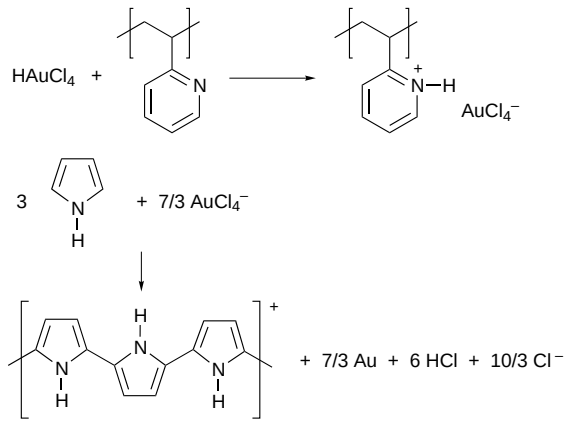
Nanoparticles of gold and other noble metals and semiconductor particles, in a more general sense, exhibit a variety of useful optical, electrical and catalytic properties. All these properties strongly depend on the careful choice of preparative strategies, which could provide long term stability and ease in processability.[1–4] Polymer nanocomposites is one such approach and one of the important objectives in recent research is to prepare monodisperse particles, regularly dispersed in a polymer matrix. The synthesis of noble metal sols in a polymerising nonconducting system such as poly(methyl methacrylate) has recently been documented in the literature.[5]. The first prerequisite for the formation of kinetically controlled monodisperse colloids is the availability of well defined dispersions. Block copolymer micelles provide an excellent means for such dispersions,[6] by which the particles of a definite size can be formed and stabilized within the core, yielding monodisperse colloids.

With the advent of block copolymer micelles, we have demonstrated very recently, a facile and versatile route to the fabrication of monodisperse, single gold (Au) nanocluster, *ca*. 7 nm, in diameter (core) surrounded by a shell of polypyrrole (PPY), both within the spherical microdomains.[7–9] In this report, the first observation of different, novel nanostructures of Au–PPY, is described.

In the first method, a micellar solution of polystyrene-block-poly(2-vinylpyridine) (0.5 mass%) in toluene was treated with tetrachloroauric acid (0.5 and 0.7 equiv. to 2VP units) which got selectively bound within the P2VP cores of the micelles. When this solution was treated with pyrrole (PY), polymerization occurred, yielding polypyrrole under concurrent formation of Au nanoparticles, as supported by FTIR and UV–VIS measurements. The bipolaron bands at 1210 and 925 cm^{-1} indicated the formation of PPY in its doped state.[7] The chemical conversion is depicted in Scheme 1.

TEM images were acquired with a Philips 400 microscope operating at 80 kV. The samples were prepared by placing a drop of the colloidal polymer solution onto a carbon-coated Cu grid on an underlying tissue paper, leaving behind a thin colloidal film. In a typical concentration, *i.e.* $[PY]/[HAuCl_4]$ = 4.0, uniform, monodisperse Au particles with a mean diameter of 7 and 9 nm, are vividly seen with a shell of PPY, respectively in Fig. 1(*a*) and (*b*), upon annealing the thin film at 130 °C for 1 h. When the above procedure is repeated, but with



Scheme 1

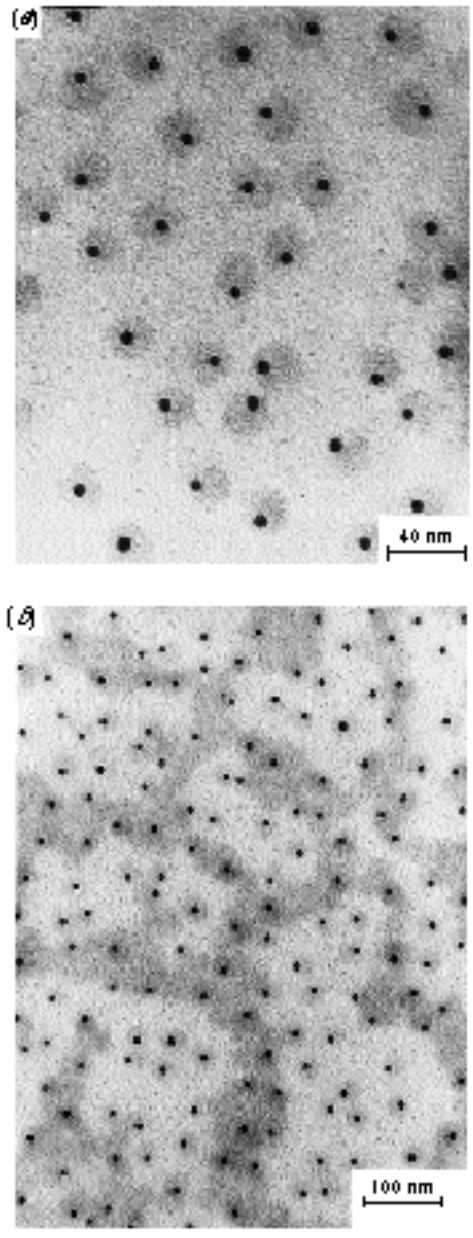


Fig. 1 Transmission electron micrographs of thin colloidal polymer films ($[PY]/[HAuCl_4]$ = 4.0) after annealing at 130 °C for 1 h. (*a*) 7 nm Au ($[HAuCl_4]/[2VP]$ = 0.5); (*b*) 9 nm Au ($[HAuCl_4]/[2VP]$ = 0.7) in each micelle. The grayish area represents PPY.

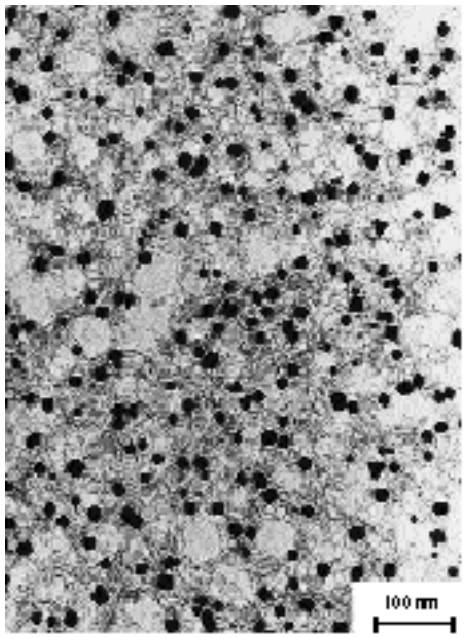

Fig. 2 Transmission electron micrograph of a thin film cast from a colloidal polymer solution (stirred heavily, but without annealing), exhibiting spherical, cubic, tetrahedral and octahedral Au particles

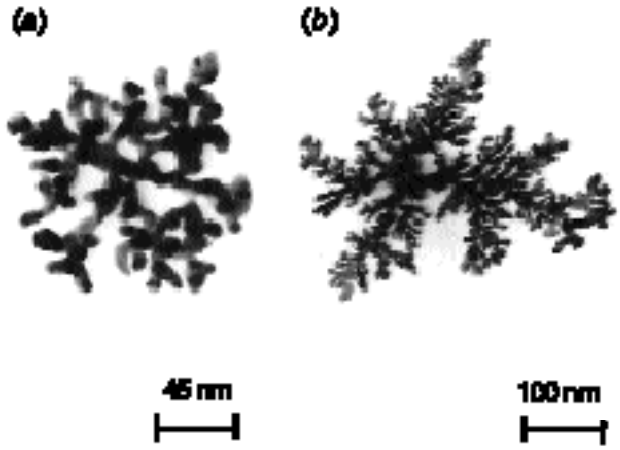

Fig. 3 TEM pictures depicting dendritic nanostructures of thin films cast from block copolymer ionomers, after vapour phase polymerization (VPP) of PY. (*a*) after 2 h of VPP; (*b*) after overnight VPP.

heavy stirring of the micellar solution and without heating, different shapes of Au particles, *viz*., spherical, cubic, tetrahedral and octahedral, are observed (Fig. 2). Here, the spherical domains cannot be seen owing to the fact that the spherical micelles coagulate with each other, yielding different shapes of Au, dispersed in a PPY matrix, marked by a grayish area. Most importantly, the nanoparticles of Au with different shapes resemble the shape-controlled synthesis of Pd nanoclusters.[10] It is obvious that an ordered aggregation produces uniform particles (Fig. 1), since a disordered aggregation would result in polydisperse particles of variable morphology (Fig. 2).

Interestingly, we have observed elegant 'dendritic' nanostructures (Au–PPY fractals?), in another different approach, by employing vapour phase polymerization of PY onto solution cast films of block copolymer ionomers (Fig. 3). Dendritic growth occurs even at a lesser polymerization time (⩽30 min). Thick branches radiated after 2 h of polymerisation. This large random supramolecular structure, known in short as DLA (diffusion-limited aggregate),[11] represents a very wide variety of growth (here, polymerization and coagulation), allowing building of one particle after the other and letting the particle diffuse and stick to the growing structure. The pioneering work of Kaufman *et al.* delineated PPY fractals obtained by the diffusion-limited electrochemical polymerization of PY.[12]

In conclusion, we have observed different elegant nanostructures of composites of Au, with a little nudge in the preparative strategies. Different (spheroids, cuboids) Au nanoparticles may have important implications in the field of catalysis. Importantly, the block copolymer architecture is useful for commercial applications of a processable form of PPY by providing colloidal stability to the suspension of PPY.[13] Furthermore, the new observation of 'dendritic' nanostructures, could open up new vistas in supramolecular structures. Over and above, conducting and semiconducting polymer/metal junctions could provide intriguing perspectives to develop novel electronic devices.[14]

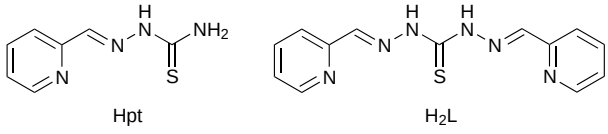
The single-crystal X-ray structure and variable temperature magnetic properties of the novel dicopper(II) anticancer drug analogue $[\{Cu_2(HL)(H_2PO_4)_2\}_2][NO_3]_2{\cdot}2H_2O$ [H_2L = bis(pyridine-2-aldehyde) thiocarbohydrazone] is determined; the complex shows a dimer of dimeric $\{Cu_2(HL)\}^{3+}$ units with dihydrogenphosphato and sulfur bridges between the inequivalent Cu^{II} centres, resulting in three antiferromagnetic exchange interactions: a dominant intradimer J of -109 to -116 cm^{-1}, and two weaker interdimer interactions.

Thiosemicarbazones have been extensively studied because of their biological properties. Cu^{II} is necessary for activity for kethoxal bis(thiosemicarbazone),[1] with the mode of action proposed to involve inhibition of DNA synthesis and oxidative phosphorylation,[2] and *N*-methylisatin-β-thiosemicarbazone can inactivate tumour viruses.[3] Attention has however focused on pyridine-2-aldehyde thiosemicarbazone (Hpt) and derivatives as the Cu^{II} complexes are more bioactive than the metal free ligands.[2,4] The metal-free 5-OH analogue underwent clinical trials as an anticancer drug but side effects such as disruption of iron metabolism prevented clinical use.[5] However, administration of a preformed metal complex may alleviate this. Adducts of $[Cu(pt)]^+$ with sulfur and nitrogen donors have been detected in biological fluids[6] with stable model thiolato complexes isolated from aqueous solution.[7] Crystallographic studies have revealed ternary nitrogen adduct formation,[7,8] complexation of dihydrogen phosphate[9] and pyrophosphate[10] and the system's remarkable ability to form complexes of both the anionic and neutral ligand.[11] The H_2L ligand may be considered as an extension of Hpt, now with a possible extra metal binding domain. Antiviral activity has been reported for 2-acetylpyridine thiocarbohydrazones[12] and H_2L is antifungal[13] and cytotoxic[14] but little chemical and no structural work has been carried out on the Cu–H_2L system. On the human leukemia cell line MOLT4 (at 10 μM), H_2L is more cytotoxic than Hpt, $Cu_2(HL)^{3+}$ and $Cu(pt)^+$ show equal activity whereas, surprisingly $Cu(HL)^+$ is the most cytotoxic.[14] Here we report the first crystallographic study of H_2L with Cu^{II}, $[\{Cu_2(HL)(H_2PO_4)_2\}_2][NO_3]_2{\cdot}2H_2O$, giving a dimer of dicopper(II) moieties with $H_2PO_4^-$ and weak sulfur bridges. Variable temperature magnetic studies reveal three antiferromagnetic exchange interactions involving superexchange pathways across the planar ligand, a three-atom $H_2PO_4^-$ bridge and direct $Cu^{II}\cdots Cu^{I}$ and/or out-of-plane (*via* S) interactions.



The starting nitrate complex, $[Cu_2L(NO_3)_2]{\cdot}3H_2O$ **1**, used in subsequent metathetical reactions with phosphate was prepared by addition of H_2L (0.616 g, 2.16 mmol) in hot ethanol (150 ml) to $Cu(NO_3)_2{\cdot}3H_2O$ (1.05 g, 4.34 mmol) in the same solvent (10 ml). After stirring for 1 h the product was filtered, washed with ethanol then dried *in vacuo* (913 mg, 72%). $[\{Cu_2(HL)(H_2PO_4)_2\}_2][NO_3]_2{\cdot}2H_2O$ **2** was prepared by dissolving **1** (157 mg, 0.267 mmol) and $NaH_2PO_4{\cdot}H_2O$ (37 mg, 0.268 mmol) in H_3PO_4 (2 ml, 2 M). Dark green crystals suitable for X-ray analysis were collected after 20 days (82 mg, 45%).

X-Ray analysis of **2**† shows the structure (Fig. 1) to be best described as a centrosymmetric dimer of dicopper(II) moieties with dihydrogenphosphato and weak sulfur bridges. Cu(1) has a square-pyramidal geometry with the monoanionic HL bound through pyridyl and imine nitrogens and sulfur. The coordination sphere is completed by phosphato oxygens O(11) and O(21). Cu(2) adopts a tetragonal '4 + 2' geometry with pyridyl, imine and deprotonated amide nitrogens from HL and phosphato oxygen in the plane. Much weaker axial interactions to O(11) and S(1A) 3.24 Å] are from symmetry related molecules. The dimeric $Cu_2(HL)^{3+}$ units are linked *via* three-atom phosphato [Cu(1)–O(21)–P(2)–O(1A)–Cu(2)] and one-atom sulfur bridges with adjacent dimers connected by the weak Cu(2)–O(11) interaction and a hydrogen-bonding network involving phosphato, water and nitrate oxygens and protonated amide [N(3)] nitrogen. Other metric parameters may be considered normal.[7–12] The two phosphate ions adopt different coordination modes, with P(2) chelating and P(1) being monodentate and P(2) binds through the keto oxygen [P(2)–O(1) 1.468(4) Å].

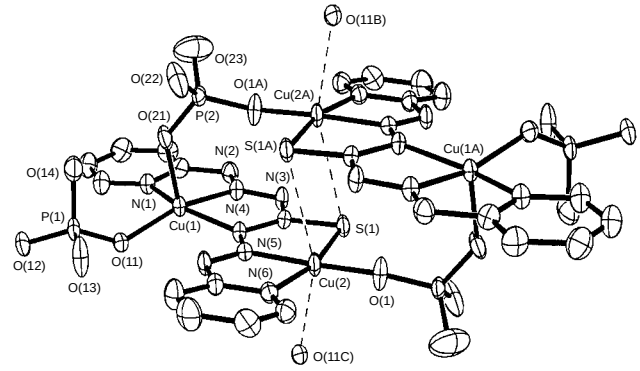


Fig. 1 Molecular structure of the dimeric dicopper(II) ion $[\{Cu_2(HL)(H_2PO_4)_2\}_2]^{2+}$ of **2**. Hydrogen atoms are omitted for clarity. Fig. 2 Temperature dependence of χ_{Cu} and μ_{Cu} *vs.* T for [{Cu_2(HL)(H_2PO_4)$_2$}$_2$](NO_3)$_2$·2H_2O **2**. Solid lines represent the best fit calculated values.

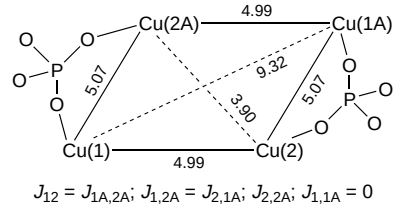
The temperature dependence of magnetic susceptibility and moment, per Cu^{II}, for **2** is shown in Fig. 2. A maximum in χ at *ca*. 180 K is clearly indicative of medium strength antiferromagnetic exchange occurring. The rapid increase in χ at low temperature is due to monomer impurity. Use of a simple dinuclear Bleaney–Bowers model[15] ($-2\,JS_1S_2$ Hamiltonian) did not precisely reproduce the shape of the susceptibility in the region of χ_{max} but did yield an approximate J_{12} value of *ca*. -105 cm^{-1}, albeit with a low g value of 1.98 and a large interdimer θ parameter (in T–θ) of -25 K. Excellent fits could be obtained when the tetranuclear model of Hatfield[16] was employed. The rhomboidal framework of the dimer of dimers is shown in Fig. 3 together with the J labels. The value of the long Cu(1)···Cu(1A) parameter $J_{1,1A}$ was set at zero and the other parameters were varied widely for best-fit. It was found that two parameter sets gave equally excellent fits *i.e.* set A: $g = 2.00 \pm 0.02$, $N_\alpha = (60 \pm 3) \times 10^{-6}$ cm^3 mol^{-1}, $J_{2,2A} = -75.4 \pm 0.2$ cm^{-1}, $J_{1,2} = -116.6 \pm 0.2$ cm^{-1}, $J_{1,2A} = -16.8 \pm 0.2$ cm^{-1}, % monomer 1.7 ± 0.1. This fit is shown in Fig. 2. Set B: $g = 2.00 \pm 0.02$, $J_{2,2A} = -46.0 \pm 0.5$ cm^{-1}, $J_{1,2} = -109.5 \pm 0.2$ cm^{-1}, $J_{1,2A} = -47.9 \pm 0.2$ cm^{-1}, % monomer 1.7 ± 0.1. Thus the dominant coupling, $J_{1,2}$, remains virtually constant in both fits and occurs across the planar thiocarbohydrazonato moiety. It involves superexchange pathways in the *x*–*y* plane such as a two-atom *trans*-Cu–N–N–Cu pathway and three- or four-atom pathways Cu–S–C–N–Cu or Cu–S–C–N–N–Cu. The value of $J_{1,2}$ is similar to that of a structurally related carbohydrazonato dinuclear analogue, reported recently[17] having $J = -106.6$ cm^{-1} (there is a factor of two error in J in ref. 17). The size of the 'edge' and 'short-diagonal' parameters $J_{1,2A}$ and $J_{2,2A}$ could not be identified unambiguously. When using set B, but with $J_{2,2A}$ set at zero or slightly positive, {as anticipated from a previous study[18] on a related S-bridged complex [CuCl(S_2CNEt)]$_4$} much poorer fits were obtained, with the calculated and observed curves crossing each other in the region of χ_{max}. Thus it appears that the Cu(2)S(1)-Cu(2A)S(1A) pathways yield stronger antiferromagnetic coupling (minimum of -46 cm^{-1}) than do related Cu(SR)CuCl or Cu(SR)Cu(SR) pathways[18] in [CuCl(S_2CNEt)]$_4$ and [Cu(S_2CNEt)$_2$]$_2$. The antiferromagnetic coupling across the three-atom $H_2PO_4^-$ bridge, with J of at least -16.8 cm^{-1}, is weak as anticipated and involves axial–equatorial d-orbital overlap, respectively on Cu(1) and Cu(2A). The uncertainties and correlation in the $J_{1,2A}$ parameters may also be influenced by the weak axial interaction Cu(2)–O(11) and Cu(2)–S occurring between teramers, although these are expected to be very weak. In this regard, the visible spectra of solid and H_3PO_4 solutions of **2** are nearly identical.



$J_{12} = J_{1A,2A}$; $J_{1,2A} = J_{2,1A}$; $J_{2,2A}$; $J_{1,1A} = 0$

Fig. 3 Rhomboidal framework for the Cu^{II} centres of **2** showing distances (Å) together with the J labels.

The X-band ESR spectrum of a neat powder of **2** at 298 K shows a broad, symmetrical signal at $g = 2.1$. At 77 K this signal is resolved into a typical axial lineshape ($g_\parallel = 2.19$, $A_\parallel = 184.6$ gauss, $g_\perp = 2.00$) probably due to the monomer impurity (*vide supra*). Triplet state lines due to $Cu^{II}\cdots Cu^{I}$ interactions[19] are evident as weak broad lines at 'half-field' (1500 G) and 3700 G. The same spectrum is observed in frozen 2 M H_3PO_4 solution, with evidence for a weaker monomer lineshape ($g_\parallel = 2.33$, $A_\parallel = 175$ G, $g_\perp = 2.06$) superimposed.

This work was supported by grants from the National University of Singapore (RP 3950651) and the Australian Research Council (Large Grants) and Dr J. J. Vittal's help with the crystallography is acknowledged.

Design, synthesis and metal binding properties of a mixed-donor macrobicycle

Mark Mascal,* Jens Hansen, Alexander J. Blake and Wan-Sheung Li

Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD

A cryptand is resolved into its three independent macrocyclic components leading to novel, dynamic metal ion complexation.

Chelating agents which operate with the benefit of the macrocyclic effect possess an exceptional complexation potential which has facilitated the study of metals in unusual circumstances, *e.g.* uncommon coordination numbers, coordination geometries, donor atoms and/or oxidation states.[1] We describe below a case where, through innovative ligand design, Cu^{I} and Ag^{I} ions are guests in a novel and dynamic environment.

Macrobicycle L^1 was conceptualised as a logical extension of an earlier study on the conformational preferences of [*n.n*]cyclophanes.[2] The molecule lies in a potential energy minimum where the aromatic rings are face to face and the three heteroatoms are in fixed equatorial positions.[3] An important design consideration of this ligand system is that sandwich-type complexation involving η^6-bonding to the benzene rings is disfavoured by the large Ar···Ar separation (*ca.* 5.0 Å), and no assistance from the nitrogens can be expected owing to the distance between these atoms and the centre of the trigonal plane (*ca.* 3.0 Å) which they define. This means that L^1, formally a cryptand, is reduced conceptually to three independent, 16-membered azamacrocycles (Fig. 1) each capable of complexing a metal, especially if some contribution from the aromatic systems was forthcoming. Since only one of these three equivalent 'facets' can be occupied at any one time, it should be possible to promote spontaneous migration of the guest from nitrogen to nitrogen within the perimeter of the benzene rings above a characteristic temperature, effectively constituting 'dynamic' sandwich complexation with the centre of gravity of the metal coinciding with the molecular C_3 axis.

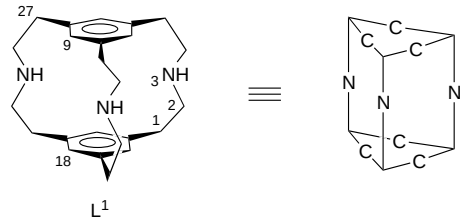

Fig. 1 Structure of L^1 and representation in terms of ligand sets

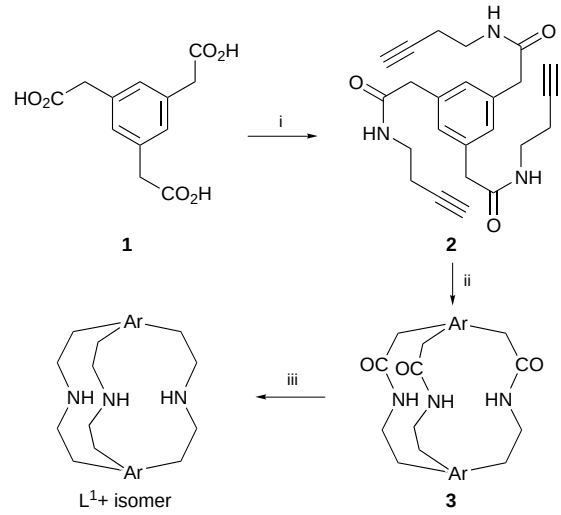
Compound L^1 can be conveniently synthesised by the cyclotrimerisation method shown in Scheme 1.[4] Thus benzene 1,3,5-triacetic acid **1**, available by Willgerodt–Kindler reaction on commercial triacetylbenzene, is condensed with 4-aminobut-1-yne to give triyne **2** in 94% yield. Reaction of **2** with catalytic $[CoCp(CO)_2]$ provides the bicyclic amide **3** as an inseparable mixture of 1,2,4- and 1,3,5-isomers (1.3 : 1, ratio) in 54% overall yield. The mixture is finally reduced with borane, whereupon L^1 can be isolated by column chromatography.

A stable complex is formed between L^1 and Cu^{I} by simply adding a solution of $[Cu(MeCN)_4]BF_4$ in acetonitrile to an equimolar quantity of the macrocycle in dichloromethane at room temp. The ^1H and ^{13}C NMR spectra of this material show a desymmetrisation of the ligand resonances consistent with the expected mode of inclusion. In particular, the aromatic CH



Scheme 1 *Reagents and conditions*: i, carbonyldiimidazole, 4-aminobut-1-yne, THF; ii, $[CoCp(CO)_2]$, *o*-xylene, heat; iii, $BH_3{\cdot}SMe_2$, THF, heat then MeOH, heat

signal associated with the Cu is shifted 0.59 ppm downfield of the other two protons, indicative of electron withdrawal to the metal bond. Mass spectral data are also consistent with the formation of a 1 : 1 complex. Colourless crystals of $[CuL^1]BF_4{\cdot}H_2O$ suitable for X-ray diffraction were obtained from dichloromethane/ether solution, and determination of the structure† (Fig. 2) served to confirm our model. The Cu sits in a general position with Cu–N bond lengths of 2.01 Å. The closing of the N···N distance in L^1 in order to achieve these bond lengths is made possible by a puckering inwards of the chains

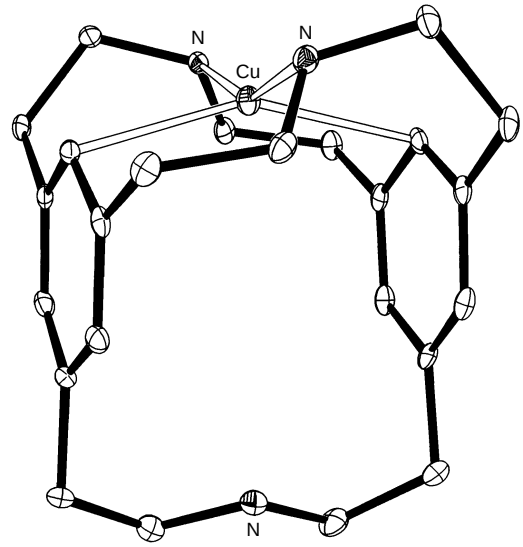


Fig. 2 Crystal structure of $[CuL^1]BF_4{\cdot}H_2O$. Displacement ellipsoids are represented at the 30% probability level. The H-atoms, counter-ion and water of crystallization are omitted for clarity.

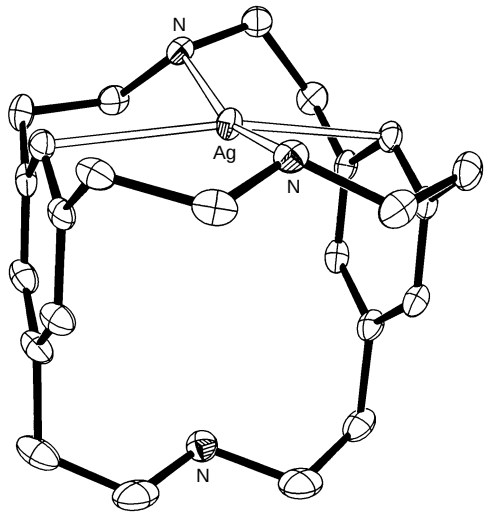

Fig. 3 Crystal structure of [AgL¹]OTf. Displacement ellipsoids are represented at the 20% probability level and the H-atoms and counter-ion are omitted for clarity. Only the major component of disorder affecting the free nitrogen [N3] is shown.

between which the metal is located. An interesting feature of this structure is the relationship of Cu to the benzene rings. This may involve either the metal acting as an electron acceptor in η^1 bonds to C,[5] or three-centre, two-electron σ complexation to the aromatic C–H bonds.[6] The Cu···C distances are 2.38 and 2.40 Å, and the 0.57 Å displacement of the metal away from C(9)–C(18) axis puts the contacts to the midpoint of the C–H bonds at 2.37 and 2.39 Å. The downfield shift in the NMR of the protons involved argues in favour of this type of interaction and against agostic bonding to the H, which would normally result in an upfield shift.[7] It is noted that interactions between copper(I) and aryl rings are somewhat of a novelty in any case, with only five other structurally characterised examples appearing in the literature.[8] All of these show exclusively η interactions to carbon, most with the Cu located over a π bond in an η^2 fashion.[9]

We then examined the dynamics of ligand exchange in [CuL¹]. The ^{1}H NMR spectrum ($CDCl_2CDCl_2$) shows temperature dependent fluxional behaviour, with collapse of the two aromatic signals to a single, broad peak occurring around 95 °C. Migration of the copper nominally involves breaking away from one of the nitrogens and both carbons [or C–H(σ) → Cu bonds] of a C_2N_2 ligand set before regaining the same from another set, although progression from site to site would take place under the continuous influence of the π system.

Reaction of the macrobicycle with AgOTf in THF gave the corresponding complex [AgL¹]OTf. Unlike [CuL¹]BF_4, the proton NMR (CD_2Cl_2) of this material showed a single resonance in the aromatic region at room temperature, and only on cooling below −50 °C did the signal split analogously to the copper(I) system into two sharp peaks (1 : 2), separated in this case by 0.27 ppm. This indicated a much greater degree of mobility for the silver ion than for Cu^I. The X-ray crystal structure of [AgL¹]OTf† (Fig. 3) was comparable to that of [CuL¹]BF_4, the major difference being that only one of the two CCNCC chains needed to distort from the ideal all-*trans* conformation to accommodate the larger silver ion (Ag–N 2.32 Å). The outward displacement of the silver from the C9–C18 axis (0.40 Å) is slightly less than that for copper(I), but the same general NMR and structural arguments apply and either η^1 complexation or two electron donation from the C–H bonds can be invoked. A longer range contact to one of the oxygens of the triflate ion (2.92 Å) is also observed normal to the (approximate) C_2N_2 plane.

Future work in this area will address the behaviour of other metal ions in the presence of L¹, as well as structural modifications to the macrocycle (O, S analogues) which should further expand its scope as a novel ligand.

This research was supported by a grant from the European Commission (to J. H.), and we would like to thank Martin Schröder for helpful discussions.

Photocatalytic decomposition of water into H_2 and O_2 on Cu_2O under visible light irradiation is investigated; the photocatalytic water splitting on Cu_2O powder proceeds without any noticeable decrease in the activity for more than 1900 h.

So far, many photocatalysts have been reported to decompose water into H_2 and O_2 under UV light irradiation.[1–5] From the view point of solar energy conversion, however, a photocatalyst which works under visible light irradiation (>400 nm) is indispensable, but such a photocatalyst has not yet been found. In this report, we introduce Cu_2O, a well-known p-type semiconductor, which acts as a photocatalyst for overall water splitting under visible light irradiation ($\leqslant$600 nm).

The solid state physics of Cu_2O, which abundantly exists as cuprite in nature, has been extensively investigated for a long time since Cu_2O is a simple metal oxide semiconductor with a small band gap energy. As shown in an energy correlation between the band gap model of Cu_2O and the redox potentials of relevant electrode reactions in an aqueous solution at pH 7,[6] the conduction and valence band edges of Cu_2O, which are separated by a band gap energy of 2.0–2.2 eV,[7,8,9] seem to be available for reduction and oxidation of water, respectively. Therefore, Cu_2O is, in principle, capable of decomposing water into H_2 and O_2 under visible light excitation. However, as yet, such a photochemical reaction has not been accomplished on any Cu_2O electrode since they undergo photodegradation in aqueous solution.[9] In fact, visible light irradiation (470 nm) of a cathode-polarized Cu_2O single crystal electrode in aqueous solution resulted in reduction of Cu_2O to metallic Cu.[10] For this reason, overall water splitting on Cu_2O photocatalysts has not been investigated despite the band structure available for the reaction. In this study, we confirmed the photocatalytic overall water splitting on Cu_2O powder under visible light irradiation.

Cu_2O powder prepared by the hydrolysis of CuCl was used in this study. CuCl was hydrolyzed by adding 1 M aqueous Na_3PO_4 (40 cm^3) to a 5 M aqueous NaCl solution containing 0.04 mol of CuCl (400 cm^3) with vigorous stirring under an Ar flow. A yellow precipitate was produced by the hydrolysis which was washed with distilled water (200 cm^3) 5–7 times followed by decantation under vacuum and drying *in vacuo*. Cu_2O powder was obtained by heating the yellow precipitate at 673 K for 24 h *in vacuo*, followed by boiling in water under an Ar atmosphere to remove unreacted CuCl from Cu_2O. The particle size and surface area of Cu_2O were estimated to be 0.3–0.5 μm and 6 $m^2\ g^{-1}$, respectively. Only the XRD pattern due to Cu_2O was seen with no evidence for other diffraction patterns such as for CuO, metallic Cu or other impurities. The XP spectra of Cu 2p and the Cu LMM Auger spectra indicated that the surface of Cu_2O was composed of Cu^{I}.[11,12] The band gap energy of Cu_2O was estimated at *ca.* 2.0 eV (λ *ca.* 620 nm) by UV–VIS spectroscopy.

The photodecomposition of water was carried out in a Pyrex cell with 0.5 g of Cu_2O and 200 cm^3 of distilled water, which was vigorously magnetically stirred. The cell was irradiated at room temperature from one side with visible light ($\lambda > 460$ nm) from a 300 W Xe lamp with a cut-off filter. A closed gas circulation and evacuation system (300 cm^3) made of Pyrex glass was connected to the reaction cell, and evolved gases were directly transferred to a gas chromatograph to avoid any contamination from air.

Fig. 1 shows several typical time courses of H_2 and O_2 evolution from Cu_2O under visible light irradiation (>460 nm). The reaction system was evacuated after each run. As shown in run 1, only O_2 evolved for 10 h after the beginning of the reaction, and then the evolution of H_2 was observed as the reaction proceeded. The rate of H_2 evolution increased gradually in the subsequent runs. The ratio of the amount of evolved H_2 to O_2 (H_2/O_2) was 0.8 in run 1 and increased to 1.8 in run 4. After run 4, the ratio was between 2.0 and 2.5. The reaction proceeds without any noticeable decrease in the activity for more than 30 runs as shown in Fig. 1. The total amounts of evolved H_2 and O_2 for 1900 h reached 3.8 and 1.9 mmol, respectively, and are comparable to the amount of Cu_2O used (0.5 g, 3.5 mmol). Furthermore, there was no noticeable difference in pH of the suspension before reaction (pH 7.3) and after run 31 (pH 7.1). In order to elucidate the origin of the evolved O_2, an experiment using $H_2{}^{18}O$ was carried out. In another small Pyrex cell (50 cm^3), 0.1 g of Cu_2O (after reaction for 400 h) suspended in a mixture of $H_2{}^{16}O$ (5 cm^3) and $H_2{}^{18}O$ (1 cm^3) was irradiated with visible light (>460 nm). H_2 and O_2 were stoichiometrically evolved after light irradiation and it was confirmed by mass spectral analysis that the ratio, $^{16}O_2 : {}^{16}O{}^{18}O : {}^{18}O_2$, in the evolved O_2 species for 24 h was 254 : 94 : 13. The result indicates that the atomic ratio, $^{16}O : {}^{18}O$, in the total amount of evolved O_2 is 5.0 corresponding to that in the mixed water. As a result, the evolved O_2 is attributed to the water cleavage on Cu_2O. The photoresponse on Cu_2O was observed for visible light through a cut-off filter of 600 nm, while there was no photoresponse at $\lambda > 650$ nm.

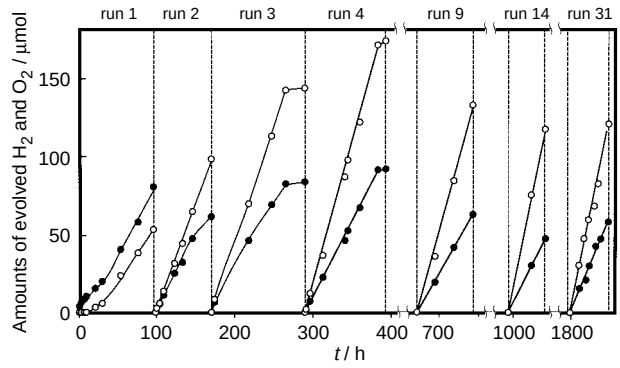

Fig. 1 Time courses of H_2 (open circles) and O_2 (filled circles) evolution in Cu_2O under visible light ($\lambda \geqslant 460$ nm) irradiation. Catalyst: 0.5 g, H_2O: 200 cm^3. The reaction system was evacuated with light irradiation after each run. Time courses in runs 5–8, 10–13 and 15–30 are omitted.

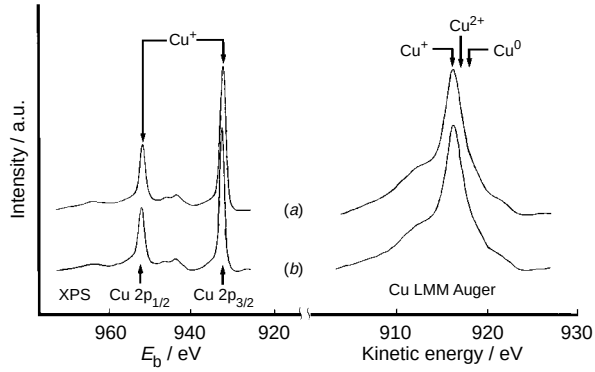

Fig. 2 X-Ray photoelectron spectra of Cu 2p and Cu LMM Auger spectra of Cu_2O before (*a*) and after (*b*) reaction for 400 h. The binding and kinetic energies were referenced to the Au $4f_{7/2}$ level at 83.8 eV.

Fig. 2 shows the XP spectra of Cu 2p and Cu LMM Auger peaks of Cu_2O before and after reaction for 400 h. There was no noticeable difference in the XP spectra of Cu_2O, indicating that Cu_2O powder was neither reduced nor oxidized after photocatalytic reaction. These results are in total contrast to the observation on Cu_2O electrodes and strongly suggest that Cu_2O powder catalytically decomposes water into H_2 and O_2 under visible light irradiation. To the best of our knowledge, such a reaction on Cu_2O photocatalysts has not yet been reported. The reaction mechanism as well as the reason for the difference between the electrode and the powder systems are still not clear. Nevertheless it is inferred that the photocatalytic reaction on a Cu_2O particle in distilled water is clearly different from the photoelectrochemical reaction on polarized Cu_2O electrodes in an aqueous electrolyte. The quantum efficiency of the photocatalytic reaction was estimated at *ca*. 0.3% between 550 and 600 nm.

One of the characteristic features of the Cu_2O photocatalyst is the excess evolution of O_2 above the stoichiometry at the early stage of the reaction (runs 1 and 2). Cu_2O is known to absorb a relatively large amount of oxygen in bulk as well as adsorbing oxygen as O^- or O_2^- on the surface.[13,14] The excess oxygen on the surface or in the bulk leads to p-type semiconducting behaviour and unique oxidation catalysis of Cu_2O. The release of these excess oxygen species from Cu_2O by visible light irradiation may cause the excess evolution of O_2 above the stoichiometry at the early stage of the reaction. Another feature to be noted is the O_2 pressure dependence of the reaction.

As shown in runs 3 and 4 of Fig. 1, the evolution rates of H_2 and O_2 became slow or stopped when the amount of evolved O_2 exceeded *ca.* 80 μmol which corresponded to 500 Pa of O_2 in our system. In all runs after run 5, H_2 and O_2 evolved without any significant decrease in the activity so long as the evolved gas was evacuated before the pressure of O_2 reached 500 Pa. These results suggest that O_2 at more than a certain pressure (500 Pa) in the reaction system inhibits the overall water splitting on Cu_2O. Such an inhibition might be attributed to the photoadsorption of oxygen on the Cu_2O surface. p-Type semiconductors are known to photoadsorb O_2 under light irradiation when O_2 in gas phase exceeds a certain pressure.[15] The photoadsorption largely depends on the O_2 pressure as well as on the wavelength and intensity of incident light, temperature, *etc.* Although the dependence of photoadsorption on O_2 pressure in a Cu_2O–H_2O–O_2/H_2 system as in the present case has not yet been investigated, it is probable that preferential O_2 photoadsorption inhibits the overall water splitting on the Cu_2O surface.

Although Cu_2O has been regarded as an unstable material for water decomposition under light irradiation from the results of photoelectrochemistry, the present study has revealed Cu_2O to be a photocatalyst able to decompose water into H_2 and O_2 under visible light irradiation. The reaction mechanism on Cu_2O is under investigation.

Recently, we have also found that $CuFeO_2$ evolves H_2 and O_2 under visible light irradiation, and detailed results will be reported soon. $CuFeO_2$ has a delafossite type layered structure where the iron oxide layers are connected to each other through linear –O–Cu^I–O– bonds.[16–18] The Cu_2O lattice consists of chains of linear bonds. This suggests that Cu^I containing materials with linear –O–Cu^I–O– bonds are available for the overall water splitting under visible light irradiation. Such Cu^I containing materials may become potential candidates for converting solar energy into H_2 energy.

Friedel–Crafts alkylation in supercritical fluids: continuous, selective and clean

Martin G. Hitzler,[a] Fiona R. Smail,[a] Stephen K. Ross[b] and Martyn Poliakoff[a]*†

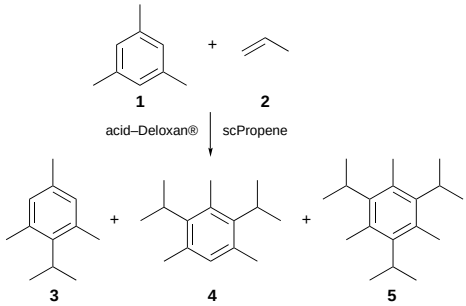
[a] *Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD*
[b] *Thomas Swan & Co. Ltd, Crookhall, Consett, Co. Durham, UK DH8 7ND*

Continuous Friedel–Crafts alkylation of mesitylene, $C_6H_3Me_3$, and anisole, C_6H_5OMe, with propene or propan-2-ol has been carried out in supercritical propene or CO_2 using a heterogeneous polysiloxane-supported solid acid Deloxan® catalyst in a small fixed bed reactor (10 ml volume); 100% selectivity for mono-alkylated products with 50% conversion could be obtained by adjusting the reaction parameters, *e.g.* temperature, pressure, flow rates, *etc.*

Numerous chemical syntheses involve Friedel–Crafts or Friedel–Crafts-type alkylation reactions, both on laboratory and industrial scales. Friedel–Crafts chemistry is therefore of major importance and research in this field is of continuing chemical interest.[1–5] Frequently, the reaction is used to add only a *single* alkyl group to the substrate, but addition of the first alkyl group activates the substrate so that subsequent alkylation is made easier. Thus, conditions have to be controlled precisely, often with long reaction times and low temperatures, to minimise the formation of poly-alkylated by-products.

Friedel–Crafts reactions are usually carried out batch-wise in a large excess of the substrate or in an organic solvent. Generally, the reaction is carried out in the presence of Lewis acid catalysts (*e.g.* $AlCl_3$, BF_3, $TiCl_4$) or strong protic acids (*e.g.* HF, H_2SO_4). Relatively high concentrations of catalyst are needed; often the amounts are near stoichiometric, especially when H_2O is generated. These problems make most Friedel–Crafts processes inherently dirty. Therefore, the development of environmetally more benign Friedel–Crafts processes is a high priority. Solid acid catalysts based on clays, zeolites or even graphite[6] could be the answer to *cleaner* Friedel–Crafts chemistry, but until recently rapid catalyst deactivation has prevented the development of a commercial process.[7] Not only can solid catalysts be easily separated from liquid products, they also offer the possibility of carrying out Friedel–Crafts reactions in continuous rather than batch reactors.[8] Continuous flow reactors can be smaller than the batch reactors needed to generate comparable amounts of product.[9] A reactor of smaller size usually increases safety and reduces capital cost.

Very recently, we described[10] how the supercritical hydrogenation of a wide a range of organic compounds can be carried out extremely efficiently in small-scale *continuous* flow reactors (5 or 10 ml) using Pd and Pt heterogeneous catalysts supported on polysiloxane (Deloxan®, Degussa AG). Here we show how the *same* reactor can be used to carry out continuous Friedel–Crafts alkylation using a commercially available solid acid catalyst based on the *same* Deloxan® support.‡ In our process,§ the organic solvent is replaced by a supercritical fluid, *e.g.* $scCO_2$. The separation of the product occurs simply by expanding the fluid to atmospheric pressure, so the crude product can be analysed without further work-up. Although reaction temperatures are high, because of short residence times, our process maintains high product selectivity.



Scheme 1

Our initial reactions involved mesitylene **1** ($C_6H_3Me_3$) with propene **2**, which acts both as alkylating agent and as supercritical solvent [scPropene, T_c = 91.9 °C, p_c = 46.0 bar (10 bar = 1 MPa)]. This reaction was chosen because the mono- **3**, di- **4** and tri-alkylated product **5** each have only *one* possible isomer (Scheme 1), which simplifies product analysis.¶

Table 1 shows that Friedel–Crafts chemistry can indeed be carried out *continuously* under these conditions. The selectivity is reasonable for 1-isopropyl-2,4,6-trimethylbenzene **3** but significant amounts of **4** and dimers of propene **2** are formed. Table 1 also shows that the yield of **3** cannot easily be improved by varying the reaction conditions.

By contrast, selectivity for the formation of **3** is much higher in the alkylation of **1** with propan-2-ol, **6**, in supercritical CO_2 ($scCO_2$, T_c = 31.1 °C, p_c = 73.8 bar) using the same solid acid Deloxan® catalyst. The reaction forms water but this is not a serious problem; the organic and water layers are easily separated after the $scCO_2$ has been vented. Initially, the reaction was carried out with a three-fold excess of **6** over **1** (total flow rate of **1** + **6**: 0.50 ml min^{-1}) at 220 bar and T_{cat} = 200 °C with a gaseous CO_2 flow rate of 0.43 l min^{-1}. Analysis of the organic layer showed that the conversion of **1** was 46% with **3** as the major product (40% yield). As side-products, **4** was found in 5% yield along with traces of diisopropyl ether (1%). Table 2 summarises the results obtained by varying the reaction conditions. The yield of **3** can be improved by optimising the temperature and raising the pressure. When **1** is in excess, **3** *is the only detectable organic product.*

Previous attempts to run *continuous* Friedel–Crafts alkylation have frequently been thwarted by poor catalyst lifetimes but the lifetime of the Deloxan® catalyst is relatively long. In fact, when the reaction was started using a *fresh* sample of ASP I/7 acid Deloxan® catalyst, the activity actually increased after an induction period of *ca.* 100 min and was maintained for at least a further 15 h operation. We initially attributed this induction to some activating effect of the H_2O formed in the reaction. However, the yields of **3** were dramatically lower

Table 1 Alkylation of mesitylene **1** with propene **2** at 200 bar pressure[a]

			Yield (%)

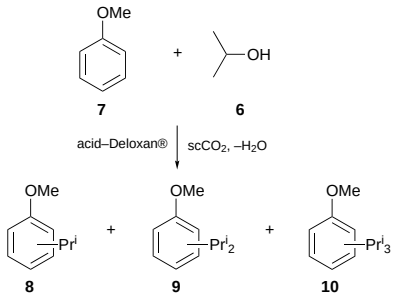
[a] All reactions carried out in $scCO_2$ (0.65 l min^{-1}) with **3** as the only detectable product. [b] Product analysis was by ^{1}H NMR spectroscopy ($CDCl_3$). [c] Based on the amount of **6** in the initial reaction mixture. [d] Yield based on **1**. In addition, 3% of **4** and traces of side-products were found.



Scheme 2

when the catalyst was conditioned with water for 30 min prior to use. When operated for maximum flow of **3** (see Table 2) the catalyst can produce twice its volume of **3** per hour.

The supercritical reactor can also be applied sucessfully to the continous alkylation of anisole **7** by scPropene **2** or by propan-2-ol **6** in $scCO_2$ (Scheme 2). As with the alkylation of **1**, there is significant selectivity in favour of the mono-alkylated product. Thus, **6** reacted with **7** at a molar ratio of 1.0 : 3.0 to form isomers of **8** (30% yield) and **9** (*only* 6% yield).‖ No further products could be detected by GC–MS. When **7** was alkylated at a flow rate of 0.2 ml min^{-1} with scPropene (flow rate of gaseous propene: 0.43 l min^{-1}) under the same conditions, the yield of **8** was 38% with the same isomer ratio as was found with propan-2-ol.‖ However, the yield of **9** increased to 18% (three isomers at a ratio of 5 : 2 : 1). In addition, **10** was found in 5% yield (peak ratio 5 : 2 at a mass of 234) as well as trace amounts (3%) of propene di- and tri-mers.

The supercritical fluid probably plays several roles in these reactions. Compared to liquid phase reactions, the fluid reduces mass transport restrictions at the surface of the catalyst. Compared to a gas phase reaction, it increases the density of the reaction medium and hence increases the residence time of the substrate in a given size of reactor. This allows continuous alkylation to be caried out on a reasonable scale in a small reactor. Finally, it may reduce coking of the catalyst preventing premature deactivation of the catalytic sites.

This investigation has shown that aromatic substrates can undergo *continuous and sustainable* Friedel–Crafts alkylation in supercritical fluid solution over solid acid heterogeneous catalysts. The reactions can be carried out in a flow reactor, which differs only in the peripheral pipework from that used for the supercritical hydrogenation of organic compounds.[10] The method of alkylation has features of potential importance for the manufacture of fine chemicals. It is selective, organic solvents are eliminated and a *clean* heterogeneous catalyst replaces a liquid–based system. Thus, supercritical alkylation is a step closer to ennvironmentally acceptable Friedel–Crafts chemistry.

We thank Thomas Swan & Co Ltd for fully funding this work and D. Campbell, S. K. Ross and J. C. Toler for their assistance. We are grateful to Degussa AG for donating the catalysts. We thank M. W. George, M. Guyler, S. M. Howdle, K.-H. Pickel, K. Stanley, T. Tacke and S. Wieland for their help. M. P. thanks the EPSRC/Royal Academy of Engineering for a Fellowship.

‡ Deloxan® ASP catalysts (ref. 11) are specially designed polysiloxane based solid acids, formed by sol-gel condensation of alkyl sulfonic acid functionalized organosilane monomers, *e.g.* $HO_3SCH_2CH_2CH_2Si(OH)_3$, which overcome the drawbacks of organic polymers by virtue of their inert matrix material and excellent compatability with almost all organic solvents. The sol-gel process yields products with a relatively narrow particle size distribution, high porosity, large pore diameters (> 20 nm) and high BET surface areas (300–600 m^2 g^{-1}).

§ The substrate, reactant and supercritical fluid are brought together in a heated mixer, passed through the hot reactor (10 ml volume; 9 mm i.d., length 152 mm) containing the catalyst, and then expanded to separate the product from the fluid. The reactor is assembled from commercially available units: $scCO_2$ and scPropene pump PM 101 and Expansion Module PE 103 (all from NWA GmbH, Lörrach, Germany), a high pressure mixer (Medimix) and Gilson pumps 303, 305 (for substrate and reactant). ***SAFETY NOTE:*** *Reactions in supercritical fluids involve high pressures and should only be carried out with appropriate equipment.*

¶ Product analysis by GC–MS or ^{1}H NMR spectroscopy.

‖ Pressure, 220 bar; catalyst temperature, 200 °C, flow rate of gaseous CO_2 of 0.2 l min^{-1}; total flow rate of **6** + **7**, 1.0 ml min^{-1}. The product analysis is more complicated for the reactions of **7** than for those of **1** becasue the products (**8**, **9** and **10**) all have more than one possible isomer. Thus, GC–MS gave *three* peaks for **8** (*m*/*z* 150) in the ratio of 13 : 12 : 1, corresponding to the *ortho*, *para* and *meta* isomers. Similarly, *two* peaks (*m*/*z* 192) were found in the ratio 4 : 1 for the isomers of **9**.

A new promising π-donor of the tetrathiafulvalene series: bis(2,3-dithiabutane-1,4-diyl)tetrathiafulvalene, the symmetrical outer S-position isomer of BEDT-TTF

C. Durand,[a,b] P. Hudhomme,*[a]† G. Duguay,[a] M. Jubault[b] and A. Gorgues*[b]‡

[a] *Laboratoire de Synthèse Organique, Université de Nantes, UMR-CNRS 6513, 2 rue de la Houssinière, F-44322 Nantes Cedex 3, France*

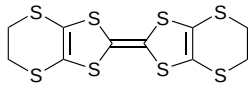
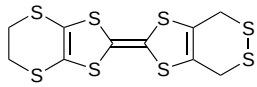
New functionalities are introduced into the 2-(thi)oxo-1,3-dithiole system and applied to the synthesis of the title compound.

Among the organic donors of the tetrathiafulvalene (TTF) family,[1] bis(ethylenedithio)tetrathiafulvalene **1** (BEDT-TTF or ET) is still regarded as the best precursor for superconducting organic metals[2] endowed with the highest T_c in that series.[3] In their solid state structure, the related radical cation salts exhibit bidimensional character mainly originating from strong peripheral S···S intermolecular interactions. Therefore, modifications of ET are of interest to establish relationships between the solid state structure and the transport properties of the corresponding salts, particularly by varying the position and the nature (S, Se, Te) of the chalcogen.[2b,4]

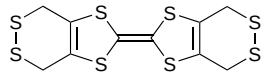
In this context, we have become interested in the unsymmetrical and symmetrical S-position isomers of ET, **2** and **3** respectively, with the aim of understanding the possible role of the position of the peripheral sulfur atoms on the dimensionality of the related materials.[5] After our previous study devoted to the unsymmetrical ET isomer **2** and some of its charge transfer salts,[6] we have extended this work to the symmetrical ET isomer **3**. We report here on the synthesis of the latter, based on the introduction of new functionalities on the 2-(thi)oxo-1,3-dithiolic precursors,[7] and also describe some preliminary electrochemical results emphasizing its promising π-donor ability for molecular conductors.



1 (BEDT-TTF or ET)



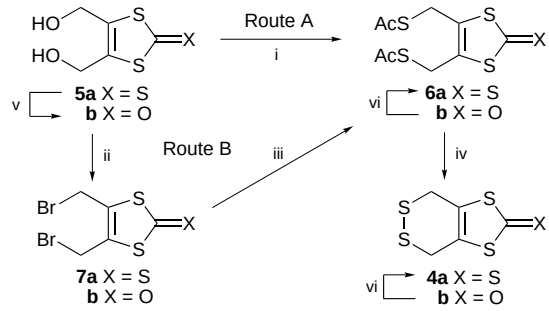
2



3

In our synthetic approach, we first studied a pathway involving the standard symmetrical or cross-coupling of the corresponding 2-(thi)oxo-1,3-dithioles **4a** and **4b**. These were synthesized according to Scheme 1 *via* two possible routes, A and B.

In route A, we used our standard procedure[6] allowing the conversion of the 4,5-bis(hydroxymethyl)-2-(thi)oxo-1,3-dithiole **5a**[8] or **5b** to **6a** or **6b** with thioacetic acid, either *via* the Mitsunobu reaction[9] (32% yield for **6a**) or after activation of the alcoholic groups with *N*,*N*-dimethylformamide diethyl acetal[10] (52% yield for **6b**). In route B, diol **5a** was easily dibrominated with PBr_3 in 94% yield,[11] similar results being also obtained for **5b**. Upon treatment of **7a** and **7b**[12] with thioacetic acid and pyridine or its potassium salt, the corresponding thioesters were formed in good yield (*ca*. 90%), even on a large scale. To achieve the S–S intramolecular closure, best results were

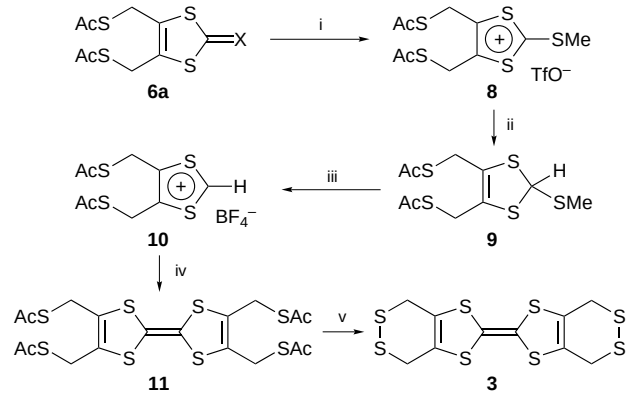


Scheme 1 *Reagents and conditions*: i, (for **6a**) DEAD, PPh_3, AcSH, THF (32%); (for **6b**) $Me_2NCH(OEt)_2$, CH_2Cl_2, 40 °C (52%); ii, PBr_3, THF–CCl_4 (1 : 2, v/v) (**7a** = 94%, **7b** = 62%); iii, AcSH, THF, Py or ACS^-K^+, THF (**6a** = 94%, **6b** = 89%); iv, CsOH, MeOH, then I_2, Et_2O (**4a** = 85%, **4b** = 46%); v, $Hg(OAc)_2$, AcOH–$CHCl_3$ (44%); vi, P_4S_{10}, toluene, 100 °C (**6a** = 28%, **4a** = 37%)

obtained by cleaving[13] the thioester groups with CsOH in MeOH and by oxidizing the corresponding generated dithiolate with iodine in Et_2O. Note that the $NaBH_4$–LiCl mediated cleavage successfully used in the corresponding TTF series[6] affords **4a** or **4b** in poorer yields.§

Whereas the trialkyl phosphite induced self- or cross-coupling reaction of 2-(thi)oxo-1,3-dithioles is a classical method for TTF core building,[14] all attempts from **4a** and **4b** were inefficient, as they were when using octacarbonyl dicobalt.[15] A similar failure was observed of **6a** and $P(OMe)_3$, the expected derivative **11** being formed only as a side product (5% yield), besides the main product, the oxo derivative **6b** (70% yield).[16]

Given these results, we investigated the other pathway depicted in Scheme 2. Methylation of **6a** with MeOTf in dry



Scheme 2 *Reagents and conditions*: i, MeOTf, CH_2Cl_2 (98%); ii, $NaBH_4$, Pr^iOH–MeCN (1 : 8, v/v) (82%); iii, HBF_4, Ac_2O (83%); iv, Et_3N, MeCN (61%); v, MeO^-Na^+, MeOH–DMF (10 : 1, v/v) (63%)

Table 1 Oxidation peak potentials[a] $E\text{pa}_1$ and $E\text{pa}_2$

Compound	E/V *vs.* SCE[b]		
	$E\text{pa}_1$	$E\text{pa}_2$	$\Delta E\text{p}$
BEDT-TTF **1**	0.51	0.92	0.41
2	0.49	0.93	0.44
3	0.54	0.99	0.45

[a] Pt electrode, 20 °C, under nitrogen atmosphere, $Bu_4N^+PF_6^-$ 0.1 M in CH_2Cl_2, scan rate 0.1 V s^{-1}, [compound] ≈ 10^{-3} M. [b] Saturated calomel electrode.

CH_2Cl_2 afforded the corresponding salt **8** quantitatively. Reduction of the latter with $NaBH_4$ in Pr^iOH–MeCN at 0 °C produced **9** in 82% yield. Subsequent conversion to the 1,3-dithiolium tetrafluoroborate **10** was performed under classical conditions (HBF_4–Ac_2O) (83% yield).[17] Upon immediate treatment of **10** with an excess of Et_3N in MeCN, the TTF derivative **11** was obtained in fairly good yield (61%). Finally, transformation of **11** to the required target compound **3** could also be carried out as indicated above for the analogous conversion of **6** to **4**, but the yields were improved (63%) by treatment of **11** with MeO^- in MeOH–DMF, without isolation of the dithiolate intermediate.¶

The cyclovoltammogram of **3** resembles that of TTF derivatives, with two reversible oxidation peaks indicative of the successive generation of stable radical cation $\mathbf{3}^{\bullet+}$ and dication $\mathbf{3}^{2+}$, at potential values ($E\text{pa}_1$ and $E\text{pa}_2$) close to those of their isomeric counterparts **1** (ET) and **2** (Table 1). This π-donor behaviour is also confirmed by the ready formation of black charge transfer salts upon oxidation with Br_2, I_2 and TCNQ, and also upon electrooxidations in the presence of various anions, structural studies of the resulting materials being currently underway.

Incorporation of hydrophobic helix-bundle peptides into lipid bilayer membranes facilitated by a peptide-umbrella structure

Hiroki Ueda,[a] Shunsaku Kimura*[a] and Yukio Imanishi[b]

[a] *Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto, Japan 606-01*

[b] *Graduate School of Material Science, Nara Institute of Science and Technology, 8916-5 Takayama-cho, Ikoma, Nara, Japan 630-01*

Hydrophobic helical peptides, which are covered by hydrophilic peptides, are transferred into a phospholipid bilayer to form helix-bundle structures as a consequence of their peptide-umbrella structure.

The hydrophobic helix-bundle structure is one of the common structures for membrane proteins found in nature, for example, in receptors of peptide hormones[1] and ion channels.[2] Therefore, phospholipid bilayer membranes embedded with helix-bundle peptides are of research interest for developing information-processing systems. However, a difficulty in the preparation of the molecular system exists in the insolubility of hydrophobic peptides in water, which restricts distribution of peptides in water to a phospholipid bilayer membrane. For this reason, water-soluble amphiphilic helical peptides have been synthesized[3] which form helix-bundle structures by association in water, and which have their hydrophilic surface facing outward and the hydrophobic surface facing inward. Generally, however, transfer of charged amino acid residues from the aqueous phase to the hydrophobic core region of the membrane is energetically unfavourable,[4] and most of amphiphilic peptides tend to stay at the membrane surface.[5] To realize a transmembrane helix-bundle in high yield, hydrophobic helices may be more favourable than amphiphilic helices,[6] and thus the design of hydrophobic helices able to be solubilized in water is presented here.

We have conceived a novel class of peptide molecules that mimic the structure of umbrellas, *i.e.* peptide molecules that are composed of hydrophobic helices in a 'handle' structure with hydrophilic segments shielding the helices. Upon binding to phospholipid bilayer membranes, the hydrophobic helices are inserted into the membrane vertically, with the hydrophilic segments staying at the membrane surface or in the aqueous phase just like an open umbrella. Regen[7] also presented a 'molecular umbrella' concept, but their molecules are designed for drug delivery and not for a functional membrane peptide.

In the present study, hydrophobic helix-bundle peptides were designed and synthesized with an umbrella structure, and their interaction with a phospholipid bilayer membrane was investigated. The molecular structures of the peptides are shown in Fig. 1. Two or three hydrophobic helices were connected together through pentaoxyethylenebis(amine) or tris(3-aminopropyl)amine in a parallel arrangement of helices. The hexadecapeptide –(Ala-Aib)$_8$– was chosen as the hydrophobic helix peptide because Boc–(Ala-Aib)$_8$–OMe has been found to have an α-helix conformation by X-ray diffraction[8] and to form a bundle structure for a voltage-dependent ion channel in a lipid membrane.[9] A naphthyl group was connected as a fluorescent probe. Oligosarcosine chains were connected to the hydrophobic peptides (**2αZ** and **3αZ**) to make them soluble in water (**2αS** and **3αS**). Nap–(Ala-Aib)$_8$–OBz **1α** (Nap represents a β-naphthaleneacetic group) was used as a reference hydrophobic helix peptide. The peptides were synthesized *via* conventional liquid phase methods.

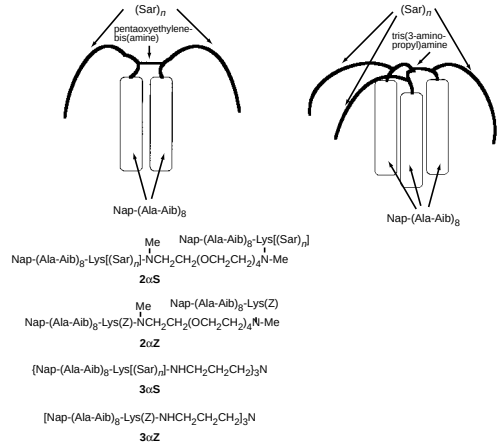

Fig. 1 Molecular structures of the hydrophobic helical peptides and peptide umbrellas. The average degree of polymerization of Sar is 11 for **2αS** and 9 for **3αS**.

The conformations of the peptides were investigated by circular dichroism (CD) spectroscopy. The CD spectra of the peptides showed a double-minimum pattern, indicating formation of an α-helical conformation in MeOH solution (Fig. 2). The helix content increases in the order **1α** < **2αZ** ≈ **2αS** < **3αZ** ≈ **3αS**. It is considered that the presence of helix chains in close proximity favours the formation of a helical conformation due to Van der Waals interactions. On the other hand, the introduction of oligosarcosine chains does not influence the conformation of the peptides in MeOH (**2αZ** ≈ **2αS** and **3αZ** ≈ **3αS**), suggesting the absence of any interactions between the oligosarcosine chains and the helix chains. However, in water

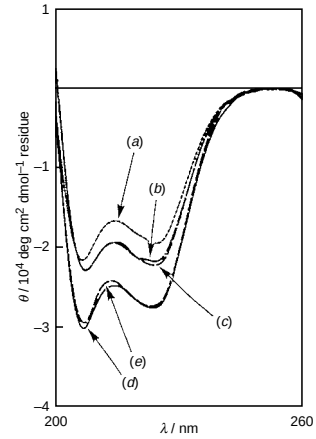

Fig. 2 CD spectra of the peptides in MeOH (**3αZ** and **3αS**) or MeOH–EtOH [2 : 1 (v/v), **1α**, **2αZ** and **2αS**]: (*a*) **1α**, (*b*) **2αS**, (*c*) **2αZ**, (*d*) **3αS** and (*e*) **3αZ**. Total concentration of Ala and Aib residues = 0.5 mM. The molar ellipticity stems from the amino acid residues of the helix segments.

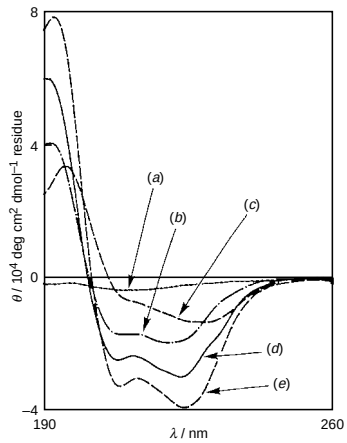

Fig. 3 CD spectra of the peptides in water: (*a*) **1α**, (*b*) **2αS**, (*c*) **2αZ**, (*d*) **3αS** and (*e*) **3αZ**. Total concentration of Ala and Aib residues = 0.5 mM.

the peptides show different CD spectra (Fig. 3). Compound **1α** showed very weak ellipticity due to low solubility in water. Compound **2αZ** showed a shoulder at 208 nm and a broad peak centred at 228 nm, suggesting the occurrence of severely distorted helices by strong aggregation in water. On the other hand, **2αS** shows the double-minimum pattern with increasing negative intensity at 222 nm, suggesting a weak association of helix chains in water.[10] It is evident in these CD patterns that the oligosarcosine chains of **2αS** suppresses the strong aggregation seen for **2αZ** by increasing water solubility. Compounds **3αZ** and **3αS** showed increasing negative intensity at 224 nm and their CD patterns are similar to those of **2αS** and **2αZ**. The oligosarcosine chains of **3αS** should stabilize the helical conformation of the peptide in water by avoiding strong aggregation. Unexpectedly, **3αZ** showed evidence of stable helix-bundle structures in water. It is considered that the tertiary amino group of the peptide increases the hydrophilicity of the molecule to form a micelle structure *via* self-assembly, which remains to be investigated.

The interactions of the peptides with DMPC liposomes was investigated by CD spectroscopy (Fig. 4). Compound **1α** showed a double-minimum-type CD spectrum with increasing negative intensity at 225 nm, indicating spontaneous distribution of the peptides to the membrane and formation of a helix-bundle structure. On the other hand, CD spectra of **2αZ** and **3αZ** showed a weak Cotton effect in the presence of DMPC liposomes. The liposome suspension became turbid upon addition of the peptides, indicating aggregation of liposomes triggered by enhanced hydrophobic contact of liposomes and/or

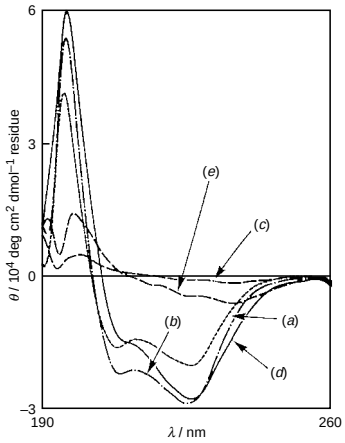

Fig. 4 CD spectra of the peptides in the presence of DMPC liposomes: (*a*) **1α**, (*b*) **2αS**, (*c*) **2αZ**, (*d*) **3αS** and (*e*) **3αZ**. [DMPC] = 1.0 mM. DMPC liposomes were prepared by the sonication method using Tris buffer (0.01 M, pH 7.4) containing NaCl (0.1 M) and EDTA (0.1 mM). Total concentration of Ala and Aib residues = 0.5 mM.

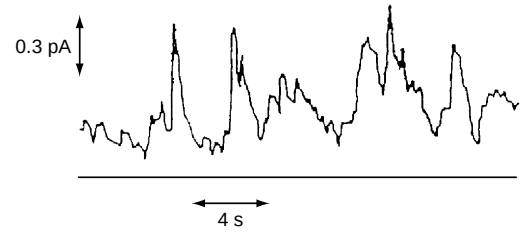

Fig. 5 Current fluctuation of the bilayer lipid membrane (BLM) in the presence of **3αS**. The membrane is made of soybean lectin and formed on an aperture of 0.2 mm diameter. Aqueous solution contains 1 M KCl. A membrane potential of 190 mV was applied using a salt bridge. [**3αS**] = 0.026 μM.

membrane disorder caused by the hydrophobic peptides. Notably, aggregation of liposomes was not induced by the addition of **2αS** or **3αS**, and the peptides were taken in spontaneously by the phospholipid membrane. Oligosarcosine chains should suppress liposomal aggregation by making the liposome surface hydrophilic. With **2αS** and **3αS**, the relative molar ellipticity at 208 nm to that at 225 nm was smaller in the presence of DMPC liposomes than in pure water, suggesting a stronger aggregation of the helix chains in the lipid membrane than in water.[10]

Distribution of the peptides into the phospholipid membrane was also investigated by fluorescence quenching of the naphthyl group with acrylmaide, which is a water-soluble quencher. The Stern–Volmer constants[11] for the collisional quenching process K_{SV} (mM^{-1}) were 8.3 for **2αS** in buffer, 1.8 for **2αS** with liposome, 6.5 for **3αS** in buffer and 2.1 for **3**α**S** with liposome. The lower K_{SV} values in the presence of liposomes indicate that the naphthyl groups are buried in the hydrophobic core region of the membrane due to vertical insertion of the helices.

It is considered that the helix-bundle structure, in which the peptide chains take a parallel arrangement, should function as ion channels in the lipid membrane. Compound **3αS** (0.026 μM) was added to the bilayer lipid membrane (BLM) to measure the current–voltage response. Current fluctuation at an applied voltage of 190 mV was observed (Fig. 5). Current peaks of the same level were observed frequently, but were not detected with **1α** at the same concentraton. This indicates an important contribution from the umbrella-like structure of **3αS** in the formation of the ion channel under a transmembrane electric potential. An unusual observation was that the current fluctuation was not a stepwise response typical of ion channels. Probably, a part of the current response may be due to disorder of the membrane produced by the peptide insertion.

Efficient synthesis of a new, highly versatile chiral derivatizing agent, α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA)

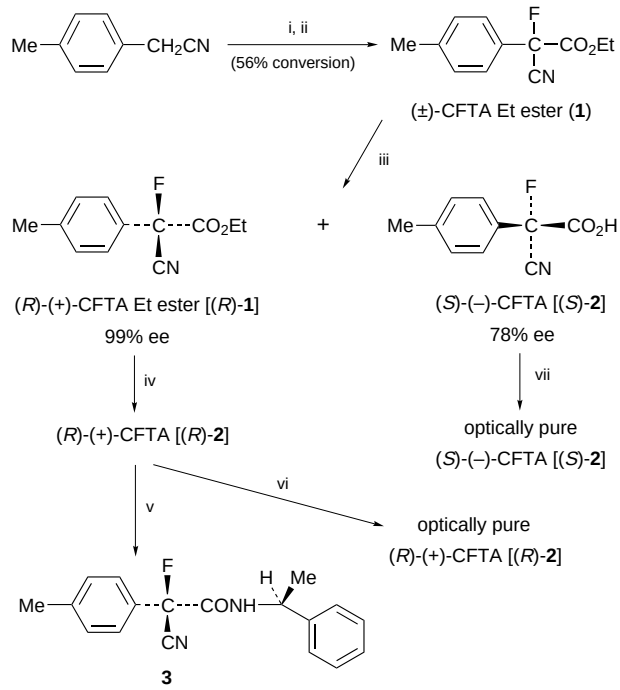
The new and versatile chiral derivatizing agent, α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA), has been efficiently synthesized in optically pure form by *Candida rugosa* lipase-mediated kinetic resolution of racemic CFTA ethyl ester, the latter being readily prepared by fluorination of ethyl α-cyano-*p*-tolylacetate with $FClO_3$.

Rapid progress has been made in the development of techniques for determination of ees of chiral molecules. However, despite many advances, there are few agents that can be applied to a broad spectrum of molecules encountered in modern synthetic and analytical chemistry.[1] We recently developed one such agent, α-cyano-α-fluorophenylacetic acid (CFPA), which far surpassed the capabilities of existing chiral derivatizing agents (CDAs) with respect both to reactivity[2] and resolution efficiency.[3] However, the involved synthesis of this agent has precluded its general use. We now report a related CDA, α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA), that retains the merits of CFPA but, through effective use of enzymatic resolution, is readily available in its optically pure state.

Treatment of *p*-xylyl cyanide with $CO(OEt)_2$ produced ethyl α-cyano-*p*-tolylacetate which, in turn, was treated with $FClO_3$† to give CFTA ethyl ester **1** in excellent overall yield. Among twenty commercial hydrolytic enzymes that were screened for the enantioselective hydrolysis of **1**, *Candida rugosa* lipase (CRL)‡ gave the best results with respect to reactivity, although the enantioselectivity (*E* value[5] of *ca.* 3) was clearly insufficient for our purposes. Fortunately, after much investigation, we found that pre-treatment of CRL with Pr^{i}OH improved the enantioselectivity more than ten-fold, consistent with the previous results obtained by Kazlauskas for the resolution of 2-aryl- and 2-aryloxy-propionic esters.[6] Thus, hydrolysis of racemic ester **1**, catalysed by pre-treated commercial CRL [50% (v/v) Pr^{i}OH in 2-(*N*-morpholino)ethanesulfonate buffer solution (pH 6.0), according to the procedure of Kazlauskas], gave, at 56% conversion, (*R*)-**1** with an ee of 99% and (*S*)-CFTA [(*S*)-**2**] with an ee of 78%, corresponding to an *E* value of 40 (Scheme 1). This dramatic increase in enantioselectivity can be attributed to a change in stereostructure of CRL caused by Pr^{i}OH treatment, as demonstrated earlier by Kazlauskas (see below).[6]

The *R* configuration of the remaining ester **1** was determined by X-ray crystallographic analysis§ of the (*S*)-α-phenethylamide **3** prepared from **1**. Therefore, the more readily hydrolysed ester has the *S*-configuration and (*S*)-**2** is enriched in the product. Kazlauskas proposed an empirical rule¶ to predict the stereochemical outcome of ester hydrolysis catalysed by Pr^{i}OH-treated CRL, as shown in Fig. 1.[7] The active site of the CRL apparently accepts F as a replacement for H, with CN corresponding to the medium-sized substituent.

(*R*)-CFTA [(*R*)-**2**] was obtained by LiOH hydrolysis of the remaining ester (*R*)-**1**. The (*S*)-α-phenethylamine salt of (*R*)-**2** and the (*R*)-α-phenethylamine salts of the (*S*)-**2**-enriched hydrolysis product were each recrystallized from $CHCl_3$–hexane to afford optically pure enantiomers, the (*R*)-α-phenethylamine salt of (*S*)-CFTA {mp 135–137 °C, $[\alpha]_D^{25}$ −3.3 (*c* 0.99, MeOH)} and the (*S*)-α-phenethylamine salt of (*R*)-CFTA {mp 135–137 °C, $[\alpha]_D^{25}$ +3.3 (*c* 0.99, MeOH)}. These enantiomeric salts were treated with acid to afford (*R*)-CFTA {$[\alpha]_D^{25}$ +36.8 (*c* 1.21, $CHCl_3$)} and (*S*)-CFTA {$[\alpha]_D^{25}$ −36.3 (*c* 1.05, $CHCl_3$)} as colourless oils in isolated overall yields of 38 and 19%, respectively, from racemic CFTA ethyl ester.‖



Scheme 1 *Reagents and conditions*: i, NaH, $CO(OEt)_2$, THF, reflux, 2 h, 98%; ii, NaH, THF, room temp., 1 h, then $FClO_3$, room temp., 40 min, 90%; iii, Pr^{i}OH-treated CRL, isooctane, 1 M phosphate buffer (pH 7.0), 25 °C, 41% for (*R*)-**1** (99% ee), 46% for (*S*)-**2** (78% ee); iv, 1 M LiOH, THF–H_2O (1 : 1), room temp., 5 min, 100%; v, (*S*)-α-phenethylamine, DCC, CH_2Cl_2, room temp., 6 h, 95%; vi, (*S*)-α-phenethylamine, recrystallization, then 1 M HCl, 78%; vii, (*R*)-α-phenethylamine, recrystallization, then 1 M HCl, 41%

The chemical shift differences between the two diastereomers ($\Delta\delta$ values)** in both the ^{19}F and ^{1}H NMR spectra for several CFTA and MTPA esters are shown in Tables 1 and 2, respectively.†† The greater efficiency of CFTA compared to MTPA in ee determinations is apparent from the much greater $\Delta\delta$ values consistently obtained for the CFTA derivatives.[8–10] Furthermore, in addition to the greater magnitude of the $\Delta\delta$ values, the consistency of the sign of these shifts suggests that the CFTA procedure is more reliable[11] than the Mosher method in assigning absolute configurations of secondary alcohols based on ^{19}F NMR[8,9] and ^{1}H NMR[9,10] spectroscopy. We are currently investigating in greater detail the relationship between stereostructure and chemical shift value, especially in the ^{19}F NMR spectra.

We thank Ms H. Kakuda for the X-ray crystallographic analysis of **3**. This work was supported by a Grant-in-Aid from the Ministry of Education, Science, Sports and Culture, Japan and a grant from the Ciba-Geigy Foundation (Japan).

† $FClO_3$ gas diluted with N_2 is safely and conveniently generated in ordinary glassware by reaction of $KClO_4$ with FSO_3H (ref. 4).

‡ Lipase OF (CRL) was purchased from Meito Sangyo Co., Ltd.

§ *Crystal data* for **3**: $C_{18}H_{17}FN_2O$, M = 296.34, monoclinic, a = 9.647(2), b = 17.686(3), c = 9.915(2) Å, β = 109.64(1)°, U = 1593.3(5) Å^3, T = 203 K, space group $P2_1$ (no. 4), Z = 4, μ(Cu-Kα) = 0.698 mm^{-1}, 2626 reflections measured, 2469 reflections unique, 1322 reflections observed [$I > 3\sigma(I)$]. Two aryl groups (phenyl and *p*-tolyl) were disordered over two positions with occupancies 0.5 for all disorder components. For this reason, the R value was relatively high. The final cycle of full-matrix least-squares refinement (for 218 parameters) was converged with R_w = 0.111, R = 0.116. CCDC 182/709.

¶ The rule was derived from the results of enantioselective hydrolysis of 16 esters, where L is a large substituent such as Ar or OAr, and M is a medium-sized substituent such as Me or OH (refs. 6 and 7).

‖ The enantiomeric purity of both (*R*)- and (*S*)-CFTA was determined to be > 99.5% by comparison of the ^{1}H and ^{19}F NMR spectra of their cholesteryl esters with those of the cholesteryl ester of recemic CFTA.

** The $\Delta\delta$ value is defined as the difference in the ^{19}F (F or CF_3 signal for CFTA or MTPA ester, respectively) or ^{1}H (Me signal of R^1 and R^2) NMR chemical shifts for the (*S*)-agent/(*R*)-alcohol diastereomer (δ_{SR}) and the (*R*)-agent/(*R*)-alcohol diastereomer (δ_{RR}) for each CFTA or MTPA ester (ref. 9).

†† The preparation of CFTA chloride and condensation of CFTA chloride with chiral alcohols were carried out according to procedures described for derivatization of CFPA (ref. 3).

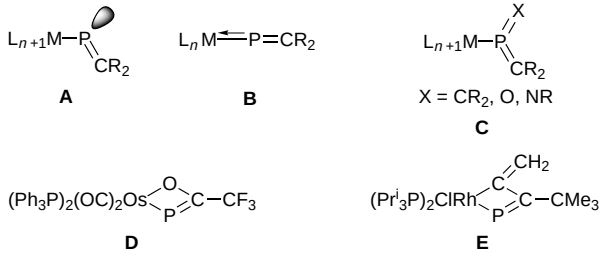
A metallacyclic λ⁵-phosphaalkenyl complex of ruthenium(II): X-ray structure of [Ru{κ²-P(=O)CBu^{t}C(=O)}(CNBu^t)$_2$(PPh$_3$)$_2$]

Anthony F. Hill,*†[a] Cameron Jones,*‡[b] Andrew J. P. White,[a] David J. Williams[a] and James D. E. T. Wilton-Ely[a]

[a] *Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY*
[b] *Department of Chemistry, University of Wales, Swansea, Singleton Park, Swansea, UK SA2 8PP*

The reaction of [Ru(P=CHBu^t)Cl(CO)(PPh$_3$)$_2$] 1 or [Ru(P=CHBu^t)Cl(CNBu^t)(CO)(PPh$_3$)$_2$] 2b with excess pivalo isonitrile under aerobic conditions provides the novel metallacyclic λ⁵-phosphaalkenyl-*P* complex [Ru{κ²-P(=O)CBu^{t}C(=O)}(CNBu^t)$_2$(PPh$_3$)$_2$], which has been crystallographically characterised.

The λ³-phosphaalkenyl-*P* complex [Ru(P=CHBu^t)Cl(CO)(PPh$_3$)$_2$] **1**[1] is intriguing in that despite effective atomic number considerations for ruthenium, both the spectroscopic features and the emerging reactivity profile[2–4] point to a nucleophilic phosphorus centre (**A**). The RuCl(CO)(PPh$_3$)$_2$ fragment, possessing 15 valence electrons might be expected to commandeer three electrons from the phosphaalkenyl ligand **B** and thereby enforce linearity and attendant electrophilic character at phosphorus. This is, however, not the case. We have interpreted this counter-intuitive behaviour with reference to a similar dichotomy which prevails for nitrosyl ligands bound to metal centres with high d-occupancies.[1] One aspect of the 'semi-bent' nature of the phosphaalkenyl ligand in **1** is that the ruthenium centre readily, though reversibly, accepts two-electron ligands, resulting in a metal centre which requires bent (one-electron) phosphaalkenyl coordination. The resulting nucleophilic nature of the phosphorus centre has been demonstrated by its reduction to a complex of the unusual fluorophosphine Bu^{t}CH$_2$PHF ligand *via* the reaction of the isonitrile adduct [Ru(P=CHBu^t)Cl(CNC$_6$H$_3$Me$_2$-2,6)(CO)(PPh$_3$)$_2$] **2a** with HBF$_4$.[2] Herein we wish to report a curious transformation of **1** into a metallacyclic phosphaalkenyl complex **3**. This is accompanied by oxidation of the phosphorus from λ³ to λ⁵ (**C**), resulting in a rare example of a trigonal phosphorus centre surrounded by three π-interactive substituents. A notable feature of **3** is that it is, we believe, the first example of a λ⁵-phosphaalkenyl-*P* complex.



Whilst complex **1** readily forms a 1:1 adduct **2a** with CNC$_6$H$_3$Me$_2$-2,6, the same reaction with pivalo isonitrile (CNBu^t) is somewhat more complex. Under strict control of reagent stoichiometry and reaction conditions it is possible to prepare the adduct [Ru(P=CHBu^t)Cl(CNBu^t)(CO)(PPh$_3$)$_2$] **2b**, spectroscopic data for which are comparable to those for **2a**.§ On occasion however, complex **2b** is contaminated with a second product, which is also formed in low yield from **2b** on standing in solution. This second compound is the exclusive product if an excess of CNBu^t is used, under aerobic conditions. Spectroscopic data§ and a crystallographic study (Fig. 1)¶ confirm the identity of the new compound as the novel metallacyclic λ⁵-phosphaalkenyl-*P* complex [Ru{κ²-P(=O)CBu^{t}C(=O)}(CNBu^t)$_2$(PPh$_3$)$_2$] **3**. Of note amongst the spectroscopic data for **3**, is the ^{31}P{^{1}H} NMR resonance for the phosphaalkenyl centre which appears as a triplet [δ 47.0 ^2J(P$_2$P) 25.2 Hz], to substantially higher field of those observed for **2b** [δ 389.8 ^2J(P$_2$P) 11.7 Hz] or **1** [δ 450.4 ^2J(P$_2$P) 10.0 Hz]. The phosphoryl group contributes to a strong absorption in the infrared spectrum at 1198 cm^{-1}(Nujol), whilst the acyl group is apparent at 1644 cm^{-1}. All other spectroscopic data are as expected and unremarkable.

The geometry at ruthenium is essentially octahedral with *cis*-interligand angles in the range 85.2(2)–96.1(3)°, the exception being P(1)–Ru–C(2) which is contracted to 66.5(2)° by virtue of the constraints of chelation. The two ruthenium isonitrile distances are 1.988(10) and 2.037(10) Å suggesting that the *trans* influence of the phosphaalkenyl ligand is comparable to that of the acyl component of the metallacycle. The principle structural feature of interest is the metallacycle, the unsaturation of which is reflected in the coplanarity to within 0.03 Å of the atoms C(5), C(1), P(1) O(3), C(2), O(4) and Ru, a planarity which extends to include the CN groups of the isonitriles. Owing to the novelty of **3**, very little directly comparable structural data exists. Two metallacyclic λ³-phosphaalkenyl complexes have been structurally characterised (**D**[5] and **E**),[6]

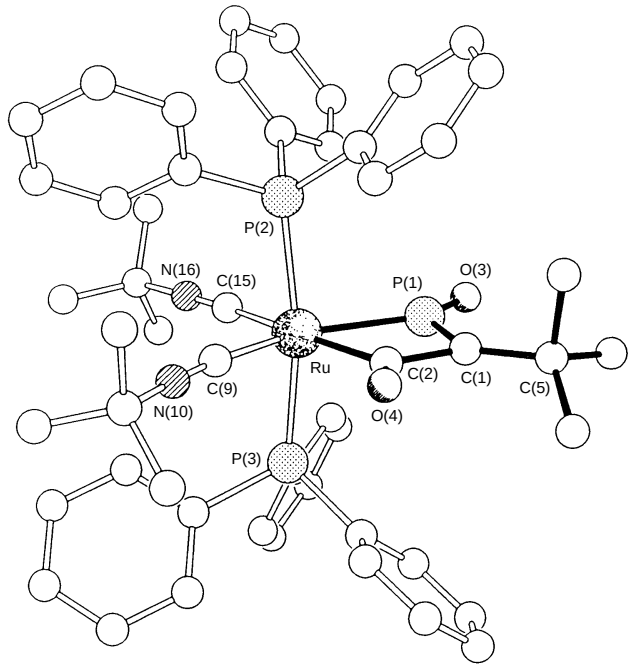


Fig. 1 Crystal structure of **3**

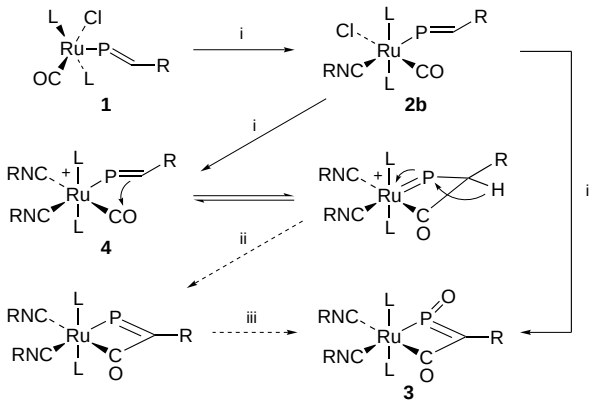
though perhaps more relevant here are the structural features of the phosphaalkene complexes [Ru{P(AuPPh$_3$)=CHBu^t}Cl$_2$(CO)(PPh$_3$)$_2$] **4**[3] and [Ru(PMe=CHBu^t)ClI(CO)(PPh$_3$)$_2$] **5**[4] where the Ru–P separations are 2.296(2) and 2.280(2) Å, respectively. The Ru–P(1) bond length of 2.350(2) Å in **3** thus indicates a substantially reduced degree of Ru–P multiple bond character, consistent with a perhaps surprising decrease in apparent π-acidity for the λ^5-phosphorus centre, notwithstanding the perturbations associated with chelation. This counter-intuitive result is possibly due to the co-ordination of a competitive π-acceptor *trans* to P(1), whilst the phosphaalkene ligands in **4** and **5** are *trans* to π-donor ligands. The P(1)–C(1) separation of 1.713(11) Å is marginally longer than the P=C bond lengths of 1.664(9) and 1.657(8) Å, found for **4** and **5**, respectively but falls within the range 1.68–1.72 Å found for free phosphaalkenes,[7] indicating substantial double bond character. In contrast the C(1)–C(2) bond at 1.54(1) Å is long for a single C_{sp^2}–C_{sp^2} bond length.

It remains for the mechanism to be established whereby **3** forms from **1** or **2b**, however we would make the following points which taken together support the route proposed in Scheme 1. The reaction proceeds in polar solvent mixtures suggesting ruthenium–chloride ionisation occurs. This is supported by the formation and isolation of the salt *cis*,*cis*,*trans*-[Ru(P=CHBu^t)(CO)(CNBu^t)$_2$(PPh$_3$)$_2$]Cl **4**§ when **1** is treated with 2 equiv. of pivaloisonitrile and isolated immediately. The β-position of vinyl ligands is typically nucleophilic in nature, in particular for later transition metals, and it seems reasonable to expect a similar property for phosphavinyl ligands. The carbonyl ligand will be activated towards nucleophilic attack as a result of the complex being cationic. Ring closure could provide the saturated metallacycle shown, and the proton which is α to both phosphorus and a carbonyl group would be expected to be acidic. Deprotonation then leads to unsaturation of the metallacycle. The aerial oxidation of the phosphorus centre is, in contrast to **1**, an endearing feature of which is its remarkable aerobic stability. Nevertheless, the Ru(CNBu^t)$_2$(PPh$_3$)$_2$ fragment would be expected to be particularly π-basic, activating the π-acid phosphorus centre towards oxidation. Notably the conversion of **4** to **3** is accelerated by addition of a non-nucleophilic base (DBU). We have so far been unsuccessful in isolating the intermediates between **4** and **3**, however the alternative route of deprotonation prior to cyclisation seems less favourable, given that it would produce a 20-valence electron phosphaalkyne complex of zerovalent ruthenium.[8]



Scheme 1 L = PPh$_3$, R = Bu^t. *Reagents*: i, CNR; ii, −HCl; iii, O$_2$.

The chemistry of λ^3 phosphaalkenyl ligands has seen substantial growth in recent times.[1–6,9] With the advent of a λ^5 example, it will be interesting to see how their respective coordination chemistries compare.

This work was supported by the EPSRC in the form of a studentship (to J. D. E. T. W.-E.) and a diffractometer and by the Nuffield Foundation (to C. J.). A. F. H. gratefully acknowledges the Leverhulme Trust and the Royal Society for the award of a Senior Research Fellowship.

Functional monoorganotin oxides and alkoxides are synthesised in high yield by hydrolysis or alcoholysis of the corresponding trialkynylorganotins; the hydrolytic behaviour of trialkynylorganotins is the same as for trialkoxyorganotins.

Most metallic oxides can be prepared by the sol–gel process, the starting materials being usually metallo-organic compounds such as alkoxides.[1] Hydrolysis and condensation reactions of these precursors lead to the formation of a metal–oxo based macromolecular network. Generally, these sol–gel derived materials are subject to shrinkage and cracking upon solvent removal. Incorporation of organic phases, linked to the metal either by metal–oxygen–carbon or metal–carbon bonds, allows a strong improvement of the mechanical properties of the resulting hybrid materials.[2,3] These types of materials have been extensively studied with silicon,[3,4] which forms hydrolytically stable metal–carbon bonds. As tin affords such stable bonds, and changes its coordination number and oxidation state more readily than Si, organotin oxide derived hybrid materials should show interesting properties. So far, few tin based hybrids have been developed using functional organotin trialkoxides as precursors.[5] However, these precursors offer only a limited number of polymerizable or reactive organic functionalities.[5,6] Indeed, alkene-type double bonds could be introduced in the precursors but ester groups were found to be incompatible with both available methods of preparation of organotrialkoxytins. Reaction of ω-(alkoxycarbonylalkyl)trichlorotins with *tert*-amyl alcohol in the presence of diethylamine[7] did not lead to completion because the coordination of the metal by the functional group decreases its electrophilic properties. On the other hand, with sodium *tert*-amylate, intractable compounds were only obtained.[8]

Thus, other precursors, filling several requirements were sought for: they should be cleaved by water, prepared from conveniently obtained trichlorides and, finally, they should be as tolerant as possible towards functional groups. As alkynyltins are moisture sensitive compounds, alkynyl groups were thought to be good replacements for alkoxy groups. Actually, the hydrolysis of the tin–alkynyl bond is the reverse reaction of the useful access to alkynyltins by reaction of stannoxanes or alkoxyorganotins with terminal alkynes.[9]

Treatment[10] of functional trichloroorganotins[6] with 3 equiv. of hex-1-ynyllithium (Scheme 1) led to the corresponding alkyltrialkynyltins in good yields. They were stable enough to be manipulated in the air for short periods of time and to be purified by column chromatography on Florisil. Main results are presented in Table 1.

1

Scheme 1 *Reagents and conditions*: i, toluene, −78 °C to room temp., 5 h; purification by chromatography on Florisil

Table 1 Preparation of trialkynylorganotins

R^1	R^2	Yield (%)[a]
Me	Ph	71[b]
Bu	Me	83[b]
Bu	Bu	79[b]
Ph	Bu	75[b]
4-$(CH_2{=}CH)C_6H_4(CH_2)_4$	Bu	60[c]
$MeO_2C(CH_2)_2$	Bu	36
$AcO(CH_2)_3$	Bu	45
$AcO(CH_2)_5$	Bu	42
$MeCH{=}CHCO_2(CH_2)_5$	Bu	46

[a] Compounds **1** were isolated and fully characterised by ^{1}H, ^{13}C, ^{119}Sn NMR spectroscopy and mass spectrometry. [b] Chromatography was not necessary. [c] This compound was obtained by direct alkylation of a tetraalkynyltin.[11]

Upon hydrolysis (Scheme 2), either in chloroform with aqueous THF or in aqueous alcohols, tin–alkynyl bonds were cleaved and Sn–O–Sn bonds were formed. For alkyltrialkynyltins, $R^1Sn(C{\equiv}CR^2)_3$, solution ^{119}Sn NMR spectroscopy of the hydrolysed product showed two equally intense sharp signals at δ *ca.* −280 and −450, accompanied by two sets of satellites corresponding to ^2J(Sn–Sn) coupling constants of *ca.* 200 and 380 Hz.† These peaks are characteristic of the *closo* cluster $[(R^1Sn)_{12}(\mu_3O)_{14}(\mu_2OH)_6](OH)_2$,[12,13] where six tins are five-coordinate and six are six-coordinate. This compound was previously obtained from the hydrolysis of tris(isopropoxy)-butyltin.[13] Thus, as these trialkynylorganotins behave similarly to the corresponding trialkoxides, alkynyl groups appear to be the viable substitutes for alkoxy groups. Moreover, substitution of the alkynyl moiety by alkyl or aryl groups has no influence on the reaction as tris(phenylethynyl)-, tri(hex-1-ynyl)- and tri-(prop-1-ynyl)-butyltins were hydrolyzed at about the same rate.

With 3-acetoxypropyl as substituent at the metal, a soluble oxo-polymer‡ in which all tin atoms are six-coordinate, a precursor of the corresponding organostannoic acid, was formed. The strong coordinating effect[14] of the functional group disfavors five-coordinate tin and formation of the corresponding *closo* cluster.

Reaction of trialkynylorganotins with alcohols was also studied (Scheme 3). To our knowledge, cleavage of [4-(ethenyloxy)but-1-ynyl]triethyltin with butanol giving butoxytriethyltin

Table 2 Preparation of trialkoxyorganotins

R^1	R^2	R^3	Yield (%)[a]
Bu	Me	Bu^s	55
Bu	Me	Bu^i	76
Bu	Me	CH_2Ph	80
Me	Ph	Bu^s	50
Bu	Ph	Pr^i	59

was the only previous example of this reaction.[15] When primary or secondary alcohols were used, cleavage of alkynyl groups occurred readily upon moderate heating. Tertiary alcohols were not acidic enough to be useful. In this way, trialkoxymethyl- and trialkoxybutyl-tins[16] were prepared in good yields and results are presented in Table 2. The results show the higher reactivity of trialkynylorganotins compared to organosilanes. Indeed, Si–alkynyl bonds can be cleaved by alcohol molecules, but only at 80 °C and in the presence of F^- as catalyst.[17]

These results show that alkynyl derivatives of tin can be used instead of the corresponding alkoxides in sol–gel process and that these alkynyl derivatives are also good precursors of alkoxides. Moreover, these new precursors offer wide scope of opportunities for the introduction of a variety of organic functionalities inside tin oxide based hybrid materials.

Isonitrile gold(I) nitrates as precursors for iron oxide-supported gold catalysts for CO oxidation

Trevor J. Mathieson,[a] Alan G. Langdon,[a] Neil B. Milestone[b] and Brian K. Nicholson*[a]

[a] *Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand*
[b] *Industrial Research Limited, Box 31-310, Lower Hutt, New Zealand*

The synthesis and X-ray crystal structure of [Au(NO_3)(CNBu^t)] are reported, a first for a C- and O-bonded gold(I) species; it is an effective precursor for chemical deposition of gold on iron oxide to give catalysts which efficiently oxidise CO in air at low temperatures.

Haruta *et al.* have shown that finely-divided metallic gold on iron oxide catalyses the oxidation of CO to CO_2 in air at ambient pressures and at temperatures as low as −70 °C, a process of technological importance for the removal of CO.[1,2] Originally, preparations involved co-precipitation from solutions of Au^{III} and Fe^{III} followed by heating to generate gold particles on the iron oxide surface.[1] This process requires careful control of the rates of addition and pH to ensure active catalysts, and thorough washing to remove chloride ions which poison the catalyst. More recently a new approach involving vapour deposition of [$AuMe_2$(acac)] onto TiO_2 has given active catalysts for CO oxidation.[3]

We are exploring an alternative method of catalyst preparation, using organometallic gold compounds as substrates for deposition. The ideal precursor should be readily prepared, should be adsorbed efficiently onto the metal oxide/hydroxide surface, and preferably should not contain elements such as Cl, S or P which may act as catalyst poisons. Iwasawa and coworkers[4] have prepared active catalysts by adsorption of [Au(NO_3)(PPh_3)] onto iron hydroxide followed by calcination, which suggests that phosphorus can be tolerated. Here, we report our parallel studies on the use of the novel gold(I) complex [Au(NO_3)(CNBu^t)] **1**, for this purpose.

Complex **1** is prepared from $AgNO_3$ and [AuCl(CNBu^t)] in CH_2Cl_2–MeOH at −45 °C.† After removal of AgCl from the mixture, **1** can be isolated in reasonable yield (65%) as colourless crystals. The compound is thermally- and light-sensitive but can be readily handled as a solid at room temperature with suitable precautions, and can be stored indefinitely in the dark at −20 °C. Solutions of **1** in CH_2Cl_2 show signs of decomposition after *ca.* 15 min at room temperature, while MeOH solutions deteriorate much more rapidly. Characterisation of **1** included a single-crystal X-ray structure analysis,‡ which confirms it as the first example of a gold(I) complex with both Au–O and Au–C bonds, incorporating a normal Bu^{t}NC ligand and an η^1-NO_3 ligand about an essentially linearly coordinated gold atom. The only previous example of a gold(I) nitrate complex to be structurally characterised is [Au(NO_3)(PPh_3)];[5] the Au–ONO_2 fragments of the two are very similar.

The major structural interest is in the cell packing and intermolecular association which is clearly controlled by secondary Au···Au interactions, as expected from the recent structural and theoretical work on 'auriophilicity' from the groups of Schmidbaur,[6] Pyykkö[7] and others.[8] As shown in Fig. 1, compound **1** adopts a puckered chain arrangement with adjacent parallel monomers packing head-to-tail with alternating Bu^{t}NC and NO_3^- ligands. The alternating Au···Au interactions are 3.296(1) and 3.324(1) Å, which are the shortest yet reported for a chain structure involving Au(CNR)X species, distances less than this having been found mainly for compounds which pack as dimers or tetramers.[6] For **1** the short distances are presumably encouraged by the small ligands with low electron-donating tendencies. For comparison the Au···Au distances in the chains found for [Au(CN)(CNBu^t)] are 3.568 Å and those in [AuCl(CNBu^t)] are 3.695 Å.[9,10]

The corresponding [Au(NO_3)(CNEt)] complex was isolated similarly, but so far we have only been able to isolate the [Au($CNC_6H_3Me_2$-2,6)$_2$]NO_3 compound from analogous reaction mixtures; these structures will be reported separately.

Preparation of a catalyst for CO oxidation from **1** was straightforward.§ A sample of **1** was added to a slurry of freshly precipitated[4] $Fe(OH)_3$ in acetone to give a *ca.* 3% Au : Fe_2O_3 ratio by mass in the final product. The gold complex appears to be completely adsorbed onto the solid phase. The suspension was dried by evaporation under vacuum and heated at 400 °C in air for 2 h to convert the adsorbed gold to the metallic state, giving a brown powder. The presence of gold in the sample was confirmed by bulk EDAX analysis, but individual particles of gold were not visible under the scanning electron microscope, suggesting that they were smaller than *ca.* 4 nm, the maximum resolving power available to us. Haruta has shown that highest activity is associated with small gold particle size.[1]

To test the catalytic activity a 10 mg sample was placed in a micro-reactor and a stream of CO (1%) in air was passed through it at 2 ml min^{-1}. The effluent stream was monitored by a fuel-cell based detector which showed complete conversion of CO was achieved down to −5 °C, the lowest temperature so far examined. Catalytic activity continued without diminution for many hours.

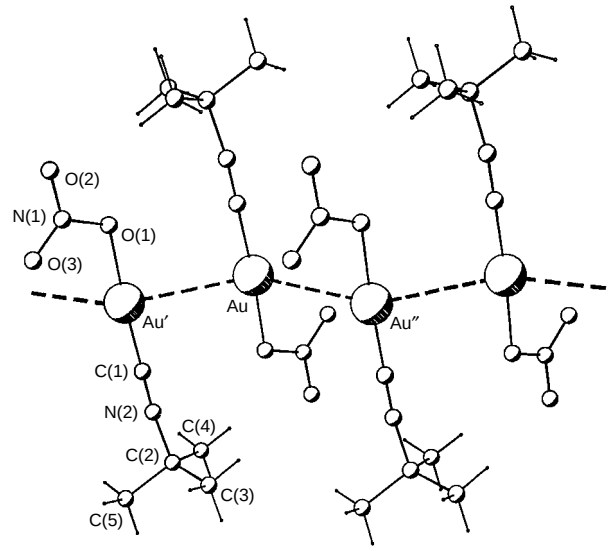

Fig. 1 The packing of [Au(NO_3)(CNBu^t)] **1** along one chain. Selected bond parameters: Au–C(1) 1.92(1), Au–O(1) 2.062(9), C(1)–N(2) 1.13(2), Au···Au′ 3.2955(8) Au···Au″ 3.3243(8) Å; C(1)–Au–O(1) 176.3(4), Au′···Au···Au″ 142.27(3)°. Symmetry operations: Au′ $-x, 1-y, 1-z$; Au″ $1-x, 1-y, 1-z$.

It is worth noting that a catalyst prepared in the same way from [AuCl(CNBu^t)] displayed no catalytic activity towards CO oxidation, even at 100 °C.

In conclusion, we have shown that isonitrile gold nitrates are stable enough for characterisation, that **1** packs with short Au···Au distances, and that chemical deposition of **1** on iron hydroxide provides a simple route to a highly active oxidation catalyst for CO.

We thank Associate Professor Cliff Rickard and Allen Oliver, University of Auckland, for collection of X-ray intensity data.

† *Synthesis* of [Au(NO_3)(CNBu^t)]. An argon-flushed Schlenk flask containing $AgNO_3$ (0.30 g, 1.8 mmol) in MeOH (30 ml) was covered in foil to exclude light, and cooled to −45 °C. To this stirred solution was added [AuCl(CNBu^t)] (0.45 g, 1.4 mmol) in CH_2Cl_2 (10 ml) with the temperature maintained at −45 °C. The mixture was stirred for 30 min. The solvent was evaporated under vacuum and the residue extracted with cold CH_2Cl_2 (5 ml). The filtered extract was treated with light petroleum (60–80 °C fraction) to precipitate [Au(NO_3)(CNBu^t)] (0.32 g, 65%) as a colourless, microcrystalline powder after drying under vacuum. Found: C, 17.76; H, 2.47; N, 8.30%. Calc. for $C_5H_9AuN_2O_3$: C, 17.55; H 2.65; N, 8.19%. IR (KBr disk, cm^{-1}): 2258 [ν(C≡N)], 1512, 1272, 977 (monodentate NO_3^- ligand[11]). NMR ($CDCl_3$): ^{1}H δ 1.60 (s, Bu^t); ^{13}C δ 29.7 [s, (*C*H$_3$)$_3$CNC], 60.1 [s, (CH$_3$)$_3$*C*NC], 122.2 [t, $^1J_{C\equiv N}$ 24 Hz, (CH$_3$)$_3$CN*C*]. **WARNING**: The crystals decompose violently without melting at *ca.* 118 °C. X-Ray quality crystals were obtained by slow diffusion of light petroleum into a CH_2Cl_2 solution of the complex.

‡ *Structure* of [Au(NO_3)CNBu^t]. $C_5H_9AuN_2O_3$, M = 342.11, monoclinic, space group $P2_1/n$, a = 6.2642(1), b = 13.5595(3), c = 10.6118(1) Å, β = 102.18(1)°, U = 881.07(3) Å^3, Z = 4, D_c = 2.579 g cm^{-3}, λ = 0.710 73 Å. T = 203(2) K, μ(Mo-Kα) = 16.661 mm^{-1}, F(000) = 624. Data were collected on a Siemens SMART diffractometer using a crystal of dimensions 0.43 × 0.34 × 0.23 mm. A total of 4203 reflections were collected to 2θ = 56°, 1921 unique (R_{int} = 0.0552), and were corrected for absorption using SADABS ($T_{max, min}$ 0.102, 0.023). The structure was solved by Patterson methods and refined on F^2 to R_1 = 0.0574 [1645 data with $F > 4\sigma(F)$], wR_2 = 0.1543, GoF = 1.002 (all data). Largest final features were +4.1, −3.9 e Å^{-3}, adjacent to the gold atom. All calculations were with the SHELX-96 suite of programs.[12] CCDC 182/738.

§ *Preparation of the catalyst.* Iron(III) hydroxide was freshly prepared by adding a solution of sodium carbonate to a solution of iron(III) nitrate.[4] The precipitate was thoroughly washed and then suspended in acetone. Sufficient solid [Au(NO_3)(CNBu^t)] was added to give an Au/Fe_2O_3 ratio of 3% by mass and the slurry was stirred for 10 h. The acetone was pumped away under vacuum and the residue was heated in air for 2 h at 400 °C to convert the adsorbed gold complex to metallic gold particles, and the $Fe(OH)_3$ to Fe_2O_3.

High solubility of $UO_2(NO_3)_2$·2TBP complex in supercritical CO_2

Mike J. Carrott,[a] Brenda E. Waller,[a] Neil G. Smart[b] and Chien M. Wai*[a]

[a] *Department of Chemistry, University of Idaho, Moscow, ID 83844, USA*
[b] *Research and Technology, BNFL, Sellafield, Cumbria, UK CA20 1PG*

$UO_2(NO_3)_2$·2TBP is highly soluble in supercritical CO_2, with concentrations of 0.0025–0.4981 M attainable at modest temperatures and pressures, demonstrating that supercritical CO_2 can provide a viable substitute for organic solvents used in nuclear fuel processing.

Recently there has been growing interest in the use of supercritical CO_2 for extracting metals and radioisotopes from waste materials. This technology is particularly attractive to the nuclear industry, where the replacement of organic solvents with supercritical CO_2 has the potential to minimize or eliminate the secondary waste produced by conventional extraction techniques, such as the PUREX process. Metal ions in solid and liquid matrices can be extracted by supercritical CO_2 using the *in situ* chelation method originally reported by Wai and coworkers.[1] This method neutralizes the charge on the metal using organic ligands dissolved in supercritical CO_2, to produce soluble metal chelates. A recent review reported the solubility data available to date for 49 metal chelates in CO_2,[2] however, the low solubility of many metal chelates in supercritical CO_2 is a major limitation of this method for practical metal processing. This problem has been partially overcome by the use of fluorinated ligands which have been shown to enhance the solubility of the resulting metal chelate by over two orders of magnitude.[3] Supercritical CO_2 has already been successfully applied to the extraction of U, Th and lanthanides from liquid and solid matrices using fluorinated β-diketone ligands.[4,5] Recent work has shown that UO_2^{2+} and Th^{4+} can be effectively extracted from nitric acid solution using CO_2 modified with tributylphosphate (TBP).[6,7] The uranyl species extracted by supercritical CO_2 is a neutral uranyl nitrate–TBP complex, $UO_2(NO_3)_2$·2TBP, which is identical to the species extracted in the PUREX process using 20% TBP in kerosene.

SFE offers several advantages over conventional solvents employed in the PUREX process, the most important of which is the potential to minimize the amount of secondary waste generated by reprocessing spent fuel. Since the solvating power of supercritical CO_2 is density dependent, extracted species are easily recovered by expanding the fluid to atmospheric pressure, thus precipitating the solutes and allowing the CO_2 to be recycled. In addition CO_2 is inexpensive, non-toxic and stable under high radiation.

In order to develop models for the extraction process and assess the feasibility of using CO_2 to replace organic solvents in the PUREX process, solubility data for the complex in supercritical CO_2 is essential. Here we report the first solubility measurements for $UO_2(NO_3)_2$·2TBP in supercritical CO_2.

$UO_2(NO_3)_2$·2TBP was prepared using a similar method reported for the synthesis of the triphenylphosphine analog.[8] Approximately 2 g of $UO_2(NO_3)_2$·$6H_2O$ were placed in a 200 ml round bottomed flask, 2 mol equiv. of TBP in 100 ml hexane were added and the mixture stirred for *ca.* 2 h at room temperature. When the uranyl nitrate had dissolved, the organic phase was separated from the water of hydration displaced by TBP, and the solvent evaporated to yield the product as a viscous yellow oil. The product was further purified by dissolving in *ca.* 15 ml hexane, freezing to −50 °C to crystallize the complex and cold filtering. This process was repeated three times to remove excess TBP. Thin film IR spectra of the liquid phase were obtained using NaCl plates; cm^{-1}: 2962s, 2878s, 1526s, 1355w, 1281m, 1192s, 939m, and the absorption bands are in good agreement with those reported by Auwer *et al.*[9]

The solubility of $UO_2(NO_3)_2$·2TBP in supercritical CO_2 was determined by UV–VIS spectroscopy,† over a pressure range of 100–300 atm and at temperatures of 40, 50 and 60 °C. Prior to the solubility measurements the molar absorptivity of the complex at 411 nm was determined using standards of $UO_2(NO_3)_2$·2TBP in hexane,‡ and found to be 8.77 l mol^{-1} cm^{-1} at 411 nm. Using Beer–Lambert's law the concentration of the complex in supercritical CO_2 was calculated from subsequent spectroscopic measurements. A typical UV–VIS spectrum of $UO_2(NO_3)_2$·2TBP in supercritical CO_2 is shown in Fig. 1. The solubility curves for $UO_2(NO_3)_2$·2TBP under the conditions investigated are presented in Fig. 2. It can clearly be seen that the solubility of the complex increases dramatically with pressure, particularly at low temperatures. At 40 °C the concentration of $UO_2(NO_3)_2$·2TBP in CO_2 increases from 0.0025 M at 100 atm to 0.4291 M at 225 atm, corresponding to 2.31 and 397.3 g l^{-1} respectively, and represents an increase in

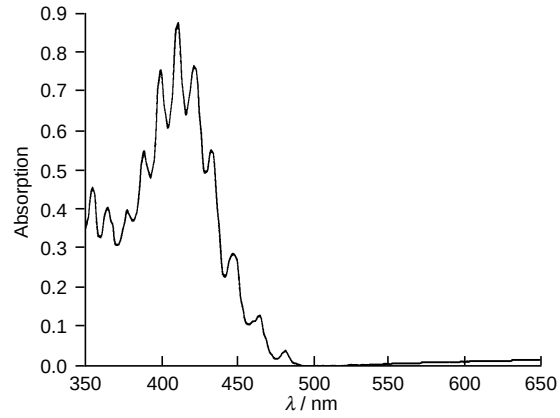

Fig. 1 UV–VIS spectrum of $UO_2(NO_3)_2$·2TBP in supercritical CO_2

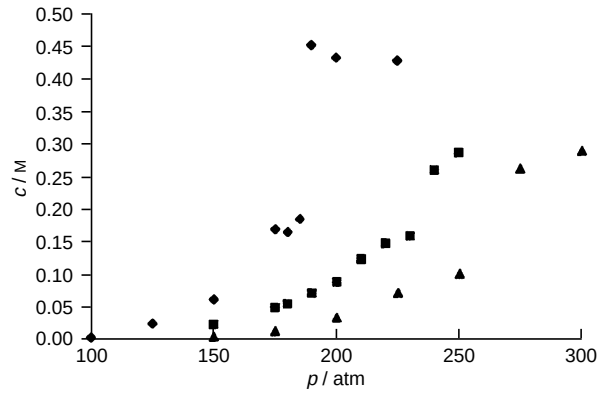

Fig. 2 Solubility of $UO_2(NO_3)_2$·2TBP in supercritical CO_2 at 40 °C (◆), 50 °C (■) and 60 °C (▲)

solubility over two orders of magnitude. Similar curves were obtained at 50 and 60 °C, although the solubility was observed to decrease with increasing temperature. This effect is due to the lower density and hence decreased solvating power of the fluid at higher temperatures. At 50 and 60 °C no appreciable solubility (< 0.001 M) was observed below 125 atm, but the concentration of $UO_2(NO_3)_2 \cdot 2TBP$ increased rapidly in excess of 0.2 M at 240 and 275 atm, respectively. The use of a high pressure view cell as a saturation vessel enabled the phase behaviour of the complex to be observed during the spectroscopic measurements. Initially two distinct phases were present, an intense yellow liquid (lower) phase due to the complex and a pale yellow supercritical (upper) phase due to the CO_2 saturated with $UO_2(NO_3)_2 \cdot 2TBP$. With increasing pressure the yellow colour of the supercritical phase became progressively more intense due to the increasing solubility of the complex, also the liquid phase became darker in colour until it appeared almost black, possibly due to CO_2 being dissolved in the liquid phase. Further increases in pressure produced a very turbid, opaque (almost black) phase in which the meniscus had virtually disappeared, and eventually resulted in an intense yellow single phase. This transition to a single phase occurred very rapidly, over a small pressure range, and is apparent from the sharp increases in concentration observed at 190, 240 and 275 atm for the solubility curves at 40, 50 and 60 °C, respectively. Upon formation of a single phase the concentration remained constant with further increases in pressure, and the solubility curve reached a plateau due to complete dissolution of the complex. Valid solubility data cannot be obtained after this point as the CO_2 was no longer saturated with the complex. Since uranyl nitrate itself is insoluble in pure CO_2 the high solubility of the complex can be attributed to the shielding of the central metal ion by the TBP ligands and increased solute–solvent interactions between the butyl groups and CO_2.

In conclusion, this study has shown that it is possible to obtain extremely high concentrations of $UO_2(NO_3)_2 \cdot 2TBP$ in supercritical CO_2, which surpasses the solubility of any metal chelate previously reported in the literature.§ Most significantly, the concentrations of $UO_2(NO_3)_2 \cdot 2TBP$ in supercritical CO_2 are comparable to those encountered in the waste streams of the PUREX process, typically 0.13–0.47 M in the organic phase.[10] In conjunction with previous extraction work,[6,7] this clearly demonstrates CO_2 can offer a viable alternative to the organic solvents currently employed in nuclear fuel processing.

The authors wish to express their gratitude to British Nuclear Fuels Ltd. (BNFL), and Idaho NSF-EPSCoR for financial support. We also thank Varian for the loan of the fibre optic interface for the Cary 1E UV–VIS spectrometer.

† Measurements were performed using high pressure fibre optic cells constructed in-house. The cells are connected in series and have path lengths of 1 cm, 733 μm and 38 μm, enabling measurements to be made over a wide concentration range. CO_2 was saturated with the complex using a high pressure view cell,[3] with a volume of 15 ml, as an equilibration vessel. Approximately 5–7 ml of $UO_2(NO_3)_2 \cdot 2TBP$ were loaded into the view cell, and, after a period of equilibration, the saturated CO_2 was introduced into the fibre optic cells and UV spectra recorded.

‡ Hexane has a similar polarity to CO_2, and UV–VIS spectra have been shown to exhibit similar absorption coefficients and negligible shifts in the positions of absorption maxima.[11] Our work has also shown that the molar absorptivity of the complex is not affected by changes in the density of the fluid. A high pressure view cell, with a path length of 5 cm and a volume of 15 ml[3], was employed to determine the effect of temperature and pressure on the spectrum of the complex. An aliquot of $UO_2(NO_3)_2 \cdot 2TBP$ was placed in the cell, such that complete dissolution of the complex was achieved under supercritical conditions. Spectra were recorded over a temperature range of 40–60 °C and at pressures of 150–300 atm. No change was observed in the absorption spectrum, thus confirming the molar absorptivity is unaffected by the temperatures and pressures employed in this work.

§ The highest solubility previously reported for a metal chelate in supercritical CO_2, was chromium(III) dipivaloylmethane, $Cr(thd)_3$, with a concentration of 0.126 M at 40 °C and 310 atm.[12]

N-Hydroxypyrazinone-bearing homotrioxacalix[3]arene: its cooperative molecular recognition by metal complexation

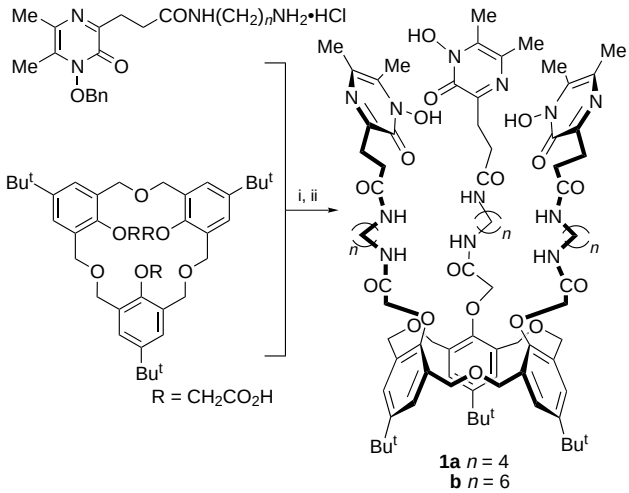
Junko Ohkanda, Hiroyuki Shibui and Akira Katoh*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

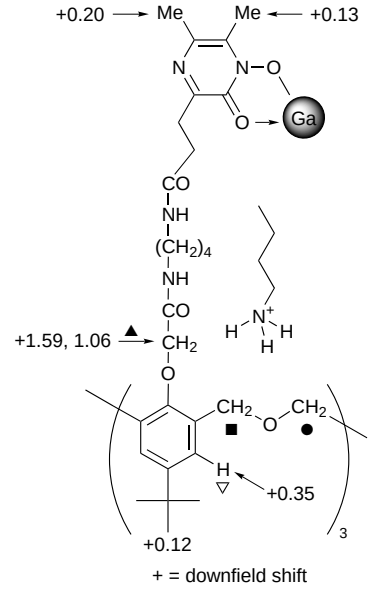
Artificial receptors in which three bidentate hydroxypyrazinones are linked to homotrioxacalix[3]arene through an α,ω-diamine as a spacer exhibited cooperative molecular recognition with gallium ion toward ammonium cations.

Recently, artificial allosteric receptors have been widely investigated from the viewpoint of the application of regulated functions controlled by cooperativity in natural proteins to biomimetic molecular recognition systems.[1] Previously we have demonstrated that *N*-hydroxyamide-containing diazines such as *N*-hydroxypyrazinones acted as a bidentate ligand to Fe^{III} and Ga^{III}.[2] Homotrioxacalix[3]arene[3] is flexible compared to calix[4]arene due to its ethereal linkages, and has a C_3 symmetrical structure which is expected to be particularly useful in receptors of primary ammonium cations.[4] We focused our interest on this compound as a platform for the construction of a flexible host molecule. In the course of our studies on the application of diazines to multifunctional receptors, new host molecules **1a**,**b**, in which three *N*-hydroxypyrazinones were linked to homotrioxacalix[3]arene by an alkyl spacer group, were synthesized. The hosts would be expected to control their cavity size and rigidity upon transition metal chelation, which enables them to exhibit cooperative molecular recognition toward primary ammonium cations. We describe herein the synthesis of the receptors **1a**,**b** and their ammonium cation extraction abilities.

Receptors **1a**,**b** were synthesized by coupling *N*-3-(1-benzyloxy-5,6-dimethyl-2-oxo-1,2-dihydropyraz-3-yl)propanoyldiaminoalkane hydrochloride (n = 4, 6)[2b] with the cone-type tricarboxylic acid[5] derived from homotrioxacalix[3]arene by using WSC·HCl and HOBt† and subsequent hydrogenation according to Scheme 1. Compounds **1a**,**b** were characterised by IR and ^{1}H NMR spectroscopy and elemental analysis, respectively.‡



Scheme 1 *Reagents and conditions*: i, WSC·HCl, HOBt, Et_3N, CH_2Cl_2, room temp., 72 h, 52%; ii, H_2, 10% Pd–C, MeOH, 70%



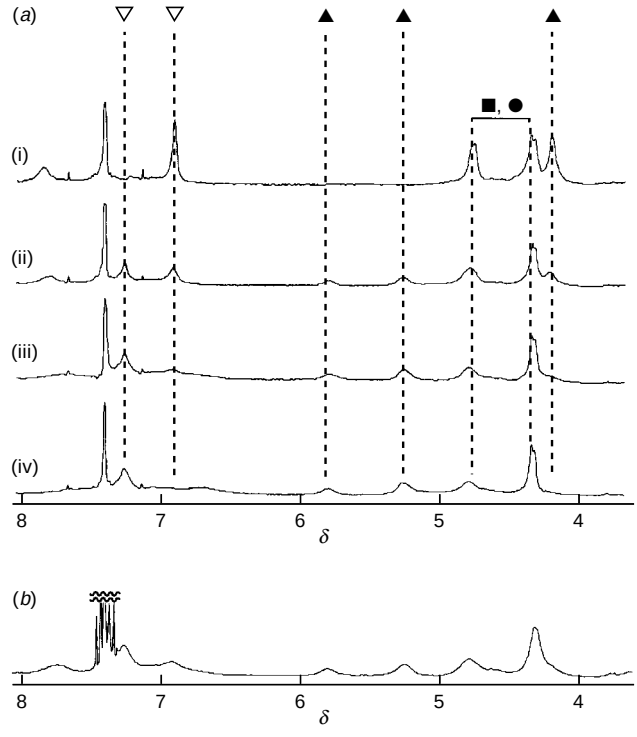


Fig. 1 (*a*) ^{1}H NMR spectra (400 MHz) of **1a** at [$BuNH_3ClO_4$] = (i) 0, (ii) 0.51, (iii) 1.02 and (iv) 1.53 mM; T = 23 °C, [**1a**] = 0.7 mM, [$Ga(acac)_3$] = 0.84 mM. (*b*) ^{1}H NMR spectrum of **1a** in the presence of $C_6H_{11}NH_3^+$; [**1a**] = 0.54 mM, [$C_6H_{11}NH_3ClO_4$] = 0.79 mM.

The 1 : 1 gallium complexation was ascertained by a mole ratio plot. In the ^{1}H NMR spectrum of **1a** with 1.2 equiv. of $Ga(acac)_3$ in 25% CD_3CN in $CDCl_3$, only the two singlets of the 5- and 6-methyl groups of the pyrazinone ring showed downfield shifts ($\Delta\delta$ +0.20 for 5-methyl, +0.13 for 6-methyl), whereas titration with $BuNH_3ClO_4$ induced large downfield shifts of the OCH_2CO (▲) and ArH (▽) protons, as shown in Fig. 1(*a*). The formation of 1 : 1 complex of **1a** with $BuNH_3^+$ was confirmed by a Job plot. It has been reported that the triester derivative of homotrioxacalix[3]arene is bound to an ammonium cation *via* the interaction of three phenolic oxygens and three carbonyl oxygens with the cation.[6] As for **1a**, the singlet for the OCH_2CO protons (▲) changed to two broad singlets when the ammonium salt was added, but no apparent downfield shifts were observed for the signals from the ethereal methylene protons (■, ●). Thus, it is likely that **1a** binds to $BuNH_3^+$ through C=O···HN‡ and ArO···HN‡ interactions similar to those previously reported.

By using a CH_2Cl_2 solution of **1** or a mixture of **1** and an equimolar amount of $Ga(acac)_3$, extraction of primary ammonium picrate from an aqueous phase was carried out. The amounts of ammonium picrates extracted into the organic phase are shown in Fig. 2.§ $Bu^tNH_3^+$ was not extracted efficiently when compared to $BuNH_3^+$ and $HexNH_3^+$, suggesting that the bulky substituent disturbs inclusion of the guest into the cavity. This result also indicates that the extracted amounts of $BuNH_3^+$ and $Bu^tNH_3^+$ increased in the presence of Ga^{3+}, indicating a cooperative molecular recognition of **1** and Ga^{3+} toward the primary ammonium cation. Furthermore, it was noted that the amount of $HexNH_3^+$ extracted by **1a** decreased in the presence of Ga^{3+}. This result was consistent with the difference in the association constants of **1a**–$HexNH_3^+$ in the absence [K_a 4375, Fig. 1(*b*)] and in the presence of Ga^{3+} (K_a 2833).¶ On the basis of molecular modelling, this observation might be attributed to the regulation of the cavity size by metal complexation; the Ga–**1** complex thus provides a rigid cavity that is suitable for selective recognition of ammonium cations.

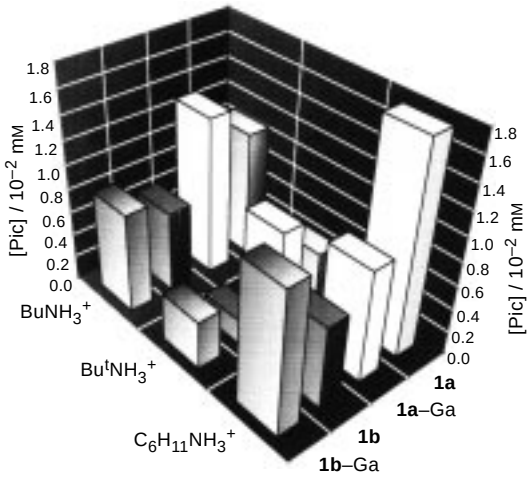

Fig. 2 Two phase solvent extraction of primary ammonium cations

Carboxylate-derived calixarenes with high selectivity for actinium-225

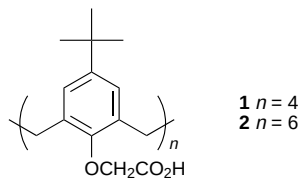
Xiaoyuan Chen,[a] Min Ji,[a] Darrell R. Fisher[b] and Chien M. Wai[a]

[a] *Department of Chemistry, University of Idaho, Moscow, Idaho 83844, USA*
[b] *Molecular Biosciences Department, PNNL, Richland, Washington 99352, USA*

The binding properties of two ligands, 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis(carboxymethoxy)calix[4]arene 1 and 5,11,17,23,29,35-hexa-*tert*-butyl-37,38,39,40,41,42-hexakiscarboxymethoxy)calix[6]arene 2, which show high selectivity for $^{225}Ac^{3+}$ (an α-emitter with $t_{1/2}$ = 10 days) over Na^+, K^+, Mg^{2+}, Ca^{2+} and Zn^{2+} are described.

In recent years there has been an increased interest in the development of monoclonal antibodies that may be linked with a radioisotope as targeting agents in radioimmunodiagnosis and radioimmunotherapy of cancer tumors.[1] The success of such approaches depends on the development of bifunctional complexing agents that can bind a specific radioisotope tightly and selectively and can be linked to antibodies. Chelators that can hold the desired radioisotope with high stability under physiological conditions are essential to deliver the radioisotope to the antigen binding site on tumor cells.[2] Linkage of β-emitters such as ^{90}Y and ^{67}Cu to the moab part of monoclonal antibodies *via* bifunctional aza- and peraza-crown ether macrocycles has shown good results for the treatment of a number of cancer patients.[3] For radioimmunotherapy, α-emitters are much better cytotoxic agents than β-emitters since they dissipate a large amount of energy along straight particle tracks of 40–70 μm (*ca*. 8 cell diameters).[4] Among the α-emitters having an appropriate physical half-life for such an application is actinium-225 ($t_{1/2}$ = 10.0 d).[5] ^{225}Ac decays through a chain of daughter products to stable ^{209}Bi with the emission of a total of four α and two β particles, releasing about 28 MeV of radiation energy to the absorbing medium.[6]

Solvent extraction experiments performed recently in our laboratory indicate that 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis(carboxymethoxy)calix[4]arene **1** and 5,11,17,23,29,35-hexa-*tert*-butyl-37,38,39,40,41,42-hexakis-(carboxymethoxy)calix[6]arene **2** (Fig. 1) exhibit high Ac^{3+} selectivity over alkali, alkaline earth, and zinc metal ions under neutral and weak acidic conditions. These calixarene derivatives were synthesized in our laboratory according to the known procedures in the literature.[7,8] The two-phase solvent extraction experiments were carried out between water (1.5 ml, [^{225}Ac] = 10^{-3} mM) and chloroform (1.5 ml, [ionophore] = 2 mM). The pH of the aqueous phase was adjusted with HCl for pH 1–3, succinic acid–NH_4OH for pH 4–6, and Tris–HCl for pH 7–8. The mixture was shaken at 25 °C for 30 min, which was long enough to reach equilibrium based on our time variation studies. The distribution ratio *D* ([Ac^{3+}] in the organic phase/[Ac^{3+}] in the aqueous phase) was determined by measuring the ^{225}Ac activity in each phase using a Ge(Li) detector. Percentage extraction of Ac^{3+} (Ex%) was calculated by $D/(1 + D)$. Fig. 2 shows Ex% of Ac^{3+} with ligands **1** and **2** plotted *vs*. pH of the aqueous phase. For **1**, Ex% becomes appreciable at pH 2.0 and reaches nearly 100% around pH 4.0. Ex% decreases rapidly at pH > 7.3 reaching only 40% at pH 8.0. Ex% for **2** shows a similar pH dependence. The Ex% increases from pH 1.5, reaching saturation at pH around 3.0 and decreasing sharply above pH 7.5.



1 *n* = 4
2 *n* = 6

Fig. 1 Structures of the carboxylate-derived calixarenes which show high selectivity for Ac^{3+}

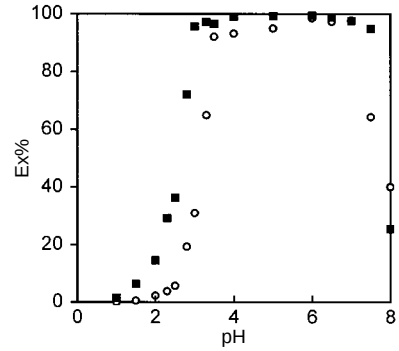


Fig. 2 pH dependence of extraction of actinium-225 with ligands **1** and **2**. The pH of the aqueous phase was adjusted with HCl for pH 1–3, succinic acid–NH_4OH for pH 4–6 and Tris–HCl for pH 7–8; (○) **1** (*n* = 4), (■) **2** (*n* = 6).

Fig. 3 shows plots of log *D vs*. −log[L] for the extraction of Ac^{3+} by ligands **1** and **2** at pH = 6.0, where [L] is the concentration of the ionophore in the organic phase. A linear relationship between log *D* and −log[L] is observed with the slope of both lines roughly equal to −1 suggesting that both **1** and **2** form a 1 : 1 complex with Ac^{3+}.

Owing to its short half-life and high radioactivity, it was not possible for us to obtain the stability constants of the ^{225}Ac complexes using common spectroscopic or potentiometric titration methods. We used a competition extraction method to obtain the relative extraction constants of Ac^{3+} by ligands **1** and **2** with respect to EDTA. To obtain the relative stability constants of the Ac complexes, the following competition experiments were performed. The Ac^{3+} in water at pH 7 was

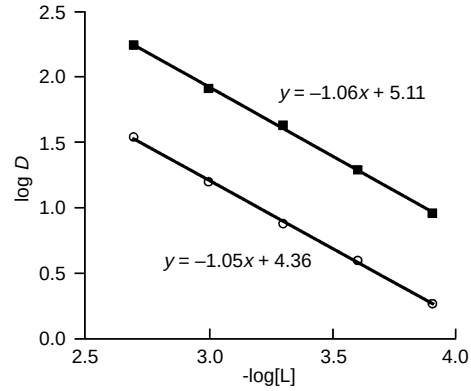

Fig. 3 Plot of log *D vs.* −log[L] for the extraction of Ac^{3+} by ligands **1** and **2**. The slopes were 1.05 and 1.06, respectively; (○) **1**, (■) **2**.

first extracted into the chloroform phase containing **1** or **2**. The organic phase was then back-extracted with an aqueous phase containing EDTA at pH = 7.0. No data for Ac^{3+} hydrolysis is available. We estimated the hydrolysis of Ac^{3+} based on the known values of Am^{3+} ($\log \beta_1 = -6.4 \pm 0.7$, $\log \beta_2 = -14.1 \pm 0.6$, $\log \beta_3 = -25.7 \pm 0.5$ at $I = 0$ and 25 °C), which fall in the range of the hydrolysis constants reported for the trivalent lanthanides.[9] According to these values, the distribution of Ac^{3+}, $Ac(OH)^{2+}$ and $Ac(OH)_2^{+}$ should be 71, 28 and 1%, respectively, at pH 6 and 17, 68 and 15%, respectively, at pH 7. Thus, ^{225}Ac could also be extracted as the Ac(OH)–calixarene complexes in near neutral solutions.

The following equilibrium relations were obtained based on the assumptions that neither $EDTA^{3-}$ nor $Ac(OH)(EDTA)^{-}$ was soluble in chloroform and the solubility of the H_2L^{2-} and $Ac(OH)(H_2L)$ in the aqueous phase was negligible. The new distribution ratio D' was taken as $[Ac(OH)(H_2L)]_{org}/[Ac(OH)(EDTA)^{-}]_{aq}$, where $Ac(OH)(H_2L)$ represented the Ac–calixarene complex.

$$EDTA^{3-} + Ac(OH)^{2+} = Ac(OH)(EDTA)^{-}$$

$$K_1 = [Ac(OH)(EDTA)^{-}]/[EDTA^{3-}][Ac(OH)^{2+}]$$

$$H_2L^{2-} + Ac(OH)^{2+} = Ac(OH)(H_2L)$$

$$K_2 = [Ac(OH)(H_2L)]/[H_2L^{2-}][Ac(OH)^{2+}]$$

$$K_2/K_1 = [Ac(OH)(H_2L)][EDTA^{3-}]/[Ac(OH)(EDTA)^{-}][H_2L^{2-}]$$

$$\log(K_2/K_1) = \log D' + \log[EDTA^{3-}]/[H_2L^{2-}]$$

A linear relationship is observed between log D' and log[EDTA]/[L] for both ligands (Fig. 4) with slope close to unity suggesting that the assumptions are reasonable. From the intercept, we obtain the extraction constants of the Ac–calixarene complexes relative to that of EDTA. Ligand **1** has $K_2 = 1.11\,K_1$ and **2** has $K_2 = 5.75\,K_1$, where K_1 is the extraction constant of Ac with H_4EDTA at pH 7.

We also investigated whether the actinium complexes could tolerate high concentrations of alkali, alkaline earth and zinc metal ions. We took aliquots of the organic phase containing the ^{225}Ac complexes and back-extracted with an aqueous solution

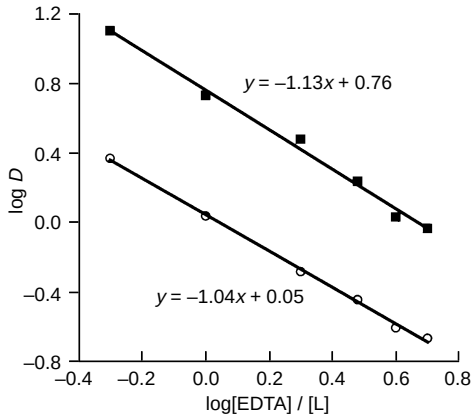

Fig. 4 Plot of log D *vs.* log[EDTA]/[L] at pH = 7.0 shows a straight line for both ligands; (○) **1**, (■) **2**

containing a mixture of 10 mM each of Ca^{2+}, Mg^{2+}, Na^{+}, K^{+} and Zn^{2+} at pH 7.0. After shaking for 5 h, ligand **1** showed no measurable loss of Ac^{3+} from the organic phase to the aqueous phase. For ligand **2**, about 5% of the Ac originally present in the organic phase was extracted to the aqueous phase. The high selectivity of the calixarene carboxylate ligands for Ac^{3+} may be related to the high charge density of the Ac^{3+} ion favoring electrostatic interactions with the anionic ligands.[10] Ligand **2** shows a slightly lower selectivity for Ac^{3+} than **1** which may be due to the structural difference between the two ligands. Because **2** has a larger and more flexible cavity, it probably can accommodate the competing cations better than **1**. Also **2** is more acidic than **1**, thus it can coordinate with the alkaline earth metal ions at lower pH values.

In conclusion, this study shows that both **1** and **2** have an ionophore cavity capable for selective complexation with Ac^{3+} in weak acid and neutral solutions. They appear to be suitable candidates as ^{225}Ac carriers. The next step in our research is to selectively functionalize the upper rim of the calixarene ring with amine, bromine, aldehyde or acid chloride forming bifunctional ligands that may be attached to the desired monoclonal antibodies.

This work was supported by the Pacific Northwest National Laboratory (PNNL).

Preparation and characterization of the kinetic and thermodynamic isomers of dinuclear molybdenum and tungsten complexes with metal–metal triple bonds supported by *p-tert*-butylcalix[4]arene anions†

Malcolm H. Chisholm,* Kirsten Folting, William E. Streib and De-Dong Wu

Department of Chemistry and Molecular Center, Indiana University, Bloomington, IN 47405, USA

The reaction between $M_2(NMe_2)_6$ and < 2 equiv. of *p-tert*-butylcalix[4]arene (H_4L) in hydrocarbon solvents leads to $(H_2NMe_2)_2[M_2(\mu,\eta^2,\eta^2\text{-}L)_2]$ 1 (M = Mo, W), which isomerizes to the unbridged isomers $(H_2NMe_2)_2[M_2(\eta^4\text{-}L)_2]$ 2 upon heating in refluxing pyridine (L = quadruply deprotonated calix[4]arene); related complexes $M_2(\eta^4\text{-}HL)_2$ 3 (M = Mo, W) are prepared from reactions involving $M_2(OBu^t)_6$ and H_4L, and these react with $HNMe_2$ to give 2 (M = Mo and W) while $[NH_2Me_2][W_2(\eta^4\text{-}L)(\eta^4\text{-}HL)]$ 4 can be obtained by the reaction between 2 and 3 (M = W) in a 1 : 1 ratio.

The recent communication of the elegant synthesis of W–W bonded complexes supported by the *p-tert*-butylcalix[4]arene tetraanion, L, namely $Na_2W_2(\eta^4\text{-}L)_2(\mu\text{-}Cl)_2$ (M=M) and $Na_2W_2(\eta^4\text{-}L)_2$ (M≡M),[1] leads us to report on our related findings concerning $(M{\equiv}M)^{6+}$ centers.

The reaction between $M_2(NMe_2)_6$ and *p-tert*-butylcalix-[4]arene, H_4L (1.7 equiv.) in a hydrocarbon solvent leads to the formation of green compounds **1** (M = Mo, W).‡ The ^1H NMR spectrum reveals one type of Bu^t group and two CH_2 groups, each being diastereotopic, consistent with the structure found for M = Mo in the solid-state shown in Fig. 1.§ The μ,η^2,η^2-L bridging of the calix[4]arene ligand is similar to that reported for the Mo–Mo quadruple bonded complex $Mo_2(OAc)_2(\mu,\eta^2,\eta^2\text{-}H_2L)$[2] but the Mo–Mo distance in the M–M triple bonded complex is larger by *ca*. 0.07 Å as is commonly seen in comparing Mo–Mo bonded complexes of bond order 4 and 3.[3] Also the Mo–O distances are somewhat shorter in the present structure consistent with the Mo_2^{6+} center. The W complex is isomorphous.§

We recently have prepared a number of complexes of the type $Mo_2(NMe_2)_2(\mu\text{-diolate})_2$ and noted that bridged diolates are often formed kinetically. The addition of pyridine and heat causes isomerization to the chelate isomers, $Mo_2(NMe_2)_2(\eta\text{-diolate})_2$, which represent the thermodynamic products.[4] We thus reasoned that the dumb-bell-like isomer $Mo_2(\eta^4\text{-}HL)_2$ might be thermodynamically favored and, indeed, upon refluxing in pyridine the green solutions of $(H_2NMe_2)_2[Mo_2(\mu,\eta^2,\eta^2\text{-}L)_2]$ **1** turn amber.‡ The ^1H NMR spectrum becomes simpler revealing again one type of Bu^t group and one CH_aH_b group with a large chemical shift difference (δ 5.3 and 3.3 ppm) as might be expected if one CH bond were proximal and the other distal to the Mo–Mo triple bond.[5] Amber crystals of $[NH_2Me_2]_2[Mo_2(\eta^4\text{-}L)_2]$ **2** were obtained that were suitable for an X-ray study and the molecular structure is shown in Fig. 2.§

It is interesting to note that in both structural determinations the calix[4]arene ligands encapsulate or attract molecules of dimethylamine, as $[NH_2Me_2]^+$ cations, and solvent molecules. However, upon heating crystalline samples of the kinetic and thermodynamic isomers in a dynamic vacuum, **1**·4thf (M = Mo) loses only thf molecules whereas **2**·4py (M = Mo) loses

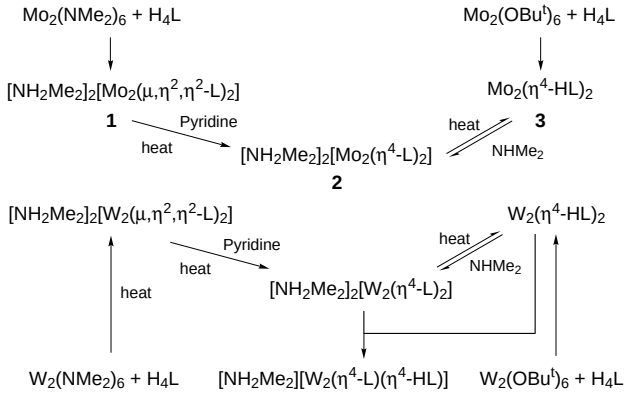
The molecule has a crystallographically imposed mirror plane.



Scheme 1

pyridine as well as $NHMe_2$ leaving behind the complex $M_2(\eta^4\text{-}HL)_2$ **3** (M = Mo) as evidenced by NMR spectroscopy. Complex **3**, as well as its tungsten analogue $W_2(\eta^4\text{-}HL)_2$, can also be prepared from the reaction of $M_2(OBu^t)_6$ (M = Mo, W) with H_4L.‡

The addition of $NHMe_2$ to **3** (M = Mo, W) in benzene leads to **2** (M = Mo, W).‡ In the case of M = W, the reaction between **2** and **3** in a 1:1 ratio gives the pale green compound $[NH_2Me_2][W_2(\eta^4\text{-}L)(\eta^4\text{-}HL)]$ **4**, which has the structure shown in Fig. 3.§ These reactions are summarized in Scheme 1 and reveal the fascinating substitution chemistry resulting from reactions involving $(M{\equiv}M)^{6+}$ complexes (M = Mo, W) and the *p- tert*-butylcalix[4]arene ligand.

‡ *Syntheses and spectroscopic data*: **1** (M = Mo): the reaction mixture of $Mo_2(NMe_2)_6$ (280 mg, 0.60 mmol) and H_4L (650 mg, 1.00 mmol) in 15 ml of benzene was stirred at room temp. overnight. The volatile components were removed *in vacuo* and the residue was suspended in hexanes to give a green precipitate **1**, which was collected and dried *in vacuo* (685 mg, yield: 90%). Crystals of **1**·4thf (M = Mo) suitable for X-ray analysis were obtained by slow evaporation of a thf solution. Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.29 (br, 8 H), 6.93 (br, 8 H), 6.46 (d, 4 H), 3.59 (d, 4 H), 3.27 (d, 4 H), 2.89 (d, 4 H), 1.22 (br, 72 H), 0.79 (t, 12 H).

1 (M = W): the same procedure as **1** (M = Mo) except stirring the mixture with refluxing (yield: 63%). Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.30 (d, 8 H), 6.96 (d, 8 H), 6.51 (d, 4 H), 3.61 (d, 4 H), 3.57 (d, 4 H), 3.03 (d, 4 H), 1.22 (br, 72 H), 0.67 (t, 12 H).

2 (M = Mo): a green solution of **1** (M = Mo) (260 mg, 0.17 mmol) in 8 ml of pyridine was refluxed for 0.5 h, the resulting amber solution was cooled and allowed to stand at room temp. overnight to yield amber crystals of **2**·4py (M = Mo) (203 mg, yield: 65%), which were suitable for X-ray analysis. Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.24 (s, 16 H), 5.29 (d, 8 H), 3.34 (d, 8 H), 1.58 (s, 12 H), 1.23 (s, 72 H). Yellow solid **2** (M = Mo) can be also prepared by addition of an excess of $NHMe_2$ to **3** (M = Mo).

3 (M = Mo): a reaction mixture of $Mo_2(OBu^t)_6$ (202 mg, 0.32 mmol) and H_4L (326 mg, 0.50 mmol) in 10 ml of toluene was stirred at room temp. for 2 days. The volatile components were removed *in vacuo* and the residue was suspended in hexanes to give a pale brown precipitate **3** (M = Mo), which was collected and dried *in vacuo* (336 mg, yield: 91%). Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.09 (s, 16 H), 5.17 (d, 8 H), 3.39 (d, 8 H), 1.12 (s, 72 H).

3 (M = W): the same procedure as **3** (M = Mo), (yield: 86%). Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.10 (s, 16 H), 5.14 (d, 8 H), 3.39 (d, 8 H), 1.12 (s, 72 H).

2 (M = W): $NHMe_2$ (2.4 mmol) was added to the frozen reddish brown solution of **3** (M = W) (480 mg, 0.29 mmol) at −196 °C employing a calibrated gas manifold. After the solution was warmed to room temp., the green precipitate **2** (M = W) was collected and dried *in vacuo* (482 mg, yield: 95%).

4 (M = W): a reaction mixture of **2** (M = W) (105 mg, 0.060 mmol) and **3** (M = W) (100 mg, 0.060 mmol) in 10 ml of benzene was stirred at room temp. The green solid was gradually dissolved in solution, and the brown solution turned green. After 3 h, the volatile components were removed *in vacuo* and the residue was suspended in hexanes to give a pale green precipitate **4** (M = W), which was collected and dried *in vacuo* (186 mg, yield: 89%). Recrystallization in benzene afforded green crystals of **4**·7C_6H_6 (M = W) suitable for X-ray analysis. Selected ^{1}H NMR data (300 MHz, C_6D_6): δ 7.20 (s, 16 H), 5.18 (d, 8 H), 3.42 (d, 8 H), 1.45 (br, 6 H), 1.20 (s, 72 H).

§ *Crystal data*: for **1**·4thf (M = Mo): T = −170 °C monoclinic, space group $P2_1$, a = 13.105(4), b = 18.631(6), c = 20.543(6) Å, β = 94.04(2)°, Z = 2. Final residuals are $R(F)$ = 0.067 and $R_w(F)$ = 0.066 using 7500 observed data.

For **1**·*x*thf (M = W): T = −170 °C: a = 13.08(2), b = 18.61(3), c = 20.60(3) Å, β = 94.03(3)°. Collection of diffraction data was not processed because of the poor quality of the crystal.

For **2**·4py (M = Mo): T = −170 °C, monoclinic, space group $P2_1/n$, a = 12.384(2), b = 22.130(3), c = 18.621(3) Å, β = 100.26(1)°, Z = 2. Final residuals are $R(F)$ = 0.059 and $R_w(F)$ = 0.058 using 4799 observed data.

For **4**·7C_6H_6 (M = W): T = −168 °C, orthorhombic, space group *Pnma*, a = 25.421(3), b = 34.611(3), c = 13.113(1) Å, Z = 4. Final residuals are $R(F)$ = 0.058 and $R_w(F)$ = 0.052 using 6231 observed data. CCDC 182/704.

The title molecule, which is obtained as the tetraphenylphosphonium salt following the reaction of InBr and $HCBr_3$, is shown to involve pseudo-tetrahedral carbon and indium(III) sites; it is a member of a series of related $[H_{4-n}C(InBr_3)_n]^{n-}$ anions.

There is increasing interest in the synthesis and structural investigation of complexes in which metal atoms cluster around a centre which may be metallic or non-metallic. Schmidbaur[1] has reviewed his extensive work on molecules in which $[(R_3P)Au]^+$ and similar gold(I) cations are bonded to a large variety of such centres, and has emphasized the important isolobal relationship between LAu^+ and the H^+ and R^+ cations.[2]

In earlier papers, the reactions of indium(I) halides (InX, X = Cl, Br, I) with halogenomethanes were shown to proceed *via* oxidative addition to give neutral derivatives of X_2InCH_2X and $X_2InCH_2InX_2$ and the anionic complexes $[X_3InCH_2X]^-$ and $[H_2C(InX_3)_2]^{2-}$ have also been reported, although not for all X.[3,4] We have now prepared the salt $[PPh_4]_3[HC(InBr_3)_3]$, and established its structure. The room temperature reaction between InBr and $CHBr_3$ (1 : 3 mole ratio, mmol quantities) in 1,4-dioxane (diox) gave, on work-up, a colourless solid, shown to be the 1 : 1 adduct $Br_2InCHBr_2$·diox. (Calc. for $C_5H_9O_2Br_4In$, In 21.4. Found: In 21.2%) ^{1}H NMR [$(CD_3)_2SO$] δ 5.36 (s, 1 H, CH), 3.60 (m, 8 H, diox). ^{13}C NMR [$(CD_3)_2SO$] δ 37.31 (CH), 67.77 (diox). This was redissolved in dioxane and treated with 2 equiv. of InBr, to give an oil, which was dissolved in acetonitrile; addition of PPh_4Br, concentration and crystallization from MeCN–ethanol gave $[PPh_4]_3[HC(InBr_3)_3]$ **1** in 84% yield.† It seems very probable that the reaction proceeds by successive oxidative additions, with the related $Br_2InCHBr_2$ and $(Br_2In)_2CHBr$ species as intermediates.

The structure of the anion of **1** is shown in Fig. 1.‡ The In–Br bond distances are similar to those for other inorganic and organometallic compounds of indium(III) [*e.g.* $InBr_4^-$, r = 2.479(2);[5] $Br_3InCH_2PPh_3$, r = 2.512(2);[3] Br_3InCH_2(tmtu), r = 2.517(6) Å (tmtu = 1,1,3,3-tetramethyl-2-thiourea)[6]], as are the In–C distances; the lengthening of the In–Br bonds relative to those in the neutral ylide adducts is ascribed to the repulsive effect of the triple negative charge on this molecule. The sum of the angles in a tetrahedral MX_4 molecule is 657°, and in the present case the corresponding sums at the three indium atoms are 655.1, 655.5 and 654.4°, respectively, so that these are pseudo-tetrahedral sites, as in the molecules previously noted. The In–C–In angles lead to a similar conclusion for the carbon atom of this molecule.

This anion can be regarded as a member of the series $[H_{4-n}C(InBr_3)_n]^{n-}$. The salts of $H_3CInX_3^-$ have been known for some time,[7] and crystallographic studies of $[H_3CInCl_3]^-$ and $[C_2H_5InI_3]^-$ have confirmed the pseudo-tetrahedral symmetry at metal and carbon atoms in such anions.[8,9] As noted above, the anions $[H_2C(InX_3)_2]^{2-}$ have also been prepared; the structure of the neutral adducts such as (tmen)$Cl_2InCH_2InCl_2$(tmen) (tmen = *N*,*N*,*N*′,*N*′-tetramethylethanediamine) demonstrates the presence of the central $H_2C(InX_2)_2$ group.[10] The series is therefore complete except for n = 4; work on this is proceeding.

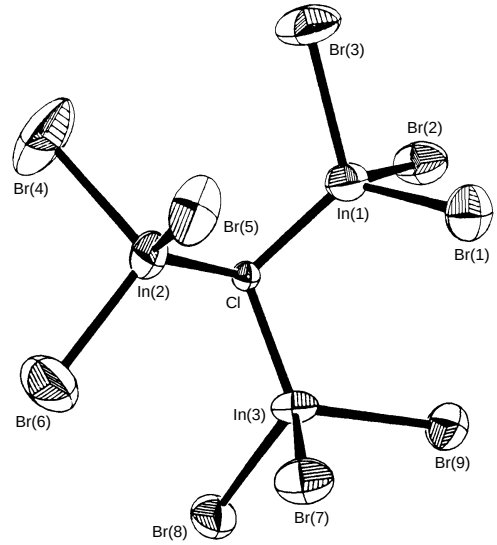

Fig. 1 Molecular structure of the $[HC(InBr_3)_3]^{3-}$ anion, showing 30% probability ellipsoids. Selected bond distances (Å) and bond angles (°): In(1)–Br (av.) 2.545, In(2)–Br (av.) 2.526, In(3)–Br(av.) 2.546, overall In–Br range 2.518(6)–2.560(5), In–C 2.11(3), 2.13(3), 2.17(3); Br–In(1)–Br (av.) 103.0, Br–In(2)–Br (av.) 104.0, Br–In(3)–Br 102.1, overall range 98.9 (2)–106.92(2), In–C–In 115(2), 112(1), 113(1).

It seems probable that similar series can be prepared with other metallo-ligands of main group elements. In particular, some members of the series of tin compounds $H_{4-n}C(SnMe_3)_n$ are already known, and analogous sets of related compounds are easily formulated, at least on paper. We also note the existence of complexes such as $[Pt(SnCl_3)_5]^{3-}$, in which the trichlorostannate group acts as an anionic ligand, and it could well be that analogous species with InX_3^- ligands will be accessible.

This work was supported in part by operating grants (to C. P.) for the Conselho Nacional de Desenvolvimento Cientifico e Tecnologico do Brasil, and by Research Grants (to D. G. T.) from the Natural Sciences and Engineering Research Council of Canada. J. A. Nobrega thanks CAPES (Brazil) for the award of a scholarship.

New synthesis of Fischer-type hydrazino(alkyl) complexes. First X-ray characterisation of a chelate hydrazino derivative

Emanuela Licandro,*[a] Stefano Maiorana,[a]† Raffaella Manzotti,[a] Antonio Papagni,[a] Dario Perdicchia,[a] Mary Pryce,[b] Antonio Tiripicchio*[c] and Maurizio Lanfranchi[c]

[a] *Dipartimento di Chimica Organica e Industriale, Università degli Studi di Milano, via C. Golgi, 19, I-20133 Milan, Italy*

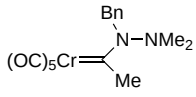
The first Fischer-type hydrazino(methyl)carbene complex has been synthesized from the appropriate acetylhydrazine and $Na_2Cr(CO)_5$; the new complex has some peculiar features in comparison with aminocarbene complexes: (i) the *E* rotamer can be completely transformed into the *Z* rotamer through the formation of its anion, and (ii) as a result of a thermal reaction, the *Z* isomer affords a new unusual chelate hydrazino(methyl)carbene complex that can be mono- or di-alkylated.

Only a few hydrazinocarbene complexes have so far been reported in the literature.[1] This is certainly due to the very limited applicability of the hydrazinolysis reaction of alkoxycarbenes,[2] which seems to be partially successful only in the case of alkynyl carbene complexes.[1b]

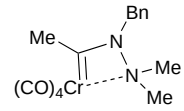
Alkyl(hydrazino)carbene complexes are unknown and could in principle have some unique features due to the potential of the β-nitrogen of the hydrazine moiety as a coordinating group to the metal, and the influence of this coordination on the stereodynamic properties of the complex and the reactivity of the α-carbanions.

We here report the synthesis of the first hydrazino(methyl)carbene complex **1**, its thermally promoted transformation, and the reaction of its anion with electrophiles. The



1

apparently simple but long-standing problem associated with the controlled synthesis of alkyl (hydrazino)carbene complexes has been solved by extending the known Hegedus method[3] for preparing amino carbene complexes from amides to hydrazide derivatives. The hydrazide **2** was reacted with disodium pentacarbonylchromate,[3] affording complex **1** as a 1 : 1.3 *E* : *Z* rotameric mixture (Scheme 1).‡ The (*E*)-**1** and (*Z*)-**1** rotamers were fully characterized after chromatographic separation over silica gel. Rotamer (*E*)-**1** proved to be thermally stable, remaining unchanged after heating in hexane at 50 °C for 2 h whereas, after heating at 39 °C in CH_2Cl_2 for 3.5 h, (*Z*)-**1** was transformed into a new, red–orange solid complex, **3**‡ with the



3

displacement of a CO ligand. As far as we know, only one example of an *N*-chelate complex with a four-membered ring has been previously reported.[4] The structure of **3** was supported by the X-ray analysis of the structure of the homologue **5a**§ whose formation is described below (Scheme 2). The pure rotamers (*E*)-**1** and (*Z*)-**1** were treated with Bu^nLi at −70 °C and quenched with a saturated aq. NH_4Cl; rotamer (*E*)-**1** was completely transformed into rotamer (*Z*)-**1**, whereas the latter proved to be configurationally stable. The complete conversion of (*E*)-**1** into (*Z*)-**1** is rather surprising since this transformation is usually incomplete in aminocarbene complexes and generally leads to a mixture of the two rotamers. The treatment of the anion generated from the pure (*E*)-**1** or (*Z*)-**1** rotamers with alkylating reagents such as iodomethane and allyl bromide gave the expected ethyl(hydrazino)carbene complexes (*Z*)-**4a** and (*Z*)-**4b**, together with the tetracarbonyl *N*-chelate derivatives **5a** and **5b** (Scheme 2).‡ It can be seen that the formation of the coordinated derivatives **3**, **5a** and **5b** is easier as the bulk of the α- substituent increases (Me < Et < allyl). Column chromatography over silica gel gave pure samples of the complexes **5a** and **5b**, whereas complexes **4a** and **4b** were always recovered in the form of mixtures with **5a** and **5b** respectively.‡ Unlike an amino(ethyl)carbene complex, the ethyl(hydrazino)carbene **5a** can easily be further alkylated with MeI to give complex **6** (Scheme 3).‡ Compound **5a** is the first structurally characterized chelate hydrazinocarbene complex (see Fig. 1). The coordination around Cr is distorted octahedrally, with the organic moiety acting as a chelating ligand through N(1) and C(5). The four-membered ring is planar, and the chelation N(1)–Cr–C(5) angle is very narrow at 62.9(2)°. Although the Cr–N bond length of 2.211(4) Å is comparable with the average

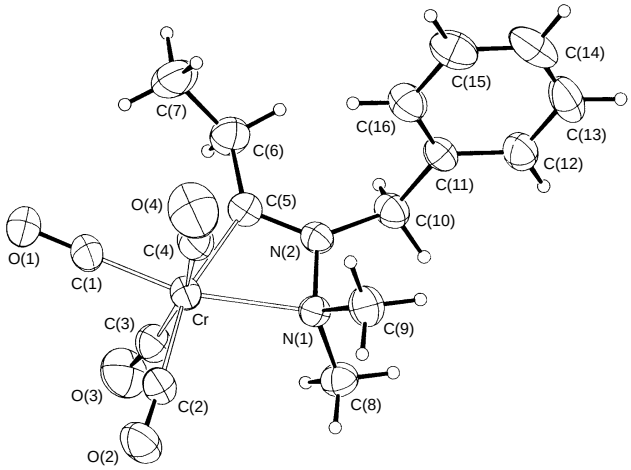

Fig. 1 View of the molecular structure of complex **5a** together with the atomic numbering system. Selected bond distances (Å) and angles (°): Cr–C(5) 2.028(4), Cr–N(1) 2.221(4), C(5)–N(2) 1.308(7), N(1)–N(2) 1.451(5), N(2)–C(10) 1.481(6), C(5)–C(6) 1.494(7); N(1)–Cr–C(5) 62.9(2), Cr–C(5)–N(2) 101.3(3), Cr–N(1)–N(2) 88.5(2), N(1)–N(2)–C(5) 107.3(3), N(1)–N(2)–C(10) 120.8(3), C(5)–N(2)–C(10) 131.8(4).

value found in complexes of Cr^0 with tertiary amines (2.21 Å), the 2.028(4) Å Cr–C(5) bond length is much shorter than those found in aminocarbene complexes of Cr^0 (in the range of 2.123–2.156 Å).[5] This means that the Cr–C(5) bond has a more noticeably double bond character than the other aminocarbene complexes. It is also worth noting that the 1.813(6) Å Cr–C(1) bond involving the carbonyl *trans* to the aminic N(1) atom is shorter than other Cr–C(carbonyl) bonds [in the range 1.871(5)–1.882(5) Å].

On the origin of the *endo*/*exo* selectivity in Diels–Alder reactions

D. Suárez and J. A. Sordo*

Departamento de Química Física y Analítica, Facultad de Química, Universidad de Oviedo, Julián Clavería 8, 33006 Oviedo, Principado de Asturias, Spain

The *endo*/*exo* selectivity in Diels–Alder reactions is analyzed in terms of the pre-reactive van der Waals complexes located on the potential energy surface.

