidates for these ionisations are the zinc-bound water molecule and Asp90. The zinc of *B. cereus* β-lactamase is co-ordinated to three protein ligands—His86, His88 and His149—and a water molecule.[63] Formally, either the pK_a of 5.6 or 9.5 could conceivably correspond to the ionisation of zinc-bound water. The pK_a of hydrated Zn^{2+} is 9.5 but the enzyme environment and the nitrogen ligands could modify this. For example, the pK_a of zinc-bound water in carbonic anhydrase is 6.8[74] and in carboxypeptidase A it is 6.2.[75] The most likely amino acid candidate for the pK_a of 5.6 is aspartate-90, which is highly conserved.

It has been possible to deduce the pK_a of the zinc-bound water in β-lactamase by determining the dependence of the inhibition constant pK_i of the thiols **14** against pH. Binding is *pH-independent* between pH 6 and 9 but decreases in both acidic and basic solution—the inflections are very similar to those observed for enzyme-catalysed hydrolysis which indicates that the ionisation states of the enzyme required for catalysis are also those required for binding the inhibitor. However, the slope on the acidic limb is 1.0, in contrast to that observed for hydrolysis, which implies that only one acidic group in the enzyme has an effect on binding the inhibitor. The pH-independent binding of the thiol inhibitor between pH 6 and 9 indicates that the pK_a of the zinc-bound water is the low value of 5.6 because the only scheme which gives pH-independent binding between pH 6 and 9 would be if the neutral undissociated thiol, pK_a 9.5, binds to the species of enzyme in which the water bound to the zinc is fully deprotonated [eqn. (8)].[73]

$$EZn{\cdot}OH + RSH \rightleftharpoons EZn{\cdot}SR + H \qquad (8)$$

A major problem with the widely accepted mechanism of general base-catalysed removal of a proton from zinc(II)-bound water in a process which is concerted with nucleophilic attack on the β-lactam carbonyl group is the relative acidity of this proton. Even if the pK_a of the zinc(II)-bound water is about 9 then 10% of the species already exists in the fully deprotonated form at pH 8 and 1% at pH 7. Presumably, the deprotonated form is a much better nucleophile than the species which is only partially deprotonated. There is little or no catalytic advantage in having a general base remove a proton when the more active species is already present. Although C–N bond fission is the most energetically difficult process in amides hydrolysis, little attention is normally given to the mechanism of the breakdown of the tetrahedral intermediate.

The mechanism which is compatible with the observation that two catalytically important groups of pK_a *ca.* 5.6 are both required in their *deprotonated* forms is shown in Scheme 11.



Scheme 11

Zinc(II)-bound water is present at neutral pH in its deprotonated form and acts directly as the nucleophile to attack the β-lactam carbonyl. Zinc(II) also acts as an electrophile to stabilise the negative charge generated on the carbonyl oxygen on forming the tetrahedral intermediate. Ring opening of the β-lactam ring is not a facile process and this first step is likely to be reversible,

i.e. collapse of the tetrahedral intermediate to regenerate the β-lactam occurs at a faster rate than C–N bond fission ($k_{-1} >> k_2$, Scheme 11). This is not surprising; carbon–oxygen bond fission expels a reasonable leaving group—the zinc bound hydroxide ion, the conjugate acid of which has a pK_a of 5.6. Carbon–nitrogen bond fission to expel the amine leaving group will not occur without protonation of nitrogen. In amide hydrolysis carbon–nitrogen bond fission is sometimes facilitated by deprotonation of the tetrahedral intermediate to generate a dianionic tetrahedral intermediate. In the metallo-β-lactamase mechanism this process could occur by the carboxylate anion of Asp90 (Scheme 11) to give a dianionic system with two negatively charged oxygens bound to zinc. The formation of the dianion of the tetrahedral intermediate nicely explains the requirement for two negative charges in the transition state. Deprotonation of the attacking zinc-bound hydroxide also avoids formation of an unstable system of a neutral undissociated carboxylic acid bound to zinc(II). The final step would then involve general acid-catalysed breakdown of the zinc-bound dianionic tetrahedral intermediate with the now undissociated Asp90 donating a proton to the departing amine nitrogen (Scheme 11). Either k_2 or k_3 could be rate-limiting, and kinetic solvent isotope effects do not distinguish between these. The proposed mechanism also suggests structures which may be suitable for inhibiting the metallo-β-lactamases.

Summary

The battle between humans and bacteria appears relentless and the ability of bacteria to develop and pass on resistance to antibiotics seems never-ending. Understanding the mechanisms of the broad classes of β-lactamases makes one contribution to overcoming this conflict.

Although there is superficial similarity between the serine β-lactamases and the more familiar serine proteases the details of the mechanisms of the necessary proton transfer steps remains unknown. We need to know more about the mechanics of C–N bond fission in the β-lactam leading to ring opening. Given the relative conformational inflexibility of the normal β-lactam substrates it is intriguing to note the apparent flexibility of the enzyme in efficiently catalysing the reactions of a wide variety of substrates and inactivators. There does *not* appear to be an exquisite positioning of the catalytic groups and, indeed, the detailed mechanism may vary with substrate structure. This may be an advantage with respect to the design of potential enzyme inactivators and inhibitors. In addition to acyl and phosphyl transfer the serine β-lactamases may catalyse other reactions.

The metallo-β-lactamases are becoming clinically more important as a form of bacterial resistance. The mechanism of their action again appears to be different from the formally similar metallo-proteases. Now that it appears that a dianionic tetrahedral intermediate is involved, the design of suitable transition state analogues may lead to effective inhibitors of the zinc-dependent β-lactamases. The importance of a second metal ion in the metallo-β-lactamases remains unknown.

Mike Page is Dean of the School of Applied Sciences at the University of Huddersfield. He obtained his Ph.D. under the supervision of Brian Capon at the University of Glasgow in 1970 and subsequently worked with Bill Jencks at Brandeis on the energetics of intramolecular reactions and enzyme catalysis. Following a post-doctoral position with Ronnie Bell at Stirling on proton-transfer he moved to Huddersfield in 1973. His research interests are organic and bioorganic reaction mechanisms, enzyme catalysis and inhibition and the use of enzymes in synthesis. In 1991 he was a recipient of the 150th anniversary *Perkin Transactions* prize.

Andy Laws graduated from Lancaster University before moving to undertake a Ph.D. in Physical Organic Chemistry at Sussex University with Dr R. Taylor. In 1987 he took up a post-doctoral fellowship at Huddersfield University with M. I. Page. Presently he holds the post of Senior Lecturer in Organic Chemistry and still works very closely with Mike Page.

Experimental evidence for a [2 + 2] mechanism in the Lewis acid-promoted formation of α,β-unsaturated esters from ethoxyacetylene and aldehydes. Synthesis and characterisation of 4-ethoxyoxetes.

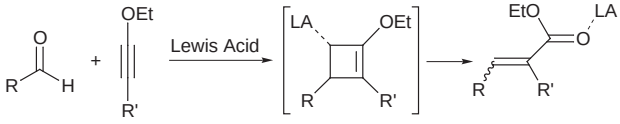
Magali Oblin,[a] Jean-Luc Parrain,[b] Michel Rajzmann[b] and Jean-Marc Pons*[a]†

[a] *Laboratoire Réactivité en Synthèse Organique (RéSo), UMR 6516, Faculté de St-Jérôme, boîte D12,13397 Marseille Cedex 20, France*

[b] *Laboratoire de Synthèse Organique, ESA 6009, Faculté de St-Jérôme, boîte D12, F-13397 Marseille Cedex 20, France*

4-Ethoxy-2*H*-oxetes 3a–c were prepared from ethoxyacetylene and alkoxy aldehydes 1a–c through $MgBr_2$–Et_2O promoted [2 + 2] cycloaddition reaction and were characterized at room temperature; their synthesis, which could occur *via* the formation of a chelate, establishes cycloaddition as the initial step in the formation of α,β-unsaturated esters 4a–c.

The formation of α,β-unsaturated esters from aldehydes or ketones and alkoxyacetylenes, under Lewis acid catalysis was first reported by Vieregge *et al*. in 1959.[1] The reaction immediately met with success as demonstrated in a review article published seven years later by the same authors.[2] In the same paper, the authors proposed that the mechanism involves the formation of an intermediate alkoxyoxete and its conrotatory ring-opening to give the corresponding α,β-unsaturated ester (Scheme 1).



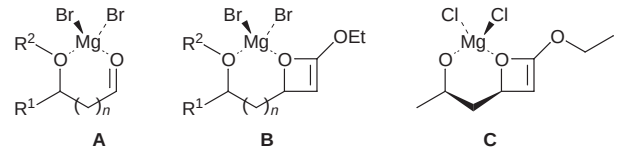
Scheme 1

The strongest evidence supporting such a mechanism at that time was the isolation by Middleton of an alkoxyoxete resulting from the non-catalyzed reaction between hexafluoroacetone and ethoxyacetylene.[3] Furthermore this oxete underwent a rearrangement to yield the corresponding unsaturated ester. Since then this reaction has attracted many experimental studies[4] and has even found application in synthesis where it can sometimes be used instead of the Wittig reaction.[5] However, to the best of our knowledge, no experimental evidence of the occurrence of a non-metallated oxete[6] in a Lewis acid catalyzed process has yet been reported. This is probably due to the instability of oxetes which have been seldom isolated or characterized.[7] Examples of alkoxyoxetes are also very scarce: in addition to the examples reported by Middleton[3] and Zaitseva *et al*.,[6] two others can be found in the literature.[8,9]

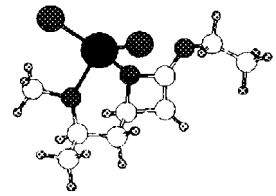
As part of an ongoing interest in Lewis acid-promoted [2 + 2] cycloadditions involving aldehydes,[10] we report the observation and characterization, at room temperature, of 2-ethoxy-2*H*-oxetes **3a**–**c**.

3-Benzyloxytetradecanal **1a** reacts with ethoxyacetylene **2** under $MgBr_2$–Et_2O catalysis in CH_2Cl_2 to yield after 30 min 2-(2-benzyloxytridecyl)-4-ethoxy-2*H*-oxete **3a** as a 4 : 1 mixture of diastereomers (Scheme 2, Table 1, entry 1).‡ 4-Ethoxy-2*H*-oxetes **3b,c**§ were also obtained (both as 9 : 1 mixtures of diastereomers) from aldehydes **1b,c** and were observed under the same conditions (Scheme 2, Table 1, entries 3 and 4).

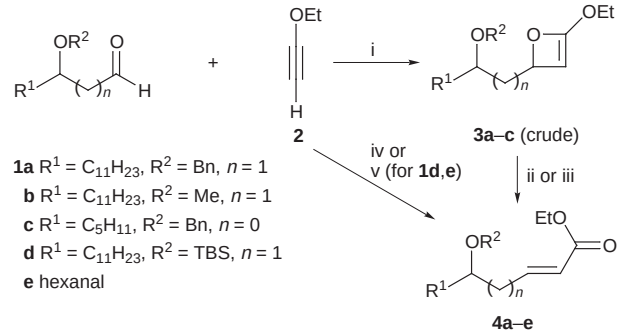
The obtention of oxetes **3a**–**c** could result from the formation of chelate **A**[11] which then would lead to the 'bicyclic' cycloadduct-chelate **B**. The rigidity of the chelate structure of **B**, *i.e.* its 'bicyclic' structure, under the reaction conditions, could then prevent the ring opening rearrangement. We have undertaken *ab initio* calculations on a model chelate **C** to establish that such an intermediate is indeed a minimum on a potential energy surface. Calculations were run at the HF/6-31G* level of theory. The total energy of **C** was found to be −1693.424205 au.



A **B** **C**



Further support for this explanation was found in the following experimental results (Table 1). When **2** and **1a** react under BF_3–Et_2O catalysis, the only product we were able to observe is α,β-unsaturated ester **4a** (Table 1, entry 2). Only traces of **3a** were identified during the monitoring of the reaction by TLC. The reaction between **2** and 3-(*tert*-butyldimethylsiloxy)tetradecanal **1d** (R^1 = $C_{11}H_{23}$; R^2 = TBDMS; n = 1) or hexanal **1e** under BF_3–Et_2O or $MgBr_2$–Et_2O catalysis leads, in all four cases (Table 1, entries 5–8), to the expected corresponding (*E*)-unsaturated esters **4d,e**. Indeed, in all these cases, the formation of chelates analogous to chelates **A** and



1a R^1 = $C_{11}H_{23}$, R^2 = Bn, n = 1
b R^1 = $C_{11}H_{23}$, R^2 = Me, n = 1
c R^1 = C_5H_{11}, R^2 = Bn, n = 0
d R^1 = $C_{11}H_{23}$, R^2 = TBS, n = 1
e hexanal

2 **3a–c** (crude) **4a–e**

Scheme 2 *Reagents and conditions*: i, $MgBr_2$–OEt_2 (3 equiv.), CH_2Cl_2, 15 min, −60 °C; ii, BF_3–OEt_2 (cal.), CH_2Cl_2, 1 min, −30 °C; iii, CH_2Cl_2 or $CDCl_3$, 2–3 h, room temp.; iv, BF_3–OEt_2 (1 equiv.), CH_2Cl_2, 30 min, −60 °C; v, $MgBr_2$–OEt_2 (3 equiv.), CH_2Cl_2, 15 min, −60 °C

Table 1 Preparation of oxetes **3a–c** and esters **4a–e** (yields are unoptimized) from aldehydes **1a–e**

Entry	Aldehyde	Lewis acid	Oxete (d.r.)	(*E*)-Ester (yield)
1	**1a**	$MgBr_2$–OEt_2	**3a** (4 : 1)	**4a** (88%)
2	**1a**	BF_3–OEt_2	—	**4a** (70%)
3	**1b**	$MgBr_2$–OEt_2	**3b** (9 : 1)	**4b** (67%)
4	**1c**	$MgBr_2$–OEt_2	**3c** (9 : 1)	**4c** (75%)
5	**1d**	BF_3–OEt_2	—	**4d** (60%)
6	**1d**	$MgBr_2$–OEt_2	—	**4d** (71%)
7	**1e**	BF_3–OEt_2	—	**4e** (56%)
8	**1e**	$MgBr_2$–OEt_2	—	**4e** (73%)

therefore **B** is not possible[12] and hence the conrotatory ring opening takes place.

Finally, although **3a–c** are stable in $CDCl_3$ solution at −20 °C,¶ their life-time at room temperature does not exceed 1 or 2 h and is a few seconds in solution at −30 °C in the presence of BF_3–Et_2O (in all three cases, ring opening leads to esters **4a–c**). This last observation gives further support for the structure of **3a–c** and to our hypothesis of the rigidity of chelate **B**.

In conclusion, we have provided the first evidence of a [2 + 2] mechanism for the studied reaction. We think that the isolation of oxetes **3a–c** at room temperature rests upon the formation of stable chelates **B** which prevents the conrotatory ring opening step of the reaction. Since the formation of **3a–c** occurs with good diasteroselectivity, studies are currently underway to use these as intermediates in synthesis.

We are grateful to Dr François Volatron (CNRS-Orsay) for useful discussions, and to Mrs Roselyne Rosas and Dr Robert Faure (Université d'Aix-Marseille) for NMR experiments.

‡ The structure of **3a** lies upon extensive 2D homo- and hetero-nuclear ^{1}H NMR experiments at 400 MHz. Experimental procedure: a solution of **1a** (0.35 mmol; 111 mg) in CH_2Cl_2 (1 cm^3) was added to a suspension of $MgBr_2$–OEt_2 (1.05 mmol; 270 mg) in CH_2Cl_2 (3 cm^3) at −60 °C under argon. After 15 min, a solution of **2** (0.70 mmol; 49 mg) in CH_2Cl_2 (2 cm^3) at room temp. was added dropwise to the suspension at −60 °C. TLC monitoring showed the reaction to be completed (no starting material left) after 15 min. The reaction mixture was diluted in light petroleum (10 cm^3) and hydrolyzed with ice–water (2 cm^3). Filtration and concentration *in vacuo* gave 126 mg of crude product; ^{1}H NMR (400 MHz) was used to establish the presence of **3a** as a 4 : 1 mixture of the two diastereomers. An increase in the temperature of the reaction mixture, up to −30 °C, prior to the hydrolysis led to unsaturated ester **4a** (88%). R_f (light petroleum–Et_2O = 7 : 3) **1a** : 0.5; **3a** : 0.25; **4a** : 0.75.

3a: major isomer: δ_H (400 MHz, $CDCl_3$) 7.35–7.25 (5 H, m, PhH), 5.12 (1 H, d, *J* 7.9, =CH), 4.60 (1 H, m, CH–O–), 4.59 (1 H, part A of AB system, J_{AB} 11.9, –O–C*H*$_a$H–Ph), 4.52 (1 H, part B of AB system, J_{AB} 11.9, –O–CH*H*$_b$–Ph), 3.89 (1 H, part A of ABX_3 system, J_{AB} 9.6, J_{AX} 7.1, O–C*H*$_a$H–Me), 3.86 (1 H, part B of ABX_3 system, J_{AB} 9.6, J_{AX} 7.0, O–CH*H*$_b$–Me), 3.66 (1 H, m, CH–OBn), 1.82 (1 H, part A of ABXY system, J_{AB} 14.5, J_{AX} 8.7, J_{AY} 3.7, O–CH–C*H*$_a$H–CH–O), 1.72 (1 H, part B of ABXY system, J_{AB} 14.5, J_{AX} 7.1, J_{AY} 3.3, O–CH–CH*H*$_b$–CH–O), 1.88–1.46 (6 H, m), 1.37–1.18 (14 H, m), 0.87 (3 H, t, *J* 7.0, –Me), 0.85 (3 H, br t, O–CH_2–*Me*); δ_C (50.3 MHz, $CDCl_3$) 138.3 (s), 138.0 (s), 128.5 (d, 2C), 128.0 (d, 2C), 127.9 (d), 111.8 (d), 77.0 (d), 77.1 (t), 68.7 (t), 68.6 (d), 39.8 (t), 33.4 (t), 32.0 (t), 29.8 (t), 29.7 (t, 2C), 29.6 (t, 2C), 29.4 (t), 25.4 (t), 22.8 (t), 14.2 (q, 2C).

§ ^{1}H and ^{13}C NMR data of **3b,c** are similar to those described for **3a**.

¶ Oxete **3c** was, for example, kept over 2 months in a NMR tube (^{1}H concentration). We first imagine that the relative stability of Lewis acid-free **3a** could result from an intramolecular π-stacking (between the double bond and the aromatic ring), but both the formation of **3b** and semiempirical (AM1) calculations were in disagreement with such an explanation.

Hydrophobic proteins: synthesis and characterisation of organic-soluble alkylated ferritins

Kim K. W. Wong,[a] Nicola T. Whilton,[a] Helmut Cölfen,[b] Trevor Douglas[a] and Stephen Mann[a]†

Alkylated derivatives of the iron storage protein, ferritin, have been prepared by carbodiimide-activated coupling of long chain primary amines to surface carboxylic acid residues; the proteins are soluble in dichloromethane as intact, non-aggregated biomolecules.

Ferritin is an unusual metalloprotein in that the inorganic centre consists of a large number of ions (up to 4500 Fe atoms) present as a biomineral (ferrihydrite, $Fe_2O_3{\cdot}nH_2O$) encapsulated within a 24-subunit polypeptide shell.[1] The organic shell is remarkably stable to thermal and chemical degradation due to strong subunit–subunit interactions, a property which offers much scope in using the protein micelle as a nanoreactor for the synthesis of biocompatible nanocolloids. Recently, we have developed synthetic routes to biomimetic ferritins reconstituted with non-native inorganic nanoparticles such as Fe_3O_4,[2,3] MnOOH,[4] FeS[5] or CdS.[6] These routes are generally dependent on a balance between the redox chemistry, oxidation kinetics and hydrolytic behaviour of metal ions, and are limited to aqueous-based media. Further developments should be possible if ferritin could be solubilized in organic media because this would allow a wide range of organometallic precursors to be used. In particular, sol–gel reactions based on alkoxide hydrolysis could be achieved within the polypeptide cage by preparing organic-soluble ferritin molecules which have a water-filled hydrophilic inner cavity and a hydrophobically modified outer surface. Such derivatives would be analogous to the reverse micellar (water-in-oil) phase of many surfactants but would have enhanced stability owing to the absence of dynamic exchange between ferritin subunits.

Here, we describe the first step towards this goal in which ferritins soluble in dichloromethane (DCM) have been prepared by alkylation reactions using long chain primary amines (C_n, n = 6, 9, 12, 14, 18). The method involves the carbodiimide activation of surface carboxylic acid groups[7] of the native protein or a demetallated derivative (apoferritin) followed by nucleophilic substitution in the presence of a large excess of the amine.‡ Coupling of hexyl, nonyl or lauryl chains produced clear red–orange (ferritin) or colourless (apoferritin) THF–H_2O solutions which were stable for at least 12 months. Similar reactions with tetradecylamine or stearylamine gave turbid mixtures which precipitated after a few days due to the reduced solubility of the longer chain amines. Each of the alkylated proteins, except for the hexyl-derivatized ferritin, were readily extracted into DCM by addition of small amounts of NaCl to give clear red–orange (ferritin) or colourless (apoferritin) organic solutions. In contrast, control experiments involving native (apo)ferritin, or reaction mixtures of (apo)ferritin in the absence of either the amine or EDC coupling reagent, showed no evidence of phase transfer into DCM. For the alkylated proteins, UV–VIS spectra of the DCM layer showed a shouldered peak at approximately 280 nm indicative of the aromatic amino acid side chains of the transferred ferritin. The ease of transfer of the alkylated ferritins into DCM was in the order tetradecyl- > lauryl- > nonyl-amine. In general, the alkylated proteins were stable for as long as six months in the DCM layer.

TEM images of unstained samples of the alkylated ferritins transferred into DCM showed discrete, electron dense iron oxide cores with an average size of 5 nm (Fig. 1). The non-aggregated and monodisperse nature of the protein when dried onto the TEM grid indicates that the derivatized polypeptide shell is structurally intact. Unlike native ferritin, the alkylated proteins could not be stained with uranyl acetate, indicating significant changes in the surface chemistry. Staining of the samples did however show evidence of a surfactant lamellar phase, presumably formed by self-assembly of excess amine molecules during air-drying of the DCM solutions.

Polyacrylamide gel electrophoresis (PAGE) showed that the native and nonyl-derivatized proteins migrated towards the positive and negative electrodes, respectively, under non-denaturing conditions (data not shown). Migration of the alkylated ferritin terminated, however, at the interface between the stacking and resolving gels, indicating only a small net positive charge on the derivatized protein.

Analytical ultracentrifuge (AUC) analysis§ of nonyl-derivatized ferritin showed evidence of a floating (excess nonylamine) and a sedimenting component (derivatized protein) in the DCM solutions. The sedimentation coefficient distributions [$g(s^*)$] showed the presence of two well defined species corresponding to nonyl-derivatized ferritin [s^* = 12.1 Sv (77.5%)] and a larger species [s^* = 21.4 Sv (21.4%), Fig. 2]. The sedimentation coefficients were consistent with those expected for a monomer–dimer system of spherical molecules, according to $s_n = s_1 n^{2/3}$ with n = 2. Significantly, the relative proportions of monomeric and dimeric species were similar to those previously measured for native ferritin (69.4% monomer, 19.5% dimer and 11.1% trimer) using flow-field–flow-fractionation.[8] This strongly suggests that the hydrophobic ferritin is structurally intact and that negligible degradation occurs during

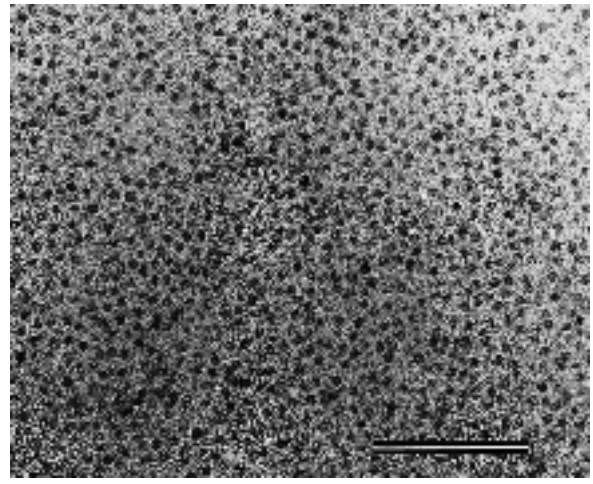

Fig. 1 TEM image of a DCM solution of nonyl-derivatized ferritin showing discrete electron dense iron oxide cores, each of which is encapsulated within an alkylated protein shell; scale bar = 100 nm

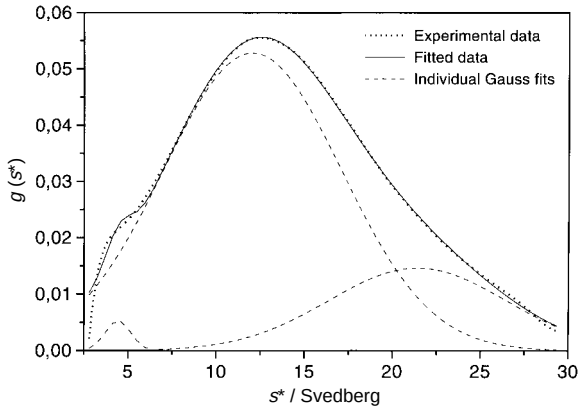

Fig. 2 Sedimentation coefficient distribution [$g(s^*)$] for a DCM solution of nonyl-derivatized ferritin showing the presence of alkylated ferritin monomers and dimers. A minor contaminant with s^* = 4.5 Sv (1.1%) is also present.

chemical functionalization in the THF–water reaction mixture.

The molar mass of nonylamine-derivatized ferritin in DCM was determined as M_w = 675 kDa from sedimentation equilibrium results. This was an approximate value because the density could only be estimated from the sample composition. However, the value was consistent with results obtained from sedimentation equilibrium data for native ferritin (M_w = 622.8 ± 4.3 kDa), assuming a similar monomer : dimer ratio and iron loading in the samples, and an additional mass due to the covalently attached nonylamine chains. The M_w for apoferritin was determined as 497.0 ± 5.0 kDa by sedimentation equilibrium, giving molar masses, M_w of 20.7 kDa and 125.8 kDa for the native subunit and FeOOH core, respectively. Assuming, M_w = 675 kDa for the derivatized ferritin, gives a value of approximately 550 kDa for the molar mass of the derivatized apoferritin (22.9 kDa per subunit) which corresponds to approximately 400 covalently coupled nonylamine groups per protein molecule. This is approximately 75% of the theoretical number of amino acid carboxyl groups (*ca.* 520) in the protein molecule.[1]

Dynamic light scattering for nonyl-derivatized ferritin in DCM gave an average hydrodynamic diameter of 35 nm, compared with 12 mm for aqueous solutions of native ferritin. Although further work is required, the results suggest that the derivatized protein is associated to some extent with the excess amine molecules present in the DCM solution. Reversed-phase HPLC data for native ferritin showed a sharp peak for the monomer at 15 min with a shoulder at 11.5 min corresponding to the dimer, whereas nonyl-derivatized ferritin showed a broad protein peak with a retention time centred at 24 min. Because the derivatized sample was run directly from the reaction mixture without dialysis, excess amine and coupling agent, as well as small molecule byproducts, were observed as relatively sharp peaks between 2 and 5 min. The reconstructed data from the electrospray mass spectra of the proteins showed a narrow (m/z 19.9–20.5 k) and wide distribution of molecular masses (m/z 20–30 k) for the native and nonyl-derivatized ferritin subunits, respectively. These values were consistent with the derivatized subunit molar mass of 22.9 kDa determined by AUC analysis.

The results indicate that alkylated ferritins with long term solubility in DCM can be readily prepared. TEM, PAGE and AUC were consistent with the preparation of intact protein molecules with significantly modified surface charge. However, HPLC and electrospray mass spectroscopy suggest that the degree of derivatization varies significantly between ferritin molecules and that a heterogeneous product is obtained. Furthermore, significant amounts of non-covalently bound amine may be strongly associated with the chemically modified protein. In this regard, it seems feasible that surfactant micellization could enhance the transfer of the alkylated ferritins into DCM, although native ferrintin could not be transferred into DCM in the presence of uncoupled amine molecules alone, indicating that alkylation is the dominant factor determining the solubility in the organic medium. Further work is in progress to expand these studies and to exploit the alkylated proteins in sol–gel reactions involving metal alkoxides.

We thank Armelle Buzy (University of Warwick) for electrospray MS, Franziska Gröhn (Teltow) for light scattering measurements, and BBSRC for financial support.

‡ Nonylamine (1.11 g, 7.77 mmol, 1.5 ml) was added to THF–H_2O (1 : 1 v/v, 8.5 ml) and the pH adjusted to *ca.* 5.5. THF was found to be a suitable solvent for amine solubilization without protein degradation. Ferritin or apoferritin (10 mg, 2.22 × 10^{-5} mmol) was slowly added, and the pH readjusted to 5.5 if required. The mole ratio of nonylamine to carboxylic acid residues was *ca.* 700 : 1, assuming a total of 520 aspartic and glutamic acid residues in the 24-meric protein.[1] 1-(3-Dimethylaminopropyl)-3-ethyl carbodiimide hydrochloride (EDC, 150 mg, 0.78 mmol) dissolved in THF–H_2O (1 : 1 v/v, 1 ml), was slowly added dropwise whilst maintaining the pH at 5.5 for 2–3 h, and the reaction mixture stirred overnight at room temperature. Samples (*ca.* 1 mg) of the alkylated protein were transferred from the reaction mixture into DCM by addition of small quantitites (5–10 mg) of dry NaCl followed by shaking. Reactions were also performed at lower concentrations of nonylamine, equivalent to 0.5, 7, 70, 170 or 340 molecules per protein carboxylic acid group. In general, ratios < 1 : 170 did not result in efficient phase transfer into DCM. Other primary amines, such as hexyl, lauryl (C_{12}), tetradecyl (C_{14}) and stearyl (C_{18}) amine were reacted with ferritin at concentrations equivalent to 125 or 500 molecules per carboxylate group, using the above procedure.

§ The sedimentation coefficient distributions [$g(s^*)$] were evaluated from sedimentation velocity data using the time-derivative method[9] and fitted with Gaussian curves. The weight average molar mass M_w was obtained from sedimentation equilibrium distributions for a concentration series by extrapolation of $M_{w,app}$ to infinite dilution. $M_{w,app}$ values were derived from direct fitting to an ideal one-component model system,[10] and also independently from the cumulative M^* approach.[11]

Luminescence response of the solid state polynuclear copper(I) iodide materials $[CuI(4\text{-picoline})]_x$ to volatile organic compounds

Elena Cariati, James Bourassa and Peter C. Ford*†

Department of Chemistry, University of California, Santa Barbara, CA 93106, USA

Exposure of the polymeric solid $[CuI(4\text{-pic})]_\infty$ to either liquid or vapor toluene leads to disappearance of this material's characteristic room temperature blue emission (λ_{max} 437 nm) and the appearance of the yellow emission (λ_{max} 580 nm) indicative of the $[CuI(4\text{-pic})]_4$ tetramer; the process is reversed when the latter is exposed to liquid or vapor *n*-pentane.

Polynuclear d^{10} metal complexes exhibit remarkably rich photoluminescent properties coupled in part to their diverse structural motifs.[1–3] The copper(I) halide adducts CuXL (X = halide, L = a nitrogen donor ligand) are particularly fascinating for the variety of structural formats which can be altered by varying the reagent stoichiometry, crystallization conditions and the reaction medium.[4–7] Many are brightly luminescent, even at ambient temperature, and the emission behavior varies markedly with structure and with environment. For example, the solid state luminescence spectrum of $[CuIpy]_\infty$ (py = pyridine), a 'stair step' polymer [Fig. 1(a)], displays a broad blue emission band at room temperature (λ_{max} = 437 nm), which does not shift upon cooling, and is probably due to an excited state with iodide to pyridine charge transfer (XLCT) character.[7,8] In contrast, the 'cubane' isomer $[CuIpy]_4$ [Fig. 1(b)] shows 'luminescence thermochromism'.[9] Room temperature, solid $[CuIpy]_4$ displays a broad yellow emission (λ_{max} = 580 nm), but, at 77 K, two bands are seen (λ_{max} = 438, 618 nm);[6,7] the higher energy one is largely XLCT in character, while that at lower energy has been assigned to a mixed halide to metal charge transfer (XMCT), d→(s,p) 'cluster centered' excited state.[8] Here we report that, for the related material $[CuI(4\text{-pic})]_x$ (x = 4 or ∞, 4-pic = 4-picoline), exposure of the solid to the liquid or the vapor phase of certain volatile organic compounds (VOCs) reversibly induces structural changes readily seen in the luminescent behavior.

Addition of neat 4-picoline to an aqueous CuI–KI solution at room temperature results in the formation of $[CuI(4\text{-pic})]_\infty$ (**A**) as revealed by a single crystal X-ray structure study.[10] Under UV illumination, the emission from this material is distinctly blue, and the room temperature luminescence spectrum displays a single broad band centered at 426 nm, which is shifted to slightly lower energy (λ_{max} 450 nm) at 77 K. Notably, similar addition of excess neat 3-picoline to aqueous CuI–KI solution gives the 'cubane' solid $[CuI(3\text{-pic})]_4$ as confirmed by a single crystal X-ray structure determination.[10] The luminescence spectrum of this solid displays a single, broad band centered at λ_{max} 614 nm at room temperature, but two bands at 77 K, one at 590 nm and one centered at 456 nm, as previously described.[6] These results may explain the observation by Hardt and Pierre that, for solids of stoichiometry CuIL, the derivative with 3-picoline emits yellow while that with 4-picoline emits blue.[11] In this context, it is notable that dissolving 3-picoline in methanol before addition to the CuI–KI aqueous solution directs the reaction pathway toward formation of the blue emitting stair-step polymer $[CuI(3\text{-pic})]_\infty$ (λ_{max} 452 nm at room temperature) whose structure was confirmed by a single crystal X-ray study.

The polymeric $[CuI(4\text{-pic})]_\infty$ solid is only very slightly soluble in most organic solvents. Despite this, we found that the addition of a small amount of toluene (far less than that needed for substantial dissolution) to a vial containing solid **A** leads to disappearance of the characteristic room temperature blue luminescence and subsequent appearance of yellow luminescence from the solid with an emission band centered at 578 nm (Fig. 2). This band corresponds to that of the tetranuclear 4-picoline complex $[CuI(4\text{-pic})]_4$ (**B**) which was independently prepared as described below and confirmed by a single crystal X-ray diffraction study. Notably, there appears to be an intermediate non-emitting species formed rapidly upon exposure of **A** to liquid toluene which more gradually undergoes

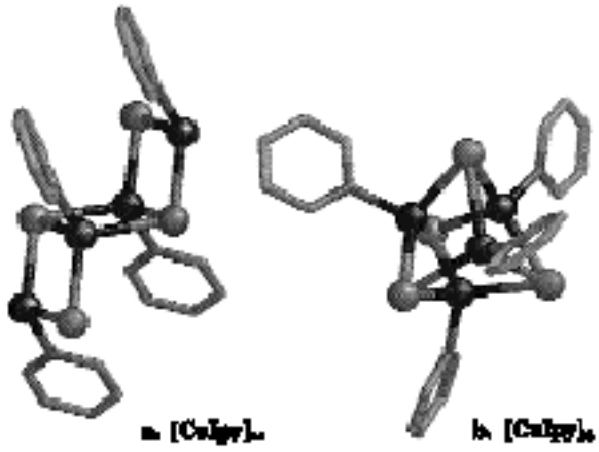

Fig. 1 Representations of the structures of the 'stair step' (a) and 'cubane' (b) forms of the compounds $[CuIpy]_x$ adapted from crystallographic data (refs. 5 and 6). Only a four copper fragment of the stair step chain of $[CuIpy]_\infty$ is shown.

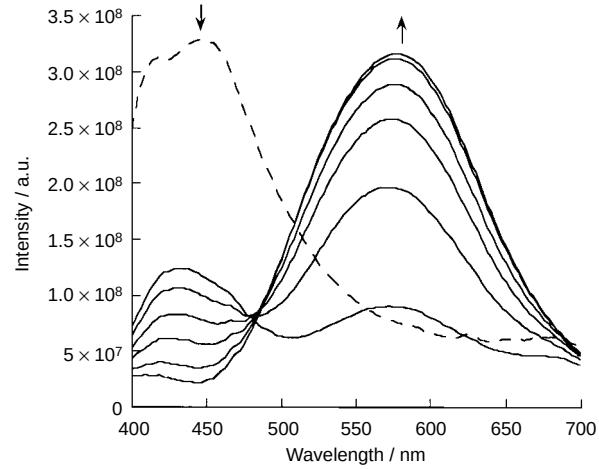

Fig. 2 Temporal emission spectra of solid $[CuI(4\text{-pic})]_\infty$ at ambient temperature before (- - -) and after (—) exposure to liquid toluene. Spectra were collected every 5 min (arrows indicate sequence of data collection).

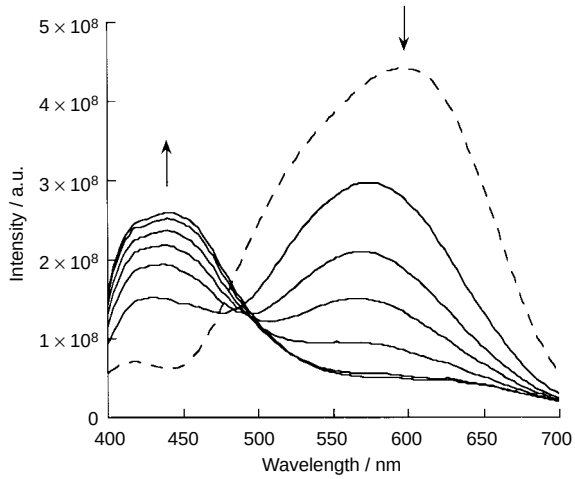

Fig. 3 Temporal emission spectra of solid $[CuI(4\text{-pic})]_4$ at ambient temperature before (- - -) and after (—) exposure to liquid pentane. Spectra were collected every 15 min (arrows indicate sequence of data collection).

transformation into **B** in a few minutes. We are attempting to characterize the non-emitting intermediate.

The toluene supernatant solution isolated from the above experiment shows a room temperature emission band at 684 nm, considerably different from the solid state emission behavior, as previously observed in the case of $[CuIpy]_4$.[7] Addition of pentane to this solution led to the isolation of trace amounts of **B**. However, exposure of the room temperature cubane solid to a small amount of liquid pentane caused it to revert to the blue emitting polymer over the course of 2 h (Fig. 3).

These surprising observations prompted us to examine the solid state behavior of the two $[CuI(4\text{-pic})]_x$ derivatives **A** and **B** in the presence of toluene and pentane vapors to test whether the same transformations could be effected by exposure to the vapors as well as to the liquids of these two solvents. This indeed turned out to be the case. When the blue emitting solid $[CuI(4\text{-pic})]_\infty$ was left in a sealed vial in contact with toluene vapors at the room temperature partial pressure, the transformation to the yellow emitting cubane solid was complete within two days. The reverse process, transformation back to **A,** was effected by exposing this sample to pentane vapors for 3 hours. Remarkably, while transformation **B** to **A** can be carried out in a few minutes by heating the sample to 343 K and appears to occur thermally over several days when simply left standing in air, the process is at least an order of magnitude faster at ambient temperature under pentane vapor. The analogous transformations between the cubane and polymeric forms do not occur when the 3-picoline analogs $[CuI(3\text{-pic})]_x$ are similarly treated with liquid or vapor toluene or pentane.

In conclusion, an unusual chromic photoluminescent behavior linked to a solid state structural change induced by exposure to the liquid or vapor phase of two VOCs has been demonstrated. This behavior is strongly ligand dependent, as revealed by our analogous studies with 3-picoline. X-Ray crystal structure determinations currently in progress[10] indicate that the cubane form of $[CuI(4\text{-pic})]_x$ displaying the yellow emission band at 578 nm has incorporated toluene into the crystal packing, and it is likely that this plays an important role in effecting the solid state isomerization from the blue emitting stair-step polymer. We have not detected analogous pentane incorporation into the structure of **B**, and are uncertain as to what role pentane plays in reformation of the more stable polymer. A recent study by Eisenberg and coworkers has described a similar 'luminescent switch for the detection of volatile organic compounds' using gold(I) dimers[12] following pioneering work by Mann and coworkers on absorption and emission spectra vapochromic Pt^{II} and Pd^{II} compounds.[13] The present work demonstrates the greater generality of such behavior, as well as the extension of this to much less expensive copper compounds, expense being a possible consideration in the design of practical sensors. An advantage of the present system is the very distinctive differences in the emission colors of the polymeric and cubane forms of $[CuI(4\text{-pic})]_4$, although the relatively slow response times would not be acceptable in the design of a practical sensor. Ongoing studies are concerned with defining the mechanisms of these structural transformations induced by exposure to VOCs as well as the photophysical mechanisms responsible for the differing luminescence responses.

Exo-ligands based on two *p*-aminopyridine interconnection by tuneable alkyl chains: design, synthesis and structural analysis of silver and palladium metallamacrocycles

Raoul Schneider,[a] Mir Wais Hosseini,*[a]† Jean-Marc Planeix,[a] André De Cian[b] and Jean Fischer[b]

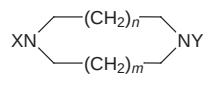
[a] *Laboratoire de Chimie de Coordination Organique, Université Louis Pasteur, F-67000 Strasbourg, France, UMR CNRS 7513*
[b] *Laboratoire de Cristallochimie et Chimie Structurale, Université Louis Pasteur, F-67000 Strasbourg, France, UMR CNRS 7513*

Exo-ligands based on functionalisation of diazacyclic cores of variable size by two pyridines has been achieved; under self-assembly conditions, their ability to form metallamacrocycles in the presence of Pd^{II} or Ag^{II} was demonstrated by X-ray crystallography.

Since the pioneering investigations by Fujita *et al.*[1] and by Saalfranck *et al.*[2] on metallamacrocycles considerable efforts have been focused on the design and synthesis of macrocyclic and macrobicyclic structures composed of metal centres connected by organic fragments.[3] The majority of metallmacrocycles reported so far are based on bis-monodentate ligands such as 4,4′-bipyridine, pyrimidine, bipyrazine, 4,7-phenanthroline or bis-pyridines interconnected by rigid or flexible spacers.[4] The same type of ligands has been also used for the formation of coordination networks.[5] *p*-Dimethylaminopyridine (dmap) shows strong alkaline character. We thought that one could take advantage of its peculiar electronic distribution for the design of ligands capable of forming metallamacrocycles. In order to interconnect two or more metals into a cyclic framework, the ligand needs to be of the *exo* type, *i.e.* it should possess at least two coordination sites oriented in divergent fashion. We have previously reported *exo*-ligands based on 2,2′-bipyridine derivatives,[6] catechol units[7] or of mercaptocalixarene type.[8] We now report the design, synthesis and structural analysis of *exo*-bis-monodentate ligands based on two dmap derivatives and of their binuclear silver and palladium metallamacrocycles.

The design of *exo*-ligands **4**–**6** (Scheme 1) was based on the interconnection of two *p*-aminopyridine substructures at the 4 position by two tuneable alkyl bridges. Ligands **4**–**6** may also be regarded as diazacycloalkanes[9] **1**–**3** bearing two pyridines. We have previously used cyclic diamines for the design of cyclospermidines and cyclospermines[10] and as backbones connecting donor and acceptor groups.[11] The design of **4**–**6** is rather versatile since, by controlling the size and thus the conformation of the medium size cyclic core and by choosing metals with specific coordination demands, one may investigate structural aspects in the formation of metallamacrocycles under self-assembly conditions.

The synthesis of **4**–**6** was achieved by treating under reflux a mixture of 4-chloropyridine, PhLi and compounds **1**–**3** in a 1 : 2.2 : 2.5 ratio in diethylether.[12] The yields reported are based on 4-chloropyridine. In all cases studied, in addition to **4**–**6**, the mono-substituted compounds **7**–**9** were also isolated. Thus,



1 X = Y = H, *n* = *m* = 0
2 X = Y = H, *n* = 0, *m* = 1
3 X = Y = H, *n* = 1, *m* = 2
4 X = Y = Py, *n* = *m* = 0
5 X = Y = Py, *n* = 0, *m* = 1
6 X = Y = Py, *n* = 1, *m* = 2
7 X = H, Y = Py, *n* = *m* = 0
8 X = H, Y = Py, *n* = 0, *m* = 1
9 X = H, Y = Py, *n* = 1, *m* = 2

Scheme 1

treatment of **1**, **2** or **3**[13] with 4-chloropyridine gave compounds **4** (20%) and **7** (22%), **5** (39%) and **8** (28%) or **6** (13%) and **9** (38%) respectively.

The formation of metallamacrocycles using Pd^{II} was achieved by mixing at room temp. an EtOH solution of ligands **4**–**6** with an aqueous solution of $[Pd(NO_3)_2(en)]$ (en = ethylenediamine). Upon addition of EtOH and Et_2O complexes were collected after several days as colourless crystalline materials. In addition to solution NMR spectroscopy, crystals were analysed by FAB^+ spectrometry which revealed the formation of a trinuclear complex $\{[\mathbf{4}_3\{Pd(en)\}_3(NO_3)_6]\}$ for the ligand **4** and binuclear complexes $\{[L_2\{Pd(en)\}_2(NO_3)_4]$, L = **5** or **6**$\}$ for ligands **5** and **6**. For the $[\mathbf{6}_2\{Pd(en)\}_2(NO_3)_4]$ complex the structure could be determined by X-ray crystallography which indeed revealed the formation of a Pd^{II} binuclear metallamacrocycle.‡ Although in the crystal H_2O and EtOH molecules were present none of them nor NO_3^- anions were clathrated in the cavity of the macrocycle. In principle, owing to the non-symmetric nature of **6**, two different isomeric complexes, one with C_{2v} and the other with D_{2h} ideal symmetry may be envisaged (Fig. 1). The difference between these two isomers originates from the mutual orientation of the cyclic cores. However in the solid state, only the complex with C_{2v} symmetry was observed (Fig. 2). The crystal structure showed the following features: (*i*) two ligands **6** bridge two Pd centres by adopting a bent conformation; (*ii*) as expected, both nitrogen atoms of the diaza core show a marked sp^2 character with an average C–N–C angle of *ca.* 120.3° and N–C distance of 1.37 Å demonstrating the delocalization of the nitrogen lone pairs on the pyridine rings; (*iii*) the coordination geometry around Pd atoms is almost square planar with the N–Pd–N angle varying from 83.7 to 93.5°; (*iv*) the average N–Pd distance is *ca.* 2.03 Å; (*v*) with Pd···Pd distance is 11.35 Å.

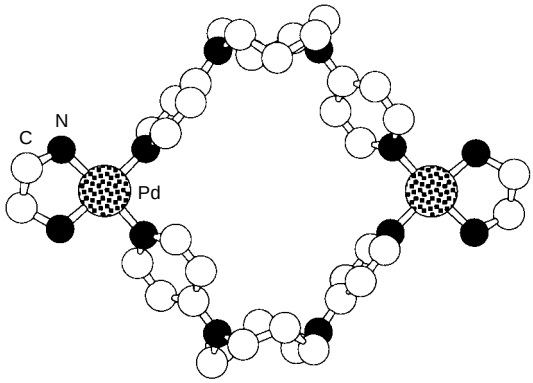

Fig. 2 Crystal structure of the [$\mathbf{6}_2${Pd(en)}$_2$ $(NO_3)_4$] metallamacrocycle (see text for bond angles and distances). Solvent molecules, anions and H atoms are not presented for sake of calrity.

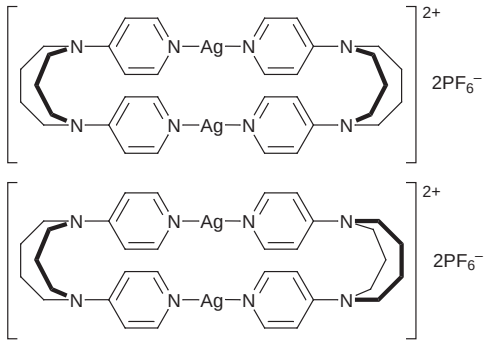

Fig. 3 Two possible isomeric structures D_{2h} (top) and C_{2v} (bottom) for the [$\mathbf{6}_2Ag_2$] metallamacrocycle

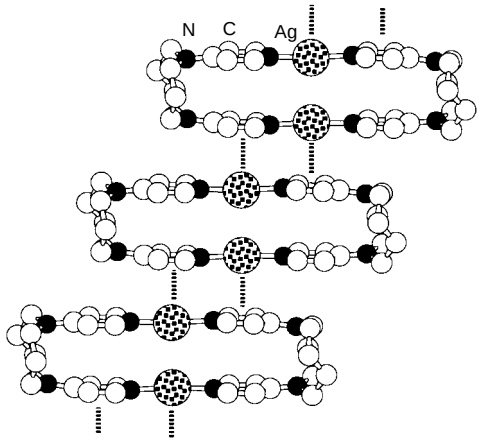

Fig. 4 A portion of the crystal structure of the [$\mathbf{6}_2Ag_2(PF_6)_2$] metallamacrocycle (see text for bond angles and distances) showing the formation of an infinite network formed by double Ag–aromatic interactions between consecutive units. Anions and H atoms are not presented for sake of clarity.

The formation of metallamacrocycles using Ag^I was investigated by diffusion at room temp. of a EtOH solution of ligand **6** with an aqueous solution of $AgPF_6$. After several days colourless crystals of the complex were filtered and further washed with Et_2O. The complex was characterised by NMR and by FAB spectrometry. Furthermore, in the solid state the structure of [$\mathbf{6}_2Ag_2(PF_6)_2$] complex was elucidated by X-ray crystallography.‡ Again, as in the above mentioned Pd case, two different isomeric complexes may be envisagted (Fig. 3). Once again the complex with C_{2v} symmetry was observed (Fig. 4). The crystal analysis showed the following features: (*i*) the binuclear metallamacrocycle is formed through the bridging of two Ag^I atoms by two pyridine units belonging to two ligands **6** which adopt a bent conformation; (*ii*) as in the previous case, both nitrogen atoms of the diaza core show a marked sp^2 character with an average C–N–C angle of *ca.* 121.1° and N–C distance of 1.36 Å; (*iii*) the coordination geometry around Ag atoms is almost linear with an average N–Ag–N angle of *ca.* 175.8°; (*iv*) the average N–Ag distance is *ca.* 2.10 Å; (*v*) the Ag···Ag distance is 3.36 Å; (*vi*) quite interestingly, in the crystal the metallamacrocycles form a one dimensional network through four strong silver–aromatic (pyridine) interactions per unit with an average Ag–centroid distance of 3.43 Å (Fig. 4).

In conclusion, it has been demonstrated that a class of exo ligands based on the interconnection of two *p*-aminopyridines forms by self-assembly metallamacrocycles in the presence of Pd^{II} or Ag^I metals. A systematic investigation on the role of the conformation of the cyclic core is under current investigation.

‘CMPO-substituted’ calix[4]arenes, extractants with selectivity among trivalent lanthanides and between trivalent actinides and lanthanides

Lætitia H. Delmau,‡ Nicole Simon,*[a]† Marie-José Schwing-Weill,*[b]† Françoise Arnaud-Neu,[b] Jean-François Dozol,[a] Serge Eymard,[a] Bernard Tournois,[a] Volker Böhmer,[c] Cordula Grüttner,[c] Christian Musigmann[c] and Abdi Tunayar[c]

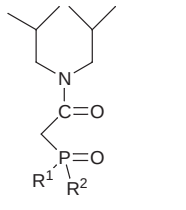
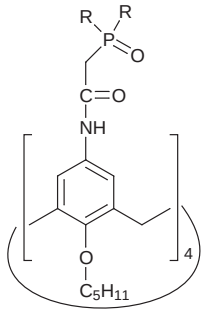
Calix[4]arenes substituted by acetamidophosphine oxide groups at their wider (upper) rim not only exhibit excellent extraction efficiency towards trivalent cations but also show pronounced selectivity for the light lanthanides and actinides in their extraction from highly saline or acidic media.

Calixarenes[1] are readily available molecular platforms, on which various functional groups may be assembled in a well defined mutual arrangement. Numerous cation extractants derived from calixarenes have been developed in the past decade, in which the preorganization of ligating functions adds favorably to their specificity.[2] Crown ethers derived from calix[4]arenes fixed in the 1,3-alternate conformation may be cited as one of the most typical examples, showing the highest potassium over sodium (crown-5)[3] and caesium over sodium (crown-6)[4] selectivities ever reported.

Carbamoylphosphine oxides **1** (CMPOs) are known to extract trivalent cations from highly acidic and highly saline media,[5] and **1a** is industrially used in the TRUEX process.[6] The extracted complex requires three molecules of **1a** per cation,[7] thus attachment of CMPO-like functions to the calixarene scaffold in the cone conformation should achieve cooperativity. Indeed, calix[4]arenes such as **2a** bearing four diphenyl acetamidophosphine oxide functions on the wider rim[8] are powerful extractants for europium and tri- and tetravalent



1a $R^1 = C_6H_5$, $R^2 = C_8H_{17}$
1b $R^1 = R^2 = C_6H_5$
1c $R^1 = R^2 = C_4H_9$



2a $R = C_6H_5$
2b $R = C_6H_{13}$

actinides with an efficiency highly superior to that of **1a**. Here we compare the two ligands **1a** and **2a**[8] with respect to their extraction efficiencies towards nine lanthanides (La, Pm, Sm, Eu, Gd, Tb, Ho, Er, Yb) and two actinides (Am, Cm).

Extractions were followed by radiotracers and were quantified by the distribution coefficient of the metallic cation M ($D_M = \Sigma[M]_{org,eq}/\Sigma[M]_{aq,eq}$). The concentrations of **1a** and **2a** were chosen to obtain comparable distribution coefficients. Preliminary experiments showed that the extraction kinetics are rapid; all reported distribution coefficients are at equilibrium.

The behavior of CMPO **1a** is in agreement with literature data,[5] while we observe for **2a** a marked decrease of the distribution coefficients along the lanthanide series, from 140 for lanthanum to 0.19 for ytterbium (Fig. 1). This corresponds to a separation factor (ratio of the distribution coefficients) of nearly three orders of magnitude. It is important to point out that distribution coefficients are independent of the equilibrium aqueous metal ion concentration. This eliminates any influence of cation concentrations on the selectivity.

In order to determine one of the possible origins of the selectivity, we modified the functional groups present on the phosphorus. The observed size selectivity nearly disappears for **2b**,[9] in which the phenyl groups of **2a** have been replaced by *n*-hexyl groups (Fig. 2). This observation is in agreement with the results obtained for the two CMPO type molecules **1b** and **1c**.[10] While the diarylphosphine oxide **1b** shows a small selectivity (separation factor $D_{La}/D_{Lu} \approx 10$), no selectivity is found for the dialkylphosphine oxide **1c**. We can conclude, therefore, that the attachment of four CMPO functions with diphenylphosphine oxide groups to the calixarene skeleton leads to a significant increase of their discriminating properties towards lanthanides and actinides.

The selectivity discussed so far is related to the extraction of trivalent cations from a highly saline but moderately acidic medium. A topic of current interest is actinide–lanthanide group mixtures separation at high acidity, which, at low acid

concentrations (pH > 1) can usually be achieved by extractants containing soft donors (sulfur or nitrogen).[11] Although a recent publication shows that calix[6]arene derivatives bearing acid and amide functions can be used for this group separation, the same pH limitations (pH > 2.5) apply.[12]

We have repeated some of our experiments with **2a** extracting the trivalent cations from 3 M nitric acid (Fig. 3). We observe essentially the same trend for both media (4 M sodium nitrate or 3 M nitric acid), which suggests the selectivity is not caused by a constituent of the aqueous phase. In particular, the potential interaction between nitric acid and the ligand has no effect on the selectivity. The separation factor D_{Am}/D_{Eu} for 3 M nitric acid (10.2) is slightly better than that for 4 M sodium nitrate (7.5), and is probably one of the best ever obtained at this acidity and this ionic strength.

In conclusion, calixarene **2a**, and more general calix[4]arenes bearing four CMPO moieties on their upper rim where the phosphorus atoms are substituted with phenyl groups, are not only excellent extractants for trivalent lanthanides and actinides, they also exhibit remarkable selectivity based mainly on the size of the cations. This selectivity can reach nearly three orders of magnitude and remains even under strongly acidic conditions. It does not yet allow complete actinide–lanthanide group mixtures separation but the separation factors could be useful for the selective extraction of actinides (or light lanthanides) from heavy lanthanides.

Novel hyperbranched polymer based on urea linkages

Anil Kumar and E. W. Meijer*†

Laboratory of Macromolecular and Organic Chemistry, Eindhoven University of Technology, PO Box 513, 5600MB Eindhoven, The Netherlands

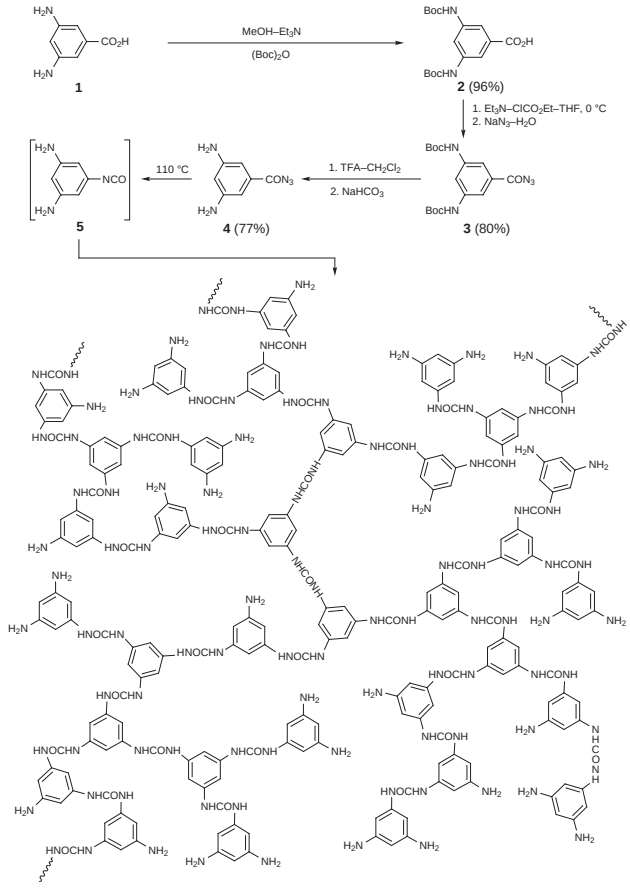
The thermal decomposition of 3,5-diaminobenzoyl azide, to generate *in situ* the corresponding 3,5-diaminophenyl isocyanate, was found to give hyperbranched polyureas, whose structure was established using IR and NMR spectroscopy.

In the last decade synthesis of three-dimensional dendritic polymers by constructing branches upon branches, either in a stepwise fashion to get dendrimers or in a one-step process to get hyperbranched polymers, has received much attention. These highly branched, untangled and globular structures have been explored because of their unusual properties.[1–5] Although dendrimers have been studied extensively for their size, shape and surface functional group related properties, their large scale synthesis has been limited to only a few structures because of the inherent difficulties in the stepwise growth process. However, whilst the one step approach for the synthesis of hyperbranched polymers has potential for large scale preparation, it lacks well defined and monodisperse dendrimers.

Hyperbranched polymers have been synthesized by self-condensation polymerization using an AB_x type monomer in which A and B are functional groups that react with each other and not with themselves. These hyperbranched polymers can be divided into two major categories depending upon the growth process. One is the classical polycondensation involving an AB_x type monomer where the growth of the polymer starts only at the already existing reaction sites A and B; in other words there is no generation of a new growing site during the polymerization. Some examples of this class are polyphenylenes,[6,7] polyesters,[8–12] polyethers,[13,14] polyurethanes,[15–17] polyamines,[18] polyamides[19] and polysiloxanes.[20] The second category is where new growing sites are generated during the polymerization reaction and examples of this class include polystyrene [21–23] and polyacrylates.[24] The consequence of these new reaction sites during polymerization is an increased number of subunits in the polymer. This leads to difficulties in estimating the degree of branching as quantification of each of the subunit structures is not possible.

Dendritic and hyperbranched structures based on amide linkage[25–31] have received considerable attention due to the fact that polyamides are commercially important and these linkages are the backbone of all the naturally occurring proteins and enzymes. Linear polyureas have been studied extensively in order to produce alternative fiber-forming polymers analogous to the polyamides.[32] There is now a much wider range of commercial polymers containing urea groups.[33] Surprisingly there are no reports on the synthesis of hyperbranched or dendritic polymers based on urea linkages. This could be due to the inherent difficulties in the synthesis and purification of monomers containing both amine and isocyanate groups, to obtain the urea linkage, as they are not compatible. Here we report synthesis and characterization of the first example of a hyperbranched polymer based on urea linkages. We developed a novel one-pot route to wholly aromatic hyperbranched polyureas, *via* the *in situ* generation of a diaminophenyl isocyanate monomer **5** by the thermal decomposition of the corresponding carbonyl azide **4** (Scheme 1).

3,5-Diaminobenzoyl azide was prepared starting from 3,5-diaminobenzoic acid as described in Scheme 1. The amine groups were protected with a Boc group[34] and the carboxylic acid was converted to carbonyl azide using the procedure described by Ghatge and Jadhav.[35] Removal of the Boc group with TFA in CH_2Cl_2 followed by treatment with saturated $NaHCO_3$ solution gave pure **4** in an overall yield of 59%. The FTIR spectrum of **4** exhibits a strong absorption at 2136 cm^{-1} indicating the presence of azide groups. Thermal decomposition of the aromatic carbonyl azides has been reported[15,16] to occur at *ca.* 107 °C and, hence, the polymerization was carried out at 110 °C by heating a solution of **4** in NMP. Rapid evolution of N_2 was observed during the initial stages of the reaction, after which the solution was maintained at 110 °C for 7 h. The polymers were precipitated into water, centrifuged, washed with acetone and vacuum dried at 90 °C to give around 90% yields of the wholly aromatic polyureas which are soluble in solvents like DMSO, NMP and DMF. The FTIR spectrum of the polymer indicates the absence of any residual azide (no absorption at 2136 cm^{-1}) or isocyanate (no absorption at 2200 cm^{-1}) and shows strong absorption at 1656 and 3352 cm^{-1} indicating the formation of



Scheme 1

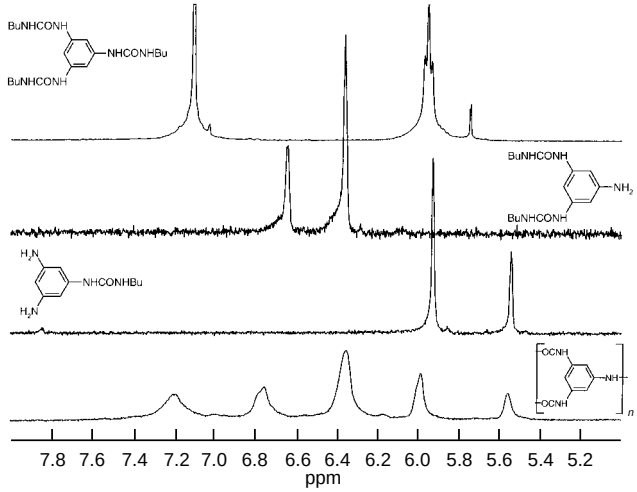


Fig. 1 300 MHz ^{1}H NMR spectra of the polymer and the model compounds in $(CD_3)_2SO$–D_2O

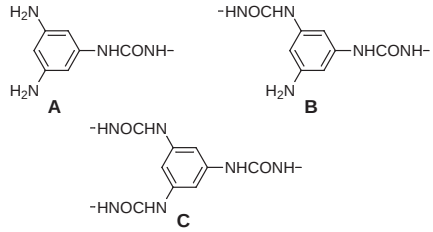
urea linkages. The ^{1}H NMR spectrum of the hyperbranched polyurea (Fig. 1) was analyzed based upon the various possible subunits (**A**–**C**) that may be present. Various peaks in the NMR spectrum of the polymer (Fig. 1) were assigned upon the NMR spectrum of three model compounds that resemble subunits **A**–**C**. The degree of branching calculated based on the ^{1}H NMR



spectrum was found to be 0.55. This suggests that the growth process is statistical in nature in agreement with other systems.[36] The molecular mass of the samples was determined by GPC using NMP as solvent and polystyrene as standard. M_w was found to be 19 500 with a polydispersity of 1.56.

The wholly aromatic linear polyureas are generally difficult to process because of their limited solubility and high melt temperatures.[32,37] One approach to increase solubility in organic solvents is the introduction of *N*-alkyl or *N*-aryl substituents along the polymer backbone. Here we have shown that the wholly aromatic hyperbranched polyureas are completely soluble. A closer look at the Boc-protected carbonyl azide **3** reveals that its a novel AB_2 type building block where both A and B groups are protected and can be generated when needed. These types of structures are ideal candidates for the stepwise synthesis of the dendrimers. Currently, work is in progress to generate the corresponding perfect polyurea dendrimers.

Irreversible conductivity change of $Li_{1-x}CoO_2$ on electrochemical lithium insertion/extraction, desirable for battery applications

Matsuhiko Nishizawa, Satoru Yamamura, Takashi Itoh and Isamu Uchida*†

Department of Applied Chemistry, Graduate School of Engineering, Tohoku University, Aramaki-aoba, Aoba-ku, Sendai, 980-8579, Japan

Electrical conductivity of a sputter-deposited $LiCoO_2$ thin film was studied *in situ* during electrochemical lithium extraction/insertion, revealing that the metallic behavior of $Li_{1-x}CoO_2$ induced by the initial lithium extraction did not revert to its original insulating state in the following successive reduction/oxidation cycles.

$LiCoO_2$ is one of the most promising cathode active materials for lithium secondary batteries, and the battery system based on the $LiCoO_2$/carbon couple has been used commercially in many types of electronic equipment.[1–8] Since the electrical conductivity of active materials is an important characteristic for the design of high performance batteries, there have been a number of reports measuring the conductivity upon taking the electrode out of the electrochemical cell; *i.e. ex situ* characterization.[9–11] In contrast, work in our laboratory has shown that the interdigitated microarray (IDA) electrode is a powerful tool for studying the dynamic changes in the DC conductivity of electroactive films *in situ*.[12–17] We recently reported that the conductivity of $Li_{1-x}CoO_2$ increased by several orders of magnitude when a very small amount of lithium was extracted ($x < 0.1$),[16] as was predicted theoretically.[1,9] Such a drastic conductivity change requires that care must be taken when using $LiCoO_2$ as a battery active material. Since our previous work was on a composite film consisting of $LiCoO_2$ powders mixed with poly(vinylidene fluoride) and acetylene black, we could not treat the measured conductivity as that of $LiCoO_2$ itself.[16] Therefore, in this study we prepared a fine $LiCoO_2$ film by sputtering onto IDA electrodes to obtain more precise and reproducible results. It was found that the metallic behavior of $Li_{1-x}CoO_2$ induced by the initial lithium extraction (charge) did not revert to its original insulating state in the following reduction/oxidation cycles, indicating that this electrode material maintains its high conductivity during the successive use of secondary batteries.

The IDA electrode was fabricated by photolithography with a sputter-deposited Pt film on a thermally oxidized silicon wafer,[12–16] to have two sets of comb-type Pt arrays; each array has 50 band-electrode elements of 10 μm wide, 2.4 mm long and 0.1 μm thick, separated by 10 μm from its adjacent elements. A $LiCoO_2$ film of 0.2 μm thickness was deposited onto the IDA electrode by RF-sputtering and annealed in air at 700 °C for 15 min. Each peak in the X-ray diffraction spectrum of the annealed film was assigned to $LiCoO_2$. During the sputtering of the $LiCoO_2$ films, the IDA substrate was masked to limit the exposed area to a 0.2 cm × 0.3 cm rectangle. Each electrochemical measurement was conducted in a glove box filled with dried Ar, by using propylene carbonate (PC) containing 1 M $LiClO_4$ as the electrolyte solution. Lithium foils were used as the reference and counter electrodes. The *in situ* conductivity measurements were carried out, as previously,[15,16] using a bipotentiostat to maintain a 5 mV potential difference between the two working electrodes. The specific conductivity of the film was calculated from the ohmic current flowing through the film under the 5 mV bias voltage.[14,15] Note, however, that our measurement is a two-point probe method and that the film is thicker than the Pt film electrodes, therefore it is still dangerous to discuss the obtained conductivity as an absolute value. Rather, this method is suited to the study of dynamic, relative changes in the conductivity taking place with redox reactions.[12–14]

Fig. 1 shows cyclic voltammograms (CVs, solid lines) and *in situ* potential–conductivity profiles (dashed lines), which were measured simultaneously. The results for the first and the sixth cycles are presented. During the initial extraction of lithium, the conductivity of the film increased by more than four orders of magnitude and saturated around the main CV peak at 3.9 V, as observed for the $Li_{1-x}CoO_2$ composite film.[16] The saturated conductivity was not varied even upon expansion of the potential range up to 4.2 V ($x \approx 0.5$ in $Li_{1-x}CoO_2$). The drastic conductivity change which appeared before the CV peak is known to be the metal–insulator transition (MIT) resulting from the possible direct overlap of cobalt t_{2g} orbitals across a shared octahedral edge.[1,9] It was found here that the increased conductivity did not revert to the initial low value in the following reduction process, and that the conductivity value remained within the same order of magnitude during the successive charging/discharging cycles. This conductivity profile hysteresis was not removed even upon reduction of the potential scan rate to 10 μV s^{-1}. Fig. 2 shows the conductivity measured under open-circuit conditions to examine the above potentiodynamic results. A known amount of charge was induced using a galvanostat (typically, 150 μC with 0.1 μA), and then the rest potential and conductivity of the $Li_{1-x}CoO_2$ film were measured after more than 2 h. The correlation between the rest potential and the conductivity, shown in Fig. 2(*a*), was essentially the same as the result obtained by potentiodynamic measurements; the initial insulating state was not reproduced. Fig. 2(*b*) represents the conductivity changes as a function of *x*, calculated using the apparent volume of the film and the density of a single crystal of $LiCoO_2$. Although the

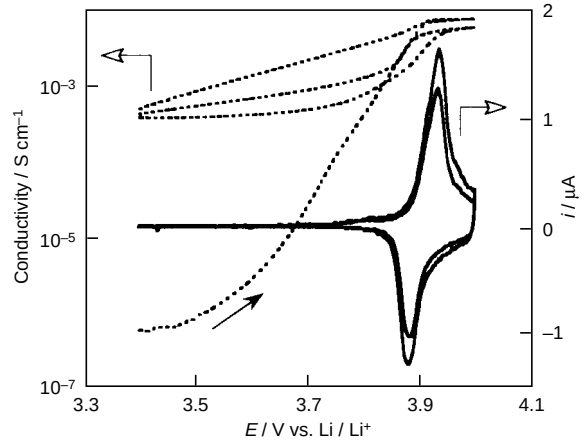

Fig. 1 Cyclic voltammograms (solid lines) and potential–conductivity profiles (dashed lines) of a $LiCoO_2$ film (0.2 μm thickness) sputter-deposited onto a Pt IDA electrode, taken in 1 M $LiClO_4$/PC at a scan rate of 0.1 mV s^{-1}. The bias voltage set between arrays was 5 mV. The first and the sixth cycles are presented.

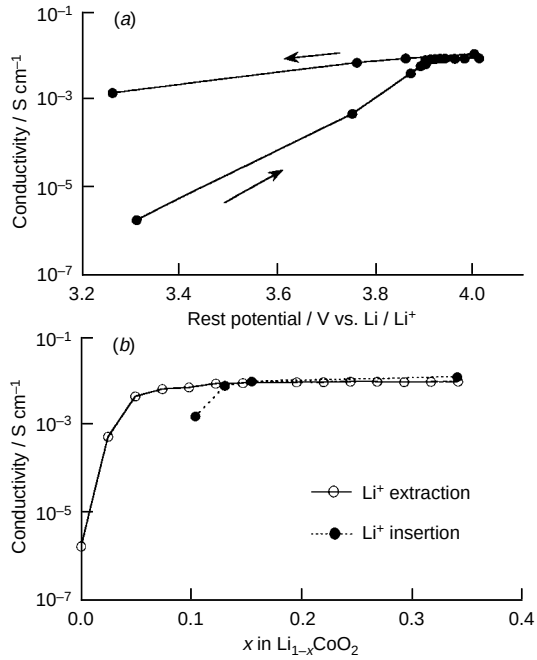

Fig. 2 The variations of the conductivity of a $LiCoO_2$ film during the first extraction/insertion of lithium as functions of (*a*) the rest potential and (*b*) x in $Li_{1-x}CoO_2$, taken in 1 M $LiClO_4$/PC with a bias voltage of 5 mV

calculated x values are not strictly accurate because of the polycrystallinity of the film and some side reactions, it was roughly confirmed that the MIT was induced by extraction of a very small amount of lithium (less than 10%) and the conductivity of the film could not revert to the initial insulating state due to the difficulty in reinserting this small amount of lithium. There are many reports showing similar irreversible capacities for the first charge/discharge cycle.[2,6–8] Crystallographic irreversibility may be the reason for this hysteresis because of the fact that a structural transformation occurs around $x = 0.1$ in $Li_{1-x}CoO_2$; within the composition range $0 < x < 0.1$, a single hexagonal phase exists, whereas within the range $0.1 < x < 0.22$, two hexagonal phases coexist.[1,6,7] Furthermore, electrochemical processes accompanied by growth of insulating phases are kinetically unfavorable in general, as seen for conducting polymers such as polyaniline.[18] Anyway, the insulating nature of $LiCoO_2$, which may be serious for battery applications, was found not to be regained within the time scale of battery applications.

The present work was supported by Grant-in-Aids for Scientific Research on Priority Area (No. 10148205 and No. 10131211 for 'Electrochemistry of Ordered Interfaces') and for Encouragement of Young Scientists (No. 09750906) from the Ministry of Education, Science, Sports and Culture, Japan, and partly by The Osaka Science & Technology Center.

Strong coordination of cycloheptynes by gold(I) chloride: synthesis and structure of two complexes of the type [(alkyne)AuCl]

Petra Schulte and Ulrich Behrens*†

Institut für Anorganische und Angewandte Chemie der Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany

Gold(I) chloride (stabilized by tetrahydrothiophene) reacts with the cycloheptynes 3,3,6,6-tetramethyl-1-thiacyclohept-4-yne-1,1-dioxide (SO_2-alkyne) and 3,3,6,6-tetramethyl-1-thiacyclohept-4-yne (S-alkyne) to afford the complexes [(η^2-alkyne)AuCl]$_n$ [n = 2 (SO_2-alkyne), n = ∞ (S-alkyne)]; the X-ray structures of both compounds show trigonal-planar gold(I) centres and very short Au–C(alkyne) bonds.

Although gold(I) complexes (*e.g.* R_3PAuNO_3) are excellent catalysts for the addition reaction of nucleophiles to alkynes,[1] little is known about the interaction of gold(I) with the C≡C triple bond. Some efforts to prepare simple gold(I) alkyne complexes were made in 1972 by Hüttel and Wittig, but most of the obtained gold compounds were thermally unstable and all were poorly characterized.[2] In 1996–97 Lang *et al*. synthesized five stable organogold(I) 3-titanapenta-1,4-diyne complexes [$Cp_2Ti(C{\equiv}CR)_2AuR$] with a trigonal-planar coordination of the gold(I) centre. These complexes were properly characterized, three of them by X-ray structure analysis.[3] The compounds can be considered as alkyne complexes although in reality heterometallic acetylide coordination compounds are present. Furthermore, in 1995 Mingos *et al*. reported on the compound [Au(C≡CBu^t)] within the structure of which η^2(C≡C)-coordinated acetylide moieties also exist.[4]

In this study, we report on the first examples of structurally well characterized [(η^2-alkyne)AuCl]$_n$ complexes (n = 2, ∞) with the gold(I) ion in a trigonal-planar environment. Complexes **1** and **2** were prepared by the reaction of [AuCl(tht)] (tht = tetrahydrothiophene) with equal amounts of the cycloheptynes 3,3,6,6-tetramethyl-1-thiacyclohept-4-yne-1,1-dioxide (SO_2-alkyne) and 3,3,6,6-tetramethyl-1-thiacyclohept-4-yne (S-alkyne), respectively (yield 90–97%).‡ Both complexes **1** and **2** form colourless crystalline powders which are thermally stable up to 150 °C. The solid compounds can be handled in air for short periods. In solution they decompose slowly when exposed to air or light. Compound **1** is soluble in tetrahydrofuran and dichloromethane, while complex **2**, due to its polymeric character in the solid state, only dissolves in strongly coordinating solvents such as mixtures of dimethyl sulfide–dichloromethane or dimethyl sulfide–tetrahydrofuran. In acetonitrile a molecular mass of 447 was found osmometrically for **1** which shows that the chloro bridges in solid **1** have been cleaved by the coordinating solvent (calc. M = 432.7 for the monomer). In chloroform a somewhat higher value (M = 580) was observed (monomer–dimer mixture in solution).

X-Ray diffraction studies were carried out on both **1** and **2** (Fig. 1 and 2).§ Compound **1** forms dimeric molecules with the gold(I) ions bridged by two chloro ligands (Fig. 1), whereas complex **2** contains a polymeric chain built up by AuCl units which are connected by S-alkyne ligands (coordination *via* the C≡C bond and the S atom; Fig. 2). The gold(I) centres exist in a trigonal-planar environment. The alkyne carbon atoms as well as the η^1-bonded Cl and S atoms are arranged in-plane, which is a typical feature for copper(I) and silver(I) η^2-alkyne complexes.[5] A very strong alkyne–gold bond is found, with the Au–C bond distances ranging from 2.050(7) to 2.100(8) Å.[6] This is close to the range for a normal Au–C-σ bond [*e.g.* Au–R-σ bond

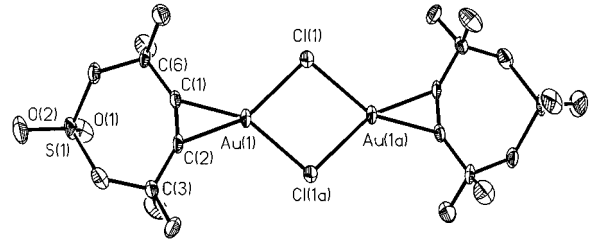

Fig. 1 View of the molecular structure of [AuCl(SO_2-alkyne)]$_2$ **1** with atomic numbering scheme (60% thermal ellipsoids). Selected bond lengths (Å) and angles (°): Au(1)···Au(1a) 3.666(1), Au(1)–Cl(1) 2.456(2), Au(1)–Cl(1a) 2.473(3), Au(1)–C(1) 2.075(9), Au(1)–C(2) 2.055(9), C(1)–C(2) 1.259(12); Cl(1)–Au(1)–Cl(1a) 83.9(1), Cl(1)–Au(1)–C(1) 121.4(2) Cl(1a)–Au(1)–C(2) 119.2(3), C(1)–Au(1)–C(2) 35.5(3), Au(1)–Cl(1)–Au(1a) 96.1(1), C(2)–C(1)–C(6) 147.3(8), C(1)–C(2)–C(3) 146.4(9).

lengths of 2.00(1), 2.018(6) and 2.079(7) Å were observed for three trigonally coordinated Au^I complexes $Cp_2Ti(C{\equiv}CR)_2AuR$].[3] The C≡C bonds are lengthened from 1.194 Å (C≡C bond distance for the free SO_2-alkyne)[7] and 1.209 Å (C≡C bond distance for the free S-alkyne)[7] to 1.259(11) Å (**1**) and 1.244(11) Å (**2**), which also proves the existence of a strong Au–η^2(C≡C) interaction. For a gold(I) complex with trigonal-planar coordination, an extremely short Au–Cl bond length of 2.409(2) Å is observed in **2**. For instance, in the complex $(Ph_3P)_2AuCl$, an Au–Cl distance above 2.50 Å is observed.[8] A value of about 2.40 Å, as in **2**, is normally found for Au–Cl bonds in square-planar neutral organyl Au^{II} complexes.[9] We therefore think that strong back-bonding from Au^I to the cycloalkyne ligand occurs in **2** (and also in **1**), which is equivalent to partial oxidation of the Au^I ion to Au^{III}. Also complex **1** is the first example of a gold(I) complex where two chloro ligands bridge two Au^I ions.[10] In gold(III) chemistry such bridging chloro ligands are only known for the structure of gold(III) chloride.[11] No aurophilic attractions (weak inter- or intramolecular Au^I···Au^I interactions resulting in Au–Au distances shorter than 3.40 Å) between the Au^I ions are found in **1** or **2**.[12] The intramolecular

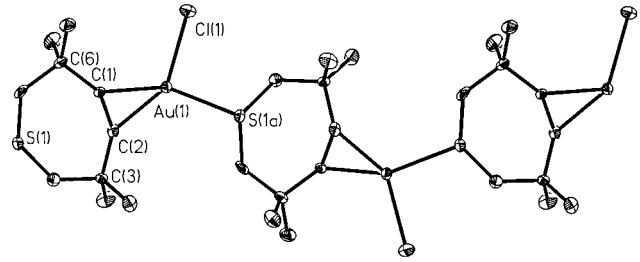

Fig. 2 Part of the polymeric chain of solid [AuCl(S-alkyne)] **2** with atomic numbering scheme (60% thermal ellipsoids). Selected bond lengths (Å) and angles (°): Au(1)–Cl(1) 2.409(2), Au(1)–S(1a) 2.415(2), Au(1)–C(1) 2.050(7), Au(1)–C(2) 2.100(8), C(1)–C(2) 1.244(11); Cl(1)–Au(1)–S(1a) 96.1(1), Cl(1)–Au(1)–C(1) 110.5(2), S(1a)–Au(1)–C(2) 118.7(2), C(1)–Au(1)–C(2) 34.9(3), C(2)–C(1)–C(6) 146.3(7), C(1)–C(2)–C(3) 146.6(7).

Au···Au distance in **1** is 3.666(1) Å; the Au–Cl–Au angle is 96.1(1)°.

The strong η^2-coordination of the alkyne triple bond is also confirmed by IR spectroscopy. The C≡C stretching vibration is shifted from 2177 cm^{-1} to 1949, 1928 cm^{-1} (**1**) and from 2188, 2161 cm^{-1} to 1930, 1910 cm^{-1} (**2**). These shifts of about 250 cm^{-1} are much larger than those found in cycloheptyne copper(I) chloride complexes (180 cm^{-1}).[13]

This study shows that angle-strained alkynes are able to interact strongly with the gold(I) ion, thus forming thermally stable complexes. An investigation of the coordination behaviour of other alkynes with gold(I) is in progress.

‡ *Experimental data* for **1**: [AuCl(tht)][14] (1.00 g, 3.1 mmol) was suspended at 0 °C in tetrahydrofuran (30 ml). 3,3,6,6-Tetramethyl-1-thiacycloheptyne-1,1-dioxide[15] (0.75 g, 3.7 mmol) was added and the solution stirred at 0 °C for 1 h. The clear solution was evaporated to dryness to remove the released tetrahydrothiophene. Cyclopentane (25 ml, 0 °C) was added to extract excess alkyne ligand. Filtration of the precipitate (washed twice with 3 ml cyclopentane) gave a yield of 1.2 g (2.8 mmol, 90%) of complex **1** in the form of a colourless crystalline powder (mp 176 °C, decomp.). The compound is insoluble in cyclopentane and benzene, but soluble in acetonitrile, dichloromethane, chloroform and tetrahydrofuran. IR (KBr) ν/cm^{-1} 1949, 1928; ^{1}H NMR (200 MHz, $CDCl_3$) δ 1.39 (s, 12H, CH_3), 3.32 (s, 4H, CH_2); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ 27.89 (CH_3), 30.35 (CCH_3), 66.76 (CH_2), 97.15 (C≡C); elemental analysis: found C 28.07, H 3.97%; calc. C 27.76, H 3.73%. For **2**: [AuCl(tht)][14] (1.00 g, 3.1 mmol) was suspended at 0 °C in tetrahydrofuran (25 ml). 3,3,6,6-tetramethyl-1-thiacycloheptyne[16] (0.9 g, 5.3 mmol) was added and the slurry stirred at 20 °C (3 days, exclusion of light). The mixture was evaporated to dryness to remove the released tetrahydrothiophene. Tetrahydofuran (20 ml) was added to extract excess alkyne ligand. Filtration of the precipitate (washed twice with 3 ml tetrahydrofuran) gave a yield of 1.2 g (3.0 mmol, 97%) of complex **2** in the form of a colourless crystalline powder (mp 245 °C, decomp.). The compound is insoluble in acetonitrile, benzene, dichloromethane, chloroform and tetrahydrofuran, but soluble in tetrahydrothiophene, dimethyl sulfide, and in mixtures of dimethyl sulfide with dichloromethane and tetrahydrofuran. IR (KBr) ν/cm^{-1} 1930, 1910; elemental analysis: found C 30.07, H 3.99%; calc. C 29.97, H 4.03%.

§ Single crystals of **1** were grown from a solution in tetrahydrofuran to which cyclopentane was slowly added *via* the gas phase. Single-crystals of **2** were grown from a solution in dichloromethane–dimethyl sulfide (15 : 1) to which cyclopentane was slowly added *via* the gas phase.

Isolation and characterization of an oxidative degradation product of a polypyridine ligand

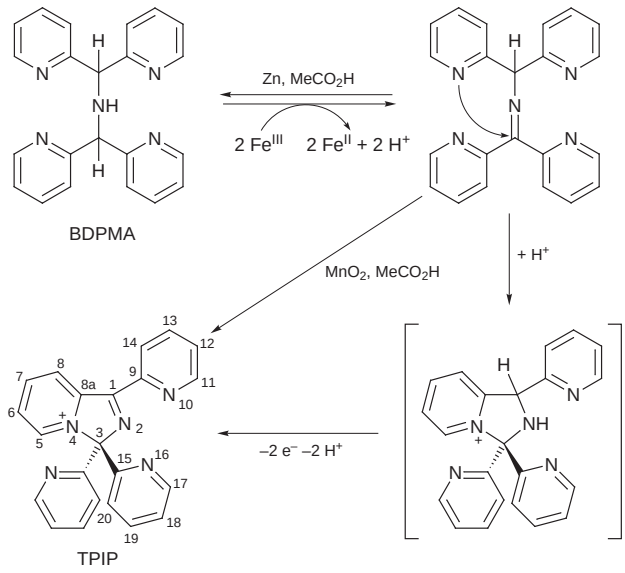
Michael Renz, Catherine Hemmert, Bruno Donnadieu and Bernard Meunier*†

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse cedex 4, France

The origin of the fragility of a polypyridine ligand under oxidizing conditions is discussed.

The catalytic activity of non-heme complexes has been recently investigated in relation to non-heme containing enzymes having one or two iron centers.[1] Mononuclear iron complexes with polypyridine ligands have been studied as potential oxidation catalysts.[2] In order to compare the activity of a mononuclear polypyridine–iron complex with porphyrin or phthalocyanine iron catalysts in the oxidative degradation of chlorophenols,[3] we synthesized a new symmetric tetrapyridine ligand, bis[bis(2-pyridyl)methyl]amine (BDPMA, Scheme 1).[4] The iron(III) complex of this ligand, $Fe(BDPMA)(NO_3)_3$, is able to catalyze the oxidative degradation of aromatic pollutants such as chlorinated phenols in the presence of $KHSO_5$.[5] Unfortunately, the oxidation stopped at the quinone level (without formation of ring cleavage products which are observed with an iron–phthalocyanine catalyst)[3] and the catalyst seemed to be short-lived. In attempts to crystallize the iron(III) complex of this tetrapyridyl ligand, we found the reason for the low catalytic activity that we observed in chlorophenol oxidations. Instead of a metal complex, the cationic compound 1,3,3-tris(2-pyridyl)-3*H*-imidazo[1,5-*a*]pyridin-4-ium (TPIP) was surprisingly obtained.‡ This degradation product of the BDPMA ligand was completely characterized by ^1H NMR, FAB-MS spectrometry and X-ray analysis (Fig. 1).§ The key feature of this structure is the presence of a pyridinium entity with the three other pyridine substituents still intact. Formally, this modified ligand TPIP can be obtained from BDPMA by abstraction of four electrons and three protons. In the crystal structure, the bond lengths of the pyridinium moiety are as expected for such rings and the shortest bond length [N(1)–C(7)] of the imidazole moiety is in agreement with a double bond. The N(2)–C(1) bond of the five-membered ring is around 4 pm longer than the N(1)–C(1) bond, as expected for a $C–N^+$ bond of a pyridinium entity (Fig. 1). The angle between the two planes formed by the imidazopyridinium and the pyridine connected to the C(7) carbon atom (Fig. 1) is only 5°, strongly suggesting that the conjugation is extended to this pyridine.

The formation of TPIP can be explained by the oxidation of BDPMA in the presence of Fe^{III} species (in the absence of metal traces BDPMA is stable and has been completely characterized). The first step consists of a two-electron oxidation of BDPMA by 2 equiv. of iron(III). The resulting imine can be activated by protonation and then attacked by a pyridine nitrogen acting as internal nucleophile to generate a five-membered ring (Scheme 1). This reaction is already known for pyridyl substituted imines, which after cyclization, are further oxidized to imidazo[1,5-*a*]pyridines.[6] This is not possible in the present case because a quaternary carbon is created during the cyclization (C^3, Scheme 1). Consequently, only one C–N double bond can be obtained by dehydrogenation of the five-membered ring (step 3, Scheme 1), and the pyridinium nitrogen remains positively charged. The cationic TPIP was obtained with nitrate as counterion (Scheme 1).



Scheme 1 Mechanism of the oxidative cyclization of BDPMA

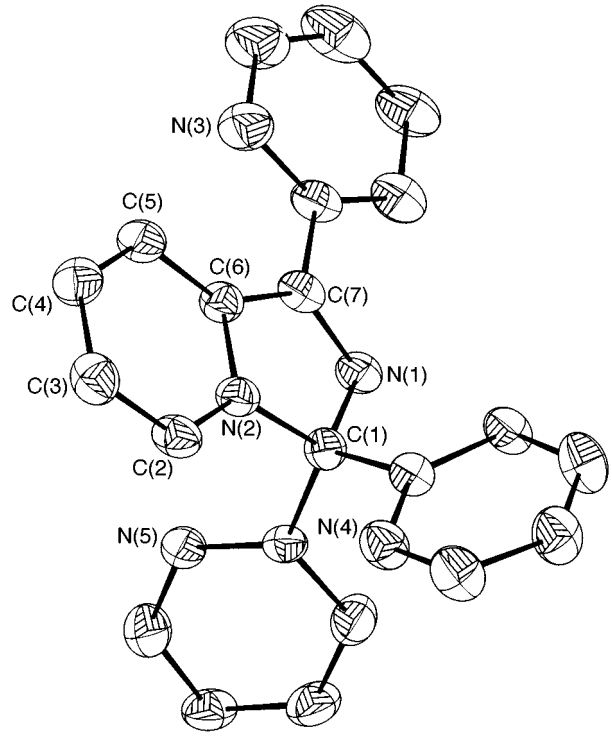


Fig. 1 Crystal structure of TPIP (atom numbering is differing from that presented in Scheme 1).§ Selected bond lengths (Å): N(1)–C(1) 1.457(4), N(1)–C(7) 1.293(5), N(2)–C(1) 1.498(4), N(2)–C(2) 1.336(4), N(2)–C(6) 1.364(4), C(2)–C(3) 1.374(5), C(3)–C(4) 1.383(6), C(4)–C(5) 1.388(5), C(5)–C(6) 1.377(5), C(6)–C(7) 1.471(5).

To prove this mechanism, we synthesized TPIP on a large scale *via* the imine. The latter is already known as precursor of BDPMA and has been reduced by Zn to obtain BDPMA.[4] For the oxidation, MnO_2 has been employed and TPIP was isolated in 73% yield.‡ A slow oxidation leading to the C–N double bond was observed in the presence of molecular oxygen, but we found that MnO_2 was the suitable oxidant to efficiently prepare TPIP.

The isolation and characterization of this degradation product is a significant illustration of the denaturation of a polypyridine ligand in oxidative conditions. The mechanism of the degradation was confirmed by the synthesis of the obtained product from the intermediary imine. The present work shows that ligands having easily oxidizable C–H bonds, *i.e.* activated in benzylic position or in α-position of a hetero atom, have to be avoided for stability reasons in the design of effective and long-lived oxidation catalysts.

We are grateful to the CNRS for financial support, especially M. R. for a postdoctoral fellowship.

‡ *Preparations*: TPIP [oxidation of BDPMA with $Fe(NO_3)_3$]: BDPMA (100 mg, 0.283 mmol) in methanol (2 ml) was added to a solution of $Fe(NO_3)_3{\cdot}9H_2O$ (105 mg, 0.260 mmol) in methanol (2 ml) and the mixture allowed to stand for 1 h. The solvent was evaporated and the residue dried under oil-pump vacuum for 3 h at 60 °C and *ca.* 10 mg of the obtained powder were dissolved in acetone. The solution was allowed to stand in an atmosphere of diethyl ether for two weeks. The solution became colorless, brown drops condensed and a large branched crystal was obtained, on which an X-ray analysis could be carried out. A yellow crystal was also obtained from an ethanolic solution in a methyl *tert*-butyl ether (MTBE) atmosphere. A part of this was cut and used for the presented X-ray structure. The remaining crystal was dissolved in dry $(CD_3)_2SO$ for ^{1}H NMR analysis and mass spectrometry. ^{1}H NMR [250 MHz, $(CD_3)_2SO$, 25 °C] δ 7.69 [dd, ^3J(HH) 7.7, ^3J(HH) 4.8 Hz, 2 H, 18-H], 7.91 [d, ^3J(HH) 7.9 Hz, 2 H, 20-H], 7.93 [ddd, ^3J(HH) 7.8, ^3J(HH) 4.8, ^4J(HH) 1.0 Hz, 1 H, 12-H], 8.14 [td, ^3J(HH) 7.7, ^4J(HH) 1.7 Hz, 2-H, 19-H], 8.32 [td, ^3J(HH) = 7.8 Hz, ^4J(HH) 1.7 Hz, 1 H, 13-H], 8.51 [ddd, ^3J(HH) 7.7, ^3J(HH) 6.2, ^4J(HH) 1.1 Hz, 1 H, 6-H], 8.75 [d, ^3J(HH) 4.8 Hz, 2 H, 17-H), 8.76 [d, ^3J(HH) 7.8 Hz, 1 H, 14-H], 9.08 [d, ^3J(HH) = 4.8 Hz, 1 H, 11-H], 9.13 [td, ^3J(HH) 7.7, ^4J(HH) 1.0 Hz, 1 H, 7-H], 9.60 [d, ^3J(HH) 8.0 Hz, 1 H, 8-H], 10.18 [d, ^3J(HH) 6.2 Hz, 1 H, 5-H]; FAB-MS (*meta*-nitrobenzyl alcohol): *m*/*z* (%): 350 (100).

TPIP (preparative synthesis): 300 mg (1.63 mmol) of bis(2-pyridyl)-ketone and 300 mg (1.63 mmol) of bis(2-pyridyl)methylamine[4] were dissolved in 10 ml of absolute isopropanol and dried over molecular sieves 3 Å for 1 h at room temperature. 350 μl (5.5 mmol) of glacial acetic acid was added under N_2 atmosphere and the reaction mixture refluxed for 5 h. 1.42 g (16.3 mmol) of MnO_2 was added (the oil bath was removed for the addition). After 1 h heating was switched off and the reaction mixture allowed to cool slowly. After 16 h, solids were removed by filtration. The solvent was evaporated (50 °C, 30 Torr) and the residue dissolved in 10 ml CH_2Cl_2 and washed with brine (2 × 5 ml). The crude reaction mixture was dissolved in MeOH and exposed to a MTBE atmosphere. 498 mg (1.19 mmol, 73%) of yellow crystals were obtained.

§ *Crystal data* for $C_{22}H_{16}N_6O_3$ (TPIP): M = 412.41, yellow pale crystal (0.20 × 0.20 × 0.10 mm), monoclinic, space group $I2/a$, a = 22.665(3), b = 8.4832(8), c = 23.415(3) Å, β = 117.83(2)°, U = 3982 Å^3, Z = 8, D_c = 1.37 g cm^{-3}, λ = 0.71073 Å, T = 160(2) K, μ(Mo-Kα) = 0.89 cm^{-1}, 25822 reflections (3166 independent) were collected on a STOE-IPDS diffractometer, 281 parameters were refined using the least-squares method on F[7], R = 0.051 and R_w = 0.055. Polymer pendant crown thioethers: synthesis and Hg^{II} extraction studies of a novel thiacrown polymer

Theodore F. Baumann,*† John G. Reynolds and Glenn A. Fox

Lawrence Livermore National Laboratory, University of California, PO Box 808, Livermore, CA 94551, USA

A novel C-substituted crown thioether has been synthesized and used to prepare a cross-linked polystyrene polymer containing pendant crown thioethers and that product has been shown to be effective in extracting Hg^{II} from acidic aqueous solutions.

Owing to increasing environmental concerns about waste water remediation, major efforts are under way to design new materials that can effectively remove and recover toxic metal ions from aqueous solutions. One approach to this problem has been to utilize organic ligands anchored to solid supports.[1] Specific binding properties of the ligands can be exploited to selectively remove a desired metal ion from a complex solution of cations. The utility of polymer pendant ligands for the extraction of a variety of metal ions from aqueous media has been previously demonstrated.[2]

We are interested in designing polymeric materials for Hg^{II} remediation in mixed waste streams. Typically, these waste streams are not only very acidic, but also contain a wide variety of other metal ions. As a result, removal of Hg^{II} requires a robust and selective sequestering agent. To address this difficult and expensive problem, we have developed the synthesis of polymer pendant crown thioethers for the selective removal of Hg^{II} from acidic aqueous media.[3] Crown thioethers[4] are well suited for this task owing to the high affinity that sulfur crowns have for the Hg^{II} ion[5] as well as their resistance to degradation under acidic conditions.[6] As pendant ligands on solid supports, crown thioethers have been shown to remove soft metal ions, such as Ag^{I}, Hg^{II} and Pb^{II}, directly from aqueous solutions.[7] Here we present the novel synthesis of a thiacrown polymer and initial results in the extraction of the Hg^{II} ion from acidic aqueous solutions.

Preparation of thiacrown polymers first required the synthesis of a sulfur crown containing a pendant arm incorporated into the carbon framework. Functionalization of this pendant arm would allow for either the attachment of the crown to a polymer support or direct polymerization of the thiacrown monomer. While there are reported syntheses for C-substituted sulfur crowns,[7d,8] those methods were not practical for our purposes, requiring a new method for the synthesis of pendant-arm crown thioethers.

The new crown thioether, 2-hydroxymethyl-1,4,8,11,14-pentathiacycloheptadecane[9] ([17]aneS_5-OH), **1**, was synthesized in a 25% yield through reaction of 2,3-dimercaptopropan-1-ol[10] with 4,7,10-trithiatridecane-1,13-di(toluene-*p*-sulfonate) (Scheme 1), using caesium carbonate mediated cyclization.[11] Advantages of this technique are: (1) it is general for synthesizing sulfur crowns of various sizes,[12] and (2) the hydroxymethyl moiety does not need to be protected prior to the condensation reaction. [17]aneS_5-OH was then treated with thionyl chloride to form 2-chloromethyl-1,4,8,11,14-pentathiacycloheptadecane ([17]aneS_5-Cl), **2** (89%), followed by conversion to 2-(*N*-methyl)aminomethyl-1,4,8,11,14-pentathiacycloheptadecane ([17]aneS_5-NHMe), **3** (65%), through reaction with methylamine. The synthesis of the 4-vinylbenzyl-substituted thiacrown **4** (60%) was readily accomplished by treating **3** with 4-vinylbenzyl chloride. Copolymerization of the 4-vinylbenzyl-substituted thiacrown **4** with DVB (80% divinylbenzene) using AIBN as the radical initiator generated the highly cross-linked crown thioether polymer **5**.[13] Elemental analysis of the resulting polymeric material showed that each gram of the polymer contained 1.53 mmol of [17]aneS_5 crown (based on % by weight of sulfur).

5

Solid–liquid extraction capabilities of the polymer pendant crown thioethers were tested in aqueous solutions. Twenty milligrams of the polymer were stirred in 5 ml of a buffered solution (ammonium acetate) containing 2.0×10^{-5} g of Hg^{II} [as $Hg(NO_3)_2$] at pH 3.60. Mixing times ranged from 30 minutes to 18 hours. At the end of the mixing, the polymer powder was separated from each solution by filtering through a cotton plug. The concentration of Hg^{II} remaining in the buffer solution was quantified spectrophotometrically using a diphenylthiocarbazone extraction method adapted from the methods of Charlot.[14] Using this method, the accuracy in determining the Hg^{II} concentration was ±1 ppm. In all cases, Hg^{II} removal was determined to be 99+%, indicating the high reactivity and extraction efficiency of the thiacrown polymer. The mercury extraction performance of the polymer under different conditions (pH and Hg concentrations), in addition to metal ion competition studies, will be reported in a full paper.

Work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under contract number W-7405-ENG-48.

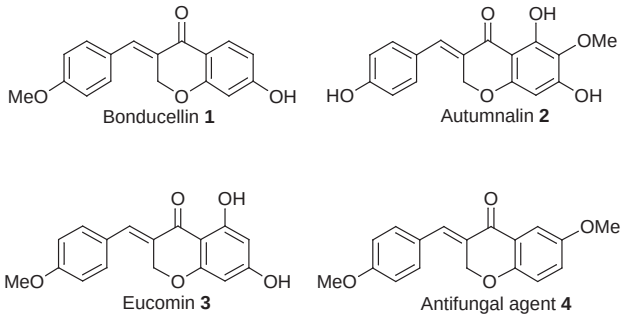
A new protocol for the syntheses of (*E*)-3-benzylidenechroman-4-ones: a simple synthesis of the methyl ether of bonducellin

Deevi Basavaiah,*† Manickam Bakthadoss and Subramanian Pandiaraju

School of Chemistry, University of Hyderabad, Hyderabad-500 046, India

Development of a simple new methodology for the synthesis of (*E*)-3-benzylidenechroman-4-ones using methyl 3-aryl-3-hydroxy-2-methylenepropanoates, the Baylis–Hillman adducts derived from methyl acrylate, and the application of this methodology for the synthesis of the methyl ether of bonducellin, an important natural product, and 3-(4-methoxybenzylidene)-6-methoxychroman-4-one, an antifungal agent, are described.

The (*E*)-3-benzylidenechroman-4-one moiety occupies a special place in the field of heterocycles as this skeleton is an integral part of many natural products and biologically active

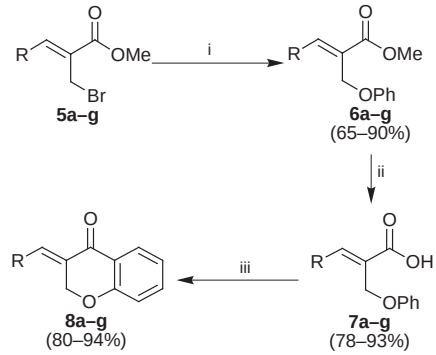


molecules. For example, bonducellin **1** is an important natural product occurring in *Caesalpinia bonducella*[1] and *Caesalpinia pulcherrima*.[2] Autumnalin **2**[3] and Eucomin **3**[4] are interesting naturally occurring molecules present respectively in *Eucomis autumnalis* GRAEB (Liliaceae) and *Eucomis bicolor* BAK (Liliaceae). (*E*)-3-(4-Methoxybenzylidene)-6-methoxychroman-4-one **4** is an antifungal agent.[5] Therefore the development of simple, general and new protocols for the synthesis of the (*E*)-3-benzylidenechroman-4-one skeleton is of considerable importance today in synthetic organic chemistry.

The classical and most of the literature methods for the synthesis of (*E*)-3-benzylidenechroman-4-ones involve the initial synthesis of the chroman-4-one skeleton, followed by the construction of the benzylidene moiety *via* acid or base catalyzed aldol condensation with aryl aldehydes.[6–8] However, to the best of our knowledge, there is no report in the literature of the synthesis of (*E*)-3-benzylidenechroman-4-one involving the initial preparation of the benzylidene moiety and then the construction of the chroman-4-one ring system. We herein disclose the first such methodology, thus developing a new protocol for the synthesis of (*E*)-3-benzylidenechroman-4-ones using methyl 3-aryl-3-hydroxy-2-methylenepropanoates, the Baylis–Hillman adducts derived from methyl acrylate.

The Baylis–Hillman reaction[9–13] has attracted the attention of organic chemists in recent years as this reaction provides synthetically useful multifunctional molecules which have been successfully employed in various stereoselective processes. In continuation of our interest in the Baylis–Hillman reaction[14–17] we have examined the possible application of methyl (2*Z*)-2-bromomethylalk-2-enoates‡ **5** derived from methyl 3-hydroxy-2-methylenealkanoates for the synthesis of (*E*)-3-benzylidenechroman-4-ones **8** according to Scheme 1.

We first selected (2*E*)-2-phenoxymethyl-3-phenylprop-2-enoic acid **7a**, which was obtained *via* the reaction of allyl



Scheme 1 *Reagents and conditions*: i, PhOH, K_2CO_3, acetone, reflux, 3 h; ii, KOH, H_2O, acetone, room temp., 14 h; iii, TFAA, CH_2Cl_2, reflux, 1 h

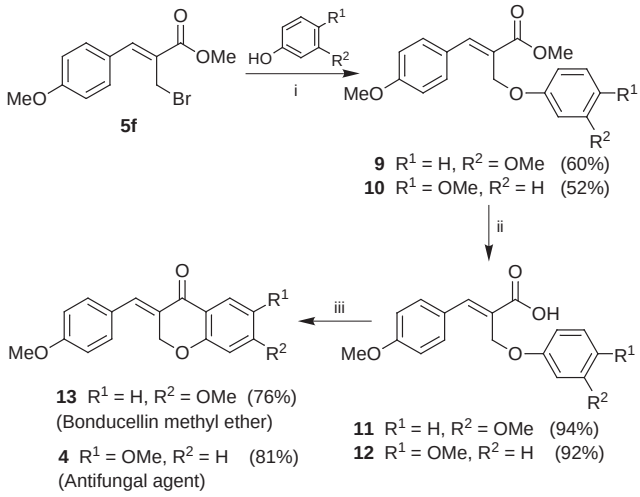

Scheme 2 *Reagents and conditions*: i, K_2CO_3, acetone, reflux, 3 h; ii, KOH, H_2O, acetone, room temp., 14 h; iii, TFAA, CH_2Cl_2, reflux, 1 h

bromide **5a**‡ with phenol followed by hydrolysis, as a substrate having a benzylidene moiety. Treatment of **7a** with TFAA in CH_2Cl_2 provided the desired (*E*)-3-benzylidenechroman-4-one **8a**§ in 91% yield. Encouraged by this success we prepared a representative class of (*E*)-3-benzylidenechroman-4-ones **8b**–**f** using (2*E*)-3-aryl-2-phenoxymethylprop-2-enoic acids **7b**–**f** obtained from methyl 3-aryl-3-hydroxy-2-methylenepropanoates (Scheme 1, Table 1). With a view to the generalization of this methodology we also synthesized (*E*)-3-butylidenechroman-4-one **8g** (R = Pr) (Table 1) starting from methyl (2*Z*)-2-bromomethylhex-2-enoate **5g**.¶

The efficiency of this methodology has been demonstrated *via* the synthesis of the methyl ether of bonducellin **13** and (*E*)-3-(4-methoxybenzylidene)-6-methoxychroman-4-one **4**, an antifungal agent, according to Scheme 2.

In conclusion, we have developed a new protocol for the synthesis of (*E*)-3-benzylidenechroman-4-ones involving the initial synthesis of the benzylidene moiety, followed by construction of the chroman-4-one system. Further application of this methodology for the synthesis of biologically active molecules is in progress in our laboratory.

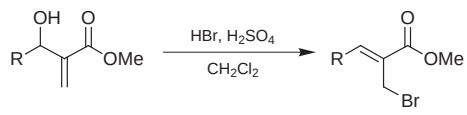
‡ The (*Z*)-allyl bromides **5** were prepared from the corresponding 3-hydroxy-2-methylenealkanoates following the literature method (ref. 18).



§ *Selected data* for **8a**: mp 110–111 °C (lit. 110–112 °C) (ref. 19); ν_{max}(KBr)/cm^{-1} 1668, 1601; δ_H(200 MHz, $CDCl_3$) 5.35 (d, 2 H, *J* 1.6) 6.95–7.60 (m, 8 H), 7.88 (s, 1 H), 8.03 (d, 1 H, *J* 7.8); δ_C(50 MHz, $CDCl_3$) 67.63, 117.93, 121.91, 122.06, 127.96, 128.74, 129.46, 129.99, 130.97, 134.43, 135.85, 137.44, 161.17, 182.17; *m/z* 236 (M^+); Calc. for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12. Found: C, 81.45; H, 5.12%.

¶ The reaction of methyl (2*Z*)-2-bromomethylhex-2-enoate **5g** with phenol in the presence of K_2CO_3 also provided *ca.* 15% of a side product, presumably methyl 2-methylene-3-phenoxyhexanoate (S_N2' product). However, the major compound methyl (2*E*)-2-phenoxymethylhex-2-enoate **6g** was obtained in pure form after silica gel column chromatography (3% EtOAc–hexane).

‖ The (*Z*)-stereochemistry of the molecules **5** and the (*E*)-stereochemistry of the molecules **6** and **7** were confirmed by ^{1}H NMR spectral analysis. It is well documented in the literature that in the ^{1}H NMR spectrum the chemical shifts of the vinylic β-proton *cis* to the ketone, ester and acid carbonyl groups and of the corresponding vinylic *trans* β-proton are well-differentiated and vinylic *cis* β-protons appear downfield in comparison with *trans* protons (ref. 20). The (*Z*)-stereochemistry of the allyl bromides **5** was assigned on the basis of the chemical shift values of the β-vinylic protons, *i.e.* δ 7.78–7.91 (when R = Ar) and 6.97 (when R = Pr) (refs. 18, 21). The (*E*)-stereochemistry of the molecules **6, 7** and **9**–**12** was assigned on the basis of the chemical shift values of the β-vinylic protons, *i.e.* δ 8.02–8.25 (when R = Ar) and 6.93–7.11 (when R = Pr) (refs. 18, 22).

** It is well established that in the ^{1}H NMR spectra of 3-benzylidenechroman-4-ones the vinylic β- proton *cis* to the carbonyl group appears at δ *ca.* 7.7 (refs. 4, 23) while the corresponding *trans* β-proton appears at δ *ca.* 6.7 (ref. 4). In the case of compounds **4**, **8a**–**f** and **13** the vinylic β-protons appear at δ 7.81–7.96. Hence (*E*)-stereochemistry was assigned to the compounds **4, 8a**–**f** and **13**. In the case of butylidenechroman-4-one **8g** (R = Pr) the vinylic β-proton appears at δ 7.04. Therefore (*E*)-stereochemistry was assigned to **8g**.

Cadmium sulfide nanoparticles have been produced *in situ* in aqueous solution at room temperature by precipitating Cd^{2+} ions with homogeneously released S^{2-} ions, which were generated from the decomposition of $Na_2S_2O_3$ by γ-irradiation.

Semiconductor particles in the nanometric range with dimensions comparable to the Bohr radius exhibit strongly size dependent optical and electrical properties. Such particles may lead to quantum dot lasers, single electron transistors and a host of other applications.[1] It is important to synthesize such particles at the desired size with a narrow size distribution and in an easy-to-handle condition. Many of the studies have focused on group II–VI semiconductor nanoparticles, in particular cadmium sulfide, because of their technological importance. Nanosized CdS particles are often prepared by precipitating Cd^{2+} ions with gaseous H_2S[2,3] as the source of S^{2-} ions. Because Cd^{2+} ions and H_2S are in separate phases and mix unevenly, the formation and aggregation of CdS particles is inevitably uneven. Other reports are of efforts in preparing CdS nanometer particles by mixing Cd^{2+} ions with Na_2S in aqueous solutions, water/oil microemulsions or other media.[4–6] As the precipitation of Cd^{2+} with S^{2-} is quicker than their homogeneous mixing, the inhomogenity at early stages results in a broadening of the size distribution. Also, deoxygenation and fresh Na_2S aqueous stock solutions are necessary in these methods to avoid the formation of colloidal sulfur and other species because of the instability of Na_2S. On the other hand, some reports have utilized other S^{2-} reservoirs, such as P_2S_5 or thioacetamide (TAA), to provide a homogeneous and rapid release of S^{2-} ions.[7,8] However, it is difficult to control the decomposition rate of P_2S_5 and TAA because non-aqueous or other complex manipulations are required.

Here we report a novel method for synthesis of the CdS nanoparticles at room temperature by utilizing homogeneous release of S^{2-} from the decomposition of sodium thiosulfate ($Na_2S_2O_3$) upon γ-irradiation.[9,10] In the presence of metal cations such as Cd^{2+} in solution, sulfide particles are formed by precipitation. To prevent the small CdS particles from coming into close contact and undergoing further aggregation, a surfactant, sodium dodecyl sulfate (SDS), is also needed in the system. Isopropyl alcohol, which is a scavenger of oxidative radicals such as ·OH, is thus added to improve the yield of nanoparticles.

Analytically pure $Na_2S_2O_3$, $3CdSO_4 \cdot 8H_2O$, isopropyl alcohol and SDS were mixed in appropriate proportions in distilled water. The solutions were irradiated by a ^{60}Co γ-ray source. After irradiation, the pale yellow product was collected and washed with distilled water. Finally, the product was dried in vacuum at 50 °C for 3 h.

X-Ray powder diffraction (XRD) was carried out on a Rigaku Dmax γ_A X-ray diffractometer with Cu-Kα radiation (λ = 0.154 178 nm). The absorption spectrum was recorded on a UV-2100 Schimadzu UV–VIS spectrophotometer using quartz cells. Transition electron microscopy (TEM) micrographs were taken with a Hitachi Model H-800 transmission electron microscope, using an accelerating voltage of 200 kV.

Fig. 1 shows the XRD pattern of a sample of CdS produced by γ-irradiation and is compared with the data of the JCPDS file.[11] The CdS particles were identified as β-CdS which belongs to the cubic crystal system. The broad peaks indicate that the dimensions of the CdS nanoparticles are very small. Employing Scherrer's equation,[12] the mean size of the CdS nanoparticles was estimated to be 2.3 nm.

The TEM image of the CdS sample of Fig. 1 is shown in Fig. 2, which reveals that small particles aggregate into secondary particles because of their extremely small dimensions and high surface energy. Therefore the size and the size distribution of the nanoparticles is difficult to determine precisely by simply viewing the TEM image.

The influence of the absorbed dose on the CdS nanoparticle size was studied by recording the absorption spectra of solutions irradiated with different absorbed doses, using aqueous solutions containing the same concentration of SDS as reference. Fig. 3 shows that the absorption spectra are structured and their absorption onset is in the violet wavelength range. It has been established that for relatively small semiconductor particles, the absorption spectrum provides a direct measure of the size of the crystallites.[2,13–15] By comparing the position of shoulders with the results of ref. 2, the particles are estimated to be *ca.* 1.5 nm in diameter. Fig. 3 also shows the progressive shift of the

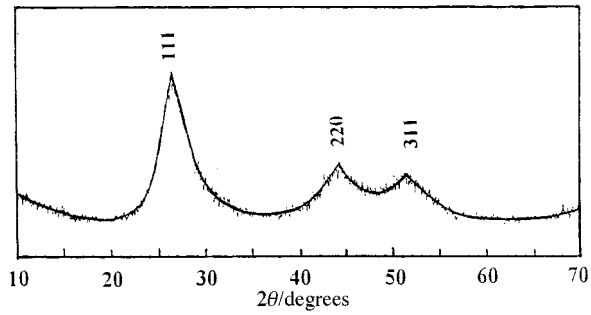

Fig. 1 XRD pattern of a CdS sample produced by γ-irradiation

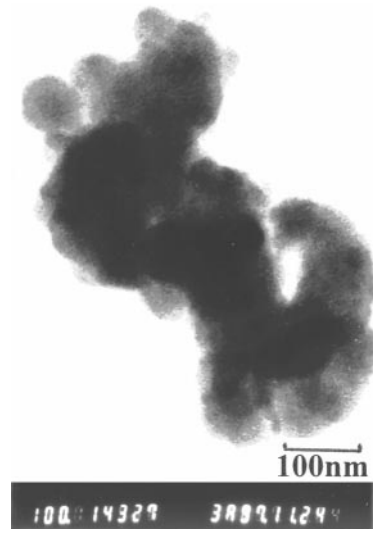

Fig. 2 TEM image of the CdS sample shown in Fig. 1

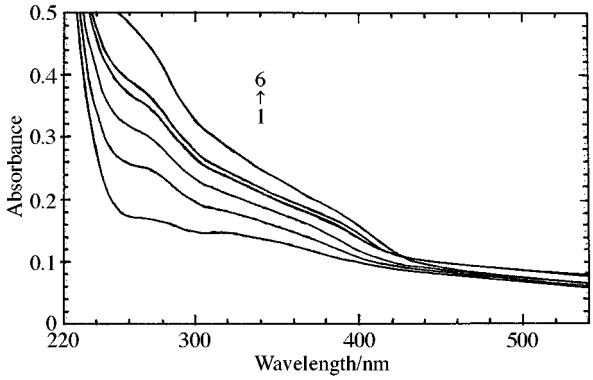

Fig. 3 Absorption spectra of irradiated CdS solutions with various absorbed doses: (1) 1000 Gy, (2) 1500 Gy, (3) 2000 Gy, (4) 2500 Gy, (5) 3000 Gy, (6) 4000 Gy. Solution: 2×10^{-4} M $CdSO_4 \cdot 8/3H_2O$, 2×10^{-4} M $Na_2S_2O_3$, 0.3 M Pr^iOH, 0.05 M SDS. Reference: aqueous solution containing the same concentration of SDS.

absorption onset with increasing irradiation dose, indicating that CdS particles gradually grow larger. The difference (in nm) between the position of the onset and the mean position of the shoulders characterizes the size polydispersity.[16] Fig. 3 reveals that the size polydispersity of the particles increases as the absorbed dose increases but does not change distinctly. It seems that the observed homogeneity is a direct consequence of the homogeneous mixing of $S_2O_3^{2-}$ and Cd^{2+}, and the even production of S^{2-} upon γ-irradiation.

Upon standing for ten days, the irradiated solutions show almost no change in absorption spectra. The system in the absence of SDS displays a weaker absorption, which shifts to longer wavelength and decays quickly upon aging. The surfactant layer around the small particles provides a microenvironment without water and other ions and inhibits the reverse (corrosion) reaction as well as coalescence; this favors the stabilization of small colloidal semiconductor particles.

In summary, γ-irradiation of the mixture provides promptly released and evenly dispersed S^{2-} ions, which then rapidly precipitate with Cd^{2+} ions and aggregate *in situ*. The surfactant prevents the small particles from coming into close contact and growing larger. A detailed study of the mechanism of the γ-irradiation route is underway and will be reported elsewhere.

Reversible anion binding in aqueous solution at a cationic heptacoordinate lanthanide centre: selective bicarbonate sensing by time-delayed luminescence

Rachel S. Dickins,[a] Thorfinnur Gunnlaugsson,[a] David Parker*[a]† and Robert D. Peacock[b]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

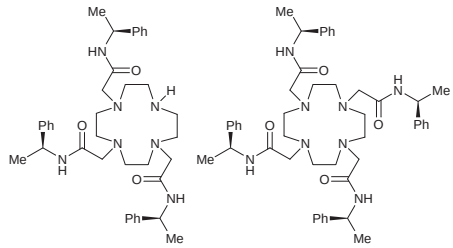
Reversible displacement of up to two metal bound water molecules at a coordinately unsaturated, cationic lanthanide centre is signalled by increases in the luminescence intensity or lifetime of the emissive lanthanide: selective chelation of hydrogencarbonate is consistent with emission spectroscopic, ESMS and CPL measurements.

Intrigued by the prospect of using a charged luminescent lanthanide receptor for the time-gated signalling of anion binding (hinted at by a brief communication[1]), we set out to prepare well-defined coordinately unsaturated Tb and Eu complexes wherein stepwise displacement of quenching metal-bound water molecules by a given anion would be signalled by increases in the lifetime or emission intensity of the lanthanide luminescence. Accordingly the enantiopure complexes $[EuL^1]^{3+}$ and $[TbL^1]^{3+}$ were devised, wherein the remote chiral centre at carbon determines the chirality of the complex in a similar fashion to that established with the Ln complexes of L^2.[2] In aqueous solution, the complexes complete their coordination number by binding two displaceable water molecules.



L^1 L^2

Reaction of 3 equiv. of (*R*)-*N*-(2-chloroethanoyl)-2-phenylethylamine with 1-(4-methoxyphenylsulfonyl)-1,4,7,10-tetraazacyclododecane (Cs_2CO_3, DMF, 70 °C) followed by reductive deprotection (Na, aq. NH_3, EtOH–THF) allowed isolation of the heptadentate, tri-*N*-substituted ligand L^1 (mp 64 °C), following chromatography on neutral alumina (CH_2Cl_2 to 1% MeOH–CH_2Cl_2). Complexation with $Eu(CF_3SO_3)_3$ or $Tb(CF_3SO_3)_3$ in anhydrous MeCN gave tripositive complexes. Analysis of $[EuL^1]^{3+}$ by ^1H NMR spectroscopy in D_2O and CD_3OD revealed only one set of four distinct broadened resonances for the most shifted axial ring proton (293 K, D_2O: +27.0, +16.1, +13.5, +8.8 ppm). A low temperature EXSY spectrum at −20 °C, clearly indicated that there were four stereoisomeric complexes (in a ratio of *ca.* 3.5 : 1 : 0.5 : 0.25) undergoing exchange by arm rotation but not ring inversion at this temperature.

The luminescence lifetimes for each complex were measured in H_2O and D_2O, initially in the absence and presence of a 10-fold excess of a selection of halides and oxyanions (Table 1). Such measurements allow the estimation of the number of coordinated water molecules ($q' = 2$ for each in the absence of added anions). A correction has been made in each case to account for the quenching effect of closely diffusing OH and amide NH oscillators.[3] In the presence of base (I = 0.14 NaCl), the lifetime of $[TbL^1]^{3+}\cdot(OH_2)_2$ increased by almost 50% and the q' value fell from 1.9 to 0.4, consistent with deprotonation and concomitant displacement of the second water molecule by Cl^-—leaving one quenching OH oscillator. The labilisation of metal bound water molecules following deprotonation is well-known with di- and poly-aqua metal ion species.[4]

Lifetimes for $[TbL^1]^{3+}$ in the presence of $I^-/Br^-/Cl^-$ and NO_3^- (pH 5.5–6.5) were virtually unchanged, whereas F^-, acetate and sulfate competed with H_2O for binding and led to the displacement of up to one of the quenching water molecules. Most striking was the behaviour of hydrogencarbonate (pH 6.5) and carbonate (pH 11) in which *both* water molecules were displaced leading to a large change in the measured lifetime (Table 1). This pattern of behaviour was echoed in lifetime measurements with $[EuL^1]^{3+}$, suggesting formation of a chelated adduct with HCO_3^-/CO_3^{2-} (Scheme 1).[5]

Further support for the distinctive nature of the anion adduct was provided by examination of the Eu emission spectra wherein the hypersensitive $\Delta J = 2$ transition at 618 nm is particularly sensitive to coordination environment.[2] The intensity ratio of the $\Delta J = 2 : \Delta J = 1$ emission bands was 4 : 1 (10-fold excess of anion in D_2O) for HCO_3^-, and the other values measured were all lower (*e.g.* F^-, 4 : 3; $H_2PO_4^-$, 2 : 1). A titration of the change in the intensity of one component of the 620 nm band as a function of added bicarbonate ($[Eu\cdot L^1]^{3+}$ = 2 × 10^{-3} M, 0–40 mM $NaHCO_3$, 293 K, 0.1 M MES buffer,

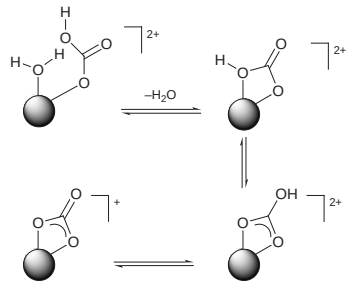
[a] Corrections for Tb complexes were to allow for the effect of closely diffusing OH oscillators (−0.06 $^{-1}$ in Δk) and used $q'_{is} = A'\Delta k_{corr.}$ where $A' = 4.9$. [b] Unchanged in 0.14 M NaCl; reduces to $q' = 0.25$ in 50 mM HCO_3^-. [c] At pH 11. [d] For Eu complexes, the correction for closely diffusing OH oscillators was −0.25 and −0.08 ms^{-1} for each amide NH, with $A' = 1.25$.



Scheme 1

Figs. 1 and 2), revealed an increase in the intensity of the band, with a switching factor of six, consistent with reversible formation of a 1:1 adduct. A similar titration with added dihydrogenphosphate showed much less change, with an enhancement factor of two in the range 0–5 mM. It is well known that hydrogenphosphate prefers to bind in a monodentate manner,[6] while carboxylates and carbonates often chelate, particularly to metal centres in higher coordination numbers.[7] Support for the existence of such a species came from ESMS, where in addition to the observation of an $[TbL^1OH]^+$ species at 831, peaks at 875.2 and 876.2 were apparent, together with 437.6/438.2 (⅔), whose relative abundance was in agreement with the isotope pattern calculated for $[TbL^1 + HCO_3]^+$ [calc.: 875.34 (100%) and 876.34 (51%)]. The structure of the excited state of lanthanide complexes is probed sensitively by circularly polarised luminescence (CPL).[8] CPL spectra for $[EuL^1]^{3+}$ in the presence of $CF_3SO_3^-$, $H_2PO_4^-$ and HCO_3^- (at pH 6.5 in an

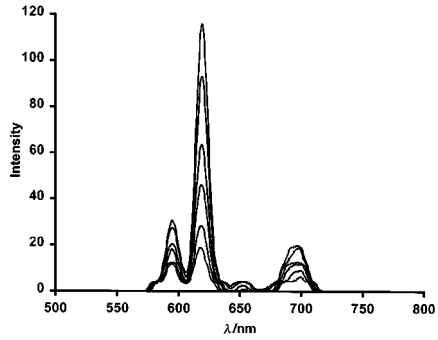


Fig. 1 Variation of luminescence intensity at 620 nm for $[EuL^1](CF_3SO_3)_3$ (pH 6.4 to 7.3 in 0.1 M MES buffer, 293 K, 1 mM) as a function of added $NaHCO_3$ in the range 1–30 mM. Emission intensities and lifetimes were unchanged (±7%) in the presence of 140 mM NaCl and in control experiments varying pH only (Perkin Elmer LS50B fluorimeter).

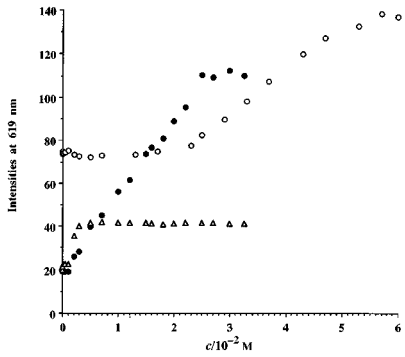

Fig. 2 Increase in the Eu emission intensity as a function of added $NaHCO_3$ (●; 293 K, pH 6.5–7.3 in an 0.1 M MES buffer, $\lambda_{exc.}$ 257 nm), NaH_2PO_4 (△) and $NaHCO_3$ (○) in a simulated clinical background of anions ($H_2PO_4^-$ 0.9 mM, 2.3 mM lactate, 145 mM Cl^-, 0.13 mM citrate)

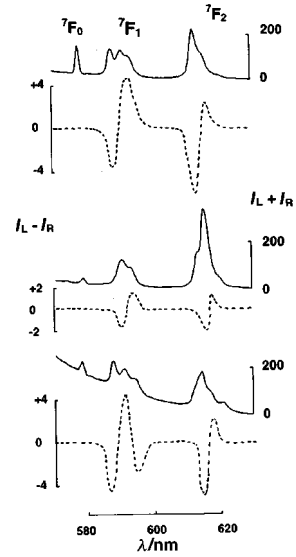

Fig. 3 Circularly polarised luminescence spectra for $[EuL^1](CF_3SO_3)_3$ (pD 6.9, 293 K, 1.0 mmol dm^{-3} in 0.1 M MES) (upper), and in the presence of 10 mM $H_2PO_4^-$ (bottom) and 40 mM HCO_3^- (centre). With $H_2PO_4^-$, the three $\Delta J = 1$ components have alternating signs while with HCO_3^- the highest energy component is absent and the signs are reversed.

0.1 M MES buffer) (Fig. 3) were measured. Distinctively different CPL spectra were found in the presence of both HCO_3^- and HPO_4^{2-} consistent with a pronounced change in the helicity of the 'anion-bound' europium excited-state structure.

In summary, measurements of the luminescence lifetime or intensity of emissive, coordinatively unsaturated enantiopure lanthanide complexes in aqueous media afford a new way of signalling the presence of selected oxyanions. Such systems may also act as simple models for studying anion binding in water that is relevant to the mode of action of alkaline phosphatase and carbonic anhydrase.

We thank the EPSRC, the BBSRC, the Royal Society and the University of Durham for support.

Zirconocene-coupling routes to conjugated polymers: soluble poly(arylenedienylene)s

Brett L. Lucht and T. Don Tilley*†

Department of Chemistry, University of California, Berkeley, Berkeley, California, 94720-1460, USA

Zirconocene-coupling of (–C≡CCH$_2$C(CH$_2$OC$_6$H$_{13}$)$_2$CH$_2$C≡C–arylene–)$_n$ polymers, followed by hydrolysis, provides a convenient, versatile route to soluble, diene-arylene polymers.

During the past decade, there have been extensive investigations on the synthesis and properties of conjugated polymers.[1] Since conjugated polymers tend to have poor solubility properties, they are frequently synthesized from more soluble precursor polymers,[2] or their solubilities are increased *via* incorporation of alkyl or alkoxy substituents as solubilizing groups.[3] Soluble conjugated polymers are desired as processible materials for numerous optoelectronic applications.[1] Particular attention has focused on poly(*p*-phenylenevinylene) derivatives, but it is clear that rather small changes in chemical structure can result in substantial changes in electronic properties for the polymer.[4]

We have recently developed a metal-coupling route to soluble poly(*p*-phenylenedienylene)s,[5] which involves palladium-catalyzed cross-coupling of diiodobenzenes with terminal dialkynylalkanes,[6] intramolecular zirconocene coupling of the alkyne units, and hydrolysis of the resulting zirconacyclopentadiene polymers[7] (Scheme 1). Variations of substituents on the phenyl ring (alkyl *versus* alkoxy) and the size of the exocyclic ring allow tuning of optical absorbances from 316–524 nm and emissions from 437–619 nm.[5] We now report a new method for the preparation of soluble conjugated polymers, based on zirconocene coupling (Scheme 2). This procedure is more versatile in that it allows for incorporation of a wide variety of aromatic units into the backbone of soluble poly(arylenedienylene)s.

Polycondensations of **1** with dibromoarenes were catalyzed by Pd(PPh$_3$)$_4$/CuI in a mixture of THF and diisopropylamine for 12–16 h at 50 °C.‡ Polymers **2a–g** were isolated as brown tars in 76–86% yield after purification by standard aqueous workup and removal of solvent. The crude polymers, which are highly soluble in THF, toluene and CHCl$_3$, contained trace quantities of the catalyst (by NMR spectroscopy). However, their structures were confirmed by ^{1}H NMR and IR spectroscopy. The IR spectra of **2a–g** contain ν(C≡C) stretches in the range 2212–2230 cm^{-1}, and their molecular weights (as determined by gel permeation chromatography, GPC; polystyrene standards) varied from 6100–20 000 (M_w; PDI ≈ 2).

Polymers **2a–g** were converted to deeply colored arylene-zirconacyclopentadiene polymers *via* additions to a solution of zirconocene, generated by the addition of Bu^{n}Li to zirconocene dichloride at −78 °C.[7b] These metal-containing polymers were converted directly to the corresponding poly(arylenedienylene)s **3a–g** by addition of aqueous HCl.§ Polymers **3a–g** were isolated as waxy solids in 82–91% yield after purification by standard aqueous workups. They are quite soluble in toluene, CHCl$_3$ and THF, and their molecular weights (Table 1) are similar to those for the precursor polymers **2a–g**, indicating that no chain degradation had occurred. The chemical structures of the polymers were determined by ^{1}H NMR and IR spectroscopies and combustion analyses.¶ The spectral data for polymers **3a–e** are consistent with the structures given in Scheme 2. Thus, the ^{1}H NMR spectra for these polymers contain vinylic and allylic resonances in the expected integrated ratios. Also, the IR spectra reveal no evidence for ν(C≡C) absorbances, indicating nearly quantitative conversion of alkyne to alkene units.

Our previous study indicated that the preparation of poly(*p*-phenylenedienylene)s *via* a multi-step process involving the conversion of one polymer to another is potentially susceptible to incomplete conversions and incorporation of defects into the backbone.[5] The vinylic and allylic regions of the ^{1}H NMR spectra of poly(arylenedienylene)s **3f** and **3g** suggest incomplete conversion. The vinylic and allylic ^{1}H NMR resonances for **3f** consist of one primary set of resonances (> 80% by integration) along with additional resonances with lower intensities. This suggests that the polymer contains minor defects (< 20%). The vinylic and allylic ^{1}H NMR resonances for **3g** are extremely broad and ill-defined, suggesting that the conversion of **2g** to **3g** results in a complex mixture of products with few diene units. The lack of observed ν(C≡C) absorbances in IR spectra of polymers **3f** and **3g** is consistent with partial conversion, since the alkynyl absorbances of **2f** and **2g** are very weak. Given the steric bulk of the arene spacers in **2f** and **2g**, we attribute the incomplete conversions for these polymers to unfavorable interactions between the arene group and the

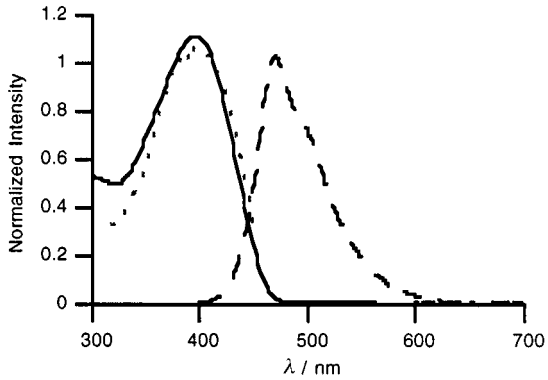

Fig. 1 Absorption (——), emission (-----) and excitation (·····) spectra of **3b**

zirconocene fragment. This is supported by observations on model zirconocene couplings with alkynes,[8] and semi-empirical PM3 calculations.

The optical properties of polymers **3a–g** were investigated by absorption, emission and excitation spectroscopy. The spectral data for polymers **3a–g** are summarized in Table 1, and Fig. 1 presents absorption, emission and excitation spectra for polymer **3b**. The observed optical properties vary considerably, according to the structure of the aromatic rings. The absorption spectrum of the pyridine-containing polymer **3c** is red-shifted (λ_{max} = 548 nm) upon treatment with 3.0 M HCl to form the pyridinium cation **3c**·HCl, as has been observed in related polymers.[9] Note that incorporation of a thiophene group leads to a red-shift (with respect to polymer **3a**), while incorporation of tetrafluorophenylene results in a blue shift. For polymer **3b**, the excitation spectrum reproduces the absorption spectrum, and the photoluminescence quantum yield is 0.043.[5,10] The photoluminescence quantum yields for **3a** and **3c–f**, on the other hand, are low ($\Phi < 0.01$). The excitation spectra for **3a** and **3c–f** exhibit maxima at shorter wavelength (by 40–120 nm) than the respective absorption λ_{max} values. Based on our previous study, we suggest that this may be attributed to efficient emission from defect sites resulting from incomplete conversion to the diene-polymer.[5]

We are currently investigating the photoluminescent and electroluminescent properties of thin films of polymer **3b**. In addition, further evaluation of the use of zirconocene couplings for the preparation of conjugated polymers is in progress.

‡ Polymer **2a**. A 100 ml Schlenk flask was charged with 1,4-dibromobenzene (0.59 g, 2.5 mmol), $Pd(PPh_3)_4$ (0.13 g, 0.12 mmol), CuI (0.04 g, 0.21 mmol), Pr^i_2NH (7.0 ml) and THF (15.0 ml). To this solution was added **1** (0.80 g, 2.5 mmol), and the reaction mixture was allowed to stir for 16 h at 50 °C. The reaction mixture was diluted with $CHCl_3$ (100 ml) and washed with diluted NH_4OH (2 × 75 ml, 1.0 M) and H_2O (75 ml). The organic layer was dried with Na_2SO_4 and the solvent was removed by rotary evaporation. This yields **2a** (79%, 0.78 g) as a light yellow–brown gummy solid. δ_H(300 MHz, $CDCl_3$) 0.86 (t, *J* 7.2, 6 H, CH_3), 1.27 (m, 8 H, CH_2), 1.33 (m, 4 H, CH_2), 1.55 (m, 4 H, CH_2), 2.61 (s, 4 H, CH_2), 3.43 (t, *J* 6.8, 4 H, CH_2O), 3.47 (s, 4 H, CH_2O), 7.29 (s, C_6H_4, 4 H); ν(film, KBr)/cm^{-1} 2954, 2930, 2859, 2223 (C≡C), 1507, 1465, 1376, 1261, 1113, 1020, 836, 800; M_n/M_w = 3600/6100 by GPC.

§ Polymer **3a**. A 100 ml Schlenk flask was charged with Cp_2ZrCl_2 (1.0 g, 3.4 mmol) and 30 ml of dry THF. The solution was cooled to −78 °C and Bu^nLi (4.0 ml, 1.6 M, 6.5 mmol) was added dropwise over 5 min. The reaction mixture was allowed to stir for 15 min at −78 °C, and then crude **2a** (0.78 g, 2.0 mmol of diyne) in 10 ml of dry THF was slowly added *via* cannula over 5 min. The reaction was allowed to stir under N_2 while warming to room temperature over 3–4 h, and was then stirred for an additional 1 h at room temperature. The phenylene zirconocyclopentadiene polymer was not isolated, but was converted directly to **3a** by addition of HCl (15 ml, 6 M). The reaction mixture was diluted with $CDCl_3$ (100 ml) and washed with HCl (75 ml, 0.5 M), H_2O (75 ml), $NaHCO_3$ (75 ml, 1.0 M), and H_2O (75 ml). The organic layer was dried over Na_2SO_4, and then the solvent was removed by rotory evaporation. This yields **3a** (85%, 0.66 g) as an orange wax. δ_H(300 MHz, $CDCl_3$) 0.87 (br, 6 H, CH_3), 1.26 (br, 12 H, CH_2), 1.53 (br, 4 H, CH_2), 2.75 (br, 4 H, CH_2), 3.23 (br, 4 H, CH_2), 3.39 (br, 4 H, CH_2), 6.99 (br, 2 H, CH), 7.43 (br, 4 H, C_6H_4); ν(film, KBr)/cm^{-1} 3021, 2954, 2930, 2857, 2793, 1598, 1464, 1376, 1261, 1112, 877; M_n/M_w 3700/7400 by GPC; (Calc. for $C_{27}H_{40}O_2$: C, 81.8; H, 10.18. Found: C, 77.5; H, 9.62%).

¶ As expected for conjugated polymers, the combustion analyses typically gave values for the carbon content that were low by a few percent.

Influence of oxygen and nitrogen on ^{7}Li MAS NMR spectra of zeolite LiX-1.0

M. Feuerstein and R. F. Lobo*†

Center for Catalytic Science and Technology, Department of Chemical Engineering, University of Delaware, Newark, DE 19716, USA

Nitrogen and oxygen were adsorbed in dehydrated samples of zeolite LiX-1.0 [$(SiAlO_4)_{96}Li_{96}$]; the ^{7}Li MAS NMR spectra of these samples were compared with the spectrum of a sample studied in vacuum; it has been shown that the line assigned to Li cations at position SIII ($\delta_{iso} = -0.7$) is influenced by the different gases, whereas lines belonging to Li cations in front of six-rings do not change (SI′ line $\delta_{iso} = 0.4$, SII line $\delta_{iso} = -0.3$).

Characterization of the acid and adsorption sites of porous materials is a key issue for understanding the adsorption process and its technical applications. LiX zeolites are commercially useful adsorbents for the production of nitrogen from air in the PSA (pressure swing adsorption) process.[1] Adsorption experiments have shown that the capacity of nitrogen adsorption correlates with the amount of the Li extraframework cations in these zeolites.[2] Recently, Plevert and coworkers[3] investigated zeolite LiX-1.0 by neutron diffraction and located Li cations in four crystallographic sites (SI′, SII, SIII and SIII′). Li cations in zeolite LiX were also studied using a combination of ^{6}Li and ^{7}Li MAS NMR spectroscopy and neutron diffraction by Feuerstein and Lobo.[4] ^{6}Li and ^{7}Li MAS NMR spectra of dehydrated LiX-1.0 show three lines belonging to Li cations in sites SI′ (δ_{iso} = 0.4), SII ($\delta_{iso} = -0.3$), and SIII ($\delta_{iso} = -0.7$). Variable temperature ^{7}Li MAS NMR spectra have shown that the cations at SIII have to be considered mobile. In this earlier study zeolite samples were dehydrated in MAS NMR glass inserts and the inserts sealed while under vacuum. Here we discuss the changes in the ^{7}Li MAS NMR spectra caused by the presence of nitrogen and oxygen on LiX-1.0.

NaKX-1.0 zeolite was prepared following a method similar to the one published by Kuehl[5] and the as-synthesized form was exchanged to the Li form by several ion exchanges (see ref. 4). The LiX-1.0 zeolites were dehydrated at 673 K and 10^{-1} Pa. The integrity of the faujasite structure was confirmed by X-ray powder diffraction. ^{29}Si MAS NMR spectra show an Si/Al ratio of 1.0 and ^{27}Al MAS NMR spectra show only the existence of tetrahedral coordinated aluminium. ^{7}Li MAS NMR spectra were recorded at a resonance frequency of 116.6 MHz using a Bruker MSL-300 spectrometer and a 4 mm double bearing Bruker probe. The sample studied in vacuum was prepared in MAS glass inserts. For the oxygen adsorption a sample was dehydrated in a MAS glass insert and sealed after filling the tube with dry oxygen (79.1 kPa). Studies of adsorption of nitrogen were performed by packing the MAS NMR rotor in a nitrogen atmosphere using a glove box.

Fig. 1 shows the ^{7}Li MAS NMR spectra of zeolite LiX under three different sets of conditions: at vacuum, and after the adsorption of nitrogen and oxygen. The lines belonging to the Li cations in front of the six-ring windows [SI′ (δ_{iso} = 0.4), and SII ($\delta_{iso} = -0.3$)] do not change after the adsorption of the different gases. Cations at SI′ do not interact with the gas molecules because the van der Waals radii of N_2 and O_2 are too large to enter the β-cages and interact with this site. On the other hand, it is known from the refinements of the neutron diffraction data of LiX-1.0 that Li cations at SII are located inside the six-ring.[3,4] Therefore, the SII cations are effectively shielded by the framework atoms and do not interact with molecules in the supercages.

The line observed at $\delta_{iso} = -0.7$ in the ^{7}Li MAS NMR spectrum of the sample studied in vacuum and attributed to the SIII cations shifts slightly to a lower frequency after the adsorption of nitrogen. This observation is explained by the preferred interaction of the nitrogen molecules with the Li cations at SIII. Interestingly, ^{23}Na and ^{7}Li MAS NMR experiments of LiNaX zeolites having different Li exchange levels had shown that the site population of Li cations at SIII correlate directly with its nitrogen adsorption capacity.[6] The presence of oxygen causes a down-field shift of the SIII line. The shift to higher frequency is explained by the paramagnetism of the oxygen molecules. Several authors have observed shorter spin–lattice relaxation times (T_1) caused by the adsorption of oxygen.[7] Recently, Norby *et al.*[8] also observed a down-field shift of lines in ^{133}Cs MAS NMR spectra (recorded at variable temperature) of a CsNaY zeolite. The down-field shift was explained by the paramagnetic interaction between the unpaired electrons of the oxygen molecules and the Cs nucleus. Variable temperature ^{7}Li MAS NMR spectra of zeolite LiX-1.0 loaded with oxygen are depicted in Fig. 2. It can be observed that as a function of temperature, (i) the lines belonging to the six-ring cations show a small high-field shift, (ii) the line at high field belonging to the cations at SIII shows a down-field shift with decreasing temperature, (iii) the line width of the SIII line is increasing with decreasing temperature.

The high-field shift of the SI′ and SII components was also observed in ^{7}Li MAS NMR spectra of LiX-1.0 recorded at variable temperature with samples studied under vacuum in a MAS glass insert. Neutron diffraction experiments have shown that in LiX-1.0 a phase transition occurs at T = 220–230 K.[4] The symmetry changes from the cubic space group *Fd*3 to the orthorhombic space group *Fddd*. This phase transition might cause a slightly different environment of the Li cations and accounts for the change in the chemical shifts of the SI′ and SII lines. This point, however, is not completely understood and needs additional study. The down-field shift of the SIII line at lower temperatures is due to the temperature dependence of the

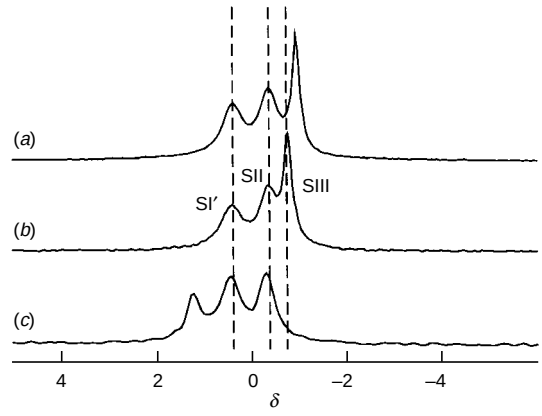

Fig. 1 ^{7}Li MAS NMR spectra of LiX-1.0, (*a*) after adsorption of nitrogen, (*b*) in vacuum, and (*c*) after adsorption of oxygen

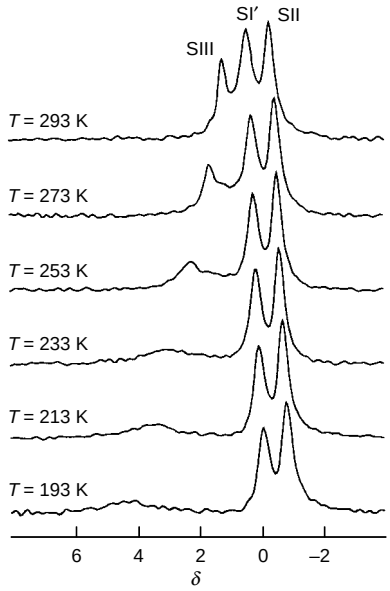

Fig. 2 Variable temperature ^{7}Li MAS NMR spectra of zeolite LiX after adsorption of oxygen

paramagnetic shift $\Delta\nu \approx 1/T$. The increase of the line broadening at lower temperatures is caused by two effects: a line broadening of the SIII line was previously observed in a study of ^{7}Li MAS NMR spectra of LiX in vacuum in the temperature range 233–253 K.[4] This effect is related to motion of the SIII cations and the line narrowing by the MAS NMR experiment. However, at temperatures below 233 K a narrow SIII line was again observed in the sample studied in vacuum. The ^{7}Li MAS NMR spectra shown in Fig. 2 differ in this point and the SIII line broadens further at temperatures below 233 K. The source of the other broadening is the paramagnetic shift due to the anisotropic interaction of the nuclear spin with the electron spin.[9]

The adsorption of oxygen can be easily used to test for accessibility of a cation site in microporous materials in general. The present work shows clearly the advantage of using ^{7}Li MAS NMR spectroscopy to study the adsorption sites in zeolite LiX, namely the Li cations at site SIII. We will discuss this topic in more detail in the future and compare the ^{7}Li MAS NMR spectra of different zeolites recorded under vacuum and after adsorption of nitrogen and oxygen.

Note added at proof: Plevert *et al.*[10] very recently reported a study of the paramagnetic shift of ^{6}Li in zeolite Li-X. Their results are fully consistent with the results presented here for ^{7}Li in zeolite Li-X.

Directed reactivity at a vanadium(II) thiolate center: synthesis and structure of a novel vanadium thiolate complex and its reaction product with azobenzene

John A. Davis, Christopher P. Davie, David B. Sable and William H. Armstrong*†

Department of Chemistry, Eugene F. Merkert Chemistry Center, Boston College, Chestnut Hill, Massachusetts, 02167-3860, USA

The vanadium(II) thiolate complex [V(tmeda)(DCTP)$_2$] [DCTP = 2,6-dichlorothiophenolate; tmeda = *N,N,N′,N′*-tetramethylethylenediamine] is obtained by the reaction of 2 equiv. of LiDCTP with [VCl$_2$(tmeda)$_2$] and reacts with azobenzene to yield the imido-containing complex [V(tmeda)(DCTP)$_2$(≡NPh)].

Low-valent vanadium thiolate complexes are of interest due in part to their potential relevance to the functioning of the alternative nitrogenase cofactor,[1] and to their presumed reactivity toward small reducible molecules in general. Recently, Coucouvanis and coworkers have shown that vanadium in a sulfur- and nitrogen-containing environment can catalyze the reduction of hydrazine to ammonia.[2] We have had considerable interest in lower-valent vanadium chalcogenide complexes, particularly with respect to their reactivity toward small molecules.[3] Herein we report the synthesis and structural characterization of a novel and rare mononuclear vanadium(II) thiolate complex containing labile coordination sites. We also provide an initial report on its reactivity with a substrate of relevance to dinitrogen reduction.

Complex **1**, [V(tmeda)(DCTP)$_2$] (DCTP = 2,6-dichlorothiophenolate; tmeda = *N,N,N′,N′*-tetramethylethylenediamine), is formed from the reaction of 2 equiv. of the lithium salt of 2,6-dichlorothiophenol (LiDCTP)‡ with 1 equiv. of [VCl$_2$(tmeda)$_2$].§[4] The crystal structure of **1** is shown in Fig. 1.¶ Bond distances and angles for **1** are consistent with those observed for other complexes of this sort, though crystallographically characterized vanadium(II) thiolates are still quite uncommon.[5] The structure of **1** reveals as well the presence of two dative, aryl–halide bonds. The observed V–Cl distances [2.515(2) Å, 2.510(2) Å] are well within the sum of radii of the atoms (3.131 Å),[6] and there is a slight lengthening of the Cl–C bond [1.758(9) Å] relative to the bond for the non-coordinated chlorine [1.727(9) Å]. While the ability of DCTP$^-$ to act as a bidentate ligand through sulfur and chlorine is unknown in the literature, such dative bonds with other halides are not unprecedented,[7] including one at a vanadium center.[8] The occurrence of such potentially labile bonds at a vanadium(II) center, and particularly at an electron-rich vanadium(II) thiolate center, gives hope that these might be sites for reactivity.

These hopes were realized in the reaction that yields complex **2**, [V(tmeda)(DCTP)$_2$(≡NPh)]. Complex **2**, whose ORTEP is shown in Fig. 2,¶ is obtained from the reaction of **1** with 0.5 equiv. of azobenzene.‖ The azobenzene is cleaved to give one phenylimido group per vanadium, with concomitant dissociation of one of the chlorine dative bonds of **1**. The other dative chlorine bond is now located *trans* to the imido group, and the V–Cl bond distance is, as expected from the strongly electron donating nature of the imido functionality, significantly lengthened relative to that seen in **1** [2.671(3) *vs*. 2.510(2) Å]. Structurally, **2** is quite similar to other vanadium(IV) and vanadium(V) arylimido complexes,[9] with the short V–N distance [1.670(7) Å] and nearly linear V–N–C angle [171.2(7)°] indicating a V≡NAr bonding moiety.[9] Other distances are as expected, though again it should be noted that

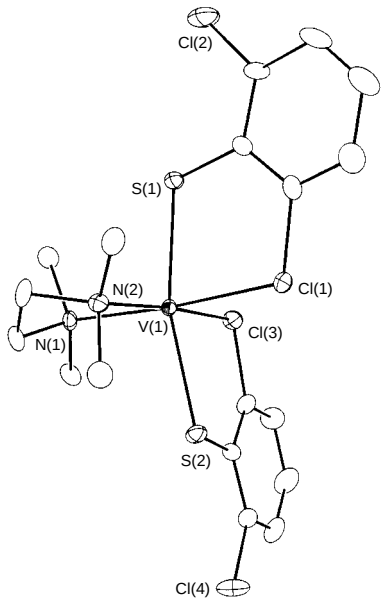

Fig. 1 ORTEP of [V(tmeda)(DCTP)$_2$], **1**, showing the 30% probability thermal ellipsoids and atom labelling scheme. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°) are as follows: V(1)–S(1) 2.468(2), V(1)–S(2) 2.464(2), V(1)–Cl(1) 2.515(2), V(1)–Cl(3) 2.510(2), V(1)–N(1) 2.206(6), V(1)–N(2) 2.220(7), S(1)–V(1)–S(2) 165.19(7), Cl(1)–V(1)–Cl(3) 92.84(6).

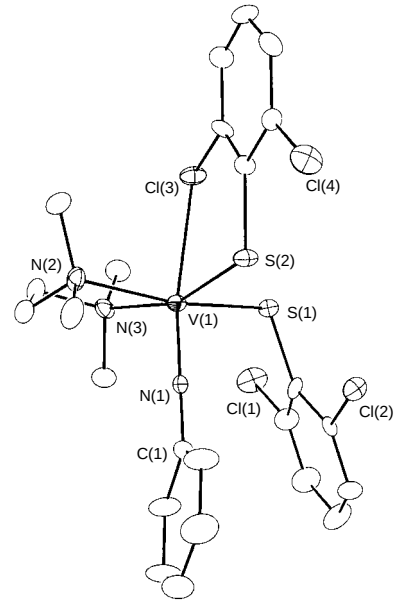

Fig. 2 ORTEP of [V(tmeda)(DCTP)$_2$(≡NPh)], **2**, showing the 30% probability thermal ellipsoids and atom labelling scheme. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°) are as follows: V(1)–N(1) 1.670(7), V(1)–S(1) 2.465(3), V(1)–S(2) 2.434(3), V(1)–Cl(3) 2.671(3), V(1)–N(2) 2.245(8), V(1)–N(3) 2.243(7), V(1)–N(1)–C(1) 171.2(7).

very few vanadium(IV) imido complexes have been structurally characterized.[10] Perhaps more interestingly, of those that have, none have been prepared from reduction of a diazo moiety. In fact, of all reported vanadium imido complexes, only one other is formed as the result of the reductive cleavage of a dinitrogen analogue.[11]

Compound **1** has also shown reactivity with many other small molecules such as *tert*-butyl isocyanide, 1,2-diphenylhydrazine and organic aldehydes. Elucidation of other reaction products and details of the reactivity of related compounds will be reported elsewhere. Further development of chemistry at other low-valent vanadium thiolate centers is under way.

For funding this work we thank the National Science Foundation (Grant CHE-8857455). We also thank the National Institutes of Health (Grant 1 S10 RR09008) and Boston College for providing funds for the purchase of a Siemens SMART single crystal X-ray diffractometer.

‡ In a typical preparation, 5.372 g (30.00 mmol) of 2,6-dichlorothiophenol (Lancaster) were added to 20 ml of toluene. 18.75 ml (30.00 mmol) of 1.6 M *n*-butyllithium (Aldrich, in hexanes) were added over 0.5 h to the thiol solution with vigorous stirring. The resulting white precipitate was washed with hexane and dried, affording an approximately quantitative yield.

§ In a typical preparation, 1.00 g (2.82 mmol) of $[VCl_2(tmeda)_2]$[4] was dissolved in 20 ml of THF. Then 1.04 g (5.65 mmol) of LiDCTP were added at once with stirring. The light blue solution turned homogeneous and emerald green. Over 0.2 h a light green precipitate of $[V(tmeda)(DCTP)_2]$ appeared. The precipitate was filtered off, washed with diethyl ether and dried *in vacuo* to give analytically pure product in 68% yield. The yield could be improved by treating the remaining filtrate with pentane. The green precipitate was filtered off and rinsed with 5 ml of diethyl ether and then 5 ml of THF. The combined solids then afforded an 82% yield. Elemental analysis was satisfactory. EPR (X-band, CH_2Cl_2, 77 K): g = 5.33, multiline.