The Diels–Alder reaction has been the subject of a wide variety of both experimental and theoretical studies.[1] Of particular relevance from the mechanistic viewpoint is the explanation of the observed *endo*/*exo* selectivity. As established from the very beginning, there is usually a preference for the *endo* adducts (*endo* Alder rule[2]). Such an *endo* preference has been ascribed to quite different factors.[3] On the other hand, the first documented example of regiospecifity of Diels–Alder reactions being primarily controlled by the dispersion (attractive van der Waals) interactions has been recently reported by Cioslowski *et al.*[4] Additional work in this direction was announced by Gillies *et al.*[5b]

The above explanations have in common that they all focus on the transition structures. The impressive advances in the last two decades leading to the development of rather sophisticated spectroscopic techniques, including Raman, microwave and infrared spectrocopies,[5c] have made it possible to gain a deeper insight into the nature of van der Waals interactions, and it has been recently recognized[5b] that the formation of van der Waals systems in the very early (pre-reactive) stages of certain cycloaddition reactions can exert a significant influence upon the stereochemical outcome. Gillies *et al.* concluded[5b] that it is possible to relate the geometry of van der Waals intermediates to the geometry of the transition structure and the product of certain cycloaddition reactions. Recent findings using intermolecular perturbation theory[6] seem to provide further support to this point. Here, theoretical evidence is presented showing the important role that pre-reactive van der Waals complexes, present in the potential energy surface, might play in determining the stereochemical outcome of Diels–Alder reactions. The prototype reaction between cyclopentadiene and maleic anhydride has been investigated.

The geometries of the significant structures located at the MP2/6-31G* level on the potential energy surface of the Diels–Alder reaction between cyclopentadiene and maleic anhydride: three van der Waals intermediates (**vdW1** and **vdW2**, leading to the *endo* and *exo* transition structures, respectively, and **vdW3**, showing a T-shaped structure intermediate between **vdW1** and **vdW2**), two van der Waals transition structures connecting **vdW1** and **vdW3** (**vdW1** → **3**) and **vdW2** and **vdW3** (**vdW2** → **3**), and two transition structures leading to the *endo* (**TS1**) and *exo* (**TS2**) products (**P1** and **P2**), are not presented because of space limitations but are available upon request. All these structures were characterized by computing the Hessian matrix (at the HF level) and checking the sign of the corresponding eigenvalues. Table 1 collects the energy results, which include single-point calculations at the MP4SDQ/6-31G* level and an estimate of the solvent effects. In cycloaddition reactions between ethylene and ozone, occurring both in the gas phase and in condensed media, a van der Waals (pre-reactive) intermediate was experimentally detected in the gas phase[5] (where rather sophisticated spectroscopic techniques are available). It is difficult to make *a priori* predictions about the role played by different solvents on the stabilization/destabilization[7a] (a detailed discussion on this point for a reaction involving a *zwitterionic* intermediate can be found elsewhere[7b]) of these van der Waals intermediates (exploratory calculations using a model where the solvent is represented by a dielectric continuum characterized by its static dielectric permittivity[7c] ε_0, suggest that the energy changes introduced by the solvent are not too drastic, see Table 1, but there is experimental evidence for the important role played by van der Waals interactions in Diels–Alder reactions in solution.[4]

In Fig. 1 a simplified scheme of the potential energy surface is presented. Examination of this figure suggests that the van der Waals structures might play a decisive role in determining the stereochemical outcome of Diels–Alder reactions. Indeed, the *endo*/*exo* ratio is related to the barrier $\Delta\Delta E^{\neq}$(**vdW**) = [E(**TS2**) − E(**vdW2**)] − [E(**TS1**) − E(**vdW1**)]. If the van der Waals structures were not present in the potential energy surface the *endo*/*exo* ratio should be computed as $\Delta\Delta E^{\neq}$(**R**) = [E(**TS2**) − E(**R**)] − [E(**TS1**) − E(**R**)] (R = reactants). In the present case (at the MP4SDQ/6-31G*//MP2/6-31G* level of theory), $\Delta\Delta E^{\neq}$(**R**) = 2.1 kcal mol^{-1} (97.1% *endo* at 298 K) and $\Delta\Delta E^{\neq}$(**vdW**) = 2.6 kcal mol^{-1} (98.8% *endo* at 298 K); the greater stability of **vdW2** leading to the *exo* transition structure **TS2** enhances the *endo* preference. The experimental *endo* preference is[8] 2.5 kcal mol^{-1} (98.5% *endo* at 298 K). It is important to remark that, while $\Delta\Delta E^{\neq}$(**R**) is affected by the basis set superposition error (BSSE)[9] [consideration of the BSSE by means of the *counterpoise* procedure,[9] including fragment relaxation terms,[10] gives $\Delta\Delta E^{\neq}$(**R**) = 2.0 kcal mol^{-1} (96.5% *endo* at 298 K), moving away from the experimental

Table 1 Relative Energies (including zero point energy correction from HF/6-31G* frequencies) of van der Waals intermediates, transition structures and products with respect to reactants for the [4 + 2] cycloaddition reaction between cyclopentadiene and maleic anhydride. Geometries were optimized at the MP2/6-31G* theory level (single-point SCRF = self-consistent-reaction field calculations to estimate electrostatic solvent effects). Relative energies of the Diels–Alder transition structures with respect to the corresponding van der Waals intermediates are shown in parentheses

	Relative energy/kcal mol^{-1}		
	MP2/6-31G*	MP2/6-31G* (SCRF[a] ε_0 = 2.24[b])	MP4SDQ/6-31G*
vdW1 *endo*	−7.4	−7.0	−3.8
TS **vdW1** → **3**	−3.2	−2.9	−2.1
vdW3	−4.2	−3.8	−3.2
TS **vdW2** → **3**	−4.1	−3.7	−3.1
vdW2 *exo*	−6.6	−5.9	−4.3
[4 + 2] **TS1** *endo*	−0.4 (7.0)	−0.8 (6.2)	14.1 (17.9)
[4 + 2] **TS2** *exo*	1.9 (8.5)	1.8 (7.7)	16.2 (20.5)
[4 + 2] *endo* Adduct **P1**	−34.1	−33.8	−29.0
[4 + 2] *exo* Adduct **P2**	−34.5	−34.0	−29.6

[a] See ref. 7(*d*) for an excellent example of how the estimate of barriers in solution by means of single-point SCRF calculations are approximate but useful indicators of energetic trends. [b] A relative permittivity of 2.24 was used to simulate benzene, which has been used as solvent in this reaction (see ref. 8).

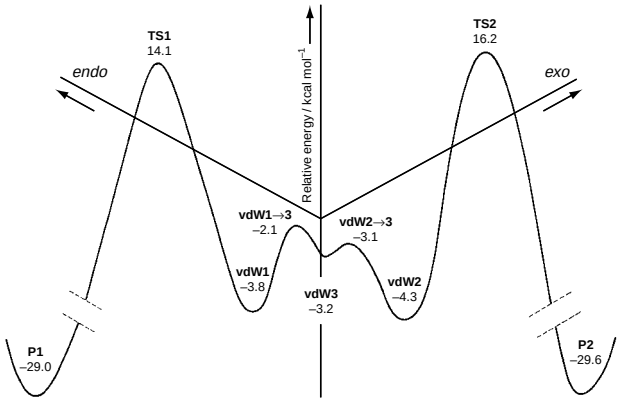

Fig. 1 Simplified scheme of the potential energy surface corresponding to the Diels–Alder reaction between cyclopentadiene and maleic anhydride

value], $\Delta\Delta E^{\neq}$(**vdW**) is BSSE free.[11]. It is important to stress at this point that the above results are consistent with the so-called Curtin–Hammett principle,[12] which states that when the barriers involving the **vdW** systems in Fig. 1 are much lower than the reaction barriers **TS1** and **TS2**, then the (*endo*/*exo*) product ratio depends only upon the difference in energy of the transition structures **TS1** and **TS2**. In the present case, the Curtin–Hammett principle should apply (see Fig. 1) and the *endo*/*exo* ratio could be estimated from $\Delta\Delta E^{\neq}$(**R**), in agreement with the above results [*i.e.* $\Delta\Delta E^{\neq}$(**vdW**) $\approx$ $\Delta\Delta E^{\neq}$(**R**)].

Although the difference between $\Delta\Delta E^{\neq}$(**R**) and $\Delta\Delta E^{\neq}$(**vdW**) is not (quantitatively) drastic in the present case, it must be stressed that a detailed inspection of the potential energy surface shows that consideration of the van der Waals structures is strictly needed to avoid serious topological inconsistencies in the computed potential energy surface. Indeed, at the MP2/6-31G* level, where optimizations were carried out, the **TS1** and **TS2** structures (without taking into account the zero-point energy correction) are energetically lower than reactants and higher than products (the energies relative to reactants are −2.3 and −0.1 kcal mol^{-1} for **TS1** and **TS2**, respectively). Therefore, if the van der Waals intermediates were not considered, **TS1** and **TS2** would not be maximums along the reaction paths and, consequently, they could not be real transition structures (saddle points separating two energy minima) in clear contradiction with the information provided by the Hessian matrix (see above). Of course, consideration of the van der Waals structures reported in this work indicates that **TS1** and **TS2** are saddle points connecting two minima (*i.e.* transition structures): **vdW1** and **P1**, and **vdW2** and **P2**, respectively (the energies of **TS1** relative to **vdW1**, and of **TS2** relative to **vdW2**, without considering the zero-point energy correction, are both positive: +7.4 and +9.1 kcal mol^{-1}, respectively).

Finally, we would like to make a short comment on the nature of the interaction in the van der Waals intermediates and transition structures. The application of a configurational analysis on the corresponding wave functions[13] shows that for **TS1** and **TS2** the most significant contributions, apart from the zero configuration AB (A = cyclopentadiene, B = maleic anhydride) come from the HOMO(cyclopentadiene) $\rightarrow$ LUMO(maleic anhydride) ($w \approx 0.35$)† A^+B^- and HOMO-(maleic anhydride) $\rightarrow$ LUMO(cyclopentadiene) ($w \approx 0.15$) A^-B^+ (back donation[14]) monotransferred configurations. The same kind of interactions, with smaller weights ($w \approx 0.10$, A^+B^-, and $w \approx 0.02$, A^-B^+) are already present in the van der Waals intermediates **vdW1** and **vdW2**. Therefore, in agreement with previous suggestions,[5] the present calculations show that the (pre-reactive) van der Waals intermediates are located at the entrance of the cycloaddition reaction (*endo*/*exo*) channels, thus being precursors to the actual Diels–Alder products.

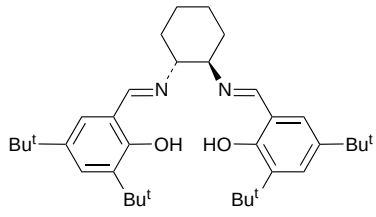
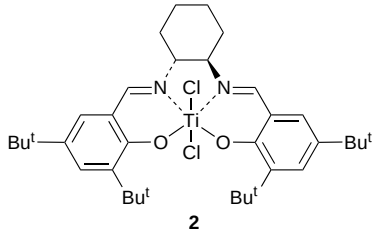
Titanium complex $TiCl_2L$ [H_2L = (*R*,*R*)-*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)hexane-1,2-diamine] 2 has been prepared, characterised by X-ray crystallography and shown to be an active catalyst for the asymmetric addition of Me_3SiCN to benzaldehyde, producing (*S*)-2-phenyl-2-trimethylsilyloxyacetonitrile in 86% ee at room temperature.

Enantiomerically pure cyanohydrins are important synthetic intermediates in the synthesis of other chiral compounds and hence are of significant industrial importance.[1] A number of catalytic methods have been reported for the asymmetric synthesis of cyanohydrins, including the use of enzymes, peptides and transition metal complexes.[2] Recently, we reported the use of chiral Ti^{IV} (salen)$(OPr^i)_2$ complexes as chiral catalysts for the asymmetric addition of Me_3SiCN to aldehydes,[3] and related work has been reported by other workers.[4] Whilst some of these catalysts have given cyanohydrin silyl ethers with > 90% ee, the structures of the catalysts have never been determined and this has restricted mechanistic investigations aimed at further improving the enantiomeric excesses and substrate tolerance. The catalysts have generally been prepared *in situ* by mixing a chiral ligand and titanium(IV) species. In the case of ligand **1**–$Ti(OPr^i)_4$ we have shown that at least three species can subsequently be detected by NMR spectroscopy.[5] Here we describe the synthesis of the first isolable and characterisable catalyst for the asymmetric addition of Me_3SiCN to benzaldehyde.



1



2

Reaction of ligand **1**[6] with titanium(IV) chloride in CH_2Cl_2 at room temperature for 2 h followed by evaporation of the solvent *in vacuo* and washing of the solid with Et_2O and Et_2O–hexane (1 : 1) gave a brown solid of structure **2** which could be recrystallised from $CHCl_3$. The spectral (^1H and ^{13}C NMR, IR) properties of compound **2** {$[\alpha]_D^{22}$ +736 (*c* 0.0125, $CHCl_3$), mp 330 °C (decomp.)} were entirely consistent with a single species of the proposed structure, and the monomeric nature and geometry of compound **2** were proven by X-ray structure analysis‡ (Fig. 1). Compound **2** has two independent molecules in the crystals, both with the *R*,*R* configuration and comparable geometry parameters. Each molecule adopts a slightly distorted octahedral geometry in which the two chlorine atoms are repelled by the *tert*-butyl groups (Cl–Ti–Cl bond angle ≈ 169°). Although X-ray structures of similar achiral titanium complexes have been reported,[7] only one other example of the X-ray structure of a monomeric, chiral (salen) titanium complex has been reported,[8] and in that case the salen ligand did not adopt four equatorial positions around the titanium.[9]

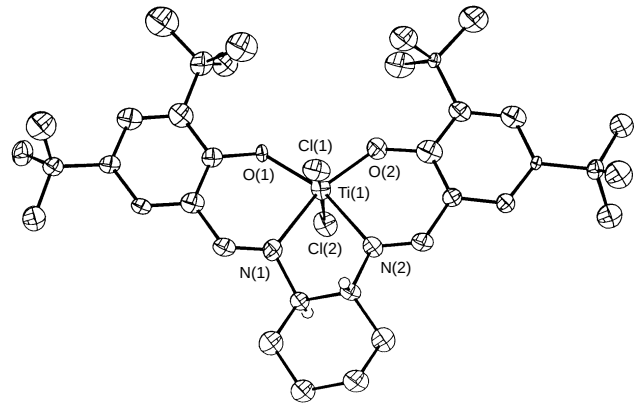


Fig. 1 Solid state structure of one independent molecule of **2**. Thermal ellipsoids are drawn at 50% probability. The structure of the other molecule is closely similar.

Compound **2** was active as a catalyst for the asymmetric addition of Me_3SiCN to benzaldehyde (Scheme 1). Thus treatment of a CH_2Cl_2 solution of benzaldehyde and Me_3SiCN (2.3 equiv.) with complex **2** (0.1 mol%) at room temperature resulted after 24 h in complete conversion of the benzaldehyde to (*S*)-2-phenyl-2-trimethylsilyloxyacetonitrile **3** in 86% ee, as determined by chiral gas chromatography. It is notable that catalyst **2** is active at room temperature and at very high substrate to catalyst ratios, results which contrast with previously reported catalysts for this reactions.[2–4]

Two versatile new routes to dinuclear molybdenum dithiolene complexes

Andrew Abbott,[a] Matthew N. Bancroft,[a] Michael J. Morris,*[a] Graeme Hogarth[b] and Simon P. Redmond[b]

[a] *Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*
[b] *Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

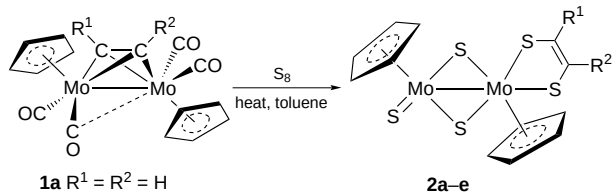
Two routes to the dithiolene complexes [$Mo_2S(\mu\text{-}S)_2(SCR^1{=}CR^2S)(\eta\text{-}C_5H_5)_2$] starting from the complexes [$Mo_2(\mu\text{-alkyne})(CO)_4(\eta\text{-}C_5H_5)_2$] are described; in one case the dithiolene ligand is derived from the alkyne, and in the other from a 1,3-dithiole-2-thione reagent.

A combination of techniques have indicated that the molybdenum atom in the molybdenum cofactor (Moco) common to a range of oxotransferase enzymes is coordinated by a pterin ligand which is bonded through a dithiolene linkage.[1] Recent protein crystallographic studies, however, have shown that in some of these enzymes the metal atom is ligated by one dithiolene ligand whereas in other cases, unexpectedly, two such ligands were present.[2] Molybdenum (and tungsten) dithiolene complexes have been known for many years,[3] and are of continuing interest as model systems for the metal site in the cofactor.

Here, we describe two versatile routes to dimolybdenum complexes containing terminal dithiolene or tetrathiooxalate ligands, both of which start with the alkyne complexes [$Mo_2(\mu\text{-}R^1C{\equiv}CR^2)(CO)_4(\eta\text{-}C_5H_5)_2$] **1a–e**. We have recently shown that reactions of these compounds with thiols often proceed with C–S bond cleavage to give sulfido-bridged species.[4] In contrast, it is notable that the reactions discussed here involve the formation of C–S bonds as well as their scission.

In the first approach we found that heating a toluene solution of **1** with elemental sulfur for 5 h provided the green dithiolene complexes [$Mo_2S(SCR^1{=}CR^2S)(\mu\text{-}S)_2(\eta\text{-}C_5H_5)_2$] **2a–e** in yields of up to 80% after isolation by column chromatography (Scheme 1). Five representative examples are given but the reaction works equally well with other complexes of type **1**. Complex **2c** and the corresponding oxo species [$Mo_2O(SCH{=}CPhS)(\mu\text{-}S)_2(\eta\text{-}C_5H_5)_2$] **3** have been prepared previously by a different route,[5] but in contrast to this report we find that complexes of type **2** are not particularly air sensitive even in solution, and only slowly convert into the oxo complexes analogous to **3**; small amounts of these were isolated from some reactions.

The dithiolene compounds were characterised spectroscopically (and by comparison with the published values for **2c**, for which our data agree exactly).† In the ^1H NMR spectrum each complex displays two rather widely separated signals for the C_5H_5 rings and appropriate resonances for the substituents R^1 and R^2. In the complexes derived from terminal alkynes, the signal for the CH group appears shifted downfield at δ 8–9. This is a characteristic feature of terminal dithiolene complexes and can be regarded as arising either from the contribution of a dithioglyoxal canonical form[6,7] or the presence of a ring current in the pseudo-aromatic metalladithiolene unit.[8] Interestingly the products all gave high intensity molecular ions in their electron impact mass spectra, but most evidently disintegrated completely when subjected to fast atom bombardment (FAB).



1a $R^1 = R^2 = H$
b $R^1 = H$, $R^2 = Me$
c $R^1 = H$, $R^2 = Ph$
d $R^1 = R^2 = Et$
e $R^1 = R^2 = CO_2Me$

2a–e

Scheme 1

The result of an X-ray crystal structure determination of **2a** is shown in Fig. 1.‡ The molecule is based on a dimolybdenum centre with a metal–metal distance of 2.984(1) Å, which is similar to that of 2.927(1) Å observed in [$Mo_2O(SCH{=}CPhS)(\mu\text{-}S)_2(\eta\text{-}C_5H_5)_2$] **3**.[5] The coordination geometry in the two complexes is also very similar. Thus Mo(1) has a pseudo-tetrahedral coordination (if the C_5H_5 ligand is regarded as occupying one site) whereas Mo(2) is in a square pyramidal environment. The $Mo_2(\mu\text{-}S)_2$ core is not planar: the dihedral angle between the two intersecting Mo_2S planes is 161.3°, whereas in **3** the corresponding angle is 144.6°. This contrasts with related Mo^V dimers with imido ligands, *e.g.* [$Mo_2(NPh)_2(\mu\text{-}NPh)_2(\eta\text{-}C_5H_4Me)_2$] which all contain strictly planar cores.[9]

The bond lengths between Mo(2) and the bridging sulfur atoms are significantly longer than the distances from Mo(1) to the same sulfurs. Together with the rather short S(4)–C(11) and S(5)–C(12) bonds within the dithiolene ligand itself, this could be regarded as evidence for some contribution of the dithioglyoxal canonical form: if the dithiolene ligand is dianionic, each Mo atom is formally Mo^V, but if it is bonded in the dithioglyoxal form, Mo(2) would be formally Mo^{III}. Again an alternative interpretation is that the dithiolene ligand acts as a delocalised 6π pseudo-aromatic system which is a better π-donor than the sulfide ligand on Mo(1).

Our second approach is shown in Scheme 2. We recently reported that alkyne complex **1e** reacted with 1,3-dithiole-2-thiones by cleavage of the C=S bond, ring opening of the resulting carbene and coupling with the alkyne ligand to

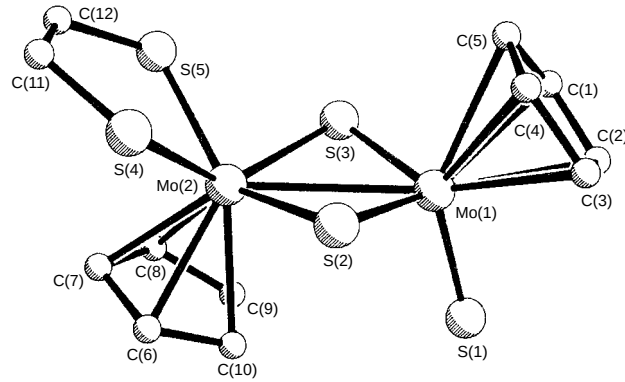


Fig. 1 Molecular structure of complex **2a** in the crystal. Selected bond lengths (Å): Mo(1)–Mo(2) 2.984(1), Mo(1)–S(1) 2.154(1), Mo(1)–S(2) 2.263(1), Mo(1)–S(3) 2.263(1), Mo(2)–S(2) 2.406(1), Mo(2)–S(3) 2.398(1), Mo(2)–S(4) 2.387(1), Mo(2)–S(5) 2.384(1), S(4)–C(11) 1.708(5), S(5)–C(12) 1.705(4), C(11)–C(12) 1.348(7).

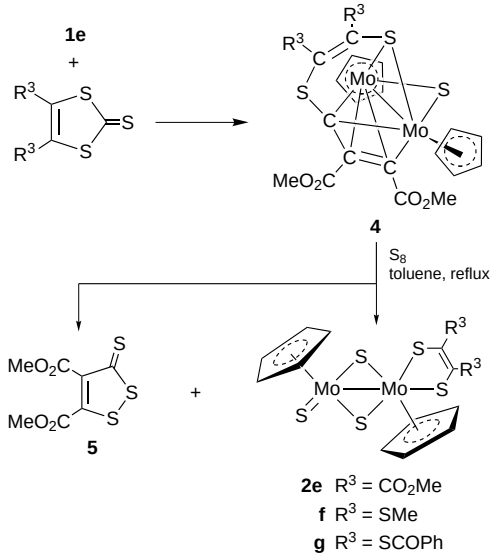

Scheme 2

produce complexes of type **4** (R^3 = CO_2Me, SMe, SCOPh).[10] Remarkably, we have now discovered that these compounds also react rapidly (2 h) with elemental sulfur in boiling toluene to give dithiolene complexes **2e**–**g**, in which the dithiolene ligand originates from the backbone of the original thione rather than the alkyne. Compounds **2f** and **2g** are rare examples of dialkyl- and diacyl-tetrathiooxalate (or ethenetetrathiolate) complexes respectively.

The alkyne ligand is recovered in the form of the interesting new sulfur heterocycle **5**, a hitherto inaccessible derivative of the important 1,2-dithiole-3-thione ring system.[11] Indeed, in the case of R^3 = CO_2Me, the reaction represents an elaborate isomerisation of the 1,3-dithiole-2-thione ring. The mechanism presumably involves insertion of three sulfur atoms into the Mo–C bonds of the bridging ligand of **4**, cleavage of the μ-C–S bond to afford the dithiolene ligand, and reductive elimination of the organic by-product **5**. It is notable that this process reforms the thione unit which is cleaved during the formation of **4**.

In summary, the two synthetic routes described here are complementary: simple dithiolene ligands are easily accessed from the appropriate alkyne by the first method, whereas in the second case the availability of convenient synthetic procedures for a large number of requisite thiones, which are readily made by alkylation or acylation of $[NEt_4]_2[Zn(C_3S_5)_2]$, should enable the introduction of a wide variety of more complex substituents including functionalised derivatives such as crown ethers, macrocycles, *etc*. Moreover, compounds containing the 1,2-dithiole-3-thione ring system have been studied for their pharmaceutical properties, particularly as anticancer agents. We are currently exploiting this methodology to synthesize a representative range of dithiolene complexes and heterocycles for further investigation.

We thank the EPSRC for the award of a studentship (M. N. B.).

‡ *Crystal data* for **2a**: $C_{12}H_{12}Mo_2S_5$, M = 508.40, monoclinic, space group *C*2/*c* (no. 15), a = 22.2528(29), b = 11.0848(21), c = 12.9379(26) Å, β = 105.933(15)°, U = 3068.7(9) Å^3, F(000) = 1984, Mo-Kα radiation (λ = 0.710 73 Å), μ(Mo-Kα) = 22.34 cm^{-1}, Z = 8, D_c = 2.20 g cm^{-3}.

Room temperature X-ray data were collected on a Nicolet R3mV diffractometer. A total of 3937 reflections (3779 unique) were measured in the range $5 < 2\theta < 50°$ by the ω–2θ scan technique, all of which were corrected for Lorentz and polarisation effects and for absorption by analysis of ψ-scans (minimum and maximum transmission coefficients 0.806 and 0.913); 2634 data with $I \geqslant 3.0\sigma(I)$ were used in the refinement. The structure was solved by direct methods and developed by alternating cycles of least squares refinement and difference Fourier synthesis. All non-hydrogen atoms were refined anisotropically while hydrogen atoms were placed in idealised positions (C–H 0.96 Å) and assigned a common isotropic thermal parameter (U = 0.08 Å^2). The last cycle of least squares refinement included 172 parameters for 2497 variables. The final R values were R = 0.035 and R_w = 0.042 and the final difference Fourier map contained no peaks > 1.00 e Å^{-3}. The structure was solved using the SHELXTL PLUS program package[12] on a Micro Vax II computer. CCDC 182/722.

***Ab initio* MO calculations at the {MP2(fc)/6-311++G(d,p)//3-21G(*)+ZPVE[3-21G(*)]} and {MP2(fc)/D95++G(d,p)//3-21G(*)+ZPVE[3-21G(*)]} levels of sophistication and also an analogous DFT/DNP study reveal that $HAlCl_4$ has a gas phase deprotonation energy of *ca.* 264 kcal mol^{-1} (1 cal = 4.184 J) being lower than the value predicted for $HTaF_6$ (269 kcal mol^{-1}).**

Superacids are a very intriguing tool in applied experimental[1–6] and theoretical[7–9] chemistry. It was previously shown[7] by applying the density functional theory (DFT) to calculating deprotonation energies (DEs) that in the gas phase $HSbF_6$ ($HF{\cdot}SbF_5$) is the strongest acid known (DE = 258 kcal mol^{-1}), in full agreement with various investigations of the corresponding Hammett acidity function in condensed media.[4] Further, $HTaF_6$ ($HF{\cdot}TaF_5$) has been predicted to be clearly weaker[7] possessing a DE of 269 kcal mol^{-1}.

On the other hand, the place of Friedel–Crafts acid of the $HX{\cdot}AlX_3$ (X = Cl, Br) type in the acidity scale is unknown thus far. Moreover, there was a controversy more than 10 years ago[4,10,11] concerning the relative strengths of $HAlBr_4$ ($HBr{\cdot}AlBr_3$). Farcasiu *et al.*[10] argued that the latter should exhibit an acidity comparable to $HSbF_6$ since it is capable of protonating benzene at 0 °C. Kramer proposed the same ranking based on his selectivity parameter.[11] However, it was claimed[4] that $HAlBr_4$ is very unlikely comparable to $HSbF_6$ as it is incapable of protonating weak bases or ionising precursors. Although the order of acidic strength might change in solution[12] it is of principal significance to determine the DEs of $HAlCl_4$ and $HAlBr_4$. Here, quantum chemical calculations on $HAlCl_4$, $AlCl_4^-$, $AlCl_3$, HCl and Cl^- are presented, which have been used to determine the energies of the following processes. (i) The DE of the superacid, $HAlCl_4 \rightarrow H^+ + AlCl_4^-$ (1); (ii) the decomposition energy of the superacid, $HAlCl_4 \rightarrow HCl + AlCl_3$ (2); (iii) the decomposition energy of the conjugated base, $AlCl_4^- \rightarrow AlCl_3 + Cl^-$ (3) and (iv) the DE of hydrogen chloride, $HCl \rightarrow H^+ + Cl^-$ (4).

The last process is considered to obtain information of the performance of the methods used.

In order to obtain reliable results we used a suggestion of Koppel *et al.*[13] that MP2(fc)/6-311++G(d,p) perform rather well already at 3-21G [or 3-21G(*) in the cases of molecules containing second row elements] fully optimised geometries. Very recently we reported[8] on the gas phase DEs of some superacids ($HClO_4$, FSO_3H, $ClSO_3H$) applying the 6-31+G(d) basis set for calculating structures. Nevertheless, we are of the opinion now that the smaller valence basis sets also attain this objective, providing deviations from experiment of < 3 kcal mol mol^{-1};[13] at this point evidence is given of the reliability of the level of sophistication mentioned above for calculating DEs of HPF_6 ($HF{\cdot}PF_5$).[9]

The geometries for two conformations of $HAlCl_4$, *cis* and *trans*, the conjugated base $AlCl_4^-$ and also for the Lewis acid $AlCl_3$ have been fully optimised (Table 1) by using the 3-21G(*) basis set followed by vibrational analyses at the same level. All stationary points were found to be minima. Then the energies were improved by carrying out MP2(fc)/6-311++G(d,p) calculations. Since for calculating the DE the energy of the low lying conformation of $HAlCl_4$ had to be used depending on the level of investigation, the corresponding values of either *cis* or *trans* geometry have been employed. Nevertheless, both conformations are almost equal in stability and, therefore, DE is practically unaffected by the energy chosen for the acid.

Details on current *ab initio* MO theory and common standard procedures are given elsewhere.[14] Furthermore, single point energy calculations have been also performed with Dunnings split valence basis set D95.[15] All *ab initio* MO calculations were performed using Hyperchem software[16] and run on a Pentium PC.

All *ab initio* DFT computations were performed with the DMol program[17] on an Indigo-2 workstation. The Becke 1988 exchange functional[18] was used in combination with the Lee–Yang–Parr correlation (LYP).[19] All electrons were taken into account and the DNP (double numeric augmented by polarization functions at both hydrogen and non-hydrogen atoms) basis set was used together with a high number of mesh points that is almost to the saturation point of the mesh grid. Completely optimised geometries as well as the corresponding energies have been calculated with this basis which is[17] comparable to 6-31G(d,p) followed by vibrational analyses. All stationary points were found to be minima. It has been shown[7] that DNP reproduces the DE of strong acids and superacids quite well.

[a] The ZPVE corrections are scaled by 0.9 for the 3-21G(*) calculations and they are unscaled when the DFT values were used. [b] Fully optimised geometries. [c] The DE when the 6-31+G(d) geometry is used. [d] Experimental values (enthalpies at 298 K) are[26] 333.4 ± 0.3 and 333.7 ± 2.2 kcal mol^{-1}.

Detailed information on the current state and performance of modern DFT theory is given in the user manual[17] and in some recent comprehensive books and papers.[20]

In order to turn out an incidental failure of the chosen procedure, the geometries have also been fully optimised employing the medium size 6-31+G(d) basis set. The gradients of the 6-311++G(d,p) energies (not given in the text) are smaller when the 3-21G(*) geometries are used and the corresponding energies (Table 1) are lower. Thus, the 3-21G(*) structures are closer to the 6-311++G(d,p) ones and they are applied throughout in this study. The DE values are practically unaffected by this difference in the geometries used. The values calculated (Table 2) are 265.0 kcal mol^{-1} (3-21G(*)) and 264.8 kcal mol^{-1} (6-31+G(d)).

It is noteworthy that the results for DE from all MO calculations rigorously depend on the size of the basis sets applied (Table 2). It was found that the MP2(fc)/6-31+(d,p) level of investigation provides a good estimate for predicting the acidity of $HAlCl_4$. On the other hand, it is remarkable that both remaining MP2 calculations provide almost identical values of DE (263.1 and 265.0 kcal mol^{-1}). Moreover, the DFT gives a value (264.1 kcal mol^{-1}) lying between the two latter ones. Thus, the mean DE of $HAlCl_4$ amounts to *ca.* 264 kcal mol^{-1}. This is less than the corresponding value for $HTaF_6$ (269 kcal mol^{-1})[7] which was obtained applying the same DFT procedure as in the present work. The order of acidity is, therefore, $HSbF_6$ > $HAlCl_4$ > $HTaF_6$ since there is a complete agreement between the experimental and DFT results of DEs on one hand[7] and the same was found for the DFT and MP2(fc)/6-311++G(d,p) sets of values, on the other hand.[8]

Beside the acidity the decomposition of the acid toward HCl and $AlCl_3$ is of interest. The positive energies for reaction (2) collected in Table 2 reveal that generation of $HAlCl_4$ is favoured, however, the values are small and indicate a weak van der Waals (vdW) interaction. Indeed, all attempts of Brown and Pearsall[21] failed to detect any complexation of $AlCl_3$ with HCl even at temperatures as low as 150 K. Many years later, however, aggregates were found[22] with a composition corresponding to $2HAlCl_4 \cdot 3Et_2O$ indicating the necessity of an auxiliary 'complexation generator'.

Finally, the stability of the anion $AlCl_4^-$ towards chloride ion detachment has been investigated (Table 2). Previously it was found[23] that the MP2/6-31+G(d) energy required to dissociate $AlCl_4^-$ in agreement with reaction (3) is 51.57 kcal mol^{-1}. The latter value is, however, erroneous. We calculated from the total energies reported[23] the correct one (77.6 kcal mol^{-1}). This result was confirmed by our calculations (Table 2).

Thus, $AlCl_4^-$ is, for example, comparable in stability to the conjugated base PF_6^- for which a fluoride ion detachment of 85 ± 10 kcal mol^{-1} was determined experimentally,[24] in complete agreement with quantum chemical calculations.[9,25]

The following significant concluding remarks can to be made. (*a*) $HAlCl_4$ belongs to the strongest superacids since its gas phase acidity is between those of $HSbF_6$ and $HTabF_6$. (*b*) The acid itself exhibits a weakly bonded vdW complex between HCl and $AlCl_3$ which is rather unstable *in vacuo* even at low temperatures. (*c*) The conjugated base ($AlCl_4^-$) is a stable species with respect to chloride ion abstraction possessing a detachment energy which is comparable to those of usual ordinary chemical bonds.

All optimised geometries are available from the authors by request. Furthermore, they will be published in a subsequent paper.

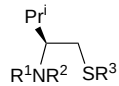
The importance of nitrogen substituents in chiral amino thiol ligands for the asymmetric addition of diethylzinc to aromatic aldehydes

James C. Anderson*† and Michael Harding

Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF

A new series of *N*,*S*-chelate ligands derived from (*S*)-valine, which possess the capability of a stereogenic nitrogen donor atom, are catalysts for the addition of diethylzinc to aromatic aldehydes and gave the product secondary alcohols in up to 82% ee.

The successful use of metal complexes for enantioselective catalysis is largely dependant upon the structure and electronic properties of chiral ligands. We set out to develop a series of new chiral *N*,*S*-chelates, derived from amino acids, that would help us understand the origins of chirality in a variety of asymmetric catalytic processes. Very recently enantiomerically pure amino thiols have been shown to catalyse the addition of diethylzinc to benzaldehyde in high enantiomeric excess. Most noteworthy are systems derived from ephedrine,[1,2] (1*R*,2*S*)-(−)-1,2-diphenyl-2-aminoethanol[3] and van Koten's *N*,*S*-chelated bis{2-[(*R*)-1-)dimethylamino)ethyl]phenylthiolato}-zinc complex.[4] All of these ligands possess a symmetrical nitrogen donor atom and we anticipated that a potentially stereogenic nitrogen donor atom could have positive effects in this reaction system and other metal catalysed processes. In the design of our ligands careful attention was paid to the notion that the chirality inherent to the backbone of the amino acid could be transmitted closer towards the reaction centre by the correct choice of substituents on nitrogen. Upon chelation, the nitrogen atom could become stereogenic and reinforce the stereoinducing power of the ligand. We have tackled this idea by preparing ligands **1**–**5** that all possess a ligating sulfur atom in place of the hydroxy group from the derived amino acid. We hoped we could get good catalytic activity as sulfur would have a high affinity towards most metals useful in catalytic reactions, and has less tendency to diminish the Lewis acidity of the metal compared to metal alcoholates.‡ For instance, when ligand **1**



1 $R^1 = R^2 = Ph$, $R^3 = H$
2 $R^1 = R^2 = Bn$, $R^3 = H$
3 R^1–$R^2 = -(CH_2)_5-$, $R^3 = H$
4 $R^1 = Ph$, $R^2 = Me$, $R^3 = H$
5 $R^1 = R^3 = Ph$, $R^2 = H$

chelates to a metal atom the nitrogen donor with two phenyl substituents will possess different orientations of its atomatic rings [Fig. 1(*a*)]. The rotational freedom of the β-phenyl ring will be restricted by the proximity of the chiral centre. The

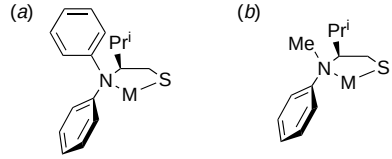


Fig. 1

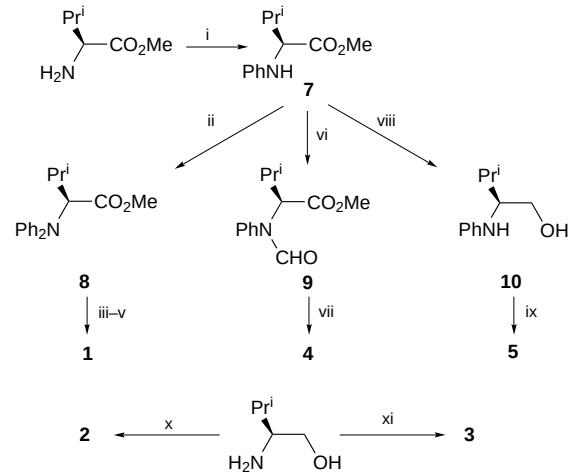
orientation of this phenyl ring will affect that of the α-phenyl ring and render the nitrogen atom stereogenic.§ In ligands of type **4** the nitrogen atom is substituted with a large and small group. Upon coordination to a metal atom the *N*-methyl substituent should occupy the same face as the chiral centre on the backbone of the chelate, forcing the larger phenyl substituent to the underface [Fig. 1(*b*)], thus again rendering the nitrogen atom stereogenic.¶ Here we report our initial studies concerning these ligands in the 1,2-addition of diethylzinc to aromatic aldehydes, in order to assay their enantioselectivity and catalytic reactivity.

The syntheses of our desired ligands were accomplished in high yield starting from either (*S*)-valine methyl ester or (*S*)-valinol derived from the reduction of (*S*)-valine (Scheme 1).[5] Diphenylation of (*S*)-valine methyl ester or (*S*)-valine was not possible using palladium catalysed methods recently reported.[6] Instead monophenylation using triphenylbismuth diacetate, promoted or catalysed by copper diacetate,[7] gave **7** in 85% yield. This material could then be phenylated again, under similar conditions, to give **8** in 69% yield. Reduction of the diphenylamine **8** with LAH was followed by substitution of the hydroxy function with sulfur under Mitsunobu-type conditions and gave ligand **1** in 75% yield. Formation of the *N*-phenylformamide by warming **7** with acetic formic anhydride[8] in 96% yield was followed by treatment with LAH to effect simultaneous reduction to the *N*-methyl substituent and



Scheme 1 *Reagents and conditions*: i, $Ph_3Bi(OAc)_2$ (1.2 equiv.), $Cu(OAc)_2$ (10 mol%), CH_2Cl_2, room temp., 24 h, 85%; ii, $Ph_3Bi(OAc)_2$ (1.5 equiv.) $Cu(OAc)_2$ (1 equiv.), CH_2Cl_2, room temp., 14 d, 69%; iii, LAH (4 equiv.), Et_2O–THF, room temp., 1 h; iv, diisopropyl azodicarboxylate (2 equiv.), Ph_3P (2 equiv.), AcSH (2 equiv.), room temp., 77% over two steps; v, LAH (4 equiv.) Et_2O–THF, 0 °C, 5 min, 98%; vi, AcOCHO (2.6 equiv.) HCO_2H (3.2 equiv.), THF, 70 °C, 2.5 h, 96%; vii, LAH (5 equiv.) Et_2O, 60 °C, 0.5 h, then (iv) followed by (v), 84% over three steps; viii, LAH (2 equiv.), Et_2O–THF, room temp., 0.5 h, 93%; ix, PhSSPh (3 equiv.), Bu_3P (4 equiv.), THF, 80 °C, sealed tube, 24 h, 75%; x, BnBr (2.2 equiv.), K_2CO_3 (2.5 equiv.), EtOH, room temp. 24 h, 91%, then (iv) followed by (v), 81% over two steps; xi, $Br(CH_2)_5Br$ (2 equiv.), K_2CO_3 (5 equiv.), EtOH, 60 °C, 48 h, 78%, then (iv) followed by (v), 72% over two steps

hydroxy function. Substitution by sulfur as before gave ligand **4** in 84% yield over three steps. Treatment of **7** with LAH gave alcohol **10** in 93% yield which was converted to the phenylthiol ligand **5** by heating in a sealed tube with diphenyl disulfide and tri-*n*-butylphosphine in 75% yield.[9]

Dibenzylation of (*S*)-valinol was achieved by treatment with benzyl bromide and potassium carbonate in 91% yield. Dialkylation of the amine function of (*S*)-valinol with 1,5-dibromopentane, under similar conditions, proceeded in 78% yield to form a piperidine. Substitution of the hydroxy function in each of these compounds by the aforementioned method gave ligands **2** and **3** in 81 and 72% yield, respectively (Scheme 1). The enantiohomogeneity of these ligands has been verified by racemic synthesis followed by NMR and HPLC comparison of their Mosher derivatives with the enantiomerically pure materials.

With these ligands in hand we screened their effectiveness as enantioselective catalysts in the addition of diethylzinc to aromatic aldehydes. Our initial experiments in this area are promising, as summarised in Table 1, and show good levels of enantioinduction in the presence of catalytic amounts (10 mol%) of the ligands **1**–**5**. Reactions were performed in toluene, at room temperature, for 3–20 h using 2.2 equiv. of diethylzinc.

These preliminary studies indicate that giving the nitrogen atom the potential to become stereogenic leads to a better system for enantioselection, as evidenced by the superior enantioselection of ligands **1** and **4** over **2** and **3** respectively. The best enantioselection (82% ee, entries 8 and 9) found with ligand **4** suggests that the donating ability of the nitrogen lone pair could be a factor in the efficiency of these ligands. This necessitates the need for further studies to try and separate the steric and electronic factors that are responsible for enhanced enantioselection. Ligands having a labile proton on nitrogen perform very poorly as catalysts in this particular reaction and along with the desired addition product, benzyl alcohol (38%) was formed from reduction of benzaldehyde.[10] These results show that non-symmetrical phenyl-substituted nitrogen donor atoms have a positive effect on the efficiency of these particular ligand systems. We believe we have a system with which we can probe the origins of chiral induction by further manipulation of the steric and electronic properties of these ligands. Further systematic modifications, studies designed to describe a transition state model and investigation of other metal catalysed systems will be reported in due course.

Radical cyclization of α-iodo enones by photoinduced electron transfer reaction

Chin-Kang Sha,*† K. C. Santhosh, Chen-Tso Tseng and Chien-Ting Lin

Department of Chemistry, National Tsing Hua University, Hsinchu 300, Taiwan, ROC

A facile intramolecular radical cyclization of α-iodo enones effected by triethylamine-mediated photoinduced electron transfer (PET) reactions is described.

Photoinduced electron transfer (PET) reactions have been widely used for one electron reduction and cyclization reactions.[1] Recently, Cossy has employed a triethylamine-promoted PET reaction for the generation of alkyl radicals[2] and for various cyclization reactions.[3] Mattay has described the radical cyclization reactions of cyclopropyl and epoxy ketones effected by triethylamine-mediated PET reactions.[4] Triethylamine-induced carbocyclization of β-bromoprop-2-ynyl ethers in pyrimidenedione has also been reported.[5] As part of our investigation directed toward the total synthesis of natural products based on α-ketone[6] and α-enone[7] radical cyclizations, we were in search of an efficient and mild alternative route to the tributyltin hydride method. In this context we examined the triethylamine-mediated PET reactions of α-iodo ketones, α-iodo enones and vinyl iodides. Herein we report the preliminary results of our investigation.

We initiated our study with α-iodo ketones.[1] α-Iodo ketone **1** or **4** with triethylamine (10 equiv.) in MeCN (0.02 M) was irradiated in a Rayonet photoreactor with low pressure mercury lamp for 15 min (Scheme 1). The reaction mixture was purified by silica-gel column chromatography to afford the cyclized product **2** or **5** in low yield (35 and 40%, respectively). The other compounds isolated were the reduction products **3** and **6**. Attempts to improve the yields of this reaction under various conditions were futile. We then examined the PET radical cyclization of α-iodo enones. The α-iodo enones were synthesized from the corresponding enones[8] *via* a literature procedure.[9] A solution of α-iodo enone **8** or **11** in MeCN (0.02 M) with triethylamine (10 equiv.) was irradiated for 45 min. Upon workup, we obtained the cyclized product **9** ($E:Z$ = 3 : 1) or **12** ($E:Z$ = 1 : 1) in 74 and 61% yield, respectively. The generality of this PET radical cyclization of α-iodo enones was then investigated. The results are summarized in Table 1.

α-Iodo vinylogous esters **14** and **20** with a terminal acetylenic moiety and **17** and **23** with trimethylsilyl acetylenic groups underwent cyclization readily. While α-iodo enones and α-iodo vinylogous esters underwent smooth cyclization, the corresponding unprotected α-iodo vinylogous amide **26** failed to cyclize under these photolysis conditions. However, *N*-protected α-iodo vinylogous amide **29** underwent clean cyclization and afforded the double bond isomerized compound **30** upon silica-gel column chromatography. In order to test the limitations of this method, we also tried a similar procedure with vinyl iodides. The required iodo compounds **31** and **33** were prepared by standard procedures.[10] Compound **31** was photolyzed with triethylamine for 2 h, but the expected cyclization did not occur. Instead **31** underwent simple reduction to give compound **32**. Similarly, iodo compound **33** failed to cyclize upon irradiation and led only to the formation of reduction product **34** (Scheme 2).

Scheme 2

In conclusion, we have achieved the efficient radical cyclization of α-iodo enones *via* triethylamine-mediated PET reactions, whereas the radical cyclization of α-iodo ketones using PET conditions afforded the cyclized product only in moderate yield. Presumably α-enone radicals, having the radical orbital orthogonal to the π-system of the enone, is more reactive and hence undergoes cyclization more effectively. Mild reaction conditions and easy product isolation make this route an attractive alternative to the tributyltin hydride method. This method eliminates the tedious separation of the tin compounds and would permit large scale preparations. The application of this method toward the total synthesis of natural products is being investigated in our laboratories.

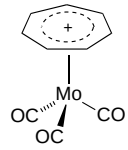
Excited state properties of the (tropylium)molybdenum tricarbonyl cation

H. Kunkely and A. Vogler*

Institut für Anorganische Chemie, Universität Regensburg, 93040 Regensburg, Germany

The electronic spectrum of $[(\eta\text{-}C_7H_7)Mo^0(CO)_3]^+$ shows its longest-wavelength absorption at λ_{max} = 379 nm which is assigned to a $Mo^0 \rightarrow \eta\text{-}C_7H_7^+$ MLCT transition; the ^{3}MLCT excited state is luminescent at room temperature; solid $[(\eta\text{-}C_7H_7)Mo^0(CO)_3]PF_6$ as well as solutions of the complex in MeCN display this emission at λ_{max} *ca.* 580 nm; the MLCT state is also reactive; in EtOH solutions $[(\eta\text{-}C_7H_7)Mo^0(CO)_3]^+$ is reduced to $[(\eta\text{-}C_7H_8)Mo^0(CO)_3]$ with ϕ = 0.18 at λ_{irr} = 366 nm.

An important family of luminescent transition metal compounds comprises polypyridyl complexes such as $[Ru^{II}(bipy)_3]^{2+}$ [1,2] and $[Re^{I}(bipy)(CO)_3Cl]$.[3–5] These emitters are characterized by a reducing d^6 metal ion of the second or third transition series and heteroaromatic ligands which provide low-energy empty π^* orbitals. The emission originates from the lowest energy metal-to-ligand charge transfer (MLCT) triplet excited state. An analogous behavior may be observed for organometallic complexes which contain aromatic molecules or ions such as benzene or cyclopentadienyl anion as 6π-electron ligands. Unfortunately, the metal $\rightarrow \pi^*$ (aromatic hydrocarbon) MLCT states of such complexes are apparently located above the lowest energy ligand-field (LF) excited states. Accordingly, these compounds do not emit under ambient conditions, but undergo photosubstitution.[3] However, an emission could occur, if by a suitable choice of the aromatic ligand, the MLCT state is pushed below the LF states. In contrast to $C_5H_5^-$ and C_6H_6, the tropylium cation is a strong acceptor.[6,7] The electronic spectra of ion pairs consisting of $C_7H_7^+$ and donor anions such as I^- show characteristic long-wavelength outer sphere CT absorptions.[7–9] It follows that the tropylium cation should be an appropriate acceptor ligand in order to observe a low-energy and hence emitting MLCT state. We explored this possibility and selected the cation $[(\eta\text{-}C_7H_7)Mo^0(CO)_3]^+$[10–13] for the present study. This complex is easily accessible from $[(\eta\text{-}C_7H_8)Mo^0(CO)_3]$[11,14] which is commercially available (Aldrich).



The electronic spectrum of $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ in EtOH (Fig. 1) shows absorptions at λ_{max} = 379 nm (ε/dm^3 mol^{-1} cm^{-1} 1200), 298 (23 800), 236 (sh, 15 800). The energy of the long-wavelength bands is scarcely dependent on the solvent polarity. Solid $[(\eta\text{-}C_7H_7)Mo(CO)_3]PF_6$ shows a yellow emission at λ_{max} = 580 nm at room temperature. In solution this luminescence is slightly shifted (Fig. 1) and appears at λ_{max} = 578 nm. The excitation spectrum of $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ matches essentially the absorption spectrum. This emission intensity is rather low in solution (ϕ *ca.* 10^{-5}). In EtOH the complex is light sensitive. The photolysis is accompanied by spectral changes (Fig. 2) which indicate the formation of $[(\eta\text{-}C_7H_8)Mo(CO)_3]$. At the isosbestic point (λ = 317 nm) $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ and $[(\eta\text{-}C_7H_8)Mo(CO)_3]$ have the same

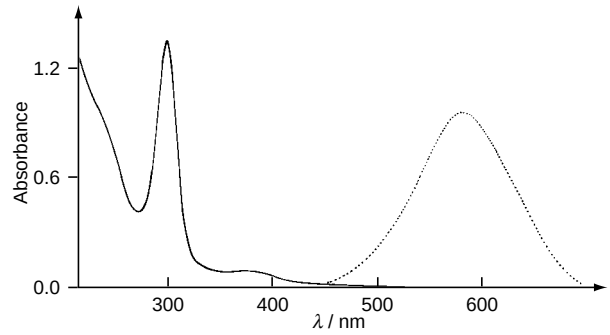


Fig. 1 Electronic absorption (—) and emission (---) spectra of $[(\eta\text{-}C_7H_7)Mo(CO)_3]PF_6$ at room temperature under argon. Absorption: 5.63 $\times$ 10^{-5} M in EtOH, 1 cm cell. Emission: in MeCN, λ_{exc} = 380 nm, intensity in arbitrary units.

absorption coefficient (4100). In a qualitative analysis protons and acetaldehyde are detected as further photoproducts. The progress of the photolysis was monitored by measuring the decrease of the optical absorption at 298 nm where the absorption coefficients of $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ and $[(\eta\text{-}C_7H_8)Mo(CO)_3]$ are 23 800 and 3700, respectively. The quantum yield of this photoreaction is ϕ = 0.18 at λ_{irr} = 366 nm.

Complexes of the type $[(arene)M^0(CO)_3]$ can be viewed as pseudo-octahedral d^6 complexes in which the arene occupies three coordination sites at the central metal. The electronic spectra and photochemistry of a variety of such complexes have been studied in the past.[3] These compounds display $M^0 \rightarrow \pi^*$ arene MLCT absorptions near 300 nm. However, LF excited states are apparently located below these MLCT states as indicated by the emission behavior and photochemical properties. While related complexes such as $[Re^{I}(bipy)(CO)_3Cl]$ are characterized by lowest energy MLCT states which are luminescent under ambient conditions,[3–5] $[(arene)M^0(CO)_3]$

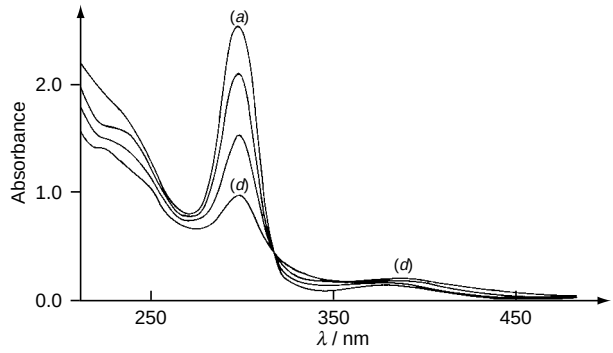

Fig. 2 Spectral changes during the photolysis of 1.06 $\times$ 10^{-4} M $[(\eta\text{-}C_7H_7)Mo(CO)_3]PF_6$ in EtOH under argon at room temp. after 0 (*a*), 5 (*b*), 10 (*c*) and 20 s (*d*) irradiation time, λ_{irr} = 313 nm (1 kW Xe/Hg 977 B-1 lamp), 0.1 cm cell

complexes are not emissive at room temperature and in solution.[3,4] The presence of lowest energy LF excited states is also consistent with the observation that these complexes undergo efficient photosubstitution reactions.[3]

If arenes in [(arene)$M(CO)_3$] are replaced by the isoelectronic aromatic tropylium cation which is a strong electron acceptor[6,7] MLCT states should be shifted to lower energies and might now occur below the photoactive LF states. The results of the present study are in agreement with this expectation.

The rather intense absorption of $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ at λ_{max} = 379 nm (Fig. 1) is assigned to the $M^0 \rightarrow \pi^*$ $C_7H_7^+$ MLCT transition. This band is scarcely solvent dependent. However, the strong interaction of the tropylium ligand with Mo[10,13,15] is certainly associated with a considerable mixing of ligand and metal orbitals. Accordingly, the CT character should be reduced and the change of dipole moment during MLCT excitation might be quite small. On the other hand, the appearance of a room temperature emission is consistent with a MLCT assignment. It is assumed that the emitting state is a triplet in analogy to many other luminescing d^6 complexes with metals of the second and third transition row.[1–5]

In ethanol $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ undergoes a photoreduction according to eqn. (1).

$$[(\eta\text{-}C_7H_7)Mo^0(CO)_3]^+ + EtOH \rightarrow [(\eta\text{-}C_7H_8)Mo^0(CO)_3] + H^+ + MeCHO \quad (1)$$

This reaction consists of a hydride transfer from ethanol to the $C_7H_7^+$ ligand yielding the cycloheptatriene complex and acetaldehyde. In the ground state only the reaction of $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ with strong H^- donors such as BH_4^- generates the trialkene complex.[12,13] Although the mechanism of the photoreduction of coordinated $C_7H_7^+$ to C_7H_8 is unknown, it should be related to the nature of the reactive excited state. In the MLCT state the complex may be regarded as a Mo^I complex which contains a C_7H_7 radical as a ligand. The C_7H_7 radical should be able to abstract a hydrogen atom from ethanol [eqn. (3)].

$$[(C_7H_7^+)Mo^0(Co)_3]^+ \xrightarrow{MLCT} [(\cdot C_7H_7)Mo^I(CO)_3]^+ \quad (2)$$

$$[(\cdot C_7H_7)Mo^I(CO)_3]^+ + EtOH \rightarrow [(C_7H_8)Mo^I(CO)_3]^+ + Me\dot{C}HOH \quad (3)$$

The $Me\dot{C}HOH$ radical is a strong reductant and transfers an electron to the oxidizing Mo^I complex yielding the final products.

In conclusion, it has been shown that $[(\eta\text{-}C_7H_7)Mo(CO)_3]^+$ is characterized by a lowest energy MLCT state which is luminescent and, in the presence of suitable substrates, also reactive.

Controlled cleavage of $R_8Si_8O_{12}$ frameworks: a revolutionary new method for manufacturing precursors to hybrid inorganic–organic materials

Frank J. Feher,* Daravong Soulivong and Andrew G. Eklund

Department of Chemistry, University of California, Irvine, CA 92697-2025, USA

Cube-octameric polyhedral silsesquioxanes ($R_8Si_8O_{12}$) react with strong acids (HX) to produce $R_8Si_8O_{11}X_2$ frameworks resulting from selective cleavage of one Si–O–Si linkage; subsequent hydrolysis affords $R_8Si_8O_{11}(OH)_2$ frameworks derived from the net hydrolysis of one Si–O–Si linkage in $R_8Si_8O_{12}$; these results demonstrate for the first time that readily available $R_8Si_8O_{12}$ frameworks can be used as precursors to incompletely condensed Si/O frameworks and have important implications for the manufacture of hybrid inorganic–organic materials based on discrete polyhedral clusters of silicon and oxygen.

Discrete polyhedral clusters containing silicon and oxygen have recently emerged as precursors to new families of network solids[1] and hybrid inorganic–organic materials.[2] Two broad families of polyhedral Si/O clusters exist: (*i*) spherosilicates (*e.g.* **1**),[1a] which are most often prepared by silylation of silicate solutions;[3] and (*ii*) polyhedral silsesquioxanes[4a] (*e.g.* **2**, **3**),

which are usually obtained from hydrolytic condensation reactions of trifunctional organosilicon monomers ($RSiX_3$),[3b,4] hydrosilylation of hydridosilsesquioxanes[2c,f,5] or 'corner-capping' reactions of trisilanols **5** and **6**.[6a,b] Both families have enormous potential as building blocks for advanced materials if cost-effective methods can be devised to produce appropriately functionalized Si/O frameworks on a large scale.

Here, we outline a new strategy for preparing functionalized silsesquioxanes from fully condensed [$R_8Si_8O_{12}$] frameworks (*e.g.* **3**). The salient feature of our approach is a general and remarkably selective method for effecting cleavage of a single framework siloxane linkage. Products from this reaction are versatile precursors to a wide range of functionalized Si/O frameworks, including several that could be manufactured on a large scale from readily available organosilicon monomers.

The addition of an excess of $HBF_4{\cdot}OMe_2$ (4.6 equiv.) and $BF_3{\cdot}OEt_2$ (6 equiv.) to a solution of **3** in $CDCl_3$ or C_6D_6 does not produce an immediate reaction at 25 °C, but upon standing for several hours or brief refluxing, NMR resonances for a new fluoride-substituted silsesquioxane appear at the expense of resonances for **3**. On the basis of multinuclear NMR data (^1H, ^{13}C, ^{29}Si, ^{19}F), a high-resolution mass spectrum, and the strong preference for stereochemical inversion at Si in related reactions,[6c,d] this product was identified as **7**, a C_{2v}-symmetric framework derived from cleavage of a single Si–O–Si linkage.† Difluoride **7** is the only Si-containing product formed by the reaction, but the reaction consistently stops at 70–85% conversion because water produced during the reaction lowers the activity of HBF_4 to a point where protonation and subsequent cleavage of Si–O–Si linkages are no longer favorable.

Like other fluoride-substituted silsesquioxanes, **7** is stable to air and water, but it can be hydrolyzed with retention of stereochemistry at Si in two steps by sequential treatment with Me_3SnOH and aqueous HCl.[6c,d] The reaction of **7** with Me_3SnOH (reflux, 46 h, $CHCl_3$) proceeds with complete retention of stereochemistry at Si to afford **8**, which reacts rapidly with dilute aqueous HCl to produce **9**. Yields for both reactions are quantitative by NMR spectroscopy, so the three-step synthesis of **9** from **3** can be accomplished easily on a laboratory scale with good overall yield.

It is tempting to conclude that cleavage of Si–O–Si bonds by HBF_4/BF_3 is driven by the formation of strong Si–F bonds, but it is clear from reactions of **3** with other strong acids that the acidity of HBF_4 is more important for Si–O–Si cleavage than the availability of fluoride. In fact, a source of fluoride is not required to induce framework cleavage. We have examined a number of strong acids, but our preliminary results with triflic acid (CF_3SO_3H, TfOH) are particularly promising.

Triflic acid is one of the strongest organic acids available, and under normal conditions it is not a source of fluoride. The reaction of **3** with an excess of TfOH (5 equiv., 25 °C, C_6H_6) occurs quickly upon mixing and within 30 min produces a quantitative yield of a new C_{2v}-symmetric ditriflate derived from cleavage of a single Si–O–Si linkage. Ditriflate **10** is the product expected if framework cleavage by TfOH is mechanistically analogous to the reaction of **3** with HBF_4/BF_3, but structure **11** is equally consistent with all of our spectroscopic data and should not be dismissed until the stereochemical consequences of silsesquioxane–triflic acid reactions (*vide infra*) are independently corroborated by X-ray diffraction studies.‡ Regardless of its structure, the ditriflate is surprisingly resistant to further framework cleavage under conditions where **3** is completely consumed. It is not obvious why this is the case because most crystallographic data suggest that $R_8Si_8O_{12}$ frameworks adopt structures with strain-free Si–O–Si linkages,[4a] but it is clear from our results that **3** is at least two orders of magnitude more susceptible to cleavage by TfOH than the ditriflate derived from cleavage of a single Si–O–Si linkage.

In stark contrast to difluoride **7**, which does not react with water (even at 80 °C in the presence of pyridine), the ditriflate obtained from **3** is very difficult to handle without producing hydrolysis products. In fact, hydrolysis of both Si–OTf groups occurs immediately upon exposure to water to produce disilanol **12** and variable amounts of **3**, which presumably forms *via* intramolecular cyclization of the intermediate monosilanol/monotriflate. When hydrolysis is performed by adding Et_2O solutions of the ditriflate and excess NEt_3 to water-saturated Et_2O, **12** and **3** are produced in a 97 : 3 ratio.

13 X = H
14 $CH_2CH_2CMe_2CH_2CO_2Me$

Structural assignment of **12** was made on the basis of multinuclear NMR spectroscopy, a high-resolution mass spectrum and combustion analysis. The *endo* orientation of both Si–OH groups is evident from the ^{1}H NMR spectrum, which exhibits a broad resonance at δ 4.44 for the two H-bonded SiOH groups. This is within the chemical shift range observed for other intramolecularly H-bonded SiOH groups[6a,e] and nearly 2.5 ppm downfield from the ^{1}H NMR resonance for the isolated SiOH groups in **9** (δ 2.00). Final confirmation of our assignment is provided by the reaction of **12** with $MeHSiCl_2$ (25 °C, NEt_3–Et_2O) which produces quantitative yields of **13**. Subsequent hydrosilylation (Kardstedt's catalyst, C_6D_6, 25 °C, 1.5 h)[5a] of **13** with $H_2C{=}CHCMe_2CH_2CO_2Me$ affords **14** as the sole Si-containing product.

The two-step synthesis of **12** from **3** requires both the reaction of **3** with TfOH and hydrolysis of the resulting ditriflate to occur with the same stereochemical consequences at silicon. Both reactions must proceed with complete inversion at Si or both must proceed with complete retention. Inversion at silicon during nucleophilic displacement reactions is usually observed when good leaving groups are replaced by poor (*i.e.* soft) nucleophiles.[7] Retention at silicon is usually favored when poor leaving groups are replaced by strong (*i.e.* hard) nucleophiles.[7] Water is a much poorer nucleophile than MeLi or hydroxide, and triflate (*i.e.* $CF_3SO_3^-$) is a much better leaving group than fluoride. Both factors should favor stereochemical inversion during hydrolysis of Si–OTf. It is therefore highly probable that both the reaction of **3** with excess TfOH (to produce **10**) and the subsequent formation of **12** proceed with complete inversion of stereochemistry at Si.

Most $R_8Si_8O_{12}$ frameworks are thermally very stable and surprisingly unreactive toward reagents that normally attack cyclic siloxanes.[4a] When framework cleavage was observed in the past, it normally produced complicated product mixtures or occurred under conditions where extensive framework degradation was followed by equilibration to other thermodynamically stable clusters ($R_{10}Si_{10}O_{15}$, $R_{12}Si_{12}O_{18}$, *etc.*).[8] The work presented here describes a revolutionary advance in the chemistry of silsesquioxanes because it demonstrates for the first time that a readily available $R_8Si_8O_{12}$ framework can be used as a precursor to incompletely condensed Si/O frameworks. In fact, the net monohydrolysis of $Cy_8Si_8O_{12}$ **3** can be accomplished selectivity with either of two useful stereochemical outcomes (*i.e.* **9** or **12**). In light of the fact that **3** can be prepared in high yield *via* the catalytic hydrogenation of $Ph_8Si_8O_{12}$ **4**,[4c] which in turn can be prepared in nearly quantitative yield from relatively inexpensive $PhSiX_3$ monomers,[4d] the transformations described here present the very real possibility that functionalized Si/O frameworks can be manufactured on a truly large scale for production of advanced inorganic–organic hybrid materials. The results from our work to expand the scope of these powerful new synthetic methods, as well as our efforts to use ditriflate **10** as a precursor to new Si/O and Si/O/M frameworks will be reported in due course.

Catalytic conversions in water. Part 9. High activity of the Pd/dpppr-s/Brønsted acid system in the alternating copolymerization of ethene and carbon monoxide {dpppr-s = C_3H_6-1,3-[P(C_6H_4-*m*-$SO_3Na)_2]_2$}

GöranVerspui, Georgios Papadogianakis and Roger A. Sheldon*†

Laboratory for Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, NL-2826 BL Delft, The Netherlands

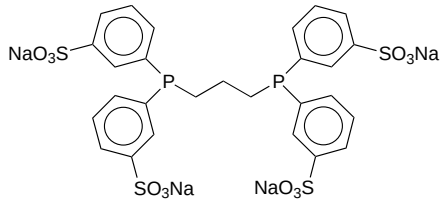
The formation of alternating copolymers of ethene and carbon monoxide proceeds rapidly in the aqueous phase in the presence of a water-soluble palladium catalyst and a Brønsted acid; activities of >4 kg of polymer per g palladium per hour were observed.

Currently there is a growing interest in organometallic catalysis in water.[1] The replacement of organic solvents by water is advantageous for environmental, safety and economical reasons and the use of biphasic systems facilitates catalyst recycling. Nevertheless, there are few examples of (biphasic) aqueous systems with acceptable catalytic activities.

The palladium catalyzed alternating copolymerization of α-olefins and carbon monoxide affords polyketones with commercially interesting properties.[2] The most active catalysts are palladium(II) complexes with bidentate phosphines, *e.g.* 1,3-bis(diphenylphosphino)propane (dpppr).[3] Jiang and Sen[4] attempted to perform the alternating copolymerization in pure water but, unfortunately, their system suffered from low catalytic activity (470 g polymer per gram Pd in 22 h).

We recently found high activities for the water-soluble palladium catalyst [Pd(tppts)$_3$] [tppts = P(C_6H_4-*m*-$SO_3Na)_3$] in the biphasic hydrocarboxylation of propene.[5] We now report on the facile formation of alternating copolymers of ethene and carbon monoxide in the presence of the bidentate water-soluble phosphine C_3H_6-1,3-[P(C_6H_4-*m*-$SO_3Na)_2]_2$ (dpppr-s) and a Brønsted acid cocatalyst (*vide infra*). Indeed, under mild and only partly optimized reaction conditions, the catalyst exhibits activities (*ca.* 4 kg polymer per gram Pd per hour, ±7600 mol ethene per mol Pd per hour) comparable to those observed with Pd/dpppr systems in organic solvents, *e.g.* MeOH which is quite extraordinary for a water-soluble catalyst.

We applied a recently developed sulfonation procedure for the synthesis of the water-soluble analogue of dpppr;[6] dpppr-s‡ was obtained in high yield (90%) and purity (98%) and its structure was confirmed by ^{1}H, ^{13}C and ^{31}P NMR and elemental analysis.



The catalyst was prepared *in situ* by addition of dpppr-s dissolved in water to an aqueous solution of [Pd{OTs}$_2${NCMe}$_2$]. Analogous to non-aqueous systems, the use of a bidentate ligand has a dramatic effect on the outcome of the reaction (Scheme 1). Whereas tppts affords predominantly propionic acid, the water-soluble bidentate dpppr-s results in the formation of the alternating copolymer. The reaction conditions§ are rather mild and only extremely low concentrations of palladium (< 0.14 mmol l^{-1}) are needed for a rapid conversion. Under these conditions no low molecular weight compounds (n = 1–6) are formed, as determined by HPLC analysis.

The optimum dpppr-s : Pd ratio is 1 : 1 (see Table 1). Without ligand metallic palladium is formed, while an excess of ligand (dpppr-s : Pd = 2 : 1) inhibits the reaction. The addition of a Brønsted acid is important for the stability of the catalyst. At low Brønsted acid concentration a lower catalyst activity is observed and large amounts of metallic palladium are formed during the reaction. The optimum results were obtained with 50 equiv. of Brønsted acid per palladium (1.0 mmol, run 7).

The anion of the Brønsted acid should be weakly- or non-coordinating, *e.g.* $CF_3CO_2^-$ or TsO^-. With the strongly coordinating iodide anion no catalytic activity was observed (run 6). These results are consistent with those observed in the Pd/tppts-catalyzed hydrocarboxylation of α-olefins.[5]

The copolymers are white solids that precipitate during the reaction, which implies that the reaction can proceed heterogeneously in aqueous media. The average molecular weights (Table 1) are lower than for copolymers obtained in the Pd/dpppr system in MeOH (6.6 *vs.* 8.5 kg mol^{-1}).[3a]

We assume that the aqueous phase copolymerization proceeds *via* a similar reaction pathway to that proposed by Drent *et al.*[3a] for the organic soluble system (Scheme 2). Initiation takes place by ethene insertion in a palladium–hydride bond. The palladium hydride [PdH{dpppr-s} {L}]$^+$ (L = H_2O,

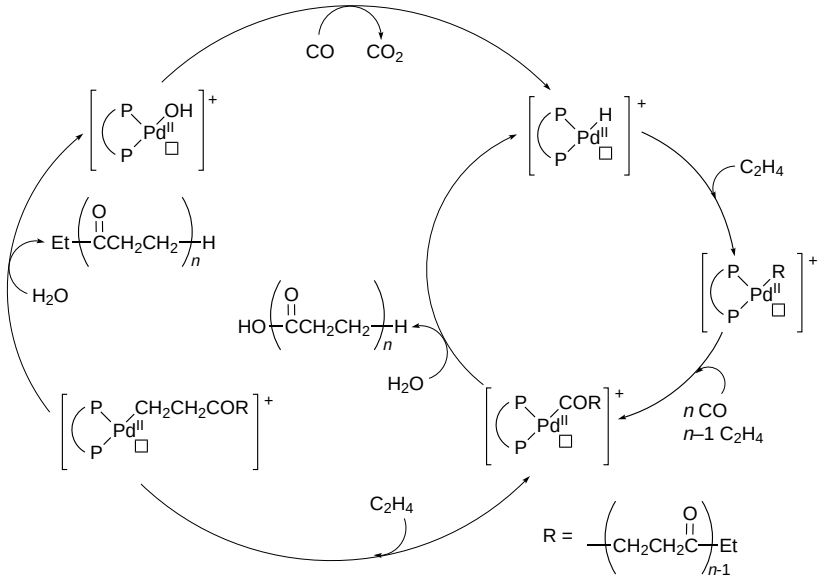

Scheme 2

NCMe, anion or monomer) can for instance be formed *in situ* by successive reduction of [Pd{dpppr-s} {L}]$_2$]$^{2+}$ by CO and water to a Pd^0 complex[7] and oxidative addition of the Brønsted acid. The initiation is followed by alternating insertion of carbon monoxide into a palladium–alkyl bond and ethene insertion in a palladium–acyl bond. The strictly alternating fashion of chain growth is terminated by hydrolysis of either a palladium–acyl or a palladium–alkyl bond, resulting in the formation of a carboxylic or a keto end group, respectively. In the latter case a palladium(II) hydroxo species is formed which can be reduced by carbon monoxide to regenerate the original hydride.

The much higher activity of our system compared to that previously reported[4] can be explained by the addition of a Brønsted acid cocatalyst and the high purity of the ligand. The addition of a Brønsted acid prevents decomposition of the catalyst and thus enhances its productivity. Moreover, impurities, such as partly oxidized ligand [Ar_2PO–$(CH_2)_3$–PAr_2] and inorganic salts can inhibit the reaction by occupying free coordination sites on the palladium.

We conclude that the alternating copolymerization of olefins and carbon monoxide in water constitute an alternative, environmentally friendly method for the preparation of new low-cost polymers with interesting properties. Studies are underway aimed at further optimization of this system and confirming the molecular weights of the polymers by alternative techniques.

Financial support by the Foundation for Chemical Research in the Netherlands (SON/NWO) is greatly acknowledged.

‡ *Ligand synthesis*: 4.95 g of dpppr (12.0 mmol) was dissolved in a solution of 4.00 g of orthoboric acid (64.7 mmol) in 37.5 ml of H_2SO_4 (98%). After *ca.* 90 min 67.5 ml oleum (65%) was added at 0–5 °C under vigorous stirring. After the addition the solution was stirred at room temperature for 48 h. The mixture was hydrolyzed at 0–5 °C with 800 ml of H_2O. The product was extracted from the water phase with tri-isooctylamine in toluene. The organic layer was washed repeatedly with water. By addition of 5% aq. NaOH, the pH was increased and the fraction of pH 4.6–12.5 was collected, washed with pentane and evaporated to dryness. Yield: 90%, purity: 98% (based on ^{31}P-NMR analysis). *Selected data*: δ_H (300.2 MHz, 25 °C, D_2O) δ: 7.70 (m, 4 H), 7.65 (m, 4 H), 7.35 (m, 8 H), 2.19 (t, *J* 8 Hz, 4 H), 1.39 (m, 2 H); δ_C (100.6 MHz, 25 °C, D_2O) 144.4 (d, *J* 6 Hz), 140.0 (d, *J* 12 Hz), 136.8 (d, *J* 17 Hz), 131.0 (s), 130.8 (d, *J* 15 Hz), 121.6 (s), 29.1 and 29.0 (dd, *J* 9 Hz), 22.7 (t, *J* 16 Hz); δ_P (121.5 MHz, 25 °C, D_2O) −16.3 (s). Calc. for $C_{27}H_{22}O_{12}P_2S_4Na_4{\cdot}4H_2O$: P, 6.67, S, 13.81. Found: P, 6.52, S, 13.6% (S/P = 2.0).

§ *Copolymerization reactions*. Under an argon atmosphere an aqueous solution of [Pd{OTs}$_2${NCMe}$_2$] (0.020 mmol), dpppr-s and Brønsted acid was transferred to a 300 ml Hasteloy C autoclave and diluted to give 141.9 g of reaction mixture ([Pd] = 0.14 mmol l^{-1}). The argon was replaced by carbon monoxide after five pressurizing–depressurizing cycles. The reaction mixture was stirred (1000 rpm) and the autoclave was pressurized with carbon monoxide *via* a stainless steel cylinder that contained 0.20 mol of ethene and heated to the reaction temperature. The pressure was kept constant by addition of carbon monoxide. After the reaction the autoclave was cooled to room temperature immediately. The reactant gasses were vented and the product was filtered, washed with water (50 ml) and EtOH (2 × 50 ml) and dried *in vacuo*. The average molecular weights of the copolymer samples were determined by quantitative ^{13}C NMR analysis in a mixture of 1,1,1,3,3,3-hexafluoropropan-2-ol and $CDCl_3$ (9 : 1).

Metal-directed assembly of a box-like structure

Edwin C. Constable* and Emma Schofield

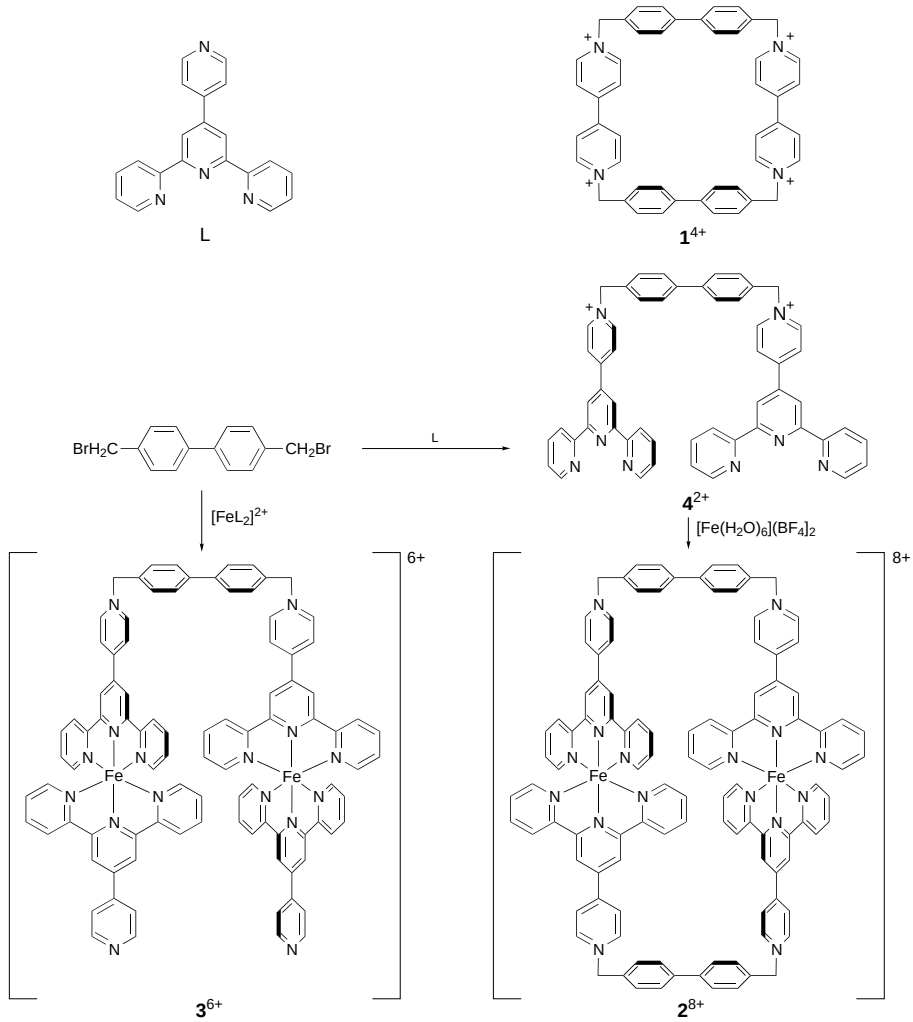
Institut für Anorganische Chemie, Spitalstrasse 51, CH-4056 Basel, Switzerland

A dinuclear octacationic box is assembled by the reaction of a dicationic bis(2,2′:6′,2″-terpyridine) ligand with iron(II); an {FeL_2} unit [L = 4′-(4-pyridyl)-2,2′:6′,2″-terpyridine] acts as an analogue of 4,4′-bipyridine.

Metal-directed self-assembly is a widely used methodology in supramolecular chemistry.[1] In the synthesis of new systems such as helicates, cyclohelicates, boxes, cylinders and grids, *inter alia*, conventional organic substructures are conceptually replaced by metal-containing units. This strategy has been successfully used by Stang and Olenyuk[2] and Lehn and coworkers[3] amongst others[4] for the synthesis of box-like structures. Here, we report the use of the $[FeL_2^{2+}$ unit [L = 4′-(4-pyridyl)-2,2′:6′,2″-terpyridine] as an analogue of 4,4′-bipyridine.

Stoddart and coworkers have reported a range of topologicaly complex structures based upon the molecular box $\mathbf{1}^{4+}$ (Scheme 1).[5] Paradoxically, the key compound $\mathbf{1}^{4+}$ remains elusive and is only obtained in low yield under forcing conditions in the absence of a template,[6] although improved yields are obtained in templated syntheses.[7] We considered the synthesis of $\mathbf{2}^{8+}$ in which the key cyclisation step involved the formation of the 4,4′-bipyridine analogue in a step involving the formation of twelve Fe–N bonds.

Our initial approach to the synthesis of $\mathbf{2}^{8+}$ was a direct analogy to the preparation of $\mathbf{1}^{4+}$ and involved the reaction in acetonitrile of 4,4′-bis(bromomethyl)biphenyl with $[FeL_2][PF_6]_2$,[8] the metallogue of 4,4′-bipyridine. The iron salt was added over 6 h to a boiling solution and heating continued for 72 h to give a dark blue solution which TLC indicated to contain one major blue component. This compound was isolated by chromatography [Kieselgel 60, gradient starting with MeCN:sat. KNO_3 (aq):H_2O (7:1:0.5) and gradually increasing the H_2O content] and identified as $\mathbf{3}[PF6]_6$ (25%).† None of the numerous minor fractions appeared to contain the desired $\mathbf{2}^{8+}$ species. Attempts to prepare $\mathbf{2}^{8+}$ by the reaction of



Scheme 1

$\mathbf{3}^{6+}$ with a second equivalent of 4,4′-bis(bromomethyl)biphenyl in acetonitrile were also unsuccessful.

Accordingly, we adopted an alternative strategy in which the iron is incorporated into the metallocycle in the final step. The reaction of L with 4,4′-bis(bromomethyl)biphenyl proceeded smoothly in acetonitrile to give $\mathbf{4}^{2+}$ which was isolated as its hexafluorophosphate salt in 62% yield (Scheme 1).‡ The subsequent cyclisation was performed under high dilution conditions (6×10^{-5} mol dm^{-3} in each component) by the addition of 1 equiv. of iron(II) tetrafluoroborate to 1 equiv. of $\mathbf{3}[PF_6]_2$ in 1 : 1 methanol–acetonitrile solution (Scheme 1). Finally, the deep blue solution was treated with an excess of NH_4PF_6 and the blue solid collected by filtration. Fractional recrystallisation yielded $\mathbf{2}[PF_6]_8$ as deep blue microcrystals in 35% yield.§ Chromatographic analysis and separation indicated that a series of higher oligomers with varying metal : ligand stoichiometries were formed.

The ^{1}H NMR spectrum of a solution of $\mathbf{2}[PF_6]_8$ in CD_3CN is surprisingly simple§ and fully confirms the structural proposal with a single chemical and magnetic 2,2′ : 6′,2″-terpyridine environment and a single AB pattern for the biphenylene unit. The primary characterisation relied upon electrospray mass spectrometry which exhibited a series of ions corresponding to the species $\{\mathbf{2}(PF_6)_n\}^{(8-n)+}$ indicating the formation of the dinuclear species rather than a higher oligomer. This was further confirmed by the preparation of the tetraphenylborate analogue by metathesis with $NaBPh_4$; the electrospray mass spectrum revealed the expected peaks assigned to $\{\mathbf{2}(BPh_4)_n\}^{(8-n)+}$. Attempts to obtain X-ray quality crystals have failed and even the very small crystals that we have obtained are extremely prone to solvent loss.

To date we have been unable to obtain NMR evidence for the inclusion of electron rich aromatic guest molecules into the cavity of $\mathbf{2}^{8+}$ although modelling studies indicate that such interactions are reasonable. We note that the compound is obtained in a highly solvated form containing significant numbers of acetone, methanol or water molecules which may be removed under high vacuum to yield material with somewhat different solubility characteristics. We are currently studying the introduction of such guest molecules.

We should like to thank the Schweizerischer Nationalfonds zur Föderung der wissenschaftlichen Forschung and the University of Basel for support.

Facile synthesis of arylated heterofullerenes $ArC_{59}N$

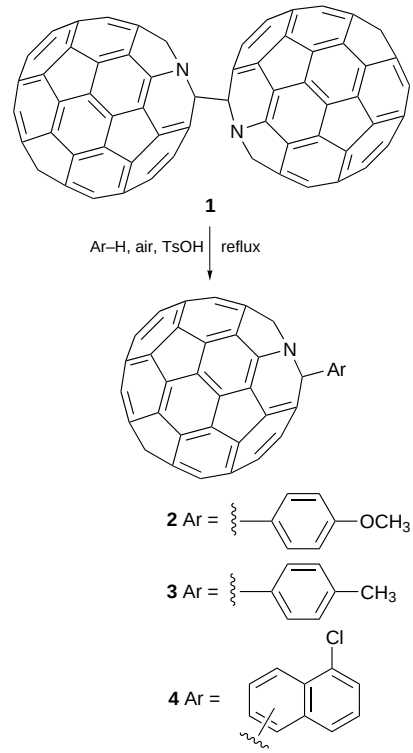
Berthold Nuber and Andreas Hirsch*

Institut für Organische Chemie, Henkestasse 42, D-91054 Erlangen, Germany

The thermal treatment of the heterofullerene dimer $(C_{59}N)_2$ with anisole, toluene and 1-chloronaphthalene in the presence of toluene-*p*-sulfonic acid and air leads to the formation monoarylated azafullerenes $ArC_{59}N$ in very good yields.

The simplest nitrogen heterofullerene $C_{59}N$ is a reactive radical intermediate and stabilizes after its formation upon dimerization to the closed shell system **1**.[1–3] So far, only a limited number of monomeric closed shell derivatives, namely the parent hydroazafullerene $HC_{59}N$ and $RC_{59}N$ (R = Ph_2CH) described by Wudl and co-workers,[4,5] as well the alkoxides $ROC_{59}N$ and $ROC_{69}N$ (R = CH_2CH_2OMe) reported by our group,[2] are known. These compounds are formed either during the synthesis of the heterofullerenes themselves as by-products or starting from the dimer **1** by trapping the homolysis product $C_{59}N$, for example, with Ph_2CH_2 in a radical substitution sequence. Here we report on an easy method for the synthesis of arylated mono adducts of $C_{59}N$ in high yields by the thermal treatment of the dimer $(C_{59}N)_2$ **1** with aromatics in the presence of acid and oxygen.

Refluxing a solution of 25 mg of **1** in 30 ml of a 5 : 3 mixture of 1,2-dichlorobenzene (ODCB) and the corresponding aromatic with 50 equivs. of toluene-*p*-sulfonic acid in the presence of air for about 2–5 h results in almost quantitative conversion to the heterofullerene derivatives **2**–**4** (Scheme 1). After chromatographic purification (silica gel; toluene) the monoadducts **2**–**4** were obtained in 78–90% isolated yield. Compounds **2** and **3** are the *para*-substitution products of anisole and toluene, whereas **4** is a mixture of different substitution products of 1-chloronaphthalene. We did not observe arylations with



Scheme 1

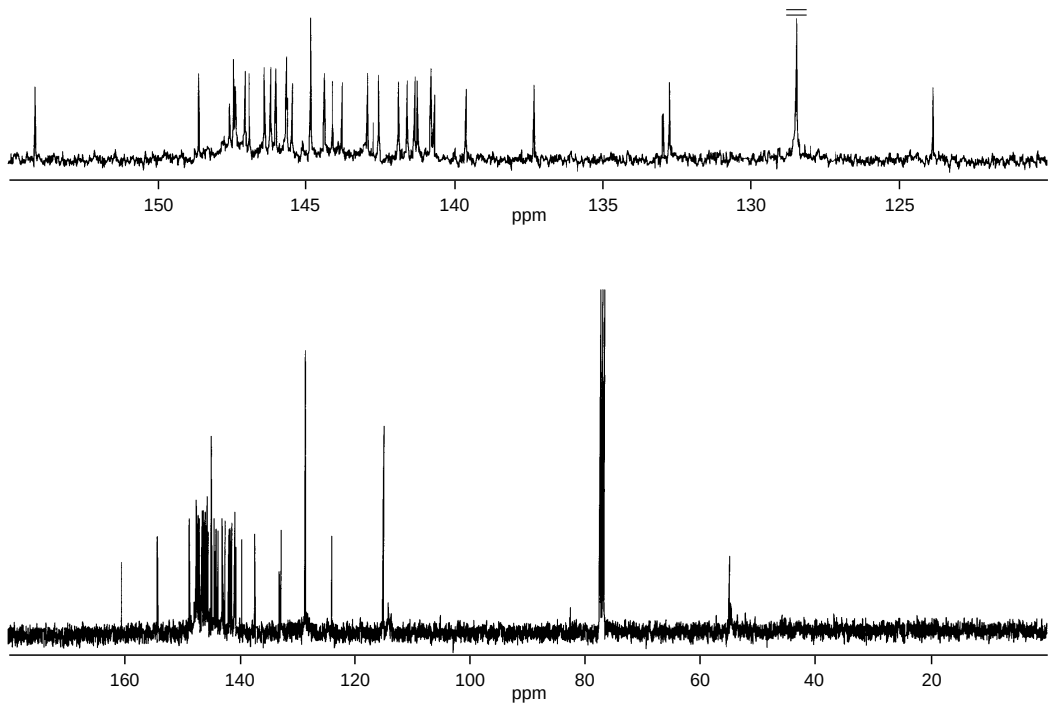


Fig. 1 ^{13}C NMR (100.5 MHz, CS_2, 20% $CDCl_3$) spectrum for **2**, (top: expanded 120–155 ppm region)

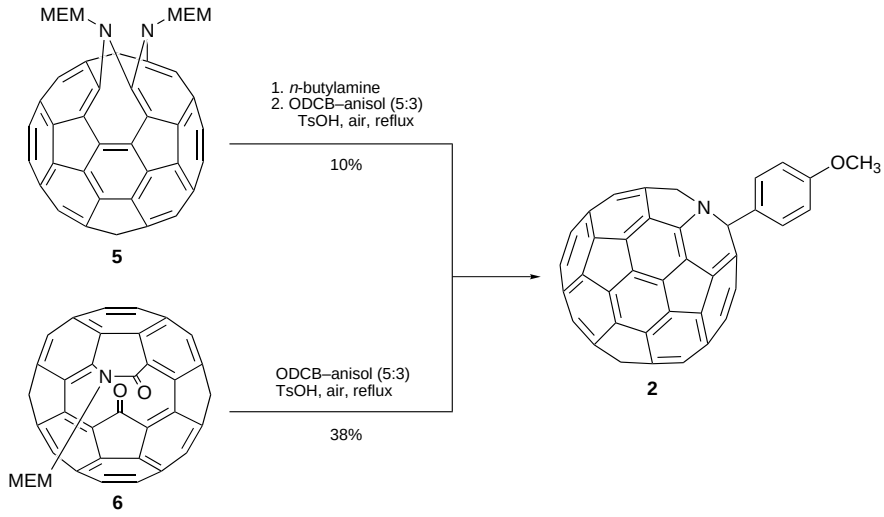

Scheme 2

deactivated aromatics, which allows use of ODCB as solvent. In the absence of an acid or oxygen these derivatizations do not take place. The arylation with *N*,*N*-dimethylaniline failed. This is presumably due to the protonation of the Me_2N group causing deactivation towards electrophilic substitution.

The monoadducts **2**–**4** were characterized by ^{1}H NMR, ^{13}C NMR, UV–VIS and FTIR spectroscopy as well as by mass spectrometry.† The ^{1}H NMR spectrum of **2**, for example, shows the expected ddd-pattern of an AA′BB′-spin system for a *para*-substituted aromatic ring. The protons of the methoxy group resonate at δ 4.03. The ^{13}C NMR spectrum of **2** (Fig. 1) clearly proves C_s symmetry showing the 30 expected fullerene resonances in the sp^2 region between δ 155 and 123. The five different C-atoms of the anisyl addend resonate at δ 160.36, 132.94, 128.47, 115.01 and 54.93. The peak at δ 82.33 is due to the resonance of the sp^3 carbon of the fullerene skeleton, which is a typical value for a corresponding C atom in $RC_{59}N$.[6] The UV–VIS spectra of **2**–**4** displaying the most intensive absorptions† at *ca*. 260, 320 and 440 nm are basically identical to that of **1**. All three compounds are green in solution. The FTIR spectra† of **2**–**4** show the typical characteristics for fullerene derivatives (monoadducts), especially the absorptions in the fingerprint region between 480 and 590 cm^{-1} with the strongest peak at about 523 cm^{-1}. MALDI-TOF mass spectrometry shows the M^+ peak of each compound together with a strong fragmentation peak at *m*/*z* 722 for $C_{59}N^+$.

We assume that the mechanism of this reaction is an electrophilic aromatic substitution (S_EAr). The electrophile is presumably $C_{59}N^+$, which might be formed *via* thermal homolysis of **1** and subsequent oxidation with O_2. The reaction times depend on the nature of the aromatic reagent used. For example, the reaction of **1** with toluene took almost 5 h, whereas quantitative conversion with anisole was achieved within 2 h, which is in line with the lower S_EAr activity of toluene. The role of the acid is not clear. It is possible that it is needed to trap the reduced oxygen species.

It is important to mention that arylated adducts like **2** can also be obtained starting directly from the precursor molecules **5** and **6**, which are usually used for the synthesis of the heterofullerene dimer **1** (Scheme 2). Although the yields are considerably lower than those of the corresponding conversions using isolated **1**, one separation step can be avoided. However, the yields can be increased upon raising the reaction temperature. The direct treatment of **5** in 1-chloronaphthalene at 220 °C leads to the formation of **4** in 46% isolated yield.

Investigations on the chemical behaviour as well as on the electronic and photophysical properties of the stable arylated heterofullerene derivates like **2**–**4** are currently underway.

We thank the DFG for financial support.

Self-assembly of carcerand-like dimers of calix[4]resorcinarene facilitated by hydrogen bonded solvent bridges

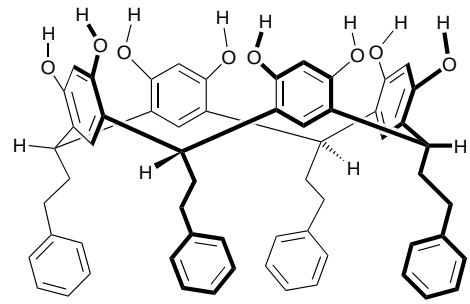
Kristie N. Rose, Leonard J. Barbour, G. William Orr and Jerry L. Atwood*†

Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65211, USA

In the presence of solvent molecules which can act simultaneously as hydrogen bond donors and acceptors, the calix[4] resorcinarene 1 can self-assemble into a dimeric carcerand-like complex utilizing an intricate array of hydrogen bonds with the solvent such that pairs of concave molecules associate indirectly in a rim-to-rim fashion to form a relatively large supramolecular cavity.

One of the main goals of supramolecular chemistry[1] is to use cleft-containing molecules to 'recognize' a substrate on the basis of size, shape, functionality and electrostatic profile. This concept was borrowed from Nature where the process of molecular recognition is central to the chemistry of life.[2] Although bowl-shaped molecules such as the calixarenes[3] and cyclodextrins[4] have been studied extensively over the last two decades, their molecular cavities are relatively small. An increasing trend towards the design of systems with larger voids has resulted in the development of systems which utilize multiple bowl-shaped molecules as building blocks. In this context, the pioneering work of Cram[5] and Collet[6] introduced the carcerands and cryptophanes—covalent cavities with the ability to confine guest molecules. Although these systems are of great conceptual importance, the guest cannot usually be removed without the rupture of at least one covalent bond of the host. Consequently, there has been much interest in the utilization of hydrogen bonded interactions to assemble concave building blocks in order to produce large cavities. In general, such cage systems are attractive because the molecular association is reversible under relatively mild conditions. Rebek and co-workers[7] have elegantly demonstrated these principles using self-complementary molecules that contain hydrogen bond donor and acceptor moieties positioned about the rims of their cavities. Moreover, one of us recently reported[8] a solid-state supramolecular assembly composed of six calix[4]resorcinarene molecules which are linked by solvent water molecules, thus forming a large cavity approximately 1375 Å^3 in volume. We are keenly interested in the supramolecular complexation of fullerenes,[9] and have been investigating the possibility of encapsulating C_{60} within a calix[4]resorcinarene hexamer. Since a solitary C_{60} molecule is too small to fill the void efficiently, the complex would also require encapsulation of a significant amount of solvent in order to stabilize the structure. During the course of our attempts at assembling such a system, we have instead produced a dimeric carcerand-like complex in which two concave calix[4]resorcinarene molecules are linked indirectly by hydrogen bond bridges involving eight propan-2-ol solvent molecules. Crystallographic characterization of a dimeric system of this nature is unprecedented and is an important extension of the work initiated by Rebek.

Single crystals suitable for X-ray diffraction analysis‡ were grown by slow diffusion of propan-2-ol into a solution of **1**[10] and C_{60} (5:1 molar ratio) in *o*-dichlorobenzene. The most striking feature of the structure is that pairs of concave calix[4]resorcinarene molecules are arranged in a rim-to-rim fashion to form dimers, as shown in Fig. 1. The eight hydroxy groups of one calix[4]resorcinarene form hydrogen bonds with eight oxygen atoms belonging to propan-2-ol solvent molecules. The latter, in turn, form hydrogen bonds to a second



1

claix[4]resorcinarene molecule, thus completing the dimer. No hydroxy group hydrogen atoms were located and hydrogen bonds are inferred from short O··O contacts. The proximate hydroxy O··O contacts within each calixresorcinarene are 2.771(7) Å, implying that these oxygen atoms are also hydrogen bonded to one another. The unique calix[4]resorcinarene-to-solvent O··O distances are 2.660(9) and 2.743(9) Å. The two calix[4]resorcinarene molecules each have C_{4v} symmetry and are related to one another by a mirror plane at *x*,*y*,0 which passes through all of the propan-2-ol oxygen atoms. The assembly of the dimer is thus facilitated by the formation of sixteen intermolecular hydrogen bonds, while a further eight intramolecular hydrogen bonds impart structural rigidity of the calix[4]resorcinarene molecules. The symmetry relationship between the constituents of the dimer requires all of the hydrogen atoms involved in hydrogen bonding to be disordered.

The effective van der Waals volume of the cavity was calculated[11] to be 230 Å^3 and its cross section, measured at *x*,*y*,0, is approximately equal in dimensions to a molecule of *o*-dichlorobenzene. In order to maintain structural stability, it is probable that the cavity contains several solvent molecules, perhaps of both *o*-dichlorobenzene and propan-2-ol. Relatively

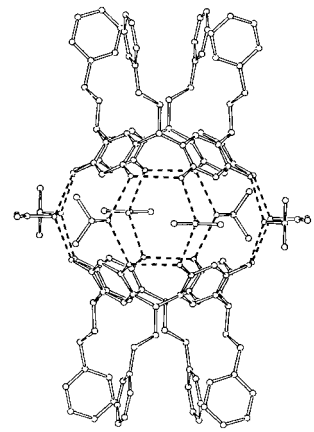


Fig. 1 Projection showing the calix[4]resorcinarene dimer. Hydrogen atoms are omitted for clarity and hydrogen bonded interactions are shown as broken bars.

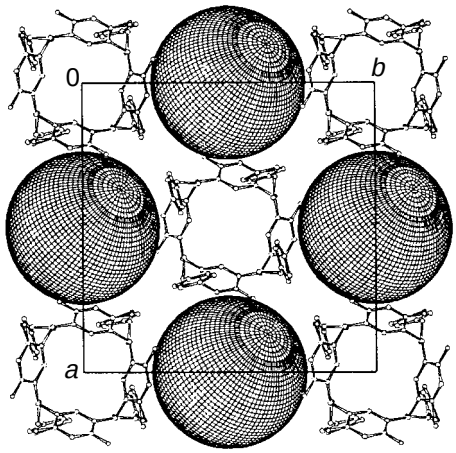

Fig. 2 Packing diagram (only calix[4]resorcinarene and C_{60} molecules are shown) viewed along [001], parallel to the molecular columns

large peaks of electron density within the cavity appear to indicate the presence of chlorine atoms, but crystallographically imposed symmetry precludes the use of a cogent model for included solvent molecules. As shown in Fig. 2, the calix[4]resorcinarene dimers are stacked in columns along 0,0,*z* and $\frac{1}{2},\frac{1}{2},z$ while the C_{60} molecules are similarly arranged along $0,\frac{1}{2},z$ and $\frac{1}{2},0,z$. The calix[4]resorcinarene columns involve alternating head-to-head and tail-to-tail associations of the molecules. The latter result in the formation of lattice voids bounded by phenethyl moieties belonging to the host and also appear to contain disordered *o*-dichlorobenzene solvent.

We have shown that the solvent-assisted hexameric assembly of calix[4]resorcinarenes to form carcerand-like complexes has a dimeric analogue. Characterization of such systems is a significant step towards understanding the principles involved in the design of supramolecular cavities of diverse shapes and sizes, and assemblies of this nature are important because, like their biological counterparts, the contents of large molecular voids are often considered[12] to represent an additional phase of matter.

We are grateful for funding from the National Science Foundation.

Sulfinyl *versus* allylic stereocontrol in Diels–Alder cycloadditions of hydroxy 2-sulfinyl butadienes

Roberto Fernández de la Pradilla,*[a]† Carlos Montero[a] and Alma Viso[b]

[a] *Instituto de Química Orgánica, CSIC, Juan de la Cierva, 3, E-28006 Madrid, Spain*
[b] *Departamento de Química Orgánica I, Facultad de Química, Universidad Complutense, E-28040 Madrid, Spain*

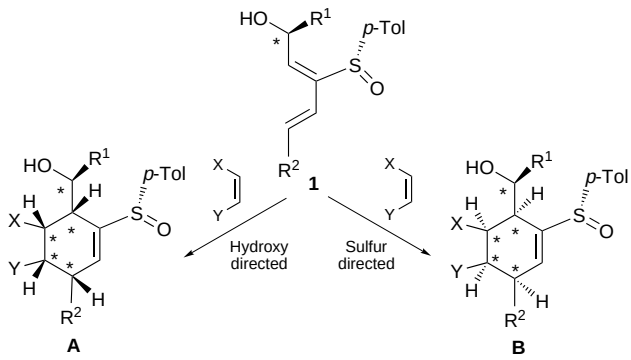
Enantiopure hydroxy 2-sulfinyl butadienes undergo a highly face selective Diels–Alder cycloaddition with *N*-phenylmaleimide and phenyltriazolinedione controlled by the chiral sulfur atom; the related enantiopure sulfonyl dienes display complimentary π-facial selectivity.

The asymmetric Diels–Alder reaction is a fundamental process in contemporary organic synthesis since up to four enantio- and diastereo-merically pure stereogenic centres are created in a single step.[1] Within this field, the use of enantiopure dienes is comparatively less developed and the clarification of issues concerning stereocontrol for these protocols is a current challenge.[2] In most studies involving enantiopure dienes, the chiral auxiliary is only utilized to induce asymmetry in the Diels–Alder process, and further asymmetric transformations are not readily envisaged. In contrast, simple 2-sulfinyl dienes are especially appealing substrates since, after a highly selective Diels–Alder cycloaddition,[3,4] a vinyl sulfoxide, which may undergo subsequent chirality transfer operations,[5] is generated. Here we report the first examples of highly diastereoselective sulfur directed Diels–Alder cycloadditions of enantiopure hydroxy 2-sulfinyl dienes which display a non-reinforcing relationship of stereocontrolling elements.[6]

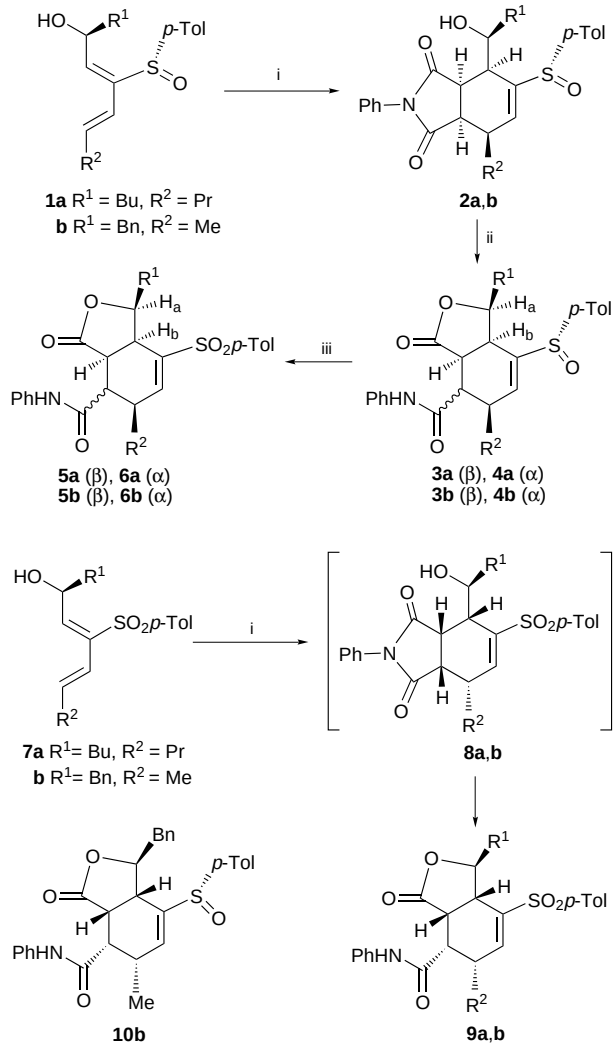
We have recently described a short and completely stereocontrolled route to enantiopure dienes **1** (Scheme 1).[7] At the onset of this research we envisioned that dienes **1** would provide a unique opportunity to assess the relative π-facial stereodirecting abilities of two powerful elements of stereocontrol in a Diels–Alder process,[4,8,9] and lead to enantiopure cycloadducts **A** or **B**. It should be noted that for dienes **1**, the allylic hydroxy-bearing stereocentre and the sulfinyl auxiliary are expected to direct the approach of the dienophile with maximum efficiency due to mutual 1,3-allylic strain,[10] and to *opposite* faces of the diene moiety.[11]

To gain insight into the stereochemical outcome of a basic intermolecular Diels–Alder process, we selected *N*-phenylmaleimide (NPM) and diene **1a**[7] for our initial studies, and the results obtained are shown in Scheme 2. In this fashion, cycloadduct **2a** was produced as a single isomer (300 MHz ^{1}H NMR analysis of the crude reaction mixture) and isolated in good yield after recrystallization. Treatment of a solution of **2a** with silica gel resulted in spontaneous lactonization and partial epimerization to produce a separable 25 : 75 mixture of amides **3a** (β-amide) and **4a** (α-amide) which displayed significant NOE enhancements between H_a and H_b (11.5 and 10.4% respectively).‡

To extend the scope of our methodology, and seeking additional support for the stereochemical assignments, we prepared enantiopure hydroxy sulfonyl diene **7a** from sulfoxide **1a** by a simple oxidation with magnesium monoperoxyphthalate (MMPP).[12] Diene **7a** underwent smooth cycloaddition



Scheme 1



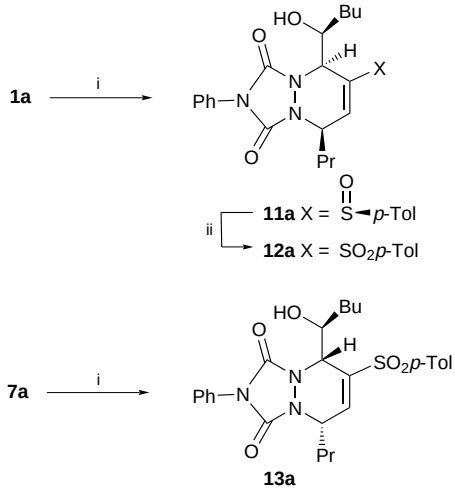
Scheme 2 *Reagents and conditions*: i, NPM (1–1.5 equiv.), toluene, room temp., 2–5 d, 70% for **2a**, 69% for **2b**, 86% for **9a** and 82% for **9b**; ii, SiO_2, CH_2Cl_2, room temp., 4 d, 91% for **3a**/**4a** and 95% for **4b**; iii, MCPBA, (1.5 equiv.), CH_2Cl_2, −78 °C to room temp., 2–5 h, 80% for **5a**, 83% for **6a** and 75% for **6b**

with NPM affording the very unstable cycloadduct **8a**§ as a single isomer which lactonized spontaneously in the reaction medium to give **9a**. This result shows that the allylic hydroxy group is a powerful element of stereocontrol in these cases.[9] The diastereomeric relationship found between amides **9a** and **5a**/**6a** (prepared by oxidation of pure samples of **3a** and **4a**), along with the NOE enhancements observed for **3a** and **4a**, conclusively establish that the π-facial selectivity of the cycloaddition between **1a** and NPM is exclusively controlled by the chiral sulfur atom.

Encouraged by these results we sought to test the generality of this sulfoxide directed cycloaddition by studying the reaction of diene **1b**,[7] with a bulkier R^1 substituent, and NPM which afforded a 95 : 5 mixture of cycloadduct **2b** and sulfinyl amide **10b**,¶ respectively, as judged by ^{1}H NMR analysis of the crude reaction mixture. Treatment of **2b**, isolated by recrystallization, with SiO_2 resulted in smooth cyclization and epimerization affording amide **4b** along with trace amounts of **3b**. Oxidation of **4b** afforded sulfone **6b** while the cycloaddition between sulfonyl diene **7b** and NPM produced diastereomeric sulfonyl amide **9b**. We believe that lactones **3a** and **3b** undergo a facile epimerization at the amide-bearing carbon due to the location of the R^1 substituent in the sterically demanding concave region of the molecule, while for lactones **9**, R^1 is placed in the convex face. The enhanced degree of epimerization found for R^1 = Bn *versus* Bu is likely to be related to the different steric requirements of these substituents.

Scheme 3 gathers our results for the cycloaddition between sulfinyl diene **1a**, sulfonyl diene **7a** and phenyltriazolinedione (PTAD). These cycloadditions took place with complete facial selectivity and in high yield to produce adducts **11a** and **13a** respectively. Standard oxidation of **11a** afforded **12a** whose spectral features clearly indicated a diastereomeric relationship to **13a**. These observations establish a sulfur-directed π-facial selectivity for hydroxy sulfoxide **1a**, and an allylic-directed π-facial selectivity for hydroxy sulfone **7a**.

In summary, readily available enantiopure acyclic hydroxy 2-sulfinyl butadienes,[7] which display a nonreinforcing relationship of stereocontrolling elements,[6] undergo a highly face-selective Diels–Alder cycloaddition with *N*-phenylmaleimide and phenyltriazolinedione to generate densely functionalized cycloadducts. To the best of our knowledge, the complete reversal of facial selectivity found for sulfoxides **1**, relative to related sulfonyl dienes **7**, is unprecedented and demonstrates that the sulfinyl functionality is not just synthetically useful but also an extremely powerful element of stereocontrol for intermolecular Diels–Alder cycloadditions, Further studies on the scope and limitations of this methodology, including its intramolecular variant as well as applications toward natural products syntheses, will be reported in due course.



Scheme 3 *Reagents and conditions*: i, PTAD (1.5–2.0 equiv.), CH_2Cl_2, −78 °C to room temp., 1 h, 87% for **11a** and 79% for **13a**; ii, MCPBA (1.5 equiv.), CH_2Cl_2, −78 °C to room temp., 4 h, 88%

We thank DGICYT (PB94-0104 and PB96-0822) for support of this research and the CAM for a doctoral fellowship to C. M.

Structural evidence for resonance-assisted O–H···S hydrogen bonding

Thomas Steiner*

Institut für Kristallographie, Freie Universität Berlin, Takustraße 6, D-14195 Berlin, Germany

By far the shortest hydrogen bonds of the O–H···S type occur in monothio-ß-diketones and related substances (H···S distances 1.9–2.0 Å); it is shown with crystal correlation techniques that this very short hydrogen bonding is facilitated by resonance assistance similar to that occurring in the oxygen analogues.

Although O–H···S hydrogen bonds occur in many chemical and biological systems, they have been little investigated until today. The first comprehensive statistical analysis of intermolecular O–H···S hydrogen bond geometries was only recently published by Allen *et al.*[1] It is observed that in intermolecular hydrogen bonds, H···S distances are restricted to values > 2.2 Å. In this present work, the database analysis of Allen *et al.* was followed, but intramolecular hydrogen bonds were also included.[2]† The distribution of H···S separations is clearly bimodal (Fig. 1). The large peak centred in the range 2.3–2.4 Å represents intermolecular hydrogen bonds, mostly of the type O–H···S=C < .[1] The small peak centred in the range 1.9–2.0 Å was not evident in the previous study and represents exclusively intramolecular hydrogen bonds, which are apparently unusually strong. To discover what kind of interactions cause this prominent peak, the examples with H···S < 2.1 Å were inspected individually. It was found that they are all structurally very similar and are formed in the structural fragments shown in Fig. 2 (numerical data given in Table 1).

The largest fraction of the data sample in Fig. 2 is composed of monothio-β-diketones in the enol tautomeric form [Fig. 2(*a*)]. As an archetypal example, the structure of 3-mercapto-1,3-diphenylprop-2-en-1-one, which has been determined by neutron diffraction,[3] is show in Fig. 3. Note that the covalent O–H bond length of 1.024(8) Å is appreciably elongated from the *ca.* 0.98 Å which is typically observed in moderate O–H···O hydrogen bonds,[4,5] indicating an interaction of considerable strength. For fragment (*b*) [2-hydroxybenzene-1-carbothioamides], IR spectroscopy shows redshifts of O–H stretching frequencies of around 450 cm^{-1} compared to free phenolic O–H, which are similar values as in the oxygen analogues.[6]

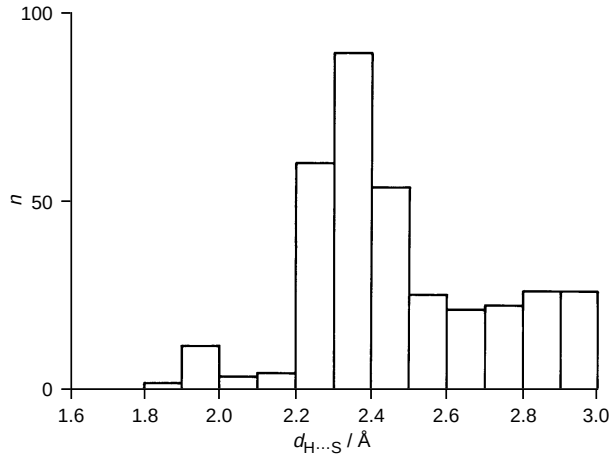

Fig. 1 Distribution of H···S distances in inter- and intra-molecular O–H···S hydrogen bonds (for normalised H-atom position). The large peak centred at 2.3–2.4 Å is derived mainly from intermolecular hydrogen bonds and the small peak centred at 1.9–2.0 Å arises exclusively from intramolecular hydrogen bonds.

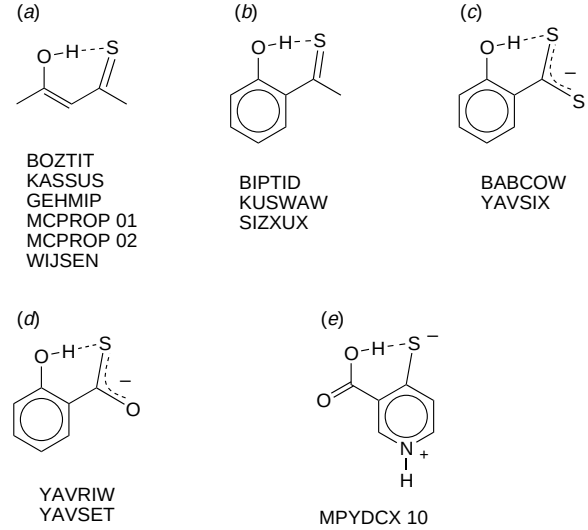

Fig. 2 The crystal structures exhibiting intramolecular O–H···S hydrogen bonds with H···S < 2.1 Å; (*a*) and (*b*) represent molecular fragments, (*c*)–(*e*) are drawn as they occur in the crystal

The short intramolecular hydrogen bonds in monothio-β-diketones lead directly to the concept of resonance assisted hydrogen bonding (RAHB), which has been introduced by Gilli *et al.* to explain the observed strong hydrogen bonding in the oxygen analogue,[7] and was later put into a wider conceptual frame.[5,8] In this model, strong hydrogen bonding is possible if a suitably polarizable system of π-bonds allows charge flow through covalent bonds from the donor to the acceptor. Such systems are provided, for example, by conjugated double bonds. This cooperativity mechanism is well established for cyclic and

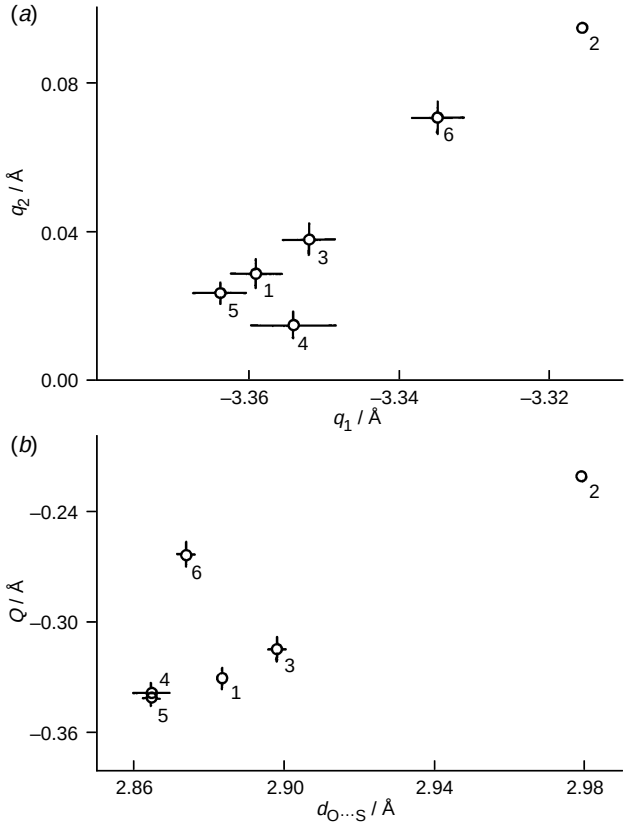

Fig. 4 (*a*) Correlation of the parameter q_1 (= $d_1 - d_4$) and q_2 (= $d_3 - d_2$). (*b*) Correlation of $Q = q_1 + q_2$ with the hydrogen bond distance O···S. The observed correlations imply that the arrangement in **1** is in fact a resonant cycle.[6] Note that a value of $q_2 = 0$ corresponds to complete π-delocalisation of C=C–C. Error bars are included where standard errors of bond lengths were given in the original publication. Data are identified as **1**: BOZTIT. **2**: GEHMIP. **3**: KASSUS. **4**: MCPROP01. **5**: MCPROP02. **6**: WIJSEN.

non-cyclic O=C–C=C–O–H systems and for related heteronuclear cases with N–H donors,[9] and has even been postulated for C–H donors.[10] Since it has not been investigated as yet for sulfur acceptors, the mechanism is looked at more closely here.

If the RAHB model is applicable to the monothio-β-diketones **1**, the situation should exactly parallel the oxygen analogue, as is shown below. Because of the hydrogen bond, the O–C and the C–C bonds gain some double bond character and are shortened, whereas the C=C and C=S bonds loose part of their double bond character and are lengthened. To see if this is more than a suggestion, and if the hydrogen bond arrangement in fact represents a resonant cycle, it is necessary to perform geometrical tests. There are several ways to quantify π-system delocalisation; to make comparison easy, the formalism used by Gilli *et al.*[6] is also used here. It is obvious that in RAHB of increasing strengths, the bond length d_1 reduces and d_4 increases; since C=S is longer than O–C, this means that the difference $q_1 = d_1 - d_4$ is negative and becomes more negative with increasing hydrogen bond strength. The difference in the C–C and the C=C bond lengths, $q_2 = d_3 - d_2$, is positive and decreases with increasing hydrogen bond strength. In the case of total π-delocalisation at C=C–C, q_2 becomes zero. If the arrangement as a whole is a resonant cycle, there must be a correlation between the parameters q_1 and q_2. Furthermore, the π-delocalisation must increase with reducing hydrogen bond distance, so that q_1, q_2 and their sum $Q = q_1 + q_2$ must correlate with O···S (or H···S). The corresponding correlation plots for the monothio-β-diketones are shown in Fig. 4. Despite the limited amount of data the correlations are sufficiently clear to show the anticipated trends [the single outlier in Fig. 4(*b*) is unexplained upon inspection]. This is conclusive evidence that the mechanism of resonance assisted hydrogen bonding is operative in this fragment.

The amount of data for the arrangements in Fig. 2(*b*)–(*e*) is insufficient for statistical analysis, but the structural and electronic similarities immediately suggest that they also represent decent RAHBs, which for arrangements (*c*)–(*e*) even contain a contribution of charge assistance.[5]

The arrangements in Fig. 2 represent by far the shortest O–H···S hydrogen bonds known, about 0.4 Å shorter than typical intermolecular hydrogen bonds. This circumstance is readily explained by the operation of resonance effects within the cyclic fragments, *i.e.* by resonance assisted hydrogen bonding which is analogous to that in β-diketones.[7] The general importance of this concept[5,7] is thereby further emphasised and its applicability for heteronuclear hydrogen bonds is confirmed. The other mechanisms that can produce strong hydrogen bonds, in particular charge assistance,[8] are not apparent in the pure form in the currently available structural data for O–H···S hydrogen bonding.

The author thanks Professor W. Saenger for giving him the opportunity to carry out this work in his laboratory.

Modeling the active sites of bacteriophage T7 lysozyme, bovine 5-aminolevulinate dehydratase, and peptide deformylase: synthesis and structural characterization of a bis(pyrazolyl)(thioalkoxy)hydroborato zinc complex, $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$

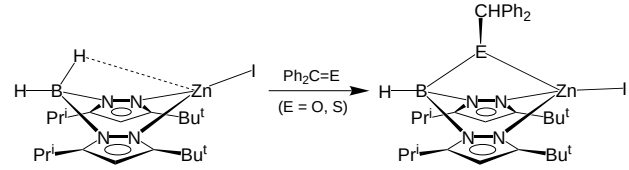
Prasenjit Ghosh and Gerard Parkin*

Department of Chemistry, Columbia University, New York, New York 10027, USA

Insertion of thiobenzophenone into a B–H bond of $[Bp^{Bu^t,Pr^i}]ZnI$ achieves the synthesis of $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$, a complex in which the *in situ* generated [NNS] donor ligand models the binding of the histidine and cysteine residues at the active sites of bacteriophage T7 lysozyme, bovine 5-aminolevulinate dehydratase and peptide deformylase.

Zinc is essential to all forms of life.[1,2] Of the trace metals, its abundance in biological systems is second only to iron, with an average human containing *ca.* 3 g of zinc. Correspondingly, there are many biological functions of zinc and a large number of zinc enzymes are known. Interestingly, the active sites of many of these enzymes exhibit a common structural motif which comprises a pseudo-tetrahedral zinc center to which a single water molecule is attached, with the three remaining sites being occupied by a combination of nitrogen, oxygen and sulfur donors provided by histidine, glutamate, aspartate and cysteine residues of the protein backbone.[3] Despite the overall similarity in the structure of the active sites of these enzymes, however, each performs a different function. It is, therefore, important to understand the manner in which a $[N_xO_yS_z]$ donor array modifies the chemistry of a tetrahedral zinc center. A first step to achieve such an objective involves the synthesis and structural characterization of well defined complexes with a series of appropriate $[N_xO_yS_z]$ donor ligands. For this reason, we are actively studying synthetic analogues of zinc enzymes which differ in the ligand complement, *e.g.* carbonic anhydrase [NNN],[4–6] thermolysin [NNO],[7] and liver alcohol dehydrogenase [NSS].[8] In this paper, we describe the construction of a [NNS] ligand which provides a model of the groups that bind zinc at the active sites of bacteriophage T7 lysozyme, bovine 5-aminolevulinate dehydratase and peptide deformylase.

Bacteriophage T7 lysozyme is a zinc enzyme which destroys bacteria by cleaving polysaccharide components within their cell walls.[9,10] X-Ray diffraction studies of a mutant lysozyme (AK6) reveal that the active site is located in a cleft within the protein which is *ca.* 22–26 Å long and 10–11 Å deep. The tetrahedral zinc center of the active site is bound to the protein backbone *via* one sulfur and two nitrogen donors of cysteine (Cys-130) and histidine (His-17 and His-122) residues; the fourth site is occupied by a water molecule.[10] Bovine 5-aminolevulinate dehydratase[11] and peptide deformylase[12] are enzymes that are related to T7 lysozyme by virtue of the common coordination of one cysteine and two histidine donors to the zinc center of the active site. In order to mimic the tetrahedral binding of zinc to the protein backbone of these enzymes, a [NNS] ligand which presents the nitrogen and sulfur donors as a facial, rather than T-shaped, array is required. For this purpose, we have focused attention on the construction of ligands in which the donor groups are linked to a common tetrahedral center, since we have previously noted that such attachment serves to enforce facial binding to zinc.[7,8] Significantly, a monomeric zinc complex containing a facially tridentate [NNS] donor ligand, namely $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$, may indeed be constructed by insertion of thiobenzophenone into a B–H of $[Bp^{Bu^t,Pr^i}]ZnI$[13] (Scheme 1).



Scheme 1

The molecular structure of $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ (Fig. 1) has been determined by X-ray diffraction.[14] Of most importance, the diffraction study demonstrates that (*i*) $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ exists as a well defined monomeric complex, and (*ii*) the [NNS] ligand supports a pseudo-tetrahedral zinc center that is structurally related to the active sites of T7 lysozyme,[15] 5-aminolevulinate dehydratase,[16] and peptide deformylase.[12]

The significance of isolating $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ is further underscored by noting that other attempts to use tridentate [NNS] ligands to support monomeric tetrahedral zinc complexes of the type [NNS]ZnX have not been very successful. For example, Vahrenkamp has used *N*-(2-mercaptoethyl)picolylamine (MEPAH) in an attempt to provide a [NNS] environment pertinent to zinc enzymes.[17] Unfortunately, however, the zinc chemistry derived from MEPAH was found to be very complex, with polymeric

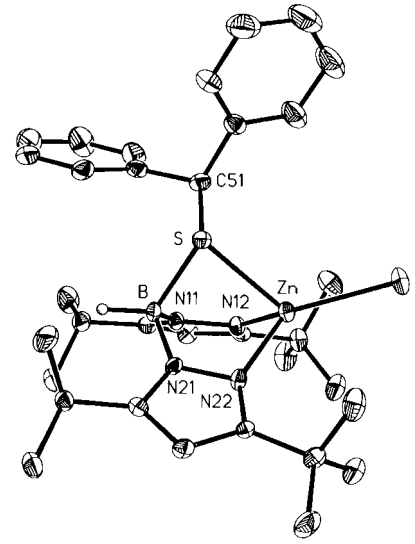


Fig. 1 Molecular structure of $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$. Selected bond lengths (Å) and angles (°): Z–N(12) 2.031(5), Zn–N(22) 2.040(5), Zn–S 2.460(2), Zn–I 2.4869(8); N(12)–Zn–N(22) 94.6(2), N(12)–Zn–S 88.61(14), N(22)–Zn–S 84.00(14), N(12)–Zn–I 125.63(13), N(22)–Zn–I 129.34(13), S–Zn–I 121.71(5).

$[(MEPA)ZnX]_n$ (X = Cl, Br), trinuclear $[(MEPA)_4Zn_3]X_2$ (X = BF_4, ClO_4, NO_3), dinuclear $[(MEPA)Zn(OAc)]_2$, and other complexes being isolated; in no instance was a monomeric tetrahedral [NNS]ZnX complex strucurally characterized.[18] Undoubtedly, one of the principal reasons for the difficulty in isolating mononuclear [NNS]ZnX complexes is associated with the propensity of sulfur to act as a bridge between metal centers.[19] In view of the difficulty associated with isolating such complexes, the *in situ* construction of a [NNS] donor ligand by elaboration of a [NN] donor ligand at a metal center therefore provides a useful method of synthesis of other [NNS]ZnX derivatives.[20]

In addition to $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$, the alkoxide analogue $[(Ph_2CHO)Bp^{Bu^t,Pr^i}]ZnI$ has also been synthesized (Scheme 1) and structurally characterized by X-ray diffraction.[21] Other than the difference in Zn–O *vs.* Zn–S bond lengths, the coordination environment about zinc is similar for $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ and $[(Ph_2CHO)Bp^{Bu^t,Pr^i}]ZnI$. The geometry at the chalcogen in each case is distinctly pyramidal, with the $[Ph_2CH]$ alkyl substituent being displaced from the B–E–Zn plane, so that both molecules are chiral. The barriers to enantiomer interconversion are, however, considerably different for the two derivatives. For example, whereas the thioalkoxide complex $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ exhibits two sets of resonances in the 500 MHz ^1H NMR spectrum at −50 °C for the two diasterotopic pyrazolyl groups, the corresponding ^1H NMR spectrum of the alkoxide analogue $[(Ph_2CHO)Bp^{Bu^t,Pr^i}]ZnI$ shows only a single set due to chemical exchange as a result of isomerization. The barrier for enantiomer interconversion, is, therefore, considerably lower for the alkoxide complex than for the thioalkoxide derivative.[22] Enantiomer interconversion for $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$ is, however, observed to occur rapidly on the NMR timescale at ambient temperature,[23] with an activation barrier ($\Delta G^{\ddagger}$) of 14.5(3) kcal mol^{-1} (1 cal = 4.184 J) at 25 °C.[24,25] Two possible mechanisms for enantiomer interconversion include (*i*) cleavage of the E → Zn dative bond, rotation about the B–E bond, followed by re-coordination, and (*ii*) pyramidal inversion at E. Although we have no evidence to distinguish between these mechanisms, if enantiomer interconversion were to proceed *via* a common mechanism, the observation that the exchange is more facile for the alkoxide than for the thioalkoxide suggests that the mechanism may involve direct inversion at the chalcogen, since barriers to inversion are typically lower for second row (*i.e.* O), as opposed to third row (*i.e.* S), elements.[22,26] Some support for this notion is provided by the observation that the $[Ph_2CH]$ substituent is much closer to planarity with the B–E–Zn plane in the alkoxide than in the thioalkoxide derivative, as judged by the respective sum of bond angles at O (336°) and S (288°). In contrast, however, if enantiomer interconversion were to require dissociation of the E → Zn dative bond, then the exchange would be expected to be more facile for the complex with the weaker bond, *i.e.* the thioalkoxide derivative.

In summary, the insertion of thiobenzophenone into a B–H bond of $[Bp^{Bu^t,Pr^i}]ZnI$ results in the synthesis of $[(Ph_2CHS)Bp^{Bu^t,Pr^i}]ZnI$. Importantly, the [NNS] ligand so obtained is capable of sustaining a monomeric tetrahedral geometry about zinc and resembles the histidine and cysteine residues that bind zinc at the active sites of T7 lysozyme, 5-aminolevulinate dehydratase and peptide deformylase.

We thank the National Institutes of Health (Grant GM46502) and Kanagawa Academy of Science and Technology for support of this research. G. P. is the recipient of a Presidential Faculty Fellowship Award (1992–1997).

20 Copper and tungsten derivatives of related $[(RS)Bp^{RR'}]$ ligands, namely $[(p\text{-}TolS)Bp^{Me_2}]CuSR$[20a] and $[(p\text{-}TolCH_2S)Bp]Mo(CO)_2(\eta^2\text{-}S_2CR)$,[20b] have also been reported, although they have not been structurally characterized. (*a*) J. S. Thompson, J. L. Zitmann, T. J. Marks and J. A. Ibers, *Inorg. Chim. Acta*, 1980, **46**, L101; (*b*) A. F. Hill and J. M. Malget, *J. Chem. Soc., Dalton Trans.*, 1997, 2003.
21 $[(Ph_2CHO)Bp^{Bu^t,Pr^i}]ZnI$ is orthorhombic, $Pca2_1$ (no. 36), a = 10.826(2), b = 16.378(3), c = 19.729(4) Å, U = 3498(1) Å^3 and Z = 4. CCDC 182/718.
22 It is also worth noting that barriers to rotation follow a similar trend. For example, rotation about the B–O bond in R_2BOR' complexes is more facile than rotation about the B–S bond in R_2BSR'. See: M. T. Ashby and N. A. Sheshtawy, *Organometallics*, 1994, **13**, 236.
23 For a brief review on dynamic NMR spectroscopy, see: G. Binsch and H. Kessler, *Angew. Chem., Int. Ed. Engl.*, 1980, **19**, 411.
24 The enthalpy and entropy of activation are: $\Delta H^{\ddagger}$ = 9(1) kcal mol^{-1} and $\Delta S^{\ddagger}$ = −19(5) cal K^{-1} mol^{-1}.
25 For other examples of inversion that have been studied by dynamic NMR spectroscopy, see: E. W. Abel, S. K. Bhargava and K. G. Orrell, *Prog. Inorg. Chem.*, 1984, **32**, 1.
26 For example, it is well documented that the inversion barrier of NH_3 is considerably lower than that of PH_3 owing to the reduced tendency of phosphorus to hybridize and obtain a planar transition state. Related effects are also observed with the chalcogens which indicate that oxygen has a greater tendency to participate in hybridization than do its heavier congeners (*e.g.* the bond angle in H_2O is considerably greater than the almost 90° bond angles in H_2S, H_2Se and H_2Te). Oxidation of organic cyclic sulfites to sulfates: a new reaction catalyzed by cyclohexanone monooxygenase

Stefano Colonna,*[a]† Nicoletta Gaggero,[a] Giacomo Carrea[b] and Piero Pasta[b]

[a] *Istituto di Chimica Organica, Facoltà di Farmacia, Università di Milano, Via Venezian 21, I 20133 Milano, Italy*
[b] *Istituto di Chimica degli Ormoni, CNR, Via Mario Bianco 9, I 20131, Milano, Italy*

Cyclohexanone monooxygenase from *Acinetobacter* catalyzes the enantioselective oxidation of organic cyclic sulfites to sulfates.

Cyclohexanone monooxygenase (CHMO) (EC 1.14.13.22) from *Acinetobacter* NCIB 9871 is a flavoenzyme of about 60 000 Daltons, active as a monomer which contains one firmly but non-covalently bound FAD unit per enzyme molecule.[1] It has wide potential for application in the manufacture of fine chemicals and in organic synthesis based on the Baeyer–Villiger reaction.[2] The only reagents consumed are dioxygen, NADPH and the substrate ketone, which are transformed enantioselectively into the corresponding ester and water.

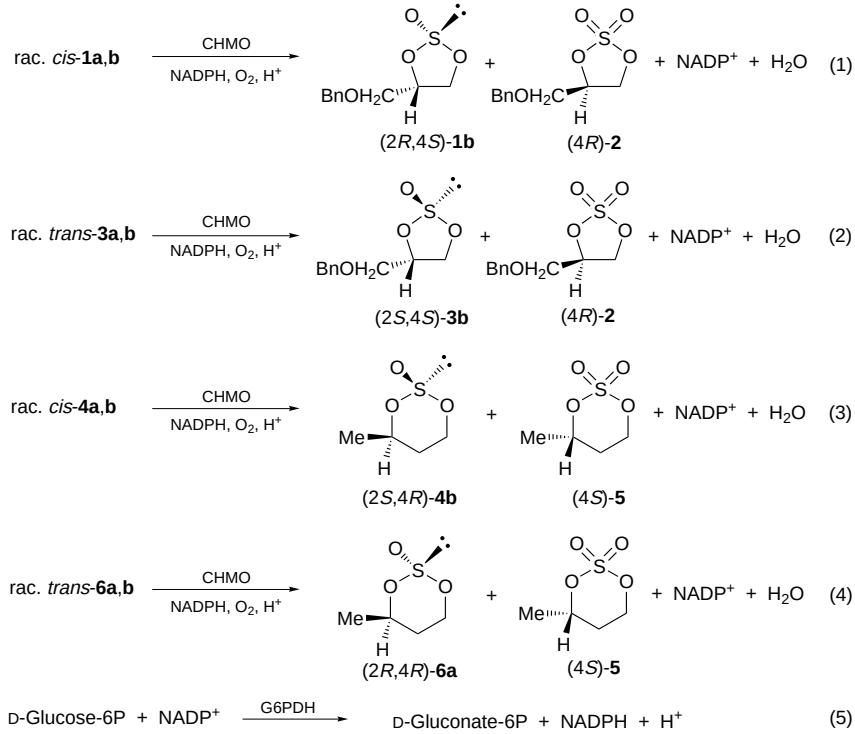
Walsh showed that CHMO can oxygenate heteroatoms, due to the high reactivity of the 4a-hydroperoxyflavin intermediate which acts as an electrophile to trimethyl phosphite and iodide ions, and as a nucleophile to boronic acids.[1] Walsh[3] and our group[4] have also shown that this enzyme catalyzes the asymmetric sulfoxidation of numerous alkyl aryl sulfides with high enantioselectivity. The versatility of CHMO in promoting enantioselective sulfoxidation was recently exploited also with 1,3-dithioacetals[5] and dialkyl sulfides.[6]

We were interested in exploring whether CHMO was able to oxidize organic cyclic sulfites to the corresponding sulfates, a reaction that, to the best of our knowledge, has not been described previously in the literature. Furthermore, this enzymatic procedure could also serve as an alternative route to the only chemical sysnthesis of sulfates of practical interest described so far. This method, developed by Sharpless and Gao, employs sodium metaperiodate as the stoichiometric reoxidant for a ruthenium tetroxide catalyst.[7] Cyclic sulfites and sulfates can be considered synthetic equivalents of epoxides, capable of reacting with a large variety of nucleophiles.[8] In many instances cyclic sulfates are more reactive than oxiranes and, unlike the latter, can lead to disubstitution products.[8]

The diastereoisomeric cyclic sulfites **1**, **3**, **4** and **6**, prepared in racemic form according to the literature,[7] were separated by flash chromatography into their *cis* and *trans* components. The enzymatic oxidation of sulfites (reactions 1–4, Scheme 1) was coupled to a second enzymatic reaction to regenerate NADPH; therefore only a catalytic quantity of NADPH was required. The regenerating system was glucose-6-phosphate and glucose-6-phosphate dehydrogenase (G6PDH) (reaction 5, Scheme 1).[3]

The time-course of reactions (1) and (2) (see Scheme 1) was monitored by HPLC both for conversion and ee. The absolute configurations of the remaining substrates **1b** and **3b** were assigned by comparison of their elution order in chiral HPLC with that of *cis*-(2*R*,4*S*)-**1b** and *trans*-(2*S*,4*R*)-**3b** prepared according to the literature.[9]

The results of the oxidation of 4-benzyloxymethyl-1,3,2-dioxathiolane 2-oxides, *cis*-**1a**, and -**1b** and *trans*-**3a** and -**3b**, reported in Table 1, show that indeed cyclohexanone mono-



Scheme 1

oxygenase in the presence of dioxygen is able to transfer an oxygen atom to the cyclic sulfite in satisfactory chemical yield. The enzymatic reaction is a 'clean' alternative to the chemical oxidation that needs a mixture of CCl_4 and MeCN as solvent. The stereoselective formation of the (4*R*)-sulfate **2** is the result of a kinetic resolution of the starting racemic substrates. The *cis* diastereoisomers (**1a** and **1b**) were more reactive than the *trans* (**3a** and **3b**), as shown by their higher conversion at the same reaction times. The enantioselectivity in the kinetic resolution was also more pronunced for the *cis* sulfite; indeed **1b** was obtained in 94% ee after 60 min, the ee of **3b** being 21%. The stereochemical course of the oxidation is dictated by the absolute configuration of the carbon atom (and not by that of sulfur) since both diastereoisomers afforded the (*R*)-sulfate **2**. The same behaviour was also shown by 4-benzylmethyl- and 4-(benzyl)-1,3,2-dioxathiolane 2-oxide, the *cis* diastereoisomers being more reactive than the *trans*. The kinetic resolution was also more satisfactory for the *cis* sulfites, the ees being in the range 15–70 and 35–50% for the starting material and the reaction products, respectively.

Interestingly, the order of reactivity and the enantioselectivity were reversed in the oxidation of 4-methyl-1,3,2-dioxathiane 2-oxides **4** and **6**. As shown in Table 1, the *trans* sulfites **6a** and **6b** reacted faster than the *cis* sulfites **4a** and **4b** and showed higher stereoselectivity. We do not know whether this behaviour is due to the more flexible nature of the five-membered ring than the six-membered ring,[10] which may affect their interactions with the active site of CHMO or, more generally, to a dramatic influence of the substrate structure on the stereochemical course of the oxidation at sulfur, as we previously found with biosulfoxidation reactions.[4]

Table 1 CHMO catalyzed oxidation of sulfites to sulfates[a]

Substrate	*t*/min	Conversion (%)	Ee (%)	
			Sulfite	Sulfate

	90	77	80	12
	120	85	93	5

[a] The oxidation of sulfites to sulfates was carried out as follows: the sulfite (10 mM) was reacted at 25 °C, under stirring, in 5 ml of 50 mM Tris–HCl buffer, pH 8.6, containing NADP (1 mM), glucose- 6-phosphate (50 mM), 10 units CHMO [purified as described by Latham and Walsh (ref. 17)] and 100 units of glucose-6-phosphate dehydrogenase. At scheduled times, the reaction mixture was extracted with ethyl acetate (3 × 5 ml), dried and analyzed by chiral HPLC or GLC to determine the degree of conversion and ee. HPLC was carried out in a Chiralpak AS column (Daicel) using *n*-hexane–propan-2-ol (9 : 1) as the mobile phase. The column separated the enantiomers of sulfites *cis*-**1** and *trans*-**3** and of sulfate **2**. The retention times were: **1a**, 9.0; **1b**, 9.9; **3a**, 12.8; **3b**, 17.3; (*R*)-**2**, 30.2; (*S*)-**2**, 31.8 min. GLC was carried out on a CP-cyclodextrin-β-2,3,6-M19 column (Chrompack) under the following conditions: oven temperature 100 to 150 °C; heating rate 1 °C min^{-1}; H_2 as carrier gas. The column separated the enantiomers of sulfites *cis*-**4** and *trans*-**6** and of sulfate **5**. Retention times were: **4a**, 17.8; **4b**, 17.1; **6a**, 10.1; **6b**, 10.6; (*R*)-**5**, 40.2; (*S*)-**5**, 40.8 min.

The absolute configurations of dioxathianes **4** and **6** were assigned by GLC comparison with authentic samples prepared according to the literature.[11]

In conclusion, this new oxidation reaction catalyzed by cyclohexanone monooxygenase, likely *via* 4a-hydroperoxyflavin as intermediate, expands the synthetic importance of this enzyme. The oxygen transfer at sulfur is enantioselective, thus allowing the obtainment of cyclic sulfites and sulfates with high ee under appropriate conditions. We are now investigating the oxidation by CHMO of other sulfites. Since the high electrophilic reactivity of 4a-hydroperoxyflavin is reminescent of that of dioxiranes we are also examining the behaviour of these oxidants in the oxidation of some substrates in organic solvents. It is worth mentioning that, so far, the only reported example of enzymatic oxidation of an organic sulfite is that of dimethyl sulfite, catalyzed by chicken liver sulfite oxidase.[12]

Concerning the scale-up of CHMO catalyzed reactions, we are assessing the possibility of using membrane reactors and macromolecular NADPH, as already done with other coenzyme dependent oxidoreductases.[13,14] However, there are some drawbacks that need to be overcome. One is represented by the stability of the enzyme, which is not very high especially in the presence of bubbling oxygen, which is an essential reagent. Considerable stability improvements have been described recently by feeding oxygen through a thin-walled silicone tube.[15] Another limitation is represented by the low water solubility of substrates. The solution to this problem could be the use of integrated extractive procedures[14] or of hydrophobic resins that act as reservoirs for both substrates and products.[16]

Financial support from CNR and MURST is gratefully acknowledged.

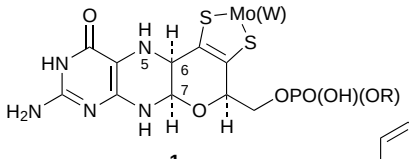
Synthesis of a cobalt complex of a pyrano[2,3-*b*]quinoxaline-3,4-dithiolate related to molybdopterin

Ben Bradshaw, Andrew Dinsmore, C. David Garner and John A. Joule*†

Chemistry Department, The University of Manchester, Manchester, UK M13 9PL

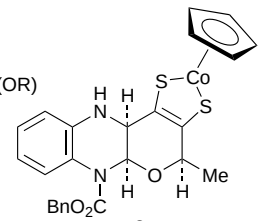
Cobalt complex 2 has been synthesised in which the key features of molybdopterin—a dithiolene ligand on a tetrahydropyrano[2,3-*b*]pyrazine—are modelled.

The pioneering analytical studies on representatives of the oxomolybdoenzymes by Rajagopalan[1] showed the presence of a pteridine (molybdopterin) carrying a C-6 side-chain having two sulfur atoms which ligate molybdenum. X-Ray crystallographic determinations on the oxomolybdoenzymes aldehyde oxidase from *Desulfovibrio gigas*,[2] DMSO reductase from *Rhodobacter sphaeroides* and *R. capsulatus*[3] and formate dehydrogenase from *Escherichia coli*[4] and on the hyperthermophilic tungsten enzyme ferredoxin aldehyde oxidoreductase from *Pyrococcus furiosus*,[5] clearly define the nature of molybdopterin and its mode of ligation to Mo and W **1**. Thus,



1

(R = H or nucleoside)
(other ligands on metal not shown)



2

the metals are chelated by an ene-1,2-dithiolate (dithiolene) which is attached at C-6 to a reduced pteridine ring, as originally proposed by Rajagopalan.[1] However, unsuspected from the degradative and spectroscopic studies of Rajagopalan,[1] all of the protein crystallographic studies observe a tetrahydropyran ring, which can be viewed as resulting from cyclisation of a side-chain hydroxy group to C-7 of a 5,6-dihydropteridine.

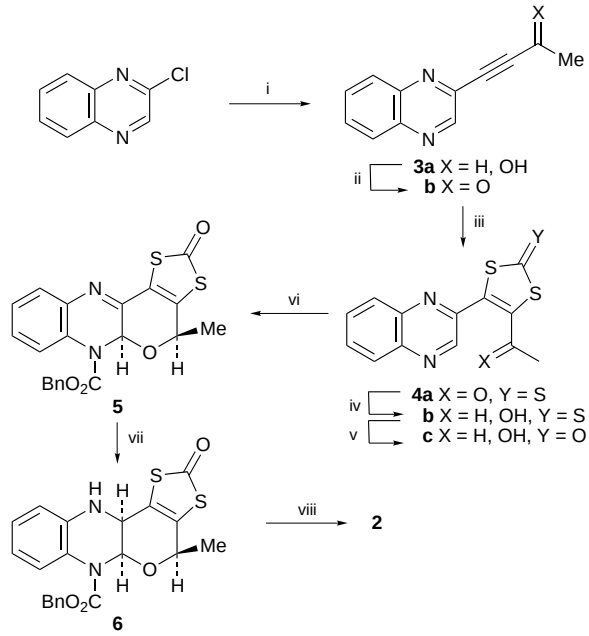
Given the results of these protein crystallographic studies, we have modified our earlier synthetic strategies[6–7] to take account of the presence of the tetrahydropyran ring and herein describe the synthesis of cobalt complex **2** which involves ligation of the metal by a dithiolene moiety linked to pyran and pyrazine rings as identified for molybdopterin.[2–5]

2-Chloroquinoxaline[9] was coupled with but-3-yn-2-ol, without protection of the alcohol, using Pd^0 catalysis, and the product **3a** was oxidised to **3b** following Taylor (Scheme 1).[10] Following precedents,[11] heating the ketone in 4-phenyl-1,3-dithiolane-3-thione[12] at 150 °C gave the 1,3-dithiole-2-thione **4a** in 75% yield. This short route to masked, unsymmetrically substituted dithiolenes has considerable advantages over those we have used earlier.[7,13]

Selective reduction of the ketone functionality with $NaBH_4$ gave alcohol **4b**; conversion to 1,3-dithiol-2-one **4c** was then achieved in high yield with mercury(II) acetate in AcOH at room temperature.

We had shown earlier[14] that treatment of 2-substituted quinoxalines with $NaBH_4$ in the presence of benzyl chloroformate leads to 2-substituted 4-benzyloxycarbonyl-1,2,3,4-tetrahydroquinoxalines, *via* initial *N*-4-acylation then trapping of the resulting quinoxalinium salt by hydride addition at C-7 and finally reduction of the remaining 5,6-imine unit. Therefore, it seemed possible that alcohols such as **4b** and **4c** might react with a chloroformate, in the absence of reductant, to form products in which a first-formed *N*-4-acylquinoxalinium salt has been trapped by an intramolecular nucleophilic attack at C-7 by the side-chain hydroxy group resulting in a cyclisation and giving a pyran ring oriented, with respect to the pyrazine, just as in molybdopterin. We were aware that simple *O*-acylation could compete with these aspirations and indeed, under most of the conditions examined in an extended study of **4b**, *O*-acylation was the only or the predominant reaction observed.

After considerable experimentation it was found that treatment of **4c** with benzyl chloroformate, in the absence of solvent or added base at room temperature, produced the desired cyclisation with no *O*-acylation. Even more rewarding was the finding that one diastereoisomer was formed almost exclusively and that the relative stereochemistry in this tricycle mirrors that in molybdopterin. Thus, **4c** was converted into tetracycle **5** in 90% yield, the relative stereochemistry in **5** being established by the observation of an NOE between the two methine hydrogen signals at δ 6.02 (s) and 4.92 (q, J 6.6) for the BnO_2CN-C*H*OCHMe and MeC*H*OCHNCO_2Bn protons, respectively. Reduction of the remaining imine unit with sodium cyanoborohydride in the presence of AcOH produced only one



Scheme 1 *Reagents and conditions*: i, HC≡CCH(OH)Me, $Pd(OAc)_2$, CuI, Ph_3P, Et_3N (88%); ii, CrO_3, H_2SO_4, Me_2CO, 0 °C (76%); iii, 4-phenyl-1,3-dithiolane-2-thione, 150 °C, N_2 (75%); iv, $NaBH_4$, THF, Pr^iOH, H_2O (69%); v, $Hg(OAc)_2$, Me_2CO, AcOH, room temp. (98%); vi, $ClCO_2Bn$, room temp., N_2 (90%); vii, $NaB(CN)H_3$, AcOH, CH_2Cl_2, MeOH, room temp. (95%); viii, CsOH, MeOH, CH_2Cl_2, room temp., then $Co(Cp)I_2$ (77%).

stereoisomer of the dihydro derivative, shown to have structure **6**, the predicted *cis* relationship of hydrogen atoms at the ring junction being confirmed by an NOE between the protons resonating at δ 5.95 (d, *J* 2.19) ($BnO_2CNCHOCHMe$) and 4.45 (d, *J* 2.19) (NCHCHOCHMe). Thus, this proligand, and the cobalt complex **2** formed from it, possess the same relative stereochemistry at the three chiral centres as in the natural cofactor. Hydrolysis of **6** with aq. CsOH at room temperature produced a solution to which was added cyclopentadienyl (diiodo)cobalt resulting in the formation of purple crystals of **2** in 77% yield, having ^{1}H NMR signals which verified that the organic ligand has been incorporated intact into the metal-containing complex.

We are currently pursuing the application of the methodology described above for the synthesis of molybdopterin, especially to ascertain the chemistry of this biologicaly important ligand. For example, it is not yet established whether the form of molybdopterin identified by protein crystallography represents the catalytically active form. Simple proton-catalysed processes would lead from the structure shown in **1** to forms in which the N–C–O unit has been cleaved, introducing a double bond into the pyrazine ring and allowing electronic communication (*i.e.* conjugation) between the metallocycle and the pteridine unit, and we have speculated on the possible involvement of such interactions in the biological mode of action of these cofactors.[15]

We thank the EPSRC for post-doctoral (A. D.) and student (B. B.) support of this work.

Calix[4]arenes with a novel proton-ionizable group: synthesis and metal ion separations

Galina G. Talanova, Hong-Sik Hwang, Vladimir S. Talanov and Richard A. Bartsch*†

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, USA

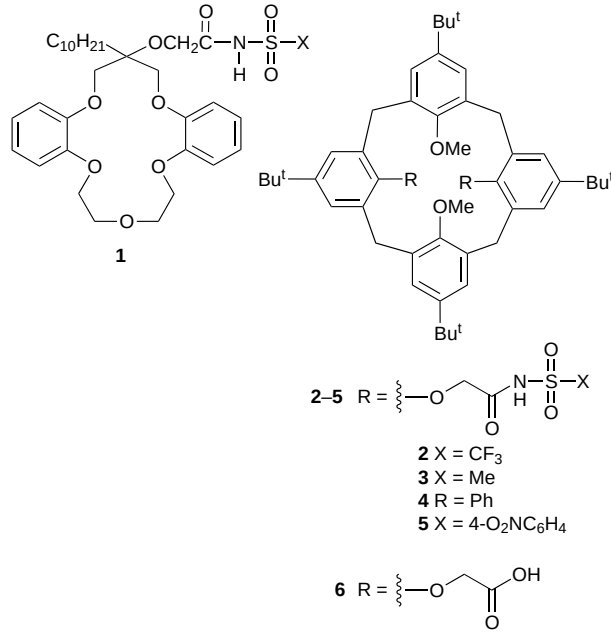
New calix[4]arenes with two *N*-(X)sulfonyl carboxamide groups of 'tunable' acidity are synthesized from the corresponding calixarene dicarboxylic acid and exhibit good to excellent extraction selectivity for Pb^{2+} over most alkali, alkaline earth and transition metal ions.

Calixarenes are an important class of macrocyclic host molecules that efficiently and selectively bind a variety of ionic and neutral guest species.[1–4] They find applications in separation processes involving organic and inorganic substances, phase transfer catalysis, chromatography, ion-selective electrodes, *etc*.[2] Calixarenes functionalized with pendent proton-ionizable groups (carboxylic acid, hydroxamic acid, phosphonic acid and phosphonic acid monoalkyl ester) are of special interest as potential agents for separations of polyvalent metal ions by liquid extraction and membrane transport[5–10] or sorption when immobilized on polymer matrices.[11–14] The ligation properties of such compounds are controlled by the nature of the ionizable groups, in particular their acidity. For example, calixarene carboxylic acids[5] were found to be much more efficient interphase carriers for alkaline earth cations than related nonfunctionalized calixarenes which contain phenolic groups on the lower rim. Developing new types of calixarenes with a wider variety of proton-ionizable functions may lead to additional applications of these compounds in metal ion separation processes.

In recent work, we have introduced the *N*-(X)sulfonyl carboxamide moiety as a novel pendent proton-ionizable group in lariat ethers **1** to obtain macrocyclic ligands with 'tunable' acidity that exhibit high Na^+ selectivity in competitive solvent extraction of alkali metal cations.[15] We now report the synthesis and application in metal ion extraction of a new type of calixarenes, the calix[4]arene bis[*N*-(X)sulfonyl carboxamides] **2**–**5**. It was anticipated that these new ligands would exhibit appreciable acidity and effectiveness in extracting divalent metal ions from aqueous solutions.

Calix[4]arenes **2**–**5**‡ were prepared in two steps from the calixarene dicarboxylic acid **6**.[16]§ The positions and shapes of the signals in the ^1H NMR spectra of **2**–**5** were found to vary with the identity of the solvent and concentration, which demonstrates that the calixarenes exist in solution as mixtures of conformers and also associate by NH··O=C hydrogen bonding. The conformational and associative behavior is especially pronounced for **5**. Solution and solid-state structures of the new ligands are under continued investigation.

The new di-ionizable calixarenes **2**–**5** efficiently extract Pb^{2+} from acidic (HNO_3) solutions into $CHCl_3$¶ (Fig. 1). The acidities of the new calixarene ligands are expected to be strongly influenced by the electron-withdrawing ability of X in the *N*-(X)sulfonyl group. Values of the pH for half-extraction ($pH_{1/2}$) in the extraction profiles are found to vary with X in the order: CF_3 (2.0) > Ph (5.2) > 4-$O_2NC_6H_4$ (5.3) > Me (5.5). Although the $pH_{1/2}$ values for **2**–**4** fall in the anticipated ordering for the electron-withdrawing ability of X,[15] that for **5** with X = 4-nitrophenyl is considerably less acidic than expected. It is suggested that the reduced acidity of **5** in $CHCl_3$ arises from inter- or intra-molecular NH··O=C hydrogen bonding or by conformational peculiarities of the compound that hinder metal ion complexation.



The extraction selectivity of **2** at pH 2.5 was examined for equimolar binary mixtures of Pb–M,‖ where M is Na^+, K^+, Cs^+, Sr^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, Cd^{2+} or Hg^{2+} (Fig. 2). High selectivity is observed for Pb^{2+} over K^+, Cs^+ and all of the transition metal ions examined except Hg^{2+}. Good extraction selectivity for Pb^{2+} over Na^+ and Sr^{2+} is also evident. Interference to Pb^{2+} extraction by the presence of Hg^{2+} was significantly reduced by the addition of chloride ions to the aqueous solution.

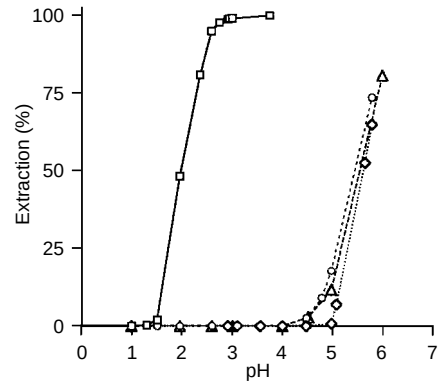


Fig. 1 pH profiles for Pb^{2+} extraction from 0.50 mM aq. $Pb(NO_3)_2$ into $CHCl_3$ with 1.00 mM calix[4]arene *N*-(X)sulfonyl carboxamides (□ **2**, (◇) **3**, (○) **4** and (△) **5**

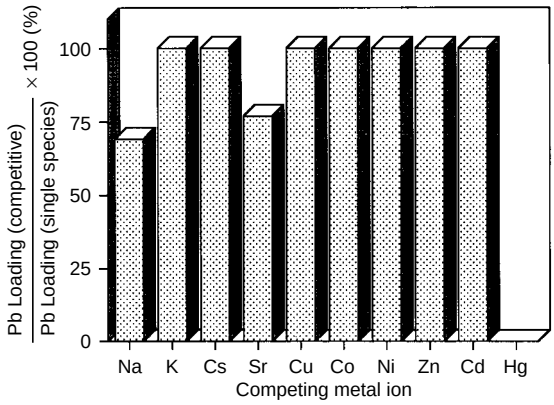

Fig. 2 Pb^{2+} loading of **2** in competitive extraction of 0.50 mM Pb^{2+} and 0.50 mM competing metal ion from an aqueous nitrate solution at pH 2.5 relative to the Pb^{2+} loading for extraction of Pb^{2+} under the same conditions, but in the absence of the competing metal ion

Further investigations of the metal ion separation properties of these novel proton-ionizable calixarenes are in progress.

§ *Typical procedure* for conversion of **6** into the corresponding bis(*N*-trifluoromethanesulfonyl carboxamide) **2**: To a solution of **6** (2.50 g, 3.15 mmol) in dry benzene (50 ml) was added oxalyl chloride (3.25 ml, 37.4 mmol). The reaction mixture was refluxed for 4 h under nitrogen and evaporated *in vacuo*. The resultant acid chloride was dissolved in dry THF (50 ml) and added to a mixture of pentane-washed KH (35% in mineral oil, 3.63 g, 31.7 mmol) and trifluoromethanesulfonamide (1.38 g, 9.3 mmol) in dry THF (25 ml). The mixture was stirred at room temperature for 10 h (1 h for **5**) under nitrogen, then water (15 ml) was carefully added to destroy the residual KH. The THF layer was separated and diluted with EtOAc (100 ml). The organic solution was washed with a 10% aq. K_2CO_3 (3 × 50 ml) and evaporated *in vacuo*. Column chromatography on alumina with CH_2Cl_2 and then MeOH–CH_2Cl_2 (1 : 9) as eluents gave a white solid which was dissolved in CH_2Cl_2 (50 ml) and washed with 1 M HCl (50 ml). The CH_2Cl_2 solution was dried over $MgSO_4$ and evaporated *in vacuo* to give a white solid which was recrystallized from Et_2O–hexanes to give **2** (2.35 g, 71%). Calixarenes **3**–**5** were prepared similarly in 60, 80 and 70% yields, respectively.

¶ A 1.0 mM solution of the calixarene in $CHCl_3$ (5.0 ml) and 5.0 ml of 0.50 mM aq. $Pb(NO_3)_2$ (pH adjusted with dil. HNO_3) in a 15 ml, metal-free capped plastic centrifuge tube was shaken on a vortex mixer for 5 min, allowed to stand for 5 min, and shaken for another 5 min. The mixture was centrifuged for 5 min and an aliquot of the aqueous phase was removed and diluted with deionized water for Pb^{2+} analysis by atomic absorption spectrophotometry.

‖ A 5.0 mM solution of **2** in $CHCl_3$ (5.0 ml) and 5.0 ml of an aqueous mixture (pH 2.5, HNO_3) which was 0.50 mM (each) in Pb^{2+} and the other metal nitrate was shaken on a vortex mixer for 5 min, allowed to stand for 5 min, and shaken again for 5 min. The mixture was centrifuged for 5 min and an aliquot was removed and diluted with deionized water. The Pb^{2+} concentration in the diluted aqueous phase was determined by atomic absorption spectrophotometry and compared with the result of Pb^{2+} extraction from the aqueous solution of 'pure' $Pb(NO_3)_2$ under the same conditions.

Transition metal complex-templated asymmetric free radical polymerisation

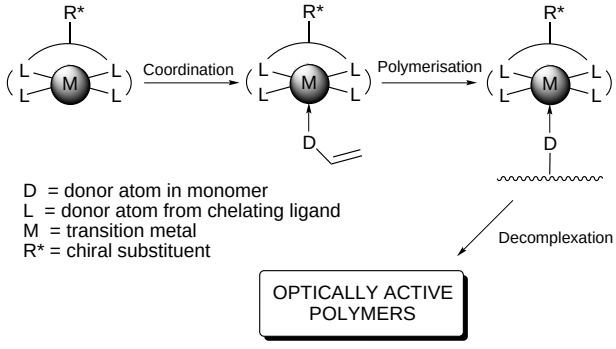
Brodyck J. L. Royles and David C. Sherrington*

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL

For the first time an amino acid Schiff base copper complex has been used as a chiral template—auxiliary for the induction of configurational asymmetry into the backbone of 4-vinylpyridine-*co*-indene polymers, yielding main chain optically active macromolecules *via* free radical polymerisation.