¶ *Crystal data* for **1**: a single crystal was mounted under the cold stream (−90 °C) of a Siemens SMART system. An initial collection of 60 frames of data yielded the crystal system (hexagonal) and unit cell [a = 7.6735(1), c = 65.3685(2) Å]. 20749 reflections were collected, of which 5003 were unique. The space group ($P6_1$, Z = 6) was chosen by systematic absences and successful refinement of the structure. No absorption correction was used. The structure was solved using SHELX 5.0 using anisotropic thermal parameters for all non-hydrogen atoms to values of R_1 = 7.35%, wR_2 = 15.7% for $I > 2\sigma(I)$. For **2**·thf: a single crystal was mounted under the cold stream (−90 °C) of a Siemens SMART system. An initial collection of 60 frames of data yielded the crystal system (orthorhombic) and unit cell [a = 13.621(4), b = 15.254(4), c = 30.410(7) Å]. 17675 reflections were collected, of which 10152 were unique. The space group ($P2_12_12_1$, Z = 2) was chosen by systematic absences and successful refinement of the structure. No absorption correction was used. The structure was solved using SHELX 5.0 using anisotropic thermal parameters for all non-hydrogen atoms to values of R_1 = 8.40%, wR_2 = 13.72% for $I > 2\sigma(I)$. CCDC 182/902.

‖ In a typical preparation, 0.25 g (0.478 mmol) of **1** was suspended with stirring in 20 ml of THF. Addition of 0.044 g (0.239 mmol) of azobenzene (Aldrich) yielded a yellow–green heterogeneous mixture which was then refluxed and became dark brown and homogeneous over 2 h. The solution was filtered, concentrated and cooled, affording brown crystals in 65% yield. Analysis was satisfactory. EPR (X-band, THF, 77 K): g = 2.0, 8 lines.

Novel chromium(III) ethene polymerization catalysts bearing bulky monoanionic N,N-chelate ligands are described.

Chromium supported on silica plays a central role in the world-wide production of polyethylene.[1] As heterogeneous catalysts they have not proved amenable to intimate study, and even to this day there remains an on-going debate about the oxidation state of the active chromium centres.[2] The development of homogeneous molecular chromium catalysts is therefore an important objective, since these offer the potential for understanding the *modus operandi* of supported chromium catalysts and may provide new opportunities for tuning activity and selectivity. A number of reports of molecular chromium catalysts have appeared in the recent literature,[3–6] the majority on half-sandwich chromium species as models for the active sites of chromocene-derived systems.[3,4]

Here we describe a series of coordinatively unsaturated chromium(III) ethene polymerization procatalysts bearing either β-diketimate or pyrrolide-imine ligands. A general feature of these ligands is the presence of bulky aryl substituents which offer protection to the active centre, a strategy that has proved successful for the stabilisation of new N,N-chelate catalysts based on early[7] and late transition metal systems.[8] A similar strategy has also recently been applied to a new catalyst system based on iron and cobalt.[9]

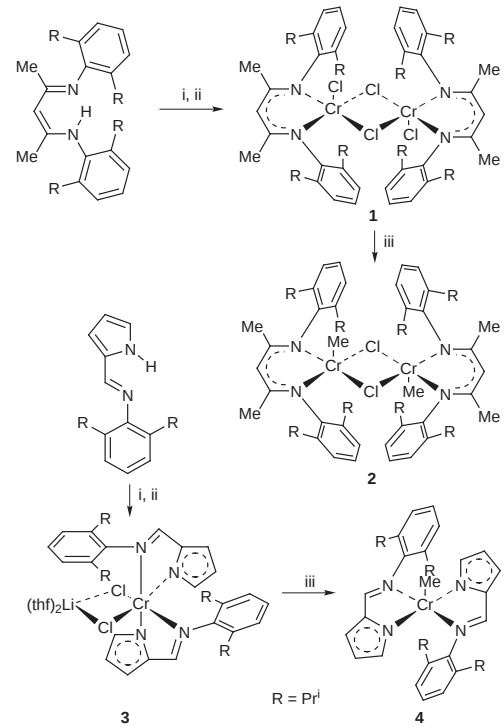
The chromium chloride complexes, **1** and **3**, were prepared in high yield by the treatment of $[CrCl_3(thf)_3]$ with the lithium salts of the β-diketimate ligand or the pyrrolide-imine ligand, respectively (Scheme 1).‡ The structures of **1** and **3** were confirmed by X-ray structure determinations.[10] Interestingly, only one β-diketimate ligand can be coordinated to chromium in **1**, while in **3** the less sterically demanding pyrrolide-imine ligand allows bis-chelation. It is also of note that the vacant sixth coordination site in **3** is unexpectedly occupied by a molecule of lithium chloride (as a thf solvate).

Complex **2**, the dimethyl derivative of **1**, has been prepared in good yield by treatment of **1** with trimethylaluminium (TMA). Crystals of **2** suitable for an X-ray structure determination§ were grown from a concentrated pentane solution. The structure is dimeric, the two crystallographically independent molecules both having C_{2h} symmetry and comprising in each case two slightly distorted square pyramidal Cr^{III} centres linked by chloride bridges, the remaining basal sites being occupied by bidentate β-diketimate ligands (Fig. 1). The apical position on each chromium centre is filled by a terminal methyl group with Cr–C distances of 2.037(7) and 2.042(8) Å for the two independent molecules. The 2,6-diisopropylphenyl rings are oriented almost orthogonally (*ca.* 87°) with respect to the basal plane.

In a similar way, complex **4** was obtained by treatment of **3** with TMA (Scheme 1). Crystals of **4** suitable for X-ray analysis were grown from a concentrated light petroleum (bp 40–60 °C) solution. The structure again reveals a five-coordinate square pyramidal Cr^{III} centre, this time coordinated basally to two chelating pyrrolide-imine ligands and apically to a terminal methyl group at 2.037(9) Å (Fig. 2). The complex has crystallographic C_2 symmetry about an axis passing through the Cr–Me bond, and the two independent Cr–N distances differ significantly, with that to the pyrrolide [2.026(5) Å] markedly shorter than that to the imine [2.073(4) Å] reflecting the formal anionic nature of N(1). The double bond character of the imine has been retained [1.318(7) Å] though there is some evidence for delocalisation between the imine and pyrrolide systems, C(5)–C(6) being short at 1.410(8) Å. As in **2**, the 2,6-diisopropylphenyl rings are steeply inclined (*ca.* 65°) to the basal plane. It is noteworthy that both of these structures provide rare examples of five-coordinate chromium(III) alkyls, only two other examples having been found on the CCDC database [to March 1998, 175 093 entries].[11]

A summary of the ethene polymerization tests for **1**–**4** is shown in Table 1. Solid polyethylene is obtained in all cases with samples displaying high molecular weights¶ and virtually no branching (by NMR). A comparison of the polymerisation runs 1–12 shows that similar activities are found for procatalysts bearing either β-diketimate (**1** and **2**) or pyrrolide-imine ligands (**3** and **4**), the highest activity being 75 g $mmol^{-1}$ h^{-1} bar^{-1} using **1** and diethylaluminium chloride (Et_2AlCl) activator (see run 2).

The nature of the activator is seen to have an important influence on activity; for example, alkylaluminium chloride activators are found to be more compatible with these



Scheme 1 Preparation of chromium complexes **1**–**4**. *Reagents and conditions*: i, Bu^nLi, −78 °C, thf; ii, $[CrCl_3(thf)_3]$, −78 °C, thf; iii, $AlMe_3$, thf.

12	4	$Et_2AlCl{\cdot}EtAlCl_2$ (0.45/30)	0.23	15

[a] *General conditions*: 1 bar ethene Schlenk test carried out in toluene (40 cm^3) at 25 °C, over 60 min, reaction quenched with dil. HCl and the solid PE washed with methanol (50 cm^3) and dried in a vacuum oven at 40 °C. [b] MAO = methylaluminoxane. [c] Solid polyethylene. [d] Activity reported per chromium centre.

procatalysts than methylaluminoxane (MAO). Moreover, diethylaluminium chloride (Et_2AlCl) is superior to aluminium sesquichloride ($Et_2AlCl{\cdot}EtAlCl_2$). Notably, the alkyl procatalysts **2** and **4** are inactive in the absence of activator.

The new catalyst types described herein represent a notable addition to the limited list of non-cyclopentadienyl chromium ethene polymerization catalysts[5,6] and highlight the importance of the choice of co-catalyst for optimal catalyst performance.

BP Chemicals Ltd is thanked for financial support. Dr W. Reed and Dr J. Boyle are thanked for GPC and NMR measurements, respectively.

‡ Satisfactory elemental analyses have been obtained.

¶ As a representative example, GPC analysis of the polyethylene obtained from run 8 afforded M_w = 293,000, M_n = 113,000; M_w/M_n 2.2. Care should be taken in the interpretation of these values, however, since in general the polymers derived from these polymerisations are not fully soluble in the 1,2,4-trichlorobenzene GPC solvent, even upon heating at 160 °C for several hours.

§ *Crystal data*: for **2**: $C_{60}H_{88}Cl_2Cr_2N_4{\cdot}0.5C_5H_{12}$, M = 1076.3, monoclinic, space group $C2/m$ (no. 12), a = 19.434(3), b = 21.764(2), c = 15.098(2) Å, β = 90.58(1)°, U = 6386(1) Å^3, Z = 4 (there are two crystallographically independent C_{2h} symmetric molecules in the asymmetric unit), D_c = 1.120 g cm^{-3}, μ(Cu-Kα) = 38.5 cm^{-1}, F(000) = 2316. A crimson prismatic needle of dimensions 0.33 × 0.17 × 0.13 mm was used. For **4**: $C_{35}H_{45}CrN_4$, M = 573.8, orthorhombic, space group $Fdd2$ (no. 43), a = 20.280(2), b = 34.103(4), c = 9.420(1) Å, U = 6515(2) Å^3, Z = 8 (the molecule has crystallographic C_2 symmetry), D_c = 1.170 g cm^{-3}, μ(Mo-Kα) = 3.79 cm^{-1}, F(000) = 2456. A green block of dimensions 0.37 × 0.37 × 0.10 mm was used. 4866 (1530) independent reflections were measured at 203 K on Siemens P4(PC) diffractometers with Cu-Kα—rotating anode source—(Mo-Kα) radiation using ω-scans for **2** (**4**), respectively. The structures were solved by direct methods and all of the major occupancy non-hydrogen atoms were refined anisotropically using full matrix least squares based on F^2 to give R_1 = 0.065 (0.049), wR_2 = 0.164 (0.094) for 3370 (1193) independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leqslant 120(50°)$] and 340 (182) parameters for **2** (**4**), respectively. The polarity of **4** was determined by a combination of R-factor tests [R_1^+ = 0.048, R_1^- = 0.050] and by use of the Flack parameter [x^+ = 0.10(1), x^- = 0.90(1)]. CCDC 182/903.

Intramolecular macrocyclization of bis(5-methylthio-1,2-dithiole-3-thione)s with triethyl phosphite. A stereoselective route to macrocyclic (*Z*)-thioxodesaurines

Sandra Rudershausen,[a] Hans-Jürgen Holdt,*[a]† Helmut Reinke,[a] Hans-Joachim Drexler,[a] Manfred Michalik[b] and Joachim Teller[a]

[a] *Universität Rostock, Fachbereich Chemie, Buchbinderstraße 9, D-18051 Rostock, Germany*
[b] *Institut für Organische Katalyseforschung an der Universität Rostock e.V., D-18055 Rostock, Germany*

Intramolecular macrocyclizations of [oligo(oxyethylene)-ethylenedithio]bridged bis(5-methylthio-1,2-dithiole-3-thione)s 5a and b with $P(OEt)_3$ in *p*-xylene furnished the macrocyclic thioxodesaurin (*Z*)-6, thioxodesaurin (*E*)-7 and 1,3-dithiafulvene (*E*)-8, respectively.

2,4-Bis(2-oxoethylidene)-1,3-dithietanes are well-known as desaurines.[1,2] In these compounds, the electron-withdrawing groups at the 2,4-dimethylene-1,3-dithietane unit can be (*E*)- or (*Z*)-configured. (*E*)-Configuration was determined for the desaurines **1a**–**d** by X-ray analysis.[3] The well-known desaurin

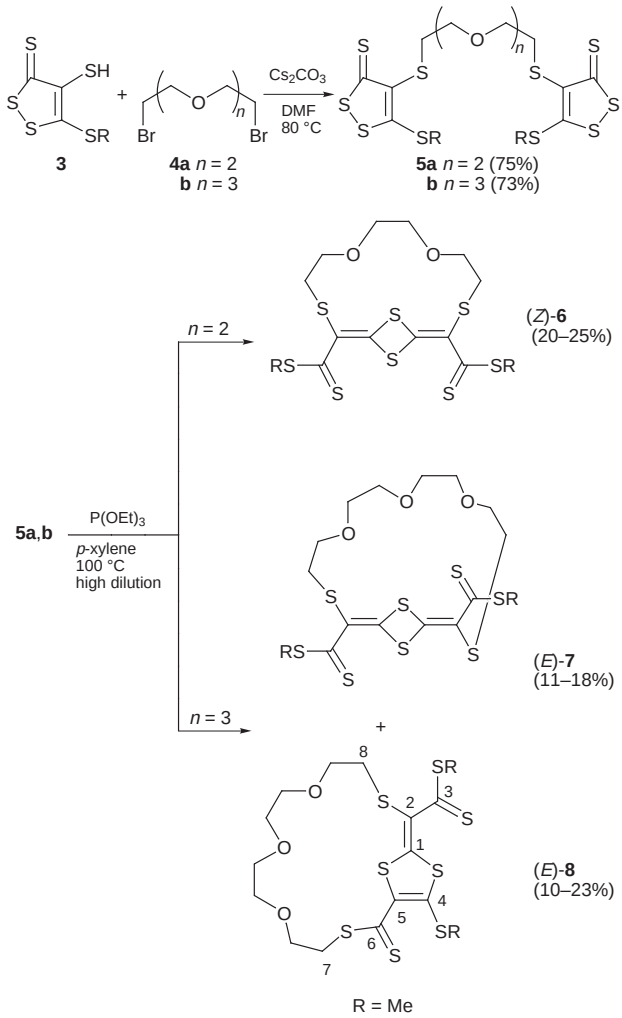
	X	R^1	R^2	ref.
1a	O	Ph	H	3(*a*)
1b	O	Me	Me	3(*b*)
1c	O	MeO	NC	3(*c*)
1d	O	Et	Ph	3(*d*)
(*E*)-**2**	S	MeS	MeS	5,7(*a*)

syntheses lead predominately to the thermodynamically stabilized (*E*)-isomer, or an (*E*)-/(*Z*)-mixture.[4] To the best of our knowledge the stereoselective synthesis of a (*Z*)-desaurin has not yet been reported.

Thioxoanalogous desaurines can be synthesized by reductive dimerization of 1,2-dithiole-3-thione derivatives containing an alkylthio substituent in the 5-position with $P(OEt)_3$.[5] Reaction of 4,5-bis(methylthio)-1,2-dithiole-3-thione[6] with $P(OMe)_3$, in refluxing benzene, yielded the (*E*)-thioxodesaurin (*E*)-**2** (35%) and its (*Z*)-isomer (*Z*)-**2** (15%).[5] We confirmed the stereochemistry of (*E*)-**2** by X-ray analysis.[7a] In (*E*)-**2** the eight sulfur and the six central carbon atoms lie almost in-plane. (*E*)-Isomers were formed exclusively by the dimerization of dodecylthio-substituted 1,2-dithiole-3-thiones and crowned 4,5-dithio-1,2-dithiole-3-thiones.[7b]

Here, we describe a novel macrocyclization reaction using bridged bis(5-methylthio-1,2-dithiole-3-thione)s **5** as precursors. Intramolecular cyclization of **5a** and **b** with $P(OEt)_3$ yielded the macrocyclic thioxodesaurin (*Z*)-**6**, thioxodesaurin (*E*)-**7** and 1,3-dithiafulvene (*E*)-**8**, respectively (Scheme 1). The length of the [oligo(oxyethylene)ethylene]dithio bridge in **5** determines the stereochemistry of the thioxodesaurin formed. With **5a** the crowned (*Z*)-thioxodesaurin (*Z*)-**6** was stereoselectively synthesized.

The precursors **5a**,**b** are obtainable in yields of up to 75% by alkylation of 4-mercapto-5-methylthio-1,2-dithiole-3-thione **3**‡ (2 equiv.) with 1,8-dibromo-3,6-dioxaoctane **4a** and 1,11-dibromo-3,6,9-trioxaundecane **4b**, respectively, in the presence of Cs_2CO_3 in DMF. Correct spectral data were obtained for both compounds. Compounds **5a**,**b** were intramolecularly cyclized under high dilution conditions with $P(OEt)_3$ in *p*-xylene. Compound **5a** provides one macrocyclic reaction product (*Z*)-**6** (20–25 %) as well as unidentified polymeric material. The ^{13}C NMR spectrum of (*Z*)-**6** revealed that this macrocycle contains the expected thioxodesaurin unit.§ The configuration of the thioxodesaurin unit in (*Z*)-**6** was determined by X-ray crystallographic analysis.¶ The crystal structure of (*Z*)-**6** shows a (*Z*)-configured planar thioxodesaurin moiety which is incorporated in a macrocyclic framework by a [bis(oxyethylene)ethylene]dithio chain [Fig. 1(*a*)]. Attempts to build CPK models of the (*E*)-isomer of (*Z*)-**6** revealed that the [bis(oxyethylene)ethylene]dithio chain is too short to bridge a planar (*E*)-thioxodesaurine unit. This is possibly the reason why the intramolecular cyclization of **5a** furnishes the (*Z*)-isomer stereoselectively. In the (*Z*)-thioxodesaurin moiety of (*Z*)-**6** the



Scheme 1

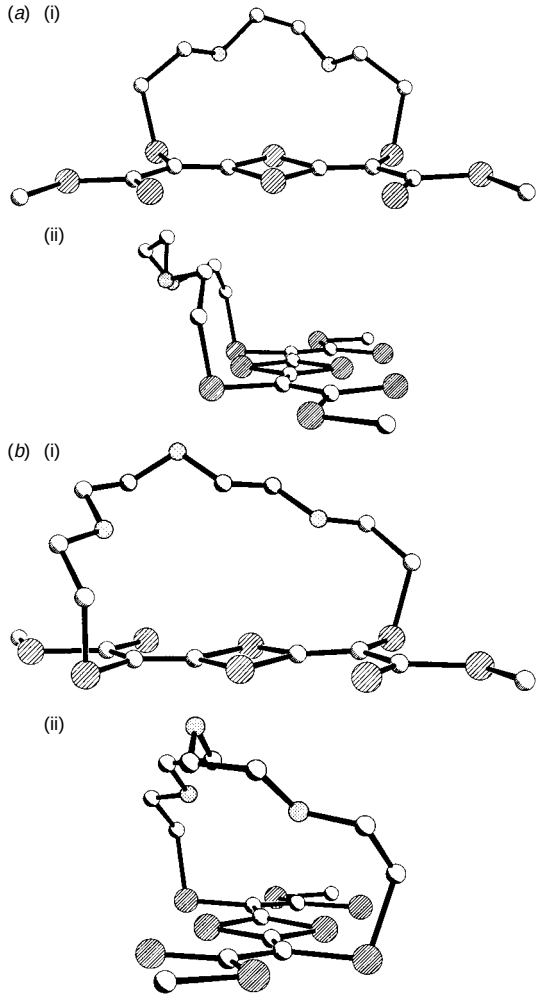


Fig. 1 Structures of the macrocyclic thioxodesaurines (*a*) (*Z*)-**6** and (*b*) (*E*)-**7** in the crystal: view of the molecules (i) orthogonal and (ii) parallel to the central 2,4-dimethylene-1,3-dithietane moiety

two carbon–carbon double bonds do not lie in line, as it is observed for the bonds in the (*E*)-thioxodesaurin units of (*E*)-**2**[7a] and (*E*)-**7** [Fig. 1(*b*)]. This deviation from 180° amounts to 9°.

In comparision to **5a**, bis(1,2-dithiole-3-thione) **5b** has a bridging chain with one more oxyethylene moiety. This chain is long enough to enable the intramolecular cyclization to form the (*E*)-thioxodesaurine (*E*)-**7** (11–18%). X-Ray analysis of crowned (*E*)-**7**¶ shows an *ansa*-compound-like molecular structure. The [tris(oxyethylene)ethylene]dithio chain, bridges the planar (*E*)-configurated thioxodesaurin unit like a handle. Since rotation of the (*E*)-thioxodesaurin moiety around the axis along the H_2C–S bonds is not possible, (*E*)-**7** has planar chirality. No (*Z*)-isomer was detected at the intramolecular cyclization of **5b**. On the contrary, we obtained the crowned 1,3-dithiafulvene (*E*)-**8** (10–23%). The molecular structure of (*E*)-**8** was determined *via* an X-ray structural investigation.[7b]

Mollier[5] and Pedersen[8] postulated thioacyl thioketenes as intermediates for the reaction of 5-alkylthio-1,2-dithiole-3-thiones with trialkyl phosphite, which dimerize in [2+2] cycloadditions to the thioxodesaurines. In a similar way bis(thioketene) intermediates of **5a**,**b** should form intramolecular macrocyclic thioxodesaurines (*Z*)-**6** und (*E*)-**7**. Compound (*E*)-**8**, which in its turn furnishes the thioxodesaurin (*E*)-**7,** cannot be formed by an intramolecular [2+3] cycloaddition of the bis(thioketene) intermediate. Therefore other thioketene intermediates must exist, at least in the reaction solution of **5b** with $P(OEt)_3$. The formation of a thioxodesaurin and a 1,3-dithiafulvene from α-thioxothioketene intermediates was recently proposed by Hartke *et al*.[9] A desaurin and a 1,3-dithiafulvene were obtained from α-oxothioketenes earlier by Voronkov.[10]

The intramolecular macrocyclization of bridged bis(5-methylthio-1,2-dithiole-3-thione)s with $P(OEt)_3$ is a simple synthetic route to macrocyclic (*Z*)- and (*E*)-thioxodesaurines and 1,3-dithiafulvenes.

We are synthesizing macrocyclic (*Z*)- and (*E*)-thioxodesaurines and 1,3-dithiafulvenes since we are interested in their redox properties and coordination chemistry. We would like to use these new macrocyclic and sulfur-rich ligands containing both endocyclic and exocyclic donor sites for the preparation of dinuclear metal complexes comprising simultaneously hard and soft metal centers, and as new components for supramolecular compounds. Full results will be reported in a full paper.

S. R. thanks the Bundesland Mecklenburg Vorpommern for a graduate stipendium.

[c] *Department of Chemistry, University of Prince Edward Island, Charlottetown, PE, Canada C1A 4P3*

N-Protonated diazomethanes have been generated successfully *via* gas phase protonation of the corresponding diazirines.

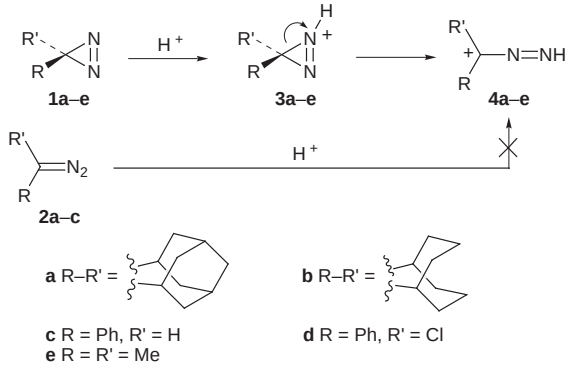
The electronic distribution in diazoalkanes is usually represented by the resonance forms **I**–**IV**. The reactivities of diazo-

I **II** **III** **IV**

alkanes with acids and electrophiles are dominated by forms **II** and **III**; forms **I** and **IV** play no role at all. An early study by Wiberg[1] postulated N-protonation, which was subsequently revised in the light of more extensive data.[2–4] Conventionally, protonation occurs at the C atom of the diazoalkanes. Since their discovery in 1966, the diazirines, cyclic diazo compounds with three-membered rings, have been added to the ranks of the well-known aliphatic diazo compounds.[5] Herein we report the successful generation of the N-protonated diazoalkanes **4a**–**d** *via* the protonation of the corresponding diazirines **1a**–**d** (Scheme 1).

The gas phase protonation of diazirines **1a**–**d** and the equilibrium constant experiments were performed on an Extrel FTMS 2001 Fourier transform mass spectrometer equipped with a 3.0 T superconducting magnet with an inlet system described in previous studies.[6] The experiment was initiated by a pulsed electron beam (electron energy of 20 eV). The detectable intermediates in the cell are evidently either the protonated diazirines **3a**–**d** or the N-protonated diazoalkanes **4a**–**d**. Since the spectra gave only the masses of the protonated species, it is not possible to distinguish whether the protonated species appear in the closed (**3**) or open form (**4**).

In order to clarify this process, we determined the gas phase basicity (GB) of diazirines **1a**–**d** and proceeded with high-level *ab initio* computations of proton affinities of diazirines **1c**,**d** and their open forms **2c**,**d** (Scheme 1). In the case of the large molecules **1a**,**b** and **2a**,**b**, proton affinities for model com-



Scheme 1

pounds, 3,3-dimethyldiazirine **1e** and 2-diazopropane **2e** were calculated.

The GB of diazirine (D) was determined by measuring the equilibrium constants of the proton-transfer reactions between D and a reference base (B_0) of known basicity [eqn. (1)].[7]

$$D + B_0H^+ \rightleftharpoons DH^+ + B_0 \quad (1)$$

The equilibrium constants are given by the ratio of pressures for a reference base to a diazirine, $[B_0]/[D]$, and the ratio of intensities of spectra for the corresponding conjugate acid, $[DH^+]/[B_0H^+]$ [eqn. (2)]. In most cases, equilibrium was

$$K = \frac{[DH^+][B_0]}{[D][B_0H^+]} \quad (2)$$

attained after a reaction period of several hundred milliseconds to 1 s. The observed free energy changes [eqn. (3)] for

$$\Delta G° = -RT \ln K \quad (3)$$

respective proton transfer equilibria and the selected GB values are summarized in Table 1. For the case of **1d**, we adopted the threshold technique[8] instead of the equilibrium method because the amount of the conjugate acid ion formed in the cell was too small to be measured quantitatively. When bases having lower basicity than butyronitrile (GB = 184.4 kcal mol^{-1}) were used as reference bases, the proton transfer reaction from the protonated reference base to the neutral **1d** occurred to give the protonated **1d**. On the other hand, when reference bases with higher basicity than acetone (GB = 187.9 kcal mol^{-1}) were used, the proton transfer reaction from the protonated reference base to the neutral **1d** was not observed. The results suggest that the basicity of **1d** would be intermediate between those of acetone and butyronitrile, *i.e.* GB = 186.4 ± 1 kcal mol^{-1}. The ΔGB values are provided for comparison. The basicities of

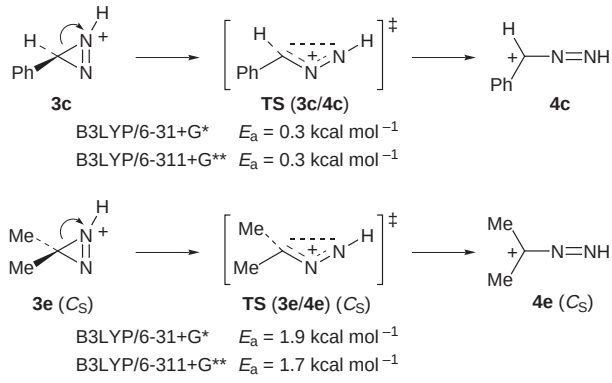
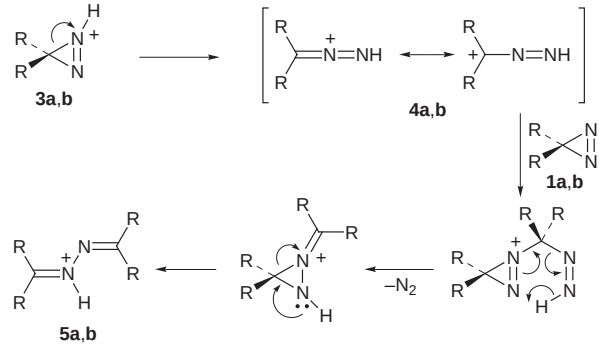


Scheme 2

diazirines **1a** and **1b** are stronger than **1c** and **1d** by approximately 6 kcal mol^{-1}.

The geometry optimizations and frequency calculations were carried out at the B3LYP hybrid density functional theoretical level with the internal 6-31 + G* and 6-311 + G** basis sets, using procedures implemented in the GAUSSIAN 94 system of programs.[9] Zero-point vibrational energy (ZPVE) corrections were scaled by a 0.98 factor. The proton affinities of diazirines **1c**–**e** and diazoalkanes **2c**–**e** obtained as the differences in the total energies of the neutral and the protonated forms, including the ZPVE corrections, are given in Table 1. The differences (ΔPA) in the calculated proton affinities (PA) between species **1c**–**e**, **2c**–**e** and a reference compound (NH_3) are also provided. Because the measured ΔGB values of the 3,3-dialkyldiazirines **1a** and **1b**, of 1.4 and 1.9 kcal mol^{-1}, and of the 3-aryldiazirines **1c** and **1d**, of 8.0 and 9.3 kcal mol^{-1}, are in much closer agreement with the ΔPA values calculated (B3LYP/6-31 + G*) for model diazoalkane **2e** (5.2 kcal mol^{-1}), and the aryldiazoalkanes **2c** (9.6 kcal mol^{-1}) and **2d** (8.3 kcal mol^{-1}) than for diazirines, we deduce that the detected species in the cell are the N-protonated diazoalkanes. As expected, the calculated PA for C-protonation of 2-diazopropane is higher (217.2 kcal mol^{-1}, B3LYP/6-311 + G**) than the PA for its N-protonation (199.0 kcal mol^{-1}). Moreover, the low calculated activation barriers for the conversion of N-protonated diazirines **3c**,**e** into the corresponding N-protonated diazoalkanes **4c**,**e** (Scheme 2) confirm the ease of the ring opening in the N-protonated diazirines under the experimental conditions.

The chemistry of the N-protonated diazoalkane in the cell is interesting due to the following observations. In particular, protonation of **3a** leads to an ion with the mass of the protonated azine **5a**, and this could occur by ring opening of the protonated diazirine **3a** into N-protonated 2-diazoadamantane **4a**, which reacts with neutral diazirine **1a** to yield the expected the protonated azine **5a**. The N-protonated 2-diazoadamantane **4a**, *m*/*z* 163, decays with the concomitant growth of the protonated azine **5a**, *m*/*z* 297, in the time frame of the experiment (1 s). A plausible mechanism of this reaction is the nucleophilic displacement by the neutral diazirine **1a** of the activated N-protonated 2-diazoadamantane **4a**. This is followed by proton transfer in concert with nitrogen extrusion to yield the protonated azine, as depicted in Scheme 3.



Scheme 3

The diazoalkane **2b** (*m*/*z* 151) has a gas phase basicity similar to that of **2a** but the formation of the protonated azine **5b** (*m*/*z* 273) occurs at a slower rate, possibly resulting from the steric effects of the flexibility on the bicyclo ring in **4b**. In contrast, the N-protonated diazoalkanes **4c**,**d** remain unreactive with their respective neutral diazirine parents even after 3 s. This may be so because the phenyl substituent in these species decreases the electrophilicity of the targeted carbon owing to the π-donor ability of the phenyl ring.

In conclusion, we have shown that N-protonated diazomethanes can be generated *via* protonation of the corresponding diazirines. Our experiments also indicate that some of the N-protonated species are reactive and can undergo further reaction with neighbouring molecules.

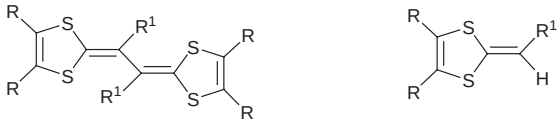
Synthesis and properties of novel tetrathiafulvalene vinylogues

Yoshiro Yamashita,*† Masaaki Tomura, M. Badruz Zaman and Kenichi Imaeda

Institute for Molecular Science, Myodaiji, Okazaki 444-8585, Japan

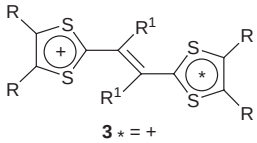
The cation radical states of novel TTF vinylogues with *o*-substituted phenyl groups at the vinyl positions are thermodynamically stable, and X-ray analyses of the cation radical salts have revealed the planar structures of the TTF vinylogue parts and unique crystal structures.

Tetrathiafulvalene (TTF) vinylogues **1** with extended π-conjugation are promising electron donors for organic



1

2



3 * = +
4 * = •

conductors due to their highly electron-donating properties and reduced on-site Coulombic repulsion.[1] The parent compound[2] and the ethylenedithio derivative[3] were synthesized several years ago. Recently the derivatives of **1** containing substituents such as aryl groups at the vinyl positions have been prepared by several groups.[4] They have been considered to be non-planar molecules due to the steric interactions between the substituents and the 1,3-dithiole parts, and X-ray analyses revealed the severely deformed structures.[4c,d,e] Therefore, those TTF molecules have not been used as components for organic conductors. However, the TTF vinylogue skeletons can be planar when the aryl substituents are twisted away from the π-conjugated framework. These compounds are expected to afford conductors with unusual structures since good molecular overlapping is disturbed by the bulky substituents. We have now prepared various derivatives **1** by a convenient method and have found that the cation radicals of **1** containing *o*-substituted phenyl groups are thermodynamically stable and can be isolated as single crystals.

The derivatives of **1** were previously prepared by electrochemical oxidative coupling of the corresponding 1,4-dithiafulvenes **2**.[4b,c,e,5] We have recently reported oxidative intramolecular cyclization to give bis(1,3-dithiole) electron donors by using tris(4-bromophenyl)aminium hexachloroantimonate as the oxidation reagent.[6] We have now used this chemical oxidation for the synthesis of **1**. First, 1,4-dithiafulvene derivatives **2** were prepared by either Wittig reaction of a phosphonium salt (for the dibenzo derivatives) or Wittig–Horner reaction of a phosphonium ester (for the ethylenedithio derivatives) with the corresponding aldehydes. Reaction of **2** with the aminium salt in CH_2Cl_2 afforded dication salts **3** which are formed by oxidative dimerization followed by oxidation. The salts **3** were reduced with zinc in MeCN to give **1**. The yields of **1** from **2** were 20–85%. It is noteworthy that the naphthyl and pyrenyl derivatives as well as phenyl derivatives were prepared.

The oxidation potentials of the donors **1** (Table 1) were measured by cyclic voltammetry (CV). The methyl derivatives **1a**,**m** and the phenyl ones **1b**,**n** show reversible one-stage two-electron redox waves. The *p*-substituted derivatives **1g**,**h**,**q** and the *m*-substituted one **1i** also undergo the similar two-electron oxidation. This fact suggests that the cation radical states of these compounds are thermodynamically unstable due to non-planar structures, similar to the reported examples. On the other hand, the *o*-substituted derivatives **1c–f**,**j**,**o**,**p**,**r** showed two reversible one-electron oxidation waves similar to the non-substituted one **1t**. This result suggests that the cation radicals of the *o*-substituted phenyl derivatives are thermodynamically stable. This can be explained by considering that the TTF vinylogue skeletons are planar when there are *o*-substituents, which increase the steric interactions and make the phenyl parts twist away from the π-conjugated framework. In the case of 1-naphthyl derivatives **1k**,**s** and 1-pyrenyl one **1l**, the cation radicals are also stable since they are also *o*-substituted phenyl derivatives. The values of the oxidation potentials are dependent on the substituents. BEDT-TTF analogues **1o**,**s** show lower first oxidation potentials than the non-substituted one **1t** and even TTF, indicating that they are stronger electron donors. The differences between the first and second oxidation potentials are smaller than those of TTF and BEDT-TTF, indicating the reduced on-site Coulombic repulsion in **1** due to the extended π-conjugation.

Electrochemical oxidation of **1j** and **1p** gave the cation radical salts **1j**·PF_6 and **1p**·$Au(CN)_2$ as stable single crystals with stoichiometries of 1:1. These are the first examples of cation radical salts of TTF vinylogues containing substituents at the vinyl positions. In order to investigate the geometries of the donors, X-ray structure analyses of the neutral compounds **1a**,**j**

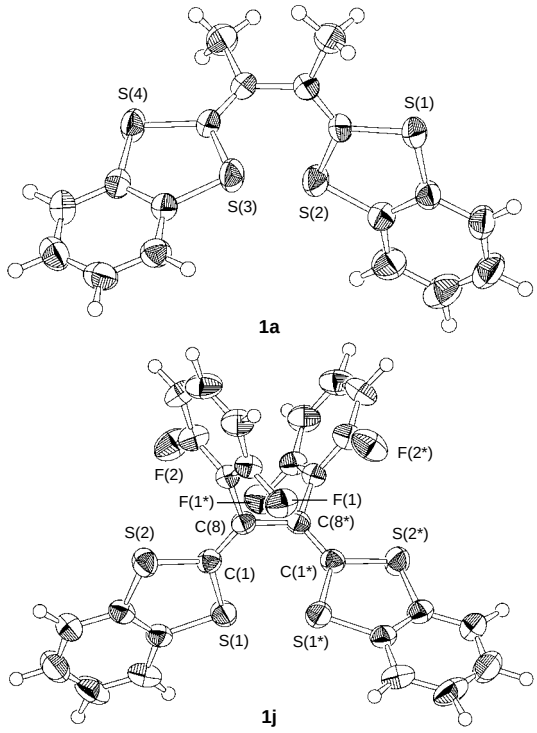

Fig. 1 Molecular structures of **1a** and **1j**

and the cation radical salts **1j**·PF_6 and **1p**·$Au(CN)_2$ were carried out.‡ As expected from the CV data, the methyl derivative **1a** has a non-planar structure (Fig. 1) as found in the substituted TTF vinylogues.[4c,d,e] The *o*-substituted phenyl derivative **1j** which undergoes step-wise oxidation was expected to have a planar TTF vinylogue framework. However, the structure was revealed to be similarly non-planar, as shown in Fig 1. In contrast, the molecular structure is drastically changed upon oxidation. The cation radical salt **1j**·PF_6 has a planar TTF vinylogue skeleton, as shown in Fig. 2. The aryl groups are twisted and almost orthogonal to the TTF vinylogue framework. The dihedral angle between the aryl group and the 1,3-dithiole ring is 83.9°. The C(1)–C(8) bond length [1.400(8) Å] in the cation radical salt is longer than that of the neutral **1j** [1.354(6) Å], while the C(8)–C(8*) bond length [1.41(1) Å] is shorter than the corresponding one in the neutral species [1.481(8) Å]. This fact suggests the contribution of a delocalized structure **4**. The donor molecules form an interesting two-dimensional columnar structure, as shown in Fig. 2. The bulky aryl groups disturb good overlapping between molecules. Instead, one molecule bridges two others; the 1,3-benzodithiole moieties form a stacking with an equal intermolecular distance of 3.6 Å. The side view of the crystal structure (Fig. 2, bottom) clearly shows a stair-like network where two-dimensional interactions can be expected. The donor molecule in **1p**·$Au(CN)_2$ also has a planar geometry of its TTF vinylogue framework. The unique crystal structure will be reported elsewhere. Unfortunately, these cation radical salts have a 1:1 stoichiometry and so they showed semiconducting behavior (**1j**·PF_6: $\sigma = 3 \times 10^{-6}$ S cm^{-1}, $E_a = 0.18$ eV; **1p**·$Au(CN)_2$: $\sigma = 10^{-2}$ S cm^{-1}, $E_a = 0.11$ eV). Studies on the preparation of other cation radical salts of **1** are now in progress.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

A novel intramolecular photocyclization of methyl 2-(2,3-dimethylbut-2-enyloxymethyl)naphthalene-1-carboxylate *via* 1,9-hydrogen abstraction

Kazuhiko Mizuno,*† Shin-ichi Konishi, Yasuharu Yoshimi and Akira Sugimoto

Department of Applied Chemistry, College of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan

Irradiation of a benzene solution containing methyl 2-(2,3-dimethylbut-2-enyloxymethyl)naphthalene-1-carboxylate 1 gave an eight-membered keto ether 2 as the main product *via* a novel 1,9-hydrogen abstraction of the ester carbonyl group.

Photochemical hydrogen abstraction reactions have been extensively investigated from synthetic and mechanistic viewpoints.[1] Intramolecular long-range hydrogen abstraction such as 'remote oxidation' is one of the most attractive subjects in the photochemistry of carbonyl groups.[2] However, little is known about the hydrogen abstraction of an excited state of an ester carbonyl group except for an intramolecular 1,5-hydrogen abstraction *via* a 6-membered transition state.[3] Intermolecular hydrogen abstraction has also been reported as a rare case although the efficiency was quite low.[4] We now report a novel intramolecular 1,9-hydrogen abstraction of an ester carbonyl group to give an eight-membered keto ether *via* an exciplex.

Irradiation of a benzene solution containing methyl 2-(2,3-dimethylbut-2-enyloxymethyl)naphthalene-1-carboxylate **1** through a Pyrex filter (> 280 nm light) under an argon atmosphere gave **2** as the main product accompanied by (2π + 2π) photocycloadducts **3** and **4** and C–O bond cleavage product **5** (Scheme 1). Similar irradiation of **1** in MeCN also gave **2**, but **5** was mainly obtained (Table 1). Irradiation of **6** in benzene did not afford the corresponding eight-membered ring compound,

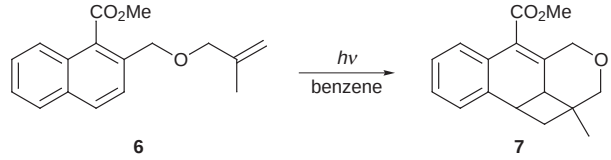
Scheme 1

Table 1 Yields for photoreaction of **1** in benzene and MeCN

	Yield (%)[a]			
Solvent	**2**	**3**	**4**	**5**
Benzene	48	6	33	13
MeCN	10	< 5	< 5	80

[a] Yields based on unrecovered **1** were determined by GLC analysis after irradiation with a 500 W high-pressure mercury lamp for 100 h.



6 **7**

Scheme 2

but instead gave (2π + 2π) photocycloadduct **7** in low yield (Scheme 2).

The products were isolated by column chromatography on silica gel. The structure of **2** was determined from its spectral data.‡ The FT-IR spectrum of **2** showed the disappearance of the ester carbonyl group of **1** at 1743 cm^{-1} and the appearance of an aromatic carbonyl group at 1682 cm^{-1}. The ^1H NMR spectrum showed the existence of three kinds of methylene group, two nonequivalent methyl groups and six aromatic protons. These data indicate the elimination of MeOH from the starting material **1**. Finally, the structure of **2** was confirmed by X-ray crystallography (Fig. 1). The structures of (2π + 2π) photocycloadducts **3** and **4** were determined from their spectral properties and comparison with the intramolecular photocycloadducts obtained from 2-(2,3-dimethylbut-2-enyloxymethyl)naphthalene-1-nitrile, previously reported by McCullough *et al.*[5] and by us.[6]

The formation of the eight-membered keto ether **2** and the photocycloadducts **3** and **4** was not sensitized by the addition of 0.1 mol dm^{-3} of Michler's ketone (E_T = 275 kJ mol^{-1}),[7] and was not quenched by 0.5 mol dm^{-3} of 2-methylbuta-1,3-diene (E_T = 251 kJ mol^{-1})[7] and molecular dioxygen. The relative intensity of the fluorescence of **1** in cyclohexane was smaller than that of methyl naphthalene-1-carboxylate. This is due to the intramolecular quenching of the fluorescence of the methyl naphthalene-1-carboxylate chromophore by the alkene moiety, although an intramolecular exciplex emission between the methyl naphthalene-1-carboxylate chromophore and the 2,3-dimethylbut-2-ene chromophore was not observed. When the

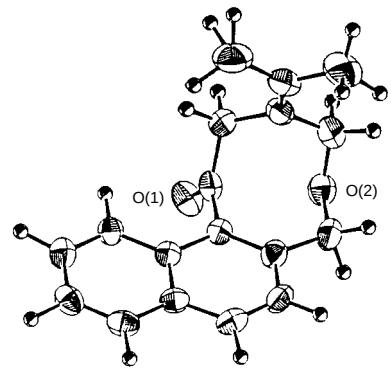


Fig. 1 X-Ray crystal structure of **2**

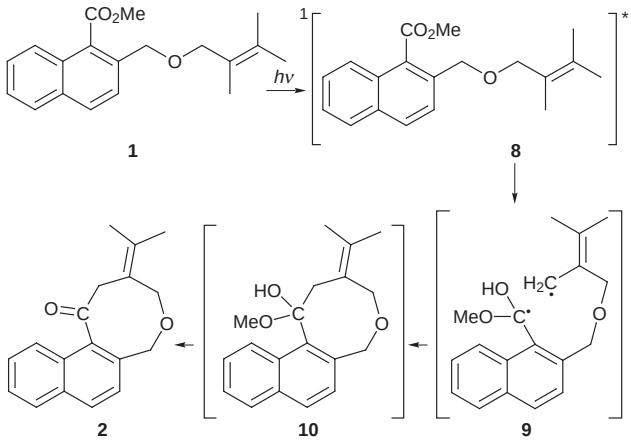

Scheme 3

fluorescence lifetime of **1** was measured by single photon counting in cyclohexane, the major component (short-lived, < 0.3 ns) was assigned to the methyl naphthalene-1-carboxylate moiety and the minor component (long-lived, 5.8 ns) to the singlet exciplex, because the fluorescence lifetime of methyl naphthalene-1-carboxylate has a value of 1.3 ns.

From these results, we propose the mechanism for the formation of the eight-membered keto ether shown in Scheme 3. The first step is the formation of an intramolecular exciplex **8** *via* the excited singlet state of the methyl naphthalene-1-carboxylate chromophore. The second step is the abstraction of an allylic hydrogen by the ester carbonyl group followed by radical coupling of **9** to give the hemiacetal **10**, which then eliminates MeOH to afford the eight-membered keto ether **2**. Although intramolecular 1,5-hydrogen abstraction by an ester carbonyl group *via* a six-memebered transition state is known, long-range intramolecular hydrogen abstraction has never been reported. The exciplex **8** also gives (2π + 2π) photocycloadducts **3** and **4**. The cleavage product **5** is probably produced *via* **9**. In the photoreaction of **1**, the charge transfer nature of the intramolecular exciplex plays an important role in the novel intramolecular 1,9-hydrogen abstraction. It is because the ester carbonyl group of **6** has a less electron donating alkene that it did not abstract the allylic hydrogen. In MeCN, the formation of the eight-membered keto ether **2** is observed in trace amounts, but the C–O bond cleavage product **5** was mainly obtained. This is reasonably explained by a photoinduced electron transfer process.[8]

We are indebted to Professor T. Takata and Emeritus Professor H. Inoue (Osaka Prefecture University) for helpful discussions. This work is partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan, and the Nagase Science and Technology Foundation.

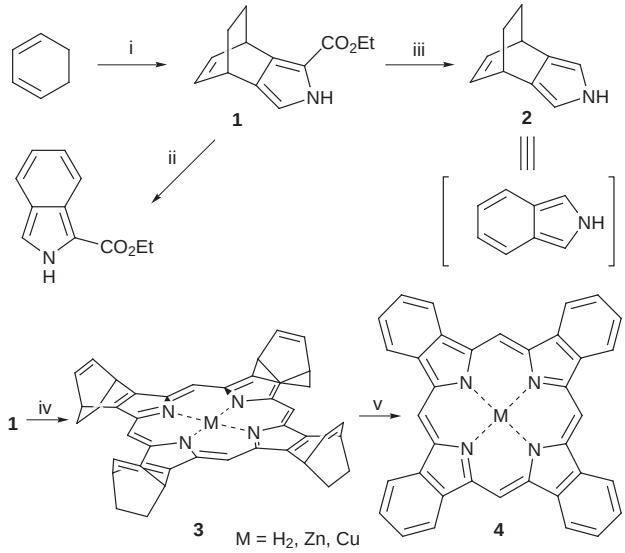
A new synthesis of benzoporphyrins using 4,7-dihydro-4,7-ethano-*2H*-isoindole as a synthon of isoindole

Satoshi Ito,[a] Takashi Murashima,[a] Hidemitsu Uno[b] and Noboru Ono*[a]†

[a] *Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho 2-5, Matsuyama 790-8577, Japan*
[b] *Advanced Instrumentation Center for Chemical Analysis, Ehime University, Bunkyo-cho 2-5, Matsuyama 790-8577, Japan*

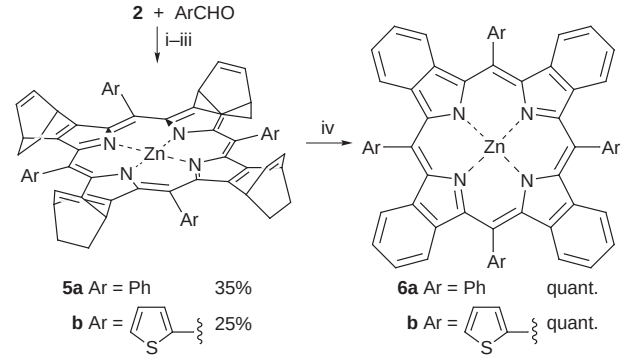
Heating 4,7-dihydro-4,7-ethano-2*H*-isoindole at 200 °C induces the retro-Diels–Alder reaction to give isoindole in essentially quantitative yield, which can be applied to a new synthesis of tetrabenzoporphyrins and monobenzoporphyrins.

Pyrroles fused with aromatic rings, namely isoindoles, may be useful as precursors of polypyrroles with low band gap[1] and benzoporphyrins.[2] However, unsubstituted isoindole is too unstable to be used directly for the preparation of such compounds.[3] Recently we have developed a new synthesis of isoindoles *via* the Barton–Zard pyrrole synthesis using aromatic nitro compounds and ethyl isocyanoacetate, from which polypyrroles and porphyrins fused with various aromatic rings have been prepared.[1,2] However, this method is not applicable to the synthesis of unsubstituted isoindole, for nitrobenzene does not react with ethyl isocyanoacetate. Here we report a very simple method for the synthesis of isoindole. Ethyl 4,7-dihydro-4,7-ethano-*2H*-isoindole-1-carboxylate **1** was prepared by the reaction of the Diels–Alder reaction of 1,3-cyclohexadiene with β-sulfonylnitroethylene followed by the treatment with ethyl isocyanoacetate.[4] De-ethoxycarbonylation by heating **1** with KOH in ethylene glycol at 170 °C gave **2**,‡ which acted as a masked isoindole (Scheme 1). Namely, heating **2** at 200–230 °C causes a retro-Diels–Alder reaction, the product of which can be trapped in about 70% yield with reactive dienophiles such as *N*-phenylmalenimide[5] Although there are many possibilities for the use of **1** or **2** as an isoindole synthon, here we focus on the synthesis of benzoporphyrins. Porphyrin **3**,[4] which was prepared from **1** *via* reduction of the ester function with $LiAlH_4$ followed by tetramerization and oxidation, was converted into tetrabenzoporphyrin **4** in 100% yield by heating at 200 °C for 10 min. In general, it is rather difficult to handle tetrabenzoporphyrin and its metal complexes due to their low solubility in most organic solvents. This difficulty is now resolved by the use of porphyrin **3** and its metal complexes, as they are soluble in CH_2Cl_2 and can be converted into **4** in quantitative yield by simply heating at 200 °C. Various kinds of metal complexes (Zn, Cu, Ni, Fe, *etc.*) of **3** were readily prepared by the conventional method[6] and purified by column chromatography and recrystallization from CH_2Cl_2–MeOH. They were soluble in $CHCl_3$ and CH_2Cl_2. The metal complexes of porpyrin **3** were converted into the corresponding metal complexes of **4** in essentially quantitative yield by heating at 200 °C. By using this method, various materials coated with metal complexes of **4** which may be important for electronic applications are readily prepared. For example, a glass slide coated with Zn-**3** (λ_{max} 405, 525, 560 nm) was prepared using a solution of Zn-**3** in CH_2Cl_2; this was changed into a glass slide coated with Zn-**4** (λ_{max} 454, 617, 696 nm) by heating at 200 °C for 10 min.

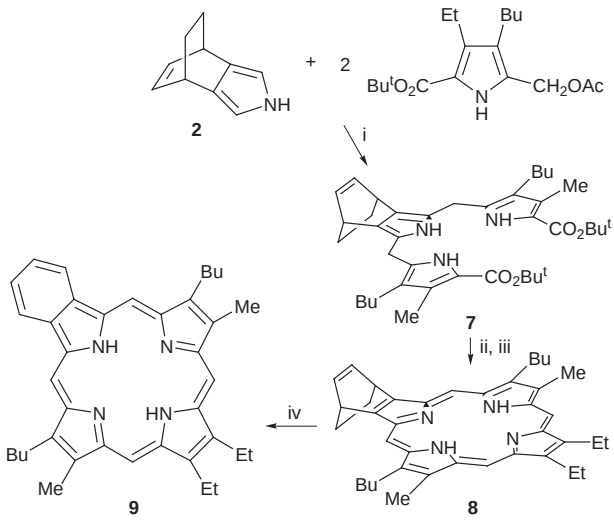


Scheme 1 *Reagents and conditions*: i, ref. 4, 60% for two steps; ii, 200 °C, 10 min; iii, KOH, $HOCH_2CH_2OH$, 170 °C, 2 h, 81%; iv, ref. 4, 30%; v, 200 °C, 10 min, quant.

Other syntheses of benzoporphyrins using **2** as an isoindole synthon are shown in Schemes 2 and 3. The reaction of **2** with aromatic aldehydes in the presence of $BF_3{\cdot}OEt_2$ followed by oxidation gave *meso*-tetraarylated porphyrins **5** in 25–35% yield, which were converted into the corresponding benzoporphyrins **6** in quantitative yield by heating at 200 °C for 10 min. Thus, pyrrole **2** can be used as a masked isoindole in benzoporphyrin synthesis. As pointed out by Bonnet, the chemistry of benzoporphyrins has been relatively neglected due to their synthesis being difficult, although they have potential uses as electro-optical, molecular electronic and photodynamic therapeutic materials.[7] Now various types of benzoporphyrins can be prepared *via* the use of **2** as an isoindole synthon. As a typical example, monobenzoporphyrin **9** was prepared in quantitative yield by heating porphyrin **8** at 200 °C for 10 min, as shown in Scheme 3. Porphyrin **8** was prepared by the well-established method *via* a 3 + 1 approach consisting of the reaction of tripyrrane **7** with pyrrole-2,5-dicarbaldehyde followed by oxidation.[8] The requisite **7** was readily prepared by the reaction of **2** with 2-acetoxymethylpyrroles. The UV–VIS



Scheme 2 *Reagents and conditions*: i, $BF_3{\cdot}OEt_2$; ii, $Zn(OAc)_2$; iii, *p*-chloranil; iv, 200 °C, 10 min



Scheme 3 *Reagents and conditions*: i, AcOH–EtOH, reflux, 16 h; ii, 3,4-diethylpyrrole-2,5-dicarbaldehyde, TFA, room temp., 2 h; iii, DDQ, $CHCl_3$, room temp., 1 h, 11% for three steps; iv, 200 °C, 10 min, quant.

spectrum of **8** (λ_{max} 398, 497, 529, 566, 619 nm; band strength IV > III > II > I) indicated that **8** was readily converted to **9** (λ_{max} 404, 504, 541, 574, 629 nm; band strength III > I > IV > II); these were in good agreement with those reported in the literature.[7,9]

In conclusion, we have described a new synthesis of benzoporphyrins using **1** or **2** as insoindole synthons which is superior to the existing methods in its simplicity and generality. It should be emphasized that formation of benzoporphyrns **4**, **6** and **9** can be achieved by simple heating. This process is a very clean reaction and purification of products is not usually necessary if precursors **3**, **5** and **8** are pure. This method could be extended to the preparation of other π-extended molecules including polypyrroles fused with aromatic rings, which is now in progress in our laboratory.

The work was partly supported by Grants-in aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan.

Synthesis of novel imidazolidinones from hexose–peptide adducts: model studies of the Maillard reaction with possible significance in protein glycation

Štefica Horvat,*† Lidija Varga-Defterdarović, Maja Roščić and Jaroslav Horvat

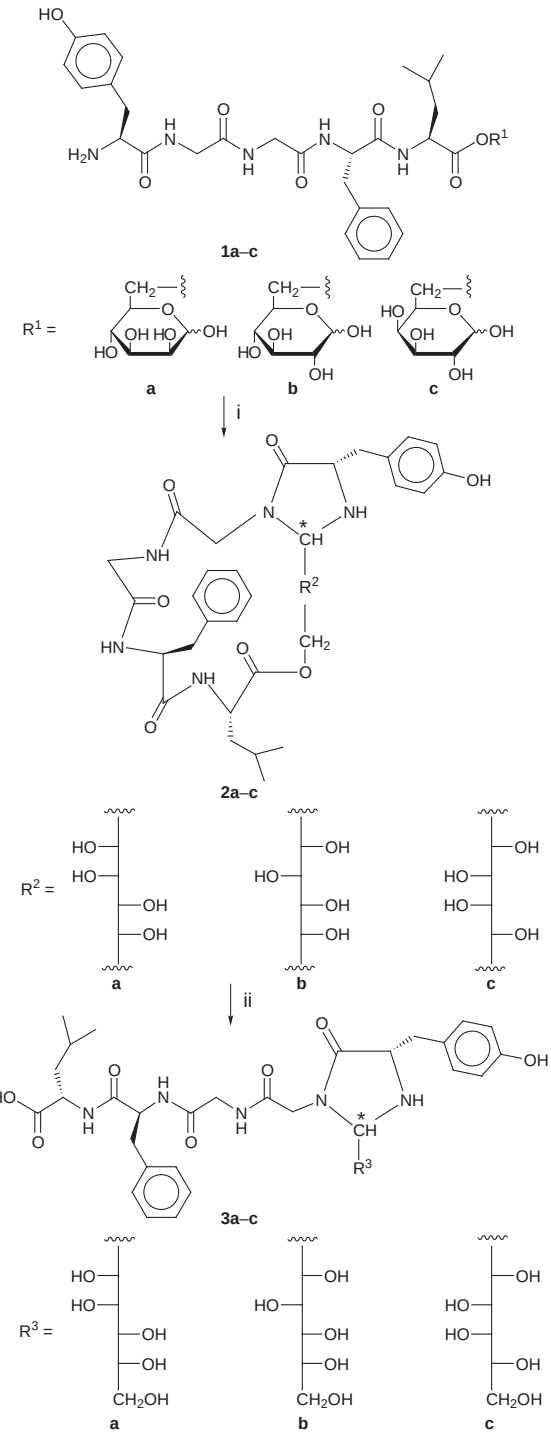
Department of Organic Chemistry and Biochemistry, Ruđer Bošković Institute, POB 1016, 10001 Zagreb, Croatia

Novel hexose-related imidazolidin-4-ones are prepared by intramolecular rearrangements of monosaccharide esters in which D-mannose, D-glucose, or D-galactose are linked through their C-6 hydroxy groups to the endogenous opioid pentapeptide, leucine-enkephalin.

Non-enzymatic glycation of proteins has been increasingly identified as an important factor in the age-dependent chemical modification and cross-linking of tissue proteins,[1] as well as in the pathogenesis of the long term complications of diabetes.[2] The sequence of non-enzymatic glycation involves the reaction of an aldose (or ketose) sugar with free amino groups of proteins (Maillard reaction) leading initially to the formation of labile Schiff bases. With the subsequent Amadori rearrangement, the aminoketoses formed undergo a variety of reactions[3] such as dehydrations, fragmentations, and the formation of highly reactive carbonyl compounds, which continue to react with free amino groups, thus leading to cross-linking of proteins *via* advanced glycation end products (AGEs) which are mainly responsible for the diabetic complications.[2] A few such adducts have been structurally identified by *in vitro* glycation of proteins or by monitoring the breakdown of isolated Amadori compounds.[4]

This study demonstrates for the first time, by *in vitro* experiments, that, in addition to Amadori rearrangement, an alternative pathway for carbohydrate-induced modification of peptides is possible, yielding imidazolidin-4-ones from the initially formed hexose–peptide adducts.

We recently reported[5] on the products of intramolecular Amadori rearrangements formed in pyridine–AcOH as the solvent from monosaccharide esters **1a**–**c**[6] in which D-mannose (**1a**), D-glucose (**1b**), or D-galactose (**1c**) are linked through their C-6 hydroxy groups to the C-terminal carboxy group of the endogenous opioid pentapeptide leucine-enkephalin (H-Tyr-Gly-Gly-Phe-Leu-OH).[7] Herein we provide evidence that synthons **1a**–**c** are also transformed to carbohydrate-related imidazolidinones **3a**–**c** (Scheme 1). Thus, incubation of monosaccharide esters **1a**–**c** in MeOH at 50–60 °C afforded, after purification by semipreparative reverse-phase high-performance liquid chromatography (RP HPLC), the corresponding imidazolidin-4-ones **2a**–**c** in acceptable yields (Table 1). We assume that, in a similar fashion to Amadori product formation from esters **1a**–**c**,[5] the first step of this reaction requires the open-chain form of the carbohydrate moieties in compounds **1a**–**c**, which is attacked by the free amino terminus of the peptide moiety. In the subsequent step, the Schiff base formed, instead of Amadori rearrangement to the corresponding keto-sugar, undergoes nucleophilic attack by the Gly[2] nitrogen to yield imidazolidin-4-ones **2a**–**c** in which C-1 of the sugar moiety forms a bridge between the α-amino group of the *N*-terminal tyrosine residue and the amide nitrogen of the Tyr[1]-Gly[2] peptide bond. As presented in Table 1, the transformation **1a**→**2a** took place completely stereospecifically, while the conversion of esters **1b** and **1c** to the corresponding imidazolidinones exhibited a low degree of stereocontrol. Rearrangements of **1a**–**c** in MeOH yield only 5% of the corresponding Amadori products.



Scheme 1 *Reagents and conditions*: i, MeOH, 50–60 °C; ii, 0.1 M NaOH, 25 °C. Asterisk indicates either (*S*)- or (*R*)-configuration at the new *N*,*N*'-acetal centre.

Table 1 Intramolecular rearrangement of esters **1a**–**c** in MeOH

Starting compound	*t*/h	*T*/°C	Product[a]	Yield (%)[b] Major	Minor
1a	24	50	**2a**	49	—
1b	72	60	**2b**	34	9
1c	48	60	**2c**	12	10

[a] Mixture of diastereomers for **2b** and **2c**. [b] Isolated yields after RP HPLC purification.

Cleavage of the ester bond in both the major and minor isomers of compounds **2a**–**c** was carried out in 0.1 M NaOH at room temperature and led to the corresponding chiral imidazolidin-4-ones of D-mannose (**3a**), D-glucose (**3b**) or D-galactose (**3c**) in 77–95% yield after RP HPLC chromatography.‡

The experimental fact that the monosaccharide esters **1a**–**c**, the behaviour of which closely resembles the reactivity of hexose 6-phosphates, yield either the corresponding Amadori products[5] or imidazolidinones **2a**–**c** points, in our understanding, to the possibility that, depending on the physiological environment, similar imidazolidinon-4-one adducts may be also generated *in vivo*.

In conclusion, the method outlined above, which is based on the intramolecular rearrangement of 6-*O*-peptidyl esters **1a**–**c,** represents an innovative route for the synthesis of hexose-related imidazolidin-4-ones, compounds useful in understanding the details of the mechanism of non-enzymatic glycation *in vivo*.

Evidence for actinide metal to ligand π backbonding. Density functional investigations of the electronic structure of [{$(NH_2)_3(NH_3)U$}$_2(\mu^2$-η^2:η^2-$N_2)$]

Nikolas Kaltsoyannis*[a]† and Peter Scott[b]‡

[a] *Centre for Theoretical and Computational Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*
[b] *Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL*

The electronic structure of [{$(NH_2)_3(NH_3)U$}$_2(\mu^2$-η^2:η^2-$N_2)$], a model for the first dinitrogen compound of an actinide, is investigated computationally using quasi-relativistic non-local density functional theory; the only significant U–N_2–U interaction is found to be U→N_2 π backbonding.

The instability of f element complexes with π acid ligands is presumed to arise from the inability of these metals to take part in metal→ligand backbonding. Indeed the bonding in f element compounds is widely regarded as being essentially electrostatic. Nevertheless the physicochemical properties of certain actinide systems cannot be satisfactorily explained without invoking appreciable metal–ligand covalency.[1–4]

We have recently reported our discovery of the first dinitrogen complex of an actinide element, [{$(NN'_3)U$}$_2(\mu^2$-η^2:η^2-N_2)] [NN'_3 = $N(CH_2CH_2NSiBu^tMe_2)_3$] **1** (Fig. 1).[5] This compound, synthesised by the exposure of the 'base-free' triamidoamine [$(NN'_3)U$] to rigorously pure dinitrogen, features an N_2 unit bridging the two uranium centres in a side-on manner. This coordination geometry raises the intriguing and fundamental question of how the N_2 ligand interacts with the metal atoms. The N–N distance [1.109(7) Å] is similar to that found in dinitrogen gas (1.0975 Å), and the magnetic susceptibility and UV–VIS spectrum are very close to those of the parent [$(NN'_3)U$]. These data led us to suggest that **1** contains essentially N_2→U σ bonds, with [$(NN'_3)U$] acting as an extremely potent Lewis acid. We noted, however, that since the unobserved 1 : 1 intermediate [$(NN'_3)U$–(N_2)] is clearly more basic than free dinitrogen, some degree of U→N_2 backbonding may be present.

In order to gain insight into the electronic structure of **1** and hence to evaluate the above suggestions, we have carried out density functional calculations§ on the model complex [{$(NH_2)_3(NH_3)U$}$_2(\mu^2$-η^2:η^2-N_2)] **2**. Bond lengths and angles were taken from the crystallographic data obtained on **1**, and the molecular structure was idealised to C_{2h} symmetry. The replacement of the triamidoamine ligand by $(NH_2)_3(NH_3)$ is necessary for calculational feasibility and, while such a simplification is not insignificant, we anticipate that the fundamental features of the U–N_2–U interaction will not be greatly affected. Indeed, we have previously used this ligand replacement in other studies.[6]

1 is paramagnetic, with a susceptibility of 3.22 μ_B per uranium atom.[5] It is therefore appropriate to address the electronic structure of **2** using the spin unrestricted approach, in which α and β spin electrons occupying a molecular orbital (MO) of a given number and symmetry are not constrained to have the same spatial wavefunction. The excess α over β spin density is a user-defined parameter within ADF, raising the question of how many unpaired electrons **1** and **2** possess. The spin-only formula is inappropriate for actinide complexes, and thus the magnetic susceptibility of **1** cannot be straightforwardly related to the number of unpaired electrons. Consideration of all the available experimental data suggests that **1** has six unpaired electrons per molecule, *i.e.* that each uranium atom is best regarded as a U^{III} f^3 centre. We have carried out a range of spin unrestricted calculations of **2**, and have found that the most stable electronic arrangement has four unpaired electrons. Imposition of six unpaired electrons produces a non-Aufbau orbital occupation and a markedly less stable structure.¶ We stress, however, that the general features of the electronic structure are very similar in all cases, and it is to these that we now turn.‖

A MO energy level diagram for **2** with four unpaired electrons is given in Fig. 2. The orbitals are labelled according to the C_{2h} irreducible representations that they span, together with an α or β designation to indicate the spin of the electron in that orbital. The use of the spin unrestricted approach doubles the number of MOs, and there are 42 such energy levels in the eigenvalue range −8.3 to −2.3 eV. Fortunately the MOs are concentrated in a few groups of similar energy and composition (represented by rectangles on Fig. 2), simplifying the analysis of the valence electronic structure. MOs around the highest occupied orbital are shown on an expanded scale.

The three groups of MOs with energies centred around −8.2, −7.5 and −5.5 eV are largely localised on the NH_2 and NH_3 ligands, with some levels also containing small contributions from the uranium atoms. These orbitals are primarily responsible for binding the NH_2 and NH_3 groups to the metal atoms, as

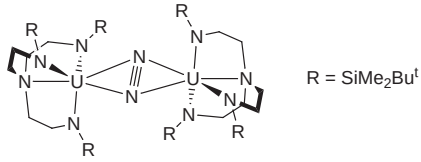

Fig. 1 The geometric structure of [{$(NN'_3)U$}$_2(\mu^2$-η^2:η^2-N_2)] [NN'_3 = $N(CH_2CH_2NSiBu^tMe_2)_3$] **1**

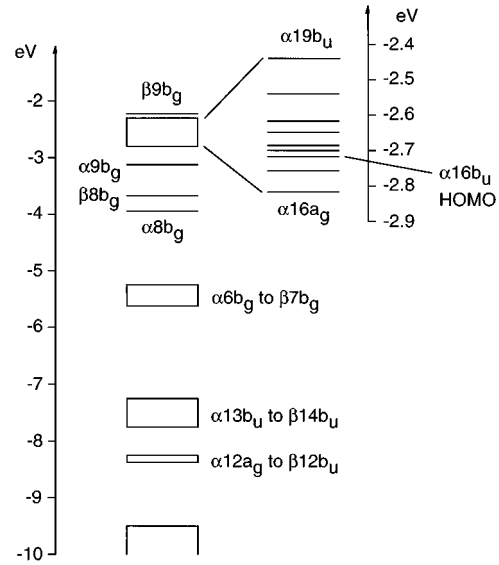

Fig. 2 Molecular orbital energy level diagram of C_{2h} symmetric [{$(NH_2)_3(NH_3)U$}$_2(\mu^2$-η^2:η^2-N_2)] **2**

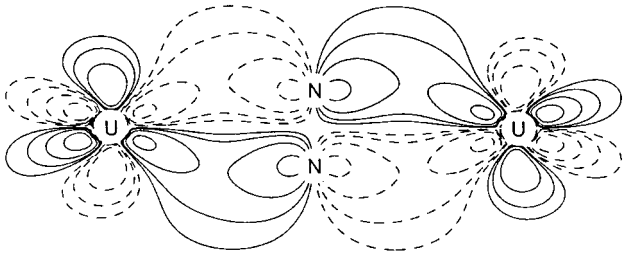

Fig. 3 Contour plot of the $\alpha 8b_g$ molecular orbital of $[\{(NH_2)_3(NH_3)U\}_2(\mu^2\text{-}\eta^2\text{:}\eta^2\text{-}N_2)]$ **2**, viewed in the plane defined by the two uranium atoms and the N_2 unit. Contour levels are ±0.2, ±0.1, ±0.05 and ±0.025.

well as for some N–H bonding. Given that we are concerned mainly with the U–N_2–U interaction, these orbitals will not be discussed further.

The six least stable electrons occupy the $\alpha 8b_g$ to $\alpha 16b_u$ orbitals. Five of these levels have α spin and one has β spin, and the spatial symmetry of the unpaired electrons is such that the overall molecular electronic state is ^5A_u. The four orbitals of α spin that have no filled β spin counterpart ($\alpha 9b_g$ to $\alpha 16b_u$) are predominantly uranium f based (⩾75% in all cases). The α and β $8b_g$ orbitals, however, are rather different from this group, in terms of both energy (> 0.6 eV more stable) and composition. These two levels are mixtures of uranium f and the N–N antibonding π_g orbital of the N_2 ligand,** and are U→N_2 π backbonding. A contour plot of the $\alpha 8b_g$ orbital is shown in Fig. 3. Analysis of all of the filled MOs of **2** shows that this is the only significant U–N_2–U interaction. MOs with contributions from the π_u N–N bonding orbital lie at much more negative eigenvalues (*ca.* −11 to −12 eV) and have negligible uranium character. The Mulliken overlap population between the uranium atoms and the N_2 fragment is +0.25 electrons, reinforcing the conclusion of appreciable U–N_2–U covalency, and the calculated charge on the nitrogen atoms of the N_2 unit (−0.49) indicates a net transfer of electron density from metal to ligand.

Population of the N_2 π_g antibonding MO would be expected to produce a lengthening of the N–N bond. That no significant increase is observed experimentally merits further investigation. The strong directionality of f orbitals (arising from their high nodality) suggests one possible explanation. Lengthening the N–N bond would reduce the overlap between the metal f and N_2 π_g levels, weakening the U–N_2–U bonding interaction. Work is in progress to evaluate this and other hypotheses.††

§ Calculations were performed with the Amsterdam Density Functional program suite.[7,8] Quasi-relativistic[9] frozen cores were used for N (1s) and U (5d). Relativistic core potentials were computed using the ADF auxiliary program 'Dirac'. An uncontracted triple-zeta Slater-type orbital valence basis set was employed for all atoms, supplemented with p and d polarisation functions for H (ADF Type V), and d and f polarisation functions for N (ADF Type V). No polarisation functions were included for U (ADF Type IV). The density functional of Vosko *et al.*[10] was employed in conjunction with Becke's gradient correction[11] to the exchange part of the potential and the correlation correction due to Perdew.[12] Mulliken population analyses were performed.[13] The calculations were performed on IBM RS/6000 and DEC 433au workstations and the EPSRC's 'Columbus/Magellan' computer.

¶ The non-Aufbau, six unpaired electron arrangement is 102 kJ mol^{-1} less stable than that with four unpaired electrons, which has an Aufbau orbital occupancy and which is 68 kJ mol^{-1} more stable than the Aufbau restricted (*i.e.* no unpaired electrons) arrangement.

‖ It should be noted that a full description of the electronic structure of **2** must include the effects of spin–orbit coupling.[14] Under these circumstances the number of unpaired electrons is a meaningless quantity, as the electronic spin and orbital angular momenta cannot be separated. We will address this issue in further studies of triamidoamine–uranium systems.

** *E.g.* the principal contributions to the $\alpha 8b_g$ orbital are 24.34% U $f_{z(x^2 - y^2)}$, 14.97% U f_{z^3}, 6.13% U d_{yz} and 40.23% N_2 π_g.

†† Two areas that we will concentrate on are (a) geometry optimisations of **2** (in order to establish if the lack of N–N lengthening is indeed a result of f-orbital/π_g overlap requirements) and (b) replacement of one of the NH_2 H atoms by a SiH_3 unit in order to model the $N(CH_2CH_2NSiBu^tMe_2)_3$ ligand more closely.

The coordination chemistry of amine triphenolate tripod ligands with iron(III). Old organic compounds but new tripod ligands

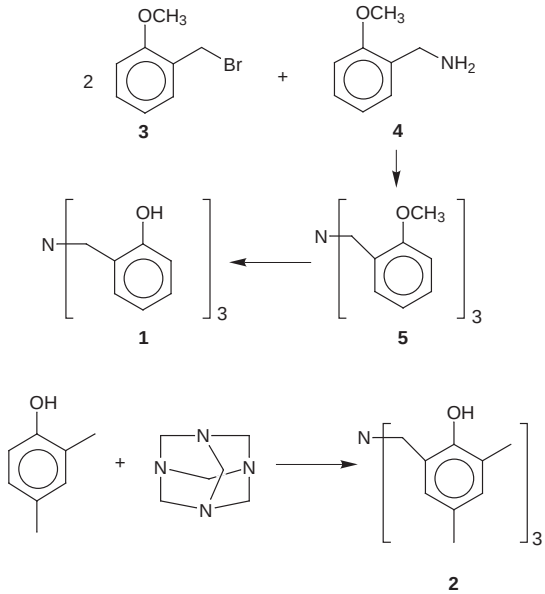
JungWon Hwang, Kumar Govindaswamy and Stephen A. Koch*†

Department of Chemistry, State University of New York at Stony Brook, Stony Brook, NY 11794-3400, USA

The coordination chemistry of new C_3 symmetric triphenolate amine tripod ligands has been demonstrated with Fe^{III}.

A key feature of the coordination chemistry of tripod ligands is their ability to divide the metal–ligand coordination sphere into non-labile sites and reactive sites. Saconni and the Florence school first demonstrated the rich coordination chemistry of tripod ligands in the 1960s and 1970s.[1,2] In the 1990s the chemistry of tripod ligands has undergone a renaissance.[3–5] We report the coordination chemistry of new polyphenolate amine tripod ligands: tris(2-hydroxybenzyl)amine (**1**) and tris(2-hydroxy-3,5-dimethylbenzyl)amine (**2**). Phenolate containing ligands are valuable in modeling the active sites of metal–tyrosine centers in metalloproteins[6] and homogeneous and heterogeneous catalysts.[7] Historically, the hydrochloride salt of **1** was the subject of its first and only report in 1922,[8] while the synthesis of **2** appeared in the literature in 1949.[9] The coordination chemistry of compounds **1** and **2** has never been previously reported.

Our route to **1,** which differs from the original synthesis, is outlined in Scheme 1. The reaction of 2 equiv. of 2-methoxybenzyl bromide[10] (**3**) with commercially available 2-methoxybenzylamine (**4**) in refluxing CH_3CN with added K_2CO_3 gives tris(2-methoxybenzyl)amine (**5**) in 80–85% yield. The methyl protecting groups are removed by refluxing **5** in toluene with 5 equiv. of $AlCl_3$ to give **1** in 70% yield. We were able to reproduce the synthesis of **2** by the one step Mannich reaction of 2,4-dimethylphenol with hexamethylenetetramine.[9] Since both **1** and **2**‡ were reported before the advent of modern spectroscopic techniques, the congruence of our compounds with the literature compounds was established by melting point comparisons.



Scheme 1

The reaction of the trilithium salt of **1** with $FeCl_3$ in the presence of 3 equiv. of 1-methylimidazole (1-Meim) in MeOH gave dark red crystals of [Fe{N(CH_2-*o*-C_6H_4O)$_3$}(1-Meim)] (**6**) in 65% yield. The structure of **6**, which was determined by X-ray crystallographic analysis§ (Fig. 1), consists of a trigonal bipyramidal structure with an N1–Fe–N2 angle of 173.4(1)°. The Fe atom is 0.045 Å out of the plane of the three oxygen donors toward the imidazole nitrogen. The FeO_3 plane shows small deviations from trigonal symmetry with O–Fe–O angles of 117.4(1) to 126.3(1)°. The average Fe–O bond distance [1.876(15) Å] is intermediate between the Fe–O in tetrahedral [Fe^{III}(OC_6HMe_4-2,3,5,6)$_4$]$^-$ [1.847(13) Å] and in octahedral Fe tris-catecholate complexes (2.02 Å).[11,12] The analogous compound, [Fe{N[CH_2-*o*-C_6H_2(OMe)$_2$-3,5]$_3$}(1-Meim)] (**7**), has also been characterized with ligand **2**.

The tripod ligand coordinates to the metal to generate a chiral C_3 conformation[13] with both enantiomeric structures present in the centric crystal lattice. These tripod ligands **1** and **2** differ from the well studied N(CH_2CH_2OH)$_3$ and N(CH_2CO_2H)$_3$ ligands in the phenolate *versus* alkoxide and carboxylate donors and by having six- *versus* five-membered metal ligand chelate rings. The aminetriphenolate ligand N(*o*-C_6H_4O)$_3$ and its coordination chemistry with Al have been reported.[14]

The thiol analog of **1** and its [Fe^{III}{N(CH_2-*o*-C_6H_4S)$_3$}(1-Meim)] complex has recently been reported.[15] The 0.43 Å change in Fe–O *versus* Fe–S bond distance reflects the difference in the ionic radii of S and O. The larger average Fe–O–C angle [134(1)°] in **6** *versus* the Fe–S–C [110(1)°] angle is

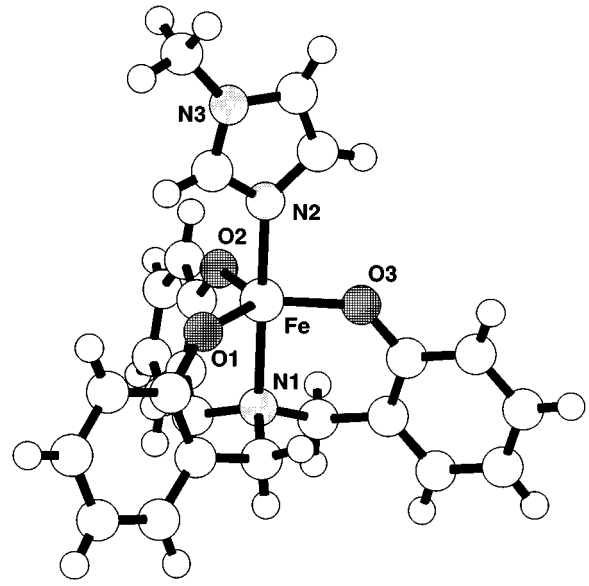


Fig. 1 Structural diagram for [Fe{N(CH_2-*o*-C_6H_4O)$_3$}(1-Meim)] (**6**). Selected distances (Å) and angles (°) Fe1–O1 1.881(3); Fe1–O2 1.888(3); Fe1–O3 1.859(3); Fe1–N1 2.191(3); Fe1–N2 2.090(4); O1–Fe1–O2–126.3(1); O1–Fe1–O3–117.4(1); O2–Fe1–O3 116.2(1); O1–Fe1–N1 87.1(1); O1–Fe1–N2 87.6(1); O2–Fe1–N1 88.9(1); O2–Fe1–N2 91.1(1); O3–Fe1–N1 89.9(1); O3–Fe1–N2 96.0(1); N1–Fe1–N2 173.4(1); Fe1–O–C_{avg} 134(1).

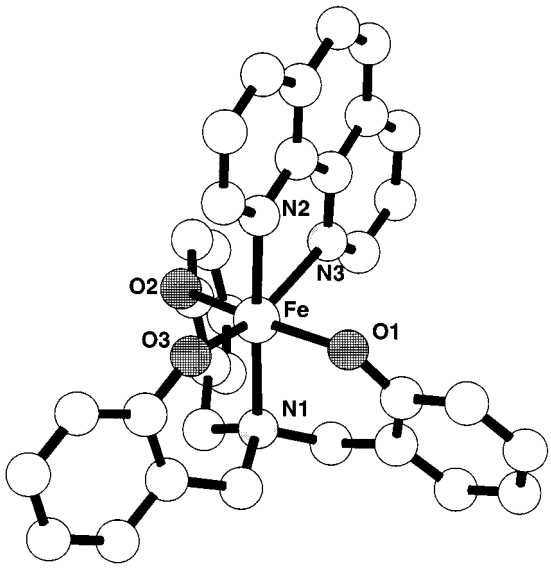

Fig. 2 Structural diagram for [Fe{N(CH_2-*o*-C_6H_4O)$_3$}(phen)] (**9**). Selected distances (Å) and angles (°): Fe1–O1 1.897(6); Fe1–O2 1.926(6); Fe1–O3 1.893(7); Fe1–N1 2.225(8); Fe1–N2 2.158(7); Fe1–N3 2.340(7); N1–Fe–O3 91.5(3); O3–Fe–N2 87.7(3); N2–Fe–N3 73.9(3); N3–Fe–N1 107.0(3); O1–Fe–O2 164.1(3); N–Fe–$O2_{avg}$ 88.4(3); N–Fe–$O1_{avg}$ 87.5(3); Fe–O–C_{avg} 128.5(7).

consistent with the known Fe^{III} coordination chemistry of thiolate and phenolate ligands.[11,16,17] In an attempt to prepare a four coordinate complex, the reaction of $Li_3N(CH_2$-*o*-$C_6H_4O)_3$] with $FeCl_3$ was repeated in the absence of 1-Meim. However the X-ray structure§ of the product, [Fe{N(CH_2-*o*-$C_6H_4O)_3$}(DMF)] (**8**), revealed that a molecule of solvent was coordinated to the iron. The crystal of **8** is isomorphous and is essentially isostructural with **6**. The atomic positions of the non-hydrogen atoms of the DMF molecule are structurally equivalent to five of the atoms of the 1-Meim in **6**. The reaction of **8** with 1,10-phenanthroline in DMF followed by the addition of MeOH gave dark red crystals of [Fe{N(CH_2-*o*-$C_6H_4O)_3$}(phen)] (**9**) in 50% yield. The structure of **9**§ (Fig. 2) demonstrates that the tripod ligands can support an octahedral coordination center. The phen ligand has a distinctly asymmetric coordination with Fe–N2 2.158(7) Å and Fe–N3 2.340(7) Å distances. The distortion results from a short contact between a benzyl proton and the hydrogen atom *ortho* to N3.

Compounds **6**–**9** have magnetic moments indicative of high spin Fe^{3+} and have an intense phenolate to Fe charge transfer transition at 399 nm (ε = 7960 dm^3 mol^{-1} cm^{-1}), 422 (8320), 405 (9700), and 399 (7751) respectively.[18] A quasireversible Fe^{III}–Fe^{II} redox couple was observed in the cyclic voltammogram of **7** occurring at $E_{1/2}$ = −0.78 V (ΔE = 107 mV) *versus* Ag/AgCl in DMF solution. Only irreversible oxidation processes were observed for all the compounds.[19]

The chemistry of these tripod ligands with other metal ions is under investigation. We thank the National Institutes of Health for support.

Transition metal imide/organic imine metathesis reactions: *unexpected observations*

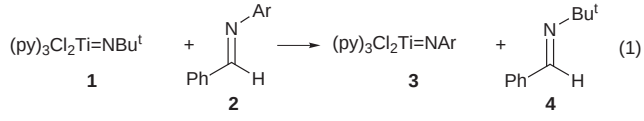
Jacqueline M. McInnes and Philip Mountford*†‡

Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD

Mixtures of [Ti(NBu^t)Cl$_2$(py)$_3$] 1 and PhC(NAr)H (Ar = C$_6$H$_3$Me$_2$-2,6 or C$_6$H$_4$Me-4) gave quantitative conversion to [Ti(NAr)Cl$_2$(py)$_3$] and PhC(NBu^t)H, the products of Ti=N-Bu^t/C=NAr transition metal imide/organic imine metathesis; examination of the kinetics for Ar = C$_6$H$_4$Me-4 showed that the rate limiting step for this process is zero order in [1], demonstrating that these reactions do not involve metal imide participation in the rate limiting step.

One attraction of transition metal imido compounds is their potential use in metal-mediated imido group (NR) transfer reactions. The addition of unsaturated substrates to M=NR linkages is now well documented, but examples of reactions resulting in complete removal (functional group transfer) of NR from metal to substrate are still somewhat more restricted, especially by comparison with the rich functional group transfer chemistry of metal oxo complexes.[1] Very recently there have been reports of transition metal imide/organic imine (L$_n$M=NR/R$_2$C=NR′) functional group metathesis reactions,[2] and these have been proposed in some instances to arise *via* metal imide-mediated processes, possibly involving cycloaddition of C=NR′ to M=NR. Such processes appear to be the aza-analogues of the widely used metal alkylidene (L$_n$M=CR$_2$)/alkene (R′$_2$C=CR′$_2$) metathesis reaction[3] and are therefore potentially hugely important transformations in stoichiometric and catalytic synthesis. Identification of the possible role(s) of the metal centre in such processes is clearly essential. As part of an ongoing study of early transition metal imido chemistry, we found that a number of titanium imido complexes undergo well characterised cycloaddition and other coupling reactions of the Ti=NR group (R = Bu^t or aryl) with organic substrates.[4] In parallel studies we have observed reactions of [Ti(NBu^t)Cl$_2$-(py)$_3$][4b] with certain mono- and α-di-imines that yield the expected products of imide/imine functional group metathesis. The results herein show that examples of apparently metal-mediated imide/imine metathesis reactions must be subjected to mechanistic investigations before they can be properly authenticated.

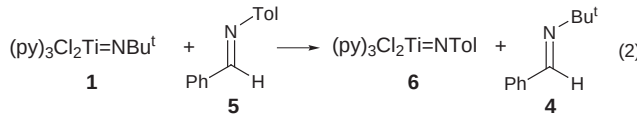
Reaction of [Ti(NBu^t)Cl$_2$(py)$_3$] **1** with one equivalent of the *N*-2,6-dimethylphenylbenzaldehyde imine **2** at 60 °C for 96 hours in CDCl$_3$ gave (by NMR) quantitative and stoichiometric conversion to PhC(NBu^t)H **4** and the arylimido compound [Ti(NC$_6$H$_3$Me$_2$-2,6)Cl$_2$(py)$_3$] **3** [eqn. (1)].§ Repeating the



(1)

Ar = C$_6$H$_3$Me$_2$-2,6

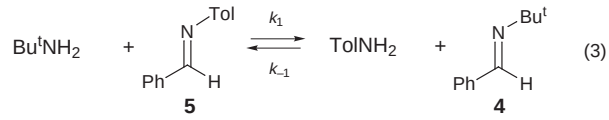
reaction on a preparative scale confirmed the exchange of *tert*-butylimide for the 2,6-dimethylphenylimide ligand. Similarly, reaction of **1** with one equivalent of the less bulky *N*-arylimine PhC(NTol)H **5** (Tol = C$_6$H$_4$Me-4) gave a quantitative yield of **4** after only 4 hours at 60 °C in CDCl$_3$, along with the tolylimido product **6** [eqn. (2)]. Products **3**, **4** and **6** were identified by comparison with authentic samples[4b] and the reactions were



(2)

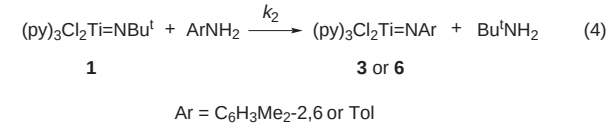
fully reproducible in both CDCl$_3$ and C$_6$D$_6$. At first sight, eqns. (1) and (2) are apparently straightforward examples of metal-mediated imide/imine metathesis reactions. Furthermore, reaction of **1** with certain *N*-aryl-α-diimines also leads to the expected arylimido titanium products and the corresponding *N*-*tert*-butyl-α-diimines.

In a separate experiment [eqn. (3)] an equimolar mixture of



(3)

Bu^{t}NH$_2$ with **5** in CDCl$_3$ (no titanium imido compound added) gave an equilibrium mixture (K_{eq} *ca.* 1, *i.e.* $k_1 \approx k_{-1}$) containing the two starting compounds along with the products TolNH$_2$ and imine **4** after 8 hours at 30 °C. Similarly, starting with an equimolar mixture of pure TolNH$_2$ and **4** also gave an equilibrium mixture of TolNH$_2$, **4**, Bu^{t}NH$_2$ and **5**. Since there is no thermodynamic driving force in eqn. (3) to account for the net quantitative reactions in eqns. (1) and (2), we infer that it is formation of the arylimide products **3** and **6** that causes these two reactions to go to completion. This hypothesis is supported by eqn. (4) which shows that addition of a stoichiometric



(4)

Ar = C$_6$H$_3$Me$_2$-2,6 or Tol

amount of arylamine to [Ti(NBu^t)Cl$_2$(py)$_3$] **1** gives quantitative formation of Bu^{t}NH$_2$ and the corresponding arylimide **3** or **6**.[4b] This process is (qualitatively) very much faster than any of the other three [*i.e.* eqns. (1)–(3)]. Further evidence for the role of **1** as an effective trap for ArNH$_2$ came from NMR experiments in which **1** was added to a pre-equilibrated mixture of Bu^{t}NH$_2$, **5**, TolNH$_2$ and **4** [eqn. (3)]: **1** and TolNH$_2$ were consumed and there was quantitative conversion of **5** to **4**.

Examination of the kinetics of eqn. (3) under pseudo-first order conditions established that this reaction [from left to right as shown in eqn. (3)] is first order in both Bu^{t}NH$_2$ and imine **5** and also allowed the direct deduction of k_1. However, reaction of [Ti(NBu^t)Cl$_2$(py)$_3$] **1** with PhC(NTol)H **5** (10, 16.5 and 20 equivs.) under otherwise identical pseudo-first order conditions showed (Fig.1) that the rate for eqn. (2) is zero order with respect to **1** and has no simple dependence on [**5**]. These observations are clearly not consistent with the expected titanium imide-mediated metathesis mechanism of the type illustrated in Scheme 1, in which a diazametallacycle **7** is formed in the rate limiting step. For such a process a rate dependency on [**1**] is required.¶ Indeed, to our knowledge, all

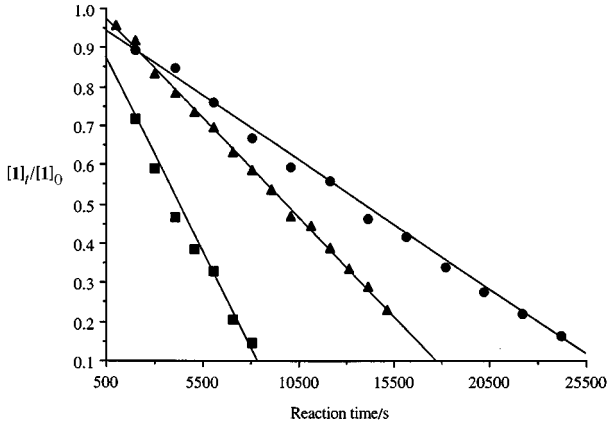


Fig. 1 Linear plots of $[\mathbf{1}]_t/[\mathbf{1}]_0$ *versus* time for the reactions with an excess of PhC(NTol)H **5** in $CDCl_3$ showing clearly the zero order dependence of rate on [**1**]. Legend: ● 10 equivalents of **5**; ▲, 16.5 equivalents of **5**; ■, 20 equivalents of **5**.

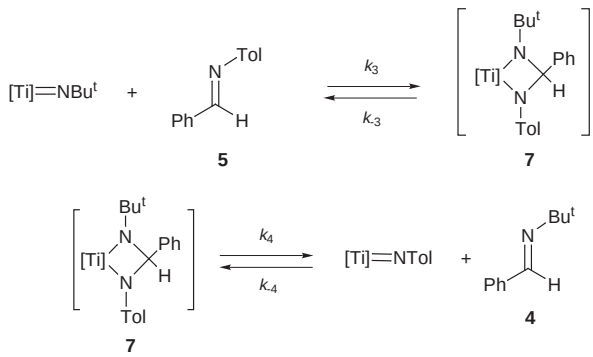

Scheme 1

kinetically characterised examples of alkene metathesis by homogeneous metal alkylidene (carbene) complexes (which proceed *via* metallacyclobutane intermediates) show a first order dependence on metal concentration.[5] Furthermore, studies by Lee and Bergman of cycloaddition reactions of the imido zirconium complex $[Cp_2Zr(NR)(L)]$ (R = But or $C_6H_3Me_2$-2,6, L = THF, $OPPh_3$ or 4-*tert*-butylpyridine) have shown them to be first order in imido complex.[6] Previously reported zirconium-mediated imine metathesis reactions also follow a first order relationship between reaction rate and metal complex, although in this instance the resting state of the complex is a diazametallacycle.[2a]

The absence of a rate dependence on [**1**] implies that one or more alternative mechanisms (to that shown in Scheme 1) must be operating in eqns. (1) and (2). At first sight, one possibility appears to be a tandem combination of eqns. (3) and (4) where traces of Bu^tNH_2 (in principle impossible to exclude for these very moisture sensitive systems, although we have no NMR evidence for its presence in mixtures of **1** and **5**) give rise to formation of imine **4**, the liberated $TolNH_2$ being scavenged by **1** forming the imido product **6**. However, the kinetic results do not support this mechanism since the rate law in this case‖ requires a first-order dependence on [**5**]. Furthermore there is no evidence for significant enough concentrations of Bu^tNH_2 in these NMR mixtures to account for the observed rate of formation of **4** and **6** in these reactions.**

In summary we have demonstrated that apparently straightforward transition metal imide/organic imine metathesis reactions do not necessarily involve metal imide participation in the rate determining step. This is in sharp contrast to the well known metal alkylidene/alkene metathesis reactions. Cases of metal imide/imine metathesis must clearly be subjected to mechanistic scrutiny before conclusions concerning either the role of the metal centre or any structure–activity relationships can be reached. Further investigations of these and other related reactions are currently under way.

‡ Philip Mountford is the Royal Society of Chemistry Sir Edward Frankland Fellow.

§ For all the rate determinations the disappearance of $[Ti(NBu^t)Cl_2(py)_3]$ **1** or Bu^tNH_2 was monitored over at least three half-lives under pseudo-first-order conditions with *p*-dimethoxybenzene as the internal standard. Both before and after each experiment the temperature in the NMR probe was calibrated using ethylene glycol (80%) in DMSO. The temperature did not vary by more than 1 °C. The samples were prepared in a dry-box using Teflon valve (Young's) 5 mm tubes, which had been rigorously dried. $CDCl_3$ and C_6D_6 were dried over calcium hydride and potassium respectively, at rt, then distilled under reduced pressure. ^{1}H NMR spectra were recorded on a Bruker DPX 300 spectrometer at 30 °C.

¶ For the process shown in Scheme 1, rate = k_{obs}[metal imide][organic imine], where $k_{obs} = k_3k_4/(k_{-3} + k_4)$, assuming the k_{-4} step is not significant at low concentrations of product imine and a steady state approximation for [**7**]. In the reactions in eqns. (1) and (2), pyridine dissociation may be required before formation of hypothetical **7**. In this instance the rate should still be dependent on [metal imide], but k_{obs} would show a dependence on [pyridine]. However, we have found that the five-coordinate bis(pyridine) complex $[Ti(NBu^t)Cl_2(py)_2]$ also reacts with organic imines at a rate not significantly different from that of **1** under the same conditions and so the presence of the third pyridine molecule is not important.

‖ Combining eqns. (3) and (4) and assuming a steady state approximation of $[TolNH_2]$ leads to the expression: rate = $k_1[Bu^tNH_2][\mathbf{5}]$ since, under the pseudo-first order conditions used here, [**5**] ≫ [**4**] and hence the k_{-1} back-reaction is negligible, especially since **1** is an effective trap for $TolNH_2$.

** From kinetic analysis of eqn. (3) we know independently the value of k_1 (1.35×10^{-3} M^{-1}s^{-1}) under analogous reaction conditions. Therefore, if indeed rate = $k_1[Bu^tNH_2][\mathbf{5}]$ then $[Bu^tNH_2]$ has to be approximately 0.10 to 0.43 M for the experiments shown in Fig. 1. From the NMR spectra the maximum possible value of $[Bu^tNH_2]$ in these experiments is < 0.005 M. However, it is possible that under the reaction conditions of eqns. (1) or (2), eqn. (3) is accelerated by Lewis and/or Brønsted acids. Indeed, tests of this hypothesis for eqn. (3) with added $[Sc(OTf)_3]$ demonstrated a rate acceleration suggesting that Lewis acids (*e.g.* **1** and/or its trace decomposition products) may make a tandem combination of eqns. (3) and (4) a possibility. Toluene-*p*-sulfonic acid had no measurable effect on the rate of eqn. (3). We cannot directly determine the influence of additional Bu^tNH_2 on the rate of reaction of **1** with **5** [eqn. (2)]: any Bu^tNH_2 added would be rapidly scavenged by **5** [eqn. (3)] since $t_{1/2}$ for the consumption of **5** in eqn. (3) is *ca.* 25 times shorter than for **5** in eqn. (2) under otherwise identical conditions.

Phosphoramidate-mediated conversion of metal carbonyls into metal isonitriles

Susan E. Gibson (née Thomas),*† Thomas W. Hinkamp, Mark A. Peplow and Mark F. Ward

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY

The reaction of metal carbonyls with readily-available phosphoramidate anions provides a new route to metal isonitriles; in particular, enantiomerically pure isonitrile complexes are easily accessed by this method.

Our recent interest in tricarbonyl(vinylketene)iron(0) complexes and their nitrogen analogues, tricarbonyl(vinylketenimine)iron(0) complexes, led us to devise a method for the conversion of the former into the latter, central to which were the anions of diethyl *N*-alkylphosphoramidates.[1] We subsequently questioned whether or not this approach could be used to convert metal carbonyls into metal isonitriles, a transformation worthy of investigation in view of the ubiquity of carbonyl and isonitrile ligands in organometallic chemistry.

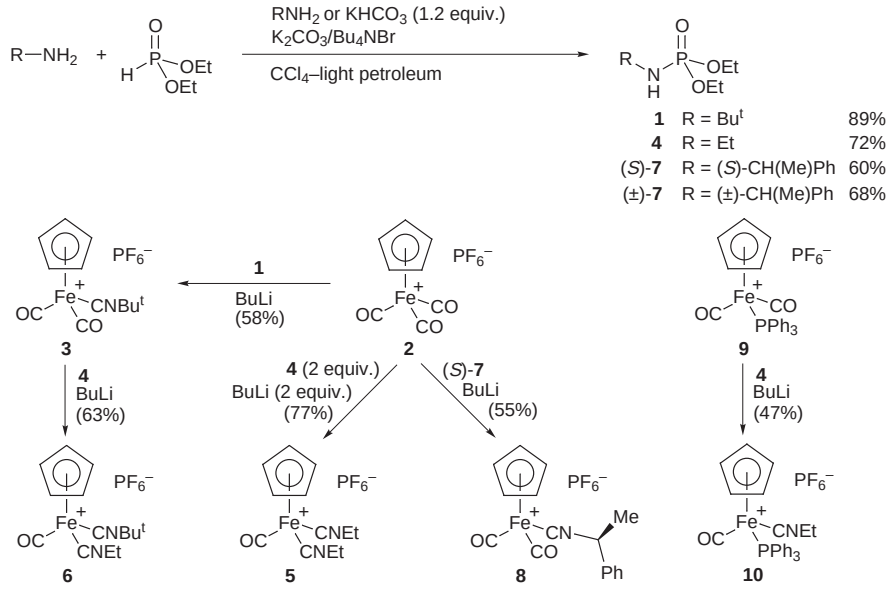
We report herein our preliminary results in this area which reveal that the phosphoramidate-mediated conversion of metal carbonyls to metal isonitriles is indeed a viable process. The reaction's potential may be summarised by the following points: (i) unlike the 'classical' carbonyl–isonitrile exchange approach to isonitrile ligands[2] the process avoids the use of 'free' isonitriles, compounds which are frequently volatile, smelly and toxic; (ii) the method introduces isonitrile ligands in a controlled manner, again in contrast to the 'classical' carbonyl–isonitrile exchange reaction which frequently delivers mixtures of products;[3] (iii) phosphoramidates are easy to synthesise[4] and handle;‡ and (iv) the method provides rapid access to non-racemic chiral isonitrile ligands, a class of ligand which has received remarkably little attention to date.§

An initial experiment was carried out using phosphoramidate **1** and the tricarbonyliron cation **2**. Phosphoramidate **1** was synthesised by stirring together 2.2 equiv. of *tert*-butylamine and 1.0 equiv. of diethyl phosphite in CCl_4–light petroleum according to literature precedent;[4a,c] work-up gave **1** as a colourless stable liquid in 89% yield (Scheme 1). The iron cation **2** was synthesised from $[(C_5H_5)(CO)_2Fe]_2$ by reduction with sodium amalgam, and sequential addition of ethyl chloroformate, hydrogen chloride and ammonim hexafluorophosphate.[8] This produced cation **2** in 81% overall yield as an orange–yellow crystalline solid.

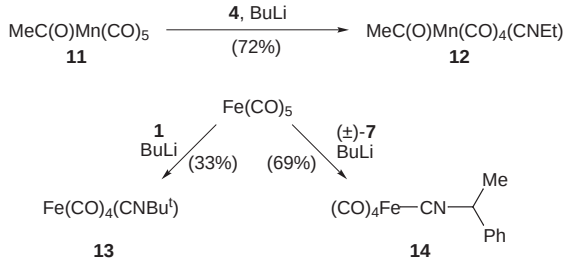
Phosphoramidate **1** was dissolved in THF, cooled to −78 °C and treated with 1 equiv. of butyllithium.¶ To this solution was added to a stirred suspension of 1 equiv. of cation **2** in THF. The resulting mixture was held at −78 °C for 6 h during which time the suspension gradually gave way to a yellow solution. Work-up of the product mixture by column chromatography and crystallisation produced a light yellow solid which was identified as the dicarbonyl isonitrile complex **3** by comparison of its ^{1}H NMR and IR spectra with literature values.[9] Cation **3** was generated in an acceptable 58% yield on a 1.0 mmol scale, thus indicating that the phosphoramidate-mediated conversion of carbonyl ligands to isonitrile ligands is indeed feasible.

Experiments to probe the scope and limitations of this process with respect to the phosphoramidate were performed next. Thus cation **2** was reacted with 2 equiv. of the ethylamine-derived phosphoramidate **4** and methyllithium. This experiment gave the diisonitrile product **5**[10] in 77% yield. Moreover reaction of cation **3** with 1 equiv. of phosphoramidate **4** and methyllithium gave the novel‖ cation **6** in 63% yield. These experiments demonstrate not only that the degree of carbonyl–isonitrile conversion can be controlled by the amount of phosphoramidate used and that the method is useful for the controlled formation of mixed isonitrile complexes, but also that complexes of volatile isonitriles are readily and conveniently formed by this approach.

In view of the rarity of non-racemic chiral isonitrile complexes, phosphoramidate (*S*)-**7** was synthesised from (*S*)-α-methylbenzylamine. Reaction of the anion of **7** with cation **2** smoothly generated the novel cation **8** in 55% yield. Thus the



Scheme 1



Scheme 2

method provides a straightforward and new way of incorporating chirality into transition metal complexes. Moreover, a wide variety of amines, which provide the chirality, is readily available.

Initial experiments on the scope and limitations of the conversion with respect to transition metal substrates have also been performed. Thus the triphenylphosphine-substituted iron cation **9** was synthesised according to a literature procedure[11] and reacted with the anion of phosphoramidate **4** to give the isonitrile **10**[12] in 47% yield. Likewise the manganese acetyl complex **11** was synthesised[13] and reacted with the anion derived from phosphoramidate **4** thus producing the novel manganese isonitrile complex **12** in 72% yield (Scheme 2), and iron pentacarbonyl was reacted with the anions of **1** and (±)-**7** to give isonitrile complex **13**[14] and the novel complex **14** respectively.

Finally, to check the stereochemical consequences of the metal isonitrile synthesis, iron pentacarbonyl was reacted with the anion of (*S*)-**7**. Chiral HPLC analysis of the products** from the reactions of iron pentacarbonyl with the anions of (±)-**7** and (*S*)-**7** revealed that the product derived from (*S*)-**7** was formed in 99 ± 1% ee, indicating that racemisation of the amine does not occur during its incorporation into the isonitrile ligand.

Notes and References

† E-mail: s.gibson@ic.ac.uk

‡ Phosphinimines, $Ph_3P{=}NR$, are known to convert metal carbonyl ligands into metal isonitrile ligands (ref. 5). In contrast to phosphoramidates, however, phosphinimines are frequently moisture and/or air-sensitivity (refs. 5, 6).

§ For example, a recent report on the enantioselective bis-silylation of alkenes using a palladium(0) chiral isonitrile catalyst (ref. 7), represents, to the best of our knowledge, the only use of chiral isonitriles in asymmetric catalysis to date.

¶ The method used for the conversion of cation **2** to cation **3** is in fact typical of the protocols used for all the other carbonyl–isonitrile conversions discussed herein. Thus, Bu^nLi (1.6 mol dm^{-3}; 0.63 cm^3, 1.0 mmol) was added dropwise to a solution of *N*-(*tert*-butyl)phosphoramidate **1** (0.209 g, 1.00 mmol) in THF (10 cm^3) held at −78 °C under nitrogen. The solution was allowed to warm to room temperature and then recooled to −78 °C for the addition, *via* a cannula and under nitrogen, of a suspension of cation **2** (0.350 g, 1.00 mmol) in THF (30 cm^3). The reaction mixture was stirred at −78 °C for 6 h. Solvent removal gave a brown solid which was subjected to column chromatography [SiO_2; light petroleum (bp 40–60 °C)–acetone, 1 : 1]. The resulting yellow solid was crystallised from acetone–CH_2Cl_2 to give cation **3** (0.235 g, 58%) as yellow crystals.

‖ The novel complexes **6**, **8**, **12** and **14** all gave satisfactory spectroscopic (IR, ^1H NMR, ^{13}C NMR and low resolution MS) and microanalytical or high resolution MS data.

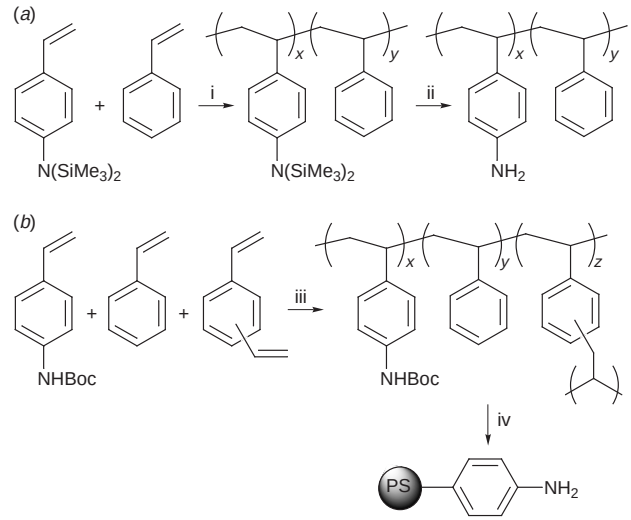
Amino-functionalised polystyrene resins have been synthesised and used as well-defined supports for imidovanadium ethylene polymerisation catalysts; a dramatic enhancement in the lifetime and productivity of the supported catalysts compared to their unsupported (homogeneous) analogues is found.

During the past decade there has been tremendous industrial and academic interest in the development of new generation, highly tunable catalysts for α-olefin polymerisation.[1] Advances in catalyst design, especially the development of well-defined 'single-site' systems,[2] and the technologically significant discovery of high performance cocatalysts such as methylaluminoxane (MAO),[3] have played a key role in driving this interest. A third and equally important component of industrially relevant catalyst systems, especially for those that operate in the gas phase, is the solid support to which the procatalyst and cocatalyst are often attached and through which the resultant polymer morphology may be controlled. A significant proportion of the world's supply of polyolefins is manufactured using catalysts supported on inorganic materials such as $MgCl_2$ (especially Ziegler-type catalysts)[4] or silica (especially chromium catalysts).[5] Silica especially is highly reactive due to the presence of surface hydroxy groups, even after prolonged calcination, and therefore is not particularly well-suited as a support for the latest generation well-defined catalyst systems which may undergo drastic chemical modification upon attachment to the SiO_2 surface. By contrast, inert organic supports can be synthesised with precision and control[6] and are readily functionalised in such a way as to allow a specific well-defined covalent linkage to be formed between the procatalyst, and possibly also the cocatalyst, and the support. Moreover, through free-radical suspension polymerisation methods, spherical polymer beads can be obtained of controlled size and porosity.[7] Carefully tailored organic supports thus offer a potentially significant development in the heterogenisation of well-defined homogeneous olefin polymerisation catalysts. Polystyrene resins impregnated with catalysts have been the focus of recent attention in industrial research laboratories[8] and covalently attached metallocenes have previously been investigated as hydrogenation catalysts.[9]

We describe herein the dramatic influence of an appropriately functionalised polystyrene on the kinetic profile of a model vanadium system. In previous work we have shown that complexes of the type $CpV(NR)Cl_2$ are active procatalysts for ethylene polymerisation.[10] However, it was found that they deactivate within minutes due to a reductive bimolecular decomposition process.[11] Recognising that isolating the active sites within an inert matrix should increase the longevity of this catalyst system, we targeted an appropriately functionalised polystyrene resin that would allow the organometallic procatalyst to be supported without loss of its integrity. In previous work, we have established that *tert*-butylimido ligands can be readily exchanged for arylimido groups upon treatment with an appropriate aniline.[11,12] This methodology offered an opportunity to (covalently) attach imidovanadium procatalysts to an inert organic support.

The amino-functionalised resins shown in Scheme 1 were targeted. The first samples were prepared *via* the living anionic polymerisation method reported by Nakahama and co-workers[13] [Scheme 1(*a*)] which involves silyl protection of the amino functionality followed by copolymerisation with styrene using sodium naphthalenide as an initiator. The resultant linear copolymers‡ were characterised by ^1H NMR spectroscopy and by GPC. The proportion of amino styrene in the polymer was determined by integration of the trimethylsilyl resonance (δ 0.05) *versus* the polystyryl backbone hydrogens. For this study we did not seek to obtain information concerning the uniformity of blockiness of the distribution of the aminostyryl units. After deprotection with HCl, the amino-functionalised polystyrene was treated with a toluene solution of $CpV(NBu^t)Cl_2$ for several days at 80 °C during which time the polymer took on the dark red coloration of the half-sandwich imido complex (Scheme 2). This supported procatalyst was then tested for ethylene polymerisation in a 1 l reactor; the results are collected in Table 1.

For comparison purposes, entry 1 shows the result of a polymerisation experiment using unsupported $CpV(NBu^t)Cl_2$ which, in combination with diethylaluminium chloride (DEAC) cocatalyst, is short-lived (< 10 min) and affords a catalyst productivity of 6.8 g mmol^{-1} h^{-1}. By contrast, treatment of the polystyrene-supported procatalyst with DEAC at 50 °C in the presence of ethylene (10 atm) affords a catalyst productivity of 77.2 g mmol^{-1} h^{-1}. Significantly, however, a steady rate of ethylene uptake ensues over the 60 min duration of the run and the polymer was obtained as a flocculent product rather than the stringy material obtained from homogeneous polymerisations.[10] The polyethylene product is unimodal, of relatively

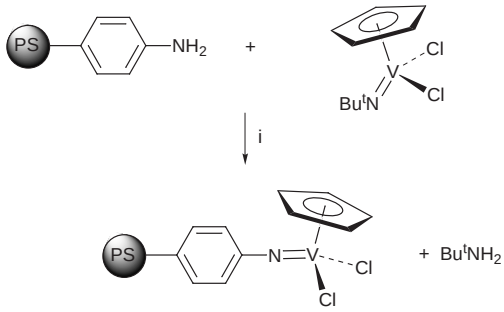


Scheme 1 *Reagents and conditions*: i, ii, ref. 13; iii, styrene, divinylbenzene, Boc-protected vinylaniline dissolved in chlorobenzene. The initiator AlBN (2 mol%) and monomer solution added to water (100 cm^3) containing calcium orthophosphate, calcium sulfate and poly(vinylpyrrolidone) as droplet stabilisers, stirring speed 200 rpm, 15 h; iv, HCl (aq) (12.6 M), THF, ultrasonic bath, 1 h

Table 1 Results of ethylene polymerisation

Run	Procatalyst[a]	Aminostyrene (mol%)	Activator (equiv.)	Ethylene pressure/atm	*T*/°C	*t*/min	Yield/g	Productivity§/ g mmol^{-1} h^{-1}
1	CpV(NBu^t)Cl$_2$ (unsupported)	—	DEAC (40)	10	50	60	1.00	6.8
2	PS–N=VCpCl$_2$	6.3	DEAC (34)	10	50	60	10.8	77.2
3	PS–N=VCpCl$_2$	6.3	DEAC (34)	10	75	60	1.9	13.7
4	PS–N=VCpCl$_2$	6.3	MAO (1000)	10	50	60	11.4	81.4
5	PS′–N=VCpCl$_2$	4.5	DEAC (20)	1	25	60	2.1	10.7

[a] PS = linear styrene–*p*-aminostyrene copolymer: PS′ = polystyrene–*p*-aminostyrene beads.



Scheme 2 *Reagents and conditions*: i, toluene, 80 °C, 9 d

high molecular weight (M_w 1.9 × 10^6, M_n 3.9 × 10^5) with little branching (< 1 per 5000 carbons) and with a molecular weight distribution (M_w/M_n) of 4.9. Raising the reactor temperature to 75 °C (entry 3) led to a reduction in productivity indicating that catalyst deactivation starts to become significant at elevated temperature. The use of a large excess of methylaluminoxane (MAO), in place of DEAC cocatalyst, whilst also giving a long-lived catalyst, did not lead to a significant increase in productivity.

The study was then extended to amino-functionalised cross-linked polystyrene beads [Scheme 1(*b*)] as a first step towards controlling the morphology of the resultant polyethylene particles. A mixture of Boc-protected *p*-aminostyrene, styrene and divinylbenzene was polymerised in an equal volume of chlorobenzene in a conventional suspension polymerisation reactor to give solvent expanded highly cross-linked (~ 12% mol%) spherical beads of fairly uniform diameter (typically 100–150 μm). After deprotection and treatment with CpV(NBu^t)Cl$_2$ under analogous conditions to those described previously, polymerisation at room temperature, this time at 1 atm ethylene pressure, gave a productivity of 10.7 g mmol^{-1} h^{-1}, a figure of merit comparable to the other supported catalysts. Once again steady uptake of ethylene was observed over the 60 min duration of the run.

In summary, the results described here on a model vanadium catalyst system highlight a strategy for covalently attaching transition metal procatalysts to an inert polystyrene support, and importantly demonstrate that dramatically improved kinetic profiles for the polymerisation of ethylene relative to their unsupported analogues can be obtained. There is considerable potential for extending this approach to differently functionalised polystyrenes that will be suited to other classes of transition metal procatalyst, offering the possibility for developing well-defined supports tailored to specific well-defined organometallic procatalysts. The fragmentation of the support will be an important future consideration for controlling the shape and morphology of the growing polyethylene particles.

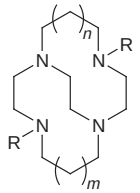
Ultra rigid cross-bridged tetraazamacrocycles as ligands—the challenge and the solution

Timothy J. Hubin,[a] James M. McCormick,[a] Simon R. Collinson,[a] Nathaniel W. Alcock[b] and Daryle H. Busch*[a]†

[a] *Chemistry Department, University of Kansas, Lawrence, KS 66045, USA*
[b] *Chemistry Department, University of Warwick, Coventry, UK CV4 7AL*

The challenge to metal ion binding that is represented by the proton-sponge nature of two-carbon cross-bridged tetraazamacrocycles has been overcome and a general method developed for the synthesis of their transiton, and other, metal complexes; these ultra-rigid ligands form complexes having remarkable kinetic stabilities.

According to modern coordination chemistry principles,[1] ligands of great rigidity impart enormous kinetic stability to their complexes, and such a property facilitates the exploitation of transition metal ions in biomimicry, catalysis, and numerous other areas. In this context, we have reexamined the cross-bridged tetraazamacrocycles[2,3] of Weisman and Ciampolini and focus on the *ultra-rigid* two-carbon cross-bridged ligands[2] **1**–**7**.



1 *n* = *m* = 0, R = H
2 *n* = *m* = 0, R = Me
3 *n* = *m* = 0, R = Bn
4 *n* = *m* = 1, R = H
5 *n* = *m* = 1, R = Me
6 *n* = *m* = 1, R = Bn
7 *n* = 1, *m* = 0, R = Me

These ligands are proton sponges (for **5**, $pK_{a1} > 24$ and $pK_{a2} = 10.8$).[2] Consequently, in protonic solvents only the proton-like Li^+ ion[2] and the most strongly binding divalent transition metal ions, Cu^{2+} and Ni^{2+}, form complexes with such ligands.[4]

We have overcome this obstacle; reaction of anhydrous metal salts with strictly deprotonated ligands (distillation from KOH after extraction from pH ⩾ 14 water) in rigorously dry aprotic solvents under a dry, inert atmosphere has yielded the first complexes of a broad array of transition metal ions. With routinely high yields, complexes of Cr^{II}, Mn^{II}, Mn^{III}, Fe^{II}, Fe^{III}, Co^{II}, Ni^{II}, Cu^{I}, Cu^{II} and Zn^{II} have been obtained.‡ In many cases, elimination of any source of protons is crucial for complexation. X-Ray crystal structures have been obtained of the Mn^{II}, Mn^{III}, Fe^{II}, Fe^{III} , Co^{II}, Ni^{II}, Cu^{I}, Cu^{II} and Zn^{II} complexes with ligands having 12- and 14-membered rings and a variety of R groups. In all cases, the ligand is folded, and in most cases it occupies two axial and two *cis* equatorial sites of a distorted octahedra. Exceptions occur with pentacoordinate copper(II) and tetracoordinate copper(I). For complexes of **5**, there is a clear correlation between the ionic radius of the metal ion and the N_{ax}–M–N_{ax} bond angle, which increases smoothly from Mn^{II} through Cu^{II} as the smaller metal ions can more easily be engulfed by the macrobicycle. Mn^{II}(**5**)Cl_2 (Fig. 1) exemplifies these structures,§ and in this example the N(3)–Mn(1)–N(4) angle is 158.0°.

Because of their great importance in catalysis[5] and bio-inorganic chemistry,[6] this report focuses on the manganese, iron and copper derivatives. Magnetic susceptibility data for [Mn(**5**)Cl_2] indicates that it is high spin d^5. Accordingly, there are no intense electronic transitions and the X-band EPR spectrum in EtOH at 77 K contains a six-line signal centered at $g = 2.026$. The cyclic voltammogram of [Mn(**5**)Cl_2] in MeCN exhibits reversible oxidation-reduction processes at +0.585 (Mn^{2+}/Mn^{3+}) and +1.343 V (Mn^{3+}/Mn^{4+}) *versus* SHE that are sensitive to solvent, macrocycle ring size and N-substitution. Since the proton-sponge behavior of the ligands that complicates complexation also interferes with the potentiometric determination of stability constants, other methods have been used to demonstrate the exceptional stabilities of these complexes. [Fe(**2**)Cl_2] and [Fe(**5**)Cl_2] show no degradation in either acidic (pH 1) or basic (pH 13) aqueous media in air for periods up to one month. After standing for several weeks in aqueous 2 M NaOH in air at room temperature, [Mn(**5**)Cl_2] produced a pure Mn^{III} complex and only traces of MnO_2 (probably from unreacted Mn^{2+} impurities).

Copper(II), known for forming the most stable, yet most labile, divalent transition metal complexes, provides a fascinating insight into the stabilities of these ultra-rigid complexes. The UV–VIS spectrum of a 0.1 mM solution of Cu(**5**)$^{2+}$ in 1 M $HClO_4$ remains unchanged over several weeks at 40 °C; from estimated errors, the lower limit of the half-life for ligand dissociation is > 6 years. This is to be compared with the rate of dissociation of Cu(tmc)$^{2+}$ (tmc = *N*,*N*′,*N*″,*N*‴-tetramethylcyclam) whose ligand is the nearest unbridged structural analogue of **5**. The ligand tmc differs from **5**, hypothetically, by breaking the C–C bridge bond and converting the residual methylenes into methyl groups. The half-life of Cu(tmc)$^{2+}$ at 25 °C in 1 M HNO_3 is only 2.0 s (calculated from the rate law[7]), at least eight orders of magnitude smaller than that of Cu(**5**)$^{2+}$. ($> 2 \times 10^8$ s

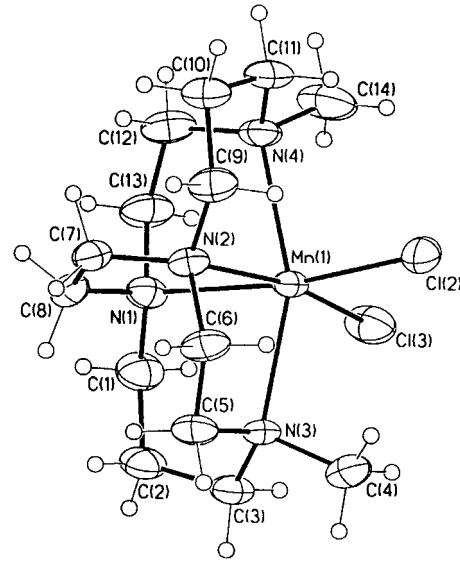


Fig. 1 Molecular structure of [Mn(**5**)Cl_2]. Selected bond lengths (Å) and angles (°): Mn(1)–N(1) 2.347(4); Mn(1)–N(2) 2.332(4); Mn(1)–N(3) 2.325(4); Mn(1)–N(4) 2.333(4); Mn(1)–Cl(2) 2.456(2); Mn(1)–Cl(3) 2.455(2); N(3)–Mn(1)–N(4) 158.0(2); N(1)–Mn(1)–N(2) 75.6(2); Cl(2)–Mn(1)–Cl(3) 98.85(6).

in 1 M $HClO_4$). The classic example of a kinetically stable Cu^{2+} complex,[8] $Cu(tet\text{-}A)^{2+}$ (tet-A = 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane), provides significant comparisons. Its blue isomer is believed to contain tet-A in the folded form, the same conformation that the bridged cyclam ligand is forced to adopt. This complex, *cis*-$Cu(tet\text{-}A)^{2+}$, loses its macrocyclic ligand in 6.1 M HCl with a half-life of about 3 min; replacement of the six *C*-methyls in tet-A by two *N*-methyl groups and the short two-carbon cross-bridge in **5** increases the kinetic stability of the corresponding complex by at least six orders of magnitude. Even the square planar red isomer of $Cu(tetA)^{2+}$ is at least 100 times more labile than the folded bridged cyclam complex $Cu(\mathbf{5})^{2+}$. Hence ultra-rigid, cross-bridged tetraazamacrocyclic complexes are indeed ultra-stable, at least in the kinetic sense.

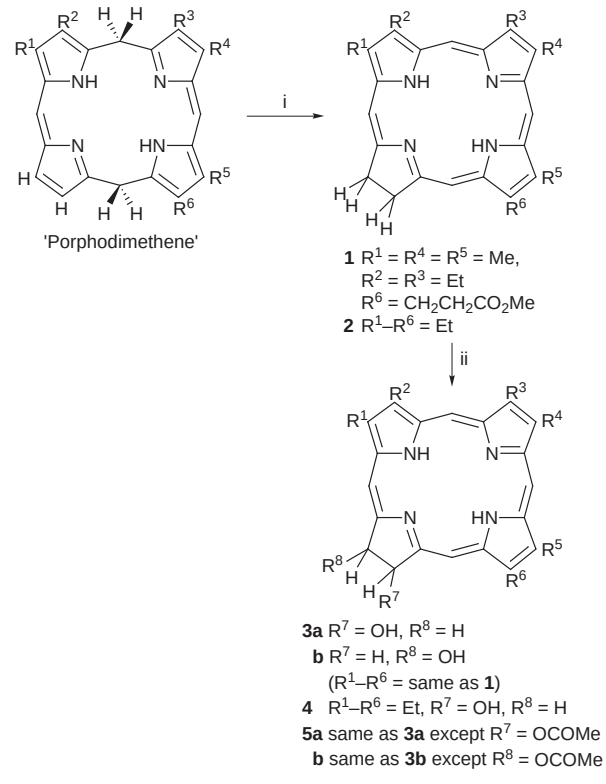
The mono-hydroxylation of a β-methylene carbon in the pyrroline ring of a chlorin requires only alumina and molecular oxygen as reagents, with good yields (70–80%) of the hydroxy chlorin obtained at room temperature in 2 h; this is the first example of a hydroxylated chlorin that has been prepared in a regiospecific manner starting from a chlorin, and the first demonstration of the mild activation of a C–H bond by alumina for its oxidation into a hydroxy group.

Chlorins serve as prosthetic groups for proteins that perform a diverse set of biological functions. Magnesium chlorins (chlorophylls) are found in the photosynthetic proteins of green plants.[1] Iron chlorins are the prosthetic groups for a number of redox proteins, such as the heme in sulfmyoglobin,[2] in the green catalases from *Neurospora crassa* and *Escherichia coli*,[3] as well as the heme (heme *d*) in cytochrome *d* of *E. coli*.[4] Additionally, several dihydroporphyrins have been isolated from marine organisms, such as the sex-differentiating pigment, bonellin, as well as (possible antioxidants) tunichlorin, cyclopheophorbide and chlorophyllone *a*.[5] Like porphyrins, the hydroporphyrins are ubiquitous in nature.

A major thrust of our efforts has been the development of facile methods to prepare the chlorin macrocycle in a regioselective manner directly from linear tetrapyrroles, and also to develop useful pathways for their further elaboration. In this latter vein, we now report the facile mono-hydroxylation of chlorins **1** and **2** (Scheme 1) on their β-methylene carbons in the pyrroline ring. Hydroxylated chlorins are of interest because the iron chlorin prosthetic group of the bacterial oxidases, heme *d*, is thought to contain a bis-hydroxylated pyrroline ring.[4] The hydroxy functional group modifies the heme *d*'s π-system, enabling it to more strongly bind molecular oxygen than heme *b* (protoheme),[6] and presumably making it less prone to oxidation. Additionally, hydroxylated chlorins have elicited interest because they exhibit potential as PDT agents.[4b] The new and simple oxidation reported here represents the first example of a hydroxylated chlorin that has been prepared in a regiospecific manner starting from a chlorin.§ Even more interesting, these results are the first demonstration of the mild activation of a C–H bond by alumina for its oxidation into a hydroxy group.¶

Preparation of chlorins **1** and **2** *via* rearrangement of their metallated porphodimethenes,[9] occurred in a regioselective manner (*i.e.* only one pyrroline ring isomer produced), as shown in Scheme 1. Monohydroxylation of chlorin **1** furnished chlorins **3a**,**b**, while mono-hydroxylation of the more symmetrically substituted chlorin **2** furnished only the one chlorin **4**. In each case, oxidation was confined to the pyrroline ring. The oxidation′s experimental procedure was simple and straightforward. A column was prepared with a slurry of Grade 3 alumina gel,‖ and a solution of the chlorin was allowed to penetrate the alumina gel column to maximize the surface area of adsorption. The mixture was allowed to stand for 2 h, whereupon the hydroxylated chlorin was eluted off the column. This remarkable oxidation of the β-carbon resulted in 70–80 % yields of the mono-hydroxylated chlorin, with little oxidation of the macrocycle to porphyrin. While chlorin isomers **3a** and **3b** were not separated efficiently by chromatography, isomer **3a** crystallized out of hexane–EtOAc in preference to **3b** (as determined by a difference NOE experiment).

The hydroxylated chlorin **3a** was characterized by IR, UV–VIS and NMR spectroscopy and high resolution mass spectrometry and elemental analysis, as well as by chemical transformation (*vide infra*).** The 400 MHz ^{1}H NMR spectrum of chlorin **1** in $CDCl_3$ exhibited a singlet proton resonance at δ 4.60, indicative of the four hydrogens on the pyrroline ring.[9] The substitution of a pyrroline ring hydrogen with a hydroxy group produced a spectrum that exhibited three new resonances for the three remaining protons on the pyrroline ring, which resonated as doublets of doublets at δ 6.60, 4.78 and 4.38, while the hydroxy proton resonated as a broad singlet at δ 2.61. The COSY spectra of chlorin **3a** (Fig. 1) clearly shows that the three proton resonances at δ 6.60, 4.78 and 4.38 are coupled to each other, as would be expected from the three protons on the pyrroline ring. Further corroboration of the structure of chlorin **3a** came from a comparison of the DEPT spectra of chlorin **1** and **3a** (Fig. 2). The spectra exhibit similar methoxy ester and ring methyl and methylene substituent ^{13}C resonances at δ 52.0 and < 22, respectively. The difference in the resonances of the pyrroline ring β-carbons was striking, however. Chlorin **1** exhibited three methylene resonances between δ 36–38, indicative of the two pyrroline ring β-carbon methylenes and



Scheme 1 *Reagents and conditions*: i, $Zn(OAc)_2$, 65 °C; ii, Al_2O_3, O_2, 25 °C

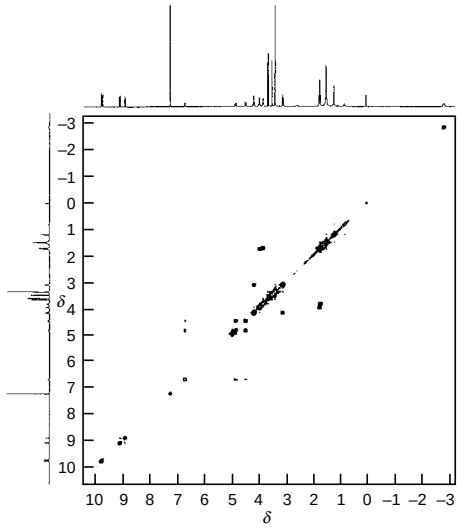


Fig. 1 400 MHz COSY spectrum of chlorin **3a** ($CDCl_3$)

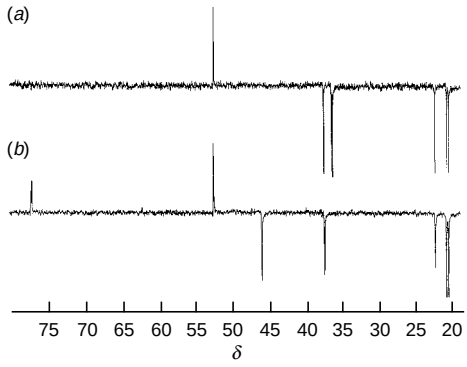

Fig. 2 100.5 MHz DEPT spectra ($3\pi/4$ pulse angle) of chlorins (*a*) **1** and (*b*) **3a** ($CDCl_3$). Peaks directed up are due to methyl and methine carbons, peaks directed down are due to methylene carbons.

the propanoate methylene adjacent to the carbonyl. While chlorin **3a** exhibited a similar propanoate methylene resonance at δ 37, the pyrroline ring β-carbon ^{13}C resonances were markedly shifted downfield. The one remaining methylene β-carbon exhibited a resonance at δ 45, and the carbon that contained the hydroxy functional group exhibited a new methine resonance at δ 77.

The mechanism of the oxidation is not well understood. The mono-hydroxylation of chlorins **1** or **2** required the presence of both alumina and molecular oxygen; no reaction occurred when the solvent was degassed with argon and the column packed and run in a glove box. Zn-chlorins were hydroxylated in the same manner as free-base chlorins, and the reaction took place in the dark. Bis-hydroxylation was not observed, even when the chlorins were left on the alumina for extended periods of time (at room temperature). One might speculate that in the tight confines of the basic alumina surface, adsorbed chlorin could be deprotonated at the pyrroline ring.†† Reaction of the newly formed chlorin anion with correctly positioned adsorbed triplet oxygen to form the chlorin radical, followed by recombination with a hydroxyl radical, is a scenario similar to the much slower, basic solution oxidation (allomerization) observed with chlorophyll *a*. The latter mechanism requires formation of an (exocyclic ring) enolate that reacts with triplet oxygen to form the chlorophyll radical, which then recombines with a hydroxyl radical to form the 13^2-hydroxy chlorophyll derivative.[11] Recombination of the chlorin radical with triplet oxygen to form the peroxyl radical, followed by decomposition to form the hydroxy group, cannot be ruled out. However, in the allomerization of chlorophyll *a*, this leads to the formation of a carbonyl and not a hydroxy functional group. While there are literature examples of hydroxy groups that undergo addition to alkenes and epoxides in the presence of alumina,[7] there is no precedence for the hydroxylation of an unfunctionalized carbon.

The hydroxylated chlorins were stable to air oxidation (unlike chlorin **1**, which slowly formed porphyrin), and stable to high temperatures under vacuum. Under strongly acidic conditions (H_2SO_4, MeOH), chlorin **3a** was slowly transformed into porphyrin (half-life of 24 h), presumably *via* loss of water. The Zn-metallochlorin was easily formed, and demetallation with TFA produced no porphyrin. Due to the apparent stability of chlorins **3** and **4**, it was anticipated that the hydroxy function could be utilized to allow for the further elaboration of the chlorin macrocycle. As an initial attempt, acetylation of a mixture of **3a** and **3b** (Ac_2O, pyridine, 10 mol% DMAP) furnished chlorins **5a** and **5b** (Scheme 1) in 95% yield. The production of **5**, which exhibited a pyrroline ring methine ester proton resonance at δ 7.65, and an acetate methyl proton resonance at δ 2.20, was additional proof for the structure of the hydroxy chlorin. Further study of the chemistry of hydroxy chlorins and their derivatives, and their use in the preparation of more complex molecules, is an ongoing project in our group.

We thank J. Homan for his assistance in the preparation of chlorin **3a**. D.H.B. gratefully acknowledges the support of this work by the National Science Foundation (CHE - 9508653), and for the support of NSF in the purchase of a departmental 400 MHz NMR spectrometer (CHE-9700421).

§ Vicinal bis-hydroxy chlorins have been prepared from porphyrins with OsO_4. The formation of the bis-hydroxy chlorins in this manner produces four regioisomers when starting from asymmetrically substituted porphyrins (ref. 4).

¶ The utilization of alumina for the oxidation of hydroxy compounds (ref.7) or the dehydrogenation of arenes (ref. 8) required an oxidant other than oxygen, or a transition metal catalyst plus oxygen.

‖ The oxidation reaction has been accomplished with several different batches of neutral alumina (60–325 mesh), received from Fisher Scientific.

** The IR spectrum of chlorin **1** exhibited only one absorption above 3000 cm^{-1} at 3345 cm^{-1}, indicative of the N–H stretch, while the hydroxy chlorin **3a** exhibited two absorptions above 3000 cm^{-1}, one at 3342 (with a shoulder at 3430) cm^{-1} and a second, weaker absorption at 3586 cm^{-1}, indicative of the N–H and O–H stretches, respectively. The UV–VIS spectrum of chlorin **3a** shows a small (10 nm) hypsochromatic shift of the Q band relative to chlorin **1**. Both HRFABMS and elemental analysis were consistent with the hydroxy chlorin.

†† Deprotonation of the pyrroline hydrogens on tetraphenylchlorin occurs with *tert*-butoxide (ref. 10).

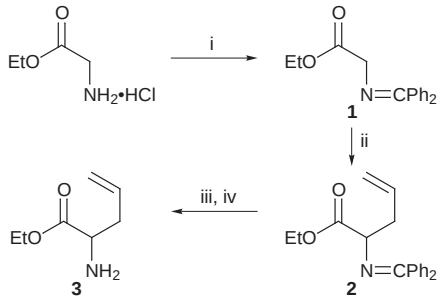
Solution- and solid-phase synthesis of novel hydantoin and isoxazoline-containing heterocycles

Kyung-Ho Park,[a] Eric Abbate,[a] Samir Najdi,[b]† Marilyn M. Olmstead[a] and Mark J. Kurth*[a]‡

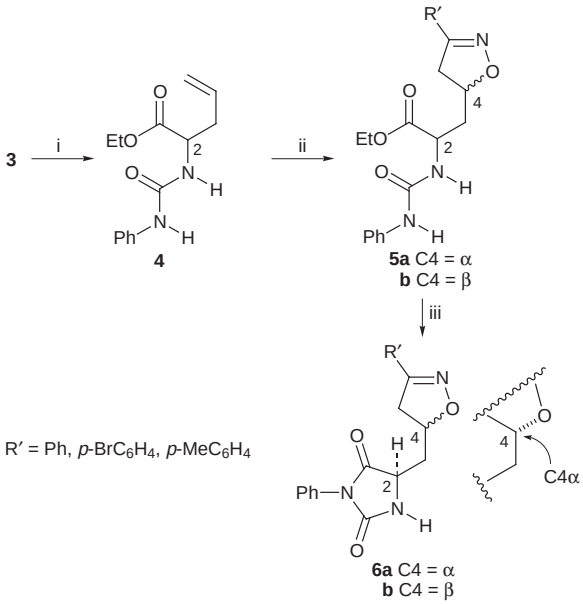
[a] *Department of Chemistry, University of California, One Shields Avenue, Davis, CA 95616, USA*
[b] *Department of Chemistry, Al-Quds University, East Jerusalem, Israel*

Exploiting 1,3-dipolar cycloaddition and carbanilide cyclization transformations, novel isoxazolylmethylimidazolidinedione heterocycles have been prepared using both solution- and solid-phase methods.

The hydantoin moiety has important medicinal[1] as well as agrochemical[2,3] activities and a large number of hydantoins have been synthesized for various biological applications.[4] Moreover, the isoxazoline heterocycle has been used extensively to modulate various other biologically active motifs.[5] As part of our efforts toward the preparation and biological evaluation of novel hydantoin-containing heterocycles, we disclose here a useful route for the synthesis of isoxazoline-containing hydantoins[6] as well as present a synthetic strategy applicable to solid-phase combinatorial approaches.



Scheme 1 *Reagents and conditions*: i, $HN{=}CPh_2$, CH_2Cl_2, room temp., ii, allyl bromide, NaH, DMF, room temp.; iii, HCl (1 M); iv, NaOH (1 M)



Scheme 2 *Reagents and conditions*: i, PhN=C=O, CH_2Cl_2, room temp.; ii, RCH_2NO_2, PhN=C=O, Et_3N, THF, 60 °C; iii, NaOEt, EtOH, room temp.

The condensation of glycine ethyl ester HCl salt with benzophenone imine gave benzophenone Schiff base **1**[7] (5 mmol scale, 95% yield) which was alkylated with allyl bromide to give protected amino ester **2** (5 mmol scale, 90% yield) (Scheme 1). Hydrolysis of the imine moiety in **2** with aq. HCl and subsequent neutralization of the resulting ammonium salt with aq. NaOH delivered **3** (5 mmol scale, 86%).

The free amine of **3** was reacted with phenyl isocyanate in CH_2Cl_2 at ambient temperature for 2 h to give urea **4** in 90% yield (5 mmol scale) (Scheme 2). 1,3 Dipolar cycloaddition to the alkene in **4** with a Mukaiyama-generated nitrile oxide[8] gave isoxazoline heterocycle **5**[9] as a C4α and C4β mixture of

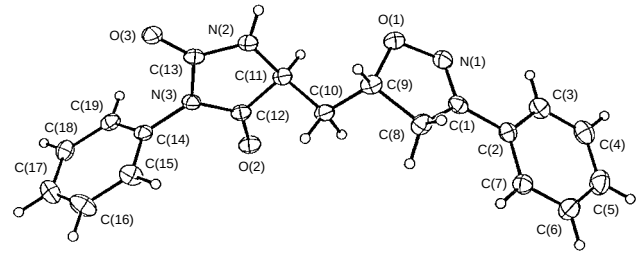


Fig. 1 Crystallographic projection of 6a (R = Ph)

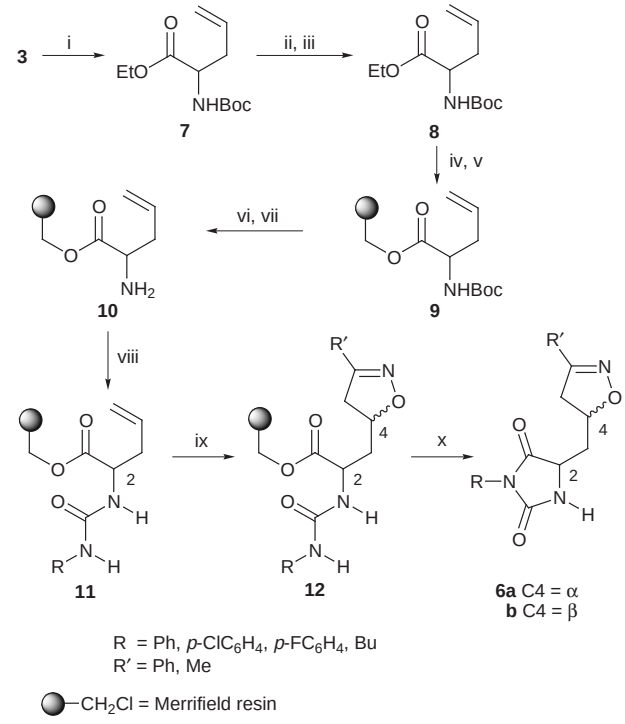

Scheme 3 *Reagents and conditions*: i, Boc_2O, CH_2Cl_2, reflux; ii, NaOH (1 M); iii, HCl (1 M); iv, KOH; v, 18-crown-6, Merrifield resin, DMF, 70 °C; vi, TFA, CH_2Cl_2; vii, Et_3N, CH_2Cl_2; viii, RN=C=O, CH_2Cl_2, room temp.; ix, $R'CH_2NO_2$, PhN=C=O, Et_3N, THF, 60 °C; x, Et_3N, THF, 60 °C

diastereomers (4 mmol scale, **5a** : **5b** : 1 : 1 ratio, yield 60–70%). While separable by flash-column chromatography, each diastereomer of **5** gave the same mixture of two diastereomeric isoxazoloimidazolidinediones **6** upon treatment with NaOEt (1.0 equiv.) in EtOH. Due to this propensity for C2 epimerization during the carbanilide cyclization (**5a**→**6a** + **6b** or **5b**→**6a** + **6b**; 4 mmol scale; **6a** : **6b** : 1 : 1; 80% yield), it was in fact most expedient to effect this transformation on the **5a**/**5b** mixture. X-Ray crystallographic analysis§ of **6a** (R = Ph) (Fig. 1) verified the relative stereochemistries of **5a**/**5b** and **6a**/**6b**.

Our solid-phase approach[10] to isoxazolylmethylimidazolidinedione **6** began with amino ester **3**, which was Boc-protected to give **7** (4 mmol scale, 95% yield) (Scheme 3). Saponification delivered **8** (4 mmol scale, 90% yield) which was coupled with Merrifield resin to give resin **9.**[11]¶ TFA-mediated removal of the Boc protecting group followed by a resin wash with Et_3N–CH_2Cl_2 delivered **10**, the solid-phase analog of **3**. Paralleling the solution results, isocyanate treatment of **10** gave urea **11** and subsequent 1,3-dipolar cycloaddition with a Mukaiyama-generated nitrile oxide gave **12**. A *ca.* 1 : 1 mixture of isoxazolylmethylimidazolidinedione diastereomers (**6a**/**6b**) was obtained on cyclative release.

We thank the National Science Foundation and Novartis Crop Protection AG for financial support of this research.

§ *Crystal data:* for **6a** (R = Ph): $C_{19}H_{17}N_3O_3$, colorless crystals, M = 335.36, orthorhombic, space group *Pbca*, a = 9.0062(11), b = 11.1037(10), c = 32.472(3) Å, U = 3247.3(6) Å^3, Z = 8, D_c = 1.372 Mg m^{-3}, μ = 0.776 mm^{-1}, R = 0.0392, wR = 0.0955, GOF = 1.092, T = 130(2) K, F(000) = 1408, 2189 independent reflections were collected on a Syntex $P2_1$ diffractometer using graphite-monochromated Cu-Kα radiation. CCDC 182/917.

¶ Typical procedure for solid-phase isoxazolylmethylimidazolidinedione synthesis: Boc-protected glycine acid **8** (130 mg, 0.6 mmol) was neutralized (room temp., 1 h) with KOH (1.0 equiv., 0.6 mmol) in EtOH–H_2O (2:1) and, after removing the solvent and drying *in vacuo*, the potassium salt was dissolved in DMF (20 ml) and reacted with Merrifield resin (300 mg, 0.3 mmol; loading *ca.* 1 mmol Cl g^{-1}) and 18-crown-6 (158 mg, 0.6 mmol). The resulting mixture was stirred at 70 °C for 40 h and then washed with DMF (20 ml), THF (20 ml), THF–H_2O (20 ml× 2), and THF (20 ml). Dried resin **9** (ν_{max}/cm^{-1} 1723) was treated with 50% TFA–CH_2Cl_2 (20 ml) at ambient temperature for 1 h, after which time the resin was washed with CH_2Cl_2 (20 ml), dioxane (20 ml) and CH_2Cl_2 (20 ml× 2). An Et_3N wash (10% in CH_2Cl_2, 20 ml) followed by CH_2Cl_2 washes (20 ml× 2) gave resin **10** (ν_{max}/cm^{-1} 3383, 1735). Phenyl isocyanate (107 mg, 0.9 mmol) in CH_2Cl_2 (20 ml) was added and, after 10 h at ambient temperature, the resin was washed with DMF (20 ml), THF (20 ml) and CH_2Cl_2 (20 ml) and dried to give resin **11** (R = Ph; ν_{max}/cm^{-1} 1740, 1700, 1662). α-Nitrotoluene (123 mg, 0.9 mmol), phenyl isocyanate (214 mg, 1.8 mmol) and Et_3N (10 µl) were added to this resin in THF (20 ml). After incubating at 60 °C for 20 h, washing the resin with DMF (20 ml), THF (20 ml) and CH_2Cl_2 (20 ml) gave resin **12** (R = R′ = Ph; ν_{max}/cm^{-1} 1738, 1699) which was finally treated with Et_3N (1 ml) in THF (20 ml) at 60 °C for 20 h. Resin was removed from the liberated product to give **6a**/**6b** (R = R′ = Ph) in 35% overall yield from Merrifield resin. These two isomers were easily separated by flash chromatography (EtOAc–hexane 1:2) to give **6a** (R = R′ = Ph; 16 mg, 16% overall yield) and **6b** (R = R′ = Ph; 19 mg, 19% overall yield). The optimized solid-phase overall yield of **6a** + **6b** is 35%, which translates to *ca.* 84% yield per step from **8**. With catalytic Et_3N, we saw no evidence for formation of **6** in **11**→**12**.

Self-assembly of a supramolecular cube

Sue Roche, Claire Haslam, Harry Adams, Sarah L. Heath and Jim A. Thomas*†

Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF

In one step, 8 octahedral metal 'corners' and 12 ligand 'edges' come together to form a supramolecular cube.

Self-assembly[1] templated by metal ions has been used as a strategy to construct compounds with large cavities.[2] Previously, using pyridyl ligands with two coordination sites and square planar metal complexes as corner templates, two-dimensional squares[3] have been synthesised. Three-dimensional architectures result when ligands with a higher number of coordination sites,[4] or metal ions with tetrahedral[5] or octahedral[6] coordination geometries, are used in the self-assembly process. It has been suggested that an appropriate octahedral metal centre could template the self-assembly of a supramolecular cube.[2] Here, we report the one-step self-assembly of 20 components into such a structure.

Reaction of [([9]aneS_3)Ru(DMSO)Cl_2][7] with a large excess of 4,4-bipyridine, bpy, yielded cationic complex **1** which would appear ideally suited to act as a corner for a supramolecular cube. X-Ray crystallography confirms that the three bpy ligands are oriented at mutual right angles‡ (Fig. 1). As a solid, and in non-coordinating solvents such as dichloromethane and nitromethane, **1** is air and moisture stable. However, solutions of **1** in coordinating solvents are unstable toward solvolysis. Using ^{1}H NMR spectroscopy, the solvolysis of **1** by acetonitrile was monitored. At room temperature, during a process which takes 2 weeks to reach completion, **1** is converted to [([9]aneS_3)Ru(bpy)$(MeCN)_2$]$^{2+}$ which has been isolated as its hexafluorophosphate salt and fully characterised by NMR and mass spectrometry, as well as elemental analysis.

Entropic and enthalpic arguments indicate that discrete supramolecular architectures are favoured over polymeric products.[8] Therefore, it was reasoned that the relative lability of **1** could be used to construct supramolecular architectures. If the correct ratio of metal ions and bpy ligands are mixed together in a non-coordinating environment, these components will undergo substitution processes, searching through possible product states to obtain the thermodynamically most stable product. Using nitromethane as the non-coordinating solvent, [([9]aneS_3)Ru(DMSO)Cl_2] was treated with bpy in an 8 : 12 stoichiometry and the reaction was monitored by ^{1}H NMR spectroscopy.

Changes in the spectral region due to bpy resonances are highly diagnostic of any self-assembly processes.[3a,4] In contrast to the synthesis of **1**, where the final product is obtained within 3 hours (Fig. 2a), a complex mixture of products is initially formed (Fig. 2b). However, further measurements taken over a period of four weeks (Fig. 2c–e) show a gradual simplification towards a single product, **2.** The slight shift observed in the bpy signals of **2** is due to the hygroscopic nature of the complex, causing the reaction solvent to absorb atmospheric water during the course of the experiment. Addition of diethyl ether to the reaction mixture isolates **2** as a hygroscopic, air and moisture stable, brown–black solid. A variety of data confirm that the structure of **2** is a cube (Fig. 3).

When compared to the ^{1}H NMR spectrum of **1,** it is clear that **2** possesses high symmetry as all the 4-pyridyl rings are now equivalent. Furthermore, the integration confirms that the ratio of bpy 'edge' to [9]aneS_3 'corner' protons is 1 : 1. This ratio, and the elemental analysis of **2**, is only consistent with closed, highly symmetrical structures such as a cube, or tetrahedron.

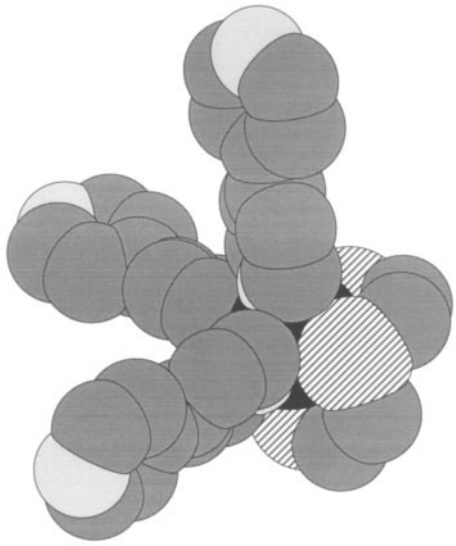

Fig. 1 Space filling model of the crystal structure of cationic complex **1**

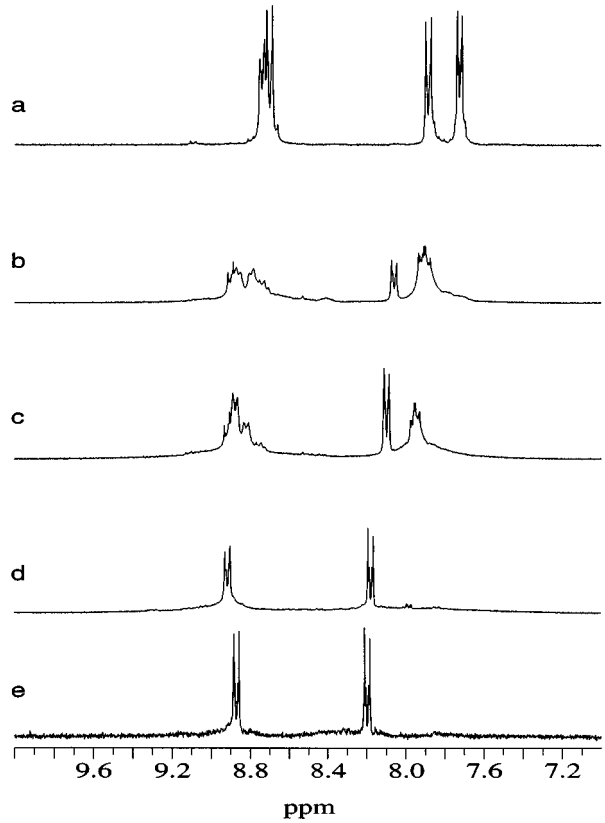

Fig. 2 ^{1}H NMR data for **1** and **2**. a, bpy region (300 Hz in nitromethane) for **1**; b, bpy region (300 Hz in nitromethane) for **2** after 3 days; c, after 1 week; d, after 4 weeks; e, isolated product in MeCN

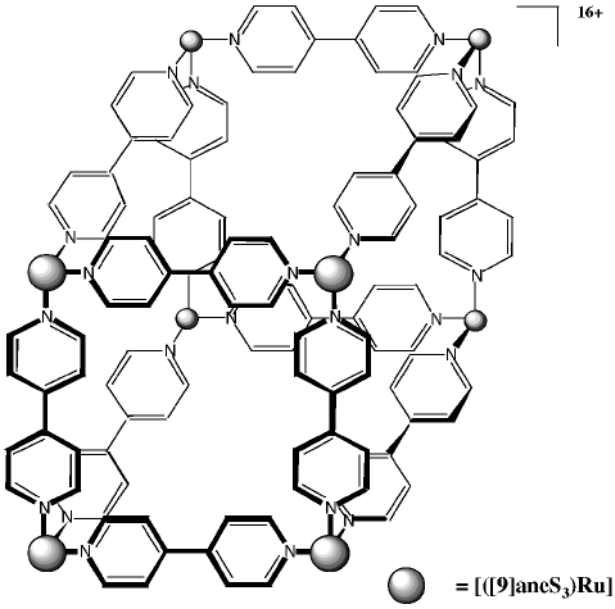

Fig. 3 Structure of **2**

However, structures other than a cube are inconsistent with the crystallographic data for **1** and highly unlikely due to steric reasons**.** For example, a tetrahedral structure would produce strained corners, with three ligands held at mutual 60° angles as they coordinate to each metal ion.

ES-MS studies on **2** show peaks centred on *m*/*z* 285 ($[\mathbf{2}\cdot(CF_3SO_3^-)]^{15+}$ requires 285), 351.8 ($[\mathbf{2}\cdot(CF_3SO_3^-)_3]^{13+}$ requires 351.78) 393.5 ($[\mathbf{2}\cdot(CF_3SO_3^-)_4]^{12+}$ requires 393.5), and 502 ($[\mathbf{2}\cdot(CF_3SO_3^-)_6]^{10+}$ requires 502.1). These peaks are not observed by conventional techniques such as FAB-MS and their shapes are consistent with theoretical isotopic patterns.

Unlike **1**, solutions of **2** in coordinating solvents such as acetonitrile are perfectly stable, showing no changes in their ^{1}H NMR spectra over a period of weeks. Again, this anomalous kinetic stability is only consistent with an unstrained cubic structure for **2**, where cooperative interactions within the assembly will 'lock' the ligands into position.

Complexes incorporating Ru^{II} metal centres bridged by oligopyridyl ligands show electrochemical interactions.[9] If the metal centres of **3** are interacting in this manner they will not all oxidise at the same potential. From simple electronic and electrostatic arguments, it is expected that the oxidation of the metal centres in **2** should occur in four steps. During each step a pair of metal ions in diagonally opposed corners of **2** will be oxidised and, for each oxidation, the required anodic potential should be progressively greater.