The synthesis of vinyl polymers whose optical activity arises solely as a result of the configuration of stereogenic carbon centres in the main chain is of increasing importance because of their unique properties and potential applications in (second order) nonlinear optics, liquid crystals, ferroelectrics and asymmetric catalysis.[1] Whereas main chain optically active (co)polymers employing non-alkene comonomers (*e.g.* CO, epoxides) have been prepared using optically active metal complex initiators, the synthesis of main chain optically active vinyl (co)polymers *via* a simple free radical mechanism remains problematical. To date, a number of ingenious strategies[1–3] have been reported which circumvent the inherent complex symmetry properties (*e.g.* glide reflection and mirror planes) associated with stereoregular macromolecular systems (*note* isotactic and syndiotactic vinyl polymers are *not* optically active), and therefore lead to main chain optically active polymers. Unfortunately, however, the majority[1,2] suffer from various disadvantages (such as multistep syntheses of monomers, expensive reagents/starting materials or products that are not readily amenable to functionalisation) that render them unsuitable for commercial exploitation. Thus for 'asymmetric synthesis polymerisation' (whereby a chiral auxiliary, or template, is attached to an achiral monomer prior to polymerisation and then removed afterwards to leave optically active polymer)[2] to achieve viability in a commercial process or as a routine laboratory procedure, the auxiliary must be of low cost, readily attached to everyday monomers and easily removed from the newly formed polymer.

We now adumbrate a novel and highly expedient strategy for preparing main chain optically active polymers in which the chiral auxiliary is a transition metal salicylidene–amino acid Schiff base complex. A vinyl monomer containing a suitable donor group (*e.g.* a vinylpyridine) will coordinate to the metal centre, thus forming a chiral monomer unit. Upon completion of the polymerisation the template complex, being attached only through relatively weak dative bonds, should be easily removed, thus liberating the vinyl polymer (Scheme 1).



Scheme 1

If a chiral monomer complex of this type were copolymerised with achiral monosubstituted or cyclic 1,1-disubstituted vinyl (or related) compounds, we realised that there would be a strong likelihood that nonsymmetric Wulff-type[1] triads (**1**) or related diads (**2**), respectively, would be formed along at least some sections of the polymer backbone. Should this in fact be the case, any such polymers would display optical activity as a result of the main chain configuration.

1 **2**

Accordingly, we have now synthesised the copper(II) amino acid Schiff base complex **3** from (*S*,*S*)-(+)-isoleucine, salicylaldehyde and copper(II) acetate in aqueous solution (see Table 1).[4] The amino acid was chosen because of its non-functionalised alkyl side chain, which provides steric bulk on the 'upper' face of the complex without the possibility of any undesirable side reactions occurring. Copper Schiff base complexes have long been known[5] and generally possess square planar geometry about the metal. Furthermore, such complexes have a high affinity for, and are readily coordinated by, one or two pyridine molecules to form five- or six-coordinate species.[5] Precedent exists for the free-radical polymerisation of transition metal complexes without any adverse interactions with the metal (*e.g.* electron transfer from a radical centre): copper[6,7] and cobalt[8] Schiff base complexes have been used to prepare imprinted polymer networks containing enzyme mimetic or chiral binding cavities, respectively.

Polymerisations were performed, under an inert atmosphere, in (deoxygenated) MeOH solutions of **3**, 4-vinylpyridine (4-VPy) **4** and indene (IN) **5** with AIBN (1 wt%) as the radical souce (Scheme 2). Evaporation of the solvent gave dark green Schiff base–polymer adducts **6**; these were not characterised except for measurement of the specific rotation in one case (see Table 2, entry 4). These adducts were broken down through acid hydrolysis before the free polymers were precipitated from the acidic aqueous solution by basifiying with aqueous ammonia. Further reprecipitation from MeOH solutions into aqueous ammonia produced the polymers **7** as off-white powders. Attempts to measure the molecular weights of **7**, using gel permeation chromatography, have so far failed because the copolymers appear to be absorbed onto the poly(styrene–divinylbenzene) column packings. This is a recognised problem

Table 1 Data for the copper(II) amino acid Schiff base complex **3** and (*S*,*S*)-(+)-isoleucine

	$[\alpha]^{25}/10^{-1}$ deg cm^2 g^{-1}	
λ/nm	(*S*,*S*)-(+)-Ile	Complex **3**
365	+6.4[a]	—[b]
436	+13.6[a]	−1014[c]
589	+27.1[a]	+128.6[c]

[a] $c = 0.14 \times 10^{-2}$ g cm^{-3} in MeOH. [b] $c = 0.07 \times 10^{-2}$ and 0.035×10^{-2} g cm^{-3} in MeOH. The sample absorbed too much light at these concentrations for a reading to be obtained. [c] $c = 0.07 \times 10^{-2}$ g cm^{-3}.

Table 2 Data for poly(4-vinylpyridine-*co*-indene) copolymer **7**

Entry	Reactants/mmol			T/°C	t/h	Polymer composition[a]	$[\alpha]^{25}/10^{-1}$ deg cm^2 g^{-1}			$c/10^{-2}$ g cm^{-3}	Solvent	Yield/g (%)
	3	**4**	**5**			4-Vpy : IN	365 nm	436 nm	589 nm			
1	5	5	5	65	18	3 : 1	—[b]	−4.0	−1.2	0.57	MeOH	0.59 (53)
2	7.5	7.5	7.5	65	18	4 : 1	−6.3	—[c]	−2.0	0.32	MeOH	0.85 (49)
3	7.5	7.5	7.5	65	16	4 : 1	−6.5	—[c]	−2.1	0.30	MeOH	0.79 (46)
4	5.2	5.2	5.2	65	18	3 : 1	−5.8	−4.2[d]	−2.3[d]	0.31	MeOH	0.58 (51)

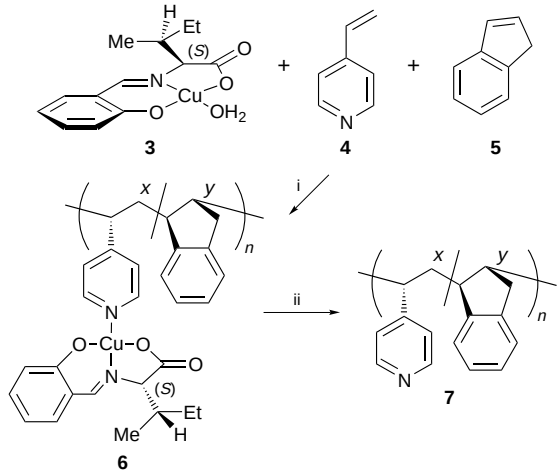
[a] Determined using ^{1}H NMR spectroscopy. [b] The sample absorbed too much light at this concentration for a reading to be obtained. [c] No readings taken. [d] Specific rotation of adduct **6** was −688.2 at 436 nm and +76.5 at 589 nm (*c* 0.017, MeOH).



Scheme 2 *Reagents and conditions:* i, AIBN, MeOH, reflux N_2; ii, 2 M HCl then NH_3 (aq)

with poly(4-vinylpyridine) systems[9] which we are currently addressing. However, the materials **7** do show all the characteristics of macromolecular systems, including broad NMR resonances and initially becoming gel-like before slowly dispersing to form isotropic solutions in organic solvents.

Each of the polymers **7a**–**d** which were prepared using the chiral auxiliary template displayed *negative* optical rotations at 365, 436 and 589 nm (see Table 2). The polymer **7e** which resulted from a blank control experiment (without template) was, as expected, optically inactive. Obviously, the asymmetric induction which has taken place during the polymerisation process is due to the stereogenic centre in complex **3**. In order to be absolutely certain that the optical activity observed arose from the main chain configuration of the polymers **7** we carried out a detailed study of the optical rotary properties of the complex **3** and the Schiff base-polymer adduct **6**, as well as (*S*,*S*)-(+)-isoleucine itself: at 589 nm all these have *positive* optical rotations of varying magnitude.

Thus we can unequivocally conclude that polymers possessing main chain optical activity have been obtained. It is important to appreciate that for a chemical process to achieve this, not only must a significant number of stereogenic centres be generated enantioselectively but it is also essential for some higher order asymmetry to be generated simultaneously. At the moment we are not able to specify precisely the configurations of the stereogenic carbon centres along the backbone although free-radical propagation of cyclic alkenes does generally proceed *via* a *trans* reaction. The overall configurations giving rise to the observed optical activity are therefore not clear cut, but there must be an excess of the diads, **2**, in the backbone.

We have described a simple, low cost and effective method for the synthesis of main chain optically active polymers. To the best of our knowledge this is the first example where a chiral transition metal complex has been employed as a template for asymmetric induction during a polymerisation reaction. It is also the first instance where non-covalent interactions have been utilised to attach the chiral auxiliary. We are currently expanding the range of copolymers produced in this way, and of course considerable scope exists for exploiting chiral Schiff base (or other) metal complexes involving other amino acids and indeed other chiral molecules.

We acknowledge the EPSRC for the award of a post doctoral fellowship to B. J. L. R. and RAPRA Technology Ltd. for help with GPC molecular weight determinations.

A tetraphenylporphyrin–peptide hybrid with high affinity for single-stranded DNA

Rishi K. Jain, David A. Sarracino and Clemens Richert*†

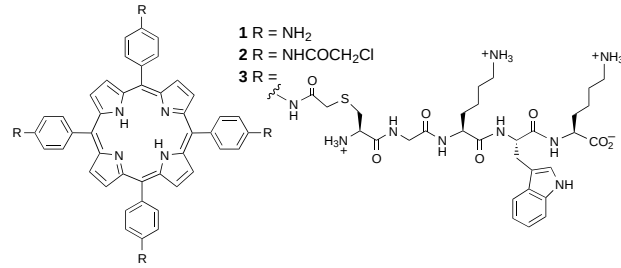
Department of Chemistry, Tufts University, Medford, MA 02155, USA

A tetraphenylporphyrin bearing four peptide chains, synthesized in two steps from *meso*-tetrakis(*p*-aminophenyl)porphyrin and the peptide CGKWK, binds single-stranded DNA oligomers with high affinity and inhibits degradation by nuclease S1.

Small ligands that bind single-stranded DNA (ssDNA) with high affinity are scarce. Non-protein ligands, such as cationic peptides with an intercalating residue,[1,2] cationic tetraarylporphyrins and sapphyrins[3] and naphthalene diimide intercalators,[4] give dissociation constants at or above the micromolar level. Lower dissociation constants are found for ssDNA binding proteins, but their crystal structures[5] do not suggest a simple way of designing small ligands with similar affinity. Further, increasing the length of a peptidic binder does not necessarily increase its affinity for ssDNA, as enthalpy gains are usually matched by entropic cost.[6] Since recent studies have shown that binding to ssDNA can inhibit polymerases, including HIV reverse transcriptase,[7,8] the search for tight ssDNA binders poses not only an intellectual challenge, but also promises to lead to drug candidates.

Presented here is the lead compound in our search for ssDNA binders. This is a tetraphenylporphyrin core molecule bearing short peptide chains. The design of this compound was based on the notions that (i) single stranded nucleic acids are highly flexible, favoring large rigid ligands to reduce the entropic penalty for complex formation, and (ii) ssDNA presents more lipophilic surface area than double-stranded DNA, where the nucleobases are buried, and its complexes may therefore gain substantial stabilization from hydrophobic interactions. Tetraphenylporphyrins are not only large, rigid and lipophilic macrocycles, they are also chromophores, allowing for sensitive monitoring of binding events. Further, tetraphenylporphyrins are straightforward to synthesize and easily detected by quantitative laser desorption mass spectrometry, a technique that has allowed us to perform monitored *in vitro* selection experiments.[9] The peptide sequence Lys-Trp-Lys (KWK), a known ssDNA-binder,[1] was chosen as substituent to provide additional binding affinity and solubility in aqueous media. A cysteinyl-glycine linker was designed to span the distance between KWK and the 'termini' of the phenylporphyrin and to provide a reactive thiol group.

Assembly of the peptide–porphyrin hybrid started from *meso*-tetrakis(*p*-aminophenyl)porphyrin **1**,[10] which was converted to the chloroacetamido derivative **2** under the conditions reported by Collman *et al.*[11] The subsequent coupling of **2** with CGKWK‡ was monitored by MALDI-TOF mass spectrometry. Thioether formation to the desired tetrapeptide **3** proceeded slowly under conditions optimized for peptide–DNA hybrids[12] (aqueous buffer, pH 7.0, 40 °C) and DMF as a co-solvent. Even with a 150-fold excess of the peptide and several days reaction time, less than 20% tetrasubstituted porphyrin **3** was found. Rigorous exclusion of air to prevent disulfide formation and stepwise addition of the peptide did not improve the yield. Further, purification of **3** from the crude product was complicated by the presence of many side products of similar molecular weight. Interestingly, coupling in dry DMF with Cs_2CO_3 as base,[13] conditions less typical for bioconjugations, proceeded smoothly with 2 equiv. peptide per chloroacetamide group.§ Despite the limited solubility of both the caesium salt and the highly charged peptide in the organic solvent, the reaction was more than 90% complete after 20 min at room temperature. Tetrasubstituted porphyrin hybrid **3** made up more than 65% of the crude product and could be obtained in satisfactory purity in a single HPLC step.¶



Addition of DNA octamers 5′-TGGTTGAC-3′ **4** and $(dC)_8$ **5** to solutions of **3** led to > 50% hypochromicity of the Sôret band but little shift of the maximum. Comparable hypochromicity has been found for a macrocyclic porphyrin-containing cryptand bound to poly(dT).[14] Unlike this single-strand specific cryptand, which is too bulky for intercalation, and cationic tetraarylporphyrins that intercalate, or, more probably, hemi-intercalate[15] into double-stranded DNA, **3** appeared to bind quite tightly to the short, single-stranded oligomers. Unconjugated KWK (2 equiv.) in the solution did not influence the binding curve measurably. Further evidence for tight binding came from the observation that the complex **3·4** did not show hyperchromicity when the NaCl concentration was raised to 3 M. In the plot of the titration data (Fig. 1) hypochromicity levels off at 1 equiv. of DNA, both at 900 and 400 nM **3**. This suggests that a 1 : 1 complex between **3** and the DNA strands is preferred when a molar excess of DNA is available, and that above 1 equiv. DNA very little unbound **3** exists at these concentrations. The latter makes it difficult to determine the dissociation constant accurately‖ but allows an estimation of $K_d \leqslant 5$ nM. This

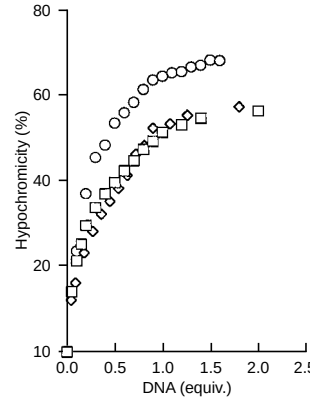


Fig. 1 Hypochromicity of the Sôret and absorption of **3** (415 nm) upon addition of DNA octamers **4** and **5**, 10 mM ammonium acetate solution, pH 6.0: (□) **3** (900 mM) + **5**, (◇) **3** (900 mM) + **4** and (○) **3** (400 nM) + **4**

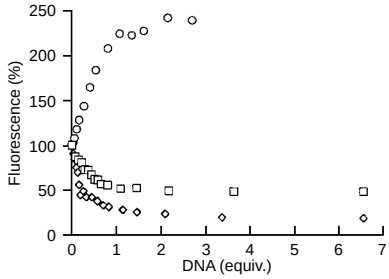

Fig. 2 Changes in fluorescence intensity (λ_{ex} = 415 nm, λ_{det} = 660 nm) upon addition of DNA octamer **4** to a solution of **3** (55 ± 10 nM) at (□) pH 6.0, (◇) 4.6 and (○) 2.5 (10 mM ammonium acetate buffers)

estimate was corroborated by fluorescence titrations performed at 55 nM **3** and increasing amounts of **4**, **5**, $(dA)_8$ **6** and 5′-GTCAAA-3′ **7** (Figs. 2 and 3). The fluorescence of **3** changed with the concentration when up to 1 equiv. DNA was added, but remained mostly unchanged at higher DNA : hybrid ratios. Only for the oligopyrimidine **5**, and the shorter oligomer **7** was a fraction of unbound porphyrin detected at 1 equiv.

When titrations with **4** were performed at pH 2.5, where the porphyrin core is at least partially protonated,[16] a fluorescence increase rather than decrease accompanied addition of DNA (Fig. 2). Apparently, **3** can reverse its fluorescence reporter properties. At a pH where the porphyrin ring is uncharged, DNA induces quenching, just like in other neutral chromophors. At low pH, however, DNA induces the fluorescence enhancement typical for cationic aromatic intercalators, such as the ethidium, acridine orange and proflavin ions. In both states, tight 1 : 1 complexes appear to form with the DNA octamer.

Exploratory experiments show that 2 equiv. of **3** inhibit the degradation of **4** by nuclease S1 by more than 50% at 37 °C [28 μM **4** in 83 mM $(NH_4)_2SO_4$–5 μM ZnSO4, pH 5.6, 0.8 u μl^{-1} nuclease, monitored by quantitative MALDI-TOF MS[17]]. Footprinting analysis[17] indicates that nuclease cleavage after the third, fourth and fifth nucleotide is similarly inhibited in the presence of **3**, with a slightly decreased protection at the latter site (not shown). This suggests that hybrid **3** covers more than a small fraction of DNA octamer **4**.

In conclusion, we report a facile synthesis of a porphyrin-peptide hybrid. The synthetic methodology requires only unmodified deprotected peptides, which are accessible *via* standard automated peptide synthesis and biotechnological processes. Hybrids prepared *via* the route presented here may become valuable bioorganic model compounds, *e.g.* as heme protein analogs[18] or photosynthetic reaction centre maquettes.[19] Further, the finding that porphyrin–tetrapeptide hybrid **3** binds ssDNA corroborates assumptions (i) and (ii) about the nature of tight ssDNA binders (*vide supra*). Initial results from a study on the binding of **3** and related compounds to double-stranded DNA, presently under way in these laboratories, shows that such hybrids can bind to short ssDNA oligomers without preventing duplex formation. Therefore, **3** may also be a lead compound for the development of protective 'coats' for antisense oligonucleotides, as, unlike complementary oligonucleotide strands, the only other known high affinity ligands to ssDNA, **3** does not seem to block Watson–Crick base pairing.

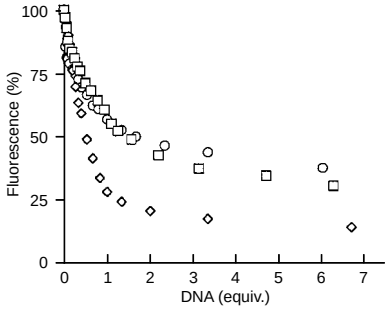

Fig. 3 Fluorescence quenching upon addition of DNA oligomers (□) $(dC)_8$ **5**, (◇) $(dA)_8$ **6** and (○) GTCAAA **7** to a solution of **3** at pH 4.6; experimental conditions are the same as in Fig. 2

‡ Synthesized *via* a standard Fmoc/Bu^t protocol. Homogeneous by RP_{18}-HPLC and single peak in MALDI-TOF MS.

§ All steps were performed under exclusion of light to prevent photosensitized oxidation. Typically, a mixture of porphyrin **3** (0.15 mg, 0.15 μmol) CGKWK (0.74 mg, 1.2 μmol), and Cs_2CO_3 (3.9 mg, 12 μmol) was dried *in vacuo*, and stirred under argon for 15 min, followed by addition of dry DMF (120 μl). The reaction was monitored by MALDI-TOF MS, and quenched after 0.7–20 h by addition of 0.2% TFA. Extended coupling (> 20 h) led to noticeable cleavage of the linking acetamide, most likely *via* transamidation to the free *N*-terminus of the peptide. Experiments with acetoxy-linked hybrids show that acyl transfer cleavage can be suppressed by acetylation of the *N*-terminus.

¶ HPLC: Vydac RP_{18} column, A = 0.1% TFA, B = MeCN, linear gradient of 0–33% B in 90 min, elution after 71 min. UV–VIS (10 mM ammonium acetate, pH 6.0) λ_{max}/nm 657, 598 (sh), 569, 527, 414, 282; δ_H([$^2H_6$]DMSO, 300 MHz, selected resonances) 8.86 (s, 8 H, pyrrole H), 8.73 (br s, 4 H, amide NH), 8.33 (br s, 4 H, amide NH), 8.19–8.03 (m, 20 H, phenyl H and amide NH), 7.83 (br s, 4 H, amide NH), 7.55, 7.31, 7.02, 6.94 (4 m, 4 × 4 H, six-membered ring H Trp), 7.14 (s, 4 H, H^{δ} Trp), −2.92 (br s, 2 H, porphyrin NH); MALDI-TOF MS (α-cyano-4-hydroxycinnamic acid matrix, positive mode, delayed extraction): calc. for $C_{164}H_{211}N_{40}O_{28}S_4$ [M + H]$^+$, 3316.5; found 3315.6. Hybrid **3** does adsorb onto glass surfaces and extensive handling and repetitive lyophilizations should be avoided. Titrations were performed from MS-checked HPLC fractions in H_2SO_4- or HNO_3-cleaned cuvettes.

Dopamine recognition in templated silicate films

Rajendra Makote and Maryanne M. Collinson*

Department of Chemistry, Kansas State University, Manhattan, KS 66506-3701, USA

Dopamine templated nanoporous silica gel films prepared *via* the hydrolysis and cocondensation of tetramethoxysilane with phenyltrimethoxysilane show an enhanced affinity for dopamine and its related structures relative to non-templated films.

Considerable attention has recently been given to the design and development of new materials with improved molecular recognition capabilities.[1] Materials with tailor-made porosity, morphology, and chemical functionality are particularly important in the development of highly selective chemical sensors, stationary phases for HPLC, binding assays, polymeric membranes, and catalytic supports. One of the most promising technologies for the creation of recognition sites within a host structure involves molecular templating.[2,3] In this approach, a polymeric network is assembled around a suitable template molecule. Upon removal of the template, microcavities with a distinct pore size, shape and/or chemical functionality remain in the host.

Sol–gel technology provides a valuable approach for the creation of nanostructured silicate materials through the hydrolysis and condensation of silicon alkoxides.[4] The inherent processing flexibility enables thin films to be readily fabricated whereas the mild polymerization conditions enable specific reagents to be readily introduced within the highly cross-linked, porous host structure without the problems of thermal or chemical decomposition.[5] In previous work it has been demonstrated that nanostructured silica with enhanced porosity can be prepared *via* template-based sol polymerization.[3] In one method, surfactant molecules are used as templates to prepare periodic mesoporous silicate materials.[3,6] In the second method, molecular sized voids are created in a silicate matrix *via* the pyrolysis of the organic functional groups[3,7] covalently bound to the silicate framework.[8] While the pore size and connectivity of the host structure can be designed at the molecular level *via* careful control of the template concentration and sol–gel process conditions,[3] improvements in chemical selectivity need to be made.

In this report, we describe a unique template based method for the fabrication of thin porous chemically selective films, that can be used to fabricate materials with improved properties. This procedure involves the blending of organosilicon precursors with the inorganic reagents to produce a composite material[8] that shows an increased affinity for a specific class of molecules once the template has been extracted from the gel. The inorganic silicon precursor acts as the cross-linking agent whereas the organosilicon precursor introduces a specific functionality in the matrix which improves chemical specificity *via* an increase in porosity, polarity and/or intermolecular interactions. The feasibility of this approach is demonstrated in this work *via* the development of a material that shows an affinity toward dopamine and its related structures. The catechol amines were selected because of the important role they play in neurotransmission and the necessity of developing methodologies that allow their differentiation in the presence of numerous interferents including ascorbic acid (AA).[9]

In these experiments, a sol stock solution was prepared by combining tetramethoxysilane (TMOS), phenyltrimethoxysilane (PTMOS), ethoxy ethanol (EE), water and 0.1 M hydrochloric acid. PTMOS was selected as the functionalized monomer because it is a trifunctional silane containing a bulky, aromatic constituent whereas EE was utilized as the solvent owing to its both polar and non-polar solvating properties. After stirring for 1 h, dopamine was added to the sol followed by the addition of potassium hydroxide to raise the pH of the sol to *ca.* 7. The molar ratio of monomers to template was 1 : 0.1 : 0.04 (TMOS : PTMOS : DA). After 30 min, a 50 μl aliquot of the sol was cast on a polished glassy carbon electrode (5 mm diameter) using an in-house built rotator (*ca.* 7000 rpm, 60 s) and the resulting films allowed to dry for 2 days in a desiccator at ambient temperature. The average film thickness as measured *via* surface profilometry was *ca.* 450 nm. The template (*e.g.*, dopamine) was leached out of the matrix by placing the film in pH 7 phosphate buffer for 2 h. Under these conditions, approximately 90% of the dopamine was leached out of the film as evident from a cyclic voltammogram (CV) of gel-encapsulated dopamine acquired before and after leaching. In control experiments, non-templated films were prepared in a similar manner with the exception that dopamine was not added to the sol.

To characterize the affinity of the templated and non-templated films for dopamine and its structurally related compounds, cyclic voltammetry was used. Fig. 1(*a*) shows a CV at a non-templated film prepared from an undoped PTMOS–TMOS sol in a solution of 0.1 mM dopamine. The lack of significant faradaic current indicates the film is compact and dopamine is unable to reach the underlying electrode surface. In distinct contrast, the films prepared from a doped PTMOS–TMOS sol show a distinguishable affinity for dopamine as evidenced from the quasi-reversible voltammogram obtained at the templated film, Fig. 1(*b*). The peak current for the oxidation of dopamine achieves a constant value within 3–4 min indicative of the relatively fast response of the templated films toward dopamine. The response of the templated film toward dopamine is *ca.* 70% of that observed for an identical solution concentration at a bare glassy carbon electrode.

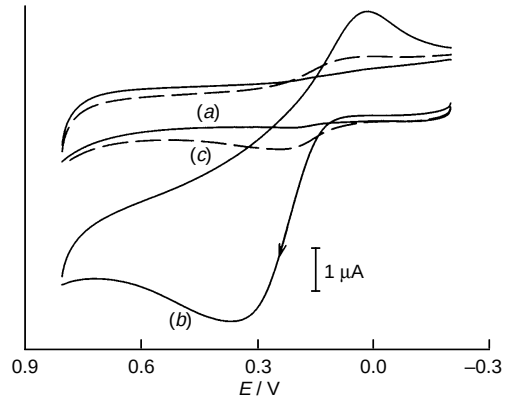

Fig. 1 Cyclic voltammograms (CVs) of 0.1 mM dopamine at (*a*) a non-templated PTMOS–TMOS film, (*b*) a templated PTMOS–TMOS film and (*c*) a templated film prepared from TMOS. The CVs were acquired after the silicate films had been in solution for 4–5 min. Solution conditions: 0.1 M, pH 7.0 phosphate buffer. Scan rate = 100 mV s^{-1}. Electrode potentials are *vs.* Ag/AgCl (1.0 M KCl).

To establish the importance of the phenyl functionality in the recognition properties of the material, templated films were prepared only from TMOS. The CV response of the templated TMOS film toward dopamine is slight as shown in Fig. 1(*c*), but significantly less than that observed at the templated PTMOS–TMOS silicate film. These results attest to the importance of the organosilicon precursor in enhancing the response of the film toward dopamine.

The dopamine templated PTMOS–TMOS films were also exposed to solutions of structurally related or biologically significant compounds including epinephrine, norepinephrine and ascorbic acid. These results showed that the templated films were not selective solely for dopamine but have an affinity for other catechol amines as well. This is expected since the host matrix is sufficiently porous and lacks specific binding sites as commonly observed for molecularly imprinted polymers.[2] The templated films, however, are able to discriminate against ascorbic acid as shown in Fig. 2. The lack of a noticeable voltammetric signal at the templated PTMOS–TMOS film and the non-templated PTMOS–TMOS film indicates that these materials have little affinity for ascorbic acid. The basis of this discrimination is likely due to electrostatics as the silicate matrix (pK_a of the silanol groups[10] is *ca*. 2) and ascorbic acid are both negatively charged at neutral pH. Alternatively, polarity may also be another factor as ascorbic acid is a relatively polar molecule whereas the phenyl-modified silicate films are more nonpolar.

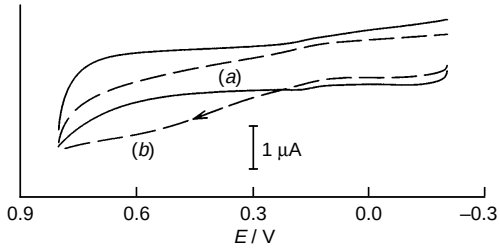

Fig. 2 Cyclic voltammograms of 0.1 mM ascorbic acid at (*a*) a nontemplated PTMOS–TMOS film and (*b*) a templated PTMOS–TMOS film. The CVs were acquired after the silicate films had been in solution for 4–5 min. Solution conditions: 0.1 M, pH 7.0 phosphate buffer. Scan rate = 100 mV s^{-1}. Electrode potentials are *vs.* Ag/AgCl (1.0 M KCl).

In summary, this study has demonstrated the feasibility of utilizing aqueous based inorganic polymerization techniques to fabricate nanoporous templated films with short response times that exhibit chemical selectivity. It is anticipated that this work will lead to promising developments in the design of improved molecular recognition materials.

Highly efficient synthesis of phosphorodithioates derived from 3′-thiothymidine by anhydro-ring opening of 2,3′-anhydro-5′-*O*-tritylthymidine with *O,O*-disubstituted phosphorodithioic acids

Wojciech Dąbkowski,[a]† Maria Michalska[b] and Izabela Tworowska[a]

[a] *Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, 90-363 Łódź, Sienkiewicza 112, Poland*
[b] *Laboratory of Organic Chemistry, Institute of Chemistry, Medical University, 90-151 Łódź, Muszyńskiego 1, Poland*

Thymidine 3′-*S*-phosphorodithioate 4 and dithymidine-3′-*S*-phosphorodithioate 7 derived from 3′-thiothymidine are synthesized in excellent yield under mild conditions by the nucleophilic ring opening of 2,3′-anhydrothymidine with phosphorodithioic acids.

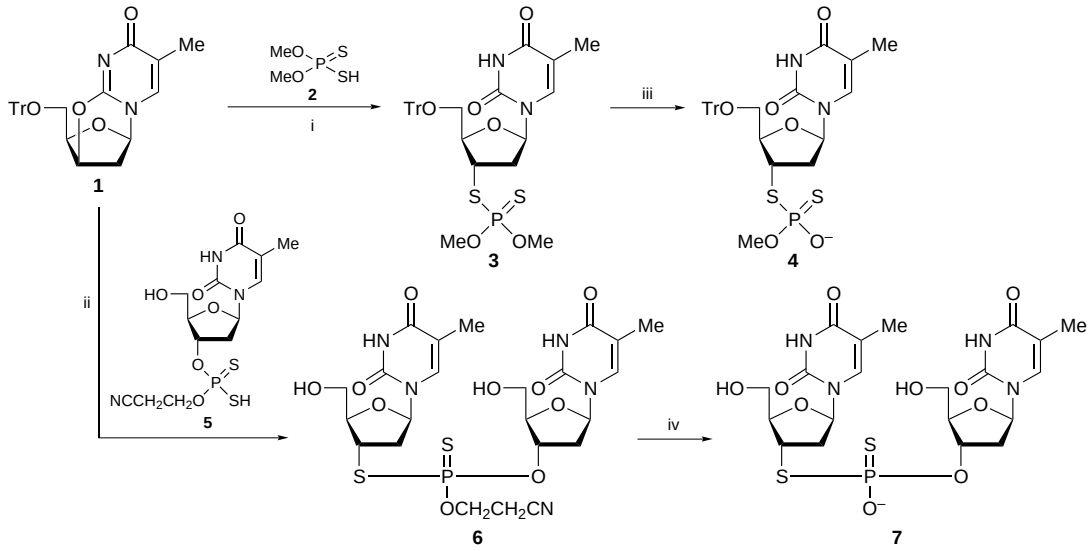
The rapid development of antisense chemotherapy[1] and studies to elucidate the mechanism of rybozyme action[2] have encouraged organic chemists to undertake the synthesis of oligonucleotide analogues in which the sugar residues and internucleotide linkages are modified. Interest in oligonucleotides containing 3′-*S*- or 5′-*S*-phosphorothioate linkages has recently increased, but methods presented to date, although elegant, are laborious and rather difficult to carry out.[3–9]

5′-Deoxy-5′-*S*-nucleosidyl phosphates have been prepared from 5′-iodo-2′-deoxynucleosides by condensation with trisodium phosphorothioate.[3] 2′-Deoxy-5′-*O*-thymidyl-5′-*S*-thymidyl phosphorothioate has been obtained by allowing thymidine 5′-phosphorothioate to react with 5′-iodothymidine.[4] A variation of this approach is the use of 5′-*O*-tosyl nucleoside for condensation with mono- or di-esters of phosphorothioic acid.[5] Cosstick has synthesized dithymidine phosphate analogues containing 3′-thiothymidine by phosphitylation of 5′-*O*-monomethoxytrityl-3′-thiothymidine.[6] The resulting dinucleosidyl phosphorothioite has been oxidized to the corresponding 3′-phosphorothioate. Dithymidine-3′-*S*-phosphorodithioate has been prepared, in an analogous fashion, as a mixture of diastereoisomers and separated after deprotection.[7]

More recently Cosstick has devised a synthesis of internucleoside 3′-phosphorothiolate linkages *via* electrophilic 3′-*S*-thymidinethiol derivatives, specifically, mixed disulfides with one strongly electronegative substituent, which were allowed to react with 3′-*O*-(*tert*-butyldimethylsilyl)thymidin-5′-yl trimethylsilyl phosphite.[8] A similar strategy has been used by Liu and Reese[9] in investigating the chemistry of RNA. Okruszek *et al.* have found that 3′-*O*-phosphorodithioates react in DMF solution with 5′-bromo-5′-deoxythymidine to give corresponding dinucleoside-5′-*S*-phosphorodithioate.[10] In spite of the elegance of Cosstick's, Reese's and Okruszek's approaches, formation of phosphorothiolate linkages requires laborious operations and depends on access to 3′-*S*- or 5′-*S*-thionucleosides and 5′-bromonucleoside which are not readily available. For this reason we have sought an alternative strategy avoiding 3′-*S*- or 5′-*S*-thionucleosides. Our long-standing interest in the chemistry of sugar thiophosphates[11] and modified nucleotides[12] also stimulated this work.

It is known that 2,3′-anhydrothymidine reacts with a variety of nucleophiles, usually under harsh conditions.[13] We discovered that 2,3′-anhydrothymidine reacts rapidly with phosphorus dithioacids [RR′P(S)SH] at ambient temperature in almost quantitative yield, and the ring opening proceeds with inversion of configuration at the 3′-carbon. Protonation of the anhydro-ring oxygen and the high nucleophilicity of phosphorus dithioacids make this procedure efficient and mild. Phosphorus dithioacids, including those derived from nucleosides,[14] are readily available.

Our methodology is exemplified by reactions of 5′-*O*-trityl-2,3′-anhydrothymidine[15] **1** with *O,O*-dimethyl phosphorodithioate[16] **2**‡ and with *O*-(5′-*O*-tritylthymidin-3′-yl) *O*-(2-cyanoethyl) phosphorodithioate **5**§ (Scheme 1). The dithioic acid **5** was prepared *in situ* by treating its DBU salt **5a** with excess of toluene-*p*-sulfonic acid monohydrate. Water introduced with



Scheme 1 *Reagents and conditions*: i, THF, 2 h, 20 °C; ii, MeCN, TsOH, 2 h, 20 °C; iii, *tert*-butylamine, 8 h, 20 °C; iv, THF–DBU (9 : 1), 1 h, 20 °C

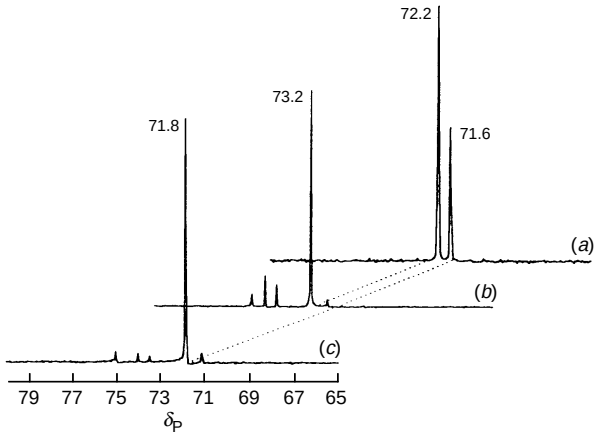


Fig. 1 The ^{31}P NMR spectra of (*a*) **4**, (*b*) **4b** (slow diastereoisomer) and (*c*) **4a** (fast diastereoisomer)

toluene-*p*-sulfonic acid does not interfere with the ring opening reaction but effects the removal of the trityl group. The analogous reaction with the DBU salt of **5a** requires severe conditions.

Both reactions proceed in THF or MeCN solution at 20 °C and are completed within 2 h yielding phosphorodithioates **3** and **6** in almost quantitative yield.

The demethylation of phosphorodithioate **3** by *tert*-butylamine and removal of the 2-cyanoethyl group of phosphorodithioate **6** leads to the corresponding salts **4a**, **b** and **7a**, **b**, respectively. These stable compounds contain a chiral phosphorus centre and are formed as a mixture of diastereoisomers. The 1 : 1 mixture of diastereoisomers **4** was separated into the 'fast' **4a** and 'slow' **4b** diastereoisomers by silica gel chromatography. ^{31}P NMR spectra of phosphorodithioates **4**, **4a** and **4b** are shown in Fig. 1.

We are currently exploring the use of nucleoside anhydrides to construct analogues of oligonucleotides containing 3′-*S*- or 5′-*S*-phosphorothiolate linkages by this methodology.

These studies were supported by grants No 3T09A 146 08 (M. M.) and No 3T09A 155 10 (W. D. and I. T.) of the Committee of Scientific Research, Poland.

‡ *Experimental procedure*: to a solution of 2,3′-anhydro-5′-*O*-tritylthymidine **1** (0.1 mmol) in 10 ml of dry THF was added a solution of *O*,*O*-dimethyl phosphorodithioate **2** (0.1 mmol) in 10 ml of dry THF and the mixture was kept for 2 h at 20 °C. The reaction mixture was concentrated under reduced pressure. The residue was purified by column chromatography on silica gel (230–400 mesh, Merck 9835) using CH_2Cl_2–Me_2CO (10 : 2 v/v) as eluent to give **3** (80%); $\delta_P(C_6D_6)$ 96.55. Compound **3** was dissolved in *tert*-butylamine, the reaction mixture was stirred for 8 h at room temperature and was solvent evaporated *in vacuo*. The product **4** was isolated by silica gel chromatography [CH_2Cl_2–Me_2CO–Et_3N, 10 : 2 : 0.5 (v/v/v)] as a mixture of diastereoisomers (1 : 1) of the *tert*-butylammonium salt of **4** (95%); $\delta_P(C_6D_6)$ 72.2, 71.6. The diastereoisomers were resolved by column chromatography using CH_2Cl_2–Me_2CO–Et_3N [10 : 2 : 0.5 (v/v/v)] as eluent and collecting small fractions. Fast diastereoisomer **4a**: $\delta_P(C_6D_6)$ 71.7. Slow diastereoisomer **4b**: $\delta_P(C_6D_6)$ 73.2.

§ A solution of 2,3′-anhydro-5′-*O*-tritylthymidine **1** (0.1 mmol) and *O*-[(5′-*O*-trityl)-thymidin-3′-yl] *O*-(β-cyanoethyl) phosphorodithioate **5** (0.1 mmol) in 10 ml of MeCN was acidified with toulene-*p*-sulfonic acid monohydrate (0.25 mmol). After 2 h at 20 °C the reaction mixture was concentrated *in vacuo* and the residue was purified by column chromatography on silica gel (230–400 mesh, Merck 9835) using CH_2Cl_2–Me_2CO [10 : 2 (v/v)] as eluent to give **6** as a mixture of diastereoisomers (95%); $\delta_P(C_6D_6)$ 92.401, 91.751 (3 : 4). A solution of **6** (0.1 mmol) in THF–DBU (9 : 1, 10 ml) was left at room temperature for 1 h. The product **7** was a mixture of diastereoisomers (3 : 2) (90%); $\delta_P(C_6D_6)$ 67.53, 67.27 (3 : 2).

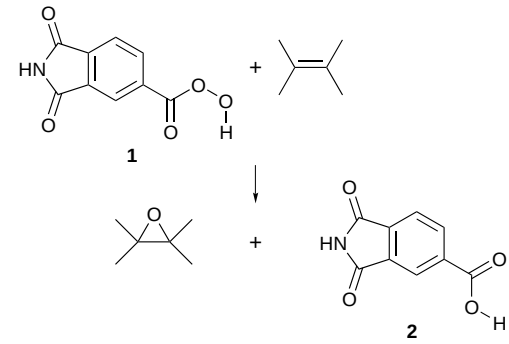
Peroxycarboxylic acids, widely used for epoxidation in industry and general research, have various drawbacks, such as difficulty of preparation in a pure state, cost and the possibly ring-opening of the product epoxides due to acid-catalysed reactions; a new reagent, 5-hydroperoxycarbonylphthalimide, overcomes these problems.

The formation of epoxides (oxiranes) from alkenes is a widely used reaction, either for the product epoxides themselves or for their preparation as intermediates in further synthesis.[1] The manufacture of epoxides ranges in scale from the small requirements of a research reaction to the huge tonnages of industrial epoxides and bis-epoxides. Hydrogen peroxide, a clean oxidant producing only water as a by-product, would be ideal if it could be used to produce epoxides directly. Although epoxidation can be effected with hydrogen peroxide through use of metal catalysts such as those of tungsten[2] or molybdenum,[3] titanium silicalites[4] and porphyrins,[5] these catalysts are not universally applicable for various reasons, including cost, lack of specificity, inability to selectively epoxidise without formation of serious quantities of by-products and lack of reactivity towards alkenes having electron-deficient double bonds. Such catalysts have not found general favour, except in some specialised instances. There is widespread use of hydrogen peroxide by first converting it into a suitably reactive form, such as *tert*-butyl peroxide and the popular peroxycarboxylic acids. Of the latter, although many are known, only a few are in general use.[6] Thus, peroxyformic, peroxyacetic, peroxybenzoic, peroxyphthalic (also as its magnesium salt), peroxytrifluoroacetic and *m*-chloroperoxybenzoic acids are the ones most frequently employed. Generally, the relatively cheap, lower molecular mass, liquid peroxyformic and peroxyacetic acids are used for large-scale industrial epoxidation and the higher molecular mass, solid *m*-chloroperoxybenzoic acid is widely employed for research or very small scale purposes. There are serious disadvantages to the use of peroxyformic and peroxyacetic acids, including their difficulty of synthesis in high concentration, their lack of stability, the need for buffering of a reaction medium to lessen acid-induced side reactions and the difficulty of recycling the parent acid. *m*-Chloroperoxybenzoic acid is not available commercially in large quantities or in pure form because of its easy thermal decomposition and sensitivity to mechanical shock;[7] the peroxyacid is also expensive because of the cost of the starting acid and the need to use methanesulfonic acid to catalyse its formation from hydrogen peroxide. Nevertheless, *m*-chloroperoxybenzoic acid does have desirable properties, in being capable of effecting many kinds of epoxidation and in giving a product acid that is relatively insoluble in non-polar solvents. The present research has shown that 5-hydroperoxycarbonylphthalimide **1** (5-PCP; 1,3-dioxo-1,3-dihydroisoindole-5-peroxycarboxylic acid; Scheme 1)[8] is an excellent, cheaper reagent for effecting epoxidation, ameliorating or overcoming many of the disadvantages listed above. Its preparation is described in a footnote to Table 1.

The alkenes shown in Table 1 were epoxidised at temperatures between 0 and 60 °C in various solvents (Scheme 1). The



Scheme 1

Table 1 Alkenes epoxidised with 5-hydroperoxycarbonylphthalimide **1** (5-PCP)[a]

Alkene	*T*/°C[b]	Solvent	*t*/h[c]
2,3-Dimethylbut-2-ene	20	CH_2Cl_2	2
Cyclohexene	20	CH_2Cl_2	6
1-Methylcyclohexene	20	CH_2Cl_2	2
	20	Toluene	3
Cyclooctene	20	CH_2Cl_2	2
α-Pinene	20	CH_2Cl_2	2
β-Pinene	20	CH_2Cl_2	2.5
Limonene	20	CH_2Cl_2	2 + 4[d]
Oct-1-ene	35	CH_2Cl_2	24
cis-Stilbene	35	CH_2Cl_2	24
trans-Stilbene	35	CH_2Cl_2	24
Allyl phenyl ether	60	$ClCH_2CH_2Cl$	113
Styrene	35	CH_2Cl_2	24
Diallyl maleate	60	$ClCH_2CH_2Cl$	150
6-Methylhept-5-en-2-one	0	CH_2Cl_2	7
1,2-Diallyloxyethane	55	EtOAc	70

[a] To conc. H_2SO_4 (29.4 g; 98% w/w) was added water (1.7 g; demineralised), with stirring and cooling, followed by hydrogen peroxide (3.66 g; 85% w/w; 0.0915 mol), maintaining the reaction temperature below 15 °C. After addition had been completed, the mixture was warmed to 40 °C, at which stage 1,3-dihydro-1,3-dioxoisoindole-5-carboxylic acid (ref. 10) (5-carboxyphthalimide **2**; 5 g) was added. The mixture was stirred at 40 °C for 45 min, after which it was cooled and quenched by addition of ice–water. 5-Hydroperoxycarbonylphthalimide **1** (5-PCP) crystallised out. The product was filtered off, washed normally with water to pH 3 and air-dried to give the pure compound in > 90% yield, mp 175 °C. [b] In a typical reaction (Scheme 1), 1-methylcyclohexene (48 mg; 0.5 mmol) in CH_2Cl_2 (2 ml) was stirred with 5-PCP (0.12 g; 0.6 mmol) at room temperature for 2 h. The course of the reaction was monitored by GC and by GC–MS. At the end of reaction, the precipitated 5-carboxyphthalimide **2** was filtered off, the solvent was evaporated and the product was weighed and examined by ^1H NMR spectroscopy. All the epoxides are known and authentic materials were used for comparison with the epoxides produced with 5-PCP. Yields were between 98–100%. [c] Approximate time to complete reaction, as revealed by the disappearance of the starting alkene. [d] With 1 equiv. of 5-PCP, only the 1,2-*mono*(epoxide) was isolated after 2 h. Addition of a further 1 equiv. of 5-PCP at this stage gave the 1,2 : 9,10 *bis*(epoxide) after a further 4 h.

alkenes were chosen to explore the general suitability of 5-PCP for epoxidation. Thus, the reactivity of the alkenes towards electrophilic oxygen ranged from the electron-rich 2,3-dimethylbut-2-ene (containing a tetraalkyl-substituted double bond) to the electron-deficient allyl phenyl ether (containing a monosubstituted, oxygen-deactivated double bond). Other alkenes were chosen to demonstrate the stability of the resulting epoxide under the reaction conditions (styrene, α-pinene, 1,2-diallyloxyethane), the stereo integrity of reaction (*cis*- and *trans*-stilbene) or the selectivity of reaction (limonene, having two different double bonds).

In each case, epoxidation proceeded to give virtually a 100% yield of very pure product epoxide. Reaction rates were as expected from the known mechanism of epoxidation with peroxyacids.[1,6] Thus, at room temperature, reaction of 2,3-dimethylbut-2-ene, 1-methylcyclohexene, cyclohexene, cyclooctene and α- and β-pinene with 5-PCP was fast in CH_2Cl_2. For the less reactive alkenes, such as oct-1-ene, allyl phenyl ether, 1,2-diallyloxyethane and diallyl maleate, higher temperatures were needed to achieve reaction in a reasonable time. Such reactions could be carried out in CH_2Cl_2 under reflux (35 °C), 1,2-dichloroethane (at 50 °C), EtOAc (at 55 °C) and toluene (at 50 °C). When the epoxidation was carried out at higher temperatures than these, reaction was faster and a clean product was still obtained, but there was some small loss of active oxygen over long periods of time. In these cases, somewhat more than a 1 equiv. of peroxyacid to each double bond was needed. Thus, after a period of about 100 h at 60 °C with 2 equiv. of 5-PCP, epoxidation of the two allylic bonds in diallylmaleate ceased at about 60–70% because of depletion of the peroxyacid; addition of a further 1 equiv. (0.5 equiv. for each bond) caused the reaction to proceed to completion and to give a very pure product.

In all of the reactions, the product acid (5-carboxyphthalimide **2**) was almost totally insoluble in the solvent. This behaviour is highly advantageous in two ways. First, the product acid can be filtered off easily from the reaction medium and re-used; this potentially low-cost acid can be recycled with hydrogen peroxide to give little or no environmentally disadvantageous by-product. Second, the insolubility of the acid, due to extensive strong intermolecular hydrogen-bonding,[9] means that the hydrogen ion concentration in solution is extremely low. In turn, this means that acid-catalysed changes in the epoxide, when formed, are reduced to a very low level, enabling the isolation of even acid-sensitive epoxides in high yield and purity. 5-PCP itself is partly soluble in the solvents described here. This implies it has all of the kinetic advantages of a homogeneous reaction but, being a very weak acid, does not produce a significant hydrogen ion concentration in the reaction medium. Thus, there is little or no effect from acid-catalysed decomposition of the product epoxide. In the most sensitive epoxides prepared in this work (*e.g.* styrene oxide), reaction proceeded to virtually 100% yield with no evidence for acid-catalysed rearrangement products (phenylacetaldehyde in the case of styrene oxide). Until full hazard information is available, 5-PCP should be treated with caution, as with any peroxy compound.

Fluorescence sensing due to allosteric switching of pyrene functionalized *cis*-cyclohexane-1,3-dicarboxylate

Carol Monahan, Jeffrey T. Bien and Bradley D. Smith*†

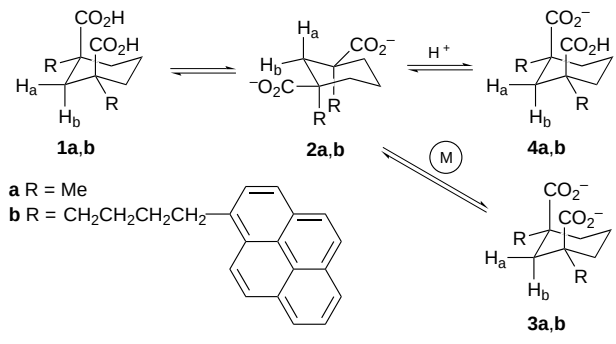
Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556, USA

The excimer/monomer fluorescence ratio for a pyrene functionalized *cis*-cyclohexane-1,3-dicarboxylate decreases upon titration with divalent and monovalent metal cations, as well as strong and weak acids.

Molecules that can be chemically switched between different conformations have been used as allosteric receptors, catalysts, transport carriers, liquid crystalline materials and sensors.[1] The main approach with allosteric sensors has been to change the proximity between two interacting fluorophores,[2] or to alter the solvent polarity surrounding a fluorophore.[3] Here we describe the allosteric properties of *cis*-1,3-disubstituted cyclohexane-1,3-dicarboxylic acids **1** and in particular how the **cis**-1,3-bispyrenyl derivative **1b** acts as a fluorescent cations sensor.[4]

Initially, the *cis*-1,3-dimethyl analogue **1a** was prepared,† and shown by ^{1}H NMR spectroscopy to adopt a chair conformation with both carboxyl groups in axial positions (Scheme 1).§ This conformational preference is in agreement with the higher steric *A* value for a methyl group compared to a carboxy group. Conversion to the dianion results in a switch to the alternate chair structure **2a** with diequatorial carboxylate groups.§ The driving force for this conformational change is the electrostatic repulsion of the proximal anionic carboxylates. In agreement with an earlier report by Menger *et al*., titration of a 1 : 1 MeOH–H_2O solution of **2a** with Mg^{2+} induces a conformational flip to **3a**.[6] Addition of Na^+, however, has a negligible effect on conformation in such a polar solvent. Two factors drive the conformational change induced by Mg^{2+}: (i) partial neutralization of the anionic carboxylates by the Mg^{2+} ion, and (ii) release of steric strain as the methyl groups transfer from diaxial to more accommodating diequatorial positions.

Based on this knowledge it was hypothesized that compound **1b** would show substantial changes in fluorescence upon conformational switching. The two pyrenyl groups in structure **2b** are in close proximity to each other and are able to exhibit intramolecular excimer fluorescence. With structures **1b**, **3b** and **4b**, the pyrenyl groups are separated and the favorability of excimer formation is decreased.[2] This was found to be the case in MeCN solution where titration of the bis(tetrabutylammonium) salt of **2b** with strong acid resulted in a stoichiometric decrease in the excimer/monomer fluorescence ratio. The titration curve (Fig. 1) indicates that only 1 equiv. of nitric acid is needed to completely switch the excimer/monomer ratio. Thus, protonation of one of the carboxylates relieves the strain due to dianionic repulsion and causes a flip to the alternate chair conformation **4b**. In contrast, alkali metal cations induce much gentler decreases in excimer/monomer ratio suggesting a gradual formation of **3b**, where M is one or two M^+ ions.§ Titration with ammonium chloride or ammonium nitrate generated plots that were identical to the nitric acid curve (Figs. 1 and 2). It appears that the ammonium also transfers a proton to **2b** and forms **4b**. Although carboxylic acids are more acidic than ammonium salts in aqueous solution, the reverse order is observed in aprotic solvents such as MeCN. For example, ammonium (pK_a 16.5) is more acidic than glutaric acid (pK_{a_1} 19.2, pK_{a_2} 29.9), a dicarboxylic acid that is structurally related to **1**.[7–9]



Scheme 1

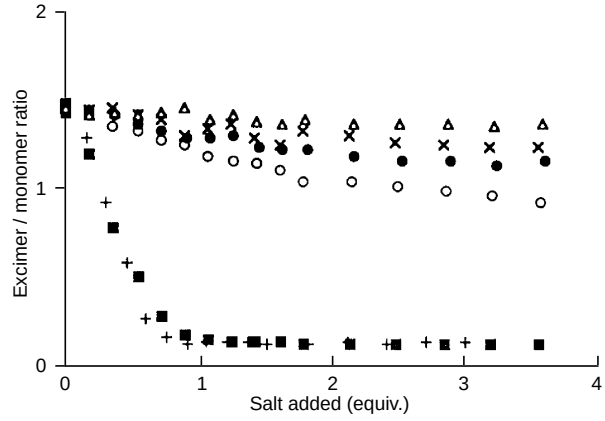


Fig. 1 Change in excimer/monomer ratio for **2b** (3 μM) in MeCN upon titration with (Δ) $CsNO_3$, (x) $RbNO_3$, (●) KNO_3, (○) $NaNO_3$, (■) NH_4NO_3 and (+) HNO_3. Excitation at 346 nm, monomer emission at 397 nm, excimer emission at 470 nm, T = 298 K.

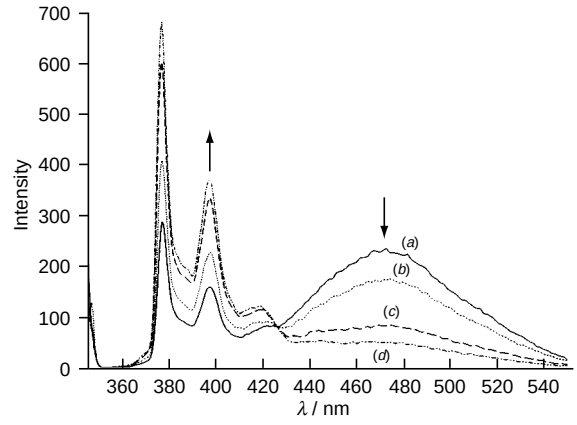

Fig. 2 Fluorescence emission for **2b** in MeCN (3 μM, excitation at 346 nm) in the presence of (*a*) 0, (*b*) 1.0, (*c*) 2.2 and (*d*) 10.6 μM of NH_4NO_3

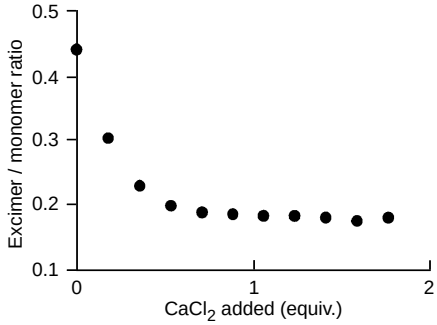

Fig. 3 Change in excimer/monomer ratio for **2b** (3 μM in MeOH upon titration with $CaCl_2$. Excitation at 346 nm, monomer emission at 397 nm, excimer emission at 470 nm, T = 298 K.

Strong evidence that the change in fluorescence is due to a conformational change was obtained from the following control experiments. (i) All of the fluorescence titrations were repeated using tetrabutylammonium pyrene-1-butyrate as a replacement fluorophore. In all cases, negligible changes in fluorescence were observed, indicating that the excimer/monomer switching is not due to due to intermolecular or environmental factors. (ii) Treatment of a CD_3CN solution of **1a** with 2 equiv. of tetramethylammonium hydroxide changes the difference in ^1H NMR chemical shifts for H_a and H_b $\Delta\delta$ = 1.36 to 0.50 ppm, which is consistent with a change from **1a** to **2a**.§ A subsequent titration of this solution with ammonium thiocyanate results in smooth migration back to $\Delta\delta$ = 1.61 ppm, suggesting that **2a** becomes protonated and converts to **4a**. The fluorescence switching effects of ammonium and alkali metal cations are essentially negligible in polar, competitive solvents such as MeOH. However, moderate descreases in excimer/monomer ratio are induced by titrating **2**b with alkaline metal dichlorides to produce **3b** (Fig. 3).

In summary, a simple but sensitive allosteric system is described that can undergo large changes in molecular shape. Depending on the experimental conditions, the conformational switching can be induced by divalent and monovalent metal cations, as well as strong and weak acids. Analogue **1b** exhibits large changes in fluorescence and is thus sensor for Lewis and Brønsted acids. Future efforts will attempt to incorporate this conformational switch into the structures of other molecular devices.

This work was supported by the National Science Foundation (USA).

Notes and References

† E-mail: smith.115@nd.edu

‡ Compound **1a** was synthesized by treating dimethyl cyclohexane-1,3-dicarboxylate with LDA (2 equiv). followed by Me_2SO_4 (2 equiv.). Saponification gave **1a** in 40% overall yield. Similarly, compound **1b** was prepared by treating the di-*tert*-butyl cyclohexane-1,3-dicarboxylate with LDA (2 equiv.) followed by 4-(pyren-1-yl)butyl trifluoromethylsulfonate (2 equiv.). Acid hydrolysis gave **1b** in 15% overall yield.

§ The conformational assignments are based on the close homology of the NMR data with Kemp *et al*. (ref. 5) and Menger *et al*. (ref. 6), who examined the conformational switching of *cis,cis*-1,3,5-trimethylcyclohexane-1,3,5-tricarboxylic acid (Kemp's triacid). In particular, the non-equivalent methylene protons between the two carboxy group in **1a** (H_a and H_b) resonate at δ 2.63 and 1.13, respectively, in 1 : 1 MeOH–H_2O ($\Delta\delta$ = 1.50 ppm). The chemical shift for H_a is strongly deshielded due to the anisotropy of the neighbouring carbonyl groups. In the case of dianion **2a**, the resonances for H_a and H_b are much closer together ($\Delta\delta$ = 0.35 ppm) indicating that they are nearly equidistant from the carboxylates, which can only occur if the carboxylates have assumed equatorial positions. Structure **3** is drawn as a classical chair with the carboxylates in diaxial positions, however, another possibility is a flattened half-chair which provides the carboxylates with slightly more spacious psuedo-axial environments. (ref. 6).

A fullerene-modified protein

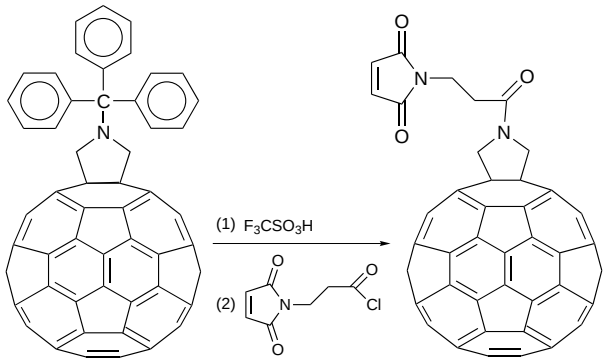
Arnd Kurz,[a] Catherine M. Halliwell,[a] Jason J. Davis,[a] H. Allen O. Hill*[a]† and Gerard W. Canters[b]

[a]*Inorganic Chemistry Laboratory, University of Oxford, Oxford, UK*
[b] *Leiden Institute of Chemistry, Leiden University, Gorlaeus Laboratories, Leiden, The Netherlands*

A surface cysteine-containing redox protein (azurin mutant S118C) has been labelled with a C_{60}-based thiol-selective reagent leading to electrochemical interactions between the fullerene and protein redox centre.

In recent years much interest has been drawn to the biological activities of fullerenes, such as cytotoxic activity,[1] selective DNA cleavage[2] and antiviral activity against HIV.[3] However, biological studies have been hindered because of the hydrophobic nature of fullerenes. In an effort to overcome problems associated with their insolubility in aqueous solution, several strategies have been developed such as the formation of complexes with cyclodextrin,[4] liposomes,[5] poly(vinylpyrrolidone)[6] and derivatization with water-solubilising moieties.[7] The C_{60} cage is able to reversibly accept up to six electrons under suitable conditions,[8] so C_{60}, that is covalently attached to biomolecules, can be sensed electrochemically. As C_{60} is insoluble in water little is known about its electrochemical behaviour in aqueous media, although the electrochemistry of films[9] and γ-cyclodextrin inclusion complexes[10] has been studied. The C_{60} radical monoanion has recently[11] been reported to be stable in water and monoanion containing salts have been isolated from aqueous solutions. We report herein the modification of a redox protein (azurin mutant S118C) with buckminsterfullerene and the electrochemical behaviour of the adduct so formed.

Azurin is a small blue copper redox protein which acts as an electron transfer agent in the denitrification chains of a number of bacteria. It has a molecular weight of about 14 000 kDa. As wild type azurin does not contain any surface cysteines (and hence free thiols), a mutant‡ containing just one surface cysteine was created by polymerase chain reaction (PCR) mutagenesis methods[12] and expressed according to published methods.[13] Serine 118 was genetically replaced by a cysteine, this being a conservative mutation to ensure the mutant closely resembled the wild type azurin. The position was chosen to allow labelling close to the redox centre, a copper ion in the case of azurin, in order to investigate the possibility of electrochemical communication between copper and fullerene. The previously described *N*-(triphenylmethyl)-3,4-fulleropyrrolidine[14] was reacted with 3-maleimidopropionyl chloride in the synthesis (Scheme 1) of a thiol selective fullerenomaleimide.§



Scheme 1

This label is not soluble in water and only sparingly soluble in polar organic solvents, but is reactive enough as a suspension to couple to the protein. For the labelling reaction, the fullerenomaleimide (in 100-fold molar excess) was suspended in a 60 μM solution of azurin S118C in 20 mM HEPES buffer at pH 7. The suspension was then stirred for 72 h at 4 °C. The originally blue solution turned green after 24 h. Over the same time period the characteristic electronic absorption band of C_{60} at 330 nm appeared (Fig 1). Unreacted fullerene was removed by size exclusion chromatography (PD-10, Pharmacia). A SDS-PAGE gel (15% polyacrylamide) indicated the presence of a new band at higher mass. The mass increase was estimated to be 5%, consistent with the addition of one fullerene moiety per protein. The reaction appeared to go to completion as no native protein could be detected by SDS-PAGE or by cyclic voltammetry. The cyclic voltammogram of the product shows the presence of a new redox couple at −302 mV assigned to the first electron reduction and reoxidation of C_{60} (Fig 2). The potential lies between that reported[11] for a solution of C_{60} in DMF (−250 mV) and a γ-cyclodextrin inclusion complex of C_{60} in water (−570 mV).[10] The redox couple of the protein copper appears at −42 mV. It is shifted by 41 mV to a more negative potential

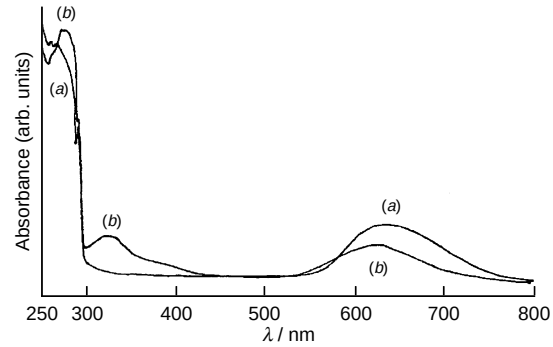


Fig. 1 UV–VIS spectrum (H_2O) of (*a*) azurin S118C and (*b*) fullerene-modifed S118C

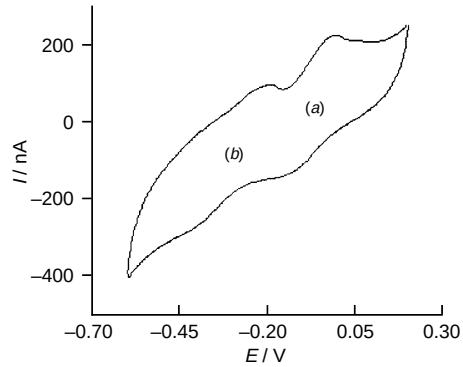

Fig. 2 Cyclic voltammogram at an edge plane graphite electrode of 65 μM fullerene modified S118C in 20 mM HEPES buffer (pH 7.0) containing 5% THF and 5% DMSO at 50 mV s^{-1} and 25 °C. The solutions were purged with argon for 60 min before measurement. (*a*) Copper redox couple Cu^{+2}/Cu^{+1} and (*b*) fullerene redox couple $C_{60}°/C_{60}^{-1}$.

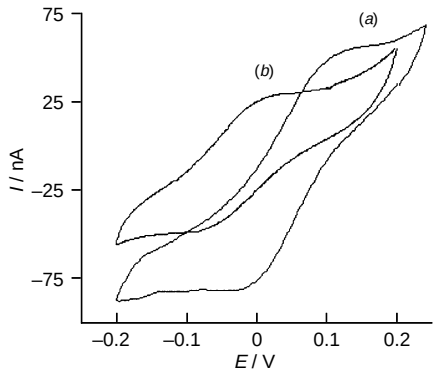

Fig. 3 Cyclic voltammogramm of (*a*) wild type azurin and (*b*) fullerene modified S118C under the same conditions as in Fig 2

compared to the unmodifed protein (−1 mV) under the same experimental conditions (Fig 3). As the fullerene is attached next to histidine 117, which is a copper ligand, modification-induced changes in the redox potential are likely. If the potential range is restricted to that of the azurin copper, a reversible couple is observed with reduction and re-oxidation peak areas of equal magnitude. If scans are continued to more negative potentials (at which the fullerene is reduced) the anodic peak of the Cu couple changes, as does the ratio of anodic to cathodic current. This behaviour suggests communication between copper centre and fullerene. Spectroscopic (UV–VIS) and electrochemical data prove that the fullerene modification did not lead to the denaturation of the protein.

The covalent modification of protein with buckminsterfullerene opens up the possibility of extensive investigations into the aqueous and biological chemistry of these 'fulleryl proteins'.

The support of the Dutch Science Foundation (C. M. H.), MediSense (A. K.) and the BBSRC (A. K., C. M. H., J. J. D.) is gratefully acknowleged. We thank Professor M. L. H. Green for access to arc vaporisation equipment and Drs P. D. Barker, M. J. Rosseinsky and G. Sanghera for helpful discussions.

‡ Preparation of S118C: Mutagenesis of azurin *Pseudomonas aeruginosa* was performed by PCR with the primers: 5′GCACCTTCCCGGGC-CAC*TGC*GCGCTGATG-3′ (5′-primer) and 5′-AAACGACGGCCAGT-3′ (3′-primer). The azurin mutant S118C was expressed and stored as the apoform. Dithiothreitol (DTT) was added to the buffers to give a final DTT concentration of 3 mM in order to prevent dimerisation. Prior to labelling the DTT was removed through the use of desalting columns (PD-10, Pharmacia). The protein was reconstituted by addition of an equimolar amount of a 10 mM solution of $Cu(NO_3)_2$.

§ Preparation of *N*-(3-maleimidopropionyl)-3,4-fulleropyrrolidine: *N*-(triphenylmethyl)-3,4-fulleropyrrolidine (30 mmol) (ref. 14) in dry CH_2Cl_2 (10 ml) was treated with trifluoromethanesulfonic acid (100 μl) for 1 h. The precipitate was washed with Et_2O–H_2O and dried. The amine was suspended in dry CH_2Cl_2 (10 ml) and dry pyridine (1 ml). A 30 molar excess of *N*-maleoylpropionyl chloride was added. After stirring for 3 h at room temperature the mixture was purified on silica gel (CH_2Cl_2): δ_H (500 MHz, CS_2–[$^2H_6$]benzene 4 : 1) 6.78 (s 2 H), 5.47 (s 2 H), 5.37 (s 2 H), 3.84 (t 2 H), 3.19 (t 2 H); *m*/*z* (MS-FAB) 913 (M-1, 50%), 720 (C_{60}, 100); λ_{max} (CH_2Cl_2)/nm 232, 260, 332, 406.

Separation of carbon nanotubes by size exclusion chromatography

G. S. Duesberg,* M. Burghard, J. Muster, G. Philipp and S. Roth

Max-Planck-Institut für Festkörperforschung, Heisenbergstr. 1, D-70569 Stuttgart and EU TMR network Namitech, Germany and University of Dublin, Trinity College, Physics Department, Dublin 2, Ireland

Size exclusion chromatography has been performed on micellar aqueous dispersions of soot from an arc discharge experiment to yield chemically unmodified, almost impurity free and size separated multiwall nanotubes.

Several large-scale synthesis routes for carbon nanotubes (NTs) have been reported,[1–3] however, they lead to by-products of other carbon species. In addition to multiwall NTs the soot of a conventional arc discharge experiment contains fullerenes, carbon polyhedra, and amorphous carbon, which are interconnected in a dense network. For a number of proposed applications of NTs, which include field emission[4] and electronic devices,[5,6] their purification and size separation is of great importance.

In destructive methods, like oxidation, the soot material is purified by decomposition of the small particles while some tubes remain. However, the caps of the tubes are opened and chemical functionalities are introduced on the tube surface.[7,8] In addition, no size separation of the tubes can be accomplished by these methods.

Non-destructive methods like filtering or flocculation have been reported but their efficiency is limited,[9,10] and especially in filtration techniques blocking of pores is a severe problem.

Here, we report the purification and size separation of multiwall NTs by size exclusion chromatography (SEC), which is a multistep process using a stationary phase with defined pore sizes. SEC is a powerful tool for the separation of large molecules, *e.g.* biological macromolecules or virus particles.[11]

A dispersion of multiwall NTs in water was prepared with the aid of sodium dodecyl sulfate (SDS). Through the action of the surfactant the carbon particles were incorporated into micelles.[10] 10 mg of the raw soot from a conventional arc discharge experiment was added to 2 ml of a 1 mass% aqueous SDS solution and sonicated for 5 min with an ultrasonic tip. After a settling time of 15 min a black supernatant was obtained, leaving a sediment of some undispersed aggregates. The colloidal dispersion was stable for days and was used directly for chromatography.

Two successive columns were used for the fractionation. The purpose of the first column was to remove the gross of small particles and fullerenes. The packing (7 × 2 cm) consisted of controlled pore glass (CPG) with an average pore size of 140 nm (CPG 1400 Å, Fluka). This material is characterized by a narrow pore size distribution and is chemically inert. The column was loaded with 1.5 ml of the supernatant and eluted with a 0.25 mass% aqueous SDS solution buffered at pH 7. The flow rate was adjusted to 9 ml h^{-1}. After a void volume of 16 ml, two fractions of 6 ml were collected. The first fraction was concentrated to 1.5 ml by addition of 100 mg of polyacrylamide adsorbent gel (Fluka) followed by continuous shaking for 30 min. No darkening of the gel was observed, indicating that this technique allows the concentration of aqueous NT dispersions without an apparent loss of material.

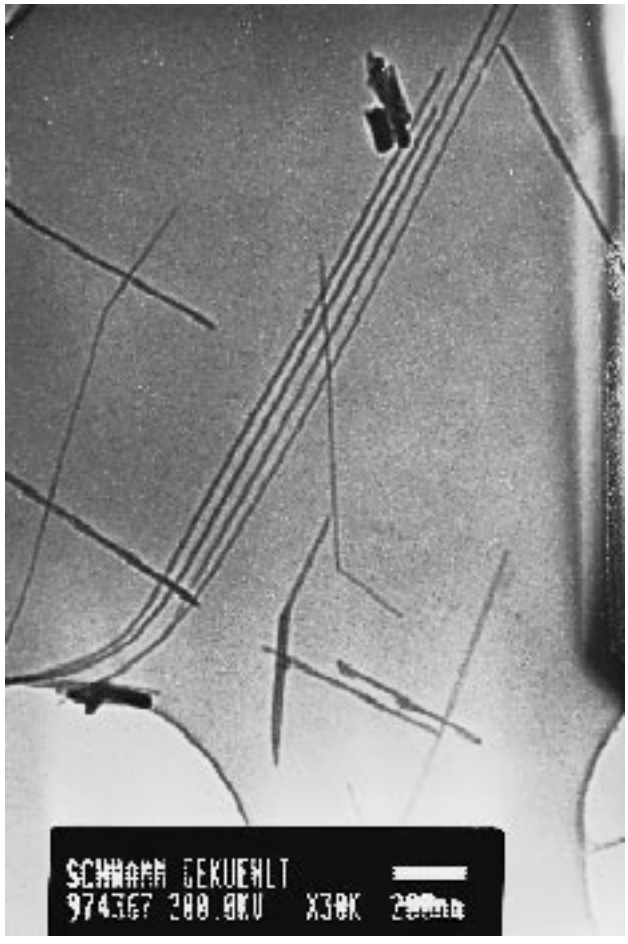

Fig. 1 Transmission electron micrograph of fraction 3: multiwall nanotubes purified by size exclusion chromatography

Fig. 2 Scanning electron micrograph of purified carbon nanotubes adsorbed on a chemically modified Si wafer

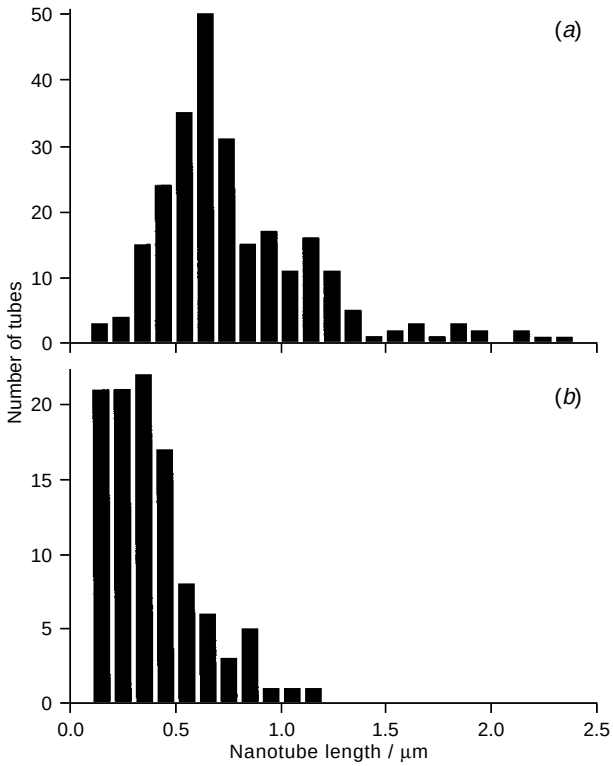

Fig. 3 Histograms of nanotube lengths in the third fraction (*a*) and sixth fraction (*b*)

The concentrated first fraction was loaded into the second column (33 × 1 cm) filled with CPG with an average pore size of 300 nm (CPG 3000 Å, Fluka). The same eluent as before was used with a flow rate of 5 ml h^{-1}. After a void volume of 16 ml, eight fractions of 1.5 ml were collected.

The fractions were characterised by transmission and scanning electron microscopy (TEM/SEM) as well as atomic force microscopy (AFM). For the TEM investigations, the carbon grids were treated with a fraction for 15 min and then rinsed briefly with water. Fig. 1 shows a typical TEM micrograph of the third fraction. Individual NTs are clearly recognized, demonstrating that the network of the soot was successfully disintegrated by the surfactant. Furthermore, scarcely any small spherical particles were observed in this fraction, revealing successful purification of the NTs.

For the determination of NT sizes in the different fractions, the NTs were adsorbed onto chemically modified Si wafers. The wafers were silanized for 30 min in an aqueous solution of 3-aminopropyltriethoxylsilane (2.5 mM), and then treated with the NT dispersion for 30 min. After drying, they were immersed in water for 1 min to remove the surfactant. The adsorbed NTs were investigated by SEM and AFM, which revealed that the surfactant was removed from the surface by the washing step.

In the first fraction from the second column (fraction 1), aggregates of NTs and other carbon species were found while fractions 7 and 8 contained mainly spherical particles and a few short tubes, both < 0.1 μm. Fractions 2–6 consisted of individual nanotubes and, for the later fractions, a low content of spherical particles. Fig. 2 presents a representative SEM image of the third fraction. It shows individual NTs, mainly with a length of *ca.* 1 μm.

A statistical evaluation of the size distribution was performed using the NT lengths determined from a number of SEM and AFM images. The histograms of fraction 3 and 6 are shown in Fig. 3(*a*) and (*b*), respectively. There is a significant difference in the length distribution of the NTs: the average NT length in fraction 3 was calculated to be 0.8 μm and in fraction 6 to be 0.4 μm.

In conclusion, the chromatographic technique presented is an effective, non-destructive method for purification and size separation of carbon NTs. This type of chromatography should also be applicable to micellar dispersions of single wall NTs. This work is now in progress. In addition, the method can easily be scaled up and by the use of more sophisticated chromatographic systems, *e.g.* HPLC, the size separation could be improved.

Supported by EU TMR network Namitech.

The structures of premithramycinone and demethylpremithramycinone, plausible early intermediates of the aureolic acid group antibiotic mithramycin

Jürgen Rohr,*[a]†‡ Ulrike Weißbach,[a] Claus Beninga,[a] Eva Künzel,[a] Karsten Siems,[b] Kai U. Bindseil,[b] Felipe Lombó,[c] Laura Prado,[c] Alfredo F. Braña,[c] Carmen Méndez[c] and Jose A. Salas[c]

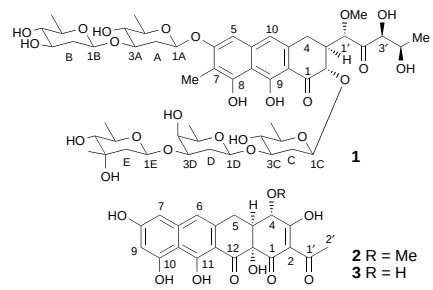
The structures of premithramycinone and its demethyl analogue suggest that the aureolic acid antibiotics are biosynthetically formed *via* a tetracycline-type, and not a tetracenomycin-type, folded decaketide.

Mithramycin[1] **1** (aureolic acid, plicamycin, mithracin, LA-7017 *etc*.[2]) and related aureolic acid group antibiotics, such as the chromomycins, olivomycins and UCH9, are important anticancer agents, effective against various experimental and human tumours.[1–6] Mithramycin in particular has been clinically used for the treatment of certain tumours as well as for Paget's bone disease.[7,8] For its mechanism of action, a Mg^{2+} dimer complex binding to GC-rich DNA regions has been investigated.[9]



Incorporation experiments on chromomycin A_3 with various single and double ^{13}C labelled acetates by Montanari and Rosazza revealed that all carbon atoms of the aglycon moiety of the aureolic acid group antibiotics are acetate, *i.e.* polyketide, derived.[10] Because of the unexpected incorporation pattern, hypotheses were raised in which two or three independent acetate chains are condensed to form the aglycon.[10] Recent molecular biology experiments[11,12] confirmed our earlier hypothesis[13] that the entire aglycon backbone of such compounds derives from a single decaketide chain. To explain Rosazza's acetate incorporation pattern, a tetracenomycin-type intermediate was suggested.[11–13] Therefore, the aureolic acid group was proposed to be biosynthetically closely related to the tetracenomycins. The tetracenomycins, produced by *Streptomyces glaucescens*, are unique among the polycyclic aromatic polyketides insofar as the formation of their tetracyclic ring skeleton requires a folding of the hypothetical decaketide intermediate leading to a first cyclization between carbons 9/14, instead of the more typical first cyclization between carbons 7/12 which is found, *e.g.* for anthracyclines, angucyclines and tetracyclines.[13–15]

Premithramycinone **2** and its demethyl analogue **3** (in smaller amounts) are accumulated by the disrupted M7D1 mutant of *Streptomyces argillaceus* ATCC 12956, which is a mithramycin producer. In the mutant M7D1 the *mtmD* gene encoding a glucose-1-phosphate : thymidylyl transferase[16,17] was inactivated through the insertion of an apramycin resistance cassette into a unique *Bam*Hl site of this gene and through gene replacement of the wild type region of the chromosome by the *in vitro* mutated one.[16] Glucose-1-phosphate : TTP thymidylyl transferase is a key enzyme of the deoxysugar biosynthesis. As a consequence, no sugar substrates for the glycosyl transfer steps in the mithramycin biosynthesis can be provided, and an aglycon substrate can be expected to be accumulated in such a mutant strain, as was discussed previously.[16] However, a wrong structure was initially suggested for premithramycinone.

The (revised) structures of **2** and **3** were determined on various physicochemical data, in particular on one- and two-dimensional ^1H and ^{13}C NMR spectra (Tables 1 and 2, Fig. 1).[18] Fig. 1 shows the $^nJ_{C,H}$ couplings (n = 2,3; HMBC) found for **2** (for **3** analogously), including the key couplings supporting these structures *vs*. the formerly suggested premithramycinone structure which can be observed between 2′-CH_3/1′-C=O and 2′-CH_3/C-2. The stereochemistry shown in **2** and **3** is suggested taking into consideration the observed H,H and C,H couplings

C-8	164.0 (s)	163.9 (s)			

[a] 125.7 MHz. [b] 100.6 MHz. [c] Interchangeable due to tautomerisation.

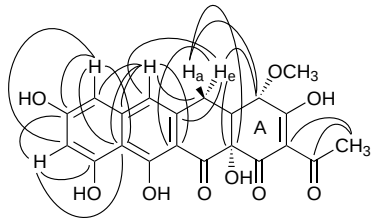

Fig. 1 $^{2,3}J_{C,H}$ Couplings observed in the HMBC spectra of **2** and **3**. Several theoretical couplings in ring A are not detectable due to tautomerisation

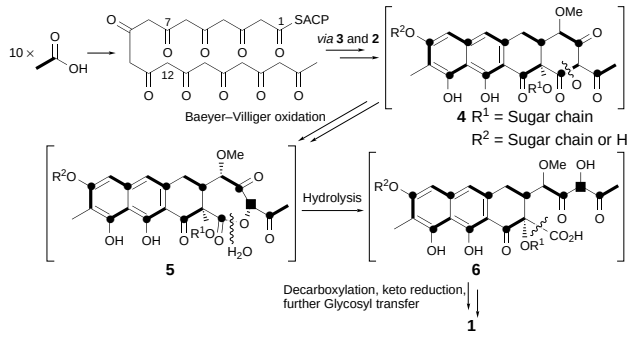
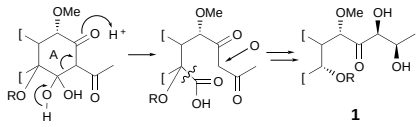
(Table 1, Fig. 1) and the given stereochemistry of **1** along with the conversion mechanism involving a Baeyer–Villiger type oxidation (Scheme 1). The structures **2** and **3** resemble certain tetracyclines, *e.g.* the aglycon moiety of chromocyclomycin,[19] BMS-192548 and others.[20]



Scheme 1

Thus, **2** is plausibly the substrate for the first glycosyl transfer reaction, and its glycosylated derivative[21] is likely to be the substrate for an enzyme responsible for a C–C bond scission leading to the typical tricyclic aureolic acid chromophore. For this cleavage reaction, we suggest here also[22] a Baeyer–Villiger type oxidation of **4** leading to the ε-lactone containing intermediate **5**. Its subsequent hydrolysis to **6** along with a decarboxylation reaction and eventual further glycosylation reaction leads to **1**. As an alternative, a retro-aldol-type cleavage and a subsequent oxidation of the resulting side chain (Scheme 2) may also be taken into consideration.[23] Both mechanistic sequences (Schemes 1 and 2) are also in agreement with Rosazza's and our own ^{13}C labelled acetate incorporation pattern.[10,24]



Scheme 2

The studies described here show the (presumably oxidative) C–C bond cleavage of a tetracyclic compound to be the biosynthetic key step leading to the aglycon skeleton of the aureolic acid group antibiotics, as was suggested earlier.[11–13] However, the tetracyclic compounds **2** and **3**, which are presumably biosynthetic intermediates of mithramycin, are structurally related to the tetracyclines, and not to the tetracenomycins. Thus, a tetracycline-type folding (Scheme 1) rather than a tetracenomycin-type folding and a standard first cyclase reaction between carbons 7/12 of the hypothetical decaketide intermediate (Scheme 1) is also true in the biosynthetic formation of the aureolic acid antibiotics, and all former hypotheses involving a tetracenomycin-type intermediate[12–15] have to be corrected, including the previously suggested wrong structure for premithramycinone.[16]

The authors thank the European Community (BIO4-CT96-0068), the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (SFB 416), the Deutsche Akademische Austauschdienst (314-Al-e-dr) and Plan Nacional en Biotecnología (BIO94-0037) for generous financial support of this cooperation project on antitumour agents, and R. Machinek, Institut für Organische Chemie, Universität Göttingen, Germany, for excellent NMR spectra. Both referees are acknowledged for their constructive suggestions.

Structure and molecular magnetism of the rutile-related compounds $M(dca)_2$, M = Co^{II}, Ni^{II}, Cu^{II}, dca = dicyanamide, $N(CN)_2^-$

Stuart R. Batten,[a,b] Paul Jensen,[b] Boujemaa Moubaraki,[b] Keith S. Murray*[b] and Richard Robson*[a]

[a] *School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia*

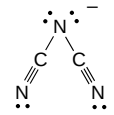
The isomorphous rutile-related network structures of $Co(dca)_2$, $Ni(dca)_2$ and $Cu(dca)_2$, dca = dicyanamide, $N(CN)_2^-$, are shown to behave as ferromagnets (T_c = 9 and 20 K) and a near-paramagnet, respectively.

The deliberate design and construction of coordination polymers with predetermined topology is an area of much current interest.[1–3] A number of new compounds with interesting properties such as high porosity and catalytic activity has been made following these principles. Here, we describe a series of such compounds which display unusual magnetic properties, including long-range ferromagnetic ordering. A number of existing coordination polymers are already known to display unusual magnetic properties. For instance, $(rad)_2Mn_2[Cu(opba)]_3(Me_2SO)_2{\cdot}2H_2O$, opba = *o*-phenylenebis(oxamato), rad^+ = 2-(4-*N*-methylpyridinium)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide consists of two sets of 2D hexagonal sheets of $Mn_2[Cu(opba)]_3^{2-}$ which interpenetrate each other at an angle of 72.7°.[4] Rad^+ cations connect the sheets, and the solid behaves as a magnet below 22.5 K. The magnetic properties of a large number of bimetallic oxalate structures, $AMM'(ox)_3$ ($A^+ = NR_4^+$), which have a hexagonal sheet structure, have also been studied recently.[5] There is a great need to explore bridging groups other than these N,O-bonded oxamides and O-bonded oxalates.

The results described herein form part of a study we are undertaking on the binary structures of metal–pseudohalide compounds. The structures of $M(tcm)_2$, tcm = tricyanomethanide, $C(CN)_3^-$, M = Cr^{II}, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, Cd^{II}, Hg^{II}, consist of two interpenetrating rutile nets,[6] and have been found to display weak antiferromagnetic coupling.[7] The structures and novel magnetochemistry of the binary metal complexes of dicyanamide, dca, $N(CN)_2^-$, are now described.

dca =



Following the method of Köhler,[8] combination of aqueous solutions of cobalt nitrate, nickel nitrate or copper nitrate with aqueous solutions of sodium dicyanamide results in small pink rods of $Co(dca)_2$, a blue microcrystalline powder of $Ni(dca)_2$, and green rods of $Cu(dca)_2$, respectively. As in Köhler's original work, there is evidence from IR and microanalytical data† for a small amount of water in $Ni(dca)_2$ even when we prepared it from $Ni(NO_3)_2{\cdot}6H_2O$ in MeCN using $[N(PPh_3)_2](dca)$.

The structure of $Cu(dca)_2$ was determined by single crystal X-ray crystallography.‡ It was found to consist of a single rutile-related network (Fig. 1). Each dca is coordinated to three metal atoms *via* the two nitrile nitrogens and the central amido nitrogen. Each copper in turn is coordinated to six dca ligands, four *via* the nitrile nitrogens and two *via* the amido nitrogens. The copper shows considerable Jahn–Teller distortion, with the two axial amido nitrogens considerably further from the copper [2.478(2) Å] than the four equatorial nitrile nitrogens [1.975(1) Å]. There is evidence of π–π interactions between pairs of dca ligands across the square channels seen in Fig. 1, with the closest interactions being N_{amido}–N_{amido} 3.463 Å, C–C 3.513 Å and N_{amido}–C 3.603 Å. The distortions in the framework seen in Fig. 1 may maximise these interactions. The structures of polycrystalline $Co(dca)_2$ and $Ni(dca)_2$ have been shown by X-ray powder diffraction to be isomorphous with $Cu(dca)_2$,§ but with a few very small peaks not indexing and not present in the XRD of $Cu(dca)_2$.

It is interesting to compare the structures of $M(dca)_2$ and $M(tcm)_2$. In both cases the networks have a rutile-like topology with six-connected metal centres and three-connected ligands. In $M(tcm)_2$, all three connections between the trigonal centres and the octahedral centres of the rutile networks are C–CN–M (*ca.* 4.50–4.99 Å), and the structures are composed of two interpenetrating networks. The interpenetration produces a tightly packed structure in which each of the nets is considerably distorted to accommodate the other. In $M(dca)_2$, two of these connections are N–CN–M (4.368 Å), which are comparable with those in $M(tcm)_2$. The third connection between trigonal and octahedral nodes, however, is a direct N–M bond [2.478(2) Å], and there is no longer enough room within the structure for a second rutile-related net to be accommodated. Indeed, the packing efficiency of $Cu(dca)_2$ is very similar to that of $Cu(tcm)_2$ (D_c = 2.01 and 1.918 g cm^{-3}, volume/atom = 14.7 and 14.1 $Å^3$, respectively.)

While Hvastijova *et al.*[9] have made many studies of the magnetism of chain-like compounds of type $M(tcm)_2L_2$ and $M(dca)_2L_2$, where L = pyridine, imidazole, pyrazole, there have been no detailed studies until now on the parent

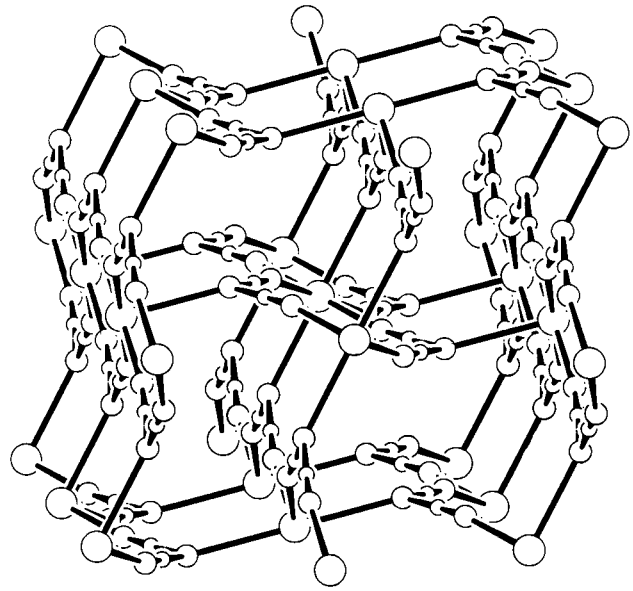


Fig. 1 The rutile-related structure of $Cu(dca)_2$. The circles represent in order of decreasing size Cu, N and C.

compounds. We find that $Cu(dca)_2$ shows near-Curie behaviour in a field of 1 T (C = 0.438 cm^3 K mol^{-1}, θ = −1.8 K) indicative of extremely weak antiferromagnetic coupling. The μ_{eff} values decrease a little from 1.87 μ_B at 300 K to 1.77 μ_B at 4.2 K. Magnetization studies in a field of 5 Oe show that long-range ordering is not occurring above 2 K. Chain-like $Cu^{II}(dca)_2L_2$ adducts also display very weak coupling and long-range ordering at low temperautres has occasionally been claimed but without proof.[9]

In contrast, the $Co(dca)_2$ and $Ni(dca)_2$ samples both display well behaved long-range ferromagnetic ordering with T_c values, respectively, of 9 and 20 K. The first evidence of ferromagnetism is given in the Curie–Weiss susceptibility plots obtained in fields of 1 T. Positive Weiss constants are noted with best-fit parameters of C = 2.074, θ = +6.1 K (Co) and C = 1.086, θ = +21.4 K (Ni). In small applied fields of 5 Oe, the χT values increase sharply at T_c reaching values much higher than anticipated for short-range order. Plots of field-cooled (FCM), zero-field cooled (ZFCM) and remanent magnetization (RM), shown in Fig. 2 for $Ni(dca)_2$, are typical of those expected for a magnetically ordered system.[10] The very sharp increase in the magnetization isotherms at small field values, followed by a gradual increase towards a saturation magnetization value of $2N\mu_B$ [for $Ni(dca)_2$] in high fields (Fig. 2), lends further support for a ferromagnetic phase transition. Hysteresis loops are observed with the value of the coercive field for $Ni(dca)_2$ being 191 Oe.

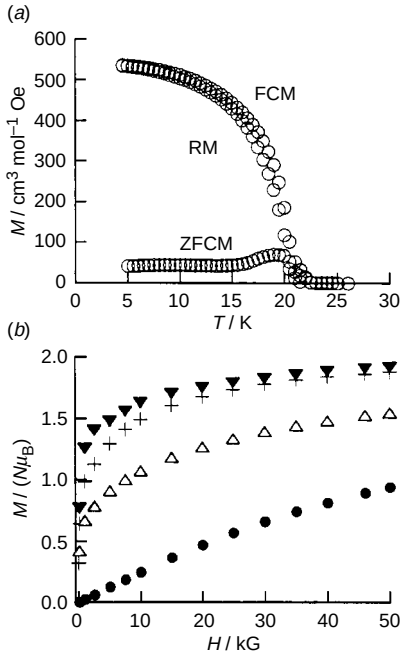

Fig. 2 (*a*) Plots of field-cooled (FCM), zero field-cooled (ZFCM) and remanent magnetization (RM) *vs.* temperature for $Ni(dca)_2{\cdot}xH_2O$ and (*b*) plots of magnetization, M (in units $N\mu_B$) *vs.* applied field at various temperatures for $Ni(dca)_2{\cdot}xH_2O$: (●) 30 K, (△) 20 K, (+) 10 K, (▼) 5 K

The origin of ferromagnetic ordering in the Co^{II} and Ni^{II} dca compounds and the lack thereof in the structurally characterized Cu^{II} species is intriguing and is being vigorously pursued. If we assume that the majority *Pnnm* phase in all three samples (*vide supra*) is responsible for the magnetic behaviour then Jahn–Teller distortions in $Cu(dca)_2$, along the Cu–N(amido) links, may prevent magnetic interactions between $Cu(dca)_2$ chains in the crystal, while such interchain interactions can occur in the Co and Ni derivatives. This contrasts with the situation in one of the few know homometallic ferromagnetic systems $(NH_3R)_2[MX_4]$, (Mn^{II} = Cu, Cr; X = Cl, Br), in which Jahn–Teller elongated M–X bonds within metal–halide layers are orthogonal from one MX_6 octahedron to the next,[10,11] thus giving the required orthogonality of neighbouring magnetic orbitals. Orthogonality relationships are not obvious from Fig. 1 but presumably must involve the M–N≡C–N–M pathways otherwise $Cu(dca)_2$ should behave likewise. In conclusion, it is clear that some of these d-blocks pseudohalide species provide new and fascinating examples of molecular magnets.

Neutral anion receptors: design and application

Martijn M. G. Antonisse and David N. Reinhoudt*†

Department of Supramolecular Chemistry and Technology, MESA Research Institute, University of Twente, PO Box 217, 7500 AE Enschede, Netherlands

After the development of synthetic cation receptors in the late 1960s, only in the past decade has work started on the development of synthetic neutral anion receptors. Combination and preorganization of different anion binding groups, like amides, urea moieties, or Lewis acidic metal centers lead to receptor molecules that strongly bind inorganic anions with high selectivity. Combined with neutral cation ligands, ditopic receptors were obtained for the complexation of inorganic salts. The molecular complexation properties of anion receptors has been transduced into macroscopic properties in membrane separation processes and in sensors for selective anion detection.

Introduction

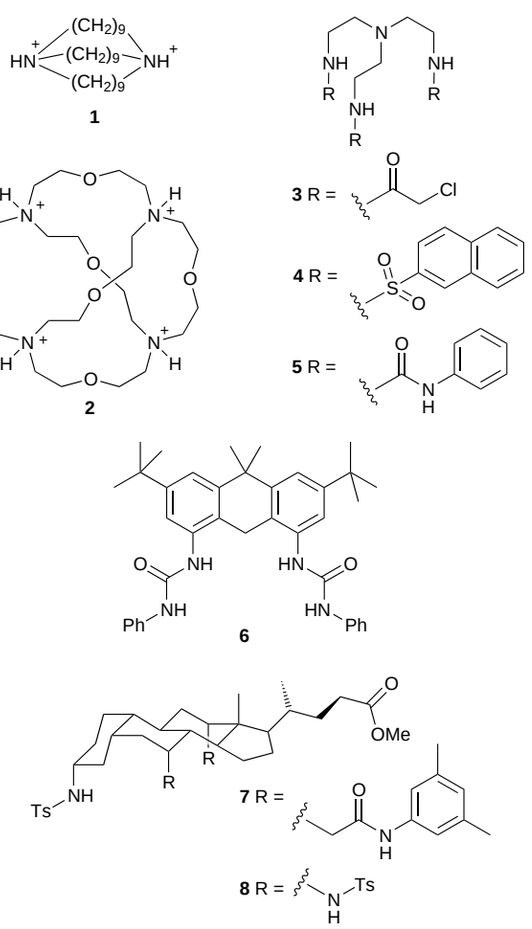
Host–guest systems for ionic species have played an important role in the development of the field of supramolecular chemistry, the chemistry of the non-covalent interactions. The research of Pedersen in 1967 on the complexation of alkali metal ions by crown ethers initiated the development of many other neutral host species for metal ions.[1,2] Compared with the cation receptors, anion receptors were developed much later, although already in 1968 the first synthetic receptor for inorganic anions was reported[3] (size selective binding of Cl^- anions was described with diprotonated 1,11-diazabicyclo-[9.9.9]nonacosane **1**). The field started to develop in 1976 when Graf and Lehn reported that *protonated* cryptate **2** encapsulates F^-, Br^- and Cl^- anions.[4] Since then several other *positively charged* anion receptors have been developed that have protonated nitrogen atoms or metal ions.[5] In these receptors mainly coulomb interactions contribute to the attractive force.

In Nature, the transport of sulfate or phosphate anions through cell membranes is regulated by *neutral* anion binding proteins.[6] The high specificity is due to a recognition site in which the anion is completely desolvated and bound exclusively *via* hydrogen bonds. Furthermore, a so-called macrodipole effect, caused by orientation of the amino terminus of the protein backbones towards the negative guest, contributes to the stability of the complex.[7] This article will focus on the recent developments in the design of synthetic *neutral* receptors for inorganic anions. The individual interactions in these receptors are weaker than coulomb interactions and strongly depend on the directionality of the interaction and on the electron density of the anion. Nevertheless, combination and preorganization of several binding sites can lead to selective neutral receptors for anions.

The neutral anion binding receptors can be divided into two classes: receptors that bind anions exclusively by hydrogen bonding or ion–dipole interactions, and receptors that coordinate anions at the Lewis acidic centers of a neutral organometallic ligand. The corresponding ditopic receptors that are formed by the combination of neutral anion and cation receptor sites are included in the second part of this review. Finally some applications of anion receptors in anion transport and sensing will be discussed.

Anion recognition by hydrogen bonding

In an attempt to mimic nature in its high binding selectivity, several anion receptors have been developed with three-dimensional arrangements of hydrogen bond donating moieties, like amides, sulfonamides, and (thio)ureas. Receptor **3**, which has three amido substituents connected *via* a tris(aminoethyl)amine spacer, binds $H_2PO_4^-$ with an association constant of 6100 M^{-1} in MeCN.[8] The increased electrophilicity of the sulfonamide NH moieties in **4**, in combination with preorganization of the binding site by Π-stacking, enhances the $H_2PO_4^-$ binding with **4** ($K_a = 1.4 \times 10^4$ M^{-1}) and results in an almost 400-fold selectivity over HSO_4^-. The tris(aminoethyl)amine spacer was also used to preorganize urea moieties (receptor **5**).[9] This receptor strongly binds PO_4^{3-} ($K_a = 1.4 \times 10^4$ M^{-1} in [$^2H_6$]DMSO) and SO_4^{2-} ($K_a = 3 \times 10^3$ M^{-1}). Reduction of the rotational freedom of the urea substituents with the *cis*-1,3,5-tris(aminomethyl)cyclohexane spacer lowers the PO_4^{3-} association to 1100 M^{-1}. Recently Umezawa and coworkers reported bis(*N*′-phenylthioureylene)xanthene **6**.[10] The rigid spacer prevents the self-association of the urea substituents



and consequently the association constant for $H_2PO_4^-$ is very high. The value of 1.95×10^5 M^{-1} in [$^2H_6$]DMSO was obtained from an NMR titration experiment in competition with 10 equiv. of Cl^- (K_a = 1000 M^{-1}). Davis and co-workers have utilized cholic acid as a building block for neutral anion receptors.[11] Bis-carbamate **7** preferentially binds F^- over other halides, but does not discriminate between chloride or bromide. Functionalization of cholic acid with sulfonamido moieties (**8**) yields a receptor that binds the more basic chloride more strongly than bromide (K_a = 92 000 and 9200 M^{-1}, respectively, in $CDCl_3$).

Calixarenes are versatile building blocks that have been used in the design of many cation receptors.[12] Hydrogen bond donating substituents at either the *upper* or *lower* rim yield receptor molecules suitable for anion binding. Functionalization of a calix[4]arene with upper rim sulfonamido substituents leads to a three-dimensional cavity (receptor **9**) which complexes

tetrahedral HSO_4^- better than spherical Cl^- or planar NO_3^-.[13] We also introduced octylurea moieties at the upper rim of a calix[4]arene tetra(ethyl ester) yielding calix[4]arene **10**. However, upon addition of Bu_4NCl or Bu_4NBr in $CDCl_3$ no complexation of halide anions was observed.[14] This is due to the strong intramolecular hydrogen bonding between the diametrically positioned urea moieties, stabilizing **10** in a pinched cone conformation.[15] This conformation is stable up to at least 120 °C in $C_2D_2Cl_4$. In contrast to the upper rim functionalized derivatives, calix[4]arenes functionalized at the lower rim with urea substituents bind specifically halide anions. The tetrakis(phenylurea) derivative **11** binds Cl^- and Br^- ions in $CDCl_3$ with association constants of 2015 and 1225 M^{-1}, respectively.[16] The very strong hydrogen bond acceptors F^- and $H_2PO_4^-$ are not bound by **11**. Although bidentate phenylurea derivative **12** has only four hydrogen bond donor sites, the association constants are significantly higher than with **11** and the selectivity for Cl^- over Br^- is enhanced (K_a = 7105 and 2555 M^{-1}, respectively). The extent of inter- and intramolecular hydrogen bond formation is much lower in **12** than in the tetrakis(phenylurea) derivative **11**, favouring the complexation of anions. The larger binding cavity in tris(phenylurea) calix[6]arene derivative **13** reverses the selectivity and Br^- binding is favoured over Cl^-.[17] Beer *et al.* covalently linked the upper and lower rim of two calix[4]arenes with hydrogen bond donating amide bonds.[18] The resulting cavity is too small for encapsulation of $H_2PO_4^-$ or HSO_4^-, but Cl^- and F^- are bound, favouring F^- with one order of magnitude.

Recently, Sessler and co-workers reported the anion binding ability of calixpyrroles.[19] These *meso*-substituted porphyrinogens are, unlike porphyrinogens with *meso*-hydrogen atoms, stable towards auto-oxidation, and can adopt cone and 1,3-alternate conformations like calix[4]arenes. Crystal structures show that calix[4]pyrrole **14** is fixed in a cone conformation upon Cl^- or F^- binding. The receptor preferentially binds F^- (K_a = 1.7 $\times 10^4$ M^{-1} in CD_2Cl_2) over Cl^- (K_a = 350 M^{-1}) or Br^- (K_a = 10 M^{-1}). Substitution of **14** with electron-withdrawing bromine atoms increases the anion binding (K_a = 2.7 $\times 10^4$ M^{-1} and 4.3 $\times 10^3$ M^{-1} for F^- and Cl^-, respectively).

Phosphine oxide disulfoxide **15** binds halide ions ($Cl^- \approx Br^- > I^- > F^-$) *via* ion–dipole interactions.[20] The association with Cl^-, Br^- (both K_a = 65 M^{-1}) and I^- (K_a = 40 M^{-1}) was investigated by NMR titration in 2 vol% CD_3OD in $CDCl_3$. A similar experiment with F^- induced only small shifts. Also the macrotricyclic borane–amine adduct **16** encapsulates anions driven by ion–dipole interactions.[21] All four borane–amine bonds are in a fixed orientation with the positive ends pointing to the center of the cavity. The small Cl^- and CN^- anions can easily enter the cavity with only a little conformational adaptation of the host. Optimal association was observed for Br^-. Zwitterionic macrotricycle **17** is able to recognize anions in water.[21b] Halides are complexed in a 1 : 1 stoichiometry with association constants from 270 M^{-1} for Cl^- to 6480 M^{-1} for I^-.

Anion recognition with organometallic ligands

Several Lewis acidic atoms have been investigated for binding of anions. In particular, group 14 metals have been used extensively in macrocyclic organometallic anion receptors. 12-Silacrown-3 **18** preferentially binds Cl^- over all other halides in bulk liquid membrane transport experiments.[22] Takeuchi and co-workers investigated several organogermanium macrocycles (receptor **19**) as carrier in bulk liquid membranes.[23] The Lewis acidity of bis-methyl or bis-phenyl substituted germanium was too low for anion transport. The enhanced acidity of methyl(chloro)germanium results in effective Cl^- binding, and transports Cl^- with selectivity over Br^-. Methyl(bromo)-bis(chloro)- and bis(bromo)-germanium are unsuitable due to easy decomposition by hydrolysis. The halide substituted tin centers at the bridgehead position of macrobicycle **20** coordinate with encapsulated Cl^- or Br^-.[24] Optimal selectivity in the case of Cl^- is obtained with eight methylene units between the tin centers; for Br^- a larger cavity is necessary (10 methylene units).

Mercury has also been used for the design of Cl^- receptors. Two phenylene-1,2-dimercury dichloride molecules coordinate with an additional Cl^- anion in the electrophilic cavity that is formed by the four C–Hg–Cl arms.[25] Hawthorne and Zheng studied the anion recognition of carborane-supported multidentate mercury hosts.[26] Cl^- can coordinate with the four mercury atoms in the preorganized cavity of mercuracarborand **21**. Iodide anions are bound in a 1 : 2 host–guest stoichiometry with the I^- ions slightly above and below the plane formed by the mercury atoms.

Katz developed F^- receptors with Lewis acidic boron centers.[27] Both naphthalene-1,8-diylbis(dimethylborane) and (8-trimethylsilyl)-1-naphthyl(dimethylborane) coordinate the anion between the two electron accepting atoms. The boron atom of ferroceneboronic acid binds F^- with an association constant of 1000 M^{-1} (in MeOH–H_2O 1 : 9).[28] The association is reflected in a strong decay in the absorbance at 665 nm. Other ions, like Cl^- or Br^-, hardly affect the absorbance.

In our group we have developed neutral anion receptors based on an immobilized uranyl cation. Complexed in a salophen unit the uranyl cation prefers a pentagonal bipyramidal coordination, with the two oxygen atoms at the apical positions and four of the equatorial positions occupied by the salophen ligand. The fifth equatorial position can coordinate to nucleophilic guest species. This can either be a nucleophilic moiety (*e.g.* C=O or S=O) of a neutral molecule,[29] as we illustrated with the transport of urea with carrier **22** through supported liquid membranes,[30] or anionic species.[31,32] Uranyl salophen **23** binds $H_2PO_4^-$ more strongly than Cl^- (K_a = 1.5 × 10^4 and 4.0 × 10^2 M^{-1} in MeCN–DMSO 99 : 1), which is in accordance with the principle that the hard Lewis acidic uranyl cation favours interactions with hard Lewis basic anions. The advantage of our system is that additional hydrogen bond binding sites can be introduced close to the uranyl center and this makes it possible to improve or change the selectivity in anion binding. Hydrogen bond accepting methoxy substituents (**24**) enhance the $H_2PO_4^-$ over Cl^- selectivity. The crystal structure of the $H_2PO_4^-$ complex of **24** (Fig. 1) clearly shows the additional hydrogen bond between the anion and the methoxy oxygen atom. Salophen **27**, with *N*-(4-methylphenyl)acetamide moieties, has both hydrogen bond accepting ether oxygens and hydrogen bond donating amide functions. This salophen binds $H_2PO_4^-$ by coordination at the uranyl center and three hydrogen bonds. These additional interactions are reflected in the increased association constant for $H_2PO_4^-$ (K_a > 5 × 10^5 M^{-1}). Recently we have synthesized uranyl salophen **28** with hydrogen bond *donating* acetamido moieties close to the uranyl coordination site. The resulting F^- binding is reflected in the selectivity of sensors based on this receptor. According to ^1H NMR titrations in $CDCl_3$ a 2 : 1 host–guest complex is formed in which the fluoride anion is hydrogen bonded to the amide moieties and coordinated to the uranyl centers.

Ditopic receptors, combined recognition of anions and cations

The new neutral anion receptors opened the way for neutral *ditopic* receptors that complex *both* anions and cations. Anion binding, based on hydrogen bonds or coordination to Lewis acids, has been combined with cation binding, *e.g.* crown ethers or calix[4]arene derivatives. We combined the anion binding uranyl salophen building block with several cation ligands. Ditopic receptor **29** binds K^+ between the crown ether substituents, while the uranyl center can coordinate with phosphate.[33] The binding was investigated by ^1H NMR spectroscopy, cyclic voltammetry and fast atom bombardment mass spectroscopy (FAB-MS). The spectra of the latter technique show intense peaks for [**29** + K^+]$^+$ and [**29** + $H_2PO_4^-$]$^-$, while the signal of [**29** + K^+ + $H_2PO_4^-$]$^-$ is also present, which clearly proves the complexation of the salt. In the ditopic receptor **30** a Cs^+ selective 1,3-alternate calix[4]arene crown-6 is combined with a uranyl salophen and this receptor complexes CsCl.[34] Furthermore, the Na^+ selective calix[4]arene tetra(ethyl ester) was linked at the upper rim *via* amide bonds to a uranyl salophen unit.[35] FAB-MS spectra of the NaH_2PO_4 complex of this receptor show intense signals for the receptor + Na^+ and for the receptor + $H_2PO_4^-$.

Also Reetz and co-workers combined Lewis acidic centers with a cation binding crown ether. Boronic acid crown ether derivative **31** forms a ditopic complex with KF when the receptor is added to a suspension of the salt in CH_2Cl_2.[36] Other potassium salts (KBr or KCl) do not exhibit either monotopic or hetrotopic interactions. This selectivity is also observed in

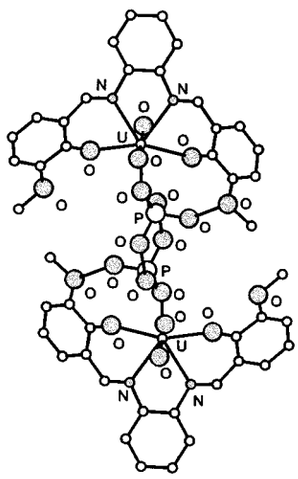

Fig. 1 Crystal structure of the complex **24**·H_2PO_4. Hydrogen atoms are omitted for clarity.

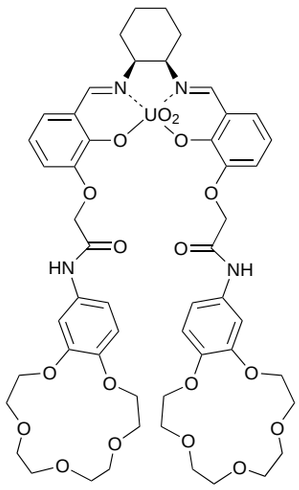
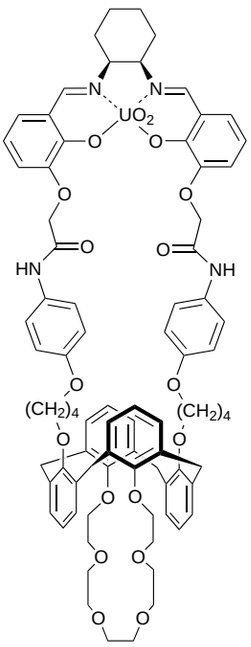
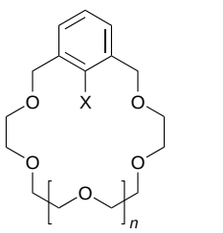


29



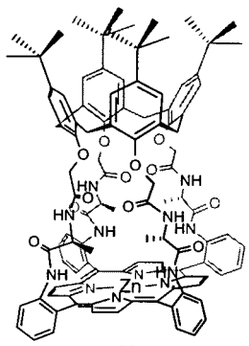
30



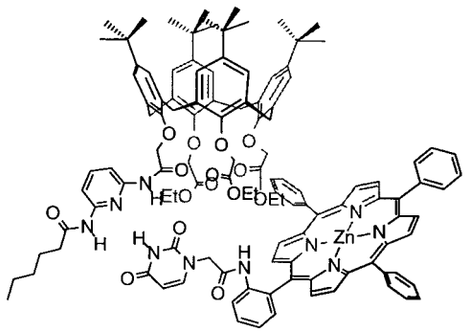
31 n = 2, X = 
32 n = 1, X = $OAlMe_2$

competition experiments, as in a mixture of KF, KCl, KBr and KI, the KF adduct of **31** is exclusively formed. With aluminium phenolate as the Lewis acid (receptor **32**) the selectivity is reversed. With the Li^+ or K^+ salts of F^- no binding is observed, whereas Cl^-, Br^-, or I^- salts all show ditopic binding. Shinkai and co-workers combined a calix[4]arene with a neutral anion binding porphyrin–Zn^{2+} complex (receptor **33**).[37] The two building blocks are covalently linked *via* lower rim amido substituents. The cation (*e.g.* Na^+ or K^+) is coordinated by the four $OCH_2C(O)NH$ linkages and a cavity is formed between the two metal ions. In the case of the K^+ complex strong I^- complexation is observed. For the Na^+ complex the association constant for encapsulation of I^- is lower. This is due to the different electron accepting character of Na^+ and the larger distance between the Zn^{2+} and Na^+ ion. Anion binding porphyrin **34** and cation binding calix[4]arene **35** form a bifunctional receptor by self-assembly.[38] The hydrogen bonds between the diaminopyridine and thymine moieties brings the two recognition sites into close proximity. When no cation is bound in the cavity formed by the ethyl ester moieties, the diaminopyridine fragment interacts with these substituents *via* hydrogen bonding and cannot form the aggregate with the thymine units. Sodium complexation of **35** initiates the self-assembly as it coordinates with the ethyl ester carbonyl oxygen atoms. The self-assembly of the bifunctional receptor enhances the binding of the investigated anion (SCN^-) to the porphyrin. The association constant of the self-assembled complex (**34**·SCN^-)(**35**·Na^+) is 2.5×10^4 M^{-1} in toluene, and is very different from that for free **34** which binds SCN^- only weakly (K_a = 10 M^{-1}).

When we investigated anion binding *via* hydrogen bonds with the above mentioned urea-functionalized calix[4]arene **10** it was observed that cation complexation is essential for anion complexation (positive heterotropic allostery). The tetra ester functionalized lower rim of **10** is a ligand that is highly selective



33

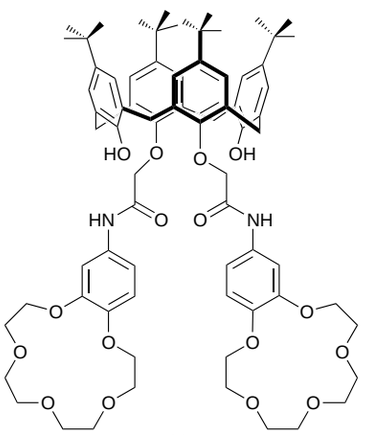


34•35

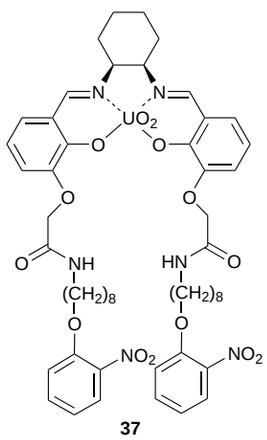
for Na^+.[39] Upon complexation of Na^+, the conformation of the calix[4]arene is converted from a pinched cone to a symmetrical cone.[14] In this conformation intramolecular hydrogen bonding is not possible and the urea moieties become available for hydrogen bonding to anions. The Na^+ complex of **10** prefers Cl^- binding over the 'softer' Br^- anion. Calix[4]arene **10** is capable of solubilizing simple alkali salts in $CHCl_3$. The selectivity of the cation binding part of the receptor is expressed by the relative amount of Cl^- alkali salt complex that is transferred in liquid–solid extractions. NaCl results in 100% of [Na^+·Cl^-·**10**] complex, but with KCl only partial complexation is observed (29%). No complexation of CsCl is observed, apparently because Cs^+ is too large to fit in the cavity. Beer *et al.* reported NMR studies with the K^+ or NH_4^+ complex of calix[4]arene **36**.[40] K^+ or NH_4^+ form a sandwich complex with the bis(crown ether), rigidifying the hydrogen-bonding arrangement of the two amides and the two phenolic protons in a pseudo-tetrahedral cavity in which Cl^- or HSO_4^- is bound.

Anion transport and sensing

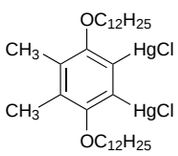
Supramolecular chemistry has always been associated with possible applications. As in the case of cation receptors, anion receptors are now applied as the selector element in separation membranes[41] and in ion-selective electrodes.[42] Recently we have studied anion transport through supported liquid membranes (SLMs). The pores of a microporous film are filled with a solution of anion receptor in *o*-nitrophenyl octyl ether and the film is placed between two aqueous phases: a source phase with the anion to be transported and a receiving phase. The transport of KH_2PO_4 is facilitated by a 1 : 1 mixture of anion receptor **36** and the K^+ selective calix[4]arene crown-5.[43] Salt transport solely by the cation receptor is very low (0.6×10^{-8} mol m^{-2} s^{-1}) due to the low partition of $H_2PO_4^-$. Transport of KH_2PO_4 by **37** alone increases the transport (5.1×10^{-8} mol m^{-2} s^{-1}), but the flux is much larger using a mixture of cation and anion receptor (12.5×10^{-8} mol m^{-2} s^{-1}). A transport selectivity for $H_2PO_4^-$ over Cl^- of 143 for the combination of the cation carrier and **36** is observed. Bifunctional receptor **29** transports CsCl and the flux has been compared with the transport of $CsNO_3$.[34] The interactions of *both* the anion and the cation of CsCl with **29** is reflected in a higher transport rate for CsCl than



36



37



38

for $CsNO_3$. Tsukube *et al.* applied neutral tris(β-ketonate) lanthanide complexes as anion carriers in bulk liquid membrane transport experiments.[44] The transport of Cl^- is more efficient than that of the more lipophilic Br^- I^- or ClO_4^-.

In potentiometric sensors, *e.g.* ion-selective electrodes (ISEs) or chemically modified field effect transistors (CHEMFETs[45]), the molecular interaction between the receptor and the ionic species can be converted into an electronic signal. Most anion receptors applied in potentiometric sensors are organometallic molecules, but recently Umezawa and co-workers reported the application of **6** as a sensor selector.[46] Remarkably, $H_2PO_4^-$ could not be detected as would be expected based on the association constants; instead a moderate Cl^- sensor was obtained. The potentiometric selectivity coefficient *vs.* Br^- ($\log K^{Pot}_{Cl,Br} = 0.4$) reflects almost equal sensitivity for Cl^- and Br^-. Simon and co-workers developed chloride selective electrodes with organometallic trialkyltin derivatives as the neutral anion receptor.[47] With di- or tetra-dentate organotin derivatives the selectivity favours the binding of $H_2PO_4^-$.[48] The sensors show selectivity over the very lipophilic anions, *e.g.* SCN^- and ClO_4^-. Sensors with a high chloride selectivity are based on lipophilic *ortho*-dimercury aromatic compounds like **38**.[49] Chloride is preferred over other halides, as expressed by the potentiometric selectivity coefficients *vs.* I^-, Br^- and F^- of respectively −1.7, −1.4 and −6.6 ($\log K^{Pot}_{Cl,j}$).

Recently in our group we investigated uranyl salophen derivatives as anion receptors in CHEMFETs that are selective for hydrophilic anions.[32,50] For this purpose novel derivatives were synthesized with lipophilic substituents to enhance the solubility in the membrane matrix. The high association constants of uranyl salophen derivatives for $H_2PO_4^-$ could be transduced into sensors with high sensitivity and selectivity for this anion. Application of uranyl salophen **25**, the lipophilic equivalent of **23**, results in sensors that start to respond to $H_2PO_4^-$ at activities $\geqslant 6 \times 10^{-4}$ M. Even in the presence of the more lipophilic NO_3^- anion the sensor is twenty times more sensitive for $H_2PO_4^-$ ($\log K^{Pot}_{H_2PO_4,NO_3} = -1.3$). The introduction of hydrogen bond donating methoxy substituents (receptor **26**) increases the $H_2PO_4^-$ binding and consequently an improved detection limit of 1.6×10^{-4} M is obtained. Also the selectivity in the presence of halides and SO_4^{2-} is further enhanced by a factor 3 to 10. Incorporation of salophen derivative **28** in the CHEMFET membrane gives excellent F^- sensitivity and selectivity. The strong binding of the hydrophilic F^- anion in the small cleft is reflected by the hundred-fold or higher selectivity ($\log K^{Pot}_{F,j} \leqslant -2.0$) for fluoride over other halides, nitrate and sulfate. As shown in Fig. 2, even in the presence of a large excess of the very lipophilic ClO_4^- anion (0.1 M) it is possible to detect F^- at the (sub)millimolar level ($\log K^{Pot}_{F,ClO_4} = -1.7$).

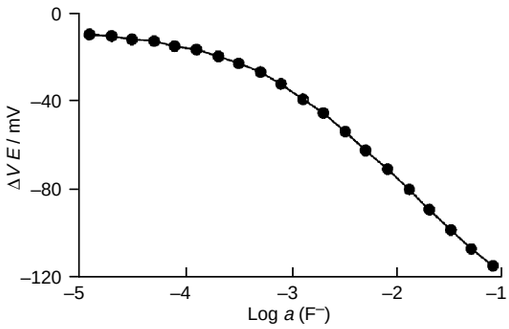


Fig. 2 Fluoride response of CHEMFET with receptor **28** in the presence of 0.1 M ClO_4^- (in 0.01 M MES buffer, pH 6.0)

Conclusions

This article illustrates that neutral anion receptors with high binding selectivity can be synthesized. The organometallic ligands show the highest association constants, but three-dimensional arrangements of hydrogen bond donating ligands are promising recent developments. The combination of anion receptors with cation receptors revealed interesting events like synergistic effects and (positive) heterotropic allostery.

Acknowledgments

We thank all our colleagues and co-workers, several of whose names appear in the references, for their valuable contributions to this work. The Netherlands Organization for Scientific Research (NWO) and the Technology Foundation (STW), Technical Science Branch of NWO are gratefully acknowledged for financial support.

David N. Reinhoudt was born in Wolfaartsdijk, The Netherlands. He received his MSc (1966) and PhD (1969) from Delft University of Technology. In 1970 he joined the Koninklijke/Shell Laboratories in Amsterdam as a research chemist in the Department of Organic Chemistry. In 1975 he was appointed as a part-time Professor (extraordinarius) in Organic Chemistry (now Supramolecular Chemistry and Technology) at the University of Twente, followed by a full-time appointment in 1978. His research deals with supramolecular chemistry, *e.g.* the synthesis of supramolecular building blocks such as crown ethers, calixarenes and (hemi)spherands, complexation studies with neutral and charged guests, and the technological application of the molecules in membrane transport, electronic or optical sensors, catalysis and molecular (NLO) materials.

Martijn M. G. Antonisse was born in Boskoop, The Netherlands. He received his MSc (1994) from the University of Twente and is currently a PhD student in the Department of Supramolecular Chemistry and Technology at the University of Twente. He is involved in the development of novel anion

receptors and their application in durable potentiometric sensors (CHEMFETs).

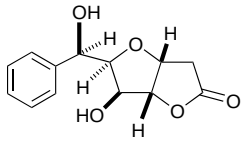
Indium-mediated highly diastereoselective allenylation in aqueous medium: total synthesis of (+)-goniofufurone

Xiang-Hui Yi, Yue Meng and Chao-Jun Li*

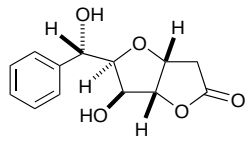
Department of Chemistry, Tulane University, New Orleans, Louisiana 70118, USA

(+)-Goniofufurone was synthesized from D-glucurono-6,3-lactone *via* an indium-mediated highly regio- and diastereo-selective allenylation of carbonyl compounds in aqueous medium.

The Asian trees of the genus *Goniothalamus* have long been recognized as a potential source of chemotherapeutical agents. The extracts and leaves of *Goniothalamus* have traditionally been used for the treatment of edema and rheumatism,[1] a pain killer and a mosquito repellent,[2] as well as used as an abortifacient.[3] Recently, from the constituents of these plants, McLaughlin discovered a number of novel styryl lactones which were found to possess moderate to significant cytotoxicities against several human tumors. These findings have attracted considerable biological and synthetic attention to these styryl compounds. Among the key components in the extracts are (+)-goniofufurone **1**[4] and (+)-7-*epi*-goniofufurone **2**.[5] The



1 (+)-Goniofufurone



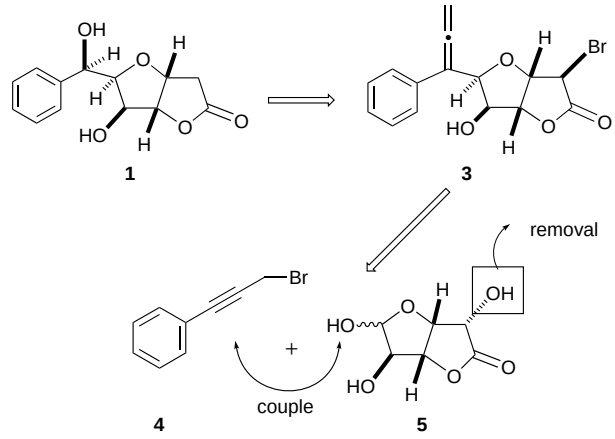
2 (+)-7-*epi*-Goniofufurone

absolute stereochemistry of (+)-goniofufurone was established by Shing through the total synthesis of *ent*-(−)-**1**.[6] Subsequently, several synthetic studies have been carried out on the synthesis of **1**.[7–13]

The recent advances in Barbier–Grignard type carbon–carbon bond formations in aqueous medium[14] offer opportunities to synthesize various heavily oxygenated biologically important agents in a concise manner. Out continued interest in metal mediated carbon–carbon bond formation in aqueous media, particularly the synthetic application of these reactions, drew our attention to these styryl compounds. Here we report a highly regio- and diastereo-selective indium-mediated allenylation[15,16] of carbonyl compounds in aqeuous medium, which leads to a concise total synthesis of (+)-goniofufurone from a readily available starting material. The retrosynthetic analysis of (+)-goniofufurone is illustrated in Scheme 1.

Initially, the coupling between 1-phenyl-3-bromopropyne and several carbohydrate substrates mediated by indium were investigated in aqueous EtOH (Table 1). In each case, the corresponding allenylation product was obtained with high diastereoselectivity, favoring the *syn* diastereomer. The high diastereoselectivity of this indium-mediated allenylation reaction could be attributed to chelation control.[17]

The results of the allenylation study confirmed the key step for the outlined synthesis. Thus, the commercially available D-glucurono-6,3-lactone **5** was readily converted into the corresponding bromo compound **6** based on the modification of a literature procedure for synthesizing a related chloro derivative.[18] Then allenylation of the compound with prop-2-ynyl bromide **4**, mediated by indium in aqueous EtOH, generated a mixture of allenylation products (56%) in which the allene **7** is the major component, together with debromination and re-

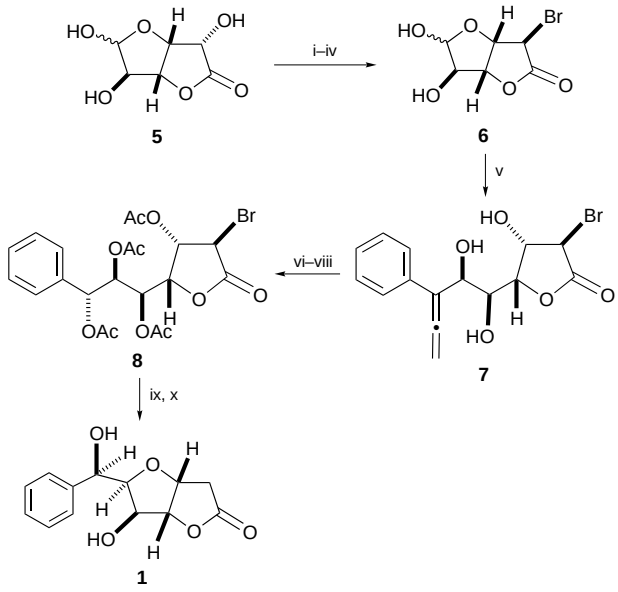


Scheme 1

Table 1 Diastereoselective allenylation of carbonyl compounds

Entry	Carbonyl compound	Product	Diastereo-selectivity	Yield (%)[a]
1			—	57
2			(10:1)	63[b]
3			(>10:1)	63[b]
4			(9:1)	72
5			(8:1)	49[b]

[a] The yields were those of the isolated major isomers after column chromatograph on silica gel and were not optimized. [b] Determined after peracetylation. Conditions: stirred in 0.1 M aq. HCl–EtOH (1 : 9) overnight at room temperature.



Scheme 2 *Reagents and conditions*: i, acetone, H_2SO_4, room temp., 5 h, 86%; ii, Tf_2O, Py, CH_2Cl_2, −40 °C, 94%; iii, LiBr, acetone, room temp., 1 h, 97%; iv, TFA–H_2O (3 : 1), room temp., 4.5 h, 98%; v, **4**, In, 0.1 M HCl–EtOH (1 : 9), room temp., 14 h; vi, O_3, MeOH, −78 °C, then DMS; vii, $NaBH_4$, MeOH, −10 °C, 30 min, then AcOH quench; viii, H_2SO_4, Ac_2O, room temp., 75% from **7**; ix, Na_2HSO_3, Na_2SO_3, MeOH–H_2O, room temp., 3 h, quant.; x, HCl (g), MeOH, room temp., 2 d, 44% from **8**

ductive elimination products. The allene **7** again shows a high (> 10 : 1) *syn* diastereoselectivity (the desired isomer). Standard ozonolysis of the allene compound in MeOH, followed by a diastereoselective reduction with $NaBH_4$, provided the corresponding alcohol as the predominant product (de = 3 : 1). The initial assignment of the stereochemistry for the reduction was confirmed after completion of the total synthesis. Subsequent reaction of the polyol with conc. H_2SO_4 in Ac_2O generated the peracetylation product **8** (*ca.* 75% from **7**) which decomposed on silica gel. Direct treatment of the peracetylation product with Na_2HSO_3 and Na_2SO_3 in MeOH–H_2O generated an α,β-unsaturated γ-lactone, as shown by ^{1}H NMR analysis of the crude material. In order to remove the acetyl protecting groups, the crude product was treated with HCl in MeOH resulting in the deprotected product which cyclized *in situ* giving the target natural product in 44% yield over two steps. The spectroscopic data and melting point of the target molecule synthesized by this method are consistent with previous literature reports.[7]

In conclusion, (+)-goniofufurone has been synthesized in a short sequence from D-glucurono-6,3-lactone using an indium-mediated, highly regio- and diastereo-selective allene formation in aqueous medium. The scope and application of the current indium-mediated method to the syntheses of other carbohydrates is presently under investigation.

An E_4O_4 heterocubane structure with a trivalent element of group 13 realized in $In_4O_4[C(SiMe_3)_3]_4$

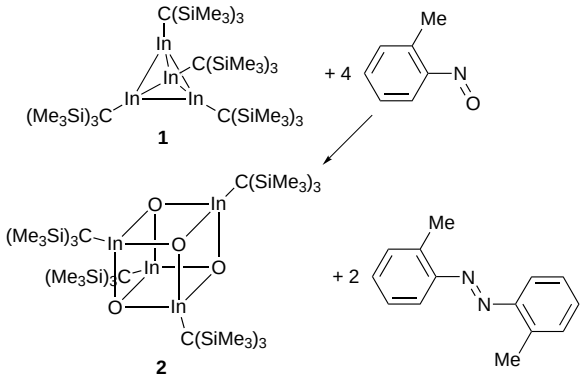
Werner Uhl* and Michael Pohlmann

Fachbereich Chemie, Universität, Postfach 2503, D-26111 Oldenburg, Germany

The tetrahedral indium(I) compound $In_4[C(SiMe_3)_3]_4$ 1 reacts with the oxygen donor *o*-nitrosotoluene to form the extremely hygroscopic $In_4O_4[C(SiMe_3)_3]_4$ 2 in moderate yield, which exhibits a distorted In_4O_4 molecular center with normal In–O bond lengths, but short intracage In···In and O···O distances.

Although heterocubane type compounds $X_4(ER)_4$ with E a group 13 element, X a chalcogen atom and R an alkyl or aryl group have been known for several years with a continually increasing number of X = S, Se or Te,[1–4] no information concerning the properties or structure of the oxygen analogues is available from literature. Recently, a new method for the synthesis of such derivatives was developed by the treatment of tetrahedral element(I) clusters like $In_4[C(SiMe_3)_3]_4$ **1**[3,5] with elemental sulfur, selenium or tellurium, which gave the heterocubane compounds in high yields.[3,4] Their formation and structure can be described by the occupation of all tetrahedral faces of the cluster by chalcogen atoms. Dry oxygen and **1** gave no isolable products and, as previously reported,[5] moist air yielded the compound $In_4O(OH)_6[C(SiMe_3)_3]_4$[6] upon partial hydrolysis. Therefore, we searched for a suitable oxygen donor to oxidize **1** under mild conditions and to synthesize the up to now unknown In_4O_4 derivative.

Phosphane oxides or trimethylamine *N*-oxide did not react with **1**, and mixtures of unknown products resulted with bis(trimethylsilyl)peroxide. *p*-Nitrotoluene gave the In_4O_4 product **2** in a low yield, but the reaction was not well reproducible. The best result was obtained with *o*-nitrosotoluene (Scheme 1),† which formed, upon transfer of its oxygen atom to **1**, the corresponding dark red diazobenzene derivative identified by IR, NMR and UV–VIS spectroscopy. Mixed crystals of both products were isolated from hexane, in which the diazo compound was so strongly disordered that the structure could not be refined satisfactorily. Treatment with toluene to dissolve the more readily soluble diazo compound and recrystallization from hexane gave the colorless In_4O_4 derivative **2** in a yield of 24%. Compound **2** is hygroscopic and forms $In_4O(OH)_6[C(SiMe_3)_3]_4$[6] upon hydrolysis, which can be separated from the less soluble **2** by recrystallization. Crystalline **2** decomposes at 390 °C and is thermally more stable than its analogues with heavier chalcogens, for which decomposition points gradually decrease (330 °C for X = Te).[3,4] The molecule does not dissociate in benzene, as shown by the cryoscopically determined molar mass.



Scheme 1

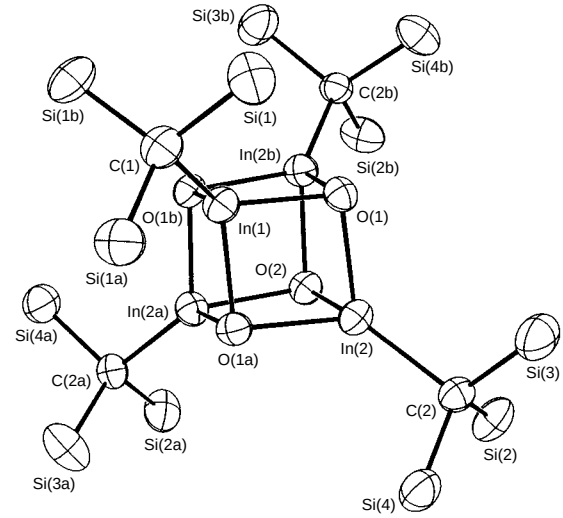


Fig. 1 Molecular structure of **2**. Selected bond lengths (pm) and angles (°): In(1)–O(1) 214.3(5), In(2)–O(1) 213.3(5), In(2)–O(1a) 214.0(5), In(2)–O(2) 213.8(5), In(1)–C(1) 222(1), In(2)–C(2) 216.5(7); O–In–O 84.4(2)–84.8(2), In–O–In 95.0(3)–95.3(2).

The structure of **2** (Fig. 1) shows a distorted In_4O_4 heterocubane in the molecular center with normal In–O bond lengths [213.3(5)–214.3(5) pm] and each In atom bound to a terminal alkyl group.‡ To the best of our knowledge, similar structures have not been observed before. The compounds $[MeIn(OH)(O_2PPh_2)]_4 \cdot 4py$ (py = pyridine) and $Ga_8(pz)_{12}O_4Cl_4$ (pz = pyrazolate) exhibit an $In_4(OH)_4$ or a Ga_4O_4 cube,[7] but due to the coordination number of four at the oxygen atoms and the bridging of faces or edges of the cages they are not comparable to the $E_4X_4R_4$ compounds discussed here. Also, the thallium(I) alcoholates with $Tl_4(OR)_4$ heterocubanes,[8] μ_3-OR groups and no alkyl substituents at the Tl atoms belong to another class of compounds. The series of the tetrachalcogen derivatives of **1** is completed with the synthesis of **2**. Comparison of important structure parameters in Table 1 shows that, with the exception of the oxygen compound **2**, the sum of

Table 1 Comparison of important structure parameters of the heterocubane molecules $In_4X_4R_4$ [X = chalcogen, R = $C(SiMe_3)_3$, Σr(X) = sum of the van der Waals radii of the chalcogen atoms,[9] Σr(In) = 380 pm]

	In–X/ pm	In–X–In/°	X–In–X/°	In···In/ pm	X···X/ pm	Σr(X)/ pm
$In_4O_4R_4$	214.0	95.1	84.6	315.7	287.9	300
$In_4S_4R_4$	254.9	86.8	93.1	350.4	370.0	360
$In_4Se_4R_4$	267.1	85.4	94.4	362.1	392.1	380
$In_4Te_4R_4$	286.4	83.7	95.6	382.9	425.2	420

the van der Waals radii[9] is exceeded between the chalcogen atoms, which may be caused by the charge distribution in the cage and a strong electrostatic repulsion between the more electronegative atoms. In contrast, the In–In distances are equal to (X = Te) or smaller (X = S, Se) than the sum of the van der Waals radii (380 pm). The difference between the intramolecular In···In and X···X distances increases from 20 pm for X = S to 42 pm for X = Te with the smallest distance always between the In atoms. The situation changes with the oxygen derivative **2**, where the In···In distance (315.7 pm) is larger than the O···O distance (287.9 pm). Both are smaller than the sum of the van der Waals radii, and the In···In distance approaches the bond length in the indium(I) compound **1** (300.2 pm)[3] indicating a considerable steric stress in the molecule. The inverse ratio of the homoatomic intracage distances leads to quite different bond angles. The most acute angles (< 90°) of **2** are observed at the In atoms, while with X = S, Se and Te they occur at the chalcogen atoms. The largest distortion of the cube is observed for the Te derivative, it decreases gradually to X = S and is reversed between X = S and O. The bond angles in **2** are in good agreement with values predicted by Barron and coworkers from a relation between intracage bond angles in known E_4X_4 cubane molecules and the ratio of the covalent radii of the elements.[2]

Tertiary amine–S_2Cl_2 chemistry: interception of reaction intermediates

Carlos F. Marcos,[a] Oleg A. Rakitin,[b] Charles W. Rees,[c] Ljudmila I. Souvorova,[b] Tomás Torroba,[a] Andrew J. P. White[c] and David J. Williams[c]

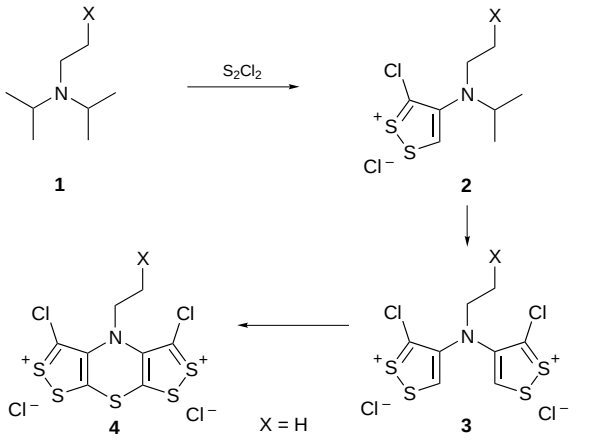
The reaction of *N*-(2-chloroethyl)diisopropylamine 1a with S_2Cl_2 allows the selective one-pot preparation of the tricyclic 4-(2-chloroethyl)bisdithiolothiazines 8 and 9 or, by addition of phosphorus pentasulfide at a late stage of the reaction, of the dithiolothiazine 6b characterised by X-ray crystallography; the chloroethyl derivative 8 is also obtained from (2-diisopropylamino)ethanethiol 1b and its disulfide 1c and S_2Cl_2, in a rare conversion of a thiol or disulfide into the corresponding chloro compound.

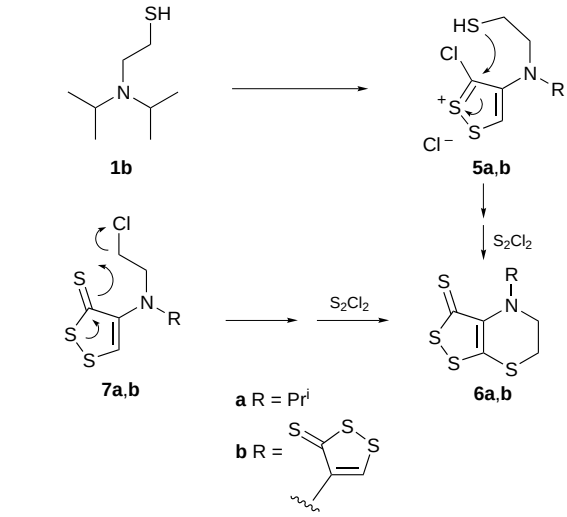
We have shown that Hünig's base, a simple saturated tertiary amine, is converted in a one-pot reaction by disulfur dichloride S_2Cl_2 into the fully unsaturated tricyclic bis[1,2]dithiolo[3,4-*b*:4′,3′-*e*][1,4]thiazine ring system[1] or, at a higher temperature, into the bis[1,2]dithiolo[4,3-*b*:3′,4′-*d*]pyrrole system[2] by selective sulfur extrusion from the thiazine.

Only the isopropyl groups of Hünig's base reacted with S_2Cl_2, the ethyl group being untouched. This led us to consider the reactivity of functionalised ethyl groups, both to broaden the reaction scope and hopefully to intercept proposed intermediates on the long reaction pathway, by cyclisations involving the ethyl group substituents. The key intermediates in our earlier proposals[6] were considered to be **2**, **3** and **4** (Scheme 1) when X = H, with **4** finally reacting with sulfur and oxygen nucleophiles to give the observed products. If X is a sufficiently nucleophilic group such as SH, the intermediates **2** and **3** could be diverted (arrows in **5**), to give the bicyclic compounds **6a**, or **6b** (Scheme 2). If X is a leaving group such as Cl then, at a later stage in the reaction when the dithiolium salt has been converted into the thione **7**, nucleophilic displacement could lead to the same bicyclic intermediates **6** (Scheme 2).

We therefore selected the commercially available *N*-(2-chloroethyl)diisopropylamine **1a**, which was readily converted into the thiol **1b** and its disulfide **1c**.[3] These compounds (1 equiv.) were each treated with S_2Cl_2 (10 equiv.) and DABCO (10 equiv.) in 1,2-dichloroethane for 3 d at room temperature.



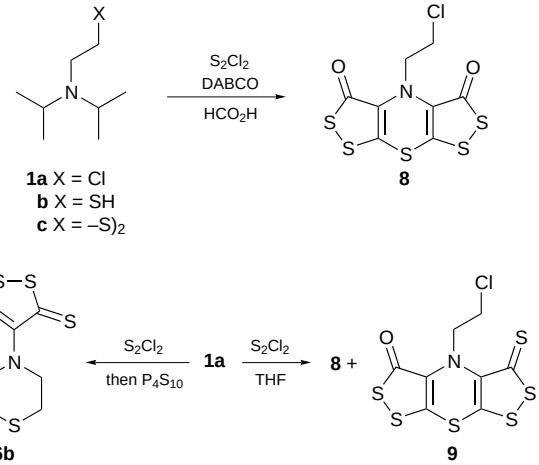
Scheme 1



Scheme 2

Formic acid (20 equiv.) was then added and the mixture heated under reflux for 1 h, since we find that this treatment gives clean reactions by converting the 3-chlorodithiolium salts into dithiol-3-ones. To our surprise all three starting materials **1a–c** gave exactly the same product **8** as a yellow solid, mp 175–177 °C (16–25%) after chromatography (Scheme 3). When the reaction of **1a** (1 equiv.) with S_2Cl_2 (1 equiv.) was performed in THF without addition of DABCO or formic acid, the oxo thione **9** was obtained as an orange solid, mp 256–258 °C (10%),† together with **8** (30%)† (Scheme 3). The structures of **8** and **9** were fully supported by all their spectroscopic properties.

In these reactions the chloroethylamine **1a**, the mercaptoethylamine **1b** and the disulfide **1c** reacted with S_2Cl_2 in the same way as Hünig's base itself, without detectable diversion of



Scheme 3

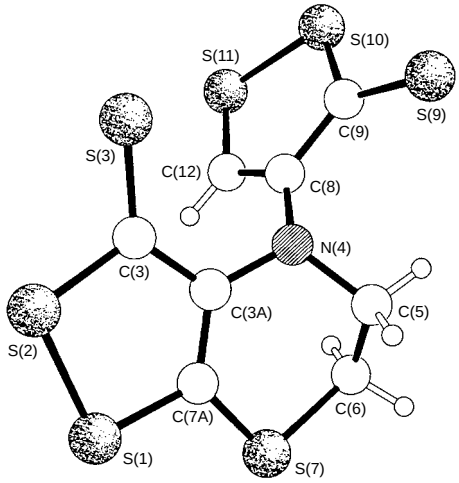


Fig. 1 The molecular structure of **6b**. Selected bond lengths (Å), S(1)–S(2) 2.057(1), S(2)–C(3) 1.731(3), C(3)–C(3A) 1.431(3), C(3A)–C(7A) 1.371(4), C(7A)–S(1) 1.729(3). C(3A)–N(4) 1.410(3), N(4)–C(8) 1.418(4), C(8)–C(9) 1.437(4), C(9)–S(10) 1.729(3), S(10)–S(11) 2.055(1), S(11)–C(12) 1.705(3) and C(12)–C(8) 1.348(4).

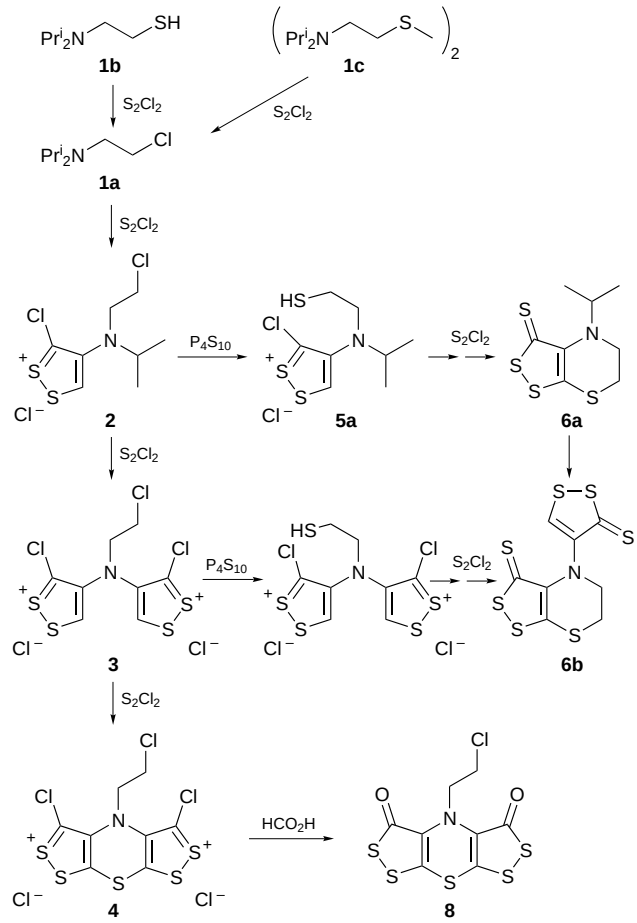
the reaction pathway, but with the additional conversion at some stage of the thiol and disulfide into the corresponding chloro compound. This last transformation is surprisingly rare, but has been achieved with sulfuryl chloride, followed by treatment with triphenylphosphine.[4]

These results suggest that S_2Cl_2 reacted with the sulfur groups faster than with the isopropyl groups; we therefore decided to try to regenerate a thiol derivative from the chloro compound by addition of a sulfur nucleophile at a late stage in the reaction. Treatment of the 2-chloroethylamine **1a** (1 equiv.) and S_2Cl_2 (1 equiv.) in THF for 3 d at room temperature was followed by addition of phosphorus pentasulfide (P_4S_{10}, 0.3 mol) and heating under reflux for 5.5 h. Chromatography gave new compound **6b** ($C_8H_5NS_7$) as shining orange needles, mp 240–241 °C (40%)† (Scheme 3). This did not contain chlorine (mass spectrum), although two different methylene groups were still present, together with an aromatic methyne group (^{1}H and ^{13}C NMR spectra) and a thiocarbonyl but not a carbonyl group (IR). The presence of an aromatic proton indicated that the fully fused tricyclic system of **8** and **9** had not been reached, and suggested the presence of a 1,2-dithiole with one ring hydrogen; structure **6b** was confirmed by X-ray crystallography (Fig. 1).‡ The partially saturated 1,4-thiazine ring has an 'envelope' conformation with C(5) lying 0.7 Å out of the plane of the remaining five atoms (which are co-planar to within 0.07 Å). There is a noticeable pyramidalization at N(4), the nitrogen atom lying 0.28 Å out of the plane of its substituents. The two dithiole rings are oriented approximately orthogonally (*ca*. 80°) thereby minimising interactions between them.

Taken in conjunction with our previous work on the conversion of Hünig's base with S_2Cl_2 into the *N*-ethyl analogues of compounds **8** and **9**,[1] the present results can be explained by the overall mechanism outlined in Scheme 4. The basic '*N*-ethyl' reaction does extend to other *N*-substituents and an appropriate functional group can divert the proposed reaction intermediates to form, in the present case, the new [1,2]dithiolo[3,4-*b*][1,4]thiazine ring system of **6b**. These complex 1,2-dithioles, now readily available from commercial materials in one-pot reactions, may be useful in the chemistry of new materials[5] and in pharmaceutical research.[6]

We gratefully acknowledge financial support from the Dirección General de Enseñanza Superior of Spain (DGDES Project ref. PB96-0101), the Consejería de Educación de la Junta de Extremadura y Fondo Social Europeo (ref. PRI97C123) and the NATO Linkage Grant 970596, and we thank the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.



Scheme 4

Notes and References

† In the absence of DABCO, yields are calculated on the basis of 15 mol of amine **1** giving 1 mol of product and 14 mol of amine **1** hydrochloride.

‡ *Crystal data* for **6b**: $C_8H_5NS_7$, M = 339.6, orthorhombic, space group *Pbca* (no. 61), a = 14.672(1), b = 8.757(2), c = 19.626(2) Å, V = 2521.7(6) Å^3, Z = 8, D_c = 1.789 g cm^{-3}, μ(Cu-Kα) = 113.2 cm^{-1}, λ = 1.54178 Å, F(000) = 1376. An orange platy needle of dimensions 0.67 × 0.22 × 0.02 mm was used. Data were measured on a Siemens P4/PC diffractometer with Cu-Kα radiation (graphite monochromator) using ω-scans. 2089 Independent reflections were measured ($2\theta \leqslant 128°$) of which 1855 had $|F_o| > 4\sigma(|F_o|)$ and were considered to be observed. The structure was solved by direct methods and the non-hydrogen atoms were refined anisotropically by full-matrix least-squares based on F^2 using absorption corrected data (face-indexed numerical, maximum and minimum transmission factors 0.80 and 0.16, respectively) to give R_1 = 0.036, wR_2 = 0.096 for the observed data and 146 parameters. A novel class of nucleic acid analogues, termed LNA (locked nucleic acids), is introduced. Following the Watson–Crick base pairing rules, LNA forms duplexes with complementary DNA and RNA with remarkably increased thermal stabilities and generally improved selectivities.

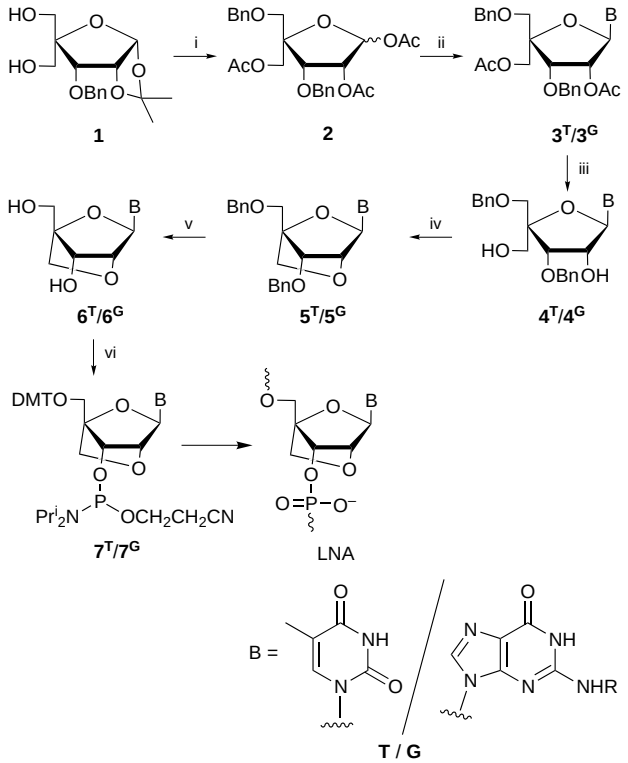
During the last decade a plethora of DNA and RNA analogues have been chemically synthesized,[1–6] *e.g.* with the aim of improving nucleic acid recognition. We[7] and others[8] have reported promising, but not satisfactory, properties of oligonucleotides containing conformationally restricted monomers. We report here the synthesis of a novel conformationally restricted nucleic acid mimic, LNA (see Scheme 1). Molecular modelling† and simple model building suggested to us that the LNA monomers would be favourably preorganized in an N-type conformation thus enabling the formation of entropically favoured duplexes with complementary DNA and RNA. As an attractive feature, the structural change from DNA (or RNA) to LNA is limited from a chemical perspective, namely the introduction of an additional 2′-*C*,4′-*C*-oxymethylene link.



Scheme 1 *Reagents and conditions* (for **7T**): i, (*a*) NaH, BnBr, DMF, (*b*) Ac_2O, Py (64%, two steps), (*c*) 80% AcOH, (*d*) Ac_2O, Py (86%, two steps); ii, thymine, *N*,*O*-bis(trimethylsilyl)acetamide, TMS triflate, acetonitrile (76%) [for **3G**: 2-*N*-isobutyrylguanine, *N*,*O*-bis(trimethylsilyl)acetamide, TMS triflate, dichloroethane]; iii, NaOMe, MeOH (97%); iv, (*a*) TsCl, Py (47%), (*b*) NaH, DMF (89%); v, 20% $Pd(OH)_2$/C, EtOH, H_2 (98%); vi, (*a*) DMTCI, Py (93%), (*b*) *N*,*N*-diisopropylethylamine, 2-cyanoethyl *N*,*N*-diisopropylphosphoramidochloridite, CH_2Cl_2 (70%)

For synthesis of the LNA monomers we chose a strategy starting from the known 4′-*C*-hydroxymethyl pentofuranose derivative **1**[9] (Scheme 1). Regioselective 5-*O*-benzylation, acetylation and acetolysis, followed by another acetylation, afforded furanose **2**, a key intermediate for coupling with silylated nucleobases. Stereoselective reaction with silylated thymine[10] yielded nucleoside **3T** which was deacetylated to give nucleoside diol **4T**. Tosylation followed by base-induced ring closure afforded the 2′-*O*,4′-*C*-linked bicyclic nucleoside derivative **5T**. Debenzylation yielded the unprotected analogue **6T** as the first example of a nucleoside diol with the (1*S*,3*R*,4*R*,7*S*)-7-hydroxy-1-hydroxymethyl-2,5-dioxabicyclo-[2.2.1]heptane structure. The assigned structure of **6T** was verified by NMR spectroscopy, including NOE experiments.‡ The absence of a coupling constant between 1′-H and 2′-H, and the unusual and strong mutual NOE effects (9%/8%) between 3′-H and 6-H (thymine base), strongly indicate structural preorganization of the pentofuranose ring of the LNA monomer into an N-type conformation.[5,11] Similar synthetic procedures were applied to synthesize the guanine derivatives **3G**–**6G** *via* coupling of **2** and 2-*N*-isobutyrylguanine. Transformation of nucleosides **6** into the 5′-*O*-4,4′-dimethoxytrityl (5′-*O*-DMT) protected analogues and subsequently into the phosphoramidite derivatives **7**§ yielded the desired monomeric building blocks for automated oligonucleotide synthesis.

LNAs¶ and unmodified reference strands (Tables 1 and 2) were effectively synthesized using the phosphoramidite approach.[12] Stability against 3′-exonucleolytic degradation is a prerequisite for most *in vivo* applications of oligonucleotide analogues The LNA 5′-$\mathbf{T^L}_{13}$T displayed complete 3′-exonucleolytic stability when measured by a procedure described earlier using snake venom phosphodiesterase.[13] The thermal stabilities (melting temperatures, T_m) of duplexes involving LNA oligonucleotides towards both DNA and RNA complements were determined and compared to their unmodified references (Tables 1 and 2). In all experiments, sharp monophasic transitions were observed with hyperchromicities of 1.2–1.4. No transitions were observed when running LNAs without complements in control experiments.

[a] A = adenosine monomer, C = cytidine monomer, G = guanosine monomer, U = uridine monomer, T = thymidine monomer, $\mathbf{T^L}$/$\mathbf{G^L}$ = LNA monomers. Oligodeoxynucleotide sequences are depicted as d(sequence). 'Ref' indicates reference duplex. Hybridization mixtures of 1 ml were prepared using a buffer solution (10 mM Na_2HPO_4, pH 7.0, 100 mM NaCl, 0.1 mM EDTA) and equimolar (1.0 or 1.5 μM) amounts of the oligonucleotides. The absorbance at 260 nm was recorded while the temperature was raised linearly from 10 to 93 °C (1 °C min^{-1}). The melting temperatures (T_m values) were obtained as the maxima of the first derivatives of the melting curves.

The results for oligothymidylates are depicted in Table 1. Generally, significant increases in T_m values were obtained. Against complementary DNA (dA_{14}), the results ranged from no effect (incorporation of one LNA monomer, entry 2) to an increase in T_m of 4.9 °C per $\mathbf{T^L}$ incorporated for the LNA $\mathbf{T^L}_9$T (entry 7). The effect on the thermal stabilities of duplexes towards RNA (A_{14}) was significant (and additive) in all experiments (entries 2–9, increases in T_m of 4.0–6.0 °C per $\mathbf{T^L}$ incorporated).

The remarkable nucleic acid recognition potential of oligothymidylate LNAs was extended to mixed sequences containing the pyrimidine LNA monomer $\mathbf{T^L}$ and/or the purine LNA monomer $\mathbf{G^L}$ (Table 2). Thus, convincing stabilizing effects were observed when hybridizing nonamer LNAs towards DNA (ΔT_m = +5.3 °C per LNA monomer incorporated), whereas unprecedented increases in thermal stability (ΔT_m = +7.3 and +8.3 °C per LNA monomer incorporated) of the corresponding LNA:RNA duplexes were observed. The selectivity of the mixed sequence LNAs is, if anything, improved compared to the corresponding DNA references. This can be extracted from experiments where mis-matched nucleotides were in turn introduced in the position opposite to the middle $\mathbf{T^L}$/$\mathbf{G^L}$ monomers (and T/G monomers). The decreases in thermal stabilities obtained were slightly more pronounced for the LNAs compared to the reference DNAs (representative results are shown in entries 3–5; similar results were obtained when evaluating the binding selectivity of $\mathbf{G^L}$ and the binding selectivity against complementary RNA). These results indicate that LNA obeys the standard Watson–Crick pairing rules and that the complexes are bimolecular duplexes.**

In this report it has been demonstrated that preorganized LNAs display 3′-exonucleolytic stability and excellent ability to recognize complementary DNA and RNA. These results should make LNA a prime candidate for development of oligonucleotide-based therapeutics and diagnostic probes, and LNA-mediated nucleic acid recognition a novel concept of general applicability.

† Molecular modelling was performed using HYPERCHEM™ version 4.0; MM+ force field; Polak-Ribiere conjugate gradient geometry optimization.

‡ *NMR data* for $\mathbf{6^T}$ (conventional nucleoside numbering is used): δ_H [$(CD_3)_2SO$] 11.33 (1 H, br s, NH), 7.62 (1 H, d, *J* 1.1, 6-H), 5.65 (1 H, d, *J* 4.4, 3′-OH), 5.41 (1 H, s, 1′-H), 5.19 (1 H, t, *J* 5.6 Hz, 5′-OH), 4.11 (1 H, s, 2′-H), 3.91 (1 H, d, *J* 4.2, 3′-H), 3.82 (1 H, d, *J* 7.7, 5″-H_a), 3.76 (2 H, d, *J* 5.7, 5′-H), 3.63 (1 H, d, *J* 7.7, 5″-H_b), 1.78 (3 H, d, *J* 0.7, CH_3); key NOE contacts, signifying close interatom distances, were identified between: 5″-H_b and 1′-H, 6-H and 3′-H, 5′-OH and 5′-H, 5′-OH and 3′-H, and 5′-OH and 6-H.