The electrochemistry of **2** was investigated using cyclic voltammetry. Since all the oxidation processes for **1** and **2** showed varying degrees of irreversibility E_p was obtained using convolution/deconvolution techniques.[10] In contrast to **1**, which displays only one oxidation process, **2** displays three oxidations. The first oxidation wave is at 1.18 V (*vs.* SCE) while the second and third are at 1.38 V and 1.63 V respectively. The first oxidation wave is notably broader than the second and third, consistent with it incorporating two closely overlapping oxidation couples.

The incorporation of electroactive metal centres into the assembly is significant, it opens up the possibility of constructing a variety of novel molecular devices, such as tuneable sensors or multiple state switches. In this context, the host–guest chemistry of **2**, and physical studies on electron/energy transfer within its molecular architecture, are being investigated. The self-assembly of similar structures incorporating other ligands and metal ions will be described elsewhere.

We gratefully acknowledge the support of The Royal Society (J. A. T., S. A. H.), the EPSRC (S. R.) and Professor Bill Clegg, University of Newcastle-upon-Tyne, for use of the diffractometer.

The azuliporphyrin-carbaporphyrin connection†

Timothy D. Lash*‡

Department of Chemistry, Illinois State University, Normal, Illinois 61790-4160, USA

Under base catalyzed conditions, reaction of azuliporphyrin 3 with *tert*-butyl hydroperoxide affords the benzocarbaporphyrins 2a and 2b; a mechanism for the formation of 2b is proposed.

Recently, diverse monocyclic dialdehydes have been shown to condense with tripyrranes [2,5-bis(pyrrol-2-ylmethyl)pyrroles] under the so-called '3 + 1' conditions[1] to give structural analogs of the porphyrins including oxybenziporphyrin **1**[2] and carbaporphyrins **2**.[3–6] Lash and Chaney reported[4] that azulene-1,3-dicarbaldehyde condensed with a tripyrrane in the presence of 5% TFA in CH_2Cl_2 to give the unique borderline aromatic macrocycle 'azuliporphyrin' **3** (Scheme 1) in good yield. In complete contrast, Breitmaier[5] found that under somewhat different conditions these reactants afforded low yields of benzocarbaporphyrins **2a–c** where the seven-membered ring of the azulene precursor has undergone a ring contraction to give the fused benzo moiety of **2**. No explanation for the origins of these materials was offered, but it should be noted that **2a** can be more directly obtained in excellent yields and isomerically pure form from 1,3-diformylindene.[3] Azuliporphyrin **3** is a cross-conjugated system for which dipolar resonance contributors (*e.g.* **4**) can be written that impart a degree of porphyrinoid aromaticity onto the macrocycle and this view is supported by the observation of a weak diatropic ring current in the proton NMR spectrum of **3**.[4] This feature is greatly enhanced in the presence of acid due to the increased ability of the aromatic species to allow charge delocalization.[4]

1

2a X = Y = H
b X = CHO, Y = H
c X = H, Y = CHO

Scheme 1

During the course of our studies, we noted that addition of small amounts of pyrrolidine to an NMR solution of the sparingly soluble azuliporphyrin caused the green solution to turn brown. The resulting NMR spectrum (Fig. 1) displayed a carbaporphyrin-like ring current[3] where the internal CH was shifted upfield from δ 1.5 in **3** to δ −7 and the external *meso*-protons were similarly deshielded to resonate near δ 10. The seven-membered ring protons nearest to the macrocycle produced a broadened 2H doublet at δ 7.85 and a 2H dd was noted near δ 6. These data implied that **3** had undergone a nucleophilic substitution on the seven-membered ring to give the pyrrolidine–carbaporphyrin adduct **5** (Scheme 1). The process must be regioselective as a single symmetrical isomer dominates the NMR spectrum, but the reaction is reversible and removal of pyrrolidine simply afforded starting material. Further evidence for the formation of a carbaporphyrin structure comes from UV–VIS spectroscopy; addition of pyrrolidine causes a Soret-like band to emerge near 400 nm (Fig. 2).

The observed reactivity of the seven-membered ring suggested that the azuliporphyrin system could be functionalized

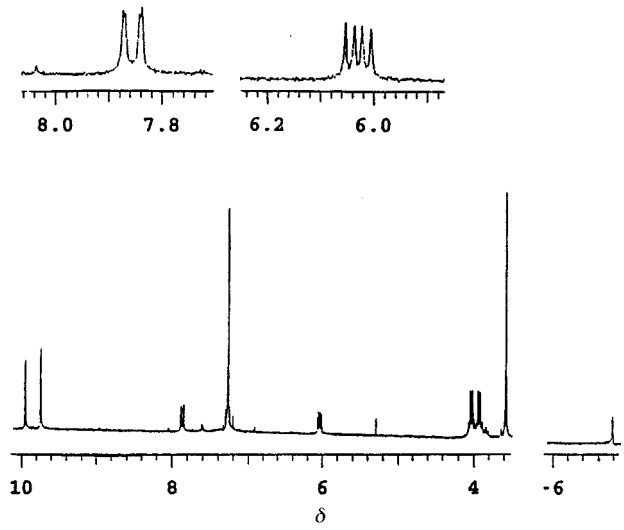

Fig. 1 Partial 300 MHz ^{1}H NMR spectrum of azuliporphyrin **3** in the presence of trace pyrrolidine in $CDCl_3$. The region between δ 1 and 4 is obscured by the pyrrolidine absorptions.

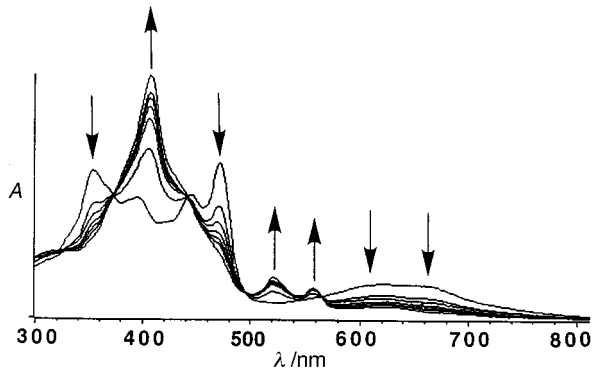

Fig. 2 Electronic absorption spectra of azuliporphyrin **3** in $CHCl_3$ with 0, 1000, 2000, 3000, 4000, 5000 or 9000 equiv. of pyrrolidine. The development of a Soret band near 400 nm is clearly evident.

under suitable reaction conditions. We were particularly interested in the possibility of generating the fused tropone structure **6**, which might be formed by an addition-elimination process. However, attempts to form **6** by reacting **3** with NaOCl were unsuccessful. Alkaline solutions of H_2O_2 reacted with **3** to give complex mixtures of products that appeared to be carbaporphyrins, and this prompted us to investigate the reaction of **3** with *tert*-butyl hydroperoxide. Interestingly, when the reaction was carried out with Bu^{t}OOH (5 equiv.) in KOH–MeOH and CH_2Cl_2 at room temperature, benzoporphyrin **2a** was the main isolatable product (30%) together with a small amount of **2b**. On the other hand, the formyl derivative **2b** was the predominant product (40%) when the reaction was carried out with Bu^{t}OOH and Bu^{t}OK in CH_2Cl_2, although some **2a** (15%) was also isolated in this case. Carbaporphyrin **2a** was identical to our previously synthesized material[3] and structure **2b** was fully characterized by NMR and mass analysis.§

The formation of **2b** can be rationalized by the mechanism shown in Scheme 2. Following nucleophilic attack by the *tert*-butyl peroxide anion, the adduct **7** may undergo a Cope rearrangement to give the cyclopropane **8** and subsequent elimination of *tert*-butyl alcohol would give the aldehyde **2b**. A third carbaporphyrin appears to be present by TLC (very minor) and may correspond to **2c**; this would result from the initial nucleophilic attack occurring at a different position on the azulene ring. The formation of **2a** may also arise from intermediate **8**, in this case by elimination of *tert*-butyl alcohol and carbon monoxide. Aldehyde **2b** cannot be an intermediate in the formation of **2a** as it does not decarbonylate or oxidize under these reaction conditions, although it is possible that **2a** arises from the elusive tropone **6** instead. It is noteworthy that tropylium salts also ring contract, in this case to form benzene, upon oxidation with hydrogen peroxide or MCPBA and a similar mechanism has been proposed for this chemistry.[7] Clearly our observations help to explain the results obtained by the Bonn group, although the complex mixtures of reagents used in their studies makes mechanistic investigations impractical. The new results also demonstrate that isomerically pure functionalized carbaporphyrins are easily obtainable from azuliporphyrin and this will allow further aspects of the chemistry of this remarkable new carbaporphyrin family to be explored.

Two novel reactions of ruthenated aniline. Structure and bonding in bis-chelated ruthenium complexes of quinone related ligands

Kedar Nath Mitra,[a] Shie-Ming Peng[b] and Sreebrata Goswami*[a]†

[a] *Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta, 700032, India*
[b] *Department of Chemistry, National Taiwan University, Taipei, Taiwan, Republic of China*

Two novel examples of oxidative *ortho* coupling of ruthenated aniline are described; the products are fully characterised by X-ray and other physicochemical data.

In a recent communication[1] we reported the formation of $RuCl_2(PhNH_2)_2(L^1)$, **1** (L^1 = *N*-phenyl-1,2-phenylenediimine), from the reaction of hydrated $RuCl_3$ and $PhNH_2$ [eqn. (1)].

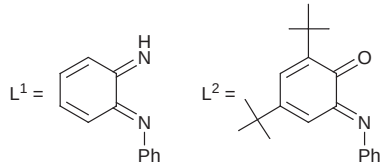
$$RuCl_3{\bullet}3H_2O \xrightarrow{\text{aniline}} \underset{\mathbf{1}}{RuCl_2(PhNH_2)_2(L^1)} \qquad (1)$$

Although ruthenium(II) aniline complexes are known,[2] complex **1** represents the first example of a structurally characterised aniline complex of ruthenium. One of the principal interests in **1** was the possibility to study the chemical reactions of the coordinated aniline. In this report we present two such novel examples.

The reaction of $RuCl_2(PhNH_2)_2(L^1)$ and 3,5-di-*tert*-butylcatechol occurs smoothly in methanol at room temperature to produce a blue compound of composition $RuCl_2(L^1)(L^2)$, **2** [eqn. (2)], in 55% yield. This compound is highly soluble in

$$\underset{\mathbf{1}}{RuCl_2(PhNH_2)_2(L^1)} + \text{3,5-di-}\textit{tert}\text{-butylcatechol} \xrightarrow{CH_3OH} \underset{\mathbf{2}}{RuCl_2(L^1)(L^2)} \qquad (2)$$

common organic solvents and the solution shows an intense transition in the visible region at 627 nm. Verification of the composition and geometry of **2** was ascertained by the



determination of its single crystal X-ray structure.‡ A view of the molecule is shown in Fig. 1 and selected bond distances are collected in Table 1. The results reveal the oxidative coupling of coordinated aniline and catechol to result in an *N*-phenyliminoquinone ligand, L^2, with the formation of a C–N bond. This transformation was not known previously. The formulation of the diimine oxidation state of L^1 (N,N) is evident[1] from the structural data of **2**. The imine C–N bond lengths, average 1.315(6) Å, are considerably shorter than the C7–N2 single bond, 1.444(6) Å, present in the same ligand. Considering the diimine oxidation state of the ligand L^1, two charge distributions for the RuL^2 moiety are possible in the above complex, either Ru^{II}–L^2 BQ (**2a**) or Ru^{III}–L^2 SQ (**2b**). Compound **2** is diamagnetic and shows two sharp *tert*-butyl proton resonances at δ 0.993 and 1.267. The C14–O bond length of the coordinated L^2 is 1.280(5) Å and the C13–N3 bond length is 1.339(6) Å. This C–O bond length is longer than the C=O bond length [1.239(7) Å] observed[3] in free 2,4,6,8-tetra-*tert*-butylphenoxazin-1-one (Phenox BQ) but it falls below the range observed[4] (1.29 Å and above) for a coordinated semiquinone ligand. For comparison, the C–O bond length[3a] in $Ru(PPh_3)_2Cl_2$-(phenox SQ) (phenox SQ = 1-hydroxy-2,4,6,8-tetra-*tert*-butylphenoxyzinyl radical) is 1.300(4) Å and the average C–O bond length[5] in $Ru(bpy)_2(DBSQ)^+$ (bpy = 2,2′-bipyridine, DBSQ = 3,5-di-*tert*-butyl-1,2-semiquinone) is 1.308 Å. The C–N bond length of coordinated L^2 is within the range of values expected[6] for imine ligands. Moreover, the C15–C16 and C17–C18 bonds have almost localised double bond character which is also consistent[4b] with the iminobenzoquinone formulation (**2a**). Their average distance of 1.355(6) Å is significantly shorter than the other four bonds of the ring (Table 1). To the

2a **2b**

best of our knowledge compound **2** represents the first example[7] of a mixed ligand compound containing both 1,2-diimine (N,N) and 1,2-iminoquinone (N,O) which gives an opportunity for the direct comparison of bonding between an (N,N) and an (N,O) donor. Furthermore, we wish to note here that structurally characterised Ru 1,2-diimines (N,N) are scarce[6] and there is only one example[3] of a ruthenium complex of 1,2-iminosemiquinone, the structure of which has been reported. Synthetic difficulties[7] have inhibited the study of iminoquinone complexes.

It was observed that prolonged exposure of a brown solution of **1** to air led to formation of a blue solution. A similar transformation occurs instantaneously and smoothly when a solution of **1** in CH_2Cl_2 is treated with H_2O_2. Chromatographic work up followed by crystallisation of the crude product yielded crystalline $RuCl_2(L^1)_2$, **3**, in 45% yield [eqn. (3)]. The three-

$$\underset{\mathbf{1}}{RuCl_2(PhNH_2)_2(L^1)} \xrightarrow[CH_2Cl_2]{H_2O_2} \underset{\mathbf{3}}{RuCl_2(L^1)_2} \qquad (3)$$

dimensional X-ray structure of **3** authenticates the formation of the compound from reaction (3). The isomer geometry of the ruthenium complex is identical[8] to that of the analogous dibromo osmium complex, $OsBr_2(L^1)_2$. The bond distances of the coordinated diimine ligand in the above two ruthenium and osmium compounds are similar. (Details of the X-ray structure of **3** will be reported elsewhere.) The compound shows an intense transition at 590 nm in the visible region.

The above coupling reactions [(2) and (3)] do not occur with uncoordinated aniline. These reactions therefore may be classified as reactions of the activated coordinated aniline. In reaction (2) one of the coordinated anilines coupled with externally added 3,5-di-*tert*-butyl catechol to form an *N*-phenyl substituted derivative of *o*-iminobenzoquinone.[7] It is possible that oxidation of catechol followed by condensation with the coordinated aniline have occurred during the above transformation. Reaction (3) formally involves many operations which are believed to occur simultaneously: isomerization of the starting compound to bring the two interacting aniline molecules into close proximity, oxidative coupling of two aniline molecules to *o*-semidine and further oxidation of *o*-semidine to diimine. For comparison, the reaction[8] of aniline with $[OsBr_6]^{2-}$ resulted in formation of a bis-chelated complex, $OsBr_2(L^1)_2$, directly. In contrast, a similar reaction[1] using hydrated $RuCl_3$ as the starting material yielded only a monochelated diimine complex, $RuCl_2(PhNH_2)_2(L^1)$, where two out of the four coordinated aniline molecules underwent oxidative dimerisation. Our present results have been able to demonstrate clearly that further oxidative coupling of the coordinated anilines in $RuCl_2(PhNH_2)_2(L^1)$ is possible by the use of a suitable oxidant. Our preliminary results in the area of oxidative coupling reactions of coordinated aromatic amines[2] in $[Ru(ArNH_2)_6]^{2+}$ and related substrates are highly encouraging and the scope of these reactions is very high.

We are grateful to the referees for their suggestions. Financial support received from the Council of Scientific and Industrial Research, New Delhi is gratefully acknowledged.

Novel products from bromination reactions of 5,10,15,20-tetraisopropylporphyrins

Nora Y. Nelson, Craig J. Medforth, Richard G. Khoury, Daniel J. Nurco and Kevin M. Smith*†

Department of Chemistry, University of California, Davis, CA 95616, USA

Bromination reactions of nickel(II) or copper(II) complexes of 5,10,15,20-tetraisopropylporphyrin afford the unusual porphodimethenes 2–5; crystallographic data for some of these compounds are presented and possible mechanisms for their formation are discussed.

2,3,7,8,12,13,17,18-Octahalo-5,10,15,20-tetraarylporphyrins have recently received considerable attention due to their usefulness as catalysts for the oxidation of organic substrates.[1] Although the syntheses and properties of these porphyrins have been extensively investigated, comparatively little is known about the bromination reactions of other porphyrins such as those with alkyl substituents. Bonnett *et al.*[2] have reported that halogenation of deuteroporphyrins preferentially yields peripherally as opposed to *meso* halogenated products, and that attempts to brominate 2,3,7,8,12,13,17,18-octaethylporphyrin (H_2OEP) resulted in bromodealkylation and benzylic-type subsitution reactions. Vicente and Smith[3] have also shown that treatment of H_2OEP with NBS in the presence of AIBN affords *trans*-(2-bromovinyl)heptaethylporphyrin, as well as (1-alkoxyethyl)heptaethylporphyrins when alcohols are present. We have recently described the novel chemical and spectroscopic properties of some 5,10,15,20-tetraalkylporphyrins with isopropyl or *tert*-butyl substituents.[4,5] We now show that one of these porphyrins also yields unexpected and unusual products upon bromination with NBS or Br_2.

When the nickel(II) complex of 5,10,15,20-tetraisopropylporphyrin **1a** was treated with 8 equiv. of NBS, or excess Br_2 in $CHCl_3$ in the dark at room temperature, a dark green solid **2** was isolated as the major product in 7.2 and 46% yield, respectively. The structure of **2**, as determined by X-ray crystallography,‡ is shown in Fig. 1. The structure reveals a cyclic tetrapyrrole in which all of the pyrrole 3,4-positions have been brominated. Remarkably, the macrocycle is no longer a porphyrin but has a porphodimethene-like structure with two exocyclic double bonds on opposite *meso* positions. The molecule also adopts an extremely nonplanar ruffled conformation, with a maximum deviation of the 24 core atoms from the mean plane of 1.44 Å (for a *meso* carbon atom) and an average deviation from the mean plane of 0.57 Å. As is expected for such a nonplanar macrocycle, the average Ni–N distance is very short (1.88 Å). The absorption spectrum, which shows two broad bands at 482 nm (ε 48 100) and 594 (30 700), resembles that of 5,15-dimethyl-2,3,7,8,12,13,17,18-octaethyl-5H,15H-porphinato)nickel(II).[6] The ^{1}H NMR spectrum, which features two sets of methyl protons [δ 1.74 (d, 12H), 2.11 (s, 12H)] and one set of isopropyl methine protons [δ 4.42 (septet, 2H)], is consistent with the observed symmetrical structure.

5 M = Cu

Only a few porphyrins bearing exocyclic double bonds have been described in the literature; these include a cyclic tetrapyrrole bearing four *meso* exocyclic carbonyl groups (octaethylxanthoporphyrinogen),[7] the exocyclic alkene analogue octaethyl-*meso*-tetrakis(methylene)porphyrinogen,[8] and certain oxidation products of *meso*-tetrakis(3,5-di-*tert*-butyl-4-hydroxyphenyl)porphyirn described by Milgrom.[9] The formation of compounds with exocyclic double bonds from the bromination of **1a** suggests that the reaction may involve the addition of HBr or Br_2 across the opposite *meso* carbons of a partially brominated species, followed by elimination of one or two molecules of HBr, respectively, to yield compounds **3** and **4** or compound **2**. Addition of molecules to the porphyrin periphery in this fashion has previously been observed in

When compound **1a** was treated with 8 equiv. or less of Br_2, two other compounds were also isolated. These materials did not yield crystals suitable for X-ray structure determination but the structures **3** (10% yield) and **4** (75%) were established from NMR experiments and mass spectral data. Both compounds share a common porphodimethene-type structure with one exocyclic double bond and one sp^3 *meso* carbon atom. Interestingly, in compound **4** the β-pyrrolic carbons have been brominated in a regiospecific fashion.

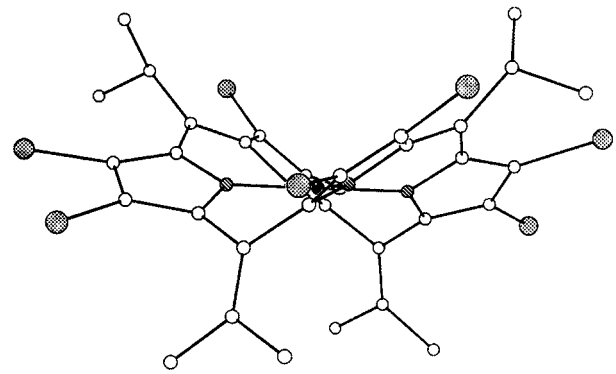

Fig. 1 Molecular structure of **2**. Hydrogen atoms are omitted for clarity.

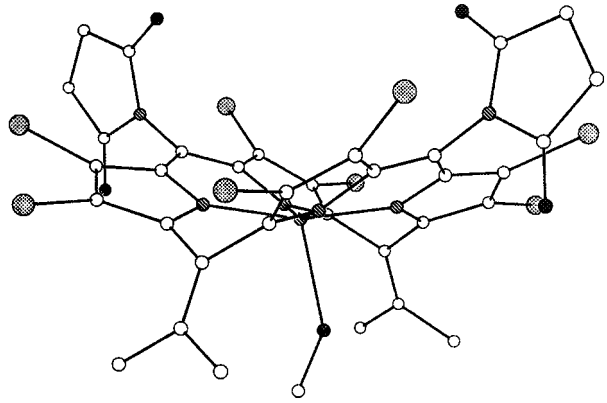

Fig. 2 Molecular structure of **5**. Hydrogen atoms are omitted for clarity.

5,10,15,20-tetra-*tert*-butylporphyrin and some of its metal complexes.[4] We believe that similar addition reactions may occur for compound **1a** because they result in a release of steric congestion between the *meso* isopropyl and the adjacent pyrrole bromo groups. In theory, bromination could also occur at the isopropyl benzylic positions *via* a radical mechanism when NBS is used as the brominating agent. If followed by elimination of the benzylic bromine atom and loss of a methine proton from the opposite isopropyl group, this would also furnish the two opposite exocyclic double bonds seen in compound **2**.

In order to investigate the effects of different metals on the bromination reaction, the copper(II) complex (**1b**) of 5,10,15,20-tetraisopropylporphyrin was treated with 8 equiv. of NBS in $CHCl_3$ in the dark at room temperature. One of three major products (**5**) isolated from this reaction gave high quality crystals enabling its definitive characterization by X-ray crystallography§ (Fig. 2). Compound **5** is similar to compound **2** in that all of the pyrrole positions have been brominated, and the macrocycle has a very ruffled porphodimethene-like structure; the maximum and average deviations of the 24 core atoms from the macrocycle mean plane in **5** of 1.27 and 0.51 Å, respectively, are slightly smaller than those seen for **2**. An unusual feature of the structure is that it no longer has any isopropyl groups attached to the porphyrin periphery! Instead, it bears two exocyclic alkene groups and two succinimido moieties. In addition, the copper atom is penta-coordinated, with a MeOH molecule serving as the fifth ligand (Cu–O 2.29 Å, Cu–$N_{average}$ 1.98 Å**).** This unusual axial ligation is presumably a consequence of the very electron-deficient nature of the macrocycle. It has previously been shown that 5-succinimido-OEP can be obtained when zinc(II)-OEP is treated with NBS in the presence of AIBN.[3] When *N*-chlorosuccinimide was used in place of NBS under the same conditions, however, only the mono- and di-*meso*-chloroporphyrins were obtained. This, and our current data, suggest that bromodeprotonation and bromodealkylation of the *meso* proton and isopropyl groups, respectively, could be intermediate steps in the formation of these unusual *meso*-succinimido products.

Synthesis and characterization of the monomeric molybdenum trithiolate Mo(η⁷-dmpt)(η¹-dmpt)$_2$ (dmpt = 2,6-dimesitylphenylthiolate)

Birsen S. Buyuktas, Marilyn M. Olmstead and Philip P. Power*†

Department of Chemistry, University of California, Davis, California 95616, USA

Treatment of $MoCl_3(THF)_3$ with 3 equiv. of $LiSC_6H_3Mes_2$-2,6 (Mes = $C_6H_2Me_3$-2,4,6) (Lidmpt) affords the monomeric molybdenum trithiolate Mo(η⁷-dmpt)(η¹-dmpt)$_2$, 1, which is spectroscopically and structurally characterized; the MoS_3 array has distorted trigonal pyramidal geometry which is caused by strong π-interactions between molybdenum and an *ortho*-mesityl group from one of the thiolate substituents.

Stable, well characterized examples of monomeric, three-coordinate Mo^{III} complexes are rare. In general, such compounds are dimerized to form triply bonded species of formula $L_3Mo{\equiv}MoL_3$ (L = uninegative ligand) which have been extensively studied.[1] Although it is probable that the incompletely characterized, sterically encumbered derivatives $Mo\{N(Pr^i)_2\}_3$ and $Mo\{N(SiMe_3)_2\}_3$ are monomers,[2] the first well established three-coordinate Mo^{III} compound was $Mo[N\{C(CD_3)_2CH_3\}C_6H_3Me_2\text{-}3,5]_3$[3] which, like the related molybdenum triamidoamine derivative [Mo(OTf)({C_6F_5N-$(CH_2)_2$}$_3$N)],[4] activates dinitrogen at room temperature to form a variety of complexes, including imines and nitrides. The stabilization of these unusual and interesting complexes by bulky aryl amido substituents suggested that it should be possible to isolate further examples of monomeric, low coordinate trivalent complexes with other ligands. Here it is shown that the use of the thiolate ligand $SC_6H_3Mes_2$-2,6 (dmpt)[5] enables the isolation of the first monomeric homoleptic molybdenum trithiolate complex Mo(η⁷-dmpt)(η¹-dmpt)$_2$, **1**.

Complex **1** was synthesized in moderate yield‡ by the reaction of 3 equiv. of $LiSC_6H_3Mes_2$-2,6 with $MoCl_3(THF)_3$.[6] The dark red, almost black, crystalline product, **1**, has good solubility in hydrocarbon solvents. The electronic absorption spectrum is almost featureless with a rapid rise in absorption at < 400 nm and a very weak shoulder at 490 nm (ε = 4600) is apparent. Magnetic studies confirm the paramagnetic character with μ_B = 3.6 (T = 293 K). The monomeric structure of **1** was established by a single crystal X-ray crystal study of its pentane solvate, **1**·0.25pentane.§ The Mo atom is bound to three thiolate sulfurs and two of the Mo–S distances have almost equal values of 2.393(2) and 2.394(2) Å, whereas the other is slightly shortened to 2.314(2) Å. The MoS_3 array is grossly distorted from planarity as indicated in the three S–Mo–S angles, which have the values 88.68(6), 105.59(7), and 91.67(7)°. The Mo–S–C angles also are different with an angle of 102.3(2)° being observed at S(1) (which bears the mesityl ring that interacts with Mo, *vide infra*) which is 14–16° narrower than the corresponding angles at S(2) and S(3). The coordination sphere of Mo is completed by a strong interaction with the C(11) *ortho*-mesityl ring. This ring is bent along the C(7)···C(10) axis (fold angle = 159.4°) such that these two atoms are closest to Mo [Mo–C distances = 2.220(6) and 2.248(7) Å] while the Mo–C distances to the remaining ring carbons are in the range 2.295(6)–2.502(6) Å.

Previous examples of related Mo^{III} thiolates [*e.g.* $Mo_2(SMes)_6$[7] or the heteroleptic species $Mo_2\{S(Bu^t)\}_2(NMe_2)_4$[8]] have been shown to be dimeric with Mo–Mo triple bonds. The monomeric structure observed for **1** (Fig. 1) is a consequence of the large size of the $SC_6H_3Mes_2$-2,6 ligand and the π-interaction between one of the mesityl groups on the ligand and the metal. The metal–ligand π-interaction may arise in part from the unique reactivity of the trigonal Mo^{III} fragment[4] which in the case of the $Mo[N\{C(CD_3)_2CH_3\}C_6H_3Me_2\text{-}3,5]_3$ complex is capable of activating N_2[3b,9] to afford, *inter alia*, the nitride $N{\equiv}Mo[N\{C(CD_3)_2CH_3\}C_6H_3Me_2\text{-}3,5]_3$. In the case of **1**, the strong interaction between the metal and a π-ring system apparently prevents the dinitrogen activation observed for the amide complexes. Note that the synthesis and manipulation of **1** were conducted under an N_2 atmosphere. Furthermore, hexane solutions of purified **1** show no sign of reaction with N_2 upon standing for 3 days at room temperature. Although the structure of **1** is unique it may be compared to that described for the Mo^{II} species [Mo(η⁷-dpt)(η¹-dpt)(CO)], **2** (dpt = $SC_6H_3Ph_2$-2,6)[10a] which also possesses a Mo–η⁶-Ph ring interaction involving a thiolate ligand.[10b] However, the η⁶-coordination of the *ortho*-phenyl ring may be displaced by the addition of CO or bidentate neutral ligands such as 2,2′-bipyridyl. The Mo–S distances in **2** [2.239(4) and 2.358(3) Å] are quite similar to those in **1**. However, the distortions in the geometry of the η⁶-interacting Mes ring in **1** are not observed in the η⁶-Ph ring of **2** although in the latter the *ipso*-carbon is displaced slightly (by *ca*. 0.14 Å) from the averaged plane of the other five ring carbon atoms.

The structural distortion observed in the mesityl ring which interacts with Mo has similarities to those observed in a variety of transition metal complexes.[11] In many instances this results in a 1,4-diene type of localization of multiple bond character within the aromatic ring. In **1**, however, the localization does not show a regular pattern. Thus, although the C(8)–C(9) distance, 1.360(9) Å, is short, the C(11)–C(12) distance, 1.420(10) Å, is

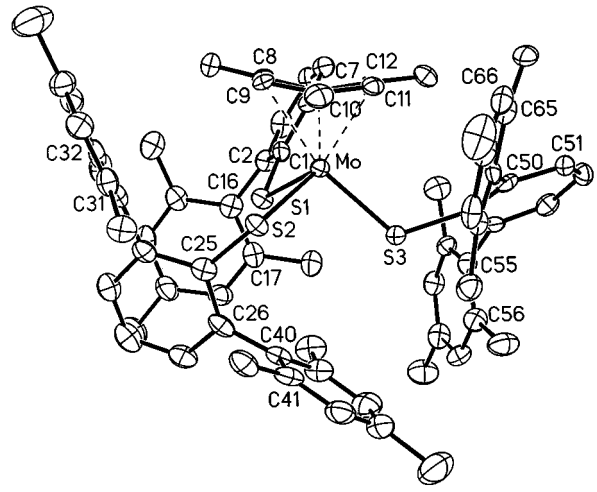

Fig. 1 Thermal ellipsoid plot of **1**. Important bond distances (Å) and angles (°) are as follows: Mo–S(1) 2.393(2), Mo–S(2) 2.394(2), Mo–S(3) 2.314(2), Mo–C(7) 2.220(6), Mo–C(8) 2.502(6), Mo–C(9) 2.433(6), Mo–C(10) 2.248(7), Mo–C(11) 2.295(6), Mo–C(12) 2.389(8), S(1)–Mo–S(2) 88.68(6), S(1)–Mo–S(3) 105.59(7), S(2)–Mo–S(3) 91.67(7), Mo–S(1)–C(1) 102.3(2), Mo–S(2)–C(25) 116.1(2), Mo–S(3)–C(49) 118.6(2)°.

near normal for an aromatic ring, whereas the C(7)–C(8) bond is lengthened to 1.494(9) Å. Perhaps the most structurally related Mo environment to that seen in **1** is in $[\{(\eta^6\text{-PhMe})Mo(\mu\text{-}SMe)_2\}_2][PF_6]_2$.[12] In this case, the oxidation state of Mo is also 3+; however, the Mo–S distances [2.451(1)–2.462(1) Å] are, of course, considerably longer owing to their bridging nature. Nonetheless, the range of Mo–C distances [2.287(3)–2.416(3) Å] is similar to the 2.220(6)–2.502(6) Å range observed in **1**. In essence, the Mo–ring π-interaction in **1** is as strong as that seen for other Mo species with neutral 6π-electron ring donors. Furthermore, the Mo–S distances are similar to those observed in $Mo_2(SMes)_6$[7] but longer than the 2.262(1) Å in the Mo^{4+} species $Mo(SC_6H_2\text{-}Pr^i_3\text{-}2,4,6)_4$.[13]

In summary, the $SC_6H_3Mes_2$-2,6 ligand permits the isolation of the first monomeric complex of formula $Mo(SR)_3$ (R = alkyl or aryl group). However, intramolecular interactions between the Mo atom and a ligand Mes ring prevent the molecule from displaying significant reactivity toward N_2 under ambient conditions.

‡ All manipulations were carried out under anaerobic and anhydrous conditions. The thiol $HSC_6H_3Mes_2$-2,6 was synthesized as described in the literature.[5] **1**·0.25pentane: $HSC_6H_3Mes_2$-2,6[5] (1.91 g, 5.5 mmol) was dissolved in diethyl ether (25 ml) and treated slowly with Bu^nLi (3.6 ml of a 1.6 M solution in hexane; 5.5 mmol) with cooling in an ice bath. The mixture was stirred for 30 min at 0 °C and allowed to warm to room temperature with continuous stirring for a further 1 h. The solution was then added slowly to a suspension of $MoCl_3(THF)_3$[6] (0.767 g, 1.83 mmol) in diethyl ether (25 ml) at *ca.* 0 °C. The mixture became deep red and stirring was continued for 18 h at room temperature. The precipitate was allowed to settle and the supernatant, deep red solution was decanted to another Schlenk tube *via* a cannula. The ether was evaporated under reduced pressure and hexane (40 ml) was added to the dark red residue. Filtration through Celite gave a clear, dark red solution. Reduction of the volume under reduced pressure to *ca.* 15 ml and storage of the solution in a −20 °C freezer gave black crystals of **1**·0.25pentane, which were suitable for X-ray structure determination. Total yield: 1.08 g, 51%, mp 112–115 °C. Anal. Calc. for **1**, $C_{72}H_{75}S_3Mo$: C, 76.36; H, 6.68. Found C, 75.94; H, 6.81%. UV–VIS (λ_{max}, ε): 490 nm (sh), 4600 $dm^3\ mol^{-1}\ cm^{-1}$. 1 (R = TMS, H)

intermediates due to their high reactivity,[1] and simple fragmentation at their cyclopropanol system is familiar as the procedure for the α-homologation of ketones. Several methods have been developed to achieve specific cleavage at bond 'a'[2] or 'b'.[3] The methods of bond cleavage at both 'a' and 'b' have been reported by Rubottom and co-workers[4] and ourselves.[5]

Here we describe a novel reaction involving the treatment of tertiary cyclopropyl silyl ethers or tertiary cyclopropanols (**1**) with a catalytic amount of vanadyl actylacetonate‡ under an O_2 atmosphere in EtOH to cause a ring fragmentation resulting in the formation of β-hydroxy ketones and β-diketones§ (Scheme 1). These results are summarised in Table 1. In the case of 1-(trimethylsiloxy)bicyclo[*n*.1.0]alkanes or bicyclo[*n*.1.0]alkanols (entries 1–6), the 'b' bond was specifically cleaved to afford ring-enlarged β-hydroxy ketones and β-diketones. As noted in entry 6, the cyclopropane ring without oxygen-functionality did not react under these reaction conditions.

β-Diketones were not obtained by the reaction of β-hydroxy ketones with $VO(acac)_2$. These results mean that β-diketones were directly produced from the cyclopropanol systems. Molecular oxygen acts as the co-oxidant and reoxidises the low valent vanadium compound formed, thus a stoichiometric amount of $VO(acac)_2$ reacted with 1-(trimethylsiloxy)-bicyclo[4.1.0]heptane in the absence of oxygen (Scheme 2).

Although $VO(acac)_2$ did not react with **1** in an aprotic solvent (*e.g.* CH_2Cl_2), it reacted with **1** in trifluoroethanol to afford β-diketones (**3**) predominantly (Scheme 3).

Interestingly, 5-but-3-enylbicyclo[4.1.0]heptan-1-ol (**4**) did not cause tandem ring expansion–cyclisation but caused simple ring expansion to afford **5** and **6**. This result is in sharp contrast to iron(III) chloride[3c,d] or manganese(III) picolinate[3g] that causes the tandem reaction (Scheme 4). We also found that a radical inhibitor [2,6-di(*tert*-butyl)-*p*-cresol] did not interfere with the reaction of $VO(acac)_2$ with **1**.

Although the reaction mechanism is unknown, these results suggest that this reaction is different from the other specific 'b'

‡ The reaction with pentavalent vanadium compounds [*e.g.* dichloro(ethoxy)(oxy)vanadium] did not afford β-hydroxy ketones or β-diketones, giving instead complex mixtures.

§ A typical experimental procedure is as follows: a mixture containing tertiary cyclopropyl silyl ethers (or tertiary cyclopropanols) (0.5 mmol), $VO(acac)_2$ (0.05 mmol) and EtOH (5 ml) was stirred at room temperature under an oxygen atmosphere for 1.5–35 h. Water (3 ml) was added to the reaction mixture, and the resulting mixture was extracted with ethyl acetate (20 ml × 3). The combined organic extracts were washed with brine, dried over magnesium sulfate, and evaporated to afford the crude mixture of β-hydroxy ketones and β-diketones. Separation and purification by chromatography (silica gel, hexane–ethyl acetate) gave pure samples.

Electrochemical reduction of CCl_2F_2 on Nafion solid polymer electrolyte composite electrodes

E. Delli, S. Kouloumtzoglou, G. Kyriacou*† and C. Lambrou

Department of Chemical Engineering, Aristotle University of Thessaloniki, Thessaloniki 54006, Greece

The electrochemical reduction of CCl_2F_2 (CFC-12) was carried out at Pd, Au, Cu and Ag cathodes, which were chemically deposited on Nafion 117 (H^+ form) membrane; the main electrolysis product at −1.0 V *vs.* Ag/AgCl at Au, Pd and Cu was CH_4, with current efficiencies (CE) of 14, 15 and 47% respectively, while at Ag cathode, in addition to CH_4, a considerable quantity of CH_2F_2 (CE 60%) was also detected, which might be used as a new technology refrigerant.

The production of chlorofluorocarbons (CFCs) has been stopped since 1996, in line with the Montreal Protocol, because of their ability to react in ways that destroy tropospheric ozone.[1] At present, almost 2×10^6 tonnes of these compounds are stored in various freezing devices, the bigger percentage of which is CFC-12.[2] These large quantities must be destroyed or preferentially converted to other useful products. Recently Cabot and co-workers[3,4] achieved the electrosynthesis of trifluoroethene and difluoroethene from 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113) in organic solvents.

This work deals with the possible conversion of CFC-12 to non-polluting substances *via* electrochemical reduction at metallic electrodes which are deposited on Nafion 117 (H^+ form) membrane. These electrodes enable us to perform electrochemical reactions with reactants that are insoluble in water, without employing organic solvents.

For the metal deposition, aqueous 0.1 M solutions of $AgNO_3$, $HAuCl_4$, $Pd(OAc)_2$ and $CuSO_4$ were used, combined with 10% aqueous $NaBH_4$ solution, using the method previously described for copper.[5] The charged side of the metal surface of the membrane, having an apparent effective area of 2.35 cm^2 was in contact with CFC-12, while the other side was in contact with 2 M aqueous NaOH solution (10 cm^3), as shown in Fig. 1. As a reference, an Ag/AgCl electrode was used. The analysis of the products was performed by gas chromatography using a flame ionization detector and a Porapak QS 1/8 in, 4 m column at 120 °C.

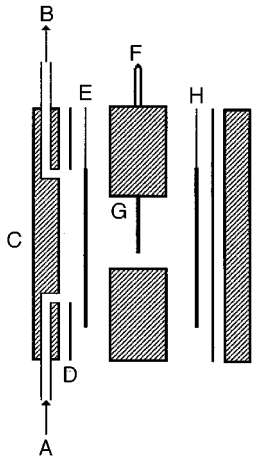

Fig. 1 Exploded view of the electrolysis cell: (A) gas inlet, (B) gas outlet, (C) PTFE gasket, (D) silicone screen spacer, (E) Nafion SPE electrode, (F) reference electrode, (G) electrolyte chamber and (H) Pt anode

The voltammogram at the Ag electrode, between −0.7 and −1.6 V *vs.* Ag/AgCl (Fig. 2), showed that the reduction of CCl_2F_2 was taking place at potentials more negative than −0. 8 V, while hydrogen was produced at cathodic potentials more negative than −1.3 V. This value is in accordance with hydrogen evolution at Ag wire at the same pH value.[6]

Based on the voltammetry results, constant potential electrolysis was performed in the region −0.8 to −1.6 V *vs.* Ag/AgCl. The main products of the electrolysis were CH_2F_2 and CH_4 at all potentials examined. CH_2F_2 is a compound of great practical importance, due to its application as a new technology refrigerant which does not cause ozone depletion.[7] Small amounts of $CHClF_2$, CH_3F and HCF_2CF_2H were also detected in the reaction products.

Fig. 3 illustrates the rate of CF_2H_2 production *vs.* cathodic potential where a sharp maximum was observed at about −1.4 V. The rate of CH_4 production was slightly increased at potentials more negative than −1.4 V. The CEs of CF_2H_2 and CH_4 formation at −1.4 V were 60 and 30%, respectively. Repeated experiments showed that the distribution of products was as shown by the curves of Fig. 3, with a reproducibility of about 15%. The form of these curves can be explained by a consecutive reaction mechanism corresponding to $CCl_2F_2 \rightarrow CH_2F_2 \rightarrow CH_4$.

Theoretical analysis of consecutive electrochemical reactions showed that the effect of potential on the selectivity and yield of the intermediate compound could be considered analogous to that of temperature in the conventional chemical reactions. In this case the selectivity of the intermediate product *vs.* potential

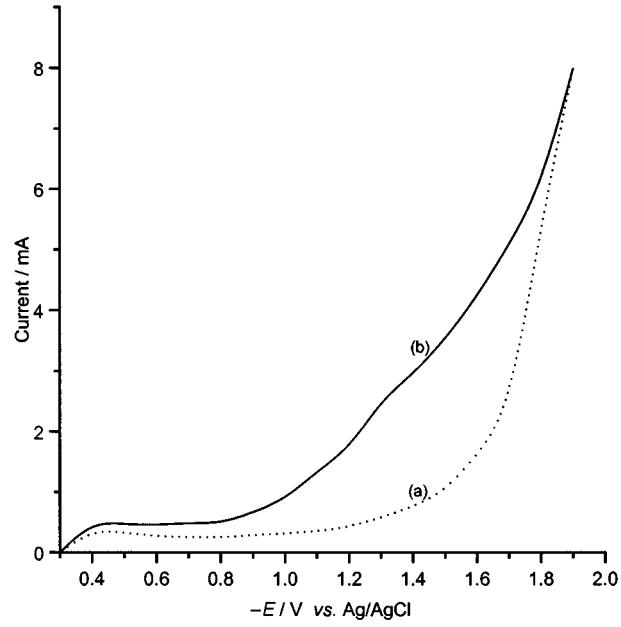

Fig. 2 Polarization curves at silver cathode, in 2 M KOH electrolyte at 10 mV s^{-1} (a) with N_2 and (b) with CFC-12

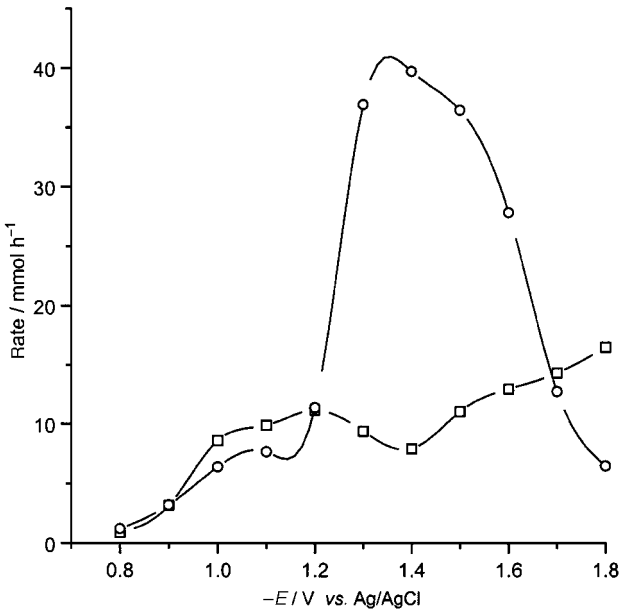

Fig. 3 Rate of (○) CH_2F_2 and (□) CH_4 production *vs*. cathodic potential at a silver electrode in 2 M KOH electrolyte

could show one or more maxima.[8] A similar consecutive reaction mechanism scheme was proposed for the hydrogenolysis of CCl_2F_2 in the gas phase.[9]

The electroreduction of CCl_2F_2 was also studied at −1.0 V *vs*. Ag/AgCl using Pd, Au and Cu electrodes. In all cases, the main product of the reduction was CH_4, with mean CEs of 14, 15 and 47%, respectively. The current density and time function shows that the current density stabilises after 30 min and remains stable for a long period of time. This implies that the electrode is not deactivated and the membrane is not destroyed. The current density at Ag, Cu and Pd was about 5 mA cm^{-2}, whereas at Au it is four times smaller.

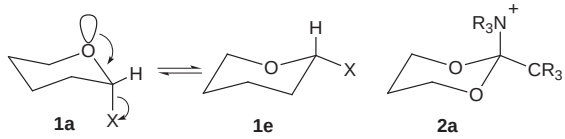
A test for the reverse anomeric effect

Peter G. Jones, Anthony J. Kirby,*† Igor V. Komarov‡ and Peter D. Wothers

University Chemical Laboratory, Cambridge, UK CB2 1EW

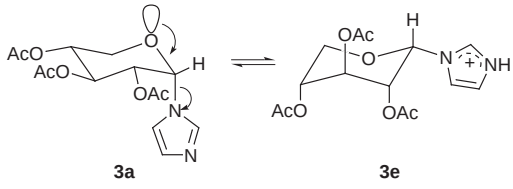
Conformational preferences and the geometry at the anomeric centre of a 1,3-dioxane with a trialkylammonium group in the 2-position (stable because part of a 1-azaadamantane) are consistent with a small, normal anomeric effect.

The anomeric effect—the preference for an electronegative substituent X in the 2-position of a tetrahydropyran for the axial conformation (**1a**)—is a well-characterised exception to the usual rules of conformational analysis.[1,2] The reverse anomeric effect (RAE)[3]—an apparent increased preference of a positively charged electronegative substituent for the *equatorial* conformation (**1e**)—is thus an exception to the exception, and presents something of a conceptual problem. The simplest solution to the problem would be that the effect does not exist.[3–6] We report the conformational preferences of a novel sterically balanced system (general structure **2**) consistent with this conclusion.



The normal anomeric effect can be understood in terms of a stereoelectronic effect involving the lone pair electrons of the ring oxygen: the stabilising n_O–$\sigma^*_{C–X}$ interaction (arrows in **1a**, possible only for the axial geometry) outweighing the steric preference for the equatorial position.[1,2] Through-bond interactions of this sort play an important role in controlling reactivity as well as conformation[7,8] and thus in the way we think about both. They should not depend on the charge on the electronegative substituent X—hence the conceptual problem.

Experimental support for the RAE is neither extensive, nor generally clear-cut. The best experimental evidence,[9] recently reconfirmed,[10] is that N-protonation of *N*-triacetyl-α-D-xylopyranosylimidazole **3a** leads to an increase in the (already

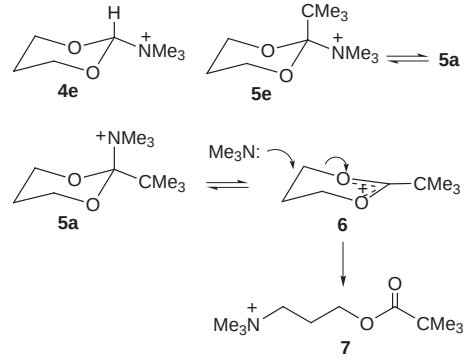


considerable) population of the $^1C_4$-conformation **3e**: corresponding to a RAE of 0.8–1.4 kcal mol^{-1}. On the other hand Perrin[5] concluded that the corresponding shift in the position of this equilibrium for a series of glucopyranosylamines could be accounted for on the basis of steric effects and a small, normal anomeric effect. (These results are not necessarily contradictory: the positions of such anomeric equilibria are known to depend on the structure of the sugar, with acetoxy groups in particular showing unusually small 1,3-diaxial interactions;[11] it has been suggested that the steric effect of an imidazole group may be increased on protonation.[5]) The most convincing evidence consistent with the operation of a small, normal anomeric effect comes from the NMR titration experiments of Fabian *et al.*,[6] which show that the axial imidazole is the more basic in an anomeric mixture of glucosylimidazoles.

We sought a direct experimental test for the existence of the RAE in a simple sterically balanced system, uncomplicated as far as possible by solvation effects. In order to maximise stereoelectronic effects we chose to work with the dioxane ring, and to set trialkylammonium, with a full positive charge on N, against an isosteric tertiary alkyl group. The problems involved are illustrated by the following sequence of results. Simple systems with X = R_3N^+ already have a strong steric preference for the equatorial conformation:[12] thus 2-trialkylammonium systems **4e**, although stable, are exclusively equatorial. But the sterically balanced system **5e** is not isolable: addition of Me_3N to the dioxocarbenium ion **6** probably gives **5a** as a kinetic product, but what we isolate is the pivalate ester **7**, formed by the alternative (S_N2) reaction shown (Scheme 1).

To encourage the three heteroatoms to stay together on the quaternary center of interest we embedded it in the azaadamantane structure **8**. The critical test for RAE *vs.* normal anomeric effect now becomes simply the conformational preference of the dioxane ring. The conformational equilibrium **8a**⇌**8e** is as far as possible sterically neutral: because the CH_3–N^+ bond is shorter than CH_3–C it will have a slight preference for the conformation (**8e**) favored by RAE. In solution we find a clear preference for a conformation closer to **8a**, and in the crystal the pattern of bond lengths at the 'anomeric' centre expected if a normal anomeric effect is operating. However, the evidence from two crystal structures shows that the conformational picture is not as simple as depicted by **8a**⇌**8e**.

In the ^{1}H NMR spectrum protons H^a and H^b of **8** show nuclear Overhauser effects[13] of 12.3% to the $^+NCH_3$ and 2.0% to the CCH_3 groups, respectively, and vicinal couplings (*J* 11.4, 5.6 Hz for H^a, *J* 2.4, 2.4 Hz for H^b) not far from the expected magnitudes for conformation **8a**. However, X-ray structure determinations[14] of two different salts show pronounced flattening of the dioxane ring at the two oxygen centres. This is the not unexpected result of steric interactions—almost equally severe in either chair conformation—between the two O–CH_2 bonds and the $^+$N–CH_3 and C–CH_3 groups (in **8a** and **8e**, respectively: indicated by the open arrows in Fig. 1). What *is* unexpected is that the conformations of the iodide and hydrogenfluoride salts in the crystalline state differ sig-



Scheme 1

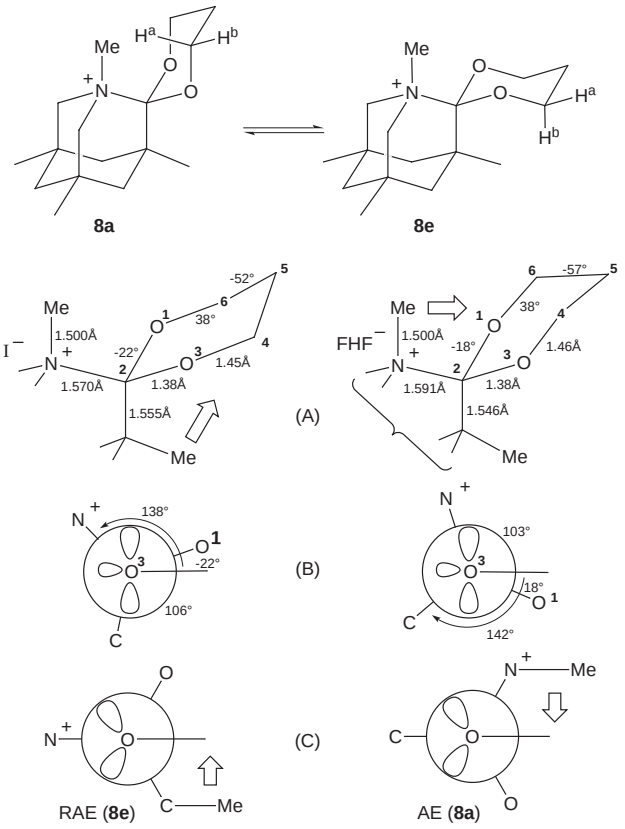


Fig. 1 Selected structural features at the anomeric centre of the iodide (left) and hydrogenfluoride (right) salts of **8**. The cation is formally (although not crystallographically) symmetrical about the mirror plane through C(2) and C(5) of the dioxane ring: mean values of bond lengths and angles are given. Individual bond lengths and angles have esd values of ±0.003 Å and 0.2°, respectively. (A) Observed conformations of the dioxane ring (in-ring torsion angles are given) and bond lengths at the anomeric centre. (B) Torsion angles at the anomeric centre, compared with (C) the geometry expected for a (hypothetical) system with normal bond angles showing the reverse (RAE) or normal (AE) anomeric effect. The open arrows represent major steric interactions responsible for flattening the dioxane chair of **8** (see the text).

nificantly, being closer in the former case to **8e** and in the latter to **8a**.

The differences are limited to the $(CH_2)_3$ chain of the dioxane ring: the structures are otherwise identical—and remarkable. The COC bond angles (120 ± 1.4°) show that the two dioxane oxygens are effectively sp²-hybridised. This, together with the large OCO bond angle (118.0 ± 0.5°) and very long C(2)–N^+ and short O–C(2) bonds at the anomeric centre [Fig. 1(A)] is consistent with a well-developed n_O–$\sigma^*_{C–N}$ interaction, and thus a normal anomeric effect, with C–N^+ bond breaking being well advanced in the ground state. (The extent of the effect shows very clearly why simpler systems like **5** are not viable synthetic targets.) The C(2)–N^+ bonds are in both cases close to parallel to p-type non-bonding electron pairs on oxygen, which allows relatively efficient p_O–$\sigma^*_{C–N}$ overlap: closer in the case of the hydrogenfluoride [Fig. 1(B)], which—presumably consequently—has the longer C(2)–N^+ bond. This lengthening of the bond to N^+ can be interpreted as the stereoelectronically most efficient means of relieving strain at the crowded anomeric centre: there is very little lengthening of the equally crowded C(2)–C bond.

The observed conformations of the dioxane ring of the cation **8** represent two different compromises between stereoelectronic effects and powerful steric forces. It is reasonable to expect a unique minimum energy conformation, so the difference in the crystalline state may be presumed to derive from anion-related packing forces.§ (Iodide and hydrogenfluoride differ markedly in size, shape and charge-density.) Since the conformation in solution is clearly closer to **8a** we conclude that there is no conclusive evidence for a reverse anomeric effect in this test system. As found by Perrin,[5] in a very different system, the observed conformations can be explained on the basis of steric effects and a small, normal anomeric effect.[15]

§ The inference is clear that this difference in conformation is driven by a packing-induced ring-flip at C(5), the most flexible part of the system. The conformation of the rest of the dioxane ring must adjust to accommodate this change: ending up much the way it started, except that N^+ and C have changed places [Fig. 1(B)].

13 NMR spectra were measured in $CDCl_3$ on a Bruker 500 MHscz instrument. NOEs were obtained from NOE build-up curves according to K. Stott, J.H. Keeler, Q. N. Van and A. J. Shaka, *J. Magn. Reson*., 1997, **125**, 302.
14 *Crystal data* for **8** (iodide salt): $C_{16}H_{28}INO_2$, colourless tablet, 0.4 × 0.3 × 0.15 mm, monoclinic, *Cc*, a = 7.8145(6), b = 14.9324(12), c = 14.5044(14) Å, β = 96.171(8)° (at −100 °C), μ = 1.906 mm^{-1}, Z = 4. Final $wR2$ = 0.040, $R1$ = 0.018, S = 1.00 for 3349 reflections and 186 parameters. For **8** (hydrogenfluoride salt): $C_{16}H_{29}F_2NO_2$, colourless tablet, 0.6 × 0.6 × 0.3 mm, monoclinic, $P2_1/c$, a = 10.206(2), b = 11.797(3), c = 26.344(7) Å, β = 92.09(3)° (at −130 °C), μ = 0.098 mm^{-1}, Z = 8 (two independent molecules). Final $wR2$ = 0.129, $R1$ = 0.049, S = 1.02 for 5584 reflections and 395 parameters. The nitrogen atoms were clearly distinguished from their carbon counterparts at C2 (Fig. 1) by comparison with the R values and displacement parameters for a refinement with C and N transposed. For the iodide salt, which represents an extreme case (heavy-atom structure, non-centrosymmetric), refinement of a C/N disorder model gave the occupation factor 0.89(2) for the structure as reported, *i.e*. there is no significant component with C and N exchanged. CCDC 182/929.
15 We find further support for this conclusion in the crystal structures of two *gem*-diols, hydrates corresponding to the acetal **8** (N. Feeder, A. J. Kirby and I. V. Komarov, *J. Am. Chem. Soc*., in the press, and unpublished work). For both NH^+ and NMe^+ compounds the two O–H bonds adopt conformations corresponding to **8a**. Steric effects are reduced in these systems, and C–O–H angles are closer to tetrahedral values.

A macrobicyclic Ag^{I}_3 cage encapsulating two cobalt(III) ions: synthesis, structure and reactivity

Takumi Konno,*[a]† Keiji Tokuda[a] and Ken-ichi Okamoto[b]

[a] *Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma, 376, Japan*
[b] *Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

Reaction of the S-bridged $Co^{III}_2Ag^{I}_3$ pentanuclear complex, $[Ag^{I}_3\{Co^{III}(aet)_3\}_2]^{3+}$ (1; aet = $NH_2CH_2CH_2S^-$), with paraformaldehyde in basic acetonitrile, followed by adding aqueous ammonia, produces the aza-capped complex, $[Ag^{I}_3\{Co^{III}(L)\}_2]^{3+}$ [2; L = $N(CH_2NHCH_2CH_2S^-)_3$] , in which two Co^{III} atoms are encapsulated in a macrobicyclic cage consisting of two aza-capped ligands L and three Ag^{I} atoms; 2 is converted to the aza-capped $Co^{III}_4Zn^{II}_4$ octanuclear complex, $[Zn^{II}_4O\{Co^{III}(L)\}_4]^{6+}$, by the reaction with I^- in the presence of ZnO and Zn^{2+} in water, retaining the chiral configuration of the aza-capped $[Co^{III}(L)]$ units.

Since the discovery of the formation of the aza-capped cage complex, $[Co(sepulchrate)]^{3+}$, by the facile condensation of formaldehyde and ammonia with $[Co(en)_3]^{3+}$ (en = $NH_2CH_2CH_2NH_2$),[1] similar preparative techniques have been applied to obtain analogous metal complexes with a macrobicyclic cage, which exhibit unique stereochemical and redox properties.[2–10] The cage complexes of this type have been derived from mononuclear metal complexes and thus contain only one metal ion. In order to expand the co-ordination chemistry of metal ions encapsulated in a macrobicyclic cage, it is desirable to introduce two or more metal ions in one cage. We report here the synthesis and structure of a new class of macrobicyclic cage complex encapsulating two cobalt(III) ions, $[Ag_3\{Co(L)\}_2]^{3+}$ [L = $N(CH_2NHCH_2CH_2S^-)_3$], together with its conversion to the $Co^{III}_4Zn^{II}_4$ octanuclear complex, $[Zn_4O\{Co(L)\}_4]^{6+}$.

Treatment of a dark purple acetonitrile solution of the S-bridged $Co^{III}_2Ag^{I}_3$ pentanuclear complex, $[Ag_3\{Co(aet)_3\}_2](BF_4)_3\cdot H_2O$ [**1**$(BF_4)_3\cdot H_2O$; aet = $NH_2CH_2CH_2S^-$],[11] with paraformaldehyde and triethylamine at room temperature gave a dark red solution, which turned dark purple upon the addition of aqueous ammonia. A dark purple powder [**2**$(NO_3)_3\cdot 4H_2O$] was isolated from the dark purple reaction solution by adding an aqueous solution of $NaNO_3$ (80% yield).‡ The absorption spectrum of **2** is quite similar to that of **1** over the whole region. In the ^{13}C NMR spectrum **2** gives three sharp signals at δ 34.64, 61.62, and 69.76, which is distinct from the two ^{13}C NMR signals at δ 36.64 and 51.41 observed for **1**.[11] From these facts and elemental analysis, it is assumed that **2** has an aza-capped $Co^{III}_2Ag^{I}_3$ pentanuclear structure in $[Ag_3\{Co(L)\}_2]^{3+}$ [L = $N(CH_2NHCH_2CH_2S^-)_3$]. **2** was optically resolved into its enantiomers, $(+)^{CD}_{580}$ and $(-)^{CD}_{580}$, by SP-Sephadex C-25 column chromatography using $[Sb_2(R,R\text{-tartrato})_2]^{2-}$ as eluent. The CD spectrum of $(-)^{CD}_{580}$-**2** corresponds well with that of the $\Delta\Delta$ isomer of **1**, which implies that the two [Co(L)] units in $(-)^{CD}_{580}$-**2** have the Δ configuration.

The structure of **2** was established by a single crystal X-ray analysis of the PF_6^- salt [**2**$(PF_6)_3\cdot H_2O$], which was prepared by adding an aqueous solution of $NaPF_6$ to the aqueous solution of **2**$(NO_3)_3\cdot 4H_2O$.§ The total occupancy factor of the PF_6^- anions implies that the entire complex cation **2** is trivalent. As shown in Fig. 1, the entire complex cation **2** contains two Co^{III} and three Ag^{I} atoms. Each Co^{III} atom is surrounded by an aza-capped hexadentate N_3S_3 ligand L to form an approximately octahedral $[Co^{III}(L)]$ unit. The two $[Co^{III}(L)]$ units are spanned by three Ag^{I} atoms, such that the three S–Ag–S linkages form a triple helical structure. As a result, the two Co^{III} atoms are encapsulated in a macrobicyclic metallo-cage, $[Ag^{I}_3(L)_2]^{3-}$, in which each of three Ag^{I} atoms is linearly coordinated by two S atoms from two aza-capped ligands L. Except for the presence of the two terminal aza caps, the overall structure of **2** is similar to that of the parent complex **1**.[11] In particular, the bond distances and angles around the Co^{III} atoms in **2** [average Co–S = 2.243(8) Å, Co–N = 2.02(3) Å, S–Co–S = 91.3(3)°, N–Co–N = 89(1)°] are in good agreement with those in **1** [average Co–S = 2.248(8) Å, Co–N = 2.03(3) Å, S–Co–S = 92.1(3)°, N–Co–N = 90(1)°]. However, the averaged Ag–S distance in **2** [2.417(8) Å] is *ca*. 0.04 Å longer than that found in **1** [2.378(8) Å]. Moreover, the S–Ag–S angles [average 177.9(4)°] in **2** are closer to 180° than those in **1** [average 174.6(3)°], which permits the slightly shorter Ag···Ag separations in **2** [average 2.956(4) Å], compared with the separations in **1** [average 3.029(3) Å].

The two [Co(L)] units in **2** have the same chiral configuration to form the $\Delta\Delta$ and $\Lambda\Lambda$ isomers; the former isomer is illustrated in Fig. 1. This is compatible with the fact that **2** was optically resolved into its enantiomers. In the crystal lattice the $\Delta\Delta$ and $\Lambda\Lambda$ isomers co-exist in a disordered manner with a site occupancy of 0.5, which indicates that crystal **2** is not a racemic compound but a solid solution.[12] All the six bridging S atoms are fixed to the *S* configuration for the $\Delta\Delta$ isomer and *R* for the $\Lambda\Lambda$ isomer. The helical structure due to three S–Ag–S linkages is left-handed for the $\Delta\Delta$ isomer and right-handed for the $\Lambda\Lambda$ isomer. These stereochemical properties are the same as those in **1**.[11] However, it should be noted that in **2** all the five-membered N,S-chelate rings adopt the *lel* conformation, which is in contrast to the fact that the *ob* conformation as well as the *lel* one has been found in **1**. All the six asymmetric N atoms in **2** have the *R* configuration for the $\Delta\Delta$ isomer and *S* for the $\Lambda\Lambda$ isomer.

Attempts to fit the S-bridged $Co^{III}_4Zn^{II}_4$ octanuclear complex, $[Zn_4O\{Co(aet)_3\}_4]^{6+}$,[13] with aza caps by a similar condensation reaction were unsuccessful, because of the decomposition of $[Zn_4O\{Co(aet)_3\}_4]^{6+}$ in basic conditions. Instead, the corresponding aza-capped complex, $[Zn^{II}_4O\{Co^{III}(L)\}_4]^{6+}$ (**3**), was successfully derived from **2** (Scheme 1). That is, treatment of **2** with a stoichiometric amount of NaI in the presence of excess ZnO and $Zn(NO_3)_2\cdot 6H_2O$ in water at

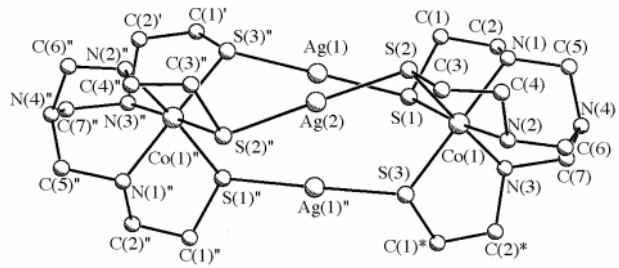

Fig. 1 A perspective view of the complex cation **2** (the $\Delta\Delta$ isomer) with the atomic labeling scheme. The overlapped $\Lambda\Lambda$ isomer is omitted for clarity

Scheme 1 Conversion of the $Co^{III}_2Ag^{I}_3$ pentanuclear structure in **2** to the $Co^{III}_4Zn^{II}_4$ octanuclear structure in **3**

room temperature gave a dark blue–purple solution, from which a black powder [**3**$(ClO_4)_6$·$7H_2O$] was isolated by adding an aqueous solution of $NaClO_4$ (50% yield).¶Compound **3** was characterized by (i) elemental and plasma emission spectral analyses, (ii) electronic absorption spectroscopy, the spectral features of which coincide well with that of $[Zn_4O\{Co(aet)_3\}_4]^{6+}$, and (iii) ^{13}C NMR spectroscopy which gives three sharp signals at δ 32.63, 61.15, and 69.51. The cyclic voltammogram of **3** at a glassy-carbon electrode in a 0.2 mol dm^{-3} aqueous $NaNO_3$ solution yields four consecutive redox couples (E = −0.43, −0.55, −0.62, and −0.75 V *vs*. Ag/AgCl, 100 mV s^{-1}). Similar redox behavior is characteristically observed for $[M_4O\{Co(aet)_3\}_4]^{6+}$ (M = Zn, Hg) having a *T*-symmetrical $Co^{III}_4M^{II}_4$ octanuclear structure.[13,14] Thus, it is confirmed that **3** has the S-bridged $Co^{III}_4Zn^{II}_4$ octanuclear structure in $[Zn^{II}_4O\{Co^{III}(L)\}_4]^{6+}$. Compound **3** was optically resolved into its enantiomers, $(+)^{CD}_{580}$ and $(-)^{CD}_{580}$, by SP-Sephadex C-25 column chromatography. Since the CD spectrum of $(-)^{CD}_{580}$-**3** is very similar to that of the ΔΔΔΔ isomer of $[Zn_4\{Co(aet)_3\}_4]^{6+}$, it is assumed that the four [Co(L)] units in $(-)^{CD}_{580}$-**3** have the Δ configuration. When ΔΔ-**2** was used as the starting complex, instead of the racemate of **2**, only the ΔΔΔΔ isomer of **3** was formed. This result indicates that the $Co^{III}_2Ag^{I}_3$ pentanuclear structure in **2** is converted to the $Co^{III}_4Zn^{II}_4$ octanuclear structure in **3** with retention of the chiral configuration of the [Co(L)] unit. Similar conversion reactions of **2** to other S-bridged polynuclear structures are currently under way.

DNA alkylation sites of nitrogen mustards conjugated to polyamines and their implications for polyamine–DNA interactions

Paul M. Cullis,*† Louise Merson-Davies, Michael J. Sutcliffe and Richard Weaver

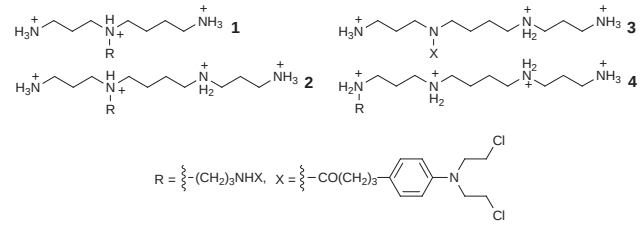
Department of Chemistry and the Centre for Mechanisms of Human Toxicity, Leicester University, Leicester, UK LE1 7RH

Polyamines conjugated to the nitrogen mustard chlorambucil increase the efficiency of DNA alkylation at N^7 of guanine by factors in the range 10^3 to 10^4; the sequence selectivity of this alkylation (the alkylation 'finger-print') is largely unchanged, which is consistent with flexible, electrostatic binding and incompatible with tight, sequence-specific binding of the polyamine moiety.

Polyamines are low molecular weight cations, essential for growth and differentiation,[1,2] that are present in high concentration in all cells. Polyamine–DNA interaction is associated with the physiological role of polyamines,[3–9] and there has been conflicting speculation concerning the nature and site of such interactions including reports of binding in the major[3] and minor groove,[4] spanning the minor groove[5,8] and theoretical studies that suggest interaction with the phosphate backbone or some sequence-specific interaction.[6] The crystal structure of a spermine–B-DNA complex[9] exhibits aspects of both charge–charge interactions with the phosphate backbone, and direct or water-mediated hydrogen bonds with bases and van der Waals interactions with hydrophobic regions. We previously determined the preferred cross-linking site on DNA for chlorambucil and both a spermidine– and spermine–chlorambucil conjugate.[10] The interstrand cross-link for each of these was at a 5'-GNC sequence within defined oligonucleotides, and this did not appear to be perturbed by the polyammonium moiety, despite a major enhancement of the efficiency of cross-linking. We interpreted this observation in terms of non-specific electrostatic interaction between the polyammonium cation and DNA. However, there may be a rather tight structural requirement for successful cross-linking which could be expressed in the second, interstrand alkylation step and which might potentially overwhelm the polyammonium ion binding preferences. Here we report the sequence specificities for mono-alkylation of DNA at N^7 of guanine shown by chlorambucil–polyamine conjugates and compare this to the known selectivity shown by chlorambucil itself.

The major alkylation site of DNA by chlorambucil is the N^7 of guanine bases.[11] The sequence selectivity in terms of guanine N^7 alkylation is demonstrated by converting these sites into strand breaks on treatment with hot piperidine and analysing the resulting fragments by denaturing polyacrylamide gel electrophoresis (PAGE). It has been shown that chlorambucil shows a significant sequence dependence in terms of the mono-alkylation sites,[11] with guanosine residues within runs of Gs being the most reactive.[12] In energetic terms, the enhanced reactivity in such regions as compared with isolated Gs represents a comparatively small difference, and a degree of alkylation at each G site can be detected on denaturing PAGE analysis of the cleavage products. In the case of the polyamine–chlorambucil conjugates it would be reasonable to expect that such small rate differences between the various alkylation reactions might be readily perturbed by the non-covalent binding interactions with the polyammonium moieties that are clearly promoting in some manner the eventual covalent step. We therefore anticipated that the alkylation selectivity could provide a potentially sensitive probe of the nature of the interaction between DNA and polyammonium cations. For example, it has been shown that the alkylation specificity of some aromatic nitrogen mustards is perturbed on conjugation to intercalators such as acridine, in a manner that reflects the acridine binding specificity.[13]

A DNA sequence of 276 base pairs was 5′-end-labelled and cleaved from linearised pBR322. Treatment of this double-stranded DNA with chlorambucil, or one of the polyamine–chlorambucil conjugates **1**–**4**,[14] followed by exposure of the



alkylated DNA to hot aqueous piperidine led to a family of DNA fragments that arise because of the lability of the DNA

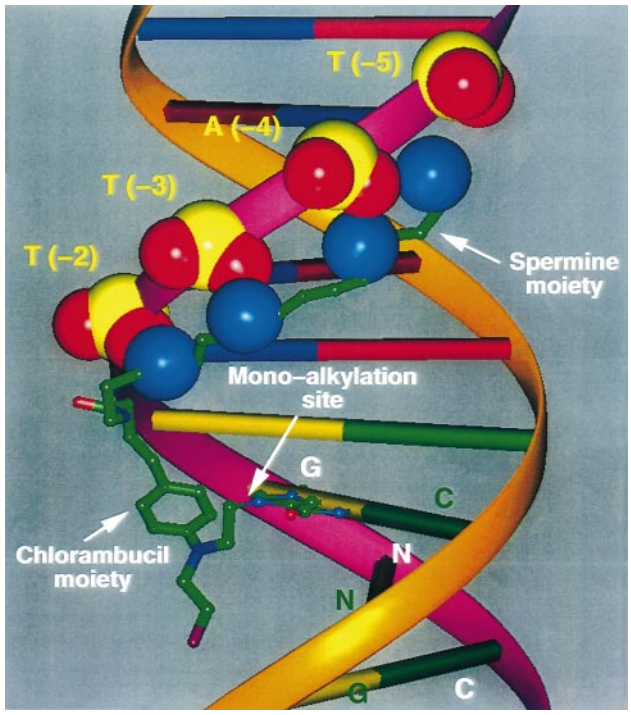

Fig. 2 Schematic representation of one of the molecular models for the B-DNA duplex d(CTATATTG**G**GCGGGATTAA)/d(TTAATCCCGCC-CAATATAG) monoalkylated by conjugate **4**, showing a low energy conformation in which the polyamine interacts with the phosphates 5′ to the alkylation site

alkylated at N^7 of the guanine bases. These cleavage products could be distinguished by denaturing PAGE (Fig. 1).[15] For chlorambucil the intensities of individual bands vary depending on the neighbouring sequence, confirming that guanine alkylation shows significant sequence selectivity, as reported previously[11] for a number of aromatic nitrogen mustards. More interestingly, all of the polyamine–chlorambucil conjugates show identical alkylation 'finger-prints', over a range of concentrations and molar ratios, but comparable levels of alkylation being observed with chlorambucil at 0.2 mM and conjugate **4** at 0.1 μM. Thus the presence of the polyamine moiety significantly enhances the alkylation by factors in the range 10^3 to 10^4 but does not alter the selectivity.

We have reported that chlorambucil and conjugate **1** hydrolyse and react with simple nucleophiles at the same rate and by the same mechanism.[16] The enhanced reactivity of the conjugates with DNA compared to chlorambucil is therefore a result of the polyamine–DNA interaction and in free energy terms this corresponds to about 23 kJ mol^{-1} (calculated for a 10^4-fold increased reactivity). The degree of enhanced reactivity, as with the observations on cross-linking efficacy, depends on the number of positive charges. The selectivity between different individual guanine bases is typically a factor of 2–3, which corresponds to an energy difference of 2–3 kJ mol^{-1}. The close similarity between the gel scans shown in Fig. 1, despite significant changes to the structure of the polyamine conjugate, must mean that the presence of the polyammonium moiety in the conjugate is able to enhance the reactivity at *all* of the guanine sites *and to the same extent.* A corollary to this is that although the polyammonium moiety has a high affinity for the DNA, it is not interacting at discrete sites and that there must therefore be significant mobility in the complex. This is consistent with a non-sequence selective, largely electrostatic interaction, and incompatible with sequence-specific H-bonded interactions. The similarities between the alkylation profiles is striking; however, close inspection of Fig. 1 does reveal a greater extent of alkylation by the polyammonium conjugate at a single site in the sequence GTCGTTG**G***CGTGGA [arrow in Fig. 1(*c*)]. This enhanced alkylation is reproducible but its structural basis is not evident.

Preliminary molecular modelling studies were performed to probe the nature of the interactions between DNA and these conjugates.[17] We have explored the covalent and non-covalent interactions of the spermine–chlorambucil conjugate by using B-DNA as the target and forming the first covalent link to N^7 of the more reactive guanine residue. Using this constrained adduct we have sought to probe three aspects: (i) whether the polyammonium moiety can make reasonable electrostatic interactions in such an adduct; (ii) whether the interactions are sensitive to the conjugate structure; and (iii) whether the cross-linking step involves much distortion of the conjugate or DNA structure. It is clear from the structure shown in Fig. 2 that in the adduct the polyammonium moiety can adopt a conformation that places the positive charges in good juxtaposition to the phosphate anions of the backbone. It is also clear that several alternative orientations of the polyammonium moiety are possible and of very similar energy. Similar interactions are possible for all of the conjugates **1**–**4** despite the structural differences, *e.g.* branched *vs.* non-branched. There is a trend in the strength of the interaction which increases with the number of positive charges. However, the differences in these values are close to the errors in the calculations and therefore should not be over-interpreted. It is very clear from the modelling that the formation of the cross-link requires appreciable distortion of the conjugate–DNA structure, and that this can be achieved whilst maintaining the interaction between the polyammonium moiety and the DNA. Thus the computational modelling is fully consistent with the conclusions drawn from the experiments.

Valence delocalisation in a strongly coupled (K_c = 10^{14}) molecule-bridged cyanodiiron(III,II) species

Michael Ketterle,[a] Jan Fiedler[b] and Wolfgang Kaim*[a]†

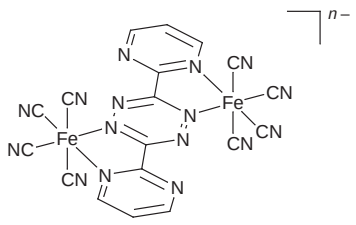
[a] *Institut für Anorganische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70550 Stuttgart, Germany*
[b] *J. Heyrovsky Institute of Physical Chemistry, Academy of Sciences of the Czech Republic, Dolejškova 3, 18223 Prague, Czech Republic*

A hybrid between the Prussian Blue and Creutz–Taube mixed valent species is presented in the form of the bmtz-bridged bis[tetracyanoiron(+2.5)] complex 1^{3-} [bmtz = 3,6-bis(2-pyrimidyl)-1,2,4,5-tetrazine] which exhibits a very large comproportionation constant of 10^{14} and a delocalised structure, according to UV–VIS–NIR–IR spectroelectrochemistry in acetonitrile solution.