§ *NMR data* for: $\mathbf{7^T}$ δ_P($CDCl_3$) 149.06, 148.74. For $\mathbf{7^G}$ δ_P ($CDCl_3$) 148.17, 146.07.

¶ The term LNA describes oligonucleotides containing one or more LNA monomer(s). For synthetic convenience, the LNAs of this first study were synthesized (0.2 μmol scale) on commercial supports carrying a natural 2′-deoxynucleoside. Step-wise coupling yields: $\mathbf{7^T}$ > 98% (12 min coupling), $\mathbf{7^G}$ > 95% (12 min coupling), deoxynucleoside phosphoramidites > 98% (2 min coupling). After standard cleavage and deprotection, capillary gel electrophoresis or reversed-phase HPLC was used to verify the purity (> 90%) of the synthesized oligonucleotides. Selected MALDI-MS experiments: 5′-$T_5\mathbf{T^L}_4T_5$ [M − H]$^-$ 4307.0 (calc. 4307.8); 5′-$\mathbf{T^L}_{13}$T [M − H]$^-$ 4557.8 (calc. 4559.7); 5′-d(G$\mathbf{T^L}$GA$\mathbf{G^L}$A$\mathbf{T^L}$GC) [M − H]$^-$ 2862.2 (calc. 2861.9).

** At pH 7.0, cytosine nucleobases are non-protonated and thus unable to form triple-helical structures. Triple-helical complexation for the oligothymidylate LNAs of Table 1 is theoretically possible, but no biphasic transitions were detected, even for the lower melting complexes. As further evidence, strikingly similar CD curves for LNA complexes and the corresponding reference duplexes were obtained.

Intramolecular [4 + 2] cycloadditions involving transient phosphaalkene intermediates as dienophiles: a useful entry to phosphabicyclo[4.3.0]non-4-ene derivatives

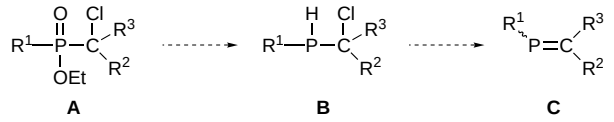
Jean-François Pilard, Annie-Claude Gaumont, Céline Friot and Jean-Marc Denis*†

Synthèse et électrosynthèse organiques, UMR 6510, Université de Rennes 1, Campus de Beaulieu, F-35042, Rennes, France

Three representative phosphabicyclo[4.3.0]non-4-ene derivatives are formed in high yields and various diastereomeric forms by [4 + 2] intramolecular cycloadditions involving transient phosphaalkenes as dienophiles; complete diastereoselectivity is observed with the P-substituted derivative.

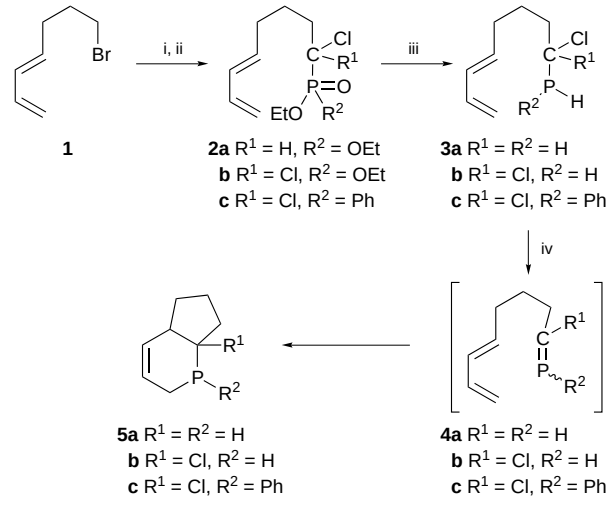
Free cyclic phosphines and their metal coordination complexes are valuable intermediates in organophosphorus chemistry.[1] They are prepared by many different approaches, among them, cycloaddition reactions involving C=P double bonds with dienes and dipoles appear to be of synthetic value.[1,2] the main problem encountered by using this methodology is keeping the reactivity of the P=C double bond under control. Self-condensations are usually avoided by steric or electronic effects and by complexation with a transition metal. Some cycloadditions lacking stabilisation of the P^{III} intermediate occur in high yield,[3] especially when the cycloadducts spontaneously aromatize, thus giving a useful entry to functionalised phosphinines;[4] in most cases however the desired cycloadducts are accompanied of various amounts of self-condensed products.[2d] In order to circumvent this problem we thought to trap the transient species by internal cycloaddition. Under these conditions, the rates of the reactions are expected to be strongly enhanced by entropic assistance, hopefully making the self-condensation reactions of transient species negligible. Intermolecular reactions between conjugated dienes and phosphaalkenes have been recently reviewed.[2a] It is now well established that, with the exception of some derivatives bearing electronegative substituents, the reaction takes place with retention of the phosphaalkene stereochemistry. Furthermore, at least with cyclopentadiene derivatives, the *endo* preference is respected with substituents on phosphorus. Thus, the potential versatility of intramolecular cycloadditions involving low coordinated phosphorus derivatives as dienophiles should afford a useful entry to tailored and hopefully stereocontrolled polycyclic systems. As a first evaluation of this methodology, we present here the synthesis of three differently substituted 2-phosphabicyclo[4.3.0]non-4-ene phosphines **5a**–**c** by intramolecular [4 + 2] cycloadditions involving the corresponding terminal phosphaalkenes **4a**–**c** as dienophiles. Conditions for controlling the stereochemistry are described.

We have recently developed a general route to non-stabilized phosphaalkenes which involves as a key step the dehydrohalogenation of α-chloroalkylphosphines with a Lewis base[2d,5] (Scheme 1). This procedure is attractive for the following reasons: (i) the α-chlorophosphonate and phosphinate precursors **A** are readily available by conventional anionic routes,[6,7] allowing introduction of the desired substituents both on phosphorus and carbon, (ii) the reduction of esters **A** into phosphines **B** with dichloroalane is chemoselective,[8] and (iii) HCl elimination occurs under mild conditions at a temperature which depends both on the strength of the base and the P–H acidity of the phosphine, allowing us to determine the best conditions for the trapping of the transient phosphaalkene **C**. We decided to adopt this strategy for the synthesis of the phosphabicyclononenes **5a**–**c** (Scheme 2).



Scheme 1

Chlorophosphonate **2a** was prepared by halogen–metal exchange of trichloromethylphosphonate $[Cl_3CP(O)(OEt)_2]$[6] with BuLi (2 equiv.) followed by selective monosilylation [Me_3SiCl (1 equiv.)], alkylation [(*E*)-1-bromohepta-4,6-diene **1** (1 equiv.)][9] of the resulting lithiated intermediates and subsequent hydrolysis in basic media.[10] The phosphonate **2b** and phosphinate **2c** were prepared by halogen–metal exchange of trichloromethylphosphonate $[Cl_3CP(O)(OEt)_2]$ and trichloromethylphenylphosphinate[6] $[Cl_3CP(O)(OEt)Ph]$[7] respectively with BuLi (1 equiv.) followed by alkylation of the resulting intermediates with **1** (Scheme 2). The yields of **2a** and **2b** were greater than 85% after purification by chromatography on silica. The yield for **2c** is lower (57%), a small amount of the starting material **1** being recovered at the end of the reaction. Chemoselective reduction of esters **2a**–**c** with dichloroalane[5,8] in THF afforded the free phosphines **3a**–**c**. The low volatility of the latter prevents purification by the general procedure involving successive vacuum transfers.[5] The following protocol was used: after hydrolysis of the crude mixture at −10 °C with deoxygenated water, the organic solution was filtered off under a slight pressure of neutral gas, washed again and then dried.



Scheme 2 *Reagents and conditions*: i, THF, BuLi (2 equiv. for **2a**, 1 equiv. for **2b,c**), −85 °C, then $Cl_3CP(O)(OEt)_2$; ii (for **2a**), −85 °C, Me_3SiCl (1 equiv.), then −85 °C, $Br(CH_2)_3CH{=}CHCH{=}CH_2$, then 20 °C, aq. LiOH; (for **2b,c**), −85 °C, $Br(CH_2)_3CH{=}CHCH{=}CH_2$; iii, '$AlHCl_2$', THF, −80 to 20 °C, then deoxygenated H_2O, −10 °C, then $MgSO_4$; iv (for **5a,b**), −60 °C, Py (3 equiv.), then −60 to 20 °C; (for **5c**) −30 °C, Et_3N (2.5 equiv.), then −30 to 20 °C

Solutions were used without further purification, and the chlorophosphines **3a–c** were stable in the absence of oxygen. Yields determinated by NMR spectroscopy with an internal reference were greater than 70% (purity > 90%). The characterisation was supported by HRMS and ^{31}P, ^{1}H and ^{13}C NMR data, all of which were consistent with the assigned structure.‡

We have shown in our previous work that (i) transient phosphaalkenes are detectable by ^{31}P NMR spectroscopy in the dehydrochlorination of primary and secondary α-chloroalkylphosphines[2d,5] under controlled temperature conditions (from −80 to 20 °C) and (ii) polymerisation of the chlorophosphaalkene intermediates was observed in the elimination of HCl from α,α′-dichlorophosphines by a weak Lewis base (pyridine) in the absence of a trapping agent.[11,12] Whatever the nature of the Lewis base, we never detected in this work the expected phosphaalkene intermediates **4a–c** starting from **3a–c**. The only observed products were the cycloadducts **5a–c** characterized by new signals in the ^{31}P NMR spectra and the corresponding J_{PH} couplings: cyclic phosphines **5a** and **5b** were observed when the temperature rose to −60 °C in the presented pyridine (3 equiv.). Due to the lower P–H acidity[5] of secondary phosphines, elimination of HCl from α,α′-chlorophosphine **3c** occurred at −30 °C with a stronger base [NEt_3 (2.5 equiv.)]. Intramolecular [4 + 2] cycloaddition of **4a–c** with the diene counterpart is consequently a fast step. Self-condensations are strongly inhibited, as was confirmed by the high yield of cycloadducts (*i.e.* yield for **5c** > 80%, determined by ^{31}P NMR spectroscopy with an internal reference). All these results are consistent with entropic activation.

Since cycloaddition reactions take place with retention of stereochemistry at the P^{III} centre,[2a] both (*Z*)- and (*E*)-phosphaalkene intermediates are expected from elimination of HCl from α-chlorophosphines **3**, giving four isomeric cycloadducts. The observed stereochemical course differs strongly with the structure of the dienophile. We observed a weak selectivity starting from **4a** [four isomers, at δ −91.5 (d, $^{1}J_{PH}$ = 187 Hz), −88.4 (d, $^{1}J_{PH}$ = 191 Hz), −85 (d, $^{1}J_{PH}$ = 182 Hz) and −68.7 (d, $^{1}J_{PH}$ = 178 Hz); ratio = 57 : 20 : 14 : 9, respectively]. A higher selectivity is encountered for **4b** [two isomers at δ −76 ($^{1}J_{1PH}$ = 186 Hz) and −65 ($^{1}J_{PH}$ = 195 Hz); ratio = 81 : 19, respectively]. These results are consistent with the presence of the two (*Z*)- and (*E*)-phosphaalkene intermediates for **4a** and **4b**. On the other hand, intramolecular cycloaddition of **4c** is highly selective, and only one isomer is observed. The stereochemistry of the P(1), C(8) and C(9) centres is controlled (Scheme 3). (i) The relative configuration at P and C(8) of **5c** was established on the basis of the $^{2}J_{PC(7)}$ coupling constant: the observed value (15 Hz) favours a *trans* relationship between the lone pair and C(7).[3,13,14]§ (ii) The *cis*-fused cycloadduct is proposed to take into account the preference of the P-substituent for the *endo* postions.[2a,15,16] The phenyl and chloride substituents in **4c** are consequently in a *trans* relationship. The ^{1}H, ^{31}P and ^{13}C NMR data and mass spectra (HRMS) of **5a–c** are fully consistent with their assigned structures.

4c **5c**

Scheme 3

In summary, we have shown that intramolecular [4 + 2] cycloadditions involving phosphaalkenes can be considered as a potentially useful route for the construction of stereocontrolled polycyclic structures bearing a phosphorus atom, with the entropic effect suppressing the polymerisation of the transient intermediate. A more detailed mechanistic study of this reaction is under active investigation.

Asymmetric tandem reactions based on nitroalkenes: a one-pot construction of functionalized chiral bicycles by a three-component reaction

Martín Avalos,*† Reyes Babiano, Pedro Cintas, José L. Jiménez, Juan C. Palacios and María A. Silva

Departamento de Química Orgánica, Facultad de Ciencias, Universidad de Extremadura, E-06071 Badajoz, Spain

Asymmetric tandem cycloaddition of a chiral carbohydrate nitroalkene with ethyl vinyl ether in the presence of electron-withdrawing alkenes produces a facile assembly of bicyclic systems, which can further be selectively cleaved to give homologated carbohydrates.

The construction of complex organic molecules by sequential transformations is one of the most important and efficient synthetic strategies. The advantages of these so-called tandem or domino reactions are many and have been thoroughly discussed.[1] Sequential [4 + 2]/[3 + 2] cycloadditions relying on nitroalkenes have been developed by Denmark and his group over the last decade, exploiting the use of a homochiral auxiliary on the dienophile and demonstrating the versatility of this methodology in alkaloid synthesis.[2]

Recently we have also demonstrated the efficiency of the tandem nitroalkene cycloaddition as a viable approach to densely functionalized molecules, but the heterodiene now imparts chirality by using a readily available carbohydrate-appended nitroalkene (Scheme 1).[3] These processes occur through the intermediacy of nitronate species such as **2**.

Given the distinctive electronic character of nitroalkenes and nitronates, it would be possible to perform a multicomponent reaction combining electron-rich and electron-withdrawing alkenes without them interfering with each other. Thus when the heterodiene **1** was reacted with excesses of ethyl vinyl ether (EVE) and an electron-withdrawing alkene such as methyl vinyl ketone (MVK), methyl acrylate (MA), acrylonitrile (AN) and dimethyl maleate (DMM) in ethanolic solution at room temperature for 5–7 days, the corresponding nitrosoacetals **4**–**7** were obtained as crystalline solids (Scheme 2 and Table 1).‡ The initial inverse electronic demand [4 + 2] cycloaddition occurs with ethyl vinyl ether, whereas the resulting nitronate will react exclusively in a [3 + 2] fashion with the electron-deficient alkene.

Analyses of crude samples by ^{1}H NMR spectroscopy ($CDCl_3$, 400 MHz) reveal that the reactions are regiospecific and exhibit a pronounced facial diastereoselectivity. Only two diastereoisomers were detected, one of which was always prevalent. Remarkably, the mixtures could be purified by flash chromatography (ethyl acetate–hexane eluent system) and the major isomers were obtained as diastereoisomerically pure samples by crystallization from EtOH. In the cases of the MA and AN reactions, the minor isomers could also be obtained in crystalline form in 4 and 10% yields, respectively.

We have confirmed by X-ray diffractometry that the initial [4 + 2] cycloaddition occurs with a complete *endo* selectivity to the *re* face of the heterodiene, whereas the [3 + 2] cyclization follows in the *exo* sense, which is sterically more favorable than the competitive *endo* approach.[3] This type of *exo–endo* facial selectivity has been observed before with related 5,5-fused systems.[4] Based on such results and with the information provided by proton coupling constants, suggesting that both substituents of five- and six-membered fused rings are located at α-equatorial positions, we have tentatively assigned the absolute stereochemistry of the major isomers **4**–**7**. Because similar coupling constants have also been found for the isolated minor isomers, their formation must have taken place with the opposite *endo* orientation in the [3 + 2] cyclization.

The usefulness of these functionalized polyhydroxyalkyl heterocycles was further illustrated through their selective six-membered ring opening under mild conditions. Cleavage of nitrosoacetals may be induced by acidic treatment with dilute AcOH in ethanolic solution, but reaction mixtures were difficult to purify owing to the presence of unidentified side products. However, when cycloadducts were heated at reflux in a 1 : 1 EtOH–H_2O mixture, homologated sugar aldehydes[5,6] such as **10** and **11** were cleanly obtained in quantitative yield (Scheme 3).‡ These substances were further characterized by preparing their hydrazone derivatives **12** and **13**, respectively. Compounds **10**–**13** also bear an attractive isoxazoline ring that could

be further manipulated to afford vicinal amino alcohols and crossed aldol products.[7,8]

In conclusion, we have successfully explored a tandem cycloaddition which involves *in situ* formation of a chiral nitronate having a sugar moiety and its subsequent diastereofacial selective dipolar cycloaddition with a series of electron-deficient alkenes. Variations in the system undergoing cyclization allows subsets of richly functionalized nitrogen-containing polycycles to be produced from an acyclic precursor. The formation of homologated carbohydrates in a few steps is also notable. With the understanding of transition state preferences, this methodology will become a useful element in synthetic design and further investigations are currently under way in our laboratories.

Novel conformationally constrained glutamate analogues are readily available from (*S*)-pyroglutamic acid; using a bicyclic lactam template, diastereocontrolled and sequential modification of the pyrrolidine ring is possible, allowing a versatile access to several glutamate and kainoid analogues; variations in the C(2)H–C(3)H coupling constants were observed depending upon the nature of remote substituents on the heterocyclic ring, consistent with modification of the ring conformation.

Nitrogen heterocycles occur widely in nature, in isolation and as structural subunits in many families of alkaloids, and possess wide ranging biological and pharmacological activities.[1–3] Of particular current interest are conformationally constrained glutamines,[4] which have been shown to possess potent activity at both the ionotropic and metabotropic receptors.[5,6] These receptors are selectively activated by excitatory amino acids, and are known to play an important role in various physiological processes, such as memory and learning, neuroendocrine regulation, and acute and chronic neuronal disfunction.[7] Excessive activation of these receptors can in some cases lead to cell death.[8] The search for selective agonists and antagonists offers the potential for both the structural and physiological characterisation of the receptors, and treatment of a range of physiological disorders, in particular Alzheimer's and Parkinson's diseases. Highly functionalised pyrrolidines have been found to have activity at these receptors,[9] and there has therefore been considerable recent interest in the development of practical and versatile methodology for the preparation of this important class of compound;[10,11] particularly elegant protocols have been developed by Shirahama[12,13] and by Baldwin[14–16] which use 4-hydroxyproline as a chiral starting material, and which offer considerable simplicity and generality for the introduction of the ring substituents. We report here an alternative but equally versatile and simple approach to functionalised pyroglutamates which uses a sequential conjugate addition/alkylation or arylation strategy to a $\Delta^{3,4}$ pyrrolidinone derivative. This method has been applied to the synthesis of a novel class of conformationally restricted glutamates, which possess a similar ring substitution pattern to the kainoid group of amino acids.

We used the recently described and readily available lactam **1** as a template for manipulation to a variety of functionalised pyrrolidinones.[17,18] Thus, conjugate addition of the Reformatsky reagent derived from *tert*-butyl bromoacetate generated in THF and DMPU with ultrasonic irradiation gave the diester **2**, in 77% yield as a mixture of diastereomers at the C(7) position, using our previously reported method;[19] conjugate additions to a related enone have been reported previously, although not with Reformatsky reagents.[19,20] This compound was readily functionalised at C(7) by direct arylation using several aryllead triacetates [$ArPb(OAc)_3$, $CHCl_3$, Py, reflux, 72 h][21,22] to give the aryl derivatives **3a**–**d** in good yield as mixtures of diastereomers at C(7) (Table 1) which could be separated only with some difficulty.[23] In the case of **3a**,**b**, the stereochemistry of the C(7)–Ar *exo*- diasteromer was assigned by a series of NOE experiments. Alternatively, alkylation with benzyl bromide under previously reported conditions (NaH, THF, reflux)[24] gave the derivative **3e** as a separable mixture of diastereomers in very good yield. In all arylations, a diastereomeric mixture was obtained, in which preferential addition of the aryl substituent to the *exo* face of **2** was predominant, although for the alkylation with benzyl bromide, a slight preference for *endo* addition was observed.

Fig. 1 NOE enhancements for **6a** and **6b**

In the case of the arylated derivative **3a**, acidic deprotection of the hemiaminal ether function gave the separable diastereomeric alcohols **4a**,**b** in 28 and 52% yield, respectively. Treatment of **4b** with 1 M NaOH in EtOH gave the hydrolysed and decarboxylated products **4c**,**d** on extraction of the basic mixture with EtOAc, and a mixture of the acid **4e** and product **4c**,**d** on extraction of the aqueous mixture after acidification with 2 M HCl. Heating of this mixture at 135 °C at 0.8 mBar for 30 min gave the product **4c**,**d** as a 1 : 1 mixture of diastereomers, in a combined yield of 82%. Acidic deprotection (TFA–CH_2Cl_2) of the *tert*-butyl ester function of **4c**,**d** and then oxidation (RuO_2, $NaIO_4$, MeCN, CCl_4, H_2O) afforded the acid **5** [as a mixture of diastereomers at C(4)] which was partially purified using base wash and then treated with MeOH–H_2SO_4 (catalytic) giving the diesters **6a** and **6b** each in 33% yield (from **4c**,**d**), whose relative stereochemistry was determined by NOE experiments (Fig. 1). An alternative route to **6a**,**b**, which involved treatment of **3a** with 2 M NaOH–EtOH at 50 °C for 5 h to give concomitant ethyl ester hydrolysis, decarboxylation and *tert*-butyl ester hydrolysis, was limited by incomplete and variable hydrolysis of the ester functions, leading to impure **7a**,**b**.

The benzyl derivative **3e** was also amenable to similar manipulation. Thus, hemiaminal ether cleavage of each of the benzyl diastereomers of **3e** (TFA in CH_2Cl_2) afforded the products **4f**,**g**. Hydrolysis (NaOH–EtOH) of **4f** gave **4h** in 99% crude yield, which after heating to effect decarboxylation, and then *tert*-butyl ester removal, oxidation (RuO_2, $NaIO_4$, MeCN, CCl_4, H_2O) and esterification (CH_2N_2) provided the separable diastereomeric benzyl derivatives **6c**,**d** in a ratio of 1 : 4.4 and 38% overall yield. An alternative path, involving hydrolysis of **4g**, followed by direct *tert*-butyl ester removal, oxidation, and esterification using the above conditions gave a 1 : 1 mixture of products **6e**,**f**, indicating that the initial hydrolyis was incomplete.

Pyrrolidinones which were unfunctionalised at C(4) were also available by this route. Thus, direct decarboxylation of the starting lactam **2**, by treatment with ethanolic NaOH followed by thermolysis and deprotection with TFA, afforded **4i** in 33% yield, a compound which has been previously reported in the literature.[25] Conversion to lactam **6h** was achieved by *tert*-butyl ester removal, oxidation as before and esterification (CH_2N_2) in 53% yield over the three steps.

Noteworthy was variation of the C(2)–H/C(3)–H vicinal proton coupling constants for each of the substituted pyroglutamates **6** (Table 2); molecular modelling studies of each of these compounds[27] indicated that the dihedral angle of the energy minimised structures also varied with the nature of the C(4) substituent, particularly for the more sterically congested C(4)–aryl series of compounds **6a**,**b**. Thus, it would appear that analogues of well-defined glutamate conformers could be available by variation in the C(4) substituent of compounds of type **6**.

Table 2 Proton–proton C(2)–H/C(3)–H coupling constant data and corresponding dihedral angles

Compound	*J*/Hz[a]	Dihedral angle (°)[b]
6h	5.5 (5.5)	117
6a	6.5 (6.5)	121

6c	2.5 (2.5)	125
6d	6.0 (6.5)	118

[a] In $CDCl_3$ (in C_6D_6). [b] Ref. 27.

This route represents a novel and simple, but potentially generalisable, approach to highly functionalised pyrrolidinones, and is complementary to existing literature protocols. It in particular provides access to novel pyroglutamate analogues of the kainoid group of amino acids possessing substituents with π-electron density at C(4).

Highly efficient and regioselective cyclization catalyzed by titanium silicate-1

Asim Bhaumik† and Takashi Tatsumi

Engineering Research Institute, The University of Tokyo, Yayoi, Tokyo 113, Japan

Highly regioselective cyclization of 3,4, 4,5 and 5,6 unsaturated alcohols to tetrahydrofuranols and tetrahydropyranols is reported using the TS-1–H_2O_2 system for the first time.

Since the discovery of the titanium silicate molecular sieve, TS-1,[1] and its use in liquid phase heterogeneous oxidation catalysis[2] in the presence of dilute hydrogen peroxide, it has been the subject of tremendous research activity to establish its applicability to various organic transformations.[3–7]

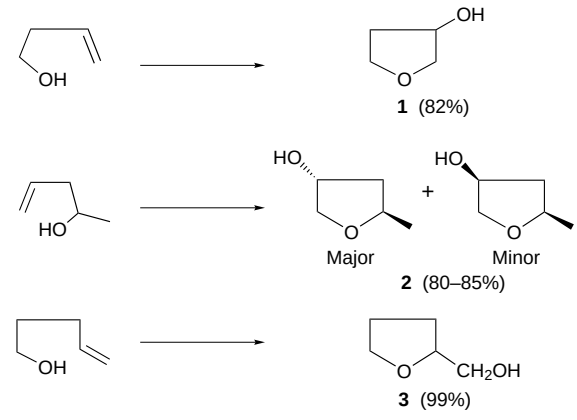
Substituted tetrahydrofuran and tetrahydropyran rings are common in many natural products, and thus play an important role as building blocks for the synthesis of various biologically active organic target molecules.[8] Hence, new methods for the synthesis of these oxacyclic compounds have long been sought. A strategy involving electrophilic activation of the double bond[9,10] in pent-4-en-1-ol or hex-5-en-1-ol followed by intramolecular nucleophilic attack of the oxygen atom of the hydroxy group offers a convenient route for the stereoselective synthesis of these compounds. Ring closure of substituted pent-4-en-1-yloxy and hex-5-en-1-yloxy radicals[11,12] is also of notable synthetic utility. Here, we report a highly efficient regioselective cyclization of such olefinic alcohols over TS-1, under mild reaction conditions using dilute hydrogen peroxide as oxidant. A similar oxidative cyclization (bifunctional behavior, epoxidation followed by acid catalyzed cyclization) was observed in the oxidation of linalool[13] over Al-Ti-Beta and Al-Ti-MCM-41, where the acidity at the Al sites was responsible for the cyclization.

TS-1 used in the present study was synthesized by the standard literature procedure[1] and thoroughly characterized *via* X-ray diffraction and FT-IR and UV-VIS spectroscopy. The liquid phase reaction was carried out in a two-necked glass reactor fitted with a water condenser under an N_2 atmosphere at the required temperature (298 and 333 K) with vigorous stirring. In a typical reaction the following constituents were employed: substrate (0.02 mol), aq. H_2O_2 (0.02 mol, 30 wt%), catalyst (TS-1, Si/Ti = 27, 20 wt% with respect to the substrate), acetone (10 g), butan-2-ol or H_2O (in a three phase system). At various reaction times products were analyzed *via* capillary gas chromatography (Shimatzu 14 A, OV-1 and Chiraldex G-TA with Flame Ionization Detector). Products were identified *via* GC retention times and GC–MS using authentic reference samples. When authentic samples were unavailable identification was performed *via* ^{1}H NMR spectroscopy.

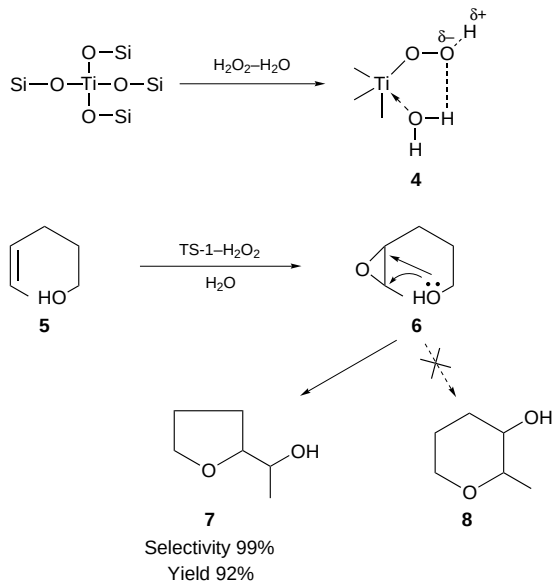
Cyclization of the simplest molecule in this series, but-3-en-1-ol, occurs at room temperature using the TS-1–H_2O_2 system. In butan-2-ol the reaction rate is slow and it takes 18 h to reach a yield of 82%, 3-hydroxytetrahydrofuran **1** being the sole product (Scheme 1). However, in the presence of water as the dispersion medium (solid catalyst, aq. H_2O_2 and organic substrate initially forms three distinct phases) reaction proceeds at a faster rate (93.6% conversion after 6 h). Selectivity towards **1** decreases to 75.5%. In this case oxirane ring opening *via* attack of external H_2O molecules from the medium competes with intramolecular cyclization, leading to dihydroxylation (butane-1,2,4-triol, selectivity 24.5%). Interestingly, increasing the reaction temperature to 333 K in the latter case decreases the yield of **1** to 2.5% with selective dihydroxylation.[14] Unlike the benzenesulfenyl chloride system,[10] the cyclization of but-3-en-1-ol is relatively efficient in the present TS-1–H_2O_2 system. Another important aspect of the TS-1 catalyzed cyclization is that, unlike the radical addition reaction, the products are hydroxy-substituted oxacyclic compounds.

The tetrahydrofuran derivative 2-methyl-4-hydroxytetrahydrofuran **2** (*trans* : *cis* ratio 70 : 30) was formed from (±)-pent-4-en-2-ol in acetone (80% yield at room temperature after 18 h). In water at room temperature, the selectivity for **2** drops to 70%, with a *trans* : *cis* ratio of 67 : 33 after 12 h. At higher temperature in a water dispersion medium the dihydroxylation product predominates in a manner similar to that for but-3-en-1-ol. Interestingly, here also the intermediate epoxide is highly reactive and undergoes very rapid oxirane ring opening *via* either intramolecular cyclization or hydrolysis. However, using butan-2-ol as solvent **2** forms as the sole product in 84% yield (*trans* : *cis* ratio 72 : 28). The high *trans* selectivity among the diastereomers of **2** may be due to the higher stability of the transition state at the active site.

The cyclization of pent-4-en-1-ol occurred regioselectively to the 5-*exo* product tetrahydrofuran-2-methanol **3**. Attack of the hydroxy nucleophile definitely does not take place at the other carbon atom of the intermediate oxirane ring. Irrespective of the reaction medium (butan-2-ol, acetone or water), **3** was exclusively obtained in 98–99% yield. This is interesting, since 2,4,6,6-tetrabromocyclohexa-2,4-dienone-induced[9] cyclization leads to a mixture of tetrahydopyran to tetrahydrofuran in the ratio 3 : 1. In water at high temperature (333 K) no dihydroxylation product is formed. Although theoretical calculations on the transition state energies for the pent-4-en-1-yloxyl radical[11] indicates that the 5-*exo* product is strongly favored, and in the TS-1–H_2O_2 system oxidation is believed to occur *via* titanium hydroperoxo species **4**[15] (Scheme 2) and is thus essentially ionic in nature. Restricted geometry inside the TS-1 channel (MFI topology with intersecting 10-membered rings of 5.3 × 5.6 and 5.1 × 5.5 Å pore diameters and 0.10 $cm^3\ g^{-1}$ internal void volume helps in bending the chain) might play a crucial role in the regioselectivity of the cyclization. The decreasing trend for the ratio of tetrahydropyran to tetrahydrofuran from mesoporous MCM-41 to large pore Beta[13] followed by exclusive formation of tetrahydrofuran rings over medium pore TS-1 supports the above proposition.



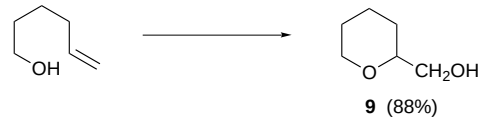
Scheme 1



Scheme 2

One might suggest that the 5-*exo* product formation from **3** could be accounted for by the acidic nature of TS-1; if the reaction follows an S_N1 pathway, the hydroxy group would attack preferentially at the more substituted carbon atom due to the higher stability of the corresponding carbocation. On the contrary, alkyl group substitution at C_5 does not cause any change in the regioselectivity of cyclization as observed for *cis*-hex-4-en-1-ol **5** (Scheme 2). Between the two possibilities for the ring-opening of the intermediate oxirane **6**, the 5-*exo* product, 1-(tetrahydro-2-furyl)ethanol **7**, forms exclusively in 92% yield in acetone at 333 K. The 6-*endo* product, 2-methyl-3-hydroxytetrahydropyran **8**, is not formed. The titanium hydroperoxo species 4 protonates the oxirane **6** and thus activates[13] it for the nucleophilic attack of the hydroxy groups at C_1.

For the cyclization of hex-5-en-1-ol, where two products are possible, tetrahydropyran-2-methanol **9** only is formed in 90% yield in acetone at 333 K (Scheme 3). Interestingly, no intermediate epoxide was detected while studying the kinetics of various constituents of the reaction mixture by GC, indicating that TS-1 catalyzed the present cyclization process at a very fast rate and that ring closure takes place inside the cages of the zeolite immediately after the epoxidation.



Scheme 3

In conclusion, we can say that, in the presence of aq. H_2O_2, TS-1 generates titanium hydroperoxo species **4**, which not only efficiently epoxidizes the double bond of the olefinic alcohols, but catalyzes epoxy ring-opening *via* intramolecular attack of the hydroxy nucleophile leading to oxacyclic ring formation. This reaction not only has enormous potential for the regioselective synthesis of substituted tetrahydrofuran and tetrahydropyran derivatives, but also opens up a new area involving the use of titanium silicates in cyclization reactions.

Hydrogen bonding and cooperativity effects on the assembly of carbohydrates

Manuela López de la Paz, Jesús Jiménez-Barbero and Cristina Vicent*†

Departamento de Química Orgánica Biológica, Institut de Química Orgánica, CSIC, Juan de la Cierva 3, E-28006 Madrid, Spain

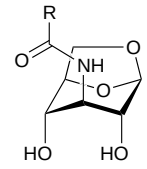
The effect of intramolecular hydrogen bonds on the cooperative assembly of carbohydrate derivatives has been evaluated; the 1,3-diaxial OH··OH intramolecular hydrogen bond is at the origin of the dimerization of diol 1; and one intermolecular OH··OH bond accounts for 2.5 kcal mol^{-1} in $CDCl_3$ and 3 kcal mol^{-1} in $CDCl_3$–CCl_4.

Hydrophobic interactions, hydrogen bonding and cation binding are at the origin of the recognition processes in which carbohydrates are involved. The study of carbohydrate OH··OH hydrogen bond energetics is of fundamental interest for understanding these recognition processes.

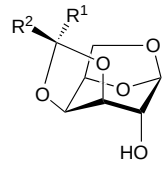
One particular characteristic of hydrogen bonding is cooperativity, considered as the enhancement of the first hydrogen bond (HB) between a donor and an acceptor when a second HB is formed between one of these two species and a third partner.[1] A quantitative treatment of HB cooperativity was described initially by Huyskens.[2] Theoretical[3] and experimental[4] methods have also allowed the quantification of this effect. Evidence of intramolecular σ-cooperativity in carbohydrates has arisen from neutron diffraction data of crystalline structures of mono- and di-saccharides.[5] In solution, intramolecular cooperativity has been studied by NMR spectroscopy in polar solvents[6] and by FTIR.[7] In contrast, evidence of intermolecular cooperativity in carbohydrates has only come from neutron diffraction data of carbohydrates[8] and protein–carbohydrate complexes.[9]

This report represents a contribution within a project to design self-assembled structures based on carbohydrate intermolecular OH··OH hydrogen bonds.[10] Here we have evaluated the energetic advantage of establishing cooperative intermolecular HBs for assembling simple carbohydrates. In addition, we have also studied the relative stereochemistry of OH groups that favour this process.

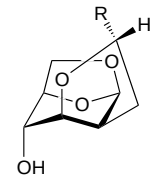
The possibility of self-assembly of diols of 1,6-anhydro-β-D-glycopyranosides of different relative configuration and position with respect to the anomeric centre [2,4 (*a*,*a*) *cis*-diol **1**, 3,4 (*a*,*e*) *cis*-diol **4**, 2,3 (*e*,*a*) *cis*-diol **5** and 3,4 (*e*,*e*) *trans*-diol **6**] has been explored.‡ The only diol that showed significant aggregation behaviour in $CHCl_3$ was the glucose 1,3-diaxial diol **1**.



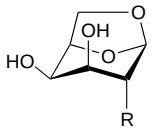
1 R = $C_{15}H_{31}$



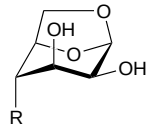
2a R^1 = R^2 = Me
b R^1 = Ph, R^2 = H



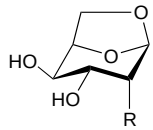
3a R = C_6H_4OMe
b R = Ph



4 R = OAc



5 R = OBn



6 R = OBz

A detailed study of the intramolecular HB network for the monomer of **1** was carried out in dilute $CDCl_3$ solution by ^{1}H NMR spectroscopy. Additionally, the axial monoalcohols, 1,6-anhydro-β-D-glycopyranosides **2a** and **3a**, were used as models to study the influence of a second hydroxy group with a 1,3-diaxial orientation, as present in diol **1**, on intermolecular cooperativity.

Monoalcohols **2a** and **3a** in $CDCl_3$ at low concentration show high $^3J_{CH,OH}$ values (9 Hz), consistent with a fixed conformation of the CHOH angle (larger than 150°), which can be attributed to an hydrogen bonded OH.[6c] For the 1,3-diaxial diol **1**, the OH(2) resonance follows the same trend [as expected for hydrogen bonding to OH(4) or O(5)] but, in contrast, the OH(4) resonance now has a medium size $^3J_{CH,OH}$ value, indicating that it is not hydrogen bonded. Neither of the OH(2) or OH(4) resonances achieve exchange decoupling at any accessible concentration, a characteristic feature of fixed OHs.[6c]

Partial deuteration of **1** in $CDCl_3$ at low concentration shows that the OH(2) resonance has a negative isotopic effect (−0.0165 ppm), consistent with OH(2) being a donor.[6b] Therefore, these results show that both monoalcohols **2a** and **3a** have their hydroxy groups intramolecularly fixed by a HB to O(5). In contrast, for **1** the 1,3-diaxial orientation of both hydroxy groups favour OH(2) to be hydrogen bonded, as a donor, to OH(4). These HBs must affect the self-assembly characteristics of the different compounds.

The characterization of the aggregates in solution was performed using different methods. ^{1}H NMR dilution experiments in $CDCl_3$ at 299 K of **1**–**6** allowed us to calculate the stability constants of the dimerization process.§ Neither of the monoalcohols **2a** or **3a** dimerize.¶ In contrast, diol **1** [2,4(*a*,*a*)] presents a dimerization constant of 70 M^{-1} at 299 K ($\Delta G°$ = −2.5 ± 0.1 kcal mol^{-1}).

Vapour pressure osmometry measurements (VPO)[11] in $CHCl_3$ suggested that, for a concentration range between 0.05–0.01 M, the monoalcohols **2a** and **3a** are monomers. On the other hand, **1** presents a molecular weight which corresponds to 1.6 times that of the monomer. This value is in agreement with the percentage of dimer which is present in solution according to the NMR-derived stability constant (80%).

Chemical shifts, ^3J values and temperature coefficients also indicate that the assembly is mediated by OH··OH hydrogen bonds. Table 1 shows that the coefficients of OH(2) for **2a** and OH(4) for **3a** are not concentration dependent, in contrast with the observations made for **1**.[12] The $^3J_{CH,OH}$ values of **1**–**3** at high concentration indicate their involvement in HBs, with the exception of OH(4) of **1** which shows a *J* value of 5.4 Hz at all concentrations. The NH of **1** does not show any concentration dependence for the NMR parameters. This experimental evidence is consistent with the amide not being involved in the self-association process.‖

The clear difference in the solution self-assembly behaviour of **1** with respect to monoalcohols **2a** and **3a** indicates that the addition of the extra OH in a pyranoid ring having a 1,3-*syn* diaxial orientation accounts for an extra stabilization of the dimer of 2.5 kcal mol^{-1} in $CDCl_3$ compared to the monoalcohols. As a test for a non-intramolecular hydrogen bonded OH, ethanol under the same conditions measured for **1**–**6** did not show any measurable dimerization constant.

Thermodynamic parameters for the dimerization of **1** in $CDCl_3$–CCl_4 (1–1.3) were obtained from a Van't Hoff plot (from 296–318 K). Values of $\Delta H°$ = −6.5 kcal mol^{-1} and $\Delta S°$

	0.05	—	—	—	2.304	9.3	-2.4×10^{-3}

[a] Data at 298 K. [b] Measured between 297 and 313 K.

= +11.8 kcal mol^{-1} K^{-1} were estimated. The stability constant of the dimer at 299 K was 150 M^{-1} ($\Delta G° = -3.0 \pm 0.1$ kcal mol^{-1}). Ethanol under the same conditions showed a dimerization constant of 0.1 M^{-1}.

To quantify the effect of cooperativity on the dimerization process, it is important to know the structure of the dimer. In principle, the structure of the dimer present in solution could be of two types: an open dimer with one cooperative intermolecular HB stabilizing the dimer [Fig. 1(*a*)], and a closed dimer with two intermolecular HBs established in a cyclic and cooperative way [Fig. 1(*b*)]. The implication of O(5) in the network cannot be excluded.

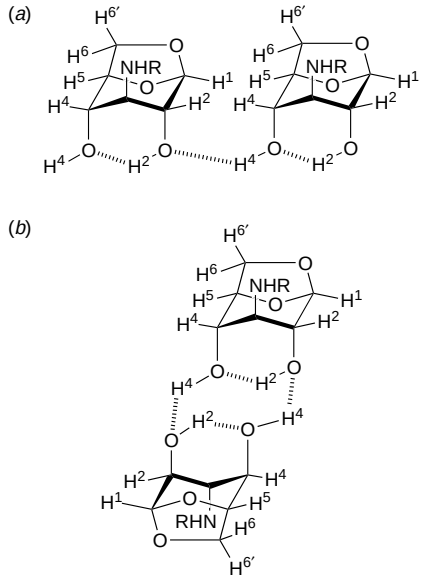

Fig. 1 Schematic representation of two possible dimeric structures for **1**: (*a*) open dimer and (*b*) closed dimer

NOESY experiments of a concentrated solution of **1** (0.1 M) were performed in order to obtain structural information about the dimer. Since two free OH groups are present in the molecule, regular experiments as well as MINSY-type spectra[13] were recorded in order to exclude chemical exchange-mediated cross peaks. Thus, besides the regular NOESY spectrum, additional experiments saturating OH(2) and OH(4) hydroxy groups were recorded. The obtained results unambiguously indicate the presence of intermolecular NOEs. In particular, H(1)/H(6*exo*), H(1)/H(6*endo*), H(1)/H(5), H(2)/H(4), H(5)/H(2) and H(1)/H(4) cross-peaks were detected. These NOEs are not seen when the experiments are carried out at low concentration and are only compatible with the existence of an open dimer structure. This open structure is also supported by the measured $^3J_{CH,OH}$ values. MM2* calculations** of this structure show that it is stable and account for the observed NOEs. This structure shows that the carbonyl group cannot be hydrogen bonded to any donor moiety.

Thus, a single cooperative intermolecular OH··OH bond accounts for 2.5 kcal mol^{-1} in $CDCl_3$ and 3 kcal mol^{-1} in $CDCl_3$–CCl_4.

The difference in the self-assembly behaviour of **1** with respect to diols **4**, **5** and **6** has to be related to the difference in strength and directionality of the intramolecular HBs.[7c,14]

We are now extending this study to diols involving other positions in the pyranoid ring in order to evaluate the energetic advantage of intermolecular HB cooperativity.

Financial support by DGICYT (Grant PB96-0833) is gratefully acknowledged. M. L. P. thanks Comunidad de Madrid for a fellowship. C. V. thanks Dr Soledad Penadés for introducing her to the field of carbohydrate recognition. We thank Dr Jose García de la Campa for helpful discussions.

Notes and References

† E-mail: cristina@csic.es

‡ All new compounds gave satisfactory elemental analyses and spectroscopic data. ^3J analysis shows that all compounds adopt a chair conformation in $CDCl_3$ solution.

§ All dilution experiments were carried out three times and the $\Delta G°$ values were reproducible within ±0.1 kcal mol^{-1}. Dilution data were fitted to a dimerization process using an infinite non-cooperative model. We thank Dr C. A. Hunter (University of Sheffield) for kindly providing the fitting program.

¶ Diols **4** and **5** showed small dimerization constants (1.8 and 1.4 M^{-1}, respectively).

‖ Additionally, a concentration dependent FTIR experiment shows no evidence for intermolecular hydrogen bonded species involving the NH or C=O of the amide (ν_{NH} 4335 and ν_{CO} 1772 cm^{-1} at high and low concentration).

** Molecular Mechanics Calculations were carried out using MM2* with the GB/SA solvent model for $CHCl_3$.

Anion coordination by aminoglycosides: structural and charge effects

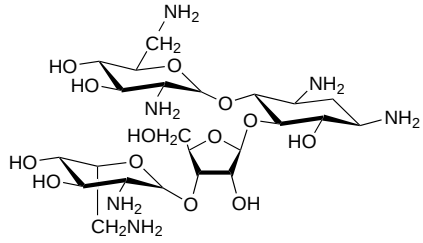
Tsuyoshi Ohyama, Dongqing Wang and James A. Cowan*†

Evans Laboratory of Chemistry, The Ohio State University, 100 West 18th Avenue, Columbus, Ohio 43210, USA

Aminoglycosides provide new approaches to the recognition and specific binding of anionic species, and show promise for development as anion sensors in biological and separation science.

Aminoglycoside antibiotics constitute a large family of molecules that find extensive clinical use in the treatment of gram-negative infections.[1] Recent reports have also demonstrated specific and high affinity (μM) binding of aminoglycosides to RNA structural motifs.[2–6] Aminoglycoside complexes of metal ions have previously been reported,[7–10] however, the large positive charge density of the drug in neutral solution suggested to us that such molecules might prove to be efficient anion complexing agents. This work contrasts with earlier studies of anion binding that have focused on polyamine macrocycles including hexaaza ligands and porphyrin derivatives,[11–14] Novel advances in this chemistry should afford significant opportunities for the development of anion sensors,[15–17] and in separation science.[18–20] Here, we communicate our initial findings on the coordination chemistry of neomycin B **1** with a variety of negatively charged species. Binding thermodynamics have been evaluated by isothermal titration calorimetry (Fig. 1), and structural insight obtained by ^{1}H, ^{13}C, ^{15}N and ^{31}P NMR spectroscopy.‡ These studies complement recent work on ferrocenyl receptors of anions.[16] In contrast to the classic inner-sphere coordination chemistry of metal ions, anion binding more typically involves outer-sphere binding of multi-atomic species; although outer-sphere interactions of cationic complexes are also well established in biological chemistry.[21–24]

Neomycin B, **1**, possesses six ionizable amino functional groups, with pK_as > 6.5, and it was expected that such a highly charged molecule might complex anionic species with moderate to high affinity. Fig. 1 establishes this fact with K_a varying from 332 dm^3 mol^{-1} for CrO_4^{2-} to 1.3 × 10^5 dm^3 mol^{-1} for



1

$Fe(CN)_6^{4-}$. The coordination chemistry of neomycin B has been explored with two classes of anionic species, differing in their distribution of charge density and described as spherical [$Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$, $Cr(C_2O_4)_3^{3-}$, CrO_4^{2-}], where the charge is confined in a spherical array, and linear [AMPH$^-$, ADPH^{2-}, ATPH^{3-}, and adenosine tetraphosphate (AtetraPH^{4-})], where the charge is spread along a chain of atoms. Distinct thermodynamic data (Fig. 1) were obtained for the spherical and linear charged species. Also the binding affinity is found to increase with increasing charge on both the aminoglycoside and bound anion, although different factors control the experimental K_as for each class of anion. The linear adenosine phosphate series demonstrates an approximately constant binding enthalpy [ΔH *ca.* −6.6 kcal mol^{-1} (1 cal = 4.184 J), Fig. 1], with the charge dependence of the binding affinity arising through variation of the entropy term, presumably as a result of more extensive disruption of the solvation state for the longer phosphate chain. In contrast, the spherical charged species show a marked variation for both the entropy and enthalpy terms; although for both spherical and linear charged species the magnitude of the ΔH term demonstrates that binding is enthalpically controlled. This contrasts with binding to oligo- or poly-nucleotides where ligand binding is typically entropically driven.

Our attention was drawn to the mode of binding of the anions to the aminoglycosides. None of the anion–aminoglycoside complexes demonstrate the direct inner-sphere binding mode typical of classical metal ion coordination to a basic ligand. Rather, outer-sphere binding must be mediated either through hydrogen bonding and/or electrostatic interactions. The similarity in binding affinity for ATPH^{3-}, $Fe(CN)_6^{3-}$ and $Cr(C_2O_4)_3^{3-}$, and their very different hydrogen-bond accepting abilities (decreasing across the series), suggest the dominance of electrostatic attraction in defining K_a. Further support for this conclusion came from the salt dependence of K_a. In the Debye concentration range, the linear dependence of ln K_a with [NaCl]$^{1/2}$, where NaCl is the background electrolyte, is consistent with outer-sphere complex formation and long-range electrostatic interactions.[25] Plots of ln K_a *vs.* [NaCl]$^{1/2}$ for $Fe(CN)_6^{4-}$, ATPH^{3-} and CrO_4^{2-} binding to neomycin B were fitted to the equation, $\ln K_a = \ln\{(4\pi N_L a^3)/3000\} + b - ab\{(2Z^2e^2)/(\varepsilon\varepsilon_0 kT)\}^{1/2}[\mathrm{NaCl}]^{1/2}$, where symbols are defined in ref. 25. In each case linearity was maintained in the Debye range, and gradients of −5.7, −11.9 and −9.4, were obtained, respectively.

Structural aspects of anion binding to neomycin B have been evaluated by heteronuclear 1D and 2D NMR methods.

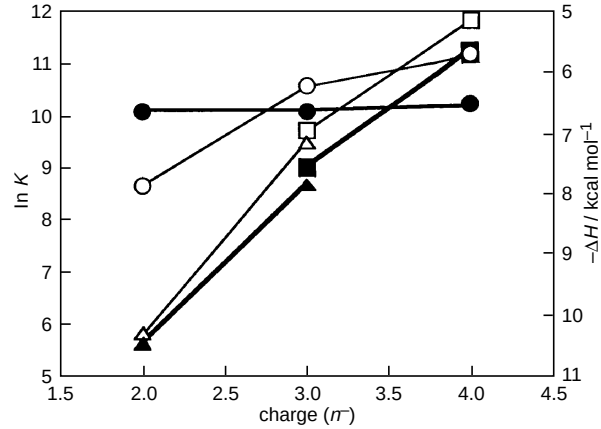


Fig. 1 Variation of thermodynamic binding parameters with the total charge of the anionic species (*n*). ADPH^{2-}, ATPH^{3-}, AtetraPH^{4-} (circles); $Fe(CN)_6^{3-/4-}$ (squares); CrO_4^{2-}, $Cr(C_2O_4)_3^{3-}$ (triangles), where open and closed symbols refer to ln *K* and ΔH data, respectively. Data were collected on a Microcal OMEGA isothermal titration calorimeter at pH 5.5 in 10 mM sodium acetate. No evidence for irreversible or covalent interactions was noted with these complexation reactions. Errors are within the radius of the symbols.

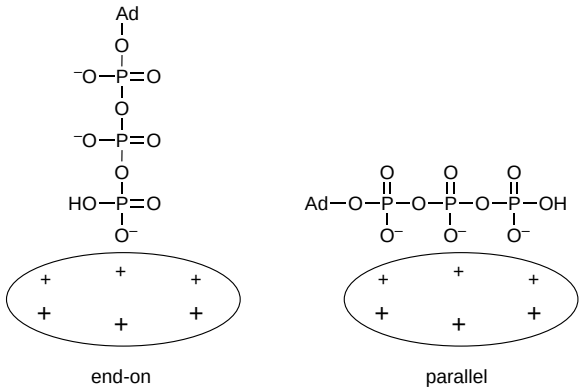
Assignments for ^{1}H, ^{13}C and ^{15}N resonances of neomycin have been previously reported.[26,27] Neither ^{1}H, ^{13}C, nor ^{15}N resonances or crosspeaks in 1D or 2D NMR experiments, respectively, demonstrated a significant change after binding of any of the anionic species to neomycin B, and so complex formation does not involve significant structural perturbation of the sugar rings. Fast exchange is indicated by the occurrence of only sharp exchange-averaged resonances for bound and free forms. ^{31}P NMR spectra of $ADPH^{2-}$, $ATPH^{3-}$ and $AtetraPH^{4-}$ show significant changes in the shift value of only the terminal phosphate upon binding to neomycin B. Also double protonation of the terminal phosphate at ATP at reduced pH (= 5) resulted in loss of binding, even though the overall charges of $ADPH^{2-}$ and $ATPH_2^{2-}$ are identical. These results support an end-on binding mode rather than a parallel mode (below). Such a hypothesis is also consistent with the approximately constant ΔH for binding of the adenosine phosphates (Fig. 1) to neomycin B, since only the terminal phosphate serves as an hydrogen-bond acceptor.



In conclusion, aminoglycosides have been shown to bind a variety of negatively charged species with moderate to high affinities, and structural differentiation of charge arrays (spherical and linear) has been demonstrated. The critical need for such molecules as biological sensors[10,17] and in separation science,[18–20] will fuel further efforts in our laboratory.

‡ ^{1}H, ^{13}C, ^{31}P and ^{15}N NMR spectra were recorded on a Bruker 300 MHz spectrometer. ^{15}N measurements were made in 10 mm sample tubes with 200 mM solutions of neomycin. Other experiments were performed in 5 mm tubes with 100 mM neomycin solutions. A 200 mM sodium acetate buffer solution (pH 5) was used with 10% D_2O for spin lock. Buffer concentrations were higher than for calorimetry experiments to accommodate the increased neomycin concentration. 2D C–H correlation spectra were recorded with a phase-sensitive DEPT polarization transfer pulse sequence.

Highly dissymmetric chelate coordination of 3,4,7,8-tetramethyl-1,10-phenanthroline to Cu^{I}(SR)

Andreas F. Stange, Torsten Sixt and Wolfgang Kaim*

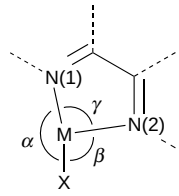
Institut für Anorganische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70550 Stuttgart, Germany

Not only Au^{I} and Hg^{II} species but also Cu^{I}(SR) fragments can bind in a highly dissymmetrical fashion to symmetrical diimine chelate ligands; the 2 + 1 coordination arrangement observed for the metal in two complexes (tmphen)Cu(SR) (tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline) is characterised by obtuse angles *α*[N(1)–Cu–S] > 159° and by two very different distances Cu–N(1) and Cu–N(2).

The copper(I) state is characterised by the lack of a clear preference for specific coordination numbers (CN) or coordination geometries, the most common arrangements being close to tetrahedral (CN 4) or trigonal planar (CN 3).[1,2] Higher and lower coordination numbers, in particular CN 2, have also been documented.[2]

In probing copper–thiolate–N-chelate ligand chemistry to mimic the Cu_A dinuclear electron transfer center of enzymes[3] we reacted the α-diimine ligand 3,4,7,8-tetramethyl-1,10-phenanthroline (tmphen)[4] with electrolytically[5] obtained 2,4,6-trimethyl- and 2,6-diphenyl-thiophenolatocopper(I), Cu(SMes) and Cu(SDpp). The result† was not a di- or tetra-nuclear arrangement[3c,d] but mononuclear copper(I) complexes which could be crystallised for structural characterisation (Figs. 1 and 2).‡

Copper(I) does not normally display the same strong preference for a coordination number of two with linear coordination geometry as do gold(I) or mercury(II) centres, yet the list in Table 1 illustrates that the complexes (tmphen)Cu(SR) exhibit unusually distorted geometries as evident from very obtuse angles α and large differences between the distances Cu–N(1) and Cu–N(2), despite the formal equivalence of both nitrogen donor sites and the symmetry of the aryl groups, R (Table 1).



Gold(I) or mercury(II) centres which strongly prefer the linear geometry can be forced to accept a third donor atom *via* chelate coordination. Structurally characterised examples related to the neutral species (tmphen)Cu(SR) include the ionic systems [(bpy)Au(PPh_3)]PF_6[6a] and [(bpy)HgMe]NO_3 (Table 1; bpy = 2,2′-bipyridine).[6b] Ligands, especially thiolates, with steric bulk may cause a similar distortion from the trigonal geometry of d^{10} metal centres as has been realized in the T-shaped $(Et_2O)Zn^{II}(SC_6H_2Bu^t_3\text{-}2,4,6)_2$[7b] and, in attenuated form, with the compound (phen)Cu[$SSi(OBu^t)_3$] (phen = 1,10-phenanthroline).[7b]

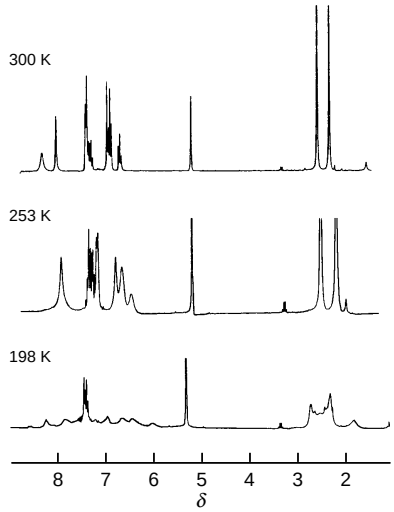

Fig. 3 Temperature-dependent ^{1}H NMR spectra of (tmphen)Cu(SDpp) in CD_2Cl_2 (300, 253 and 198 K, from top to bottom; 250 MHz)

The unsymmetrical coordination of the chelate ligand to the Cu^I center as observed in the solid state is probably responsible for the selective broadening in the ^{1}H NMR spectrum of (tmphen)Cu(SDpp) (Fig. 3).

These observations suggest a low but non-negligible barrier for the 'movement' of Cu between two equivalent energy minimum sites, separated by *ca*. 0.28 Å. No intermolecular interactions were recognised in the crystal structures which can be made responsible for this unusual copper(I)–thiolate[3c,d,8] coordination arrangement. To rationalise the observed dissymmetry we thus invoke the strong σ and π donor effect of thiolate groups SR and the donor substitution of the α-diimine tmphen.[4] There appears to be no need then for full coordination of a third donor atom to the electron-rich copper(I) centres, leaving the inevitably close second nitrogen atom N(2) of the chelate ligand as a lesser coordinated donor centre to result in the observed coordination number 2 + 1.

† *Synthesis*: Arylcopper(I) precursors were obtained by electrolysing[5] solutions of the thiophenols[9,10] in acetonitrile–2 mmol dm^{-3} NBu_4ClO_4 in a cell containing a copper anode.

(2,4,6-Trimethylthiophenolato)(3,4,7,8-tetramethyl-1,10-phenanthroline)copper(I) was prepared by adding 250 mg (1.18 mmol) of the thiolatocopper precursor to a suspension of 278 mg (1.18 mmol) tmphen in 20 ml toluene. After reflux for 2.5 h the clear brownish solution was filtered hot, cooling produced 352 mg (62%) of (tmphen)Cu(SMes)·C_7H_8. Single crystals suitable for X-ray diffraction were obtained from acetone as (tmphen)Cu(SMes)·0.5C_3H_6O (correct C, H, N elemental analysis). ^{1}H NMR (CD_2Cl_2, 300 K): δ 2.16 (s, 6 H, Mes-4-CH_3), 2.41 (s, 24 H, tmphen-3,8-CH_3 and Mes-2,5-CH_3), 2.65 (s, 6 H, tmphen-4,7-CH_3), 6.66 (s, 4 H, Mes-3,5-H), 8.03 (s, 4 H, tmphen-5,6-H), 8.34 (s, 4 H, tmphen-2,9-H).

(2,6-Diphenylthiophenolato)(3,4,7,8-tetramethyl-1,10-phenanthroline)copper(I) was prepared by adding 120 mg (0.37 mmol) of the thiolatocopper precursor to a solution of 87 mg (0.37 mmol) tmphen in 25 ml toluene. After reflux for 1 h the clear brownish solution was filtered hot, and careful cooling produced 50 mg (24%) of the compound, partially as single crystals suitable for X-ray diffraction. Correct elemental analysis (C, H, N). ^{1}H NMR (CD_2Cl_2, 300 K): δ 2.45 (s, 6 H, 3,8-CH_3), 2.70 (s, 6 H, 4,7-CH_3), 6.79 (t, *J* 7.4 Hz, 2 H, aryl-H), 6.96–7.05 (m, 5 H, aryl-H), 7.35–7.50 (m, 6 H, aryl-H), 8.11 (s, 2 H, 5,6-H), 8.40 (br s, 2 H, 2,9-H). Selective broadening of the resonances was observed upon cooling to 198 K (Fig. 3).

‡ *Crystallography*: (tmphen)Cu(SMes)·0.5C_3H_6O: $C_{25}H_{27}CuN_2S$·0.5C_3H_6O, M = 480.16, crystal size 0.4 × 0.4 × 0.4 mm, monoclinic, space group $P2_1/n$ (no. 14), a = 8.1319(7), b = 14.8164(12), c = 19.6605(12) Å, β = 98.388(8)°, U = 2343.5(3) Å^3, D_c = 1.351 g cm^{-3}, μ(Mo-Kα) = 1.039 mm^{-1}, F(000) = 994, Wyckoff scans, 6561 measured reflections, 6156 independent reflections, 5830 reflections used for refinement, Lorentz polarisation, R = 0.0501 for 4244 reflections with $I > 2\sigma(I)$; 183 K, Siemens P4 diffractometer with graphite monochromator and Mo-Kα radiation (λ = 0.710 73 Å). The structure was solved by direct methods (Siemens SHELXTL-PC) and refined (SHELXL-93) by full-matrix least squares on F^2 (362 parameters). One half equivalent of a solvent molecule had to be included. Hydrogen atoms were introduced at calculated positions and refined freely; (tmphen)Cu(SDpp): $C_{34}H_{29}CuN_2S$, M = 561.19, crystal dimensions 0.4 × 0.4 × 0.3 mm, monoclinic, space group $P2_1/n$ (no. 14), a = 11.949(2), b = 13.284(2), c = 17.636(2) Å, β = 104.56(1)°, U = 2709.5(6) Å^3, D_c = 1.376 g cm^{-3}, μ(Mo-Kα) = 0.909 mm^{-1}, F(000) = 1168, Wyckoff scans, 6188 measured reflections, 5971 independent reflections, 5499 reflections used for refinement, Lorentz polarisation, R = 0.0687 for 3490 reflections with $I > 2\sigma(I)$; 183 K, Siemens P4 diffractometer with graphite monochromator and Mo-Kα radiation (λ = 0.710 73 Å). The structure was solved by direct methods (Siemens SHELXTL-PC) and refined (SHELXL-93) by full-matrix least squares on F^2 (430 parameters). Hydrogen atoms were introduced at calculated positions and refined freely. CCDC 182/737.

Enzyme assay using ultra-low volume surface micromachined sensors

Craig D. T. Bratten,[a,b] Peter H. Cobbold[b] and Jonathan M. Cooper*[a]

[a] *Bioelectronics Group, Department of Electronics and Electrical Engineering, University of Glasgow, UK G12 8QQ*
[b] *Department of Human Anatomy and Cell Biology, University of Liverpool, Liverpool, UK L69 3BX*

We demonstrate an amperometric enzyme-linked assay within an ultra-low volume (600 pl) micromachined device for the rapid determination of (hypo)xanthine *via* a catalytically generated hydrogen peroxide intermediate, thereby illustrating the potential of this technology in a variety of bioanalytical measurements involving the oxidases.

Techniques used in planar microfabrication have shown considerable promise in analytical biotechnology by enabling miniaturised metallic sensing electrodes to be made routinely, with precise control over their two-dimensional geometry.[1–5] More recently, however, micromachining has provided a complementary technology (to microfabrication), allowing for a greater degree of flexibility in structural design, by defining the geometry of a device in all three dimensions.

In general, the analytical benefits of miniaturisation of such devices become apparent through the scaling laws (which dictate that, for example, within a diffusion limited system, as the dimension of the structure is reduced, so transport of analyte becomes more efficient, with an improvement in both response times and signal to noise).[5,6] As a consequence, within the last two years, the potential for performing biological analyses within micromachined structures has been demonstrated, including examples of novel device configurations, capable of electrophoretic separation of high molecular mass analytes,[6] 'on-chip' PCR[7] and electrophoretic manipulations of cells.[8]

Many of the devices which have been machined have been generated by the annealing of glasses and/or silicon to form three-dimensional channels and chambers.[6–8] However, there are still technical problems in introducing functional sensors or actuators within a micromachined volume. For example, although Clark *et al.*,[9] have embossed very low volume polystyrene vials for electrochemical analysis, the electrodes must be introduced into the device as 'probes' from above. Recently, in order to overcome this problem, we described the use of a photoactive polyimide (Probimide 7020), which can be used in combination with two-dimensional (planar) microfabrication procedures to produce low volume (sub-nl) titre chambers with integrated electrochemical microelectrodes. We have previously characterised these devices by investigating the electrochemistry of the inorganic redox mediator, ferrocene monocarboxylic acid.[10]

The method by which we fabricated this surface micromachined device was adapted from procedures which have previously been described,[10] and involved using photolithography, metal evaporation and lift-off to produce a planar two-electrode array, consisting of gold micro-ring electrodes, adhered on a glass slide using a Ti/Pd underlayer (Ti/Pd/Au 10 : 10 : 100 nm). Importantly, in order to prevent subsequent fouling of the gold electrochemical surface during microchamber processing, the gold was coated with a 10 nm sacrificial layer of NiCr (60% : 40%, also known as 'nichrome'). The volume above the microelectrode (600 pl) was defined by photopolymerisation of the light sensitive polyimide (λ = 436 nm) through an appropriate chrome on quartz mask, followed by exposure to the OCG™ developer. The diameter of the chamber was 200 μm, and the depth of the chamber, as defined by the thickness of the polymer was 20 μm.[10]

After producing the chamber, residual polyimide was removed from the electrochemical surface by wet etching the 'sacrificial' nichrome in 0.6 M acetic acid and 0.37 M ammonium cerium(IV) nitrate, followed by ultrasonication (undercutting the polymer, and thus freeing it from the metal). Fig. 1(*a*) shows the electroanalytical device, coated with the nichrome layer and the contaminating polymer, prior to the wet etching process. Subsequently, Fig. 1(*b*) and (*c*) show the sequential 'cleaning' of the gold by nichrome etching, leaving the electrochemical surface available for further functionalisation (see below).

In order to produce a stable electrochemical surface, platinum was electrodeposited galvanostatically onto both the working and counter gold electrodes from a solution containing 24 mM platinum(IV) chloride and 2.1 mM lead acetate, maintaining a constant current of 1 μA for 1 min.[11,12] Bioelectrochemical measurements were made in a two-electrode configuration, with an outer (larger) micro-ring (inner diameter 120 μm, width 20 μm) acting as the platinum pseudo-reference counter (+270 mV *vs.* Ag/AgCl), and a smaller inner ring electrode (inner diameter 100 μm, width 10 μm) as the (platinum coated) working electrode, see Fig. 1(*a*). The ratio of the respective geometric areas of the counter and the working electrode was > 2 : 1.

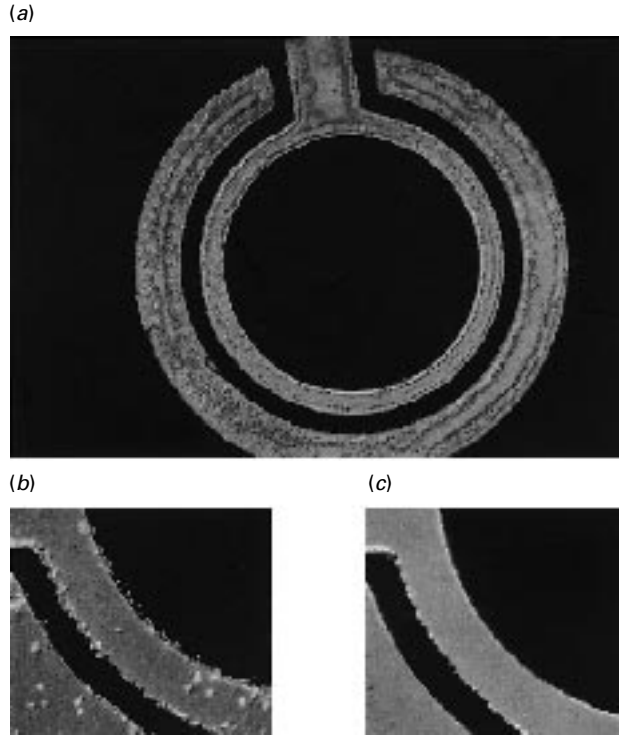

Fig. 1 A method for producing polyimide free electrodes, within the μ-electrochemical chamber: (*a*, above) shows the nichrome layer (with contaminating polymer); (*b*, below, left) and (*c*, below, right) show the sequential etching of the 'sacrificial' nichrome to remove the polymer residue. The opaque polymer surrounding the microelectrode is the photocured polyimide, which defines the three dimensional structure.

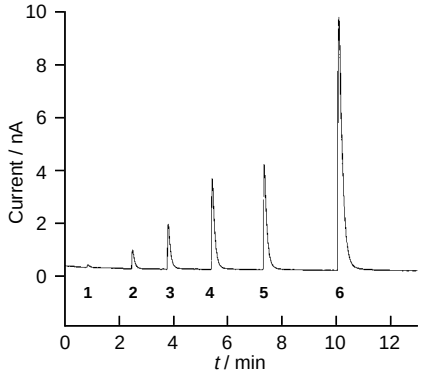

Fig. 2 *i–t* responses for successive additions of 8 pl buffer (1) and subsequently 1 pl (2), 8 pl (3), 30 pl (4), 66 pl (5) and 220 pl (7) of hydrogen peroxide to 600 pl μ-electroanalytical chamber containing a platinised micro-ring working electrode (geometric area = 3.3×10^3 μm²), poised at a potential equivalent to +420 mV *vs.* Ag/AgCl

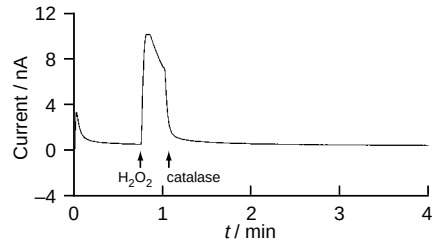

Fig. 3 Corroborative evidence that the responses in Fig. 2 are due to the electro-oxidation of hydrogen peroxide, shown by the addition of 2.5 nmol of catalase (equivalent to 25 units of enzyme), thereby acting as an effective catalytic scavenger. Responses were measured at a potential equivalent to +420 mV *vs.* Ag/AgCl.

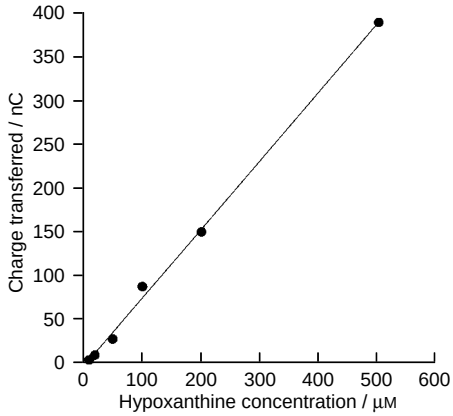

Fig. 4 Calibration curve for hypoxanthine in the concentration range between 10 μM (60 fmol) and 500 μM (3 pmol), (r = 0.99). Substrate additions were made to stock solutions of Ringers buffer containing 1.75×10^{-5} units of XOD in a volume of 600 pl.

In the first instance, hydrogen peroxide was ultramicropipetted into the μ-electroanalytical chamber through a layer of mineral oil (to prevent solvent evaporation),[10] and *i–t* measurements were made using a BAS CV 37 potentiostat (Bioanalytical Systems, UK) at a potential equivalent to +420 mV *vs.* Ag/AgCl.[11,12] Responses to successive additions of hydrogen peroxide are shown in Fig. 2, which are very fast, owing to the short electrode diffusion lengths. Measurements were integrated, as the total oxidation charge for hydrogen peroxide, giving a linear calibration curve over a range of analyte concentrations between 8.3 μM (5 fmol) and 1.83 mM (1.10 pmol), *i.e.* $y = 0.1\,x + 6.1$ nC (r = 0.99, n = 3). That the observed signals were generated by the electro-oxidation of hydrogen peroxide was corroborated by the addition of catalase during one such experiment (Fig. 3), which scavenged the analyte efficiently, as expected.

In order to further demonstrate the potential application of this device to bioanalytical measurements, a series of experiments involving the measurement of hypoxanthine were performed, using the oxidase enzyme, xanthine oxidase (XOD). The quantification of hypoxanthine is of interest in biomedicine, not least as it is produced during purine catabolism, and therefore has relevance in assessing the nucleotide pool in tissue. In the XOD catalysed reaction, under study here, two hydrogen peroxide equivalents are generated as a consequence of the oxidation of hypoxanthine, Eqn. (1) and (2), and these are subsequently measured through their electrochemical oxidation at the working electrode, according to Eqn. (3).

$$\text{Hypoxanthine} \xrightarrow[\text{XOD, pH 7.4}]{} \text{Xanthine} + H_2O_2 \quad (1)$$

$$\text{Xanthine} \xrightarrow[\text{XOD, pH 7.4}]{} \text{Uric acid} + H_2O_2 \quad (2)$$

$$H_2O_2 \xrightarrow[+420\text{ mV } \textit{vs.}\text{ Ag/AgCl}]{} O_2 + 2H^+ + 2e^- \quad (3)$$

The calibration curve for the electrochemical measurement of hypoxanthine is shown in Fig. 4. Measurements are the integral of the total (*i–t*) response, as before, after the addition of substrate within the range 10 μM (60 fmol) to 500 μM (3 pmol), $y = 0.79\,x - 5.04$ nC (n = 1, r = 0.99).

Although in both cases (for the generalised measurement of H_2O_2 and for the specific measurement of hypoxanthine) the responses do not correspond exactly to theoretical values, calculated on the assumption that all analyte is consumed, the results do demonstrate the general principle of bio-electrochemical detection within a confined ultra-low volume.

At present, routine *in situ* single cell measurements are limited to determinations of ions and ATP. The technique that we have developed has potential implications for the rapid, low volume detection of a wide range of new analytes, *e.g.* for determinations from single cells using oxidase enzymes to catalytically generate an electroactive coproduct, including glucose (*cf.* glucose oxidase) or lactate (*cf.* lactate oxidase).

The authors wish to thank the Wellcome Trust and Glaxo-Wellcome for their support.

Self-assembling chiral monolayers of helical peptides bound to gold *via* side-chain thioethers

Andrew E. Strong and Barry D. Moore*

Department of Pure and Applied Chemistry, University of Strathclyde, Thomas Graham Building, 295 Cathedral Street, Glasgow, UK G1 1XL

A helical oligopeptide containing three methionine residues, positioned so their side-chains align along one side of the helix, forms self-assembled monolayers on gold as characterised by cyclic voltammetry and reflection–absorption IR spectroscopy.

Self-assembling monolayers (SAMs) of sulfur-containing molecules on gold are attractive systems for tailoring surface properties and the study of interfacial phenomena.[1] Our aim is to develop this technology so that ordered surfaces can be prepared featuring different functional groups positioned at relative predetermined positions on the nanometer scale. To this end we are investigating the formation and structure of self-assembling monolayers of helical oligopeptides. A few examples of self-assembled monolayers of peptides have recently appeared.[2,3] In all of these cases the peptides had only one strong attachment point to the gold surface, either through the side-chain of an N-terminal Cys residue[2] or *via* a thioalkyl carboxylic acid coupled to the N-terminal.[3] In order to obtain a defined alignment parallel to the surface we investigated binding a helical peptide to gold *via* multiple weaker interactions arising from methionine (Met) thioether side-chains. Peptides bound in this way provide maximum scope for organisation of other amino acids at the outer face to produce functionalised chiral surfaces.

Peptide **1**, Fcb-Ala-Aib-Ala-Met-Aib-Ala-Ala-Met-Ala-Aib-Met-Ala-Ala-NH_2, was designed so that in an α-helical conformation the thioether-containing side-chains of the three Met residues would align along the same side of the helix, able to bind to a gold surface. The remaining amino acids used, Ala and Aib (α-aminoisobutyric acid), are known strong helix formers in organic solvents[4] and have small methyl side-chains to minimise unfavourable steric interactions with the surface. The N-terminus was acylated with ferrocene butyric acid (Fcb) to provide a convenient electrochemical label. Peptide **2**, Fcp-Ala-Aib-Ala-Ala-Leu-Aib-Ala-Ala-Ala-Aib-Leu-Ala-NH_2, available from previous studies provided a convenient, non-sulfur-containing control of similar length, composition and secondary structure to **1**.

The peptides were prepared by conventional solid-phase peptide synthesis on a modified Rink-type resin using Fmoc chemistry and PyBOP® coupling protocols.† N-Acylation with the ferrocene carboxylic acids was carried out on the resin. Analysis of the cleaved precipitated products by reversed-phase HPLC and electrospray mass spectrometry‡ showed that in each case they were > 90% the desired peptide. Attempts to further purify peptide **1** invariably led instead to introduction of other impurities due to autooxidation of the methionine groups and hence the peptide was used freshly cleaved.

The CD spectra of peptide **1** in methanol and acetonitrile are shown in Fig. 1. The double minima at 208 and 222 nm are characteristic of a predominantly α-helical structure.[5] Analysis of the spectra[6] indicated that **1** was > 65% α-helical in methanol and 50% α-helical in acetonitrile. Other contributions can be assigned to 3_{10}-helix or random coil caused by fraying of the helix ends. Formation of the observed α-helix preorganises the three thioether side-chains to favour multipoint binding to a metal surface.

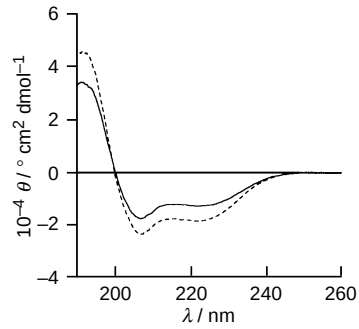

Fig. 1 CD spectra of oligopeptide **1** in MeCN (continuous line) and in MeOH (dashed line) at room temperature

Cyclic voltammetry was used as a convenient tool for monitoring the formation and relative stability of self-assembled monolayers of sulfur-containing peptide **1** compared to sulfur-free **2**. Ethanolic solutions of each peptide (*ca*. 1 mM) were contacted with a polished gold disk electrode for 20–26 h.§ Following rinsing with pure solvent, cyclic voltammograms were measured in ethanol (Fig. 2). Peaks characteristic of reversible electrochemistry of the covalently attached ferrocene were observed for both peptides. However the wave for peptide **2** was typically < 15% of peptide **1**.¶ Monolayers formed by peptide **1** were found to be remarkably stable to repetitive cycling. In fact, cycling appeared to condition the film so that the background current and peak to peak separation reduced while the Faradaic current remained constant [Fig. 2(*a*)]. In contrast the wave associated with the monolayer of peptide **2**

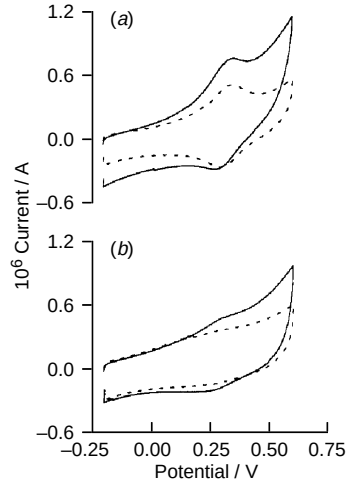

Fig. 2 (*a*) Cyclic voltammograms of films of peptide **1** adsorbed at a gold electrode, continuous line: recorded on immersion, dashed line: after sweeping for 30 min. (*b*) As above but for peptide **2**. The CVs were recorded at 0.5 V s^{-1} in 10 mM $NBu^n_4BF_4$ in EtOH *vs*. Ag/AgCl.

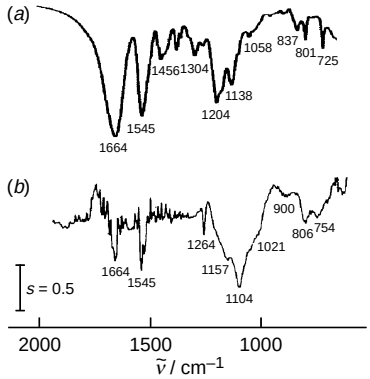

Fig. 3 IR spectra of oligopeptide **1**. (*a*) KBr spectrum and (*b*) reflection–absorption spectrum of the self-assembled film [scale bar applies to (*b*) only]

rapidly decreased during cycling under the same conditions [Fig. 2(*b*)]. The high stability of monolayers of **1** in ethanol, where hydrophobic interactions are absent, is consistent with the proposed mode of self-assembly *via* binding of the thioether side-chains to the gold surface.

The conformation and orientation of the adsorbed peptides were investigated by reflection–absorption IR spectroscopy (RAIRS).‖ The spectra of peptide **1** in a KBr pellet and self-assembled at gold** are shown in Fig. 3. The main indication of peptide secondary structure is the frequency of the amide I band (1600–1700 cm^{-1}).[7] Bands at 1620–1640 and above 1680 indicate β-structures while those at 1650–1658 are typical of α-helices. Interestingly the amide I band of peptide **1** appears at 1664 cm^{-1} close to that previously observed for 3_{10}-helices of Aib-containing peptides.[8]

The RAIRS technique also allows the orientation of the peptides at the surface to be inferred using the surface selection rule, because only vibrations with a component normal to the surface are enhanced.[9] The main component of the amide I band is stretching of the carbonyl groups and in a helical peptide these will be aligned along the helix axis. The main contributions to the amide II and III bands are in-plane bending of N–H and C=O, and C–C and C–N stretching.[10] For each of these vibrations the transition dipole moment subtends a range of angles to the helical axis. In the self-assembled peptide monolayers, binding *via* the methionine side-chains is expected to align the helical axis parallel to surface. This is expected to lead to a dramatic reduction in the intensity of the RAIRS amide I band relative to the amide II and III bands, as compared to the powder spectra. It can be seen in Fig. 3 that this is exactly what is found. The amide I band at 1664 cm^{-1} is significantly weaker in the reflectance spectra relative to the respective amide II and III bands at 1545 and 1264 cm^{-1}. RAIRS of peptide **2**, which lacks the thioether groups, showed weak bands consistent with a helical conformation at 1660, 1540 and 1300 cm^{-1} in the reflectance spectra. However their relative ratios were similar to those in the powder spectrum suggesting no particular orientation of the peptide at the surface.

We have shown peptide **1** adopts a helical secondary structure resulting in preorganisation of three surface binding thioether groups along one side of the helix. The peptide forms stable monolayers on gold with the helix aligned parallel to the surface. Future work will involve introduction of other amino acids into the sequence to produce functionalised chiral surfaces.

We thank EPSRC, Sharon Kelly and the BBSRC CD facility at Stirling University, Ras Raval and Elaine Cooper at University of Liverpool and Novabiochem.

† The oligopeptides were synthesised using a Novasyn Crystal solid-phase peptide synthesiser, Novasyn PR500 resin, Fmoc protected amino acids and PyBOP coupling chemistry. Each residue was double coupled using a threefold excess (for **1**) or a twofold excess (for **2**) of amino acid. Cleavage was with 10% TFA in CH_2Cl_2 for 2 × 45 min.

‡ Analytical HPLC was *via* reversed-phase HPLC on a C_8 column using an MeOH–H_2O gradient. ESMS data: peptide **1**, *m/z* 1417.6, found at *m/z* 1418.4 ($M + H^+$), 1400.7 ($M + H^+ - NH_3$), 740.9 ($M + Na^+ + K^+$), 732.6 ($M + 2Na^+$), 700.9 ($M + 2H^+ - NH_3$), 665.4 ($M + 2H^+ - Ala - NH_3$). Peptide **2**, *m/z* 1236.3, found at *m/z* 1274.8 ($M + K^+$), 1258.8 ($M + Na^+$), 1236.8 ($M + H^+$), 1219.8 ($M + H^+ - NH_3$), 638.1 ($M + K^+ + H^+$), 629.9 ($M + Na^+ + H^+$), 619.1 ($M + 2H^+$), 610.3 ($M + 2H^+ - NH_3$), 585.6 ($M + 2H^+ - Ala$).

§ The gold disk electrode (2 mm in diameter, purchased from Oxford Electrodes) was manually polished with alumina paste, rinsed with H_2O and immersed in 4 : 3 : 1 H_2O–conc. HCl–conc. HNO_3 for 60 s, rinsed with H_2O for 10 s and immersed in the peptide solution.

¶ A surface coverage of 17% was calculated modelling the helices as 27 × 12 Å rectangles and using a surface roughness of 2.

‖ RAIRS spectra were accumulated over 200 scans at 4 cm^{-1} resolution using a Unicam Galaxy Series FTIR 7000 spectrometer equipped with a Hg–Cd–Te detector and FT85 specular reflector from SpectraTech Inc. The sample compartment was purged with dry air.

** Peptide monolayers were assembled by evaporating 5 nm Cr and 50 nm Au onto a glass slide. The wafers were placed in 0.4 mmol dm^{-3} solutions of peptide **1** (in MeCN) for 16 h or peptide **2** (in CH_2Cl_2) for 4 h, rinsed with solvent and dried gently in a stream of He.

‘Self-complexing’ tetrathiafulvalene macrocycles; a tetrathiafulvalene switch

Mogens Brøndsted Nielsen, Steen Brøndsted Nielsen and Jan Becher*

Department of Chemistry, Odense University, DK-5230 Odense M, Denmark

Two ‘self-complexing’ macrocycles based on the electron donor TTF and a cyclic bipyridinium acceptor are prepared.

The construction of molecular devices which can operate as machines upon external energy transfer has been of high interest recently, as such systems may be able to store and process information at the molecular level.[1,2] A recent example is provided by a pseudorotaxane system in which a naphthalene or hydroquinone π-donor and the π-acceptor cyclobis(paraquat-*p*-phenylene) are covalently linked.[3]

We have prepared a number of donor–acceptor catenanes by incorporating the π-donor tetrathiafulvalene (TTF) into macrocyclic systems,[4] as well as systems in which the TTF unit and the bipyridinium unit are linked, either in a rigid conformation, *e.g.* as a donor–acceptor cyclophane, or in a noncyclic system.[5] Here we have extended these concepts by incorporating TTF into macrocycles which may self-complex in order to investigate their switching properties. For synthetic reasons we attached the TTF unit to the unsymmetrical *m*-*p* linked cyclophane of cyclobis(paraquat-*p*-phenylene).[6] The corresponding symmetric *m*-*m* linked cyclophane was discarded due to its poor ability to act as a host, as reported by Stoddart.[7]

First, **2** and **3** were prepared by *O*-alkylations of dimethyl 5-hydroxyisophthalate **1** (Scheme 1). The TTF derivative **4** was deprotected with CsOH (1 equiv.) (Scheme 2),[8] and the resulting monothiolate was treated *in situ* with **2** or **3** affording **5** and **6**, respectively. The two ester groups were reduced with $LiAlH_4$ followed by mesylation in the presence of DBU. The mesylated compounds were converted directly to the corresponding chloro compounds by reaction with an excess of LiCl, giving fair yields of **9** and **10**. Subsequent Finkelstein reactions with LiBr gave the TTF-linked *m*-xylene dibromides **11** and **12**.†

The new anchimeric-complexed‡ macrocycles **14a** and **15a** were obtained by treating **11** and **12**, respectively, with the dipyridinium dication of **13** under ultra-high pressure (10 kbar) for 6 days (Scheme 3). The crude green products were subjected to column chromatography and ion exchange.[4] During work-up of **15a**, partial isomerisation ‘decomplexation’ to the orange coloured form **15b** was observed. Repeated fractional crystallization *via* slow evaporation of Pr^i_2O into MeCN solutions of **14a** and **15a** resulted in removal of small amounts of impurities. In this way it was possible to obtain **14b** and **15b** as orange microcrystalline compounds, *e.g.* in the completely ‘decomplexed’ forms. Redissolution of **15b** in MeCN initially gave an orange solution which slowly turned greener on standing due to partial anchimeric complexation. However, an MeCN solution of ‘decomplexed’ **14** did not change colour, and according to UV–VIS spectroscopy only a very small charge-transfer (CT) absorption could be detected after several days. Thus, when first ‘decomplexed’, the short linker of **14b** more or less prevents the TTF unit from intramolecularly slipping back into the cyclic acceptor. Besides, the persistent orange colour indicates the absence of intermolecular complexation.

The UV–VIS absorption of the initially orange crystals of **15b** dissolved in MeCN was followed over time [Fig. 1(*a*)]. After about 20 h the equilibrium between **15a** and **15b** was established, as seen from the constant CT absorption (λ_{max} ~785 nm). The relatively weak CT absorption indicates that only a small degree of anchimeric complexation occurs, which was confirmed by ^1H NMR spectroscopy (estimated ratio **15a** : **15b**: 1 : 10). The anchimeric complexation results in a complicated set of bipyridinium proton resonances and a downfield shift of the SMe protons in agreement with observations for comparable TTF-based catenanes.[4d] The question is whether the complexation is truly of the auchimeric

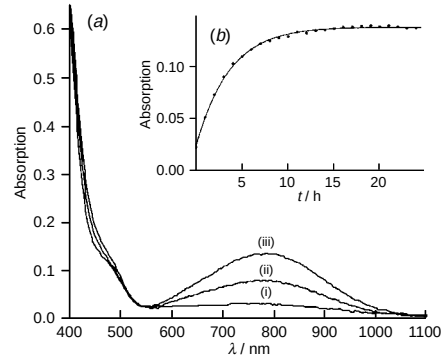

Fig. 1 (*a*) The UV–VIS absorption spectrum of the initially decomplexed **15b** in MeCN at (i) 0, (ii) 3 and (iii) 19 h. (*b*) The time variation of the maximum absorbance (λ_{max} ~785 nm) of initially decomplexed **15b**. A first-order fit matches the points very well. Concentration of compound = 0.26 mmol dm^{-3}.

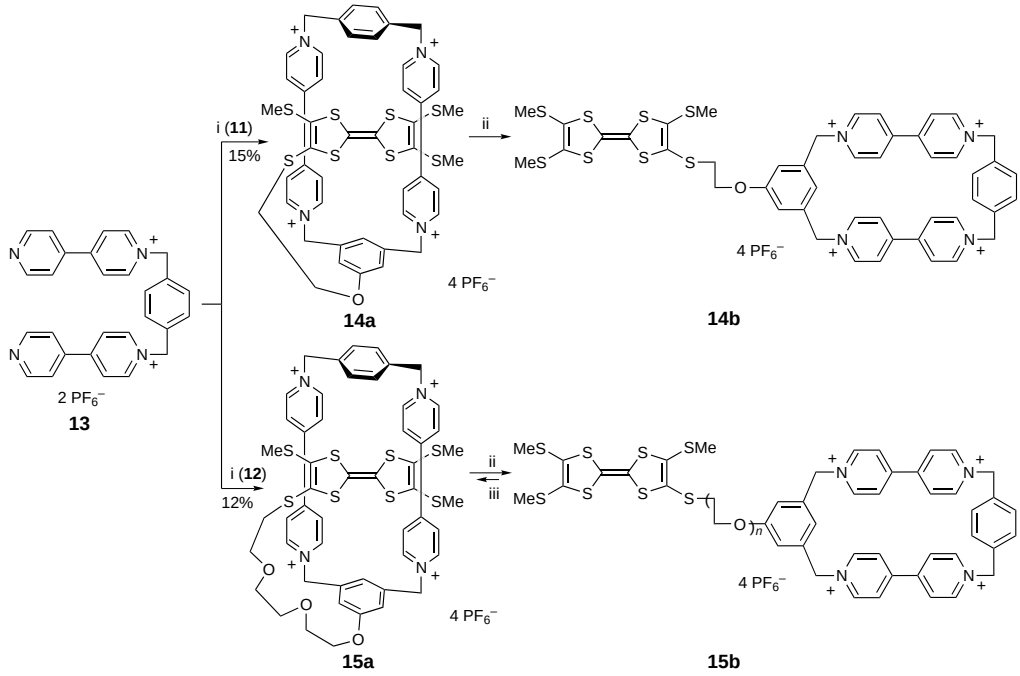

Scheme 3 *Reagents and conditions*: i, DMF, 10 kbar, room temp., 6 d; ii, fractional crystallization; iii, equilibrium in MeCN

type. The formation of an intramolecular 'complex' by anchimeric complexation would be expected to follow a first-order rate equation. In Fig. 1(*b*) the observed absorption maxima are plotted against time, and a curve fitted using eqn. (1)§ confirms that the data are in good agreement with first-order conditions. Of course this is not a final proof for exclusive anchimeric complexation. Nevertheless, since **14b** did not readily undergo intermolecular slipping in dilute solution, we would not expect this to be likely for **15b** either.

Refluxing the equilibrium solution of **15a,b** in MeCN for 45 min caused almost complete conversion to **15b**. However, the next day a CT absorption close to the starting equilibrium absorption at room temperature was reestablished. This anchimeric decomplexation/recomplexation could be repeated.¶ Thus, **15** behaves as a thermal molecular switch, the state of which is determined by both thermodynamics and kinetics. The solution of **15a,b** was subjected to 10 kbars of pressure (room temp., 4 days); however, this caused no significant change in absorption, *i.e.* in no displacement of the equilibrium.

Compounds **14** and **15** were characterized by electrospray mass spectrometry (ESMS) showing peaks assignable to $[M - nPF_6]^{n+}$ (n = 1–4), $[M - nPF_6]^{(n+1)+}$ (n = 1–3) and $[M - nPF_6]^{(n-1)+}$ (**14**, n = 3,4). Furthermore, a $[2M - 3PF_6]^{3+}$ ion was observed in the gas phase, but whether this is a real dimer or a dimeric cluster ion cannot be concluded. Collisional activation (MS/MS) of the mass selected $[M - 4PF_6]^{4+}$ ions caused similar fragmentations of the cyclic acceptor, as already observed for related TTF based catenanes.[4d]

‡ Anchimeric assistance is normally used to describe neighbouring group participation in a reaction. The expression 'complexation' is incorrect when used to describe an intramolecular reaction. We suggest using the expression 'anchimeric complexation' to describe the present type of isomerisation ('self-complexation') taking place between two covalently linked groups.

§ The time-dependence of the absorbance (A) for first-order recomplexations with rate constant k_+ is shown by eqn. (1),

$$A = A_0 \exp[-(k_+ + k_-)t] + \text{constant}\cdot\{1 - \exp[-(k_+ + k_-)t] \qquad (1)$$

where k_- is the rate constant for the decomplexation reaction.

¶ A small decrease of the equilibrium CT absorption (*ca*. 5%) was observed after each experiment, which may be due to a chemical decomposition upon refluxing.

Electrochemical immobilization of a pH sensitive fluorescein derivative: synthesis and characterization of a fluorescein-derivatised polythiophene

David Millar, Mahesh Uttamlal,*† Ross Henderson and Alexis Keeper

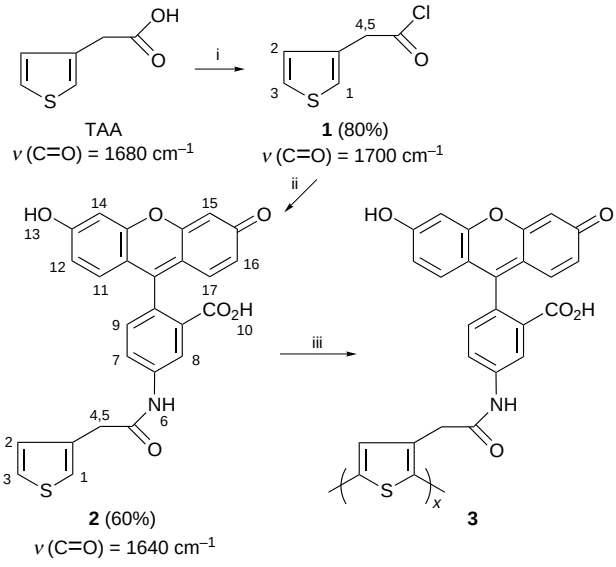
Department of Physical Sciences, Glasgow Caledonian University, City Campus, Cowcaddens Road, Glasgow, Scotland, UK G4 0BA

The electrochemical immobilization of a pH sensitive fluorescein derivative was achieved by preparing a fluorescein-substituted thiophene species, followed by its electropolymerization on a Pt electrode.

Immobilization of fluorescein[1] for the preparation of fibre-optic pH sensors has been achieved using several techniques.[2] Simple entrapment in sol-gel matrices has been reported by several workers.[3] Fluorescein derivatives have also been used to create a covalent link between the indicator and the optical fibre surface.[2] The photochemical covalent immobilization of fluoresceinamine has been reported for the preparation of fibre-optic chemical sensors (FOCSs) for pH measurement.[4] Here we report the first example of the electrochemical immobilization of a pH sensitive fluorescein derivative.

Electropolymerization is a simple and attractive approach for the immobilization of fluorophores in the form of a polymer on a substrate surface. The process of electropolymerization can be controlled by electrode potential and allows accurate control of the amount of fluorophore immobilized. In this work the electrochemical immobilization of fluoresceinamine is being undertaken in order to prepare a FOCS for pH and to study the effect of electrode potential on the fluorescence properties of the new polymer.

Scheme 1 shows the reaction for the preparation of fluorescein-derivatised polythiophene. The new monomer for electropolymerization was prepared using thiophene-3-acetic acid (TAA), a well characterized compound for preparing conducting polymers.[5] From TAA, thiophene-3-acetyl chloride (TAC) **1** was prepared *via* reaction with thionyl chloride.[6]‡ TAC was then reacted with fluoresceinamine, to yield **2**.§



Scheme 1 *Reagents and conditions:* i, excess $SOCl_2$, 60 °C, 2 h (ref. 6); ii, fluoresceinamine, acetone, reflux, then $CHCl_3$–H_2O extraction; iii, electrochemical polymerisation (ref. 7)

Polymer **3** was prepared *via* the electrochemical polymerization on Pt coated glass in MeCN using the method reported for the preparation of poly-TAA.[7]¶ Polymer **3** was produced as a golden film. Under the experimental conditions used, the polymer film produced is probably over-oxidised and consequently non-conducting. However, the electrical properties of the polymer are not of interest here and will not be discussed further.

Fluorescein itself in aqueous solution occurs in cationic, neutral and anionic forms, making its absorption and fluorescence properties strongly pH dependent.[1] It has been shown to be electrochemically active in non-aqueous media.[8] At neutral and high pHs in aqueous media the equilibrium shown in Fig. 1 dominates.

The fluorescence intensity ratio *vs.* pH curves for sodium fluorescein (NaFlu) and for **2** in aqueous solution are given in Fig. 2. The emission wavelength for **2** was identical to that of NaFlu and had a value of 515 nm. The two titration curves have very similar characteristics and indicate that the modification of fluorescein with thiophene has little effect on the pH sensitivity of the fluorescein moiety. The solid lines are theoretical plots generated by fitting Eqn. (1) to the data. This model yields approximations for the pK_a of the indicators. For NaFlu the pK_a is 6.3 and that for **2** it is 6.2. The reported value for fluorescein is in the range 6.2–6.9.[1]

Fig. 2 also shows the pH titration curve for **3**. Polymer **3** shows a well-defined titration with a lower pH sensitivity compared to NaFlu and **2** in solution. The decrease in sensitivity is attributed to small changes in the fluorescence properties of the fluorescein moiety in its new environment. This phenomenon is also observed for photochemically immobilized fluorescein in hydrogel films.[4]

This work has for the first time reported an electrochemical immobilization method for a pH sensitive fluorescein derivative. We have shown that the pH sensitive polymer has similar response characteristics to that of fluorescein in solution. Current investigations are concerned with the effect of electrode potential on the fluorescence properties of the polymer and the preparation of copolymers with TAA. Indole and pyrrole derivatives as alternative monomer units are also being investigated.

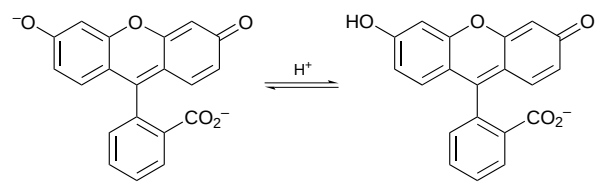


Fig. 1 Dominant equilibrium of fluorescein at neutral and high pH. Fluorescein has a high molar absorbitivity at 488 nm, a large fluorescence quantum yield and high photostability. An attractive feature of this indicator is that it has an excitation maximum at 488 nm, and a pH insensitive shoulder at 430 nm making it suitable for use in the 'ratiometric' mode which overcomes problems in measurement associated with photobleaching, light intensity fluctuation in the excitation source, ionic strength and indicator concentration (ref. 9).

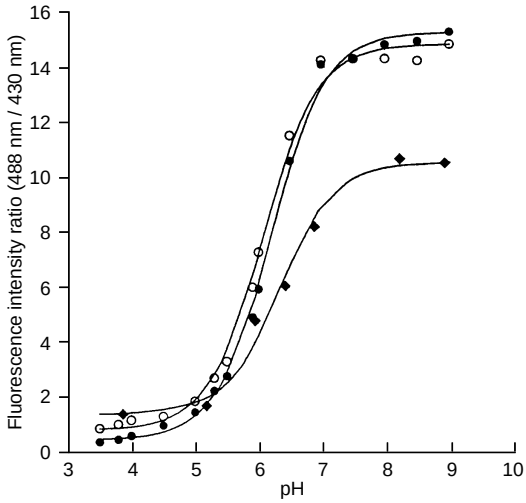

Fig 2 pH Titration curve for (○) **2** (pK_a = 6.1), (◆) **3** (pK_a = 6.3) and (●) NaFlu (pK_a = 6.2). The overall equilibrium can be written. HIn ⇌ H^+ + In^-, where HIn (not fluorescent) and In^- (fluorescent) are the protonated and deprotonated forms of the indicator respectively. The pH is related to the fluorescent intensity by pH = pK_a + log[I/(I_o − I)] (ref. 2) where the fluorescence intensity (or intensity ratio) I = [In^-] and I_o = [In^-]$_o$ where I_o is the maximum fluorescence intensity. This equation can be re-written in terms of I to give eqn. (1):

$$I = \frac{I_o}{1 + (10^{\mathrm{pH} - \mathrm{p}K_a})^{-1}} + B$$

An additional term B is introduced where B is the fluorescence intensity when [In^-] = 0. The solid lines are theoretical fits using eqn. (1).

The authors thank Miss Katrina Rae and (the late) Mr Joe Gillick for technical assistance, Mr Jim Gall (Department of Chemistry, Glasgow University) for NMR analysis and Drs P. A. Bather and J. MacLachlan for helpful discussion. This work was funded by a grant from The Nuffield Foundation (NUF-URB97). This communication is dedicated to Mr Joe Gillick, Senior Chemistry Technician, who died suddenly on 25th May 1997. Mr Gillick gave 22 years service to chemistry education at the institution.

‡ *Experimental procedure* for **1**:[6] The reaction of TAA (1.00 g, Acros, 98%) with $SOCl_2$ (0.8 cm³) at 60 °C for 2 h in dry conditions gave an orange–brown liquid **1** (the excess $SOCl_2$ was evaporated *in vacuo* at 35 °C) with a yield of *ca*. 80%. δ_H (360 MHz, [$^2H_6$]acetone) 7.24 (d, H1), 7.21 (d, H3), 7.05 (s, H2), 4.25 (s, H4, H5).

§ *Experimental procedure* for **2**: Compound **1** (0.74 g) was reacted with fluoresceinamine (4.00 g) in boiling acetone (125 cm³) and cooled. Chloroform (100 cm³) and de-ionised water (100 cm³) were added to the reaction mixture, which was transferred to a separation funnel with 25 cm³ of 5% NaOH. The aqueous layer containing the product was removed and 100 cm³ of 5% HCl was added. Vacuum filtration and recrystalisation from EtOH–H_2O (1 : 1) gave orange crystals of **2** with a yield of *ca.* 60%. δ_H(360 MHz, [$^2H_6$]acetone 9.82 (s, H10), 8.94 (s, H13), 8.42 (s, H15), 7.96 (s, H14), 7.48 (d, H9), 7.33 (d, H7), 7.18–7.16 (2d, H2, H3), 6.82–6.76 (2d, H11, H12), 6.7–6.68 (2d, H8, H1), 6.62–6.59 (2d, H16, H17), 3.79 (s, H4, H5), 2.83 (s, H6).

¶ *Experimental procedure* for polymer **3**: Electrochemical cell consisted of a Pt coated glass working electrode, Ag/Ag^+ reference electrode and Pt gauze counter electrode. The electrolyte solution was 0.10 mol dm^{-3} tetrabutylammonium perchlorate (TBAP) and 0.021 mol dm^{-3} **2** in MeCN. Compound **2** was deposited using cyclic voltammetry. The potential was applied *via* an Oxford Electrodes potentiostat at 100 mV s^{-1} between −0.2 and 2.6 V *vs.* Ag/Ag^+ reference electrode for 20 cycles. A golden film was produced on the electrode surface.

Fluorescence emission intensities were measured on a Perkin-Elmer LS50B luminescence spectrophotometer. The fluorescence intensity ratio was measured using excitation at 430 and 488 nm The emission wavelength was 515 nm.

Platinum deposition on glass was achieved using thermal vapour deposition.

Synthesis and reactivity of α-allenylhydroxylamines: a new efficient access to 3,6-dihydro-1,2-oxazines

Estelle Dumez and Jean-Pierre Dulcère

RéSo, Réactivité en Synthèse organique, UMR 6516, Faculté des Sciences et Techniques de St. Jérôme, Boîte D 12, Av. Esc. Normandie-Niemen, F-13397 Marseille Cedex 20, France

SmI_2-promoted reduction of α-allenyl nitro derivatives 2a–f using controlled conditions provides either 3-amino-4-vinylidenetetrahydrofuran 3a or 3-hydroxylamino-4-vinylidenetetrahydrofurans 4b–f, which undergo intramolecular cyclization consistent with a reverse Cope elimination to afford 3,6-dihydro-1,2-oxazines 5b–f.

The *C*-nitroso group (R–N=O) acts as a heterodienophile in hetero-Diels–Alder reactions with 1,3-dienes to afford regioselectively 3,6-dihydro-1,2-oxazines.[1] The intramolecular variant Diels–Alder reaction has received some attention since resulting 3,6-dihydro-1,2-oxazines are involved in strategies for the synthesis of indolizidine alkaloids.[2] The most useful synthetic application of these cycloadditions is the easy cleavage of the N–O bond in the adduct to generate 1,4-bifunctional groups.[3]

Despite their synthetic potential, 3,6-dihydro-1,2-oxazines have exclusively been prepared by [4 + 2] cycloaddition.[4] Nevertheless, the well documented electrophilic-catalyzed intramolecular cyclizations of β-allenyl alcohols into dihydropyrans[5] suggest that cyclic derivatives of hydroxylamines, namely 3,6-dihydro-1,2-oxazines, should alternatively be provided by related cyclization of α-allenylhydroxylamines.

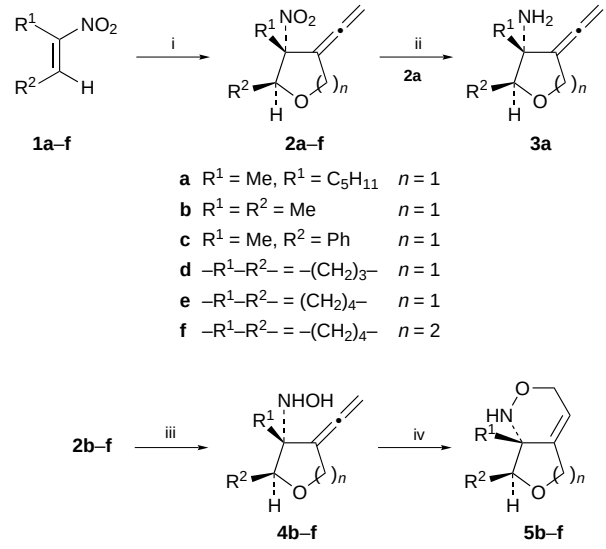
Although a number of methods are available for the synthesis of allenic amines,[6] to the best of our knowledge, among nitrogen related derivatives with higher oxidation state, allenylhydroxylamines have never been described. Nevertheless, addition of alkylhydroxylamines to allenyl carbonyl compounds provides allenyl nitrones which have been postulated as intermediates[7] in 1,3-dipolar cycloadditions leading to bicyclic isoxazolidines. Moreover, a diastereoselective synthesis of nitroallenes has recently been reported.[8]

We disclose here the efficient reduction of nitroallenes **2b**–**f** upon treatment with SmI_2 to the corresponding hydroxylamines **4b**–**f**, which are subsequently converted into 3,6-dihydro-1,2-oxazines **5b**–**f** by remarkably facile cyclization (Scheme 1).

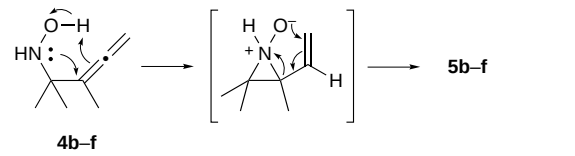
3-Nitro-4-vinylidenetetrahydrofurans **2a**–**e** were prepared[8] by tandem oxa-Michael addition–S_N2' substitution of 4-chlorobut-2-yn-1-ol with nitroalkenes **1a**–**e**, while the same sequence with **1f** afforded 3-nitro-4-vinylidenetetrahydropyran **2f** when 5-chloropent-3-yn-1-ol was used as nucleophile. Reduction of nitro compounds has been used for a long time as a routine method for the preparation of various nitrogen derivatives such as amines and hydroxylamines;[9] however, in many cases over reduction occurs and further reduction to amines is difficult to avoid. Since the previous work of Kagan and co-workers on the reactivity of SmI_2 with nitrogen compounds,[10] alkylhydroxylamines and alkylamines have been prepared selectively from nitroalkanes and SmI_2 under mild conditions.[11]

According to this procedure, allenyl amine **3a**† was obtained by treatment of **2a** with 6 equiv. of SmI_2 in THF–Bu^{t}OH, while reaction of **2b**–**f** with 4 equiv. of SmI_2 allowed the isolation of the corresponding hydroxylamines **4b**–**f** in 60–65% yield.‡§

Upon standing at room temperature without catalyst, **4b**,**c**,**e**,**f** (6 h) or **4d** (15 d) were converted into **5b**–**f**¶ in 62–92% yield. This non-catalyzed intramolecular cyclization of hydroxylamines is in contrast to the well-known electrophilic catalysis required for the cyclization of functionalized allenic derivatives.[5,12] Although intramolecular cyclization of α-allenyl amines proceeds according to a 5-*endo-trig* mode to afford pyrroline derivatives[13] the chemo- and regio-selectivities of the cyclization of **4b**–**f** allow the formation of **5b**–**f** *via* apparently exclusive intramolecular *O*-alkylation. Nevertheless, while it is premature to propose a definitive mechanism, the fact that the cyclizations proceed uncatalyzed at ambient temperature strongly suggests a pathway which features a reverse Cope elimination [eqn. (1)].[14]‖ Moreover, this pathway proceeds according to the usual reactivity of hydroxylamines, which undergo alkylation on nitrogen rather than on oxygen by addition to the activated double bond.[15]



Scheme 1 *Reagents and conditions*: i, **1** (1 equiv.), THF, Bu^{t}OK (1.5 equiv.), $ClCH_2C{\equiv}C(CH_2)_nOH$ (1.5 equiv.), 0 °C, 10 min, then room temp., 15–30 min, n = 1 (ref. 8), n = 2 (74%); ii, SmI_2 (6 equiv.), THF, Bu^{t}OH, 15 min, 42%; iii, SmI_2 (4 equiv.), THF, Bu^{t}OH, 15 min, 60–65%; iv, room temp., 6 h to 15 d, 62–92%



In conclusion, the SmI_2-controlled mild reduction of **2b**–**f** constitutes a new access to allenyl hydroxylamines **4b**–**f** which are precursors of 3,6-dihydro-1,2-oxazines **5b**–**f**, probably by reverse Cope elimination.

LiOH promoted allomerization of pyropheophorbide *a*. A convenient synthesis of 13²-oxopyropheophorbide *a* and its unusual enolization

Andrei N. Kozyrev, Thomas J. Dougherty and Ravindra K. Pandey*†

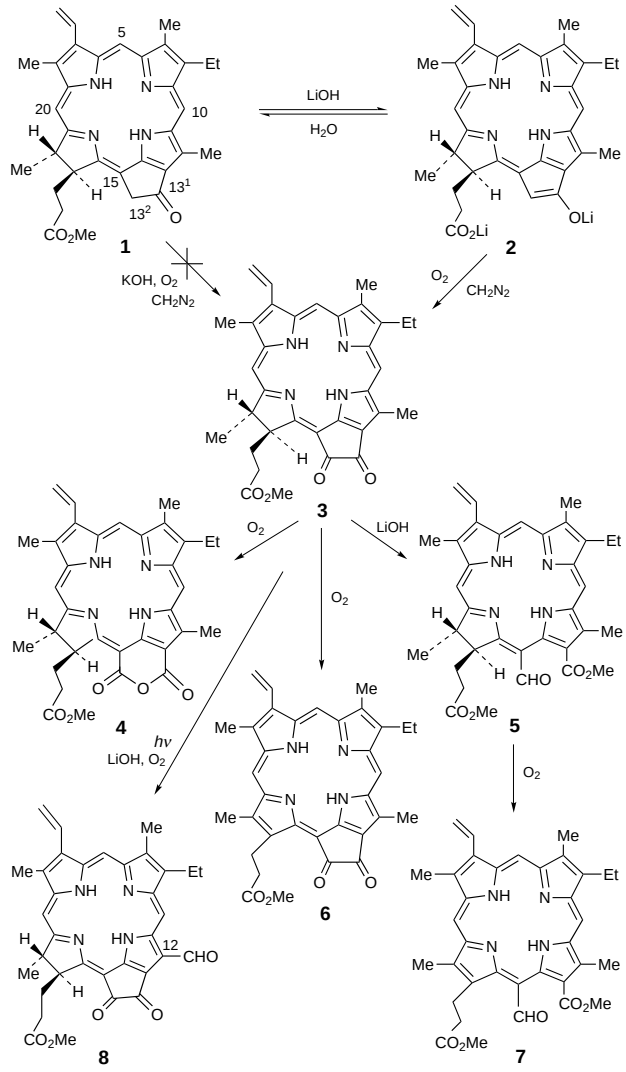
Chemistry Section, Department of Radiation Biology, Division of Radiation Medicine, Roswell Park Cancer Institute, Buffalo, NY 14263, USA

Treatment of pyropheophorbide *a* with aqueous LiOH–THF gave the corresponding enolate, which on *in situ* oxidation produced the corresponding 13²-oxo derivative in 79% yield; prolonged autoxidation gave purpurin-18 and purpurin-5 as major products and a mechanism for the formation of 12-formyl derivative from 13²-oxopyropheophorbide *a* under unusual enolization is discussed; the electronic absorption spectroscopy data of the enolic intermediates showed a considerable perturbation in the π-systems of the macrocycle.

The term 'allomerization' was first introduced to chlorophyll chemistry by Willstatter,[1] who used it to describe then unknown modification reactions of chlorophylls occurring on standing in alcohol solution in contact with air. Thus, allomerization is identical with the term 'autoxidation', which implies oxidation by triplex oxygen ($^3O_2$). In chlorophyll chemistry, besides allomerization, the enolization of the isocyclic ring has been studied extensively and it is now well established that allomerization takes place after the formation of chlorophyll enolates.[2] The isocyclic ring of all chlorophylls (except the chlorobium Chls) is a substituted β-keto ester and therefore has a tendency to enolize. Due to the activation by the two carbonyl functions, the 13²-hydrogen atom is abnormally acidic. On the basis of oxidation potentials, Wasielewski *et al.*[3] have proposed an enolate ion of chlorophyll *a* as the possible primary electron donor in Photosystem I of plant photosynthesis.

We recently reported the formation of a formyl analog as a minor product in the synthesis of purpurin-18 imides.[4] In our investigation on the mechanism for the formation of such formyl derivatives, we used a variety of chlorins including 13²-oxopyropheophobide *a* as substrates. Here we report a simple and efficient method for the preparation of diketone **3**, its 'alomerization' behavior, spectroscopic studies and a possible mechanism for the formation of the corresponding 12-formyl analog.

In contrast to natural chlorophylls and their free bases, pyropheophorbide *a* **1** which lacks an acidic hydrogen at 13²-position was believed not to undergo enolization. This was further confirmed by Conant and Hyde[5] on the basis of a negative Molisch 'phase test'. We reinvestigated this reaction under milder basic conditions, and observed that pyropheophorbide *a* on treatment with LiOH indeed produced stable enolate derivative **2** (Scheme 1), which was detected spectroscopically. It exhibited a characteristic UV–VIS spectrum with the split and red shifted Soret band at λ_{max} = 449 nm. Stronger bases, such as KOH and NaOH, did not produce any spectroscopic changes. This phenomenon could be explained due to the well-known property of lithium salts to form partially covalent bonds.[2] As a result of enolization, methyl pyropheophorbide *a* **1** was completely autoxidized on stirring in THF at room temperature for extended time (12 h) to produce 13²-oxo derivative **3** in 79% yield. Prolonged oxidation (72 h) gave the products of further degradation, which after standard work-up and CH_2N_2 treatment were separated by preparative chromatography. The faster moving band was identified as purpurin-18 methyl ester **4** (32%).[6] The slower moving band was characterized as purpurin-5 dimethyl ester **5** (a key product inWoodward's 'purpurin reaction') and was isolated in 38% yield.[7] The formation of chlorin **5** is obviously due to the basic hydrolysis of the dicarbonyl C–C bond of the diketocyclopentane ring. The other two gray–green porphyrins were isolated in small amounts (*ca*. 2%) and were identified as 13²-oxophylloerythrin methyl ester **6** and 15-*meso*-formylrhodoporphyrin XV dimethyl ester **7**. Both porphyrins showed unique 'reverse-rhodo' visible absorption spectra (Fig. 1) which were found to be different from those generally reported in porphyrin chemistry.[8] These newly discovered green porphyrins can be compared to those related to verdins, or recently reported emeraldins containing fused anhydride or imide ring systems.[9]



Scheme 1

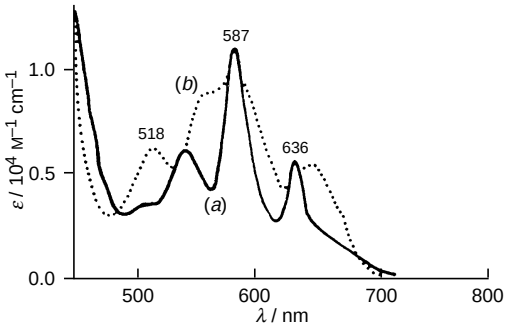


Fig. 1 Electronic absorption spectra (in CH_2Cl_2) of (*a*) dioxoporphyrin **6** and (*b*) porphyrin **7**

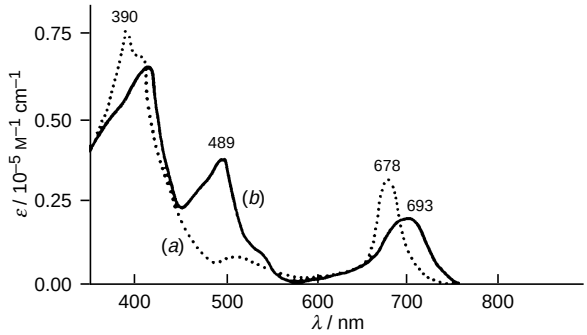

Fig. 2 Electronic absorption spectra (in CH_2Cl_2) of (*a*) chlorin **3** and (*b*) its enolate **3a**

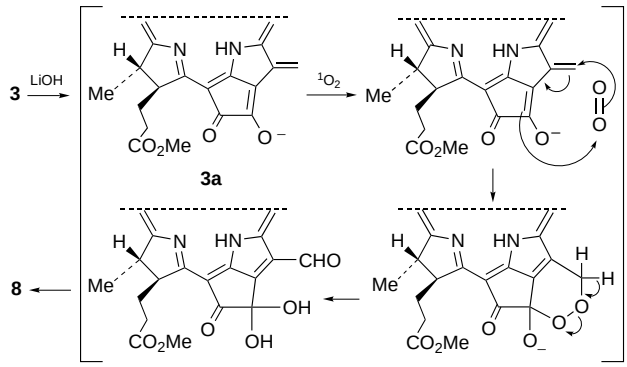
Further purification of this complex mixture also gave a novel chlorin (5% yield) with a significantly red shifted absorption Q_y-band at 710 nm and a Soret band at 440 nm. Compared to 13²-oxopyropheophorbide *a*, the ^{1}H NMR spectrum of this chlorin showed the presence of a distinctive singlet for a formyl group at δ 11.08 and disappearance of the resonances for the 12-methyl protons. The mass spectrum of this product gave a molecular ion peak at *m/z* 576, confirming the replacement one of the methyl group by a formyl substituent. The ^{1}H NMR and 2D ROESY data supported the structure as 12-demethyl-12-formyl-13²-oxopyropheophorbide *a* methyl ester **8**. The formation of chlorin **8** from 13²-oxopyropheophorbide *a* **3**, which lacks protons at 13²-position, possibly proceeds *via* a vinylogous enolization involving the methyl protons attached to the adjacent pyrrolic ring (ring C). This process would certainly be facilitated by the presence of strong electron-withdrawing carbonyl functions at the adjacent cyclopentane ring. A proposed mechanism for the formation of chlorin **8** is shown in Scheme 2. The key step in this reaction is the formation of a reactive intermediate species **3a**. Reaction of enolate **3a** with singlet oxygen, *via* [4 + 2] cycloaddition and subsequent rearrangement, would generate the 12-formyl analog **8**. Chlorins in general are known to convert molecular oxygen to singlet oxygen ($^1O_2$) on irradiating with light. In order to further confirm the [4 + 2] cycloaddition mechanism with singlet oxygen, we used purpurin-18 imide,[4] as a more stable substrate, which could also undergo vinylogous enolization similar to **3a**. Photooxidation of purpurin-18 imide in aqueous LiOH–THF on exposing to sunlight produced the corresponding 12-formyl derivative in high yield (up to 60%). When the reaction was performed in the dark, the 12-formyl analog was not detected.[10]

Despite intensive studies in chlorophyll chemistry, this is the first example in which this type of enolization is observed. The



Scheme 2

evidence of enolization in 13²-oxopyropheophorbide *a* **3** was also confirmed by its specific UV–VIS spectrum (splitting of the Soret band), a characteristic property of enolates in pheophorbide system (Fig. 2). The enolic form **3a** produced under other basic conditions (KOH, NaOH) was found to be stable in non-polar solvents. However, traces of alcohol or water completely destroyed the potassium and sodium enolates, while the lithium salt appeared to be quite stable.

The chemistry discussed here might explain the origin of deoxophylloerythrioetioporphyrin (12-demethyl-DPEP), a minor petroporphyrin structure isolated by Callot.[11]

The newly discovered LiOH promoted enolization of pyropheophorbide *a* has opened a simple and effective way for the preparation of 13²-oxopyropheophorbide *a* **3** which had previously been isolated as a by-product in minor quantities.[6] Further studies are underway to explore the reactivity of the cyclopentanedione ring system for the preparation of novel chlorins with linear conjugation as photosensitizers for photodynamic therapy and models for photosynthetic reaction centers.

Cyclic enediynes: relationship between ring size, alkyne carbon distance, and cyclization barrier

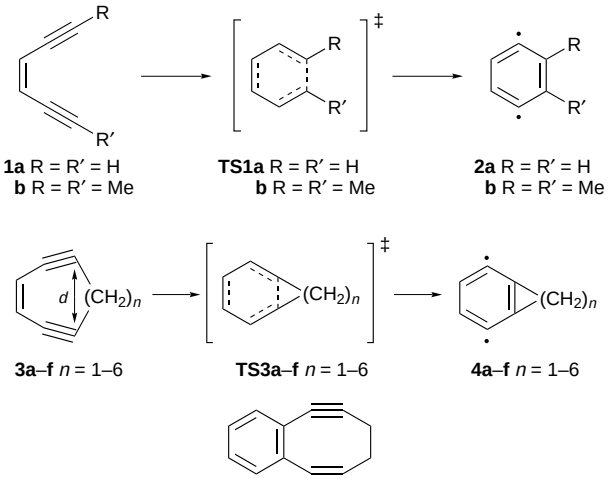
Peter R. Schreiner

Institut für Organische Chemie der Georg-August Universität Göttingen, Tammannstr. 2, D-37077 Göttingen, Germany

This work presents the first detailed study on a series of cyclic hydrocarbon enediynes showing that the cyclization barrier depends upon the ground state energy differences of the biradical products, and that pure density functional methods can be used reliably to estimate the activation enthalpies of the Bergman reaction.

While the Bergman-3-enecyclization[1] of (*Z*)-hex-1,5-diynes (**1**, enediynes) is driven thermodynamically by subsequent formation of two C–H bonds, the pharmacological activity[2] of cyclic enediynes (**3**)[3] is also related to changes in ring strain upon cyclization.[4,5] Ring closure in enediyne carrying drugs complexed to the minor grove of DNA is triggered by subtle structural perturbations.[4] Hence, enediynes are highly promising pharmacophors, but reactivity control is still a problem.

It has been suggested that if the distance *d* of the acetylene carbons forming the new bond is in the critical range of 3.31–3.20 Å, cyclization should occur at room temperature.[6] Based on experimental activation enthalpies, X-ray structures of C_9–C_{12} cyclic enediynes and empirical computations, it was proposed that differential molecular strain in the educts and transition states is most important.[7–10] There have been several studies attempting to clarify the relationship between *d* and cyclic enediyne cyclization as well as the ground state energy differences, but transition structures for other than the smallest enediynes were never computed.[9–14] The modeling of larger enediynes is currently only possible with molecular mechanics,[13] semiempirical[10,14] or lowest-level *ab initio* methods,[11] but these cannot be used to compute accurate enediyne transition structures and activation energies; much higher level treatments are needed,[12,15,16] Density functional theory (DFT) offers a suitable compromise for multi-reference cases, as it is the electron density instead of the wavefunction which is the decisive quantity.[17] While hybrid Hartree-Fock DFT methods like B3LYP do not perform well for computing the heat of formation of *p*-benzyne **2a**,[16] 'pure' (*i.e.* non-hybrid DFT treatments give acceptable accuracy (Table 1).[18] We have therefore used the BLYP/6-311+G**//BLYP/6-31G* level throughout, unless noted otherwise.[19]



Scheme 1

The experimental activation enthalpies are well reproduced at our reference level: (theory *vs.* expt.) 28.4 *vs.* 28.2 kcal mol^{-1} for **TS1a**;[20] 25.0 *vs.* 23.8[6] and 24.0 kcal mol^{-1} for **TS3d**.[21] Enediynes **1a** and **1b** have almost the same *d* value but the difference in $\Delta H^{\ddagger}$ values is 7 kcal mol^{-1}. This is primarily due to the fact that methyl groups stabilize (by *ca.* 10 kcal mol^{-1}) acetylenic (**1b**) much more than olefinic bonds (partially developed in **TS1b**). Thus, dialkyl substitution increases both the activation barriers and the reaction endothermicities of the Bergman reaction for acyclic enediynes.

As expected, both **3a** and **3b** do not cyclize, despite small *d* values; **5** was found experimentally not to cyclize either.[22] The cyclization products would contain highly strained [olefin strain (OS) = 54.4 kcal mol^{-1}, Table 1][23] cyclopropene (in **3a**) and cyclobutene moieties (in **3b** and **5**; OS = 30.6 kcal mol^{-1}).[23] Nine-membered **3c** was suggested to cyclize spontaneously at room temperature,[4,6] and the relatively low activation barrier of 16.3 kcal mol^{-1} for **TS3c** supports this finding. While **3d** with *d* = 3.413 Å[21] cyclizes spontaneously at room temp., **3e** does not, despite *d* being only slightly larger (3.588 Å).[4] Part of the activation enthalpy difference (7 kcal mol^{-1}) is due to olefin strain (OS) energy differences[23] between the cyclohexene (OS = 2.5 kcal mol^{-1}) and cycloheptene (OS = 6.7 kcal mol^{-1}) moieties in the products. Thus, there is no linear relationship between the alkyne carbon distance *d* and $\Delta H^{\ddagger}$ for Bergman-cyclization of monocyclic enediynes.

The reaction enthalpy ($\Delta_r H_{OK}$, Table 1) of the Bergman reaction is more difficult to compute than the activation enthalpies due to the pronounced multi-reference-character of

Table 1 Parameter *d* (in Å), activation enthalpy ($\Delta H^{\ddagger}$/kcal mol^{-1}), reaction enthalpy ($\Delta_r H_{OK}$/kcal mol^{-1}) for the Bergman reaction of **3a–f**; olefin ring strain (OS) of non-benzenoid product ring and stability of enediyne at room temperature. Level of theory: BLYP/6-311+G**//BLYP/6-31G*, unless noted otherwise

Ring size	Species (PG)[a]	*d*	$\Delta H^{\ddagger}$	$\Delta_r H_{OK}$	Corrected[b] $\Delta_{cr} H_{OK}$	OS[c]	Stable at 25 °C
—	**1a** (C_{2v})	4.548	28.4	17.6	8.5	—	yes[d]
—	**1b** (C_{2v})	4.571	35.6	29.9	20.8	—	yes[d]
7	**3a** (C_{2v})	2.512		—[e]		54.4	n.a.
8	**3b** (C_{2v})	2.636		—[e]		30.6	yes[f]
9	**3c** (C_s)	2.924	16.3	11.4	2.3	6.8	no[g]
10	**3d** (C_2)	3.413[h]	25.0[i]	18.3	9.2	2.5	no[g]
11	**3e** (C_2)	3.588[j]	31.9	25.4	16.3	6.7	yes[g]
12	**3f** (C_2)[k]	4.353	40.3	36.3	27.2	7.4	yes[g]

[a] PG = point group. [b] Corrected for the computational error in $\Delta_r H_{OK}$ of **2a** at 0 K (correction = −9.1 kcal mol^{-1}). [c] Ref. 23. [d] Ref. 24. [e] No ring closure, see text. [f] Ref. 22. [g] Ref. 6. [h] Experimentally estimated distance *ca.* 3.4 Å (refs. 24 and 21). [i] Experimental activation barrier = 23.8 (ref. 6) and 24.0 kcal mol^{-1} (refs. 14 and 21). [j] Experimental distance (X-ray) = 3.661(5) Å (ref. 6). [k] Using a 6-311G** basis set for the energy single point. Despite extensive efforts, the wavefunction did not converge with added diffuse ('+') functions on the heavy atoms.

2a. It is therefore sensible to correct $\Delta_r H_{OK}$ for the error (9.1 kcal mol^{-1}) in evaluating the enthalpy of the parent reaction. This correction seems reasonable based on the fact that nine- and ten-membered enediynes cyclize reversibly.[4,24] Larger enediyne cyclizations are much more endothermic and the corresponding transition structures are product-like.[12,15] This is confirmed by the increase in the activation enthalpy of the parent (**1a** → **TS1a**: $\Delta H^{\ddagger}$ = 28.4 kcal mol^{-1}) *vs*. the dimethyl enediyne system (**1b** → **TS1b**; $\Delta H^{\ddagger}$ = 35.6 kcal mol^{-1}): **TS1b** already experiences part of the higher relative energy of the product, where the methyl groups at olefinic carbons are less stabilizing.

The relationship between $\Delta H^{\ddagger}$ for Bergman cyclization of monocyclic enediynes can thus roughly be estimated from the endothermicity of eqn. (1).

$$\Delta H^{\ddagger} = \Delta_{cr} H_{OK} + 14 \pm 2 \text{ kcal mol}^{-1} \quad (1)$$

In conclusion, there is excellent agreement between the experimental and pure DFT-computed $\Delta H^{\ddagger}$ values for Bergman cyclization of monocyclic enediynes. There is no predictive linear relationship between *d* and $\Delta H^{\ddagger}$, but the 'critical range' for 3.31–3.2 Å for spontaneous cyclization may be extended to 3.4–2.9 Å. However, cyclization may be inhibited by large olefin strain in the products. Although dialkyl substitution increases the endothermicity of the Bergman reaction, ring strain effects can dominate.

The author thanks the Fonds der Chemischen Industrie (Liebig-Fellowship), the Deutsche Forschungsgemeinschaft, the RRZ Niedersachsen and Professor de Meijere for support. Discussions with Professors R. R. Squires and C. J. Cramer are highly appreciated.

Montgomery, K. Raghavachari, M. A. Al-Laham, V. G. Zakrzewski, J. V. Ortiz, J. B. Foresman, C. Y. Peng, P. Y. Ayala, W. Chen, M. W. Wong, J. L. Andres, E. S. Replogle, R. Gomperts, R. L. Martin, D. J. Fox, J. S. Binkley, D. J. Defrees, J. Baker, J. J. P. Stewart, M. Head-Gordon, C. Gonzalez and J. A. Pople, Pittsburgh, 1995. The computed transition structures of the parent system were characterized by second derivative calculations. This is, however, computationally not feasible for the larger structures. In this case, the updated Hessian matrix was used to characterize stationary points as ground or transition states. Although solvent effects are not overly important for uncharged species, these could be computed with reaction field models. However, these methods are of limited applicability for non-dynamic DFT-work and were thus not utilized.

First X-ray crystal structure and NMR spectroscopic analysis of a lithiated 1,2-diazapentadiene

Arndt Krol, Roland Fröhlich and Ernst-Ulrich Würthwein*†

Institute of Organic Chemistry, Westfälische Wilhelms-Universität, Corrensstr. 40, D-48149 Münster, Germany

Deprotonation of 1,2-diazapentadienes in Et_2O leads to the respective lithium compounds which, in the case of $[(\eta^1\text{-PhNLiNCHCMeCHPh})\cdot Et_2O]_3$, consists of an almost planar $(Li–N)_3$ hexagon resulting in a tunnel-like arrangement of the W-shaped 1,2-diazapentadienyl chains; the X-ray structure, solution NMR spectra and reactions with electrophiles are reported.

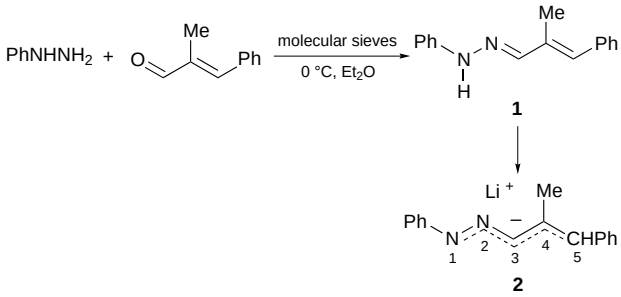
Nitrogen containing organolithium compounds[1] play a major role in synthetic organic chemistry. Therefore, much effort has been focused on the elucidation of the coordination chemistry of lithium bases,[2,3] lithium hydrazides[4] or azapolyenyl metal compounds.[5] In spite of their widespread use in organic chemistry only rarely has evidence for solution or solid state structures of lithiated hydrazone intermediates been published.[2,6,7]

We became interested in the theoretical, synthetic and structural aspects of aza- and diaza-polyenyl metal compounds. Our studies involve the dependence of the electronic and structural behaviour of the intermediates on the positions and nature of the heteroatoms within the conjugated lithiated polyenyl chain.[5] Here we report on the single crystal X-ray structure and NMR spectroscopic analysis of the hitherto unknown 4-methyl-1,5-diphenyl-1,2-diazapentadienyllithium.

4-Methyl-1,5-diphenyl-1,2-diazapentadiene **1** was obtained by condensation of phenylhydrazine and 2-methylcinnamaldehyde following the method of Schantl and Hebeisen.[8] Subsequent deprotonation with LDA or Bu^nLi in Et_2O or THF at −78 °C yielded a dark red solution of the respective lithium hydrazide **2** (Scheme 1).

^1H and ^{13}C NMR spectra of **2** in [$^2H_8$]THF were recorded in the temperature range −80 to 50 °C.‡ The spectra show two sets of signals which have been assigned to the W-shaped conformers **2a** and **2b** (Scheme 2) in a ratio 65 : 35 (**2a** : **2b**), which remains constant over the whole temperature range.

The equilibrium between the two isomers (Scheme 2) could not be frozen out. At 50 °C the spectra resulting from NOE experiments surprisingly show a negative NOE of one isomer upon saturation of the other. Although coalescence could not be achieved this NOE must be due to a transfer of saturation from **2a** to **2b** which can be observed beneath the coalescence temperature when the equilibration occurs faster than the relaxation of the spin system.[9]



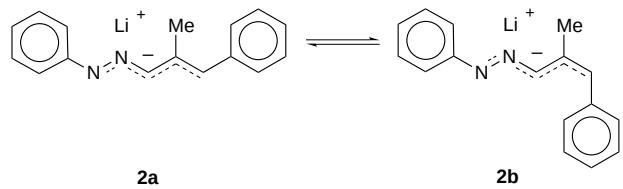
Scheme 1

In the ^{13}C NMR spectra of **2** the resonance frequencies of C(5) and C(3) are shifted by about 11 ppm to higher field, while for C(4) a downfield shift of about 5 ppm relative to the resonances of **1** can be observed. This can be explained by delocalization of the negative charge in the diazapentadienyl unit producing large HOMO coefficients on atoms 1, 3 and 5 and approximately nodal positions on atoms 2 and 4. So, C(3) and C(5) are positioned on centres of high electron density while C(4) is deshielded. As indicated by the ^{13}C NMR shifts, the phenyl substituents are also involved in the charge delocalization, which is additionally confirmed by the deep red colour of the reaction solution. The exact position of the lithium cation will be determined using Li NMR techniques in further experiments.

Crystallization from Et_2O–*n*-hexane leads to yellow single crystals of the trimeric compound **2a**§ whose molecular structure is shown in Fig. 1.

The X-ray diffraction analysis¶ reveals the trimeric structure $[(PhNLiNCHCMeCHPh)\cdot Et_2O]_3$ of **2a** (containing one hexane molecule per unit cell) in which the lithium cations are η^1-coordinated to the nitrogen atoms N(1) of two W-shaped diazapentadienyl moieties and to one Et_2O molecule. Each metal cation is involved in one shorter Li···N link of 1.995(7) Å [2.022(6) and 2.020(6) Å, respectively] and one longer metal–nitrogen contact of 2.066(7) Å [2.085(6) and 2.051(6) Å, respectively]. Such values are typical for end-on bound lithium hydrazides.[10] The resulting $(Li–N)_3$ hexagon with a diameter of 4.05 Å shows a slight boat-shaped distortion. The average Li···Li distance of 3.35 Å implicates a weaker intermetal contact than reported by Nöth *et al.*[10] which can be explained by the steric hindrance caused by the ligands. The lithium centres exhibit a trigonal planar coordination formed by two N(1) nitrogen atoms and one Et_2O molecule.

The nitrogen atoms N(1) in the $(Li–N)_3$ hexagon show a trigonal pyramidalically distorted tetrahedral geometry. The average N–N–Li angle of 109.3 Å and the Ph–N–N angle of 111.5 Å indicate sp^3 hybridization of the hydrazide nitrogen atom N(1). The short N–N distance of 1.38 Å is in remarkable contrast to the N(1)–N(2) distances of 1.55 Å reported for bis-silylhydrazides by Klingebiel[11] or 1.47 Å of Nöth *et al.*[10] in Li–diethylhydrazides and corresponds to non-negotiable double bond character. The N(2)–C(3) bond length of 1.29 Å correlates with the value of 1.305(5) Å found by Collum[12] in the dimeric lithiated 2-methoxycarbonylcyclohexanone dimethylhydrazone for which they postulate the contribution of C–N single and C=N double bond character. The C–C bond distances implicate a localized bond structure containing alternating single and double bonds with delocalization to a small extent. The solid



Scheme 2

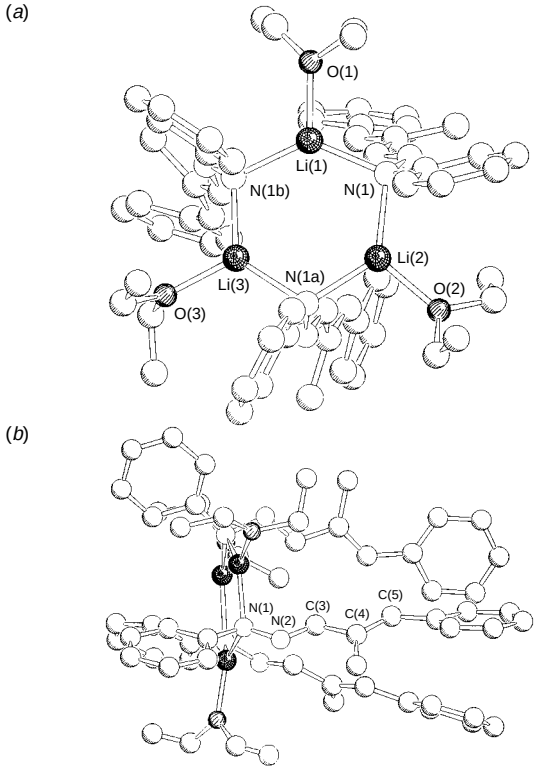


Fig. 1 Molecular structure of **2a**: (*a*) top view and (*b*) side view (hydrogen atoms omitted for clarity)

state structure can best be described as an end-on lithiated hydrazide with some contribution of a 1,2-diazaallyllithium resonance structure.

According to semiempirical calculations using PM3[13] the trimer of **2a** corresponds to a minimum on the potential energy hyperface in the gas phase, which indicates that the tunnel-like structure of the diazapentadienyl chains is not due to crystal packing forces. The W-shaped geometry of the unsubstituted 1,2-diazapentadienyl anion has also been obtained as the energetically most favoured conformer in *ab initio* calculations using the MP2/6-31+G*//RHF/6-31+G*[14] basis set.[15]

Reaction of the intermediate **2** with several alkyl or acyl electrophiles leads regioselectively to the N(1)-substituted *E,E*-hydrazones. *Ab initio* calculations indicate that the 1,2-diazapentadienyl anion bears the highest electron density on N(1)—as expected—and so, structure **2** implicates an electrophilic attack on N(1) which may also be the result of thermodynamic control. Regarding the solid state structure of **2a** the regioselectivity can be explained by a metal controlled nucleophilic substitution at the attacking electrophile.

The authors thank Mr L. Terfloth for valuable help in NMR analysis. We gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft, by the Graduiertenkolleg 'Hochreaktive Mehrfachbindungssysteme' (DFG) at the University of Münster and by the Fonds der Chemischen Industrie.

‡ *Synthesis and ^1H and ^{13}C NMR analysis* of **2**. The lithium compound **2** was prepared by use of the syringe technique directly in the NMR tube. To a white slurry of LDA (0.5 mmol; from 0.3 ml Bu^{n}Li in *n*-hexane and 0.075 ml Pr$^i_2$NH) in 0.3 ml [$^2H_8$]THF was added a solution of **1** (85 mg, 0.36 mmol) in 0.3 ml [$^2H_8$]THF at −78 °C with shaking. The NMR tube was sealed with Parafilm and analysed *via* NMR spectroscopy. δ_H(599.77 MHz, 223 K, [$^2H_8$]THF): **2a** 2.34 (s, 3 H, 10-H), 6.02 (s, 1 H, 5-H), 6.20 (dd, ^3J 7.7, 7.1, 1 H, H_{arom}), 6.85 (t, ^3J 7.3, 2 H, H_{arom}), 6.98 (t, ^3J 7.2, 2 H, H_{arom}), 7.22 (m, 3 H, H_{arom}), 7.29 (d, ^3J 8.2, 2 H, 7′-H), 7.47 (s, 1 H, 3-H); **2b** 2.17 (s, 3 H, 10-H), 5.94 (s, 1 H, 5-H), 6.21 (t, ^3J 7.3, 1 H, H_{arom}), 6.85 (t, ^3J 7.3, 2 H, 7-H), 7.00 (t, ^3J 7.2, 2 H, H_{arom}), 7.19 (m, 3 H, H_{arom}), 7.26 (d, ^3J 8.2, 2 H, 7′-H), 8.02 (s, 1 H, 3-H). δ_C(150.85 MHz, 223 K, [$^2H_8$]THF): **2a** 14.9 (C-10), 113.2 (C_{arom}), 115.2 (C_{arom}), 121.2 (C-5), 124.5 (C_{arom}), 128.5 (C_{arom}), 128.7 (C_{arom}), 128.9 (C-3), 129.7 (C_{arom}), 140.8 (C-4), 140.8 (C-6′), 160.8 (C-6); **2b** 14.2 (C-10), 113.7 (C_{arom}), 115.2 (C_{arom}), 118.0 (C-5), 124.8 (C_{arom}), 128.4 (C_{arom}), 128.8 (C_{arom}), 129.4 (C_{arom}), 135.1 (C-3), 139.4 (C-4), 140.9 (C-6′), 160.7 (C-6).

§ *Synthesis* of [(PhNLiNCHCMeCHPh)·Et$_2$O]$_3$ **2a**. To a solution of Bu^{n}Li (2.8 ml, 4.5 mmol in *n*-hexane) in 15 ml Et$_2$O was added dropwise a solution of **1** (0.74 g, 3.1 mmol) in 25 ml Et$_2$O at −78 °C. After stirring the red solution for 30 min, the mixture was warmed to −20 °C. Recrystallization of the yellow precipitate from Et$_2$O–*n*-hexane yielded yellow crystals.

¶ *Crystal data* for [(PhNLiNCHCMeCHPh)·Et$_2$O]$_3$, monoclinic, space group $P2_1/c$ (No. 14), with unit cell parameters a = 12.013(1), b = 17.608(3), c = 28.633(2) Å, β = 97.69° (1), V = 6002.1(12) Å^3, ρ_{calc} = 1.098 g cm^{-3}. The crystals were analyzed using an Enraf Nonius automatic CAD4 Diffractometer with Cu-Kα radiation (λ = 1.54178 Å) utilizing a graphite monochromator. The yellow single crystal of $(C_{20}H_{25}N_2OLi\cdot 1/6C_6H_{14})_3$ (M = 992.16, crystal size: 0.50 × 0.30 × 0.30 mm^3) was measured at −50 °C. 10391 reflections were collected ($\pm h$, $+k$, $+l$) leading to 10 170 independent and 6106 observed [$(\sin\theta)/\lambda]_{max}$ = 0.59 Å^{-1}. An empirical absorption correction *via* ψ-scan data (0.914 ⩽ C ⩽ 0.999) was carried out, absorption coefficient μ = 5.12 cm^{-1}. 672 refined parameters. R = 0.085, R_w^2 = 0.259, max. residual electron density ρ = 0.53 (−0.35) e Å^{-3}. The structure was solved and refined using SHELXS-86 and SHELXL-93 with hydrogens calculated and refined as riding model, graphics SCHAKAL92. The unit cell contains one totally disordered hexane molecule which has been refined isotropically. CCDC 182/774.

Optically active 'adjacent' type non-centrosymmetrically substituted phthalocyanines

Nagao Kobayashi†

Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan

Optically active 'adjacent' type non-centrosymmetrically substituted phthalocyanines (Pcs) and benzo-substituted Pcs having π-systems with C_{2v} symmetry have been synthesized in high yields in a mixed condensation using bisphthalonitriles (which do not racemize under general Pc formation conditions) and a second phthalonitrile, and characterized by UV–VIS, natural and magnetic circular dichroism spectroscopy.

Control of the molecular symmetry of Pcs is not always easy. Here we describe a convenient route leading to *adjacent* and non-centrosymmetrically substituted *optically active* Pcs.

Our key starting materials are compounds **1** which can be obtained *via* a single step high yielding reaction (more than 90%) from commercially available (*S*)-(−)- or (*R*)-(+)-2,2′-dihydroxy-1,1′-binaphthyl and 3-nitrophthalonitrile without optical loss.[1,2] The most important property of compounds **1** is that they do not racemize under general Pc synthesis conditions because of the large steric hindrance due to the two bulky dicyanophenoxy groups, and of course no opposite isomer is produced. In addition, since the distance between the two phenoxy groups is close to the minimum to link two adjacent benzene rings of Pc, the formation of oligomeric Pcs is suppressed. Compounds (*S*)-**1** and (*R*)-**1** were converted to isoindoline derivatives by bubbling ammonia gas in dry MeOH[3] followed by reaction with 2 equiv. of 4,5-dimethoxyisoindoline[4] in refluxing *N*,*N*-dimethylaminoethanol for 3 h.[3] After evaporation of the solvent, the residue was separated on a basic alumina column (Act III) using CH_2Cl_2–MeOH (9 : 1 v/v) and then CH_2Cl_2–pyridine (1 : 1 v/v). The blue–green fraction was collected and separation was attempted by gel-permeation chromatography using Bio-beads SX-2 (Bio-rad) and CH_2Cl_2–MeOH (9 : 1 v/v). Three blue–green bands appeared, but the separation between the first and second bands was too small to effect separation. The third band (blue) was identified as (*S*)-**$H_2$2** and (*R*)-**$H_2$2** with two binaphthyl units *via* FAB mass spectroscopy (5–7%).[2,5,6] The first and second bands were accordingly mixed together and then separated on a column of Bio-beads SX-8 using THF as eluent. The first band was collected and recrystallized from CH_2Cl_2–EtOAc and then THF–EtOAc to give the optically active non-centrosymmetric (*S*)-**$H_2$3** and (*R*)-**$H_2$3** as a blue–green powder in 21–26% yield. Similarly, (*S*)-**$H_2$4** was prepared from the diiminoisoindoline derivatives of (*S*)-**1** and 6-*tert*-butyl-2,3-dicyanonaphthalene in 9% yield. Interestingly, the NMR signal of the pyrrole protons of (*S*)-**$H_2$4** appeared at two separate positions, one at δ −2.40 and the other at −4.05 (one proton each).[2] Judging from the fact that the ring current in naphthalocyanine (Nc) is smaller than that in Pc,[7] the signal from the former may be attributed to a pyrrole proton at the naphthalene ring site. The zinc and cobalt derivatives [*i.e.* (*S*)-**Zn3**, (*R*)-**Zn3**, (*S*)-**Co3**, (*R*)-**Co3** and (*S*)-**Co4**] were prepared by refluxing (*S*)-**$H_2$3** and (*R*)-**$H_2$3** with $Zn(OAc)_2$ and $CoCl_2$, and (*S*)-**$H_2$4** with $CoCl_2$, as previously described.[1]

Fig. 1 shows the electronic absorption, magnetic circular dichroism (MCD) and circular dichroism (CD) spectra of (*S*)-**$H_2$2** and (*R*)-**$H_2$2** in two solvents. In the absorption spectra, the four component Q band, characteristic of metal-free Pc, is seen and the spectra on the shorter wavelength side of the Soret band are to some extent deformed by the superimposition of the absorption due to the ^1L_a transition of naphthalene.[8] In the 220–250 nm region, a strong absorption attributable to the ^1B_b transition of the naphthalene moiety is observed. The MCD

(*S*)-**Co4** M = Co

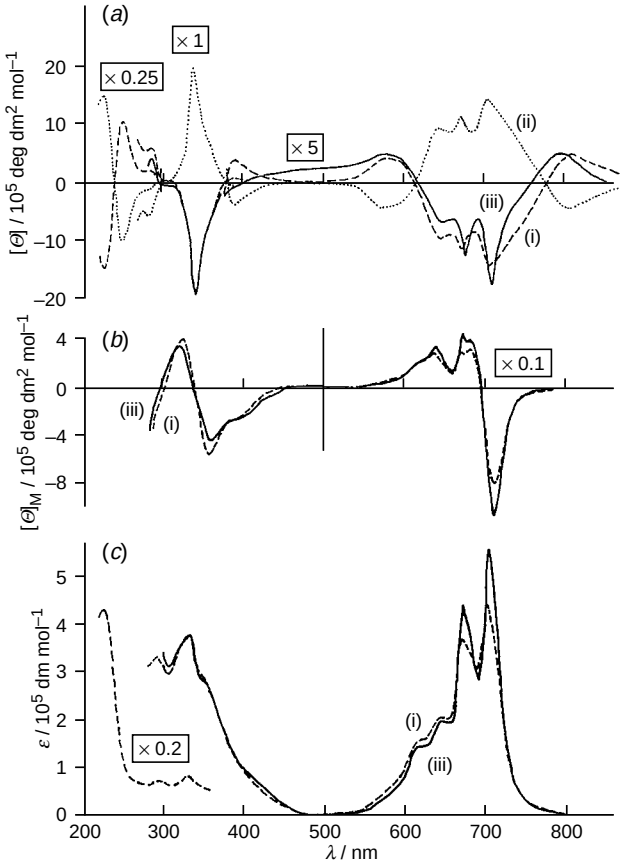

Fig. 1 (*a*) CD, (*b*) MCD and (*c*) electronic absorption spectra of (i) (*S*)-**H$_2$2** and (ii) (*R*)-**H$_2$2** in THF and (iii) (*S*)-**H$_2$2** in toluene

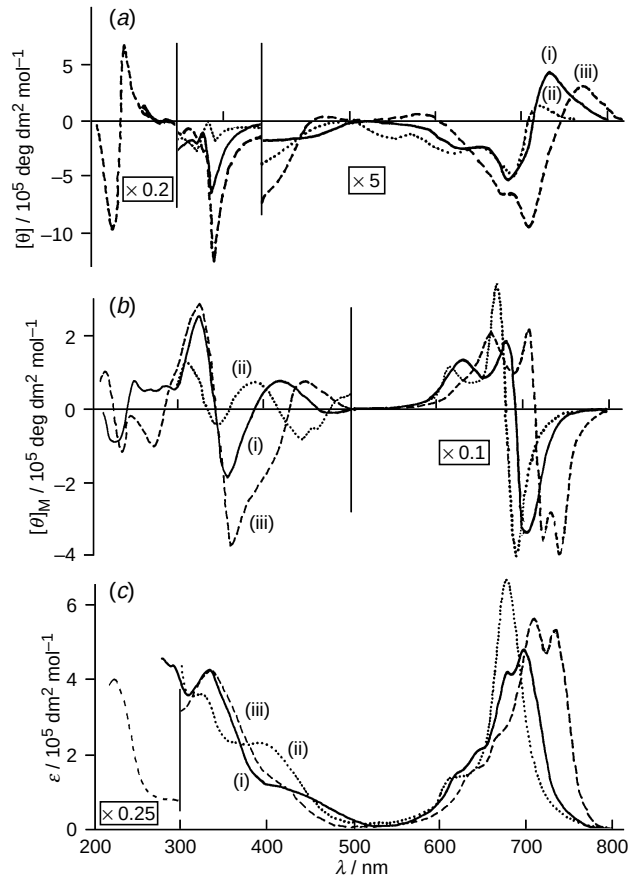

Fig. 2 (*a*) CD, (*b*) MCD and (*c*) electronic absorption spectra of (i) (*S*)-**H$_2$3**, (ii) its (pyrrole proton) deprotonated species and (iii) (*S*)-**H$_2$4** in THF

spectra are characteristic of the metal-free Pcs, producing Faraday *B*-terms approximately corresponding to the absorption maxima or shoulders.[9] Although the solvent effect is discernible in the absorption and MCD spectra, it is most clearly seen in the CD spectra. The shape of the spectrum in toluene is similar to that in the absorption spectrum, while in THF it deviates significantly, as seen typically in the Q band region, reflecting perhaps a tendency to higher aggregation trend in the latter solvent.[10] Thus, subtle differences in the absorption spectra are amplified in the CD spectra. Corresponding to the main Soret and Q band, the *R* and *S* enantiomers show mainly positive and negative CD envelopes, respectively.

The spectra of (*S*)-**H$_2$3** and its deprotonated species and (*S*)-**H$_2$4** are shown in Fig. 2. Compared with the spectra in Fig. 1, the Q bands are broadened and shifted to longer wavelength, and the CD spectra are mostly negative in sign through the Q and Soret regions. The Q band of (*S*)-**H$_2$4** lies at longer wavelength and is stronger than that of (*S*)-**H$_2$3**. (*S*)-**Co4** also shows the Q_{0-0} band at longer wavelength (708 nm in CH_2Cl_2) than is usual for CoPcs.[9] In compounds **1**–**4**, the binaphthyl moiety of all the *S* isomers is right-handed while that of the *R* isomers is left-handed, judging from the CD pattern in the 220–270 nm region.

The method shown here has general applicability, and the yields are very high for a reaction of this type. Diphthalonitriles linked by short chains (*ca*. 5–6 atoms) can be used as precursors of non-centrosymmetic Pcs such as **2**–**4**.

1 Reaction was carried out at room temperature for three days (C. C. Leznoff, S. M. Marcuccio, S. Greenberg and A. B. P. Lever, *Can. J. Chem.*, 1985, **63**, 623).

2 All compounds gave satisfactory elemental analytical data. *Selected data* for **1**: Off-white needle [silica, benzene–EtOAc (2 : 1 v/v), R_f 0.58], recrystallized from MeCN–Et_2O, mp 230–231 °C; yield: 95.2 and 90.4% for (*S*)-**1** and (*R*)-**1**, respectively. $[\alpha]_D$ −29.2 and 29.6 for (*S*)-**1** and (*R*)-**1**, respectively (*c* 1, CH_2Cl_2); δ (60 MHz, $CDCl_3$) 7.7–8.1 (m, 4 H), 7.0–7.6 (m, 14 H); *m/z* (EI) 538 (100%, $[M^+]$); For **H$_2$2**: δ_H (500 MHz, CD_2Cl_2) 6.0–9.2 (m, 36 H, arom), −4.54 (s, 2 H, pyrrole); *m/z* (FAB) 1078.3 (100%, $[M^+]$); a yield by direct methods was 35.7% for (*S*)-**H$_2$2**, recrystallized from CH_2Cl_2–MeOH. For **Co2**: *m/z* (FAB) 1135 (54%, $[M^+]$), 533 (41), 459 (100). For **H$_2$3**: *m/z* (FAB) 916 (100%, $[M^+]$). For **Zn3**: δ_H (500 MHz, CD_2Cl_2) 6.5–8.7 (m, 22 H, arom), 4.15 (br s, 12 H, OCH_3). For (*S*)-**H$_2$4**: δ (500 MHz, CD_2Cl_2) 6–9 (m, 28 H, arom), 1.3–1.8 (m, 18 H, CH_3), −2.40 (br s, H, pyrrole H at naphthalene site), −4.05 (br s, H, pyrrole H at benzene site). Since, as shown in Fig. 1, UV–VIS absorption, MCD and especially CD spectra change depending on the solvent the details of these spectra will be reported in a full paper.

Host–guest complexation: a new strategy for electrodeposition of processable polythiophene composites from aqueous medium

C. Lagrost, J. C. Lacroix, S. Aeiyach, M. Jouini, K. I. Chane-Ching and P. C. Lacaze*

Institut de Topologie et de Dynamique des Systèmes de l'Université Paris 7-Denis Diderot, associé au CNRS (URA 34), 1 rue Guy de la Brosse, 75005 Paris, France

For the first time host–guest complexation is used to (i) electrosynthesize polybithiophene in an aqueous medium and (ii) generate polybithiophene with electroactivity in water, enhanced solubility in common solvents and processability.

Electropolymerization of aromatic and heteroaromatic compounds, leading to anodic deposition of films, is one of the most valuable techniques for obtaining electrically conducting organic polymers which suffer from very low solubility and poor processability. With the exception of polyaniline and polypyrrole, which are sometimes electrosynthesized in aqueous solutions, most conducting polymers are synthesized in organic media.[1,2] The reasons are the very low water-solubility of monomers, whose oxidation potential is, moreover, higher than that of water decomposition, and the relatively high reactivity of the initially formed radical cations with water molecules.[2] For practical and industrial applications, however, water is the ideal solvent. Acidic solutions of various compositions[3–5] and anionic micellar media have been proposed for the electrosynthesis of polythiophene (PT) films in aqueous solution.[6] Furthermore, soluble and processable conducting polymers are needed in terms of industrial and practical applications. To enhance the processability of these materials, grafting long alkyl groups onto the polymer backbone has been used. This strategy induces modifications of the interchain interactions and makes, for instance, poly(octylthiophene) soluble in most common solvents.[7] We report here a new strategy which allows the synthesis of soluble polythiophene composites from an aqueous medium with no covalent modification of the polymer backbone. It uses host–guest complexation, without any covalent bonds being formed[8] prior to the electropolymerization step, cyclodextrin being the host, bithiophene being the guest.

Cyclodextrins have been widely studied because of their ability to form inclusion compounds with a large variety of molecules. They are cyclic oligosaccharides consisting of six, seven or eight glucose units (α-, β- and γ-cyclodextrins) with a hydrophobic inner cavity and a hydrophilic outer side. They, therefore, readily form inclusion compounds with hydrophobic species in aqueous media.[9] We have chosen to use hydroxypropyl-β-cyclodextrin (HPβCD), because of the size of its cavity and its good water-solubility, and bithiophene (BT) as the monomer, because it fits the β-cyclodextrin′s cavity, is a rather hydrophobic molecule and has a lower oxidation potential than water.

The water-solubility of BT is very low ($< 10^{-4}$ M) but is dramatically increased in the presence of HPßCD. Aqueous solutions of 10^{-3} and 10^{-2} M BT can be easily prepared with 10^{-1} M HPβCD, indicating the formation of an inclusion compound between BT and HPβCD. Fluorescence analyses were carried out by increasing the HPβCD concentration progressively. Emission spectra exhibit variations showing a change in the chemical environment of BT: the fluorescence intensity increases with the HPβCD concentration. This fluorescence amplification is typical of an inclusion phenomenon.[10]

BT was electropolymerized in aqueous HPβCD. Polybithiophene (PBT) thin films can be produced by electrooxidation of an aqueous solution of 10^{-2} M BT, 5.10^{-2} M HPβCD and 10^{-1} M $LiClO_4$ at platinum electrodes, using cyclic voltametry and the galvanostatic method. Multicycle voltammograms were recorded between −0.2 and 1.15 V *vs*. SCE at a scan rate of 100 mV s^{-1}. The first anodic sweep shows a wave at 1.0 V *vs.* SCE, corresponding to the oxidation of BT; additional anodic and cathodic peaks increase regularly with the number of successive cycles (Fig. 1). A thin, homogeneous and adherent film is obtained at the platinum electrode. It shows electroactive and electrochromic properties (Fig. 2) whereas PT and PBT films prepared from an organic solution (without cyclodextrins) do not show any electroactivity upon electrochemical cycling in aq. $LiClO_4$ solutions. Depending on the applied potential, the film is red (reduced state) or green (oxidized state). Similar films can be synthesized by applying constant current densities of 0.05, 0.1 and 0.2 mA cm^{-2} for 15 min. The chronopotentiometric responses of the electrode exhibits an instantaneous rise of the potential close to 1 V. Using higher current densities leads to non-adherent films.

The resonance Raman spectra (Fig. 3), performed *ex situ* with an excitation wavelength of 514.2 nm on a reduced film, are similar to those of PBT films formed in organic media. The most intense band at 1455 cm^{-1} is assigned to the symmetric stretching mode of the aromatic C=C band, while a weaker band at 1492 cm^{-1} is attributed to the antisymmetric stretching vibration. Other, weaker bands at 1364 and 1268 cm^{-1} are

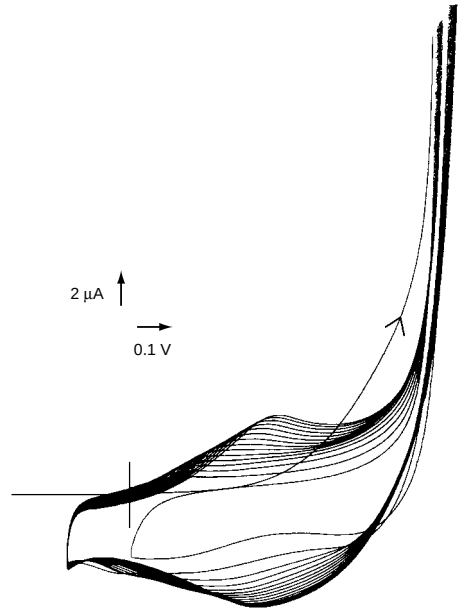

Fig. 1 Voltametric synthesis of PBT film from aq. BT (10^{-} M), HPβCD (5×10^{-2} M) and $LiClO_4$ (10^{-1} M) on Pt electrode (v = 100 mV s^{-1}): (arrow denotes first cycle)

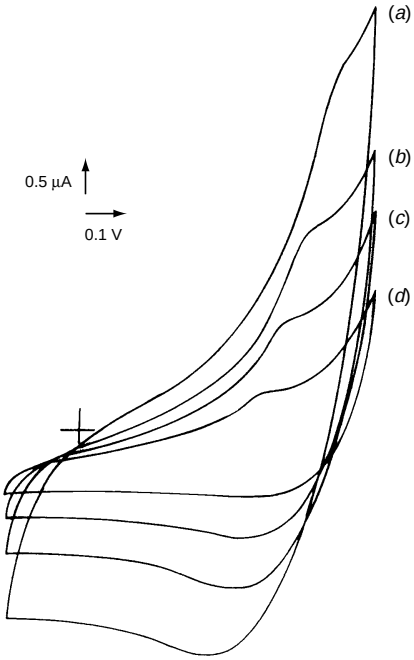

Fig. 2 Electroactivity of a PBT composite in aq. $LiClO_4$ (2.10–1.00 M) for various scan rates: (*a*) 200, (*b*) 100, (*c*) 50 and (*d*) 20 mVs^{-1}

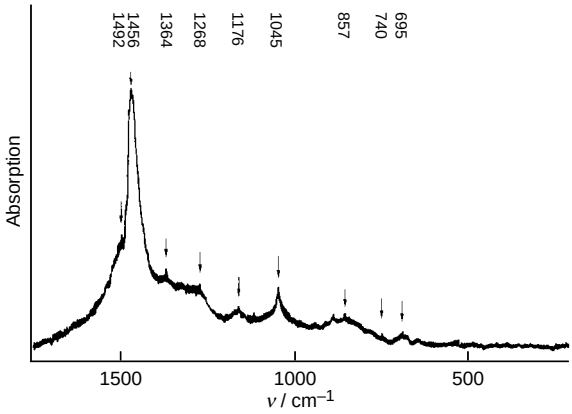

Fig. 3 Resonance Raman spectrum of PBT films deposited from aq. HPβCD

assigned to the stretching mode of the single C–C bond and the C–C inter-ring bond, respectively. The bands at 1045 and 695 cm^{-1} are attributed to the deformation modes of the C–H bond and the C–S–C aromatic bond (Fig. 3). The FT-IR spectra are also very similar to those of PBT films prepared in organic media but display strong bands at 3400, 2960 and 2930 cm^{-1} characteristic of cyclodextrins. A film washed in water for three days in order to eliminate residual cyclodextrins molecules still exhibits these strong bands, showing that cyclodextrins remain in the polymer film. The PBT films deposited from aq. HPßCD solutions are soluble in DMF, DMSO and THF, while PBT films prepared in MeCN are insoluble in these solvents. Since it is well-known that, for β-substituted oligothiophenes, the variation of the absorption maximum energy as a function of the inverse of the chain length is linear,[11] an average conjugation length of 15 thiophene units is estimated from UV–VIS spectroscopy (performed on the fully reduced film), indicating that the material does not consist of low molecular weight oligomers.

We have demonstrated that electropolymerization of BT in an aqueous solution of HPßCD is possible and leads to a homogeneous films similar to that produced in organic media. According to our first analyses, it seems that cyclodextrins persist in the film. The abnormal solubility in common solvents of PBT films electrosynthesized in aq. HPβCD, associated with a high conjugation length, strongly suggests that the polymer chains are partially encapsulated by cyclodextrins. Further work is in hand to confirm this interpretation.

Photogeneration of an *o*-quinone methide from pyridoxine (vitamin B_6) in aqueous solution

Darryl Brousmiche and Peter Wan*†

Department of Chemistry, Box 3065, University of Victoria, Victoria, British Columbia, Canada V8W 3V6

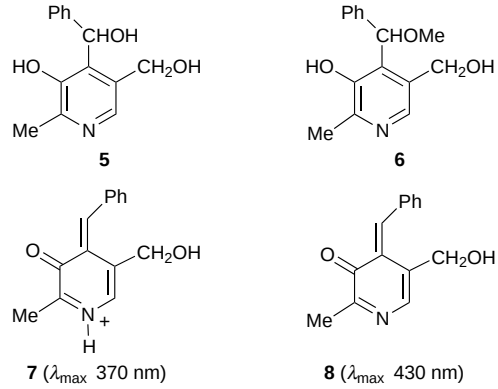
Photolysis (254, 266 or 308 nm) of pyridoxine (vitamin B_6) in aqueous solution gives an *o*-quinone methide efficiently which is trapped by MeOH and ethyl vinyl ether.

Over the past several years there has been a great deal of interest in the biological chemistry of quinone methides‡ (QMs), due mainly to their toxicological properties against both normal and cancerous cells, as well as their proposed intermediacy in the formation of many biologically important polymers (melanin, lignin and insect cuticles).[1,2] These properties have been attributed to the electrophilic nature of QMs which can result in both alkylation of DNA and amino acids, and in self polymerization. QM reactivity in biological systems has been studied extensively with QM precursors such as butylated hydroxytoluene (BHT), eugenol, mitomycin C and the anthracyclines.[1,2] The formation of these QMs has traditionally been *via* thermal reaction, through the use of enzymes *in vivo*, oxidation of phenols, or nucleophilic substitution of silyl or quartenary ammonium groups, amongst others.[1–5] Recently, however, our group has developed a clean and efficient photochemical method for the formation of *o*-, *m*- and *p*-QMs *via* UV (254 nm) photolysis of hydroxybenzyl alcohols.[6] Pyridoxine **1** (vitamin B_6) provides an ideal system for the continued study of photochemically generating QMs as it is a biologically relevant molecule and it contains the required hydroxybenzyl alcohol-type system. Moreover, it allows for a competition between the formation of an *o*-QM *vs*. a *m*-QM due to the presence of a second CH_2OH group *meta* to the aromatic hydroxy group. Formation of a QM from **1** *via* exposure to UV light§ could lead to cell and DNA damage which to the best of our knowledge has not been explored.

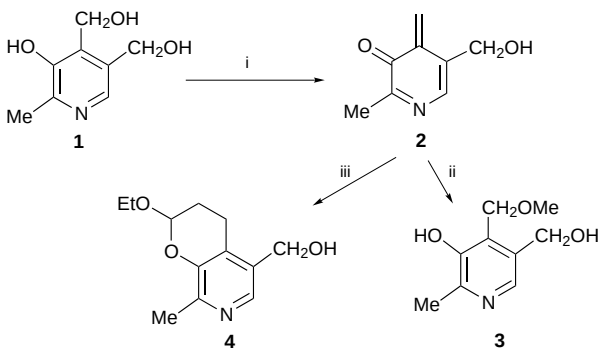
Photolysis of **1** and **5** (10^{-4} M; Rayonet photoreactor; 254 nm; *ca*. 15 °C; argon) in 1 : 1 MeOH–H_2O gave the corresponding methyl ethers **3** and **6** ($\phi \approx 0.2$ for reaction of **5**) cleanly (> 40%) at low conversion (Scheme 1). The location of the methoxy group was unambiguously assigned based on NOE data. Previous work by this group[6] has shown that the quantum yield of methyl ether formation from *m*-QMs is approximately half of that from the corresponding *o*-QM. Thus, if the *m*-QM was formed competitively with the *o*-QM of **1**, it would be easily discernable by formation of the corresponding methyl ether. Interestingly, none of the product studies show any evidence for the formation of the *m*-QM, thereby indicating that *o*-QM **2** is formed selectively.

Photolysis of **1** in 1 : 1 H_2O–MeCN with 0.26 M ethyl vinyl ether (EVE) gave the Diels–Alder adduct **4**¶ cleanly (> 70%) in a regioselective fashion (Scheme 1). Formation of **4** is only possible through the intermediacy of a 1,4-dipolar species and therefore provides conclusive evidence for the efficient photogeneration of *o*-QM **2**.

We have shown[6] that laser flash photolysis (LFP) provides an effective method for the direct detection of appropriately substituted *o*-, *m*- and *p*-QMs. The choice of **5** for these studies



will enable the resulting QM to be more readily detectable due to the expected longer wavelength of absorption and correspondingly larger extinction coefficient. LFP of **5** (λ_{exc} = 266 or 308 nm, YAG or excimer lasers, < 20 mJ per pulse) in 100% H_2O (oxygen purged to remove triplet states and possible radical species) yielded a species at 370 nm, which is observed at pH 7 (τ > 10 ms) and 12 (τ *ca*. 2 ms) (Fig. 1). When LFP experiments were carried out at pH 1, this band can be seen



Scheme 1 *Reagents and conditions*: i, *hν*; ii, MeOH–H_2O (1 : 1); iii, EVE (0.26 M), MeCN–H_2O (1 : 1)

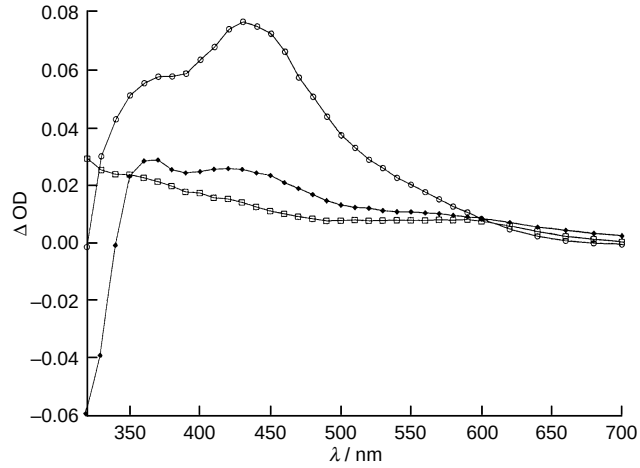


Fig. 1 LFP spectra (λ_{max} 308 nm; 100% H_2O; O_2 purged) of **5** at (□) pH 1, (◆) 7 and (○) 12

below 350 nm (τ < 50 μs). In all three cases, however, there is rapid drop-off signal (bleaching) as the wavelength of observation approaches the region where the ground state material absorbs,‖ thereby masking the true extent of this band. Another species with λ_{max} at 430 nm is apparent in the pH 7 (τ > 10 ms) and 12 (τ *ca*. 2 ms) spectra (Fig. 1). The relative intensities of the bands change with pH (there is no 430 nm band at pH 1), with an 'inflection' point in the pH 4–7 region. We have assigned the 370 nm band to *o*-QM **7** which is protonated at nitrogen. This is clearly the most basic site of the *o*-QM; protonation at oxygen (the other possible basic site) is unlikely at this pH as this would generate a highly reactive diarylmethyl carbocation. The 430 nm band is thus assigned to neutral *o*-QM **8**.

The lifetime of simple QMs is expected to be lower in basic and acidic media than at pH 7, due to attack by either H^+ or OH^- at the appropriate sites of the QM (carbonyl oxygen and exocyclic vinyl carbon, respectively). The transient lifetimes at pH 7 for both **7** and **8** are approximately five times longer than at pH 12, while the lifetime of **7** at pH 1 is approximately two hundred-fold shorter than in neutral solution, consistent with QM reactivity. The heteroatom present in the pyridine ring will also have an influence on the QM lifetime at low pH, where it is fully protonated: it should act a powerful electron-withdrawing group, making the QM more reactive, and this is consistent with the much shorter lifetime observed in pH 1.

It has been shown *via* LFP,[6] in the case of the simple hydroxybenzhydrol systems, that at elevated pH (> 10) QMs are formed more efficiently (higher quantum yields) than at neutral pH, as the phenolate is already present. This appears to be verified in our system as much stronger signals are observed when LFP experiments are carried out at pH 12. Moreover, product studies on the formation of **3** from **1** (1 : 1 MeOH–H_2O) at pH 7 and 12 gave yields of 9 and 15% (performed under low conversion conditions and in which samples received the same UV dose), respectively, consistent with the notion that the QM is more efficiently formed at high pH.

In summary, we have shown that the corresponding *o*-QMs of **1** and **5** can be formed readily in aqueous solution *via* irradiation with UV light. The *o*-QM is formed selectively in all cases, although *m*-QM formation is a possibility. The QM can exist as the free base or in the iminium ion form, which differ in reactivity. The pH of the solvent leads to significant differences in both the lifetime and amount of QM formed, with the QM being longest-lived at pH 7. These results suggest the possibility that **2** can be formed inside biological systems, leading to cell and DNA damage. We believe this to be the first example of the photogeneration of a quinomethane from an important biomolecule (*i.e.* **1**). Since pyridoxal is the active form of pyridoxine, and is known to be extensively hydrated in aqueous solution, we are investigating the possibility of analogous photochemistry for this compound.

We acknowledge support of this research by the Natural Sciences and Engineering Research Council (NSERC) of Canada. D. B. thanks the University of Victoria for a graduate fellowship.

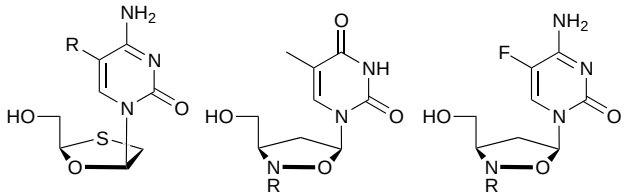
Modified nucleosides from nitrones: a new and efficient stereoselective approach to isoxazolidinyl thymidine derivatives

Pedro Merino,*† Santiago Franco, Natalia Garces, Francisco L. Merchan and Tomas Tejero

Departamento de Quimica Organica, ICMA, Universidad de Zaragoza, Zaragoza, E-50009 Aragon, Spain

The addition of the sodium enolate of methyl acetate to the *N*-benzyl nitrone 4 derived from D-glyceraldehyde affords the 3-substituted isoxazolidin-5-one 6a with a high degree of *syn* selectivity and in quantitative chemical yield; its further elaboration leads to the preparation of the important isoxazolidine nucleoside analogue 2a in enantiomerically pure form.

Nucleoside analogues have aroused a considerable amount of attention because of their biological activity.[1,2] In particular, modified nucleosides, such as lamivudine **1a** and its 5-fluoro derivative **1b** show potent specific, competitive anti-HIV activities.[3] Also, nucleosides **2** and **3** containing an isoxazolidine moiety have been described to have promising



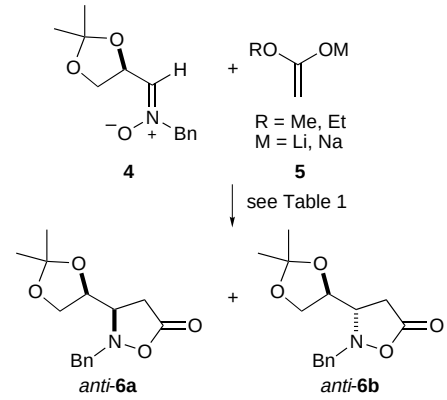
1a R = H **2a** R = Me **3a** R = Me
b R = F **b** R = Bn **b** R = Bn

therapeutic utility in the development of anti-AIDS agents.[4] As a consequence, syntheses of isoxazolidinyl nucleosides of type **2** and **3** have been recently reported.[5,6]

Recent investigations in this laboratory have revealed that chiral α-alkoxy and α-amino nitrones serve as versatile chiral building blocks in the preparation of several naturally occurring nitrogen-containing compounds.[7] Here we present a successful implementation of this strategy directed to the stereoselective synthesis of isoxazolidinyl nucleosides **2**.

The key step of our approach consists of the stepwise addition of an ester enolate to a chiral nitrone in order to construct the isoxazolidine ring. It had been described by Trombini and co-workers that both ketone silyl enol ethers and vinylketene acetals add to nitrones in the presence of trimethylsilyl triflate.[8] Kita and co-workers reported that α-alkoxy nitrones undergo nucleophilic additions with ketene silyl acetals to give the corresponding β-(siloxyamino) esters in good yields and stereoselectivity.[9] With this background in mind we felt that the ready availability of the enantiomerically pure nitrone derived from 1,2-di-*O*-isopropylidene-D-glyceraldehyde[10] and the well-precedented stereodirecting effect of the dioxolane group[7] made **4** an ideal starting material. The addition of nitrone **4** to 1.5 equiv. of the lithium enolate of methyl acetate (LDA and methyl acetate) afforded a 75:25 mixture of diastereomeric isoxazolidinones **6** in 60% isolated yield (Scheme 1).‡

The β-(hydroxyamino) ester was not observed in the crude product and only compounds **6**, coming from an intramolecular cyclization, were obtained. The stereochemistry of the obtained isoxazolidines **6** was ascertained by an X-ray crystallographic analysis of a single crystal of the major diastereomer *syn*-**6a**.§



Scheme 1

The stereochemical outcome of the reaction is in accord with Kita's results[9] and our own previous data concerning the nucleophilic additions to α-alkoxy nitrones.[11] Efforts to improve both the diastereoselectivity and the chemical yield by variation of the counterion and the solvent, plus attempts of stereocontrol of the reaction by addition of a Lewis acid, are summarised in Table 1.

In all cases, sodium enolates afforded the *syn* adduct **6a** as the only product of the reaction (ds ⩾ 95%) in excellent chemical yield (Table 1, compare entries 1–4 with 5, 6 and 9), the solvent only having a slight influence on the chemical yield of the process. Guided by our previous results[11] on nucleophilic additions to **4** we next carried out the reaction in the presence of 1.0 equiv. of diethylaluminium chloride (Table 1, entries 7, 8 and 10). Unfortunately, the chemical yield was rather low (20–25%) in all cases, substantial amounts of starting nitrone being recovered. This behaviour suggests that the Lewis acid used as a pre-complexing agent of the nitrone eliminates the sodium enolate from the reaction mixture by forming the corresponding aluminium enolate, which is unable to react with **4**.

Thus, metal exchange should proceed rapidly at the expense of nucleophilic addition, which proceeds in only 20–25%

Table 1 Stereoselective addition of enolates to nitrone **4**

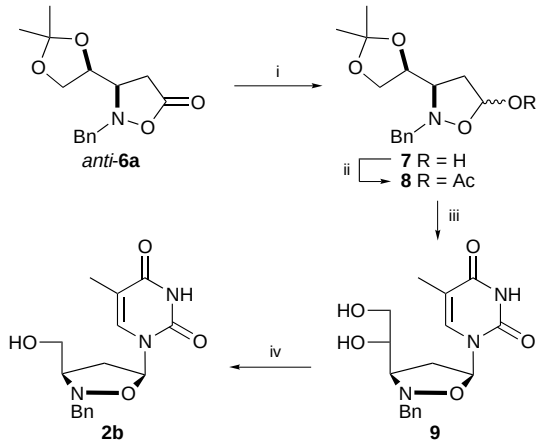

Scheme 2 *Reagents and conditions*: i, DIBAL-H, −80 °C, CH_2Cl_2, 2 h, 80%; ii, Ac_2O, Py, 0 °C, 1 h, 82%; iii, 2,4-bis(trimethylsilyloxy)-5-methylpyrimidine, TMSOTf, CH_2Cl_2, room temp., 2 h, 63%; iv, $NaIO_4$ (aq.), SiO_2, CH_2Cl_2, room temp., 20 min, then $NaBH_4$, MeOH, 0 °C, 90 min, 89%

yield.¶ The lower reactivity of aluminium enolates has been described in nucleophilic additions to imines.[12] A further confirmation of that hypothesis emerged from the fact that an identical result was obtained when nitrone **4** was made to react with the aluminium enolate of methyl acetate prepared *in situ* from methyl acetate and diethylaluminium chloride as described.[13] Nevertheless, despite these adverse results concerning the chemical yield, a reversal of the diastereofacial selectivity was observed (Table 1, entries 7, 8 and 10) and the *anti* isomer **6b** could be fully characterized‡ and used in further transformations.

Treatment of *syn*-**6a** with DIBAL-H in CH_2Cl_2 at −80 °C afforded lactols **7** as a 60 : 40 mixture of anomers. The first order 300 MHz ^{1}H NMR spectrum of the mixture provided unequivocal information on their structures.‖ Acetylation of **7** as described[6] afforded only unreacted starting material when stoichiometric amounts of reagents were used; on the other hand, an excess reagents led to deprotection of the acetonide moiety. If, however, compounds **7** were treated at 0 °C with Ac_2O and pyridine a 76 : 24 mixture of anomeric acetates **8** was formed in 82% combined yield, with the α anomer predominating. Coupling of **8** with 2,4-bis(trimethylsilyloxy)-5-methylpyrimidine[14] using the glycosylation methodology developed by Vörbruggen[15] afforded the N^1-nucleoside **9** as a 22 : 78 mixture of α/β anomers‖ in which the acetonide moiety had been hydrolysed (Scheme 2). The major β isomer (depicted in Scheme 2) was easily separated by column chromatography (100% EtOAc, R_f α-isomer = 0.13, R_f β-isomer = 0.23, visualized with UV at 254 nm). Finally, oxidative cleavage ($NaIO_4$) of the diol unit followed by *in situ* reduction with $NaBH_4$ generated the desired isoxazolidine nucleoside **2b** in good overall yield as summarised in Scheme 2.

As expected from these results, nitrone **4** behaved as an excellent precursor to other related isoxazolidinyl nucleosides, and thus further studies on its reactivity are underway.

This research was supported by MEC (Madrid, Spain). We are grateful to Professor S. Castillon for helpful discussions. One of us (S. F.) thanks the MEC (Madrid, Spain) for a contract.

§ *Crystal data* for **6a**: $C_{15}H_{19}NO_4$, monoclinic, space group $P2_1$, a = 6.011(1), b = 8.039(1), c = 15.598 (2) Å, β = 92.680 (10)°, V = 752.9(2) Å^3, Z = 2, D_c = 1.223 g cm^{-3}, μ = 0.089 mm^{-1}. Of the 1452 unique measured reflections, 1182 with $I \geqslant 2\sigma(I)$ were used in the refinement. R(on F^2) = 3.83, R_w = 9.07. The data were collected on a Siemens P4 diffractometer with graphite monochromated Mo-Kα radiation ω–2θ scan technique (2.61 ⩽ θ ⩽ 23.99). The structure was solved by direct methods using the SHELXS-86 package.[16] All other calculations were accomplished by SHELXL-93.[17] CCDC 182/729.

¶ Similar results were observed with other Lewis acids such as $ZnCl_2$, $ZnBr_2$ or $MgBr_2$. In all cases the yield dropped considerably.

‖ The anomeric configurations were confirmed by ^{1}H NMR (300 MHz) and NOE experiments.

Facile and highly selective monoacylation of symmetric diols adsorbed on silica gel with acetyl chloride

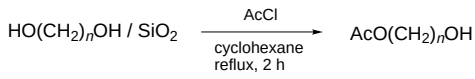
Haruo Ogawa,*[a]† Misa Amano[a] and Teiji Chihara[b]

[a] *Department of Chemsitry, Tokyo Gakugei University, Koganei, Tokyo 184, Japan*
[b] *The Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 351-01, Japan*

Monoacetylated alcohols of symmetric 1,*n*-diols are synthesized quantitatively by refluxing a suspension of the diols adsorbed on silica gel with acetylchloride.

The application of solid adsorbents such as alumina and silica gel as solid supports in organic synthesis affords a new procedure for selective reactions[1] involving oxidation,[2] alkylation,[3] condensation,[4] acetylation[5] and monomethyl esterification.[6] The significant potential of adsorbents is due to the milder reactions conditions and simpler work-up required and the selective organic transformations that they allow. It is important for organic chemists to develop methods that permit the selective protection or functionalization of one functional group of a bi- or multi-functional molecule. Monoprotection of polyols is achieved in some cases by carefully controlled reaction conditions,[7] continuous extraction,[8] the use of silica gel,[9] alumina,[10] phase-transfer catalysts[11] and insoluble polymer supports,[12] or *via* the formation of cyclic compounds.[13] Protection of hydroxy groups by acylation is common in organic syntheses and here we report the facile and highly selective monoacetylation of symmetric diols with acetyl chloride (AcCl) by use of silica gel.

Acetylation of symmetric diols adsorbed on silica gel was performed *via* the following method (adsorption method) (Scheme 1). Alcohols were adsorbed on silica gel (C-200, Wako Chemicals) as follows: 1 g of silica gel was added to a Et_2O solution of the alcohol; solvent was then eliminated under reduced pressure. The obtained solid (adsorption sample) and AcCl were introduced to 50–100 ml of cyclohexane and refluxed for 2 h. The reaction period of 2 h was sufficient for the reaction to reach completion. After the reaction the mixture was filtered and the solid was washed with distilled water and DMF. The washings plus the filtrate were concentrated, and the products were analyzed by GLC with higher hydrocarbons such as dodecane and heptadecane used as an internal standard. The products were spectrometrically identified *via* comparison with the authentic samples.



Scheme 1

The results of acetylation of symmetric diols are listed in Table 1. According to the adsorption method the monoacetylated products of 1,*n*-diols were quantitatively obtained, while in the case of cyclohexane-1,4-diol the products were obtained in lower yield. Even with a larger amount of decane-1,10-diol in the adsorption sample (3.2×10^{-3} mol g^{-1} SiO_2), the same result (quantitative monoacetylation) was observed. This adsorption method is insensitive to the amount of AcCl added, *e.g.* 2.5–20 equiv. of AcCl were effective for the quantitative formation of the monoacetylated alcohol of decane-1,10-diol.

The dependence of selectivity on reaction temperature was investigated in order to improve the selectivity in the reaction of cyclohexane-1,4-diol, which showed the lowest selectivity. Higher selectivity was observed with a decrease in the temperature. Selectivity was improved to 73% at 0 °C, and to 76% at 0 °C in hexane suspension (Table 2). Silica gel is considered to play a role as a protecting reagent for the counterpart hydroxy group of the symmetric diol, which is presumably adsorbed as a monomolecular layer on the surface of silica gel as in the case of the methylation of decan-1-ol on silica gel with CH_2N_2.[14] This explains why a large excess of AcCl yields only the monoacetylated alcohols of 1,*n*-diols. No further evidence has been obtained at the present time, however, this adsorption method should be applicable to the selective monoprotection or monofunctionalization of polyols.

Table 1 Monoacetylation of symmetric diols adsorbed on silica gel[a]

Substrate	Amount of AcCl[b] (in homogeneous reaction) (equiv.)	Yield (%)		Selectivity[c] (%)	Maximum yield in homogeneous reaction[d] (%)
		monoacetate	diacetate		
Butane-1,4-diol	9.0 (2.0)	99.5	0.0	100	52.3
Hexane-1,6-diol	5.0 (7.0)	99.5	0.0	100	58.6
Octane-1,8-diol	1.2 (7.0)	99.8	0.0	100	54.3
Decane-1,10-diol	2.5 (20.0)	99.8	0.0	100	56.5
Decane-1,10-diol[e]	2.5 (20.0)	98.3	1.7	98.3	56.5
Decane-1,10-diol[f]	3.0 (20.0)	99.0	1.0	99.0	56.5
Dodecane-1,12-diol	3.0 (3.0)	99.9	0.0	100	66.5
Hexadecane-1,16-diol	10.0 (5.0)	99.9	0.0	100	30.2
Cyclohexane-1,4-diol	4.0 (4.2)	29.9	40.8	42.7	32.6
trans-Cyclohexane-1,4-diol	4.0 (7.0)	39.9	30.1	50.1	43.1
Benzene-1,4-dimethanol	3.2 (3.0)	36.0	47.5	74.2	52.5

[a] Each experiment was carried out under reflux in cyclohexane for 2 h. Adsorption sample contains 3.2×10^{-4} mol g^{-1} SiO_2. [b] Minimum amount of AcCl. The same results were observed by the use of AcCl in the amount from the minimum to 20 equiv. [c] The value of [yield of the monoacetylated alcohol/(100 − intract diol)] × 100. [d] 2.5×10^{-2} M solution of diols in DMF in the presence of pyridine (1 equiv.). [e] Gas–solid phase reaction at room temperature in the bsence of cyclohexane solvent. [f] An adsorption sample containing 3.2×10^{-3} mol g^{-1} SiO_2 of the alcohol was used.

Table 2 Dependence of the monoacetylation of 1,4-cyclohexanediol on reaction temperature

	Yield (%)		
T/°C	monoacetate	diacetate	Selectivity[b] (%)
80.2 (reflux)	29.9	40.8	42.7
17.0	54.6	41.6	56.8
0.0	52.4	19.3	73.1
0.0[c]	61.4	19.4	76.0

[a] Adsorption sample of cyclohexane-1,4-diol (3.2×10^{-4} mol g^{-1} SiO_2) was used in cyclohexane suspension with 4.0 equiv. of AcCl. Other conditions as in the main text. [b] The value of [yield of the monoacetylated alcohol/(100 − intact diol)] × 100. [c] In hexane suspension.

Chiral dendrimers with backfolding wedges

H. W. I. Peerlings, D. C. Trimbach and E. W. Meijer*†

Laboratory of Macromolecular and Organic Chemistry, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands

Dendritic wedges with a substitution pattern that forces the growth inwards are introduced and the use of this new building strategy is exemplified in the synthesis and chiroptical properties of a chiral dendrimer.

The first reports on the synthesis and properties of dendrimers[1] initiated many studies towards this new class of highly branched macromolecules. A wide variety of synthetic routes have led to the production of a large number of new dendritic structures, even leading to structures that are now commercially available.[2] The branching pattern of many, if not all, of these dendrimers is designed to facilitate the growth of each next generation outwards. As a result, dendrimers can be obtained that possess a highly packed periphery and cavities in the interior, making for example, encapsulation of guest molecules possible.[3] Recently, however, it has been indicated that many of the structures studied so far have a rather flexible conformation, leading to an average density that is not different for interior and periphery. So far, conformational rigidity in these structures has only been found at higher generations of dendrimers.[3–6] Restricted flexibility at lower generations, however, has not been observed before and is of interest for many applications foreseen for dendrimers, *e.g.* molecular recognition and catalysis.[7] Also our search for an optically active chiral dendritic object, which owes its chirality to the presence of constitutionally different wedges attached to a central carbon atom, is hampered by this flexibility.[8] Recently, the enantiomerically pure dendrimer (*S*)-**1** was described (Fig. 1); however, no detectable optical activity was observed.[9] Here, we present the concept of backfolding wedges in the synthesis of dendrimers with restricted flexibility at lower generations. The effect of these wedges is exemplified in a chiroptical study based on the modification of the Fréchet-type poly(benzylether) wedges by changing from a 3,5- to a 2,6-dibenzyloxy substitution pattern.

2,6-Dihydroxybenzoic acid was used as a starting material for the synthesis of both desired backfolding dendritic wedges. The first generation was synthesized starting from a reaction of 2,6-dihydroxybenzoic acid with 3 equiv. of benzylbromide, yielding benzyl 2,6-dibenzyloxybenzoate **2**, which was reduced by a reaction with $LiAlH_4$ to 2,6-dibenzyloxybenzyl alcohol **3** (Scheme 1). Bromination of **3** was accomplished by a reaction with PBr_3, yielding 2,6-dibenzyloxybenzyl bromide **4**, the first generation bromide backfolding dendrimer. For the synthesis of the second generation of bromide backfolding dendritic wedge, first 2,6-dihydroxybenzoic acid was converted into methyl 2,6-dihydroxy benzoate **5** *via* reaction with methyl iodide in DMF in the presence of $NaHCO_3$. In our first approach to backfolding, the normal Fréchet-type dendritic wedge of the first generation was brought into reaction with **5**, yielding **6**. After reduction to the corresponding benzyl alcohol **7**, the desired benzyl bromide **8** was obtained *via* reaction with PBr_3. The crystalline benzyl bromides **4** and **8** proved to be rather acid sensitive and compound **8** even decomposes on standing in a $CHCl_3$ solution.

The effect of the backfolding dendritic wedges was tested in the synthesis of (*S*)-**9**, the conformationally more rigid analogue of (*S*)-**1** (Fig. 1). The assigned conformational flexibility in (*S*)-**1** is based on the chiroptical study, as there is no detectable optical activity in terms of optical rotatory dispersion (ORD), circular dichroism (CD) or optical rotation,[9] and therefore this compound can be referred to as being cryptochiral.[10]

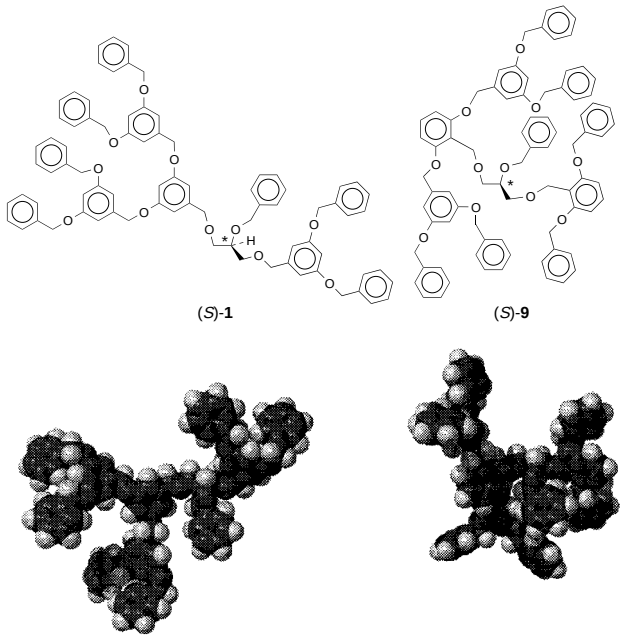

Fig. 1 Modelling study of (*S*)-**1** and (*S*)-**9**

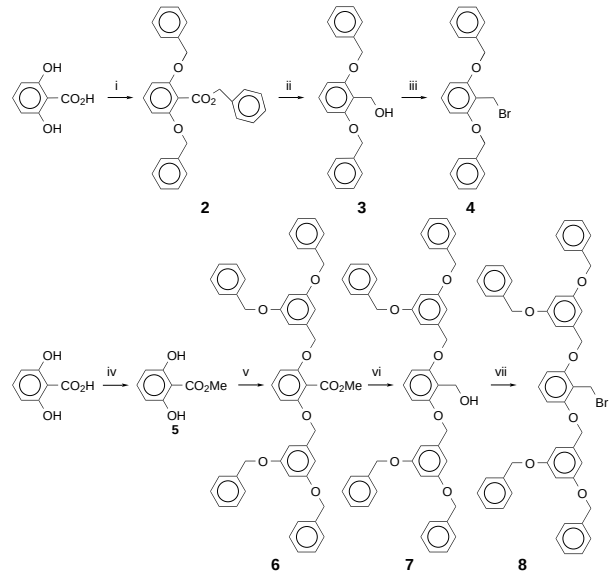
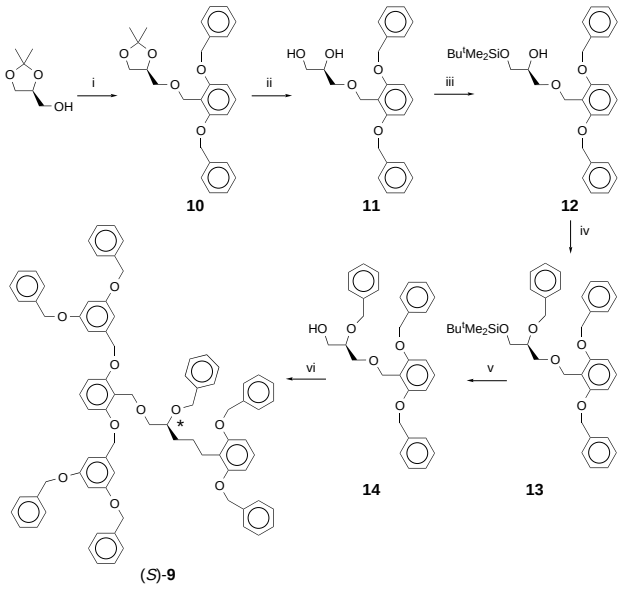


Scheme 1 *Reagents and conditions*: i, BnBr, K_2CO_3, 18-crown-6, acetone; ii, $LiAlH_4$, Et_2O, 65% for two steps; iii, PBr_3, Et_2O, 96%; iv, MeI, $NaHCO_3$, DMF, 77%; v, [G-1]Br, K_2CO_3, 18-crown-6, acetone, 67%; vi, $LiAlH_4$, THF, 75%; vii, PBr_3, Et_2O–THF, 74%



Scheme 2 *Reagents and conditions*: i, **4**, NaH, THF, 98%; ii, TsOH, MeOH, 75%; iii, NaH, Bu^{t}Me$_2$SiCl, THF, 54%; iv, NaH, BnBr, THF, 77%; v, Bu_4NF, THF, 77%; v, **8**, NaH, THF, 68%.

The synthetic approach to chiral dendrimer (*S*)-**9** is similar to the synthesis of (*S*)-**1**, with normal Fréchet-type wedges, as reported before.[9] However, due to the acid-sensitivity of the dendritic wedges the use of strong acidic conditions in the synthetic route had to be circumvented. Enantiomerically pure (*S*)-2,2-dimethyl-1,3-dioxolane-4-methanol [[α_D^{20}] +15.2 (neat, 25 °C)] was used as a starting material for the synthesis of the backfolding dendrimer (*S*)-**9**. The free alcohol functionality was brought into reaction with the first generation of backfolding bromide **4**, yielding **10**. Deprotection of the acetal protecting group was performed under mild acidic conditions, making use of a catalytic amount of toluene-*p*-sulfonic acid in MeOH, leading to diol **11**, which could be obtained as a white crystalline solid. In order to differentiate between the two alcohol functionalities a bulky protecting group was introduced *via* a reaction with NaH and Bu^{t}Me$_2$SiCl. Only the desired monosubstituted product **12** and unreacted product **11** could be obtained after the reaction, which could be separated by washing with hexane (in which only the product dissolved). The free secondary alcohol functionality was reacted with benzyl bromide (the zeroth generation of dendrimer), yielding **13**. Subsequently, the Bu^{t}Me$_2$Si group was removed by reaction with Bu_4NF to yield precursor molecule **14**. In the final step the free primary alcohol functionality of **14** was reacted with the second generation of backfolding bromide **8** in a Williamson synthesis, leading to target molecule (*S*)-**9**. Except for **11**, all chiral compounds were oils that had to be purified using column chromatography. All spectroscopic data are in full agreement with the compounds obtained.‡

Backfolding dendrimer (*S*)-**9** exhibited, in sharp contrast to (*S*)-**1**, an optical activity of $[\alpha]_D^{20}$ +0.8 (*c* = 2.2, CH_2Cl_2). A more thorough study was performed using ORD, UV and CD measurements. For the CD measurements, destilled CH_2Cl_2 was used and spectra were measured at λ = 320–220 nm. A very weak signal was found at λ = 280 nm, at a temperature of 15 °C, indicative of an induced chiral effect. However, at more elevated temperatures (30 °C) this signal vanished, indicating that the conformational flexibility/rigidity can be triggered by temperature. The difference in chiroptical effects for (*S*)-**1** and (*S*)-**9** are proposed to be the result of more conformational rigidity in the latter.

In conclusion, we present the concept of a backfolding dendritic wedge by modifying the branching pattern of Fréchet-type dendritic wedges. The backfolding character of this new type of dendrimers is illustrated in chiral dendrimer (*S*)-**9**, which exhibits optical activity. The chiroptical properties show that when introducing these conceptually new wedges an overall conformationally more rigid structure is obtained. The use of this new type of wedge enables us create more conformational rigidity at low generations, which up to now was only possible at very high generations.

The authors thank The Netherlands Foundation for Chemical Research (SON) and The Netherlands Organization for Scientific Research (NWO) for financial support. DSM Research is gratefully acknowledged for an unrestricted research grant. Sergey Nepogodiev and Peter Ashton are acknowledged for the LSIMS measurement of chiral dendrimer (*S*)-**9**.

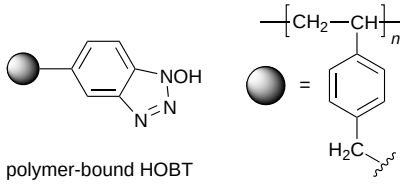
HOBT immobilized on macroporous polystyrene beads: a useful reagent for the synthesis of amides

Kleanthis Dendrinos, Jeannie Jeong, Wei Huang and Aristotle G. Kalivretenos*†

Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore, MD 21250, USA

Polymer-supported 1-hydroxybenzotriazole (P-HOBT), prepared from macroporous polystyrene beads, was used to synthesize amides from primary and secondary amines.

Combinatorial chemistry has led to much research in the use of solid-phase organic synthesis techniques.[1] Polystyrene-supported 1-hydroxybenzotriazole (**P**-HOBT) was originally developed as a highly reactive *N*-acylating agent for the formation of peptide bonds.[2] Ongoing studies in our laboratory are directed at the development of **P**-HOBT as a generally useful acylating agent. We have utilized **P**-HOBT for the synthesis of medium-ring lactams from linear precursors,[3] the preparation of *N*-hydroxysuccinimide (NHS) esters[4] and the carbamate protection of amines.[5] A recent report describes the use of HOBT immobilized on an aminomethylated Merrifield resin for the synthesis of simple amides.[6] We are interested in utilizing **P**-HOBT for the derivatization of naturally occurring amines for improved chromatographic separation and identification properties. The use of HOBT immobilized on Merrifield type polystyrene resins, whose degree of swelling varies greatly depending on the solvent, would limit the variety of solvents utilized for amide formation. Herein, we report the use and advantages of HOBT immobilized on macroporous polystyrene beads for the amide derivatization of amines.



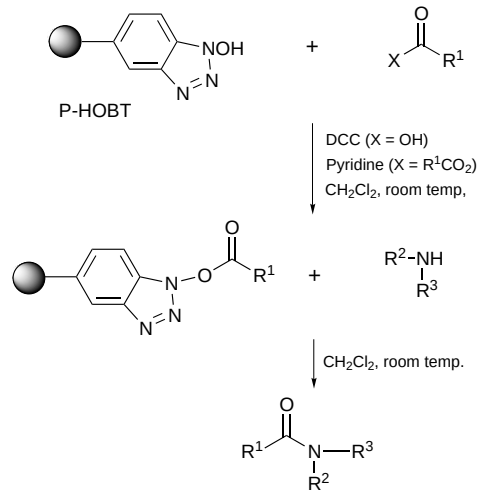
polymer-bound HOBT

We prepared **P**-HOBT using Bio-Rad SM-2 dried macroporous beads (polystyrene–divinylbenzene copolymer resin, 100–200 mesh, MW cutoff 2000) according to the method of Fridkin and Patchornik.[2]‡ We chose to use the macroporous SM-2 beads, designed as a chromatographic support for hydrophobic interaction chromatography, due to their ability to be used in aqueous, as well as organic solvents without swelling or contraction.[7] The number of active sites on the resin was determined by forming the polymer-bound acetate ester, followed by subsequent treatment with isopropylamine (large excess) to yield *N*-isopropylacetamide and recovered polymer. Based on the yield of recovered *N*-isopropylacetamide, three batches of polymer-bound reagent were prepared with activities of 0.27 (**1**) 0.25 (**2**) and 0.25 mmol g^{-1} (**3**), respectively.§ Polymers **1** and **2** were prepared and stored undessicated at room temperature for two years. At this time, both polymers retained *ca.* 90% of their original activity.

With the polymer in hand, the synthesis of a variety of amides was completed, as shown in Scheme 1. Acetamides, benzamides and amides of pyrene-1-carboxylic acid were chosen due to their potential for use as derivatization reagents for naturally occurring amines for improved chromatographic separation and detection properties. In general, the polymer-bound ester was formed by addition of the acid anhydride to the immobilized HOBT group in the presence of pyridine, or by coupling of the free carboxylic acid to the polymer using DCC as catalyst. The solvent in both cases was CH_2Cl_2. After washing the activated resin thoroughly, it was suspended in a solution of CH_2Cl_2 containing 0.8 equiv. of amine based on polymer activity. The reaction mixture was rocked for 4 h at room temperature, at which time filtration of the resin and subsequent concentration of the filtrate yielded the desired amide as the only observable product.¶‖ A summary of these results is given in Table 1. Of particular interest is entry **8**, in which water was used as a co-solvent to enhance the solubility of 6-aminohexanoic acid. The use of water did not have any deleterious effects on overall reactivity or diffusion through the polymer.

We have previously shown the **P**-HOBT reagent to be completely recyclable for the synthesis of NHS esters.[4] Here we have re-used the same batches of **P**-HOBT **2** and **3** for the synthesis of all amides *via* two protocols. The first method involves reactivation of used **P**-HOBT to synthesize amides utilizing the same carboxylic acid partner. Once used, the resin was washed with CH_2Cl_2, Pr^iOH–CH_2Cl_2 and Et_2O to remove any remaining unbound reagents. The washed **P**-HOBT was then reactivated using the carboxylic acid or the acid anhydride as described above, followed by subsequent treatment with an amine to yield the amide product. Alternately, the spent **P**-HOBT was used to synthesize amides utilizing a different acid coupling partner, following a two step reactivation procedure. The used polymer was reacted with a large excess of isopropylamine (based on polymer activity), followed by a rigorous washing protocol, utilizing CH_2Cl_2, Pr^iOH–CH_2Cl_2, DMF, CH_2Cl_2 and Et_2O to yield the clean polymer. The regenerated polymer was subsequently used to prepare amides *via* the general protocol described above.

In summary, polymer-supported HOBT, synthesized from macroporous polystyrene beads, has been utilized for the synthesis of amides from carboxylic acids and primary and



Scheme 1

Table 1 Amide formation utilizing P-HOBT

Entry	Carboxylic acid	Amine	Yield (%)[a]
1	AcOH	Pr^iNH_2	88
2	AcOH	Cyclohexylamine	97
3	AcOH	Piperidine	87
4	AcOH	*n*-Hexylamine	91
5	AcOH	$BnNH_2$	96
6	AcOH	Pr^nNH_2	96
7	AcOH	3-Aminopropan-1-ol	99
8	AcOH	6-Aminohexanoic acid[b]	83
9	AcOH	Pyrrolidine	85
10	AcOH	1,5-Diaminopentane[a]	96
11	BzOH	Pr^iNH_2	83
12	BzOH	Cyclohexylamine	99
13	BzOH	Piperidine	96
14	BzOH	*n*-Hexylamine	94
15	BzOH	$BnNH_2$	86
16	BzOH	Pr^nNH_2	91
17	BzOH	3-Aminopropan-1-ol	63
18	BzOH	Pyrrolidine	77
19	BzOH	1,5-Diaminopentane[c]	72
20	Pyrenecarboxylic acid	Pr^iNH_2	92
21	Pyrenecarboxylic acid	Piperidine	99
22	Pyrenecarboxylic acid	3-Aminopropan-1-ol	79

[a] The amides were recovered as the only product (purity determined by ^1H NMR spectroscopy) and the yields were based on the amount of amine used. [b] DMF–H_2O (70 : 30) used as solvent in place of CH_2Cl_2. [c] Formed *N*,*N*′-diacetyl-1,5-diaminopentane.

secondary amines. The polymeric reagent displays high reactivity, is recyclable and can be used with a variety of solvents, including water. We feel that this reagent provides an efficient and facile pathway to prepare amides in high yields and purity. We are currently utilizing this method for the derivatization of amines from biological sources, and for the preparation of small molecule amide libraries.

‡ *Immobilization of HOBT on polystyrene beads* (ref. 2): A suspension of 3-nitro-4-chlorobenzyl alcohol (5.01 g, 26.7 mmol), dried BioRad SM-2 macroporous beads (5.00 g, polystyrene–divinylbenzene copolymer resin, 100–200 mesh, MW cutoff 2000, Bio-Rad Laboratories) and anhydrous $AlCl_3$ (5.01 g, 37.6 mmol) in 30 ml of nitrobenzene was heated at 65–70 °C for 3 days. The suspension was cooled to room temperature and filtered. The polymer was then washed with a solution of 1 M HCl in dioxane (3 × 25 ml), DMF (3 × 25 ml), MeOH (3 × 25 ml) and CH_2Cl_2 (3 × 25 ml), and finally dried *in vacuo*. The 3-nitro-4-chloro benzylated polystyrene was heated to reflux in a mixture of hydrazine monohydrate and ethylene glycol monoethyl ether (4 : 6, v/v; 30 ml) for 20 h. The reaction mixture was cooled to room temperature and the polymer was filtered and washed with H_2O (3 × 25 ml) and CH_2Cl_2 (3 × 25 ml). The polymer was resuspended in a mixture of concentrated aq. HCl and dioxane (1 : 1, v/v; 50 ml) and the suspension was heated at reflux for 20 h. At this time, the polymer was filtered and washed with H_2O (5 × 50 ml), MeOH (3 × 50 ml) and Et_2O (3 × 25 ml), and finally dried *in vacuo* at room temperature to yield 4.90 g of **P**-HOBT.

§ *Assay of hydroxy group content in P-HOBT* **2**: To a suspension of **P**-HOBT **2** (0.450 g) in CH_2Cl_2 (5 ml) was added Ac_2O (0.32 g, 0.30 ml, 3.1 mmol) and pyridine (0.20 g, 0.20 ml, 2.5 mmol). The suspension was subsequently rocked for 1 h at 25 °C. At this time, the polymer was filtered, washed with CH_2Cl_2 (25 ml), DMF (2 × 40 ml), CH_2Cl_2 (3 × 25 ml) and anhydrous Et_2O (3 × 25 ml). The polymer was re-suspended in CH_2Cl_2 (5 ml) followed by the addition of isopropylamine (0.208 g, 0.300 ml, 3.52 mmol). The suspension was rocked at 25 °C for 3.5 h. The polymer was then filtered and washed with CH_2Cl_2 (3 × 25 ml). The filtrate and washings were combined and concentrated to yield 0.0113 g of *N*-isopropyl acetamide as a clear oil. This gave an activity of 0.248 mmol g^{-1} for **P**-HOBT **2**. All other polymers were tested in this fashion.

¶ *Typical experimental procedure for the synthesis of amides:* A suspension of **P**-HOBT **2** (0.33 g, 0.25 mmol g^{-1}, 0.083 mmol), Ac_2O (0.026 g, 0.024 ml, 0.25 mmol, 3.0 equiv.) and pyridine (0.021 g, 0.021 ml, 0.26 mmol, 3.2 equiv.) in CH_2Cl_2 (10 ml) was rocked for 1 h at 25 °C. At this time, the polymer was filtered, washed with DMF (2 × 10 ml), CH_2Cl_2 (3 × 10 ml) and anhydrous Et_2O (3 × 10 ml). The polymer was resuspended in CH_2Cl_2 (10 ml) followed by the addition of 3-aminopropan-1-ol (0.0051 g, 0.0052 ml, 0.068 mmol, 0.82 equiv. based on **P**-HOBT **2**). The suspension was rocked at 25 °C for 3.5 h. The polymer was then filtered and washed with CH_2Cl_2 (3 x 15 ml). The filtrate and washings were combined and concentrated to yield 0.0079 g (99%) of *N*-acetyl-3-aminopropan-1-ol as a white solid.

‖ All other amides were formed in an analogous fashion as *N*-acetyl-3-aminopropan-1-ol. The ^1H NMR and mass spectral data of all of the prepared compounds were consistent with the expected structures.

A weak adsorption state of CO, characterized by extremely high binding energy photoemission features, was formed on samarium oxide film prepared in UHV.

Molecule/surface interactions on metal oxides are of interest owing to the importance of metal oxides in catalysis. A number of investigations of the chemisorption properties of metal oxides have been carried out under ultrahigh vacuum (UHV) conditions.[1] Little work, however, has dealt with molecular adsorbates on rare earth oxide surfaces,[2,3] since it is difficult to obtain well defined surfaces of such materials. In order to investigate the chemisorption property of a rare earth oxide in detail with surface science techniques, we prepared a samarium oxide (SmO_x) film in UHV. Here, we report the interaction of CO with the surface of the SmO_x film, using ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS) and temperature programmed desorption (TPD).

All experiments were performed in a commercial UHV apparatus (ESCALAB Mark II) with a base pressure of $< 1 \times 10^{-8}$ Pa. The SmO_x film was prepared in the UHV system by oxidizing a Sm overlayer, which was vapor-deposited on a Ru(001) single crystal sample (*ca*. 10 mm diameter and 1 mm thickness). Since the SmO_x films obtained here completely covered the Ru(001) surface, we did not have to take into account any effect of the Ru surface or the Ru/SmO_x interface on CO adsorption. UP and XP spectra were recorded at *ca*. 105 K using He II and Al-Kα radiation, respectively.

Fig. 1(*a*) shows the UP spectrum for the SmO_x film on Ru(001), which was prepared by repeating cycles of Sm deposition at 300 K and heating to 800 K in O_2 (*ca*. 10^{-5} Pa). The thickness of the SmO_x film was determined to be *ca*. 4.5 nm from the attenuation of Ru 3d signal intensity. Fig. 1(*b*) was recorded after the surface was saturated with CO at *ca*. 105 K. The difference spectrum, (*b*) − (*a*), shows the appearance of a pair of peaks at *ca*. 11.8 and 14.3 eV below E_F. These two peaks disappeared after heating to 150 K and desorption of CO was observed at *ca*. 125 K in TPD measurements at a heating rate of 5 K s^{-1}. These results suggest that the two observed peaks are attributed to CO species, which adsorbs weakly on the SmO_x surface. Supposing a first-order desorption, the activation energy of desorption of *ca.* 31 kJ mol^{-1} was obtained for this CO species from the desorption temperature of 125 K and a frequency factor of 10^{13} s^{-1}.

As shown in Fig. 1(*e*), two peaks at *ca*. 8.0 and 11.0 eV were observed for CO on the Ru(001) surface, which have been assigned to 5σ/1π and 4σ emissions, respectively.[4] The binding energies of the two peaks from CO on SmO_x are remarkably larger than those of CO on Ru(001) as well as on other metal surfaces. Similar very high binding energy features have been reported for CO on a partially reduced Cr_2O_3(111) surface.[5] This CO species interacts weakly with chromium atoms, and was not observed on a completely oxidized Cr_2O_3(111) surface. The higher binding energies of photoemissions compared with those of CO on metal surfaces were explained by σ bonding between CO and chromium atoms without π* back-donation, which plays an important role in CO adsorption on most metal surfaces. The bonding character of this distinct CO species is essentially different from that of CO on a metal surface.

Fig. 1(*c*) and (*d*) were recorded for an Ar^+-ion-bombarded SmO_x surface before and after CO adsorption, respectively. In the difference spectrum, (*d*) − (*c*), two peaks also appear, at *ca*. 11.8 and 14.3 eV. The intensities of these two peaks are apparently larger than those observed in (*b*) − (*a*) for the non-bombarded surface, suggesting that the Ar^+-ion-bombardment of the surface caused an increase in the number of CO adsorption sites. An explanation for this result is that the adsorbed CO molecules interact with defect sites, which are likely to increase for the rough ion-bombarded surface.

According to a previous report for a TiO_2 surface,[1] the lower part of the valence band (*ca*. 4 eV below E_F) is mostly composed of non-bonding 2p orbitals of oxygen in the oxide. Comparing Fig. 1(*c*) with (*a*), the non-bonding O 2p peak decreases in intensity significantly as a result of the ion bombardment. This fact suggests that the population of the oxygen atoms located at the SmO_x surface, which are less coordinated compared with bulk oxygen atoms, are reduced by the ion bombardment. Therefore, the ion-bombarded surface has a number of oxygen vacancy defect sites, where samarium

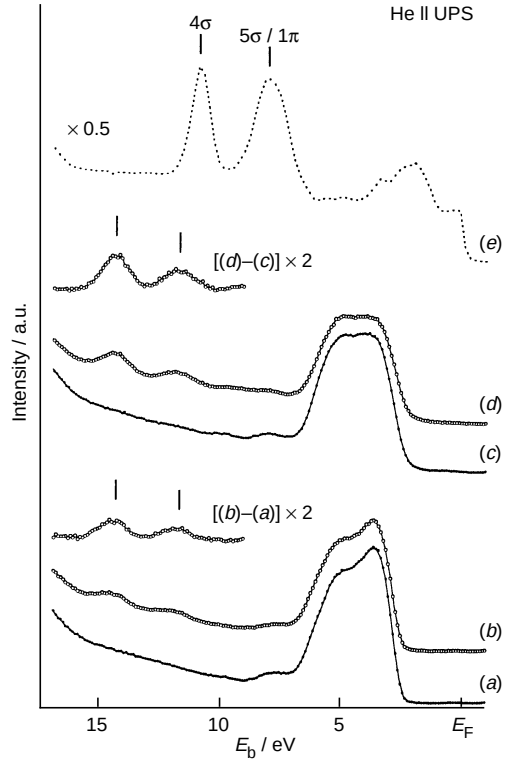

Fig. 1 He II UP spectra recorded on a SmO_x film surface (*a*) before and (*b*) after saturating with CO at *ca*. 105 K and on the Ar^+ ion bombarded SmO_x surface (*c*) before and (*d*) after saturating with CO. Spectrum (*e*) was recorded for CO on Ru(001).

atoms are exposed and probably exhibit an ability to bond to CO.

Fig. 2(*a*) and (*b*) show XP spectra in the O 1s region, which were recorded on a SmO_x film before and after CO adsorption at *ca*. 105 K, respectively. The main O 1s peak at *ca*. 529.6 eV is due to oxygen atoms in the SmO_x film. Comparing the peak area of this O 1s feature with that of Sm 3d, we obtained the stoichiometry of SmO_x : *ca*. 1.44 for *x*. This result is consistent with a previous report for the oxidation of a Sm metal surface by O_2 exposure in UHV system, where Sm_2O_3 was obtained.[6] The difference spectrum (*b*) − (*a*) has a small peak at *ca*. 537.8 eV. Since this O 1s feature disappeared after heating the sample to 150 K, it can be attributed to the weakly adsorbed CO species described above. The binding energy of this O 1s feature is much larger than that of CO on most metal surfaces, as well as those of the valence level emissions. Additionally, a high binding energy feature of C 1s was also observed at *ca*. 291.8 eV for this CO species. These higher binding energies must result mainly from poor screening of the holes induced by photoemission processes, and suggest a lack of π* back-donation and a very weak interaction of CO with the SmO_x surface.

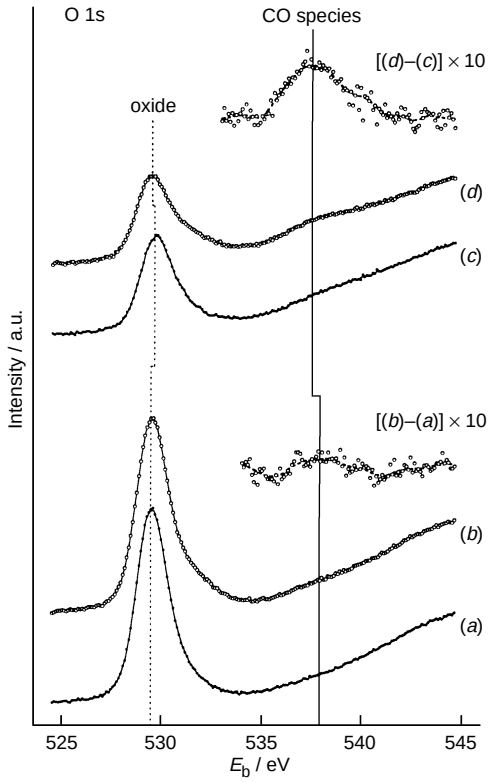

Fig. 2 O 1s XP spectra recorded on a SmO_x film prepared by oxidation of Sm with O_2, (*a*) before and (*b*) after saturating with CO at *ca*. 105 K and on the SmO_x film, which was prepared by oxidation of Sm with CO, (*c*) before and (*d*) after saturating with CO

Fig. 2(*e*) was recorded on a SmO_x film which was prepared by the reaction of deposited Sm with CO in UHV. In this spectrum, the O 1s feature at *ca*. 529.6 eV is obviously smaller than that in Fig. 2(*a*) for the SmO_x produced by O_2 exposure, although the amounts of deposited Sm were almost the same (*ca*. five monolayers). For this CO-produced SmO_x film, which probably consists of the corresponding amount of carbon as a component, the stoichiometry was determined to be *ca*. 0.73 for *x*. It is expected that the CO-produced SmO_x film has a larger number of exposed Sm atoms on the surface than the O_2-produced SmO_x film.

Fig. 2(*d*) was recorded on the surface of this SmO_x film after exposure to CO at *ca*. 105 K. In this spectrum, a more intense O 1s feature at *ca*. 537.6 eV was observed than in Fig. 2(*b*). Comparing the O 1s peak area with that of a saturated CO layer on Ru(001), the coverage of CO observed here was estimated to be *ca*. 0.2 with respect to the Ru(001) substrate. The SmO_x film produced by CO exposure has a larger number of weak CO bonding sites than that produced by O_2 exposure. This result also supports the fact that the weakly bound CO species interact with samarium atoms at oxygen vacancy defect sites.

With respect to the catalytic abilities of rare earth oxides for CO hydrogenation, Sakata *et al.* have studied CO adsorption on a practical Sm_2O_3 catalyst, using *in situ* IR spectroscopy.[7] They have reported that CO chemisorbed reactively on a Sm_2O_3 surface to form several types of species, which were also detected on other rare earth oxides.[8] On the other hand, under UHV conditions, no CO chemisorption was observed on rare earth oxide films[2] or single crystal surfaces of a rare earth oxide[3] at room temperature. The characteristic weak adsorption state of CO observed here on the SmO_x surface was not stable at room temperature under UHV condition. Under atmospheric pressure, however, it may be possible that this CO species becomes a precursor of the species such as those reported by Sakata *et al.*, or plays other important roles in catalytic reactions.

Synthesis and extraction studies of 1,2- and 1,3-disubstituted butylcalix[4]arene amides with oxyions; geometric and conformational effects

Olusegun M. Falana,[a] H. Fred Koch,[a] D. Max Roundhill,*[a] Gregg J. Lumetta[b] and Benjamin P. Hay[b]

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, USA
Pacific Northwest National Laboratory, P.O. Box 999, Richland, Washington 99352, USA

26,28-(Dibutylcarbamoyl)methoxy-5,11,17,23-*tert*-butylcalix[4]arene and two geometric isomers of 27,28-(dibutylcarbamoyl)methoxy-5,11,17,23-*tert*-butylcalix[4]arene have been used to extract U^{VI}, Mo^{VI}, Cr^{VI} and Se^{VI} from aqueous solution into toluene or isooctane.

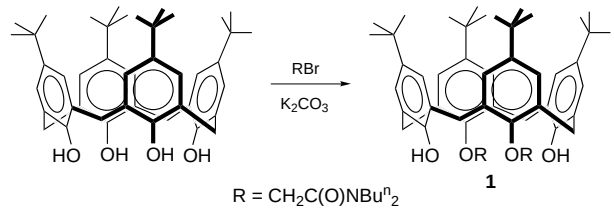
The selective extraction of metal cations and anions from aqueous solution into an organic phase is an important goal, especially if the particular ions are toxic and present in the environment in significant quantities.[1,2] Three such metals are uranium,[3] chromium[4–10] and selenium,[11] all of which exist primarily in their hexavalent forms. Although there is considerable diversity between these species there are also some similarities. The main difference is that whereas Se^{VI} and Cr^{VI} are anions in strongly acidic solution, U^{VI} is a cation. An important similarity, however, is that these species are high valent oxophiles, and an amide functionality can potentially act as a complexant for each of these species. This premise is based on the logic that such a functionality should not only coordinate as a hard N,O-donor ligand to such high-valent centers, but should also function as a neutral host to hydrogen bond with the protonated form of the oxyanion.

In developing extractants it is important to target specific solvent systems as well as complexants. Although in earlier work with calix[4]arenes we have used chloroform as the organic phase,[12–19] we have always been aware that it would be advantageous to use a less toxic organic such as an alkane. We have now prepared the geometrically isomeric 1,2- and 1,3-calix[4]arene amides having appended *n*-butyl substituents in order that they can be more compatible with such an alkane phase. In addition to solvent selectivity, the effect of both geometric and conformational properties of the complexant needs also to be considered. Since the 1,2 isomer has been obtained as a separable mixture of geometric isomers, the availability of such a pair of isomers affords us the opportunity to compare their relative extraction properties.

These three new calix[4]arene amides have been synthesized using the same general procedures.[20] The precursor compound *N*,*N*-dibutyl-2-bromoacetamide has been synthesized in 82% yield by stirring a mixture of bromoacetic acid and *N*,*N*-dibutylamine in dichloromethane with 1,3-dicyclohexylcarbodiimide for 12 h.

The synthetic route of the calix[4]arene amides involves reacting 5,11,17,23-*tert*-butylcalix[4]arene with *N*,*N*-dibutyl-2-bromoacetamide (2.2 equiv.) in the presence of a base. For the case of 26,28-(dibutylcarbamoyl)methoxy-5,11,17,23-*tert*-butylcalix[4]arene **1** the conditions use potassium carbonate in refluxing acetone for 18 h (Scheme 1), and for the two isomers of 27,28-(dibutylcarbamoyl)methoxy-5,11,17,23-*tert*-butylcalix[4]arene (**2**, **3**), sodium hydride in DMF at 60 °C for 26 h is used (Scheme 2). Compounds **2** and **3** were obtained in the same reaction mixture and separated by column chromatography.

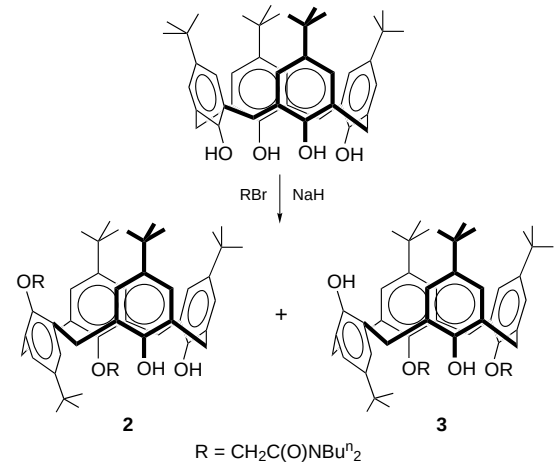
These compounds have been structurally characterized by NMR spectroscopy. Compound **1** (yield 65%; mp 130–132 °C) is characterized as being in the cone conformation by the presence of a single triplet resonance in the ^{1}H NMR spectrum



Scheme 1

due to the NCH_2 group at δ 3.36, a singlet at δ 4.81 due to $OCH_2C(O)$ and an AB pair for the bridging methylenes at δ 3.27 and 4.46 [^2J(HH) 13 Hz]. The $^{13}C\{^1H\}$ NMR spectrum shows the amide carbonyl resonance at δ 168.0. Compound **2** (yield 9.0%; mp 130 °C) is characterized as being in the partial cone conformation with the bis-(dibutylcarbamoyl)methoxy groups on opposite rims by the presence of a multiplet resonance due to NCH_2 groups at δ 3.21–3.42, two inequivalent singlets at δ 5.24 and 5.29 due to the pair of $OCH_2C(O)$ groups, and two sets of AB pairs for the inequivalent bridging methylenes at δ 4.34 and 4.96 [^2J(HH) 13 Hz], and at δ 4.68 and 4.70 [^2J(HH) 14 Hz]. The $^{13}C\{^1H\}$ NMR spectrum shows the amide carbonyl resonance at δ 170.0. Compound **3** (yield 9.6%; mp 174–175 °C) is characterized as being in the partial cone conformation with the bis-(dibutylcarbamoyl)methoxy groups on the same side of the upper rim by the presence of a multiplet resonance due to the NCH_2 group at δ 3.39–3.49, a singlet for $OCH_2C(O)$ at δ 4.98, along with two sets of AB pairs for the inequivalent bridging methylenes at δ 3.41 and 4.63 [^2J(HH) 13 Hz] and at δ 3.43 and 4.37 [^2J(HH) 14 Hz]. The OH resonances are found at δ 9.76 and 10.48. The $^{13}C\{^1H\}$ NMR spectrum shows the amide carbonyl resonance at δ 169.0. Both the ^{1}H NMR and ^{13}C NMR spectra show additional corresponding resonances for the other functional groups in these structures of **1**–**3**.

Extraction studies have been carried out with isooctane and toluene, along with the compounds **1**, **2** and **3** (1 mM solutions of each), and aqueous solutions of the metal salts (1 mM in



Scheme 2

Table 1 Extraction of oxyions by **1**, **2** and **3**

Compound	Solvent	Extraction (%)[a]			
		UO_2^{2+}	MoO_3(aq)	$Cr_2O_7^{2-}$	$HSeO_4^-$
1	Toluene	3	< 1	20(2)[b]	1
	Isooctane	31(3)	20(2)	< 1	< 1
2	Toluene	13(1)	7(1)	20(2)	11(1)
	Isooctane	25(2)	20(2)	< 1	< 1
3	Toluene	14(1)	< 1	32(3)	13(1)
	Isooctane	39(4)	40(4)	< 1	15(1)

[a] Extractions were carried out by vigorous shaking for 1 min with both the calix[4]arene and the metal salt as 1 mM solutions. The aqueous solution is at pH 0.85. [b] The initial and final metal concentrations were measured by ICP and the errors are estimated from multiple measurements.

0.14 M HNO_3). Equal volumes of the organic and aqueous solutions are then shaken for 1 min. The resultant aqueous layer is then separated and the remaining metal concentration in that layer analyzed by ICP. These data with estimated errors in parentheses are collected in Table 1. From these data it is apparent that the oxyions can be extracted into toluene or isooctane from an aqueous solution at pH 0.85 in the presence of these three hydrophobic calix[4]arene amides. These data also show differences between both these two solvents and the isomers of **1**, **2** and **3**. Although these data may not represent equilibrium conditions, they are viable because for an extractant to be useful the phase transfer of the species must be rapid, therefore these data reflect this property. From these preliminary data with these compounds it appears that both UO_2^{2+} and molybdenum trioxide have a slight preference for isooctane over toluene, with the reverse trend being observed for the two oxyanions. The differences between **1**, **2** and **3** are less apparent, but it does appear that there may be a preference of **3** being an extractant for transferring these oxyions into isooctane. Interestingly, this particular isomer is the one that has the amides in a potentially chelating geometry, with a hydrophobic *tert*-butyl group projecting into this lower rim binding cavity. Further use of these compounds as extractants will be reported in due course.

We thank the US Army Research Office and the US Department of Energy, through the Pacific Northwest Laboratory, for financial support.

Optical limiting properties of a pentanuclear 'open' structural inorganic cluster have been studied with 7 ns laser pulses of 532 nm wavelength; the limiting threshold of the cluster $[WS_4Cu_4(SCN)_2(py)_6]$ is 0.3 J cm^{-2}, which is about five times better than that observed in C_{60}.

Optical limiting materials are substances whose transmission is high when they are illuminated by low-intensity light but low when exposed to intense laser radiation. Because of their potential applications in the protection of optical sensors from high-intensity laser beams, the search for better optical limiting materials has become increasingly intensive. The most frequently reported materials are fullerenes (C_{60})[1,2] and phthalocyanine complexes,[3,4] which are generally regarded as the best compounds for optical limiting. Recently, large non-linear optical effects have also been found in inorganic clusters.[5–22] The structures of these clusters vary widely, they include butterfly-shaped clusters,[6] trinuclear linear clusters,[7] nest-shaped clusters,[8–10] 'half-open' cubane-like clusters,[11,12] cubane-like clusters,[13–16] hexagonal prism-shaped clusters,[17,18] twin-nest-shaped clusters[19,20] and twenty-nuclear supracage-shaped cluster.[21]

A good optical-limiting material should possess strong limiting responses to ns laser pulses in the visible and near-IR spectral regions. This is because the most likely encountered powerful light sources are Q-switched Nd : YAG lasers. In this regard, the optical limiting properties of cubane-like clusters and hexagonal prism-shaped clusters have been found to be the best amongst all the clusters studied, with limiting threshold in the order of *ca.* 0.1 J cm^{-2}.[13–15,17] This is comparable to those of phthalocyanine derivatives and better than that of C_{60}.[2,3] However, such performances were achieved under the single-shot condition; and when the pulse repetition rate exceeded 1 Hz, photodegradation occurred.[13] To overcome this problem, we have investigated different structural types of inorganic clusters. Here, we report the observation of superior limiting behavior in a pentanuclear 'open' structural cluster $[WS_4Cu_4(SCN)_2(py)_6]$ with a pulse repetition rate of up to 10 Hz.

The preparation of the cluster $[WS_4Cu_4(SCN)_2(py)_6]$ was reported elsewhere.[23,24] We obtained the cluster $[WS_4Cu_4(SCN)_2(py)_6]$ by the reaction of $[NH_4]_2WS_4$, CuSCN and KSCN with py. The structure was identified from IR spectra, elemental analysis and unit cell parameters.† The cluster has an 'open' structure with five metal atoms (one W and four Cu atoms) in the same plane. Four S–S edges of the tetrahedral WS_4^{2-} core are coordinated by four Cu atoms, giving a WS_4Cu_4 aggregate of approximate D_{2h} symmetry, as shown in the inset of Fig. 1. Its electronic spectrum in Fig. 1 illustrates that there is a relatively low linear absorption in the visible and near-IR region. A broad transparent range is an important criterion in the assessment of optical limiting materials.

Fig. 2 displays measurements of optical limiting effects in a DMF solution of $[WS_4Cu_4(SCN)_2(py)_6]$‡ with 532 nm laser pulses of 7 ns duration. The transmittance defined here is the ratio of the transmitted pulse energy to the incident pulse energy at 532 nm. It is obvious that the solution transmittance is independent of the incident fluence at < 0.1 J cm^{-2}. (The linear transmittance is 63%, which includes the Fresnel reflection losses of the two surfaces of the cell. If the surface losses are excluded, the transmittance of the solution is 69%.) When the

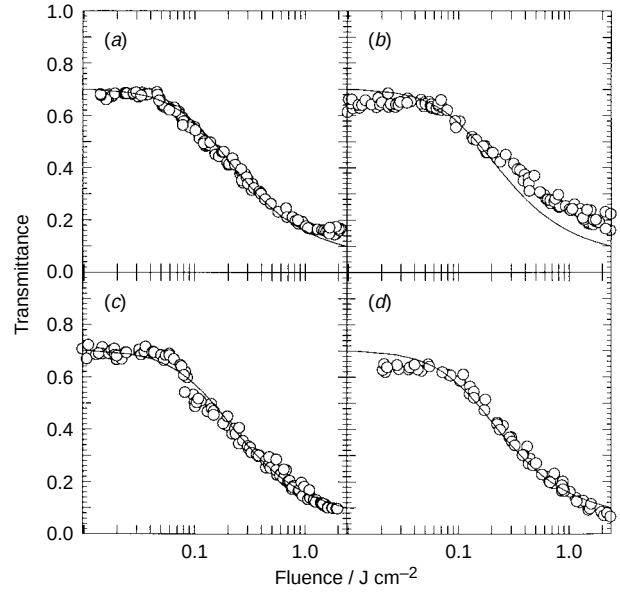

Fig. 2 Energy dependent transmittance of a $[WS_4Cu_4(SCN)_2(py)_6]$ DMF solution (1.1×10^{-3} M). Optical path: 1 mm; laser wavelength: 532 nm; pulse duration: 7 ns; and repetition rates: (*a*) 10, (*b*) 5, (*c*) 1 Hz and (*d*) single shots (30 s interval)

Table 1 The limiting thresholds of compounds measured at 532 nm with ns laser pulses

Compound	Solvent	Linear transmission (%)	Limiting threshold/ J cm^{-2}	Ref.
C_{60}	Toluene	62	1.6	2
$[NBu^n_4]_3[WCu_3Br_4S_4]$	MeCN	70	1.1	15
$[NBu^n_4]_3[WAg_3Br_4S_4]$	MeCN	70	0.6	15
$[NBu^n_4]_3[WAg_3BrI_3S_4]$	MeCN	70	0.5	15
$[NBu^n_4]_3[WAg_3BrCl_3S_4]$	MeCN	70	0.6	15
$[WS_4Cu_4(SCN)_2(py)_6]$	DMF	69	0.3	This work
Phthalocyanine derivatives	Toluene	85	≈0.1	3, 4
$[Mo_2Ag_4S_8(PPh_3)_4]$	MeCN	92	≈0.1	17

incident fluence exceeds 0.1 J cm^{-2}, the solution transmittance decreases as the incident fluence is increased, thus exhibiting a typical optical limiting effect. The limiting threshold is defined as the incident fluence at which the solution transmittance falls to 50% of the linear transmittance. From Fig. 2, we determine the limiting threshold of the $[WS_4Cu_4(SCN)_2(py)_6]$ DMF solution to be *ca.* 0.3 J cm^{-2}.

Fig. 2 also displays the optical limiting performance of the cluster measured with the pulse repetition rate ranging from single shots to 10 Hz. Within our experimental errors, no significant difference is found among these measurements, thereby indicating that the photostability of $[WS_4Cu_4(SCN)_2(py)_6]$ is considerably better compared to the cubane-like and hexagonal prism-shaped clusters.[13–15,17]

It is interesting to compare this new cluster with other well known optical limiting materials for 7 ns pulsed radiation of 532 nm wavelength. Table 1 shows the limiting thresholds of the cluster $[WS_4Cu_4(SCN)_2(py)_6]$, cubane-like clusters, hexagonal prism-shaped clusters, C_{60} and phthalocyanine derivatives. It is clear that the limiting performance in the $[WS_4Cu_4(SCN)_2(py)_6]$ DMF solution is five times better than that displayed in C_{60} and three times higher than that in phthalocyanine derivatives. It should be emphasized, however, that the Q absorption band in phthalocyanine derivatives makes them narrow-band limiters, while the spectrum of $[WS_4Cu_4(SCN)_2(py)_6]$ shown in Fig. 1 indicates that the new cluster should be a broad-band limiter.

It should be pointed out that our measurement of the transmitted pulse energy was conducted with a full collection of the transmitted pulse, and no aperture was used. Therefore, the observed optical limiting originates from a non-linear absorptive process. The limiting mechanism in cubane-like clusters has been studied in detail.[15] The initial linear absorption promotes electrons from the ground to an excited singlet state. These excited electrons are transferred to the lowest triplet state mainly by a process of ionization and germinate recombination. If the absorption cross-section of the triplet state is greater than that of the ground state, then reverse saturable absorption occurs, resulting in the optical limiting effect.

We have found that this non-linear process can be approximately expressed by[15]

$$T = \frac{(1-R)^2 \exp(-\alpha L)}{\sqrt{1 + B[1-\exp(-\alpha L)]F_{in}^2}}$$

where T is the transmittance, R is the reflectance of the cell surface, L is the optical path, α is the linear absorption coefficient, F_{in} is the incident fluence, and B is a parameter determined by the product of the lifetime and ionization cross-section of the excited singlet state, the absorption cross-section of the excited triplet state, and the probability of the germinate recombination. The solid curves in Fig. 2 are calculated by this expression with $B = 4.3 \times 10^4$ cm^4 J^{-2}. Nearly perfect fits indicate that the optical limiting in the cluster is caused by the absorption of the excited triplet state whose population is generated mainly by the process of ionization and germinate recombination.

This research was supported by the National Natural Science Foundation of China, the Hong Kong Research Grants Council, the University of Hong Kong, and the National University of Singapore.

† IR spectra: ν(W–S_{br}), 435 cm^{-1}; ν(SCN), 2081 cm^{-1}; ν(py), 1595, 1441, 752, 695 cm^{-1}. Anal. Calc. for $C_{32}H_{30}Cu_4N_8S_6W$: C, 33,22; H, 2.61; Cu, 21.97; N, 9.68; W, 15.9. Found: C, 33.00; H, 2.40; Cu, 21.78; N, 9.80; W, 16.3%. The cluster is orthorhombic, space group *Pbcn* (no. 60) with a = 19.786(2), b = 13.629(2), c = 15.080(2) Å.

‡ The optical limiting effects were observed with 532 nm wavelength laser pulses of 7 nanosecond duration. The laser pulses were produced by a frequency-doubled, Q-switched Nd:YAG laser operated with multiple axial modes. The pulse energy was spatially filtered to be a nearly Gaussian profiles and then was split into two parts: one was used as a reference for the incident energy and the other was focused onto the sample. The sample was a solution of $[WS_4Cu_4(SCN)_2(py)_6]$ dissolved in DMF (1.1×10^{-3} M) and contained in a 1 mm thick quartz cell. Both incident and transmitted pulse energy were measured with two pyroelectric probes (RjP-735, Laser Precision), simultaneously. The measurements were conducted over *ca.* 8 h.

Novel reactivity of photoexcited iron porphyrins caged into a polyfluoro sulfonated membrane in catalytic hydrocarbon oxygenation

A. Maldotti,* A. Molinari, L. Andreotti, M. Fogagnolo and R. Amadelli

Dipartimento di Chimica, Centro di Studio su Fotoreattività e Catalisi del CNR, Università degli Studi di Ferrara, Via L. Borsari 46, 44100, Ferrara, Italy

Heterogenization of iron porphyrins inside Nafion creates new photocatalytic systems which can be used to oxidize cyclohexene and cyclohexane with sunlight and O_2 under mild conditions (room temperature, atmospheric pressure); the polymeric matrix makes the iron porphyrin a good photocatalyst for the monooxygenation of the substrate and increases both its photocatalytic efficiency (about ten times) and its stability (turnover values > 1000).

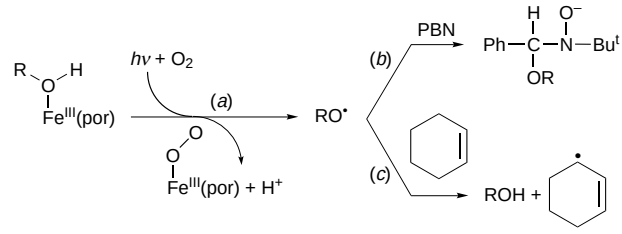
As a development of an important field of research dealing with photoexcited iron porphyrins in the catalytic oxygenation of hydrocarbons,[1] we have recently investigated photocatalytic composite systems in which the porphyrin complexes are confined inside cross linked polystyrene,[2] bound on semiconducting transition metal oxides such as TiO_2[3] or interacting with polyoxotungstates.[4] Generally speaking, the use of heterogeneous media or organized systems is a suitable means to control the reaction environment in order to promote specific processes of interest in biomimetic catalysis by iron porphyrins.[5]

This work deals with composite systems in which iron porphyrin complexes are caged inside Nafion,[6] a commercial polyfluorosulfonated membrane consisting of sulfonic groups connected to a polymeric structure of polytetrafluoroethylene. We have chosen this support because (*i*) it is chemically inert also in strong oxidizing media; (*ii*) it is totally transparent to the light of interest in metal porphyrin photochemistry; (*iii*) it is expected to cage the monocationic porphyrin complexes inside its large anionic cavities where the SO_3^- groups are located; and (*iv*) dioxygen concentration inside Nafion is more than ten times higher than in organic solvent.[7]

The photocatalytic activity of these composite systems is demonstrated in the oxygenation of cyclohexene and cyclohexane by O_2 and sunlight under mild conditions (20 °C, 760 Torr of O_2). A comparison with the photocatalytic properties of the same iron porphyrins in homogeneous solution reveals that the polymeric matrix strongly affects the chemioselectivity of the oxidation process and increases both the photochemical efficiency and the stability of the iron porphyrin.

The following iron(III) porphyrins have been chosen on the basis of their well known[1] behaviour in homogeneous solution: iron(III) *meso*-tetraphenylporphyrin $[Fe^{III}(tpp)]^+$, iron(III) *meso*-tetrakis(2,6-dichlorophenyl)porphyrin $[Fe^{III}(tdcpp)]^+$, iron(III) *meso*-tetrakis(pentafluorophenyl)porphyrin $[Fe^{III}(tf_5pp)]^+$. Their absorption into Nafion was carried out in CH_2Cl_2–alcohol at 40 °C after swelling the membrane in EtOH or Pr^{i}OH. Typically the uptake of 0.5–0.8 μmol of complex in 1 g of resin occurs in a few minutes.

The UV–VIS spectra of the modified resin after swelling with EtOH or Pr^{i}OH are exactly those of the starting iron porphyrin dissolved in acidified alcohol media, which an extensive literature[8] ascribes to the monocationic species having an alcohol molecule bound to the axial position.† We then infer that heterogenization does not affect the nature of the iron porphyrin axial ligand. In support of this conclusion, an EPR spin-trapping investigation indicates that heterogenization does not affect even the primary photochemical process consisting of the homolytic cleavage of the Fe^{III} axial ligand bond according to step (*a*) in Scheme 1, which is a type of reaction already observed for many other iron porphyrin complexes in homogeneous solution.[1*a*,*b*,8,9] In fact, photoirradiation‡ of the iron porphyrin/Nafion composite systems in alcohol in the presence of the spin trap phenyl-*tert*-butylnitrone (PBN) inside the cavity of an EPR spectrometer yields spectra exhibiting the typical signals of the adducts between PBN and alkoxy radicals [step (*b*)].[10]



Scheme 1

Since the substituents on the *meso*-aryl groups of $[Fe^{III}(tdcpp)]^+$ and $[Fe^{III}(tf_5pp)]^+$ prevent the formation of a μ-oxo dimer complex,[11] the very fast reaction of the iron(II) porphyrin with O_2 is expected to restore the starting Fe^{III} complex, so inducing the reductive activation of O_2 itself[1*b*,12] (Scheme 1). In this way, using dioxygen and sunlight, the iron porphyrin/Nafion systems are able to form, in a cyclic way, reactive intermediates which are expected to induce the oxidation of hydrocarbons. The results obtained in the oxidation of cyclohexene and cyclohexane are summarized in Table 1.

Table 1 shows that irradiation of $[Fe^{III}(tdcpp)^+$ in EtOH–cyclohexene (25% v/v) results in the formation of cyclohex-2-en-1-one, cyclohex-2-en-1-ol and *trans*-cyclohexane-1,2-diol monoethyl ether. Interestingly, if the same experiment is carried out using Pr^{i}OH instead of EtOH, the ether represents about 90% of the overall oxidized alkene, and allylic oxidation products are formed only in very minor amounts. The presence of the ether indirectly reveals the formation of cyclohexene epoxide which, in the strong acidic environment inside Nafion, likely undergoes a nucleophilic attack by the alcohol, leading to the epoxide ring opening.§ Oxidation of cyclohexene is also observed with $Fe^{III}(tf_5pp)$/Nafion even though the ratio of allylic oxidation products increases significantly in Pr^{i}OH. For the latter system we obtain the maximum initial oxidation rate of *ca.* 8.5 turnovers min^{-1}.

Photoexcitation of $[Fe^{III}(tdcpp)]^+$ in homogeneous alcoholic solution gives totally different results: (*i*) the photooxidation is slower than in heterogeneous conditions; (*ii*) no ether is obtained; (*iii*) in addition to allylic oxidation products, cyclohexanol and cyclohexanone are formed, as we discussed earlier.[13]

The turnover values reported in Table 1 indicate that heterogenization significantly increases (about ten times) the stability of $[Fe^{III}(tdcpp)]^{3+}$. The Nafion matrix does not undergo any degradation and can be utilised several times. $[Fe^{III}(tpp)]^+$ is much less stable inside Nafion than both $[Fe^{III}(tdcpp)]^+$ and $[Fe^{III}(tf_5pp)]^+$. This indicates that, as in homogeneous sol-

Table 1 Photocatalytic[a] oxygenation of cyclohexene and cyclohexane

[a] Six hours photoirradiation, see footnote ‡. [b] Reaction products were determined by gas chromatography and gas mass analyses. Reported values are ±10%. Cyclohexane-1,2-diol monoethers have been separated on an SiO_2 column and characterised by proton NMR spectroscopy. [c] Mol of product formed per mol of consumed iron porphyrin.

utions,[1c,9] halogen substituents on the *meso* aryl groups play a fundamental role in restoring the starting iron porphyrin during the photocatalytic cycle, avoiding both a too fast oxidative degradation of the porphyrin ring and the formation of μ-oxo-dimers.

Upon irradiation of Fe^{III}(tdcpp)/Nafion in Pr^iOH containing cyclohexane (25% v/v) the concentration of oxidation products was $< 10^{-5}$ mol dm^{-3}, on the same timescale as for cyclohexene. On the other hand, the alkane undergoes hydroxylation when cyclohexene is present as a co-substrate (cyclohexane 12.5% v/v, cyclohexene 12.5% v/v). This suggests that cyclohexene plays a dominant role in the formation of active monooxygenating species during the photocatalytic process.

Cyclohexene is expected to capture efficiently alkoxy radicals originating from the photochemistry of iron porphyrins through an allylic hydrogen abstraction process [step (*c*) in Scheme 1].[14] This hypothesis is confirmed by experiments in which the intensity of the EPR signal of the adduct between PBN and alkoxy radicals is followed as a function of irradiation time. We observed that the signal intensity is unchanged in the presence of cyclohexane, while it is reduced by about 75% if cyclohexene is present. Apparently, the latter is able to compete efficiently with PBN in the reaction with the radical intermediates giving relatively stable cyclohexenyl radicals. Reaction of O_2 with these radicals in the presence of the iron porphyrin can give efficient monooxygenating species[1b] as in the catalytic cycle of cytochrome P450.[15] As a tentative explanation, the polymeric matrix may favour the above reactions in the proximity of the metal centre and, at the same time, inhibit the escape of radical intermediates that initiate autooxidation processes.¶ Our previous work in the homogeneous phase shows that photoexcited porphyrins under aerobic conditions can oxidise cyclohexane even in the absence of cyclohexene.[1c] However, in that case, the active species are OH· radicals which are more reactive than alkoxy radicals in extracting hydrogen atom from hydrocarbons.[16]

† Exchange of the acid membrane with NaCl causes a red shift of the Soret band, in keeping with the deprotonation of the coordinated alcohol molecule and the formation of a neutral porphyrin complex. In fact, in this case we observe experimentally that the complex is released by the membrane after a few hours in alcohol. The spectral variations described are exactly the same as those for the starting iron porphyrin in alcohol with added CF_3SO_3H or $HClO_4$. In the acidified alcohol medium one should reasonably have an equilibrium among more species, with the anions or the alcohol molecules as axial ligands in the porphyrin complex.

‡ Irradiation was carried out at 20 ± 1 °C with a Hanau Q 400 mercury lamp (15 mW cm^{-2}), under oxygen at 760 Torr. Selection of wavelength between 330 and 400 nm was performed by use of a glass cut-off filter.

§ This statement is confirmed by the observation that the epoxide in acidic solution undergoes a nucleophilic attack with the formation of the same *trans*-cyclohexane-1,2-diol monoalkyl ether during the photocatalytic oxidation.

¶ The effect of the matrix is not just that of providing an acid environment. In fact, photooxidation of the cycloalkenes by $[Fe^{III}(tdcpp)]^+$ dissolved in EtOH or Pr^iOH acidified with trifluoromethanesulfonic acid leads to the formation of a mixture of various oxygenation products which, on the other hand, does not include the ethers.

Synthesis and electrochemistry of a tetrathiafulvalene $(TTF)_{21}$–glycol dendrimer: intradendrimer aggregation of TTF cation radicals

Christian A. Christensen,[a] Leonid M. Goldenberg,[b] Martin R. Bryce*[b]† and Jan Becher[a]

[a] *Department of Chemistry, Odense University, DK-5230 Odense M, Denmark*
[b] *Department of Chemistry, University of Durham, Durham, UK DH1 3LE*

The convergent synthesis of a TTF–glycol dendrimer is reported: thin layer cyclic voltammetric studies on $(TTF)_{21}$ system 11 show that all the TTF units undergo two single-electron oxidations to produce the 42+ redox state spectroelectrochemical studies establish that there are intradendrimer interactions between partially-oxidised TTF units.

The study of dendrimers is a burgeoning topic.[1] These macromolecules possess well-defined, three-dimensional structural order, and they provide unique frameworks for placing functional groups in predetermined spatial arrangements in a polymeric structure. In the context of functional dendrimers,[2] a variety of redox-active groups have been incorporated into the structures.[3]

Tetrathiafulvalene (TTF) dendrimers should be very interesting materials as the TTF system possesses a unique combination of properties,[5] *viz*. (i) oxidation to the cation radical and dication species occurs sequentially and reversibly, (ii) the oxidation potentials can be finely tuned by substituents on the TTF ring system, (iii) TTF cation radicals are thermodynamically very stable, and (iv) oxidised TTF units have a high propensity to form dimers or higher aggregates. A large number of multi-TTF derivatives[5] and some main- and side-chain polymeric TTFs[6] are known, but dendrimeric TTFs are largely unexplored.[7] Here we present the synthesis of a novel $(TTF)_{21}$ dendrimer with TTF units placed at peripheral sites and within the branches of the structure, and we report the electrochemistry and spectroelectrochemistry of this polymer. Glycol chains were incorporated into the branches to impart solubilty in organic solvents, and air stability, and to provide a flexible structure to facilitate interactions between the TTF units.

The synthesis of dendrimer **11** uses a convergent strategy, with the caesium salts of TTF thiolate anions (Scheme 1) (generated by the *in situ* deprotection of their cyanoethyl derivatives)[8] as key intermediate species in the iterative steps. Compound **1** was deprotected by reaction with CsOH, and the resulting dithiolate reacted *in situ* with glycol derivative **2** to yield compound **3** in 63% yield. Cross-coupling of thione **3** with ketone **4**[8b] in the presence of $P(OEt)_3$ gave the TTF derivative **5** in 67% yield. Halogen exchange to yield diiodide **6** (NaI, 84% yield) was followed by reaction of **6** with 2 equiv. of the thiolate anion derived from **7**,[8c] to afford tris(TTF) system **8** in 77% yield. In an iterative procedure, the thiolate anion derived from **8** (2 equiv.) reacted with **6** to furnish the heptakis(TTF) dendron wedge **9** in 79% yield. Finally, the thiolate anion derived from **9** (3 equiv.) smoothly displaced the benzylic bromides of the core reagent **10** to furnish the dendrimer **11** possessing 21 TTF units (75% yield) as an air-stable, orange toffee-like solid, which has good solubility in a range of organic solvents (*e.g.* CH_2Cl_2, $CHCl_3$, THF, toluene, dichlorobenzene and CS_2) and was insoluble in water.‡

The solution electrochemistry of **11** in CH_2Cl_2 was studied using thin layer cyclic voltammetric (TLCV) techniques in which the current is not limited by mass transport to the electrode.[9] Integrating the voltammetric waves against the one-electron reduction peak of the internal standard 2,3-dichloronaphthoquinone (DCNQ) provided clear evidence that complete oxidation occurs for all the TTF units, thus ultimately generating the 42+ oxidation state of the dendrimer.§ We note that the second TTF oxidation wave was slightly narrower than the first wave, which was probably due to adsorption phenomena. Fig. 1 shows the TLCV of **11** in the presence of DCNQ.

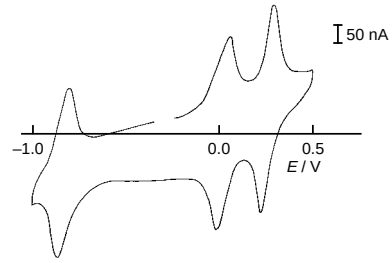

Fig. 1 TLCV of dendrimer **11** (0.5×10^{-4} M) and DCNQ (1.05×10^{-3} M) in Bu_4NClO_4 (1 M)/CH_2Cl_2, solution, *vs*. Ag/Ag^+, scan rate 2 mV s^{-1}

The spectroelectrochemistry of dendrimer **11** is shown in Fig. 2. The spectrum obtained at 0 V [Fig. 2(*a*)] is consistent with neutral TTF units; upon oxidation at 0.7 V, the characteristic absorptions of TTF cation radicals are seen: the new band at λ_{max} 425 nm is assigned to isolated (non-interacting) TTF cation radicals, while the absorption at λ_{max} 800 nm is diagnostic of interacting TTF cation radicals (π–π dimers).[10] On increasing the potential [Fig. 2(*c*)], as oxidation of the system proceeds the higher energy absorption decreases in intensity while there is a concomitant increase in the lower energy absorption, suggesting more of the partially-oxidised TTF units are now dimerised. Even when the spectrum was obtained at the threshold potential for oxidation, both bands were always present, which suggests that the cation radicals interact even when they are present in very low concentration: we therefore assign this to an intradendrimer interaction, achieved due to the flexibility of the glycol spacers. To the best of our knowledge, this is the first observation of π–π interactions (either intra- or inter-molecular) in oxidised dendrimers. This is timely in the light of studies of π–π stacking at the periphery of functionalised PAMAM dendrimers,[12] and the intermolecular self-association of dendrimers mediated by hydrogen bonding[13] or coordinative bonds.[14]

This work was funded by the EPSRC and NATO (C. A. C.) and the Royal Society (L. M. G.).

Luminescent europium tetraazamacrocyclic complexes with wide range pH sensitivity

Thorfinnur Gunnlaugsson and David Parker*

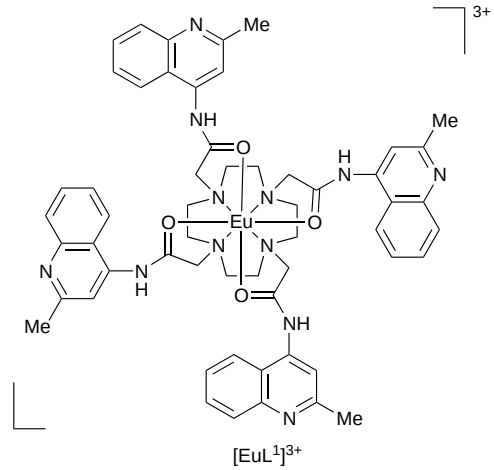
Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE

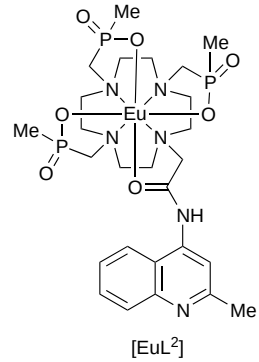
The complexes $[EuL^1]^{3+}$ and $[EuL^2]$ function as luminescent pH sensors over an extended pH range; two distinguishable pH switching ranges are observed: the delayed europium emission is switched on in acidic solution, whereas the fluorescence emission spectra show a pronounced pH dependence only in alkaline media.

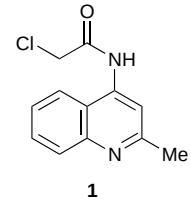
Luminescent chemosensors offer an attractive method for the detection of various physiological ions and molecules.[1] Fluorescent sensors may be adversely affected by autofluorescence and by light scattering from an active physiological environment.[2] Delayed luminescence affords an attractive means of overcoming some of these obstacles.[3] In solution, the application of lanthanide luminescence, has generated a great deal of interest owing to the long wavelength of the emission (large Stokes' shifts) and the long lifetimes (in the ms range).[4] An example of such a Tb^{III} and Eu^{III} sensory PET (photoinduced electron transfer) system has been reported recently for pH measurement in aqueous solution.[5] Various lanthanide complexes of tetra-substituted derivatives of 1,4,7,10-tetraazacyclododecane (cyclen) have been synthesised either as contrast agents in magnetic resonance imaging[6] or as luminescence probes.[7] In water, these complexes are kinetically stable with respect to dissociation and possess low hydration numbers ($q \leqslant 1$). In further developing this work, we have recently demonstrated the effect of protons, oxygen and halide anions on the luminescence emission spectra of some Eu^{III} phenanthridinium conjugates.[8] Here we introduce the cationic Eu^{III}–tetraamide $[EuL^1]^{3+}$ and the neutral monoamide $[EuL^2]$ quinolyl derived conjugates. In addition to acting as an efficient antenna sensitiser[4,6,7] the chromophore can reversibly switch, *via* an energy transfer mechanism,[4] the lanthanide emission on and off as a function of pH. At the same time, the fluorescence emission spectrum is only dependent on the hydroxide ion concentration, so that these conjugates show a dual pH dependence spanning a wide pH range.

The tetraamide ligand L^1 was synthesised by reaction of the α-haloamide **1** with 1,4,7,10-tetraazacyclododecane in DMF at 80 °C (4.1 equiv. Cs_2CO_3). The tribasic ligand H_3L^2 was synthesised by reacting the molybdenum tricarbonyl complex of cyclen with the same amide (1 : 1) in DMF–Cs_2CO_3, with a subsequent phosphinoxymethylation in THF followed by basic hydrolysis. The Eu^{III} complexes of L^1 and L^2 were made by reaction of the ligand with equimolar quantities of europium triflate in acetonitrile.[9]

The absorption spectra in water of $[EuL^1]^{3+}$ and $[EuL^2]$, were similar to those observed for the intermediate amide **1**. The spectra showed a pH dependent bathochromic shift (λ_{max} = 314 nm, log ε = 4.18) with an isosbestic point at 296 nm, and revealed the formation of a new band at 261 nm (log ε = 4.0) following protonation with CF_3CO_2H. The fluorescence emission spectrum of **1** did not show any substantial pH dependence below pH 8 when excited at 330 nm.† The same trend was observed for $[EuL^1]^{3+}$ and $[EuL^2]$, when excited at 330 nm; the fluorescence emission spectra decreased in intensity in alkaline media, as shown in the pH–luminescence profile of $[EuL^1]^{3+}$ (Fig. 1). In contrast, when excited at the isosbestic wavelength, the fluorescence emission spectra increased in intensity in







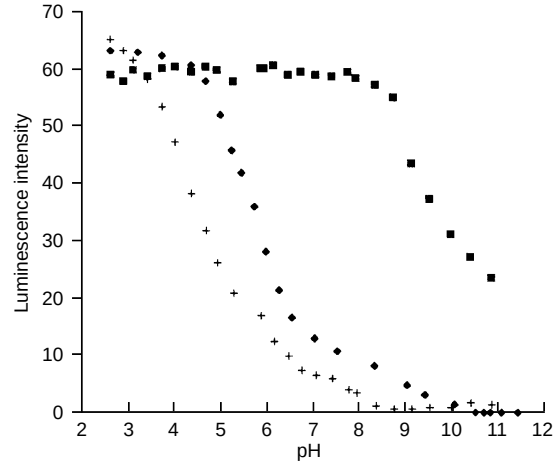


Fig. 1 Enhancement of the luminescence of europium complexes as a function of pH: (■) quinolyl fluorescence in $[EuL^1]^{3+}$; (+) metal-based emission (594 nm) in $[EuL^1]^{3+}$; (◆) metal-based emission in $[EuL^2]$

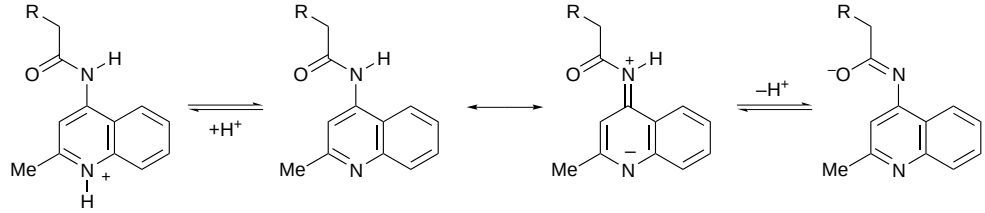

Scheme 1

alkaline solution. In both cases, λ_{max}(fluor.) shifted to longer wavelength in the presence of base, and pH titrations revealed formation of an isoemissive point, for $[EuL^1]^{3+}$ at 377 nm and [for EuL^2] at 375 nm. The estimated pK_a values of 9.4(3) and 9.6(3) were determined from these changes for $[EuL^1]^{3+}$ and $[EuL^2]$, respectively, which relate to the deprotonation of the aryl amide nitrogen.

The largest and the most significant pH dependence was observed in the delayed europium emission. The emission was independent of pH in alkaline solution (above pH 10) for $[EuL^1]^{3+}$, with only very small changes observed for $[EuL^2]$ (overall, contributing around 8–12% of the total emission). Significant 'off–on' luminescence switching was observed when the quinolyl nitrogen was protonated {Fig. 1 for $[EuL^1]^{3+}$}. The luminescence enhancement was at least 250 for $[EuL^2]$ (λ_{exc} = 330 nm), while a more modest factor of 30 was obtained with $[EuL^1]$, in each case observing Eu emission at 594 nm (ΔJ = 1).‡ The europium emission therefore signals the protonation of the remote chromophore, a feature which is not seen in the fluorescence emission spectrum.

Upon protonation of the quinolyl nitrogen atom the n–π* transition is removed, and the π–π* shifts to lower energy (as revealed by the excitation spectra for $[EuL^2]$ and $[EuL^1]^{3+}$ as a function of pH). The internal charge transfer (ICT) excited state which is populated in the neutral chromophore is probably modified upon protonation and deprotonation (Scheme 1). The switching between pH 4.5 and 6.5 for $[EuL^2]$ is in accordance with simple ion-binding equilibria[1,5,8] and a pK_a value of 5.8(2) was determined. The pH switching of the cationic complex $[EuL^1]^{3+}$ is over a broader range and is shifted by one pH unit lower. In addition a small inflection in the metal-based luminescence is apparent at *ca*. pH 7 for $[EuL^1]^{3+}$ and 8.5 for $[EuL^2]$: this feature, apparently not ligand based, could be related to the deprotonation of the proximate water molecule. The extended pH sensitivity range of the tricationic complex, *i.e.* in the region between pH 6.5 and 2.5, may be related to the successive protonation of each of the four nitrogens of the chromophore. The overall pH dependence is then a function of four stepwise equilibria, taking place over almost 4 pH units, rather than the pH range of two associated with a single protonation. In accord with this observation a pH-metric titration of fully protonated $[EuL^1]^{3+}$ revealed that 4 equivalents of base were consumed in the range 2.5–6. Similar behaviour has previously been observed for some fluorescent anthrylaza-macrocycle PET systems,[10] where the switching was considered to be linear over five pH units, although a detailed investigation into this behaviour has not subsequently been reported. In water at pH = 1.80, the luminescence emission lifetimes τ_{H2O}, for $[EuL^1]^{3+}$ and $[EuL^2]$ were measured to be 0.55 and 0.71 ms, respectively, while in D_2O, the lifetimes were 1.55 and 1.98 ms, respectively, consistent with an overall hydration state of 0.8 (inner + outer sphere) for both $[EuL^1]^{3+}$ and $[EuL^2]$ (after correcting for the quenching effect of the amide NH oscillators).[9,11]

In summary, the two europium complexes possess distinctly different pH sensitivity. The delayed europium emission is highly dependent on pH changes over the range 3–7 making these complexes interesting candidates for pH measurement in competitive media.

We gratefully acknowledge the BBSRC for grant support, and Drs Stephen Faulkner and Gareth Williams for helpful discussions.

† The fluorescence emission spectrum of **1** gave spectra consistent with a weak internal charge transfer excited state. In solvents of increasing polarity (CH_2Cl_2, Et_2O, MeCN, MeOH, H_2O) a bathochromic shift was observed in λ_{max} and at pH 3 the ICT band was less apparent.

‡ These large enhancement factors are not explained simply by the suppression of photoinduced electron transfer following N-protonation (although this effect contributes a factor of *ca*. 3 per N, as seen by excitation at the isosbestic wavelength). Only when protonated, do the Eu complexes significantly absorb photons at 330 nm.

Reaction of aromatic amines and ethyl acetoacetate promoted by zeolite HSZ-360. Phosgene-free synthesis of symmetric diphenylureas

Franca Bigi, Raimondo Maggi, Giovanni Sartori*† and Elena Zambonin

Dipartimento di Chimica Organica e Industriale dell'Università, Viale delle Scienze, I-43100 Parma, Italy

Reaction of aromatic amines 1 with ethyl acetoacetate 2 in the presence of the commercially available acid zeolite HSZ-360 gives symmetric diphenylureas 3 in good yields and excellent selectivities.

Zeolites and other solid acids have opened new perspectives in synthetic organic chemistry not only in terms of yield and selectivity, but also concerning the work-up and the effluent pollution.[1] The use of both solid acids and non-toxic reagents leads to a substantial reduction in cost and environmental impact of the production processes.[2] Here we report preliminary results of our study concerning the synthesis of symmetric diphenylureas (DPUs) from aromatic amines and ethyl acetoacetate under solid acid catalysis.

Substituted ureas have received considerable attention due to their wide range of applications, *e.g.* for use as antidiabetic and tranquillizing drugs, antioxidants in gasoline, corrosion inhibitors and herbicides.[3] The conventional methods reported for the urea synthesis are essentially based on phosgene and isocyanates,[4] phosgene substitutes,[5] carbonates and carbamates[6] or carboxylic acid derivatives.[7] However, phosgene and isocyanates are toxic and expensive to handle and the above methods are often difficult to apply. There is, thus, a continuing interest in the catalytic synthesis of ureas *via* phosgene-free reactions. Our strategy, utilizing ethyl acetoacetate as carboxylating agent in place of phosgene and solid acids as catalysts represents an efficient, innovative and environmentally safe method for the synthesis of DPUs.

The reaction of aromatic amines **1** with ethyl acetoacetate **2** has been described in the literature to produce ethyl β-arylaminocrotonates or acetoacetoanilides,[8] depending on the temperature. We found that DPUs could be obtained as the sole reaction products by heating the same mixture in the presence of different solid acids (Table 1).

The reaction of *p*-anisidine, selected as the model substrate, with **2** in the presence of zeolite HSZ-360[9] in *o*-dichlorobenzene at 180 °C for 5 h gave *N*,*N*′-bis(4-methoxyphenyl)urea which was isolated in 60% yield and 93% selectivity (entry g). Zeolite HSZ-330,[10] with higher acidity and comparable surface area, was less effective (entry f). The use of two montmorillonites, K10 and KSF,[11] gave the product with lower yield and similar, high selectivity independent of surface area and acidity (entries d and e).

The acidity of the catalyst is likely to play an important role in the activation of **2**. Note that the present system seems to require an optimum acidity level with respect to both strength and nature of the individual Brønsted and Lewis sites. Indeed, the more active zeolite HSZ-360 has a lower concentration of acid sites than HSZ-330, but the individual sites are more strongly acidic.[9,10] Moreover the use of typical hard Brønsted and Lewis acids such as TsOH, $ZnCl_2$ and $AlCl_3$ results in the production of untractable mixtures of compounds (entries a, b and c).

The best result was achieved by carrying out the reaction with zeolite HSZ-360 under solventless conditions (76% yield, 95% selectivity) (entry h). This result is of particular interest since *o*-dichlorobenzene is on the 'black list' of the environmentally incompatible solvents.[12]. In the control experiment with no zeolite catalyst only *p*-methoxyacetoacetanilide was recovered as reported above.[8] The general applicability of the present

[a] Untractable mixture of compounds.

DPU synthesis was demonstrated by extending the reaction to different aromatic amines **1** and recovering the products **3** with good yields and excellent selectivities (entries h–l).

A representative procedure for the preparation of DPUs is as follows: a flask containing a mixture of the selected aromatic amine **1** (10 mmol) and zeolite HSZ-360 (0.5 g) was placed in a hot oil bath (180 °C) and **2** (0.8 g, 0.8 ml, 6 mmol) was added dropwise during 1 min. The mixture was efficiently stirred at the same temperature for 5 h.[13] After cooling to room temp. the slurry was washed with boiling MeOH containing 5% water (2 × 100 ml). After filtration the product was recovered from the solution by addition of more water and cooling.[14] Alternatively, hot DMSO could be successfully utilized under the same conditions.

The formation of compounds **3** could be attributed to the initial production of acetoacetanilides and their subsequent reaction with a second molecule of aromatic amine to give DPUs and acetone. This hypothesis was in part confirmed by quantitative production of diphenylurea by heating a 1 : 1 mixture of acetoacetanilide and aniline in the presence of zeolite HSZ-360. We then estimated the catalyst activity on reuse. Our results confirmed that the activity of HSZ-360 recovered by filtration, washed with acetone and reactivated by heating at 500 °C for 8 h was the same for 5 runs.

In conclusion the above reported method of utilizing **2** as carboxylating agent, zeolite HSZ-360 as solid catalyst and avoiding the use of any solvent, represents an innovative phosgene-free route for the selective synthesis of symmetric diphenylureas.

Thanks are due to the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST), Italy, and the Consiglio Nazionale delle Ricerche (CNR), Italy, for financial support. The authors are also grateful to the Centro Interfacoltà Misure (C.I.M.) for the use of NMR and mass spectrometry instruments and to Mr Pier Antonio Bonaldi for technical assistance.

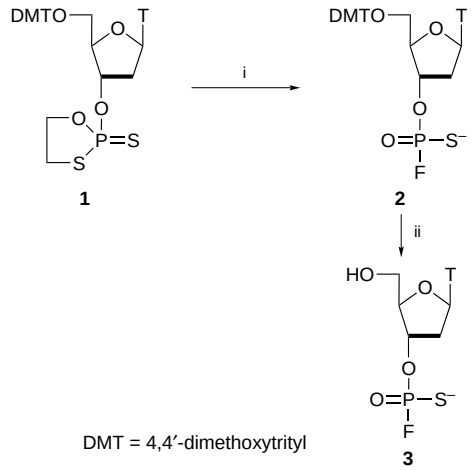
Synthesis and chemical and enzymatic reactivity of thymidine 3′-*O*- and 5′-*O*-phosphorofluoridothioates

Konrad Misiura, Daria Szymanowicz and Wojciech J. Stec*†

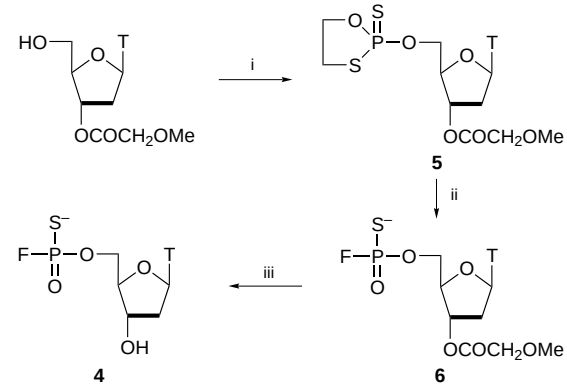
Polish Academy of Sciences, Centre of Molecular and Macromolecular Studies, Department of Bioorganic Chemistry, Sienkiewicza 112, 90-363 Lódź, Poland

5′-*O*- or 3′-*O*-Protected thymidine 3′-*O*- or 5′-*O*-(2-thiono-1,3,2-oxathiaphospholanes) react with triethylammonium fluoride in a presence of DBU and furnish, after deprotection, thymidine 3′-*O*- and 5′-*O*-phosphorofluoridothioates; the latter undergoes stereoselective hydrolysis by *snake venom* phosphodiesterase.

Within the course of our studies on the development of oxathiaphospholane methodology for phosphorylation,[1] phosphorothioylation[2] and phosphorodithioylation[3] of biomolecules we have found that the endocyclic P–S bond of a 2-thio-substituted 1,3,2-oxathiaphospholane ring attached to nucleoside moiety can be easily broken in the presence of DBU by fluoride ions leading, after spontaneous episulfide elimination, to 3′-*O*-methoxyacetyl nucleoside 5′-*O*-phosphorofluoridothioates or 5′-*O*-dimethoxytrilyl nucleoside 3′-*O*-phosphorofluoridothioates.[4,5] Thus, 5′-*O*-dimethoxytritylthymidine 3′-*O*-(2-thiono-1,3,2-oxathiaphospholane) **1** (ratio of diastereomers *ca.* 1:1), after treatment with triethylammonium fluoride‡ in a presence of DBU gives 5′-*O*-dimethoxytritylthymidine 3′-*O*-phosphorofluoridothioate **2**§ in 78% yield (Scheme 1). The dimethoxytrityl protecting group was removed by the treatment of **2** with 80% AcOH. The final product, thymidine 3′-*O*-phosphorofluoridothioate **3**,¶ was purified by anion-exchange chromatography on Sephadex A-25 using triethylammonium hydrogen carbonate buffer (pH 7.5, 0.02–0.5 M) as eluent. Pure **3** has also been obtained from **1** in 68% yield in a one-pot synthesis. Reaction of **1** with triethylammmonium fluoride in a presence of DBU is, unlike the 1,3,2-oxathiaphospholane ring-opening condensation with alcohols[2] or amines,[6] a non-stereospecific process. Starting from a mixture of partially separated diastereomers of **1** [ratio 73:27, δ_P (CD_3CN), 105.78 and 105.83] diastereomers of **2** were obtained in a ratio of 54:46 [δ_F (CD_3CN), −30.06 and −29.96]. The epimerisation at phosphorus was not unexpected in the light of published earlier results on the stereochemistry of nucleophilic substitution at phosphorus by fluoride ion.[7,8] Also, thymidine 5′-*O*-phosphorofluoridothioate **4** has been synthesized according to the reaction sequence presented in the Scheme 2. Phosphitylation of 3′-*O*-methoxyacetylthymidine with *N*,*N*-diisopropylamino-1,3,2-oxathiaphospholane[2] in a presence of 1*H*-tetrazole, followed by sulfurization yielded oxathiaphospholane **5**. Reaction of **5** with triethylammonium fluoride–DBU furnished intermediate 3′-*O*-methoxyacetylthymidine 5′-*O*-phosphorofluoridothioate **6** which subsequently was deprotected with a concentrated solution of ammonia providing, after purification on Sephadex A-25, the final product **4**** in 75% yield. The phosphorofluoridothioate monoesters **3** and **4** were hydrolytically stable even under basic conditions (conc. ammonia, room temp., 1 h), as proven by ^{31}P NMR assay. Similarly, the resistance of **3** and **4** towards methanolysis, attempted in the presence of triethylamine or pyridine, has been observed. Attempts at internucleotide bond formation in reaction of **2** with 3′-*O*-acetylthymidine in the presence of strong bases such as Bu^{t}OK, DBU and 2-*tert*-butylimino-2-diethylamino-1,3-dimethyl-1,3,2-diazaphosphinane (BEMP) have failed. Reactions were performed in DMF and their progress was followed by ^{31}P NMR spectroscopy. Under these conditions, even after 18 h, formation of dithymidylyl (3′,5′)phosphorothioate ($T_{PS}T$) was not observed. Instead, both **3** and **4** underwent intramolecular cyclization in the presence of an excess of Bu^{t}OK (five-fold molar excess) leading to thymidine cyclic (3′,5′)phosphorothioate (cTMPS). Similarly, as previously observed[9] for Bu^{t}OK-catalyzed cyclization of nucleoside 5′-*O*-*p*-nitrophenyl phosphorothioates, in the reactions of phosphorofluoridothioates **3** and **4** [S_P]-cTMPS[10] was also formed preferentially (ratio of [S_P]-: [R_P]-cTMPS *ca.* 2:1). Yields of Sephadex-purified cTMPS obtained from **3** and **4** were 57 and 38%, respectively. The lack of formation of $T_{PS}T$ in Bu^{t}OK assisted condensation of **2** with 3′-*O*-acetylthymidine was rather unexpected in the light of the results of von Tigerstrom and Smith[11] on effective formation of T_PT and other medium-sized oligothymidylates in the reaction of protected thymidine 3′-*O*-phosphorofluoridate with 3′-*O*-acetylthymidine.



Scheme 1 *Reagents and conditions*: i, Et_3NHF, DBU, MeCN, 15 min; ii, 80% AcOH, 1 h



Scheme 2 *Reagents and conditions*: i, *N*,*N*-diisopropylamino-1,3,2-oxathiaphospholane, 1*H*-tetrazole, 2 h, then elemental sulfur, 18 h; ii, Et_3NHF, DBU, CH_2Cl_2 MeCN, 15 min; iii, conc. NH_4OH, EtOH, 2.5 h

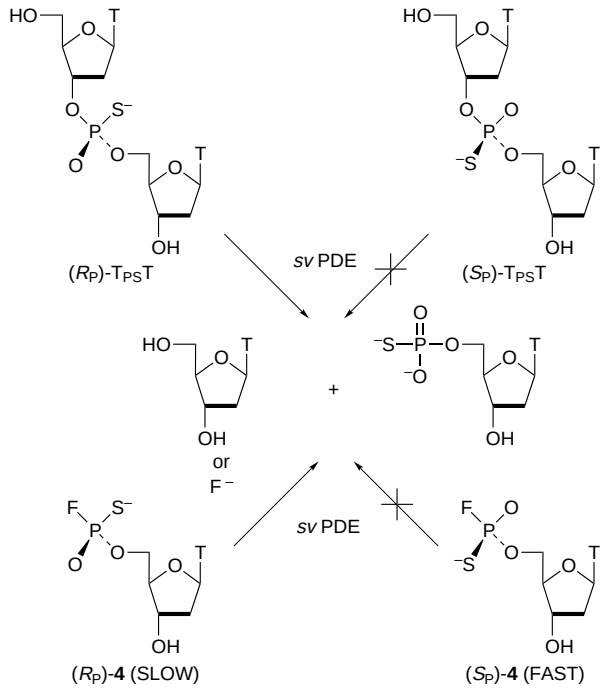


Fig. 1 Tentative assignment of absolute configuration of diastereomers of **4**

In the light of earlier results on an enzymatic cleavage of thymidine 5′-*O*- or 3′-*O*-phosphorofluoridate assisted by *snake venom* (*sv* PDE)[12,13] and *spleen*[12] phosphodiesterases (*spleen* PDE) it was tempting to study the thio analogues **4** and **3** as substrates for these enzymes. From the pioneering work of Eckstein[14] and Benkovic[15] demonstrating the stereoselectivity of *sv* PDE towards P-chiral diesters of phosphorothioic acid it was of interest to check if this enzyme can discriminate between the diastereomers of **3** or **4**.

5′-*O*-Phosphorofluoridothioate **4** was incubated with *sv* PDE†† and the progress of the enzymatic digestion was analyzed by RP-HPLC. It was found that *sv* PDE, if added to a diastereomeric mixture of **4**, causes the stereoselective hydrolysis of the P–F bond of slow-eluted **4** leaving the fast-eluted diastereomer intact. Also, in the case of diastereomeric mixture of **3**†† only slow-eluted **3** underwent hydrolysis in a presence of *sv* PDE, albeit the reaction proceeded much slower than that observed for slow-eluted **4**. Interestingly, under analogous conditions, the rate of hydrolysis of slow-**4** by *sv* PDE was similar to that obtained during digestion of dithymidylyl (3′,5′)phosphate (T_PT). In the presence of *spleen* PDE both diastereomers of **3** were hydrolyzed while both diastereomers of **4** were resistant to this enzyme.** It was also found that **3** and **4** have no inhibitory activity§§ towards either phosphodiesterase. Results on the use of **4** for inhibition of thymidylate synthase will be published separately.[16]

In conclusion, we have found that the 1,3,2-oxathiaphospholane ring can be opened in the presence of DBU by fluoride anion leading to the appropriate phosphorofluoridothioates. The nucleoside 5′-*O*- or 3′-*O*-phosphorofluoridothioates obtained can be used in studies of the mode of action of nucleolytic enzymes. Comparative topological analysis of diastereomers of $T_{PS}T$ and **4** undergoing *sv* PDE- assisted hydrolysis allows the tentative assignment of absolute configuration of the slow-eluted **4** as R_P (Fig. 1). *Spleen* and *sv* PDE-assisted hydrolysis of P–F bonds in compounds **3** and **4** is in agreement with earlier findings[12,13] that these enzymes split nucleoside 3′-*O*- or 5′-*O*-phosphorofluoridate, respectively, giving rise to the appropriate nucleoside phosphates. From this perspective our data on enzymatic hydrolyses of **3** and **4** disagree with the results of Dabkowski *et al.*,[17] who characterized thymidine 3′-*O*-phosphorofluoridate as the product of *spleen* PDE-assisted degradation of thymidin-3′-yl 2′-deoxyadenosin-5′-yl phosphorofluoridate. Adenosine 5′-*O*-phosphorofluoridate was found as the product of *sv* PDE-assisted hydrolysis of the same substrate. Besides the hydrolytic instability of the P–F bond of dinucleoside (3′,5′)phosphorofluoridates in buffered aqueous media[18] yielding appropriate phosphates, even if thymidine 3′-*O*-phosphorofluoridate or adenosine 5′-*O*-phosphorofluoridate were the respective products of PDE-catalyzed hydrolyses, they would necessarily undergo further enzymatic degradation to phosphomonoesters.

Studies presented here were financially supported by the State Committee of Scientific Research (KBN), grant no 4 PO5F 023 10.

§ Compound **2** consists of a 1 : 1 mixture of diastereomers, δ_P(CD_3CN, 81 MHz) 54.52 ($^1J_{P–F}$ 1043 Hz), 54.58 ($^1J_{P–F}$ 1046 Hz); *m/z* (−FAB) 641.4 ($M^{+\cdot}$ −1).

¶ Compound **3** consists of a mixture of diastereomers (ratio 48 : 52), δ_P(D_2O, 81 MHz) 53.72, ($^1J_{P–F}$ 1053 Hz), 53.74 ($^1J_{P–F}$ 1055 Hz); δ_F(D_2O, 188 Mz) −31.4 ($^1J_{P–F}$ 1043 Hz), −31.2 ($^1J_{P–F}$ 1046 Mz); *m/z* (−FAB) 339.1 ($M^{+\cdot}$ −1).

‖ Compound **5** was obtained as a mixture of diastereomers, δ_P($CDCl_3$, 81 MHz) 106.64, 106.82 (ratio 1 : 1); *m/z* (+FAB) 453.2 ($M^{+\cdot}$ +1).

Compound **4 consists of mixture of diastereomers (ratio 59 : 41), δ_P(D_2O, 81 Mz) 54.17, 54.20 ($^1J_{P–F}$ 1053 Hz); δ_F(D_2O, 188 Mz) −35.6, −35.7 ($^1J_{P–F}$ 1053 Hz); *m/z* (−FAB) 339.2 ($M^{+\cdot}$ −1).

†† The reaction mixture consists of 0.1 mM **4** or **3**, 100 mM Tris–HCl pH 8.0, 20 mM $MgCl_2$, and *sv* PDE (0.01 U ml^{-1}); 37 °C; incubation time: 0.5 h for **4** and 16 h for **3**.

‡‡ The reaction mixtures consist of 0.1 mM **3** (or **4**), 50 mM acetate buffer pH 5.0, and *spleen* PDE (0.15 U ml^{-1}), 37 °C; incubation time: 1 h for **3** and 16 h for **4**.

§§ Enzymatic digestions were performed under conditions mentioned above. T_PT and **3** (or **4**) were used at equimolar concentrations (0.1 mM).

Tetrahedral chlorometal derivatives of redox-active cyanomanganese ligands: synthesis, structures and solvatochromic properties of a new class of cyanide-bridged complexes

Neil G. Connelly,* Owen M. Hicks, Gareth R. Lewis, A. Guy Orpen and Andrew J. Wood

School of Chemistry, University of Bristol, Bristol, UK BS8 1TS

First row transition metal (M = Mn–Ni) dichlorides react with cyanomanganese(I) carbonyl ligands to give novel paramagnetic bi- and poly-nuclear cyanide-bridged complexes, X-ray structural studies on which are consistent with $Fe^{III}Mn^{I}$, $Fe^{III}Mn^{II}$ and $Mn^{II}Mn^{II}$ core oxidation states for $[Cl_3M(\mu\text{-NC})Mn(CO)(dppm)_2]^z$ (M = Fe, z = 0, 1; M = Mn, z = 0) respectively; $Fe^{III}Mn^{I}$ complexes show strong solvatochromism, consistent with low spin d^6 octahedral Mn^{I} to tetrahedral d^5 Fe^{III} charge transfer.

The archetypal mixed valence complex Prussian Blue, $Fe_4^{III}[Fe^{II}(CN)_6]_3$, has been known since the early 18th century,[1] yet the origin of its unusually intense colour was not understood until the 1960s.[2] Now it, analogues such as $Mn^{II}[Mn^{IV}(CN)_6]$, $CsM[Cr^{III}(CN)_6]$ (M = Mn^{II}, Ni^{II}) and $M_3[Fe^{III}(CN)_6]_2$ (M = Co^{II}, Ni^{II}),[3] and other novel cyanide-bridged complexes[4] are under intensive investigation as substances with novel electrochemical, opto-electronic and magnetic properties.

Our studies of cyanide-bridged[5] complexes are based on the systematic construction of bi- and poly-nuclear species by *N*-binding a second metal centre ML'_x to the redox-active, low spin Mn^{I} cyanomanganese carbonyl ligands *trans*-$[Mn(CN)(CO)(dppm)_2]$ and *cis*- and *trans*-$[Mn(CN)(CO)_2\{P(OR)_3\}(dppm)]$ (R = Et, Ph).[6] The resulting complexes are of interest not only in that one-electron oxidation of the Mn^{I} centre of $Mn(\mu\text{-CN})ML'_x$ may induce reactivity at M, but also in allowing studies of the interactions between two or more Mn^{I}–Mn^{II} redox centres within the cyanide-bridged cores $\{Mn(\mu\text{-CN})\}_nML'_x$ (n = 2–4, *etc.*). Our synthetic strategy may be viewed as complementary to that based on the use of $[M(CN)_6]^{z-}$ (M = Mn, Fe, Co, *etc.*) as building blocks where *N*-binding to other metal sites leads to three-dimensional solid-state arrays by a divergent pathway. The binding of two or more monocyanide donors, such as *trans*-$[Mn(CN)(CO)_2\{P(OEt)_3\}(dppm)]$ to M can be viewed as a convergent route to polynuclear molecular species.

Our previous studies have centred on systems where M is a low oxidation state metal centre such as Rh^{I},[7] Fe^{-I}[8] and Au^{I}.[9] Here, we describe simple species in which the cyanomanganese ligands bind to high spin, tetrahedral 3d metal centres in 'normal' oxidation states, and for which unusual electronic and magnetic properties may be anticipated.

Treatment of $MCl_2{\cdot}nH_2O$ (M = Mn, Co, Ni) with $[Mn(CN)L_x]$ [L_x = *cis*- or *trans*-$(CO)_2\{P(OR)_3\}(dppm)$; R = Et, Ph] gave $[Cl_2M\{(\mu\text{-NC})MnL_x\}_2]$ which show room temperature magnetic moments consistent with the presence of tetrahedral M. (Representative examples of the new complexes† are shown in Table 1.) These complexes are precursors to higher nuclearity species or can be oxidised to products in which low spin, paramagnetic Mn^{II} is bound to high spin tetrahedral centres. Thus, for example, treatment of $[Cl_2Co\{(\mu\text{-NC})MnL_x\}_2]$ [L_x = *trans*-$(CO)_2\{P(OEt)_3\}(dppm)$] **1** with 1 equiv. of $[Mn(CN)L_x]$ in the presence of $TlPF_6$ gives $[ClCo\{(\mu\text{-NC})MnL_x\}_3][PF_6]$ **2** [L_x = *trans*-$(CO)_2\{P(OEt)_3\}(dppm)$]; use of 2 equiv. gives $[Co\{(\mu\text{-NC})MnL_x\}_4][PF_6]_2$ **3**. Complexes **1**–**3** show room temperature magnetic moments in accord with the presence of tetrahedral, d^7 Co^{II}.[10] In CH_2Cl_2 the cyclic voltammograms of complexes **1** and **2** show two oxidation waves the separation of which (*ca.* 100 mV) is consistent with weak interactions between the manganese centres in the oxidation products. Chemical oxidation of **1** with $[N(C_6H_4Br\text{-}4)_3][SbCl_6]$ gives deep blue $[Cl_2Co\{(\mu\text{-NC})MnL_x\}_2][SbCl_6]_2$ [L_x = *trans*-$(CO)_2\{P(OEt)_3\}(dppm)$] $\mathbf{1}^{2+}$ the room temperature magnetic moment of which (μ_{eff} = 5.0 μ_B) indicates some spin pairing between the d^7 Co^{II} and two low spin d^5 Mn^{II} centres.

The reactions of $MCl_2{\cdot}nH_2O$ with the more electron-rich and sterically demanding ligand *trans*-$[Mn(CN)(CO)(dppm)_2]$ in thf give $[Cl_2(thf)M(\mu\text{-NC})Mn(CO)(dppm)_2]$ (M = Mn, Co, Ni)

[a] In CH_2Cl_2. Strong absorptions unless stated otherwise; vs = very strong, m = medium, w = weak, vw = very weak. [b] Very weak A-mode given in parentheses. [c] In thf.

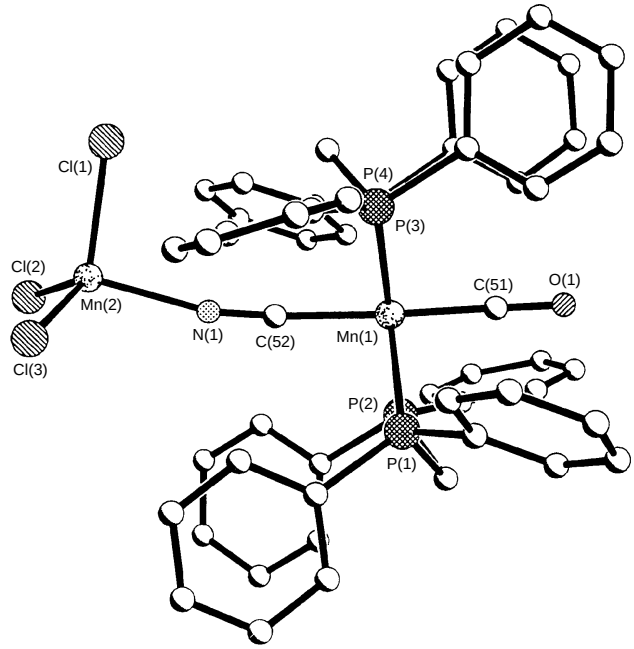

Fig. 1 Structure of **6** (hydrogen atoms and solvent molecule omitted for clarity); the molecular structures of **4** {as its $[FeCl_4]^-$ salt} and **5** are similar. Important bond lengths and angles: **4**, Fe–Cl 2.166, Mn–P 2.345; **5**, Fe–Cl 2.193, Mn–P 2.283; **6**, Mn–Cl 2.341, Mn–P 2.345. (Individual bond lengths have estimated standard uncertainties in the range 0.001–0.005 Å.)

which can be converted into $[PPN][Cl_3M^{II}(\mu\text{-}NC)Mn^{I}(CO)(dppm)_2]$ {PPN = $[N(PPh_3)_2]^+$} and $[Cl_3M^{II}(\mu\text{-}NC)Mn^{II}(CO)(dppm)_2]$ (M = Mn, Ni) by successive reactions with [PPN]Cl and $[Fe(\eta\text{-}C_5H_5)_2][PF_6]$.

Anhydrous $FeCl_2$ reacts with $[Mn(CN)L_x]$ [L_x = *cis*- or *trans*-$(CO)_2\{P(OR)_3\}(dppm)$, R = Et, Ph] in air to give very different products from those of the other metals noted above, namely the intensely coloured (blue to purple) complexes $[Cl_3Fe^{III}(\mu\text{-}NC)Mn^{I}L_x]$. The reaction of *trans*-$[Mn(CN)(CO)(dppm)_2]$ with $FeCl_2$ in air gives $[Cl_3Fe^{III}(\mu\text{-}NC)Mn^{II}(CO)(dppm)_2][Fe^{III}Cl_4]$ which can be reduced by $[Fe(\eta\text{-}C_5Me_5)_2]$ to $[Cl_3Fe^{III}(\mu\text{-}NC)Mn^{I}(CO)(dppm)_2]$. The presence of Mn^{I} and Fe^{III} in the neutral species is in marked contrast to the $M^{II}Mn^{II}$ cores of $[Cl_3M(\mu\text{-}NC)Mn(CO)(dppm)_2]$ (M = Mn, Co, Ni).

The assignments of oxidation state, based on the IR carbonyl spectra, are supported by X-ray structural studies of $[Cl_3Fe(\mu\text{-}NC)Mn(CO)(dppm)_2][FeCl_4]\cdot 2.5CHBr_3$ **4**, $[Cl_3Fe(\mu\text{-}NC)Mn(CO)(dppm)_2]\cdot CH_2Cl_2$ **5** and $[Cl_3Mn(\mu\text{-}NC)Mn(CO)(dppm)_2]\cdot CH_2Cl_2$ **6** (all three show similar structures‡). The structure of **6** is shown in Fig. 1, together with important bond lengths for **4**–**6**. As noted previously,[11] the Mn–P bond distances of the $(\mu\text{-}NC)MN(CO)(dppm)_2$ fragment are diagnostic of the oxidation state of Mn. Thus, **4** and **6** contain Mn^{II} and **5** contains Mn^{I}.

The intense colours of $[Cl_3Fe(\mu\text{-}NC)MnL_x]$ are in striking contrast to that of $[FeCl_4]^-$ (pale yellow) despite the presence of tetrahedral Fe^{III} in all cases. These intense colours arise from strong absorptions (ε_{max} *ca.* 3000 $dm^3\ mol^{-1}\ cm^{-1}$) in the visible spectrum which are highly solvatochromic (*e.g.* $[Cl_3Fe(\mu\text{-}NC)MnL_x]$ [L_x = *cis*-$(CO)_2\{P(OPh)_3\}(dppm)$ (λ_{max} = 508 nm in *n*-hexane; λ_{max} = 599 nm in 1,2-$C_2H_4Cl_2$), implying extensive intramolecular charge transfer.

Cyclic voltammetry provides some insight into the origin of the very different oxidation state distribution in the iron complexes compared with that in $[Cl_3M^{II}(\mu\text{-}NC)Mn^{II}(CO)(dppm)_2]$ (M = Mn, Co, Ni). Thus, **5** shows one oxidation wave ($E^{0\prime}$ = 0.43 V) and one reduction wave ($E^{0\prime}$ = 0.02 V) associated with the Mn^{I}–Mn^{II} and Fe^{II}–Fe^{III} couples respectively; no equivalent wave for the M^{II}–M^{III} couple is observed for M = Mn, Co or Ni. These results also suggest that the colour and solvatochromism of the iron complexes result from Mn^{I} to Fe^{III} charge transfer through the cyanide bridge. {In this respect, it is noteworthy that $[Cl_3Fe^{III}(\mu\text{-}NC)Mn^{II}(CO)(dppm)_2]^+$, where Mn^{II}-to-Fe^{III} charge transfer is impossible, is not solvatochromic.}

The magnetic behaviour of the iron complexes is also of interest. The magnetic moments of **4**, **5** and $[Cl_3Fe(\mu\text{-}NC)Mn(CO)(dppm)_2][BF_4]$ **7** {prepared by $[Fe(\eta\text{-}C_5H_4COMe)Cp][BF_4]$ oxidation of **5**} are 8.2, 5.6 and 5.8 μ_B respectively at 295 K. Detailed studies of the magnetic and electronic properties of these complexes are in progress.

We thank the EPSRC for studentships (to O. M. H., G. R. L. and A. J. W.).

Molecular recognition of a tris(histidine) ligand

Shuguang Sun, Jennifer Saltmarsh, Sanku Mallik*†‡ and Kathryn Thomasson

Department of Chemistry, Box: 9024, University of North Dakota, Grand Forks, ND 58202, USA

Design and synthesis of a tri-Hg^{2+} complex to selectivity recognize a tris(histidine) ligand is presented.

We are interested in the design and synthesis of transition metal ion based receptors for histidine-containing peptides.[1] Histidine-to-metal ion interactions (Cu^{2+}, Ni^{2+}, Zn^{2+} *etc*.) have been used for various applications, *e.g*. protein purification,[2] cross-linking,[3] targeting proteins to lipid bilayers.[4] It is these strong, directed metal ion-to-histidine interactions that we are using as the basis of the recognition process.[5]

As a model system for peptide recognition, we have chosen the ligand **L** to position three (*S*)-histidines 12 Å apart (Fig. 1). The compound **C**, with one histidine, served as the control for our studies. **L′** and **C′** were tested as histidine-mimetic ligand and control, respectively. Three-dimensional structures for the receptor and ligands were constructed using the molecular modelling software INSIGHT II and DISCOVER (ver. 95.0, BioSym Technologies/MSI, San Diego, CA) and energy-minimized in the gas phase using the consistent valence force field (cvff).

Syntheses of the receptor **R**, ligands **L**, **L′** and the control **C**, **C′** are shown in Scheme 1. Selective protection of three nitrogens of the cyclam (1,4,8,11-tetraazacyclotetradecane) ring **1** was carried out following a literature procedure.[6]

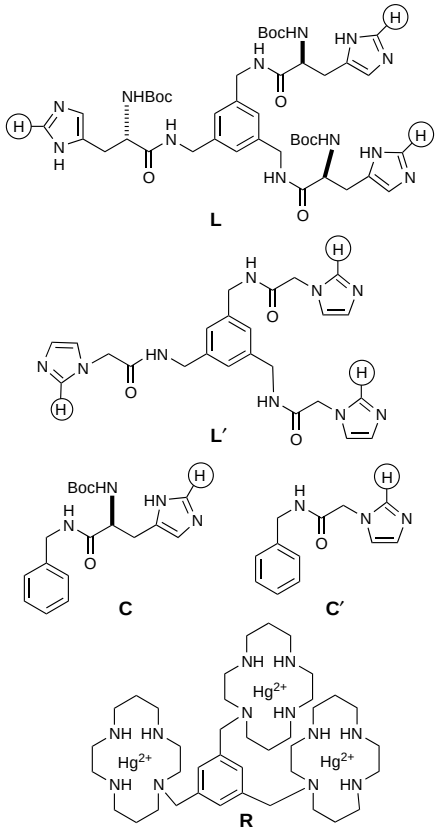

Fig. 1 Structures of the tris(histidine) ligand **L**, histidine mimetic ligand **L′**, controls **C**, **C′** and the designed receptor **R**. Hydrogens monitored in the titration studies are circled.

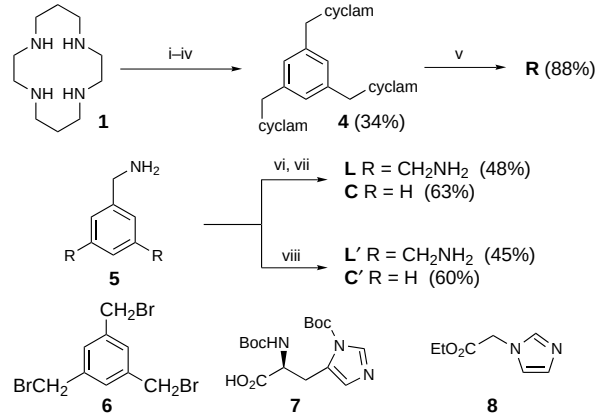

Scheme 1 *Reagents and conditions*: TsCl, Et_3N, $CHCl_3$; ii, **6**, K_2CO_3, MeCN, sonication; iii, HBr, AcOH, 70 °C; iv, ion exchange; v, $Hg(ClO_4)_2.3H_2O$, MeOH–MeCN; vi, *N*-hydroxysuccinimide, DCC, Et_3N, THF, **7**; vii, NaOH; viii, **8**, EtOH, sonication

Reaction of cyclam tritosylate **2** with 1,3,5-tris(bromomethyl)benzene **6**[7] proceeded smoothly in MeCN (using powdered K_2CO_3 as the base) under sonication (8 h). The crude product was purified by flash chromatography, using 5% MeOH–CH_2Cl_2 as the solvent (R_f 0.3). This reaction was found to yield a complex mixture of products under reflux. Removal of the tosyl groups was carried out in HBr–AcOH at 70 °C (10 h). Free ligand **4** was isolated by ion-exchange chromatography (IRA-400 column, hydroxide form) using water as eluent. Receptor **R** was synthesized by adding a solution of the free ligand **4** in MeCN to a methanolic solution of $Hg(ClO_4)_2.3H_2O$. Receptor **R** was isolated as the air-stable perchlorate salt after addition of Et_2O to the reaction mixture. (**Note**: we did not observe any explosive tendency for this compound.)§

Ligand **L** is known in the literature[8] and control **C** was synthesized by an analogous procedure. Reactions for the synthesis of **L′** and **C′** gave higher yields under sonication compared to refluxing conditions. Control **C′** was purified by recrystallization from $CHCl_3$–hexane and **L′** was purified by flash chromatography using MeOH as the eluent (R_f = 0.3).§ In the binding studies, a diamagnetic metal ion (Hg^{2+}) with strong affinity for histidine ($> 10^3$ M^{-1}) was used so that the binding could be monitored by ^{1}H NMR spectroscopy. Since the receptor **R** contains the embedded distance information, cyclam was used to hold the metal ions. Cyclam has very high affinities ($> 10^{20}$ M^{-1}) for transition metal ions. This ensures that the metal ions will not get displaced from **R** at high histidine concentrations. Cyclam also gives us the flexibility to synthesize the receptor with a variety of transition metal ions and to optimize the recognition properties.

Recognition studies were conducted in highly polar [$^2H_6$]DMSO, and were followed by ^{1}H NMR spectroscopy. The C-2-H of the imidazole moieties (indicated in Fig. 1) of **C** and **C′** were found to be shifted downfield (0.80 ppm for **C**; 0.87 ppm for **C′**) upon complexation with the Hg^{2+} ions of the receptor **R** (10 mM in **R**, 0–60 mM in **C** or **C′**). Both of these controls were in fast exchange with the receptor and an average signal was observed in each case. Resultant titration curves are

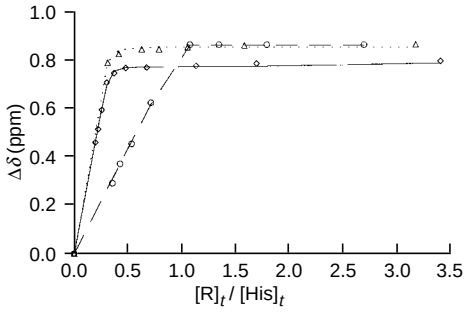

Fig. 2 Titration curves for (◇)C, (△)**C′** and (○) **L′**. The curves indicate the calculated titration curves with the reported binding constants.

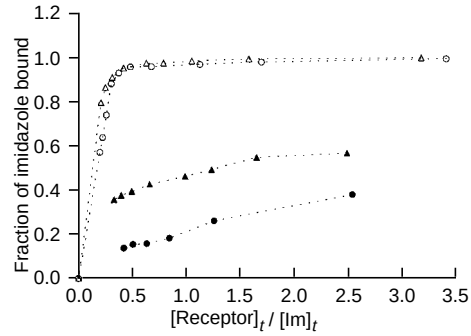

Fig. 3 Fraction of bound (●) **C** and (▲) **C′** in the competition experiments. The corresponding fractions bound in the titration experiments for (○) **C** and (△) **C'** are also plotted.

shown in Fig. 2. The turning of the titration curves at a 3 : 1 ratio of $[R]_t/[His]_t$ indicated a 3 : 1 stoichiometry of binding between **R** and **C** (or **C′**).[9]

For data analysis, the three metal ions were taken as interacting independently. Also shown in Fig. 2 are the calculated titration curves with the best-fit estimates of the binding constants. Non-linear regression analysis of the binding data following a previously-developed procedure[5] (SIGMA PLOT 4.0 for Windows, Jandel Scientific Inc.) provided the value of the binding constants (K_{RC} = 1.1 × 10^4 M^{-1}, $[\mathbf{R}]_t$ = 10.25–6.5 mM; $[\mathbf{C}]_t$ = 0–32 mM; $K_{RC'}$ = 10^4 M^{-1}, $[\mathbf{R}]_t$ = 9.6–6.6 mM; $[\mathbf{C'}]_t$ = 0–32 mM; in both regressions, error: < 10%). The regression analysis converged to these numbers starting from either a smaller or a larger value as the initial estimate.

Ligand **L′** was also in fast exchange with the receptor (Fig. 2). The sharp turning of the titration curve at [**R**]/[**L′**] = 1 indicated a 1 : 1 stoichiometry of the complex and a high affinity. Due to the high affinity, only a lower limit of *K* can be estimated from the binding data ($K_{RL'} > 10^5$ M^{-1}).

Similar titration experiments (10 mM in **R**, 3–30 mM in **L**) showed that **R** interacts differently with **L** compared to **C**. The ligand **L** was found to be in slow exchange with **R**.[10] Two different C-2-H signals were observed for the free (δ 7.67) and bound (δ 8.605) ligand. The amounts of free **L** (measured by the integration of bound and free C-2-H resonances) were very small up to 1 : 1 stoichiometry and then the amount of free **L** increased rapidly. The aromatic hydrogens of **L** were shifted upfield by 0.8 ppm in the presence of the receptor **R**. These observations indicated that **R** is forming a 1 : 1 complex with **L** and that the benzene rings of **R** and **L** are stacking. This was corroborated by the observance of a cross-peak between the aromatic ring hydrogens of the two benzene rings of **R** and **L** in a NOESY spectra and by molecular modeling. The binding constant was estimated from the integration of bound and free signals of **L**.[11] Owing to inherent errors in the integration of very small peaks in ^{1}H NMR spectra, only a lower limit of K_{RL} can be obtained ($K_{RL} > 10^5$ M^{-1}).

In order to determine the binding selectivity of **R** and **L** (or **L′**) over **C** (or **C′**), competitive titration experiments were conducted (Fig. 3).[5] A 10 mM solution of **R**.**L** (or **R**.**L′**) was titrated with **C** or **C′** (1–30 mM). The C-2–H chemical shift of **C** (or **C′**) was followed to measure the concentration of **C** (or **C′**) bound to **R**. The fraction of **R** bound to **L** (or **L′**) compared to the fraction of **R** bound to **C** (or **C′**) was taken as the measure of selectivity. **R** was found to be selective for **L** compared to **C** by a factor of 20; its selectivity for **L′** over **C′** was 10. This difference in selectivity may be due to the difference in inter-imidazole distances of **L** and **L′** and the resultant strain in the complexes arising from non-optimal distance matching between the receptor and the ligand. We are currently probing this by synthesizing tris(histidines) with varying inter-imidazole distances.

Thus, the designed receptor **R** is indeed selective for pattern matched tris(histidine) ligand **L** compared to the control **C**. Studies are currently underway to optimize the selectivity by changing the spacer of the tris(histidine) ligand **L**.

FEATURE ARTICLE

Understanding structure and reactivity of new fundamental inorganic molecules: metal sulfides, metallocarbohedrenes, and nitrogenase

Ian Dance

School of Chemistry, University of New South Wales, Sydney 2052, Australia

A large number of new and unexpected molecules, fundamentally inorganic and containing just metal and sulfur, or metal and carbon, can be synthesised in the gas phase, and their reactivities investigated. In the absence of bulk samples and definitive characterisation data they can be very profitably investigated using density functional calculations. A valuable perspective places these new and unprotected molecules in the context of related non-molecular solids, and terminally ligated molecules. The Fe_7MoS_9 cluster which effects the mild reduction of N_2 at the active site of nitrogenase is similarly undercoordinated, floppy, and reactive. Density functional calculations reveal the characteristics of the Fe_7MoS_9 site and elucidate postulated mechanisms for the reduction.

Introduction

Consider this experiment: cobalt sulfide, as the familiar black insoluble solid, is energised with a high power pulse of a 1064 nm laser, in a high vacuum chamber. A plasma occurs at the surface, and after collisional cooling the products formed are trapped as negative ions, and assayed mass spectrometrically. The resulting mass spectrum reveals 83 binary species $[Co_xS_y]^-$, ranging in size up to $[Co_{38}S_{24}]^-$.[1]

What have we done? We have prepared 83 structurally-molecular forms of a fundamental inorganic binary compound, cobalt sulfide, which previously had been known only with non-molecular structure. This experiment is the metal sulfide analogue of the better known laser ablation of a non-molecular allotrope of carbon (graphite) to generate the family of fullerenes, which are elemental carbon in molecular form.

This feature article is about newly discovered inorganic molecules which are comprised of just two (or at most a few) elements, and yet which are unprecedented in composition and structure and reactivity. These molecules are at the core of inorganic chemistry, but they do not adhere to the traditional notions of composition or oxidation state or valence, and they require new concepts of structure and bonding. Very often these new molecules have their genesis in the gas phase (like the fullerenes). However, as described below, metal sulfide cores are also deployed by evolved biological chemistry to effect significant reactivity which is beyond current human capability in the laboratory.

Molecular binary metal chalcogenides

By gas phase experiments like that already outlined, the generation of metal sulfide (and selenide and telluride) molecular clusters $[M_xE_y]^-$ has been achieved for all of the first row transition metals, and others.[2–4] We know that these new molecules are formed in the gas phase by associative processes involving atoms, ions and/or electrons generated in a high energy plasma, and that our experiment does not merely excise various fragments from the solid metal sulfide. This conclusion derives from the result that the distributions of product ions are largely independent of the properties of the solid precursor, and the fact that laser ablation of a mixture of elemental copper and selenium gives the same distribution as copper selenide precursors.[5,6] Through this experimental program we now know of the existence of many hundreds of unprecedented molecular metal sulfides $[M_xS_y]^-$, and have information about their relative abundances, stabilities, and reactivities.[1,2,4,6–13]

Before considering the position of these metal sulfide molecules in the menagerie of chemistry, it is worth mentioning a related inorganic experiment also performed in the cell of the Fourier transform ion cyclotron resonance (FTICR) mass spectrometer: this cell can be regarded as a gas-phase 'beaker', in which we can undertake controlled synthesis and purification of new species, and investigate their reactivities, reactions, and dissociations.[13,14] All of the metals (except Tc) can be isolated as M^+ in this cell, and reacted with the elemental reagent $S_{8\,(g)}$, forming numerous cations $[MS_n]^+$. This is comparative inorganic chemistry *par excellence*: it compares all metals, in the same oxidation state, reacting with the same reagent under the same conditions.[14,15]

Inorganic perspectives: non-molecules, exposed molecules, and protected molecules

What structural perspective best serves the numerous questions which arise for these and related newly discovered molecules? A threefold overall classification is valuable. At one extreme are binary and ternary compounds which are structurally non-molecular (in one, two or three dimensions) and which therefore occur only in the solid state, and for which detailed structural data are available crystallographically. At the other extreme are conventional molecular compounds in which a metal cluster core is terminally ligated by ligands: this is the class of 'protected molecules'. In the third class, the new molecules considered here have only the cluster core, and no ligand termination, and so are named 'exposed molecules'. This classification is illustrated in Fig. 1 for nickel chalcogenide systems, by NiS (the mineral millerite) as the non-molecular solid, by $[Ni_{11}S_8]$[12] as the exposed molecule and by $[Ni_{34}Se_{22}(PPh_3)_{10}]$[16] as the protected molecule. To illustrate again with the familiar carbon systems, diamond is non-molecular carbon, C_{60} is exposed molecular carbon, and the hydrocarbon dodecahedrane $C_{20}H_{20}$ represents protected C_{20}. This tripartite perspective is valuable and stimulates research in other fields of contemporary inorganic chemistry: some examples from metal–carbon systems are developed below. The concepts of non-molecularity, exposure and protection also pervade surface chemistry.

Metallocarbohedrenes

In 1992 a class of naked metal carbide clusters known as metallocarbohedrenes (or met-cars) was discovered.[17] These metallocarbohedrenes are synthesised when reactive metal clusters dehydrogenate hydrocarbons in the gas phase. The prototypical species was $[Ti_8C_{12}]^+$, but now more than a hundred metal–carbon molecules have been detected for metals

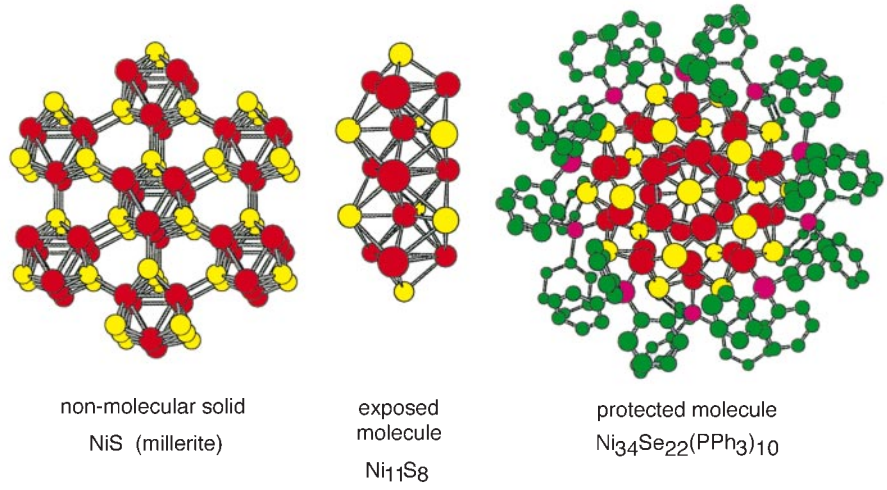

Fig. 1 Illustrations of the classification of non-molecular solids, exposed molecules, and protected molecules. Non-molecular NiS in the mineral millerite, the exposed molecule [$Ni_{11}S_8$] observed in the gas phase,[12] and the phosphine-protected nickel selenide core of [$Ni_{34}Se_{22}(PPh_3)_{10}$] prepared in solution and characterised crystallographically:[16] Ni red, S, Se yellow, P magenta, C green.

in groups 4–8 and 11. While many of these M_xC_y molecules have $y > x$ and an even number of C atoms and are believed to contain C_2 groups, there is a subset with $y \approx x$, believed to be fragments of a cubic metal carbide lattice containing C atoms.[18] The reactivities and transformations of metallocarbohedrenes are now well known,[18,19] but no pure bulk sample has been prepared. In the classification of Fig. 1, these exposed metal–carbon molecules lie between the non-molecular metal carbides[20] and organometallic clusters containing C_n moieties.[21]

Nitrogenase

Nitrogenase is the enzyme which reduces dinitrogen to ammonia, under conditions (ambient) which are far milder than those of the best industrial practice for reduction of N_2 with H_2 to form ammonia (the Haber–Bosch process, 400–500 °C, 100–1000 atm). The crystal structure of the FeMo protein of nitrogenase was determined in 1992, and subsequently improved,[22] revealing that the metal sulfide cluster (Fe_7MoS_9) at the active site is different from the many predictions, and unprecedented. The tantalising chemical question is 'how can a metal sulfide cluster enclosed in protein reduce one of the most recalcitrant molecules of chemistry under such mild conditions?' This question is another mantra in the philosophy of biognosis which holds that sophisticated chemistry can be learned from evolved biology.

The essential features of the Fe_7MoS_9 cluster at the active site are shown in Fig. 2. A six-coordinate Mo atom is coordinated by a side-chain histidine, bidentate homocitrate and three triply bridging sulfide ions to one triangular end of a trigonal prism of Fe atoms. The opposite end of this trigonal prism is connected through three triply bridging sulfides to the seventh Fe atom, whose tetrahedral coordination is completed by a cysteine residue. Around the equatorial belt of the trigonal prism there are three doubly-bridging sulfide ions. The significant features of the cluster are the threefold coordination of each of the six Fe^3 atoms† in the trigonal prism, the doubly-bridging S^2 atoms bridging the axial edges of the trigonal prism, and the connection of the cluster to the protein only at two end positions. The nakedness of the central Fe^3 and S^2 atoms is a conceptual link with the exposed metal sulfide clusters in the gas phase. Of course the essential Fe_7MoS_9 cluster is enclosed by protein, and the sophistication of the catalysis effected by nitrogenase depends on the cooperative action of cluster and protein, and the hydrogen bonds which link them. The Fe_7MoS_9 cluster participates in a rich sequence of reactions which probably depend, at least in part, on the reactivity of nakedness. There is another conceptual link between nitrogenase and the

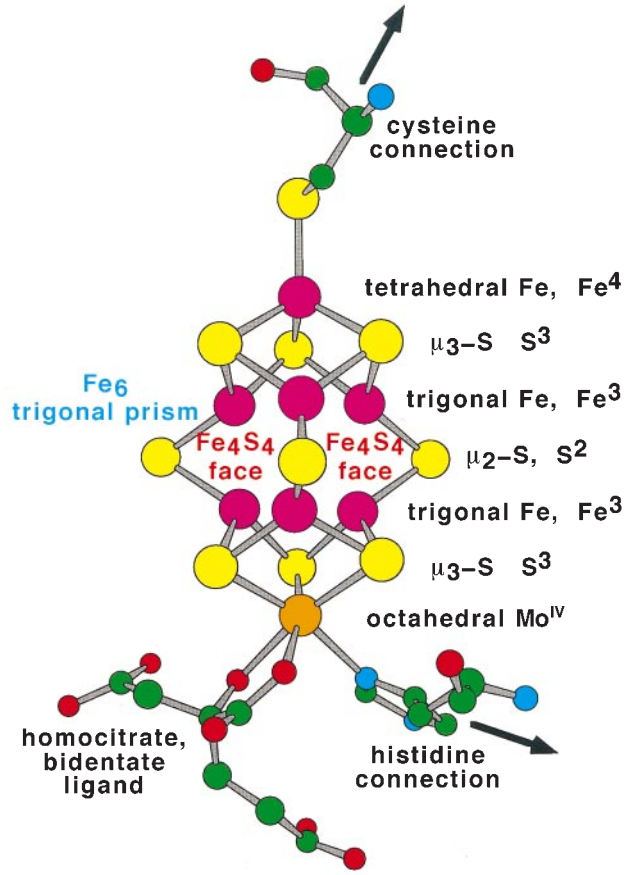

Fig. 2 The essential features of the Fe_7MoS_9(cysteine)(histidine)(homocitrate) cluster at the active site of the enzyme nitrogenase: Fe magenta, Mo orange, S yellow, C green, N blue, O red

gas phase metallocarbohedrene chemistry, in that the C_2^{2-} ligand of the metallocarbohedrenes is isoelectronic with the primary substrate N_2 of nitrogenase.

Determination of the crystal structure of the key protein of nitrogenase revealed the stage on which the marvellous molecular dance occurs, but provided no direct information about the dancers or the choreography.[23] The question now is how to determine that choreography.

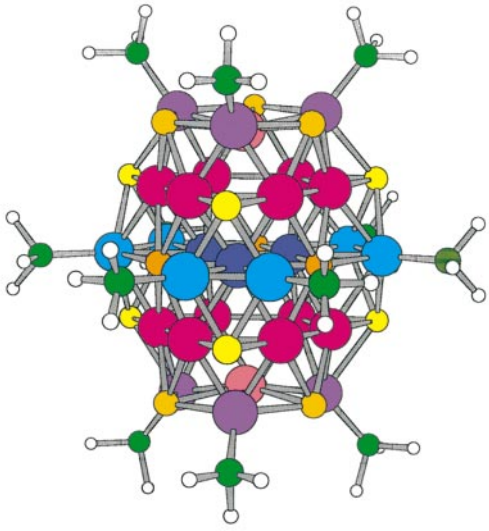
Similar questions arise for the new exposed inorganic molecules. Their compositions and reactions are known mass

spectrometrically, but not their structures. In all of these contexts, powerful density functional theory provides valuable insights.