Mixed-valent compounds with electron transfer sites of similar or identical composition have become the focus of research for a number of reasons.[1–3] These include their function in biochemical systems,[1a] their model character for inner-sphere electron transfer,[1b,c] their special spectroscopic or other physical properties,[1d] their potential in 'molecular electronics'[1e] and their role as test systems for theory.[1d,f] Among the best known such mixed-valent coordination compounds are the cyanoferrate(III,II) species[2] Prussian Blue $Fe^{III}_4[Fe^{II}(CN)_6]_3$ and the molecule-bridged dinuclear Creutz–Taube ion $[(H_3N)_5Ru(\mu\text{-}pz)Ru(NH_3)_5]^{5+}$ (pz = pyrazine) with delocalised valencies of +2.5 for the equivalent metal centres.[1b,c,3] Although molecule-bridged diiron(III,II) species have been reported with various comproportionation constants K_c,[4] cyanoiron compounds like $[(NC)_5Fe(\mu\text{-}pz)Fe(CN)_5]^{5-}$ or $[(NC)_4Fe(\mu,\eta^4\text{-}bpym)Fe(CN)_4]^{3-}$, bpym = 2,2′-bipyrimidine, showed only small values $K_c < 10^3$ in aqueous media and thus weak metal–metal interaction.[5]

$$K_c = 10^{\Delta E/59\ mV} = [M^{(n-1)}]^2/[M^n][M^{(n-2)}] \qquad (1)$$
$$M^n + M^{(n-2)} \rightleftharpoons 2\ M^{(n-1)}$$

In the course of exploring the potentially tetrafunctional ligand bmtz [3,6-bis(2-pyrimidyl)-1,2,4,5-tetrazine][6] we discovered that the ligand can serve as an efficient bridge for promoting metal–metal interactions. The diruthenium compound $[(bpy)_2Ru(\mu,\eta^4\text{-}bmtz)Ru(bpy)_2]^{5+}$ [6] and the related $[(H_3N)_4Ru(\mu,\eta^4\text{-}bptz)Ru(NH_3)_4]^{5+}$ [7] showed unusually large K_c values of $> 10^{10}$ and $10^{15.0}$, respectively. Reacting bmtz with $FeCl_2$ and $[NEt_4]CN$‡,§ we have now found that the resulting redox system $[(NC)_4Fe(\mu,\eta^4\text{-}bmtz)Fe(CN)_4]^{n-}$ $\mathbf{1}^{n-}$ exhibits a diiron(III,II) state (n = 3) with an enormous stability constant K_c and delocalised vacancies.



In MeCN–0.1 M $[NBu_4]PF_6$ the redox system $\mathbf{1}^{n-}$ exhibits four reversible one-electron waves between the n = 6 and n = 2 oxidation states at −1.92, −1.41, −0.32 and +0.52 V *vs.* $Fc–Fc^+$. The paramagnetic intermediate states with n = 3 (K_c = $10^{14.1}$) and n = 5 (K_c = $10^{8.7}$) could be characterised by EPR after *in situ* electrolytic generation from the diiron(II) precursor (n = 4).[8] Whereas the reduced form clearly shows a ligand-centered radical species at g = 1.998,[6–9] the oxidation produces an EPR signal with g components at 2.57, 2.44 and 1.78 in frozen acetonitrile solution. This result points to a metal-based oxidation process, implying the formation of a mixed-valent species.[1a,4] The corresponding data for the Creutz–Taube ion showed a similar splitting of g components at 2.799, 2.489 and 1.346,[10] the larger g anisotropy resulting from higher spin–orbit coupling effects from the heavier element (Ru *vs.* Fe).

Electronic absorption spectra of the n = 3, 4, 5 forms were obtained by spectroelectrochemistry in MeCN–0.1 M $[NBu_4]PF_6$, the isolated n = 4‡ and 3§ forms could also be studied separately. The intense (ε = 19 840 $dm^3\ mol^{-1}\ cm^{-1}$) metal-to-ligand charge transfer (MLCT) band at 831 nm of the diiron(II) form is shifted to higher energy, both on reduction and oxidation (Fig. 1). Oxidation to the mixed-valent state produces an asymmetrical intervalence charge transfer (IVCT) transition at 2245 nm. While the corresponding energy of 4450 cm^{-1} suggests weaker metal–metal interaction than in the Creutz–Taube ion,[3] the low intensity at ε = 750 $dm^3\ mol^{-1}\ cm^{-1}$ reflects the bis-chelate nature of the system with a chelate-enforced orientation unfavourable for orbital overlap. It was shown previously[7,11] that the IVCT features in dinuclear complexes with related bis(bidentate) bridging ligands exhibit very low-intensity IVCT bands in spite of large comproportionation constants K_c.

The question of localisation or delocalisation in mixed-valent complexes in solution may be most elegantly answered by vibrational spectroscopy.[12,13] On the corresponding time scale of about 10^{-12} s the appearance of averaged bands in relation to the neighbouring oxidation states suggests delocalisation whereas the appearance of separate or broadened features indicates localisation. The redox system $\mathbf{1}^{n-}$ was thus studied in the cyanide stretching region for n = 3, 4 and 5 (Fig. 2). The direction of shifts of the typically single band (very close A_1, B_1 and B_2 features) corresponds to charge alteration,[11–13] however, the oxidation to a metal-based mixed-valent species and the

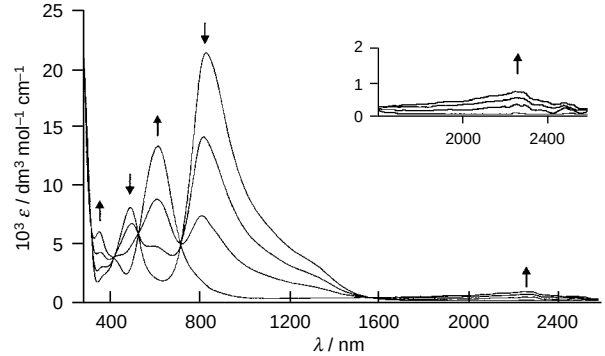


Fig. 1 UV–VIS–NIR spectroelectrochemical response of the $\mathbf{1}^{4-}$ ion (831 and 489 nm) on one-electron oxidation (2245, 613 and 354 nm) in MeCN–0.1 M $[NBu_4]PF_6$

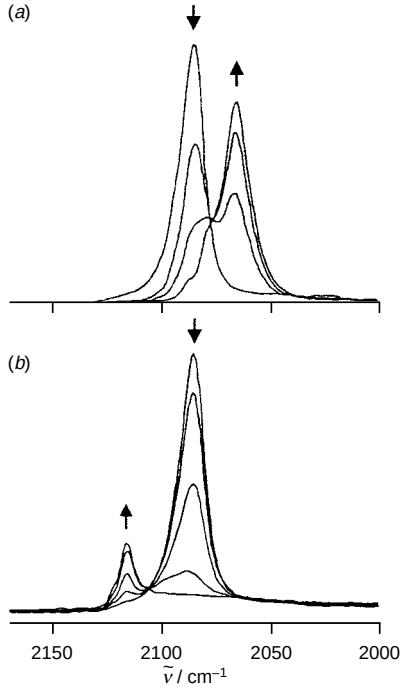

Fig. 2 IR-spectroelectrochemical response of the $\mathbf{1}^{4-}$ ion (ν_{CN} = 2085 cm^{-1}) on one-electron reduction (*a*) (2064 cm^{-1}) and oxidation (*b*) (2116 cm^{-1}) in MeCN–0.1 M [NBu_4]PF_6

reduction to a ligand-centered radical complex produce rather similar amounts of high- and low-energy shifts, respectively. As noted previously,[11] such band energy differences are thus not suitable to unambiguously clarify the site of electron addition or removal. However, the appearance of only one albeit intensity-diminished CN stretching band at an intermediate value after one-electron oxidation clearly confirms the delocalised nature of the mixed-valent Fe_2[2,5] species $\mathbf{1}^{3-}$ in agreement with the very large K_c value and the relatively narrow IVCT band ($\Delta\nu_{\frac{1}{2}}$ = 1200 cm^{-1}). Further studies of this and related systems will also focus on the solid state properties of such materials.

‡ A solution of 940 mg (6.0 mmol) [NEt_4]CN in 50 ml MeOH was slowly added to a mixture containing 60 mg (0.25 mmol) bmtz[6] and 190 mg (1.5 mmol) $FeCl_2$ in 50 ml MeOH. After completion of the reaction the green solution was concentrated and the product precipitated by adding acetone and diethyl ether. Recrystallization from EtOH–Et_2O–acetone (1 : 6 : 3) yielded 35% of [NEt_4^+]$_4$ [$\mathbf{1}^{4-}$] as black microcrystals. Correct C, H, N analysis; ^{1}H NMR (CD_3OD): δ 9.67 (dd, H^4), 7.56 (dd, H^5), 8.93 (dd, H^6). UV–VIS (MeCN): λ_{max} = 831 nm (ε = 19 840 dm^3 mol^{-1} cm^{-1}).

§ 50 mg (0.05 mmol) of [NEt_4^+]$_4$[$\mathbf{1}^{4-}$] were oxidized electrolytically at a platinum electrode in MeCN–0.1 M [NBu_4]PF_6. The reaction was monitored by UV–VIS spectroscopy. Precipitation with diethyl ether and washing twice with THF yielded 10 mg (12%) of deep blue [NBu_4^+]$_3$[$\mathbf{1}^{3-}$], identified *via* EPR, IR and UV–VIS–NIR spectroscopy.

Effects of metal ion complexation on the spiropyran–merocyanine interconversion: development of a thermally stable photo-switch

James T.C. Wojtyk,[a] Peter M. Kazmaier[b] and Erwin Buncel*[a]†

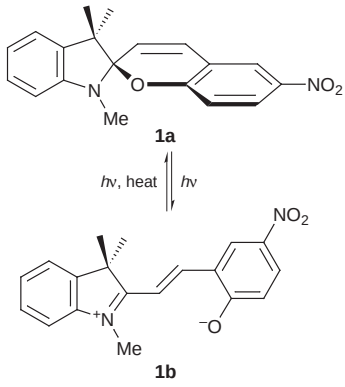
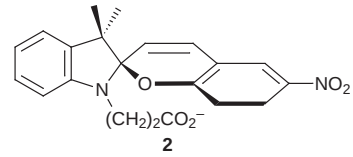
Spectrophotometric absorption and fluorescence measurements of spiropyrans 2 and 3 modified with chelating functionalities, in the presence of Ca^{2+} and Zn^{2+}, provide evidence of a thermally stable spiropyran–merocyanine photoswitch that is modulated by the metal cations.

The potential application of spiropyran–merocyanine equilibria (SP⇌MC), *e.g.* **1a⇌1b**, in molecular devices (sensors, switches, signal transducers) has led to burgeoning activity aimed at exploitation of these systems.[1] A conceptually attractive possibility is the modification of the spiropyran moiety to enable chelation by metal ions and preferentially, stabilize the open MC form.[2] Other approaches to a molecular switch exploit the photoactive anthracene moiety bound to an aza crown ether which upon irradiation undergoes photocyclisation to form a cryptand, with the forward and the thermal reverse reactions strongly affected by metal cations.[3] One can thus envisage a photosensitive molecular switch with selectivity for particular metal cations. However, none of the studies reported to date have provided the necessary requirements[4] of a molecular switch: two thermodynamically stable states, or bistability, with facile interconversion between the two states.

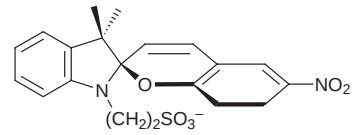


Following our previous studies of SP⇌MC systems and structural/solvent changes thereupon,[5] here we report our results on intramolecular electrostatic bridging in molecules **2** and **3**, *via* addition of a divalent metal ion to stabilize the MC form from thermal decay. Furthermore, the open MC forms of these molecules undergo the ring closure back-reaction through photo-activation at wavelengths appreciably different from the SP→MC light irradiation. Evidence for a dual wavelength photoactivation molecular switch is presented.

Spiropyrans **2** and **3** were synthesized by reaction of 2,3,3-trimethylindolenine with β-iodopropionic acid[6] and γ-sultone, respectively, followed by condensation with 5-nitrosalicaldehyde in the presence of Et_3N and were fully characterized. Studies on the effects of $CaCl_2$ and $ZnCl_2$ on the SP⇌MC process for **2**, **3** and **1a** as a control were conducted in acetone. Following the injection of 1, 2, 5 and 10 equiv. of the dry metal halide salt in acetone into the cuvette containing an acetone solution of the SP (1×10^{-5} M), the cuvette was



2



3

irradiated with a 15 W UV lamp (λ = 254 nm) for 1 min; the MC→SP reaction was monitored spectrophotometrically, scanning at 1 min intervals over a period of 30 min at 25 °C.

A control experiment on the decay of the MC form (λ_{max} = 572 nm) of **1** showed a first-order process, $k_{obs} = 7.30\times 10^{-3}$ s^{-1} [Fig. 1(*a*)], and addition of $CaCl_2$ had no effect on the rate or on the nature of the spectra. However, addition of $ZnCl_2$ resulted in the appearance of two distinct photo-reversible species: one corresponding to the free MC (λ_{max} = 566nm) and the other to a MC–Zn^{2+} complex (λ_{max} = 502 nm). Spectra [Fig. 1(*b*)] generated in the presence of 10:1 ratio of $ZnCl_2$:**1** showed that the amount of the MC–Zn^{2+} complex depended on the $ZnCl_2$:SP ratio. Furthermore, there was a significant decrease in the rate constant for MC decay, from $k_{obs} = 7.3\times 10^{-3}$ s^{-1} when $[Zn^{2+}] = 0$ to $k_{obs} = 3.3\times 10^{-3}$ s^{-1} when $ZnCl_2$:**1** = 10:1. A similar hypsochromic shift was observed upon addition of $ZnCl_2$ or $CaCl_2$ to sodium *p*-nitrophenoxide in acetone, with λ_{max} shifting from 428 nm when $[M^{2+}] = 0$, to 310 nm upon addition of 1 equiv. of MCl_2. Addition of either

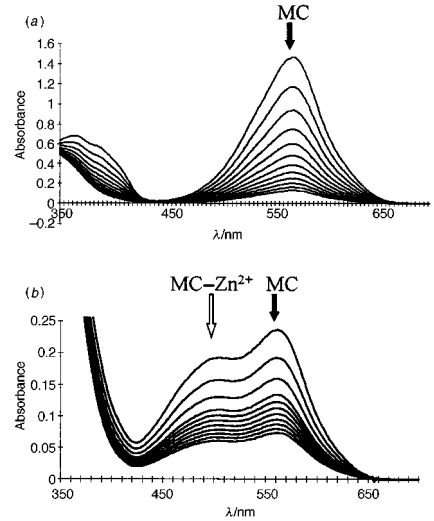


Fig. 1(*a*) Spectra illustrating the first order thermal reversion of the MC form **1b** at 25 °C in acetone (scanning at 1 min intervals). (*b*) Thermal reversion of the free and complexed forms of **1b** (MC and MC–Zn^{2+}) in the presence of $ZnCl_2$:**1** = 10:1.

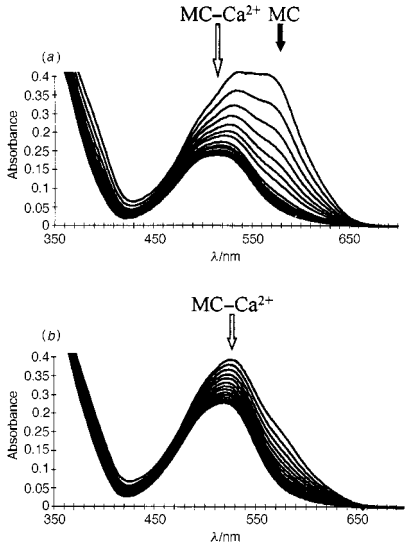

Fig. 2 Illustration of the thermal reversion of the MC and MC–Ca^{2+} forms of **2** in the presence of (*a*) 1 and (*b*) 10 equiv. $CaCl_2$

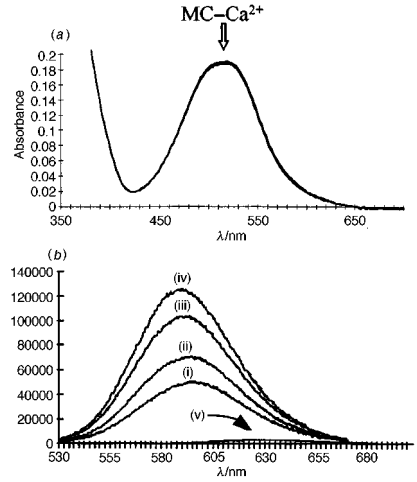

Fig. 3 (*a*) Overlay spectra illustrating the stabilization of the MC–Ca^{2+} form of **3** to thermal reversion in the presence of $CaCl_2$:**3** = 1:1. (*b*) Emission spectra (λ_{ex} = 520 nm) of the MC–Ca^{2+} form of **2** with increasing Ca^{2+}:SP ratios of (i) 1:1, (ii) 2:1, (iii) 5:1 and (iv) 10:1 compared to (v) MC.

metal salt to *p*-nitrophenol had no effect on the absorption spectra, which points to complexation of M^{2+} to the phenoxide moiety in the case of **1b** as the cause of the spectral changes.

For **2** in the absence of metal ion, the first-order decay of the MC form (λ_{max} = 572 nm) occurred with $k_{obs} = 20.0 \times 10^{-3}$ s^{-1} . Addition of Zn^{2+} generated a new photo-reversible peak (λ_{max} = 502 nm) with peak intensity and k_{obs} both being dependent on added [$ZnCl_2$]: $k_{obs} = 9.70 \times 10^{-3}$ s^{-1} for a 5:1 ratio of $ZnCl_2$:**2.** Addition of Ca^{2+} similarly generated a new photo-reversible peak at λ_{max} = 520 nm, the intensity and k_{obs} being dependent on added Ca^{2+} [Fig. 2(*a*),(*b*)]: $k_{obs} = 9.03 \times 10^{-3}$ s^{-1} for $CaCl_2$:**2** = 5:1, *i.e.* half the initial value.

The above results show that introduction of a chelating moiety onto the SP indoline ring results in an electrostatic bridge being formed that inhibits the thermal reversion of the MC form to the SP. In contrast to the lack of effect of Ca^{2+} on ring closure with control SP **1,** Ca^{2+} had a significant effect on the ring-closure of **2**. In addition, the contrasting k_{obs} values and λ_{max} for MC–Ca^{2+} and MC–Zn^{2+} complexes of **2** and the free MC forms demonstrate that stabilization of the MC form to thermal reversion through complexation is metal-dependent.

Similar experiments with **3** showed totally different behaviour. With a 1:1 ratio of Ca^{2+} and Zn^{2+}, complete stabilization of the MC form towards thermal decay was observed [Fig. 3(*a*)], no free MC being detected. The photo-stable form was found to persist for at least three days in the dark but exposure to visible light resulted in rapid decay of the spectrum of the complex.

Fluorescence measurements provided further information on the roles of Ca^{2+} and Zn^{2+} complexation with the MC form of **2** and **3**. As shown in Fig. 3(*b*), the fluorescence intensity increased on increasing the metal halide concentration. Moreover, Fig. 3(*b*) illustrates the overlapped emission spectra using excitation wavelengths of 520 nm for the MC–Ca^{2+} complex (for the MC–Zn^{2+} complex, λ_{oxc} = 502 nm). These observations reveal two main features which inherently facilitate application of these MC–M^{2+} complexes to optical data storage. The first is that fluorescence of the complexed forms is more intense compared to the free MC form, which fluoresces only weakly at these wavelengths. Secondly, the fact that fluorescence occurs at 587 nm for both Ca^{2+} and Zn^{2+} complexed forms, and that the absorption and fluorescence envelopes do not overlap, eliminates the possibility of 'cross-talk' and points to the suitability of fluorescence as the method of choice for 'reading' data that has been 'written' into these systems.

In order to investigate the light-induced reversion of the metal-complexed MC form to SP, a solution of **3**–Ca^{2+} was irradiated continuously with a 520 nm light source. The measured fluorescence intensity decreased gradually over a 30 min period, signifying reversion to the closed SP form. Since the above UV–VIS measurements have shown that the MC form of **3** does not decay over a three day period, this reversion of the complexed MC to the SP form must be a photo-induced process. Clearly, the reversion would be more efficient upon irradiation at shorter wavelengths. Hence switching between the colorless SP and the colored MC–M^{2+} forms can be modulated *via* irradiation at two wavelengths: SP→MC–M^{2+}, 254 nm; MC–M^{2+}→SP, 520 nm (or lower λ).

The results of this work have shown that the MC form of **3** has been stabilized towards thermal reversion, a key requirement of optical data storage systems.[4] Importantly, this system exhibits bistability at room temperature and is photo-switchable with two different light energies.

In conclusion, this report documents the first thermally stable SP–MC photo-switch *via* intramolecular bidentate metal ion chelation. Further investigations are ongoing into the effects of alkyl chain length and metal ion complexation ability in stabilizing the MC form. Optimization, *via* molecular modeling, enforcing ligand conformation and varying the heteroatom substitution and the nature of the metal, may lead to a prototypical device based on these systems.

Reaction in supercritical CO_2; an intercalation of 4-phenylazoaniline between layers of montmorillonite pillared with tetramethylammonium ions

Ryo Ishii,*† Hideo Wada and Kenta Ooi

Shikoku National Industrial Research Institute, 2217-14 Hayashi-cho, Takamatsu-shi, Kagawa, 761-0395, Japan

The intercalation reaction of 4-phenylazoaniline into montmorillonite pillared with tetramethylammonium ions has been performed successfully in supercritical CO_2 (SCC) at T = 313 K (P = 15 MPa), demonstrating that SCC is a better medium than organic solutions for intercalating large amounts of guest molecules into a host compound without the contamination of solvent.

The host–guest chemistry of intercalation systems have attracted attention for synthesis strategies for nanostructured functional materials.[1] These syntheses are usually achieved by promoting the intercalation reaction in the liquid phase. However, the solvent molecules inevitably participate in diffusion and adsorption of solutes in the reaction. A supercritical fluid (SCF) has several advantages for such an adsorption reaction with porous materials. First, solute transfer through the solid–SCF interface is smooth because of the low surface tension of SCF as well as its low viscosity. Second, the adsorption amount can be varied by controlling the dissolving power for the solute *via* the temperature and the pressure of the SCF. Third, the competitive adsorption of the solvent on the porous material is rare because of the weaker interactions between the solid surface and solvent molecules in a supercritical state than in the interaction in the liquid state. For material processing, these advantages lead us to anticipate the development of composite materials containing a large amount of functional adsorbate in the pores, but little contaminant by solvent molecules. Here we present a new intercalation technique using supercritical CO_2 (SCC) as the reaction medium. 4-Phenylazoaniline (PAA) was used as the intercalating molecule and montmorillonite (Mnt) pillared with tetramethyl ammonium (TMA) ions as the layered host (TMA-Mnt). This composite material is of interest as a candidate for photo-functional molecular devices.[2]

Gray colored TMA-Mnt was synthesized *via* the ion exchange method reported by J.-F. Lee *et. al.*[3] using tetramethylammonium chloride (Tokyo Kasei Co., purity : > 98%) and montmorillonite (Kunimine Industries Co., cation exchange capacity: 119 mequiv per 100 g). Chemical analysis of the nitrogen and carbon in TMA-Mnt indicated that 80 ± 3% of Na^+ ions were replaced by TMA ions. XRD analysis showed a layered structure for TMA-Mnt with basal spacing of 1.387 nm. The N_2 adsorption at 77.4 K indicated the presence of slit-shaped pores with a BET surface area of 180 $m^2\ g^{-1}$ and a pore volume of 0.068 $cm^3\ g^{-1}$.

The intercalation of PAA into TMA-Mnt was performed using a critical point dryer (HCP-2, Hitachi Koki Co.). After batches of TMA-Mnt (400 mg) and PAA (100 mg) were placed separately in the high pressure cell of the apparatus, CO_2 gas was supplied and then liquefied in the cell at 263 K. The liquid CO_2 was gradually heated to 313 K (pressure: 15.0 ± 0.5 MPa), at which point the CO_2 (T_c = 304.21 K, P_c = 7.13 MPa) was in a supercritical state. Separate batches were maintained in this state for 1, 6, 12, 24, 48 and 72 h, respectively. The cell temperature was then cooled to 293 K and the CO_2 liquid vented. The samples after SCC treatment were washed once with 50 cm^3 n-hexane to remove the residual PAA from the surface. Total nitrogen (TN) and total carbon (TC) contents of the SCC treated samples were determined by GC with a SUMIGRAPH GCT-12N (Sumika Bunseki Center Co.). The PAA uptake by TMA-Mnt in each sample was evaluated from the TN value by subtracting that due to TMA ions. The solubility of PAA in the SCC phase was roughly determined from the weight loss of PAA solid by SCC treatment in the absence of TMA-Mnt. The solubility was estimated as 0.3 mg cm^{-3}, considered reasonable since Hildebrand's solubility parameter of SCC at T = 313 K and P = 15 MPa is similar to that of n-hexane, which shows saturated solubility of 1.8 mg cm^{-3}.[4]

Yellowish samples were obtained by the SCF treatment. The PAA contents estimated from the TN values are listed in Table 1. The CO_2 residue was found to be negligible since the ratios of TN uptake to TC uptake were between 0.20 and 0.25; these are close to the TN to TC ratio (0.25) of PAA molecules. The PAA content increases rapidly during the first 24 h of treatment and is then almost constant from 24 to 72 h. The adsorption rate is relatively slow compared to the conventional dissolution rate of solute in SCF media.[5] The relatively slow rate may be caused by the slow diffusion of PAA molecules through the internal pores of TMA-Mnt. Since the pore size is near the lower limit for PAA diffusion, the intraparticle diffusion of PAA molecules may be the rate determining step in the present case, rather than the PAA transfer through the SCC–solid interface. The N_2 adsorption isotherms are analyzed with V_l *vs.* t plots, using the t values of Lecloux and Pirard[6] and C constants determined by BET plots, as shown in Fig.1. The V_l *vs.* t plot for the untreated TMA-Mnt shows a downward deviation from the straight line at t > 0.4 nm, indicating the presence of micropores around 0.4 nm in width. The downward deviation is not observed for the samples treated with SCC for 6 h or more. This demonstrates that the micropores disappear with the increase in the PAA uptake. The BET surface area, micropore volume, and the basal spacing determined by XRD analysis are given for the SCC-treated samples in Table 1. The specific surface area and the micropore volume decrease significantly with the PAA content.

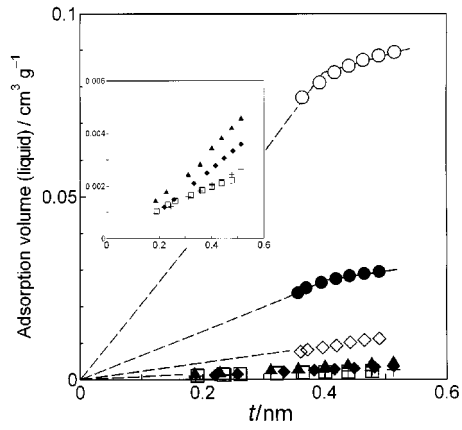

Fig. 1 V_l *vs.* t plots of TMA-Mnt and PAA-TMA-Mnt composites: (○) untreated TMA-Mnt, and SCC treatment for (●) 1, (◇) 6, (□) 12, (▲) 24, (◆) 48 and (+) 72 h

Table 1 PAA content, basal spacing, BET surface area and micropore volume of PAA-TMA-Mnt composites produced with SCC as a medium

Reaction time/h	PAA content/ mg g^{-1}	Basal spacing/ nm	BET surface area/m^2 g^{-1}	Pore volume/ cm^3 g^{-1}
0	0	1.38(7)	180	0.068
1	8.6	1.39(6)	60	0.018
6	29	1.40(7)	22	n.d.[a]
12	38	1.41(3)	5	n.d.
24	70	1.43(6)	7	n.d.
48	75	1.43(9)	6	n.d.
72	80	1.43(9)	4	n.d.

[a] n.d. = Values not determined.

In addition, the basal spacing, which corresponds to the interlayer distance of the PAA-TMA-Mnt composite, increases slightly with an increase in the adsorbed amount. These results clearly indicate that most of the PAA molecules are intercalated in the interlayer of TMA-Mnt. The equilibrium PAA uptake is evaluated as 75 mg g^{-1} (0.38 mmol g^{-1}) from the time courses of PAA adsorption in Table 1. The intercalation capacity is calculated as 124 mg g^{-1} from the micropore volume of TMA-Mnt and the geometric volume of a PAA molecule ($1.2 \times 0.5 \times 0.3$ nm). The PAA uptake reached 60% of the intercalation capacity, indicating that SCC is an efficient intercalation medium as compared with PAA uptakes in the solution stated below.

Liquid-phase intercalation reactions at 313 K for 48 h with acetone and n-hexane were investigated for comparison with the reaction in SCC phase. We confirmed that the liquid-phase reactions attain equilibrium after treatment for 48 h. The adsorption isotherms of PAA in the organic solutions are given in Fig. 2 together with the PAA uptake in the SCC system. The PAA adsorptivity is much higher in the SCC phase than those in the organic systems at the same PAA concentration. The PAA uptake (31 mg g^{-1}) in n-hexane solution is less than half that (80 mg g^{-1}) in the SCC phase at a PAA concentration of 0.3 mg cm^{-3}. The PAA uptake is estimated to be negligible in acetone solution at the same PAA concentration. The difference in PAA adsorptivity can be explained by considering two factors; the dissolving power of the solvent for the solute and the influence of competitive adsorption of solvent on the intercalation site. The lower dissolving power of SCC makes the PAA molecules unstable in the fluid phase, driving the migration of solutes from the fluid to the TMA-Mnt phase. Also, competitive adsorption may not occur in the SCC system, since the kinetic energy of CO_2 molecules is higher than the interaction energy between CO_2 and the pore wall.[7] On the other hand, TMA-Mnt shows high adsorptivity (more than 50 mg g^{-1}) for hydrocarbon and organic solvents at 323 K.[8] The competitive adsorption of solvent molecules causes a decrease of PAA uptake, depending on PAA concentration. These two factors are likely to be responsible for the higher PAA adsorptivity in the SCC system.

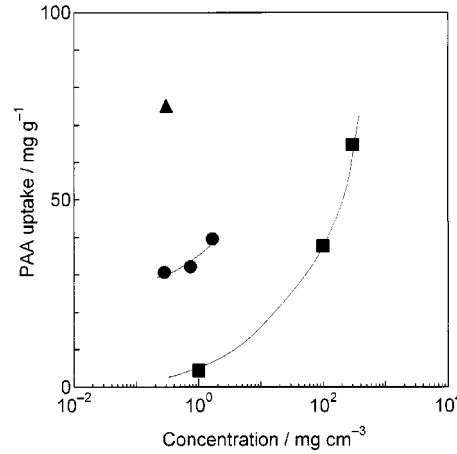

Fig. 2 PAA uptakes into TMA-Mnt in (●) n-hexane, (■) acetone and (▲) SCC

In conclusion, we have successfully intercalated PAA into TMA-Mnt using SCC as a medium. The resultant PAA-TMA-Mnt composite has relatively large amounts of PAA without CO_2 contamination. This demonstrates that SCC is a highly suitable medium for the intercalation reaction. The SCF technique can be expected to find application as a unique method for the synthesis of the nanostructural functional materials.

The authors are grateful for invaluable discussions and suggestions from Dr E. Kanezaki at the University of Tokushima. We also thank Kunimine Co. Ltd., for supplying Mnt samples.

Solid state coordination chemistry of the copper cyanide–organoamine system: hydrothermal syntheses and structural characterization of $[\{Cu_2(bpy)_2(CN)\}Cu_5(CN)_6]$ and $[Cu_4(CN)_4(biquin)]$

Douglas J. Chesnut and Jon Zubieta*†

Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA

The hydrothermal reactions of CuCN and $Cu(NO_3)_2{\cdot}2.5H_2O$ with the appropriate organonitrogen ligand in water yielded a one-dimensional chain, $[Cu_4(CN)_4(biquin)]$ 1, and a material with a two-dimensional anionic honeycomb network and interpenetrating binuclear cations, $[\{Cu_2(bpy)_2(CN)\}Cu_5(CN)_6]$ 2.

The contemporary interest in solid state inorganic materials reflects their properties, which endow these materials with applications ranging from heavy construction to microcircuitry.[1] A powerful synthetic approach for the manipulation of the microstructures of solid state inorganic materials exploits the incorporation of organic components, which contribute to the increased complexity as one constituent in a hierarchical structure exhibiting a synergistic interaction between the organic and inorganic substructures.[2,3] Organic materials have been demonstrated to play an important role in five subclasses of the oxide family of materials: zeolites,[4] mesoporous oxides of the MCM-41 type,[5] biomineralized materials,[6] microporous octahedral–tetrahedral framework transition metal phosphates[7] and organically templated molybdenum oxides.[8] We have recently extended this concept of templating anionic inorganic networks with organic constituents to the copper halide system, as represented by $[\{Cu(en)_2\}_2Cu_7Cl_{11}]$.[9] The rich supramolecular chemistry of the metal derivatives of the pseudohalide cyanide[10] encouraged us to expand our investigations to the copper–cyanide–organoamine family of materials, exploiting the bridging cyano ligand as a rigid tether in the propagation of Cu^I geometry in solid state materials. These studies have resulted in a variety of one- and two-dimensional materials of which $[Cu_4(CN)_4(biquin)]$ **1** and $[\{Cu_2(bpy)_2(CN)\}Cu_5(CN)_6]$ **2** are representative (biquin = 2,2′-biquinoline; bpy = 2,2′-bipyridine).

Compound **1** was prepared as yellow–orange crystals in *ca.* 15–25% yield from the reaction of CuCN, $Cu(NO_3)_2{\cdot}2.5H_2O$, 2,2′-biquinoline and H_2O in the mole ratio 4.2 : 0.99 : 1.0 : 280 at 170 °C for 86.5 h. Compound **2** was prepared as light orange crystals in *ca.* 35% yield in a similar fashion from the reaction of CuCN, $Cu(NO_3)_2{\cdot}2.5H_2O$, 2,2′-bipyridine and water in the mole ratio 6.3 : 1.0 : 1.0 : 290. Compound **1** cocrystallized with a red phase, identified as $[Cu_2(CN)_2(biquin)]$, while compound **2** cocrystallized with bright red crystals of [Cu(CN)(bpy)].[11] Curiously, the preparation of **1** and **2** in crystalline form and reasonable yields requires the presence of a Cu^{II} precursor. We have noted previously[12] that organoamines function as reducing agents in hydrothermal reactions, perhaps serving to generate a repository of reduced metal species for further aggregation. Optimization of yields may be accomplished by employing an excess of organonitrogen ligand to Cu^{II} precursor.

As shown in Fig. 1, the structure of **1**‡ exhibits a backbone constructed from a zigzag chain of two-coordinate $\{Cu(CN)_2\}$ sites and three-coordinate $\{Cu(CN)_3\}$ sites, with $\{Cu_2(CN)(biquin)\}$ groups projecting from the chain. The Cu–CN backbone and its attendant side chains are nearly planar with the best plane parallel to the 101 crystallographic plane.

While Cu–CN chain structures have been reported,[13] the greater structural complexity of **1** derives from the presence of the biquinoline ligand, which may serve to passivate the copper chain with respect to extension in two or three dimensions.

The structure of **2**† consists of sheets of fused 36-membered puckered honeycomb rings interpenetrated by $[(bipyCu)_2CN]^+$ cations, shown in Fig. 2. The rings are composed of two nearly linear $\{Cu(CN)_2\}$ sites, four 'bent' $\{Cu(CN)_2\}$ moieties and six $\{Cu(CN)_3\}$ distorted trigonal planar sites which serve as junctions between adjacent rings. As illustrated by the view of Fig. 3, each ring is interpenetrated by two space-filling and charge compensating $[Cu_2(bpy)_2(CN)]^+$ cations at an oblique angle to the {Cu(CN)Cu} axis of the cation with respect to the face of the ring. The honeycomb layers are offset along the stacking axis *b*, so as to generate channels of approximate dimensions 5.4 × 9.0 Å occupied by the cations (Fig. 4). Each cation interpenetrates rings from two adjacent layers, which are separated by 3.5 Å. While two-dimensional Cu–CN networks have been observed for $[Cu_3(en)_2(CN)_4]{\cdot}6H_2O$[14] and $K[Cu_2(CN)_3]{\cdot}H_2O$,[15] the layers are constructed from significantly smaller 15 and 18 membered rings.

The structures of **1** and **2** demonstrate the power of hydrothermal synthesis in the preparation of organic–inorganic composite materials. Not only are differential solubility problems avoided, reducing the tendency to phase segregate, but structurally more complex metastable phases are favored.[16] The structural complexity, in general, reflects the versatility of the organonitrogen component which may function as counterion,

ligand to the copper cyanide backbone or ligand in a coordination complex anion. In its role as ligand, the biquinoline in **1** serves to passivate the copper so as to prevent extension of the structure in more than one dimension. The increased hydrophobicity of biquinoline relative to bipyridine may result in the larger nonpolar domains localized in the interstrand regions. The role of the organic ligand as a component of a coordination complex cation, a recurring theme in metal oxide–organoamine chemistry,[17] appears to extend to the metal–halide and metal–psuedohalide phases. The large ring sizes of the copper cyanide networks of **2** are required to accommodate the large binuclear cations, suggesting that cation size in such structures may be a determinant not of interlamellar spacing but of ring topology and channel dimensions. We are investigating the roles of coordination complex cations of various sizes and shapes in defining the structures of metal halide and metal pseudohalide phases.

Hydrothermal synthesis and structure of a three-dimensional open-framework cobalt molybdenum(VI) phosphate containing ethylenediammonium ions: $(C_2H_9N_2)_6[Co_3Mo_4P_4O_{28}]$

Jian J. Lu, Yan Xu,*† Ngoh K. Goh and Lian S. Chia

Division of Chemistry, School of Science, Nanyang Technological University Singapore 259756, Republic of Singapore

The first microporous cobalt molybdenum(VI) phosphate, crystallised under hydrothermal conditions, is constructed from unique $CoMo_2P$ tetrahedral units connected by CoO_4 tetrahedra and by sharing corners; the framework contains interlocking cavity units and unusual 7-ring intersecting channels that are filled with charge-compensating ethylenediammonium ions.

While the synthesis and characterisation of three-dimensional framework aluminosilicate zeolites[1] and aluminophosphate materials[2] has been an actively pursued area of materials chemistry, only in recent years have other open-framework inorganic materials started to emerge. The driving force behind the effort is to engineer open-framework materials with desired chemical and catalytic reactivities. One of the strategies adopted is to incorporate d-block elements into these materials as stoichiometric framework constituents through the combined effects of hydrothermal synthesis and amine templates. Practicing this strategy results in the successful synthesis of open-framework reduced molybdenum phosphates,[3] mixed valent molybdenotungsten phosphates,[4] vanadium phosphates,[5] cobalt phosphates,[6] vanadium oxides,[7] non-oxide solids[8] and a number of layered molybdenum(VI) solids.[9] However, three-dimensional open-framework molybdenum(VI) solids remain largely unexplored except for a hexagonal molybdenum trioxide phase.[10]

In the course of our investigation on the synthesis of molybdenum(VI) polyoxoanion based solid materials, we have hydrothermally synthesised a series of novel one- and two-dimensional organically templated solids.[11] Extending this idea, we explored the incorporation of 'heteroatoms' as tetrahedral tethers and applied the 'magic' F^- mineraliser[12] to assemble molybdenum(VI) polyoxoanions forming three-dimensional open frameworks. Here, we report the synthesis and structural characterisation of the first open-framework cobalt molybdenum phosphate with entrenched charge-compensating ethylenediammonium ions, $(C_2H_9N_2)_6[Co_3Mo_4P_4O_{28}]$ **1**.

Compound **1** was prepared from the hydrothermal reaction of $CoCl_2{\cdot}6H_2O$, $MoO_3{\cdot}H_2O$, H_3PO_4 (85 mass%), NaF, ethylenediamine and H_2O in a mole ratio of 1 : 2.2 : 3.3 : 3.1 : 1.2 : 407. Ethylenediamine was introduced at the last stage into the clear solution of $CoCl_2{\cdot}6H_2O$, $MoO_3{\cdot}H_2O$, H_3PO_4, NaF and H_2O resulting in a pinkish slurry. Crystallisation was carried out in a sealed Teflon-lined stainless-steel autoclave reactor at 160 °C and autogenous pressure for 3 days. The presence of NaF was found to be critical for the successful synthesis of **1**. The use of $Co(NO_3)_2{\cdot}6H_2O$ instead of $CoCl_2{\cdot}6H_2O$ resulted in the crystallisation of the same product **1**. The chemical analysis in combination with the single crystal X-ray structure determination‡ and thermogravimetric analysis confirmed the chemical formula of $C_3H_{13.5}N_3Co_{0.75}MoPO_7$ and the absence of F^- ions from the crystal structure of **1**. Simultaneous TG/DT analysis and *in-situ* powder XRD studies§ indicated that ethylenediamine can be removed at 360 °C and the structure of **1** remained intact until *ca.* 700 °C. By replacing the heteroatom Co^{2+} with Al^{3+} and Zn^{2+}, a few new organic/MoPO hybrid phases crystallised as identified by both the single and powder X-ray diffraction methods. One of the organic/MoPO hybrid phases, $(C_2N_2H_{10})_2[Mo_5P_2O_{22}]{\cdot}H_2O$, crystallised in monoclinic symmetry.¶

As shown in Fig. 1, the three-dimensional framework of **1** is constructed from the unique $CoMo_2P$ pseudo-tetrahedral building units (Fig. 1 inset) which consist of crystallographically independent one MoO_6 octahedron, one PO_4 tetrahedron and a half CoO_6 octahedron. The $CoMo_2P$ units are linked into a covalently bonded three-dimensional framework through (i) direct and (ii) indirect connection modes as shown in Fig. 2(*a*). The direct connection mode refers to the connection between two adjacent $CoMo_2P$ units by corner-sharing Mo and Co atoms. The indirect connection mode refers to the connection of four 4_1-screw-axis-related $CoMo_2P$ units, each linking to a common CoO_4 tetrahedron *via* a corner-shared oxygen atom from PO_4 of the respective $CoMo_2P$ unit. This gives rise to two cavity units, A and B, of **1** as shown in Fig. 2(*b*). The cavity A is circumscribed by four MoO_6, four CoO_6, four PO_4 and two CoO_4 units and contains four identical 3- and 7-ring windows. In the cavity B, five MoO_6, five PO_4, two CoO_6 and two CoO_4 units are linked up *via* corner-shared oxygen atoms forming one 8-ring window, three distinct 3-ring windows and three 7-ring windows of two distinct types (I: $Mo_2Co_3P_2$ and II: $Mo_3Co_2P_2$). The cavities **A** and **B** are interlocked by a single 7-ring window encircled by one CoO_4, two PO_4, two MoO_6 and two CoO_6 units (highlighted). The three-dimensional framework of **1** can also

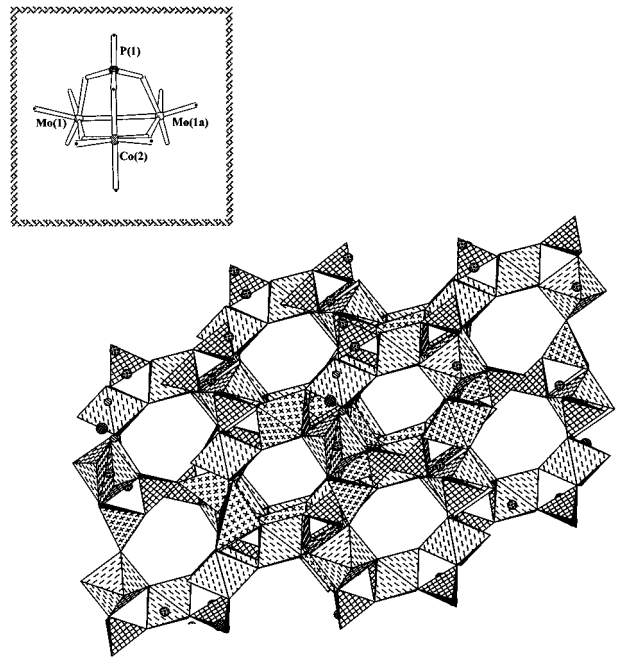

Fig. 1 A polyhedral view of $(C_2H_9N_2)_6[Co_3Mo_4P_4O_{28}]$ **1** showing the intersecting 7-ring channels. Inset shows the $CoMo_2P$ tetrahedral unit.

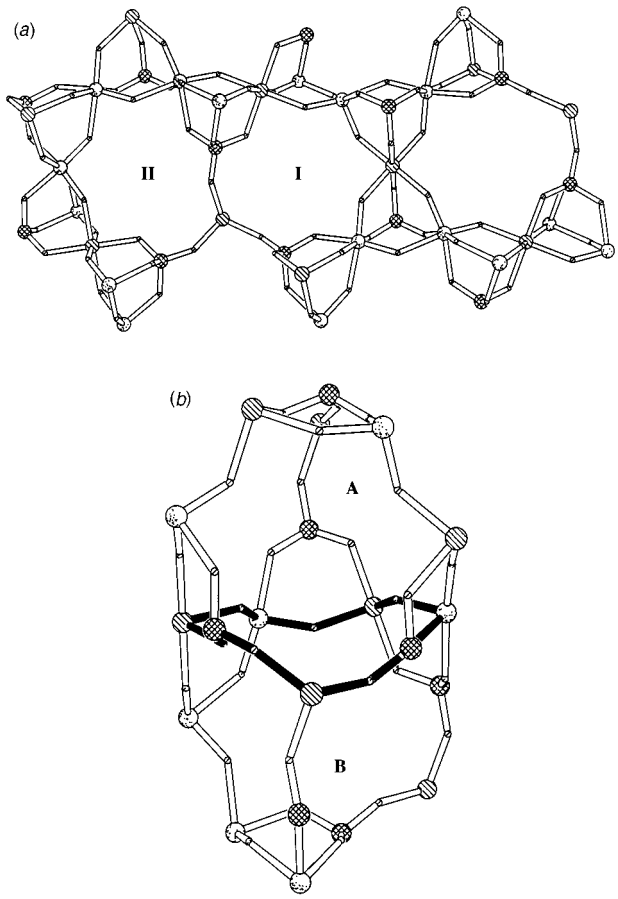

Fig. 2 (*a*) A general view of $(C_2H_9N_2)_6[Co_3Mo_4P_4O_{28}]$ **1** showing the two types of connection modes of the $CoMo_2P$ units and two types of 7-ring windows. (*b*) A view of interlocked cavities **A** and **B** by a single 7-ring window (with highlighted bonds) showing the 3-, 7- and 8-ring windows. The atoms shown are: dotted circles for Mo, cross-hatched circles for P, shaded circles for Co and small circles for O.

be envisioned as being built up in space group $I4_1/a$ from the aforementioned interlocking cavity units [**A** + **B**] by sharing the $CoMo_2P$ units. Two types of intersecting 7-ring channels are formed in the so-packed cobalt molybdenum phosphate framework as shown in Fig. 1 and 2(*a*).

The 7-ring channels of **1** are filled with partially protonated ethylenediamine molecules. The ethylenediammonium ions interact with the framework through contacts between the N atoms of the ethylenediammonium ions and the O atoms of the framework with N(H)···O 2.82–2.94 Å. One of the two nitrogen atoms of the ethylenediammonium ion is found to be involved in the N(H)···O interactions, supporting the assignment of partial protonation of ethylenediamine molecules. However, uncertainty is encountered in locating H atoms attached to the N atoms due to the severe disordering of the ethylenediammonium ions in the crystal packing of **1**.

The asymmetric unit of **1** consists of one MoO_6 octahedron, one PO_4 tetrahedron, a half CoO_6 octahedron, a quarter CoO_4 tetrahedron, and one and a half ethylenediammonium ions. The coordination geometry of the three framework atoms, Mo, P and Co, is exclusively defined by unsymmetrically corner-shared oxo groups. The geometric parameters of the cobalt molybdenum phosphate framework which are reasonably well determined (data:parameters ratio *ca.* 10:1) show that the Mo–O contacts are in the range 1.767(3)–2.198(3) Å, the P–O contacts in the range 1.517(4)–1.556(3) Å, the Co(1)–O contact 1.928(4) Å (tetrahedral Co, T_{Co}) and the Co(2)–O contacts in the range 2.066(3)–2.102(3) Å (octahedral Co, O_{Co}). The P–O and Co–O (at both T_{Co} and O_{Co} sites) contacts are within the expected range.[6a,13] The molybdenum site exhibits short-to-medium bond length pattern regardless of the absence of terminal oxo groups which is not uncommon to molybdenum(VI) oxides containing unsymmetrical bridging oxo groups.[14] This may also be attributed to the existence of moderate hydrogen bonds involving some of the O atoms of the MoO_6 units.

The cobalt molybdenum phosphate **1** reported here represents the first successful synthesis and characterisation of covalently bonded three-dimensional open-framework structure in the metal molybdenum(VI) phosphate compositional domain. The enhanced solvating effect of water and mineralising effect of F^- under the hydrothermal autogenous conditions evidently provide the environment required for the assembly of an open-framework from molecular precursors. It opens up the possibility of applying this method for assembling other three-dimensional metal molybdenum phosphates with potentially interesting or useful properties.

Intensity data were collected by $\theta/2\theta$ scans on a Siemens P4 X-ray diffractometer with graphite-monochromated Mo-Kα radiation. Empirical absorption corrections were made from ψ-scan data using an applied program at the data reduction stage along with the correction of Lorentz and polarization factors. The structure was solved by direct methods and refined using full-matrix least squares on F^2 using the SHELXTL-PLUS package. The final refinement was based on 1384 reflections with $I > 2.0\sigma(I)$ for 135 parameters and converged to R_1/wR_2 = 0.0303/0.0742 (R_1/wR_2 = 0.0388/0.0896 for all data). CCDC 182/933.

§ *Powder XRD data*: *in situ* XRD patterns were collected on a Siemens D5005 diffractometer with graphite-monochromated Cu-Kα radiation (λ = 1.5406 Å). Heating was conducted in the temperature range room temp.–1000 °C under vacuum.

¶ *Crystal data* for the monoclinic $(C_2N_2H_{10})_2[Mo_5P_2O_{22}]\cdot H_2O$ phase: M_w = 1035.9, space group $C2/c$ with unit cell dimensions a = 17.642(4), b = 10.039(2), c = 13.777(3) Å, β = 96.92(3)°, V = 2422.4(8) Å^3.

Reaction of *S*-nitrosothiols with ascorbate: clear evidence of two reactions

Anthony J. Holmes and D. Lyn H. Williams*†

Chemistry Department, University of Durham, South Road, Durham, UK DH1 3LE

Ascorbate reacts with *S*-nitrosothiols at pH 7.4 *via* two pathways, in which ascorbate (at low concentration) acts as a reducing agent generating Cu^{I}, and (at high concentration) acts as a nucleophile, attacking the nitroso group.

We have shown[1] that *S*-nitrosothiols (RSNO) decompose in aqueous buffer at pH 7.4 to give nitric oxide and the corresponding disulfides, in a reaction brought about by Cu^{I} [eqn. (2)], which is generated from Cu^{II} by reduction with thiolate anion [eqn. (1)]. Often there is enough Cu^{II} present in the water/buffer system to effect reaction, and usually there is enough thiolate present in equilibrium[2] with RSNO [eqn. (3)] to bring about the reduction. In addition it has been shown[3] that Cu^{II} bound in proteins, peptides and amino acids can also be reduced by thiolate and effect RSNO decomposition, so that it is not necessary for the Cu^{II} to be present as free solvated Cu^{2+}. It follows that other reducing agents should be capable of the copper reduction, and it has been shown[1] that added ascorbate does indeed behave in a similar fashion to added *N*-acetylpenicillamine in the decomposition of *S*-nitroso-*N*-acetylpenicillamine, but hitherto no detailed mechanistic study has been carried out.

$$2Cu^{2+} + 2RS^{-} = 2Cu^{+} + RSSR \quad (1)$$

$$Cu^{+} + RSNO = Cu^{2+} + RS^{-} + NO \quad (2)$$

$$RSH + HNO_2 = RSNO + H_2O \quad (3)$$

Recently, however, it has been reported, (i) that ascorbate will promote NO release from *S*-nitroso albumin and *S*-nitroso glutathione (GSNO) in blood plasma even in the presence of metal chelating agents,[4] and (ii) in a separate study[5] using plasma and fractions of liver and kidney extracts, it is also claimed that ascorbate promotes the decomposition of GSNO, again in the absence of copper ions. A further paper in the biological literature[6] found glutathione and nitrite as the products of the reaction of GSNO with ascorbate. These findings prompted us to examine further the effect of ascorbate on RSNO decomposition.

We have examined the decomposition at pH 7.4 of GSNO, generated in solution from glutathione and nitrous acid, in the presence of a low concentration of ascorbic acid and with added Cu^{2+} (1×10^{-4} mol dm^{-3}). Fig. 1 shows the resulting absorbance–time plots measured at 545 nm.‡ Trace (*a*) shows the small extent of decomposition (< 10% in 3 h) which occurs when no ascorbic acid is present. This probably represents the spontaneous thermal decomposition. This is in marked contrast to trace (*b*) which results from the same experiment with added ascorbic acid (2×10^{-4} mol dm^{-3}). Here, reaction goes to completion by a first order process with a half life of *ca.* 18 min.

This reaction is dramatically stopped, virtually completely (over the time scale examined), by the addition, at the start, of EDTA (1×10^{-3} mol dm^{-3}), as shown in trace (*c*). Further, when the experiment of trace (*b*) is repeated, and EDTA (1×10^{-3} mol dm^{-3}) is added after about one half life, then the reaction is stopped suddenly at this time point, as shown in trace (*d*). These experiments show clearly that the GSNO decomposition under these conditions *is* a metal ion promoted reaction, almost certainly a Cu^{+} catalysed reaction, in which the ascorbate ion is acting as a reducing agent for Cu^{2+}, in the same way as thiolate does in the earlier experiments,[1] and leading to disulfide formation. A similar reaction using *S*-nitrosocysteine (which is much faster than the reaction of GSNO), with added Cu^{2+} (5×10^{-6} mol dm^{-3}) and ascorbic acid (5×10^{-6} mol dm^{-3}), generated 86% NO as detected by a commercial NO electrode.

However at higher ascorbate concentrations the situation is somewhat different. For example, when the GSNO experiments are repeated with ascorbate at a ten-fold higher concentration (2×10^{-3} mol dm^{-3}), there is a slow first order decomposition, which is completely unaffected by the addition of EDTA (1×10^{-3} mol dm^{-3}) after roughly one half life. Furthermore the reaction seems to be quite general, since the decomposition of the more reactive *S*-nitrosopenicillamine occurs readily in the presence of EDTA, and the rate is clearly dependent on the [ascorbate], as shown in Fig. 2. When reactions are carried out under conditions of [ascorbate] >> [RSNO], then we find a good first order dependence on both reactants, for a number of RSNO structures. The products of this reaction at higher [ascorbate] are NO and the thiol. For example, in the reaction of *S*-nitrosocysteine with 0.1 mol dm^{-3} ascorbate, the thiol was detected by the Ellman procedure[8] in > 80% yield. This contrasts markedly with the copper-promoted reaction carried out at 1×10^{-5} mol dm^{-3} ascorbate, where the thiol

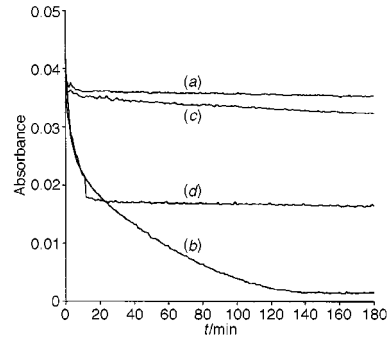

Fig. 1 Absorbance–time plots (measured at 545 nm) for the decomposition of GSNO (2×10^{-3} mol dm^{-3}) with added Cu^{2+} (1×10^{-4} mol dm^{-3}) at pH 7.4: (*a*) with no added ascorbic acid, but with added EDTA (1×10^{-3} mol dm^{-3}); (*b*) with added ascorbic acid (2×10^{-4} mol dm^{-3}); (*c*) as (*b*) but with added EDTA (1×10^{-3} mol dm^{-3}); (*d*) as (*b*) but with EDTA (1×10^{-3} mol dm^{-3}) added after 14 min

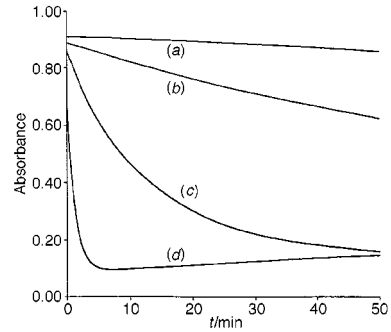

Fig. 2 Absorbance–time plots (measured at 340 nm) for the decomposition of *S*-nitrosopenicillamine (1×10^{-3} mol dm^{-3}) in the presence of EDTA (1×10^{-3} mol dm^{-3}) and (*a*) 0, (*b*) 1×10^{-4}, (*c*) 1×10^{-3} and (*d*) 1×10^{-2} mol dm^{-3} ascorbate

concentration in the product is < 5%. Similarly we were able to detect NO in high yield (78%) from the same reaction at high [ascorbate] (0.01 mol dm^{-3}) in the presence of EDTA (1×10^{-3} mol dm^{-3}) using the NO electrode. Similar results were obtained for the *S*-nitrosothiols derived from captopril, *N*-acetylpenicillamine, homocysteine and thioglycerol.

This reaction bears a close similarity to that recently reported for the reaction of ascorbate with an alkyl nitrite.[9] That reaction, also yielding NO, was studied at high pH (10–12), and was thought to involve initial attack at the nitroso nitrogen atom by the dianion of ascorbic acid. In our case, it is likely at pH 7.4 that the reactant is the monoanion of ascorbic acid, given that the two pK_a values of ascorbic acid are 4.3 and 11.8.

Nucleophilic attack at the nitroso nitrogen atom of *S*-nitrosothiols (and alkyl nitrites) is well-known for the thiolate ion [eqn. (4)], as the transnitrosation reaction, and has been

$$\text{RSNO (or RONO)} + \text{R}'\text{S}^- = \text{RS}^- \text{ (or RO}^-\text{)} + \text{R}'\text{SNO} \quad (4)$$

studied mechanistically.[10,11] More recently we have found[12] that other nucleophiles, such as amines, hydrazine, azide ion, and sulfite ion, will also act in this way; in each case the *S*-nitrosothiol acts as an electrophilic nitrosating species. *N*-Nitroso species, particularly *N*-nitrososulfonamides, have also been shown to be able to act as electrophilic nitrosating species towards a large range of nucleophiles.[13]

It is therefore not surprising that the ascorbate ion can also be nitrosated in a direct reaction with *S*-nitrosothiols. Nitrosation of ascorbic acid by nitrous acid is a well-known reaction which has been studied mechanistically.[14,15] Reaction is thought to involve *O*-nitrosation, followed by homolytic cleavage of the O–NO bond to give NO and a radical or radical ion species, which yields dehydroascorbic acid as the final product, by reaction with more nitrous acid. Alternatively, initial attack could (by analogy with nitrosation of some phenols[16]) occur at carbon, as an electrophilic addition to a very reactive alkene, followed by homolytic fission to give NO.

Whatever the detailed mechanism of NO release in these reactions with ascorbate, it is clear that there is a reaction pathway for NO formation from *S*-nitrosothiols which is independent of the presence of metal ions, particularly Cu^{2+}. This reaction is dominant at high [ascorbate], whereas at low [ascorbate], where the direct ascorbate reaction is too slow to be significant, the Cu^+-promoted reaction takes over. Presumably the copper reaction is suppressed anyway at high [ascorbate], by complexation and hence removal of Cu^{2+}, just as is the case for many of the Cu^+-promoted reactions where thiolate ion is the reducing agent.

These results show clearly that there are two reactions between ascorbate and *S*-nitrosothiols, and explain the observations[4,5] that GSNO can still undergo decomposition in the presence of ascorbate, even when Cu^{2+} ions are removed, so long as the [ascorbate] is high enough to ensure a reasonable rate of reaction.

We thank the EPSRC for a research studentship to A. J. H.

‡ For the slower reactions we worked at 545 nm, rather than at the more usual wavelength of 340 nm (where there is a higher extinction coefficient), to avoid the increasing absorbance towards the end of the reactions in the 340 nm region, which occurs because of the decomposition reaction of the product dehydroascorbic acid (ref. 7).

Unprecedented electron deficient bridging between zinc atoms by boron atoms of *nido*-carborane anions: preparation, crystal and molecular structure of the dimer $[(nido\text{-}C_2B_9H_{11})ZnNMe_3]_2$

Andrés E. Goeta, Judith. A. K. Howard,* Andrew K. Hughes,*† Andrew L. Johnson and Ken Wade*

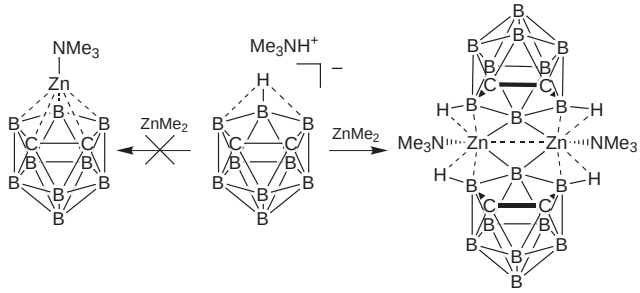
Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE

The alkane elimination reaction between $ZnMe_2$ and $[(NMe_3H)^+(nido\text{-}C_2B_9H_{12})^-]$ gives the macropolyhedral dimer $[(nido\text{-}C_2B_9H_{11})ZnNMe_3]_2$, containing an unprecedented planar diamond-shaped Zn_2B_2 ring at its core.

The capacity of the *nido*-carborane anion $[C_2B_9H_{11}]^{2-}$ to bond cationic metallic units at sites on its open pentagonal face that reflect the frontier orbital characteristics of the metallic cations has long been recognised.[1] The σ^2,π^4 arrangement of the frontier orbitals of $[C_2B_9H_{11}]^{2-}$ is similar to those of the cyclopentadienyl, $(C_5H_5)^-$, and imido, RN^{2-}, ligands.[2] Both $[C_2B_9H_{11}]^{2-}$ and RN^{2-} act as 4 electron LX_2 ligands.[3] Metallic residues that are isolobal with BH^{2+} can bond η^5 to the face, and so effectively complete the c*loso*-metallacarborane. It has been recognised that metal fragments with full, or almost full, d shells tend to occupy 'slipped' positions over the open face, even though the metal fragment formally has the three vacant orbitals of a BH^{2+} unit (one radially, two tangentially oriented).[4] Coordination in an η^1 mode is also observed when the metal fragment has fewer than 3 vacant orbitals, as in $[(\eta^1\text{-}C_2B_9H_{11})SnPh_3]^-$.[5] Alternative cluster geometries may also be observed even when the metal fragment has three vacant orbitals but is not isolobal with HB^{2+}.[6]

Noting that the only structurally characterised zinc borane species are a number of tetrahydridoborate complexes,[7] ionic compounds containing the $[Zn(B_{10}H_{12})_2]^{2-}$ anion,[8] and small zinc boranes,[9] and that complexes of boranes or carboranes[10] with group 2[11] or group 12 metals are rare (except for linear complexes of Hg^{2+}), we explored the reaction‡ between $[(Me_3NH)^+(nido\text{-}C_2B_9H_{12})^-]$ and $ZnMe_2$, which by loss of two moles of methane was expected to afford a monomeric icosahedral metallacarborane $Me_3N\text{-}ZnC_2B_9H_{11}$, Scheme 1. The units $Me_3N\text{-}Zn^{2+}$ and HB^{2+} are formally isolobal, and so in principle HB^{2+} units of borane clusters might be expected to be replaced by $Me_3N\text{-}Zn^{2+}$ units. The analogous beryllium complex, $[Me_3N\text{-}BeC_2B_9H_{11}]$, is believed to be isostructural and isoelectronic with *closo*-$C_2B_{10}H_{12}$.[12] The stoichiometry of our product was indeed as expected; however, an X-ray crystallographic study§ has shown it to have an alternative remarkable macropolyhedral dimeric structure, $[(nido\text{-}C_2B_9H_{11})ZnNMe_3]_2$ **1**, shown in Fig. 1. Although the molecule has approximate C_{2v} molecular symmetry it has no crystallographically imposed symmetry. Two *nido*-$C_2B_9H_{11}$ fragments are connected through the unique boron atoms of the *nido* carborane residues and a $Me_3NZnZnNMe_3$ unit, in which the two zinc atoms are at a separation of 2.800(1) Å (*cf.* 2.665 Å for the shortest Zn–Zn distance in metallic Zn). The bonding of these boron atoms (coordination number 7) and of the zinc atoms (coordination number 8) are we believe unprecedented, and involve a planar diamond-shaped Zn_2B_2 ring system [angles at Zn 108.1(1)° and 105.5(1)°; two equal angles at B 73.2(1)°]. This is reminiscent of the 3-centre 2-electron (3c2e) bonds in the M_2C_2 ring systems of electropositive metal alkyls, as in Al_2Me_6,[13] or $(BeMe_2)_n$,[14] with characteristically acute angles at the alkyl carbon and obtuse angles at the electropositive metals. By contrast, zinc alkyls, ZnR_2 (R = Me, Et, Pr^n) are monomeric by gas-phase electron diffraction,[15] although in the solid state, diphenyl zinc is dimeric, $[(C_6H_5Zn)_2(\mu\text{-}C_6H_5)_2]$ [Zn–Zn = 2.685 Å], with unsymmetrical bridges, assigned to σ-covalent and π-dative bonds.[16] The Zn–Zn separations observed in amide-bridged $[(MeZn)(\mu\text{-}NPh_2)]_2$ (2.913 Å),[17] chloride-bridged $[Zn_2Cl_6]^{2-}$ (typically 3.06 to 3.3 Å)[18] and other electron-precise species, are longer than that in **1**.

In addition to the Zn_2B_2 ring the coordination about each zinc atom is completed by one NMe_3 ligand and interaction of a pair of B–H bonds with each zinc atom. Since Me_3N-Zn is isolobal with BH, compound **1** would be isolobal with the (unknown) species $C_4B_{20}H_{24}$ and $[B_{24}H_{24}]^{4-}$. The closest known carborane is $C_4B_{18}H_{22}$, which contains two $C_2B_9H_{11}$ residues directly fused.[19] Other clusters distantly related to **1** include *syn*-$B_{14}H_{20}$[20] and *anti*-$\{[Pt(PMe_2Ph)]_2(nido\text{-}B_6H_9)_2\}$ containing



Scheme 1 Expected and isolated products from the reaction of $ZnMe_2$ and $[(NMe_3H)^+(nido\text{-}C_2B_9H_{12})^-]$. Terminal hydrogens on each boron and carbon atom are omitted.

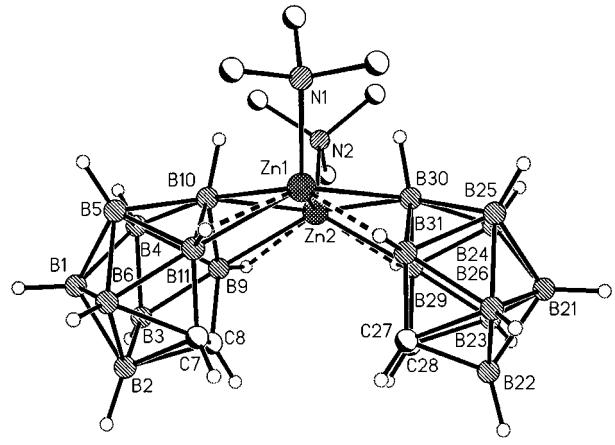


Fig. 1 A view of the 'head-set' or 'ear-muff' molecular structure of $[(nido\text{-}C_2B_9H_{11})ZnNMe_3]_2$, showing the adopted atom numbering scheme. Hydrogen atoms on the NMe_3 ligands are omitted for clarity. Selected bond lengths (Å) and angles (°): Zn(1)–B(10) 2.315(3), Zn(1)–B(11) 2.177(3), Zn(1)–B(30) 2.340(3), Zn(1)–B(31) 2.165(3), Zn(2)–B(9) 2.160(3), Zn(2)–B(10) 2.380(3), Zn(2)–B(29) 2.163(3), Zn(2)–B(30) 2.352, Zn(1)–N(1) 2.065(2), Zn(2)–N(2) 2.062(2), Zn(1)–Zn(2)–N(2) 127.30(8), Zn(2)–Zn(1)–N(1) 126.87(6); other values are given in the text.

square planar 16 electron platinum.[21] There is some structural resemblance to the μ-allyl ligand bridging two metal atoms in $[W_2(\mu;\eta^3\text{-}C_3H_5)_2(NMe_2)_4]$,[22] though in this allyl complex the central W_2C_2 ring is far from planar.

The geometry of the Zn_2B_2 ring at the centre of the structure of **1** prompts us to interpret the metal–ligand bonding primarily in terms of two 3c2e Zn–B–Zn bonds. However, it should be noted that there is a roughly tetrahedral coordination about each metal atom if one counts the other metal atom, and trimethylamine ligand, and two BH units (connected to the bridging B atom) as defining the ligand sphere and ignores the bridging boron atoms. It is clear that a rationalisation of this structure in terms of a localised bonding model has its limitations. We are undertaking more detailed investigations of the bonding in $[(nido\text{-}C_2B_9H_{11})ZnNMe_3]_2$ using molecular orbital methods, and these will be reported in a subsequent publication.

We acknowledge the award by the University of Durham of a Sir Derman Christopherson Fellowship to J. A. K. H. and the support of the EPSRC and Kværner Process Technology (CASE award to A. L. J.).

A novel layered indium sulfide inorganic/organic composite material has been synthesized under solvothermal conditions and characterized *via* single crystal X-ray diffraction.

Metal sulfide based microporous solids were first reported by Bedard *et al.* in 1989.[1] The ability of main group metals to coordinate tetrahedrally with sulfur, as Al and Si do with oxygen in the molecular sieve oxides[2] suggested that a new family of materials with structures resembling those of the zeolites (for example) could exist. These compounds however, did not contain the MS_4 tetrahedra that might be expected in materials structurally related to the oxides. Rather, complex building units such as the $Sb_3S_6^{3-}$ semi-cube,[3] the Sn_3S_4 semi-cube,[1,4] the $[Ge_4S_{10}]^{4-}$ adamantine unit,[5] and the $[In_{10}S_{20}]^{10-}$ and $[Sn_{10}S_{20}O_4]^{8-}$ supertetrahedra[6,7] condense to form structures analogous to zeolites,[5c] neso-,[5d] iono-[5e] and tecto-silicate materials.[5a,b] We report here the synthesis and structure of a novel layered sulfide material consisting of linked InS_4 tetrahedra: DPA-InS-SB3 [DPA = dipropylamine, $(C_3H_7)_2NH$].

The synthesis of DPA-InS-SB3 (**1**) was achieved by reacting elemental In and elemental S with the organic structure directing agent dipropylamine in the approximate molar ratio 1 : 2.3 : 3.5. Reactant slurries were sealed in Pyrex tubes and held static at 180 °C under autogenous pressures for 5 days. The resultant product, a white powder, was washed with ethanol and water and allowed to air dry. Large single crystals up to 0.2 mm on edge were obtained and isolated for X-ray diffraction. Qualitative electron probe microanalysis (EPMA) on the crystals revealed the presence of In, S, and N.

The structure of **1** was determined from single crystal X-ray diffraction† data and is shown in Fig. 1. The primary structural building units of this material are InS_4 tetrahedra which corner and edge link to form layers that stack along (100). Alternatively, the structure can be viewed in terms of In_6S_{11} subunits that form infinite chains running along (010) [Fig. 1(*b*)]. Within the chains, all tetrahedra are linked to one another *via* corner sharing of vertex sulfur atoms. Between chains however, InS_4 tetrahedra edge share [In6–S11–In6; Fig. 1(*b*)] to stitch the chains together approximately along (011) and (0$\bar{1}$1). This connectivity gives rise to pores within the layers that measure 6.9 × 12.8 Å and an interlayer spacing of 8.8 Å as determined from the shortest S–S distances. The layers are similar to those found in Sn–S compounds,[4] but stack such that the pores are aligned throughout the entire structure in a direction perpendicular to the In–S sheets. Although the structure of **1** is not a three-dimensional framework, its unidimensional pore topology (Fig. 1) resembles zeolites such as theta-1[8] and ZSM-23[9] and certain aluminophosphates.[10]

The In–S bond lengths range from 2.420 to 2.534 Å, with an average of 2.432 Å. These values are consistent with those reported in other In–S materials containing tetrahedrally coordinated In.[11] Bond valence sums[12] gave no indication of any mixed valency in indium, which has been observed previously in In–S compounds.[13] Sulfur coordination with In ranges from one to three. The singly coordinated sulfur [S7, Fig. 1(*b*)], is also bound to a hydrogen atom to form a terminal –SH group. The edge sharing of two InS_4 tetrahedra gives one short In–In (In6–In6) contact of 3.299 Å, as opposed to an average of about 3.9 Å for other In–In distances within **1**, and 3.24 Å in indium metal.[14]

The strain associated with this geometry is reflected in the S–In6–S [S11, 10, 6; Fig. 1(*b*)] bond angles which range from

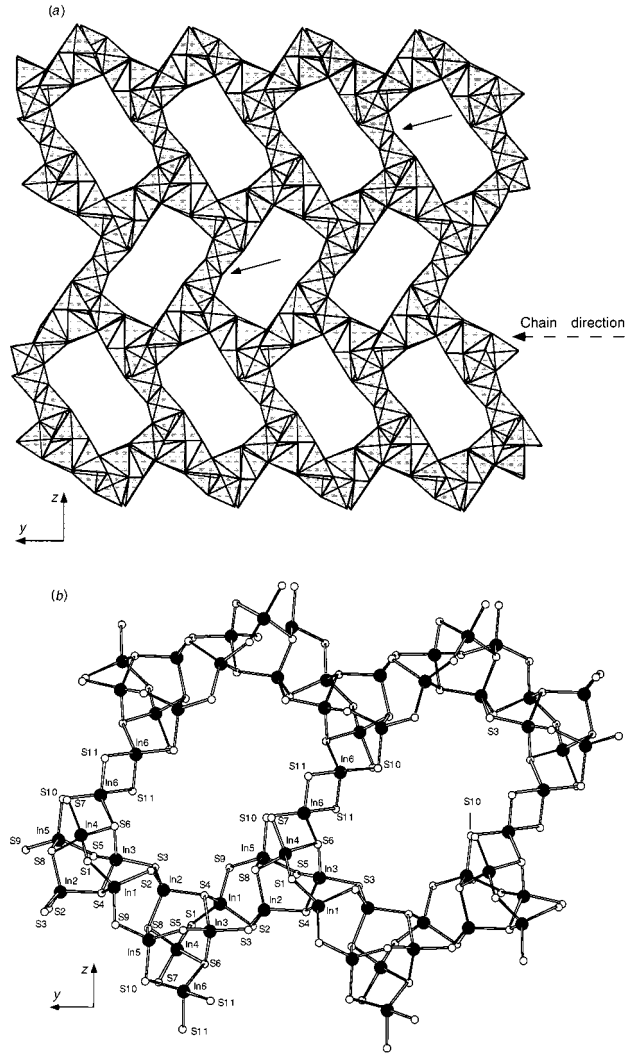

Fig. 1 (*a*) A view down (100) of a single layer of DPA-InS-SB3: $[(C_3H_7)_2NH_2]_3In_6S_{11}H$. This polyhedral representation shows the corner linking of tetrahedra within the In–S chains along (010) (dashed arrow) and the edge sharing of tetrahedra (bold arrows) to link chains together. For clarity, the ordered DPA cations have been omitted and only two edge sharing locations are labeled. (*b*) A labeled portion of two pores from a single layer of **1** in the same orientation as in (*a*). The pore size (6.9 × 12.8 Å) was determined from S3–S3 and S10–S10 distances.

96.23(6) to 120.01(8)° as opposed to an ideal tetrahedral value of 109.5°.

The organic component of **1** is located within the extra-framework voids of the structure. A hydrogen bonded host/guest relationship is proposed as protons on the nitrogen atoms are within 2.3–2.6 Å of sulfur atoms on the In–S framework. IR spectroscopy suggests that the DPA molecules are protonated although a second hydrogen on one of the three N atoms was not located in the X-ray analysis. A medium absorption band at 1579 cm^{-1} corresponding to a N–H bend of a secondary amine salt and strong N–H stretching bands (3000–2700 cm^{-1}) were observed.[15] A weak band at 2515 cm^{-1} was assigned to the S–H stretching vibration[15] of S7–H (see above). With respect to these designations, all nitrogen atoms were assumed to be protonated to balance the 3− charge on the $In_6S_{11}H$ framework, thus giving an overall stoichiometry of $[(C_3H_7)_2NH_2]_3In_6S_{11}H$.

Other experiments involving treatment of elemental In and S in the presence of amines have resulted in formation of the $[In_{10}S_{20}]^{10-}$ supertetrahedral building unit.[6] It is possible that the amount of water or the size of the amine in a preparation dictates which building unit will form. An investigation of the mother liquors from which these In–S materials crystallize is in progress.

Reversible occlusion of CO in Cs-impregnated X and Y zeolites

Cs_2O in the supercages of Cs-impregnated X and Y zeolites attacks the siliceous portions of the lattice (siloxane bridges), with formation of $(Si–O^-Cs^+)_2$ groups which allow the occlusion (reversible at high temperature) of CO in the sodalite units, as indicated by the formation of an IR band at 2150 cm^{-1}.