Calculating the structures and reactions of big molecules

Density functional theory (DFT) is now well established as a valuable quantum method for the calculation of the electronic structure and energy, and derived properties, of large molecules and molecules containing atoms which contribute many electrons.[11,24] DFT includes a computationally efficient account of the correlation and exchange energies (the electron–electron energies) which have complicated and prolonged traditional quantum chemical calculations. Apart from the selection of functionals to describe exchange and correlation, the DFT method is *ab initio*.

The performance of DFT calculations is impressive for molecules like those introduced above. For a calculational effort which scales with the number of electrons more favourably than any comparable method, optimised geometries are obtained with an accuracy sufficient to address the big-picture questions. As illustration, Fig. 3 shows the optimised structure of



Bond	Obs	R=H: vwn/b88e

Fig. 4 The structure of $[Fe_6S_6(PR_3)_6]^{2+}$: large spheres are Fe atoms, colour coded according to chemical type and connectivity (point group C_{2v}), small yellow, light orange and deep orange spheres are S, green P and white H. The tabulation of colour-coded bond types compares the distances observed for R = Et with the distance calculated (in C_{2v}) for R = H, using the Lee–Yang–Parr gradient-corrected correlation functional[30] and Becke's gradient-corrected exchange functional.[29]

$Cu_{29}Se_{15}(PH_3)_{12}$ (which contains 1566 electrons) in comparison with the observed (X-ray crystal structure[25]) geometry for $Cu_{29}Se_{15}(PPr^i_3)_{12}$, and Fig. 4 shows the results for the 'basket cluster' $[Fe_6S_6(PR_3)_6]^{2+}$ (R = H calculated, R = Et observed[26]). In both molecules it can be seen that the calculated interatomic distances are generally within 0.05 Å (and often 0.02 Å) of those observed, and that the variability of bond type and length is reproduced, including long Fe–Fe distances which are not bonds. This augurs well for application to molecular metal sulfide clusters and to nitrogenase. There are extensive checks of calculated energies against experimental data.[27]

In exploring the geometry–energy hypersurface for new chemical systems it is also desirable to locate transition states (saddle points) and to calculate reaction profiles. The method used here is to postulate a saddle geometry, then follow the geometry change on its steepest downhill energy path, and then to iterate through a cycle of geometry adjustment and energy minimisation until the lowest energy transition state is found.

Answering the questions: transferring concepts

The new inorganic molecules and their reactions present innumerable questions. In DFT we have a powerful tool for answering those questions, or at least for the design of fruitful further experiments. The key challenge—and the exciting appeal of this research—is in devising the best hypotheses. In

my view the quality of research of this type is determined more by the quality of the ideas to be tested than by the computational methodology to be deployed.

In the following sections I outline some responses to the questions raised, with emphasis on the transferability of ideas and insight from metal sulfides to metallocarbohedrenes to nitrogenase, and the incorporation of structural data and principles from related non-molecular solids and protected molecules.

Structures of molecular metal sulfides

The compositions of the observed molecules $[M_xS_y]$ are plotted on maps of y *vs.* x, and show several significant general characteristics. Firstly, the x/y distribution is a continuous extended domain which is relatively narrow in y. In the case of $[Cu_xS_y]^-$, the main sequence of larger species can be described by the equations $x = 2y - 1$ and $x = 2y - 2$,[4,6] while for $[Mn_xS_y]^-$ the ions are described by $x = y$ and $x = y - 1$.[8] The continuous narrow regions of observability accentuate in contrast the emptiness of the composition maps and the many species which are not observed. Secondly, while for any metal there are variations in intensity along these sequences, there are no pronounced discontinuities in abundance which might signify special stability or structure. Thirdly, it must be remembered that observability on the composition map need not represent inherent stability, and could be due to favourable electron affinity in the competition for electrons during the formation of the anions. Fourthly, the slopes (y/x) of the domains of observability correlate with the number of valence electrons provided by M, and a qualitative electron counting pattern has been identified.[1,4]

The first issue for the new molecules is geometry: what is $[Mn_{20}S_{20}]^-$, or $[Fe_{11}S_{10}]^-$, or $[Co_{38}S_{24}]^-$, or $[Ni_{15}S_{10}]^-$, or . . .? And then, is there a fundamental structural principle for each metal? And are there structural principles which allow almost continuous growth, rather than special stability at certain sizes? In answering questions about geometry, knowledge of the many structures of terminally ligated metal chalcogenide clusters[2] provides inspiration for postulates to be tested.

In the case of $[Cu_xS_y]^-$ clusters, the enhanced stability of $[Cu_3S_3]^-$, $[Cu_6S_4]^-$ and $[Cu_{10}S_6]^-$ has been traced to cluster structures which contain local S–Cu–S linear (or near-linear) coordination, and the other reactive clusters are those which have exposed Cu atoms without this geometry.[4] For the $[Mn_xS_y]^-$ set,[8] 61 isomers for 23 compositions up to $[Mn_{15}S_{15}]^-$ have been evaluated by DFT in terms of optimised geometrical structure, electronic structure, and electron affinity.[7] Structures based on stacks of Mn_3S_3 triangles are favourable, as are regular Mn_x polyhedra with (μ_3-S) caps, and trigonal MnS_3 local coordination occurs in the more stable isomers.

Structures of metallocarbohedrenes

The prototypical metallocarbohedrene Ti_8C_{12} was postulated to have a structure (symmetry T_h) in which six C_2 units cap the faces of a Ti_8 cube, with the C_2 parallel to the edges of Ti_4 squares.[17] In this, the Ti–C and C–C bonds constitute a pentagonal dodecahedron, with analogy to C_{20}. My idea that there could be alternative stable structures came from a quite different field, metal thiolate clusters. The $M_8(SR)_{12}$ based clusters had been investigated earlier, when it was recognised that the M_8 polyhedron could be either a cube or a tetracapped tetrahedron, and that the bridging S atoms could constitute either a cuboctahedron or an icosahedron.[31,32] Therefore I explored alternatives for Ti_8C_{12}, and recognised a high symmetry (T_d) structure in which the Ti_8 set was a tetracapped tetrahedron, with the six C_2 groups bonded diagonally on each of the six folded Ti_4 rhombuses (or butterflies) on the Ti_8 surface (see Fig. 5). DFT calculations readily showed that the T_d structure was very much more stable than the T_h structure,[33] and this was confirmed by other theoretical investigations.[18,34] There are other isomers for M_8C_{12} which have lower symmetry arrangements of the diagonally bound C_2.[34] Subsequently I characterised the barrierless transformation of T_h-Ti_8C_{12} to T_d-Ti_8C_{12}, outlined in Fig. 5.[35]

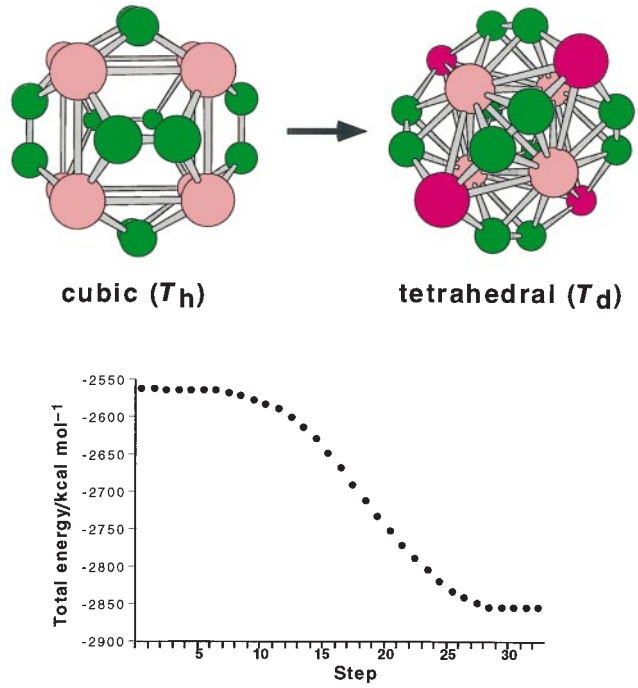

Fig. 5 The T_h and T_d isomers of Ti_8C_{12} (C green), and the barrierless energy change of 300 kcal mol^{-1} (1 cal = 4.184 J) in the transformation (in point group D_2) of T_h to T_d. In the T_d isomer the inner and outer Ti atoms are coloured pink and purple, respectively.

The concept of C_2 bonded diagonally across an M_4 rhombus rather than parallel to edges of an M_4 quadrilateral is entrenched in the models of many other metcars, such as the photodissociative transformation of $Ti_{14}C_{13}$ to Ti_8C_{13},[36] the structures of the unusual niobium carbohedrenes,[37] and the copper carbohedrenes.[38] Copper is unique in being the only late-transition metal reported to form metallocarbohedrenes: carbohedrenes are not known for metals in groups 9 or 10.

Copper carbohedrenes Cu_xC_y were observed in the series $[Cu_{2n+1}C_{2n}]^+$ for $1 \leqslant n \leqslant 10$, as well as $[Cu_7C_8]^+$, $[Cu_9C_{10}]^+$, $[Cu_{12}C_{12}]^+$, $[Cu_{16}C_{16}]^+$ and $[Cu_{20}C_{18}]^+$.[18] I noted a similarity between these compositions and those of the naked copper sulfide clusters $[Cu_xS_y]^-$, if C_2 was stoichiometrically equivalent to S. This similarity is shown on the composition map in Fig. 6. This is reasonable because both S^{2-} and C_2^{2-} can be isovalence-electronic in their bonding in metal clusters, both providing four donor electron pairs and having empty acceptor orbitals, as shown diagrammatically in Fig. 7.

Figs. 8 and 9 illustrate analogies between copper sulfide structures and copper carbohedrenes. The high symmetry structures of $Cu_{12}S_7$ (point group O_h) and $Cu_{13}(C_2)_6$ (point group T_h) have the same connectivity with either S or C_2 bound to the Cu_4 units of a cuboctahedron (see Fig. 8): the stoichiometry difference is accounted for by the presence of S at the centre of $Cu_{13}S_7$ and Cu at the centre of $Cu_{13}(C_2)_6$. This structural homology can be extended through larger clusters, to $Cu_{24}S_{13}$ and $Cu_{25}C_{24}$,[38] shown in Fig. 9.

While much further investigation is required to reveal the structures of the large numbers of exposed metal sulfide and metallocarbohedrene molecules, some guiding principles are becoming clear, and the analogies between the sulfide and carbide clusters stimulate hypotheses.

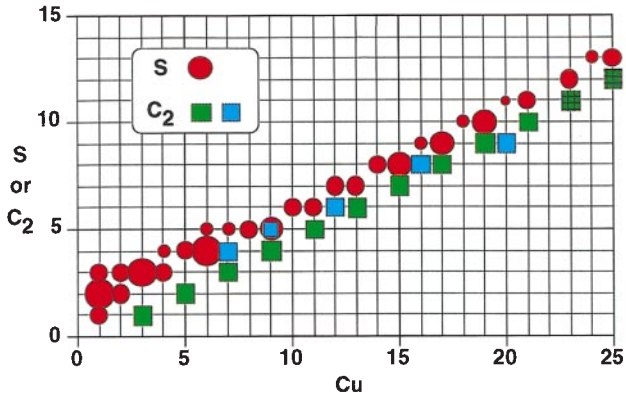

Fig. 6 Map of the compositions of $[Cu_xS_y]^-$ (red) and $[Cu_x(C_2)_y]^+$ (green, blue) in the gas phase: the vertical axis plots the number of S atoms or C_2 groups. The green compositions belong to the series $[Cu_{2n+1}C_{2n}]$, but the hatched green species were not observed.[18]

Fig. 7 Comparison (diagrammatic, not stereochemical) of the electronic components of sulfide S^{2-} and acetylide C_2^{2-} available for bonding participation in metal clusters. Both have four donor electron pairs marked as heavy lines (for C_2^{2-} these are the terminal σ pairs and the two π bonding pairs) and both have empty orbitals marked as lobes, being d orbitals at S and π* orbitals on C_2^{2-}: not all of these empty orbitals are shown.

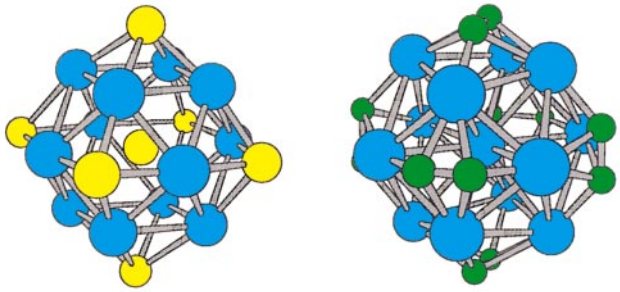

Fig. 8 Comparison of the optimised structures of $[Cu_{12}S_7]$ and $[Cu_{13}(C_2)_6]^+$, in which S and C_2 groups interchangeably cap the faces of a Cu_{12} cuboctahedron

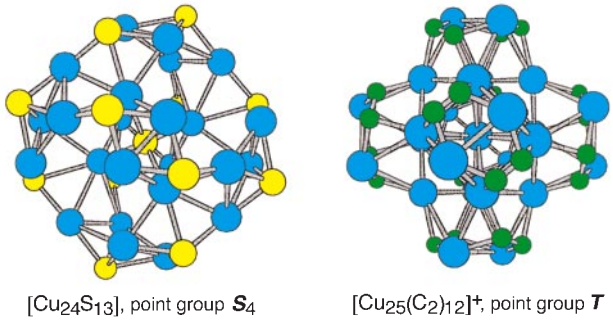

Fig. 9 Comparison of the optimised structures for $Cu_{24}S_{13}$ and $[Cu_{25}(C_2)_{12}]^+$, in which S and C_2 groups occupy similar positions on the surface of a Cu_{24} framework which is a distorted hexacapped cuboctahedron. The differences are due to tetrahedral coordination of the central S in $Cu_{24}S_{13}$ but cuboctahedral coordination of the central Cu in $[Cu_{25}(C_2)_{12}]^+$.

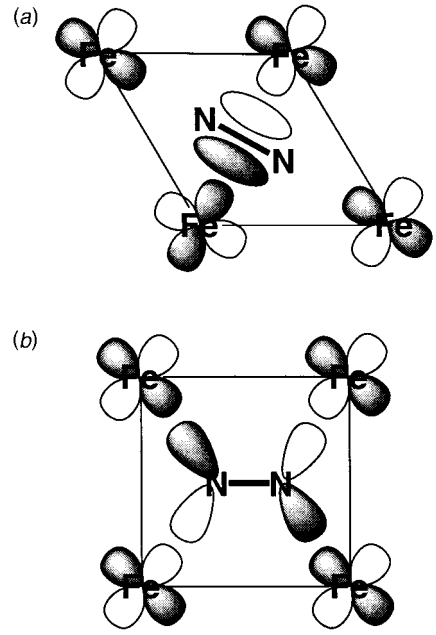

Fig. 10 Hypotheses for N_2 binding to an $(Fe^3)_4$ face of the Fe_7MoS_9 cluster of nitrogenase. (*a*) The twist or rhombus configuration allowing overlap between the Fe orbitals and N_2 π-bonding orbitals. (*b*) The parallel or rectangle configuration in which the Fe orbitals overlap with N_2 π-antibonding orbitals.

Tantalising nitrogenase

As already mentioned, the structure of the resting FeMo protein revealed nothing about the mechanism for conversion of N_2 to NH_3. There is however a very large amount of data on the kinetics and spectroscopy (mainly EPR) of the enzyme with various substrates and inhibitors, impressive model chemistry, and information about the effects of site-directed mutations.[22,39] An issue is how to incorporate the new structural data into a more detailed and chemical description of the mechanism. More specifically there are questions about the location and geometry for the initial binding of N_2, the bonding geometry which activates N_2, the effects of introduction of electrons, the proton approach pathways, details of the binding of the intermediates, and the pathway for egress of products. Nitrogenase reduces protons in amounts determined by the availability of N_2, and H_2 inhibits N_2 reduction, and so there are related key questions about the binding of H^+, H and H_2 at the active site.

The first question (although not necessarily the first step in the mechanism) concerns the binding of N_2. In 1993, a lecture by Doug Rees about the cluster structure triggered the idea that the metallocarbohedrene experience was relevant. The hypothesis was:[40]

(*i*) metallocarbohedrenes have C_2 bound most stably along the long diagonal of a M_4 rhombus, while C_2 bonding parallel to the edges of an M_4 rectangle is less stable;
(*ii*) the $(Fe^3)_6$ trigonal prism of nitrogenase has three $(Fe^3)_4$ rectangular faces;
(*iii*) rotation of a trigonal prism about its threefold axis changes the rectangular faces to rhombuses;
(*iv*) N_2 is isoelectronic with C_2^{2-};
(*v*) therefore the N_2 could be bound stably to an $(Fe^3)_4$ rhombus face of a twisted form of the $(Fe^3)_6$ trigonal prism [Fig. 10(*a*)];
(*vi*) rotation back to the trigonal prismatic $(Fe^3)_6$ geometry with a rectangular $(Fe^3)_4$ face could weaken the N–N bond [Fig. 10(*b*)], which is the objective.

This hypothesis was fully consistent with the binding of the Fe_7MoS_9 cluster to the protein, because the cluster is anchored at the six-coordinate Mo end, but able to rotate the other end

about the pseudo-threefold axis coincident with the Fe–S_{cys} bond.

The feasibility of an $(Fe^3)_4$ face of the cluster as N_2 binding site was developed by examination of the protein surrounds and hydrogen bonds, revealing that the $(Fe^3)_4$ face capped by the extended side chain of arginine-359 was much better positioned than the other two for substrate binding:[79] this full $[(Fe^3)_4(S^2)_2(S^3)_2]$ face proposed for action is named the front face. DFT calculations demonstrated the feasibility of N_2 binding at this face, and also revealed that reduction of the cluster concentrated negative electron density on the S (rather than Fe or Mo) atoms, and particularly on the S^2 atoms flanking the binding face. Since these two flanking S^2 atoms are hydrogen bonded to protein from behind the front face, this result inspired the important mechanistic concept of proton transfer to bound substrate *via* these S^2 atoms according to their redox-moderated basicity, along the pathway illustrated in Fig. 11.

Continued application of DFT to the questions about nitrogenase structure and mechanism has provided further insight[41] into: (*a*) the flexibility of the Fe_7MoS_9(cys)(his)(cit) core structure; (*b*) the influence of redox level (both electronation and hydrogenation) on the geometry of the core; (*c*) the optimum geometries for N_2 bound to the core in various ways, and their relative energies; (*d*) the sliding of H atoms around the cluster atoms, in relation to the $2e^- + 2\,H^+ \rightleftharpoons H_2$ processes and the exchangeable and non-exchangeable hydrogen binding sites; (*e*) the binding of inhibitor CO and alternative substrates; and (*f*) the formation of NH_3.

The initial idea of the trigonal prism twisting about its threefold axis has been expanded to include and explore all of the conformational freedom of the Fe_7MoS_9 cluster. Because this cluster is undercoordinated it was expected to be floppy. Using the distortions shown in Fig. 12, DFT calculations with the 38-atom asymmetric model (Fig. 12) show that the energy surface for these distortions is relatively flat. Variations of Fe–Fe distances by up to 1 Å involve energy changes of < 10 kcal mol^{-1}: the flatness of the energy surface is dependent on the redox level.

A number of geometries for N_2 binding to the Fe_7MoS_9 cluster have been investigated theoretically.[40,42] My DFT calculations show that terminal η^1 binding of N_2 to one of the Fe^3 atoms is energetically favourable, and draws the Fe^3 atom out of the cluster to achieve local trigonal pyramidal coordination. However this does not elongate N–N as much as does η^2, μ_4 binding of both N atoms of N_2 to an $(Fe^3)_4$ face. The lowest energy η^2, μ_4 geometry is the conformation shown in Fig. 13(*left*), and dubbed 'oblique arrow' to describe the approach of N_2 to the $(Fe^3)_4$ face. One N atom, labelled $N^{proximal}$, is bonded to all four Fe^3 atoms, while the other (N^{distal}) is bonded to two Fe^3. This configuration is *ca.* 27 kcal mol^{-1} more stable than the symmetrical configuration of Fig. 13(*right*), and the N–N bond in the oblique arrow geometry is 1.29 Å relative to 1.10 Å in free N_2. The 'direct arrow' configuration in which N_2 is bound symmetrically to $(Fe^3)_4$ through only one N atom is not an energy minimum.

The N^{distal} atom in the oblique arrow conformation is positioned between three S atoms (two S^3, one S^2) on the front face, with N···S distances of 2.7–3.0 Å. Electronation of the cluster is calculated to increase the basicity of these S atoms, allowing H^+ ions to be transferred to them *via* hydrogen bonds, and after inversion at S^2 the resulting bound H atoms are within hydrogen bonding distance of the N^{distal} atom. This suggested a

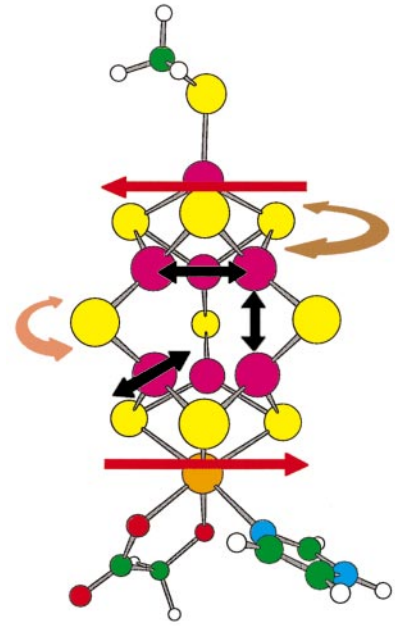

Fig. 12 Conformational freedom of the Fe_7MoS_9(cys)(his)(cit) cluster. The red arrows represent lateral shear, the brown arrow represents torsional twist about the pseudo-threefold axis, the orange arrow represents flapping of the S^2 atoms, and the black arrows represent various expansions and/or contractions of the $(Fe^3)_6$ trigonal prism.

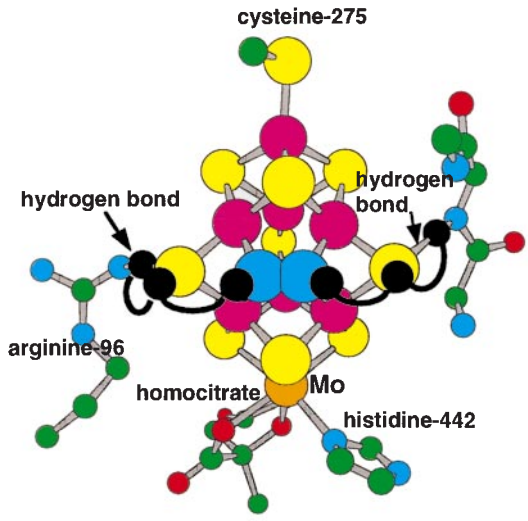

Fig. 11 The Fe_7MoS_9(cysteine)(histidine)(homocitrate) cluster, showing hydrogen bonds from behind the S^2 atoms flanking the front face, and the postulated transfer of H to bound N_2 by inversion of (S^2–H)

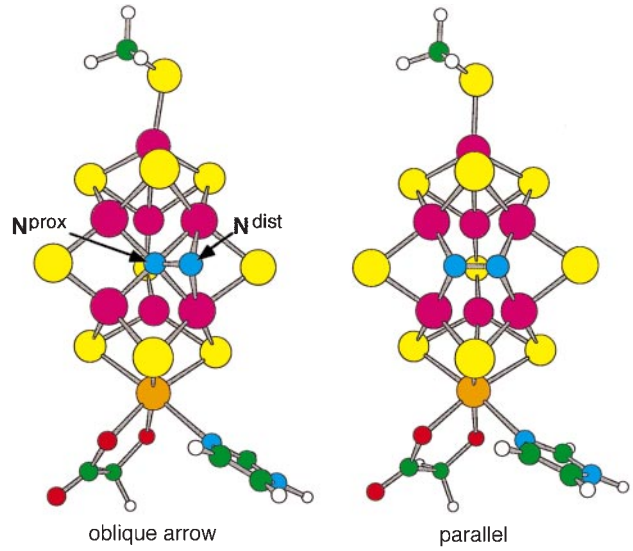

Fig. 13 The oblique arrow and parallel binding geometries for N_2 on the $(Fe^3)_4$ face of the Fe_7MoS_9(cys)(cit)(his) cluster. The calculated N–N distances are 1.29 and 1.25 Å, respectively.

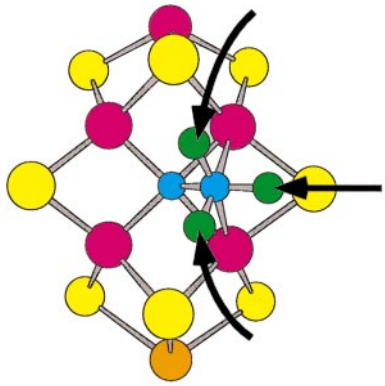

Fig. 14 Part of the front face of the Fe_7MoS_9(cys)(his)(cit) cluster showing N_2 bound in the oblique arrow configuration, the proposed trajectories for protonation of N^{distal}, and the H atom locations in the postulated transition state

mechanism for hydrogenation of N^{distal}. The transition state shown in Fig. 14 for transfer of these H atoms to N^{distal} was postulated, and on energy minimisation the N–N bond broke and NH_3 formed as N^{distal} separates.[43] This process is calculated to be exergonic by many tens of kcal mol^{-1}. Similar protonation of $N^{proximal}$ *via* the closest S atoms, in concert with electronation *via* the cluster, is postulated for subsequent formation of the second NH_3 product.[43]

The chemistry of hydrogen at the active site, while not as dramatic as the breaking of a very strong triple bond, is almost as intriguing. Some facts[39] are that proton reduction always accompanies N_2 reduction, in amounts depending on the availability of N_2; $H_{2\,(g)}$ inhibits N_2 reduction; the reductive formation of $HD_{(g)}$ from protons in the presence of $D_{2\,(g)}$ occurs in the presence of N_2 and with the same kinetics as N_2 reduction. A mechanistic requirement is that H atoms from the gas phase must always remain distinguishable from H atoms from water.[39]

The bonding and sliding of H atoms over the Fe and S atoms of the cluster can be investigated by DFT. One result is that H atoms bound to S atoms weaken their ligating ability, lengthening Fe^3–S bonds and shortening Fe^3–Fe^3 distances, while H atoms bonded to Fe^3 lengthen Fe^3–Fe^3 distances.[41] Other calculations show how H_2 can bind to Fe. Various $2H \rightleftharpoons H_2$ interconversions on the Fe_7MoS_9 cluster can be demonstrated.[41] As an illustration of the type of calculation which can inform this cluster–hydrogen chemistry, Fig. 15 outlines the main features of a calculated reaction coordinate for a symmetrical $2(S^2\text{–}H) \rightleftharpoons H_2$ interconversion on a $Fe_8S_9(SMe)_2$ model.

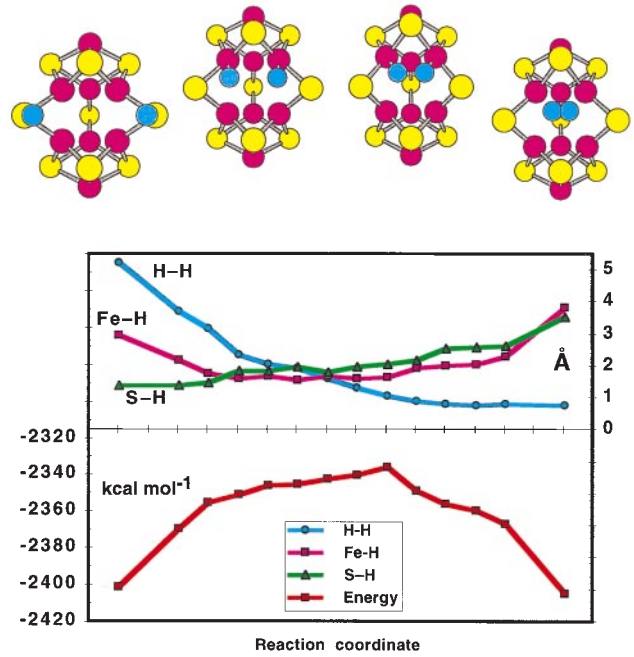

Fig. 15 Calculated reaction coordinate for a $2(S^2\text{–}H) \rightleftharpoons H_2$ transformation occurring on an $Fe_8S_9(SMe)_2$ model with C_s symmetry. Four structures in the sequence are shown at the top (with SMe groups omitted): in the left diagram two H atoms (blue) are bound to S^2 atoms, then move together *via* the mediation of Fe^3–H bonds, and then form H_2 which separates from the cluster. Interatomic distances and total energy through 14 points around the transition state are presented in the box.

Prospectives

This short account has provided glimpses of (1) the new chemistry which occurs for unprotected fundamental inorganic molecules, (2) consideration of this new molecular chemistry in the context of the more familiar non-molecular and protected analogous compounds, (3) the value of DFT, and (4) the value of concept-transfer between rather different chemical systems. But overall this has raised more questions than answers, and so I conclude with some prospectives for further research.

Continuing investigations of the formation and reactions of fundamental inorganic molecules in the gas phase, free of the ameliorating influences of solvation or crystal surrounds, will reveal more rule-breakers and expand the conceptual basis of fundamental inorganic chemistry.

A key objective is the preparation of bulk samples of the new molecules: this can be approached by condensation from the gas phase (*cf.* the fullerenes), or by planned reactions in relatively inert solution. The preparation of phosphine-protected copper sulfide clusters inspired by the gas phase results has been reported.[44] Preparation from the gas phase is likely to require condensation into a milieu which is inert or contains protecting ligands, to restrict conversion to non-molecular solids. On the basis of observed reactivities in the gas phase, the demonstrated successes of Dehnen and Fenske[44] using protecting ligands, and the calculated correlations of structure and reactivity, copper appears to be the most promising metal for preparation of the new molecules.

The Fe_7MoS_9 molecule at the catalytic site of nitrogenase is unprotected, in the sense of being undercoordinated, and is calculated to be reactive like other exposed metal sulfide molecules. It is also calculated to be floppy. The Fe_7MoS_9 cluster probably requires its protein cage for restraint of distortions, as well as restraint of some reactivity. The concerted enhancement of the catalytic reactivity of the Fe_7MoS_9 molecule by the protein surrounds is likely to occur primarily through the S atoms.

In an experimentally complex system such as the active site of nitrogenase, powerful DFT methods can provide insight and guidance to the experimental program.

Acknowledgments

I thank my coworkers and colleagues named in the references for their experimental efforts, vigorous discussions, and provision of information in advance of publication. This research is funded by the Australian Research Council and the University of NSW, and the Australian Nuclear Science and Technology Organisation provided computational resources.

Ian Dance is Professor of Inorganic Chemistry at the University of New South Wales. His formative research was under the direction of Professors Hans Freeman (Sydney), Jack Lewis (Manchester) and Richard Holm (MIT). He served on the faculty of the University of Wisconsin, Madison before joining the University of New South Wales in 1975. He won the Inorganic Award of the Royal Australian Chemical Institute in

1996, and was elected to Fellowship of the Australian Academy of Science in 1997.

Reappraisal of the spin-forbidden unimolecular decay of the methoxy cation†

Massimiliano Aschi, Jeremy N. Harvey, Christoph A. Schalley, Detlef Schröder and Helmut Schwarz‡

Institut für Organische Chemie der Technischen Universität Straße des 17. Juni 135, D-10623 Berlin, Germany

The mechanism of the unimolecular loss of H_2 from triplet methoxy cations ($^3CH_3O^+$) is revised.

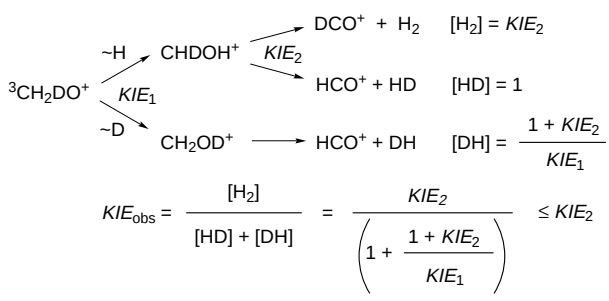
The mental representation of chemical reactions relies on the paradigm of the potential energy surface (PES): the reactive system moves from the reactant minimum of the PES through a transition state to the product minimum. Reactions which involve a change in total spin appear to violate this paradigm, since they must necessarily occur on two or more PESs. For this reason, they have been difficult to understand, both qualitatively and quantitatively.[1] A typical example which has been the subject of numerous studies[2] is the unimolecular decomposition of triplet methoxy cation ($^3CH_3O^+$) to form H_2 and formyl cation (HCO^+), both singlet species. The present consensus (path A) is that this process occurs in a *stepwise* manner, *i.e.* first

$$^3CH_3O^+ \rightarrow {}^1CH_2OH^+ \rightarrow {}^1HCO^+ + H_2 \qquad \text{Path A}$$

$$^3CH_3O^+ \rightarrow {}^1HCO^+ + {}^1H_2 \qquad \text{Path B}$$

hydrogen shift, concurrent with spin change, to form *singlet* hydroxymethyl cation ($^1CH_2OH^+$), then the well documented[3] [1,2]-elimination to yield HCO^+ and H_2. The main support for this mechanistic scheme is derived from the observation of almost identical kinetic energy releases associated with the losses of molecular hydrogen from both $[C,H_3,O]^+$ cations.[2e] However, neither this experimental nor the computational evidence are conclusive. Indeed, a *concerted* pathway (path B) involving simultaneous spin change and [1,1]-elimination from $^3CH_3O^+$ has been suggested, but not established.[2f] Here we present experimental results[4–6] for the H/D isotope effect on unimolecular hydrogen loss from $[C,H_2,D,O]^+$ isotopomers of the methoxy and hydroxymethyl cations,[7] and discuss the mechanistic implications on the basis of supporting computational results in order to clear up the long-standing questions concerning the unimolecular decay of methoxy cation.

Assuming that only the *stepwise* mechanism occurs, Scheme 1 implies that the observed kinetic isotope effect KIE_{obs} for loss of molecular hydrogen from $^3CH_2DO^+$ is expected to be smaller than the kinetic isotope effect for loss of hydrogen from the intermediate $CHDOH^+$ (KIE_2), *whatever* the actual values of KIE_1 and KIE_2.[8] Assuming that KIE_2 does not depend much on the way in which $CHDOH^+$ is formed,[9] it can be obtained from the decay of independently generated $CHDOH^+$ cations. The relevant metastable ion (MI) spectra[4] (Fig. 1) lead to $KIE_{obs} = 8.0 \pm 1.0$ and $KIE_2 = 1.3 \pm 0.1$, respectively.[10] This value of KIE_{obs} is inconsistent with the above analysis, therefore



Scheme 1

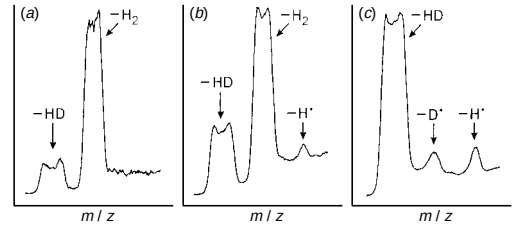


Fig. 1 MI spectra of (*a*) $^3CH_2DO^+$, (*b*) $CHDOH^+$ and (*c*) CH_2OD^+. Note that weak H/D atom losses are observed for the hydroxymethyl cations, which can be distinguished from H_2 loss by their peak shapes.

the stepwise path A alone cannot account for the experimental findings. Other mechanisms must strongly contribute; an obvious candidate is the *concerted* pathway B which could well have a kinetic isotope effect larger than KIE_2.

Further evidence comes from eqns. (1) and (2) for the relative yields of ideal *stepwise* and *concerted* mechanisms, respectively.[11] The experimental kinetic isotope effect for HD *vs.*

$$[HD] = 0.5\,([H_2] + [D_2]) \qquad (1)$$

$$[HD] = \sqrt{[H_2] \cdot [D_2]} \qquad (2)$$

D_2 loss from $^3CHD_2O^+$ cations[2e] is 10 ± 2, which, together with a kinetic isotope effect of 8.0 for H_2 *vs.* HD loss from $^3CH_2DO^+$, gives a branching ratio of $[H_2] : [HD] : [D_2] = 100 : 12.5 : 1.25$. Based on the measured $[H_2]$ and $[D_2]$ abundances, eqns. (1) and (2) predict [HD] values of 51 and 11 for *stepwise* and *concerted* pathways, respectively. Within the error margins, the observed [HD] figure of 12.5 is identical with the latter value, again suggesting that dehydrogenation of methoxy cation occurs in a concerted manner.

The $[C,H_3,O]^+$ hypersurfaces have been the subject of several computational studies.[2,3] The key events in the present reactions are, however, the spin changes, which can be assumed to proceed through surface hopping in the vicinity of the minimum energy crossing points (MECPs) between the PESs of different spin. Any computational description of unimolecular reactivity must therefore also consider the MECPs for paths A and B. This can be done with several methods which use analytical energy gradients.[1,12] The MECP corresponding to the *concerted* pathway (MECP1) has been described in the literature,[2f] but not that for the hydrogen migration in the *stepwise* route (MECP2).

Table 1 and Fig. 2 show the calculated[14] PESs for singlet and triplet $[C,H_3,O]^+$, including both MECPs. The key point is that MECP1 is slightly lower than MECP2 at each of the three levels of theory considered, although the relative energies of the two MECPs compared to $^3CH_3O^+$ vary somewhat. Further, the surface-hopping probability at the MECPs depends strongly on the spin-orbit coupling constant H^{SO} between the two wavefunctions. In fact, if the values of H^{SO} were very different at MECP1 and MECP2, the pathway with the larger H^{SO} could dominate, whatever the energies. To evaluate this possibility, we calculated[16] the value of H^{SO} at both MECPs, and obtained similar results, 50 cm^{-1} for H^{SO} (MECP1) and 56 cm^{-1} for H^{SO} (MECP2). With the present energies and H^{SO} values for MECP1 and MECP2, it is thus reasonable to expect that the

Table 1 Calculated (ref. 14) energies relative to $^3CH_3O^+$ at different points on the $[CH_3O^+]$ PESs, based on total energies[a] with no zero-point energy corrections

Species	UMP2	B3LYP	CCSD(T)	G2[b]
$HCO^+ + H_2$	−65.1	−38.4	−51.8	−54.5
CH_2OH^+	−92.4	−76.5	−85.6	−88.3
TS for H_2 loss	−6.4	11.7	2.5	−0.5
MECP1[c]	11.6	17.6	13.2	—
MECP2[c]	13.7	19.4	14.3	—

[a] Total energies (in Hartrees) for methoxy cation are −114.37456 (UMP2/BSI), −114.70013 (B3LYP/BSI), −114.47930 (CCSD(T)/BSII//B3LYP/BSI) and −114.50621 (G2). [b] G2 total energies are taken for comparison from ref. 13. [c] The calculated geometries for each MECP are very similar at all levels. The results for MECP1 reported in ref. 2(*f*) are similar to those obtained here.

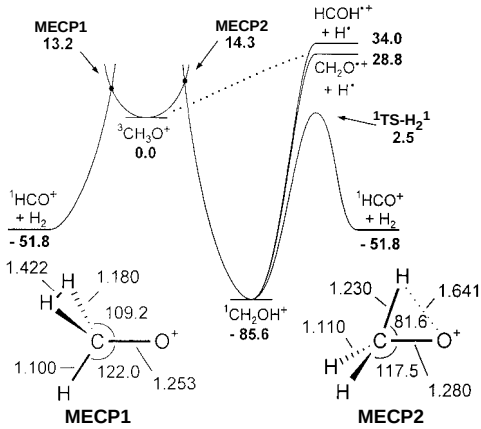

Fig. 2 Relevant parts of the triplet and singlet potential energy surfaces of $[C,H_3,O]^+$ cations calculated at the CCSD(T)/BSII//B:3LYP/BSI level (ref. 14). Bond lengths are given in Å and angles in degrees. Energies relative to the methoxy cation are given in kcal mol^{-1}.

concerted mechanism should at least be favoured over the *stepwise* pathway, although precise quantitative predictions would require a much more thorough analysis.[18]

The observation of nearly identical kinetic energy releases from both $[C,H_3O]^+$ cations[2e] is an argument in favour of the *stepwise* mechanism. However, if one considers that the height of MECP1 is less than 11 kcal mol^{-1} higher than ^{1}**TS-H$_2$**$^+$ (see Fig. 2), then it can be seen that these identical kinetic energy releases could come from different mechanisms.

In conclusion, the kinetic isotope effect results reported here provide very strong support for a reappraisal of the mechanism of unimolecular decomposition of the triplet methoxy cation and the present results suggest a [1,1]-elimination in which dehydrogenation and spin crossover occur in concert.[19,20]

6 B. A. Rumpf, C. E. Allison and P. J. Derrick, *Org. Mass Spectrom*., 1986, **21**, 295.

7 The MI mass spectra of $[C,H_3,O]^+$ and $[C,D_3,O]^+$ were also recorded, and the results are consistent with the present analysis.

8 KIE_1 and KIE_2 are product determining. Intermolecular kinetic isotope effects have not been taken into account, but, of course, would not affect the qualitative conclusions made here.

9 The effect of different internal energies of non-ergodicity on KIE_2 is probably small; an *enormous* change would anyway be needed to modify the conclusions outlined in Scheme 2.

10 For evaluation of the kinetic isotope effects, several experiments were averaged and the intensities were corrected for mass discrimination (see ref. 6) and for the statistical weights of H_2, HD and D_2.

14 Calculations at the UMP2 and B3LYP levels of theory were performed with GAUSSIAN94 [ref. 15(*a*)] and the 6-311+G(d,p) (BSI) basis set. The MECPs were located using our recently described method (ref. 12), and the gradients at these points were inspected to verify that they connect to the relevant minima. The CCSD(T) calculations at B3LYP optimized geometries were performed in MOLPRO [ref. 15(*b*)] with the cc-pVTZ basis set, omitting the *d* functions on hydrogen (BSII). At this level, the MECPs were optimized using the hybrid method of ref. 12 with B3LYP/BSI gradients.

15 (*a*) GAUSSIAN 94, Revision E.1, Gaussian, Inc., Pittsburgh, PA, 1995; (*b*) MOLPRO 96.4 is a package of *ab initio* programs written by H.-J. Werner and P. J. Knowles; (*c*) GAMESS USA (18th March 1997 version), M. W. Schmidt, K. K. Baldridge, J. A. Boatz, S. T. Elbert, M. S. Gordon, J. H. Jensen, S. Koseki, N. Matsunaga, K. A. Nguyen, S. J. Su, T. L. Windus, M. Dupuis and J. A. Montgomery, *J. Comput. Chem*., 1993, **14**, 1347. PC version compiled by A. A. Granovsky, Moscow State University.

16 These calculations were performed using an approximate one-electron Hamiltonian (ref. 17), as implemented in GAMESS [ref. 15(*c*)]. The GAMESS TZV basis set was used with one heavy atom d-polarisation function; the singlet and triplet states were described by CI wavefunctions expanded within a basis of HF orbitals generated either for the singlet or the triplet; the effective nuclear charges used were those recommended in ref. 17. The CI expansion included all possible determinants formed by allocating the eight valence electrons into five orbitals, and by allowing single excitations into the virtual orbitals. The value reported is the magnitude of the H^{SO} complex matrix element between coupled substates.

Stereoselective synthesis of a new optically active phosphinoacyloxazolidinone *via* enantioselective hydrogenation

Pierre Le Gendre, François Jérôme, Christian Bruneau* and Pierre H. Dixneuf*†

Laboratoire de Chimie de Coordination et Catalyse, UMR 6509, CNRS-Université de Rennes, Campus de Beaulieu, F-35042 Rennes, France

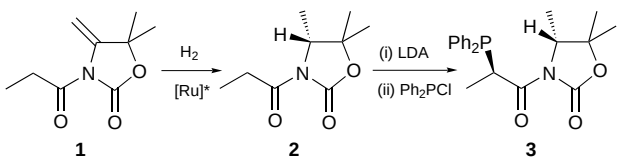
The preparation of a new optically active phosphinoacyloxazolidinone, based on the enantioselective hydrogenation of a 4-methylene-*N*-propionyloxazolidinone in the presence of [(*R*)-BINAP]Ru(O_2CCF_3)$_2$ catalyst followed by stereoselective phosphinylation, is reported.

Chiral diphosphines coordinated to a transition metal centre have demonstrated their power in asymmetric catalysis.[1] More recently, optically active heterobidentate ligands containing only one phosphorus group have proved to be very efficient in a variety of catalytic reactions. Thus, the diphenylphosphino group attached to a functional group such as an amine,[2] an oxazoline,[3] a pyrazole[4] or a quinoline[5] moiety has led to a variety of new P–N ligand–metal catalysts which have contributed to the improvement of enantioselectivity in various catalytic reactions. Other heterobidentate functional phosphine ligands with an additional coordinating oxygen atom have also been used successfully in asymmetric catalysis.[6–9]

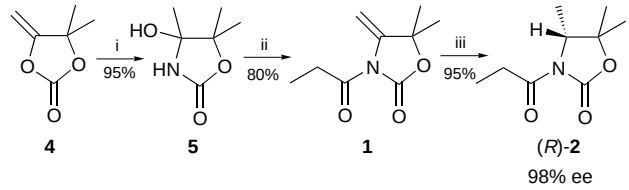
Here we report the preparation of a new P–O heterobidentate ligand of high optical purity based on the synthesis of an optically active acyloxazolidinone followed by its phosphinylation. This synthesis does not involve substrates from the natural chiral pool but is based on two successive selective reactions: (i) the enantioselective hydrogenation of a 4-methylene-*N*-propionyloxazolidin-2-one **1**, and (ii) the stereoselective phosphinylation of the resulting optically active acyloxazolidinone **2**, according to Scheme 1.

Whereas optically active acyloxazolidinones are usually prepared by acylation of oxazolidinones arising from optically active natural amino acids *via* multistep syntheses,[10,11] we have shown that it is possible to obtain both enantiomers of the acyloxazolidinone **2** *via* enantioselective hydrogenation of the 4-methylene-*N*-acyloxazolidinone **1** in the presence of a ruthenium catalyst containing an optically pure diphosphine ligand.

The bubbling of ammonia through an EtOAc solution of the carbonate **4**[12] at room temperature led to 95% yield of the hydroxyoxazolidinone **5**. The treatment of this cyclic carbamate with an excess of propionyl chloride in refluxing CH_2Cl_2 in the presence of $CaCl_2$ led to the isolation of the acyloxazolidinone **1** (80% yield) in a one pot acylation–dehydration reaction. The enantioselective hydrogenation of **1** was performed under 10 MPa of H_2 in MeOH at 50 °C for 18 h in the presence of 1 mol% of [(*R*)-BINAP]Ru(O_2CCF_3)$_2$ as catalyst and led to the (*R*)-*N*-propionyloxazolidinone (*R*)-**2** in 95% yield. Thus, in a four step synthesis involving only small simple molecules (prop-2-ynylic alcohol, CO_2, NH_3, AcCl and H_2), the (*R*)-*N*-propionyloxazolidinone (*R*)-**2** was isolated with an enantiomeric excess



Scheme 1



Scheme 2 *Reagents and conditions*: i, NH_3, room temp.; ii, EtCOCl, CH_2Cl_2 reflux; iii, H_2, [(*R*)-BINAP]Ru(O_2CCF_3)$_2$, MeOH, 50 °C

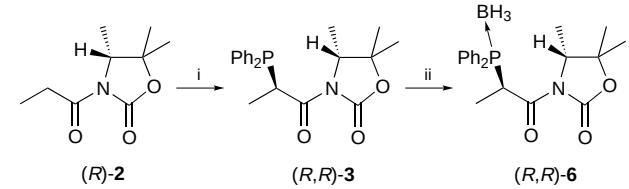
of 98%, according to Scheme 2.‡ Compound (*R*)-**2** appears to be the simplest (*R*)-enantiomer of the family of Superquats, the (*S*)-enantiomer of which has already been prepared from an amino acid.[11]

Advantage was taken of the asymmetric induction offered by chiral acyloxazolidinones to stereoselectively introduce an electrophile on the acyl group.[10,11] We thus attempted to transform (*R*)-**2** into a functional phosphine of type **3** by addition of the electrophilic diphenylphosphino group after deprotonation of the acyl moiety of (*R*)-**2** (Scheme 3).

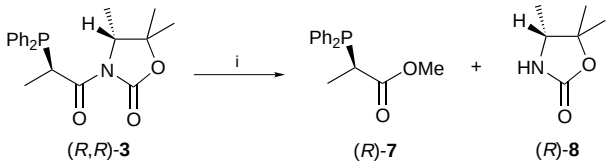
The *N*-propionyloxazolidinone (*R*)-**2** (4.3 mmol) was first deprotonated in THF at −90 °C using LDA (1 equiv.). Then, chlorodiphenylphosphine (4.3 mmol) was added and the reaction mixture was kept at −90 °C for 15 h before warming to room temperature. The resulting phosphinoacyloxazolidinone (*R*,*R*)-**3** was purified by chromatography over alumina and isolated in 87% yield. The ^{31}P NMR spectrum of the crude oil showed two singlets at δ 5.84 and 4.87, indicating the presence of the two diastereoisomers in the ratio 95 : 5. This result shows that the novel transformation of acyloxazolidinones by phosphinylation is stereoselective and that the optically pure *N*-propionyloxazolidinone (*R*)-**2** provides efficient asymmetric induction as already observed for the alkylation with BnBr, of (*S*)-**2** prepared *via* a different route.[11]

This functional phosphine is very air-sensitive and it is preferable to stabilize it as a phosphine–borane adduct. The addition of BH_3·SMe at −80 °C at the end of the reaction leading to **3** made possible the preparation of the corresponding phosphine–borane (*R*,*R*)-**6**.§ Chromatography over silica gel allowed the isolation of only the major diastereoisomer in 47% yield (100% de).

Cleavage of the *N*-acyl bond of (*R*,*R*)-**3** was carried out under mild conditions in MeOH at room temperature in the presence of K_2CO_3 and led to the chiral oxazolidinone auxiliary (*R*)-**8** and



Scheme 3 *Reagents and conditions*: i, LDA, THF, −90 °C, then Ph_2PCl, −90 °C to room temp.; ii, BH_3·SMe_2



Scheme 4 *Reagents and conditions*: i, MeOH, K_2CO_3, room temp.

the optically active phosphine methyl ester (*R*)-**7** in 90% yield after column chromatography under N_2 (Scheme 4).

In conclusion, we report the selective preparation of an optically pure phosphinoacyloxazolidinone. The synthesis involves the preparation of an optically active acyloxazolidinone *via* catalytic enantioselective hydrogenation and its use as chiral inductor for stereoselective phosphinylation. This type of new compound has potential as a new heterobidentate ligand in asymmetric catalysis, and as a building block for access to a variety of optically active phosphorus derivatives *via* cleavage of the oxazolidinone ring.

Properly activated Mg–Al hydrotalcite (Mg : Al = 3 : 1) is found to be a highly active, selective and regenerable heterogeneous catalyst for Meerwein–Ponndorf–Verley reduction of carbonyl compounds in the liquid phase.

The reduction of carbonyl compounds is one of the most widely practised operations in the synthetic organic, fine and perfumery chemical industries. Of particular importance is selective reduction of carbonyl groups in the presence of other functional groups. New methods, new catalysts and new reagents which offer greater activity, selectivity and reusability are constantly being sought.

The Meerwein–Ponndorf–Verley (MPV) reduction of aldehydes and ketones is one such reaction when high selectivities are obtained using metal alkoxides as catalysts, such as $Al(OPr^i)_3$ and $La(OPr^i)_3$.[1] However, the metal alkoxide catalysts are homogeneous, create problems during separation and are not reusable. Hence, reusable heterogeneous catalysts will have a distinct advantage if they can match the performance of homogeneous catalysts. In this regard, Posner *et al.*[2] were first to report the use of Al_2O_3 as a catalyst. However, a large amount of catalyst needed to be used (1–2 g Al_2O per mmol substrate) to achieve high conversions. Recently, Van Bekkum[3] showed that properly activated zeolite β was a highly active and stereoselective catalyst for the reduction of 4-*tert*-butylcyclohexanone to *cis*-4-*tert*-butylcyclohexanol. However, the use of zeolite β has limitations due to its pore size (7.4 × 6.5 Å). Kaspar *et al.*[4] have reported the use of MgO as a moderately selective catalyst for the reduction of α,β-unsaturated ketones in a fixed bed reactor using vapour phase conditions. In a fundamental study Ivanov *et al.*[5] have shown that MPV reductions can be catalysed by both basic and acid sites. Niyama *et al.*[6] reported that catalysts having adequate acidity and basicity show high activity in this reaction.

Here we report that properly activated Mg–Al hydrotalcite having a Mg/Al ratio of 3 : 1 is a highly active, selective and regenerable catalyst for MPV reduction of carbonyl compounds in the liquid phase. The high activity of these catalysts is attributed to the presence of both strongly basic and mildly acidic sites.

Mg–Al hydrotalcites having different ratios were synthesised using the procedure reported by Miyata *et al.*[7] The presence of pure hydrotalcite structure was confirmed by PWXRD. The catalysts activated in N_2 upto 550 °C showed a MgO pattern by X-ray diffraction indicating the formation of a solid solution of Al in MgO. The catalytic test was carried out using propan-2-ol as the hydrogen donor at 82 °C. The catalyst was pre-treated in N_2 at the desired temperature and carefully transferred to the reactor containing propan-2-ol without exposure to air, after which the substrate was introduced. Periodically withdrawn samples were analysed by gas-liquid chromatography.

The preliminary testing of hydrotalcites having different Mg/Al ratios and different calcination temperatures was carried out for the reduction of 4-*tert*-butylcyclohexanone to 4-*tert*-butylcyclohexanol. The hydrotalcite having a Mg : Al ratio of 3 : 1, calcined at 450 °C, was found to be the most active (Table 1). Hence all further studies were carried out using this catalyst.

Table 1 Effect of Mg : Al ratio and calcination temperature on the activity of Mg–Al hydrotalcites for MPV reduction of 4-*tert*-butylcyclohexanone[a]

Mg : Al ratio	Activation temperature/°C	Initial rate/10^4[b]
2 : 1	450	0.27
3 : 1	350	0.85
3 : 1	450	4.12
3 : 1	550	2.22
5 : 1	450	0.73
3 : 1[c]	450	4.09

[a] Reaction conditions: 4-*tert*-butylcyclohexanone (13 mmol), propan-2-ol (10 ml), catalyst (0.15 g) activated in N_2, reaction temperature 82 °C; [b] In mol per min per g catalyst. [c] Catalyst regenerated after one use in N_2 at 450 °C.

To allow comparison with the results reported by Van Bekkum[3] the same reaction was carried out using similar conditions on a reduced scale. Under these conditions, even with a lower catalyst loading (0.075 g instead of 0.1 g), 98% conversion was reached within 4 h with selectivity for alcohol greater than 95% (Fig. 1) (*trans* to *cis* alcohol ratio: 85 : 15). This shows that the activity of the catalyst prepared from hydrotalcite precursor is substantially higher than that reported for alumina, silica–alumina and Y-zeolite.[3]

The reusability of the catalyst was checked *via* solid separated by filtration and reactivated in N_2 at 450 °C. The reused catalyst showed similar activity to a fresh sample (Table 1).

The study was extended to the reduction of some industrially important unsaturated carbonyl compounds, such as cinnamaldehyde, citral and citronellal, to the corresponding unsaturated alcohols, which are high value perfumery chemicals. The results are summarised in Table 2. As can be seen, the catalyst is both active and highly selective.

The higher selectivities obtained are rather unexpected as hydrotalcites are strongly basic and one would have expected the aldol condensation reaction to be predominant. However, as we have already shown in our previous publication, the aldol

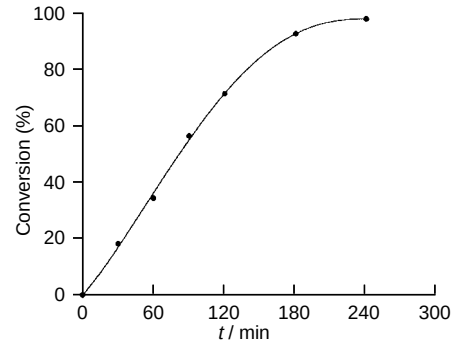

Fig. 1 Conversion *versus* time plot for reduction of 4-*tert*-butylcyclohexanone using Mg–Al hydrotalcite (Mg : Al = 3 : 1). Reaction conditions: same as Table 1 except 4-*tert*-butylcyclohexanone (1 mmol) catalyst (0.075 g) activated in N_2 at 450 °C.

Table 2 MPV reduction of unsaturated aldehydes to unsaturated alcohols over Mg–Al hydrotalcite (Mg : Al = 3 : 1)[a]

Aldehyde	*t*/h	Conversion (%)	Selectivity for unsaturated alcohol (%)
Citronellal	4	90	95[b]
Cinnamaldehyde	5	75	92[c]
Citral	5	83	70[d]

[a] Reaction conditions: aldehyde (1 mmol) catalyst (0.14 g) activated in N_2 at 450 °C, propan-2-ol (10 ml), T = 82 °C, stirring speed = 900 rpm. [b] Citronellol. [c] Cinnamyl alcohol. [d] Nerol + geraniol.

condensation reaction is catalysed by Brönsted bases (OH^- groups) and calcined hydrotalcites, which are Lewis bases, do not catalyse this reaction.[8] As we have used catalysts activated in N_2 at 450 °C having only Lewis basicity, they do not give aldol products under the mild reaction conditions used; this is consistent with the previous work.

The high activity of calcined hydrotalcites probably comes from the synergetic effect of strong Lewis basicity and mild acidity, as shown in Fig. 2. This mechanism agrees with that proposed by Ivanov *et al.*[5] based on *in situ* IR experiments.

In summary, we have shown that properly activated Mg–Al hydrotalcite (Mg : Al = 3 : 1) is a highly active, selective and regenerable catalyst for Meerwein–Ponndorf–Verley reduction of carbonyl compounds under liquid phase conditions.

Liquid-crystalline mixed [60]fullerene–ferrocene materials

Robert Deschenaux,*[a] Michael Even[a] and Daniel Guillon[b]

[a] *Institut de Chimie, Université de Neuchâtel, Av. de Bellevaux 51, 2000 Neuchâtel, Switzerland*

[60]Fullerene was functionalized with a mesomorphic malonate derivative containing two ferrocene units; the targeted compound showed thermotropic liquid-crystalline properties.

Recently, we reported the first [60]fullerene-containing thermotropic liquid crystal.[1] The C_{60} core was functionalized with a twin cholesterol malonate derivative following well established literature procedures.[2] The targeted fullerene derivative showed a monotropic smectic A phase.[1] This finding is of interest regarding the increasing activity which is currently devoted to the design of fullerene-based new materials.[3] On the other hand, photoinduced electron transfer reactions in fullerene–ferrocene dyads have been investigated[4] (intramolecular quenching of C_{60} singlet excited state by the ferrocene framework was observed). Such studies are interesting with a view to elaborating new optical and electronic molecular devices.[3,4] The design of fullerene–ferrocene compounds showing liquid-crystalline behavior is attractive as such structures would lead to new multicomponent mesomorphic materials.

This communication describes the synthesis and liquid-crystalline properties of the mixed fullerene–ferrocene thermotropic liquid crystal **1** which represents the first member of this new family of mesomorphic materials. Malonate derivative **2** was selected to functionalize the C_{60} core owing to the high mesomorphic character of the twin cholesterol liquid crystals.[1]

The synthesis of **1** is presented in Scheme 1. 1-Carboxybenzyloxy-1′-chlorocarboxyferrocene[5] (**3**) was reacted with cholest-5-en-3β-yl-4-(10-hydroxydecyloxy)benzoate[1] to give protected ferrocene **4**. Deprotection of the latter species gave acid **5**, the esterification of which with hydroquinone monobenzyl ether led to benzyl derivative **6**. Removal of the benzyl protecting group furnished phenol intermediate **7**, which was subsequently *O*-alkylated with 6-bromohexanol to give **8**. Condensation of **8** with malonyl chloride led to **2**. Finally, treatment of **2** with [60]fullerene adapting a literature procedure[6] gave the targeted structure **1**, as a dark solid. The latter species was purified by column chromatography (silica gel, eluent: toluene–AcOEt 20 : 1 v/v) and precipitation (dissolution in CH_2Cl_2 and precipitation in MeOH). Its structure and purity were confirmed by NMR spectroscopy, UV–VIS spectroscopy and elemental analysis.† As expected, the [6,6]-closed methanofullerene derivative was obtained.[1,2]

The thermal and liquid-crystalline properties of **1**, **2**, **7** and **8** were investigated by a combination of polarized optical microscopy (POM), differential scanning calorimetry (DSC) and X-ray diffraction studies.‡ Compounds **2** (Cr 73 S_A 134 I)§ and **7** (Cr 112 S_A 151 I)§ gave an enantiotropic smectic A phase and **8** (Cr 63 S_A 125 N* 127 I)§ showed enantiotropic smectic A and chiral nematic phases. The liquid-crystalline phases were identified by POM from the observation of typical textures (smectic A phase: focal conic texture and homeotropic areas; chiral nematic phase: plane texture). The POM observations were confirmed by X-ray diffraction analysis.

During the first heating, DSC analysis of **1** gave two endotherms at 66 (onset, ΔH = 12.9 kJ mol^{-1}) and 118 °C (onset, ΔH = 11.7 kJ mol^{-1}), which were indicative of the formation of a liquid-crystalline phase. On cooling an exotherm was obtained at 113 °C (onset, ΔH = 10.5 kJ mol^{-1}) as well as a T_g at 61 °C (onset). Reversibility of the cooling transitions was observed during the second heating run. POM observations supported the DSC data: a viscous liquid-crystalline phase formed between the two endotherms (fluidity increased from *ca*. 80 °C). The transition at 118 °C corresponded to the clearing point, whereas the transition at 66 °C reflected softening of the sample. The low enthalpy value which is associated to this latter transition could be the consequence of a semicrystalline character of the sample, which was precipitated during the purification process (see above). Neither slow cooling of the sample from the isotropic liquid nor annealing of the sample near the clearing point led to the formation of a typical texture. This is often the case for viscous materials. Careful examinations of small droplets revealed the presence of a focal-conic texture and homeotropic zones.

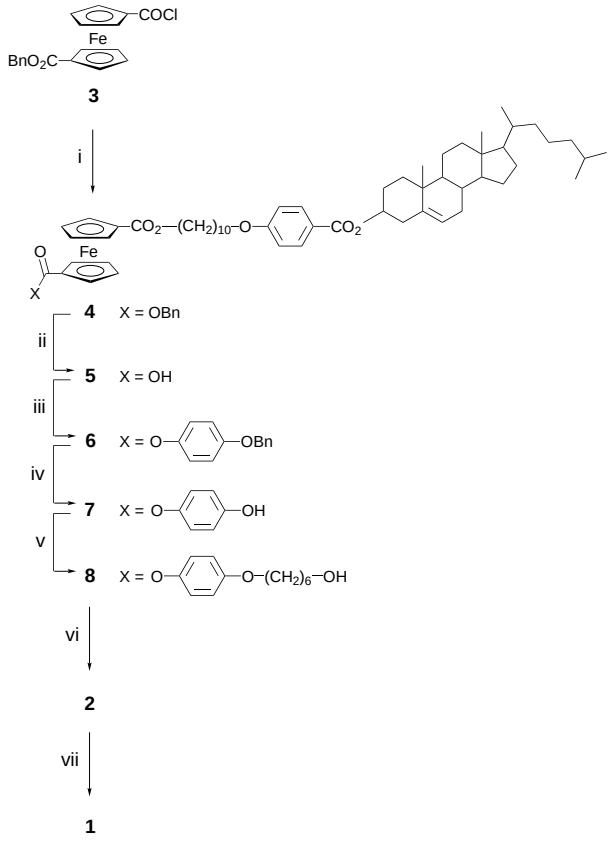

Scheme 1 *Reagents and conditions*: i, cholest-5-en-3β-yl-4-(10-hydroxydecyloxy)benzoate,[1] triethylamine (Et_3N), CH_2Cl_2, room temp. (16 h) and then reflux (overnight), 61%; ii, H_2, Pd/C, CH_2Cl_2–EtOH, room temp., 4 bar, overnight, 85%; iii, hydroquinone monobenzyl ether, *N*,*N*′-dicyclohexylcarbodiimide (DCC), 4-pyrrolidinopyridine, CH_2Cl_2, room temp., 3 h, 76%; iv, H_2, Pd/C, CH_2Cl_2–EtOH, room temp., 4 bar, overnight, 93%; v, 6-bromohexanol, K_2CO_3, acetone–THF, 60 °C, 24 h, 36%; vi, malonyl chloride, Et_3N, CH_2Cl_2, room temp., 2 h, 76%; vii, [60]fullerene, I_2, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), toluene, room temp., 3 h, under N_2, 35%

To further investigate the nature of the liquid-crystalline phase displayed by **1**, X-ray diffraction studies were performed from 120 to 30 °C (the sample was heated into the isotropic fluid and then cooled to the desired temperature). Diffraction patterns typical of disordered smectic phases (*i.e.* smectic A or C) were recorded. They consisted, in the low-angle region, of two sharp diffraction peaks, the corresponding spacings of which are in a 1 : 2 ratio, and in the wide-angle region, of a diffuse signal. A representative diffractogram is shown in Fig. 1. The *d*-layer spacing was found to be independent of the temperature (a *d*-value of 74.5 Å was measured at 110 °C; from CPK molecular models, an approximate molecular length of 120 Å was measured for **2** in its fully extended conformation). The layered structure was retained at room temperature. The X-ray diffraction data and POM observations suggest that the liquid-crystalline phase could be smectic A in nature.

Finally, thermogravimetry (10 °C min^{-1}, under N_2) revealed good thermal stability for **1**: mass losses of 1, 5 and 10% were detected at 270, 295 and 309 °C, respectively.

The possibility to exploit the properties of the fullerene[3] and ferrocene[7] units within the same liquid-crystalline molecular framework represents an important step towards the development of multifunctional new materials.

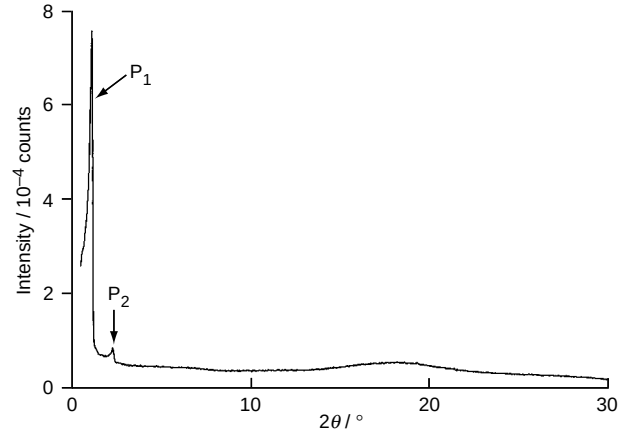

Fig. 1 X-Ray diffraction pattern of **1** recorded at 110 °C. P_1 and P_2 refer to the first and second order signals corresponding to the layer periodicity. The diffuse signal at large angles corresponds to the liquid-like arrangement of the molecules within the smectic layers.

Electroreductive coupling of vinylpyridines and vinylquinolines: radical anion–substrate cycloaddition?

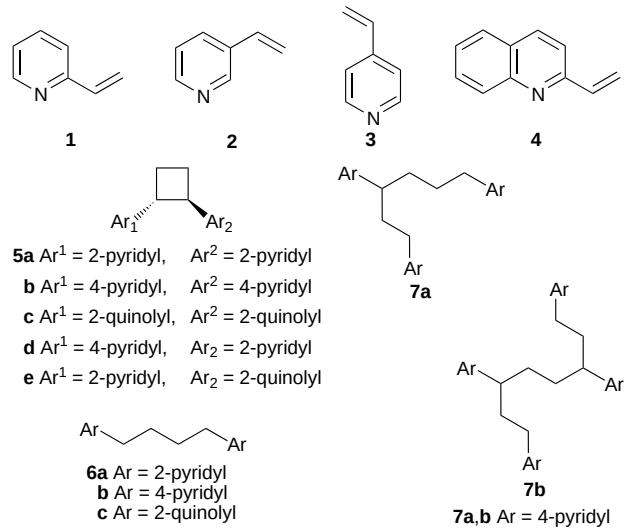
Robert G. Janssen, Majid Motevalli and James H. P. Utley*†

Department of Chemistry, Queen Mary & Westfield College, University of London, Mile End Road, London, UK E1 4NS

Cathodic reduction of 2- and 4-vinylpyridine and of 2-vinylquinoline gives *trans*-1,12-di(heteroaryl)cyclobutanes as major products; they arise *via* radical anion–substrate cycloaddition.

Much recent evidence[1,2] is in favour of electrohydrodimerisation (EHD) proceeding through the coupling of the initially-formed radical anions (the radical anion–radical anion route). An alternative, less well supported, is attack on the starting material by conjugate addition (the radical anion–substrate route) or, much less discussed, by cycloaddition between radical anion–substrate. Oxidative analogues of this possibility are well-known,[3] and there is one report[4] of the formation of cyclobutanes from aryl vinyl sulfones in a cathodically initiated reaction.

In examining templating effects on the stereoselectivity of EHD reactions[2] we explored the controlled potential cathodic



reduction of 2-vinylpyridine **1** at a mercury cathode in DMF (see Table 1). Compound **1** has a potentially ligating nitrogen atom which is close to the reaction centre for EHD. Previously the EHD reactions of both **1** and 4-vinylpyridine (**3**) were reported[5] to give, respectively, only the linear hydrodimers **6a** and **6b**. However, we discovered that substantial amounts of pyridine-substituted cyclobutanes were formed, together with the expected linear hydrodimers **6a** and **6b**. We now find that cyclobutane formation is quite general for vinylpyridines **1** and **3** and the vinylquinoline **4**. We present here compelling evidence for the proposed cycloaddition between radical anion–substrate.

Controlled potential electrolysis (CPE) of alkenyl-substituted pyridines and quinolines gave the *trans*-1,2-di(heteroaryl)-cyclobutanes **5a-e**. For two examples **5b** and **5c** this conclusion was established by X-ray crystallography,[6] which in turn allowed unambiguous interpretation of high-field NMR spectroscopic data used to characterise all of the cyclobutane products.[7] The other major products of the electrolyses were the linear hydrodimers **6a**–**c**.

From **3** and **4** substantial amounts (*ca*. 30%) of oligomers were formed and found, for **3**, to be the trimer **7a** and the tetramer **7b**. The position of vinyl-substitution is important; electrolysis of 3-vinylpyridine **2** gave predominantly cathodic hydrogenation of the double bond with only a 22% yield of an inseparable mixture of the corresponding cyclobutane and linear hydrodimer (3 : 7 ratio). The results of controlled potential electrolyses and the conditions used are summarised in Table 1.

The cyclobutanes **5a**–**c** have also been made[8] by a photochemical method which gave in our hands inseparable mixtures of the *cis*- and *trans*-isomers in case of cyclobutanes **5a** and **5b** with overall yields substantially lower than those reported. In addition to its mechanistic significance the electrochemical method is superior with regard to yield and product selectivity.

The cyclobutanes are electroactive at potentials close to the reduction potentials of the starting materials. Similar reduction, with ring opening, of cyclobutanes occurs in pulse radiolysis[9] of the methyl esters of truxillic acids. Cyclic voltammetry typically indicates an irreversible reduction followed by reversible reduction of the corresponding linear hydrodimer. Controlled potential electrolysis of cyclobutane **5c** gave linear hydrodimer **6c** quantitatively in a 2 F process. Electrolysis was therefore carried out at the foot of the relevant cyclic voltammetric wave, usually at low current density (1–3 mA

Table 1 Preparative scale controlled potential electrolyses[a]

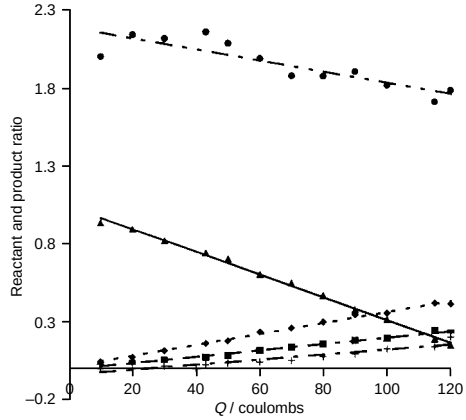

Fig. 1 Reaction profile for controlled potential electrolysis of **1** (see Table 1); (●) (CB)/(EHD), (▲) (VP)/[Total], (◆) (CB)/[Total], (■) (EHD)/[Total], (+) (VPH_2)/[Total]. [Total] = (VD) + (CB) (EHD) + (VPH_2).

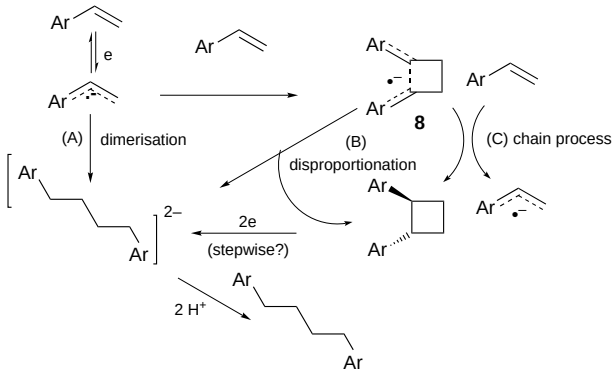
cm^{-2}) for concentrations in the range 60 mM–0.3 M. Relevant reduction potentials[10] are given in Table 2.

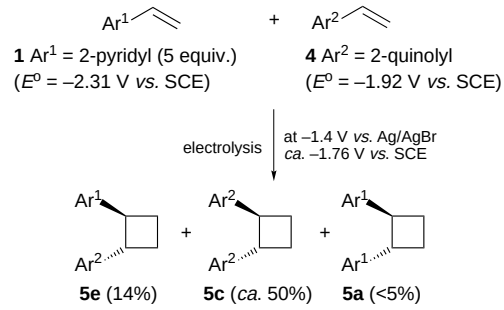
Vinylpyridines **1** and **3** give chemically irreversible reduction on cyclic voltammetry at low scan rates but reversibility is apparent for the reductions of **2** and **4** at modest scan rates (< 10 V s^{-1}). Thus, apart from direct further reduction of the cyclobutanes it is possible that electron transfer from the persistent first-formed radical anions will take place to give redox-catalyzed cleavage of the cyclobutanes.

A reaction profile was constructed (Fig. 1) for cathodic constant potential reduction of **1** by using GLC analysis to follow relative concentrations of reactant and products as a function of charge passed. The results show clearly that **1** (VP) was consumed using 0.70 F. Furthermore cyclobutane **5a** (CB) and linear hydrodimer **6a** (EHD) were formed in almost constant proportion (2 : 1) throughout the electrolysis. A third product was that of 2 F cathodic hydrogenation (2-ethylpyridine). The profile and coulometry are consistent with consumption of the first-formed radical anion in parallel reactions; dimerisation leading to linear EHD, cycloaddition leading in a catalytic chain process to the cyclobutane, and cathodic hydrogenation leading to 2-ethylpyridine. The final molar proportions of products were **6a** (0.29), **5a** (0.51) and 2-ethylpyridine (0.20). Consequently the proportion of charge consumed, given that EHD is a 1 F process and hydrogenation a 2 F process, must be linear hydrodimer (0.29 F) and 2-ethylpyridine (0.4 F), totalling 0.69 F. 2-Vinylpyridine **1** was consumed in 0.70 F, which indicates that the cyclobutane is formed without overall charge consumption. This experiment is reproducible and repeated experiments gave similar results.

The possibilities are detailed in Scheme 1, which illustrates formation of the linear hydrodimer by the usual radical anion–radical anion route (A), by disproportionation of the first product of cycloaddition, the radical anion route (B), and by subsequent 2e reduction of the cyclobutanes. The 1,2-di(hetero-



Scheme 1



Scheme 2

aryl)cyclobutanes are formed by oxidation of the intermediate radical anion (tentatively represented as **8**); in principle this could be the result of disproportionation (route B) or of a chain process as in the vinyl-sulfone case[3] (route C). The results from the reaction profile (Fig. 1) indicate cyclobutane formation *via* the chain process with no overall consumption of charge.

Co-electrolysis gives further insight (Scheme 2 and Table 1). Co-electrolysis of **3** in the presence of a five-fold excess of **1**, at the potential of the more easily reduced substrate **3**, gave the cross-coupled cyclobutane **5d** and the homo-coupled cyclobutane and linear dimer **6b**, respectively. Cyclobutane **5a** was found in only trace amounts. Similar behaviour was observed for the co-electrolysis of **4** and **1**. Cross-coupled cyclobutanes are therefore formed by reaction between the radical-anion formed at the lower potential and the other, unreduced, component. Formation of both radical anions, *e.g.* by homogeneous electron transfer, would give all three possible cyclobutanes in comparable amounts.

Thus there is compelling evidence for the formation of the cyclobutanes by allowed cycloaddition between vinylpyridines or vinylquinolines and the radical anions derived from them. A detailed mechanistic and kinetic examination is underway, aimed at distinguishing conclusively between the possibilities for the follow-up reactions as outlined in Scheme 1.

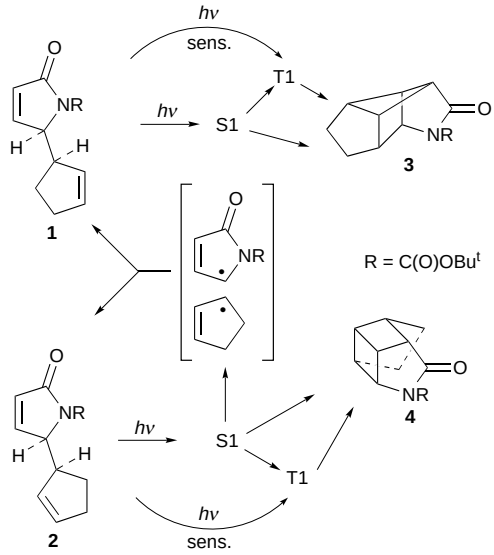
Diastereomer-differentiating photoisomerization of 5-(cyclopent-2-en-1-yl)-2,5-dihydro-1*H*-pyrrol-2-ones

Matthias N. Wrobel and Paul Margaretha*

Institut für Organische Chemie, Universität Hamburg, D-20146 Hamburg, Germany

The diastereomeric *l*- and *u*-dihydropyrroles 1 and 2 photoisomerize to azatetracyclodecanones 3 and 4, respectively.

According to the reactant-based Izumi–Tai classification,[1] reactions wherein a *l*(ike) and an *u*(nlike) diastereomer exhibit differing behaviour are termed 'diastereomer differentiating'. Here we report the first example of a photochemical reaction where two diastereomeric hexa-1,5-dienes undergo photoisomerization to a crossed and a straight cycloadduct,[2] respectively. The 1 : 1 diastereomeric mixture of *tert*-butyl 5-(cyclopent-2-en-1-yl)-2-oxo-2,5-dihydro-1*H*-pyrrole-1-carboxylates **1** and **2** was available in 36% yield by alkylation of *tert*-butyl 2-*tert*-butyldimethylsilyloxy-1*H*-pyrrole-1-carboxylate[3] with 3-bromocyclopentene. Separation was achieved by chromatography (SiO_2, Et_2O–hexane 1 : 1) affording the *u*-diastereomer **1**, mp 86 °C, whose structure was confirmed by X-ray analysis, and the *l*-diastereomer **2**, mp 104 °C. Both $(CD_3)_2CO$-sensitized[4] (300 nm) or direct (254 nm) irradiation of **1** afford the Boc-protected 5-azatetracyclo[4.4.$0^{2,8}$.$0^{3,7}$]decan-4-one **3** (mp 94 °C) in nearly quantitative yield. In contrast, sensitized irradiation of **2** affords the Boc-protected 4-azatetracyclodecan-3-one **4** (oil) selectively (9 : 1) in 75% yield, but on direct irradiation a 1 : 1 mixture of **3** and **4** is formed. In both sets of experiments the conversion of **2** to product(s) proceeds slower than that of **1**.



Scheme 1

The fact that in the sensitized runs both diastereomers undergo regioselective intramolecular [2 + 2]cycloaddition but on direct irradiation only **1**, and not **2**, exhibit this behaviour can be explained in terms of differential ratios of efficiencies of cycloadduct formation *vs.* cleavage to a radical pair for singlet and triplet excited states of **1** and **2**, respectively. The results indicate that only for singlet excited **2** does this racemization, which causes cleavage, become competitive, most probably reflecting the higher activation energy barrier in the formation of a bicyclo[2.2.0]hexane unit, as in **4**, compared to the less strained[5] bicyclo[2.1.1]hexane moiety of **3**. This differential behaviour is expected to be typical for all compounds containing a 3-(cyclopent-2-en-1-yl)cyclopentene framework.

The new compounds **1**–**4** have been fully characterized and have spectroscopic properties compatible with the structures assigned.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for support.

Heterogeneous $Cs_3PW_{12}O_{40}$ photocatalysts

Duane A. Friesen, David B. Gibson and Cooper H. Langford*

Department of Chemistry, University of Calgary, 2500 University Drive NW, Calgary, Alberta, Canada T2N 1N4

Colloidal $Cs_3PW_{12}O_{40}$ shows promise as a heterogeneous photo-oxidant, oxidizing alcohols in aqueous solution upon UV irradiation.

Polyoxotungstate clusters such as the Keggin ion ($XW_{12}O_{40}^{n-}$, where X is a heteroatom such as P or Si) are well known thermal catalysts for the oxidative transformation of various organic molecules in solution.[1,2] These species can also function as photocatalysts upon UV irradiation, promoting the oxidation of alcohols to aldehydes or ketones,[3–5] the functionalization of alkanes to form alkenes or ketones,[6] and the dimerization of alkenes.[7] Recent interest in the photochemical properties of these compounds has included the degradation of chlorophenols *via* oxidative processes.[8]

Much work has been done studying polyoxometalates as heterogeneous thermal catalysts and applying them for industrial purposes.[2] However, studies of the photo-oxidative behaviour of polyoxometalates have been with homogeneous solutions. Comparisons of the photo-oxidative activity of these solutions with conventional heterogeneous photocatalysts (*e.g.* TiO_2) have been made.[2d] For many applications, it is desirable to have the photoactive agent in a more recoverable form. Recently, progress has been made with placing polyoxotungstates (soluble forms such as $H_3PW_{12}O_{40}$ or insoluble forms such as $Cs_{2.5}H_{0.5}PW_{12}O_{40}$) on solid supports for liquid phase reactions in order to enhance recovery from the reaction mixture.[9] The utility of the Cs^+ salt for heterogeneous thermal catalysis has been proven.[2,10] There is a need for the potential of these systems for heterogeneous photo-oxidation to be investigated. Here, we demonstrate that a water-insoluble colloid, $Cs_3PW_{12}O_{40}$, can function as an effective photo-oxidative agent for the oxidation of propan-2-ol to acetone.

Colloidal $Cs_3PW_{12}O_{40}$ was synthesized by metathesis of $H_3PW_{12}O_{40}{\cdot}nH_2O$ and CsCl in H_2O. The precipitate was centrifuged, washed twice with water, and dried at 85 °C. Silica-supported photocatalyst materials were made using the sol–gel procedure of Izumi *et al.*[9a,b] A mixture of 1 g $Cs_3PW_{12}O_{40}$, 3 ml ethanol, 3.5 g tetraethoxysilane (TEOS), and 1.5 g H_2O was heated at 80 °C until dry. The resulting granular material was calcined at 300 °C for 4 h and washed with hot H_2O to separate soluble and fine colloidal materials.

Filtration and light scattering experiments suggested that a large fraction of the unsupported $Cs_3PW_{12}O_{40}$ powder was submicrometer in size, *i.e.* 300 nm in diameter. This value probably represents the size of aggregates of smaller particles as noted previously.[9a] The powder X-ray diffraction patterns of the uncalcined colloid and the calcined $Cs_3PW_{12}O_{40}$–SiO_2 composite were the same, indicating that the crystallinity of the polyoxometalate was not altered significantly during the calcination procedure.[2b,9d] From nitrogen adsorption measurements, it was determined that the $Cs_3PW_{12}O_{40}$ powder had a specific surface area of 126 $m^2\ g^{-1}$, in agreement with previous values.[10c] In comparison, the surface area for TiO_2 (Degussa P25) is 55 $m^2\ g^{-1}$. The calcined, sol–gel supported tungstate material was extremely porous, with a pore size distribution centered at 23 Å, a surface area of 677 $m^2\ g^{-1}$, and a total pore volume of 0.46 ml g^{-1}. This compares favorably with values obtained for the supported thermal catalyst $Cs_{2.5}H_{0.5}PW_{12}O_{40}$–$SiO_2$ and silica gel itself.[9a,b,11]

The insolubility of the $Cs_3PW_{12}O_{40}$ material in water is a critical factor for its potential use for the photo-oxidation of organic species in water, considering the solubility of $H_3PW_{12}O_{40}$. When the granular $Cs_3PW_{12}O_{40}$–SiO_2 composite (several hundred mg in 2 ml H_2O) was stirred at room temperature for *ca.* 3 h, the amount of $PW_{12}O_{40}^{3-}$ in the water at the end of this period was *ca.* 3×10^{-7} M as determined by UV–VIS spectroscopy. This was a factor of 100 less than the solubility of uncalcined $Cs_3PW_{12}O_{40}$ in H_2O at natural pH (5–6) and represented a leakage of $< 0.01\%$.

The photochemical oxidation of alcohols by dissolved $PW_{12}O_{40}^{3-}$ upon UV irradiation is well documented.[3–5] We demonstrate here that desolubilized polyoxometalate colloids also show photocatalytic behavior. Reflectance spectroscopy was used to observe reduction of the photoexcited $Cs_3PW_{12}O_{40}$ colloid suspended in neat propan-2-ol. An opaque suspension of $Cs_3PW_{12}O_{40}$ in N_2-purged propan-2-ol was irradiated in a 2 mm quartz cell using the output from a 200 W Xe(Hg) arc lamp with a 300 nm cutoff filter. UV–VIS spectral changes in the suspension were monitored using a fibre-optic diffuse reflectance probe coupled to an Ocean Optics S1000 absorption spectrometer. Fig. 1 shows changes in the reflectance spectrum upon irradiation of the slurry. Absorptions in the red region of the visible spectrum are those of the reduced tungstate.[3,4,6d,12] At early irradiation times the absorption maximum is at 760 nm, corresponding to the production of $PW_{12}O_{40}^{4-}$. Longer irradiation periods resulted in a blue-shift of the spectral maximum which may be due to > 1 electron reduction at some sites. After irradiation, the blue colloid was allowed to settle. The propan-2-ol liquid phase was uncolored, indicating that bleeding of the desolubilized metalate into solution remained negligible for the reduced forms. Subsequent experiments with silica-supported $Cs_3PW_{12}O_{40}$ yielded similar results under the same conditions. As shown in the figure, reduction is stoichiometrically significant.

This system was also investigated for product formation *via* photo-oxidation of the alcohol. Granules of $Cs_3PW_{12}O_{40}$–SiO_2 (200 mg) were added to 2 ml of 0.5 M aqueous propan-2-ol

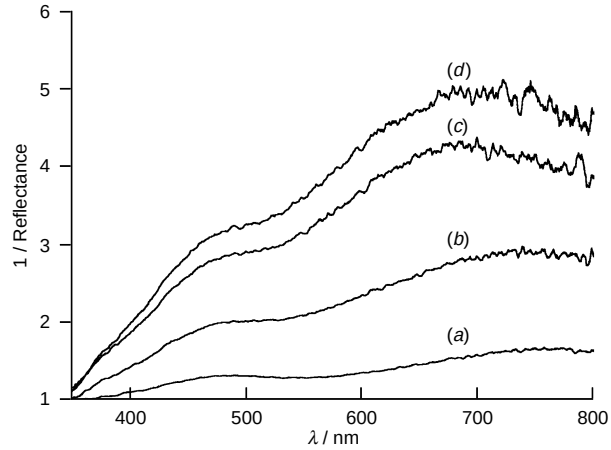

Fig. 1 Visible reflectance spectra for the irradiation (> 300 nm) of an N_2-purged slurry of $Cs_3PW_{12}O_{40}$ in propan-2-ol: (*a*) 7 min, (*b*) 12 min, (*c*) 17 min, (*d*) 22 min

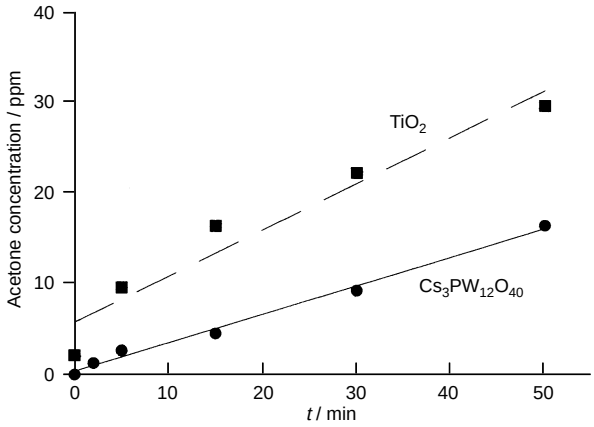

Fig. 2 Production of acetone by the irradiation (254 nm) of $Cs_3PW_{12}O_{40}$ and TiO_2 (2 g l^{-1}) in an aqueous solution (pH 3, $HClO_4$) of propan-2-ol (610 ppm)

(aerated) in a 1 cm quartz cell. The mixture was irradiated with the output of a 200 W Xe(Hg) lamp and 300 nm cutoff filter. The solution was sampled at regular intervals using an HP 5880 GC with FI detector and a 0.53 mm i.d. fused silica column with DB-WAX polyethylene glycol stationary phase (J&W Scientific). Acetone was produced steadily during the irradiation as found previously for dissolved solutions of $PW_{12}O_{40}^{3-}$. In this case formation of the heteropoly blue was not visually evident, due to reoxidation of the metalate by dissolved O_2.[13]

Determination of an accurate quantum yield is not facile, as demonstrated by Sun and Bolton for TiO_2 colloids.[14] However, we have performed a comparative study of the unsupported tungstate with TiO_2 (Degussa-P25), a commercially-available material for photocatalytic oxidations. Equal mass loadings of $Cs_3PW_{12}O_{40}$ or TiO_2 powder (2 g l^{-1}) in a 610 ppm solution of propan-2-ol were placed in an annular quartz cell irradiated by a low pressure mercury lamp (Philips TUV, 15 W, λ = 254 nm). The 4 mm pathlength and irradiation wavelength ensured near-total absorption of photons by the colloidal photocatalysts. The solutions, after allowing 1 h for dark adsorption, were irradiated. Samples were withdrawn and analyzed (GC–FID) for the production of acetone and loss of propan-2-ol. Fig. 2 illustrates the production of acetone by both species. From the data, it appears that the rate of conversion of propan-2-ol to acetone is approximately one-half for $Cs_3PW_{12}O_{40}$ colloid relative to TiO_2. That is, a first unoptimized preparation of a heterogeneous polyoxometalate is very competitive with a widely used form of TiO_2 for photo-oxidation. The apparent reactivity of the tungstate per unit area of catalyst is approximately one quarter that of TiO_2. This is very approximate due to the difficulty of determining the actual surface area illuminated.

The photo-oxidative ability is not limited to alcohols; upon broad-band irradiation [1000 W Xe(Hg) lamp, Pyrex cutoff], an aqueous solution of a model aromatic compound, acetophenone, shows > 99% degradation to hydroxy- and dihydroxyacetophenones over a 3 h period using $Cs_3PW_{12}O_{40}$. This underlines the possible importance of these systems for contaminant degradation, parallel to TiO_2.

In summary, desolubilized polyoxotungstates can function as heterogeneous photocatalysts for the oxidation of organic species in solution. These materials show promise as easily-recovered materials for photochemical oxidations.

The authors would like to thank Dr Alex Starosud for N_2 adsorption and determinations and Mr Fred Henselwood for light scattering measurements. The support of the Natural Sciences and Engineering Research Council of Canada is greatly appreciated.

Unique ligand imposed distortions in a nickel(II) 1,5,9-triphospha-cyclododecane complex

Peter G. Edwards,* Florent Ingold, Simon J. Coles and Michael B. Hursthouse

Department of Chemistry, University of Wales Cardiff, PO Box 912, Cardiff, UK CF1 3TB

1,5,9-Triethyl-1,5,9-triphosphacyclododecane ([12]ane-P_3Et_3, L) reacts with $NiBr_2$ to afford the salt [NiLBr]Br which is shown by X-ray crystallography to have an unusually distorted structure as a result of constraints imposed by the ligand L.

Triaza and trithia cycloalkanes are well known to form stable nickel compounds in a variety of oxidation states and with properties that are unique to complexes of these ligand sets.[1] There are few examples of Ni complexes of macrocyclic polyphosphines and none with macrocyclic triphosphines. In view of the coordination control as well as the relative kinetic stability that may arise in complexes of phosphorus macrocycles, we have studied reactions of 1,5,9-triethyl-1,5,9-triphosphacyclododecane ([12]aneP_3Et_3, L) and report preliminary results of this study here.

Reactions of L with $NiBr_2$ in ethanol give rise to deep red solutions from which red crystals of **1** may be isolated and for which analytical data indicate the formula $NiLBr_2$.† The crystals are only slightly air-sensitive but solutions are readily oxidised by air giving rise to oxides of L. **1** is readily soluble in Me_2SO but is insoluble in hydrocarbons and aliphatic ethers and only poorly soluble in relatively polar organic solvents such as THF, CH_2Cl_2 and $MeNO_2$. **1** has only been isolated in reasonable yield when prepared in alcohols, black oils are formed in THF or CH_2Cl_2. **1** is a conductor in Me_2SO (Λ_M = 21 cm^2 ohm^{-1} mol^{-1}), a value close to other monocationic Ni^{II} complexes such as $[Ni(NP_3)I]BF_4$ [Λ_M = 14 cm^2 ohm^{-1} mol^{-1}, NP_3 = $N(CH_2PPh_2)_3$][2a] and is thus better formulated as the salt $[NiLBr]^+Br^-$. **1** is also diamagnetic, giving rise to sharp NMR spectra and so presumably does not have a tetrahedral Ni^{II} atom. The $^{31}P\{^1H\}$ NMR spectrum consists of a singlet (δ −3.0) indicating fluxionality in solution since a static distorted four-coordinate geometry would not have magnetically equivalent phosphorus atoms. The spectrum is temperature invariant (25 to −70 °C). This fluxionality may in part be due to halide lability since warming solutions of **1** in Me_2SO gives rise to solutions for which conductivity measurements indicate the solute to be dicationic (Λ_M = 229 cm^2 ohm^{-1} mol^{-1}) by comparison to related dicationic Ni complexes {*e.g.* for [Ni{η^2-1,2-$C_6H_4(PEt_2)_2$}$_2$], Λ_M = 182 cm^2 ohm^{-1} mol^{-1}}.[3]

The structure of the cation of **1** is presented in Fig. 1.‡ The geometry around the four-coordinate d^8 Ni atom is heavily distorted from either of the common, regular four-coordinate geometries.

Whereas the Ni–P distances are all similar [av. 2.151(1) Å] $[Ni(NP_3)I]^+$ [av. 2.22(1) Å],[8] the distortion is manifested in the bond angles around Ni where one of the P–Ni–P angles is considerably larger than the other two [126.43(4)° *vs*. 94.80(4) and 96.29(4)°]; similarly one of the Br–Ni–P angles is much larger than the other two [155.60(4)° *vs*. 94.52(3) and 96.19(3)°]. Distortions from square planar towards tetrahedral structures arising from steric encumbrance of the ligands are well known for Ni^{II} phosphine complexes. Examples are $[Ni(CH_2SiMe_3)Cl(PMe_3)_2]^+$ and $[Ni(CH_2SiMe_3)(PMe_3)_3]^+$ where the substitution of Cl, in the former, by PMe_3 increases the distortion around Ni, albeit less severe, approaches that in **1**.[4] Other than the direct bonding contacts between Ni and the three phosphorus and one bromine atoms in **1**, the closest intramolecular interaction with the nickel is to a P–Et hydrogen atom on C(15) at 2.85 Å and is thus considered to be non-bonding. There are no other interactions that could explain the distortion. A striking comparison is with the related ligands [12]aneN_3 and [12]aneS_3 which both form high-spin octahedral complexes with Ni^{II}, the latter forms a bis-macrocycle sandwich with six coordinated S atoms.[1,5] The related 9-membered nitrogen macrocycles, [9]aneN_3 and [9]aneN_3Me_3, also favour octahedral geometries, although the latter is reported not to form a bis-ligand complex of Ni^{II} owing to steric interactions between the methyl substituents.[1] It appears then that steric crowding is not responsible for forcing the distortion observed in **1** unlike in the PMe_3 complexes above, however space filling models[6] give a better view of its coordination sphere (Fig. 2) showing the apparent coordination vacancy arising from the distortion. This vacancy is highlighted by rotation of the P–Et[C(14)] bond [Fig. 2(*b*)], which might be expected to be facile in solution, such that the methyl group [C(15)] is removed from the proximity of the nickel atom. These views indicate that the structure might best be described as a distorted trigonal bipyramid with a vacant vertex. Although this behaviour is unexpected and unique for d^8 Ni^{II} phosphine complexes, there are other examples of four-coordinate d^8 complexes that show distortions from either square-planar or tetrahedral geometries as a result of electronic influences.[7] A relevant comparison with **1** in this context is the structure of $[Ru(CO)_2(PBu^t_2Me)_2]$ **2** which exhibits a similar distortion from a square-planar geometry and whose structure was also described as trigonal bipyramidal in which one equatorial ligand is absent; the '*transoid*' (P–Ru–P) and '*cisoid*' (C–Ru–C) angles are

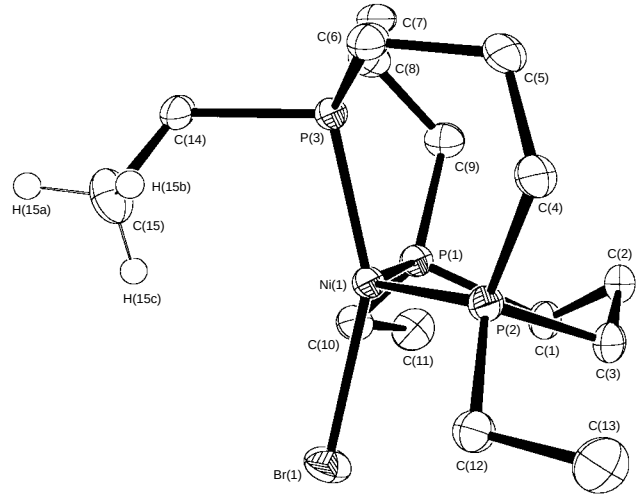

Fig. 1 The molecular structure and atom labelling scheme of [NiLBr]Br **1**. Isotropically refined hydrogen atoms closest to Ni [on C(15)] are included, all others are excluded for clarity. Selected bond lengths (Å) and angles (°): Br(1)–Ni(1) 2.329(1), Ni(1)–P(3) 2.124(1), Ni(1)–P(1) 2.163(1), Ni(1)–P(2) 2.167(1), P(3)–Ni(1)–P(1) 94.80(4), P(3)–Ni(1)–P(2) 96.29(4), P(1)–Ni(1)–P(2), 126.43(4), P(3)–Ni(1)–Br(1) 155.60(4), P(1)–Ni(1)–Br(1) 94.52(3), P(2)–Ni(1)–Br(1) 96.19(3).

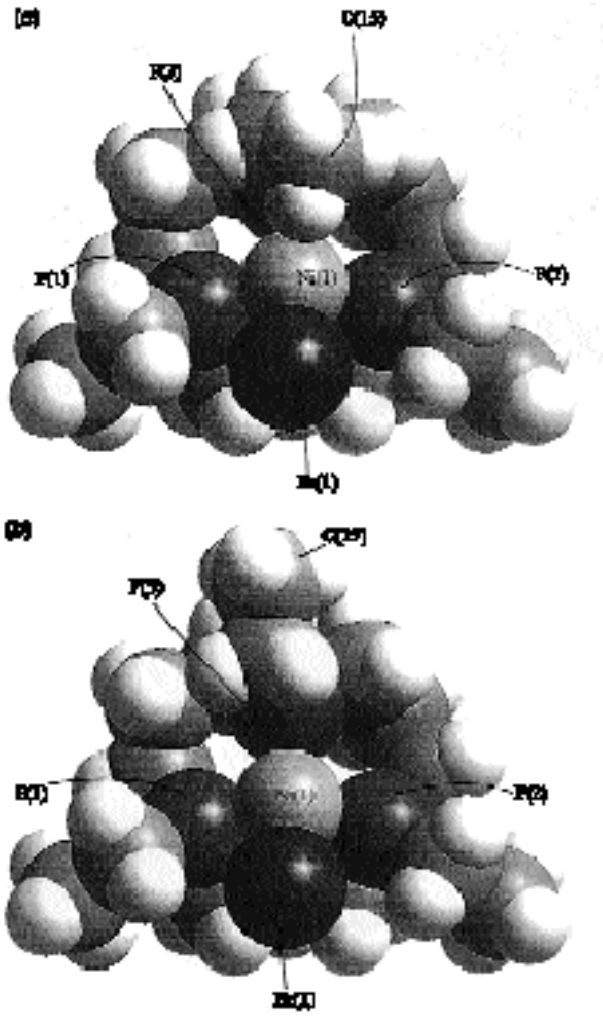

Fig. 2 Space filling models of $[Ni([12]aneP_3Et_3)Br]^+$; (*a*) crystallographically determined configuration, (*b*) ethyl group rotated away from Ni [around P(3)–C(14)]

165.56(8) and 133.3(4), respectively.[8] In this case, *ab initio* calculations (on the PH_3 analogue) at the RHF/MP2 level indicated that the observed structure was very close to the most stable ground state configuration and a more regular square-planar geometry was disfavoured. This is in contrast to analogous Rh^I complexes where the reverse is true; this difference was said to arise from a π-bonding stabilisation in the Ru carbonyl that is not as significant in Rh^I owing to differences in d-orbital energies. This explanation also implies that related Ni^{II} compounds would favour regular square-planar geometries in the ground state and especially in **1** where the tertiary alkyl phosphine donors are expected to be less efficient π acceptors than CO in **2**. The electronic preference for a square-planar ground state configuration in **1** is further supported by EHMO calculations[9] on the idealised system, $[Ni(PH_3)_3Br]^+$. Three geometries were studied: square planar, trigonal bipyramidal having a vacant equatorial site, and tetrahedral. The square-planar geometry is found to be the most stable owing to minimisation of antibonding Ni–Br interactions; the bipyramid and tetrahedron are destabilised by 133 and 204 kJ mol^{-1} respectivley.

The structure of **1** also contrasts with Ni^{II} complexes of tripodal ligands such as $N(CH_2L')_3$ (L′ = PPh_2, SH) for which trigonal-bipyramidal geometries predominate.[2] A related tripodal tris-amidate ligand $\{N[CH_2C(O)NBu^t]_3{}^{3-}\}$ has been shown to support a high-spin trigonal monopyramidal structure in its Ni^{II} complex although the absence of one axial ligand (*trans* to tertiary N) was explained as due to the steric bulk of the tertiary butyl groups precluding coordination of the fifth ligand.[10]

It appears then that the distortion observed in **1** is not due to either electronic influences or steric factors arising from ligand substituents but rather to the unique feature of the macrocycle in restricting the freedom of the phosphorus donors, forcing them to adopt the coordination configuration observed. The strong preference of the nickel for a low-spin configuration in the presence of the three high-field phosphorus ligands also clearly dominates, destabilising tetrahedral or octahedral coordination geometries. This demonstrates a marked difference in the coordination behaviour of this [12]aneP_3 macrocycle in comparison to directly analogous N_3 and S_3 macrocycles as well as related tripodal ligands; it also indicates that the properties of its complexes will differ markedly from those of other ligands.

The synthesis of other Ni complexes and their reactions with small molecules and unsaturated substrates are currently being studied; preliminary results indicate that tetrahedral Ni^0 carbonyl complexes of L $\{[NiL(CO)_3]_3$, $[NiL(CO)]$ and $[NiL(CO)]^+\}$ are readily formed.

We thank the EPSRC for a research grant (GR/L06508) and for support of the X-ray crystallography unit in Cardiff.

Structural authentication of an N-functionalised disecondary diphosphane

Philip C. Andrews, Simon J. King, Colin L. Raston* and Brett A. Roberts

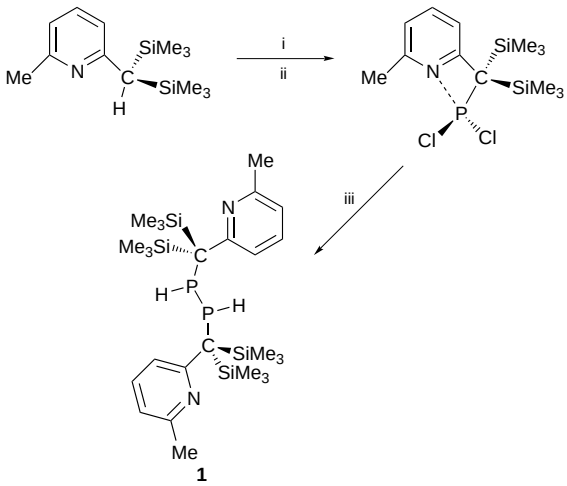
Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

The reaction of $RPCl_2$ [R = (6-Me-2-pyridyl)$(SiMe_3)_2C^-$] with $LiAlH_4$ in Et_2O gives the novel N-functionalised disecondary diphosphane compound [R(H)P–P(H)R] rather than the expected phosphorus dihydride complex RPH_2; the *meso* and *rac* isomers of the diphosphane crystallise separately with the *meso* isomer being structurally authenticated.

Disecondary diphosphanes,† $(R'PH)_2$ (R′ = alkyl or aryl) normally formed in the equilibration reaction of organophosphide oligomers, $(R'P)_n$, with organophosphorus hydrides, $n\,R'PH_2$, have been studied extensively in solution by NMR spectroscopy.[1] However in the solid state examples are limited to those where they have been synthesised *in situ* and isolated as Lewis base donors, bonding through phosphorus, and bridging two metal centres; namely Cr in {[$Cr(CO)_5$][MesP(H)P(H)Mes][$Cr(CO)_5$]}[2] (Mes = 2,4,6-$Me_3C_6H_2$), Mn in {[$MnCp(CO)_2$][PhP(H)P(H)Ph][$MnCp(CO)_2$]}[3] and Ag in $[PhPH_2Ag\{\mu\text{-}(PhPH)_2\}]_2[AsF_6]_2$.[4] The mechanism of formation of the diphosphanes is in each case unknown but has been attributed to the dimerisation of the reactive radical [R′(H)P]· species which is also accessible from the deprotonation of protic and/or polar solvents by a reactive phosphinidene intermediate [R′P:].[5]

Herein we report the synthesis and characterisation of the first non-complexed N-functionalised disecondary diphosphane, **1**. In attempting to synthesise the simple phosphorus dihydride derivative of the bulky alkyl ligand (6-Me-2-pyridyl)-$(SiMe_3)_2C^-$, R, *via* the reduction of $RPCl_2$ with $LiAlH_4$ we observed that on each occasion the product obtained by crystallisation was not the dihydride but the diphosphane, [(6-Me-2-pyridyl)$(SiMe_3)_2$CPH]$_2$ **1**. This was totally unexpected given that $LiAlH_4$ is an almost ubiquitous reagent used in the formation of $R'PH_2$ species from various phosphine, phosphinous and phosphonic sources.[6]

In a typical reaction (Scheme 1) an Et_2O solution of a slight stoichiometric excess of $LiAlH_4$ was added to a pale orange Et_2O solution of the crystals of the dichloride complex $RPCl_2$, formed from the metathetical reaction of $RLi\cdot Et_2O$ and PCl_3, at −78 °C and the reaction mixture allowed to warm slowly to ambient temperature over 4 h. Filtration followed by *in vacuo* concentration of the solution and cooling to −30 °C allowed for the growth of a moderate yield of **1** as colourless needles.‡



Scheme 1 *Reagents and conditions*: i, Bu^nLi, Et_2O, −78 °C; ii, PCl_3, Et_2O, −78 °C, 2 h; iii, $LiAlH_4$, Et_2O, −78 °C, 4 h

The structure (Fig. 1) of the single crystal analysed by X-ray techniques proved to be the *meso* isomer: crystallising in the triclinic space group $P\bar{1}$ (no. 2) with two molecules in the unit cell, each molecule possessing a centre of inversion.§ The P–P bond distance of 2.222(3) Å is comparable with that of 2.258(3) Å in the Mn complex, 2.253(2) Å in the Cr complex and 2.202(4) Å in the Ag complex. The pyridyl nitrogens are located away from the P centre indicating there are no N···P interactions.

Two significantly different melting points, 122–123 and 177–178 °C with decomposition to dark red products, were obtained for different crystals taken from the same sample. This coupled with the fact that NMR data obtained on several different samples was consistent and reproducible is indicative that both the *meso* and the *rac* (DL) isomers co-crystallise from solution. The NMR data also revealed that the *meso* and *rac* isomers were always present in solution in 1 : 0.6 ratio, respectively; a ratio which did not change in the temperature range −90 to 80 °C. There was no spectroscopic evidence that the target dihydride complex was formed either directly as originally proposed or by the disproportionation of the diphosphane into higher phosphide oligomers and the accompanying hydride species. This implies that the diphosphane is

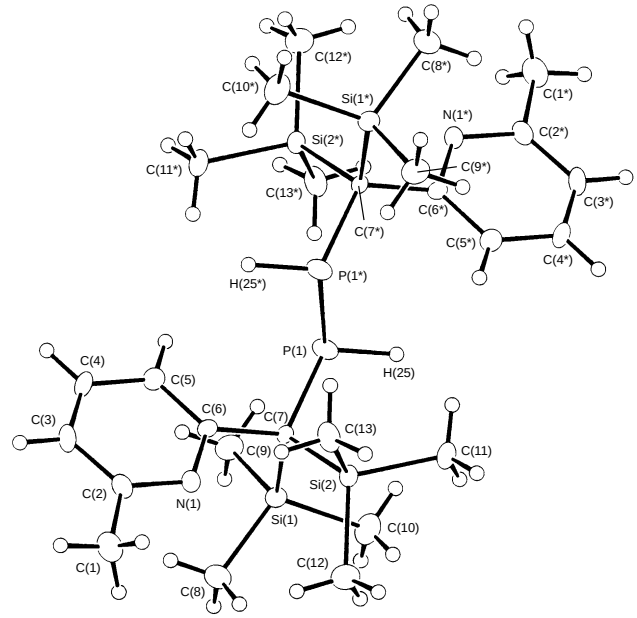


Fig. 1 Crystal structure of **1**. Selected distances (Å) and angles (°): P(1)–P(1*) 2.222(3), P(1)–C(7) 1.872(4), C(7)–C(6) 1.528(6), C(7)–Si(1) 1.931(4), C(7)–Si(2) 1.934(5), P(1*)–P(1)–C(7) 104.5(2), P(1)–C(7)–Si(1) 103.8(2), P(1)–C(7)–Si(2) 111.1(2), P(1)–C(7)–C(6) 116.4(2).

thermally robust and requires greater temperatures to force the creation of the equilibrium observed for other diphosphanes.

The NMR data on **1** can be compared with those obtained and compiled by Albrand and Taïeb[1] on a series of disecondary diphosphanes, R′ = Ph, Me, Et, cyclohexyl, CF_3, all relating to an AA′XX′ spin system. The $^{31}P\{^1H\}$ spectrum has two peaks at δ −99.5 (*rac*) and −91.5 (*meso*). The undecoupled ^{31}P spectrum has the two peaks split into two symmetrical sets of doublets of doublets, the coupling constants for the peaks centred at δ −99.5 being $^1J_{PH}$ 128 and $^2J_{PH}$ 74 Hz and for the peaks centred at δ −91.5 being $^1J_{PH}$ 152 and $^2J_{PH}$ 61 Hz. While the ^{31}P chemical shifts correlate most closely with those for R′ = Et (δ −99.6 and −93.8) the $^1J_{PH}$ and $^2J_{PH}$ values of 192.9, 192.9 and 11.2, 6.5 Hz, respectively, are clearly very different, as they are for all of the diphosphanes investigated, and must relate to the increased polarisation of the C–P bonds induced by the proximity of the two $SiMe_3$ groups.

The ^1H NMR spectrum also shows the high degree of P–H coupling. Two sets of doublets of doublets are present, one centred on δ 3.82 with coupling constants corresponding to those of the *meso* isomer at δ 91.5 in the ^{31}P spectrum and the other at δ 4.48 with coupling constants relating to the *rac* isomer at δ 99.5 in the ^{31}P spectrum. The two inner peaks of the doublet of doublets at δ 3.82 also show $^3J_{HH}$ splitting with a coupling constant of 4.89 Hz while those centred on δ 4.48 are smaller at 1.6 Hz. The differing electronic environments of the isomers are highlighted by the four signals present for the four $SiMe_3$ groups in both the ^1H and the ^{13}C spectra with the largest chemical shift separation (*cf.* δ 0.51 and δ 0.24 with δ 0.42 and δ 0.34) occurring for those relating to the *rac* isomer.

The mechanism of formation of the diphosphane can as yet only be speculated upon but two possibilities exist; dimerisation of a monohydride species, [R(H)P], radical or otherwise, occurring more rapidly than replacement of a remaining chloride by a hydride or formation of the diphosphene [RP=PR] which is subsequently hydrogenated by the $LiAlH_4$. Why this should occur for (6-Me-2-pyridyl)$(SiMe_3)_2CPCl_2$ and not, for example, 2,4,6-$Bu^t_3C_6H_2PCl_2$,[7] is puzzling though in several EPR studies we have shown that it is possible for the pyridyl system to stabilise a radical species for a significant amount of time. Thus [(2-pyridyl)$(SiMe_3)_2CHg]^{\cdot}$,[8] generated from {(2-pyridyl)$(SiMe_3)_2C_2$}M on exposure to unfiltered UV light at 100 K, gave a decaying EPR signal with $t_{0.5}$ = 300 s while $t_{0.5}$ for the radicals [{(2-pyridyl)$(SiMe_3)_2C$}$_2$M]$^{\cdot}$ (M = Al, Ga)[9] generated by the Na/K reduction of the {(2-pyridyl)(Si-$Me_3)_2C$}$_2$MCl complexes were of the order of 3600 s, though coupling in this case occurred, not unexpectedly, through the γ position of the pyridyl ring. Clearly in the absence of metallic centres and the absence of unfavourable M–M bond formation the possibility of [R(H)P]$^{\cdot}$ coupling exists as a viable mechanism. The attempt to form the As analogue by the same route resulted in crystallisation of only the thermally unstable $RAsH_2$ complex.

Compound **1** should prove to be a valuable, flexible and interesting new ligand having, with the added functionality of the two pyridyl nitrogens, four possible donating sites. We are currently investigating the potential of forming novel metal complexes of **1**.

We thank the Australian Research Council for financial support.

Aggregation of lithium and mixed thallium(I)–lithium amides through η^3- and η^6-π-arene interactions in the solid

Konrad W. Hellmann,[a] Christian Galka,[a] Lutz H. Gade,*[a] Alexander Steiner,[b] Dominic S. Wright,[b] Thomas Kottke[a] and Dietmar Stalke[a]

[a] *Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany*
[b] *University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

The mixed Li–Tl amide $[C_{10}H_6\{N[Li(thf)_2]SiMe_3\}\{N(Tl)SiMe_3\}]$ has been synthesized and shown to aggregate *via* η^6-arene–thallium coordination in the solid; a related pattern of aggregation is found for the partially solvated homometallic Li amide $[C_{10}H_6\{N[Li(thf)]SiMe_3\}\{N(Li)SiMe_3\}]$ which displays an unusual η^3-arene–lithium interaction.

A comparison of the structural patterns observed in the solid state structures of lithium and thallium(I) amides reveals marked differences in the bonding patterns. Mainly ionic forms of aggregation controlled by electrostatic interactions and the steric demand of the organic periphery occur in the case of lithium amides (and other alkali metal amides).[1] However, the few structurally characterized thallium(I) amides known to date are not well described by the electrostatic model but rather display attractive intermolecular contacts between the heavy metal atoms which appear to arise from weak dispersion forces.[2,3] Another significant difference is the tendency for solvation of the metal atoms, with lithium being most readily coordinated by donor solvents while monovalent thallium appears to be more resistant to increasing its coordination number by donor solvation.

Here, we give a first account of our systematic attempts to break-up the hitherto established structural patterns in Tl^I–amide chemistry by incorporating potentially coordinating molecular units into the ligands employed, and to obtain mixed alkali metal–thallium amides which combine the characteristics of the two structural regimes mentioned above. As the ligand precursor we chose the known 1,8-bis(trimethylsilylamino)naphthalene **1** containing an aryl backbone[4] which may potentially interact with the metal centres and thus generate novel forms of aggregation. In this context it should be noted that MO calculations reported for the related dilithiated α-naphthylamine already suggested metal–C-8 interactions in the gas phase which were, however, not found in the decameric solid state structure $[(C_{10}H_7NLi_2)_{10}(Et_2O)_6]$.[5] With this in mind, we assumed that the formal addition of a donor functionality in or close to the C-8 position of the naphthyl unit would generate a significantly different structural pattern.

Lithiation of **1** in thf cleanly yielded the solvated Li–amide $[C_{10}H_6\{N[Li(thf)_2]SiMe_3\}_2]$ **2** which was isolated and employed as a starting material. Stirring **2** with 1 equiv. of TlCl in thf for 5 h followed by work-up by removal of the solvent, extraction with toluene and crystallization at −35 °C gave an orange crystalline solid in moderate yield. The analytical data and the ^1H and ^{13}C NMR spectra were consistent with its formulation as $[C_{10}H_6\{N[Li(thf)_2]SiMe_3\}\{N(Tl)SiMe_3\}]$ **3**, *i.e.* the first example of a mixed Tl^I–Li amide.† While cryoscopy in benzene indicated the presence of monomeric units in solution, its crystal structure revealed an intriguing dimeric aggregation in the solid (Fig. 1.)‡

The two halves of the dimer, in which a Tl^I atom and a $(thf)_2Li^+$ cation bridge the amido-N atoms, are related by a crystallographic centre of symmetry. The Tl···Tl distance of 3.982(2) Å does not indicate a significant metal–metal interaction. Instead, the interaction between the Tl centres and one of the naphthalene arene rings appears to provide the driving force for the dimeric aggregation in the solid. The distance between the Tl atom and the centroid of the η^6-coordinated arene ring of 3.5106 Å is somewhat greater than some of the previously reported Tl–arene contacts, in particular that found in $[\{2,6\text{-}Pr^i_2C_6H_3N(Tl)SiMe_3\}_4]$ (3.11 Å),[6a] but clearly within the range expected for a heavy metal arene coordination.[6b–d] The crystal structure of **3** nicely illustrates the structural principles outlined above, the solvation of the 'peripheral' Li atoms and aggregation involving the arene unit in the ligand backbone.

When the Li–Tl exchange is carried out with 2 molar equiv. of TlCl the completely transmetallated amide $[C_{10}H_6\{N(Tl)SiMe_3\}_2]$ **4** is formed which has a much decreased solubility in hydrocarbon solvents. It is therefore thought to be polymeric in the solid possibly as a result of metal···arene interactions similar to those established for **3**.

That the 1,8-naphthadiyl backbone of the bidentate amido ligand may strongly influence the aggregation of its metallated derivatives became apparent upon stirring the Li–amide **2** for

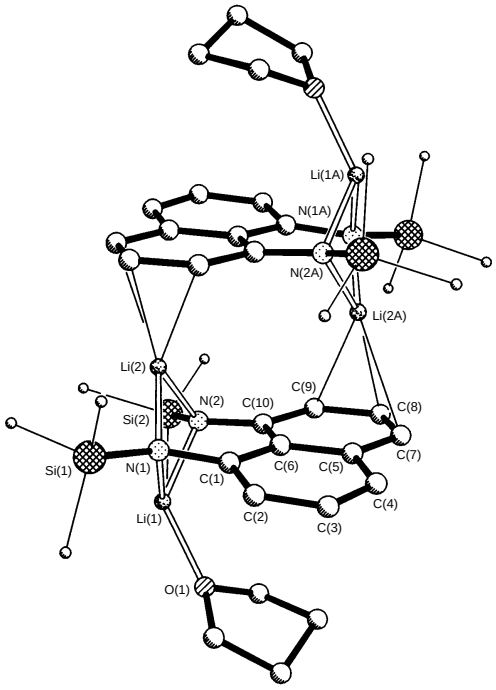

Fig. 2 Molecular structure of **5**. Selected atomic distances (Å) and interbond angles (°): N(1)–Li(1) 1.989(6), N(2)–Li(1) 1.995(6), N(1)–Li(2) 1.987(6), N(2)–Li(2) 1.861(4), Li(1)–O(1) 1.917(5), Li(2)–Li(2A) 4.117(6), Li(2)–C(9A) 2.596(6), Li(2)–C(8A) 2.399(6), Li(2)–C(7A) 2.577(6); Li(1)–N(1)–Li(2) 86.3(2), Li(1)–N(2)–Li(2) 86.3(2), N(1)–Li(1)–N(2) 89.2(2), N(1)–Li(2)–N(2) 89.6(2).

ca. 15 h in dioxane or toluene in the absence of TlCl. Instead of the disolvated Li–amide **2** large single crystals of a monosolvate $[C_{10}H_6\{N[Li(thf)]SiMe_3\}\{N(Li)SiMe_3\}]$ **5** were obtained.† The displacement of three of the thf ligands under these conditions was unexpected and indicated the formation of an unusual amide structure. This was confirmed by the single crystal X-ray structure analysis of the compound which revealed a dimeric structure closely related to that of **3** (Fig. 2).‡

The two molecular units are again related by a centre of inversion which generates a structural array which closely parallels that of the mixed metal amide **3**. The Li cation which has lost all of its donor ligands is coordinated by one of the naphthalene arene rings in an η^3-fashion [Li(2)–C(9A) 2.596(6), Li(2)–C(8A) 2.399(6), Li(2)–C(7A) 2.577(6) Å; nearest non-bonding Li–arene distances: Li(2)–C(5A) 2.956(6), Li(2)–C(10A) 2.992(6) Å]. The second Li atom which is located at the periphery is coordinated by only one thf molecule. At the vacant coordination site, which is occupied by a second thf molecule in **3**, a methyl group of the neighbouring dimeric unit is located [Li(1)–C(14′) 3.656(6) Å]. Although π-interactions of lithium cations with arene rings are known,[7] the η^3-mode of π-coordination observed in **5** is unprecedented in lithium amide chemistry.

Since lithium has a smaller ionic radius than thallium(I) and, consequently, forms shorter metal–arene distances, the two naphthalene ring systems are considerably closer in **5** than in **3** (lengths of the normal vectors between the arene planes in **3**: 5.41, **5**: 3.60 Å).

In conclusion, these first results indicate that the use of polydentate amido ligands containing potentially ligating backbone units generates structural arrays which differ markedly from those previously obtained with amido ligands containing an 'inactive' alkyl or silyl periphery.[3]

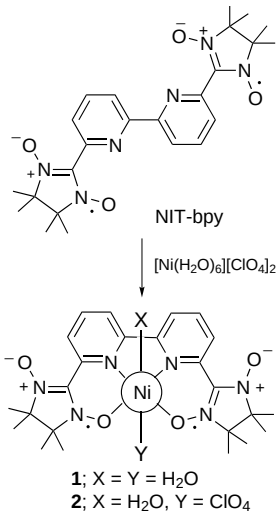
Complexation of a bipyridine-based nitronyl nitroxide biradical with nickel(II) affords two complexes that differ by the nature of one axial ligand and by their magnetic behaviour: in both cases ferromagnetic interactions between high-spin nickel(II) and the radicals are observed.

A key concept for the design of molecular ferromagnets involves the pre-programmed overlap of magnetic orbitals.[1] Thus far interest has focused on the preparation of multi-dimensional inorganic assemblies,[2,3] hybrid inorganic/organic systems[4] and organic radicals.[5] Coordination of nitroxide radicals to acidic paramagnetic metal centres provides valuable magnetic properties and, in certain cases, ferromagnetic ordering has been attained.[6,7] Surprisingly, chelating radicals have received scant attention despite the fact that they introduce important stereochemical constraints concerning the overlap of magnetic orbitals while favouring utilization of metal centres that are not strongly acid.[8,9] Here we report on the preparation, crystallographic analysis and magnetic properties of two nickel(II) complexes obtained from NIT-bpy, these being the first complexes to exhibit ferromagnetic Ni^{II}–radical interactions.

Complexes **1** and **2** were synthesised (Scheme 1), respectively, by mixing NIT-bpy with $[Ni(H_2O)_6][ClO_4]_2$ in methanol or in a mixture of dichloromethane–ethyl acetate.†

Single crystals of **1** were grown by slow evaporation of methanol.‡ Both the ORTEP view and the magnetic properties are shown in Fig. 1. It is seen that the NIT-bpy behaves as a pincer occupying the basal plane of the nickel octahedron. Two ancilliary ligands [H_2O molecules at a distance of 2.08(1) Å] complete the cation coordination sphere. Relevant structural features which have an impact on the magnetic properties are as follows: the O(1)N(1)C(1)N(2)O(2) mean plane containing one unpaired electron makes an angle of 14.07° with the equatorial plane N(5)N(6)O(1)O(3), 86.10 and 77.60°, respectively, with the N(5)O(w1)O(3)O(w2) and N(6)O(w1)O(1)O(w2) planes. The second O(3)N(3)C(12)N(4)O(4) mean plane exhibits an angle of 2.74° with the equatorial plane N(5)N(6)O(1)O(3), 89.50 and 88.97°, respectively, with N(5)O(w1)O(3)O(w2) and N(6)O(w1)O(1)O(w2) planes. The tilt angle about the exocyclic central C–C bond in the bpy subunit is 11.09°.



Scheme 1

The magnetic properties of these two nickel(II) complexes were studied by use of a SQUID susceptometer. For **1**, the product of molar susceptibility and temperature (χT) at 300 K corresponds to the calculated value expected for three uncorrelated spins (Ni^{II} $S = 1$ and two radicals $S = 1/2$) (Fig. 1). With decreasing temperature, χT shows a shallow decrease until a sharp breakdown occurs at around 220 K, presumably due to a phase transition. Then a continuous decrease is observed until a plateau is reached around 50 K, where $\chi T = 1.13$ emu K mol^{-1}. At still lower temperature an abrupt decrease occurs, indicating the onset of weak intermolecular antiferromagnetic interactions. A good fit of these experimental data could be obtained by allowing for the fact that coupling between each radical and the metal centre is different. One radical is coupled

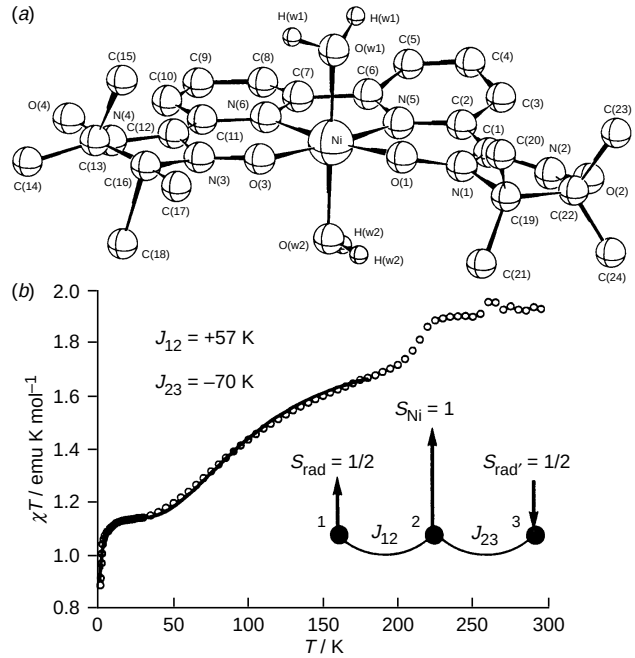


Fig. 1 (*a*) ORTEP view of the $[Ni(NIT\text{-}bpy)\cdot 2H_2O]^{2+}$ cation in complex **1** and (*b*) temperature dependence of the product of the magnetic susceptibility with temperature, χT *vs.* T, for **1**. The solid line represents the best-fit calculated values. Inset: magnetic interations network and values of the coupling constants.

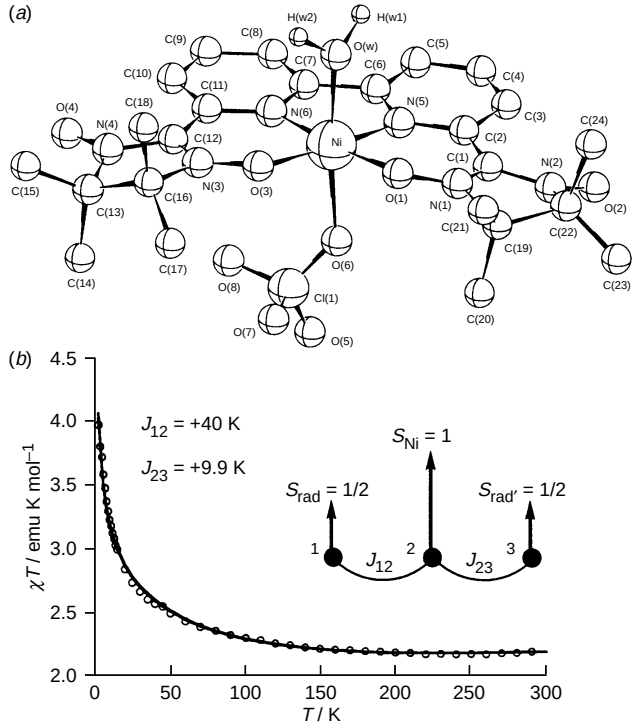

Fig. 2 (*a*) ORTEP view of the $[Ni(NIT\text{-}bpy)\cdot H_2O\cdot ClO_4]^{2+}$ cation in complex **2** and (*b*) temperature dependence of the product of the magnetic susceptibility with temperature, χT *vs.* T, for **2**. The solid line represents the best-fit calculated values. Inset: Magnetic interactions network and values of the coupling constants.

ferromagnetically (J_{12} = +57 K) while the second interaction (J_{23} = −70 K) is antiferromagnetic. The value obtained for the plateau corresponds to the value calculated for an S = 1 ground spin state arising from antiferromagnetic coupling between a spin 3/2 and a spin 1/2 of the second radical. The best fit in the low temperature regime was obtained with a mean field approximation (zJ' = −0.47 K).

At a first glance the crystal structure of complex **2**‡ looks very close to that of **1** (Fig. 2). However, careful examination of these structures reveals some important differences concerning relevant angles. Indeed, for **2** the O(1)N(1)C(1)N(2)O(2) system containing one unpaired electron is planar and makes an angle of 14.20° with the equatorial plane N(5)N(6)O(1)O(3), 81.48 and 78.68°, respectively, with the N(5)O(w)O(3)O(6) and the N(6)O(w)O(1)O(6) planes. The O(3)N(3)C(12)N(4)O(4) plane makes an angle of 9.43° with the equatorial plane N(5)N(6)O(1)O(3), 78.20 and 84.44°, respectively, with the N(5)O(w)O(3)O(6) and the N(6)O(w)O(1)O(6) planes. The tilt angle between both pyridine rings in the bpy subunit is only 2.54°. The axial ligands in **2** comprise a water molecule, located at 2.085(4) Å, and a perchlorate anion located at 2.178(4) Å.

Complex **2** exhibits disparate magnetic properties when compared to **1** (Fig. 2). The χT product measured at 300 K is somewhat higher than that calculated for three uncorrelated spins. With decreasing temperature, χT continuously increases over the entire temperature range reaching a value of 3.96 emu K mol^{-1} around 1.8 K. This value is higher than that calculated for two radicals ferromagnetically coupled to Ni^{II} (3.63 emu K mol^{-1}). This reveals that intermolecular ferromagnetic interactions are effective in this complex. The experimental data could be well explained by taking into account two intramolecular ferromagnetic interactions between the radicals and the Ni^{II} centre (J_{12} = +40 K and J_{23} = +9.9 K) as well as a weak intermolecular ferromagnetic interaction calculated by using a mean field approximation (zJ' = + 1.0 K). In **1** and **2**, as well as in the corresponding diamagnetic zinc(II) complex, intramolecular spin coupling between the radicals is insignificant since no sizeable magnetic interactions are observed when χ is measured in a frozen and dilute solution.

Analysis of the overlap between magnetic orbitals indicates that ferromagnetic interactions should be observed for the ideal case where the N_2O_2 ligand is planar. In fact, this conformation forces overlap between the π^* orbital of each radical and the magnetic orbitals of Ni^{II} to be orthogonal (for $d_{x^2-y^2}$) or symmetry forbidden (for d_{z^2}). However, slight deviation from orthogonality should induce the appearance of antiferromagnetic components. One radical in **1** is almost planar along the basal plane of the octahedron, thereby favouring ferromagnetic interaction. The second radical exhibits a prominent deviation from planarity, giving rise to strong antiferromagnetic interaction. Consequently, the overall magnetic behaviour of **1** is antiferromagnetic. The two radical centres in **2**, however, deviate only slightly from planarity and remain ferromagnetically coupled to the Ni^{II} centre.

This study has demonstrated that effective ferromagnetic coupling between Ni^{II} and nitronyl nitroxide radicals belonging to a tetradendate N_2O_2 tweezer ligand is possible. This is due to near orthogonality of the magnetic orbitals and was previously observed only for Cu^{II} complexes of nitronyl nitroxides in axial positions.[10] It is further shown that chelating ligands provide an excellent structural scaffold on which to assemble molecular ferromagnets. Future work will concentrate on the optimisation of these ligands both for their coordinative properties and for their ability to maintain strict orthogonality between the magnetic orbitals.

Dioxygen binding to immobilized Co^{II} complexes in porous organic hosts: evidence for site isolation

John F. Krebs[b] and A. S. Borovik*[a]

To model channel motifs and site isolation properties found in metalloproteins, a series of Co^{II} Schiff base complexes have been immobilized in porous organic hosts which stabilize Co–O_2 species at room temperature.

Immobilization of metal complexes in porous hosts is an effective way to regulate metal-based chemistry. In natural systems, this is exemplified by metalloproteins where the microenvironments around the metal-based active sites are controlled by protein structure.[1] In most cases, the active sites are located within the interior of the proteins, isolated from each other to prevent undesirable interactions. Access to external ligands (or substrates) is provided by channels that connect the active sites to the surface of the protein. To mimic these two structural properties in synthetic systems, *i.e.* site isolation and channel structure, we are using template polymerization techniques to immobilize metal complexes within porous organic hosts.[2,3] Results described herein show the feasibility of this approach in isolating metal sites in porous hosts *via* the stabilization of Co–O_2 adducts at room temperature.[4]

Incorporating metal sites with polymeric materials to model the dioxygen binding properties of metalloproteins has been reported.[5–7] While some promising results have been obtained, several of these systems use < 10% crosslinked polymers that do not sufficiently isolate the metal sites or utilize only a small percentage of their immobilized metal sites in the binding of dioxygen.[8] Our approach for site isolating metal complexes is modeled after methods developed to make templated network polymers.[9] We have modified these published methods by using substitution-inert metal complexes as templates. Utilizing kinetically inert metallo-templates that are synthesized prior to polymerization is advantageous because they provide a way of controlling the architecture of the metal sites in the porous hosts. Copolymerization of the metallo-template with a large excess of an organic crosslinker in the presence of a porogenic agent results in materials with immobilized metal complexes that are dispersed throughout highly crosslinked hosts. In addition, the porous structure of the host permits the immobilized complexes to be chemically modified to bind dioxygen. To evaluate the extent of site isolation achieved by this approach, we have examined dioxygen binding to immobilized Co Schiff base complexes: these complexes are known to bind dioxygen to form superoxide adducts, yet at room temperature most complexes undergo rapid reactions to yield Co^{III}_2–peroxide species.[10] Thus monitoring the formation and stability of the cobalt–superoxide species in the porous hosts at room temperature will indicate whether the metal sites have the appropriate architecture to bind additional ligands, and provide a measure of the number of metal sites isolated within the host.

The kinetically inert six-coordinate $[Co\mathbf{1}(dmap)_2]^+$ containing the styrene-modified salen ligand **1**[11] and two axially coordinated dimethylaminopyridine (dmap) ligands was immobilized into a methacrylate host by the procedure shown in Scheme 1. After grinding and sieving a dark red solid P-**1**$[Co(dmap)_2]$([Co] = 180 μmol g^{-1})[12] was obtained with a particle size of ⩽125 μm and an average pore diameter of 80 Å. The nearly quantitative (> 90%) removal of Co^{III} ions and the dmap ligands was achieved by refluxing P-**1**$[Co(dmap)_2]$ in an aqueous solution of 0.1 M Na_2H_2edta at a pH *ca.* 4. This metal ion removal process hydrolyzes the immobilized salen ligand to yield sites composed of two salicylaldehyde moieties covalently attached to the organic host [P-**1**$(saI)_2$]. This assignment is based on (i) the almost complete loss of nitrogen content in the polymer, (ii) the loss of the signature salen absorbance band at 380 nm, and (iii) the appearance of the characteristic carbonyl signal of salicylaldehyde at 1653 cm^{-1} in the DRIFT spectrum. The predisposition of the salicylaldehyde groups allows for regeneration of the salen ligands within the porous host by treating a suspension of P-**1**$(sal)_2$ in methanol with ethylenediamine under N_2 which affords P-**1**.

The immobilized sites in P-**1** can rebind metal ions to form four-coordinate complexes: the EPR spectra of P-**1**[Co] and P-**1**[Cu] are consistent with the immobilized complexes having the expected square-planar arrangement of donors around the metal ions.[13] Note that these immobilized sites also have sufficient axial space for the coordination of external ligands, such as nitrogeneous bases and dioxygen. This space is a consequence of the $[Co\mathbf{1}(dmap)_2]^+$ complex used in the copolymerization. Hence, > 80% of the immobilized Co^{II} sites are converted to five-coordinate complexes when P-**1**[Co] is treated with *ca.* 15 equiv. of either pyridine or dmap under an Ar atmosphere. Fig. 1(*a*) shows the rhombic EPR spectrum of P-**1**[Co(dmap)] measured at 77 K which is indicative of a low-spin Co^{II} complex where the dmap ligand binds axially to afford a square-pyramidal coordination geometry around the Co^{II} ions.[11,14,15] These five-coordinate Co sites in P-**1**[Co(dmap)] and P-**1**[Co(py)] form 1 : 1 Co–O_2 adducts at room temperature under 1 atm of O_2: the EPR spectra of both systems contain the characteristic EPR signals of Co–superoxide complexes (Fig. 1).[10] Double integration of the 77 K EPR signal for P-**1**$[Co(dmap)(O_2)]$, shows that 70% of the immobilized five-coordinate Co^{II} sites in P-**1**[Co(dmap)] form Co–O_2 adducts.[16] For P-**1**$[Co(py)(O_2)]$, the percentage of stable Co–O_2 sites is

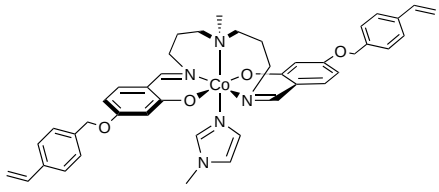
slightly less at 52%. In contrast to these results, monomeric Co**1**(dmap) and Co**1**(py) complexes dissolved in a 1 : 1 CH_2Cl_2–toluene mixture yield < 10% of the Co–O_2 adducts 1 h after exposure to dioxygen at room temperature.

The above results demonstrate that the porous organic host can influence the chemistry of the immobilized metal complexes compared to that observed in solution. The design of P-**1** requires the binding of an external base to efficiently bind dioxygen. To circumvent the need for an external base, immobilized sites containing the pentadentate Schiff base ligand bis(2-hydroxybenzyliminopropyl)methylamine (smdpt) were synthesized using [Co**2**(1-MeIm)]$^+$ as the template complex. [Co**2**(1-MeIm)]$^+$, modeled after a similar complex



[Co**2**(1-MeIm)]$^+$

reported by Marzilli *et al.*,[17] was copolymerized into a methacrylate host following the procedure used for P-**1**[Co(dmap)$_2$]. P-**2**[Co],[18] having a cobalt concentration of 150 μmol g^{-1} readily forms Co–O_2 adducts: double integration of the EPR signal obtained for P-**2**[Co–O_2] shows that 88% of the immobilized cobalt sites bind O_2 at room temperature and 1 atm of O_2 [Fig. 1(*b*)]. After 40 h at room temperature, the Co–O_2 EPR signal corresponds to 62% of the immobilized sites Co–O_2 adducts.[19] Reversion of P-**2**[Co–O_2] to P-**2**[Co] (40 h after the initial O_2 exposure) is accomplished by flushing the system with N_2 for 30 min. Rebinding of O_2 to P-**2**[Co] produces an identical EPR spectrum to that obtained after 40 h [Fig. 1(*b*)].[20]

The room temperature dioxygen binding properties of P-**1**[Co] and P-**2**[Co] illustrates that this approach for immobilization of metal complexes in porous organic hosts is a useful method for designing functional metal complexes. For comparison, the large number of cobalt sites that stabilize Co–O_2 adducts in these materials are a significant improvement over results reported for similar complexes immobilized in zeolite cages: only 1% of the immobilized [Co(salen)(py)] in zeolite NaY form Co–O_2 adducts and 25% of the immobilized Co(smdpt) in zeolite NaEMT bind O_2.[7] The highly crosslinked porous hosts in P-**1**[Co] and P-**2**[Co] provide robust matrices that are sufficiently rigid to retain the metal site architecture and isolate the metal sites. This type of porous host thus prevents unwanted metal–metal interactions that are observed in solution. Extension of this technique toward the design of new reactive metal complexes is underway.

We thank the donors of Petroleum Research Fund administered by the American Chemical Society (26743-G3), NSF (OSR-9255223) and ONR (N00014-96-1-1216) for financial support of this work.

Synthesis of copper(I) complexes with a novel naphthyl-appended macrocyclic ligand, including the crystal and molecular structure of the first copper(I)–η^2-naphthyl complex

William S. Striejewske and Rebecca R. Conry*

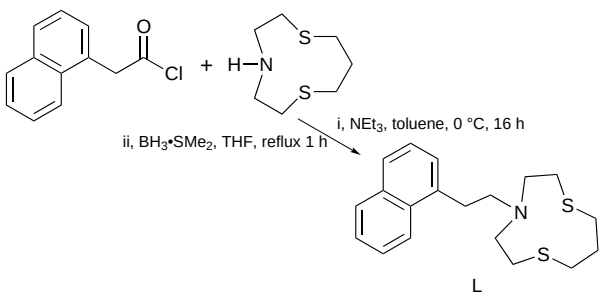
Department of Chemistry/216, University of Nevada, Reno, Nevada, 89557 USA

A new ligand, *N*-[2-(1-naphthyl)ethyl]-1-aza-4,8-dithiacyclodecane (L), and two of its copper(I) complexes [CuL(MeCN)]PF_6 and [CuL]PF_6, have been synthesized and characterized, including crystal structures of the two copper complexes.

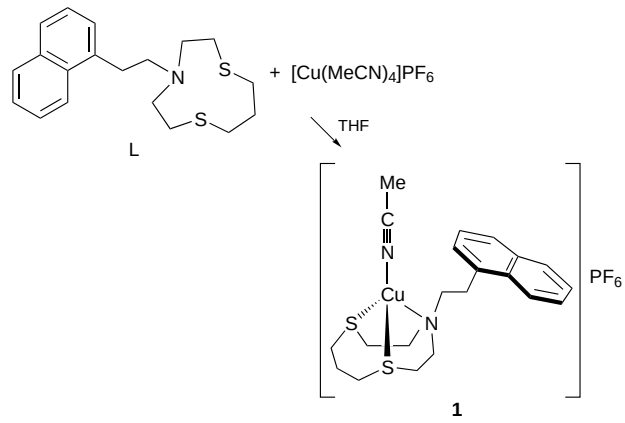
Organocopper compounds are among the most widely used organometallic reagents in the synthetic organic chemist's arsenal, valued for diversity and versatility in effecting transformations.[1] However, knowledge of the structural chemistry for organocopper compounds is as yet underdeveloped.[1a] While a number of σ-bonded alkyl- and aryl-copper(I)[1a,2] as well as copper(I) π-alkene complexes[3] have been structurally characterized, there are only a handful of such reports for copper(I) π-arene and π-aryl complexes. These include a couple of η^5-cyclopentadienyl-ligated copper complexes,[4] and two η^2-benzene complexes, $(C_6H_6)CuAlCl_4$[5] and $(CuO\text{-}SO_2CF_3)_2C_6H_6$.[6] There are also accounts of weak interactions in the solid state between a Cu^I center and an arene ring, with long distances, typically in the range 2.7–3.0 Å.[7] Here, we report the synthesis and characterization of the first example, to our knowledge, of a structurally characterized copper complex containing a π-bound naphthalene ligand, plus details for a related complex, where an acetonitrile ligand is ligated instead of the naphthyl group, and the synthesis of the naphthyl-appended, macrocyclic-NS_2 ligand.

The novel ligand L, *N*-[2-(1-naphthyl)ethyl]-1-aza-4,8-dithiacyclodecane, consists of the NS_2-macrocyclic ligand reported by Chandrasekhar and McAuley[8] to which we have added a pendant naphthalene group. L was synthesized in two steps from the parent macrocycle, Scheme 1. The first step involves formation of a precursor amide by reaction of 8-aza-1,5-dithiacyclodecane with 1-naphthylacetyl chloride (prepared from 1-naphthylacetic acid and PCl_5 by literature methods[9]). The amide was isolated and purified by column chromatography [silica gel, ethyl acetate–hexanes (35 : 65)] and was then, in the second step, reduced to L with borane. The ligand L was isolated as an oil after purification by column chromatography [silica gel, ethyl acetate–hexanes (30 : 70)], in 44% overall yield for the two steps.†

The acetonitrile complex, [CuL(MeCN)]PF_6 **1**, was synthesized by the stoichiometric reaction of $[Cu(MeCN)_4]PF_6$[10] with



Scheme 1



Scheme 2

L in THF at ambient temperature, Scheme 2. Recrystallization from acetonitrile–diethyl ether gave a 61% yield of **1** as yellow crystals. Elemental analysis, as well as ^1H and ^{13}C NMR and IR spectroscopic results are consistent with the formulation for **1**.‡ The solid-state structure (Fig. 1) shows that the geometry about the copper ion is slightly distorted from tetrahedral,§ with unexceptional bond lengths and angles.

In order to open a coordination site on the copper center, we wanted to remove the acetonitrile ligand from **1**. We first accomplished this, to synthesize [CuL]PF_6 **2**, by stirring **1** in CH_2Cl_2 under a CO atmosphere, followed by removal of the solvent and CO *in vacuo*. Thus, we were taking synthetic advantage of the tendency many copper(I) complexes have to bind CO weakly and reversibly.[11] However, we found that the CO was not necessary; the acetonitrile ligand from **1** was sufficiently labile that several of cycles of stirring the complex in CH_2Cl_2 followed by removal of the solvent *via* vacuum distillation also yielded **2** in > 85% isolated yield, Scheme 3.¶

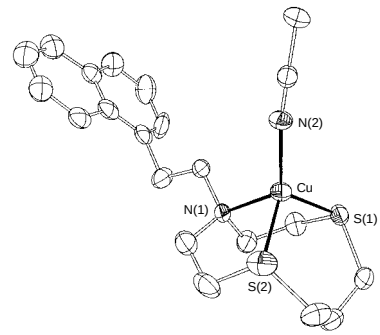


Fig. 1 Thermal ellipsoid plot of the solid-state structure of $[CuL(MeCN)]^+$ at the 25% probability level (hydrogens omitted for clarity). Selected bond distances (Å) and angles (°): Cu–N(1) 2.167(4), Cu–S(1) 2.2687(14), Cu–S(2) 2.260(2), Cu–N(2) 1.923(4); N(1)–Cu–N(2) 118.0(2), S(1)–Cu–N(2) 119.32(14), S(2)–Cu–N(2) 121.73(14), N(1)–Cu–S(1) 90.26(11), N(1)–Cu–S(2) 90.76(12), S(1)–Cu–S(2) 109.04(6).

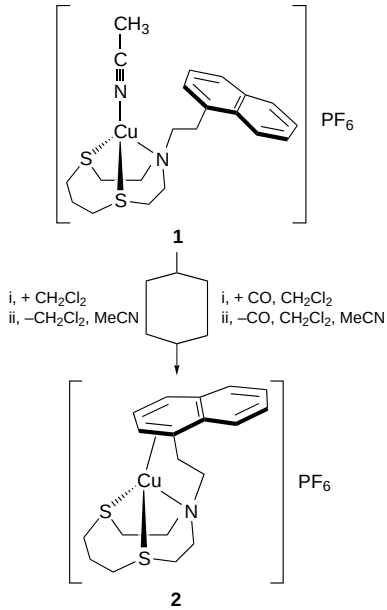

Scheme 3

Slow diffusion of hexane into a saturated CH_2Cl_2 solution of **2** yielded crystals suitable for X-ray diffraction.§

The solid state structure of **2** (Fig. 2) shows that the copper ion attains a distorted tetrahedral geometry by coordination of the pendant naphthyl group in an η^2-fashion. This binding occurs at the position adjacent to the ethylene linker chain and is unsymmetrical, with the Cu–C(10) and Cu–C(11) distances being 2.414(6) and 2.129(6) Å, respectively [the distance from the Cu to the center of the C(10)–C(11) bond is 2.168 Å]. These distances are comparable to the Cu–C distances in the two known Cu^I–η^2-benzene complexes,[5,6] which range from 2.09 to 2.30 Å. The binding in the previously reported complexes is also unsymmetrical, although it is less pronounced (differences in the pairs of Cu–C distances of 0.03–0.15 Å). Presumably the more accentuated unsymmetrical binding of the η^2-arene in **2** is at least partially due to the relatively short tether chain.

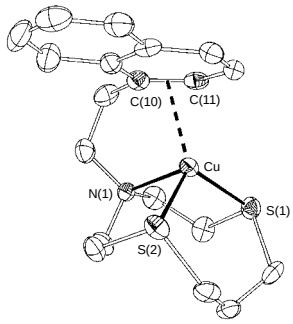

Fig. 2 Thermal ellipsoid plot of the solid-state structure of $[CuL]^+$ at the 25% probability level (hydrogens omitted for clarity). Selected bond distances (Å) and angles (°): Cu–N 2.146(5), Cu–S(1) 2.268(2), Cu–S(2) 2.233(2), Cu–C(10) 2.414(6), Cu–C(11) 2.129(6); N–Cu–S(1) 90.5(2), N–Cu–S(2) 91.89(14), S(1)–Cu–S(2) 111.08(7), N–Cu–C(10) 81.3(2), N–Cu–C(11) 105.4(2), S(1)–Cu–C(10) 133.8(2), S(1)–Cu–C(11) 108.2(2), S(2)–Cu–C(10) 114.5(2), S(2)–Cu–C(11) 136.7(2).

The C(10)–C(11) distance is essentially no longer in **2** [1.384(9) Å] than in **1** [1.343(11) Å]; no discernible differences in the coordinated C–C distances were observed in the two copper–benzene structures either.[5,6] Close comparison of the IR spectra of L and **2** shows that two bands, 1596 and 1509 cm^{-1}, are present in both spectra. In addition, there is a third band that has shifted from 1574 cm^{-1} for L to 1586 cm^{-1} for **2**; we tentatively assign these bands as C=C stretches. The C=C stretches for Cu–alkene complexes have been reported to shift from 15 to 170 cm^{-1} upon coordination.[3c,i,12]

We are currently exploring the properties of these novel complexes, to offer further insights into the chemistry of this interesting system.

The authors are grateful to the University of Nevada, Reno, the National Science Foundation, NSF Nevada EPSCoR, and the American Chemical Society-Petroleum Research Fund for funding. In addition, we thank Quynh Anderson, Angela Caffaratti and Lew Cary for technical assistance.

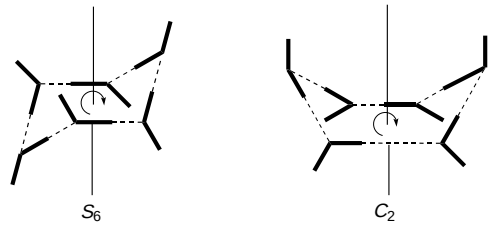
The structure of the S_6-symmetric methanol hexamer assembled in a supramolecular hydrophobic cavity

Frank Nils Penkert, Thomas Weyhermüller and Karl Wieghardt*

Max-Planck-Institut für Strahlenchemie, P.O. Box 10 13 65, D-45413 Mülheim an der Ruhr, Germany

The structure of the cyclic S_6-symmetric hexamer of methanol has been established by X-ray crystallography in crystals of $[GaLF_3](MeOH)_{6/2}\cdot(MeOH)_3\cdot CH_2Cl_2$ 1; the hexamer has been proposed to be the dominant species in liquid methanol.[4]

Crystalline, solid methanol consists of infinite zigzag chains of hydrogen bonded methanol molecules with an O···O distance of 2.66 Å at −110 °C.[1] Upon melting long chains and/or cyclic oligomers $(MeOH)_n$ form (n = 3–20).[2] In his famous book *The Nature of the Chemical Bond*, Pauling has depicted the cyclic hexamer $(MeOH)_6$ with six O–H···O bonding contacts as an example.[3] This cluster has later been proposed to be the dominant species in liquid methanol at room temperature[4] and its structure and vibrational spectrum in the gas phase have been repeatedly calculated.[5] Two conformers of nearly equal energy apparently exist: an S_6 and a C_2 symmetric form (Scheme 1) both of which have been generated by the method of size selection of clusters by momentum transfer in a scattering experiment with atoms in the gas phase.[5a,6] Upon vaporization of methanol the tetramer $(MeOH)_4$ has been shown to be the major component of the vapour.[7] To date none of these cyclic structures has been found in the solid state and, consequently, they have not been characterized by single crystal X-ray crystallography.



Scheme 1

We report here the crystal structure of $[GaLF_3](MeOH)_{6/2}\cdot(MeOH)_3\cdot CH_2Cl_2$ **1**† where L represents the neutral pendent arm macrocycle 1,4,7-tris(2-amino-3,5-di-*tert*-butylbenzyl)-1,4,7-triazacyclononane. In crystals of **1** the cyclic $(MeOH)_6$ hexamer is assembled in a hydrophobic ligand cavity.

The reaction of L with $GaF_3\cdot 3H_2O$ (1 : 2) in refluxing ethanol produces colourless microcrystals of $[GaLF_3]$ upon addition of water to the above mixture. Colourless crystals of **1** were obtained from a dichloromethane–methanol (1 : 5 v/v) solution of $[GaLF_3]$ at −20 °C. Details of the ligand and complex syntheses will be reported elsewhere.

The solid state structure of **1** consists of neutral $[GaLF_3]$ molecules shown in Fig. 1 where the 1,4,7-triazacyclononane backbone of the macrocycle L is bound to a GaF_3 fragment. The three 2-amino-3,5-di-*tert*-butylbenzyl arms are not coordinated. A *cis*-N_3F_3Ga octahedron is formed. The molecule possesses C_3 symmetry. The three uncoordinated pendent arms adopt a conformation where they are folded upwards toward the coordinated nine-membered 1,4,7-triazacyclononane ring. An approximately circular bowl-shaped hydrophobic 'surface' is formed with six bulky tertiary butyl groups at the rim of this

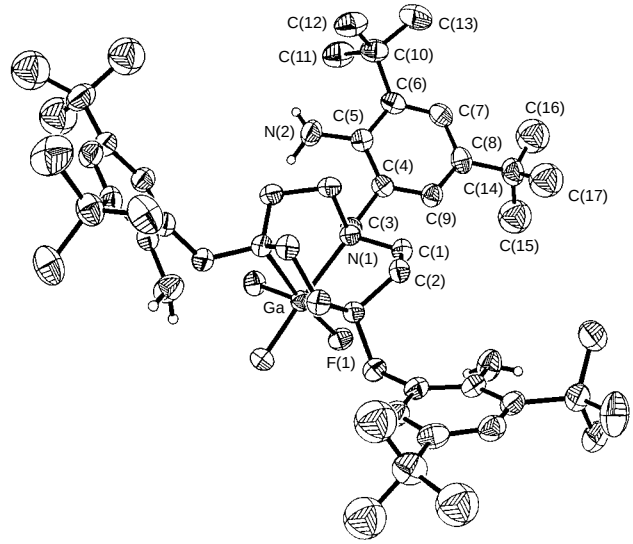


Fig. 1 Molecular structure of the neutral $[GaLF_3]$ complex in crystals of **1**. Selected distances (Å) and angles (°): Ga–N(1) 2.147(3), Ga–F(1) 1.849(2), C(5)–N(2) 1.397(6), F(1)–Ga–F(1′) 94.1(1), N(1)–Ga–N(1′) 82.8(1), N(1)–Ga–F(1) 88.7(1).

bowl. Two such $[GaLF_3]$ molecules are then packed together in a fashion which brings the two hydrophobic bowl-shaped surfaces facing each other. The two sets of three pendent arms are staggered. This 'dimer' is held together by van der Waals forces only. Roughly, its shape may be viewed as clam-like with S_6 symmetry. The inner surface of this clam is of purely hydrophobic nature since it comprises exclusively phenyl rings and methylene hydrogen atoms of the two ligands L. The discus-shaped cavity inside is filled with six methanol molecules as is shown in Fig. 2. Fig. 3 shows the six MeOH molecules forming a cyclic structure *via* six O–H···O hydrogen bonding contacts [O···O 2.62(1) Å]. The methyl groups are staggered; the hexamer adopts S_6 symmetry. The methyl groups form weak van der Waals contacts to the hydrophobic inner

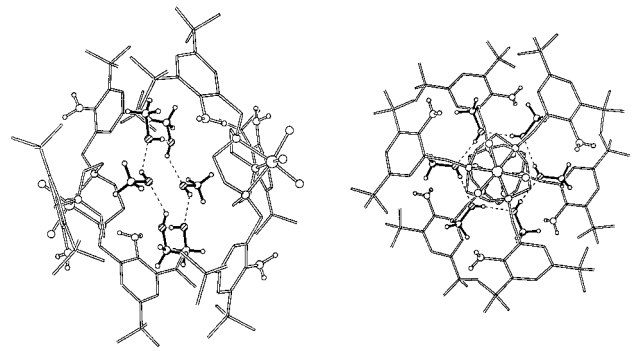

Fig. 2 Schematic representation of the $[GaLF_3]_2\cdot(MeOH)_6$ unit in **1**. Left: side-view looking into the 'clam' composed of two $[GaLF_3]$ shells. Right: view down the S_6 axis on which the two Ga^{3+} ions (only one is seen) lie.

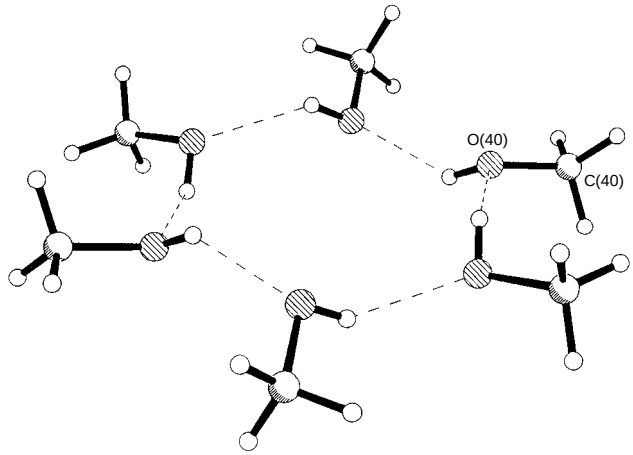

Fig. 3 Schematic representation of the S_6 symmetric methanol hexamer in **1**. Selected distances (Å): O(40)···O(40′) 2.62(1), O(40)–C(40) 1.394(9).

surface of the cavity only. The O–H···O bonds are asymmetric and the twelve-membered ring is puckered.

The outer surface of the clam exposes two sets of (*a*) three fluoro ligands and (*b*) of three amino groups; it is 'sticky'. Three additional methanol molecules per $GaLF_3$ unit form each a strong O–H···F contact at 2.58(1) Å and two somewhat weaker O···H–N interactions with the amino groups at 2.94(1) and 3.39(1) Å. The latter two interactions enforce an ordered packing of the clams relative to each other in the solid state ('inter-clam' contacts).

Synthesis of mesoporous aluminophosphates using surfactants with long alkyl chain lengths and triisopropylbenzene as a solubilizing agent

Tatsuo Kimura,[a] Yoshiyuki Sugahara[a] and Kazuyuki Kuroda*[a,b]

[a] *Department of Applied Chemistry, School of Science and Engineering, Waseda University, Ohkubo-3, Shinjuku-ku, Tokyo 169, Japan*

[b] *Kagami Memorial Laboratory for Materials Science and Technology, Waseda University, Nishiwaseda-2, Shinjuku-ku, Tokyo 169, Japan*

Mesostructured organo-aluminophosphates were prepared by using surfactants with long alkyl chain lengths (C_{16} and C_{22}) and by utilizing solubilization of triisopropylbenzene; calcination of the mesostructured materials yielded thermally stable mesoporous aluminophosphates with surface areas > 700 m^2 g^{-1} and with pore diameters in the range 1.8–3.9 nm.

Mesoporous silicas, denoted FSM[1] and M41S,[2] are very attractive materials for catalysts, catalyst supports and adsorbents for larger molecules than those treated in microporous crystals. Since microporous $AlPO_4$-*n* materials are known,[3] it is expected that mesostructured organo-aluminophosphates are useful for the formation of mesoporous aluminophosphates to enlarge the variety and possible applications of mesoporous materials. We have already reported the successful formation of a hexagonal mesostructured aluminophosphate (AlPO) by using hexadecyltrimethylammonium chloride.[4] Feng *et al.* also reported a hexagonal mesostructured material prepared in the presence of F^- ions, however, the porous structure collapsed upon calcination.[5] Recently a mesoporous aluminophosphate with large surface area (790 m^2 g^{-1}) was reported by Zhao *et al.*[6] Although the pore diameter of the product was reported to be *ca.* 4.0 nm, this value is somewhat questionable because it is too large judging from the values observed for ordered mesoporous silicas.[1,2] On the other hand, Holland *et al.*[7] and Cheng *et al.*[8] reported mesoporous aluminophosphate-based materials *via* layered intermediates; the porous materials, prepared by solvent extraction, are thermally unstable.

The hexagonal mesostructured AlPO reported by us had a less condensed framework, so that a microporous material formed after calcination in air.[4] Based on this result, it is expected that mesoporous AlPOs can be obtained by utilizing mesostructured AlPOs with larger hexagonal arrays. Here, we report the successful synthesis of thermally stable mesoporous AlPOs, based on this strategy.

Hexagonal mesostructured AlPOs were prepared by using $C_{16}H_{33}NMe_3Cl$ (C_{16}TMACl) and $C_{22}H_{45}NMe_3Cl$ (C_{22}TMACl), denoted as C_{16}-AlPO and C_{22}-AlPO, respectively. C_{16}-AlPO was prepared according to our previous paper.[4] C_{22}-AlPO was prepared as follows: C_{22}TMACl (containing a small amount of shorter alkyl chains), tetramethylammonium hydroxide (TMAOH, 25 mass% in water), 85% H_3PO_4, and water were mixed for several hours. Aluminium triisopropoxide was added to this mixture under vigorous stirring, and the stirring was continued for 1 day. The composition of the starting mixture was $Al_2O_3 : P_2O_5 : C_{22}$-TMACl : 2.0 TMAOH : 65.0 H_2O. The starting mixture was dispersed in distilled water at 70 °C, with formation of a white solid. This solid was washed with distilled water heated at 70 °C repeatedly, and dried at 80 °C. Solubilization of 1,3,5-triisopropylbenzene (TIPBz) into surfactant assemblage was also carried out for C_{22}TMACl; TIPBz has already been known to act as a solubilizing agent.[9] The synthesis procedure was the same as described above and TIPBz was added before the addition of aluminium triisopropoxide. The molar ratio of TIPBz/C_{22}TMACl in the starting mixture was 1, and this product was denoted as TIPBz/C_{22}-AlPO; the molar ratio of TIPBz/C_{22}TMACl in the TIPBz/C_{22}-AlPO was *ca.* 0.67 based on the CHN analysis, indicating that not all the TIPBz was solubilized in the surfactants. All the products were heated at 600 °C for 1 h in flowing N_2, followed by calcination at 600 °C for 1 h in flowing air. The calcined products were analyzed by XRD, N_2 adsorption, and ^{27}Al and ^{31}P MAS NMR spectroscopy performed on a JEOL GSX-400 with a spinning rate of 5 kHz (for ^{27}Al: frequency: 104.05 MHz; pulse angle: 45°; recycle time: 5 s, for ^{31}P: 161.70 MHz; 60°; 20 s, respectively).

The XRD patterns of all the products before calcination are shown in Fig. 1. The XRD peaks of the C_{16}-AlPO can be assigned to (100), (110) and (200) of a hexagonal phase. The XRD peaks of both C_{22}-AlPO and TIPBz/C_{22}-AlPO can also be assigned to (100), (110), (200) and (210) of hexagonal phases. The lattice parameters (a_0) of the C_{16}-AlPO, C_{22}-AlPO and TIPBz/C_{22}-AlPO were 4.8, 5.8 and 7.2 nm, respectively. These XRD results indicate the formation of mesostructured AlPOs with large hexagonal arrays by utilizing C_{22}TMA and solubilization of TIPBz.

In the XRD patterns of the calcined products (Fig.1), the d_{100} peak shifted from 4.1 to 2.8 nm for C_{16}-AlPO after calcination, and the XRD patterns showed a shift from 5.1 to 3.7 nm for C_{22}-AlPO and a shift from 6.2 to 4.6 nm for TIPBz/C_{22}-AlPO. The lattice parameters (a_0: $2d_{100}/\sqrt{3}$) of the calcined C_{16}-AlPO, calcined C_{22}-AlPO and calcined TIPBz/C_{22}-AlPO were 3.2, 4.3 and 5.3 nm, respectively, if we assume that the calcined products retain the hexagonal structures. The shrinkages are

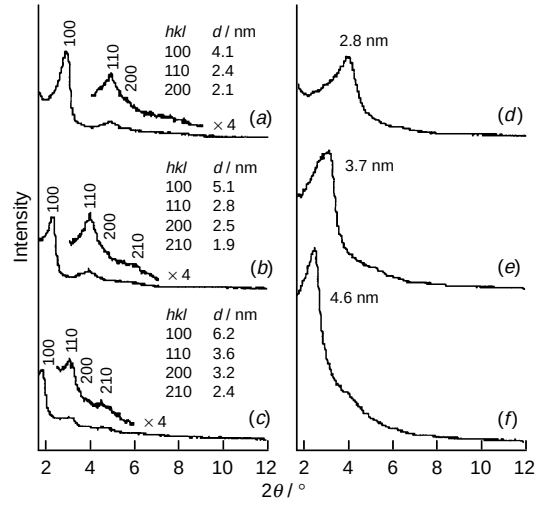

Fig. 1 XRD patterns of (*a*) C_{16}-AlPO, (*b*) C_{22}-AlPO and (*c*) TIPBz/C_{22}-AlPO, (*d*) calcined C_{16}-AlPO, (*e*) calcined C_{22}-AlPO and (*f*) calcined TIPBz/C_{22}-AlPO. These patterns were recorded on a Mac Science M03XHF[22] diffractometer with monochromated Fe-Kα radiation.

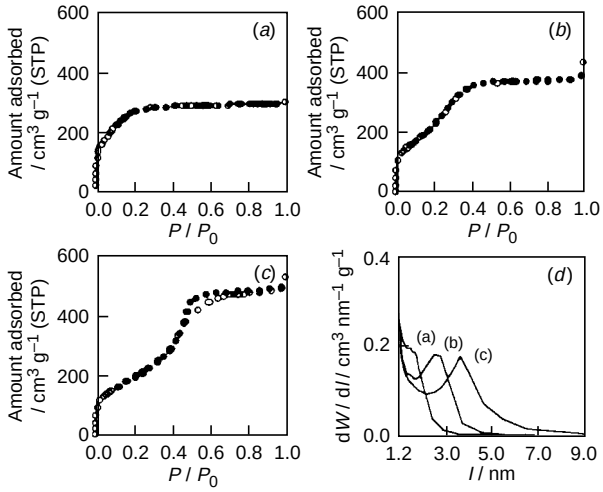

Fig. 2 N_2 adsorption isotherms of calcined (*a*) C_{16}-AlPO, (*b*) C_{22}-AlPO and (*c*) TIPBz/C_{22}-AlPO. Filled symbols denote desorption. Corresponding pore size distributions of the calcined products are shown in (*d*). These isotherms were obtained by a BELSORP 28 (Bel Japan, Inc.) at 77 K.

larger than those observed for silica-based mesoporous materials[2] because of less condensed frameworks as described below. In addition, the XRD peaks of all the products were broadened after calcination. These results suggest that the porous structures remained, although the sizes and the regularities of the hexagonal arrays decreased upon calcination.

Hexagonal arrays with relatively ordered arrangements were observed in the TEM images of all the products before calcination. After calcination, disordered arrays were obtained, and the periodic distances of these arrays decreased. These TEM images are in agreement with the XRD results. No other phases were detected in any TEM images.

The N_2 adsorption isotherms and the pore size distributions of the calcined products, calculated by the Horváth–Kawazoe method,[10] are shown in Fig. 2. The N_2 adsorption isotherm of calcined C_{16}-AlPO showed almost type I behavior, indicating the presence of micropores; the pore diameter was *ca.* 1.8 nm. In contrast, the isotherms of the calcined C_{22}-AlPO and TIPBz/C_{22}-AlPO showed type IV behavior. The calcined C_{22}-AlPO had a BET surface area of 760 $m^2\ g^{-1}$, a pore volume of 0.56 $cm^3\ g^{-1}$ and an average pore diameter of 2.8 nm. For the calcined TIPBz/C_{22}-AlPO, the BET surface area and the pore volume were 720 $m^2\ g^{-1}$ and 0.72 $cm^3\ g^{-1}$, respectively. The pore diameter was *ca*. 3.9 nm.

The structural changes during calcination can be monitored by ^{27}Al and ^{31}P MAS NMR measurements before and after calcination. The ^{31}P MAS NMR spectra of the uncalcined products showed several peaks in the range δ 0 to −20, indicating the uncalcined products had less condensed frameworks.[4,11,12] A broad peak centered at δ −21 was observed after calcination indicating condensation of the frameworks.[11,12] The ^{27}Al MAS NMR spectra of the uncalcined products showed that signals due to both four- (Al^{IV}) and six-coordinate Al (Al^{VI}) at δ *ca.* 43 and 1, respectively. Based on the Al^{IV}/Al^{VI} intensity ratios, varying from *ca.* 0.6 (C_{16}-AlPO) to *ca*. 0.3 (C_{22}-AlPO and TIPBz/C_{22}-AlPO), a large amount of Al^{VI} is present in the uncalcined products and they may be coordinated with not only PO_4 units but also water molecules,[4] being related to less condensed frameworks. Only a broad signal due to Al^{IV} was observed at *ca*. δ 39 for each calcined product; the chemical shift strongly suggesting that the $Al^{IV}O_4$ units are surrounded by mainly P.[11,13] Although the Al/P ratios (1.5), discussed below, might suggest the presence of Al–O–Al bonds, such bonds are unlikely, judging from very different chemical shifts expected for [$Al^{IV}O_4$(*n*Al)] (*n* = 1–4).[13]

Both N_2 adsorption and NMR results indicate that the pore sizes can be controlled although shrinkage must be taken into consideration, so that the C_{22}-AlPO and TIPBz/C_{22}-AlPO changed to mesoporous materials after calcination owing to the larger hexagonal arrays.

The C_nTMA/(Al + P) ratios were 0.25 (C_{16}-AlPO), 0.19 (C_{22}-AlPO) and 0.16 (TIPBz/C_{22}-AlPO), and the Al/P ratios of all the products were *ca.* 1.5. This Al/P value is different from unity which would be expected for an ideal three-dimensional $AlPO_4$-*n*.[3] The Al/P ratios of mesostructured and/or mesoporous aluminophosphates reported by Feng *et al.*,[5] Zhao *et al*.,[6] Holland *et al.*,[7] and Cheng *et al*.[8] are 2.9, 0.64, 1.5, and 1.0, respectively. Although the Al/P ratios of mesoporous AlPOs reported here are similar to those reported by Holland *et al.*,[7] the coordination of Al atoms is six for their materials while it is mainly four for ours. For the other three materials, the Al/P ratios are clearly different. Nevertheless, the coordination of Al atoms in the material reported by Feng *et al*.[5] is similar to ours. However, because there is little information on the aluminophosphate frameworks in those reports, appropriate comparison with our materials is not possible at present.

In conclusion, thermally stable mesoporous AlPOs were obtained by calcination of hexagonal mesostructured AlPOs prepared by using both C_{22}TMA as a micelle aggregate and TIPBz as a solubilizer. This method can be applicable for the preparation of various mesoporous materials from less condensed inorganic units–surfactant mesostructured materials, which normally afford microporous materials owing to substantial shrinkage. A study on the surface structure of these mesoporous AlPO is now in progress.

Sonophotoluminescence: pyranine emission induced by ultrasound

Muthupandian Ashokkumar and Franz Grieser*

Advanced Mineral Products Research Centre, School of Chemistry, University of Melbourne, Parkville, 3052, Australia

Sonoluminescence has been used to excite the water soluble acid–base fluorescent indicator trisodium 8-hydroxy-1,3,6-pyrenetrisulfonate, leading to light emission (sonophotoluminescence) from the dye.

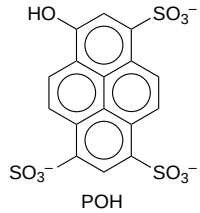
The acoustic driven collapse of microbubbles in solution results in a phenomenon referred to as sonoluminescence.[1] The emission spectrum obtained from multibubble sonoluminescence (SL) in water is quite broad, ranging from 200 to above 800 nm, with a maximum in the region of 250–350 nm.[1–3] In addition to SL, emission stemming from the ground state chemical reaction of ultrasonically generated oxidising radicals with luminol has also been observed.[4] In the latter case the spectrum obtained is similar to the chemiluminescence of luminol.

The broad band emission from SL raises the question of whether it can be conveniently used as an internal light source to excite other molecules in solution. To explore this possibility we have examined the 'trivial' excitation of trisodium 8-hydroxy-1,3,6-pyrenetrisulfonate (pyranine, POH), by SL, and the ensuing emission, which can be referred to as sonophotoluminescence (SPL).

Details of the experimental system used are given elsewhere.[5] Briefly, a modified Undatim D-Reactor (515 kHz) was fitted into the cavity of a spectrofluorimeter (Hitachi, F-4500) and spectra recorded directly. A full scan (200–800 nm) could be measured in *ca.* 2 min. The sonication of the aqueous solutions was carried out in pulsed mode using 4 ms pulses with a 1 : 3 duty cycle. The reactor was operated at *ca.* 15 W into 50 ml solutions. Under these conditions the temperature rise of the solutions sonicated was *ca.* 1° min^{-1}.

All solutions were made with Milli-Q water and used on the day of preparation. Pyranine was obtained from Molecular Probes Inc. and used as received. The UV-VIS spectrum of pyranine in water agreed with that reported by others.[6] The temperature of the solutions remained in the range of 20–25 °C while spectra were recorded.

Pyranine is a highly water soluble compound with well characterised photophysical properties.[6,7] Its chemical structure is shown below.



POH

Pyranine has a ground state pK_a = 7.2 but on excitation pK_a* = 0.5.[7] Its excited state lifetime is also sufficiently long (5 ns) such that deprotonation occurs over a wide pH range.[7] It is only when the pH is < *ca.* 2 that the emission from the POH* form begins to dominate. These photophysical properties of pyranine are evident in the absorption and fluorescence spectra (Fig. 1), at pH values above and below its ground state pK_a.

Fig. 2 shows the emission observed when pyranine solutions (at several pH values) are sonicated. These spectra can be compared with the equivalent pH fluorescence spectra shown in Fig. 1. Close correspondence of the two sets of spectra is evident although there are some differences. Fig. 3 directly compares the standardised fluorescence and SPL from pyranine at pH = 6.4. Also shown is the SL signal obtained from water in the absence of pyranine. As can be seen, the SPL signal is slightly broader than the fluorescence band with a shoulder at 450 nm. The broadness and the shoulder are both due to the residual SL emission that has not been absorbed by ground state pyranine. It can be seen from Fig. 1 that at pH = 6.4 there is no substantial light absorption by ground state pyranine above *ca.* 440 nm.

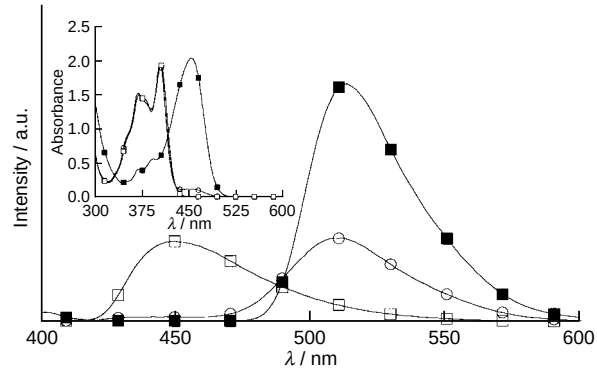


Fig. 1 Emission spectra (λ_{ex} = 350 nm) of 0.1 mM pyranine in water at various pH. Insert shows the absorption spectra obtained from the same solutions. Emission and absorption spectra were measured in standard 1 cm pathlength cuvettes. (Emission spectra are uncorrected.) pH = 10.7 (■), 6.4 (○), 0.7 (□).

At a pH of 10.7 all the pyranine exists in its ionised form, PO^-, and its absorption spectrum extends to *ca.* 500 nm (Fig. 1). Under these conditions all of the SL is absorbed at wavelengths below 500 nm and therefore the shoulder seen at 450 nm is no longer present.

At pH = 0.7 the reaction,

$$PO^{-}* + H^{+} \rightarrow POH* \quad (1)$$

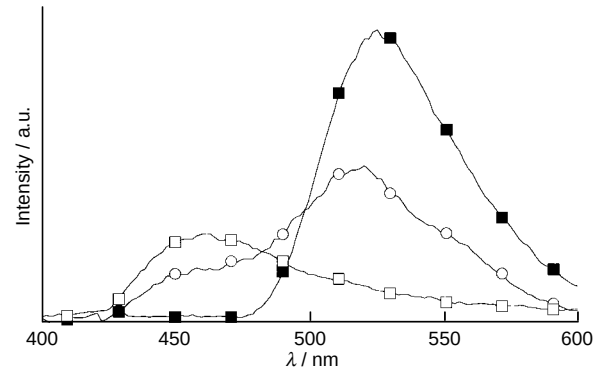

Fig. 2 Sonophotoluminescence of 0.1 mM pyranine in water at various pH. The emission is produced in a 4 cm diameter cell using a 3.5 cm diameter transducer plate. (Emission spectra are uncorrected.) pH = 10.7 (■), 6.4 (○), 0.7 (□).

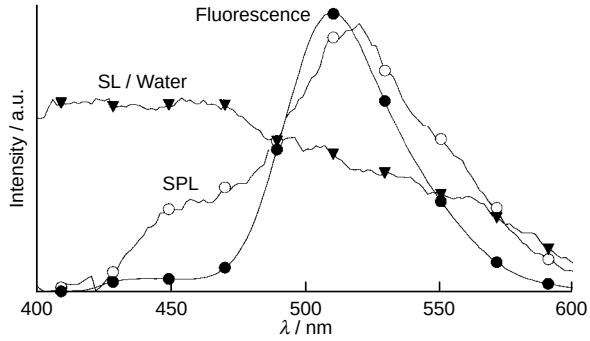

Fig. 3 A comparison of the fluorescence and SPL spectra of pyranine at pH = 6.4. The intensity maxima of the bands have been normalised to allow a better comparison. Under the quite different excitation conditions used the fluorescence intensity is *ca.* 600 times stronger than the SPL. Also shown is the SL from water. The intensity is on the same scale as that of the SPL. (Emission spectra are uncorrected.)

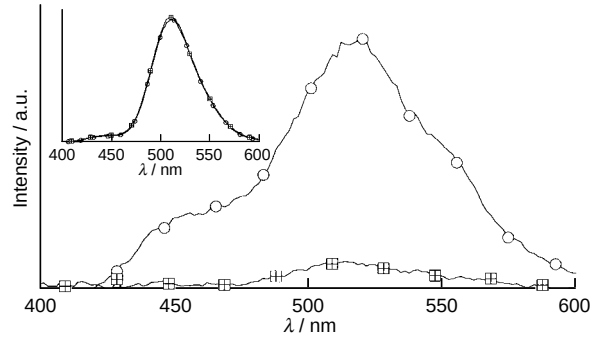

Fig. 4 Sonophotoluminescence spectra of 0.1 mM pyranine in water in the absence (○) and presence ⊞ of 0.1 M butan-1-ol at pH = 6.4. Insert shows the fluorescence spectra (λ_{ex} = 350 nm) of the same solutions. (Emission spectra are uncorrected.)

prevents emission from the PO^{-}* form and the emission recorded is a combination of SL and SPL from the POH* species.

In order to confirm that it is sonoluminescence that excites pyranine and not some thermal activation from heat leaking away from the acoustically collapsed bubble some experiments were carried out in the presence of butan-1-ol. Butanol has been found to quench the SL intensity from water[5] while enhancing sonochemical reactions in solution.[8,9] The latter indicates that bubble collapse in the presence of butanol still occurs and local heating still produces radicals that are responsible for the chemical reactions in solution.

Fig. 4 shows the effect that 0.1 M of butan-1-ol has on pyranine fluorescence and its SPL signal. It can be seen that butanol has a minimal effect on the fluorescence signal but almost completely quenches the SPL emission. This is consistent with butan-1-ol quenching the SL and hence eliminating photon excitation of pyranine.

The results presented clearly show that SL can be used to excite solution solutes. One of the advantages offered by this method is that no external light source is required and photon excitation can, in principle, be achieved in optically opaque and remote sites. For example, photosensitizing drugs within a human body could be activated using SPL generated by an ultrasound source external to the body. We note also that since sonoluminescence is observed in a wide range of liquids[1,10,11] it should be possible to generate SPL in systems other than water.

A new type of allylation: synthesis of β,γ-unsaturated ketones from α-halogenated aryl ketones using an allyltributyltin(IV)–tin(II) dichloride–acetonitrile system

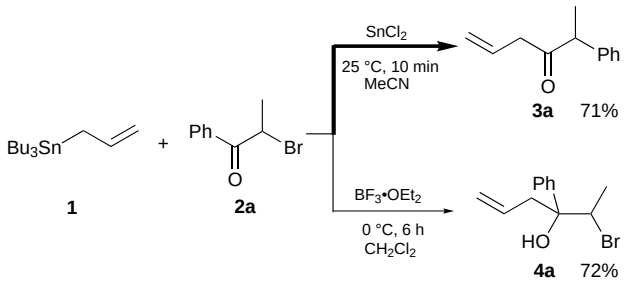
Makoto Yasuda, Makihiro Tsuchida and Akio Baba*†

Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565, Japan

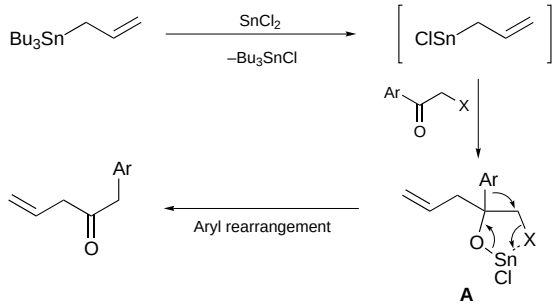
Allylation of α-halogenated aryl ketones with an allyltributyltin–tin dichloride–acetonitrile system gave β,γ-unsaturated ketones in high yields *via* selective aryl rearrangement.

Allylation of carbonyl compounds has been intensively studied for carbon–carbon bond formation, affording homoallylic alcohols.[1] We have recently reported an allylic tin(II) species as powerful allylation reagents toward aldehydes, ketones or imines in preference to the corresponding tin(IV) species.[2] The tin(II) species, which have vacant orbitals to accept electrons, contribute to the selective carbonyl allylation *via* a cyclic transition state owing to the strong affinity between the tin(II) atom and the carbonyl oxygen.[2] The tin(II) center would be expected to interact even with a halogen atom because the latter bears unshared electron pairs for coordination to tin(II). Herein, we report a new type of allylation system for α-halogenated aryl ketones.[3] This reaction proceeds *via* carbonyl allylation and subsequent aryl rearrangement to give β,γ-unsaturated ketone derivatives in high yields, in which reaction the tin(II) species characteristically effects the rearrangement.

A mixture of tin dichloride ($SnCl_2$) and 2-bromopropiophenone **2a** in MeCN was treated with allyltributyltin **1** at room temperature for 10 min to afford, unexpectedly, the β,γ-unsaturated ketone **3a**, whereas general activation by a Lewis acid, boron trifluoride–diethyl ether,[1,4] gave the homoallyl alcohol **4a** exclusively (Scheme 1). In the allyltributyltin–$SnCl_2$ system, migration of the phenyl group takes place as shown in Scheme 2. The homoallylic tin alkoxide **A** is a key intermediate



Scheme 1



Scheme 2

in which the interaction between the tin(II) atom and the halogen directs the aryl rearrangement.[5] This type of interaction is unlikely to occur using allyltin(IV) reagents, which have a weaker affinity for halogen than the tin(II) species. Allylation using tin(IV) reagents of α-halo ketones proceeds *via* cyclization of the intermediate tin alkoxides to give oxiranes exclusively, and no rearrangement is observed.[6–8] Other solvents examined (THF, toluene, CH_2Cl_2, $CHCl_3$) in the presence of $SnCl_2$ gave low yields of **3a** (0–24% yield) at room temperature for 1 h. These facts strongly support the participation of the allylic tin(II) species in the rearrangement, because our previous report[2] has already shown the efficiency of MeCN as the solvent of choice for transmetalation of allyltributyltin **1** with $SnCl_2$. Allylaton of **2a** in MeCN for 24 h without $SnCl_2$ did not proceed at all. Considering these results, we suppose that this new type of allylation system giving the β,γ-unsaturated ketone evolves from the unique character of the tin(II) reagents.

We then explored the generality of the reaction by varying the aryl halo ketones. As shown in Table 1, β,γ-unsaturated ketones

Table 1 Synthesis of β,γ-unsaturated ketones **3**

	Halo ketone **2**					Yield (%)	
Entry	Ar	R	X	t_1/h	t_2/h	**3**	**4**
1	4-$MeOC_6H_4$	H	Br	1	0	98	0
2	4-MeC_6H_4	H	Br	1	0.5	81	0
3	4-PhC_6H_4	H	Br	1	0.5	65	0
4	4-PhC_6H_4	H	Br	1	0	0	89
5	Ph	H	Br	1	0.5	60	0
6	4-ClC_6H_4	H	Br	1	0.5	26	27[a]
7	4-$O_2NC_6H_4$	H	Br	1	0.5	0	16
8	2-naphthyl	H	Br	1	1	74	0
9	2-naphthyl	H	Br	1	0	0	95
10	2-thienyl	H	Br	0.25	0.5[b]	72	0
11	2-thienyl	H	Br	1	0	0	76
12	3-thienyl	H	Br	1	0.5	61	0
13	3-thienyl	H	Br	1	0	0	83
14	Ph	Me	Br	24	0	98	0
15	Ph	Me	Cl	1	0.5	71	0
16	Ph	Me	Cl	0.25	0	0	90[c]
17	Ph	Ph	Cl	1	0	86	0

[a] 2-(*p*-Chlorophenyl)pent-4-enal (*ca*. 10% yield) was obtained as a side product (see ¶). [b] 50 °C. [c] Isomeric ratio = 61 : 39.

3 were effectively obtained.‡ The aryl rearrangement often required high temperature conditions (80 °C) because homoallyl alcohols **4** were formed exclusively at 25 °C (entries 4, 9, 11, 13 and 16). This result suggests that the reaction includes the intermediate **A** illustrated in Scheme 2. The effect of different aromatic substituents was interesting. Generally, the allylation of aryl-substituted carbonyls is enhanced by an electron-withdrawing group on the aromatic substituents since the electrophilicity of the carbonyl group is increased. The opposite effect was observed in entries 1–3 and 5–7 in regard to the synthesis of **3**. The unrearranged products **4** were observed in the reaction with the substrates bearing chloro or nitro groups (entries 6 and 7). These substituent effects are explainable by the rate-determining migration of the aryl groups,[9] as the allyltin(II) species have an adequate ability to promote carbonyl allylation.[2] The thienyl ring is tolerated in this reaction system (entries 10–13), in which sulfur did not reduce the activity of the tin(II) reagent at all. The secondary bromo or chloro ketones also gave **3** exclusively (entries 14, 15 and 17). The rearrangement took place readily without the need for high temperatures (entries 14 and 17). The interaction of tin(II) with the halogen (in **A**) would generate cationic halide carbon species, which are more stable for secondary substrates.

On the other hand, α-halogenated alkyl ketones showed a different reaction course, without any rearrangement; allyloxazolines were formed by the addition of solvent nitriles to the tin alkoxide intermediate, albeit in low yields.§

This work describes a new allylation system for the synthesis of β,γ-unsaturated carbonyl compounds, in which an unusual reaction course, including aryl rearrangement, is proposed. The selective rearrangement is promoted by the properties of the tin(II) species. Further investigaton of allylic tin(II) species is in progress.

This work was supported by a Grant-in-Aid for Scientific Research on Priority Area No. 09231229 from the Ministry of Education, Science, Sports, and Culture, of the Japanese Government. Thanks are due to Mr H. Moriguchi, Faculty of Engineering, Osaka University, for assistance in obtaining mass spectra.

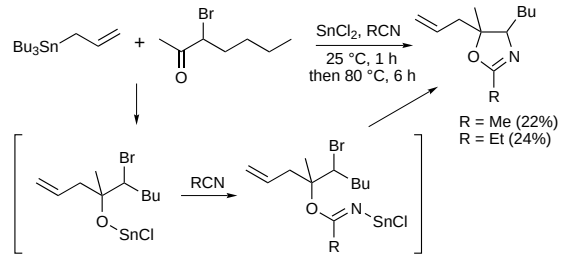
‡ *Typical experimental procedure*: Allyltributyltin **1** (1.0 mmol) was added to a stirred suspension of $SnCl_2$ (1.0 mmol) and α-halo ketone **2** (1.0 mmol) in dry MeCN (1.0 ml), and the mixture was stirred under the conditions noted in the text. Et_2O (100 ml) and aq. NH_4F (15%; 40 ml) were added, the organic layer was separated and washed with water (50 ml × 2), dried ($MgSO_4$) and evaporated to give β,γ-unsaturated ketone **3**. The crude product was further purified by flash chromatography on silica gel.

§ Since the alkyl group has a low aptitude for migration, reaction of the intermediate with the solvent nitrile occurred.



¶ The aldehyde, 2-(*p*-chlorophenyl)pent-4-enal, was formed *via* 2-allyl-2-(*p*-chlorophenyl)oxirane. The transformation of oxirane to aldehyde commonly proceeds in acidic conditions.

First characterisation of zirconium enolate radical cations in solution and their mesolytic bond cleavage to zirconocene cations

Michael Schmittel* and Rolf Söllner

Institut für Organische Chemie, Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany

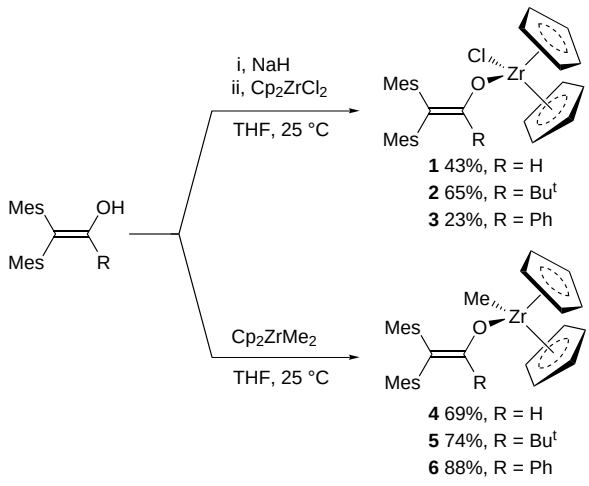
Zirconocene enolate radical cations are generated and characterised in solution for the first time; the sterically congested radical cations undergo a mesolytic Zr–O bond cleavage process yielding zirconocene cations, the kinetics of which are determined.

In light of the importance of transition metal enolates for organic synthesis[1] we have recently become interested in the redox umpolung of these nucleophilic species.[2] We were able to show that titanium enolate radical cations can undergo carbon–carbon bond formation to 1,4-diketones, a reaction which can even be conducted in a diastereoselective fashion.[3] In the present paper we describe for the first time the properties and reactions of zirconium enolate radical cations and their clean mesolytic† bond cleavage to zirconocene cations. The latter are well known as the catalytic active species in the Ziegler–Natta polymerization of α-alkenes.[4]

Since zirconium enolates constitute highly reactive compounds with a high sensitivity towards hydrolysis, only a small number of zirconium enolates[5] has been isolated and investigated. The kinetic stability of zirconium enolates should be largely increased by starting from sterically bulky β,β-dimesitylenols.[6] These were deprotonated quantitatively with sodium hydride in THF at room temperature and subsequentially reacted with stoichiometric amounts of zirconocene dichloride. All chloro zirconocene enolates could be obtained as bright yellow crystals by crystallisation from *n*-hexane or *n*-hexane–toluene.

A route leading to the methyl zirconocene enolates was realised by reacting dimethyl zirconocene with the corresponding β,β-dimesitylenols accompanied by elimination of methane. The zirconocene enolates **4**–**6** could be obtained in analytically pure form as pale yellow solids by crystallization from acetonitrile–dichloromethane mixtures (Scheme 1).

In standard cyclic voltammetry (CV) experiments all zirconocene enolates showed irreversible oxidation waves (E_{pa}; Table 1) in acetonitrile at 100 mV s^{-1}. By changing the solvent to dichloromethane and increasing the scan rates up to 1000 V s^{-1} reversible waves could be obtained. We observed partially reversible waves for **1**–**3** and **5** already at scan rates $\nu \geqslant 100$ V s^{-1}, for **4** at $\nu \geqslant 200$ V s^{-1}, and for **6** at $\nu \geqslant 50$ V s^{-1}. This represents the first direct observation of zirconium enolate radical cations in solution, allowing for the determination of their thermodynamically relevant redox potentials $E_{\frac{1}{2}}^{Ox}$ (Table 1). The oxidation potentials fall in the range +0.35 to +0.57 V *vs.* ferrocene–ferrocenium† and are *ca.* 100 mV more anodic than those of structurally analogous titanocene enolates,[2] an effect which is already known from simple titanocene and zirconocene compounds.[7]



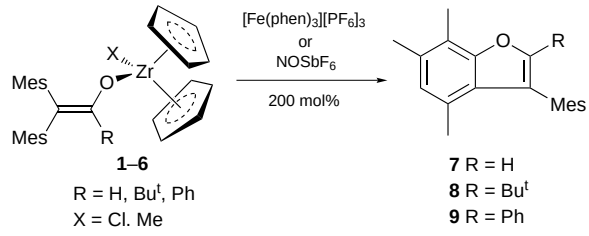
Scheme 1

Table 1 Oxidation potentials of zirconocene enolates determined by CV

Zirconocene enolate	E_{pa}[a,b]/V	$E_{\frac{1}{2}}^{Ox}$[a,c]/V	Yield of benzofuran
1	+0.45	+0.57	95% of **7**
2	+0.32	+0.43	90% of **8**
3	+0.41	+0.44	88% of **9**
4	+0.51	+0.46	82% of **7**
5	+0.30	+0.35	86% of **8**
6	+0.35	+0.36	80% of **9**

[a] *vs.* Fc–Fc†. [b] In acetonitrile at ν = 100 mV s^{-1}. [c] In dichloromethane at ν = 1000 V s^{-1}.

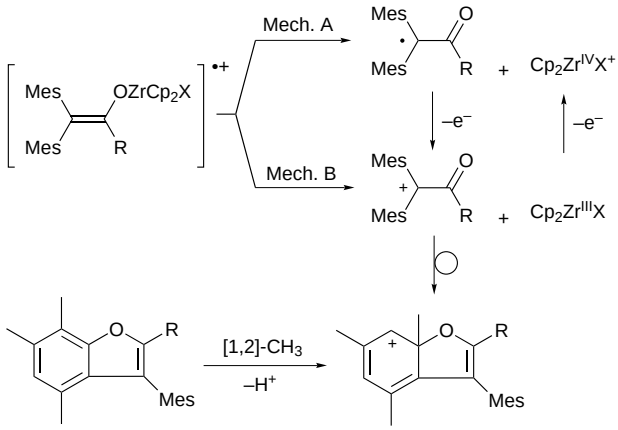
The chemical one-electron oxidations of the zirconium enolates **1**–**6** which were performed on a preparative scale using tris(1,10-phenanthroline)iron(III) hexafluorophosphate ($E_{\frac{1}{2}}$ = +0.69 V), as a well-defined outer-sphere one-electron oxidant, or nitrosonium hexafluorophosphate ($E_{\frac{1}{2}}$ = +0.89 V) in acetonitrile–dichloromethane afforded the benzofuran derivatives **7**–**9** in good yields (Scheme 2, Table 1).



Scheme 2

Formation of benzofurans by one-electron oxidation of stable enols[8] and various enol derivatives[9] (including titanium enolates[2]) is known to be initiated by a mesolytic bond cleavage of the O–X bond followed by several reaction steps that are well established (Scheme 3).

For the zirconocenes the Zr–O bond must have been broken at the stage of the enolate radical cation since the direct cyclization is highly unfavourable because of steric reasons. Equally, a dissociative electron transfer process can be ruled out since all the radical cations could be characterised at high scan rates in the CV experiment. Hence, we conclude that mesolytic Zr–O bond cleavage is the primary follow-up reaction of the



Scheme 3

radical cations **1**$^{\bullet+}$–**6**$^{\bullet+}$ which can follow two distinct mechanistic pathways:[9d] the heterolytic scission (Mech. A) would result in the formation of an α-carbonyl radical and a zirconocene cation, the homolytic variant (Mech. B) would lead to an α-carbonyl cation and a zirconocene(III) species. Both cleavage selectivities are known for enol radical cations: homolytic cleavage can be observed for radical cations of enol esters,[9a] enol carbonates and enol carbamates[9d] whereas the radical cations of enols, silyl enol ethers,[9b] enol phosphites and enol phosphinates[9c] and of the structurally very closely related titanium enolates[2] follow the heterolytic variant.

When the oxidation potentials of the homolytic cleavage fragments (α-carbonyl radicals and $Cp_2Zr^{III}X$) are known then the selectivity of such fragmentation processes can be determined by using a simple thermochemical cycle calculation. The fragments which are split off in a cationic form must have the lower redox potential. We hence measured the oxidation potential of $Cp_2Zr^{III}Me$ to $E_{pa} = -1.9$ V§ and compared it with those of the relevant α-carbonyl radicals. Since the latter are much more positive (0.15–0.36 V)[8a] it is clear that mesolytic bond cleavage of the methyl zirconocene enolates **4**–**6** takes place according to the heterolytic pathway (Mech. A). This result is in analogy to Jordan's findings, who performed one-electron oxidations of dimethyl zirconocene and other dialkyl zirconocenes with equimolar amounts of ferrocenium and isolated the cationic complexes $[Cp_2ZrR]^+$ after Zr–C bond cleavage.[10] Owing to the much larger differences of the oxidation potentials between oxidant and substrate the desired reaction time of this conversion is much longer (10 h) than in our experiments (1 min). In case of the chlorine substituted model compounds **1**–**3** simple considerations¶ propose that their fragmentation should follow the same pathway.

The knowledge of the exact mechanism of this process enabled us to determine the lifetime of zirconocene enolate radical cations by following the kinetics of the mesolytic bond cleavage through fast scan cyclic voltammetry at ultramicro electrodes in dichloromethane. From the ratio of cathodic to anodic peak current I_{pc}/I_{pa} the kinetic parameter kt was evaluated according to the method of Nicholson and Shain[11] applying a working curve for an $EC_{irr}E$ mechanism (electron transfer–chemical reaction–electron transfer). The working curve had been obtained from digital simulation of cyclic voltammograms using the implicit Crank–Nicholson technique.[12] This kinetic analysis at room temperature provided a first order-rate constant of $k_f = 3.3 \times 10^2$ s^{-1} ($t_{\frac{1}{2}} = 2.1 \times 10^{-3}$ s) for the mesolytic bond cleavage of **2**$^{\bullet+}$, $k_f = 3.1 \times 10^2$ s^{-1} ($t_{\frac{1}{2}} = 2.2 \times 10^{-3}$ s) for that of **3**$^{\bullet+}$, $k_f = 8.3 \times 10^2$ s^{-1} ($t_{\frac{1}{2}} = 8.4 \times 10^{-4}$ s) for that of **4**$^{\bullet+}$ and $k_f = 5.0 \times 10^2$ s^{-1} ($t_{\frac{1}{2}} = 1.4 \times 10^{-3}$ s) for that of **5**$^{\bullet+}$.

In conclusion, we have characterised for the first time zirconium enolate radical cations in solution and identified them as rapidly cleaving precursors for zirconocene cations. Work is in progress to use this mesolytic cleavage reaction in photoinduced electron transfer reactions for triggering polymerisation.

We gratefully acknowledge the financial support by the Deutsche Forschungsgemeinschaft (SFB 347: 'Selective Reactions of Metal Activated Molecules'). In addition, we are most indebted to the Fonds der Chemischen Industrie for the ongoing support of our research as well as to Degussa for a generous gift of electrode materials.

† The expression mesolytic was coined by Maslak to describe bond cleavage of radical ions to yield radical and ionic products: P. Maslak and J. N. Narvaez, *Angew. Chem., Int. Ed. Engl.*, 1990, **29**, 283.

‡ All potentials are referenced to the ferrocene–ferrocenium (Fc) redox couple unless otherwise noted. To obtain values *vs.* SCE, simply add +0.39 V.

§ We determined the reduction potential of the corresponding cation $[Cp_2Zr^{IV}Me(MeCN)_2]BPh_4$ to $E_{pc} = -1.94$ V (in acetonitrile at 100 mV s^{-1}; supporting electrolyte: $NaBPh_4$). The preparation of this cation is described in: R. F. Jordan, C. S. Bajgur, W. E. Dasher and A. L. Rheingold, *Organometallics*, 1987, **6**, 1041.

¶ The difference between the oxidation potentials of $Cp_2Zr^{III}Me$ and $Cp_2Zr^{III}Cl$ can be approximated by the difference between the half-wave potentials of Cp_2ZrMe_2 ($E_{\frac{1}{2}} = -3.06$ V) and Cp_2ZrCl_2 ($E_{\frac{1}{2}} = -2.04$ V). As the potential of $Cp_2Zr^{III}Me$ is $E_{pa} \approx -1.9$ V we assume that that of $Cp_2Zr^{III}Cl$ is $E_{pa} \approx -0.9$ V_{Fc} being distinctly lower than those of the α-carbonyl radicals.

Extended rim redox active tris-metallodioxolene derivatives of cyclotricatechylene

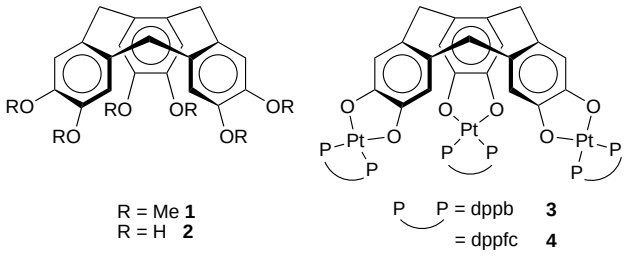
D. Scott Bohle* and Daniel Stasko

Department of Chemistry, University of Wyoming, Laramie, WY 82071-3838, USA

Triple metallation of cyclotricatechylene (CTC) results in new cavitands with significantly extended rims and three reversible redox couples as determined by single-crystal X-ray diffraction and electrochemistry.

Supramolecular constructs based on cyclotriveratrylene (CTV) **1** are versatile cavitands which form inclusion compounds for a diverse group of guests ranging from buckministerfullerene[1] and carboranes[2] to halocarbons,[3] anions,[4] and cationic organometallic sandwich complexes.[5] As has been recently recognized, the solid state structures of these host–guest complexes are either columnar, with the guests often packing between the CTV units, much like a typical solvate, or, as in the case of the fullerene inclusion compounds, the cavity is fully utilized to maximize the non-covalent interactions in the $C_{60}\subset$CTV aggregate.[1,5,6] One strategy to more fully utilize the cavitand scaffold offered by the CTV unit is to extend the rim by building off from the three catechol moieties; while a wide range of alkyl and pendant ligand derivatives have been so prepared,[7–9] we are unaware of any reports where transition metal complexes have been used to directly extend the rim of the CTV cavity. Herein, we describe (*i*) the preparation and characterization of two such derivatives; (*ii*) the structure of one as its bisdimethylacetamide (DMA) inclusion adduct; and (*iii*) the redox activity of these new hosts. These compounds provide unusual new examples of a redox active hosts where the redox units are incorporated directly into the framework of the host.

Cyclotriveratrylene, **1** was converted into the tris-catechol derivative, cyclotricatechylene **2** with boron tribromide.[10] Compound **2** was then treated for several hours in deoxygenated DMA solutions with a slight excess of $LPtCl_2$ [(L = diphenylphosphinobenzene (dppb) or diphenylphosphinoferrocene (dppfc)] in the presence of a methanol/potassium carbonate mixture acting as a base. The product was isolated as an orange solid collected by precipitation with diethyl ether and recrystallization from dichloromethane–acetone. The two materials, (CTC)[Pt(dppb)]$_3$ **3** and (CTC)[Pt(dppfc)]$_3$ **4**, were both obtained in moderate yields and appear indefinitely stable in air in the solid state; the latter slowly decomposes in solution after a few days.



Characterization† of these compounds has led to the formulation of the materials as the triply metallated platinum(II)–tris-catecholate species. Support for this assignment comes from the presence of a strong IR active band at 1270 cm^{-1} attributable to a ν(C–O–M) mode. In addition, the ^{31}P NMR spectral data for these species are indicative of complete

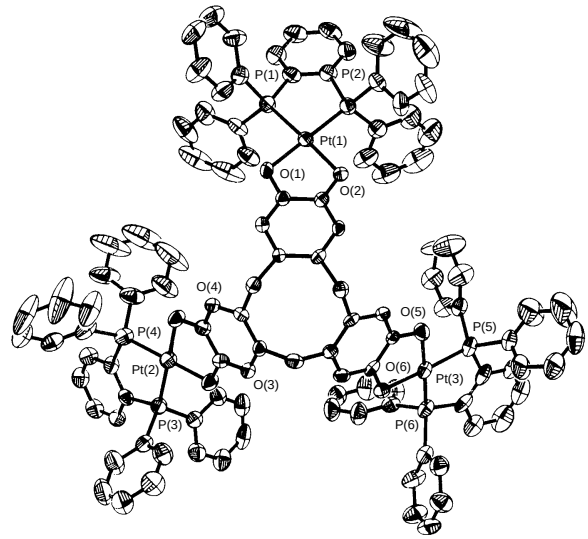


Fig. 1 Structure of (CTC)[Pt(dppb)]$_3$ **3** viewed looking down from the top of the bowl, ORTEP (50% thermal ellipsoids); solvent and hydrogens removed for clarity. Average Pt–Pt distance 9.85 Å.

substitution, showing only one phosphorus signal with corresponding platinum satellites. The ^{1}H NMR spectrum also shows this symmetrical substitution, indicated by a singlet representing the aromatic CTC protons. The geminal coupling of the protons on the methylene bridgehead carbons, characteristic CTC markers due to the rigid conformation of the bowl,[7] also suggests that the sterically bulky phosphine ligands do not significantly perturb the shape.

Structural characterization of **3** by single-crystal X-ray diffraction‡ confirms that the tris-catecholate complex retains the original bowl structure of the cavitand (Fig. 1). Moreover, the square planar coordination of the platinum centers within the molecule and their metrical data are consistent with the formulation of the compound as a Pt^{II} catecholate.[11] As shown in the graphical abstract a crystallographic inversion center leads to the formation of a cage in the solid state. The resulting shell incorporates four DMA molecules, disordered over eight positions, within its interior. While this is expected from the known ability of CTV compounds to form inclusion type complexes,[7,8] what is especially striking is that the guests are now completely enclosed within the rim of the host; derivatization at the rim of the CTV bowl with LPt extends the depth of the cavity while also maintaining the host character of the parent compound.

The electrochemical properties of the two compounds, **3** and **4**, were examined by cyclic voltammetry.§ Upon sweeping the voltage to oxidizing potentials, a three wave voltammogram (Fig. 2) appears, with the first oxidation taking place at approximately 50 mV (*vs.* NHE). These reversible oxidations corresponds to the three separate one-electron oxidations of each catecholate (cat) moiety of the CTC unit to a semiquinoid (sq) species (Table 1). This behavior is quite different to that of the parent CTV compound which shows two irreversible waves

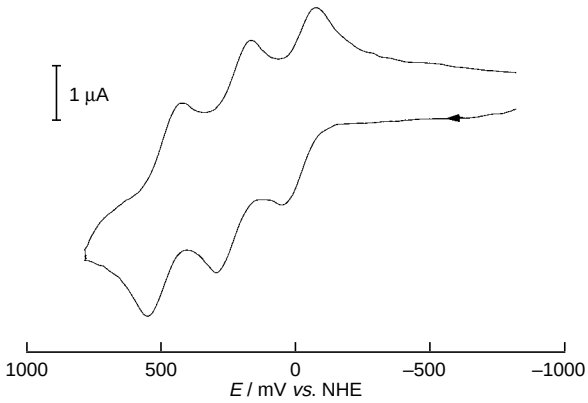

Fig. 2 Cyclic voltammogram of (CTC)[Pt(dppfc)]$_3$ **4** reversible cat–sq couples. Referenced *vs*. NHE, scan rate = 100 mV s^{-1}. See Table 1 for experimental conditions.

	470	
	≈ 1150 (irr.)	sq–quin (decomp.)

[a] Experiments were carried out using CH_2Cl_2 as the solvent with 0.1 M $NBu^n_4PF_6$ as the supporting electrolyte, Pt disc working and Pt wire auxiliary electrodes, and an Ag–$AgNO_3$ non-aqueous reference electrode. Half-cell potentials were calibrated against an internal Fc–Fc$^+$ standard. Reported values are referenced *vs*. NHE.

at much higher potential, 1670 and 1830 mV (*vs*. NHE).[12] Though the electrochemical properties of **3** and **4** are very different from **1**, the first oxidation potentials are similar to those observed for the first oxidation of simple platinum catecholate derivatives.[13] Sweeping to greater oxidizing potentials produces a fourth irreversible couple resulting in decomposition of the CTC complex. This fourth oxidation is observed at *ca*. 1100 mV and most likely is attributed to quinoid formation and loss of coordination of the CTC moiety to the platinum center. For **4**, this oxidation and decomposition appears to be coincident with oxidation of the ferrocene moiety of the chelating phosphine. The three cat–sq waves indicate communication between the metal centers; since the potential is characteristic of CTC based catecholate oxidations, this communication is likely to be mediated primarily by the CTC framework itself, either through a through-space interaction from the increased charge density on the aromatic ring, or from a through-bond interaction at the bridging methylene spacers. The electron rich CTV based cryptophanes are known to form radical cations which are thought to be stabilized through extended delocalization of the unpaired electron over the CTV units.[12] The communication observed between the redox centers of **3** and **4** may be attributed to a similar phenomenon.

This set of compounds extends the family of known CTC derivatives to include the new dioxolene species which incorporate a previously unexamined aspect of metallated host–guest chemistry. Current efforts are directed towards exploring the range of complexes that can be created and characterizing their binding and catalytic properties.

We gratefully acknowledge support from the DOE (Grant DE-FCO2-91ER) and the Camille and Henry Dreyfus Foundation teacher/scholar award (D. S. B). We would also like to thank Dr Navamoney Arulsamy for assistance with the crystallography.

§ Anaerobic dichloromethane solutions of **3** and **4**, with 0.1 M $NBu^n_4PF_6$ as supporting electrolyte, were examined using a Pt disk working electrode, a Pt wire auxiliary electrode, and a nonaqueous Ag/$AgNO_3$ reference electrode. Potentials and corresponding currents were examined at various scan rates, ranging from 25 to 1000 mV s^{-1}. Reversibility was determined by examination of cathodic and anodic peak current ratios as well as peak symmetry and by examination of the linearity of plots of $\Delta E = E_{ox} - E_{red}$ *vs*. the square root of the scan rate. Measured potentials were calibrated through the use of an internal Fc–Fc$^+$ standard, with the reported values referenced against NHE.

Reaction of the dipeptides H_2Gly-Tyr and H_2Gly-Phe with VCl_3 and 1,10-phenanthroline affords the compounds [V(Gly-Tyr)(phen)]Cl·3MeOH 1 and [V(Gly-Phe)(phen)]Cl-·3MeOH 2; aerial oxidation of the complexes 1 and 2 gives their oxovanadium(IV) analogues [VO(Gly-Tyr)(phen)] 3 and [VO(Gly-Phe(phen)] 4, respectively; the X-ray crystal structure of 3 is reported.

Vanadium is an essential nutrient for higher animals,[1] although this has not yet been clearly established as such to human life.[2] Nevertheless, vanadium *in vivo* generates significant physiological responses;[3] for example, vanadate inhibits ion transport ATP-ases,[4] phosphotyrosine phosphatase,[5] *etc.* Beyond dispute, the most important physiological response of vanadium is its insulin-mimetic properties.[6] Our understanding of the mechanism of vanadium insulinomimetic action is still in its infancy.[6] In addition to the above mentioned roles of vanadium, the oxovanadium(IV) center is an excellent EPR spectroscopic probe for various naturally occurring vanadoproteins and oxovanadium(IV)-substituted protein systems.[7] Detailed structural, physicochemical and kinetic investigations on synthetic model complexes of vanadium with peptides, that are the most closely related models to proteins, will contribute greatly to our understanding of the mechanism of insulinomimetic action of vanadium as well as of its biological role in general. To date, there are only two vanadium(V) complexes structurally characterized with the dipeptide glycylglycine.[8a,b] The preparation of two vanadium(IV) compounds with the dipeptides glycylglycine and glycylalanine has also been reported.[8c] Herein, we describe the synthesis of the first vanadium(III) complexes with dipeptides, namely, with glycyl-L-tyrosine (Gly-Tyr) and glycyl-L-phenylalanine (Gly–Phe) and their oxovanadium(IV) analogues. The X-ray crystal structure of VO^{2+} with Gly-Tyr is reported, as well as the electrochemistry and the EPR spectra of the VO^{2+} compounds. To our knowledge, the structure of VO^{2+} with the dipeptide Gly-Tyr is the first example of a structurally characterized vanadium(IV) complex with a peptide.

Vanadium(III) chloride (2 mmol) was dissolved in methanol at ambient temperature, then the solution was cooled to −20 °C. Sequential addition of 1,10-phenanthroline (2 mmol), of the dipeptide (2 mmol) and an excess of triethylamine (10 mmol) to the vanadium solution, followed by slow warming under magnetic stirring to room temperature, induced a sequence of color changes (from red through red-brown to brown-purple) and resulted in the formation of the complexes [V(Gly-Tyr)(phen)]Cl·3MeOH **1** (yield 70%) and [V(Gly-Phe)-(phen)]Cl·3MeOH **2** (yield 50%). Air oxidation of **1** and **2** gives their oxovanadium(IV) analogues, [VO(Gly-Tyr)(phen)] **3** (yield 80%) and [VO(Gly-Phe)(phen)] **4** (yield 65%), respectively. The elemental analyses for complexes **1**–**4** are in accord with the formulas given above.

The molecular structure of the complex **3** (Fig. 1), shows the vanadium atom possessing a severely distorted octahedral coordination. The vanadium atom is **3** is ligated to a tridentate Gly-Tyr^{2-} ligand at the N_{amine} atom N(11) the deprotonated $N_{peptide}$ atom N(12) and one of the $O_{carboxylato}$ atoms O(14), as well as an oxo group O(1) and two phenanthroline nitrogens N(1) and N(10) and is 0.33 Å, above the mean equatorial plane, defined by the three ligating atoms of the dipeptide [N(11), N(12), O(14)] and a phenanthroline nitrogen N(1), in the direction of the oxo ligand. The peptide functionality N(12)C(12)O(12)C(11) [maximum deviation of C(12) is 0.02 Å] is planar within the limits of precision. The ligand Gly-Tyr^{2-} forms two five-membered fused chelate rings and is meridionally ligated to VO^{2+} center with the amine nitrogen and carboxylato oxygen atoms lying in *trans* position. The $V–N_{peptide}$ bond length [1.927(7) Å] is indicative of a very strong bond of the deprotonated peptide nitrogen to vanadium, and may reflect some V=N character[9] due to donation of electron density from the deprotonated peptide nitrogen into metal d orbitals. The oxovanadium(IV)–amidate N distance in complex **3** is significantly shorter (*ca.* 0.07 Å) than seen in the related complex $[NHEt_3][V^{IV}O(mpg)(phen)]CH_3OH$[8c,10] **5** [$V–N_{amide}$ = 1.997(4) Å] which is the only other oxovanadium(IV) complex which contains an aliphatic $V–N_{amide}$ bond. This significant difference could be ascribed to ligand constraints in **3** and to the weaker dianionic ligand set (Gly-Tyr^{2-}) in complex **3**, compared to trianionic ligand set (mpg^{3-}) in complex **5**, which results in a higher effective charge on the vanadium center and shorter V–N distances. Nevertheless, the $V–N_{amide}$ and $V–N_{amine}$ bond lengths in **3** are longer (*ca.* 0.03 and 0.06 Å, respectively) from the analogous distances found in the complexes $[Cu(Gly-Tyr)(H_2O)_2]·2H_2O$ **6**[11] [Pd(Gly-Tyr)-(cyd)]·$6.5H_2O$ **7**[12] [complexes **6** and **7** are the only two other Gly-Tyr compounds with transition metal ions] but the $V–O_{carboxylato}$ bond distance in **3** is shorter (*ca.* 0.03 and 0.07 Å for **6** and **7** respectively); this is expected[13] as the $V^{IV}O^{2+}$ center

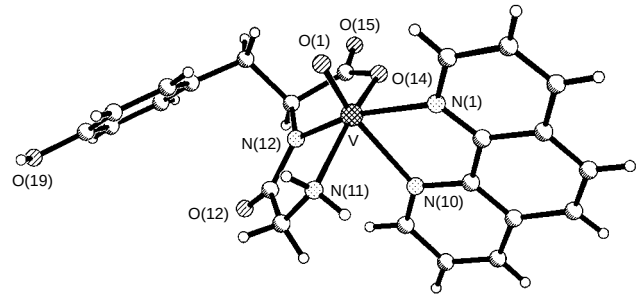

Fig. 1 The X-ray structure of **3**. Selected interatomic distances (Å) and angles (°): V–O(1) 1.574(5), V–O(14) 1.946(5), V–N(1) 2.105(7), V–N(12) 1.927(7), V–N(11) 2.075(7), V–N(10) 2.351(7); O(1)–V–N(12) 106.9(3), N(12)–V–O(14) 80.2(2), N(12)–V–N(11) 78.8(3), O(1)–V–N(1) 91.5(3), O(14)–V–N(1) 91.6(2), O(1)–V–N(10) 162.7(3), O(14)–V–N(10) 82.7(2), N(1)–V–N(10) 72.0(2), O(1)–V–O(14) 103.5(3), O(1)–V–N(1) 98.0(3), O(14)–V–N(11) 153.4(3), N(12)–V–N(1) 161.1(3), N(11)–V–N(1) 103.3(3), N(12)–V–N(10) 90.0(2), N(11)–V–N(10) 81.3(2).

Table 1 EPR parameters for the complexes **3** and **4**

Compound	Donor set	g_x	g_y	g_z	10^{-4} A/cm^{-1} A_x	A_y	A_z	$A_{z,amide}$
3	N_3O	1.982	1.984	1.952	53.0	58.0	160.0	35
4	N_3O	1.981	1.983	1.951	54.0	58.0	159.0	34

is considered a 'hard acid', Cu^{2+} a borderline acid and Pd^{2+} a soft acid and oxygen a harder base than nitrogen. The side chain aromatic ring is tilted to the equatorial coordination plane of vanadium (the dihedral angle between these planes is 31°) and in the opposite direction from it, in marked contrast to complexes **6** and **7** where the aromatic ring is roughly above the coordination plane of the metal atom; this conformation of the tyrosine residue in **3** may be imposed by the presence of the axial ligand (O^{2-}), that pushes away the aromatic ring.

The V–Cl stretch is absent from the IR spectra of complexes **1** and **2**. This, in combination with the molar conductance of these complexes in methanol, which is characteristic of 1 : 1 electrolytes led us to the conclusion that the chloride atom is not coordinated to vanadium. The magnetic moments of complexes **1**, **2** and **3**, **4** are in accord with the spin-only value expected for d^2 and d^1 systems, respectively.

The redox properties of **4** in acetonitrile (complexes **1**, **2** and **3** are not soluble enough to be studied in MeCN) have been studied by cyclic voltametric and polarographic techniques. The complex displays a reversible one-electron redox process [eqn. (1); $E_{\frac{1}{2}}$ *vs.* NHE].

$$[V^{IV}O(Gly\text{-}Phe)(phen)] + e^- \rightarrow [V^{III}O(Gly\text{-}Phe)(phen)]^- \; E_{1/2} = -1.26 \text{ V} \quad (1)$$

The continuous wave (cw) EPR parameters for the two oxovanadium(IV) complexes **3** and **4** (Table 1) were determined by computer simulation of the experimental cw EPR spectrum. Comparison of the cw EPR data of the complexes **3** and **4** with those reported for various oxovanadium(IV) species[14] with different equatorial donor sets (*e.g.*, O_4, N_2O_2, N_2S_2, *etc.*) indicates that their equatorial donor set should be N_3O. Application of the additivity relationship[15] for complexes **3** and **4** gives an A_z value of 159.6×10^{-4} cm^{-1} [= $(40.1 + 42.7 + 35 + 41.8) \times 10^{-4}$ cm^{-1}] which is almost identical to the experimental values for both complexes (Table 1). Electron spin echo envelope modulation (ESEEM) experiments, that were performed on complexes **3** and **4** verified the existence of three different ^{14}N atoms ligated to the equatorial plane of the oxovanadium(IV) center. Thus, it was concluded that in solution, as well as in the solid state, the VO^{2+} center is coordinated to three nitrogen atoms in the equatorial plane. The experimental values for $A_{z,amide}$ (35×10^{-4} and 34×10^{-4} cm^{-1} for complexes **3** and **4**, respectively) do not deviate from the average $A_{z,amide}$ value (34×10^{-4} cm^{-1}) reported by Cornman *et al.*[16] for oxovanadium(IV) complexes with various aromatic amides and from the $A_{z,amide}$ for the complexes $[V^{IV}O(Gly\text{-}Gly)(phen)]\cdot 2MeOH$ and $[V^{IV}O(Gly\text{-}Ala)(phen)]\cdot MeOH$ (36×10^{-4} cm^{-1}). Solution studies (water) of the VO^{2+} with a number of peptides[17] also gave a value of *ca.* 35×10^{-4} cm^{-1} for $A_{z,amide}$.

We gratefully acknowledge support of this research by the Greek General Secretariat of Research and Technology (Grant no. 1807/95) and Mrs F. Masala for typing the manuscript.

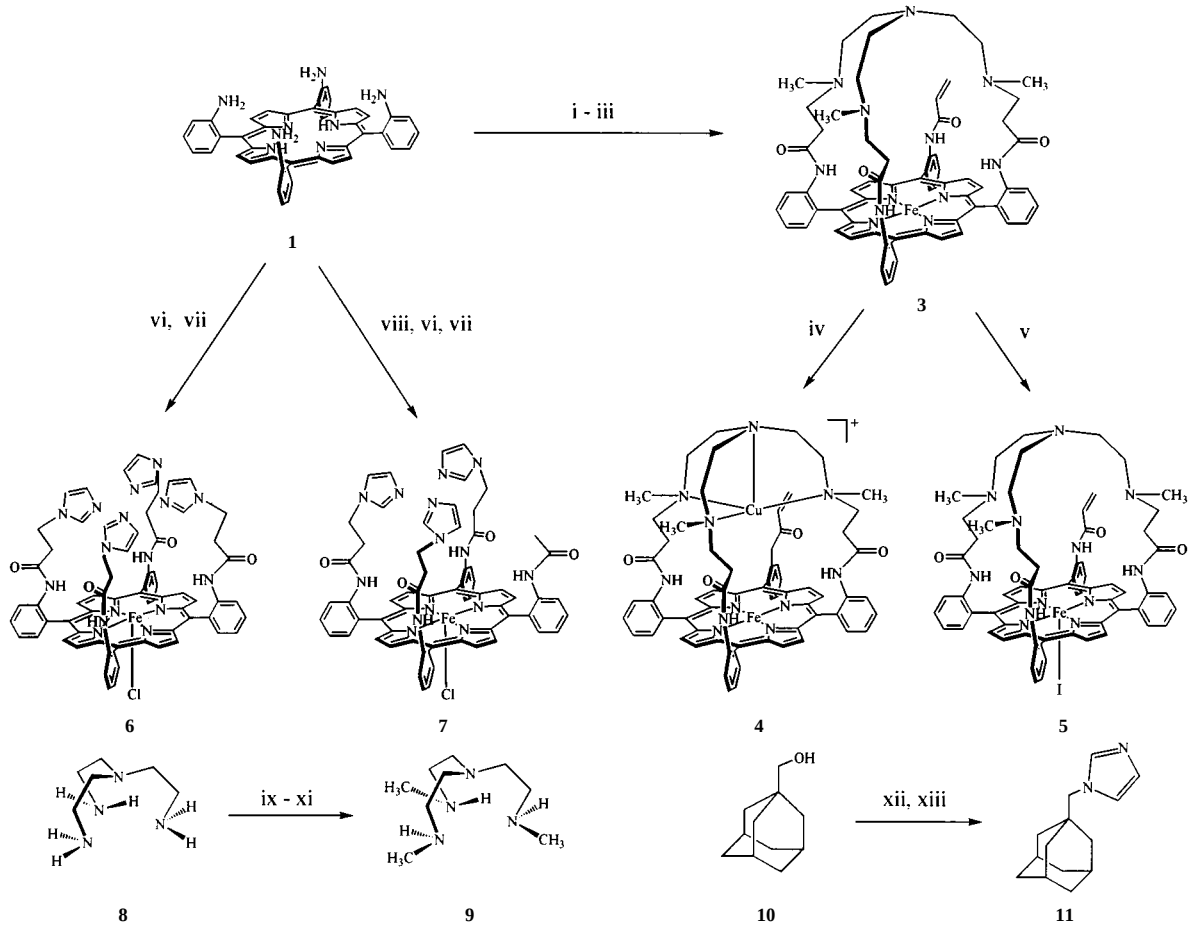
Covalently supported porphyrins as ligands for the preparation of heme a_3/Cu_B binuclear active site analogues of heme–copper terminal oxidases and metallation under mild conditions

Jin-Ook Baeg and R. H. Holm*

Department of Chemistry and Chemical Biology, Harvard University, Cambridge, Massachusetts 02138, USA

New covalently supported binucleating porphyrins have been prepared as potential structural and/or functional ligands for the iron–copper (heme a_3/Cu_B) active sites of heme–copper oxidases, and the introduction of iron and copper into one porphyrin under mild reaction conditions has been developed.

Essential to the elucidation of the mechanism of dioxygen reduction to water and its inhibition at the binuclear heme a_3/Cu_B active sites of heme–copper oxidases[1–5] is the construction of a functional enzyme analogue system. This can presumably be achieved by synthesizing covalently supported binucleating heme ligands whose iron–copper arrangement approaches the enzyme active site stereochemistry. Collman *et al.*[6–9] have reported the synthesis of several such ligands by a congruent Michael multiple addition method, including one ligand whose Co^{II}–Cu^{I} derivative shows catalytic activity in the four-electron reduction of dioxygen to water.[9,10] These systems primarily contain 1,4,7-triazacyclononane-, cyclen-, or cyclam-adapted copper binding sites. Our previous investigations of binuclear heme–Cu bridged assemblies have featured a variety of unsupported bridges suitable for structural and electronic elucidation.[11–20] To extend our investigation to reactivity with dioxygen and inhibiting ligands such as cyanide, we have undertaken the design and synthesis of covalent binucleating ligands and their complexes capable of sustaining various Fe–X–Cu bridges. Here we report the preparation of three new porphyrin ligands, using Michael addition methodology for one of them, with structural features somewhat different than those previously described.[6–9]



Scheme 1 *Reagents and conditions*: i, H_2C=CHCOCl, Et_3N, CH_2Cl_2, 46%; ii, $[Fe(OH_2)_6][BF_4]_2$, 2,6-dimethypyridine, THF, 90%; iii, **9**, CH_2Cl_2, MeOH, 48 h, 32%; iv, $[Cu(MeCN)_4]PF_6$, THF, 24 h, 70%; v, I_2, THF, 12 h, 82%; vi, **15**, $SOCl_2$, DMF, 20 h, 60%; vii, $FeSO_4$, HOAc, O_2, NaOH, HCl, 57–60%; viii, MeCOCl, Et_3N, CH_2Cl_2, 2 h, 50%; ix, PhCHO, 1 N HCl, benzene, molecular sieves, $NaBH_3CN$, 85%; x, HCO_2H, HCHO, 110 °C, 12 h, 76%; xi, $Pd(OH)_2$ on carbon, MeOH, H_2 (1 atm), 60 °C, 20 h, 90%; xii, PBr_3, quinoline, bromobenzene, 24 h, 165 °C, 65%; xiii, sodium imidazolate, Me_2SO, 150 °C, 20 h, 84%

Synthetic pathways for ligands and complexes are depicted in Scheme 1.† Reactions were carried out at ambient temperature unless noted otherwise. A key starting material, as in related work,[6–8] is *meso*-α,α,α,α-tetrakis(*o*-aminophenyl)porphyrin **1**.[21] Treatment of **1** with acryloyl chloride and triethylamine in dichloromethane affords the corresponding tetrakis(acryloylamidophenyl)porphyrin **2**[6] (46%). The new tetraamine **9** was prepared in three steps from tris(2-aminoethyl)amine **8** in 58% overall yield. Reaction of **8** with benzaldehyde in dry benzene containing ethereal 1 M HCl and molecular sieves, followed by reduction with $NaBH_3CN$, gave tris[2-(benzylamino)ethyl]amine **12** (85%). Subsequent reaction of **12** with formic acid and formaldehyde solution afforded tris[2-(benzylmethylamino)ethyl]amine **13** (76%). Palladium hydroxide catalyzed the selective debenzylation of **13** under 1 atm of dihydrogen at room temperature for 20 h to afford **9** (90%). Iron(II) was inserted into **2** at room temperature by reaction of $Fe[BF_4]_2$ in the presence of 2,6-dimethylpyridine to give [Fe^{II}(**2**)] (90%). Metal insertion under these mild conditions is necessary to minimize undesirable porphyrin isomerization. In the next step, reaction of the Michael acceptor [Fe^{II}(**2** −2H)] with tetraamine **9** in dichloromethane for 48 h gave the covalently capped iron(II) porphyrin **3** (32%, λ_{max} 426 nm, *m/z* 1133) with a vacant tetraaza binding site. The free ligand of **3** (λ_{max} 424 nm, *m/z* 1079) was obtained by the same reaction in comparable yield using **2**. Treatment of **3** with 1 equiv. of $[Cu(MeCN)_4]PF_6$ in THF for 24 h afforded the binuclear Fe^{II}–Cu^{I} assembly **4** (70%, λ_{max} 426 nm, *m/z* 1196). Complex **3** was readily oxidized by excess iodine in THF to give the iron(III) complex **5** (82%, λ_{max} 417 nm, *m/z* 1260) in which the iodide ligand is presumed to occupy an axial position on the unhindered heme face as shown. The EPR spectrum shows **5** to be high spin ($g_{\|}$ = 2.03, $g_{\perp}$ = 5.73; acetonitrile, 10 K).

Ligand binding by complexes **3**–**5** at the iron site could introduce ligands internal to the tetraaza cavity or on the unhindered face. To direct ligands to the desired internal venue, an exceptionally bulky axial base, incapable of residing in the cavity, has been prepared. Selective bromination of 1-adamantylmethanol using PBr_3 gave 1-bromomethyladamantane **14** (65%). Reaction of **14** with equimolar sodium imidazolate in Me_2SO at 150 °C yielded the *N*-adamantylimidazole **11** (84%).

Spectroscopic evidence has supported the coordination of three imidazole groups from histidyl residues by Cu_B,[1,2,5] a matter recently confirmed by the X-ray structures of two enzymes in the oxidized form.[3,4] To our knowledge, no binucleating porphyrin having this type of binding potentiality with copper is available, the closest approach being those with pyrazolyl binding sites.[22] We have sought binucleating ligands of this sort from the reactions of **1** and the acyl chloride of 3-(*N*-imidazolyl)propionic acid **15**.[23] Treatment of **1** with an excess (5 equiv.) of **15** and $SOCl_2$ in DMF for 20 h produced the free base of **6** (60%, λ_{max} 421 nm, *m/z* 1163). In another experiment, **1** was monoprotected by reaction with 1 equiv. of acetyl chloride in dichloromethane for 2 h to give the triphenyl(*o*-methylamidophenyl)porphyrin, which was resolved from an isomeric mixture by preparative TLC (acetone–chloroform, 3 : 7 v/v; 50%). This compound was subjected to reaction with 4 equiv. of **15** and $SOCl_2$ in DMF to give the desired free base of **7** (58%, λ_{max} 420, *m/z* 1083) containing three imidazole groups. Both free bases could be metalated by the $FeSO_4$/HOAc method:[24] **6** [60%, λ_{max} 425 nm, *m/z* 1252]; **7** [57%, λ_{max} 424 nm, *m/z* 1172].

In summary, we have prepared three new types of binucleating porphyrin ligands and their iron complexes capable of covalently supporting Fe–X–Cu bridges. The ligand of **3**–**5** furnishes a trigonal four-coordinate tetraaza binding site, one feature of which is direction of the magnetic orbital of Cu^{II} toward a bridging ligand such as dioxygen, hydroxide or cyanide, thereby optimizing magnetic coupling of the iron atom across the bridge.[20] Complex **6** is favorable to planar coordination by Cu^{II}, while **7** provides the tris(imidazole) binding site of the native oxidases. The binding sites in **3**–**5** and **7** are necessarily displaced off a perpendicular through the iron atom normal to the heme plane, as is the case for two crystalline oxidases.[3,4] The sterically demanding ligand **11** has been developed as a promotor of the bridging *vs*. terminal ligand binding mode.

This research was supported by National Science Foundation Grant CHE 94-23830.

Various binding sites in DNA bases and base pairs as predicted by rigorous analysis of the molecular electrostatic potential (MESP) are explored for coordination with Li^+ and Ca^{2+} cations; the electrostatics is generally seen to provide an explanation for the observed trends in binding upon subjecting the anticipated structures to optimization at a high level *ab initio* theory.

The interactions between metal cation and the bases of DNA are being widely studied for gaining insights into the origin of stabilization or destabilization of DNA due to the presence of such ions.[1] In the polynucleotide DNA sequence, most of the cations predominantly interact with the backbone phosphate groups,[2] the charge neutralization leading to an enhancement of stabilization of the sequence. However, the cation–base interaction is not negligible.[1] In fact, some transition metal ions like Zn^{2+} and Cd^{2+} are found[2] to interact extensively with the bases facilitating renaturation of thermally denatured DNA.

Theoretical Hartree–Fock calculations carried out for the Watson–Crick (WC) base pairs with minimal basis[3] revealed that metal ion binding, in general, leads to an increased stability of the complementary base pairs. It is observed experimentally that the purine–purine–pyrimidine (PuPuPy) type triplexes respond differently to various cations.[4] For example, the GGC triplexes are found to be stabilized by divalent alkaline earth as well as transition metal cations while AAT triads are stabilized exclusively by the latter. The observed differential stabilization also finds support from the recent high level *ab initio* calculations by Sponer *et al*.[5] who have explained the phenomenon on the basis of missing lone-pair interactions with d orbitals in the case of alkaline earth cations.

An important issue concerning DNA–metal cation interactions is the relative energetic preference of the various lone-pair sites in the bases. There seems to be a general consensus that the N^7 site in guanine is the most favored one among all the bases for a given cation,[1,6] although the recent theoretical treatment[1] also emphasizes the influence of the O^6 atom in stabilizing the cation. The larger stabilization in G–cation complexes has been[1] accounted for by the large dipole moment of the base.

The interactions of DNA with the metal cation are mostly driven by electrostatics. However, an analysis of the binding sites in terms of the complete electrostatic description of bases and base pairs is conspicuous by its absence from the earlier literature. The MESP,[7] V, at a point $\boldsymbol{r}$ due to nuclear charges $\{Z_\Lambda\}$ at $\{\boldsymbol{R}_\Lambda\}$ and the electronic charge density $\rho(\boldsymbol{r})$ is defined as

$$V(\boldsymbol{r}) = \sum_{\mathrm{A}} \frac{Z_{\mathrm{A}}}{|\boldsymbol{R}_{\mathrm{A}} - \boldsymbol{r}|} - \int \frac{\rho(\boldsymbol{r}')}{|\boldsymbol{r}' - \boldsymbol{r}|} d^3r'$$

$V(\boldsymbol{r})$ can assume both positive and negative values and can provide useful information regarding electron-rich sites. It is interesting to see[8a,b] whether all the negative valued critical points (CPs) in MESP of the base (and the base pair) turn out to be the binding sites for cations and also whether any of the amino-lone pair sites are accessed by them. Since the reported findings[1,3] are based on calculations with either the effective core potentials or basis sets of limited extent for the metal species, there is a need for employing better quality basis sets including polarization functions. Here, we report the findings of base–cation as well as WC base pair–cation interactions using an electrostatic approach at a high level *ab initio* theory.

Planar optimized structures at 6-31G** basis set are used for the bases A, G, T, C and the WC base[9] pairs AT and GC. A 6-31G* basis set is employed for Li while for Ca, use is made of TZV* basis. The topography of MESP[10] of the organic molecules is used for initial positioning of Li^+ or Ca^{2+}. The cation is docked by keeping the base (or base pair) geometry fixed until the electrostatic interaction energy[11] attains a minimum. The resultant structure obtained by electrostatic docking is consequently subjected to full *ab initio* geometry optimization carried out on Fujitsu VPP300 with the GAUSSIAN94 package tuned for this platform. The single point energy (ΔE_S) values as well as the interaction energies of the fully optimized structures (ΔE_F) are reported in Table 1.

It can be seen that the relative ordering of the interaction energies for Li^+ and Ca^{2+} with various hosts is according to the depth of negative potential at the CP positions. On *ab initio* optimization, it is found that the distance of the cation from the nearest atom in the host is similar to the distance of the

Table 1 Interaction energies [kcal mol^{-1} (1 cal = 4.184 J)] with single point SCF calculations at the electrostatically docked geometry, ΔE_S, and full optimization, ΔE_F for various DNA···cation interactions[a]

[a] The relevant CPs in MESP (Fig. 1) of the bases and the WC base pairs are employed as starting positions of the cations. The numbers in parentheses for AT and GC are the base pair stabilization energies on cation binding. [b] These structures are similar to those obtained from different starting guess. [c] Amino group is twisted to facilitate manifold coordination of the cation. [d] Cation is sandwiched between two bases splitting the base pair.

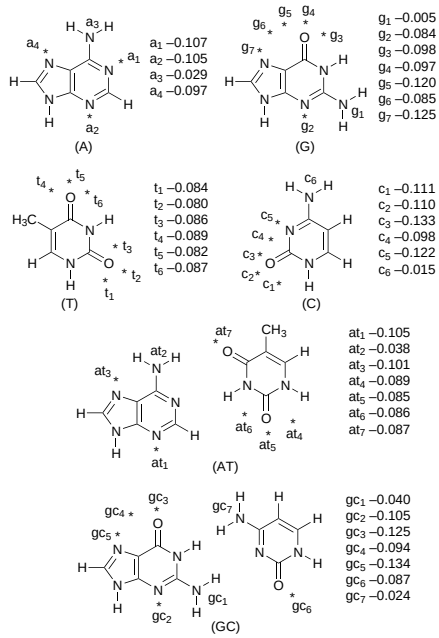

Fig. 1 MESP topographical features of DNA bases A, G, T and C as well as Watson–Crick base pairs AT and GC. The CPs are marked by * and corresponding MESP values given alongside.

corresponding MESP CP. Whereas the binding energies at various sites in A as well as in T are quite close, the region between the O^6 and N^7 atoms in G shows much more binding strength than other sites. From an electrostatic point of view, it is natural to expect that the extensive negative MESP region constituted by a number of CPs stabilizes the cation to a greater extent in G and C. In T, the cation enjoys a surrounding negative MESP region when it is close to t_2 or t_5, the saddles in MESP. Thus, rather than relying upon the partial information such as moments of various orders, the MESP topography leads to a more complete picture of these interactions. This is evident from the fact that all the negative MESP regions which are disjoint give rise to distinct optimum structures.

Electrostatic energy minimization predicts off-plane binding for both the cations with A and G near the amino nitrogen but not for C, probably due to the high negative potential region being concentrated only near O^2 and N^3 in C. Further optimization at the SCF level leads Li^+ to converge to the position a_1 (rather than a_4) in A without affecting the geometry of the NH_2 group. In G, however, full optimization leads Li^+ to the g_2 site with an out of plane twisting of the amino group. The cation is thus able to coordinate with the N^2 as well as N^3 atoms forming a bidentate structure. Using the wavefunction of this twisted amino-G, it is observed that the MESP minimum at N^3 (g_2) deepens to $-0.100\ E_h$. This is reflected in the improvement in the stabilization energy ΔE_F which is much more than the value for the monodentate structure at the N^3 site. The differential behavior of Li^+ towards N^6 in A and N^2 in G could arise due to a relatively deep negative MESP region in the former and a very weak one in the latter (*cf.* Fig. 1). Similar bidentate structure is formed by Ca^{2+} with A (coordinating with N^1 and N^6) while the optimized structure for G–Ca^{2+} has the cation occupying the off-plane site. The discrimination between the two purine bases by the divalent cation could arise due to higher ionic charge as well as polarization effects.

From Table 1, the coordination of cations at various sites in WC base pairs is enhanced as compared to individual bases. This appears to be due to increased charge concentration upon base pairing, which is reflected in the MESP topography (Fig. 1). Thus MESP seems to govern the relative binding affinities of various sites in base pairs. In some cases (site at_7 in AT accessed by Li^+ and gc_4 in GC accessed by Ca^{2+}), the interaction energy at the electrostatically docked geometries is < 2 kcal mol^{-1} ($< 2\%$) away from the value for the final optimized structure. There are other instances when ΔE_S and ΔE_F differ substantially owing to large changes in the geometrical orientation of the bases within the pair upon optimization. These structures, however, may not have much significance in biological systems. Geometry optimization could not be achieved for Ca^{2+} at the N^7 position of A in AT. This observation is consistent with the finding of Sponer *et al.*[5] resulting in the inability of alkaline earth cations to stabilize the AAT triplex.

Base pair stabilization due to cation binding is calculated according to Anwander *et al.*,[3] although the interaction energies are not corrected for basis set superposition error. The earlier calculations[3] are based upon optimization of a cation bound to a single base and the use of inter-base geometry determined by X-ray crystallography, though their trends generally agree with our results for GC. Thus, the largest stabilization occurs at the purine N^3 site in GC for both cations. For AT, the present full optimization at higher level does not lead to binding of Ca^{2+} at N^7 and N^3 positions (the base pair is split) which may be interpreted as a destabilization effect. The AT pair is stabilized due to the cation only if it binds near the O^2 of thymine, reports[3] also predict this site to be the most stabilizing.

The outcome of this work is that the strength of MESP at CPs can be meaningfully employed for predicting the sites of cation coordination in bases and base pairs as well as the respective binding energies. In general, Li^+ and Ca^{2+} do not prefer to occupy amino-nitrogen lone pair sites with the exception of G–Ca^{2+} complex. In all those structures where the base pair geometry does not alter much, the initial site predicted by electrostatics is very close to the final optimized one. In conclusion, electrostatics may be used as a powerful tool for a qualitative and semiquantitative prediction of cation coordination sites in DNA bases and base pairs.

[2 + 2] Cycloaddition derivatives of stiba(III)alkene (Sb=C) and arsa(III)imine (As=N) intermediates

Philip C. Andrews,[a] Colin L. Raston,*[a] Brian W. Skelton,[b] Vicki-Anne Tolhurst[a] and Allan H. White[b]

[a] *Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia*
[b] *Department of Chemistry, University of Western Australia, Nedlands, WA 6907, Australia*

Mild thermolysis of (2-pyridyl)$(SiMe_3)_2CSbCl_2$ and [2-(6-Me)pyridyl](SiMe$_3$)$NAsCl_2$ affords, respectively, the chloro-bridged polymeric geminal C-centred distibine(III) complex $[(2\text{-pyridyl})(SiMe_3)CSbCl]_\infty$ 1 and the geminal N-centred arsenic(III) amide $[\{2\text{-(6-Me)pyridyl}\}NAsCl]_2$ 2; the proposed mechanism involves the elimination of Me_3-SiCl and a [2 + 2] stereospecific *cis*-cycloaddition of the stibaalkene (Sb=C) and arsaimine (As=N) intermediates.

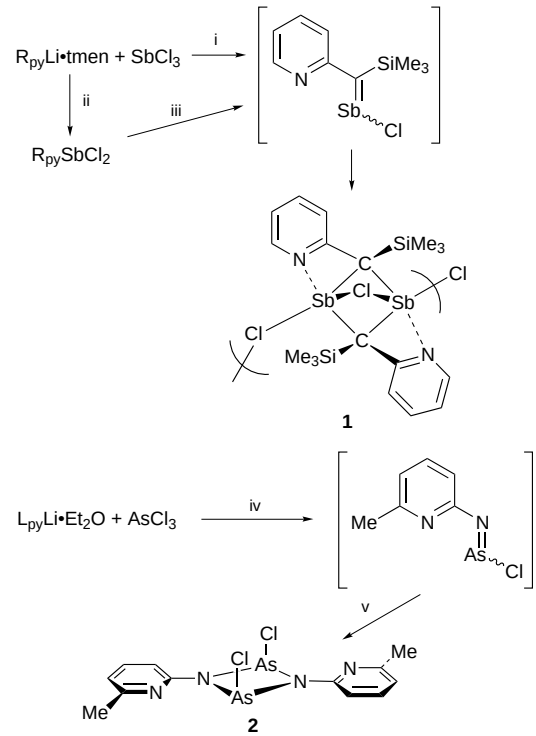
In developing the main group chemistry of the bulky alkyl ligand, (2-pyridyl)$(SiMe_3)_2C^-$, R_{py}, and the related amido ligand, {2-(6-Me)pyridyl}$(SiMe_3)N^-$, L_{py}, the presence of the Me_3Si group has been important in the kinetic protection of any metal(loid) centre.[1] However another important aspect of this chemistry is the potential present for the low energy β-elimination of Me_3SiCl from substituted metal(loid) chloride complexes resulting in novel and/or rare multiply bonded species. As such the elimination of halosilane from $R_{py2}SbCl$ proved useful in synthesising the novel geminal Al^{III}/Sb^{III} bimetallic heterocycle[2] and has been important in the preparation of phosphaalkenes and alkynes.[3] In contrast to N, and to a lesser degree P, the multiply bonded species of the heavier group 15 elements have a tendency to oligomerise unless this thermodynamically favoured process is offset by the presence of bulky ligands.[4] However this can be utilised in the formation of C-centred geminal organodimetallics which are receiving increasing attention as a result of their potential in developing new synthetic routes to complex organic molecules.[5]

Herein, we report the synthesis and characterisation of the chloro-bridged polymeric C-centred geminal distibine, $[(2\text{-pyridyl})(SiMe_3)CSbCl]_\infty$ **1** and the dimeric N-centred amidoarsine, $[\{2\text{-(6-Me)-pyridyl}\}NAsCl]_2$ **2** derived from the doubly bonded intermediate species [(2-pyridyl)$(SiMe_3)$C=SbCl] and [{2-(6-Me)pyridyl}N=AsCl] *via* the elimination of Me_3SiCl from $R_{py}SbCl_2$ and $L_{py}AsCl_2$.

In contrast to its As and P analogues, which undergo Me_3SiCl elimination at below −20 °C, $R_{py}SbCl_2$ can be prepared, as previously described,[6] from the 1:1 metathesis reaction of $R_{py}Li\cdot tmen$ and $SbCl_3$. However Me_3SiCl elimination can be achieved in two ways, as shown in Scheme 1, to give bright yellow rod-like crystals of **1**.† The crystals, which melt at 201–203 °C after gradually becoming opaque and then blackening, are relatively stable to air and atmospheric moisture, slowly becoming white and opaque, On melting further Me_3SiCl elimination occurs giving the appearance of effervescence.

Pale yellow prismatic crystals of **2** were obtained in a similar manner to the thermal elimination synthesis of **1**.† These crystals also decompose slowly in air, and melt in the range 187–189 °C.

X-Ray diffraction studies on **1**‡ revealed a geminal distibine structure. Such geminal distibine complexes are extremely rare with only a few structurally authenticated Sb^V and Sb^{III} methylene bridged complexes.[7] The repeating unit of the polymer contains, as its core, an almost square, but buckled, C_2Sb_2 ring internally bridged by a single Cl lying on a 2-symmetry axis, as does the other Cl which provides the



Scheme 1 *Reagents and conditions*: i, thf, −78 °C to room temp., 3 days; ii, Et_2O, −78 °C; iii, toluene, 50 °C, 4 h; iv, Et_2O, −78 °C; v, toluene, 80 °C, 4 h

connecting points along the chain (Fig. 1). The geminal carbon is formally bonded to two Sb^{III} centres with bond distances of 2.180(9) and 2.219(9) Å. Furthermore each Sb centre is bound to a pyridyl N [2.220(8) Å] a ring bridging Cl(1), [2.850(3) Å] and a linking Cl(2) [3.054(2) Å] making each Sb five coordinate. The stereochemically active lone pairs occupy a position *trans* to one of the geminal C-centres. The Sb–Cl distances in **1** are much longer than those found in $R_{py}SbCl_2$, 2.373(2) and 2.469(2) Å, while the Sn–N distance is actually

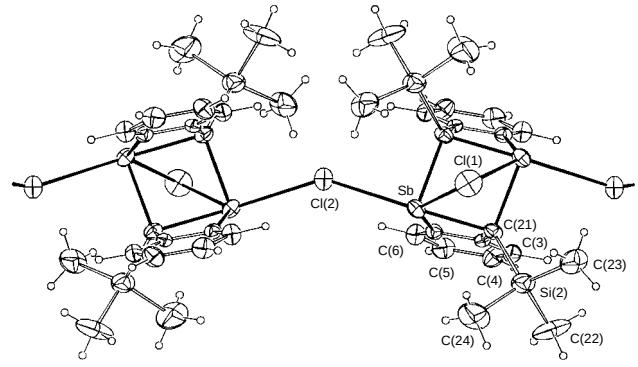


Fig. 1 Crystal structure of **1**

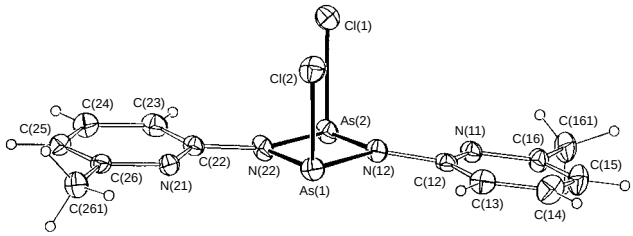

Fig. 2 Crystal structure of **2**

shorter, *cf*. 2.317(7) Å. The C(21)–Sb–N(1) angle of 63.1(3)° is comparable with that of 61.4(2)° found in $R_{py}SbCl_2$. The Sb–C distance of 2.213(5) Å in $R_{py}SbCl_2$[4] is only comparable with the longer Sb–C bond distance found in **1** despite the greater coordinative saturation at the Sb centre, *i.e.* five over four, while the Sb–C(–Al) distance in the recently reported Sb/Al geminal metallocycle,[2] in which Sb is only three coordinate, is shorter than both Sb–C bonds in **1**, being 2.167(7) Å. The bridging Cl(1) directly straddles the two Sb centres in the repeating unit at an angle of 67.4(1)° while the linking Cl(2) forms an angle of 149.3(1)° between the Sb centres of two different repeating units. Surprisingly the pyridyl rings are *cis* to the $(CSb)_2$ ring and almost eclipse each other.

The symmetry of bond distances and angles, and hence charge distribution, within the dimeric repeating unit must be the result of an initial [2 + 2] cycloaddition reaction of the stibene units, [(2-pyridyl)($SiMe_3$)C=SbCl], prior to polymerisation through the linking chlorides (Scheme 1). The concomitant stereochemical requirements of such a reaction may explain the *cis* arrangement of the pyridyl rings. However, it is noted that such reactions for alkenes are photolytically induced. The presence of the metal and thus some ionic character may render the cycloaddition more facile.

This argument can also be proposed in explaining the dimeric structure of the amidoarsine, **2**. The sp^2 geometry at the amido N requires that the $(NAs)_2$ ring and the (Me)pyridyl fragments are coplanar (Fig. 2), dihedral angles 8.6(3) and 4.4(2)°, though from an examination of the bond lengths there is no evidence of delocalisation. The unusual *cis* orientation of the Cl atoms relative to the $(NAs)_2$ ring is most likely, once again, a result of the stereochemical outcome of the [2 + 2] cycloaddition. Olah and Oswald[8] noted that the reaction of Bu^tNH_2 with $AsCl_3$ resulted in the formation, *via* HCl elimination, of the imidochloroarsenite $Bu^tN{=}AsCl$. The subsequent crystal structure[9] showed the complex to be dimeric, $(Bu^tNAsCl)_2$ **3** sharing the same structural features as **2**; the geometry around N being essentially planar and the Cl atoms *cis* to the $(NAs)_2$ planar ring. There is a great deal of similarity in the bond distances and angles of the $As_2N_2Cl_2$ cores: As–N bond lengths in **2** range from 1.809(7)–1.857(7) Å compared with 1.799(5)–1.827(4) Å in **3**, however the As–Cl bond distances in **2** of 2.228(2) and 2.233(2) Å are shorter than those in **3**, 2.249(3) and 2.252(2) Å, while the As···As–Cl angles in **2** are 103.72(8) and 103.75(8)° and 111.1(1) and 110.5(1)° in **3**. To date the only structurally characterised compound containing an $As^{III}{=}N$ bond is [2,4,6-$Bu^tC_6H_2N$(H)–As=$NC_6H_2Bu^t_3$-2,4,6],[10] the aryl groups of which are significantly more bulky than L_{py}. Dimerisation in **2** is not unexpected given the loss of a bulky Me_3Si moiety.

At room temperature the ^1H and ^{13}C NMR spectra of **2** suggest one dominant species (> 95%) with only one other set of minor signals indicating other possible oligomeric species. At low temperature these two species integrate almost equally. No coalescence occurs so it is unlikely that there is restricted rotation around the C–N bond. A more reasonable assumption is the presence of either monomers or higher oligomers. The NMR spectra of **1** show no evidence of polymer disintegration in solution but reveal that the polymer crystals often retain residual solvents in their structure. The structure shown in Fig. 1 contains 0.5 toluene situated between layers of the polymeric chain in the interstices formed by four $R_{py2}Sb_2Cl_2$ units.

† (*i*) $R_{py}SbCl_2$ was prepared as previously described.[4] The *in vacuo* removal of Et_2O from this reaction, followed by the addition of toluene, subsequent filtration to remove LiCl and heating to 50 °C for 4 h leads to the precipitation of a pale yellow powder. Removal of toluene and recrystallisation at 4 °C from thf–toluene results in bright yellow rod-like crystals of **1**. (*ii*) Alternatively, the metathesis reaction of $R_{py}Li$ and $SbCl_3$ can be carried out in thf at −78 °C, allowed to warm slowly to room temp. and stirred for 3 days. The thf is removed *in vacuo* and a CH_2Cl_2 extraction of the remaining solids allows for the crystallisation of **1**, again at 4 °C. Yield 63% (not maximised). Mp 201.203 °C. ^1H NMR (300 MHz, CD_2Cl_2, 25 °C) δ 7.76 (d, br, 1 H), 7.57 (t, 1 H), 7.14 (br, d, 1 H), 6.73 (t, 1 H), 0.34 (s, 9 H), residual thf (0.25) 3.68 (m, 1 H), 1.80 (m, 1 H), residual toluene (0.33) 7.17 (m, 1.7 H) 2.11 (s, 1 H). ^{13}C NMR (100.6 MHz, CD_2Cl_2, 25 °C) δ 160.6, 144.1, 138.0, 128.1, 119.1, 45.7 (CH_2), 2.8. Satisfactory elemental analysis obtained.

2. A toluene solution of $L_{py}AsCl_2$, prepared from the metathesis reaction of $L_{py}Li{\cdot}Et_2O$ with $AsCl_3$, was heated at 80 °C for 4 h. The *in vacuo* reduction of the solution and cooling slowly from 50 °C to room temp. resulted in pale yellow prismatic crystals of **2**. Yield 94%. Mp 187–189 °C. ^1H NMR (300 MHz, C_7D_8, 25 °C) (major component, > 95%) δ 6.89 (m, 1 H), 6.45 (d, 1 H, *J* 8 Hz), 6.30 (d, 1 H, *J* 8 Hz), 2.26 (s, 3 H, Me), (minor component) 6.73 (t), 6.50 (d), 6.40 (d), 2.19 (s). ^{13}C NMR (100.6 MHz, C_7D_8, 25 °C) δ 169.0, 156.5, 139.0, 115.0, 105.6. 23.8. Satisfactory elemental analysis obtained.

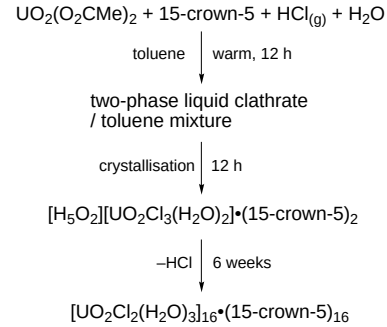
Reaction of uranyl acetate with HCl and 15-crown-5 in toluene results in the formation of a liquid clathrate phase from which crystals of $(H_5O_2)[UO_2Cl_3(H_2O)_2]\cdot(15\text{-crown-}5)_2$ 1 are deposited; on standing, loss of HCl results in the isolation of a second product $[UO_2Cl_2(H_2O)_3]_{16}\cdot(15\text{-crown-}5)_{16}$ 2 which displays an extremely complex hydrogen bonded chain structure in the solid state.

In crystal growth the task presented to Nature is one of three dimensional tesselation. Often irregular molecular shapes must be fitted together in such a way as to minimise the amount of wasted space (vacuum) within the crystal.[1] In some cases, particularly those in which the molecule to be crystallised possesses a molecular cavity or cleft, the occurrence of vacant space is difficult to avoid and adventitious molecules of solvent, other species present in the reaction mixture or even gases[2,3] are incorporated within the crystalline lattice. The study of this phenomenon has given birth to the rich field of inclusion chemistry.[4,5]

A significant amount of work within the field of crystal engineering has been devoted in attempts to predict how Nature will solve the crystal 'tesselation' problem for a wide range of solid compounds.[6,7] Many synthetic chemists are, however, familiar with compounds which 'just will not crystallise'. The amorphous nature of such solids, which are often found to form oils in which a well defined ratio of solvent and solute comprises a separate phase from the bulk solvent, may often be rationalised in terms of molecular size and shape and its consequences on the lattice energy of the crystalline solid.[1] An excellent, and well studied example of this phenomenon is the formation of liquid clathrates in which an aromatic solvent serves to separate anions and cations of widely differing shape and size.[8–10] Under certain circumstances however, liquid clathrates may be decomposed by, for example, loss of HCl from the reaction medium and a consequent gradual decrease in polarity. In this way, studies of crown ether/metal salt mixtures in liquid clathrate media[8] have resulted in the isolation of a wide range of crystalline arrays of type '$H(H_2O)_n^+$(crown ether)-(anion)' in which the oxonium ion acts as a hydrogen bond donor and the crown ether as a hydrogen bond acceptor, thus giving insight into the precursor solution species.[11–14] In the case of the larger crown ethers such as 18-crown-6 and 21-crown-7 the oxonium cation is encapsulated by the macrocycle.[11,12,15] For 15-crown-5 and 12-crown-4, extended hydrogen bonded arrays are formed involving alternating hydrogen bond donors and acceptors, as a result of the inability of the small crown ether to surround the oxonium cation.[16]

The key to the production of materials with predictable crystal structures lies in the engineering of complementary crystal building blocks either by consideration of molecular shape,[17,18] electronic properties,[19] or hydrogen bond donor/acceptor ability.[20] We report herein the preliminary results of crystal engineering studies carried out in liquid clathrate media between hydrogen bond donor–acceptor pairs, which are not sterically complementary, and exhibit a symmetry mismatch.

The reaction of uranyl acetate with HCl and 15-crown-5 in toluene was carried out as shown in Scheme 1. This resulted in the formation of a large, yellow liquid clathrate layer over a period of *ca*. 12 h. Upon standing for a further 12 h gradual loss of HCl resulted in the deposition of crystals of formula $(H_5O_2)[UO_2Cl_3(H_2O)_2]\cdot(15\text{-crown-}5)_2$ **1**. The X-ray crystal structure† of this complex is shown in Fig. 1 and consists of an infinite chain comprising alternating $H_5O_2^+$ and $[UO_2Cl_3(H_2O)_2]^-$ anions linked by hydrogen bonding *via* 15-crown-5 molecules. Within the $H_5O_2^+$ cation the O···O distance is extremely short at 2.371(8) Å (*cf*. typical values of O···O separations 2.40–2.45 Å[11,15,21–23]) although distances as low as 2.336(14) Å have been noted.[24] Oxonium–crown contacts are in the range 2.70–3.20 Å, while the opposite face of each crown ether is hydrogen bonded to coordinated water molecules at distances of 2.92–3.04 Å. The $[UO_2Cl_3(H_2O)_2]^-$ anion itself exhibits normal bond lengths and angles with U=O 1.743(6), U–OH_2 2.37(3), 2.45(5) [O(2) and O(3) are disordered] and U–Cl 2.708(3), 2.709(3). This may be compared to typical distances of 1.763, 2.455 and 2.653 respectively.[25] The $[UO_2Cl_3(H_2O)_2]^-$ anion adopts a pentagonal bipyramidal geometry resulting in the hydrogen bond donating H_2O ligands both residing in the equatorial plane with a O–U–O angle of 146.4(9)°. This, in turn, enforces a zigzag structure to the $[UO_2Cl_3(H_2O)_2]^-\cdots$15-crown-5 chain.



Scheme 1 Formation of the hydrogen bonded array $[UO_2Cl_2(H_2O)_3]_{16}\cdot(15\text{-crown-}5)_{16}$

Over a period of six weeks continued loss of HCl from the same reaction mixture results in the replacement of the yellow rectangular crystals of complex **1** by large, multifaceted crystals of a second product of empirical formula $[UO_2Cl_2(H_2O)_3]\cdot$15-crown-5. X-Ray crystallographic analysis† revealed a striking structure of trigonal symmetry, space group $P3_2$, consisting of sixteen unique uranium complexes and 15-crown-5 molecules, Fig. 2. The structure is arranged in sheets consisting of approximately linear, infinite hydrogen bonded strands, which

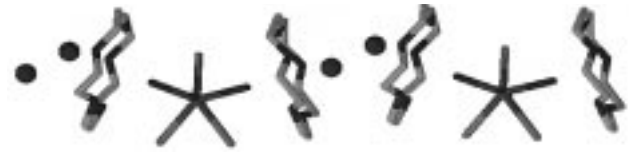


Fig. 1 Infinite chain structure of $H_5O_2^+$ and $[UO_2Cl_3(H_2O)_2]^-$ linked by 15-crown-5

Fig. 2 The asymmetric unit of $[UO_2Cl_2(H_2O)_3]_{16}\cdot(15\text{-crown-}5)_{16}$ **2** comprising four parallel, helical columns of alternating $[UO_2Cl_2(H_2O)_3]$ and 15-crown-5 (end and side views)

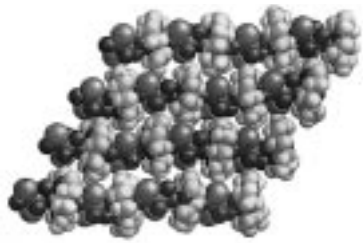

Fig. 3 Space filling plot of **2** showing the interlocking of the chains

repeat every four uranium centres. The strands are held together by interactions between the crown oxygen atoms and water molecules O(*n*3) and O(*n*4) (where *n* represents the number of the uranium centre to which the atom is attached) which form the most nearly linear H_2O–U–OH_2 angle of *ca*. 152° [the analogous O(*n*3)–U–O(*n*5) angle is *ca*. 140°]. Typically both O(*n*3) and O(*n*4) form two hydrogen bonds to an adjacent crown ether with a wide range of $O_{water}\cdots O_{crown}$ distances of between 2.60(2) and 2.92(2) Å highlighting the individual nature of each of the sixteen crown–metal complex pairs. In addition, O(*n*5) forms a single short hydrogen bond to a further crown oxygen on the same side as O(*n*4) with distances ranging from 2.49(2) to 2.71(2) Å. While some disorder was evident in the 15-crown-5 molecules of **1**, complex **2** is ordered at −100 °C with each of the sixteen 15-crown-5 units exhibiting a structure in which three oxygen atoms point towards O(*n*4) and O(*n*5) of one metal complex and two others interact with O(*n*3) on the next. It is the unsymmetrical nature of this conformation with three donor atoms one side and two on the other, which, in the absence of oxonium ions, leads to such a complicated structure. In forming the interactions to water ligands O(*n*4) and O(*n*5) with three of the crown oxygen atoms, two are left for forming the next interaction to an adjacent anion [*via* O(*n*3)]. This results in the docking of this anion in such a way as to maximise O(*n*3)···crown interactions, in the process fixing its orientation. Hydrogen bonding from O(*n*4) and O(*n*5) to the next crown ether must now necessarily occur in a different orientation to the previous member of the chain. This results in a rotation perpendicular to the chain direction of *ca*. 25–35° accompanied by a tilt along the chain axis of *ca*. 10°. The net result is that it is not until the fifth such donor–acceptor pair that the crown has rotated back to its starting point. Furthermore, the displacement of the uranium centres to one side of the chain axis as a consequence of the non-linear O(*n*3)–U–O(*n*4) axis results in the formation of grooves in the chain into which the crown ethers of adjacent stacks slot. Again, the steric requirements of one chain dictate the orientation of the next such that each chain is rotated with respect to its neighbour. This pattern also does not repeat itself until the fifth chain resulting in a unique 4 × 4 array of donor acceptor pairs, Fig. 3.

In summary, the rigid and uncomplementary nature of both uranyl species in **1** and **2** results in interesting crystal packing motifs. In the former case the presence of a linear oxonium ion serves to simplify the crystal packing. For **2** a highly complex crystalline array is required before the problem of three-dimensional tessellation of such mismatched building blocks can be solved.

We thank the EPSRC and King's College London for funding of the diffractometer system. Grateful acknowledgement is also given to the Nuffield Foundation for the provision of computing equipment.

Synthesis of Si and Ti-Si-MCM-48 mesoporous materials with controlled pore sizes in the absence of polar organic additives and alkali metal ions

Avelino Corma,* Qiubin Kan and Fernando Rey

Instituto de Tecnologia Química, UPV-CSIC, Universidad Politécnica, Avda. de los Naranjos, S/N, 46022 Valencia, Spain

A new route for the synthesis of Si- and Si-Ti-MCM-48 has been developed which allows these materials to be obtained without using polar organic additives and alkali metal ions; this procedure not only produces more active and selective Ti-MCM-48 oxidation catalysts than those reported before, but also permits the synthesis of MCM-48 with controlled pore diameters.

The development of ordered mesoporous materials (M41S) containing different atoms in the pore walls has opened up new possibilities for the use of mesoporous molecular sieve materials in the field of catalysis.[1–7] These materials have large channels with regular pores which can be varied in some cases from 1.5 to 7.0 nm, and which are ordered in a hexagonal (MCM-41), cubic (MCM-48), or laminar (MCM-50) array. All these materials are characterised by extremely narrow pore size distributions in the mesoporous region, long range order, high surface areas (> 700 m^2 g^{-1}) and are stable after calcination. From the point of view of catalytic activity the most interesting materials are the MCM-48 array, because its pore structure is built up of two independent tridirectional channel systems.[8] However, little research has been carried out on MCM-48, probably due to the difficulty of its synthesis compared with the more studied MCM-41, and also the difficulty of controlling its pore size. In general, MCM-48 is prepared with high surfactant to silicon ratios (0.65–1.5),[9] and the presence of polar organic additives in the reaction mixture is believed to be essential for a successful synthesis of MCM-48[10,11] when cetyltrimethylammonium ion (CTA^+) surfactant is used as the structure-directing agent. To achieve the latter, tetraethylorthosilicate (TEOS) is usually used as the silicon source for preparation of MCM-48 since in this case the ethanol produced from the hydrolysis of TEOS acts as the required polar organic additive. When sodium silicate or other silica sources were used without addition of polar organics, MCM-41 was produced instead.[10,12] Furthermore, in most of the reported syntheses of pure siliceous MCM-48 materials and their metal derivates, NaOH was introduced in the synthesis gel.[9,12–14] It is known however, that there is a detrimental effect of alkali metal ions on the catalytic properties of titanium silicate molecular sieves.[15,16] We have found only one report in which pure siliceous and titanium-containing MCM-48 were prepared in absence of sodium ions by using TEOS as the silicon source.[17] Unfortunately, the synthesis was poorly reproducible due to the ill defined and critical ethanol evaporation step, which is required for the synthesis. While MCM-41 can be prepared with a large range of pore diameters, even in the absence of added organics,[18] this is not the case for the MCM-48 structure where relatively small changes in the pore diameter could only be achieved by using surfactants with different chain length, and pore sizes larger than *ca.* 2.8 nm have not been reported.

It is possible to overcome the above synthetic shortcomings and to produce high quality MCM-48 samples in the absence of polar organics and alkali metal ions, as well as enabling the pore diameter to be increased to *ca.* 3.8 nm. These achievements certainly open more possibilities for the use of MCM-48 as catalysts as is illustrated for Ti-MCM-48.

The hydrothermal synthesis of Si-MCM-48 was carried out with the following molar composition: 1.0 SiO_2 : x CTAOH/Br : 32.0 H_2O, x = 0.18–0.35; the source of silicon was amorphous silica (Aerosil 200, Degussa) and an aqueous solution of CTAOH/Br with a OH/Br ratio of 90/10 was used. The homogenous gel was sealed in Teflon-lined stainless steel autoclaves and heated at 60–150 °C under static conditions. The time of synthesis was varied from 1 to 7 days depending on the temperature of synthesis and the pore size to be obtained. The resulting solid products were recovered by filtration, washed and dried at 60 °C for 24 h. The occluded organic was removed by heating the samples at 540 °C under a continuous flow of N_2 for 2 h, followed by calcination in a flow of air at 540 °C for 6 h.

From the XRD patterns presented in Fig. 1 it can be seen that highly ordered MCM-48 mesoporous materials consistent with an *Ia*3*d* cubic symmetry were obtained. In our procedure we succeeded in synthesising the MCM-48 structure at low surfactant to silicon ratios (0.20–0.28), unlike in the synthesis reported by Mobil Researchers where higher ratios seem to be mandatory to obtain the cubic structure.[9] However, following our synthesis procedure it is critical to stay in between the limits given above for the surfactant/silicon ratio, since when this ratio reached 0.35, a lamellar phase (MCM-50) was formed under the same reaction conditions, and MCM-41 was produced when the ratio was lower than 0.18. The reaction temperature and crystallisation time were the key variables to control the pore diameter of the resultant samples. For instance, two different MCM-48 samples with cell parameters a_0 = 92.8 Å and a_0 = 98.6 Å were obtained after 24 h crystallization at 135 °C and 150 °C, respectively. Longer reaction times at 150 °C, *e.g.* 3 or 5 days, resulted in the swelling of the unit cell volume of the MCM-48 to a_0 = 112.7 and 116.8 Å, respectively. Moreover, after 5 days of crystallization a lamellar structure starts to appear due to a phase transition of MCM-48 (Fig. 1), producing a pure lamellar phase after 7 days of synthesis. The nitrogen

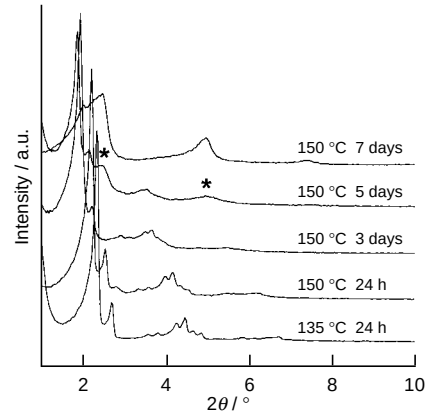

Fig. 1 X-Ray diffraction patterns of mesophases (MCM-48) synthesised at various temperatures and different reaction times. The phase transition from MCM-48 to the lamellar structure (*) upon extended synthesis times can be clearly seen.

Table 1 Unit cell parameter a_0 upon calcination at 540 °C, pore diameter, BET surface area and pore volume of MCM-48

Sample	Synthesis conditions		Unit cell, a_0/Å		Unit cell contraction/ Å	Pore diameter, d/Å	Surface area, s/m^2 g^{-1}	Pore volume, v/cm^3 g^{-1}
	T/°C	t/h	as[a]	ca[a]				
1	135	24	92.8	84.6	8.2	24	1121	0.87
2	150	24	98.6	92.1	5.5	28	1026	1.00
3	150	72	112.7	110.9	1.8	36	961	1.09
4[b]	150	120	116.8	115.4	1.4	38	800	0.93

[a] as = as-synthesized, ca = calcined. [b] Containing lamellar phase (see Fig. 1).

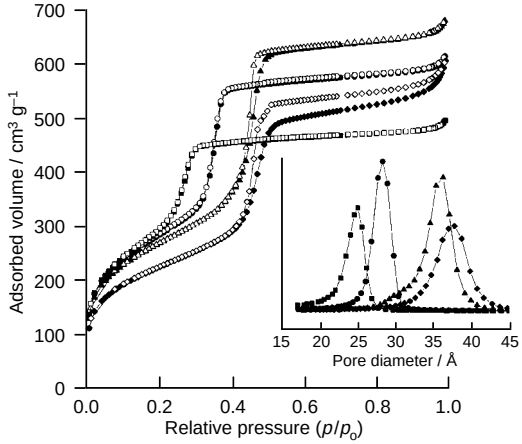

Fig. 2 Nitrogen adsorption–desorption isotherms of calcined MCM-48 materials with unit cell a_0 = 84.6 Å (■), a_0 = 92.1 Å (●), a_0 = 110.9 Å (▲) and a_0 = 115.4 Å (◆); inset: pore distribution of calcined MCM-48 materials with different unit cell parameters (calculated from N_2 adsorption isotherm branch)

adsorption–desorption isotherms of the corresponding calcined samples and the pore size distribution deduced from them are illustrated in Fig. 2. Table 1 lists the physicochemical characteristics of the as-synthesised and calcined samples, showing that swelling of the pore diameter occurs when the unit cell parameter increases.

If lower reaction temperatures are used the formation of MCM-41 is favoured. For instance, mesoporous materials with the MCM-41 structure were generated at 60 and 100 °C after 3 days when the synthesis gel composition given above was used. The effect of temperature on the structure of the mesoporous products is probably associated with the modification of the packing parameter g ($g = V/A_0l$) of the surfactant organisation,[19,20] where V is the surfactant tail volume, l is the length of surfactant chain and A_0 is the effective head group area at the micelle surface. At lower temperatures, *e.g.* at 60 or 100 °C, where MCM-41 is produced, the effective g value for CTA^+ ions is smaller[21] than that at 135 to 150 °C when MCM-48 is generated.

By following the above procedure for the synthesis of Si-MCM-48, Ti-MCM-48 with Si/Ti = 100 has been successfully obtained. UV–VIS spectra for the as-synthesised and calcined Ti-MCM-48 show a main band at *ca.* 200–210 nm assigned to isolated framework titanium in tetrahedral coordination. The catalytic reactions for epoxidation of cyclohexene with *tert*-butyl hydroperoxide (TBHP) over the Ti-MCM-48 was carried out at 60 °C with an alkene/TBHP ratio of 4.0 and 5 mass% of catalyst and following the reaction and analytical procedure described previously.[4] The Ti-MCM-48 prepared here in the absence of alkali metal ions shows an initial reaction rate of 1.642 mol g^{-1} h^{-1}. The sample with the same Si/Ti ratio obtained in the presence of sodium ions using the method described in ref. 15 gives an initial reaction rate four times lower (0.448 mol g^{-1} h^{-1}) than that over the Ti-MCM-48 reported here, illustrating the beneficial effect of the novel synthesis procedure presented here.

In conclusion, it has been proven that it is possible to carry out the synthesis of mesoporous materials having the MCM-48 structure without using polar organics and alkali metal cations in the synthesis mixture. When the synthesis is carried out in the absence of alkali metal ions, the Ti-MCM-48 produced is a more active epoxidation catalyst than the Ti-MCM-48 synthesised following the conventional procedure in the presence of Na^+. Finally, by precisely controlling the synthesis conditions, *i.e.* composition of the gel, synthesis temperature and time, it was possible to produce MCM-48 samples with different pore diameters up to 3.8 nm.

The authors thank CICYT for financial support (MAT97-1207-C03-01).

Self-assembly of coordination polymeric chains: crystal structures of silver(I) complexes with 3,6-bis(diphenylphosphino)pyridazine and 2,6-bis(diphenylphosphino)pyridine

Shan-Ming Kuang,[a] Zheng-Zhi Zhang,*[b] Qi-Guang Wang,[a] and Thomas C. W. Mak*†[a]

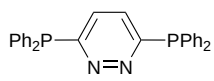
[b] *Elemento-Organic Chemistry Laboratory, Nankai University, Tianjin, China*

Site-specific metal–ligand interactions lead to self-assembly of coordination polymeric chains in the crystal structures of silver(I) complexes with 3,6-bis(diphenylphosphino)pyridazine and 2,6-bis(diphenylphosphino)pyridine.

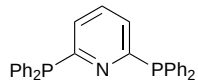
The design of solid-state architectures has become an area of increasing interest in recent years.[1–6] Much attention has centered upon the use of supramolecular contacts, particularly hydrogen bonding, between suitable molecules to generate multidimensional arrays or networks.[1,3,4] In comparison, the design of inorganic networks is less well developed though catching up fast in recent years.[7–11]

The self-assembly of coordination polymeric chains presents an interesting challenge. We reasoned that, with judicious design, it should be possible to assemble linear chains in a single process involving simple mixing of metals and ligands. Such a strategy requires the design of a ligand with two or more coordination sites that are juxtaposed in such a way that they cannot all coordinate to the same metal ion, and interaction between the ligand and a linear sequence of metal ions must occur in a logical fashion to form a polymeric chain.

With this in mind, we decided to conduct a test case with N,P-donor ligands with suitable binding sites and idealized C_{2v} molecular symmetry. The substituted pyridazine ligand 3,6-bis-(diphenylphosphino)pyridazine (L^1), which was synthesized in



L^1



L^2

an earlier study,[13] is constrained by its connectivity to act as a tetranucleating ligand, presenting a pair of N,P-bridging sites to a linear arrangement of four metal ions. Here we report the self-assembly reaction of L^1 with $[Ag(MeCN)_4]ClO_4$ to generate a zigzag polymeric chain in the silver(I) complex $\{[Ag_2(MeCN)_2(\mu\text{-}L^1)]\}_n[ClO_4]_{2n}$ **1**. In contrast, the use of the related ligand 2,6-bis(diphenylphosphino)pyridine (L^2)[14] in the same reaction gave $\{[Ag(MeCN)_2(\mu\text{-}L^2)]\}_n[ClO_4]_n$ **2** with a different metal : ligand molar ratio and exhibiting a simple linear chain.

The reaction of $[Ag(MeCN)_4]ClO_4$[15] with L^1 in MeCN at room temperature (Scheme 1) leads to the rapid formation of a colorless solution from which $\{[Ag_2(MeCN)_2(\mu\text{-}L^1)]\}_n[ClO_4]_{2n}$ **1** was isolated.‡ Elemental analysis results are consistent with the stoichiometric formula $Ag_2(MeCN)_2(L^1)(ClO_4)_2$. Slow diffusion of diethyl ether into an acetonitrile solution afforded colorless crystals of **1**, the structure of which was determined by single crystal X-ray analysis.§

As anticipated, the L^1 ligand bridges between metal centers *via* coordination by its P,N-donor sets (Fig. 1). Each silver(I) center is bound to a P atom from one L^1 ligand and a N atom from the other, resulting in the formation of a polymeric zigzag chain running in the direction of the *c* axis (Scheme 1, left); note that the centers of eight-membered $(PCNAg)_2$ rings are located at successive inversion centers. The highly distorted trigonal-planar coordination sphere about each Ag^I atom is completed by an acetonitrile ligand that stabilizes the resulting 16-electron configuration, so that the repeating structural unit is $Ag_2(MeCN)_2(\mu\text{-}L^1)$. The sums of the three bond angles at Ag(1) and Ag(2) are 358.3 and 357.8°, respectively. The intermolecular Ag(1)···Ag(1a) and Ag(2)···Ag(2b) distances are 3.005(2) and 3.184(2) Å, respectively, which are in agreement with those [3.162(1)–3.223(1) Å] in $[Ag\{HC(PPh_2)_3\}_2Cl][ClO_4]_2\cdot 2MeCN$,[16] and those [2.943(2)–3.014(2) Å] in $[Ag_3(dppp)_2(MeCN)_2(ClO_4)_2]^+$ [dppp = bis(diphenylphosphinophenylphosphine)],[17] but much shorter than that [3.641(2) Å] in $\{[AgL^3(MeCN)_2]\}_n[BF_4]_n$ (L^3 = 2,7-diazapyrene).[9] The Ag(1)···Ag(2) contact is 3.535(2) Å.

The silver(I) complex $\{[Ag(MeCN)_2(\mu\text{-}L^2)]\}_n[ClO_4]_n$ **2** was obtained from the reaction of $[Ag(MeCN)_4]ClO_4$ with L^2 in 1 : 1 molar ratio. The crystal structure of **2**§ consists of a packing of linear chains of alternating Ag^I and L^2 units (Fig. 2 and Scheme 1, right) and perchlorate ions. In each coordination polymeric chain the repeating unit $Ag(MeCN)_2(\mu\text{-}L^2)$ is held together by the P atoms of ligand L^2, whose pyridyl N atom takes no part in metal coordination. The coordination geometry of the silver(I) center is distorted tetrahedral, stabilization being achieved by linkage to two acetonitrile ligands. The Ag–N distances of 2.332(8) and 2.419(9) Å are much shorter than those [2.871(4), 2.926(4) Å] found in $\{[AgL^3(MeCN)_2]\}_n[BF_4]_n$.[9]

In summary, we have taken advantage of the different site-specific ligating capacities of P,N-donor ligands L^1 and L^2 in generating coordination polymeric chains with $[Ag(MeCN)_4]ClO_4$. In complex **1**, successive L^1 ligands lie on alternate sides of the zigzag silver(I) chain, while in **2** the L^2 ligand is repeated by the *a* translation to generate a simple linear chain. The latter case contrasts sharply with the related one-dimensional gold(I) polymer $\{[Au_2(\mu\text{-}L^2)(C{\equiv}CPh)_2]\}_n$ in which the L^2 ligands are arranged in a zigzag fashion along the chain.[18] That the silver(I) and gold(I) complexes of L^2 adopt different linear polymeric structures can be attributed to the difference in number, charge and bulkiness of the respective acetonitrile and phenylacetylide

N-Methyl-1,3,5,2-trioxazinane, a possible spontaneous ignition sensitiser†

Wai-To Chan, DeLin Shen‡ and Huw O. Pritchard*§

Department of Chemistry, York University, Downsview, Ontario, Canada M3J 1P3

***N*-Methyl-1,3,5,2-trioxazinane (or *N*-methyl-2,4,6-trioxapiperidine), by analogy with *s*-trioxane, should decompose thermally into MeNO + $2CH_2O$; this substance does not appear to have been made, but molecular orbital calculations show that it should be almost as stable as *s*-trioxane.**

Nitrogen dioxide, from the thermal decomposition of alkyl nitrates, sensitises the spontaneous ignition of fuel in a diesel engine;[1] likewise, so does formaldehyde, from the thermal decomposition of *s*-trioxane.[2] Synergy occurs between CH_2O and NO_2, so that if both are released simultaneously, the ignition quality of the fuel is even more enhanced. The efficiency of 2-ethylhexyl nitrate as a sensitiser of diesel-fuel ignition arises because following its dissociation into NO_2 and an alkoxy radical, a fraction[3] of these radicals goes on to eliminate CH_2O. However, with increasing legislative pressure to minimise NO_x emissions,[4] strategies for increasing the ratio of CH_2O/NO_2 formation could be beneficial.

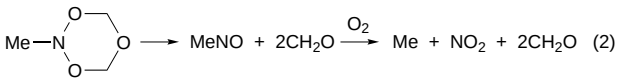
An obvious choice is the thermal decomposition of phenethyl nitrate [eqn. (1)], not only giving the desired

$$PhCH_2CH_2ONO_2 \rightarrow PhCH_2CH_2O + NO_2 \rightarrow PhCH_2 + CH_2O + NO_2 \quad (1)$$

products in equal amounts, but yielding also benzyl radicals, which are powerful ignition sensitisers.[5] The hoped-for advantage, however, does not materialise in engine measurements[6] because in the temperature range of interest (*ca.* 650–800 K), phenethyl nitrate[7] decomposes an order of magnitude more slowly than does 2-ethylhexyl nitrate[3a]

(phenethyl nitrate: $k = 5.0 \times 10^{13} e^{-35,600/1.987T}$ s^{-1};
2-ethylhexyl nitrate: $k = 2.5 \times 10^{15} e^{-37,500/1.987T}$ s^{-1}).

N-Methyl-1,3,5,2-trioxazinane, by analogy with the thermal decomposition of *s*-trioxane into three CH_2O molecules (or other symmetrically substituted alkyltrioxanes into three aldehyde molecules),[8] should yield two CH_2O molecules and MeNO, the latter decomposing rapidly to give NO and thence NO_2 in the presence of excess oxygen [eqn. (2)].



(2)

Thus, we explored a parallel set of GAUSSIAN 94 molecular orbital calculations[9] for these two molecules. Their equilibrium geometries were found at the RHF/6-31G** level of theory, as were the transition states for the concerted dissociations [eqns. (3) and (4)], with key energies further

$$(CH_2O)_3 \rightarrow 3CH_2O \quad (3)$$

$$MeNO(CH_2O)_2 \rightarrow MeNO + 2CH_2O \quad (4)$$

refined at the MP2 and/or MP4 levels. All characteristic structures were verified by harmonic vibration analysis, and by demonstrating that equivalent structures could be found by non-local density functional calculations; in the case of *s*-trioxane, all of the reported structures were duplicated with both the B3LYP and BHandHLYP functionals, but for brevity only the latter results are presented. Also, for the *N*-methyl-1,3,5,2-trioxazinane molecule, because of its increased size and complexity, slightly less demanding levels of approximation were used, and extensive searches were made for both singlet and triplet configurations to eliminate the possibility of a lower energy path for the breakup or structural rearrangement. The results of these calculations are collected together in Tables 1 and 2.

For *s*-trioxane, the minimum energy configuration is, as expected, in the chair form, with C–O and C–H bond lengths each within 1% of 1.40 and 1.08 Å, respectively, in all levels of approximation. Also, there is always a local minimum for the $(CH_2O)_2$ configuration, with bond lengths approximately 1% longer than in *s*-trioxane. The transition state for the dissociation was characterised by an imaginary vibrational degree of freedom which corresponds precisely to a concerted dissociation into three CH_2O molecules. At the energy maximum, the C–O bonds now alternate between 1.25 and 1.90 Å in length, compared with the calculated C–O distance in formaldehyde itself of *ca.* 1.20 Å. Concerted dissociations of six-membered ring compounds into three identical fragments, *viz*. 1,3,5-triaza-

[a] ‡ Signifies the transition state. [b] 1 a.u. = $2I_H$ = 27.2 eV = 627.5 kcal mol^{-1} = 2625.5 kJ mol^{-1}. Figures in parentheses in kcal mol^{-1}.

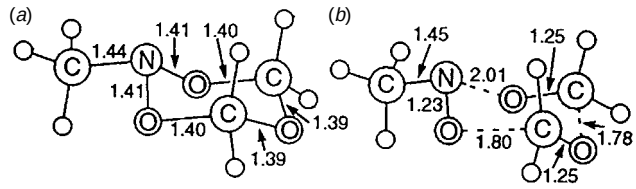

Fig. 1 Structures of (*a*) the lowest energy conformer of *N*-methyl-1,3,5,4-trioxazinane and (*b*) the transition state for dissociation. Distances are in Å.

cyclohexane → $3H_2C{=}NH$, trinitro-1,3,5-triazacyclohexane → $3H_2C{=}N{-}NO_2$ and *sym*-triazine → 3HCN, have been studied previously by molecular orbital methods.[10]

The thermochemical results for dissociation into three CH_2O molecules are typical of what one can expect at the present time for a reaction with unequal numbers of reactants and products. The latest thermochemical data for *s*-trioxane[11] and for formaldehyde[12] give $\Delta H_{298} \simeq +33$ kcal mol^{-1}, or about +30 kcal mol^{-1} at 0 K; an alternative datum for formaldehyde[13] gives values of +28 and +25 kcal mol^{-1} respectively. The results for 0 K from these calculations are +22, +27, +28 and +20 kcal mol^{-1} from the RHF, DFT, MP2 and MP4 calculations respectively; unscaled zero point energies (zpe) are used in all calculations.

For *N*-methyl-1,3,5,2-trioxazinane there are six conformers, with the one of lowest energy being again in a chair configuration; we did not examine the other five structures beyond RHF/6-31G**. Again, all the C–H distances are about 1.08–1.09 Å and the lowest path to dissociation is a concerted one, but the structure of the transition state is slightly asymmetric; the two structures are shown in Fig. 1. Comparison of the energies given in Table 2 would suggest that both the enthalpy and activation energy for the dissociation into three fragments are about 10 kcal mol^{-1} less for this molecule than for *s*-trioxane.

There have been several kinetic studies of the thermal decomposition of *s*-trioxane: in the 500–800 K temperature range, three conventional studies[14] all gave activation energies of between 47–48 kcal mol^{-1}, and frequency factors of $10^{14.80}$ to $10^{15.28}$ s^{-1}; in addition, a high-temperature shock tube study[15] gives results that extrapolate nicely into this body of measurements. By comparison, our MP2 and MP4 results for the activation energy at 0 K are 49 and 45 kcal mol^{-1} respectively.

A straightforward transition state calculation[16] of the rate constant for the thermal dissociation of *s*-trioxane over the temperature range 500–800 K yields an Arrhenius *A* factor of $10^{15.56}$ s^{-1}, and an activation energy of 52.1 or 48.1 kcal mol^{-1}, depending upon which value of the critical energy is used.¶ These results compare favourably with the experimental ones quoted above.

Likewise, for *N*-methyl-1,3,5,2-trioxazinane decomposing into $2CH_2O$ + MeNO, we find an Arrhenius *A* factor of $10^{15.25}$ s^{-1}, and an activation energy of 41.7 kcal mol^{-1}, using the frequency data and the MP2 result for the critical energy of activation.¶ These rate parameters are rather similar to those for 2-ethylhexyl nitrate, noted above, making this new substance an ideal candidate for a diesel-fuel ignition sensitiser.

The close parallels between the various structures in the two systems, and moderate acceptability of the *s*-trioxane results (both for the thermochemistry and the reaction rate), tend to suggest that the calculations on *N*-methyl-1,3,5,2-trioxazinane can be accepted with a reasonable degree of confidence. Thus, *N*-methyl-1,3,5,2-trioxazinane should be a stable molecule, with an activation energy for concerted dissociation into nitrosomethane and formaldehyde in the region of 35–40 kcal mol^{-1}. In which case, it may seem surprising that this heterocycle has apparently never been reported, particularly since quite a number of examples of *N*,*N*-dialkoxy-*N*-alkylamines or *N*,*N*-dialkoxybenzamides are known.[17]

This work was supported both by the Natural Sciences and Engineering Research Council of Canada and by Imperial Oil Products Division, Sarnia. We also thank Dr D. N. Butler for suggesting this idea, and for many helpful comments.

On the 'Novel two-phase oxidative cross-coupling of the two-component molecular crystal of 2-naphthol and 2-naphthylamine'[1]

Štěpán Vyskočil,*[a,b] Martin Smrčina,[a] Miroslav Lorenc,[a] Vladimír Hanuš,[c] Miroslav Polášek[c] and Pavel Kočovský*[b]†

[a] *Department of Organic Chemistry, Charles University, 128 40, Prague 2, Czech Republic*

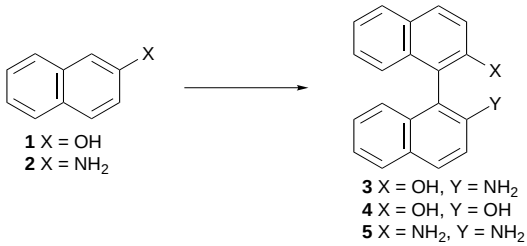
The $FeCl_3$-mediated, heterogeneous cross-coupling of the title compounds (1 + 2 → 3) has been re-examined and formation of the molecular crystal (1 + 2) shown to be irrelevant to the selectivity observed; a comparison of Fe^{III} and Cu^{II} as reagents is presented.

Oxidative self-coupling of 2-naphthol **1** is a well known reaction; the resulting BINOL **4** constitutes a pivotal intermediate in the synthesis of numerous chiral ligands, such as BINAP and MOP.[2] A number of mild oxidants have been reported to effect this coupling, in particular Cu^{II}, Fe^{III} and Mn^{III} salts.[3]

In a recent paper, Ding *et al.*[1] reported on the Fe^{III}-mediated, two-phase oxidative cross-coupling of the title compounds to produce (±)-2-amino-2′-hydroxy-1,1′-binaphthyl (NOBIN) (**1** + **2** → **3**, Scheme 1) and rationalised this outcome as being due to the unique formation of the molecular crystal **1** + **2** prior to the reaction. We challenge this communication for the following reasons. Firstly, in 1991, we had published the very same cross-coupling (**1** + **2** → **3**), mediated by Cu^{II} in a methanolic solution,[4,5] which demonstrates that this selectivity is not exclusive to the heterogeneous system. Secondly, this is not the only case of a highly selective cross-coupling; there are about twenty examples of this kind known to date which all occur in a homogeneous solution.[4–8] Thirdly, Ding's mechanism[1] is in conflict with that proposed by us.[6] Here we present a direct comparison of Ding's protocol with our published procedure and offer evidence which does not support the mechanism proposed by Ding.

We have shown that 2-naphthol **1** and 2-naphthylamine **2** can be cross-coupled by treatment with a complex generated *in situ* from $CuCl_2$ and an amine, such as $BnNH_2$ or Bu^tNH_2; in a methanolic solution and under anaerobic conditions, the resulting NOBIN **3** is obtained in up to 85% yield. As by-products, we have detected the diol **4** (6%) and diamine **5** (2%). The presence of an amine is crucial for high conversion and selectivity;[4–7] if a chiral amine is employed, acceptable enantioselectivity is attained (46% ee in the case of **3** and up to ⩾99% ee for **4**).[5]

In contrast to the previous experiments, which were carried out in homogeneous solutions,[3–8] Ding *et al.*[1] used a suspension of the pre-formed mixture of **1** and **2** in water and $FeCl_3$ as the oxidant. At 55 °C the conversion was practically quantitative and the yields fo **3** were in the range of 71–82% in typical instances; **4** (13–19%) was identified as the only by-product, while **5** was not detected.



1 X = OH
2 X = NH_2

3 X = OH, Y = NH_2
4 X = OH, Y = OH
5 X = NH_2, Y = NH_2

Scheme 1

We have rationalised the striking preference for the cross-coupling as follows: in the pair to be cross-coupled, one partner has to be prone to a ready, one-electron oxidation (as documented by cyclic voltammetry and *ab initio* calculations) and the other should be capable of trapping the radical-like species thus generated;[6]‡ the coupling itself apparently occurs in the co-ordination sphere of the metal (*vide infra*).[5b,6,8d,8e] If the redox potentials of the two partners differ sufficiently (as is the case for **1** and **2** and several other combinations), high preference for the cross-coupling can be anticipated. On the other hand, if the latter difference is small, the reaction becomes non-selective and mixtures of cross- and self-coupled products are obtained.[6] Ding *et al.* proposed a different mechanism, according to which **1** and **2** form a molecular crystal (or a molecular compound) and the coupling occurs either in the solid state or at the boundary between the solid and liquid phases.[1] The favourable orientation of **1** and **2** in the latter crystal is then assumed to control the coupling reaction to produce mainly **3**, whereas the self-coupling processes, which would lead to **4** and **5**, are suppressed.[1]

Ding's molecular crystal (or compound) is, presumably, formed as a result of interaction of a weak Brønsted acid **1** with a weak base **2**. Therefore, the differences in the IR spectra and in the powder X-ray diffraction characteristics he reported for the crystal and the individual components[1] are not unexpected.§

In a typical experiment, carried out with a suspension of the molecular crystal in an aqueous solution of $FeCl_3$ at 55 °C, high preference for the cross-coupling was observed (82% of **3** and 14% of **4**), ¶‖ which was interpreted by Ding as evidence for the crucial role of the molecular crystal in controlling the chemoselectivity.[1] On the other hand, when solid **1** and **2** were added separately to an aqueous solution of $FeCl_3$ at 55 °C, very similar selectivity was observed (78% of **3** and 20% of **4**).[1] To account for this result, Ding suggested a rapid formation of the molecular crystal prior to the coupling.[1]**

We find little support for the proposed mechanism on the grounds of the experiments[1] presented. First of all, neither **1** nor **2** is entirely insoluble in water: 1 g of **1** is dissolved in 1 l of water at ambient temperature, while the same amount will dissolve in 80 ml of boiling water.[9] According to our experience, the solubility of **2** is similar to that of **1**.†† Hence, appreciable amounts of each of **1** and **2** must be dissolved under the reaction conditions both at room temp. and, especially, at 55 °C. This alone casts doubts on Ding's mechanism and suggests that the oxidative coupling does, in fact, occur in the aqueous phase and is controlled by the factors[6] we have identified. Furthermore, Ding observed a loss of selectivity when $FeCl_3$ was replaced by other Fe^{III} salts, namely $Fe_2(SO_4)_3$ or NH_4FeCl_4, as oxidants. We believe this is further in conflict

with Ding's hypothesis. Should the selectivity originate from the molecular crystal, the nature of the metal ligands would be irrelevant.‡‡

To address these issues, we have carried out the following experiment: equimolar amounts of **1** and **2** were dissolved in CH_2Cl_2 and stirred vigorously with an aqueous solution of $FeCl_3$ at room temp. for 48 h. With this two-phase system we obtained similar selectivity to that reported by Ding¶‖ (the ratio of **3**, **4** and **5** was 79 : 9 : 12, as revealed by GC), although the conversion (*ca*. 50%) was not as high, presumbably owing to the lower temperature and the lower concentration of the reactants in the aqueous phase in our case.

In conclusion, we have shown that the cross-coupling of **1** and **2**, suspended in an aqueous solution of $FeCl_3$, most likely occurs in solution (note that the reactants are sparingly soluble in water). The selectivity observed does not originate from the existence of the molecular crystal and can be attributed to the different redox properties of the reaction partners, as proposed earlier by us.[6] Since the product **3** is much less soluble than the reactants, its formation siphons off the reactants from the solution and the system obeys the Le Chatelier–Braun principle. Under these conditions, BINOL **4** is the main contaminant. When carried out in a methanolic solution with Cu^{II}, less BINOL is formed but some diamine **5** can be detected (*vide supra*).[6] These marginal differences between the two methods are presumably associated with the nature of the oxidant (Fe *vs.* Cu) rather than with the homogeneity or non-homogeneity of the reaction mixture. Carrying out the reaction in aqueous suspension appears to have the advantage of simplicity if racemic NOBIN **3** is required. However, its asymmetric verison remains to be developed if this method is to be competititve with the homogeneous protocol. The same conclusion holds for the synthesis of BINOL **4** by the self-coupling of **1**.

We thank the GAČR for grant No 203/97/1009, GAUK for grant No 86/95 and the Britisch Council and the University of Leicester for additional support.

Notes and References

† E-mail: pk10@le.ac.uk

‡ Ding *et al.* [ref. 3(*k*)] proposed an analogous mechanism for the self-coupling of **1** to give **4** after our original communication (ref. 6).

§ Ding has reported the following IR peaks: **1**, 3250; **2**, 3375, 3290, 3170; **1** + **2**, 3350, 3260 cm^{-1}. Our values (obtained in substance by means of the 'Golden Gate' technique) were as follows: **1**, 3197; **2**, 3390, 3302, 3197; **1** + **2**, 3363, 3275 cm^{-1} (or 3364, 3357 sh, 3283 cm^{-1} for a suspension of the latter mixture in fluorolube). On the other hand, a 10^{-3} M solution of the mixture in CCl_4 represented a clear superposition of the spectra of the two components. All this indicates a strong intermolecular hydrogen bonding between **1** and **2** in the solid state, which disappears on dissolving in a nonpolar solvent; therefore, selective pairing in protic solvents, such as water or alcohols, is unlikely.

¶ A rigorous, quantitative interpretation of Ding's experiments is difficult. Based on the HPLC analysis, he claimed to obtain **3** (82%) and **4** (14%) at 100% consumption of **1**. Since *two* molecules of **1** are required to form **4**, these yields would appear to be impossible since the total would exceed 100% (see note ‖).

‖ We have repeated Ding's experiment. A capillary GC (using a DB5 column, 15 m × 0.5 mm, at 220 °C) with FID gave a 90 : 8 : 2 ratio of **3**, **4** and **5** in the crude product.

** In this instance, the molecular crystal is presumably formed in an equilibrium process that involves partial dissolving of each of the components and crystallisation of the less soluble molecular crystal.

†† Note that both **1** and **2** can be purified by crystallisation from hot water.

‡‡ The ligands' crucial role is further evidenced by asymmetric induction, observed in the presence of enantiopure amines (ref. 5). Moreover, this effect indicates that the coupling does occur in the co-ordination sphere of the metal (or, at least, in its vicinity) (ref. 5), rather than *via* a free-radical species. For details and further discussion, see refs. 5(*b*), 8(*d*) and 8(*e*).

Five-membered aliphatic guests X(CH$_2$)$_3$Y (X, Y = Me, OH, Cl, Br) adopt equilibrium positions in the asymmetric *p-tert*-butylcalix[4]arene cavity formed in the solid state and reveal a marked aversion of the host pocket for halogen end-groups.

Weak interactions are expected to play an important role in the construction of complex materials *via* self-assembly processes.[1] Although there are many studies of interactions involving H-bonding or π-stacking, there appear to be few methods where the relative importance of other weak interactions can be gauged in an unambiguous way.[2] Here we report on the use of the deep pocket in solid *p-tert*-butylcalix[4]arene host–guest materials as a site for testing relative interaction strengths, a concept also explored for guests in channel clathrates.

Recently we have reported the preparation and structural characterization of *p-tert*-butylcalix[4]arene (*t*-BC) compounds with aliphatic guests.[3] One example is the compound with pentane where the diffraction studies show that the guest molecule is inserted along the four-fold symmetry axis of the calix in the all-*trans* conformation with one methyl group deeply inserted in the calix cavity. It is therefore quite interesting that the ^{13}C NMR spectrum of the solid shows the presence of a single methyl resonance with a chemical shift close to where it is expected for pentane in solution (**1**, Table 1) rather than resonances for inequivalent methyls with one resonance shifted upfield by *ca*. 5 ppm owing to ring current effects from the four proximate aromatic rings of the calix.[4,5] The conclusion is that the pentane molecule can invert itself in the cavity on an NMR timescale. This process probably involves low concentrations of transient *gauche* isomers invisible in the diffraction experiment. The important conclusion is that linear molecules with an equivalent length of up to five carbon atoms are free to take up equilibrium orientations and conformations inside the calix cavity. This differs from monosubstituted and *para*-disubstituted aromatic guests in *t*-BC,[5,6] where the orientation of the guest is locked in during crystallization. The strongly asymmetric calix cavity therefore offers the unique possibility of using the deep pocket as a test site for molecular recognition for molecules of the type X(CH$_2$)$_3$Y (Table 1). A somewhat similar strategy has been followed in the pursuit of end group interaction energies for guests in channel clathrates.[12]

Table 1 45.3 MHz ^{13}C CP MAS NMR chemical shifts for the guest in *p-tert*-butylcalix[4]arene·guest compounds **1**–**5**; $\Delta\delta$ refers to the difference in the guest carbon chemical shift between $CDCl_3$ solution and the host

Guest X(CH$_2$)$_3$Y	X	Y	Carbon chemical shifts

[a] Solid-state NMR spectra were obtained on a Bruker CXP-180 spectrometer under cross-polarization and magic angle spinning conditions. Probe: Bruker 7 mm; number of acquisitions 200–500; recycle time 4 s; 90° pulse 3.5 μs; contact time 3–5 ms; 4 K data points acquired and zero-filled to 16 K before processing; spectral width = 20 kHz; ν = 3.5 kHz. [b] The guest resonance in the solid is hidden under host resonances.

Examination of the ^{13}C NMR spectra of the guest inclusions with 1-chlorobutane and 1-bromobutane indicates that in this case the methyl resonances show the expected high field shifts for methyl groups inserted deeply inside the cavity (Table 1). This implies that the halogens are excluded from the cavity. A single-crystal X-ray diffraction study of the 1-chlorobutane compound confirms that this is indeed the case (Fig. 1).‡ The alkyl chain is inserted in the pocket, with the chlorine outside the cavity and situated just off the calixarene four-fold axis. The depth of penetration is limited by the unusual conformation of the chain which places C^2 and C^3 in close contact with the calix walls. We can exclude the influence of Cl···Cl interactions on the guest orientation,[2,7] as the Cl atoms are at least 6 Å apart. Although the X-ray structure is not of as high a quality as the

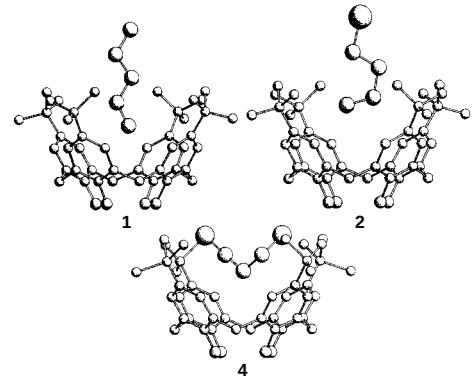

Fig. 1 Geometry of *p-tert*-butylcalix[4]arene inclusion compounds with pentane (**1**), 1-chlorobutane (**2**) and 1,3-dichloropropane (**4**). Only one of four symmetry-related guests is shown for **1** and **2**. For **4**, there is a second independent guest orientation, giving eight positions in all.

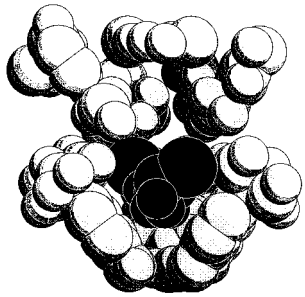

Fig. 2 A cutaway view of the highly anisotropic *p-tert*-butylcalix[4]arene cavity, showing the location of the 1,3-dichloropropane guest (**4**). The chlorophobic pocket is at the bottom in the cleft between aromatic rings.

others, the orientation of the guest is certain. Placing the chain with Cl in the cavity decreases the quality of the refinement.

Examination of the crystal structure of the compound with 1,3-dichloropropane (Fig. 1) is even more instructive, as now both chlorine atoms are excluded in favour of penetration of the cavity by a methylene group. The guest molecule is disordered equally over two orientations not related by symmetry which are in turn disordered equally about the compound's fourfold symmetry axis. Well defined positions for all guest atoms can be found, thus yielding eight possible orientations for the 1,3-dichloropropane guest. The carbon chemical shifts show only two guest lines (Table 1), indicating that the observed guest conformations are able to interchange. Considerable mobility of the guests is confirmed by dipolar dephasing experiments,[8] which show that both the terminal and central methylenes are mobile on an NMR timescale. It is interesting to note that the central methylene resonance is shifted by *ca*. 4 ppm, consistent with considerable penetration of the deep pocket by this group as observed in the diffraction study. This is also illustrated in Fig. 2, which shows a cutaway view of the calixarene cavity and illustrates its highly anisotropic nature. For the structure in question, the upper part of the cavity is occupied by a water molecule for about half the cages in the structure.

Since the steric requirements for a chlorine atom and a methyl group are very similar, one must conclude that there are very specific electronic effects that cause the exclusion of the chlorine atom. It is clear that the approach presented here is able to distinguish quite small energy differences. For instance, for **2**, complete exclusion of Cl requires that the energy difference between Cl_{in} and Cl_{out} is at least *ca*. 4 *kT*, *ca*. 10 kJ mol^{-1}.

It is not expected that dipole moments play a determining role in orienting the guest. This was checked by studying a *t*-BC compound with an *n*-butanol guest. It is clear from the NMR results that for this guest (**5**) there is little or no preference for either CH_3 or OH in the deep pocket (Table 1). The diffraction results indicate that the guest is located in the structure as a *gauche* conformer with the penetrating group on the axis (as in **2**). It makes no difference to the refinement whether OH or CH_3 is taken to be the penetrating group. Interactions involving acidic H such as O–H$\cdot\cdot\pi$ and alkyne C–H$\cdot\cdot\pi$ interactions have been duly studied.[2,9,10] More specifically, interactions between electron-rich calix[4]resorcarene hosts and CH-containing guests have been described in terms of a polarization-induced dipole interaction between a soft base (the host) and soft acid (the guest).[11] In the *n*-butanol case, the O–H$\cdot\cdot\pi$ interaction seems to be no stronger than the interaction of the aliphatic methyl group with the calix pocket. As well as being polarizable (*i.e.* soft) the *t*-BC cavity is also basic due to the electron-donating CH_2, Bu^t and OH substituents on the aromatic rings that form the deep pocket. While the OH group is more acidic than the CH_3 group, it is also less polarizable (*i.e.* harder) and the observed lack of specificity likely reflects a balance between the hard/soft and acid/base characteristics of the guest end groups. For the Cl-bearing groups in **2** and **4**, Cl is a hard base that does not show any attractive interaction with the soft and basic host, and thus gives rise to the observed orientations.

We note that the study of *t*-BC compounds with guests that have one more carbon atom per chain also are likely to give new insight, as preliminary X-ray diffraction evidence suggests that the hexane molecule forms a 2 : 1 compound with both ends inserted deeply in the *t*-BC pocket.

In conclusion, pentane-like linear guest molecules are free to take up equilibrium orientations and conformations inside the *p-tert*-butylcalix[4]arene cavity. The soft and basic *t*-BC pocket includes the guest deep in the cavity with the preference: $CH_3 \approx OH > CH_2 > Br, Cl$. It is hoped that modelling calculations should be able to provide significant new insight into the detailed nature of the interactions governing the guest orientations.

Enantioselective epoxidation catalysed by ruthenium complexes with chiral tetradentate bisamide ligands

Nicole End and Andreas Pfaltz*

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim an der Ruhr, Germany

Ruthenium complexes with chiral bis(dihydrooxazolylphenyl)oxalamide ligands catalyse the epoxidation of (*E*)-stilbene and (*E*)-1-phenylpropene with 69 and 58% ee, respectively, using $NaIO_4$ as oxidant.

The development of efficient catalytic methods for the enantioselective preparation of epoxides is an important objective of current research.[1–6] The most general and most effective catalysts available today are titanium–tartrate complexes for the epoxidation of allylic alcohols[6] and manganese–salen complexes[3,5] which allow the preparation of epoxides from certain *cis*-disubstituted, tri- and tetra-substituted alkenes with high ees. However, for other important classes of substrates such as terminal and *trans*-disubstituted olefins efficient enantioselective epoxidation catalysts are still lacking.

A method for the epoxidation of alkenes using $RuCl_3$, 2,2′-bipyridyl and $NaIO_4$ in a two-phase reaction medium has been reported.[7] Several attempts were made to render this system enantioselective by replacing bipyridyl with chiral ligands.[8,9] However, only low enantioselectivities have been obtained so far.

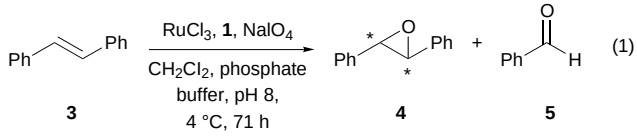
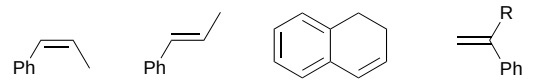
2a–e

a R = Me, **b** R = Pr^i, **c** R = Bu^t, **d** R = Bn, **e** R = Ph

We have recently developed an efficient synthesis of chiral C_2-symmetric oxalamides **1**, starting from readily available 2-(2-aminophenyl)oxazolines **2** and oxalyl chloride.[10] Oxalamides of this type possess a number of features which make them attractive ligands for enantiocontrol of metal-catalysed reactions, in particular for oxidations. A variety of differently substituted derivatives can be readily prepared in both enantiomeric forms starting from commercially available enantiopure precursors. The doubly deprotonated oxalamide **1** can act as a tetradentate ligand. Due to the π-acceptor properties of the α-dicarbonyl unit and the oxazoline rings, these ligands are expected to be quite resistant to oxidation and hence suitable for the formation of stable high-valent metal complexes. Here we report that ligands **1** can be used for the enantiocontrol of ruthenium-catalysed epoxidations.



In preliminary experiments, following Balavoine's procedure,[7a] with 2 mol% of $RuCl_3 \cdot H_2O$ and 2 equiv. of $NaIO_4$ in the presence of 12 mol% of ligand **1b**, (*E*)-stilbene was epoxidised in 31% yield with an ee of 43%. Higher ees and somewhat better yields were obtained when an aqueous buffer was used instead of water [Table 1, reaction (1)]. In addition to the desired



6 **7** **8** **9** R = H **10** R = Me

epoxide, significant amounts of benzaldehyde were formed. Control experiments showed that the epoxide **4** is stable under the reaction conditions. This implies that benzaldehyde is formed directly by oxidative cleavage of the olefin rather than by degradation of the epoxide.

Among the different oxalamides **1a–e**, the isopropyloxazoline derivative **1b** was found to be the most effective ligand. In contrast, the *tert*-butyloxazoline derivative **1c** gave poor ees and low yields of epoxide due to the formation of benzaldehyde, which is the main reaction in this case. Ligands **1a** and **1d** gave similar yields of epoxides as **1b** but somewhat lower ees. Interestingly, with ligand **1e** the opposite enantiomer of **4** was formed in 21% ee. In the absence of catalyst, (*E*)-stilbene was not oxidised by $NaIO_4$ under otherwise identical conditions. Replacing $NaIO_4$ by NaOCl resulted in very low yield and enantiomeric excess.

One of the problems in this reaction is the formation of benzaldehyde, which is rapid in the beginning (Fig. 1). In the initial period up to *ca*. 60% conversion, the alkene is consumed at about the same rate as benzaldehyde is formed while the formation of epoxide is much slower. The ee is very low in the beginning but increases significantly during the course of the reaction. We thought that these problems could possibly be overcome if the catalyst was treated with the oxidant prior to addition of the substrate. Indeed, the catalytic performance could be significantly improved using the following protocol. A suspension of $RuCl_3 \cdot H_2O$ (3.5 mg, 14 μmol) and ligand **1**

Table 1 Ruthenium-catalysed epoxidation of **3** using ligands **1a–e**

[a] Determined by GC integration based on tridecane as internal standard. The yields of **4** and **5** are based on the conversion of alkene. [b] Determined by GC using a chiral capillary column (Chiraldex γ-CD-TFA, 30 m × 0.25 mm, 1 bar H_2, 150–157 °C (0.5° min^{-1}), 157 °C (1 min), 157–180 °C (30° min^{-1}), t_R = 11.9/12.1 min). [c] The absolute configuration was determined based on the sign of the optical rotation, see ref. 13.

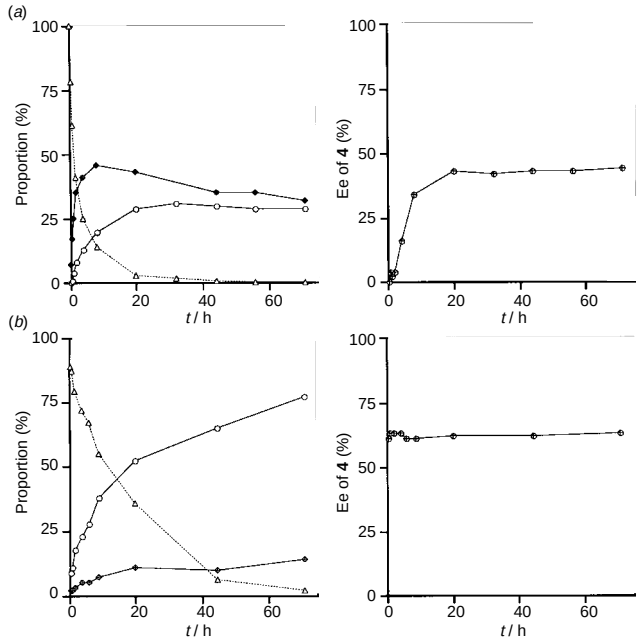

Fig. 1 Epoxidation of (*E*)-stilbene using ligand **1b** under (*a*) non-optimised (see text) and (*b*) optimised conditions: (△) **3**, (○) **4** and (◇) benzaldehyde **5**

(80 μmol) in aqueous buffer (2 ml, pH 8, 20 mM sodium phosphate) was stirred for 30 min at 4 °C. Subsequently, CH_2Cl_2 (3 ml) was added, followed by $NaIO_4$ (300 mg, 1.403 mmol). The resulting two-phase system was vigorously stirred for 4 h at 4 °C. Then (*E*)-stilbene (**3**) (125 mg, 0.694 mmol) was added and stirring continued for another 67 h. As shown in Fig. 1(*b*), the epoxide is now the major product and the enantiomeric excess remains constant during the reaction. Under these conditions **3** was converted to **4** in 74% yield (determined by GC based on tridecane as internal standard) with 69% ee. In a larger scale experiment with 3.5 mmol of **3**, the product **4** was isolated in 60% yield with the same ee after column chromatography. This is the best result obtained so far in the ruthenium-catalysed epoxidation of **3** with $NaIO_4$. After completion of this work, a ruthenium catalyst derived from a chiral bis(oxazolinyl)pyridine ligand was reported which gave up to 74% ee in the epoxidation of **3** with $PhI(OAc)_2$.[11] Interestingly, only benzaldehyde formation but no epoxidation was observed in this case when $NaIO_4$ was used as oxidant.

Using the same procedure, other alkenes were tested as substrates in the ruthenium-catalysed epoxidation with ligand **1b**. The epoxidation was found to be stereospecific for both (*E*)- and (*Z*)-alkenes. (*Z*)-1-Phenylpropene **6** was converted to the *cis*-epoxide in 50% yield with 25% ee. Significantly higher enantioselectivity was achieved for the epoxidation of the corresponding (*E*)-isomer **7** (58% ee, 40% yield). In this respect the ruthenium–oxalamide complexes resemble chromium–salen complexes[12] which also give higher ees with **7** than with the (*Z*)-isomer **6**, but differ from related manganese–salen or –porphyrin complexes[3–5] which afford higher ees for (*Z*)- than for (*E*)-olefins. Olefins **8**–**10** could not be used as substrates because the corresponding epoxides were not stable under the reaction conditions.

Binding of the uranyl moiety by an Amavadin-style complex; synthesis and characterisation of $[\{UO_2(H_2O)_3\}\{\Delta\text{-}V(hida)_2\}\cdot 2H_2O]_n$

Robert E. Berry, Paul D. Smith, Spencer M. Harben, Madeleine Helliwell, David Collison and C. David Garner*

Department of Chemistry, The University of Manchester, Oxford Road, Manchester, UK M13 9PL

$[\Delta\text{-}V(hida)_2]^{2-}$ (H_3hida = *N*-hydroxyiminodiacetic acid) and UO_2^{2+} form the solid $[\{UO_2(H_2O)_3\}\{\Delta\text{-}V(hida)_2\}\cdot 2H_2O]_n$ which is comprised of left-handed helical arrays, linked by H-bonding networks, in which the V^{IV} is eight-coordinate and the U^{VI} seven-coordinate.

Recent studies in these laboratories have established that 2,2′-(*N*-hydroxyimino)dicarboxylic acid proligands form a range of distinctive eight-coordinate complexes with early d-transition metal centres such as Ti^{IV}, V^{IV}, V^{V}, Nb^{V}, Ta^{V} and Mo^{V}.[1–5] This work was initiated by the discovery of Amavadin,[6] originally isolated from mushrooms of the genus *Amanita* and constituted as a 1 : 2 complex of V^{IV} with (*S*,*S*)-2,2′-(*N*-hydroxyimino)dipropionic acid (H_3hidpa).[7] Amavadin possesses a novel eight-coordinate geometry, with each $hidpa^{3-}$ ligand bonding *via* an η^2-NO group and two unidentate carboxylate groups. This coordination geometry leads to chirality at the vanadium and the isolated natural product Amavadin contains an approximately equimolar mixture of the Δ- and Λ-isomers of $[V\{(S,S)\text{-}hidpa\}_2]^{2-}$.[1,8] Amavadin-style anions form extended structures with cations such as Ca^{2+} *via* bridging caboxylate groups.[4,5] We have explored the possibility of extending this 'cation-trapping' by Amavadin-style complexes to other metals and, herein, we report the synthesis and characterisation of $[\{UO_2(H_2O)_3\}\{\Delta\text{-}V(hida)_2\}\cdot 2H_2O]_n$ **I** [H_3hida = 2,2′-*N*-hydroxyimino(diacetic acid)].

I was formed by the addition of $UO_2(O_2CMe)_2\cdot 2H_2O$ to an aqueous solution of $H_2[\Delta,\Lambda\text{-}V(hida)_2]$[9] and obtained as brown prismatic crystals.† The V^{IV} centres (Fig. 1) consist exclusively of $[\Delta\text{-}V(hida)_2]^{2-}$ moieties, each with the eight-coordinate geometry characteristic of Amavadin[1] with two mutually *trans* η^2-NO groups and four unidentate carboxylate groups. The dimensions of the V^{IV} centres are very similar to those obtained previously for this anion and its close relatives.[1,4,8,12] A striking aspect of **I** is that only the Δ-form of $[V(hida)_2]^{2-}$ was observed in the crystal subjected to X-ray crystallographic analysis; no vanadium-containing material remained in solution after crystallisation and we presume that a racemic mixture of 'left' and 'right' handed crystals was produced and one hand was arbitrarily selected for study.

In **I**, each U^{VI} centre is seven-coordinate (Fig. 1) with a pentagonal bipyramidal coordination geometry; the *trans* oxo-groups [O(11) and O(15)] are the axial ligands and the equatorial plane is comprised of three H_2O molecules [O(12), O(13) and O(14)] and two carboxylate oxygens from different $[\Delta\text{-}V(hida)_2]^{2-}$ centres [O(2*) and O(9)]. An approximate twofold axis of symmetry is located along the U–O(13) bond; O(11)–U–O(15) is effectively linear [177.1(6)°] and perpendicular (90.0°) to the least-squares plane of U and the five equatorial oxygen atoms; O(9) and O(14) sit above (0.05 and 0.06 Å, respectively) and U, O(12), O(13) and O(2*) sit below (−0.01, −0.02, −0.02, −0.06 Å, respectively) the least-squares plane. This coordination geometry is well known for seven-coordinate U^{VI} compounds[13] and may be directly compared with that of $[UO_2(orotato)_2(H_2O)_3]$‡,[14] which involves two orotato ligands in *cis* positions in the equatorial plane each coordinated *via* a unidentate carboxylate group. The U–O distances of **I** are similar to those in $[UO_2(orotato)_2(H_2O)_3]$ and related U^{VI} complexes.[13,14]

The unit cell of **I** is comprised of four identical and parallel left-handed helical chains centred on cell edges, each contributing its atoms to four unit cells; each turn of the helix is composed of six V^{IV} and six U^{VI} centres (Fig. 2). There are four solvent fragments in the lattice beyond the helical chains which, in the crystallographic refinement, were assumed to be H_2O molecules at 0.5 occupancy each. There is a network of short interhelix contacts, consistent with extensive H-bonding throughout the lattice, in particular: the uranyl *trans* oxo-groups H-bond to protons on different anions in neighbouring chains, O(15)···H(6b) and O(11)···H(3b) (2.4, 2.4 Å, respectively); and the water molecule O(13) coordinated to the U^{VI} has close contacts with carboxylates on different helical chains, O(13)···O(4) and O(13)···O(7) (2.5, 2.5 Å, respectively); these carboxylates also have close contacts with hydrogens on neighbouring anions, O(4)···H(7b) and O(7)···H(2b) (2.6, 2.7 Å, respectively); uncoordinated water molecules also have close contacts with water molecules coordinated to U^{VI}, O(12)···O(17) and O(14)···O(16) (2.7, 2.7 Å, respectively).