Basic zeolites (bearing alkali metal counterions) arouse much interest these days, because they may possibly replace in catalysis harsh chemicals like sodium hydroxide. Besides cationic exchange of the original Na^+ for Cs^+, to increase basicity, samples are further impregnated[1] with Cs acetate, which, on thermal treatment, converts to Cs_2O. The nature of such an oxide in the zeolite matrix depends on the activation conditions and is currently under discussion.[2]

In the course of a systematic study of basic centres in Cs-exchanged and Cs-impregnated X and Y zeolites,[3] we made the intriguing observation that a weak band at 2150 cm^{-1} is formed in the IR background spectrum, recorded at room temperature, of impregnated (but not simply exchanged) samples in the activation step (lower curve in Fig. 1). This activation step consists of thermal treatment (during which decomposition of the acetate takes place) and subsequent oxidation under oxygen at 823 K as described by Laspéras *et al*.[3]

Two Cs impregnated samples, with different Cs contents (8 and 24 atoms per unit cell) were considered, with both Y and X zeolites. IR spectra were recorded on a Perkin-Elmer 1760-X spectrophotometer equipped with a MCT cryodetector, at a resolution of 2 cm^{-1}.

The intensity of the IR band at 2150 cm^{-1} was larger for Y than for X zeolites, and it varied with the Cs_2O content. Outgassing at about 820 K depletes the band. Its peak position is strongly indicative of CO interacting with Na^+ cations, which

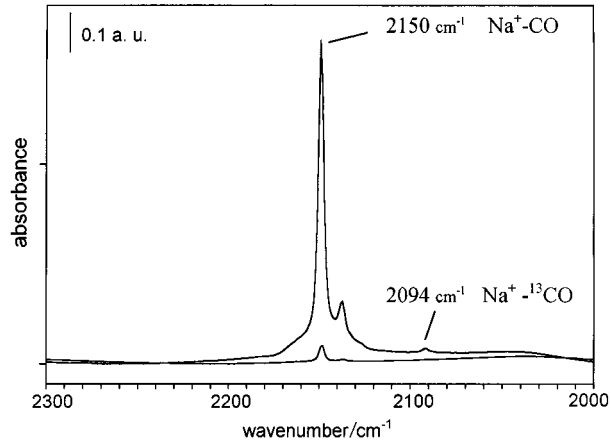

Fig. 1 Infrared spectra of Cs impregnated X zeolite (24 Cs per unit cell). Lower curve: after activation at 823 K; upper curve: after heating in CO atmosphere at 770 K for 1 hour and cooling in the same atmosphere.

are left behind in the exchange process. Thermal decomposition of the acetate is likely to yield CO: such an assignment cannot, however, be made lightly, because CO adsorption on alkali-exchanged zeolites only takes place at temperatures around 77 K[4,5] under substantial CO pressure.

Heating of the impregnated samples in a CO atmosphere at temperatures around 770 K followed by cooling in the same atmosphere leads to an enormous increase in the intensity of the 2150 cm^{-1} band (upper curve in Fig. 1), so that even the ^{13}C satellite band can be observed, though the natural abundance of ^{13}C is only 1%. This confirms beyond doubt that the band is due to CO held in the solid. The nature of the species giving rise to the peak appearing at 2137 cm^{-1} is not discussed here. If heating in CO is followed by evacuation at the same temperature before cooling, a decrease of the original band is observed: CO contact at room temperature has no effect. Prolonged heating of the samples holding CO at 823 K in vacuum depletes the band.

A plausible assignment of the band under discussion is the stretching mode of CO molecules interacting with Na^+ cations: these latter, however, are not those normally exposed at the supercages, but are instead the Na^+ cations inside the sodalite cages, usually not accessible to molecules, though the mineral sodalite is known to occlude large rare-gas atoms like Kr.[6]

We favour Na^+ over Cs^+ as the centre of interaction for the following reasons: (i) the ν(CO) frequency is closer to the values reported in the literature for the former cation; (ii) if reference is made to the standard geometry of the sodalite cage. There is not enough room for Cs^+ cations and CO molecules to coexist in the cage.

We have checked, by means of computer graphics, that a CO molecule may be occluded in the sodalite cages of an X zeolite, of composition close to the one studied by us, for which structural data are available.[7] One CO molecule may be hosted in the cavity: little room is left, however, so that the molecule is actually trapped in the sodalite cage. Indeed, the ratio between the frequencies of ^{12}CO and ^{13}CO (see Fig. 1) indicates that the motion is particularly anharmonic. The peculiarity of such an interaction occurring at room temperature also accounts for the lower frequency observed for related CO in comparison with that observed for CO interacting at 77 K with Na^+ cations in supercages (2154 cm^{-1}).

Thermal treatments in CO, even at high temperatures, of the simply exchanged samples do not cause the appearance of the 2150 cm^{-1} band. This is therefore strictly related to the presence of Cs_2O. On the other hand, the intensity of the 2150 cm^{-1} band is much higher with Y than with X zeolite, *i.e.* the occlusion of CO is greater, the larger the Si content of the sample. Chemical attack of the lattice by Cs_2O is indicated by the loss of crystallinity we observed in the XRD patterns for thermal treatment above 670 K. A plausible mechanism is then the reaction of siloxane bridges with caesium oxide: $Si–O–Si + Cs_2O \rightarrow (Si–O^-Cs^+)_2$, to yield a microcluster of Cs silicate, according to rather elementary chemistry. The cleavage of the

siloxane bridge widens the window giving access to the sodalite cage, which is partially obstructed by the Si–O^{-}Cs^{+} groups. At high temperatures, thermal movement of these groups may give CO molecules access to sodalite cavities, which is then prevented at low temperatures.

Whereas occlusion phenomena are known in some fields of chemistry (clathrates, matrix isolation), to our knowledge, the phenomenon reported here is the first case of reversible occlusion in the solid state: it may probably be extended to other suitably sized molecules like nitrogen and oxygen, and to other zeolitic systems.

Halogen exchange during atom transfer polymerisation of methyl methacrylate mediated by copper(I) *N*-alkyl-2-pyridylmethanimine complexes

David M. Haddleton,*† Alex M. Heming, Dax Kukulj and Stuart G. Jackson

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL

Highly efficient exchange between the halogen arising from the copper(I) halide and the alkyl halide originating from the initiator occurs during atom transfer polymerisation of methyl methacrylate mediated by copper(I) *N*-alkyl-2-pyridylmethanimine complexes.

Living/controlled polymerisations of vinyl monomers lead to the synthesis of polymers with well controlled architecture and predetermined molecular weight. Living/controlled *radical* polymerisation is of increasing importance due to the resilience of free-radical polymerisations to impurities and protic species invariably present in the monomer, solvent, *etc*. Transition metal mediated atom transfer polymerisation has been pioneered by Matyjaszewski, using $Cu^{I}X$ (X = Cl, Br) in conjunction with 2,2-bipyridine[1] and substituted bipyridines,[2–5] and Sawamoto, using $[Ru(PPh_3)_3Cl_2]$.[6–8] Since then a number of different systems using transition metal complexes to polymerise styrenes, methacrylates and acrylates have been reported including $[Ni(PPh_3)_3X_2]$,[9] $[Ni\{o,o\text{-}(Me_2NCH_2)_2C_6H_3\}Br]$,[10] $[Pd(OAc)_2(PPh_3)_4]$,[11] $[Rh(PPh_3)_3Cl]$,[12] and [Cu(*N*-alkyl-2-pyridylmethanimine)$_2$X].[13] More recently Teyssie has reported $FeCl_3$ mediated polymerisation in the presence of PPh_3 for the living/controlled polymerisation of methyl methacrylate (MMA) initiated with a conventional free-radical initiator, AIBN.[14]

It has been previously demonstrated that atom transfer polymerisation is an excellent one step method for the preparation of α-functional polymers.[15–17] The alkyl halide initiator can possess a wide variety of functionalities without causing loss of performance or control over the reaction. Although the existence of several different functionalities at the α-terminal end group has been demonstrated, no detailed study has been made on the nature of the ω-terminal end group. The assumption has been that the ω-terminal end group contains the halogen atom originating from the initiator molecule.

The aim of the work reported here was to investigate the possibility, and extent, of halogen exchange between polymer and catalyst in the polymerisation of methyl methacrylate mediated by [Cu(*N*-alkyl-2-pyridylmethanimine)$_2$X] complexes. During the course of this work two papers appeared referring to the possibility of halogen exchange in atom transfer polymerisation. Sawamoto reported observing the presence of both bromide and chloride ω-end groups in the ^{1}H NMR spectrum of PMMA from bromomalonate initiation catalysed with $Ru(PPh_3)_3Cl_2$.[18] Matyjaszewski *et al.* stated that exchange can occur between the halogen from the initiator and the halogen on the catalyst for BnBr and 2-bromopropionate with $Cu^{I}X$/4,4-di(nonan-5-yl)-2,2-bipyridine catalyst; however, no experimental details were provided.[19] In addition, Matyjaszewski reported similar exchange occurring during the polymerisation of MMA based on matrix-assisted laser desorption ionisation time of flight (MALDI-TOF) and electro-spray ionisation (ESI) mass spectrometry;[19] again, no spectra or experimental details were provided. We have found that this approach is fraught with difficulties due to the ease of fragmentation of these type of polymers within the mass spectrometer.[20]

Table 1 Reaction conditions and results for poly(methyl methacrylate) produced using atom transfer polymerisation with sulfonyl halide initiators and copper halide catalysts

Reaction[a]	Initiator[b]	Mediator	*t*/h	M_n[c]	PDI[d]	Halogen on ω-end group
A	TsBr	CuBr	3	4130	1.10	Br
B	TsCl	CuCl	48	2170	1.06	Cl
C	TsCl	CuBr	22	1900	1.08	Cl
D	TsBr	CuCl	11	4170	1.09	Cl

[a] See footnote ‡. [b] Synthesis of TsBr modified from the preparation of TsI by Truce *et al*. (ref. 22). [c] Number average molecular weight measured by SEC, using THF as eluent at 1 ml min^{-1} calibrated with narrow molecular weight distribution PMMA standards. [d] Polydispersity index from SEC.

In order to study the effects of halogen exchange, PMMA was synthesised using four different combinations of initiator and copper(I) halide (Table 1, reactions A–D). In each case the ligand used to complex copper(I) was *N*-pentyl-2-pyridylmethanimine and the polymerisation was carried out in xylene solution (35% w/w). The polymerisations were allowed to proceed until the number average molecular weight, M_n, reached approximately 2000–4000 g mol^{-1} (20–40% conversion), as monitored by size exclusion chromatography (SEC). Polymerisations were stopped, by cooling to room temperature, at low conversion in order to minimise termination by conventional radical-radical interactions. Low molecular weights were targeted to enable end group analysis by ^{13}C NMR spectroscopy. Fig. 1 shows the ^{13}C NMR spectra of the products from reactions A–D between δ 68 and 58, the –*C*–X region, to focus on the nature of the ω-end group. For reaction A the ω-terminal [–*C*(CH$_3$)(CO$_2$Me)Br] can be seen as three peaks between δ 58.9 and 58.3, Fig. 1(*a*), which correspond to *racemic*

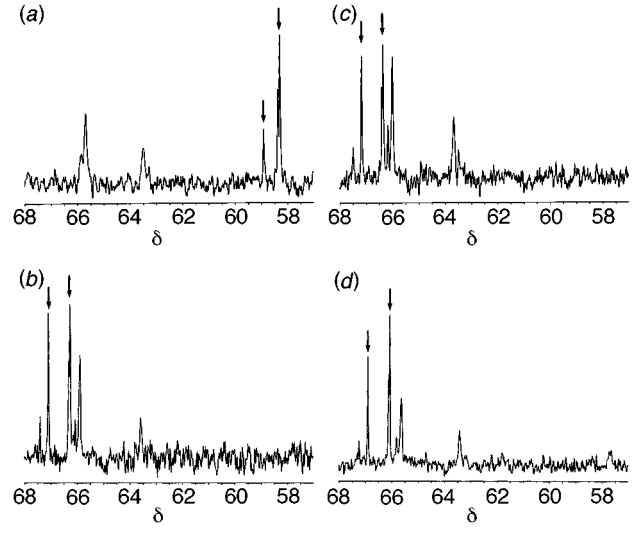

Fig. 1 ^{13}C NMR spectra of PMMA made by ATP, initiated with (*a*) TsBr and CuBr, (*b*) TsCl and CuCl, (*c*) TsCl and CuBr, and (*d*) TsBr and CuCl. Marked peaks are from halogenated ω-end groups.

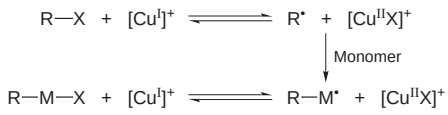
(syndiotactic) and *meso* (isotactic) terminal units respectively. The position of the halogenated carbon atom was verified by comparison with a spectrum of a model compound, methyl-2-bromoisobutyrate, $[(CH_3)_2C(CO_2Me)Br]$, δ 55.4. The product from reaction B shows a similar set of peaks due to $[-C(CH_3)(CO_2Me)Cl]$ shifted downfield, between δ 67.1 and 66.3 [Fig. 1(*b*)], as expected for a chlorinated carbon relative to a brominated one. On examining the spectrum from the product of reaction C [Fig. 1(*c*)] it can be seen that the polymer has exclusively chlorinated ω-end groups with peaks between δ 67.2 and 66.4, *i.e.* the product is the same as that from reaction B. There are no peaks observed in the region δ 58.0 to 60.0 corresponding to a bromine ω-end group functionality. Thus, no observable halogen exchange occurs between the bromide originating from copper(I) bromide and the propagating polymer end capping group, a chlorine atom originating from the initiator. This result is what might be expected for the generally accepted mechanism for atom transfer polymerisation (Scheme 1), *viz.* the halogen atom that originated on the initiator is



Scheme 1

transferred between transition metal complex and polymer chain end throughout the reaction and is present as the ω-end group of product. For reaction D, three peaks between δ 66.9 and 66.1 are observed corresponding to $[-C(CH_3)(CO_2Me)Cl]$ with no peaks upfield due to brominated ω-end groups [Fig. 1(*d*)]. This result is surprising because the polymer exclusively has chlorinated ω-end groups even though a sulfonyl bromide initiator was employed, so complete halogen exchange has occurred.

Our results show that polymerisation of MMA by atom transfer polymerisation mediated by a Cu(*N*-alkyl-2-pyridylmethanimine)$_2$X complex in xylene at 90 °C in the presence of both bromine and chlorine atoms results in solely chloro ω-functional polymer. This can be attributed to the greater strength of the C–Cl bond compared with the C–Br one, *i.e.* the formation of a C–Cl bond is energetically favourable and its homolysis is less facile. This result differs from that of Sawamoto, who found a mixture of Cl and Br in the ω-end group when polymerising MMA initiated with a bromomalonate compound and $Ru(PPh_3)_3Cl_2/Al(OPr^i)_3$ in toluene at 80 °C,[18] and Matyjaszewski, who claimed to have observed a mixture of Cl and Br ω-end groups.[19] Therefore, the tendency for exchange to occur must be effected by the transition metal complex and/or reaction conditions.

The observation of halogen exchange shows that the mechanism of atom transfer polymerisation is more complicated than first thought.[13,19] It is likely that, in reactions where both Cl and Br species are present, the Cu^{II} species contains both in similar states regardless of their origin (initiator or catalyst) and exchange could then occur as the propagating polymer centre abstracts one or other halogen in the deactivation step. Alternatively, exchange may occur by nucleophilic attack of the halide counter-anion from the catalyst at the alkyl halide group of initiator or deactivated polymer. The reaction may also involve bimetallic species with bridging halide or oxygen containing ligands.[3,21] It is not yet known whether exchange occurs at the first reaction step or whether several halogen transfer cycles are involved.

The occurrence of halogen exchange results in competitive rates of polymerisation which complicates the polymerisation kinetics. This may result in a broadening of the molecular weight distribution of the product and also effect the evolution of number average molecular mass with conversion when the reaction is carried out to high conversion. To avoid these effects, therefore, it is advisable to match the halides between the copper(I) salt and the initiator. This is currently under further investigation in our laboratory. It is also noted that this is the first instance of sulfonyl bromides being used as effective initiators for atom transfer polymerisation.

We thank the EPSRC for funding of this work (A. M. H. studentship and D. K. GR/L10314).

‡ In a typical polymerisation, CuX (0.93 mmol) and TsX (0.93 mmol) ([Cu]:[initiator] = 1:1) were placed in a predried Schlenk flask which was evacuated and then flushed with dry nitrogen three times. Methyl methacrylate (10 ml, 93 mmol) was added and the suspension stirred while adding *N*-pentyl-2-pyridylmethanimine (1.87 mmol, [ligand]:[Cu] = 2:1) which instantaneously formed a deep brown solution. Xylene (20 ml) was added and the flask was heated in a thermostatted oil bath at 90 °C. The polymer was isolated by passing the cooled reaction solution down a column of activated basic aluminium oxide to remove catalyst and precipitating into hexane. ^{13}C NMR spectra were recorded on a Bruker 400 MHz spectrometer with a minimum of 4000 scans.

Synthesis and first structural characterisation of a homoleptic tetraorganochromate(III) salt

Pablo J. Alonso, Larry R. Falvello, Juan Forniés,* M. Angeles García-Monforte, Antonio Martín, Babil Menjón and Gerardo Rodríguez

Instituto de Ciencia de Materiales de Aragón, Facultad de Ciencias, Universidad de Zaragoza-C.S.I.C., Pza. S. Francisco s/n, E-50009 Zaragoza, Spain. E-mail: forniesj@posta.unizar.es

The homoleptic, pseudo-octahedral, d³ species $[Li(thf)_4][Cr^{III}(C_6Cl_5)_4]$ 1 has been obtained and characterised by analytical, spectroscopic and X-ray diffraction methods.

The synthesis of aryl derivatives of chromium(III) and the study of their properties have drawn the attention of numerous research groups since the very beginning of this century, shortly after the synthesis of the first organomagnesium reagents. Early reports, however, were discouraging[1] or puzzling[2] and it was not until the late fifties that σ-aryl complexes of chromium(III) were isolated and recognised as species of limited stability, which are prone to rearrange, eventually yielding π-arene compounds of low-valent chromium.[3] This tendency to decompose is more pronounced in compounds with some degree of coordinative unsaturation,† which may be a principal reason for the lack of homoleptic (*i.e.*, not bearing additional stabilising ligands) organometallic compounds of formula $[Cr^{III}R_4]^-$. As far as we know, the only organometallic precedents for this stoichiometry are probably the salts $Li[Cr(C_6H_4OMe\text{-}2)_4]\cdot Et_2O$[5] and $Li[Cr(C_6H_2Me_3\text{-}2,4,6)_4]\cdot 4thf$;[6] however, no structural information is available for them.‡ Interestingly, some related tetraalkylchromate(III) salts had also been detected as solution species but could not even be isolated because they readily suffered oxidation giving the more stable neutral tetraalkychromium(IV) derivatives.[8]

We have prepared the tetraorganochromate(III) salt $[Li(thf)_4][Cr^{III}(C_6Cl_5)_4]$ **1** by arylation of $[CrCl_3(thf)_3]$[9] with LiC_6Cl_5[10] in 1 : 5 molar ratio.§ Complex **1** is a violet solid of limited thermal stability; since it is also air- and moisture-sensitive, it must be synthesised, stored and handled under an inert atmosphere and at low temperatue (below 0 °C).

The solid-state structure of **1** has been established by single-crystal X-ray diffraction analysis.¶ The lattice contains the separate ions $[Li(thf)_4]^+$ and $[Cr(C_6Cl_5)_4]^-$ together with interstitial solvent molecules. The cation has a tetrahedral geometry (local at the Li^+ ion) as usually found in other salts.[13] The core of the anion contains four σ Cr–C bonds and two additional Cr–Cl interactions, thus resulting in a pseudo-octahedral environment for the Cr atom (Fig. 1). Two of the C_6Cl_5 groups act as monodentate σ-bonded ligands, while the other two act as chelating ligands through their *ipso*-C and one of the *o*-Cl atoms. The small bite-angle of the chelating C_6Cl_5 group yields two strained four-membered metallacycles with C–Cr–Cl angles of *ca*. 60°. These acute angles are responsible for the severe deviations of the metal coordination environment from the ideal octahedral geometry. The two Cr–C distances involving C-*trans*-to-Cl atoms are virtually identical and in good agreement with those described in other σ-aryl derivatives of Cr^{III} (mean value 207 pm).[14] The two Cr–C distances involving C-*trans*-to-C atoms are slightly longer, probably due to the higher *trans* influence exerted by the anionic C atom of the aryl group. The Cr–Cl distances are clearly dissimilar and much longer than found in standard terminal chloro-complexes of chromium (mean value 232 pm).[14] The long Cr–Cl distances can be ascribed to both the poor donating ability of halocarbons and the strain of the metallacycle formed. The overall geometry of the $[Cr(C_6Cl_5)_4]^-$ anion is similar to that found in the related heavy-metal complexes $[Pt(C_6Cl_5)_4]$[15] and $[Rh(C_6Cl_5)_4]^-$.[16]

The EPR spectrum of **1** was registered (Fig. 2)‖ and analysed as a particular case** of an (S = 3/2) spin system that behaves as an (S = 1/2) system with the following spin Hamiltonian:

$$H = \mu_B B(g_x' l_x S_x + g_y' l_y S_y + g_z' l_z S_z) \qquad (1)$$

In the preceding equation l_i ($i = x, y, z$) are the direction cosines of the magnetic field of magnitude B referred to the principal axes of the $\tilde{\boldsymbol{g}}$-tensor. Using this spin-Hamiltonian and assuming Lorentzian line shapes, we have obtained an excellent agreement between the experimental [Fig. 2(*a*)] and calculated [Fig. 2(*b*)] spectra for the following set of effective principal g-values and band halfwidths: $g_x' = 4.02$, $g_y' = 3.55$, $g_z' = 1.946$; W_x = 15.0 mT, W_y = 22.5 mT, W_z = 10.0 mT. The relationship between the effective and true principal g-factors is a function of the *a priori* unknown η-parameter which accounts for the departure from axial symmetry.** Since the observed EPR spectrum is practically axial it is reasonable to assume an axial true $\tilde{\boldsymbol{g}}$-tensor as well. Under this assumption the following true g-values have been derived: $g_\parallel = 1.98$ and $g_\perp = 1.90$ with η = 0.08(1). It is interesting that, while the $g_\parallel$-value is typical for a Cr^{3+} ion, the $g_\perp$-value departs from that of the free electron by more than what is usually observed for this paramagnetic entity. This could be attributed to an extra orbital contribution due to the ligand as a consequence of the covalent bonding.

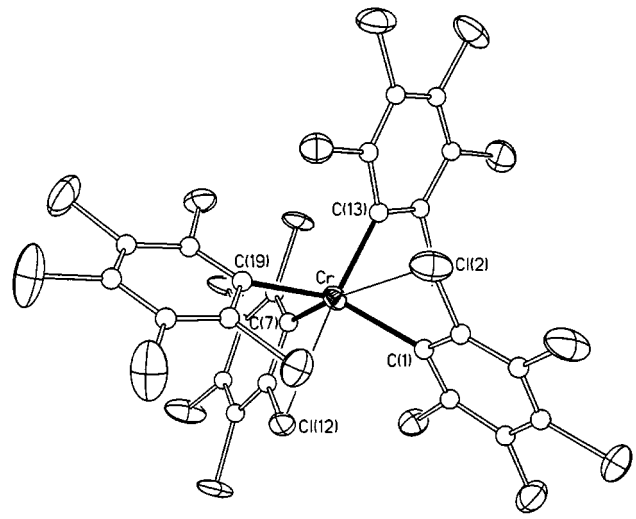

Fig. 1 Thermal ellipsoid diagram of the anion of **1**. Selected distances (pm) and angles (°): Cr–C(1) 213.7(11), Cr–C(7) 207.3(10), Cr–C(13) 208.1(10), Cr–C(19) 217.3(11), Cr–Cl(2) 300.1(4), Cr–Cl(12) 281.8(4); C(1)–Cr–C(7) 111.7(4), C(1)–Cr–C(13) 94.2(4), C(1)–Cr–C(19) 141.5(4), C(1)–Cr–Cl(2) 59.5(3), C(1)–Cr–Cl(12) 83.1(3), C(7)–Cr–C(13) 103.2(4), C(7)–Cr–C(19) 90.8(4), C(7)–Cr–Cl(2) 170.1(3), C(7)–Cr–Cl(12) 63.2(3), C(13)–Cr–C(19) 111.1(4), C(13)–Cr–Cl(2) 74.2(3), C(13)–Cr–Cl(12) 163.4(3), C(19)–Cr–Cl(2) 99.0(3), C(19)–Cr–Cl(12) 79.8(4), Cl(2)–Cr–Cl(12) 117.4(1).

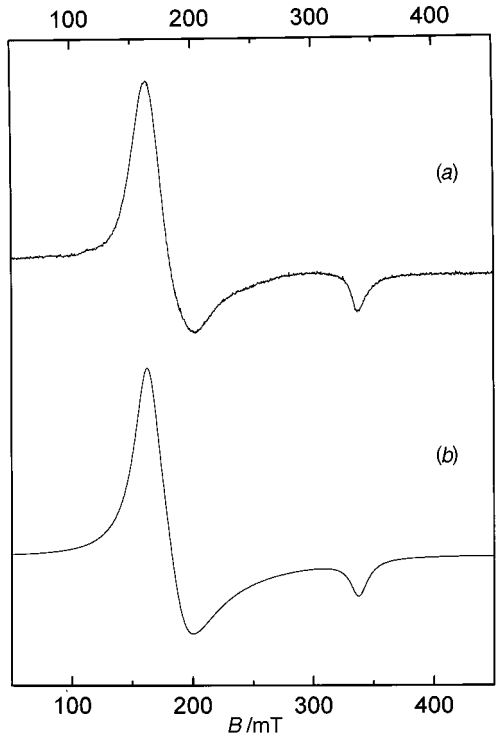

Fig. 2 EPR spectrum of a frozen CH_2Cl_2 solution of **1** at liquid nitrogen temperature (microwave frequency: 9.49 GHz): experimental (*a*) and calculated (*b*)

The homoleptic tetraorganochromate(III) salt **1** is stable enough to allow its isolation and characterisation. This reasonable stability can be ascribed to the versatility of the C_6Cl_5-group which is able to act as a standard monodentate σ-aryl ligand as well as a poor didentate one depending on the electronic and steric demands of the metal centre. Further studies aimed at exploring the chemical reactivity and redox behaviour of the new compound **1** are in progress.

We thank the Dirección General de Enseñanza Superior (Projects PB95-0003-C02-01 and PB95-0792) for financial support.

Notes and References

† The use of the very bulky bis(trimethylsilyl)methyl group has enabled Lappert and coworkers to isolate and characterise a highly unusual, coordinatively unsaturated neutral complex of formula $[CrR_3]$ (ref. 4).

‡ Hein and Schmiedeknecht reported on the synthesis of sodium and lithium tetraphenylchromate(III) salts, but the authors concluded that they were, in fact, solvent-stabilised species of formula $M[CrPh_4\cdot 2dme]\cdot 2dme$ (M = Na or Li; dme = 1,2-dimethoxyethane). The analogous thf-stabilised salts $MCrPh_4\cdot x$thf were too unstable to be isolated (ref. 7).

§ *Experimental procedure:* to a solution of LiC_6Cl_5 (*ca*. 34 mmol) in Et_2O (130 cm^3) at −78 °C was added $[CrCl_3(thf)_3]$ (2.57 g, 6.85 mmol). The suspension was allowed to warm to −10 °C and after about 4 h of stirring, the by then violet solid was filtered and extracted in CH_2Cl_2 (60 cm^3). The solvent in the extract was replaced by thf (20 cm^3) and the slow diffusion of an *n*-hexane layer (60 cm^3) into it at −30 °C yielded **1** as a violet solid in 57% yield. Anal. Found: C 36.21, H 2.02; $C_{40}H_{32}Cl_{20}CrLiO_4$ requires: C 35.73, H 2.40%. IR (KBr; cm^{-1}): 1321s, 1311s, 1281vs, 1219m, 1125m, 1059s [$\nu(COC)_{asym}$], 1043vs [$\nu(COC)_{asym}$], 915m, 887s [$\nu(COC)_{sym}$], 822vs (C_6Cl_5: X-sensitive vibr.),[11] 667vs, 600w, 415m and 349m. MS (FAB−): *m/z* 1040 $[Cr(C_6Cl_5)_4]^-$ and 828 $[Cr(C_6Cl_5)_3Cl]^-$.

¶ *Crystal data* for $\mathbf{1}\cdot 0.5OEt_2\cdot 0.5C_6H_{14}$: $C_{45}H_{44}Cl_{20}CrLiO_{4.5}$, M = 1424.74, monoclinic, a = 4151.3(6), b = 1288.25(10), c = 2387.8(3) pm, β = 117.324(12)°, U = 11.345(3) nm^3, T = 150(1) K, space group *C*2/*c* (no. 15), graphite-monochromated Mo-Kα radiation, λ = 71.073 pm, Z = 8, D_c = 1.668 g cm^{-3}, $F(000)$ = 5736, violet, approx. crystal dimensions: 0.40 × 0.25 × 0.10 mm, μ(Mo-Kα) = 1.187 mm^{-1}, measured absorption correction based on ψ scans, transmission factors: 0.899–0.793; Enraf-Nonius CAD4 diffractometer, ω–θ scans, data collection range $4.0 < 2\theta < 50.0°$, $+h$, $+k$, $\pm l$, three standard reflections showed no significant variation in intensity; 10 103 intensity data collected, 9956 unique (R_{int} = 0.0887) which were used in all calculations. The structure was solved by Patterson and Fourier methods and refined anisotropically (except for the solvent atoms) by full-matrix least squares on F^2 (program SHELXL 93; ref. 12) to final values of R_1 = 0.0870 [for 4366 data with $I > 2\sigma(I)$] and wR_2 = 0.2324 (all data) for 635 parameters; GOF = 1.037, maximum Δ/σ = 0.001, maximum $\Delta\rho$ = 1063 e nm^{-3} (−1053 e nm^{-3}) located very near the chromium atom. Hydrogen atoms were set geometrically. The weighting scheme was $w = [\sigma^2(F_o^2) + (0.0590P)^2 + 115.07P]^{-1}$, where $P = (1/3)[\max\{F_o^2,0\} + 2F_c^2]$. CCDC 182/936.

‖ EPR data were taken on a Varian E-112 spectrometer working in the X-band. The magnetic field was measured with a Bruker ER035M gaussmeter. The diphenylpicrylhydrazyl resonance signal [g = 2.0037(2)] was used to determine the microwave frequencies. The program WIN-EPR SimFonia (supplied by Bruker) was used to perform the simulation. In the calculations, the following interpolating halfwidth formula was used: $W^2(l_x,l_y,l_z) = W_x^2l_x^2 + W_y^2l_y^2 + W_z^2l_z^2$.

** The relevant spin Hamiltonian for the paramagnetic centre in **1** [Cr^{III}, d^3, S = 3/2] should read:

$$H = \mu_B\mathbf{B}\cdot\tilde{\mathbf{g}}\cdot\mathbf{S} + \mathbf{S}\cdot\tilde{\mathbf{D}}\cdot\mathbf{S}$$

where μ_B is the Bohr magneton. The first term accounts for the electronic Zeeman interaction and the second one for the zero field splitting. In the principal axes of the $\tilde{\boldsymbol{D}}$-tensor, the latter term is given by

$$\mathbf{S}\cdot\tilde{\mathbf{D}}\cdot\mathbf{S} = D[\{S_z^2 - \tfrac{1}{3}S(S+1)\} + \eta(S_x^2 - S_y^2)]$$

where η can always be set to a value of $< 1/3$ by an appropriate choice of principal axes. In the absence of any applied magnetic field, the quartet corresponding to the (S = 3/2)-system splits into two doublets separated by $\Delta_o = 2D(1 + 3\eta^2)^{\frac{1}{2}}$, which can be treated independently if Δ_o is greater than the Zeeman energy. Moreover, for low values of the rhombic parameter, the only transition actually observed is the one among the states of the $S = \pm 1/2$ doublet. Under these conditions, the initlal S = 3/2 problem reduces to a quasi-axial S = 1/2 spin system, with the spin Hamiltonian given in eqn. (1). If the principal axes of the $\tilde{\boldsymbol{g}}$- and $\tilde{\boldsymbol{D}}$-tensors coincide the relationship between the effective (g_i') and the principal (g_i) true g-factors is given by

$$g_x' = g_x(1 + \cos 2\beta + \sqrt{3}\sin 2\beta)$$
$$g_y' = g_y(1 + \cos 2\beta - \sqrt{3}\sin 2\beta)$$
$$g_z' = g_z(2\cos 2\beta - 1),$$

where $\tan 2\beta = (\sqrt{3})\eta$.

Regioselective directed lithiation of *N*-Boc 3-hydroxypyrrolidine. Synthesis of 2-substituted 4-hydroxypyrrolidines

Mihiro Sunose,[a] Torren M. Peakman,[a] Jonathan P. H. Charmant,[a] Timothy Gallagher*[a]† and Simon J. F. Macdonald[b]

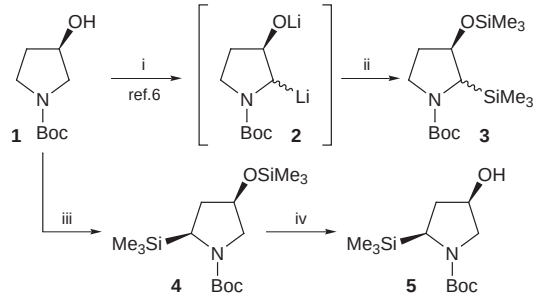
[a] *School of Chemistry, University of Bristol, Bristol, UK BS8 1TS*
[b] *GlaxoWellcome Research and Development, Medicines Research Centre, Gunnels Wood Road., Stevenage, UK SG1 2NY*

***N*-Boc 3-hydroxypyrrolidine 1 undergoes directed *C*-lithiation at C5 and not, as previously reported, at C2; the resulting dilithiated intermediate 6 has been trapped by a range of electrophiles to give 2-substituted 4-hydroxypyrrolidines 7.**

Directed metallation provides a versatile method for achieving substitution adjacent (α) to an amino moiety and this is a process which has found widespread application within heterocyclic chemistry.[1] The presence of additional and appropriately positioned heteroatom residues can, by providing additional activation, also enable regiochemical control to be exercised in the metallation (usually lithiation) step.[2–4] For example, *N*-Boc pyrrolidines[3] and piperidines[4] carrying a methoxy residue at C3 have been shown to undergo lithiation at C2 which is then followed by loss of MeOLi to give the corresponding cyclic enamine. Choosing a C3 substituent that is a poorer leaving group should, by suppressing β-elimination, allow this residue to be retained in the resulting product and this concept has been successfully applied to *O*-based heterocycles.[5]

More recently, this approach has also been utilised for *N*-heterocycles and Pandey and Chakrabarti[6] have reported that *N*-Boc 3-hydroxypyrrolidine **1** undergoes lithiation (at −78 °C using Bu^{s}Li, THF–TMEDA) followed by silylation to give exclusively the *C,O*-disilylated adduct **3** (in 86% yield), an intermediate that was then later employed in an alkaloid synthesis (Scheme 1).‡ These authors suggest that the sense of regiocontrol 'was expected due to the directing effects of the hydroxy group for the initial metallation reaction' and the implication of this claim is that the *C,O*-dilithiated species **2** is involved.

As part of a broader programme, we have had cause to examine the lithiation of **1** and two key issues are apparent. Firstly, in our hands, *C*-lithiation of **1** does not occur at −78 °C and, secondly, at higher temperatures when *C*-lithiation does take place, the only products observed are those resulting from lithiation distal to the C3 hydroxy, rather than proximal as claimed by Pandey. We have achieved lithiation of *N*-Boc 3-hydroxypyrrolidine **1** using Bu^{s}Li (2.2 equiv.) in THF–TMEDA at −78 °C and then allowing the solution to warm to −46 °C. After 2 h, the mixture is then recooled (to −78 °C) and Me_3SiCl (2.2 equiv.) was added giving, after work up, the *cis*-2,4-disubstituted adduct **4** as the only observed disilylated product (Scheme 1).



Scheme 1 *Reagents and conditions*: i, (ref. 6) Bu^{s}Li, THF–TMEDA, −78 °C; ii, Me_3SiCl (2.2 equiv.); iii, (this work) Bu^{s}Li (2.2 equiv.), THF–TMEDA, −78 °C to −46 °C, 2 h, cool to −78 °C, then Me_3SiCl (75%); iv, Bu_4NCl, KF, MeCN (100%)

Adduct **4** was then desilylated (at oxygen) to give **5** which proved to be a more suitable intermediate for assignment of both regio- and stereo-chemistry. This was carried out by ^{1}H NMR (COSY and NOE difference) analysis and, in addition, the relative stereochemistry of **5** has been established by X-ray crystallographic analysis (Fig. 1).§

The results of our study point towards the intermediacy of the *C,O*-dilithiated species **6** (and not **2**) as the only detectable intermediate (based on trapping) produced by lithiation of *N*-Boc-3-hydroxypyrrolidine **1**, however, the relative configuration of **6** has not been investigated.

The broader synthetic scope of this regiospecific lithiation chemistry has been further developed and intermediate **6** has been trapped with a range of electrophiles, including primary alkyl halides and enolizable aldehydes, to give the corresponding *N*-Boc 2-substituted 4-hydroxypyrrolidines **7** (Scheme 2, Table 1).¶ Yields for adducts **7**‖ have not been optimised because in most cases only modest *cis*/*trans* selectivity was observed. This likely reflects a combination of a highly reactive intermediate, *i.e.* **6**, with a lack of a significant conformational bias associated with the five membered ring, but we have established that *cis*/*trans* is kinetically controlled: attempts to lithiate *cis*-**7e** (using the standard reaction conditions), and thereby provide evidence for an equilibration pathway, failed.

In summary, *C*-lithiation of *N*-Boc 3-hydroxypyrrolidine (**1**) takes place distal to the hydroxy (lithioalkoxy) function but nevertheless offers a versatile and synthetically useful entry into 2-substituted 4-hydroxypyrrolidines. Our observations con-

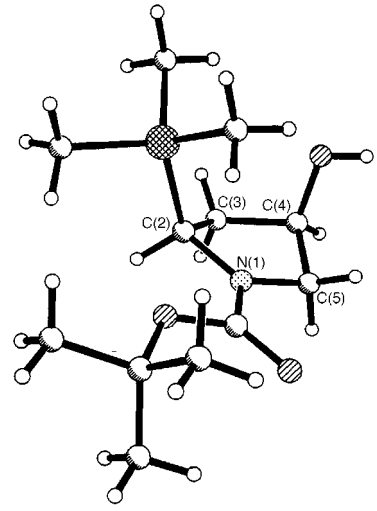


Fig. 1 Molecular structure of **5**

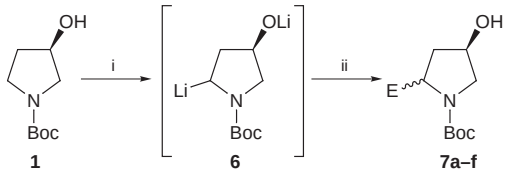

Scheme 2 *Reagents and conditions*: Bu^{s}Li (2.2 equiv.), THF–TMEDA, −78 °C to −46 °C, 2 h; ii, cool to −78 °C, then E^+ (2.2 equiv.) (see Table 1)

Table 1 Trapping of **6** with different electrophiles

Electrophile	2-Substituted 4-hydroxypyrrolidine (**7**) % yield and *trans*/*cis* ratio
Bu_3SnCl	 **7a** 50% 1 : 1
Br–Me	 **7b** 37% 1 : 1
Br–Me	 **7c** 39% 1 : 1
Br	 **7d** 59% 1 : 1
Me_2SO_4	 **7e** 65% 5 : 1 (see text)
Octanal	 **7f** 39% 1 : 1 (see text)

cerning *C*-lithiation clearly conflict with those described earlier[6] by Pandey and Chakrabarti. This is a concern but until this group publishes either detailed experimental protocols or compound data, it is not possible to identify those factors that might account for this apparent contradiction.

We thank The Overseas Research Students Awards Scheme and GlaxoWellcome Research and Development for financial support (to M. S.), and acknowledge use of the EPSRC's Chemical Database Service at Daresbury.[7]

‡ Metallation of **1** is described[6] as having taken place at −78 °C. No spectroscopic data was reported for the *C*,*O*-disilylated adduct **3** which was also indicated as an unspecified mixture of diastereomers.

§ When we carried out lithiation and quenching of **1** at −78 °C (and the solution was not allowed to warm above this temperature) then only the *O*-silyl ether of **1** was observed. This monosilylated product was also observed as a minor component (in 15% yield) in the generation of **4**. The exclusive formation of *cis*-**4** has not yet been investigated but intramolecular delivery involving participation by oxygen cannot be ruled out. Data for **4**: $[\alpha]_D^{24}$ + 43.3 (*c* 1, CH_2Cl_2); δ_H(400 MHz, C_6D_6) 4.03 (1 H, m, H4), 3.69 (1 H, m, H5), 3.30–3.23 (2 H, m, H2 and H5), 1.91 (1 H, m H3), 1.78 (1 H, m, H3), 1.56 (9 H, s); δ_C(100 MHz, $CDCl_3$) (doubling due to rotamer populations) 154.9/154.5, 79.6/78.6, 71.0/70.2, 54.5/54.3, 46.3/46.0, 37.3/36.8, 28.5, −0.2, −1.8. Data for **5**: mp 107–110 °C (pentane–EtOAc); $[\alpha]_D^{24}$ + 57.4 (*c* 1, CH_2Cl_2); δ_H(300 MHz, $CDCl_3$) 4.39 (1 H, pentet, *J* 5.9, H 4α), 3.78 (1 H, d d, *J* 11.7, 5.9, H5α), 3.30 (1 H, dd, *J* 9.2, 7.2, H2α), 3.05 (1H, dd, *J* 11.7, 5.9, H5β), 2.26 (1 H, dddd, *J* 12.8, 9.2, 5.9, 0.7, H3α), 1.78 (1 H, m, H3β), 1.69 (1 H, br s, OH), 1.46 (9 H, s, Bu^t) and 0.10 (9 H, s, Me_3Si). Stereochemical assignments are based on NOE difference studies. The crystal structure of **5** was determined from data collected on a Siemens SMART diffractometer (λ = 0.71073 Å) at 173(2) K. The structure was solved by direct and Fourier methods and refined by least squares against all F^2 data corrected for absorption. *Crystal data*: $C_{12}H_{25}NO_3Si$, *M* = 259.4, orthorhombic, space group $P2_12_12_1$, *a* = 6.159(1), *b* = 24.957(4), *c* = 9.709(2) Å, *U* = 1492.5(5) Å^3, *Z* = 4, D_c = 1.15 g cm^{-3}, μ = 0.156 mm^{-1}, 3382 unique data, θ < 27.4°, R_1 = 0.043. CCDC 182/194.

¶ All lithiation reactions shown in Table 1 were carried out as described in the following example: to a solution of *N*-Boc (3*R*)-hydroxypyrrolidine **1** (189 mg, 1 mmol) in THF (5 cm^3) at −78 °C was added TMEDA (0.34 cm^3, 2.21 mmol) followed by Bu^{s}Li (1.7 cm^3, 1.3 M in cyclohexane, 2.21 mmol). The resulting bright yellow reaction mixture was warmed to −46 °C, stirred for 2 h, then recooled to −78 °C, and dimethyl sulfate (0.21 cm^3, 2.21 mmol, dried over 4 Å MS) was added dropwise. The reaction mixture was then allowed to warm slowly to room temperature (over 5 h) and, after this time, water (5 cm^3) and CH_2Cl_2 (7 cm^3) were added and the organic layer was separated. The aqueous layer was extracted with CH_2Cl_2 (2 × 5 cm^3), the organic extracts were combined, and dried (K_2CO_3). Concentration *in vacuo* and purification of the residue by flash chromatography (light petroleum–EtOAc) gave *N*-Boc 2-methyl-4-hydroxypyrrolidine **7e** (131 mg, 65%) as a 5 : 1 mixture of diastereomers. Recrystallisation gave the major (*cis*) diastereomer as colourless crystals. Data for *cis*-**7e**: mp 88–89 °C (light petroleum–EtOAc); $[\alpha]_D^{24}$ + 21.1 (*c* 1, CH_2Cl_2). The *cis* stereochemistry of this major adduct has also been conformed by X-ray crystallographic analysis, details of which will be described elsewhere.)

‖ Enantiomerically pure (*R*)-**1** was used in these initial studies. Carbamate resonance complicated interpretation of the NMR data associated with adducts **7** but where this was an issue it was overcome by *N*-deprotection (using TFA, CH_2Cl_2, room temp.) to give the corresponding free amine. The formation of stereoisomers at C2, rather than a mixture of C2/C5 regioisomers, was confirmed by Swern oxidation of the *cis*/*trans* mixture to give a single 2-substituted pyrrolidin-4-one; this process was carried out for adducts **7b**–**e**. Octanal gave **7f** as an inseparable 1 : 1 mixture of two of the four possible products, but the stereochemistry of these products has not been assigned. In addition, all new compounds have been characterised by spectroscopic methods and either elemental analysis or HRMS.

The synthesis of the new zeolite, ERS-7, and the determination of its structure by simulated annealing and synchrotron X-ray powder diffraction

Branton J. Campbell,[a] Giuseppe Bellussi,[b] Luciano Carluccio,[b] Giovanni Perego,[b] Anthony K. Cheetham,*[a]† David E. Cox[c] and Roberto Millini*[b]

[c] *Physics Department, Brookhaven National Laboratory, Upton, NY 11973, USA*

The new zeolite ERS-7 (EniRicerche-molecular-Sieve-7), which was synthesized within a narrow temperature and compositional range using *N*,*N*-dimethylpiperidinium as a structure directing agent, has a structure consisting of 17-sided ($4^6 5^4 6^5 8^2$) picnic-basket-shaped cages connected by 8-membered ring windows.

The discovery of new zeolites is closely linked to the use of increasingly complex and novel structure directing agents (SDAs). The syntheses of extra-large pore UTD-1[1] and CIT-5[2] zeolites, for example, were recently accomplished by using Cp_2Co^+ and N(16)-methylsparteinium, respectively. Because of the lack of selectivity typical of many SDAs, good results may also be achieved by carefully controlling other synthesis parameters. This is the case with the 'simple' *N*,*N*-dimethylpiperidinium cation, which was reported to favor the crystallization of ZSM-51 (NON).[3] By systematic investigation of different synthesis parameters (*i.e*. temperature, crystallization time, and the SiO_2/Al_2O_3, SDA/SiO_2, OH^-/SiO_2 and H_2O/SiO_2 molar ratios), we have obtained several known microporous framework compounds (MOR, MTW, LEV, NON),‡ together with the hitherto unknown ERS-7 phase.[4]

To synthesize ERS-7, a reaction mixture with the composition $0.2SDA : 0.3Na_2O : 0.04Al_2O_3 : 1SiO_2 : 40H_2O$ was prepared by using sodium silicate (Carlo Erba, 27 wt.% SiO_2, 8 wt.% Na_2O) and $Al_2(SO_4)_3 \cdot 16H_2O$ as sources of silica and aluminium, respectively. Aqueous *N*,*N*-dimethylpiperidinium hydroxide (30 wt.%) was synthesized by refluxing an ethanol solution of 1,5-dibromopentane and dimethylamine; the bromide salt obtained was filtered, washed with ethanol, dried under N_2, dissolved in demineralized water and finally exchanged to the OH^- form by electrodialysis. The reaction mixture was then charged in a Teflon-lined stainless steel autoclave and heated under autogeneous pressure at 170 °C for 7 days.

The pure and well crystallized ERS-7 product was only obtained in a narrow range of SiO_2/Al_2O_3 molar ratios near 25. Increasing the aluminium content in the reaction mixture resulted in the formation of LEV (SiO_2/Al_2O_3 = 15) or a small amount of an unidentified crystalline phase (SiO_2/Al_2O_3 = 20). Pure MTW was obtained when the SiO_2/Al_2O_3 ratio was increased to 80, while NON crystallized from reaction mixtures containing little (SiO_2/Al_2O_3 = 214) or no aluminium. If instead, the SDA/SiO_2 molar ratio was decreased, MOR was formed as a product. At 155 °C, ANA crystallized first, while ERS-7 started to appear only after 7 days, the pure phase being obtained after 14 days with the consumption of ANA. Similar kinetics were observed at 170 °C, with MOR forming first, and ERS-7 completely crystallizing after 5 days.

The framework structure of ERS-7 was determined by simulated annealing.[5] As implemented by MSI for zeolite-like structures,[6] the simulated annealing algorithm required the unit cell dimensions, the space group symmetry, the total number of T-sites (or more precisely, the number of cationic framework atoms) in the unit cell, and the number of crystallographically independent T-sites. High resolution synchrotron X-ray powder diffraction data were collected at room temperature on dehydrated template-free H^+ ERS-7§ at beamline X7A of the Brookhaven National Synchrotron Light Source. The first 30 large reflections were indexed with the TREOR90 software package[7] to obtain a primitive orthorhombic unit cell (M_{30} = 50, F_{30} = 242). The space group *Pnma* was selected as a starting-point based on the unambiguous determination of extinction class and the absence of significant second-harmonic-generation emission. The framework density was determined by measuring the density of an ERS-7 precursor (2.04 g cm^{-3} using a Micromeritics AccuPyc 1330 helium displacement pycnometer) and then correcting for the thermogravimetric loss of H_2O and SDA trapped inside the pores (15.5 wt.% using a Mettler TG50 thermobalance) as well as the Na^+ content (1.2 wt.% from elemental analysis); the final value was 1.70 g cm^{-3} which corresponds to 48.1 T-sites per unit cell.

Assuming 48 total T-sites and *Pnma* symmetry, simulated annealing runs with different initial random seeds were performed for each possible number of symmetry-independent T-sites, from 6 to 12. From the 1000 runs that assumed 6 symmetry-independent T-sites, 373 unique framework topologies were generated. The correct structure was identified among these by geometry optimizing[8] the simulated structures, sim-

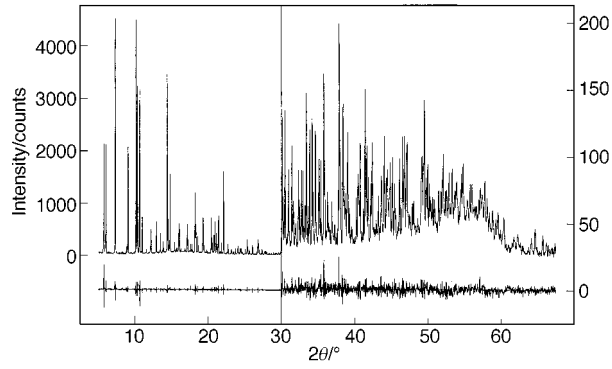

Fig. 1 Experimental and difference XRD patterns from the Rietveld refinement of the ERS-7 structure. The scale of the high angle data is expanded to better illustrate its detail. R_{wp} = 6.11%, R_p = 5.60%, χ^2 = 1.566, R_B = 3.28%, 1407 reflections, 12491 data points. A total of 195 parameters were refined: scale (1), profile shape (6), positional parameters (56), anisotropic thermal parameters (112), and 20 evenly spaced background points with linear interpolation between points. Lattice parameters were refined during the LeBail fit to the profile, but fixed during the model refinement due to slight oscillation. The pseudo-Voigt profile shape of Thompson *et al.*[10] was used including the asymmetry correction of Finger *et al.*[11] Refined profile parameters were U = 0.597, V = −0.057, and W = 0.008 (degrees squared), Lorentzian strain broadening = 0.005°, anisotropic (011) strain broadening = 0.131, and S/L = 0.013 (H/L was fixed at the measured value of 0.011). The thermal ellipsoid of O9 has one slightly negative root.

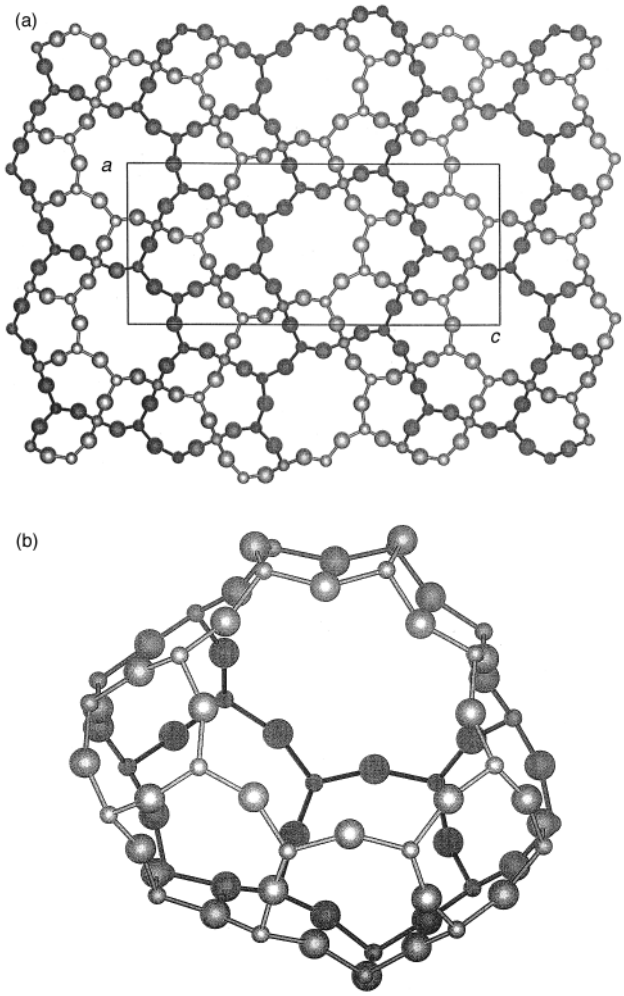

Fig. 2 (a) The [010] projection of ERS-7 showing the 8-membered ring channels. Final values for the lattice parameters were a = 9.79976(4), b = 12.41163(6), c = 22.86063(11) Å, and V = 2780.561 Å^3. (b) Schematic representation of the 17-sided ($4^6 5^4 6^5 8^2$) 'picnic-basket'-shaped cage.

ulating their X-ray diffraction (XRD) patterns and visually comparing them to the experimental XRD pattern; it also had the overall best (lowest) figure of merit (value of the cost function) of any topology generated. The structure model was then refined by the Rietveld technique from the synchrotron data using the GSAS[9] software package, resulting in the fit to the XRD data shown in Fig. 1. Each Si atom is 4-coordinated. The total number of symmetry-independent oxygens is 14. The range of Si–O bond lengths was 1.573 to 1.623 Å (avg. = 1.595 Å), and the O–Si–O and Si–O–Si bond angle ranges were 105.0° to 111.3° (avg. = 109.5°) and 139.3° to 171.4° (avg. = 155.4°) respectively.

The framework structure of ERS-7, shown in Fig. 2(a), can be described as having a one-dimensional 8-membered ring channel system running along the *b* axis, with large side-pockets along the sides of the channel. The structure can be assembled entirely by 17-sided ($4^6 5^4 6^5 8^2$) picnic-basket-shaped cages (9.0 × 7.6 × 8.2 Å) that share 6 and 8-membered ring faces, such that the channel system runs through the 'basket-handles' while the pockets form the 'basket bottoms' [Fig. 2(b)]. The 8-membered ring channels are consistent with our observations that ERS-7 adsorbs H_2O and methanol, but not *n*-hexane. The cages connected to these channels explain the fact that while *N*,*N*-dimethylpiperidinium is too large to fit into the 8-membered ring channel (7.4 × 6.2 Å), it can still be removed upon decomposition at high temperature without damaging the framework. The ERS-7 framework can also be viewed as consisting of chains of smaller 11-sided cages that share 6-membered ring faces along the *a* axis, but connect in the $b + c$ and $b - c$ directions by additional 4-rings rather than by corners, edges, or faces.

The synthesis of ERS-7 demonstrates that the preparation of new zeolites is related not only to the use of increasingly complex SDAs but also to the systematic screening of the synthesis parameters. The use of simulated annealing to solve the structure of a fairly complex new zeolite demonstrates its importance as an alternative approach when single crystals are unavailable.

‡ Synthesis products were identified by X-ray powder diffraction using a Philips PW1710 vertical diffractometer.

§ Synchrotron XRD data were collected at room temperature over the range $5° \leqslant 2\Theta \leqslant 67.45°$ in steps of 0.005° while the sample (in capillary) was rotated at *ca*. 1 Hz. For data collection, a double-crystal Si[111] monochromator set for λ = 1.1528 Å, a Ge[220] analyzer, horizontal incident and receiving slits of 13 mm and 16 mm respectively, and a sample–detector distance of 700 mm were used. Dehydrated template-free H^+ ERS-7 (SiO_2/Al_2O_3 = 16.7) was prepared by calcining at 550 °C for 5 h under flowing air, repeated ion exchange in an ammonium acetate solution at 60–70 °C, drying at 120 °C, calcining again in air and then under 10^{-5} Torr vacuum, and flame-sealing in a quartz capillary. Comparison of two means of attachment of an organometallic acid on gold surfaces by combining X-ray photoelectron spectroscopy and IR reflection spectroscopy

Caroline Chavigny,[a] Franck Le Bideau,[a] Claire-Marie Pradier,[a] Serge Palacin,[b] Pierre Brossier[c] and Gérard Jaouen[a]*†

[a] *Ecole Nationale Supérieure de Chimie de Paris, 11 rue Pierre et Marie Curie, 75231 Paris Cedex 05, France*

Two methods of immobilization of the butyric 4-oxocyclopentadienylmanganese tricarbonyl acid I on gold surface are presented: either through the assembly of a disulfide derived from the acid, or by coupling on a cystamine monolayer; the efficiency of these two ways are evaluated by IR reflection spectroscopy and X-ray photoelectron spectroscopy.

The research of new immunoassay methods avoiding the drawbacks of radioactive tracers appears to be a main line in analysis.[1] We recently demonstrated the possibility to assay drugs, hormones and pesticides by FTIR spectroscopy using organometallic markers.[2] For that purpose, we took advantage of the specific and intense ν_{CO} stretching vibration of the metal carbonyl [$M_y(CO)_x$] within 1900–2150 cm^{-1}. Moreover, this method might be one of the rare realistic approaches to multi-immunoassays thanks to the characteristic positions of the metal carbonyl groups signals.[1]

So far the analysis was performed in solution and required a separation of the free tracer and the antibody-linked tracer. This step was time demanding and turned out to be incompatible with a large scale analytical development. In order to perform this analysis in the solid state, we investigated the immobilization and detectability of organometallic-marked biological molecules. Biological material can be immobilized on a surface as a host in polymer thin films,[3] as a host or an adduct within Langmuir–Blodgett films[4] or can be grafted *via* covalent bonds on a self-assembled monolayer (SAM).[5] We selected the third method because it provides bioactive films with high accessibility for external molecules.

Self-assembled monolayers on gold surfaces are generally prepared from dilute solutions of thiols (or disulfides). Biomolecules can be attached to the surface *via* the terminal functional groups of the assembled thiolate. Before working on the biological matrix, we studied the detectability of manganese tricarbonyl complexes immobilized on the gold surface by IR reflection spectroscopy (IRS). The present study is necessary because the immobilization of metal carbonyl complexes on gold surfaces is a quite new research field.[6,7] We report here a comparison between two means of attachment of an organometallic acid, the butyric 4-oxocyclopentadienylmanganese tricarbonyl **I**, on gold surface. Acid **I** can be prepared following a known synthesis using cymantrene.[8] The attachment of the acid was carried out either in one step with a disulfide derived from the acid **I** (method A) or in two steps *via* the linkage of **I** with a chemically reactive SAM (method B). We used two different and complementary surface spectroscopies to evaluate the efficiency of these two strategies: IR reflection spectroscopy to detect the carbonyl vibrations, and photoelectron X-ray spectroscopy to compare the molecular densities through the S/Au peak area ratio.

To achieve method A, the organometallic acid **I** was transformed into a surface-active molecule. Esterification of **I** was performed with *N*,*N*,*N*′,*N*′-tetramethyl(succinimido)uronium tetrafluoroborate (TSU) and diisopropyl amine in anhydrous DMF[9] to give the *N*-hydroxysuccinimide ester **II**. The disulfide **III** was then formed by overnight reaction of the ester with cystamine in anhydrous DMF in the presence of triethylamine [Scheme 1(*a*)].

SAMs of the disulfide **III** were prepared on gold substrates[10] previously cleaned with UV/ozone treatment. The substrates were then placed in a dilute solution (1.5 mM) of **III** in distilled THF for 20 h.

The IR reflection spectra of the monolayer[11] obtained *via* method A is shown in Fig. 1(*a*). The bands at 2041 and 1968 cm^{-1} are characteristic of the metal carbonyl vibrations, and did not change with reaction time, which indicates that an equilibrium state was reached. A shift to higher frequencies is observed compared to the IR spectrum of the pure compound (the E mode vibration of the pure compound is observed at 1940 cm^{-1}). We believe that this shift is due to hydrogen bonds[12] occurring in the pure compound which lower the frequencies. On the gold surface, such interactions are prevented. The observed frequencies are the same as those in π-acetylcyclopentadienyl manganese tricarbonyl (2040 and 1965 cm^{-1} in KBr disc),[13] which has a similar electron withdrawing substituent on the ring and no possible hydrogen bonds.

In method B, we first prepared the monolayer of cystamine by soaking the gold substrates for 3 h in a solution of cystamine dihydrochloride (0.05 M) in water. Upon removal from the solution, the substrates were rinsed with 20 ml of water, 5 ml of absolute ethanol and then were dried under nitrogen.

The covalent link of the acid **I** was constructed by first activating the acid into the ester **II**. The cystamine monolayer was then immersed for 20 h in the solution, and some diisopropylethylamine added.[14] The protocol is illustrated in Scheme 1(*b*). A 'test slide' was prepared at the same time following the same procedure but without TSU, in order to check the efficiency of the activation. Both were rinsed by two 2 min immersions in DMF, then one in absolute ethanol, dried and analyzed by IRS. The IR reflection spectra obtained *via*

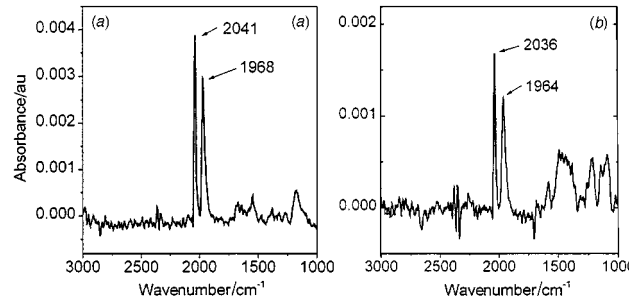

Fig. 1 IR reflection spectra of (*a*) the disulfide **III** monolayer and (*b*) the result of coupling on a cystamine monolayer

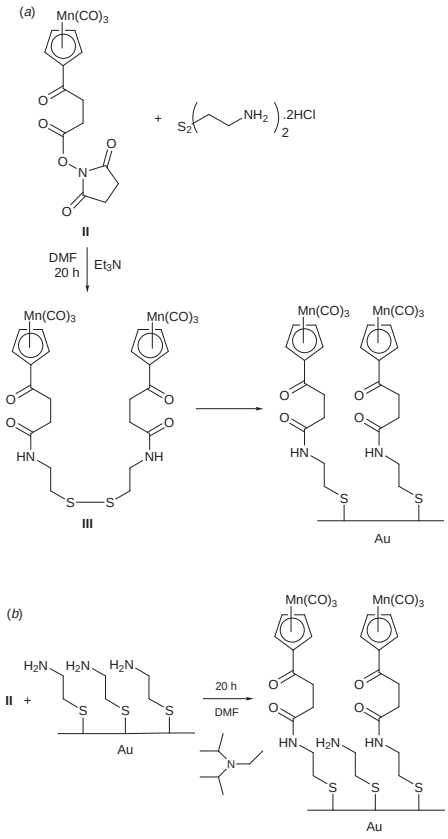

Scheme 1 Methods of attachment of acid **I** onto a gold surface; (*a*) method A and (*b*) method B

method B is shown in Fig. 1(*b*). The covalent coupling of the acid on the surface was proved by the absence of carbonyl vibration bands on the 'test gold slide'.

We now want to compare the two methods of attachment of the organometallic acid **I** on gold. The measurements of the areas of the IR bands at respectively 2041 and 2036 cm^{-1} shows that the carbonyl E vibration band is 48% lower when the attachment was performed *via* method B than *via* method A. Therefore, a discussion of this result requires an evaluation of the density of the sulfur sites within the monolayer built from the disulfide **III** and from cystamine.

We performed XPS analyses at normal incidence on both surfaces and calculated the S/Au ratio. At normal incidence, the thickness of the SAM has a negligible influence on the intensity of the XPS signal.[15] The S 2p photoelectron spectra of the layers of cystamine and disulfide **III** exhibit a peak at 162 eV which is in good agreement with the thiolate moiety on gold.[16] The ratios I_S/I_{Au} are 0.0084 for the disulfide **III** monolayer, and 0.0094 for the cystamine one, which indicates that the molecular density for the cystamine monolayer on the gold surface is a few percent higher than for **III** (considering the experimental error in XPS). We assume that this is not a significant reason for the observed variation in the infrared intensities.

Therefore, the difference in the areas of the carbonyl vibration bands between SAMs prepared *via* method A and B is mainly ascribed to the yield of attachment in the adsorbed phase. Note that the different orientations of the metal carbonyl groups may also account for variations of the IR intensities as the reflection mode is only sensitive to the contribution of the dipole moments normal to the surface. However, considering the roughness of the surface at the molecular scale, and the likely amorphous character of these monolayers constituted by molecules having bulky terminal groups, we assume that the metal carbonyl moieties of C_{3v} symmetry are randomly oriented. The observed IR signal is consequently unaffected by a preferential orientation of the molecules, but essentially determined by the number of attached metal carbonyl moieties. Therefore, the yield of attachment is the main factor for the differences in the IRS spectra. We found that the attachment *via* method B was *ca*. 45% of the attachment *via* method A (average of three experimental values taking into account the slight difference in surface densities shown by XPS).

This value can be compared to the 40% of activated CO_2H obtained after one cycle of activation of the 11-mercaptoundecanoic acid groups by *N*-hydroxysulfosuccinimide (NHSS) with EDC.[17] The limited yield of 40–45% in both cases underlines the importance of the steric effects.

An organometallic acid was covalently attached to a cystamine monolayer on gold. The amount of attachment was evaluated by combining two surface techniques, XPS and IRS, and comparing the signals of the monolayer obtained after coupling into the adsorbed phase with those from the corresponding disulfide layer.

This work allows us to envisage an immunoassay using organometallic markers in the solid phase.

Stereoselective α-glycosidation using $FeCl_3$ as a Lewis acid catalyst

Swapan K. Chatterjee and Peter Nuhn*†

FB Pharmazie, Martin Luther Universität, Wolfgang-Langenbeck-Str. 4, 06120 Halle, Germany

A simplified procedure for the stereoselective α-glycosidation of peracetylated sugars, carrying a participating group at C_2, with aliphatic alcohols in the presence of $FeCl_3$ as a Lewis acid is described.

In continuation of our work[1] on the study of cellular response towards liposomes and their cryoprotection through glycolipids and the interaction of phospholipid and glycolipids, we required large amounts of different pure anomers of glycolipids with varying numbers of spacer unit. In spite of a number of methods reported in the literature[2] *cis*-glycosidation is still a problem; in most of the reported syntheses partial or full protection of the sugar moiety is required, *e.g.* protection with Bn[3] or TBDMS.[4] The presence of an anchimeric assistant group, *e.g.* in the case of protection with an acyl group particularly at the C_2 position of the pyranose ring, leads to a cyclic transition state or non-isolable cyclic intermediate[5] (**A** in Scheme 1), thereby resulting in *trans*-glycosidation.

Partial or full protection of the glycosyl donor without a participating group at C_2 is not always easy. In our previous paper[3] we reported such a stereoselective α-glycosidation starting from a 2,3,4,6-tetrabenzyl monosaccharide. Even the most readily available partially-protected monosaccharide, 2,3,4,6-tetrabenzyl glucose, could be prepared by us in only 40–50% overall yield starting from the methyl glucoside.[6] The loss of product is occurring during the hydrolysis of methyl-2,3,4,6-tetrabenzyl glycoside due to the instability of the product to acidic hydrolytic conditions.

We report here for the first time α-glycosidation with a glycosyl derivative having a participating group at the C_2 position. Anomerisation of β-glucopyranosides is already known *via* treatment with titanium chloride,[7a] or mercuric bromide.[7b] Nakanishi[7c] first observed the anomerisation of tetrabenzyl β-methylglucoside to α-methylglucoside in the presence of $FeCl_3$. Srivastava[8] reported stereoselective peracetylation of different monosaccharides to give α-pentaacetyl pyranosides with $FeCl_3$. These observations lead us to try glycosidation with $FeCl_3$ starting directly from readily available peracetylated monosaccharide and aliphatic alcohols. Thus reaction of pentaacetyl sugar with alcohols in the presence of anhydrous $FeCl_3$ in CH_2Cl_2 at room temperature lead stereoselectively to the α-anomer.‡ This is the first observation of stereoselective α-glycosidation occurs inspite of the presence of the anchimeric assistant *O*-acetyl group at the C_2 position of the pyranose ring of glucose, mannose and galactose (Scheme 2, Table 1).

glycoproteins in cell membranes, the immune system, receptors of different bacterial cells[9] and also the human P blood-group system.[10] They are therefore of great interest for cell-cell recognition. We found that triacetyl-α-methylglycosides **4** react, in the presence of ferric chloride, with different pentaacetyl monosaccharides to give heptaacetyl disaccharides **5** in high yield where the monosaccharide moiety is stereoselectively α-orienteded to the glycosyl donor.

‡ *General procedure*: To a solution of pentaacetylmonosaccharide (2 g) in CH_2Cl_2 below 5 °C was added slowly $FeCl_3$ (1 equiv.), and the mixture was stirred for 5 min. An equimolar amount of alcohol was then added to the reaction mixture portionwise over 15 min. and stirred at room temperature. Continuous TLC monitoring showed no significant formation of the β-anomer. After completion of the reaction, indicated by the disappearance of the alcohol by TLC (there is always some transformation of the alcohol to the acetate due to transesterification) the reaction mixture was poured into sat. aq. sodium hydrogen carbonate and extracted with Et_2O. Chromatography of the resultant mixture gave the expected glycoside. GCMS and HPLC analysis showed it to be the α-anomer (Table 1), Pure anomer can be obtained *via* preparative TLC. ^{13}C and ^{1}H NMR and mass spectroscopic and other analytical data are identical to those reported previously (ref. 3).

Synthesis of heme–tris(imidazolyl)methane copper complex, the first binuclear complex bearing three imidazole ligands for copper, as an active site model of cytochrome *c* oxidase

Fumito Tani, Yasuhiro Matsumoto, Yoshimitsu Tachi, Takao Sasaki and Yoshinori Naruta*†

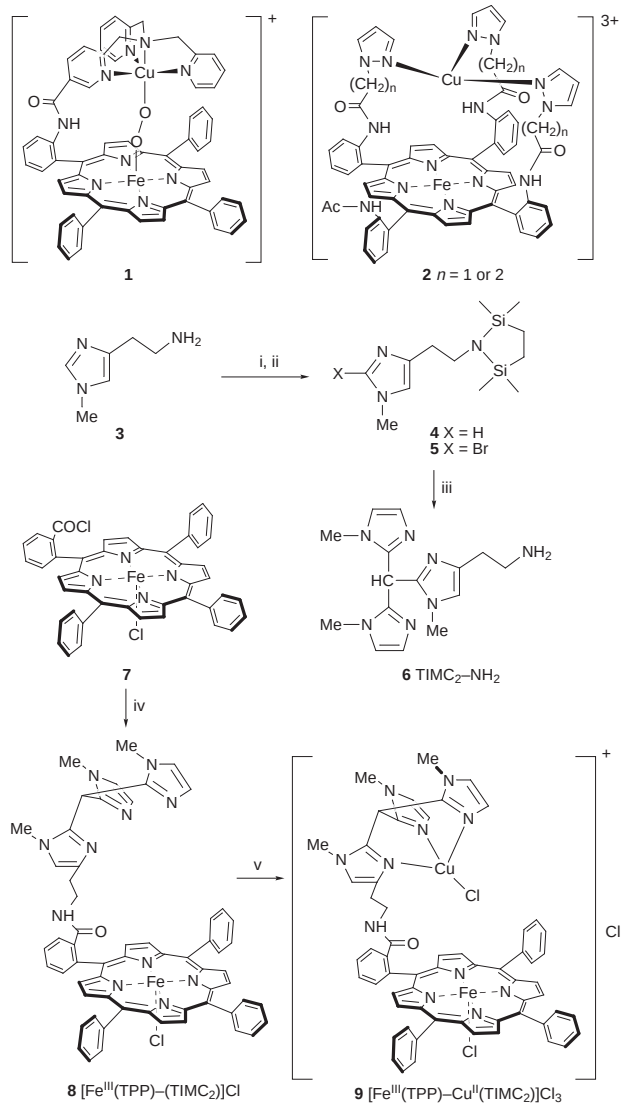
Institute for Fundamental Research of Organic Chemistry, Kyushu University, Fukuoka 812-8581, Japan

As an active site model of cytochrome *c* oxidase, a new covalently-linked binuclear complex with three imidazole ligands for copper, heme–tris(imidazolyl)methane copper, was prepared and spectroscopically characterized.

Cytochrome *c* oxidase (CcO) is a terminal respiratory protein complex which catalyzes the four-electron reduction of O_2 to water in aerobic organisms.[1] The structures of bovine heart[2] and *Paracoccus denitrificans*[3] CcOs have been independently revealed by X-ray crystallography. Heme a_3 and Cu_B, which form a unique binuclear center, are directly responsible for dioxgen reduction. The histidinyl imidazole axially ligates to the iron in heme a_3, while Cu_B has the three histidinyl imidazole ligands for the copper. The separations between the iron and the copper atoms in the active site were determined to be 4.5 Å for the bovine heart and 5.2 Å for the bacterial CcO.

A number of heme-based binuclear Fe–Cu complexes have been prepared[4] to elucidate the mechanism of O_2 reduction and/or to reproduce an EPR-silent, antiferromagnetic coupled Fe^{III}–X–Cu^{II} moiety, which are the characteristics of the resting state of CcO. We recently reported that the reduced form (Fe^{II}–Cu^{I}) of the heme–tris(pyridylmethyl)amine copper complex reacted with dioxygen to give a stable oxygenated complex **1** in a μ-1,2-peroxo fashion at ambient temperature.[5] To the best of our knowledge, this is the first well-characterized dioxygen adduct of a CcO modeling complex. Although the coordination to the copper ions is considered to affect the binding and reduction of dioxygen significantly, there have been no examples of a binuclear model complex having three imidazole ligands for the copper ion similar to the native ones. As a close model with a Cu–L_3 moiety, we reported the oxidized form of heme–trispyrazolyl copper complex **2**,[6] which, however, did not exhibit a large enough formation constant with copper ion to allow further study. Therefore, we designed and synthesized a new model complex, heme–tris(imidazolyl)methane copper [**Fe^{III}(TPP)–Cu^{II}(TIMC_2)Cl_3**]. Tris(imidazolyl)methane is a tridendate chelating ligand which can give stable complexes with copper ion.[7] The two components, porphyrin and tris(imidazolyl)methane, are connected through an amide linkage to maintain a suitable geometry and separation of the two metal ions.

The synthetic routes to the desired complex are shown in Scheme 1.‡ (*N*$^{\tau}$-Methylhistamin-2-yl)-bis(*N*-methylimidazol-2-yl)methane **6** (**TIMC_2-NH_2**) could be obtained *via* the coupling between silyl-protected *N*$^{\tau}$-methy-2-bromohistamine **5** and the lithiated anion of bis(*N*-methylimidazol-2-yl)methane[8] under $Pd(PPh_3)_4$-catalyzed conditions.[9] *N*$^{\tau}$-Methylhistamine **3** was prepared from commercially available histamine dihydrochloride in three steps according to the reported methods[10] in 71% overall yield. There were some prerequisites for the protection of the NH_2 group: first, the protecting group should be robust enough under the following strong basic conditions involving BuLi, and second, the group should be removable under mild conditions and should be easily separable from the reaction mixture. Thus, a cyclic disilyl group[11] was chosen as the protecting group. A solution of **3** and DBU§ was treated with 1,1,4,4-tetramethyl-1,4-dichlorosilylethylene to give the cyclic disilazole **4** in 90% yield. Bromination at the C-2 position of **4** was accomplished with BuLi and 1,2-dibromo-1,1,2,2-tetrafluoroethane in 94% yield with conservation of the disilyl protecting group. Litiation of bis(*N*-methylimidazol-2-yl)methane at CH_2 was performed with BuLi in THF, followed by the addition of $Pd(PPh_3)_4$ and **5** . The mixture was



Scheme 1 *Reagents and conditions*: i, DBU, 1,1,4,4-tetramethyl-1,4-dichlorosilylethylene, CH_2Cl_2, 2 h, room temp., 90%; ii, BuLi, Et_2O , 1h, −78 to −35 °C, 1,2-dibromo-1,1,2,2-tetrafluoroethane, −78 to −25 °C; iii, BuLi, bis(*N*-methylimidazol-2-yl)methane, THF, 1 h, −78 to −20 °C, $Pd(PPh_3)_4$, overnight, 50 °C; iv, **6**, Pr^i_2NEt, CH_2Cl_2, 2 h, 0 to 20 °C; v, $CuCl_2·6H_2O$, MeOH–CH_2Cl_2, 1 h, room temp.

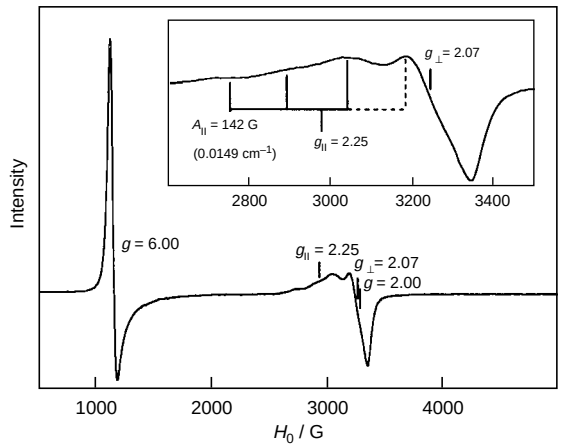


Fig. 1 EPR spectrum of **9** {**[Fe^{III}(TPP)–Cu^{II}(TIMC$_2$)]Cl$_3$**} in CH_2Cl_2 at 6 K, microwave frequncy = 9.3423 GHz, power = 1 mW

heated overnight at 50 °C to enhance the coupling reaction. The removal of the starting compounds by sublimation under high vaccum conditions afforded **TIMC$_2$-NH$_2$ 6** in 25% yield.

5-(2-Carboxyphenyl)-10,15,20-triphenylporphyrin was used as the porphyrin moiety. In order to avoid complications during the insertion of the two different metal ions to two different ligand sites, iron(III) was introduced into the porphyrin ligand prior to coupling with the **TIMC$_2$** moiety. The acid chloride **7**, obtained quantitatively from the free acid, was coupled with **6** in the presence of Pr^i_2NEt in CH_2Cl_2 to give the mononuclear complex **8** {**[Fe^{III}(TPP)–(TIMC$_2$)]Cl**; *m/z* = 993, λ_{max}/nm (ε/M^{-1} cm^{-1}) = 378 (23 200), 417 (46 700), 511 (5170), 576 (2410), 695 (1380), 775 (520)} in 31% yield. The final desired complex **9** {**[Fe^{III}(TPP)–Cu^{II}(TIMC$_2$)]Cl$_3$**} was prepared quantitatively by the addition of $CuCl_2 \cdot 6H_2O$ in MeOH–CH_2Cl_2. Its electronic spectrum [λ_{max}/nm (ε/ M^{-1} cm^{-1}) = 378 (26 900), 417 (44 700), 510 (6560), 577 (2330), 654 (2110), 687 (2110)] was similar to that of the mononuclear heme complex. Its electrospray mass spectrum showed a cluster of peaks at *m/z* 1128 as a base peak, which is assignable to the monocation **[Fe^{III}(TPP)–Cu^{II}(TIMC$_2$)Cl$_2$]$^+$**. The distribution of isotope peaks was in good accord with simulation. The high-resolution mass spectrum (FAB, NBS) also gave an acceptable mass number within 10 mmeu [Calc. for $C_{60}H_{47}N_{11}OFeCuCl_2$ ([M - Cl]$^+$): 1128.4053. Found: 1128.4101]. The EPR spectrum of this complex showed signals at g = 6.00 and 2.00, which are characteristic of typical high spin iron(III) porphyrins, and signals at $g_\parallel$ = 2.25 and $g_\perp$ = 2.07 derived from Cu^{II} (Fig. 1). The lack of a meaningful magnetic interaction in the EPR spectrum indicated a large separation of the two paramagnetic centers . The four-split hyperfine structure of Cu^{II} centered at $g_\parallel$ was observed with $A_\parallel$ = 142 G (0.0149 cm^{-1}). It has been shown that as the coordination geometry of copper in a CuL_4 center is distorted from square planar to teterahedral, $g_\parallel$ increases and $A_\parallel$ decreases with an antiparallel linear correlation.[12] Comparing the present $g_\parallel$ and $A_\parallel$ values with those of the reported Cu^{II} complexes, we conclude that the coordination geometry of the copper is distorted tetragonal rather than planar. This spectroscopic evidence substantiated the designed structure of **[Fe^{III}(TPP)–Cu^{II}(TIMC$_2$)]Cl$_3$**. Of all the CcO models, this is the first binuclear complex bearing three imidazole ligands coordinated to copper.

The reaction between the reduced form (Fe^{II}–Cu^{I}) of the present complex and dioxygen is now under investigation, along with a comparison with our previous binuclear oxygenated complex (**1**).

‡ Experimental details will be reported elsewhere. All new compounds were fully characterized by spectroscopic methods and elemental analyses. Stated yields refer to isolated compounds. Electronic spectra were measured in CH_2Cl_2.

§ Simple tertiary amines like Et_3N were ineffective for this reaction. Since the removal of generated HCl is critical for the completion of the reaction, application of amines more basic than imidazole, such as DBU, is essential.

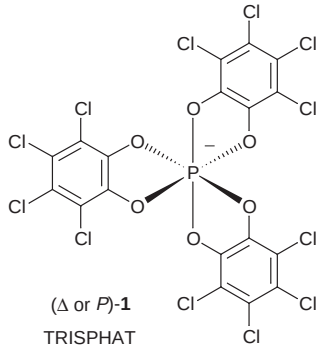
Ion pair chromatographic resolution of tris(diimine)ruthenium(II) complexes using TRISPHAT anions as resolving agents

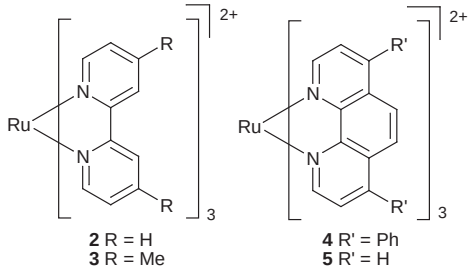
Jérôme Lacour,*† Sonya Torche-Haldimann, Jonathan J. Jodry, Catherine Ginglinger and France Favarger

Département de Chimie Organique, Université de Genève, quai Ernest Ansermet 30, CH-1211 Genève 4, Switzerland

Enantiomers of chiral tris(diimine)ruthenium(II) complexes can be separated on a polar chromatographic phase (SiO_2) when associated with TRISPHAT counterions (2 equivalents).

Chiral tris(diimine)ruthenium(II) complexes have been extensively studied in the fields of photochemistry and photophysics, and as probes in DNA.[1] Many applications require enantiopure complexes (Δ or Λ) and, for those made from achiral ligands, a resolution is usually needed due to the shortage of enantioselective methods of synthesis.[2] Traditionally, resolutions of chiral cationic tris(diimine)ruthenium(II) complexes are realised by the formation of diastereomeric ion pairs (IPs) with anionic chiral resolving agents, and then depend principally on solubility differences.[3] Ion-pair chromatographic resolutions, using cation exchangers and electrolytes with chiral anions in the mobile phase, are possible and lead to efficient separation of diastereomeric IPs.[4] Herein, we report a new chromatographic resolution procedure involving pre-formed diastereomeric mixtures of chiral tris(diimine)ruthenium(II) complexes and TRISPHAT anions (**1**, 2 equiv.). The resulting





diastereomeric IPs are poorly retained on polar chromatographic phase (SiO_2) and large differences in the retardation factors are observed.

Recently, we have shown that the easily prepared and resolved chiral TRISPHAT anion **1** [tris(tetrachlorobenzenediolato)phosphate(V)] is configurationally stable as an ammonium salt in solution.[5] Anion **1** is an efficient NMR chiral shift agent and a valuable host in molecular recognition studies, conferring unique properties to its IPs.[6] For instance, TRISPHAT modifies profoundly the chromatographic properties of cations associated with it (*e.g.* triarylcarbenium cations) and the resulting IPs are poorly retained on polar chromatographic phases.[6b] This result encouraged us to examine whether enantiopure TRISPHAT anion could be used for the IP chromatographic resolution of configurationally stable chiral cations, such as the tris(diimine)ruthenium(II) complexes. We hypothesised that selective chiral discriminating interactions would occur between these three-bladed propellers (Δ^+–Δ^- *vs.* Λ^+–Δ^-) resulting in a good separation.[6c] We decided to test this hypothesis with $[Ru(bipy)_3]^{2+}$ **2**, $[Ru(4,4'\text{-diMebipy})_3]^{2+}$ **3**, $[Ru(bathophen)_3]^{2+}$ **4** and $[Ru(phen)_3]^{2+}$ **5** complexes using the cinchonidinium-(*P* or Δ)-**1** salt (**1a**) as resolving agent.[5,6a] Complexes **2**-Cl_2 and **3**-Cl_2 were prepared following the description of Broomhead and Young,[7] and salts **3**-$(PF_6)_2$, **4**-$(PF_6)_2$ and **5**-$(PF_6)_2$ in a single step from $Ru(DMSO)_4Cl_2$ and the respective bipyridine or phenanthroline ligands (3 equiv.).[8]

The potential of TRISPHAT **1** to serve as a chromatographic resolving agent was first evaluated by analytical thin layer chromatography (TLC): Solutions of salt **1a** (2.0 equiv.) in acetone and racemic **2**-Cl_2, **3**-Cl_2, **3**-$(PF_6)_2$ or **4**-$(PF_6)_2$ (1.0 equiv.) in CH_2Cl_2 were prepared, mixed together, and the resulting solutions adsorbed on silica gel plates. Development by elution with CH_2Cl_2 or $CHCl_3$ showed the formation of two bands corresponding to the two new diastereomeric IPs, [Δ-(**2**–**4**)](Δ-**1**)$_2$ and [Λ-(**2**–**4**)](Δ-**1**)$_2$. Much reduced affinity for silica gel was exhibited as foreseen, as the (**2**–**4**)(Δ-**1**)$_2$ IPs were retained to a much lower extent (Table 1).

The retention of diastereomeric salts (**2**–**4**)(Δ-**1**)$_2$ depended upon the nature of the cation and the concentration of the salts.[6b] Solutions were thus applied (spotted) as concentrated as possible. Due to the streaking of salts (**2**–**4**)(Δ-**1**)$_2$ on TLC, we have not calculated retardation factors (R_f), but rather measured the distance moved by the analyte band to the *top* (and not to the centre) of the spot: The derived ratios, called just *R*, for the resulting IPs were in the range of 0.45–0.75 for the most eluted diastereomer and 0.35–0.54 for the least (CH_2Cl_2 as eluent). We observed rather large differences between the *R* values of the diastereomeric IPs (max. ΔR = 0.23). More lipophilic cations (**3** and **4**, entries 2–5) were retained less than **2** and **5**. The less polar $CHCl_3$ led to better separation than CH_2Cl_2. The nature of

Table 1 Retardation factors of diastereomeric $[Ru(LL)_3](\Delta\text{-}\mathbf{1})_2$

			R (**2**–**5**)(Δ-**1**)$_2$[a,b]

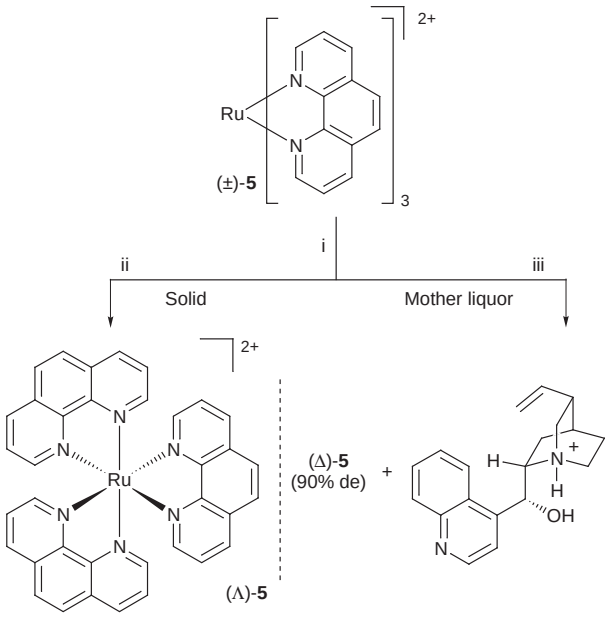
2[c]	**3**$(Cl)_2$	< 0.05	0.75	0.52	0.23
3[c]	**3**$(PF_6)_2$	< 0.05	0.76	0.54	0.22
4[c]	**4**$(PF_6)_2$	0.08	0.75	0.65	0.10
5[d]	**4**$(PF_6)_2$	0.15	0.65	0.46	0.19
6[c]	**5**$(PF_6)_2$[e]	< 0.05	0.42	[f]	[f]

[a] *R* represents the distance moved by the analyte band to the top. [b] Spotted as concentrated as possible. [c] CH_2Cl_2 as eluent. [d] $CHCl_3$ as eluent. [e] TLC done with solution containing partially resolved Δ-**5**. [f] Not applicable.



Scheme 1 *Reagents and conditions*: i, 1.0 equiv. of (±)-**5**-$(PF_6)_2$ in CH_2Cl_2, 2.0 equiv. of **1a** in acetone, CH_2Cl_2, 10 min; ii, filtration, essentially Λ-**5**; iii, mother liquor, cinchonidinium:Δ-**5** (4:1), de 90%

the anionic counterion (Cl^-, PF_6^-) in the precursor salt seems to have, within experimental error, no influence (entries 2 and 3). The behaviour of the (**2**–**4**)(Δ-**1**)$_2$ ion pairs is quite remarkable as the precursor salts (**2**–**4**)$(PF_6)_2$ migrate little under these chromatographic conditions.

TLC analysis of racemic salt **5**-$(PF_6)_2$ in the presence of anions Δ-**1** could not be completed as planned: The precipitation of an orange solid containing essentially Λ-**5** was observed in seconds upon the mixing of the solutions of **5**-$(PF_6)_2$ and **1a**.‡ A direct, yet partial, resolution of **5** was thus afforded as the filtration of the solid gave a mother liquor containing the cinchonidinium cation and Δ-**5** (90% de) in a 4:1 ratio (Scheme 1).

Preparative chromatographic resolution was possible for the ruthenium(II) diimine complexes **3** and **4**, exhibiting good solubility in CH_2Cl_2 (or $CHCl_3$) and large Δ*R* values when associated with **1**. From mixtures of **1a** (2.0 equiv.) and racemic salts **3**-$(PF_6)_2$ and **4**-$(PF_6)_2$ (1.0 equiv.), pure separated diastereomeric IPs [Δ-(**3**,**4**)](Δ-**1**)$_2$ and [Λ-(**3**,**4**)](Δ-**1**)$_2$ could be afforded in reasonable yields (Table 2):§

Table 2 Preparative ion pair chromatographic resolution

Entry	Salts	Most eluted[a]	Least eluted[a]	Mixed fraction[a]	Eluents[b]
1	**3**-$(PF_6)_2$	34%[c]	15%[d]	41%	A only
2	**3**-$(PF_6)_2$	40%[c]	—	56%[e]	B then A
3	**4**-$(PF_6)_2$	45%[c]	29%[d]	24%	B then A

[a] Yields for isolated products. [b] A = CH_2Cl_2 and B = $CHCl_3$. [c] Homochiral complex $\Delta^+(\Delta^-)_2$. [d] Heterochiral complex $\Lambda^+(\Delta^-)_2$. [e] The lower solubility of (Δ-**3**)(Δ-**1**)$_2$ in $CHCl_3$ leads to its gradual release in solution and thus to an important contamination of the least eluted fraction.

The enantiomeric excesses of the cations in the various chromatographic fractions were easily assessed by TLC and/or determined precisely by ^1H NMR analysis.¶ Due to the streaking of the IPs on silica gel, the most rapidly eluted diastereomers were always afforded in better yields than the least, and rather large fractions containing both diastereomers were isolated. Circular dichroism (CD) analyses of solutions of the most and least rapidly eluted separated diastereomers indicated that the cationic complexes had absolute Δ and Λ configurations respectively (Fig. 1). Homochiral [Δ-(**3**,**4**)](Δ-**1**)$_2$ complexes were less well retained than heterochiral complexes [Λ-(**3**,**4**)](Δ-**1**)$_2$ on silica gel.

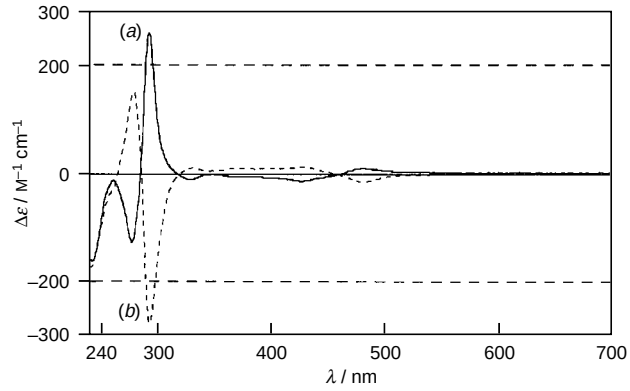


Fig. 1 CD spectra of the most and least eluted diastereomeric complexes (*a*) (Δ-**3**)(Δ-**1**)$_2$ and (*b*) (Λ-**3**)(Δ-**1**)$_2$ in CH_2Cl_2 at 20 °C

In conclusion, we have developed a new chromatographic resolution procedure for rather lipophilic cationic tris(diimine)ruthenium(II) complexes; it requires just 2 equiv. of the resolving agent and a polar chromatographic phase (SiO_2), which thus makes it economical and practical.

We are grateful for financial support of this work by the Swiss National Science Foundation. We thank Mr A. Pinto, Mr J.-P. Saulnier, Mr W. Kloeti and Mrs E. Sandmeyer for NMR and MS measurements.

‡ ^{31}P NMR analyses (20% $[^2H_6]$DMSO–$CDCl_3$) of the solid and the mother liquor reveal the presence of TRISPHAT and PF_6^- in both fractions.

§ *Typical procedure*: To a solution of 67.7 mg of **3**-$(PF_6)_2$ (71.7 μmol, 1.0 equiv.) in CH_2Cl_2 (10 ml) was added a solution of 152.7 mg of **1a** (143.5 μmol, 2.0 equiv.) in acetone (5 ml) and, after 10 min of stirring, 1.0 g of SiO_2 [J. T. Baker silica gel (30–60 μm)]. The resulting mixture was concentrated *in vacuo* affording a fine orange powder, which was placed on the top of a chromatography column (SiO_2, 3 × 18 cm). Elution with CH_2Cl_2 afforded fractions that were collected, analysed by TLC/NMR and gathered according to their enantiomeric purity.

¶ The associated TRISPHAT anions behave as NMR chiral shift agents.

Oxa-bowls: formation of exceptionally stable diozonides with novel, C–H···O hydrogen bond directed, solid state architecture

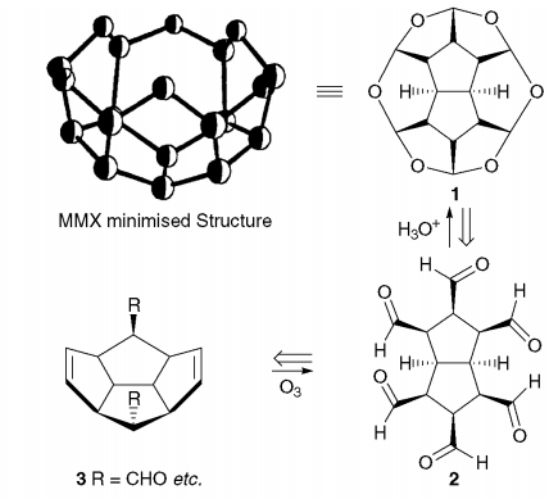
Goverdhan Mehta*† and R. Uma

Molecular Design and Synthesis Laboratory of JNCASR, School of Chemistry, University of Hyderabad, Hyderabad 500 046, India

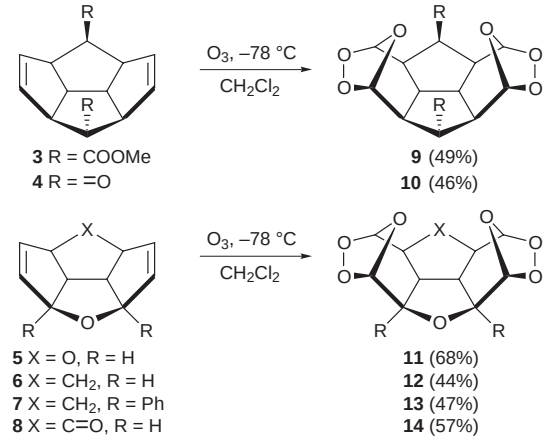
Several tetraquinane-based diolefins on ozonization furnish unusually stable diozonides of 'bowl-like' topology and their solid state structure reveals interesting architecture woven through a network of unique C–H···O interactions.

We have been engaged in the synthesis of a range of novel, high symmetry, 'bowl-shaped' molecular entities, composed of a carbocyclic base and hetero-atom speckled rim.[1] In the context of these endeavours, we became interested in an octacyclic, hexaoxa-bowl **1**, $C_{14}H_{14}O_6$, of C_{2v} symmetry, which we planned to access from the hexaaldehyde **2**, through a cascade of intramolecular acetalization protocols.[1] Compound **2**, in turn, was proposed to be prepared from the C_{2v} tetraquinane **3** *via* ozonolysis or equivalent oxidative cleavage of the disubstituted double bonds (Scheme 1). During our studies of **1**, we observed that several derivatives of **3** on ozonization furnish remarkably stable diozonides in a highly stereoselective manner. Two of these tetraquinane derived diozonides readily furnished single crystals and their X-ray crystallographic analysis shows a fascinating packing pattern and supramolecular arrangement, sustained by a network of C–H···O hydrogen bonds.[2] To the best of our knowledge, only one stable diozonide [derived from hexamethyl (Dewar) benzene] is known[3a] so far, although several stable mono-ozonides have been reported recently.[3c,d] The crystal structure[3a,b] of the diozonide from hexamethyl (Dewar) benzene has also been determined, but the authors did not observe any significant intermolecular contacts.

Tetraquinanes **3**, **4** and their oxa-analogues **5**–**8** reported earlier by us,[4] on ozonolysis in CH_2Cl_2 at −78 °C directly furnished the corresponding diozonides **9**–**14** after the removal of the solvent and could be readily crystallized (Scheme 2). All the diozonides were stable at room temperature (for months) and showed little decomposition on either moderate heating or on exposure to Me_2S and triphenylphosphine under standard conditions (stirring in CH_2Cl_2 solution). The gross structures of



Scheme 1



Scheme 2

9–**14** were fully revealed through the incisive analysis of their ^{1}H and ^{13}C NMR data.[5] However, the bowl-like *syn,syn*-stereochemistry present in **9**–**14**, with the two oxa-bridges protruding inwards could not be delineated unambiguously, although the MMX calculations showed this arrangement to be the most stable.‡ Therefore, recourse was taken to X-ray crystallography and two of the diozonides **9** and **14** furnished single crystals suitable for structure determination.

The diozonide **9** crystallized in space group *C*2/*c* and an ORTEP perspective (Fig. 1)§ revealed the stereochemistry as *syn,syn* with the O1 and O1a oxa-bridges tilting significantly inwards (O1 and O1a distance being 2.62 Å), and this orientation is facilitated by intramolecular C–H···O hydrogen bonds[2] between the bridgehead H1 and H1a atoms and the O4a

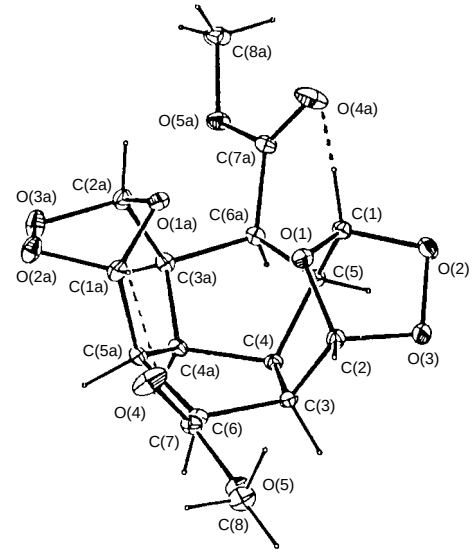


Fig. 1 ORTEP plot of **9**

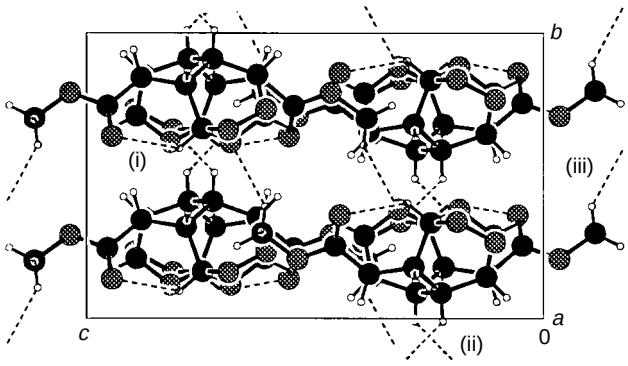

Fig. 2 Crystal packing in **9**, view down *a* axis. Selected C–H···O interactions: [H···O (Å), C(H)···O (Å), CH···O (°)]: (i) (intra, C1–H1···O4) 2.21, 2.93, 129.5; (ii) (inter, C4–H4···O2) 2.58, 3.34, 134.4; (iii) (inter, C8–H8C···O1) 2.60, 3.18, 119.5.

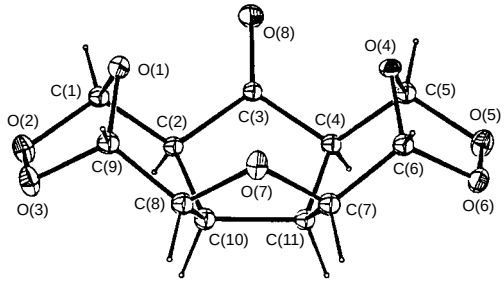

Fig. 3 ORTEP plot of **14**

and O4 carbonyl groups of the ester moieties (H···O distance 2.21 Å, C···O 2.93 Å and C–H···O angle of 129.5°) (Fig. 1). The packing pattern shows that the bowl-like molecules of **9** are stacked one over the other along the *b* axis in a columnar arrangement (Fig. 2). In the *ab* plane there are arrays of uni-directional bowls, each engaged in four C–H···O hydrogen bonds (two below and two above) to nearest neighbours through H4, H4a (ring junction protons on the diquinane moiety) and O2a, O2 oxygens of the peroxo bridge (H···O distance 2.58 Å, C···O 3.34 Å and C–H···O angle of 134.4°) along the *b* axis. The adjacent *ab* planes consist of bowls growing in opposite directions and are held by weak C–H···O contacts between the Hc protons of the ester methyls and O1 oxa-bridges of the inversion related bowls (Fig. 2).

The oxa-bowl **14** crystallizes in space group $Pca2_1$ and the molecules are tightly packed as indicated by its high density (1.681 Mg m^{-3}). An ORTEP diagram (Fig. 3)§ once again revealed the *syn,syn* stereochemistry but the two oxa-bridges are now far apart (O1 to O4 distance is 4.22 Å), perhaps due to repulsion within the congested concave surface with O7. The bowls are held by C–H···O hydrogen bonds (H···O distance 2.36 Å, C···O 3.28 Å and C–H···O angle of 155.1°) between H10 (ring junction proton on the diquinane moiety) and O7 ether oxygen, along the *c* axis, defining a ribbon-like pattern (Fig. 4). There is a bowl inversion pattern along the *a* axis and these bowls are held through a C1–H1···O5 contact. Along the *b* axis the bowls are held by C–H···O hydrogen bonds between the H7 (α to the ether oxygen) and the O8 carbonyl oxygen (H···O distance 2.57 Å, C···O 3.49 Å and C–H···O angle of 156.6°) to generate another ribbon-like pattern (Fig. 4). It is noteworthy that in the structures of both **9** and **14**, the least acidic diquinane ring junction protons are involved in the C–H···O hydrogen bonds and this is perhaps a consequence of the bowl-like topology present in these molecules.

In summary, we have described the characterization of several 'bowl-like' diozonides of exceptional stability and their X-ray structure reveals a novel architecture sustained through a network of C–H···O hydrogen bonds.

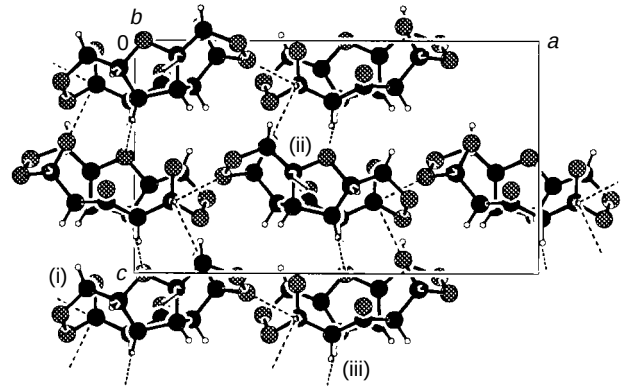

Fig. 4 Crystal packing in **14**, view down *b* axis. Selected C–H···O interactions: [H···O (Å), C(H)···O (Å), CH···O (°)]: (i) (inter, C1–H1···O5) 2.42, 3.05, 121.4; (ii) (inter, C7–H7···O8) 2.57, 3.49, 156.6; (iii) (inter, C10–H10···O7) 2.36, 3.28, 155.1.

Efficient catalytic cleavage of DNA mediated by metalloaminoglycosides†

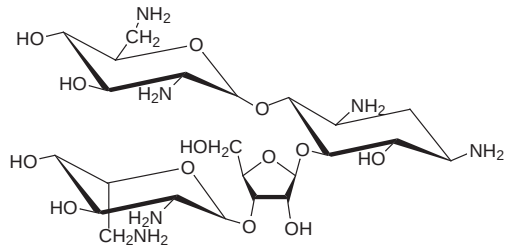
Alavattam Sreedhara and James A. Cowan*‡

Evans Laboratory of Chemistry, The Ohio State University, 100 West 18th Avenue, Columbus, Ohio, 43210, USA

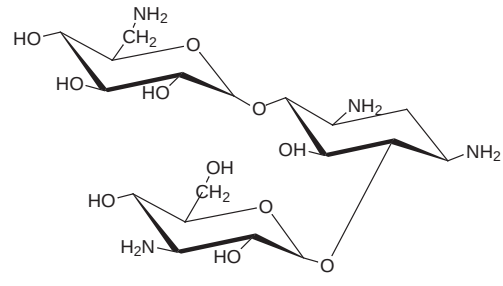
Metalloaminoglycosides have been synthesized and demonstrated to mediate catalytic cleavage of DNA at physiological pH and temperature.

Antitumor antibiotics such as neocarzinostatin,[1] bleomycin,[2] and elsamicin[3] create single or double strand nicks on duplex DNA. The latter are biologically more significant since they appear to be less readily repaired by natural DNA repair mechanisms.[4] Molecules that demonstrate DNA cleavage activity must possess either a hydrolytic, photoactivatable, or a redox active center, as well as recognition elements that target ds DNA.[5,6] We have explored the chemistry of Cu^{2+} derivatives of the aminoglycosides neomycin B (neo) and kanamycin A (kan) (Scheme 1),§ and demonstrate their ability to linearize DNA by non-random two-strand cleavage under catalytic conditions, and ultimately to effect complete degradation of plasmid DNA. Both hydrolytic and oxidative pathways have been identified.

A variety of first row transition metal ion complexes of kanamycin A were tested to assess their DNA cleavage efficiency; however, only a mixture of Cu^{2+} and kanamycin A was found capable of effecting rapid (< 1 h) degradation of plasmid DNA at 1 μM concentration. A systematic reactivity profile of the isolated and purified Cu(kan), **1**,¶ with plasmid DNA allowed observation of nicked DNA after brief (5 min) exposure to 0.5 μM complex (Fig. 1, lane 3). Both $Cu(kan)_2$, **2**, and Cu(neo), **3**, were also found capable of mediating DNA cleavage at catalytic concentrations as low as 100 nM; however, as a result of the hydrolytic instability of **2** and **3**, further DNA scission studies were focused on complex **1**.¶,‖



neomycin B



kanamycin A

Scheme 1

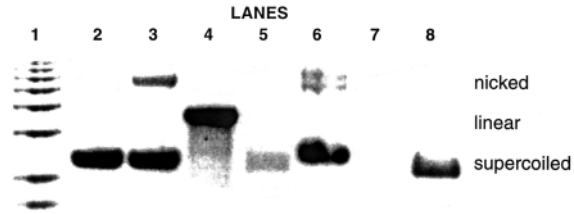


Fig. 1 Agarose gel electrophoresis of the reaction products following T4 ligase treatment of the nicked or linearized plasmid pT7-7†† obtained by reaction with Cu(kan) and BamH1, respectively. The reaction mixture (10 μl) containing plasmid DNA and metal–kanamycin complex was incubated for 1 h at 37 °C, mixed with 2 μl loading buffer (bromophenol blue, xylene cyanole and 50% glycerol) and loaded onto a 0.8% agarose gel containing ethidium bromide. Control experiments were run with plasmid DNA in the presence and absence of 5 μM kanamycin A. The gel was run at a constant voltage of 120 mV for 60–90 min in TAE buffer, washed in distilled water, visualized under a UV transilluminator and photographed on polaroid films. DNA concentrations are 50 μM: lane 1, 1 kb markers; lane 2, DNA + 0.5 μM Cu(kan), followed by treatment of reaction products with 2 units T4 ligase; lane 3, DNA + 0.5 μM Cu(kan); lane 4, DNA + 1 μl BamH1; lane 5, DNA + 0.5 μM Cu(kan) + 0.1 μM H_2O_2; lane 6, DNA + 1 μl BamH1, followed by treatment of reaction products with 2 units T4 ligase; lane 7, DNA + 0.5 μM Cu(kan) + 0.1 μM H_2O_2, followed by treatment of reaction products with 2 units T4 ligase; lane 8, DNA.

A hydrolytic degradative pathway is supported by several experimental criteria. In particular, neither standard inhibitors of reactive oxygen species (azide, superoxide dismutase, DMSO, EtOH), nor anaerobic conditions were found to inhibit DNA cleavage.[8] Further, it was found that plasmid DNA nicked by Cu(kan) (Fig. 1, lane 3) can be circularized by T4 DNA ligase (Fig. 1, lane 2),[9] while the resulting circularized plasmid demonstrates significantly higher transformation efficiencies than the nicked form.** The re-ligation and transformation efficiency indicate that DNA cleavage by Cu(kan) in the absence of external reducing agents is indeed hydrolytic.

A distinct oxidative pathway has also been identified. Addition of a reducing agent such as ascorbic acid or dithiothreitol (DTT) was found to enhance the DNA cleaving ability of **1**, and nicking was observed at nanomolar concentrations (Fig. 2). Interestingly, complete conversion of supercoiled

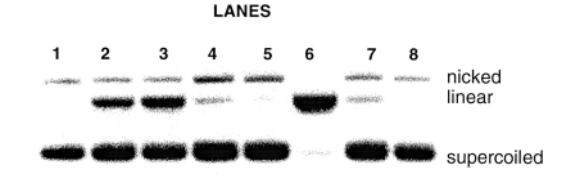

Fig. 2 Agarose gel electrophoresis of the oxidative cleavage reaction of plasmid pT7-7 by Cu(kan) **1** in the presence of ascorbate. Reactions were carried out for 1 h as follows: lane 1, 51 μM DNA; lane 2, + 1 nM **1**/10 μM asc; lane 3, + 1 nM **1**/10 μM asc; lane 4, + 1 nM **1**/1 μM asc; lane 5, + 1 nM **1**/0.1 μM asc; lane 6, + 5 nM **1**/10 μM asc; lane 7, + 5 nM **1**/1 μM asc; lane 8, + 5 nM **1**/0.1 μM asc. For lane 2, Cu^{2+}(kan) and ascorbate were mixed and preincubated at 37 °C for 30 min, to form Cu^{+}(kan), before addition of substrate DNA. The results were similar to those obtained by simultaneous mixing (lane 3). Experimental conditions for gel eletrophoresis are described in the legend to Fig. 1.

DNA (51 μM base pair) to a linear form was observed with a catalytic concentration of **1** (5 nM) in the presence of 10 μM ascorbate (Fig. 2, lane 6), while Cu^{2+}(aq) alone or with added ascorbate did not result in DNA cleavage under similar reaction conditions. This indicates non-random scission of the complementary strand in close proximity to the initial nick site, leading to production of linear DNA, since random cutting should produce a smear of fragment sizes. Complexes **1** to **3** degrade plasmid DNA completely in the presence of 10 μM H_2O_2. Fig. 1 (lane 5) shows extensive degradation of the plasmid over the time of this reaction, relative to control DNA shown in lane 8, with the range of smaller product fragments essentially undetectable. Furthermore, DNA treated with Cu(kan) and H_2O_2 is cleaved into random small and undetectable fragments that could not be ligated using T4 ligase (Fig. 1, lane 7).

In the presence of oxygen donor ligands, copper has been shown to produce a variety of oxidatively active intermediates, including a non-diffusable copper-oxene species,[10] and diffusable hydroxy radicals through Fenton-type chemistry.[11] The presence of DMSO and EtOH, which are hydroxy radical quenchers, do not have inhibitory effects on oxidative DNA cleavage by **1**. However, superoxide dismutase (SOD) and NaN_3 exhibit considerable inhibition of the oxidative DNA cleavage mediated by **1**, indicating that activated oxygen species (such as O_2^- or $^1O_2$) are most likely involved in plasmid cleavage. Also, superoxide generated by ascorbate-reduced copper can dismute to H_2O_2, which then reacts with another equivalent of cuprous ion through a Fenton mechanism to produce hydroxy radical like species, which might be metal bound. These species are analogous to metal-oxo species and are responsible for initiating the oxidative DNA strand scission chemistry. Both metal-oxo and metal-hydroxo species are expected to cleave the DNA backbone, but are not expected to be quenched by hydroxy radical quenchers,[12,13] as was observed in the case of **1**.

To address the issue of hydroxy radical involvement, production of this species was quantified using rhodamine B as a reporter molecule in the presence of **1** and ascorbic acid.[11,12] Substantial quantities of hydroxy radical were generated by Cu(kan) in the presence of ascorbate. However, in the presence of substrate plasmid no hydroxy radicals were trapped by rhodamine B. Furthermore, neither DMSO nor EtOH were able to quench the oxidative DNA scission reactions, indicating that any hydroxy radicals generated are not diffusible. A requirement of dioxygen for the oxidative scission reaction is substantiated by the fact that no hydroxy radical (determined by the rhodamine B test) and no cleavage was observed under anaerobic conditions. A mechanistic model that is consistent with these observations has a diffusible Cu^I-generated superoxide species interacting with another Cu^I center with production of the reactive metal-oxo or metal-hydroxo species.

In summary, we report the first example of catalytic cleavage and linearization of double-strand DNA by a synthetic complex at physiological pH and temperature. Both hydrolytic and oxidative pathways have been identified. Although other workers have described oxidative DNA cleavage by copper complexes,[8a,11,14–19] these are non-catalytic, requiring a large excess of reagent (from 0.1 to 1 mM copper complex with 25 nM to 10 μM DNA) and often extended reaction times of several hours to days. The cleavage efficiency and ease of synthesis of metalloaminoglycosides make them attractive molecules for therapeutic applications.

§ Aminoglycosides carry a large positive charge at physiological pH (from +3 to +6) and bind with high affinity to anions and nucleic acids *via* electrostatic and hydrogen bonding contacts.[7] Interestingly, the antitumor molecules described earlier[1–3] also contain aminated sugars in their framework.
¶ Complex **1** was synthesized by addition of $CuSO_4$ (0.0624 g, 0.25 mmol) to kanamycin A sulfate (0.1455 g, 0.25 mmol), in 5 ml water. After stirring at room temperature for 24 h, ethanol (5 ml) was added to precipitate a blue solid. This was filtered, washed twice by stirring in EtOH for 6 h, dissolved in water, and EtOH precipitated to yield **1**. Complexes **2** and **3** were formed similarly, using 2 equiv. of kan to form **2**. All products have been purified and give satisfactory elemental analysis, EPR, and UV–VIS data.
‖ Also excess metal-free aminoglycoside was found to inhibit cleavage, supporting a requirement for direct DNA binding to effect cleavage. At extreme concentrations, neomycin B alone has also been shown to mediate hydrolysis of a ribodinucleotide substrate (0.1 mM adenylyl-3,5-adenosine, ApA, and 0.3 M neomycin B).[20]
** Ligase treated Cu(kan) nicked plasmid demonstrated more than two-fold higher transformation efficiences than the nicked product itself.

Optimization of neutrocyanine chromophores based on five-membered heterocycles for photorefractive applications

Frank Würthner,*[a]† Christoph Thalacker,[a] Ralf Matschiner,[b] Katarzyna Lukaszuk[b] and Rüdiger Wortmann*[b]‡

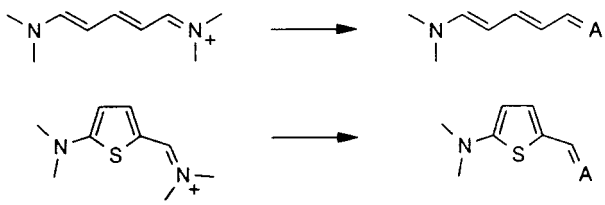
Exceptionally large photorefractive figures-of-merit are observed for neutrocyanine dyes based on dialkylaminothiophenes and −furans linked to quinoid five-membered heterocyclic acceptor groups by a methine bridge.

Chromophores based on 2-dialkylaminothiophenes with strong acceptor units in the 5-position are among the most interesting developments in dye chemistry of the last few years.[1–6] Showing enhanced electron-donating properties compared to *p*-dialkylaminobenzenes and higher thermal and chemical stability than dialkylaminopolyenes, 2-dialkylaminothiophenes became one of the most useful electron donor units for nonlinear optical (NLO) chromophores.[2–5] Furthermore, 5-dimethylamino-5'-nitro-2,2'-bithiophene is among the best indicator dyes for the study of solvent polaritity because of its outstanding positive solvatochromism.[6] Whereas all these dyes bear a chromophoric system which may be considered as 'polyene-like' with a large change of dipole moment upon optical excitation, we were recently able to polarize 2-dialkylaminothiophenes by a strong heterocyclic acceptor group up to the *cyanine limit*, which is characterized by equal dipole moments in the ground and the excited states, sharp and very intense absorption bands and vanishing solvatochromism.[7] Based on those highly polarizable dipolar dyes photorefractive (PR) materials[8] of unprecedented performance could be devised.[7,9]

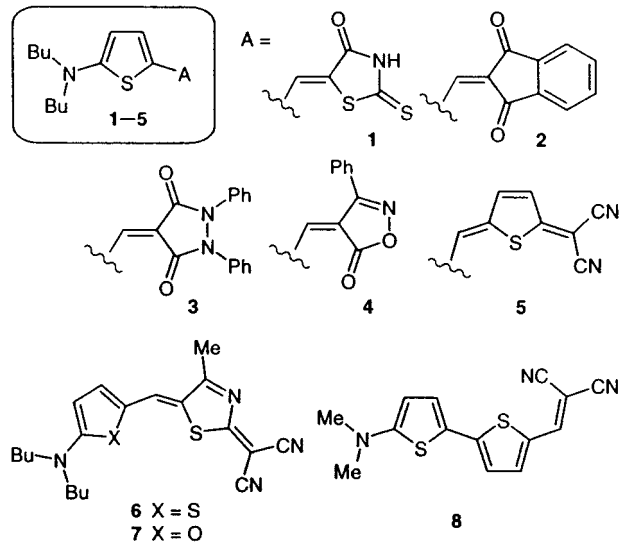
Here we present optical, electrooptical and structural properties of a new series of thiophene-based neutrocyanine dyes. Structure–property relationships will be elucidated which lead to general guidelines for the design of highly efficient PR chromophores.

According to Scheme 1, neutrocyanines (top right) are derived from cyanines (top left) by replacement of the iminium unit by non-ionic but very strong acceptor substituents (*e.g.* di- or tri-cyanovinyl). As a result, uncharged but highly dipolar chromophores are obtained. This should also be true if the conjugated chain is part of a heterocyclic system (bottom). However, since the symmetry of the cyanine chromophor is broken and aromaticity comes into play, even the tricyanovinyl acceptor group is not strong enough to polarize 2-dialkylaminothiophene to the cyanine limit.[3b] This goal may be achieved in a quite general way, however, by using heterocyclic acceptor units.

Thiophene dyes **1**−**6** and furan **7** were obtained§ by condensation reactions of the CH-acidic heterocycles with 2-dibutylamino-5-formyl-thiophene and -furan and studied by



Scheme 1



UV–VIS optical and electrooptical absorption measurements (EOAM).[10] EOAM experiments yield the dipole moment of the electronic ground state μ_g as well as the dipole change upon optical excitation $\Delta\mu = (\mu_a - \mu_g)$, whereas optical spectroscopy provides information on the transition dipole moment μ_{ag} and the absorption maximum λ_{ag}. From these data a PR figure-of-merit F_0 and a resonance parameter c^2 may be calculated according to eqns. (1) and (2).¶

$$F_0 = [54\mu_g\mu_{ag}^2\Delta\mu\lambda_{ag}^2/(hc_0)^2 + 4\mu_g^2\mu_{ag}^2\lambda_{ag}/(hc_0kT)]/M \quad (1)$$

$$c^2 = \tfrac{1}{2}[1-\Delta\mu(4\mu_{ag}^2 + \Delta\mu^2)^{-1/2}] \quad (2)$$

The PR figure-of-merit [eqn. (1)] was derived only recently[11] and established by us and others.[7,9] The two terms in eqn. (1) are commonly referred to as the electrooptical and birefringence contributions. It is found that the latter is usually dominant (> 80%).[7,11] Eqn. (2) defines a useful parameter to characterize the charge transfer properties of donor/acceptor-substituted compounds.[11] It is closely related to the BLA-parameter introduced by Marder *et al.*[12a] and the parameter MIX introduced by Barzoukas *et al.*[12b] and can be regarded as a measure of the admixture of the zwitterionic resonance structure (Scheme 2) to the electronic ground state. Thus eqn. (2) allows us to classify donor/acceptor-substituted chain molecules from polyene-type molecules($c^2 \approx 0$) to betaine-type molecules ($c^2 \approx 1$) with the neutrocyanine ('cyanine limit') being located in the middle ($c^2 \approx 0.5$).

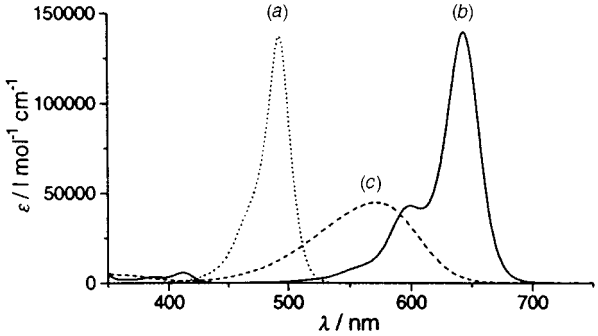

Fig.1 UV–VIS absorption spectra of PR neutrocyanine dyes (*a*) **3** and (*b*) **6** and (*c*) NLO dye **8** in CH_2Cl_2

The optical properties (λ_{ag}, ε_{max}, μ_{ag}) of neutrocyanines **1**–**7** (c^2 = 0.30–0.49) reveal intense transitions with very narrow bandwidths for their main absorption band, which is very favorable for applications in photonics (Table 1, Fig. 1). Thus dyes **1**–**7** may be used at laser frequencies significantly closer to the absorption maximum than for typical NLO chromophores such as **8**,[3] which exhibit very broad absorption bands thus causing absorption problems. Depending on the number of methine groups in the conjugated chain, we observe absorption maxima at *ca.* 500 nm for seven methine groups (**1**–**4**) and *ca.* 650 nm for nine methine groups (**5**–**7**).Whereas the optical properties of **1**–**7** exhibit very similar features, significant differences in the dipolar contributions to F_0 are found. Having about twice the number in their ground-state dipole moments μ_g, compounds **5**–**7** gain a factor of about four [second term in eqn. (1)] to F_0 compared to **1**–**4**. To explain this important point a closer look at the molecular structures and charge distributions in the ground state is helpful.‖ Semiempirical calculations indicate a high degree of charge separation for **5**–**7**. The highest electron density is found at the thiazole nitrogen (**6**,**7**) and the dicyanomethylene functionalities (**5**–**7**) of the heterocyclic acceptor at the *opposite* side of the methine bridge. In this way, a fairly extended chromophore is formed. On the other hand, **1**–**4** have their acceptor carbonyl groups *ortho* to the methine bridge. This limits the conjugated path to a rather short distance. Furthermore, the unfavorable orientation of the carbonyl group dipole moment leads to significant cancellation of the total molecular dipole moment.

Finally we note the successful tuning of the c^2 value from 0.32 in **5** to the perfectly equilibrated cyanine point (c^2 = 0.49) in **7**. Concomitantly, both the extinction coefficient and the PR figure-of-merit F_0 could be substantially increased. This improvement is particularly impressive when compared to NLO chromophore **8** which differs from **5** only by the position of the methine bridge. Moreover, the exocyclic dicyanomethylene moiety in **5**–**7** opens the way for an extension of the conjugated chain to long-wavelength neutrocyanine chromophores, which we will address in the future.

In conclusion we have presented a new series of neutrocyanine chromophores based on five-membered heterocycles. Their photorefractive figures-of-merit range from 0.22 up to 1.98, which is the highest value reported. As their use in optical devices depends on transparency at the applied laser frequency, their narrow-band absorption represents another significant advantage over currently available PR chromophores.[7–9] The possibility of building extended π-systems with alternating aromatic and quinoid moieties as suggested by **5**–**7** might be of relevance for the design of IR dyes and low band-gap polymers as well.[13]

Synthesis of methylene isosteres of α- and β-D-galactopyranosyl-L-serine

Alessandro Dondoni,*† Alberto Marra and Alessandro Massi

Dipartimento di Chimica, Laboratorio di Chimica Organica, Università, 44100-Ferrara, Italy

The $BF_3{\cdot}Et_2O$ promoted coupling of tetra-*O*-benzyl-α-D-galactopyranosyl trichloroacetimidate with a silyl enol ether carrying an oxazolidine ring leads to the α-*C*-glycosylmethyl ketone (32%, 95% ds) that is converted into the title α-*C*-glycosyl amino acid by carbonyl oxygen removal (Barton–McCombie) and oxidative cleavage (Jones) of the heterocyclic ring, and into the β-isomer by anomerization and the same two-step sequence.

Towards a better understanding and control of the function of sugars in natural glycopeptides,[1] the synthesis of their analogues in which the sugar moieties are linked to the peptide backbone by an all-carbon chain that is resistant to chemical and enzymatic degradation is a topic of increasing importance in glycobiology and medicinal chemistry. Therefore carbon-linked glycosyl amino acids as precursors to glycopeptide mimetics are current synthetic targets in various laboratories.[2] Different syntheses of methylene isosteres of *O*-glycosyl serines have been reported[2a–c,f–h] since these sugar amino acids are the most common constituents of natural glycoproteins. The *C*-glycosylation of a suitable α-amino acid equivalent[2c] appears to be the most direct route to these compounds.[3] Therefore we describe here the synthesis of α- and β-*C*-galactosyl serine **1** (Gal-CH_2-Ser), *i.e.* the methylene isosteres of D-galactose α- and β-linked to L-serine (Gal-*O*-Ser, **2**), employing the silyl enol ether **3** as a novel homoalanine carbanion equivalent. To the best of our knowledge this is the first approach to a pair of α- and β-isomer *C*-glycosyl amino acids *via* a single synthetic scheme.

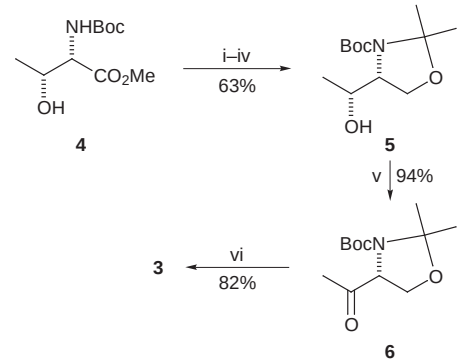
The multigram scale synthesis of **3** started from the known[4] methyl L-threoninate **4** which was transformed by a sequence of high yielding reactions into the ketone **6** (Scheme 1).‡ The enantiomeric purity of this key intermediate was established by reduction to the alcohol **5** with sodium borohydride (75% ds) and conversion of the latter into its Mosher ester. Silylation of the oxazolidinyl ketone **6** was readily effected using TMSOTf and Et_3N[5] furnishing exclusively the kinetic trimethylsilyl enol ether **3** in 82% yield.§

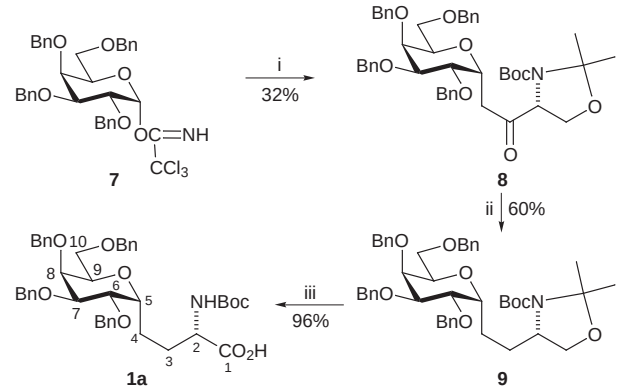
The glycosylation of the silyl enol ether **3** was carried out with the readily available electrophilic sugar tetra-*O*-benzyl α-D-galactopyranosyl trichloroacetimidate[6] **7** (Scheme 2). Unoptimized conditions involved the addition *via* syringe pumping of an Et_2O solution of **7** (2 equiv.) to silyl enol ether **3** and $BF_3{\cdot}Et_2O$ (1 equiv.) in Et_2O at −15 °C. The expected[7] major product, α-*C*-glycoside **8,** and the β-anomer **10** were isolated by column chromatography in 32% overall yield and 19:1 ratio.¶ Also isolated was the ketone **6** (45%) arising from the hydrolysis of unreacted **3**, and a mixture of anomeric galactosyl trichloroacetamides (70%). The recovery of the enantiomerically pure ketone **6** demonstrated that the configuration at the



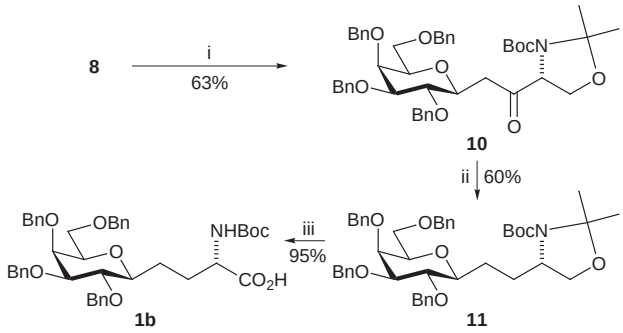
Scheme 1 *Reagents and conditions*: i, TBDMSOTf (1.2 equiv.), Et_3N, DMAP, DMF, 0 °C to room temp., 1.5 h; ii, $LiAlH_4$ (4 equiv.), THF, −50 °C, 50 min; iii, 2-methoxypropene, CSA, CH_2Cl_2, 0 °C to room temp., 1.5 h; iv, Bu_4NF, THF, room temp., 6 h; v, PCC (5 equiv.), CH_2Cl_2, 4 Å MS, room temp., 20 min; vi, TMSOTf (1.4 equiv.), Et_3N (1.6 equiv.), CH_2Cl_2, −15 °C, 1 h

stereocenter of the silyl enol ether **3** was unaffected under the glycosylation conditions. Towards the target *C*-glycosyl amino acid, the deoxygenation of the sugar ketone **8** was first carried out through the classical Barton–McCombie reduction-elimination sequence[8] affording **9** in 60% yield. Treatment of **9** with the Jones reagent induced the cleavage of the oxazolidine ring and oxidation of the alcohol in a single step to give the α-linked tetra-*O*-benzyl-*C*-galactosyl-L-serine **1a** in 96% isolated yield. This compound proved to be contaminated by *ca.* 5% (^1H NMR analysis) of the corresponding α-amino alcohol. Therefore, the amino acid **1a** was fully characterized through its methyl ester.

Guided by earlier work regarding the base-catalyzed equilibration of α-*C*-glycosides bearing a carbonyl group in the side chain,[9] the anomerization of the α-*C*-glycosylmethyl ketone **8** was carried out upon treatment with Bu^tLi in Et_2O (Scheme 3). Under these conditions a mixture of **8** and the β-anomer **10** in a



Scheme 2 *Reagents and conditions*: i, **3** (0.5 equiv.), $BF_3{\cdot}Et_2O$ (0.5 equiv.), Et_2O, −15 °C, 2 h; ii, $NaBH_4$, MeOH–Et_2O, −20 °C, 1 h, then 1,1′-thiocarbonyldiimidazole (10 equiv.), DMAP (15 equiv.), THF, reflux, 6 h, then Bu_3SnH (10 equiv.), AIBN (0.1 equiv.), toluene, 85 °C, 2 h; iii, 1 M Jones reagent (3 mol per mol of reactant), acetone, 0 °C to room temp., 3.5 h



Scheme 3 *Reagents and conditions*: i, Bu^{t}Li (1.2 equiv.), Et_2O, −78 to −20 °C, 2 h, then room temp., 2 h; ii, $NaBH_4$, MeOH–Et_2O, −20 °C, 1 h, then 1,1′-thiocarbonyldiimidazole (10 equiv.), DMAP (15 equiv.), THF, reflux, 6 h, then Bu_3SnH (10 equiv.), AIBN (0.1 equiv.), toluene, 85 °C, 2 h; iii, 1 M Jones reagent (3 mol per mol of reactant), acetone, 0 °C to room temp., 3.5 h

3:7 ratio and 90% overall yield was obtained. The isolated β-*C*-glycosylmethyl ketone **10** was subjected to the radical deoxygenation as described above for **8** to give the β-*C*-alkyl glycoside[2h] **11** (60% isolated yield). The conversion of the oxazolidine ring of this compound into the α-amino acid moiety by treatment with the Jones reagent gave the known[2b,h] β-D-linked tetra-*O*-benzyl-*C*-galactosyl-L-serine **1b** (95%). The synthesis of **1b** highlights the use of the silyl enol ether **3** as the homoalanine carbanion equivalent since a similar approach cannot be developed by using amino acid equivalents[2c,3] lacking the carbonyl group.

In conclusion, the synthesis of **1a** and **1b** demonstrates the viability of a new approach to α- and β-linked *C*-glycosyl amino acids starting from a single carbohydrate precursor. The protected hydroxy and amino groups (as *O*-benzyl and *N*-Boc derivatives) and, by contrast, the free carboxylic group constitute a synthetically convenient structure for the incorporation of these *C*-glycosyl amino acids into a peptide chain. The application of this method for the preparation of pairs of amino acids by glycosylation of the silyl enol ether **3** with other sugars is now of interest.

Deep-cavity cavitands: synthesis and solid state structure of host molecules possessing large bowl-shaped cavities

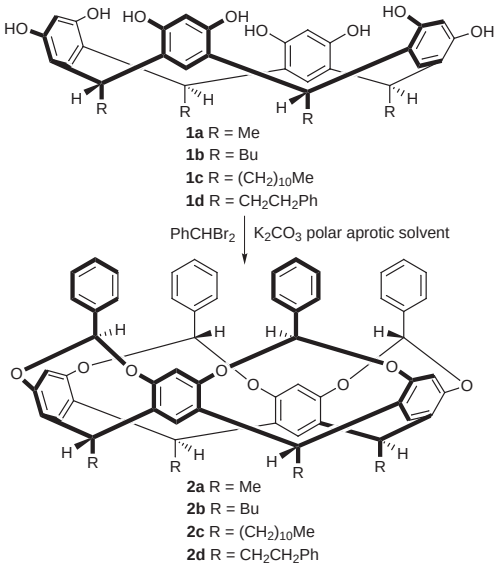
Huaping Xi, Corinne L. D. Gibb, E. D. Stevens and Bruce C. Gibb*†

Department of Chemistry, University of New Orleans, New Orleans, LA 70148, USA

A novel family of deep-cavity cavitands is prepared *via* the first examples of the stereoselective bridging of resorcin[4]arenes with carbon electrophiles.

Cavitands, molecules that contain a rigid enforced cavity, have a proven proclivity for a diverse range of applications; as molecular scaffolds,[1] as components in the formation of carceplexes,[2–4] or as host molecules in their own right.[2,5] In this later context, extending the paradigm to enzyme mimicry raises an important question; for a host with a necessarily large cavity, how do we incorporate both structural rigidity to its hydrophobic pocket while simultaneously imparting reasonable solubility on the system? This paper details our initial work towards addressing this question.

The most important factor contributing to the broad repertoire of cavitands as molecular hosts is undoubtedly the ease of synthesis of the corresponding resorcin[4]arenes (octols), *e.g.* **1a**–**d**.[6] Accordingly, attempts to increase the size of a cavitand's



cavity have centered around the bridging of the phenolic pairs of these building blocks with a variety of moieties;[7–9] an early example of cavitands with enlarged cavities being provided by Cram, with the formation of the conformationally flexible velcraplexes.[10] Here we demonstrate an important first step towards large, non-collapsing, hydrophobic pockets; the synthesis of deep-cavity cavitands[11] of the general structure **2**, *via* the stereoselective bridging of octols with benzal bromides. We believe that this procedure will provide access to a significant range of rigid hosts possessing large hydrophobic cavities,[12] as well as a variety of novel molecular building-blocks for self-assembling systems.[13]

In the standard procedure for bridging octols, for example methylene bridging with $BrClCH_2$, there are a considerable number of variables that can be adjusted. Thus, to constrain our investigations, and in an effort to more precisely define influences that may affect bridging reactions in general, we decided to modify arguably the two most influential parameters: the solvent and the rate of addition (*via* syringe pump) of the octol to the reaction. To monitor the influence of the pendent (R) groups of the octols we extended this syntheses matrix by examining the bridging of the four octols **1a**–**d**. Table 1 shows the yields of the deep-cavity cavitands **2a**–**d** from the corresponding octols using $PhCHBr_2$ as the bridging material and K_2CO_3 as base.‡ In all cases, although a total of six diastereomers could potentially be formed, only one isomer was isolated from the varying amounts of polymeric material.

The Me-octol **1a** proved resistant to benzal bridging for each of the solvents investigated;[14] a maximum yield of 10% being obtained from bulk intractable polymer. The four-fold symmetry of the cavitand was evident from the ^1H NMR data, the most characteristic feature of which was a singlet at *ca*. 5.5 ppm for the protons on the bridging carbons. That the product was indeed cavitand **2a**, and not the diastereomer with the phenyl groups pointing into the cavity, was demonstrated by X-ray crystallography.[15] Interestingly, the solid state structure (Fig. 1) also revealed that this cavitand dimerizes in a head to head fashion to generate cavities between the rigid dimers. Furthermore, the contiguous nature of these cavities results in the formation of channels (cross-section = 8.3 × 6.6 Å within a cavity, or 7.4 × 4.2 Å at the mouth of each cavity) that zigzag along a common axis.[16]

Similar low yields were obtained for **1b** in DMA and NMP. However, with the slow addition of the octol in DMPU, the deep-cavity cavitand, **2b**, was isolated in 58% yield; a remarkable yield when compared to either the statistical 6.25%, or the similar yields obtained for methylene bridging with CH_2ClBr.[17] Encouraged by this disparity between **1a** and **1b**, we investigated the bridging of **1c**. For this compound we found that the reaction was successful in either DMA or DMPU, with maximum yields somewhat lower than for **1b**. Finally, we found

Table 1 Yields for the formation of deep-cavity cavitands **2a**–**d**[a]

Entry	Octol	Product	Solvent[b]	Yield (%) *via* 4 h addn. of octol (2 d addn.)
1	**1a**	**2a**	DMA	< 5 (< 5)
2	**1a**	**2a**	NMP	< 5 (< 5)
3	**1a**	**2a**	DMPU	6 (10)
4	**1b**	**2b**	DMA	6 (< 5)
5	**1b**	**2b**	NMP	6 (7)
6	**1b**	**2b**	DMPU	35 (58)
7	**1c**	**2c**	DMA	41[c] (*c*)
8	**1c**	**2c**	NMP	< 5 (< 5)
9	**1c**	**2c**	DMPU	17 (40)
10	**1d**	**2d**	DMA	56 (51)
11	**1d**	**2d**	NMP	57 (55)
12	**1d**	**2d**	DMPU	31 (42)

[a] These results relate to 250 mmol scale reactions. However, yields were essentially identical for multi-gram reactions. [b] See ref. 14. [c] Because of crystallization problems in DMA, octol **1c** was added over a 2 h period.

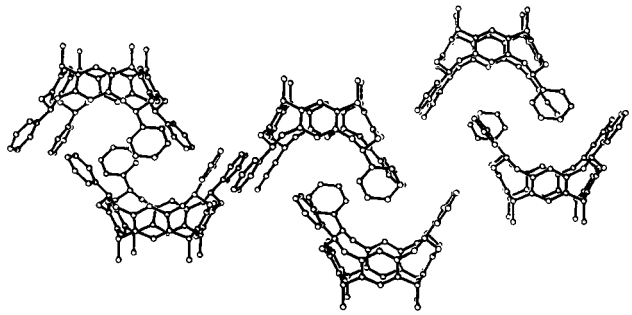


Fig. 1 Ball and stick diagram showing a view perpendicular to the direction of the channel. The central dimeric pair of deep-cavity cavitands is behind the plane formed by its adjacent neighbors. For clarity, the hydrogen atoms and the disordered solvents have been omitted.

benzal bridging of **1d** to be relatively solvent independent, with the highest yields again comparable with methylene bridging.

These results, in conjunction with uniformly poor yields obtained when the octol was added as a solid (data not shown), highlight the importance of a constant, slow rate of addition of the octol to the reaction. Equally as important, the apparently capricious nature of the solvent/R group relationship highlights the need to investigate these reactions in a variety of solvents. To gain more insight into influences that affect benzal bridging, a further series of experiments were undertaken (data not shown). Briefly, for the DMA solvated reaction with **1d**, we observed no significant dependence of the yield on reaction scale or concentration, but that the use of caesium carbonate as base, or $PhCHCl_2$ as bridging material, had a pronounced, detrimental effect on the yield.

The most significant observation from these results is that bridging is more favored for octols with larger pendent groups; a reflection, we believe, of a propensity for large groups to preorganise the octol into a bowl shaped conformation suitable for bridging. In a related issue, we attribute the apparent reduction in solvent-dependent yield with increasing size of the R group to a stronger association between such groups which pushes the equilibrium between favorable and unfavorable conformations towards the former.

Pin-pointing the precise cause of this stereoselective bridging is complicated by a lack of knowledge of the bridging mechanism in general. However, regardless of the pathway, the overall reaction is clearly highly diastereoselective, as steric demands induce a remarkable average of at least 87% stereoselectivity for each bridge.

In conclusion, we have demonstrated an approach to extending the π-surface of cavitands in a manner that should allow formation of a range of host molecules possessing large enforced cavities. With the concept of catalytic machinery preorganized within hydrophobic pockets our long term goal, we are currently extending our studies to the formation of a variety of functionalized deep-cavity cavitands.

We are grateful to John C. Sherman for helpful discussions and Richard B. Cole of the New Orleans Center for Mass Spectrometry Research for mass analyses of the products. This work was partially supported by the Louisiana Board of Regents Support Fund (1997-00)-RD-A-23, and a Research Innovation Award from Research Corporation.

‡ The following general procedure is illustrative: the octol (0.275 mmol) was added as a solution in the respective solvent (5 ml) to a stirred mixture of 450 mg of K_2CO_3 and 200 μl (1.25 mmol) benzal bromide ($PhCHBr_2$) in 12 ml of solvent. After stirring for 2 days at 25 °C, an additional 67 μl (0.42 mmol) of $PhCHBr_2$ was added and the reaction mixture warmed to 40 °C. After 1 day, a further 67 μl (0.42 mmol) of $PhCHBr_2$ was added and the temperature increased to 50 °C. This temperature was maintained for a further day, when an additional 67 μl (0.42 mmol) of $PhCHBr_2$ was added, and the reaction heated to 60 °C for 3 days. The reaction was then cooled, and the solvent removed under reduced pressure. The crude mixture was partitioned between water and $CHCl_3$, the $CHCl_3$ layer separated and the aqueous layer extracted twice with $CHCl_3$. The organic layers were then combined, dried with anhydrous $MgSO_4$, and the solvent removed under reduced pressure. Column chromatography (silica gel, $CHCl_3$–hexane, 1 : 1) afforded the corresponding deep-cavity cavitand which was dried (0.1 mmHg, 110 °C) overnight. All compounds gave satisfactory NMR, MS and elemental analysis (±0.4%).

An efficient semisynthesis of 7-deoxypaclitaxel from taxine

Radomir Matović[a] and Radomir N. Saičić*[b]†

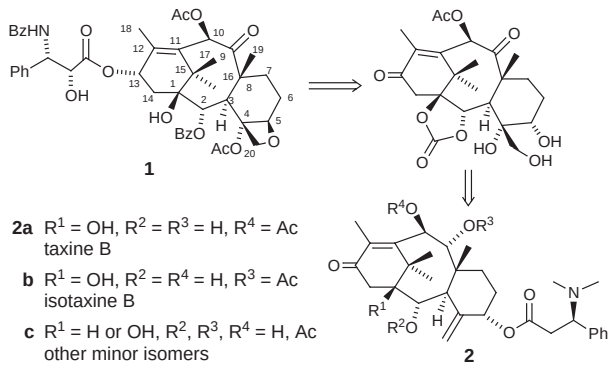
Highly cytotoxic 7-deoxypaclitaxel analogues are obtained by a semisynthesis starting from taxine—the most abundant naturally occurring taxane diterpene fraction.

Owing to its great potential in the successful treatment of many types of cancer, unusual mode of antimitotic action, and complex molecular architecture, paclitaxel has attracted enormous interest from the scientific community.[1] Paclitaxel is currently produced *via* extraction from the bark of the Pacific yew, *Taxus brevifolia*, or by semisynthesis from 10-deacetylbaccatin III, which is in turn isolated, most notably, from the leaves of the European yew, *Taxus baccata*.[2] However, 10-deacetylbaccatin III is not the most abundant secondary metabolite of the yew tree: its variable content in the needles of *Taxus baccata* ranges from 0.05 to 1 g per kg of leaves.[3] In contrast, a mixture of alkaloids collectively referred to as 'Taxine' **2** can be obtained by a simple extraction procedure in yields of 7–12 g kg^{-1},[4] the two major constituents of this fraction (*ca.* 35%) being taxine B **2a** and isotaxine B **2b**;[5] therefore, the development of the procedure that would allow for the efficient use of this starting material for the preparation of biologically active paclitaxel analogues would be of considerable interest.

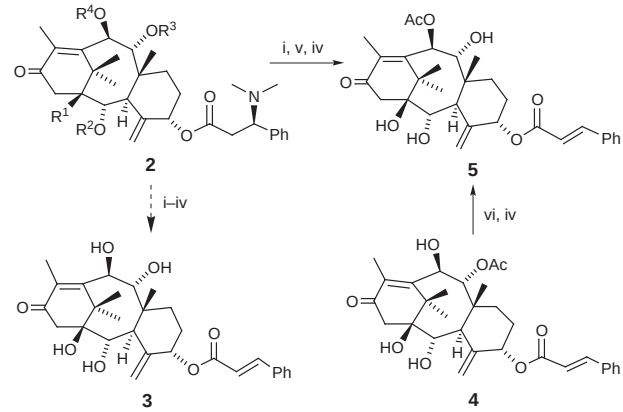
Earlier reports on 7-deoxypaclitaxel **1**, obtained by radical deoxygenation of paclitaxel, or baccatin derivative, showed this compound to be of comparable, or even superior, cytotoxic activity with respect to paclitaxel,[6] and, given the structural congruence with taxine B, indicated it as a semisynthetic target. The possibility of such a synthetic transformation was investigated by several groups.[7] As the preparative separation of taxine alkaloids is difficult, the crude taxine mixture was hydrolysed in order to obtain a well-defined starting material, *i.e.* tetraol **3**. However, the differentiation between hydroxy groups in tetraol **3** required extensive use of protective groups, leading to long synthetic sequences, and lowering considerably the overall yield.[8] We endeavoured to develop an efficient procedure for the conversion of taxine into 7-deoxypaclitaxel derivatives (Scheme 1). The accomplishment of this task was expected not only to give access to large amounts of 7-deoxypaclitaxel analogues, but also to provide additional information on the reactivity of the taxane system, as well as derivatives suitable for further SAR studies.



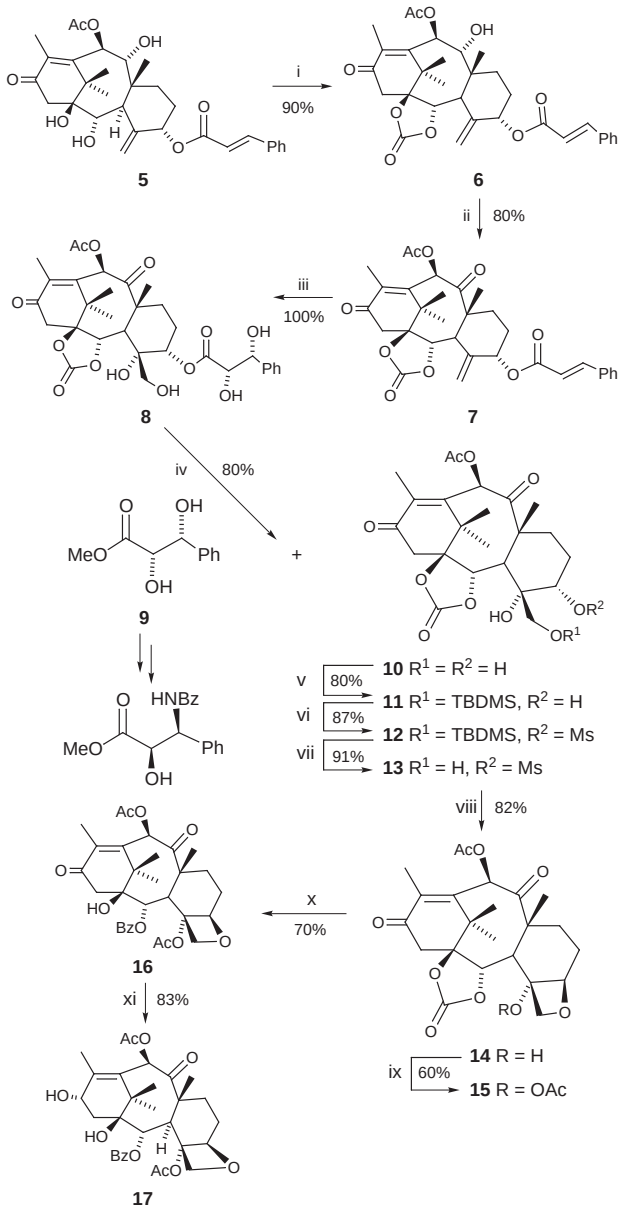
Scheme 1

We first re-examined the possibility of exploiting the favourable arrangement of functional groups in the major constituent of taxine, *i.e.* taxine B **2a** (Scheme 2). Quaternization of the crude taxine,[7a] followed by DBU induced elimination under anhydrous conditions, afforded a mixture of 9- and 10-acetyl-5-cinnamoyltaxicine I (**4** and **5**), which could be separated by a flash chromatography on a SiO_2 column, and were isolated in yields of 1 and 1.7 g kg^{-1} of needles, respectively. The former could be isomerised into the required 10-acetyl derivative **5** by treatment with methanolic KOAc (43% yield at 70% conversion, without optimisation), to afford a total of 2 g of 10-acetyl-5-cinnamoyltaxicine I **5** per 1 kg of dry leaves.

With the suitable starting compound **5** in hand, the synthesis of 7-deoxybaccatin III proceeded as displayed in Scheme 3. Treatment of **5** with phosgene, followed by hydrolytic work-up, furnished the cyclic carbonate **6** (90%), which was further oxidised to diketone **7** (Dess–Martin periodinane, 80%), thus establishing the final functionalization of the 'upper' part of the molecule. The elaboration of the oxetane ring was envisaged to proceed *via* triol **10**.[7a] For that purpose a method for selective removal of the cinnamoyl chain was needed, as the simultaneous cleavage of the C-10 acetate would require additional protective steps. To achieve this, allylic cinnamate **7** was oxidised with OsO_4/NMO, as it was anticipated that intramolecular hydrogen bonding in **8** should activate the dihydroxyphenylpropionate ester towards hydrolysis under very mild conditions. Although some concern existed about the stereochemical outcome of the osmylation, to our pleasure the reaction proceeded in quantitative yield, and with complete stereoselectivity. This structural change brought about the expected modification in the reactivity profile of **8**, as indicated by its proclivity towards spontaneous migration of the ester side chain from O-5 to O-20 on standing in solution at room temperature; treatment of **8** with K_2CO_3 or $NaHCO_3$ in MeOH–H_2O at 0 °C induced very rapid hydrolysis of the dihydroxypropanoate ester, but the hydrolysis of the C-10 acetate also



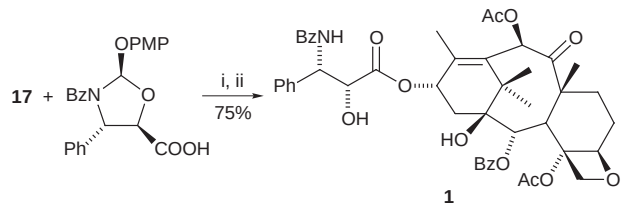
Scheme 2 *Reagents and conditions*: i, MeI, THF, room temp., 5 h; ii, K_2CO_3, H_2O, EtOH, room temp., 3 h; iii, NaOMe, MeOH, 0 °C, 16 h; iv, column chromatography on SiO_2; v, DBU, $CHCl_3$, room temp., 1.5 h; vi, 10% KOAc in MeOH, room temp., 3 h



Scheme 3 *Reagents and conditions*: i, $COCl_2$ (20 equiv.), CH_2Cl_2, 0 °C, 20 min; then Et_2O, H_2O, imidazole (cat.), 0 °C, 20 min; ii, Dess–Martin periodinane (2 equiv.), CH_2Cl_2, TFA (cat.), room temp., 12 h; iii, OsO_4 (cat.), NMO, THF, H_2O, room temp., 4 h; iv, 10% KOAc in MeOH, reflux, 30 min; v, TBDMSCl, imidazole, DMF, room temp., 3 h; vi, MsCl, Py, 0 °C to room temp., 24 h; vii, 7% HF in MeCN, room temp., 7 h; viii, Pr^i_2NEt (7 equiv.), toluene, reflux, 30 h; ix, Ac_2O (7 equiv.), DMAP (14 equiv.), CH_2Cl_2, room temp., 4 h; x, PhLi (10 equiv.), THF, −78 °C, 0.5 h; then Ac_2O, DMAP, CH_2Cl_2, room temp., 1 h; xi, $NaBH_4$ (excess), MeOH, room temp., 3 h

occurred under these conditions. Eventually, refluxing **8** with methanolic KOAc afforded the desired triol **10** in 80% yield. Optically pure (*2S*,*3R*)-(-)-methyl 2,3-dihydroxy-3-phenylpropanoate **9** was isolated as the side product of this reaction, and further converted into the paclitaxel side chain according to a previously published procedure.[9] The transformation of the key intermediate **10** into 7-deoxybaccatin III **17** was accomplished by applying a modified methodology previously developed in total syntheses of paclitaxel.[1,7a] In this way, starting from cinnamoyltaxicine I **5**, 7-deoxybaccatin III was obtained in 11.5% overall yield (unoptimized).[10]

7-Deoxybaccatin is a direct precursor of paclitaxel analogues: esterification of **17** with acid **18**,[11] followed by acidic hydrolysis (TsOH in MeOH) afforded 7-deoxypaclitaxel **1** in 75% yield (Scheme 4).[12]



Scheme 4 *Reagents and conditions*: i, DCC, DMAP (cat.), room temp., 3 h; ii, 5% TsOH in MeOH, room temp., 1 h

The described chemistry offers an efficient pathway for the preparation of new paclitaxel derivatives, and points to the naturally abundant taxane diterpene fraction—taxine—as a valuable starting material for further semisynthetic studies.