The IR spectrum of **I** contains ν(C=O) bands at 1637, 1617, and 1587 cm^{-1} and the different frequencies are consistent with the different roles of the carboxylate groups in bridging to the U^{VI} centres (Fig. 1). The ν(O=U=O) asymmetric stretching

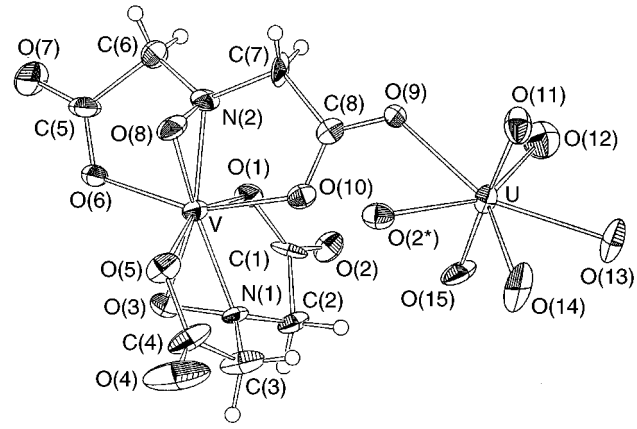

Fig. 1 V^{IV} and U^{VI} centres of **I**: selected bond lengths (Å) and interbond angles (°) U–O(2*) 2.36(1), U–O(9) 2.35(1), U–O(11) 1.71(2), U–O(12) 2.42(2), U–O(13) 2.39(1), U–O(14) 2.47(1), U–O(15) 1.69(2), V–O(1) 2.06(1), V–O(3) 1.95(2), V–O(5) 2.08(1), V–O(6) 2.07(1), V–O(8) 1.89(2), V–O(10) 2.05(2), V–N(1) 2.01(2), V–N(2) 1.95(2); O(2*)–U–O(9) 76.0(4), O(2*)–U–O(11) 92.1(7), O(2*)–U–O(14) 71.1(5), O(2*)–U–O(15) 90.3(7), O(9)–U–O(11) 88.9(7), O(9)–U–O(12) 72.2(5), O(9)–U–O(15) 93.1(6), O(11)–U–O(12) 90.1(8), O(11)–U–O(13) 89.8(7), O(11)–U–O(14) 88.5(8), O(12)–U–O(13) 69.0(6), O(12)–U–O(15) 88.6(8), O(13)–U–O(14) 71.9(6), O(13)–U–O(15) 87.3(8), O(14)–U–O(15) 90.9(8). The dihedral angle between {VNO} planes is 85.34°. * Indicates an atom derived by symmetry.

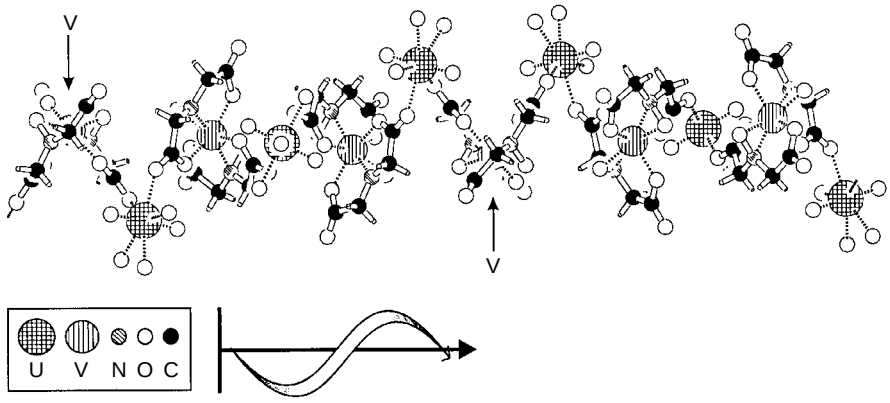

Fig. 2 Representation of a left-hand helical chain of **I**

frequency is manifest in the IR spectrum by a sharp absorption at 930 cm^{-1}.

Solid state reflectance UV–VIS data reveal absorptions due to the uranyl moiety, composed of progressions (average separation 625 cm^{-1}) arising from UO_2^{2+} symmetric stretching centred at 22 700 cm^{-1}; as well as d–d bands due to the V^{IV} centre at 12 100, 14 400 and 18 800 cm^{-1} and charge transfer transitions at $>26\,300$ cm^{-1}.

The EPR spectrum of a polycrystalline powder of **I** at Q-band frequency at room temp. comprises a single broad (ΔB_{p-p} 235 G) line with a very asymmetric derivative shape indicative of axial symmetry with $g_{\|} = 1.932$, $g_{\perp} = 1.979$. This is consistent with a magnetically concentrated sample arising from the relatively short inter- and intra-helix V–V distances.

The 'trapping' of metal cations by Amavadin-style anions may allow the selective binding of cations, either to immobilise them or for ion exchange.[15] In this context it is of interest to note that competition experiments have demonstrated the preferential precipitation of UO_2^{2+} by the diffusion of MeOH into an aqueous solution of $H_2[V(hida)_2]$ containing equimolar amounts of UO_2^{2+} and Ca^{2+}.

† [VO(pentane-2,4-dionate)$_2$] (0.13 g, 0.5 mmol) was added to a stirred solution of H_3hida (0.15 g, 1 mmol) in H_2O (5 cm^3) at room temp.;[9] after dissolution, $UO_2(O_2CMe)_2{\cdot}2H_2O$ (0.21 g, 0.5 mmol) was added and the solution stirred for *ca.* 3 h. Crystals of **I** suitable for X-ray diffraction were grown by slow vapour diffusion of MeOH into the reaction solution at 275 K. Analysis. Found: C, 14.2; H, 2.5; N, 4.0; U, 33.1 V, 7.4. Calc. for $C_8H_{18}N_2O_{17}UV$: C, 13.7; H, 2.6; N, 4.0; U, 33.9; V, 7.2%. *X-Ray crystal data for* **I**: $C_8H_{20}N_2O_{17}UV$, M = 705.22, hexagonal, space group $P6_5$ (no. 170), a = 9.534(2), c = 38.300(3) Å, U = 3014(1) $Å^3$ (by least squares refinement on diffractometer angles of 25 automatically centred reflections), λ = 0.710 69 Å, Z = 6, $F(000)$ = 1998, D_c = 2.330 g cm^{-3}, μ = 85.99 cm^{-1}, brown prismatic crystal of dimensions 0.20 × 0.22 × 0.25 mm. Data were collected at 296 K using a Rigaku AFC5R diffractometer with graphite monochromated Mo-Kα radiation and a rotating anode generator. A total of 3988 reflections were measured in the ω scan mode to a $2\theta_{max}$ of 50.1°, which gave 1849 independent reflections (R_{int} = 0.035). An empirical absorption correction was applied, based on the azimuthal scans of several reflections (transmission factors: 0.6784–1.00). A decay correction was also applied (1.39% decline). 1587 reflections had $I > 1.50\sigma(I)$. The structure was solved by direct methods[10] and expanded using Fourier techniques.[11] The non-hydrogen atoms were refined anisotropically except for O(12) and the disordered water molecules O(16)–O(19), which were refined isotropically. Hydrogen atoms were included but not refined. Refinement of the 255 variables converged with R = 0.044, R_w = 0.037. Max., min. peaks in the final difference map 0.96, −0.93 e^- $Å^{-3}$.

Careful consideration was given to the space group symmetry. There were four possible options, $P6_1$ and $P6_122$ and the alternative hands $P6_5$ and $P6_522$. The absolute configuration was determined by carrying out refinements in each space group using all of the observed data, including equivalent reflections. The detailed arguments which led to the selection of $P6_5$ as the correct space group are available as supplementary material from the corresponding author. CCDC 182/752.

‡ $[UO_2(orotato)_2(H_2O)_3]$ = dioxobis(1,2,3,6-tetrahydro-2,6-dioxo-4-pyrimidinecarboxylato)triaquauranium(VI).

Novel color isomerism and catalytic activities of Cu(salen) complex encapsulated in a zeolitic matrix

Subratanath Koner*

Catalysis Division, National Chemical Laboratory, Pune 411 008, India

The green zeolite encapsulated Cu(salen) complex on treatment with MeCN turns red and is found to be catalytically active towards oxidation reactions whereas the green species is inactive.

The development of efficient biomimetic oxidation catalysts containing metal complexes of porphyrins, phthalocyanines, Schiff-bases, *etc.* which mimic the active sites of metalloenzymes has received a lot of attention.[1] The oxidation reactions catalyzed by metal complexes are often impeded due to oxidative degradation of the complex and/or the formation of μ-oxo dimers.[1c] Several strategies, *viz.* encapsulation of those complexes within zeolitic[2,3] or polymeric matrices[4] or intercalation in clays,[2] have been adopted to enhance the stability and reactivity of such catalysts. It is now well understood that encapsulation of these complexes in zeolitic hosts can enhance the catalytic performance of the complexes in comparison to their homogeneous counterparts used in solution.[1c]

Here, we report the preparation, novel physicochemical properties and unique catalytic behavior of a zeolite (NaY) encapsulated Cu(salen) [salen = *N*,*N*′-bis(salicylaldehyde)-ethylenediimine] complex [Cu(salen)-NaY].

To prepare Cu(salen)-NaY, 2 g of calcined Cu-NaY† zeolite was mixed with 2 g of salen and placed in a sealed glass tube containing dry N_2 and heated at 150 °C with occasional stirring for 5–6 h. The green mass thus formed was then pulverized and subjected to Soxhlet extraction with MeOH and Me_2CO. The extracted green solid was then stirred with the portions of fresh MeCN several times. To our surprise during the stirring with MeCN the green mass transformed in to a red solid within a few min whereas treatment of Cu(salen) with MeCN or recrystallization of the complex from the same solvent gave no such color change. Although there is ample evidence of metal complexes recrystallized from different solvents giving different colors owing to the formation of different isomers or conformers[5,6] the present type of color isomerism among zeolite encapsulated metal complexes is rarely observed. No color change is observed when the green species is treated with other sovlents such as EtOH, Pr^iOH, CH_2Cl_2, $CHCl_3$, *etc.* Elemental analysis showed the Cu content of this solid was *ca.* 0.06%, which corresponds to encapsulation of *ca.* 26 molecules of [Cu(salen)] per 100 supercages in this solid. The Cu content of the green solid is virtually the same.

A relatively weak band in the visible region in the electronic spectra of the prepared catalysts and pure complex {590 nm for [Cu(salen)] and Cu(salen)-NaY(green); 558 nm for Cu(salen)-NaY(red)} is assigned to d–d transitions whereas two fairly strong bands appearing in the range 410–280 nm are assigned to ligand charge transfer bands {370 and 286 nm for the red and green species and 406 and 355 for the [Cu(salen)] complex} (Fig. 1).[5] All the prominent IR bands for ligand vibrations appearing in the region 1700–1250 cm^{-1} of the [Cu(salen)] species are also present in Cu(salen)-NaY. The ligand vibration bands in the other regions are obscured by the presence of zeolitic vibration bands. The principal *g* values calculated by usual methods from EPR spectra (Fig. 2) are in agreement with those reported for Cu^{II} Schiff base complexes.[7] The $g_{\|}$ and $g_{\perp}$ values of the red and green species of Cu(salen)-NaY and for [Cu(salen)] are 2.189, 2.178, 2.176 and 2.041, 2.039, 2.044, respectively.

All the above results convincingly demonstrate the presence of the [Cu(salen)] chromophore in both varieties of Cu(salen)-NaY catalysts. The shifting of the d–d transition band to shorter wavelength in electronic spectra of the red species in comparison to the green species clearly indicates that the axial ligand field around the Cu^{II} ion is weaker in the former.[6b,8b] EPR spectra are in accord with this as $g_{\|}$ values of the red species are higher than that of the green species whereas the $g_{\perp}$ values are almost the same. It is well documented that a decrease of axial ligand interaction with Cu^{II} in these types of complexes leads to a red-shift of d–d transition bands and an increase in $g_{\|}$.[6b,8] It is also noteworthy that the resolution of IR spectral bands for ligand vibrations of the red species is higher than the green species suggesting that the Cu(salen) moiety in the red species is more comfortably enclosed inside the zeolitic supercage than in the green species; which also indirectly indicates that the interaction between the Cu(salen) moiety and the zeolitic matrix in the red species is much weaker than in the green species. Therefore, it can be proposed that in the green species, Cu^{II}

	1-Naphthol	12	16.8	1,4-Naphthoquinone[a]
Cu(salen)-NaY(green)	Norbornene	12	0.1	—[b]
	1-Naphthol	12	0.2	—[b]

[a] Selectivity = 100 (mass%). [b] No expected oxidized products are detected.

forms weak Cu–O bonds with zeolitic oxygen to give either square-pyramidal or octahedral geometry around the Cu^{II} ion, which upon treatment with MeCN becomes square planar. The formation of weak Cu–O bonds between the Cu^{II} ion and zeolitic oxygen can not be ruled out since recently it has been shown by single crystal X-ray analysis that Cu(salen) forms dimers through weak Cu–O (O-salen) bonds in the solid state.[5]

The epoxidation of norbornene and hydroxylation of 1-naphthol were carried out in a glass batch reactor using TBHP (*tert*-butyl hydroperoxide) as oxidant. MeOH was used as solvent for Cu(salen)-NaY(green) while MeCN was used for Cu(salen)-NaY(red). In a typical reaction, 0.1 g of catalyst was slurried in a batch reactor with 10 g of MeCN or MeOH. To this, 0.5 g of oxidant was added and the mixture allowed to equilibrate at 50 °C in oil bath. After *ca.* 10 min the substrate was added and products collected at different time intervals and identified and quantified by GC and verified by GC–MS.

Results for both reactions (Table 1) established that the Cu(salen)-NaY(red) catalyst showed excellent product selectivity as well as activity towards oxidation reactions with exclusively one oxidized product being obtained in each case. Selectivity of products to this extent is rare among zeolite encapsulated metal complex catalysts. For the 1-naphthol hydroxylation reaction 1,4-naphthoquinone is selectively obtained among the three possible products (1,4-naphthoquinone, 1,4-dihydroxynaphthalene, 1,2-dihydroxynaphthalene)[9] whereas for norbornene only *exo*-epoxynorbornane is obtained, where *exo*- and *endo*-epoxynorbornane, cyclohexene-4-carbaldehyde and norcamphor are all possible products.[10] On the other hand Cu(salen)-NaY(green) does not show any activity towards these reactions. It should be noted that Cu is not detected in the liquid phase of the reaction mixtures (the solid catalyst is separated from the mixture by filtration at *ca.* 50 °C) after completion of experiment. Therefore, the Cu complex is not leached from the catalysts during reaction.

In conclusion, it can be stated that the catalytic activity of Cu(salen)-NaY changes dramatically with change in the coordination geometry around the Cu^{II} ion in the zeolite. The Cu(salen)-NaY(red) catalyst where Cu^{II} ion appears to possess vacant axial positions shows activity[1e,5] towards oxidation reactions whereas the green variety, where Cu^{II} ion is either five- or six-coordinate, is inactive. Further this work is a novel example where a metal complex encapsulated in a zeolitic matrix shows color isomerism upon treatment with a specific solvent.

† Cu-NaY was prepared by stirring a slurry of NaY in $Cu(NO_3)_2$ solution [1 g NaY with 0.25 g $Cu(NO_3)_2$ dissolved in 200 ml of water] at room temp. In order to control the quantity of Cu^{II} exchange in NaY-zeolite a relatively dilute $Cu(NO_3)_2$ solution was used and the stirring time was fixed at 30 min. The Cu content in the solid is found to be *ca.* 0.075%. Cu(salen)-NaY(green) was prepared following the same procedure as above (main text) avoiding treatment with MeCN. The catalysts were calcined at 120 °C for 8–10 h in dry N_2 before use in reactions. To re-exchange the unreacted Cu^{II} present in both the green and red solids by Na^+ ions they were repeatedly stirred in $NaNO_3$ solution for several hours.

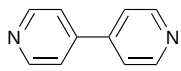
X-Ray crystal structure of $\{Cu[1,2\text{-bis}(4\text{-pyridyl})ethane]_2(NO_3)_2\}_n$: the first example of a coordination polymer that exhibits the NbO 3D network architecture†

K. Nicole Power, Tracy L. Hennigar and Michael J. Zaworotko*

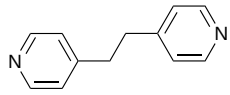
Department of Chemistry, Saint Mary's University, Halifax, Nova Scotia, B3H 3C3, Canada

The coordination polymer $\{Cu[1,2\text{-bis}(4\text{-pyridyl})ethane]_2(NO_3)_2\}_n$ does not exist as a square grid network, rather it is the first example of a twofold NbO type 3D network. A twofold level of interpenetration does not preclude the presence of 11 × 11 Å channels which contain benzene and methanol guest molecules.

Recent activity in crystal engineering has afforded several examples of coordination polymers which have open framework network structures and therefore have the potential to be functionally related to zeolites.[1–3] The architectures of coordination polymers can be either mineralomimetic or, more commonly, without precedence in naturally occurring solids. If simple linear spacer ligands such as 4,4′-bipyridine (4,4′-bipy) are utilized, the architecture of a coordination polymer is strictly limited by the stoichiometry. For example, a 1 : 1.5 ratio of T-shape, square planar or octahedral metal to 4,4′-bipy affords ladder,[4–7] brick-wall,[4] 3D frame[8,9] or bilayer structures.[7,10] These architectures, which can be regarded as being supramolecular isomers of one another,[7,10] are without precedence in naturally occurring compounds. If one considers a 1 : 2 ratio of square planar or octahedral metal to linear spacer ligand, there



4,4′-bipy

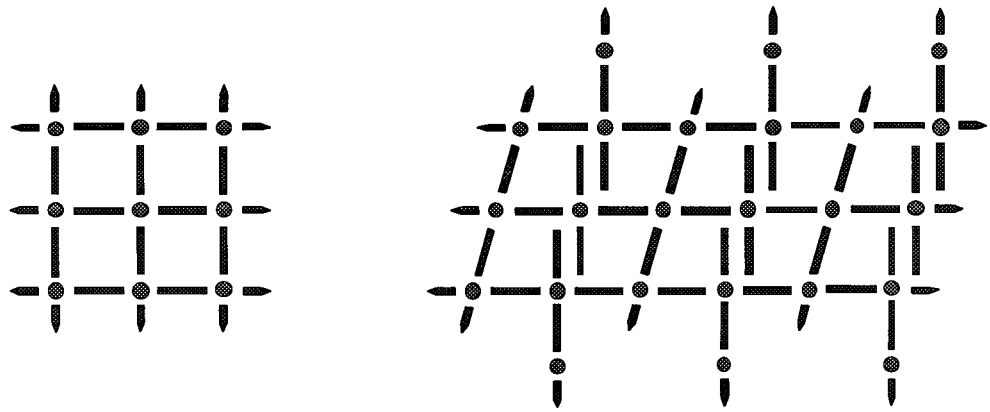


bpye

would appear to be only two likely supramolecular isomers, square 2D grids or 3D frames (Scheme 1). These supramolecular isomers could occur for either square planar or suitably substituted octahedral complexes. The former has been widely encountered in Hoffman clathrates[11] and 4,4′-bipy sustained networks[12–15] whereas the latter has to our knowledge only hitherto been observed in NbO.[16] In this contribution we report the structure of a copper(II) coordination polymer based upon the spacer ligand 1,2-bis(4-pyridyl)ethane (bpye) which represents, to our knowledge, the first example of a coordination polymer which exhibits the NbO type structure, $[Cu(bpye)_2(NO_3)_2]_n$ **1**.

Blue crystals of **1** were grown by carefully layering a methanol solution of $Cu(NO_3)_2 \cdot 6H_2O$ onto a benzene solution of bpye under ambient conditions. The ligand bpye is capable of adopting either *gauche* or *anti* conformations and can therefore act as either an angular or a linear spacer ligand, respectively.[7] As revealed by single crystal X-ray crystallography, the bpye ligands in **1** are *anti* and they sustain a 3D framework motif with channels of effective cross-section 11 × 22 Å.‡ In the structure there is a single network of **1**.† The large channels in a single framework of **1** facilitate twofold interpenetration with a second independent framework but do not result in a close-packed structure, rather, large square channels with effective cross-sectional area of 11 × 11 Å exist parallel to the crystallographic *a*-axis; these channels contain two ordered benzene molecules and one disordered methanol/benzene molecule per metal centre and crystals appear to lose solvent and crystallinity within minutes of their removal from the mother liquor.†

The coordination geometry around the Cu^{II} moiety can be regarded as pseudo-square planar since the nitrate anions are only weakly coordinated, Cu–O distances being 2.366(4) and 2.486(4) Å, significantly longer than those seen for octahedral Ni^{II} or Co^{II} analogues.[14] Other bond distances are within expected ranges. It is not clear from this study why **1** exists as a 3D NbO type framework rather than a 2D square grid framework of the type commonly exhibited by 4,4′-bipy analogues of **1**.[12–15] Indeed, we have now prepared more than twenty 4,4′-bipy square grid compounds and we have prepared more than ten bpye square grid compounds. The title compound still remains the only one that exhibits the NbO framework. It would not appear that the Jahn–Teller induced distortion from octahedral geometry is a likely factor for the observed structure since, in principle, both square planar and octahedral metal moieties should be able to sustain the NbO network. However, the length of bpye compared to 4,4′-bipy might be a factor. It is



Scheme 1

known that 4,4′-bipy sustained square grid coordination polymers can form close packed structures *via* interpenetration[12] or stable open framework structures through inclusion of aromatic molecules.[13–15] The larger cavity that would be formed by bype might not be as amenable to such behaviour. It should also be noted that bpye inherently possesses conformational flexibility and other supramolecular isomers based upon conformational isomerism[7] are therefore likely for **1**. The factors that affect the generation of supramolecular isomers of **1** and related coordination polymers, in particular the influence of guest and solvent, are currently being investigated further.

We acknowledge Dr C. Campana of Siemens Industrial Automation Ltd. for furnishing the X-ray data and the generous financial support of the NSERC (Canada) in the form of a research grant (M. J. Z.).

The first stable copper(II) complex containing four sulfide ligands: synthesis and structural characterization of $[Pt_2(dppe)_2(\mu\text{-}S)_2]$ and $[Cu\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2]^{2+}$

Mercè Capdevila,[a] Yolanda Carrasco,[a] William Clegg,[b] Robert A. Coxall,[b] Pilar González-Duarte,*[a] Agustí Lledós,*[a] Joan Sola[a] and Gregori Ujaque[a]

[b] *Department of Chemistry, University of Newcastle, Newcastle upon Tyne, UK NE1 7RU*

The synthesis and crystal structure of the novel heteropolymetallic aggregate $[\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2Cu][PF_6]_2$ 2 and of its precursor $[Pt_2(dppe)_2(\mu\text{-}S)_2]$ 1 are reported; 2 has been further characterized by EPR and electronic spectroscopies and the hinged Pt_2S_2 rings in 1 and 2 have been rationalized by *ab initio* MP2 calculations.

The ability of $[Pt_2L_4(\mu\text{-}S)_2]$ (L = phosphine) to behave as a metalloligand towards Lewis acids of p- and d-block elements is well reflected in the literature by a wide range of homo- and hetero-metallic aggregates with various nuclearities and structures.[1] However, structural data in dimeric platinum sulfide complexes are scarce and contradictory. The partially determined X-ray structure of $[Pt_2(PMe_2Ph)_4(\mu\text{-}S)_2]$ shows a hinged Pt_2S_2 ring (θ = 121°),[2] but the ring is strictly planar in $[Pt_2(dppy)_4(\mu\text{-}S)_2]$ (dppy = 2-diphenylphosphanopyridine).[3] Theoretical *ab initio* studies found a bent structure for the $[Pt_2(PH_3)_4(\mu\text{-}S)_2]$ complex.[4] Stimulated by the difficulty of stabilizating Cu^{II} in S_4 environments, relevant for the study of copper proteins, and based on the coordinative versatility of $[Pt_2L_4(\mu\text{-}S)_2]$, we targeted the synthesis of a copper(II) complex containing four sulfide ligands. The only X-ray structure of a heterometallic platinum sulfide aggregate, $[\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}Cu(PPh_3)]PF_6$,[1a] contains copper as Cu^{I}. The closest precedents to copper(II) complexes contain alkyl persulfide[5] and disulfide[6] ligands. We report the synthesis and X-ray structure of $[Pt_2(dppe)_2(\mu\text{-}S)_2]$ **1** and pentametallic $[Cu\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2](PF_6)_2$ **2**, MP2 *ab initio* calculations for the $[Pt_2(H_2PCH_2CH_2PH_2)_2(\mu\text{-}S)_2]$ complex **3** that can be taken as a model for **1**, and spectroscopic and magnetic features of **2**.

The preparation of $\mathbf{1}\cdot 2C_6H_6$ from $[PtCl_2(dppe)]$ and an excess of Na_2S in benzene by a standard method[7] led to a mixture of products. ^{31}P NMR measurements on aliquots of the reaction mixture allowed the determination of a satisfactory $[PtCl_2(dppe)]:Na_2S:$benzene ratio and of the appropriate reaction time. Slow evaporation of the mother-liquor gave orange crystals of $\mathbf{1}\cdot 2C_6H_6$ in *ca.* 90% yield,† whose structure‡ consists of neutral dinuclear molecules devoid of crystallographic symmetry elements (Fig. 1). Each molecule shows a hinged Pt_2S_2 central ring (θ = 140.2°) with the two platinum atoms bridged by two sulfide anions, coordination being completed by chelating dppe ligands. The geometries at the individual Pt sites are approximately square planar.

To understand the preference for the bent structure of **1** we have optimized complex **3** at the MP2 level§ yielding a hinged structure with θ = 118.8°. This result indicates the intrinsic preference of **3** to adopt a bent structure and allows us to disregard crystal packing effects as the cause for hinging. The energy difference with respect to an optimized structure with a fixed θ = 180° is 30.1 kJ mol^{-1} in favour of the former. This energy difference between the bent and planar forms is small enough for changes in the size of the terminal ligands to cause significant variations in the dihedral angle. Thus, **3** is more hinged (θ = 118.8°) than **1** (140.2°) and a further increase in the steric hindrance about P atoms, as happens in $[Pt_2(dppy)_4(\mu\text{-}S)_2]$, leads to planarity. Optimization of **3** with a fixed θ = 140° gives an energy only 10.0 kJ mol^{-1} above than that for θ = 118.8°. It is likely that the great coordinative versatility of $[Pt_2L_4(\mu\text{-}S)_2]$ is due to the low energy cost associated with the bending process. Moreover, this low energy cost would allow a ring reversal process and thus a fluxional behaviour in solution.[11]

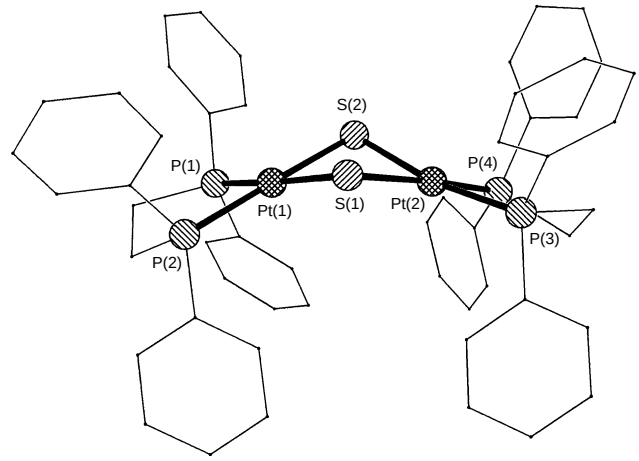

Fig. 1 View of the structure of $[Pt_2(dppe)_2(\mu\text{-}S)_2]$ in **1** with hydrogen atoms omitted, showing labelling of key atoms. Selected bond lengths (Å) and angles (°) of the Pt_2S_2 ring: Pt(1)–S(2) 2.3412(12), Pt(1)–S(1) 2.3554(12), S(1)–Pt(2) 2.3581(13), S(2)–Pt(2) 2.3437(12); S(2)–Pt(1)–S(1) 83.73(4), Pt(1)–S(1)–Pt(2) 88.60(4), Pt(1)–S(2)–Pt(2) 89.28(4), S(2)–Pt(2)–S(1) 83.61(4).

Mixing $Cu(PF_6)_2$ with **1** (1 : 2 molar ratio) in methanol gave rise to a dark solution that afforded red crystals of $\mathbf{2}\cdot 0.5Et_2O$.‡ As shown in Fig. 2, the crystallographically non-symmetrical cation $[Cu\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2]^{2+}$ comprises two $\{Pt_2S_2\}$ butterflies linked through sulfur to the Cu^{II} ion. The long S···S distance (3.1 Å) in each Pt_2S_2 moiety indicates the lack of a disulfido bond. The deviations from square-planarity around all platinum atoms are small and the hinge angles between PtS_2P_2 planes are 118.4 and 121.1°. There is a near-symmetrical chelation of both disulfide metalloligands **1** to the Cu^{II} centre. The distorted tetrahedral environment about the heterometal is shown by the two acute S–Cu–S bite angles of *ca.* 83.6° and by a torsion angle, ω = 60°, between the two S–Cu–S planes. Among the numerous geometries of the heterometal in the environment of $[Pt_2L_4(\mu\text{-}S)_2]$ there is no example where the former is tetrahedrally coordinated to two $[Pt_2L_4(\mu\text{-}S)_2]$ molecules.

The EPR spectrum of **2** in CH_2Cl_2 solution displays a signal at g_{iso} = 2.056. The hyperfine coupling constant to the copper ion (I = 3/2) A_{iso} was determined to be 58.5 × 10^{-4} cm^{-1}. The spectrum of a powdered sample of **2**, which consists of a nearly axial signal with no appreciable changes either at room

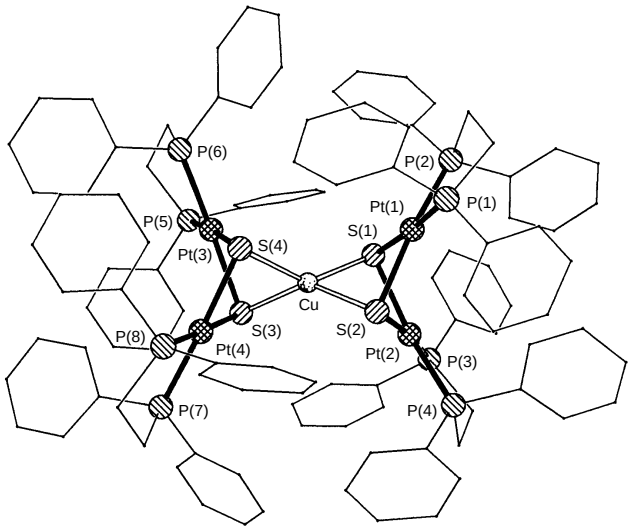

Fig. 2 The structure of the $[Cu\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2]^{2+}$ cation in **2** with key atoms labelled. Selected bond lengths (Å) and angles (°) of the $Cu\{Pt_2S_2\}_2$ core: Pt(1)–S(2) 2.355(2), Pt(1)–S(1) 2.375(3), S(1)–Pt(2) 2.362(2), S(2)–Pt(2) 2.365(2), S(1)–Cu 2.320(2), S(2)–Cu 2.318(3), S(4)–Cu 2.303(3), S(3)–Cu 2.316(3), S(3)–Pt(4) 2.359(3), S(3)–Pt(3) 2.364(3), S(4)–Pt(4) 2.366(2), S(4)–Pt(3) 2.372; S(2)–Pt(1)–S(1) 81.66(8), Pt(1)–S(1)–Pt(2) 80.86(7), Pt(1)–S(2)–Pt(2) 81.20(7), S(2)–Pt(2)–S(1) 81.75(8), S(2)–Cu–S(1) 83.65(8), S(4)–Cu–S(3) 83.54(9), S(3)–Pt(3)–S(4) 81.02(9), Pt(3)–S(3)–Pt(4) 82.98(8), Pt(3)–S(4)–Pt(4) 82.65(8), S(3)–Pt(4)–S(4) 81.26(8).

temperature or at 115 K, shows a partially good resolution of the copper hyperfine splitting, probably brought about by magnetic dilution afforded by the bulky phenyl groups of the dppe ligands on the diamagnetic $[Pt_2(dppe)_2(\mu\text{-}S)_2]$ moieties. Simple first-order spectral analysis yielded $g_z = 2.114$, $g_y = 2.055$ and $g_x = 1.994$, and $A_z = 124.4 \times 10^{-4}$, $A_y = 37 \times 10^{-4}$ and $A_x = 36 \times 10^{-4}$ cm^{-1}. These results agree with the distorted tetrahedral geometry and show that the heterometal is a copper(II) ion rather than copper(I) coordinated to a $[Pt_2(dppe)_2(\mu\text{-}S)_2]^+$ radical moiety. The unpaired electron resides in the d_{xy} orbital of the metal centre (with sulfur donor-atoms between the *x* and *y* axes).[12] No evidence of delocalization of the unpaired electron onto the platinum(II) ions has been found. Comparison of these features with EPR spectral patterns of the blue copper sites[13] indicates that $g_{x,y}$ and $A_{x,y}$ are similar, but those of the corresponding parallel parameters deviate significantly. This can be attributed to the different nature of the donor atoms bound to Cu and to the more flattened tetrahedral geometry about this metal centre in the case of the $[Cu\{Pt_2(dppe)_2(\mu_3\text{-}S)_2\}_2]^{2+}$ cation.[14]

The electronic spectrum of **2** in acetonitrile solution shows a very broad band with maximum intensity at $\nu_1 = 8550$ cm^{-1} (1170 mm, $\varepsilon = 740$ dm^3 mol^{-1} cm^{-1}), a band at $\nu_2 = 17\,700$ cm^{-1} (565 nm, $\varepsilon = 4400$ dm^3 mol^{-1} cm^{-1}), and a very strong absorption between 320 and 220 nm ($\varepsilon > 20\,000$ dm^3 mol^{-1} cm^{-1}). The position of ν_1 reveals that the distorted tetrahedral geometry of the copper ion in complex **2** is preserved in solution and compares well with the estimated value of 9800 cm^{-1} for the higher energy d–d band of a tetrahedral $CuCl_4$ core with the same degree of distortion ($\omega = 61°$) as **2**.[15] On the basis of an idealized D_2 symmetry the ν_1 band is assigned to the $^2B_1 \rightarrow {}^2A$ ($d_{z^2} \rightarrow d_{xy}$) transition. Following the EPR behaviour, both the position and the intensity of ν_2 are close to those of the characteristic band of the blue copper sites appearing at *ca.* 600 nm in stellacyanin, plastocyanin and azurin proteins. Therefore, ν_2 is assigned to a $\sigma(S) \rightarrow d_{xy}(Cu)$ LMCT transition.[13]

Catalytic disproportionation of hydrogen peroxide by calcium hydroxide generates singlet molecular oxygen $^1O_2$ ($^1\Delta_g$) through the diperoxohydrate peroxide $CaO_2{\cdot}2H_2O_2$ with a 50% yield based on the calcium peroxide.

Many inorganic compounds are known to induce the disproportionation of hydrogen peroxide into singlet oxygen ($^1O_2$, $^1\Delta_g$).[1] Among them, calcium hydroxide appears both attractive for its environmental friendly feature and amazing on account of the simplicity of the catalyst involved [eqn. (1)].

$$2\ H_2O_2 \xrightarrow{Ca^{II}} 2\ H_2O + \alpha\ {}^1O_2 + (1-\alpha)\ {}^3O_2 \qquad (1)$$

Although the formation of $^1O_2$ during reaction (1) has been established,[1] several points remain unclear: (*i*) the traps of $^1O_2$ bore carboxylate functions which precipitated partially in presence of the calcium salts, (*ii*) the calcium hydroxide did not have the highest purity commercially available, (*iii*) the influence of the main parameters on the reaction were not studied, (*iv*) no information was provided with regard to the nature of the precursor of $^1O_2$. Therefore, the system H_2O_2/Ca^{II} has been reinvestigated by resorting to two complementary techniques: the detection of the IR luminescence of $^1O_2$ at 1270 nm and the chemical trapping with a more suitable trap. In a second step, the nature of the precursor and the yield of $^1O_2$ were determined.

The monomol emission of $^1O_2$ was detected with a liquid-nitrogen cooled germanium diode equipped with a bandpass filter for 1270 ± 10 nm.[2] The assays were carried out in a thermostated cell at 50 °C filled with an aqueous (H_2O or D_2O) solution of H_2O_2 (1.0 M). After recording the baseline, solid CaO (0.2 M) of high purity (99.995%) was added and the photoemission of $^1O_2$ was monitored. The maximum values of the luminescence intensy I_p are reported in Table 1.

The luminescence intensity I_p was found to be strongly dependent on the deuteration of the solvent (Table 1, entries 1 and 2) as a ten-fold increase was observed in deuterated water (95%), in good agreement with the longer lifetime of $^1O_2$ in D_2O than in H_2O.[3] In a control experiment (Table 1, entry 3), it was shown that the disproportionation of H_2O_2 (1 M) induced by NaOH (0.4 M) did not provide any detectable signal in contrast with the finding of Smith and Kulig.[4] Accordingly, $^1O_2$ arises from the interaction between Ca^{II} and H_2O_2 and not from the base-catalyzed disproportionation of H_2O_2.

Table 1 Experimental conditions and emission intensity I_p of $^1O_2$ luminescence[a]

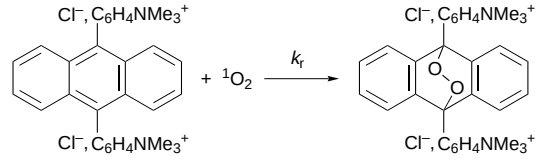
Entry	Calcium compound	$[H_2O_2]$/ mmol	[NaOH]/ mmol	Solvent	I_p/mV
1	CaO	5.0	—	H_2O	0.4 ± 0.1
2	CaO	5.0	—	D_2O	4.4 ± 0.5
3	—	5.0	2.0	D_2O	No signal
4	$CaO_2{\cdot}8H_2O$	—	—	D_2O	0.3 ± 0.1
				CD_3OD	0.5 ± 0.1
5	$CaO_2{\cdot}2H_2O_2$	—	—	D_2O	10 ± 0.5
				CD_3OD	98 ± 2

[a] Experiments were carried out with 1.0 mmol of calcium compounds at 50 °C in 5 ml of solvent.

The detection of $^1O_2$ *via* its IR luminescence requires a relatively high steady-state concentration of $^1O_2$.[5] Thus, experiments with the system H_2O_2/Ca^{II} were carried out in D_2O and with gentle warming (50 °C). On the other hand, specific chemical trapping worked in ordinary water, at room temperature, and was found to be more reliable for the quantification of $^1O_2$ than the spectral method. The new cationic water-soluble trap, 9,10-bis(4-trimethylphenylammonium) anthracene dichloride (BPAA), which efficiently reacts with $^1O_2$ giving a specific endoperoxide $BPAAO_2$ as the sole product,[6] was particularly suitable for these trapping experiments since it did not interfere with the catalytic reaction as the tetrapotassium rubrene-2,3,8,9-tetracarboxylate (RTC) did.[1] In presence of BPAA, $^1O_2$ arising from reaction (1) can either be quenched by water [eqn. (2)] and by BPAA [eqn. (3)] or react with this trap [eqn. (4)].[7]

$$^1O_2 \xrightarrow[\text{water}]{k_d} {}^3O_2 \qquad (2)$$

$$\text{BPAA} + {}^1O_2 \xrightarrow{k_q} \text{BPAA} + {}^3O_2 \qquad (3)$$



(4)

Under pseudo-stationary conditions ($d[^1O_2]/dt = 0$), processes (1)–(4) lead to eqn. (5) giving the rate of the disappearance of BPAA:

$$\frac{d[BPAA]}{dt} = -v(^1O_2)\frac{k_r[BPAA]}{k_d + (k_r + k_q)[BPAA]} \qquad (5)$$

where $v(^1O_2)$ is the rate of $^1O_2$ generation from reaction (1).

The concentration of BPAA used was very low (10^{-4} M) in order to minimize the disturbance of the process under study. Under these conditions, the quenching of $^1O_2$ by water is the main pathway for $^1O_2$ decay. Thus, $k_d \gg (k_r + k_q)$ [BPAA] and eqn. (5) reduces to eqn. (6) which allows calculation of $v(^1O_2)$ from the initial rate of BPAA disappearance, d[BPAA]/d*t*:

$$v(^1O_2) = -\frac{d[BPAA]}{dt}\frac{k_d}{k_r[BPAA]} \qquad (6)$$

In control experiments, it was shown that the oxidation of BPAA (10 mM) gives the expected endoperoxide $BPAAO_2$ identified by ^1H and ^{13}C NMR spectroscopy.[6] Accordingly, the

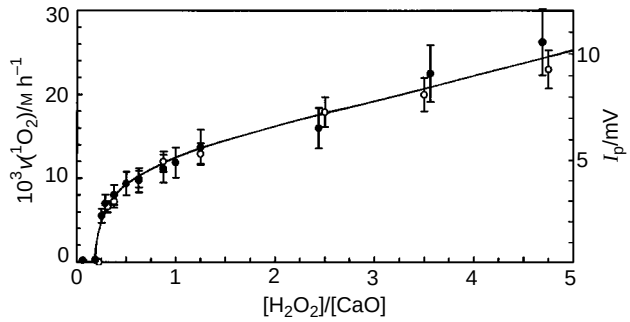


Fig. 1 $^1O_2$ formation as a function of [H_2O_2] detected by chemical trapping (○) (200 mM CaO, 0.1 mM BPAA, H_2O, 25 °C) or by IR luminescence at 1270 nm (●) (same conditions except D_2O, 50 °C)

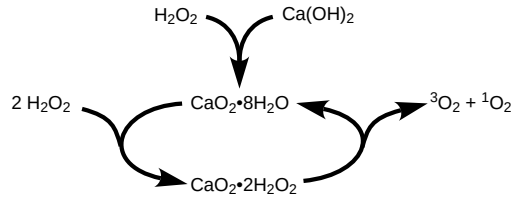
disappearance of BPAA could be confidently assigned to an oxidation through $^1O_2$. It was also shown that 50 mM CaO was able to disproportionate 500 mM H_2O_2 indicating that the Ca^{II} involved in process (1) acts as a catalyst. It is noteworthy that, whereas no H_2O_2 could be detected in the aqueous phase at the end of the reaction, the precipitate was found to contain exactly one peroxide group per Ca^{II} whatever the starting concentrations of H_2O_2 and CaO were. The final product is then probably the hydrated calcium monoperoxide $CaO_2{\cdot}8H_2O$ which is known to be stable in water.[8,9] The rate of $^1O_2$ formation was measured for various initial concentrations of H_2O_2 (Fig. 1).

This figure shows that the formation of $^1O_2$ requires at least 1 equiv. of H_2O_2. The reaction rate increases steeply at first and then moderately when the concentration of H_2O_2 is increased suggesting that the main precursor of $^1O_2$ is probably the calcium complex which bears the highest number of peroxo groups. It is noteworthy that chemical trapping and detection of the luminescence provided similar results since a mere standardization allowed the fitting of both curves.

Although numerous calcium peroxides are reported in the literature,[8–10] Karelin *et al.* have recently established that only two well defined compounds may be obtained by reaction of H_2O_2 with CaO in aqueous solution. The first is the stable octahydrate peroxide $CaO_2{\cdot}8H_2O$ and the other is the unstable diperoxohydrate peroxide $CaO_2{\cdot}2H_2O_2$ which decomposes spontaneously releasing oxygen.[10] Up to now, no report has dealt with the multiplicity of the oxygen. We looked for the possible $^1O_2$ luminescence emitted by thermolysis at 50 °C of the calcium peroxides $CaO_2{\cdot}8H_2O$ and $CaO_2{\cdot}2H_2O_2$ dispersed in deuterated methanol and water (Table 1). Deuterated solvents were preferred to take advantage of the longer lifetime of $^1O_2$ which provides an enhanced intensity of the luminescence. $CaO_2{\cdot}8H_2O$ did not emit any significant luminescence (Table 1, entry 4) whereas a similar amount of $CaO_2{\cdot}2H_2O_2$ emitted a huge signal (98 ± 2 mV) in CD_3OD. In D_2O, the signal was significant but lower probably owing to hydrolysis of the



Scheme 1

complex as for the peroxomolybdates.[11] Accordingly, we can assert that $CaO_2{\cdot}2H_2O_2$ is a precursor of $^1O_2$. A catalytic scheme may be drawn from this conclusion (Scheme 1).

In a first step, $Ca(OH)_2$ is converted into $CaO_2{\cdot}8H_2O$ which binds two molecules of H_2O_2 giving $CaO_2{\cdot}2H_2O_2$. On thermolysis at moderate temperature, this latter peroxide splits up into $^1O_2$ and $CaO_2{\cdot}8H_2O$. This catalytic cycle would operate until complete disproportionation of H_2O_2 and would leave $CaO_2{\cdot}8H_2O$ as a final product.

In order to assess the efficiency of $CaO_2{\cdot}2H_2O_2$ to generate $^1O_2$, the oxidation of 250 mM α-terpinene was performed by warming at 50 °C a suspension of 400 mM $CaO_2{\cdot}2H_2O_2$ in CD_3OD. α-Terpinene is known to trap efficiently all the $^1O_2$ released giving mainly ascaridol.[12] ^1H NMR analysis of the reaction mixture showed that, under these conditions, $CaO_2{\cdot}2H_2O_2$ converts 85% of α-terpinene into ascaridol providing a yield of $^1O_2$ formation equal to 50 ± 3% based on this calcium peroxide.

This work was supported by the CNRS (program 'Catalysis and catalysts for industry and environment').

Strong negative thermal expansion in siliceous faujasite

Martin P. Attfield and Arthur W. Sleight*†

Department of Chemistry and Center for Advanced Materials Research, Oregon State University, Corvallis, OR 97331-4003, USA

Strong isotropic negative thermal expansion ($\alpha = -4.2 \times 10^{-6}$ K^{-1}) found for siliceous faujasite over a temperature range of 25 to 573 K is attributed to transverse vibrations of the bridging oxygen atoms, a model supported by structural refinements of X-ray diffraction data as a function of temperature.

Negative thermal expansion is not a common phenomenon in solid materials. When it does arise, it is usually of small magnitude and displayed over a limited temperature range. Such thermal expansion is most usually found in anisotropic materials, for example, $LiAlSiO_4$,[1] $NbZrP_3O_{12}$[1] and $Sc_2W_3O_{12}$,[2] where the intrinsic linear thermal expansion is not more negative than -2.2×10^{-6} K^{-1}. Ceramic bodies made from such materials can show greater negative thermal expansion owing to microcracking effects which tend to become larger at lower temperatures. For instance a ceramic body of $Sc_2W_3O_{12}$, depending on how it is processed, can give a thermal expansion of up to -11×10^{-6} K^{-1}. Problems with microcracking in such ceramic bodies can be avoided if the material shows isotropic negative thermal expansion as is the case for the cubic material ZrW_2O_8 which exhibits strong isotropic negative thermal expansion (-8.7×10^{-6} K^{-1}) over a broad temperature range.[3,4]

An apparent requirement for an oxide material to have strong intrinsic negative thermal expansion is that it has an open framework structure with two-coordinate oxygen atoms. Several classes of such framework structures exist, including those of the family of SiO_2 structures and their derivatives. Various forms of the more condensed polymorphs of SiO_2 are known to exhibit negative thermal expansion over limited temperature ranges which do not include room temperature. Amorphous SiO_2 shows this behaviour below room temperature, and certain crystalline forms (quartz, cristobalite and tridymite) show weak negative thermal expansion above 1000 °C.[5] Zeolites are a group of open framework structures that derive from the SiO_2 family of structures in which some aluminium replaces the silicon atoms in the framework structure. The presence of aluminium atoms in the framework causes complications when considering thermal expansion properties. The charge of the aluminium in the framework is balanced by extraframework cations which influence the thermal expansion in several ways. In particular, bonds between framework oxygen atoms and alkali or alkaline earth cations exhibit large positive thermal expansion so these cations will provide a positive contribution to the expansion of the zeolite as the temperature increases. The position of the extraframework cations is also known to vary with temperature, as has been shown for Ca-mordenite,[6] again affecting the thermal expansion properties of the zeolite. The presence of the extraframework cations also increases the amount of water taken up by the zeolite. This water is often difficult to fully remove and can influence the thermal expansion properties of the system. These difficulties appear to play a large factor in the experimental data for the thermal expansion of Na-zeolite X, (the only data reported for the faujasite family that the authors are aware of) which has a net negative thermal expansion between 25 and 200 K and appears to expand above 200 K.[8,9]

In this work, we chose to study the thermal expansion of a purely siliceous zeolite, thus avoiding the complications associated with the extraframework cations and greatly reducing the water content of the zeolite. Here, we report the thermal expansion properties of siliceous faujasite from 25 to 573 K, it being strongly negative (-4.2×10^{-6} K^{-1}) over the entire range.

The sample of dealuminated Y (DAY) was kindly supplied by Amoco Chemical Company and was prepared as described previously.[9,10] The Al content was 120 ppm by ICP analysis. DAY was heated to 550° for 8 h in air to produce what has been referred to[9,10] as 'zero defect' DAY or ZDDAY. This treatment removes the defects caused by dealumination as determined by ^{29}Si MAS NMR; only one type of ^{29}Si is observed in ZDDAY. The sample was dehydrated for 12 h at 330 °C under a vacuum of *ca.* 10^{-5} Torr and transferred to an argon-filled glovebox where it was loaded, and sealed, into 0.5 mm and 0.3 mm diameter Lindemann glass capillary tubes. Before dehydration, the water content can be indicated as $SiO_2 \cdot xH_2O$ with $x = 0.08$. After dehydration, water was undetected indicating that x was < 0.005. Synchrotron X-ray powder diffraction data were collected on the sample at beamline X7A, National Synchrotron Light Source, Brookhaven National Laboratory. The diffractometer set up included the use of a Si(111) monochromator and a krypton filled position sensitive detector (p.s.d.). All data were collected at a wavelength of 1.099 32(6) Å. The temperature of the sample for each data collection was controlled using an Air Products Displex, and data were collected at seven temperatures between 25.16 and 297.5 K, inclusive. X-Ray data on the sample from 303 to 573 K were collected on an INEL XRG 3000 diffractometer using Cu-Kα_1 radiation monochromated by a Ge(111) crystal and adjustable vertical slits. The detector used was an INEL CPS 90 p.s.d. filled with an ethane–argon mixture. The sample was held within a capillary furnace fitted with resistive heating elements.

The synchrotron X-ray data sets were refined using the Rietveld method.[11] The refinement at each temperature was performed using the same procedure. The first four peaks were excluded from each refinement owing to their highly asymmetric peak shape. All backgrounds were fitted by linear interpolation using the same number of points in each case. The starting model for the siliceous faujasite was taken from that described by Hriljac *et al.*[10] The last cycle of least-squares refinement included the histogram scale factor, zero point, lattice parameter, five peak shape parameters, and the coordinates and isotropic temperature factors of each atom. The X-ray data sets collected on the laboratory diffractometer were fitted using the Le Bail method only.[12] Again, the background was fitted by linear interpolation and the last cycle of least-squares refinement included the zero point, lattice parameter, and five peak shape parameters. All refinements were carried out using the GSAS suite of programs.[13]

The negative thermal expansion properties of siliceous faujasite are shown in Fig. 1. An approximately linear decrease in cell dimension is seen over the entire temperature range 25.16–572.0 K. The overall coefficient of thermal expansion {defined as $(l_{T2} - l_{T1})/[l_{T1}(T_2 - T_1)]$} calculated for the whole temperature range is -4.2×10^{-6} K^{-1}. This value is in good

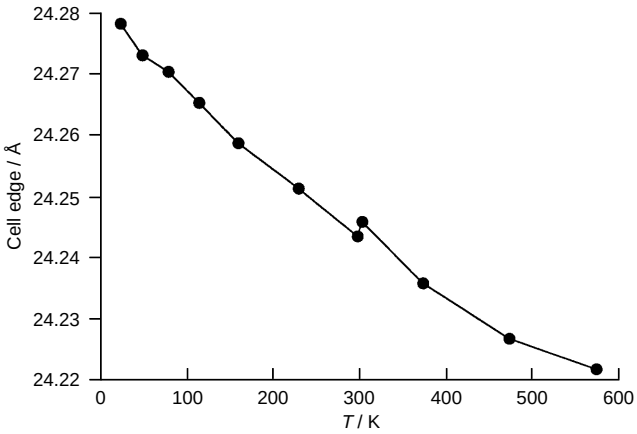

Fig. 1 Cubic cell edge as a function of temperature for siliceous faujasite

agreement with that calculated for siliceous faujasite by Couves *et al.* (-4.1×10^{-6} K^{-1}), but is significantly more negative than the values obtained from their computational and experimental studies on Na-zeolite X (-3.0×10^{-6} K^{-1} and -0.7×10^{-6} K^{-1}, respectively).[7,8]

The results from the Rietveld refinements at the seven temperatures between 25 and 298 K enable us to gain some insight into the structural changes giving rise to the negative thermal expansioin of siliceous faujasite. As in other negative thermal expansion materials,[2–4] the overall changes in bond distances and angles are small relative to their e.s.d.s. A cell dimension change of that observed between 25.16 and 297.5 K (24.2782–24.2442 Å), when placed on the same scale as a typical Si–O bond represents a change of only 1.600–1.598 Å, where a typical Rietveld e.s.d. on a bond length is only 0.002 Å.

The observed O–Si–O and Si–O–Si angles varied from 107 to 113° and 137 to 149°, respectively, with no detectable change with temperature in either case. There was an apparent decrease in the average Si–O bond distance of 1.614 to 1.610 Å from 25 to 298 K. However, after correcting for the thermal motion of oxygen,[14] there was no detectable change in the Si–O bond length over this temperature range. The fact that the bond angles and corrected bond distances within the SiO_4 tetrahedra remain essentially constant over the temperature range studied allows the latter to be considered as rigid tetrahedra.

The results from the structure refinements lead us to believe that the negative thermal expansion of this material is related to the transverse vibrations to the two-coordinate bridging oxygen atoms, a mode of lattice vibration that is of low enough energy to be readily excited at low temperatures. These vibrations lead to coupled rotations of the essentially rigid tetrahedra making up the structure of the zeolite. The lack of any systematic changes in atomic coordinates and bond angles over the temperature range studied implies that the transverse vibrations of the bridging oxygen atoms are essentially harmonic in nature and the bending of the Si–O–Si bonds is dynamic rather than static in nature. As the temperature of the material is increased, the magnitude of the transverse vibrations of the bridging oxygen atoms, as well as the resulting coupled rotations of the tetrahedra, increases, which manifests itself in the structure refinement results as a decrease in the average Si–O distance. With the decrease in the Si–O bond length accompanying the increase in temperature, a decrease in the average Si–Si non-bonding distance occurs, resulting in the negative thermal expansion observed. Again we emphasise that the apparent reduction of the Si–O bond length results from the increased thermal motion and not from actual changes in the magnitude of the Si–O vector. The explanation of the mechanism of negative thermal expansion for siliceous faujasite is the same as that suggested for other materials such as ZrW_2O_8[3,4] and the usual forms of SiO_2.[15]

The strong negative thermal expansion found in siliceous faujasite indicates that other zeolites and ALPOs might exhibit similar behaviour, as has been suggested qualitatively by computational methods.[7,8] However, the latter also predicts that some such framework materials exhibit positive thermal expansion. The reasons for the difference in behaviour for similar materials remain unclear and merit further investigation.

We thank G. J. Ray, Amoco Chemical Company, for provision of the dealuminated zeolite-Y sample. This work was supported through NSF grant No. DMR-9308530. Some data were collected at the National Synchrotron Light Source, Brookhaven National Laboratory, which is supported by the US Department of Energy, Division of Materials Sciences and Division of Chemical Sciences, under Contract No. DE-AC02-76CH00016.

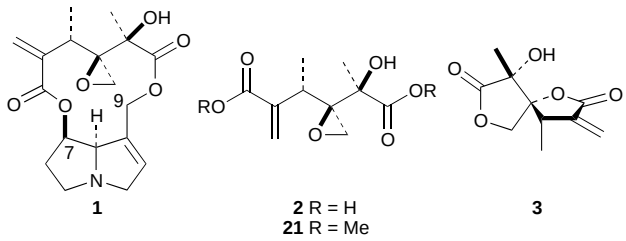
Asymmetric synthesis of dimethyl swazinecate and structural confirmation of its parent alkaloid (−)-swazine

James D. White,*† John C. Amedio, Jr., Peter Hrnciar, Nadine C. Lee, Susumu Ohira and Alexandre F. T. Yokochi

Department of Chemistry, Oregon State University, Corvallis, OR 97331-4003, USA

Synthesis of dimethyl swazinecate, a principal component of the pyrrolizidine alkaloid swazine, was completed from (*S*)-(−)-β-citronellal; an X-ray crystallographic analysis of natural swazine confirmed its absolute stereostructure.

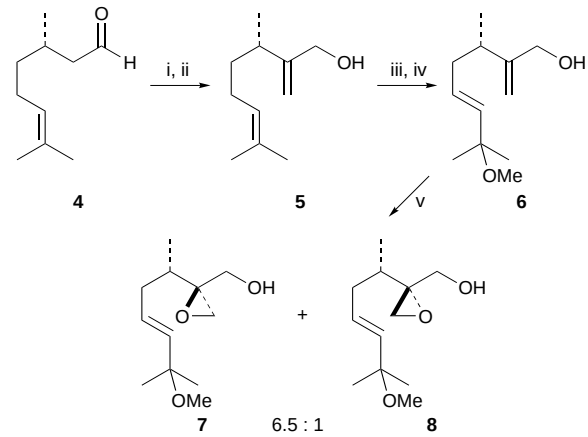
Pyrrolizidine alkaloids are widespread among plants of the *Senecio* family, many of which possess toxic properties that pose serious risk to human and animal health.[1] (−)-Swazine **1**, first isolated from *Senecio swaziensis* Compton,[2] is among the more complex members of this class of alkaloids, consisting of a functionalized adipic acid derivative **2** (swazinecic acid) that bridges the C7 and C9 hydroxy groups of the pyrrolizidine retronecine to form a twelve-membered dilactone. Neither acidic nor careful basic hydrolysis of **1** has permitted isolation of intact **2**. Instead, the constitution of this dicarboxylic (necic) acid was inferred from the spirolactone **3** obtained upon treatment of **1** with hot, 1.5 M sulfuric acid. The structure of **3** was established by X-ray crystallographic analysis of its *p*-bromobenzoate.[2] Initially, swazine was formulated as the dilactone isomeric with **1**, in which swazinecic acid **2** was connected to retronecine in the reverse orientation to that shown. This assignment was subsequently revised,[3] and the revision was accepted after a more complete degradative and spectroscopic investigation.[4] Herein, we report the first synthesis of swazinecic acid, characterized as its dimethyl ester, which confirms its absolute stereostructure as **2**. We also describe an X-ray crystallographic analysis of natural swazine which now substantiates the designation of this alkaloid as **1**.



1 **2** R = H, **21** R = Me **3**

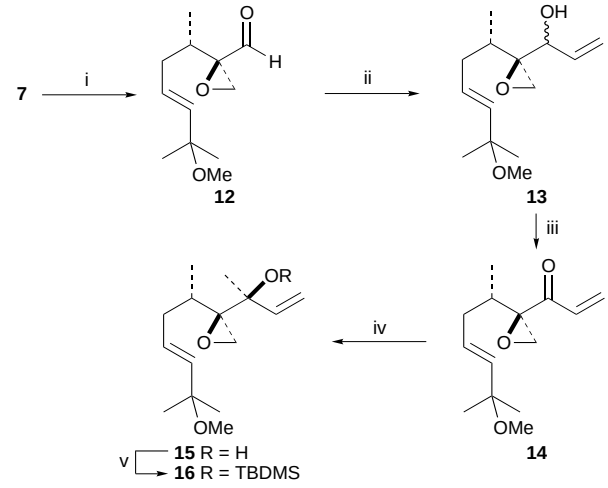
Our approach, which employs β-citronellal as the starting material,[5] hinges upon oxidative truncation of an elaborated terpenoid structure to generate a dicarboxylic acid having the requisite functionality and configuration of the necic acid.[6–10] Since our planned route to **2** involved early introduction of a relatively sensitive epoxide, it was essential that later steps in the sequence avoid reagents which would destroy this function.

α-Methylenation of (−)-**4**, followed by Luche reduction of the resultant α,β-unsaturated aldehyde (as described for the enantiomeric series),[9] gave the allylic alcohol **5** (Scheme 1). The trisubstituted olefin of this diene underwent selective methoxyselenation using Toshimitsu's conditions,[11] and the intermediate alkyl selenide was oxidized to afford **6** in good yield. Asymmetric epoxidation of **6** using (*S*,*S*)-(+)-diisopropyl tartrate (DIPT) as the chiral adjuvant[12] gave **7** and **8** in the ratio 6.5 : 1.

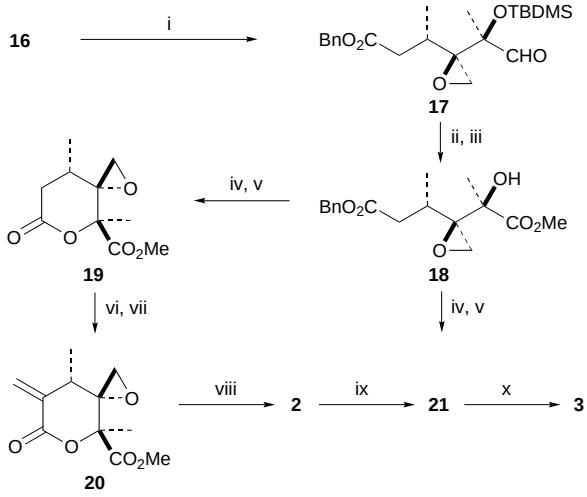


Scheme 1 *Reagents and conditions*: i, LDA, $CH_2{=}N^+Me_2I^-$, MeI, $NaHCO_3$, 94%; ii, $NaBH_4$, $CeCl_3{\cdot}7H_2O$, 93%; iii, PhSeCl, $NaHCO_3$, THF–MeOH; iv, H_2O_2, $NaHCO_3$, THF–H_2O, 82% (from **5**); v, Bu^tOOH, $Ti(OPr^i)_4$, (+)-DIPT, CH_2Cl_2, 92%

After chromatographic separation, **7** was oxidized to aldehyde **12** which was converted to alcohol **13** upon treatment with vinylmagnesium bromide at low temperature (Scheme 2). Further oxidation with Dess–Martin periodinane produced α,β-unsaturated ketone **14**. Chelation-controlled Grignard addition to this ketone was expected to occur selectively at the *re* face of the carbonyl group, and when **14** was treated carefully with methylmagnesium bromide at low temperature a single alcohol,



Scheme 2 *Reagents and conditions*: i, $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, 95%; ii, vinylmagnesium bromide, THF, −78 °C, 72%; iii, Dess–Martin periodinane, 100%; iv, methylmagnesium bromide, Et_2O, −78 °C, 60%; v, TBDMSOTf, 2,6-lutidine, CH_2Cl_2, −35 °C, 76%



Scheme 3 *Reagents and conditions*: i, O_3, $(CF_3CO)_2O$, BnOH–CH_2Cl_2, $NaHCO_3$, Et_3N, −78 °C; ii, $NaClO_2$, Bu^{t}OH, Me_2C=CHMe; iii, CH_2N_2, Et_2O, 65% from **16**; iv, H_2, Pd/C; v, 2-chloro-1-methylpyridinium iodide (Mukaiyama's reagent), 99% from **18**; vi, LDA, CH_2O, 55%; vii, MsCl, Et_3N, 96%; viii, KOH, MeOH–H_2O; ix, CH_2N_2, Et_2O, 63% from **20**; x, H_2SO_4

assigned structure **15**, was obtained accompanied by the product of conjugate addition.

Alcohol **15** was protected as its *tert*-butyldimethylsilyl ether **16** in a process that retained the epoxide intact. Ozonolytic cleavage of **16** in the presence of benzyl alcohol, trifluoroacetic anhydride and triethylamine at low temperature gave the aldehyde ester **17** in excellent yield (Scheme 3).[13] Unfortunately, the inherent instability of **17** resulting from its propensity towards intramolecular aldol condensation demanded immediate oxidation of this aldehyde to a carboxylic acid, during which the silyl ether was cleaved. Treatment of the resultant α-hydroxy acid with diazomethane afforded **18** which underwent hydrogenolysis of the benzyl ester followed by lactonization with Mukaiyama's reagent[14] to give **19**. Condensation of the lithium enolate of **19** with formaldehyde produced a stereoisomeric mixture of hydroxymethyl lactones which, when exposed to methanesulfonyl chloride and base, led directly to *exo* methylene δ-lactone **20**. Saponification of **20** furnished swazinecic acid **2** which was characterized as its dimethyl ester **21**.‡

Since there is no record of either **2** or **21** having been obtained by degradation of swazine **1**, the structure of synthetic dimethyl swazinecate was confirmed by its conversion to the spirodilactone **3** upon treatment with sulfuric acid in hot THF. The spectroscopic properties of **3** obtained by this method matched those recorded for the same substance derived from **1**.

Final confirmation of the structure, including absolute configuration, of swazinecic acid was obtained by X-ray crystallographic analysis of swazine itself (Fig. 1).§ Since hydrolysis of swazine is known to yield (+)-retronecine, whose absolute configuration has been determined by independent synthesis,[15] the full structure of **1** and hence **2** is as shown.

We are indebted to Professor S. E. Drewes, University of Natal, South Africa, for a sample of natural swazine. Financial support was provided by the National Institute of Environmental Health Sciences (ES03334).

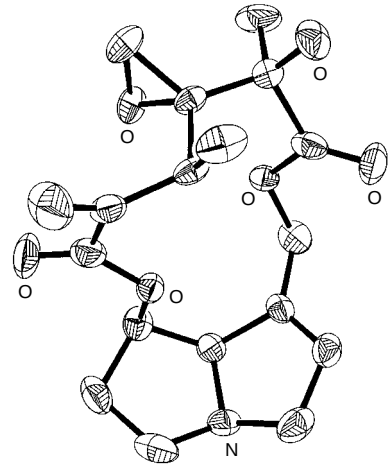


Fig. 1 ORTEP plot of the crystal structure of swazine **1**. Thermal ellipsoids are drawn at the 50% probability level.

Synthesis of DNA-binding heteroaromatic oligoamides on liquid solid support

Burkhard König*† and Martin Rödel

Institut für Organische Chemie der Technischen Universität Braunschweig, Hagenring 30, D-38106 Braunschweig, Germany

Heteroaromatic oligoamides as building blocks for the synthesis of sequence specific DNA binding molecules are obtained from nitro carboxylic acids on polyethylene glycol without the use of protecting groups

Mimicking the sequence specific DNA recognition of gene regulation proteins[1] with small molecules is not only an academic challenge: such molecules are highly desirable as regulatory factors in biotechnology or as gene specific drugs.[2] Several sequence-specific DNA-binding compounds[3] have been discovered over the last 10 years, such as triplex-forming oligonucleotids, peptide nucleic acids and minor groove binding heteroaromatic oligoamides.[3b] The stability and simple structure of the latter compounds renders them especially suitable for most applications. However, compared to the synthesis of aliphatic peptides, that of heteroaromatic imidazole/pyrrole oligoamides is difficult: the heteroaromatic amines are unstable and the carboxy group is less reactive in amide formation. To address these problems, Baird and Dervan recently reported a solid phase synthesis protocol for the synthesis of even complex hairpin oligoamides.[4] Unfortunately, the employed solid support together with the required protecting groups now make the synthesis of larger quantities of heteroaromatic oligoamides an expensive venture. In addition the current protocol is restricted to *N*-methylpyrrole and *N*-methylimidazole, so that new building blocks and coupling conditions must be developed for the introduction of each new heterocycle.[5] To remedy this situation we report here a versatile 'protecting group free' synthesis of short heteroaromatic oligoamides on polyethylene glycol 'liquid' solid support.[6]

Methoxypoly(ethylene glycol) (MeO-PEG-OH) with an average molecular weight of 5000 g mol^{-1} was used as an inexpensive solid support. By the reaction of 1-methyl-4-nitro-1*H*-pyrrole-2-carbonyl chloride **1** with MeO-PEG-OH under standard conditions the first heterocyclic unit of the peptide synthesis is introduced quantitatively *via* ester linkage (Scheme 1). A sample of 100 g of MeO-PEG-OH can so accommodate *ca.* 2.5 g of the first heterocycle. Using the advantage of a soluble solid support, the nitro group is then reduced with NH_4HCO_2–Pd/C in MeOH over 1 h at room temperature. For work-up the heterogeneous catalyst is removed by filtration and the polymer-bound amine is precipitated by the addition of Et_2O. The solid is dissolved in CH_2Cl_2, rendering it ready for the next coupling step and leaving behind excess NH_4HCO_2. Either the reaction of **2** in the presence of pyridine or the coupling of the corresponding carboxylic acid **5** with DCC–HOBt can be used to introduce the next heterocycle in excellent yield.[7] Repetition of the reduction-coupling cycle gives trimers and tetramers. Finally, treatment with base[8] allows the quantitative cleavage of the oligoamide from the polymer.‡ The so obtained molecules§ are most suitable starting materials for the construction of DNA recognizing structures: solution phase peptide chemistry allows the large scale synthesis of hairpin structures,[9] immobilization leads to new stationary chromatography phases[10] and further functionalization gives DNA markers.[11]

The described procedure allows the large scale synthesis of heteroaromatic oligoamides without the use of protecting groups and chromatography. On top of that it facilitates reaction monitoring when new analogs are prepared. Using available nitro carboxylic acids[12] a variety of carbo- or hetero-cyclic units can be introduced, whereby the successful incorporation is confirmed by NMR spectroscopy.¶ With aromatic nitro isocyanates as building blocks the amide linkage is replaced by a urea moiety. Such peptidomimetic heteroaromatic compounds may also have interesting DNA-binding properties, but this remains to be established. Examples of structures that were prepared by the reported route, including yields, are: **11** (61%), **12** (56%) and **13** (62%).

In conclusion we have shown that heteroaromatic oligoamides can be prepared in a most economical way on MeO-PEG polymer support avoiding the use of protecting groups. The procedure facilitates both large scale synthesis and reaction optimization for known and new heteroaromatic oligoamides. This will make this interesting class of compounds more easily available for the further investigation of specific molecular recognition of biological structures.

‡ *General procedure* for the reduction-coupling cycle on MeO–PEG-support: A mixture of **3** (5 g, 1 mmol), Pd/C (10%, 100 mg, 9 mol%) and NH_4HCO_2 (1 g, 16 mmol) in MeOH (50 ml) was stirred for 1 h at room temp. The catalyst was removed by filtration, Et_2O (400 ml) was added to the solution and the precipitate was collected by filtration. The white solid was dissolved in CH_2Cl_2 (25 ml), leaving behind excess NH_4HCO_2 that was filtered of. Either **2** (570 mg, 3.3 mmol) and pyridine (1 ml) or a solution of **5** (560 mg, 3.3 mmol), $HOBt·H_2O$ (510 mg, 3.3 mmol) and DCC (680 mg, 3.3 mmol) in DMF (25 ml) were added and the mixture was stirred for 12 h. The reaction mixture was filtered, the polymer-bound product was precipitated by addition of Et_2O (400 ml) and collected by filtration. The crude product was redissolved, precipitated twice and dried *in vacuo*.

§ *Selected data* for **9**: δ_H(400 MHz, [$^2H_6$]DMSO) 3.82 (s, 3 H), 3.86 (s, 3 H), 3.96 (s, 3 H), 6.85 (d, ^4J 1.9, 1 H), 7.05 (d, ^4J 1.8, 1 H), 7.26 (d, ^4J 1.6, 1 H), 7.42 (d, ^4J 1.8, 1 H), 7.59 (d, ^4J 1.9, 1 H), 8.18 (d, ^4J 1.8, 1 H), 9.94 (s, 1 H), 10.28 (s, 1 H); 12.16 (s, 1 H); δ_C(100 MHz, [$^2H_6$]DMSO) 36.1 (+), 36.2 (+), 37.5 (+), 104.6 (+), 107.6 (+), 108.4 (+), 118.7 (+), 119.6 (C_{quart}), 120.3 (+), 121.5 (C_{quart}), 122.6 (C_{quart}), 122.9 (C_{quart}), 126.3 (C_{quart}), 128.3 (+), 133.8 (C_{quart}), 156.9 (C_{quart}), 158.3 (C_{quart}), 162.0 (C_{quart}); *m*/*z* (70 eV) 370 (74%) [$M^+ - CO_2$], 275 (100).

¶ For NMR analysis, 100 mg of the polymer bound product were dissolved in 0.5 ml of $CDCl_3$. The terminal methoxy group of MeO-PEG was used to calibrate polymer loading and reaction yields. *Selected data* for **11**: δ_H(400 MHz, [$^2H_6$]DMSO) 3.52 (3 H), 4.05 (3 H), 4.10 (3 H), 6.89 (1 H), 7.44 (1 H), 7.48 (1 H), 7.49 (1 H), 7.64 (1 H), 9.05 (1 H), 9.16 (1 H). Resorcin[4]arene dimer linked by eight water molecules and incorporating a tetraethylammonium ion: guest-driven capsule formation *via* cation–π interactions

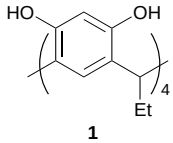
Kazutaka Murayama and Katsuyuki Aoki*†

Department of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 441, Japan

X-Ray analysis of the co-crystallization compound formed between tetraethylresorcin[4]arene 1 and tetraethylammonium ion, $Et_4N^+\cdot\mathbf{1}\cdot\mathbf{1}^-\cdot 8H_2O\cdot 2EtOH$, has shown that the two 'head-to-head' arranged resorcinarenes are linked by eight water molecules and encapsulate a tetraethylammonium ion within the cavity *via* cation–π interactions.

Molecular containers,[1–7] which have the ability to encapsulate substrates, have attracted much attention in supramolecular chemistry because of their numerous applications: the design of artificial receptors, transport and storage of small organic guests, design of chemical sensor devices, removal of pollutants from water, and use as reaction chambers. A variety of container compounds whose interior cavities are constructed by covalently linked structures, typically involving carcerands,[1,2] cryptophanes[3] or cucurbiturils,[4] have been synthesized and well characterized. More recently, self-assembly through non-covalent interactions such as hydrogen bonding has proved to give novel types of molecular containers, which we here tentatively call 'molecular capsules', the still-limited examples being glycolurils,[5] urea-substituted calix[4]arenes[6] and tetrols.[7] Most recently, MacGillivray and Atwood have reported[8] a self-assembled resorcin[4]arene hexamer, forming a shell-like molecular capsule, held together by eight water bridges in addition to direct hydrogen bonds between the substructures. We report here the preparation and crystal structure of a dimeric resorcin[4]arene molecular capsule, linked by eight water bridges and incorporating a tetraethylammonium ion inside the cavity. The formation of the capsule might be guest-driven through the cation–π interaction, an important mechanism for molecular recognition that is not yet sufficiently explored.[9]

Tetraethylresorcin[4]arene **1**‡ (0.1 mmol) and tetraethylammonium perchlorate (1 mmol) were dissolved in EtOH–H_2O (5 : 3, 8 ml). The mixture (pH 5) was allowed to stand at room temperature for three weeks to give colourless crystals with a yield of 60%,§ the structure of which has been determined.¶



1

The molecular structure of the compound with the composition of $Et_4N^+\cdot\mathbf{1}\cdot\mathbf{1}^-\cdot 8H_2O\cdot 2EtOH$‖ is shown in Fig. 1, where, coinciding with crystallographic symmetries, each macrocyclic resorcinol tetramer **1** has four-fold symmetry and the two macrocycles are related to each other by a mirror plane. The resorcinarene molecule adopts a bowl-shaped conformation with the usually observed intramolecular hydrogen bonds between neighbouring hydroxy groups: the crystallographically independent hydrogen bond O(1)···O(2′) = 2.767(9) Å. The most interesting structural feature is the formation of a molecular capsule constructed of two 'head-to-head' arranged substructures which captures a tetraethylammonium ion within the cavity.** The Et_4N^+ nitrogen atom is located at a crystallographic centre of symmetry, the point that the four-fold axis and the mirror plane intersect, and thus the ethyl groups of the cation are disordered over two sets of sites related by the mirror plane on which the central nitrogen and terminal carbon atoms ride. The architecture of the capsule structure is unique in that the two substructures are not directly but indirectly connected to each other *via* eight water bridges, because in so far reported molecular capsules[5–7] the two substructures are directly hydrogen-bonded to each other *via* functional groups, *e.g.* urea-substituents,[6] that are designed to form complementary hydrogen bonds. Thus each water molecule, which lies on the mirror plane noted above, is hydrogen-bonded to two hydroxy groups, one from each substructure, summing to a total of 16 hydrogen bonds in the capsule unit: the crystallographically independent hydrogen bonds O(3)···O(1) = 2.76(1) and O(4)···O(2) = 2.753(10) Å. The water linking is engaged also in the assembly of the tetramethylresorcin[4]arene hexamer,[8] in addition to, in this case, direct hydrogen bonds between the hydroxy groups of the 'head-to-head' arranged resorcinarenes. As shown in Fig. 2, the Et_4N^+ ion is arranged in such a way that its ethyl groups project toward the bridging C(7) carbons of **1**, where each ethyl group makes close contacts with the phenyl rings through, we suggest, multiple cation–π interactions. Since the capsule unit is negatively (monovalently) charged, the presence of the cation–π interactions between the quaternary cationic Et_4N^+ group and the aromatic rings of **1** is

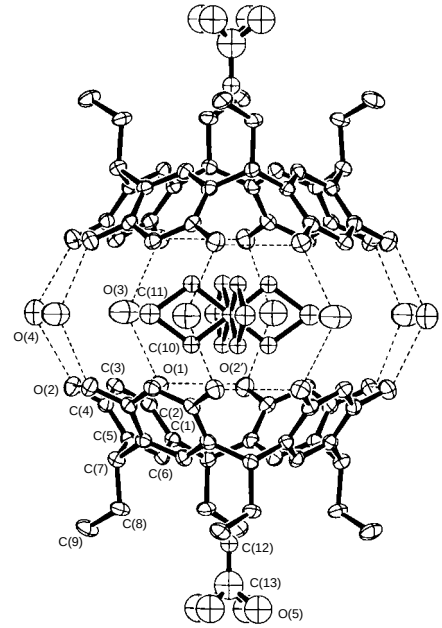


Fig. 1 Molecular structure of the capsule molecule [the ethanol solvate is disordered at four positions due to the four-fold axis passing through it, where the thermal ellipsoid of the C(12) atom is given at arbitrary scale for clarity]. O(2′) is related to O(2) by four-fold symmetry. Broken lines denote hydrogen bonds.

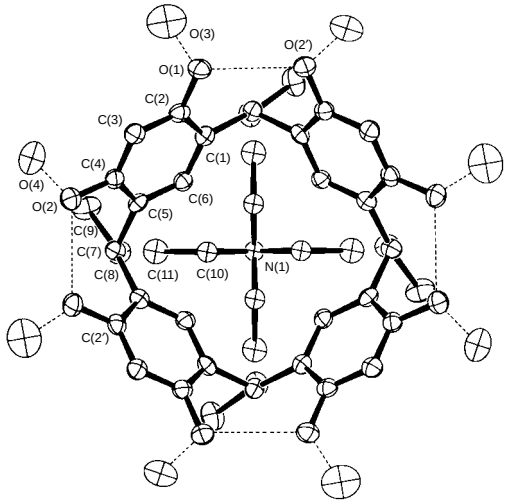

Fig. 2 A top view of the capsule molecule along the four-fold axis, showing the disposition of the Et_4N^+ ion within the cavity. Close contacts: C(2′)···C(10) = 3.58(2), C(2′)···C(11) = 3.59(1), C(4)···C(10) = 3.59(2), and C(4)···C(11) = 3.59(1) Å. O(2′) and C(2′) are related to O(2) and C(2), respectively, by four-fold symmetry. Broken lines denote hydrogen bonds.

not self-evident. However, X-ray evidence for such an interaction between the Me_3N^+ group of acetylcholine and the π-rings of the *neutral* resorcin[4]arene is available.[10] The bond lengths and angles of the resorcin[4]arene molecule are in good agreement with those in the literature.[10]

Crystallization of **1**, in the absence of tetraethylammonium ion, from EtOH–H_2O or EtOH–acetone–H_2O gave compounds, 2(**1**)·2EtOH·10H_2O or **1**·Me_2CO·EtOH·2H_2O, respectively, and their X-ray analyses have shown that in both compounds no molecular capsule is formed.[11] The lack of formation of a molecular capsule for *neutral* substrates in these two and, to the best of our knowledge, six other cases such as MeCN–H_2O,[12] acetone–EtOH–H_2O,[12] ethyl methyl ketone,[13] EtOH,[14] pyridine,[15] and MeCN–4,4′-bipyridine[15] may give circumstantial evidence for the important role of the cation–π interaction in the formation of the present resorcinarene molecular capsule, suggesting that capsule formation might be guest-driven through cation–π interactions. This is in contrast to the usually observed[5–7] host-driven capsule formation by direct hydrogen bonding between two substructures that are predesigned to form self-complementary hydrogen bonds.

The ^{1}H NMR spectrum (270 MHz, CD_3OD) of the capsule complex (1 mmol dm^{-3}) shows a quartet at δ 3.130 and a triplet at δ 1.173 for the CH_2 and CH_3 protons of Et_4N^+, respectively, whereas the corresponding signals of Et_4N^+ alone appear at δ 3.321 and 1.289. These upfield shifts for the complex are probably due to the shielding effect of the aromatic rings, indicating that the quaternary tetraethylammonium group associates preferentially with the π-rings of **1** in solution.††

In conclusion, the synthesis and isolation of the resorcin[4]arene molecular capsule incorporating an Et_4N^+ ion are straightforward, giving a moderate yield by simply mixing starting materials which are readily available. Unlike other molecular capsules,[5–7] the two substructures are *not directly* hydrogen-bonded but are *indirectly* bonded *via* water bridges. The architecture is simple and elegant: the two hemispherical resorcin[4]arenes are attached *via* their upper rims with eight water molecules to form a spherical capsule having C_{4h} symmetry. The present study provides additional X-ray evidence[10] for cation–π interaction between the quaternary ammonium group and the π-electrons of the aromatic rings, a novel type of binding force that is important in the function of biological systems.[9,16] The cation–π interaction could also play a major role in the process of the capsule formation, by forcing simultaneous interactions between a tetraethylammonium ion and two resorcinarenes. The guest-driven host construction observed here could offer a promising approach for building new supramolecular compounds.

‡ 2,8,14,20-Tetraethyl-4,6,10,12,16,18,22,24-octahydroxycalix[4]arene **1** was synthesized according to a literature procedure (ref. 17).

§ Elemental microanalysis of the compound was not possible due to its rapid decomposition out of solution. The molecular formula was determined by X-ray analysis.

¶ *Crystal data*: $C_{10.5}H_{15.875}N_{0.125}O_{3.25}$, M = 195.80, colourless columns, tetragonal, space group *P*4/*mnc*, a = 13.927(2), c = 22.434(2) Å, U = 4351.5(10) Å^3, Z = 16, D_c = 1.195 g cm^{-3}, μ(Mo-Kα) = 0.88 cm^{-1}, T = 293 K, F(000) = 1692. A crystal was sealed in a glass capillary with a drop of mother liquor. Of 2926 unique data in the range $4 < 2\theta < 45°$, 1052 data with $I > 3\sigma(I)$ were used in the refinement. Residuals of R = 0.104 and R_w = 0.115 were obtained after 127 parameters had been refined to convergence, where only the resorcinarene and water atoms were treated anisotropically while all the other atoms were treated isotropically. No attempt was made to locate the H atoms. Extensive disordering of Et_4N^+ and EtOH caused the rather high R values. CCDC 182/753.

‖ The Et_4N^+ : **1** : EtOH composition of 1 : 2 : 2 for the compound formed was consistent with its ^{1}H NMR spectra. The absence of ClO_4^- was ascertained *via* IR spectroscopy. Any one of the sixteen hydroxy substituents belonging to the two resorcin[4]arenes constituting the capsule could be deprotonated.

** Resorcin[4]arenes as receptors for tetraalkylammonium ions have been demonstrated in alkaline solution (ref. 18), where, however, a tetradeprotonated host anion is assumed to form a 1 : 1 complex with an ammonium cation.

†† A study to clarify the solution structure or structures involved in the capsule formation remains to be carried out.

Unusual C→N migration of phosphoryl group; synthesis of *N*′-phosphorylated amidines

Won Bum Jang, Kilsung Lee, Chi-Wan Lee and Dong Young Oh*†

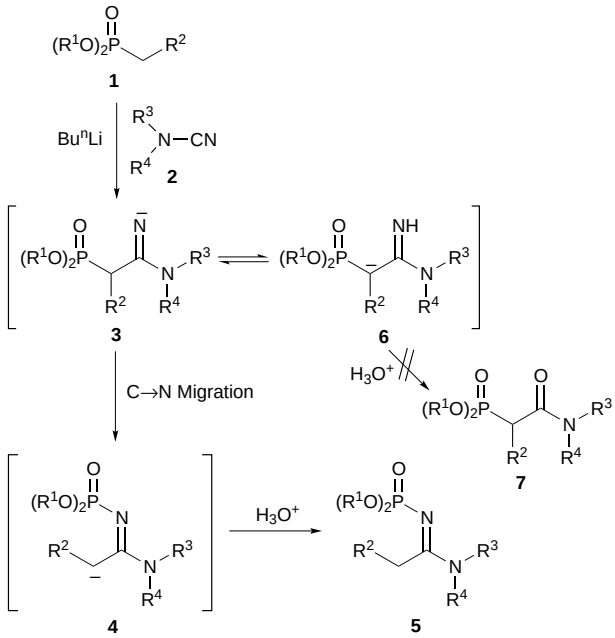
Department of Chemistry, Korea Advanced Institute of Science and Technology, 373-1, Kusung-Dong, Yusung-Gu, Taejon, Korea

Synthetically and structurally interesting *N*′-phosphoryl amidines were obtained by the reaction of lithiated alkyl phosphonates with *N*,*N*-dialkylcyanamide *via* an unprecedented migration of the phosphoryl group.

We have been interested in recent years in the reaction of α-lithioalkylphosphonates with nitriles, and we have used these as synthetic intermediates in the preparation of β-keto phosphonates,[1] α,β-unsaturated ketones,[2] deoxybenzoines[3] and *E*-allylic amines.[4] Following on from this work, we turned our attention to the question of whether the reaction of α-lithioalkylphosphonates with cyanamides (instead of nitriles) would generate intermediates **6**, in the hopes of thereby obtaining α,β-unsaturated amides.

To this end, we examined the reaction of α-lithioalkylphosphonates, derived from dialkyl alkylphosphonates, with cyanamides **2** followed by hydrolysis (Scheme 1), and we were surprised to find that the expected compounds **7** were not obtained. Good yields of compounds **5** were obtained instead. Looking closer, we found no evidence for formation of β-carbonyl phosphonate and/or enamine phosphonates on monitoring by TLC. Thus, the most reasonable explanation for the formation of **5** would be the migration of phosphoryl group (**3**→**4**). This unusual C→N migration of a phosphoryl group was observed in all other dialkyl alkylphosphonates and amides tested.‡

As shown in Table 1, the migration works well and gives good yields. All the products were characterized *via* ^{1}H, ^{13}C and ^{31}P NMR spectroscopy and HRMS. The C→N migration is so fast that the reaction was completed within 5 min at −78 °C. The α-lithio anion derived from a benzylphosphonate (**5h** in Table 1) did not give the migration product, and the starting material was recovered. This could be due to the lithiated benzylphosphonate being possibly less nucleophilic than other alkylphosphonates.



Scheme 1

Table 1 Synthesis of *N*′-phosphorylated amidines **5**

Compound	R^1	R^2	R^3	R^4	Yield (%)[a]
5a	Me	H		–(CH$_2$)$_4$–	79
5b	Me	H		–(CH$_2$)$_5$–	82
5c	Et	H		–(CH$_2$)$_4$–	81

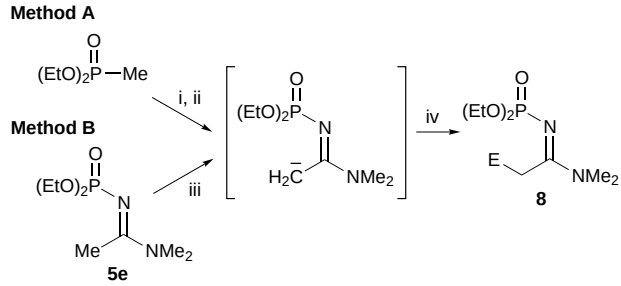
5e	Et	H	Me	Me	87
5f	Et	Allyl	Me	Me	71
5g	Et	Me		–(CH$_2$)$_5$–	73
5h	Et	Ph		–(CH$_2$)$_5$–	No reaction[b]
5i	Pr^i	H		–(CH$_2$)$_5$–	84

[a] Isolated yield. [b] Starting materials were recovered.

Intermediate **3** (or its tautomeric form **6**) seems to be very unstable. In general, amidine derivatives have a zwitterionic character but, in the case of intermediate **3**, the anion interrupts the zwitterionic resonance in the N–C=N linkage, so the migration of the phosphoryl group may not only initiate the zwitterionic resonance, but also stabilize the zwitterionic structure due to p_π–d_π interaction in the P–N bond.[5]§

In order to prepare various *N*′-phosphorylated amidine derivatives **8**, we carried out the reaction shown in Scheme 2 with several electrophiles. Our results are summarized in Table 2. All of the electrophiles gave good yields, even in the one-pot procedure.¶



Scheme 2 *Reagents and conditions*: i, Bu^{n}Li, THF, −78 °C, 1 h; ii, Me$_2$NCN, −78 °C, 10 min; iii, LDA, THF, −78 °C, 1 h; iv, electrophile, −78 °C to room temp., 1 h

Table 2 Synthesis of various *N*′-phosphorylated amidine derivatives **8**

Compound	Electrophile	E in **8**	Method[a]	Yield (%)[b]
8a	D$_2$O	D	A	78
8b	MeI	Me	A	73
8c	Allyl bromide	Allyl	A	68
8d	TMSCl	TMS	A	62
8e	PhCHO	PhCH(OH)	A	41
8e	PhCHO	PhCH(OH)	B	92

[a] See footnote ¶. [b] Isolated yield.

Rearrangements of the phosphoryl groups and other phosphorus containing functional groups are known.[6] Their mechanisms and resulting products are of importance, not only for their synthetic applications and biological activities, but also for understanding the reactivity of the phosphorus atom. However, this is to the best of our knowledge the first example of the C→N migration of a phosphoryl group.

In summary, we have developed an interesting and synthetically useful C→N migration. A study of phosphorylated amidine and its synthetic application is in progress.

Notes and References

‡ *Typical reaction procedure*: To a stirred solution of $(EtO)_2P(O)Me$ (0.167 g, 1.1 mmol) in dry THF (4 ml) was added Bu^nLi (0.68 ml, 1.1 mmol, 1.6 M in hexanes) at −78 °C under N_2. After stirring for 1 h at −78 °C, Me_2NCN (0.070 g, 1.0 mmol) was added, and the mixture warmed to room temp. After 30 min, saturated aqueous NH_4Cl (5 ml) was added, and stirring continued for 10 min. Extraction with Et_2O (3 × 20 ml), drying and removal of the solvent under reduced pressure gave the crude product. Pure **5e** was obtained (0.1933 g, 87%) by flash column chromatography (EtOAc–MeOH, 10 : 1): δ_H(300 MHz, $CDCl_3$) 1.07–1.12 (t, *J* 17.45, 6 H), 2.16 (s, 3 H), 2.86 (s, 3 H), 2.87 (s, 3 H), 3.83 (dt, J_{P-H} 7.14, J_{H-H} 7.14, 4 H); δ_C(75 MHz, $CDCl_3$) 15.88 (d, J_{P-C} 6.9), 19.40 (d, *J* 4.72), 37.55, 38.23, 61.36 (d, J_{P-C} 6.525), 166.32 (d, J_{P-C} 14.1); δ_P(120 MHz, $CDCl_3$) +6.157; HRMS (EI) calc. 222.1133, found 222.1127.

§ In general, the rotational barrier of the C–N single bond in the amidine moiety is due to its zwitterionic structure. The C–N single bond in *N*′-aryl-*N*,*N*-dimethylacetamidines, which are known for having aryl groups strongly conjugated to the N=C–N moiety, shows a relatively low coalescence temperature (T_c, −60 to 33 °C; ref. 7). However, in the case of *N*′-phosphorylated amidines, the coalescence temperature is about 80 °C (ref. 8), evidence of the extension of the conjugation in the N=C–N linkage to the phosphoryl group, involving strong p_π–d_π conjugation of the P–N bond.

¶ *Method A*: To a stirred solution of $(EtO)_2P(O)Me$ (0.167 g, 1.1 mmol) in dry THF (4 ml) was added Bu^nLi (0.68 ml, 1.1 mmol, 1.6 M in hexanes) at −78 °C under N_2. After stirring for 1 h at −78 °C, Me_2NCN (0.070 g, 1.0 mmol) was added, and the mixture warmed to −5 °C for 30 min. Allyl bromide (0.106 g, 1.0 mmol) was added dropwise and the mixture was warmed to room temp. After 1 h saturated aqueous NH_4Cl (5 ml) was added and stirring continued for 10 min. Extraction with Et_2O (3 × 20 ml), drying and removal of the solvent under reduced pressure gave the crude product. Pure **8c** was obtained (0.178 g, 68%) by flash column chromatography (EtOAc–MeOH, 10 : 1): δ_H(200 MHz, $CDCl_3$) 1.27–1.34 (t, *J* 7.06, 6 H), 2.34–2.46 (m, 2 H), 2.84–2.96 (m, 2 H), 3.00 (s, 3 H), 3.01 (s, 3 H), 4.05 (dq, J_{P-H} 5.02, J_{H-H} 5.02, 4 H), 4.98–5.14 (m, 1 H), 5.77–5.97 (m, 1 H); δ_C(50 MHz, $CDCl_3$) 16.19 (J_{P-C} 6.77), 30.71, 31.91 (J_{P-C} 6), 38.01, 38.31, 115.42, 136.42, 169.01 (J_{P-C} 15.05); HRMS (EI) calc. 262.1446, found 262.1436.

Method B: To a stirred solution of **5e** (0.244 g, 1.1 mmol) in dry THF (4 ml) was added LDA (0.53 ml, 1.1 mmol, 2.0 M in THF) at −78 °C under N_2. After stirring for 1 h at −78 °C, benzaldehyde (1.06 g, 1.0 mmol) was added dropwise. After 1 h, saturated aqueous NH_4Cl (5 ml) was added, and stirring continued for 10 min. Extraction with Et_2O (3 × 20 ml), drying and removal of the solvent under reduced pressure gave the crude product. Pure **8e** was obtained (0.302 g, 92%) by flash column chromatography (EtOAc–MeOH, 10 : 1): δ_H(300 MHz, $CDCl_3$) 1.14–1.18 (t, J_{H-H} 7.09 Hz), 1.18–1.23 (t, J_{H-H} 7.05), 2.88–2.94 (m, 1 H), 2.94 (s, 3 H), 2.96 (s, 3 H), 3.13–3.21 (m, 1 H), 3.87–3.99 (m, 4 H), 4.86 (br d, 1 H), 6.09 (br s, 1 H), 7.09–7.22 (m, 3 H), 7.30–7.33 (m, 2 H); δ_C(75 MHz, $CDCl_3$) 15.99 (d, J_{P-C} 6.975), 38.20, 38.40, 42.63 (d, J_{P-C} 6.375), 61.919 (t, *J* 5.625), 71.04, 125.10, 127.09, 128.15, 144.54, 166.59 (d, J_{P-C} 15.6); δ_P(120 MHz, $CDCl_3$) +8.083; HRMS (EI) calc. 328.1552, found 328.1579.

Novel porphyrin–viologen rotaxanes

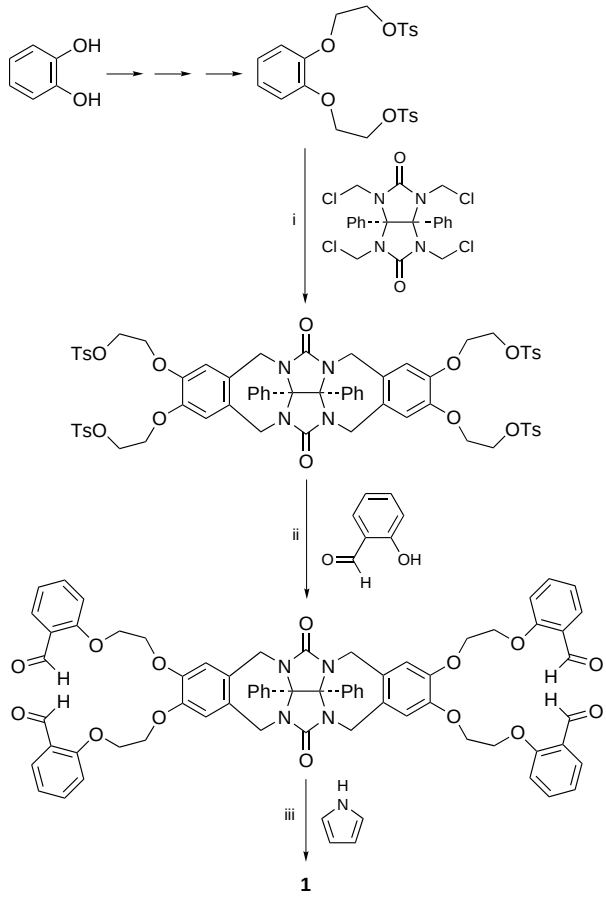
Alan E. Rowan,*† Patrick P. M. Aarts and Koen W. M. Koutstaal

Department of Organic Chemistry, NSR Center, University of Nijmegen, Toernooiveld 6525 ED Nijmegen, The Netherlands

A new porphyrin-containing host has an exceptionally high affinity for viologen guests, with binding constants as high as K_{ass} = 7 × 10^6 M^{-1} in organic solvents, allowing the construction of porphyrin–viologen rotaxanes.

The design and construction of rotaxanes and catenanes using a 'self-assembling' approach is now regularly reported in literature.[1] In general, however, few systems have been assembled which possess addressable cyclic components, with an eye toward the construction of functional devices.[2] An interesting functional species for incorporation in a rotaxane is a porphyrin. Somewhat surprisingly the inclusion of a porphyrin in such a system has only been preliminarily explored and mainly only as a photoactive endgroup.[3,4] Reported here is a new porphyrin-clip macrocycle **1** which binds methyl viologen (*N*,*N*′-dimethyl-4,4′-bipyridinium) and a variety of *N*-substituted derivatives with the highest binding constants reported to date and is an ideal basic building block for rotaxane synthesis.

Compound **1** was synthesized as depicted in Scheme 1.[5] Catechol was converted in three steps into 1,2-bis(2-*p*-tolylsulfonylethoxy)benzene (in 57% yield) which was then coupled with tetrachloromethyldiphenylglycoluril,[6] to generate the tetratosylate molecular clip. This U-shaped molecule was converted to the tetraaldehyde derivative and subsequently cyclized with pyrrole to give the porphyrin clip **1** (6%). NOESY and COSY 2D spectra revealed that the porphyrin moiety is situated rigidly and symmetrically, directly above the cavity.[5]



Scheme 1 *Reagents and conditions*: i, $SnCl_4$, $ClCH_2CH_2Cl$, 72%; ii, MeCN, K_2CO_3, 59%; iii, $BF_3{\cdot}Et_2O$, CH_2Cl_2, *p*-chloranil, 6%

The affinity of this new host for complexation with *N*,*N*′-derivatized 4,4-bipyridinium guests was investigated by UV–VIS spectroscopy. Host–guest titrations in MeCN–$CHCl_3$ (1 : 1, v/v) revealed the formation of exceptionally strong 1 : 1 charge-transfer complexes with all the viologen guests **2**. The strength and geometry of binding is strongly dependent upon the N-functionality of the guest. In the case of the methyl derivative **2a** the association constant, K_{ass} = (6.0 ± 0.9) × 10^5 M^{-1}, is several orders of magnitude higher than previously reported association constants for similar complexes.[3,7] Complexation of porphyrin clip **1** with *N*,*N*′-bis(2-hydroxyethyl)-4,4′-bipyridinium **2b**,[8] resulted in one of the strongest host–guest complexes in organic solvents reported to date [K_{ass} = (7.4 ± 0.8) × 10^6 M^{-1}]. The complex between **1** and the propylamine derivative **2c** displayed an association constant, K_{ass} = (9.0 ± 1) × 10^5 M^{-1}, which is more similar to that of the complex between **1** and **2a**.

^{1}H NMR studies on an equimolar solution of **1** and **2b** in CD_3CN–$CDCl_3$ (1 : 1, v/v) revealed large complexation shifts (see structure **1**). In the case of the porphyrin host, the central NH resonance was shifted significantly upfield by 1.16 ppm (from δ −2.79 to −3.95) implying that this proton is situated over the centre of an aromatic ring of the guest. Both sets of CH_2 protons, which link the porphyrin with the aromatic side-walls of the cavity, (ArOCH_aH_b and PorOCH_aH_b) were shifted downfield by identical amounts (+0.4 and +0.7 ppm), suggesting that these protons are at the side of an aromatic ring which is situated symmetrically between the two sets of protons. In the case of the resonances for the bipyridinium guest **2b** even larger shifts were observed, with the value of the shift diminishing as one goes from the centre of the bipyridinium ring to the end of the hydroxyethyl functions (see structure **2b** for $\Delta\delta$s). The exceptionally large upfield shifts for the β and α protons (−3.51 and −1.99 ppm) confirm that the guest sits in the cavity parallel to the porphyrin ring.

The ^{1}H NMR spectra (500 MHz) of an equimolar solution of **2a** and porphyrin clip **1** in contrast showed three broad resonances at δ 6.20, 4.13 and 3.35 for the α, β and methyl protons of the guest, respectively. The complexation shifts are even larger than those for the complex with **2b**: $\Delta\delta_\alpha$ = −2.66, $\Delta\delta_\beta$ = −4.24 and $\Delta\delta_{methyl}$ = −1.05 ppm. In contrast to the complex of **1** with **2b**, upon the addition of **2a** to the host only a very small upfield shift of the central NH proton (−0.17 ppm) was observed. The host protons ArOCH_2 of the complex with **2a** were now shifted upfield (−0.16 and −0.69 ppm) with the protons PorOCH_2 being unaffected by the complexation of the guest. The geometry of complexation of **2a** is such that the bipyridinium rings sit between the two aromatic walls of **1**, perpendicular with respect to the porphyrin. This binding geometry is different from that of **2b** but the same as that observed for complexation of this guest in a molecular basket derived from diphenylglycoluril.[7]

The difference in binding geometry of the two guests is also reflected in the UV–VIS spectra of the complexes. Upon

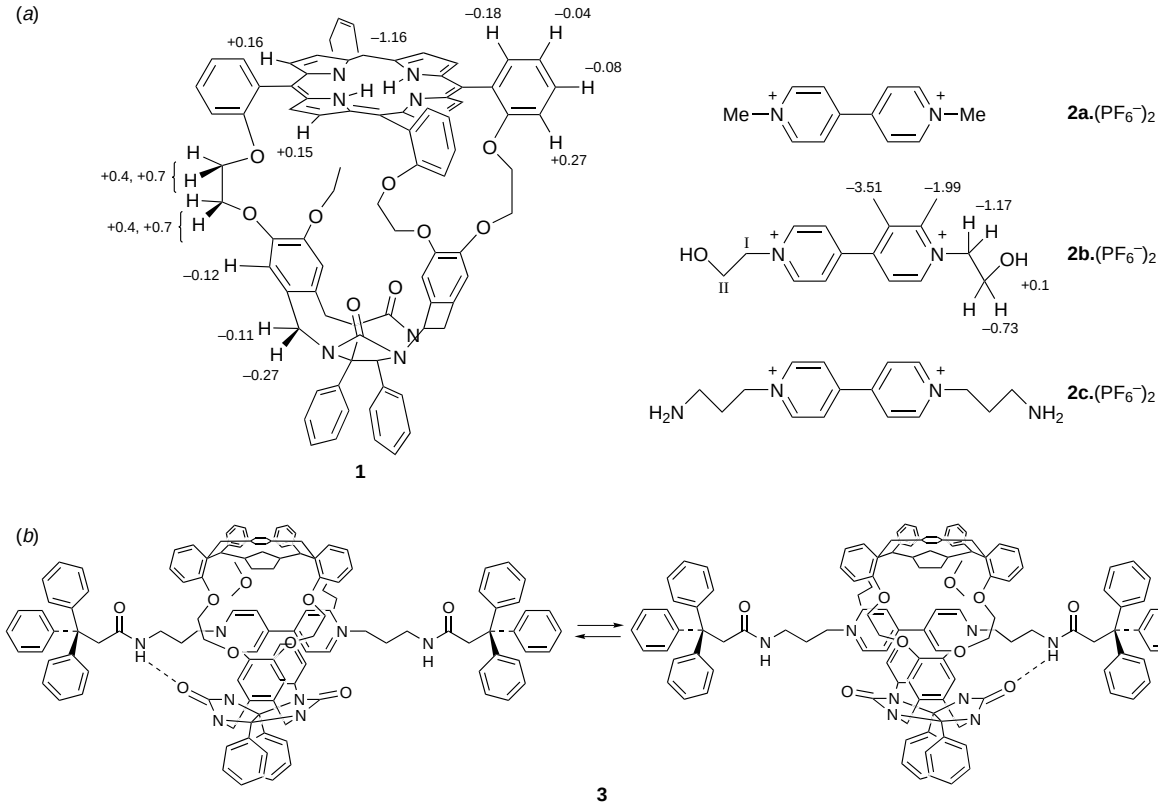


Fig. 1 (*a*) Porphyrin clip **1** and viologen guests **2**. The observed ^{1}H NMR complexation shifts for the 1 : 1 complex of **1** and **2b** ($CDCl_3$–CD_3CN) are indicated. (*b*) Rotaxane **3** assembled by the condensation reaction of 3,3,3-triphenylpropionyl chloride and the pseudo-rotaxane complex of **1** and **2c**.

addition of excess guest, the porphyrin Soret band in the UV–VIS spectrum was shifted to the red by 5 nm in the case of **2b** and only by 2 nm in the case of **2a**. The Q-bands remained unaffected. The addition of 10 equiv. of guest **2b** or 100 equiv. of the methyl derivative **2a** to the porphyrin clip caused an almost complete quenching of the porphyrin fluorescence $\{I/I_0$ at 645 nm (excitation 418 nm) = 0.02; [Host] = 2.9×10^{-6} mol l^{-1}, CH_3CN–$CHCl_3$ (1 : 1, v/v)$\}$, confirming the close proximity of the guest to the porphyrin.

Toward the construction of [*n*]rotaxanes assemblies it was decided to use the 1 : 1 complex of bis(aminopropyl)bipyridinium **2c** and porphyrin clip **1** as the basic building block. NMR studies showed that guest **2c** forms a pseudo-rotaxane complex with the NH_2 functions sticking outside the cavity. Simple condensation reactions of this 1 : 1 complex with acid chloride derivatives should enable a variety of amide rotaxanes to be formed.[9] Using the bulky stopper 3,3,3-triphenylpropionyl chloride a condensation reaction was carried out with the 1 : 1 complex of **1** and **2c**, to give molecule **3·(PF$_6$)$_2$** in 30% yield after column chromatography and counter-ion exchange. The resulting rotaxane was, surprisingly, very soluble in $CHCl_3$. ^{1}H NMR studies confirmed that the viologen is bound in the cavity, in an asymmetric geometry, rapidly exchanging between two equivalent sites in which the amide function of the thread hydrogen bonds to the carbonyl of the porphyrin clip (see structure **3**).[5]

As shown here the strong complexation between porphyrin clip **1** and bipyridinium guests **2** generates stable pseudo-rotaxane complexes. The cyclic porphyrin component allows the system to be potentially addressed by a variety of means: chemically,[3] electrochemically or photochemically.[4] Current studies are directed towards the construction of larger [*n*]rotaxane systems and arrays of porphyrin–viologens and the study of their properties.

We thank Professor R. J. M. Nolte and Professor J. F. Stoddart for discussions and their interest in this work.

Ligand and H/D exchange of $Mn(H_2O)_6^{2+}$ and $Cu(OH)(H_2O)_4^{+}$ in the gas phase

Steen Brøndsted Nielsen[a] and Gustav Bojesen*[b]

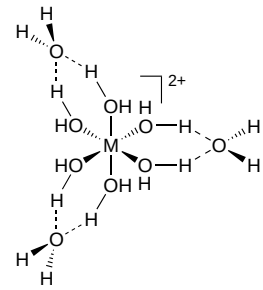
When ligand exchange of aqua complexes in the gas phase is examined by reaction with D_2O it is not accompanied by H/D exchange.

In solution, aqua complexes undergo exchange of intact ligands as well as proton exchange.[1] In the present work it is shown that whereas ligand exchange occurs in the gas phase, doubly charged aqueous complexes do not undergo proton exchange in the gas phase. Formation by electrospray of aqua complexes of doubly charged metal ions is well known.[2] However, only a few studies of ligand exchange in complexes of doubly charged metal ions in the gas phase have appeared.[3,4]

The spectra obtained when $Mn(H_2O)_6^{2+}$ is allowed to react with D_2O are shown in Fig. 1 for two different pressures of D_2O.[5] The parent ions occur at *m/z* 81.5 and the products of consecutive ligand exchange reactions occur at intervals of one *m/z* value above the parent ion. At low pressure the unexchanged reactant is the most abundant ion whereas the product of four ligand exchanges is the most abundant at high pressure. Since the ions are doubly charged, this shows that the exchange reaction leads to an increase in the mass of two Daltons. Hence the products have been formed by exchange of intact water molecules, and no evidence of hydrogen exchange is observed. The spectra shown in Fig. 1(*a*) and (*b*) include a group of peaks at *m/z* 72.5 and above which must arise from reactant ions which have lost one or more ligands. This is due to the poorly defined collision conditions when ion–molecule reactions (IMRs) are studied in a multipole. In order to optimize the yield of IMRs the axial velocity of the ions is kept low, and under such circumstances the radial RF field in the multipole may contribute significantly to the kinetic energy which is available in the collisions.[6] When the pressure of D_2O is increased, products of addition as well as ligand exchange reactions are observed [Fig. 1(*b*)]. The six equidistant peaks above that from the reactant show that at this pressure all six water molecules in the parent ion can be exchanged. The abundance of the products formed by loss of a ligand is increased, and products of addition reactions are observed. In the observed addition products all the ligands have been exchanged. This phenomenon is well known from studies of H/D exchange reactions in quadrupole instruments.[7–10] Briefly it is a consequence of the instability of the addition product relative to dissociation back into the reactants. The addition product can be stabilized by different mechanisms but these all require a pressure at which all the ligands in the parent ion have been exchanged. For most of the aqueous complexes the largest clusters which we have observed under high-pressure conditions have nine water molecules, independently of the size of the parent complex.[11] This shows that the binding of a tenth ligand is very weak. A structure which is in agreement with this is shown in Scheme 1.



Scheme 1

Whereas H/D exchange has not been observed in the doubly charged ions, it is readily observed in singly charged ions. Fig. 2 shows the spectrum obtained when $^{63}Cu(OH)(H_2O)_4^{+}$ is allowed to react with D_2O. Such hydroxidoaqua complexes are

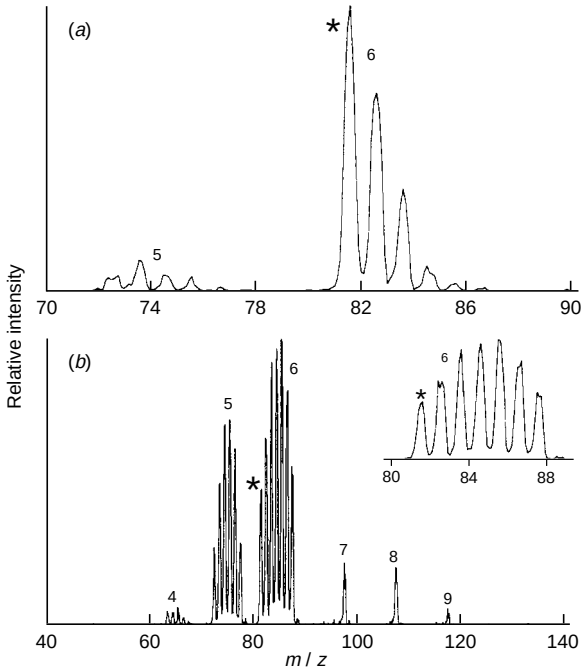


Fig. 1 Spectra obtained from the reaction between $Mn(H_2O)_6^{2+}$ and D_2O at two different pressures; (*a*) 0.20 (*b*) 0.40 mTorr. The reactant ion is indicated by *. The number at each group of peaks indicates the number of aqua ligands in the complex assigned to the peaks.

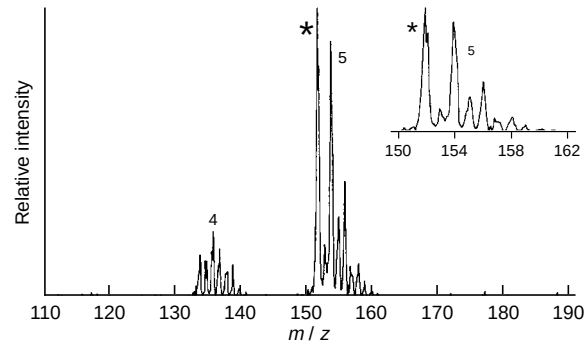

Fig. 2 Spectrum obtained from the reaction between $^{63}Cu(OH)(H_2O)_4^{+}$ and D_2O at 0.20 mTorr. The reactant ion is indicated by *. The number at each group of peaks indicates the number of ligands (including one hydroxido) in the complex assigned to the peaks.

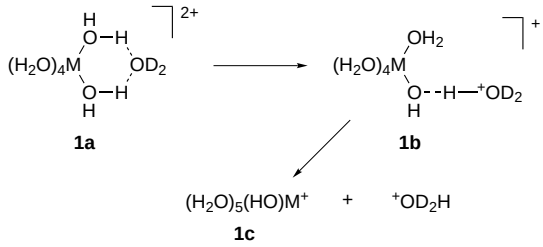

Scheme 2

formed in the source along with the aqua complexes. The equivalent complex with manganese could not be generated in sufficiently high abundance to study its reactivity in IMRs. This difference in acidity of copper and manganese aqua complexes in the gas phase has been noticed before.[2] The reactant ion $^{63}Cu(OH)(H_2O)_4^+$ gives a peak at *m/z* 152, and the products of the exchange reaction are observed at intervals of one *m/z* value above. Products of exchange and ligand loss are observed at *m/z* 134 and above. The most abundant products occur at *m/z* 154 and *m/z* 156. This seems to indicate that exchange of the intact ligand is preferred for the singly charged complex, but the observation of peaks at *m/z* 153, 155, 157 shows that in the singly charged complex the hydrogen atoms can be exchanged one at a time.

The absence of H/D exchange in the reaction between the doubly charged complex $Mn(H_2O)_6^{2+}$ and D_2O is in agreement with the model which previously has been used to rationalize the reactivity of ligated doubly charged metal ions and of doubly charged molecular ions.[12–14] Excluding exchange of hydrogen radicals or simultaneous exchange reactions, the mechanism giving exchange of a singly hydrogen would have to proceed by intermediates in which the two charges are partially separated. The overall product of the reaction will be proton transfer rather than exchange as is observed at high D_2O pressures. A possible mechanism is shown in Scheme 2.

Protonation of inner-sphere ligands has been proposed to play a role in the exchange of water complexes.[15] However, in the gas phase formation of ions such as **1b** must be energetically disfavoured.[12,13] The absence of H/D exchange indicates that when an intermediate such as **1b** is formed in an IMR, the electrostatic repulsion prevents the incipient hydroxonium ion and the complex from remaining together for long enough for back exchange of a deuteron to occur. The overall outcome of the reaction will then be transfer of a proton rather than H/D exchange.

The structure of hydrated doubly charged metal ions and the dynamics of the exchange reaction are being very actively studied both experimentally and theoretically.[16–19] In aqueous solutions of $Mn(H_2O)_6^{2+}$ ligand exchange is faster than proton exchange.[20] The results presented here show that the exchange of the intact ligand has its parallel in the gas phase, but that the very different influence of electrostatic interactions prevents the occurrence of H/D exchange reactions.

High catalytic efficiency of transition metal complexes encapsulated in a cubic mesoporous phase

M. Eswaramoorthy, Neeraj and C. N. R. Rao,*

Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur Post, Bangalore 560 064, India

Copper(II) acetate dimer and $[Mn^{II}(bipy)_2]^{2+}$ encapsulated in cubic Al-MCM-48 show high catalytic activity in the oxidation of phenol to catechol by oxygen activation, and of styrene to styrene oxide by singlet oxygen, respectively.

Transition metal complexes encapsulated in the cavities of zeolites are known to exhibit high catalytic activity in certain oxidation reactions, suggesting that these catalytic systems are good enzyme mimics.[1] Oxidation of phenols with O_2 by copper acetate dimer incorporated in MCM-22 or VPI-5 is a case in instance wherein the copper(II) complex mimics the phenolase activity of tyrosinase.[2,3] Besides the activation of O_2, there have been studies of the oxidation of organic compounds with singlet oxygen sources such as H_2O_2, by metal complexes encapsulated in molecular sieves. Selective oxidation of alkenes by bis(2,2′-bipyridyl)manganese, $[Mn(bipy)_2]^{2+}$, encapsulated in zeolites X and Y is one such example.[4] The $[Mn^{II}(bipy)_2]^{2+}$ complex immobilized in mesoporous Al-MCM-41 has been recently shown to exhibit high catalytic activity for styrene oxidation.[5] Based on the geometry of the pore structures of mesoporous solids, it was our view that the cubic phase should be an excellent host for enhancing the catalytic activity of metal complexes. We have therefore investigated the catalytic activity of two transition metal complexes incorporated in mesoporous Al-MCM-48, in oxidation reactions. The metal complexes examined are copper(II) acetate dimer which has the structural features of Cu-containing monooxygenase enzymes[2,3] and $[Mn^{II}(bipy)_2]^{2+}$. While copper(II) acetate incorporated in Al-MCM-48 was primarily meant to examine the catalytic activity for oxygen activation at ambient conditions, the manganese(II) complex system was intended to study the oxidation of styrene by singlet oxygen.

Al-MCM-48 was prepared by employing a modified procedure. To a solution of 2.9 g of cetyltrimethylammonium bromide in 40 ml of deionised water, 2.8 ml of 5 M NaOH was added and the solution stirred for 30 min. To this, a solution containing 0.09 g of aluminium sulfate dissolved in 10 ml of water was added followed by the dropwise addition of 6.2 ml of tetraethylorthosilicate. The mixture was stirred for 1 h, transferred to a stainless steel autoclave and kept at 383 K for 5 days. The final product was filtered, washed several times with deionised water, dried at 353 K for 3 h and calcined at 773 K for 10 h in air to remove the template. The Si/Al ratio in the product was *ca*. 50. The cubic nature of the mesoporous phase was confirmed by X-ray diffraction (Fig. 1). Distinct (211), (220), (321), (400) and (332) reflections were seen in the pattern. Cu-acetate-Al-MCM-48 was prepared by stirring 0.4 g of Al-MCM-48 with 0.2 g of copper acetate monohydrate in distilled, deionised water for 12 h. The product was filtered, washed with water and dried at 383 K for 24 h in vacuum. The Cu/Al ratio in the final product was 0.15. The XRD pattern given in Fig. 1 shows the cubic mesoporous nature of the catalyst. The surface area of the catalyst was 600 $m^2\ g^{-1}$. Al-MCM-48-$[Mn(bipy)_2]^{2+}$ was prepared by the treatment of Al-MCM-48 (0.3 g) with a solution of 0.3 g of $[Mn(bipy)_2][NO_3]_2$ in 20 ml of 1:9 (by volume) DMF–acetonitrile mixture at room temperature for 48 h. The sample was filtered, washed with acetonitrile and dried at 353 K under vacuum for 1 h. Chemical analysis showed that the Mn/Al ratio in the product was 0.14. The XRD pattern (Fig. 1) confirmed that the cubic mesoporous structure was retained. The surface area of the catalyst was 770 $m^2\ g^{-1}$.

The second derivative EPR spectrum of Cu-acetate-Al-MCM-48 ($g_\perp$ = 2.06, $g_\parallel$ = 2.18) exhibited the expected

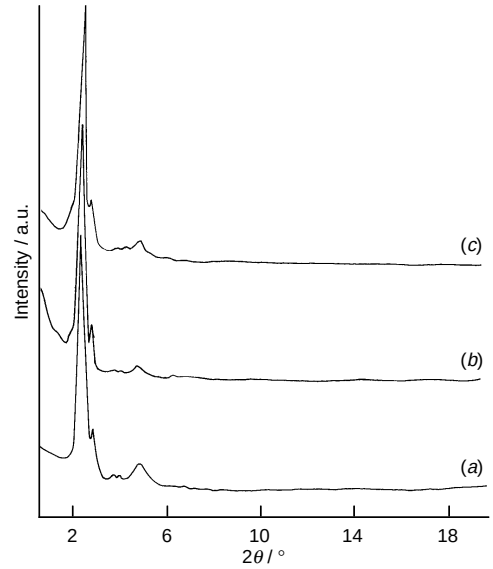

Fig. 1 X-Ray diffraction patterns of (*a*) calcined Al-MCM-48, (*b*) copper acetate dimer encapsulated Al-MCM-48 and (*c*) $[Mn(bipy)_2]^{2+}$ encapsulated Al-MCM-48

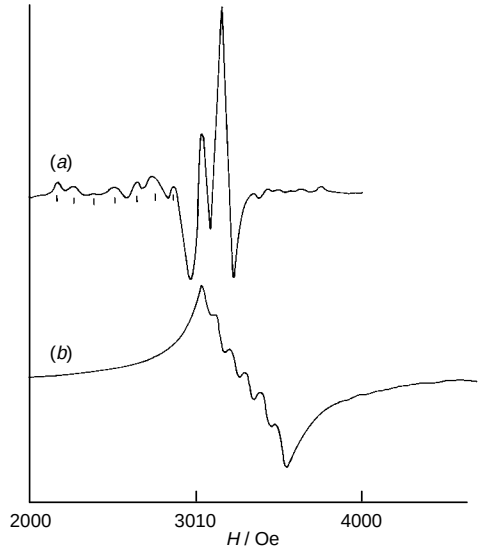

Fig. 2 EPR spectra of (*a*) copper acetate dimer and (*b*) $[Mn(bipy)]^{2+}$ encapsulated in Al-MCM-48

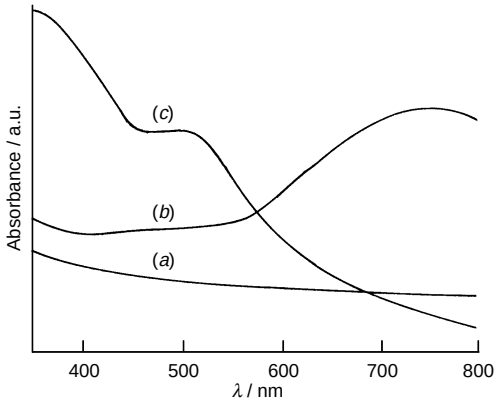

Fig. 3 Electronic absorption spectra of (*a*) Al-MCM-48, (*b*) copper acetate dimer encapsulated in Al-MCM-48

hyperfine structure [Fig. 2(*a*)], establishing the presence of the copper(II) acetate dimer.[3] The IR spectrum showed the carboxylate absorption at 1629 cm^{-1}. The diffuse reflectance spectrum [Fig. 3(*b*)] gave a band around 740 nm, just as in the case of the copper acetate encapsulated zeolites. Oxidation of phenol by the Cu-Al-MCM-48 catalyst was studied by stirring 100 mg of the catalyst in a phosphate buffer solution with 0.57 mmol of phenol in an oxygen atmosphere at 303 K. Gas chromatographic analysis of the product indicated 36% conversion, with catechol as the primary product. The turnover number was 37, a value considerably higher than that found (*ca*. 4) with copper(II) acetate alone. This result demonstrates the high catalytic activity of Cu-Al-MCM-48 in the orthohydroxylation of phenol by oxygen activation.

The Al-MCM-48-$[Mn(bipy)_2]^{2+}$ gave an EPR spectrum with the expected hyperfine structure due to Mn^{2+} [Fig. 2(*b*)]. It was pink with a broad band around 490 nm in its DRS, due to the metal–ligand charge transfer transition [Fig. 3(*c*)]. The IR spectrum showed bands at 760 and 773 cm^{-1} due to the out-of-plane C–H deformation of the bipy. Oxidation of styrene was studied by taking 100 mg of the catalyst in a solution of 0.87 mmol of styrene in 5 ml of acetonitrile, to which 3.5 mmol of H_2O_2 was added. Gas chromatographic analysis showed the conversion to be *ca*. 40% with styrene oxide as the primary product. The turnover number was 82 compared with *ca*. 7 for the $[Mn(bipy)_2]^{2+}$ complex alone. In the hexagonal mesoporous host, Al-MCM-41, the maximum turnover number was 58.[5] This result establishes Al-MCM-48-$[Mn(bipy)_2]^{2+}$ to be an excellent catalyst for such oxidation reactions. It is to be noted that the turnover number for styrene oxidation with Cu-acetate-Al-MCM-48 catalyst was 46, but there was hardly 5% conversion to styrene oxide, the main product being benzaldehyde. Similarly, the turnover number of the manganese catalyst for the oxidation of phenol through the activation of molecular oxygen was 14 and the product contained almost no catechol. These results reveal the specificity of the metal complexes encapsulated in the cubic mesoporous phase.

The present study not only demonstrates the high catalytic potential of transition metal complexes encapsulated in cubic mesoporous phases in oxidation reactions, but also the need to explore other reactions as well as mesophase compositions with different Si/Al ratios.

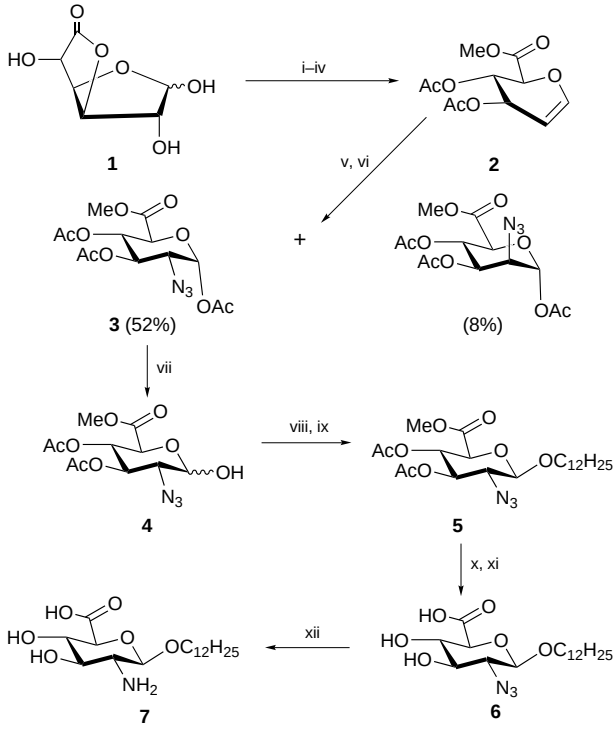
A poly(sugar amino acid) having self-assembling properties was efficiently synthesised by simple polymerisation of 1-*O*-dodecyl-2-amino-2-deoxy-β-D-glucopyranosiduronic acid 7 derived from D-glucofuranurono-6,3-lactone as the key starting material.

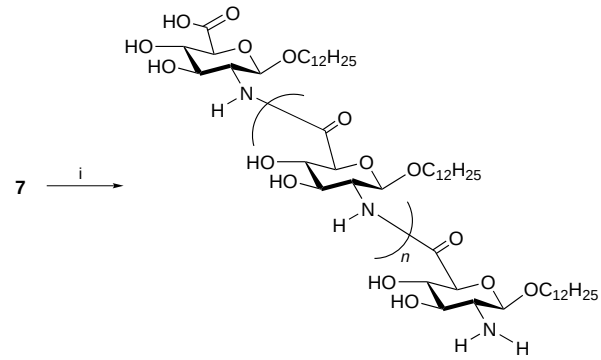
The growing importance of glycoconjugates in biology[2] and the emergence of libraries[3] for the construction of glycodrugs prompted us to design and synthesise a series of carbohydrate analogues and glycomimetics.[4] Carbopeptoids[5] (peptide-bond linked carbohydrates) are also potential candidates for functional glycomimetics having interesting biological activity as carbohydrate or peptide mimetics. Sugar amino acids (SAAs)[6,7] and their derivatives are important synthons for the preparation of a series of carbopeptoids.[8] One of the synthetic SAAs has been incorporated into a cyclic peptide with the β-turn motif of somatostatin containing Phe-Trp-Lys-Thr.[9] Poly(sugar amino acid)s [poly (SAA)s],[10] peptide-bond linked polysaccharide mimetics (polyamides[11]) derived from the SAAs, are regarded as one of the potential starting points for the synthesis of a novel class of biocompatible and/or biodegradable materials. As part of our ongoing efforts in designing artificial glycoclusters with specific functions,[12] we report herein the first synthesis of poly(sugar amino acid)s able to self-assemble to form stable monomolecular layers using the readily available D-glucofuranurono-6,3-lactone **1** ($194 per 1 kg, Aldrich Chemical Company, Inc.) as a key starting material.



Scheme 1 *Reagents and conditions*: i, NaOH, MeOH; ii, Ac_2O, C_5H_5N; iii, HBr–AcOH; iv, Zn, AcONa, $CuSO_4$, 60% from **1**; v, NaN_3 (1.4 equiv.), $Ce(NO_3)_6(NH_4)_2$ (2.3 equiv.), MeCN, −15 °C, 20 h; vi, NaOAc (3 equiv.), AcOH, 100 °C, 1 h, 52% from **2**; vii, $BnNH_2$ (1.5 equiv.), THF, 20 °C, 3 h, 99%; viii, DAST (1.2 equiv.), THF, −20 °C, 15 min; ix, $C_{12}H_{25}OH$ (2.0 equiv.), Cp_2ZrCl_2 (2.5 equiv.), $AgClO_4$ (5.0 equiv.), C_6H_6, 4 Å molecular sieves, 25 °C, 16 h, 45% from **4**; x, NaOMe (0.2 equiv.), MeOH, 25 °C, 1.5 h; xi, 1 M NaOH (aq.) (1.0 equiv.), MeOH, 25 °C, 3 h, then 1 M HCl (aq.) (pH 3), 79% from **5**; xii, Pd–C, H_2 gas, MeOH, 25 °C, 48 h, 55%

For the construction of the amphiphilic poly(sugar amino acid) we designed a D-glucosaminuronic acid derivative **7** as an amphiphilic SAA monomer. Scheme 1 summarises the synthetic route to the target compound **7** starting from **1**. Thus, manipulation of **1** by a known sequence afforded glucal derivative **2** in large quantities.[13] The latter compound was then converted to 2-azido derivative **3**, under standard conditions for the azidonitration of glucals,[14] in 52% overall yield.‡ Removal of the C-1 acetyl group of **3** was accomplished *via* treatment with benzylamine to afford hemiacetal **4** in quantitative yield. Fluorination of the 1-OH group of **4** with DAST, followed by direct glycosylation with dodecan-1-ol in the presence of Cp_2ZrCl_2–silver perchlorate (1 : 2) in benzene gave β-glycoside **5** in 45% yield from **4**.‡§ Successive treatment of **5** with NaOMe–MeOH and aq. NaOH afforded intermediate **6** in 79% overall yield.¶ Hydrogenolysis of **6** over Pd–C gave amphiphilic SAA monomer **7** in 55% yield.‡

Polymerisation of monomer **7** having two unprotected hydroxy groups at the C-3 and C-4 positions proceeded smoothly using diphenylphosphoryl azide (DPPA) according to the published procedure[15] and gave new poly(SAA) in 72% yield (Scheme 2).‖ The molecular weight of the poly(SAA) was estimated to be in the range 700–4500 (DP = 2–13) by the MALDI-TOF mass spectrum.‖ This polymer forms a stable monolayer *via* spreading of a dilute DMSO–$CHCl_3$ solution on a pure water surface. The surface pressure–area diagram shows a steep increase of the surface pressure at around 1.8 nm^2 per molecule [Fig. 1(*a*)]. This indicates that the poly(SAA) molecules are closely packed. Upon further compression the monolayer collapses, at 50 mN m^{-1}. On the other hand, compound **7**, the repeating unit of this polymeric amphiphile, exhibited a poor ability to form a monomolecular layer,



Scheme 2 *Reagents and conditions*: i, $Ph_2P(O)N_3$ (2.3 equiv.), Et_3N (2.3 equiv.), DMSO, 25 °C, 15 h, 72%

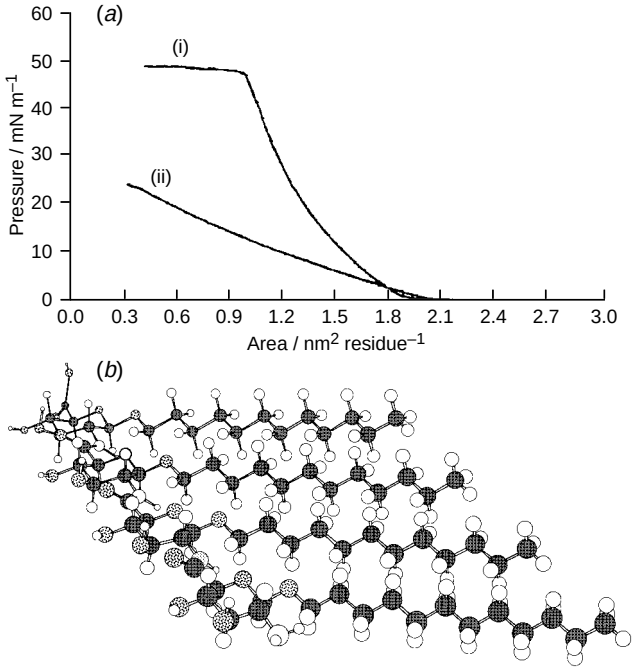


Fig. 1 (*a*) Surface pressure–area isotherms of (i) poly(SAA) and (ii) monomer **7**. (*b*) Possible molecular arrangements of the amphiphilic poly(SAA).

suggesting that the stable peptide bond-type linkages of poly(SAA) are efficient triggers for control of the orientation of the hydrophilic sugar head groups and the hydrophobic alkyl tails, as indicated in the possible molecular arrangements of the polymer [Fig. 1(*b*)]. It should also be noted that the highly ordered structure of the amphiphilic poly(SAA) will favour further chemical and/or enzymatic modification of the two hydroxy groups at the C-3 and C-4 positions. The versatility of the synthetic strategy using poly(SAAs) as 'scaffolds' allows monolayers to be applied to a variety of novel supramolecular materials[16] having specific molecular recognition sites, such as galactose and sialic acid residues.

Isolation and characterisation of the two major isomers of [84]fullerene (C_{84})

T. John S. Dennis, Tsutomu Kai, Tetsuo Tomiyama and Hisanori Shinohara*†

Department of Chemistry, Nagoya University, Nagoya 464-8602, Japan

We report the first successful separation of the two major isomers of C_{84}, *i.e.* [84-D_2]fullerene and [84-D_{2d}(II)]-fullerene, and ^{13}C NMR and UV–VIS–near IR absorption spectra of the purified materials.

[84]Fullerene, C_{84}, is one of the first higher fullerenes found in arc-processed soot, and solvent extracted in macroscopic amounts.[1] C_{84} has 24 structural isomers obeying the isolated pentagon rule (IPR).[2] Early ^{13}C NMR studies[3,4] indicated that the two major isomers of [84]fullerene have D_2 and D_{2d}(II) symmetry and a 2 : 1 abundance ratio. Theoretical calculations[5,6] predict that the D_2(IV) and D_{2d}(II) isomers are the most stable of the 24 IPR isomers. A number of spectroscopic and structural studies have been carried out on [84]fullerene during the last seven years.[7] However, since the separation of the D_2 and D_{2d}(II) isomers had not been achieved, none of these experiments have been carried out on isomer-free samples. Here we report the first successful isolation of the two major isomers of [84]fullerene.

Separation of C_{84} isomers was achieved by recycling HPLC using a Cosmosil *5PYE* column and toluene as eluent (20 mm × 250 mm; 10 ml injections of C_{84} solution; 18 ml min^{-1} flow rate).[8] Fig. 1 shows the resulting first-recycling-phase HPLC profile. In this figure, the D_2 and D_{2d} isomers are seen to be partially separated. Complete separation could not be achieved at this stage by continuing to recycle due to peak spreading. However, by cutting the sample at the line marked in Fig. 1, fractions greatly enriched in each of the two isomers were obtained. Further enrichment resulted from repeating the 20 cycle HPLC and cutting technique, and pure D_2 isomer was obtained after a third treatment. The D_2 isomer has the shorter retention time on this column, and because of the tailing of the D_2 fraction into the D_{2d}, two further recycling HPLC treatments are required to produce pure D_{2d} isomer.

Fig. 2 shows the ^{13}C NMR spectra of the purified D_2 and D_{2d} fractions. These spectra give a good indication of the purity of our samples, as there is no detectable contamination of the D_2 C_{84} fraction by the D_{2d}, or *vice versa*. Fig. 2(*a*) contains 21 lines of almost equal intensity, and Fig. 2(*b*) contains 11 lines with one being of roughly half the intensity of the others. These correspond to the D_2 and D_{2d}(II) isomers, respectively. We can confirm that the previous ^{13}C NMR spectra[3,4] of the mixture are convolutions of the present isomer-free spectra. However, owing to the 2 : 1 D_2 : D_{2d} isomer abundance ratio, in the spectrum of the mixture all lines due to the D_2 isomer and ten of the eleven lines due to the D_{2d} isomer have the same intensity. Therefore, we are also able to show for the first time which lines belong to which isomer. Since the submission of the present communication, an attempt to assign these 31 lines, on the basis of a comparison of ^{13}C NMR spectra of a central and tail cut from the main C_{84} band in an HPLC profile, has appeared in the literature.[9] This was only moderately successful, having six incorrect assignments.

Among the 24 possible IPR isomers of C_{84}, four have D_2 symmetry and two have D_{2d} symmetry. The present D_{2d} isomer can be unambiguously assigned to C_{84} isomer II. This isomer possesses 11 different carbon atom environments. One of these

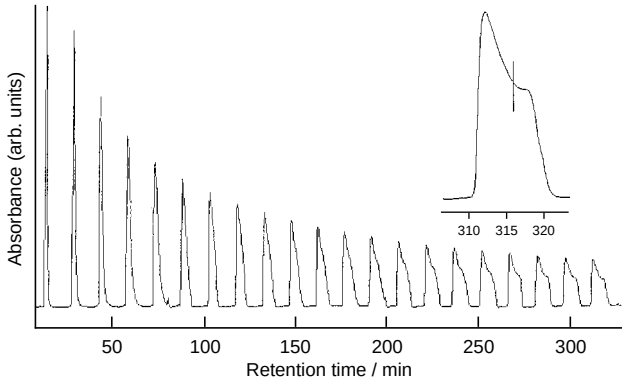

Fig. 1 HPLC profile taken from the second recycling-phase. The insert is an expanded view of the 20th cycle. Partial separation of the two major isomers of C_{84} has occurred, and by cutting at the line shown in the insert, fractions enriched in the D_2 and D_{2d} isomers are obtained. Several more recycling HLPC treatments are required to produce pure materials.

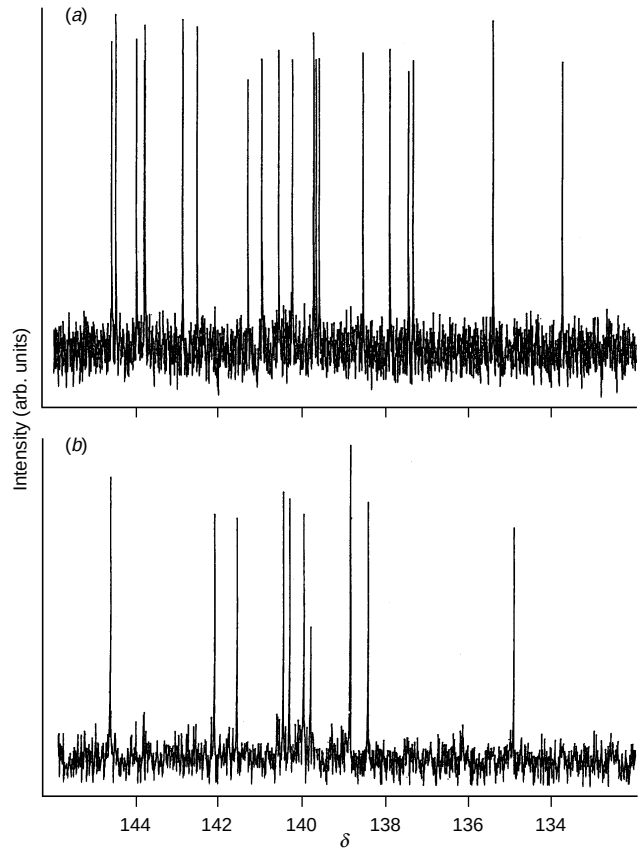

Fig. 2 ^{13}C NMR spectra of the purified two major isomers C_{84}: (*a*) one of the four D_2 IPR isomers, and (*b*) [84-D_{2d}(II)]fullerene. The measured chemical shifts for the present C_{84} isomers are: D_2 δ 133.81, 135.48, 137.39, 137.50, 137.91, 138.58, 139.63, 139.74, 139.77, 139.79, 140.32, 140.60, 141.00, 141.33, 142.58, 142.89, 143.78, 143.81, 143.98, 144.48, 144.58; D_{2d}; δ 134.98, 138.48, 138.87, 138.88, 139.82, 140.00, 140.37, 140.50, 141.57, 142.13, 144.60.

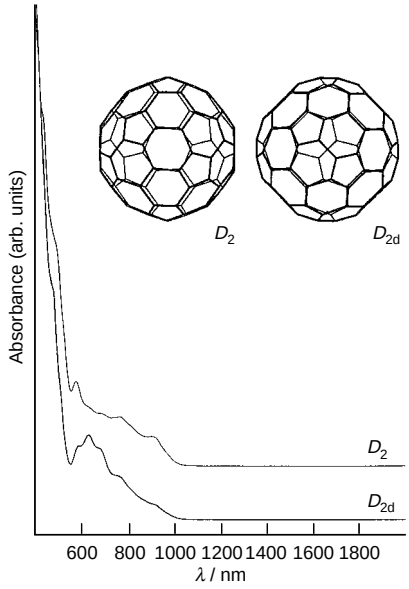

Fig. 3 UV–VIS–near IR absorption spectra of the D_2 and D_{2d}(II) isomers of C_{84}

occurs four times, and the other ten each occur eight times. This fits perfectly with the spectrum given in Fig. 2(*b*), both in terms of the number of lines and their relative intensities. An unambiguous assignment cannot be given to the D_2 isomer, as all four IPR D_2 isomers would have a one-dimensional ^{13}C NMR spectrum consisting of 21 equal-intensity lines. However, a recent two-dimensional ^{13}C NMR study[10] suggests that the present sample corresponds to $C_{84}\{D_2(IV)\}$.

Fig. 3 shows the UV–VIS–near IR absorption spectra of the purified C_{84} D_2 and D_{2d}(II) isomers. The absorption dip near 600 nm in the spectrum of the present D_{2d}(II) C_{84} sample accounts for this isomer being green; the D_2 isomer is yellow–brown in CS_2 solution.

The UV–VIS–near IR absorption spectrum of [84-D_2(II)] fullerene is considerably different from the discandium *incar*-fullerene *i*$Sc_2C_{84}\{D_2(II)\}$,[11,12] even though they share the same C_{84} isomer. This indicates that metal encapsulation alters substantially the electronic structure of the host fullerene.

Catalytic enantioselective epoxidation of alkenes with a tropinone-derived chiral ketone

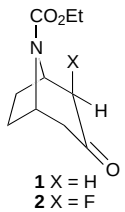
Alan Armstrong*† and Barry R. Hayter

Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD

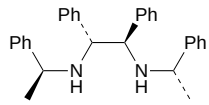
α-Fluoro-*N*-ethoxycarbonyltropinone is an efficient catalyst for the epoxidation of alkenes by Oxone® with good enantioselectivity.

The development of catalytic methods for the asymmetric epoxidation of unfunctionalised alkenes continues to be an important goal in organic chemistry.[1] The chiral manganese salen complexes developed by Jacobsen and Katsuki provide a solution to this problem for certain alkene substitution patterns, but these catalysts generally give poor enantioselectivity for epoxidation of, for example, *trans*-disubstituted alkenes.[1] Recently, attention has focused on the catalysis of Oxone® epoxidation of alkenes[2] by chiral ketones[3–6] (*via* a dioxirane[7]‡) and by chiral iminium salts[8] (*via* an oxaziridinium species) as a possible solution to this problem, and some impressive advances have been recorded. Yang and co-workers described a catalytic binaphthyl-based ketone which, with appropriate substitution, can give high selectivity [up to 84% ee for the epoxidation of (*E*)-stilbene].[3] Shi has reported a D-fructose-derived chiral ketone which gives extremely high enantioselectivities, but is destroyed under the Oxone® epoxidation conditions, presumably by Baeyer–Villiger reaction.[4] It must therefore be used in relatively large quantities, although modified pH conditions have improved the catalytic efficiency of the process.[4b] The enantiomeric catalyst derived from L-fructose is less readily available, however. Here we describe some of our own results in the development of new ketone catalysts which have led to the discovery of a new class of chiral ketone which can be used catalytically and recycled if required, as well as affording high enantioselectivities for alkene epoxidation.

Recognising the need for an efficient ketone catalyst to be activated electronically towards attack,[3,9] we initially examined several classes of α-functionalised ketone. Of these, α-amido ketones were attractive with regard to the easy introduction of asymmetry, but were prone to decomposition by Baeyer–Villiger reaction.[9] We therefore turned our attention to β-amido ketones and in particular, in view of the need eventually to prepare conformationally well-defined chiral catalysts, tropinone derivatives. Commercially available *N*-ethoxycarbonyltropinone **1** provided promising initial results: using **1** (10 equiv.) and Oxone® (10 equiv.) under the Yang MeCN–H_2O conditions,[10] (*E*)-stilbene was epoxidised completely within 3 h. Importantly, there was no evidence for decomposition of **1** under these conditions. Reasoning that electron-withdrawing substituents should further increase the activity of the catalyst,[11] we prepared the α-fluoro derivative **2** from **1** by treatment of the derived trimethylsilyl enol ether with a Selectfluor reagent.[12]§ Racemic **2** proved to be an excellent catalyst for the epoxidation of (*E*)-stilbene (Table 1): using 10 mol% **2**, reaction was complete in less than 2 h (entry 4), while reasonable conversions were possible at the 1 mol% level over longer time periods (entry 6).¶ There was no evidence for Baeyer–Villiger reaction by ^{1}H NMR spectroscopy, and the catalyst could be recovered (*ca*. 70% yield) by column chromatography.



1 X = H
2 X = F



3

In view of the extremely promising catalytic activity of **2**, we then attempted its synthesis in enantiomerically pure form. Following the work of the Simpkins group on desymmetrisation of tropinones using chiral lithium amide bases,[13] treatment of **1** with the lithium amide base derived from **3**[14] (1 equiv.) and Bu^nLi (2 equiv.) in the presence of Me_3SiCl (5 equiv.) and LiCl (1 equiv.) gave the crude silyl enol ether which was reacted without purification with the Selectfluor reagent. The resulting sample of **2** (36% yield, unoptimised), *ca*. 60% ee, was recrystallised once from Et_2O–light petroleum and then once from CH_2Cl_2–light petroleum to provide ketone **2** in > 98% ee according to chiral HPLC.‖ The relative stereochemistry of **2** was proven by X-ray crystallography;** the absolute stereochemistry is assigned based on the precedent of Simpkins, who converted the same intermediate silyl enol ether into (−)-anatoxin-a.[13] It should be noted that the antipodal form of the chiral amine **3** is also readily available,[14] and so it should be possible to access the other enantiomer of **2** by this route. We are also currently exploring resolution methods.

Enantiomerically enriched **2** was used as catalyst for the Oxone® epoxidation of a range of alkenes (Table 2) and the results are extremely promising. Enantioselectivities of up to 83% have been obtained. Interestingly, all our results to date fit a simple transition state model (Fig. 1), which assumes attack on the sterically less hindered *exo*-oxygen of the dioxirane intermediate and a spiro transition state (in accord with Yang[3] and Shi[4]). The hydrogen substituent on the alkene occupies the region of the fluorine substituent of the catalyst. In accord with this model, the epoxidation of styrene, where there are two possible hydrogens on the terminal carbon of the alkene that can occupy the catalyst fluorine region, proceeds with lower enantioselectivity (entry 5). Amongst the other substrates examined so far, it is noteworthy that α,β-unsaturated esters can be epoxidised under these conditions with moderate (but

promising) enantioselectivity (entry 6), albeit requiring longer reaction times and higher catalyst loadings.

In conclusion, we have found that α-fluoro-*N*-ethoxycarbonyltropinone is an efficient catalyst for the epoxidation of alkenes by Oxone®; it can be used in low loadings and recovered and recycled. Moreover, when prepared in enantiomerically pure form, it affords high enantioselectivity for alkene epoxidation. Attempts to prepare related bicyclo[3.2.1]octanone derivatives with alternative α-substitution, in order to improve enantioselectivity further and to clarify the factors responsible for asymmetric induction, are underway.

We thank the EPSRC, the DTI and a consortium of chemical companies for funding this work through the LINK Asymmetric Synthesis Second Core Programme. We also thank Mr T. Lowdon (Hicksons) and Dr N. Johnson (Chiroscience) for helpful discussions. We are grateful to Professor N. S. Simpkins and Mr C. D. Jones of this Department for supplies of *N*-ethoxycarbonyltropinone and of the chiral base **3**, and for helpful advice concerning the asymmetric deprotonation chemistry.

Water-soluble cationic poly-*p*-phenylene polyelectrolytes with an exceptionally high charge density

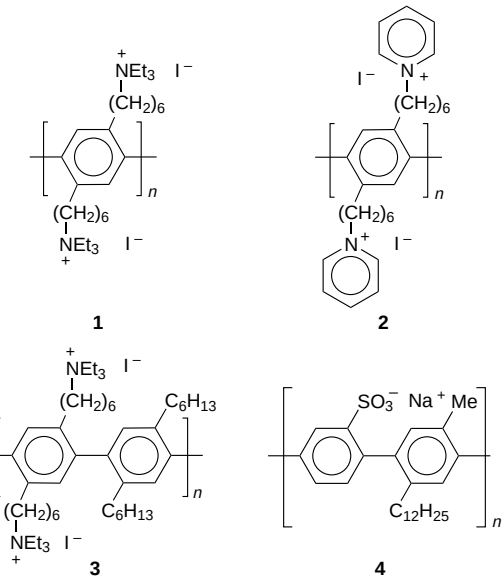
Matthias Wittemann and Matthias Rehahn*†

Polymer-Institut, Universität Karlsruhe, Kaiserstrasse 12, D-76128 Karlsruhe, Germany

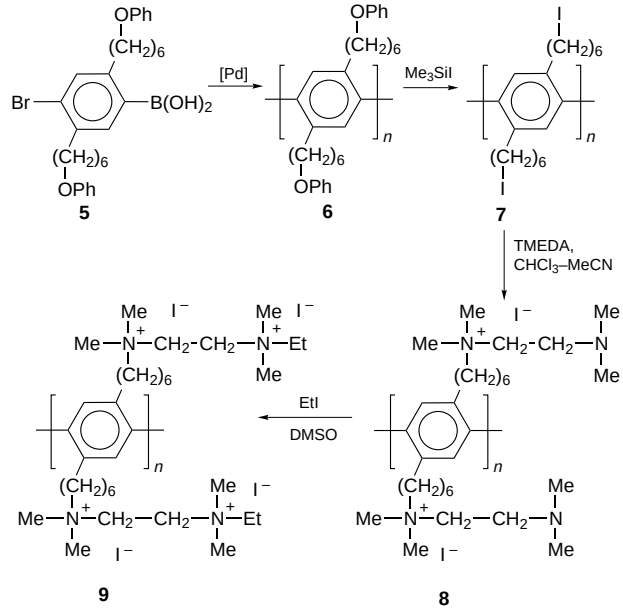
Rod-like poly-*p*-phenylene polyelectrolytes bearing four quaternized tetraalkylammonium functionalities per *p*-phenylene repeating unit are easily available *via* conversion of poly[2,5-di(6-iodohexyl)-1,4-phenylenes] with a large excess of TMEDA followed by the quaternization of the second TMEDA amino group with EtI.

Understanding polyelectrolyte behaviour in dilute solutions of low ionic strengths is an important objective in macromolecular science.[1–3] Despite much effort, however, a conclusive theoretical description of experimentally observed phenomena such as the polyelectrolyte effect is unavailable so far. One of the reasons for this is the fact that, in the case of the commonly investigated flexible-chain polyelectrolytes, various effects influence the measured quantities simultaneously whose contributions are difficult to separate properly. When, for example, measurements are carried out as a function of ionic strength, the radii of gyration of the polyelectrolytes change over the course of the experiment because the intramolecular Coulomb interactions change. However, not only do the radii of gyration increase with decreasing ionic strength but so also does the distance up to which the charged macromolecules repulse one another intermolecularly. For a more reliable interpretation of the obtained data it is therefore advantageous to additionally study polyelectrolytes which cannot change their shape. Because conformative and excluded volume effects are ruled out here, only the intermolecular Coulomb interactions will determine the solution properties. Based on these considerations, numerous studies have been performed using naturally occurring rod-like polyelectrolytes such as DNA.[4] At very low ionic strengths and at elevated temperatures, however, these systems fail because they lose their rod-like shape. Moreover, variation of the charge density, *i.e.* the number of ionic groups per unit length, is not possible with these biopolymers. To overcome the latter limitations, efficient routes to synthetic rod-like polyelectrolytes such as the poly(*p*-phenylene) (PPP) derivatives **1**–**3**[5] and **4**[6] have been developed which take advantage of both the concept of solubilizing side chains[7] and the efficient Pd-catalyzed aryl–aryl coupling reaction.[8–10] The polymers thus available combine exceptional hydrolytic, thermal and chemical stability with a high charge density of up to two ionic groups per *p*-phenylene repeating unit.

Nevertheless, further PPP polyelectrolytes having an even higher charge density would be important as well. We have now developed an efficient two-step quaternization route leading to PPP polyelectrolytes **9** with as many as four tetraalkylammonium groups per *p*-phenylene repeating unit and thus every 4.5 Å. Poly[2,5-di(6-iodohexyl)-1,4-phenylene] precursor PPP **7**, which is readily available *via* Pd-catalyzed polycondensation of 4-bromophenylboronic acid derivative **5** followed by an ether cleavage reaction, is first reacted with a 400-fold molar excess of TMEDA (Scheme 1). The large excess of TMEDA is essential in order to suppress quaternization of both TMEDA nitrogen atoms in this first step, which would lead to structural irregularities and crosslinks. Representative samples of the reaction mixture were analyzed at regular intervals using NMR spectroscopy to determine the reaction time required for a quantitative conversion. When the reaction was found to be



complete, solvents and the excess of TMEDA were removed by distillation. The residue was redissolved in water, and the last traces of organic solvents and TMEDA were carefully separated off by ultrafiltration using distilled water. Finally, PPP **8** was freeze-dried from the resulting aqueous solution. In order to quaternize the second TMEDA amino groups of **8**, the brownish, foamy materials thus obtained were redissolved in DMSO and heated in the presence of a slight excess of EtI. Here also the progress of the conversion was monitored using NMR spectroscopy. A prolonged reaction time and forcing conditions



Scheme 1

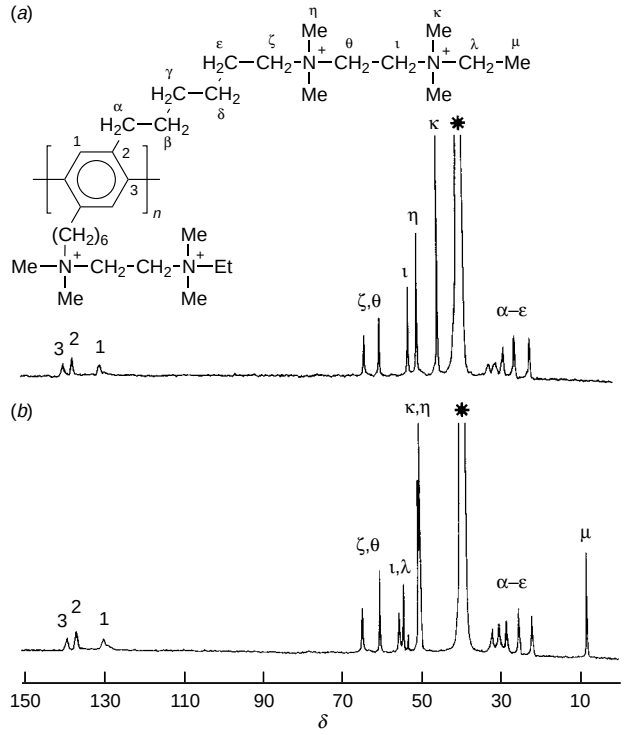


Fig. 1 100 MHz ^{13}C NMR spectra of (*a*) polymer **8** and (*b*) polymer **9** recorded in [$^2H_6$]DMSO (*) at room temperature. The signal assignment is based on the numbering given for polymer **9**.

were found to be necessary here to achieve complete conversion. Nevertheless, after heating the solutions to 60 °C for two days, complete conversion was reached. The obtained slurries were first diluted with DMSO to redissolve the formed precipitate, and a 20-fold excess of water was then added. Subsequently, the resulting polyelectrolyte solutions were purified by ultrafiltration and freeze-dried to give dark brown, foamy solids **9**.

As both the intermediate **8** and the doubly quaternized polyelectrolyte **9** readily dissolve not only in pure water but also in polar organic solvents, their homogeneous molecular constitution could be proved using NMR spectroscopy. Fig. 1 displays the ^{13}C NMR spectra of polyelectrolytes **8** and **9** together with the full signal assignment, which is based on tabulated increments and model compounds.

As is evident from these spectra, all observed absorptions are in full agreement with the expected polymer structures, and no absorptions can be detected which would point towards the formation of structural irregularities. However, not only is the homogeneous constitution of the polyelectrolytes of importance for the planned investigations, but so also is their molar masses. We therefore determined the degrees of polycondensation of precursor PPPs **6** using osmometry. Because no evidence of chain degradation was found during the conversions **6** → **7** → **8** → **9**, the only process that might result in a change of the molar masses is diffusion of low- molecular-weight polymer fractions through the membranes used for ultrafiltration. We therefore ensured that no polymeric material passed through the membranes, and we can thus also rule out any fractionation in the course of the polymer work-up processes. Consequently, the obtained polyelectrolytes **8** and **9** have the same degrees of polycondensation as the precursor PPPs **6** used for their preparation,[13] *i.e.* PPP polyelectrolytes became available in the present work with average degrees of polycondensation of P_n = 20–70 (M_n = 15 000–50 000 g mol^{-1}).

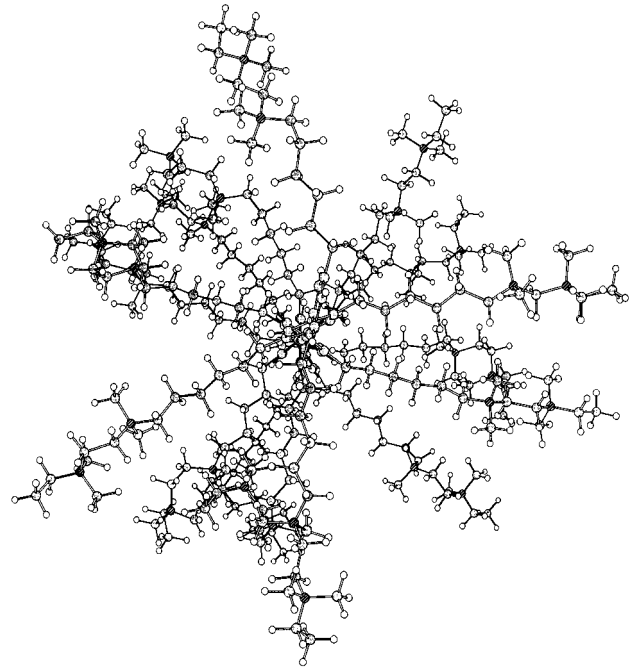

Fig. 2 Schematic illustration of the cylinder-like shape of polymers **9** (viewed along the polymer main chain), sketched according to the results of preliminary SAXS studies performed in salt-free aqueous solutions

Finally, we would like to emphasize that PPP polyelectrolytes **8** and **9** are very soluble in water, despite their highly hydrophobic skeleton. This is presumably due to the fact that these macromolecules represent cylinders of an average length of l_c = 90–300 Å and a diameter of $d_c \approx$ 10 Å whose hydrocarbon core is covered by the highly polar and thus hydrophilic shell of tetraalkylammonium groups (Fig. 2).

Presently, we are investigating the behaviour of PPP polyelectrolytes **8** and **9** in solution as a function of solvent, temperature, ionic strength and counter ion. The obtained results will be compared with those of other PPP polyelectrolytes such as **1**–**4** to gain a deeper insight into polyelectrolyte behaviour in dilute solution.

The authors are grateful to Professor M. Ballauff, Karlsruhe for his support of this work. We thank the Deutsche Forschungsgemeinschaft for financial support.

Particle size and support effects on the activity and deactivation of Pt-based catalysts for the reduction of NO by *n*-octane under lean-burn conditions

Robert Burch,*† Paolo Fornasiero and Barry W. L. Southward

Catalysis Research Centre, Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 6AD

Very high and stable activity for the reduction of NO by *n*-octane under lean-burn conditions may be achieved at temperatures as low as 180 °C by the use of supported Pt catalysts, providing the catalyst is clean and is comprised of large Pt particles.

The adverse environmental impact of NO_x is well known and is the subject of increasingly stringent emissions control legislation.[1,2] It is now accepted that diesel engines will soon require comparable exhaust emissions control to that used on petrol engines. However, despite intensive research into the field of lean $DeNO_x$,[3–6] no suitable material has yet been developed which will attain the levels of activity required under real operating conditions. The problems encountered range from SO_x poisoning to hydrothermal instability, particularly for zeolite-based materials.[1,5] In contrast, Pt-based materials are resistant to SO_x and have good hydrothermal stability.[2,4,5] However, the primary goal of obtaining stable low temperature activity has yet to be realised. Here, we address this problem and present preliminary data concerning highly active low temperature $DeNO_x$ catalysts.

The catalysts used in this study were prepared by incipient wetness impregnation using platinum dinitrodiammine precursor (ex Johnson Matthey), followed by drying (24 h, 120 °C) and calcination (12 h, 550 °C) to give nominal Pt loadings of 1%. The exception to this was the commercial catalyst Azko CK303 (0.3% Pt/Al_2O_3). All catalyst testing was performed in a standard microreactor system described elsewhere.[3] Prior to reaction all samples were aged overnight in standard reaction mixture (100 mg catalyst, 500 ppm NO, 500 ppm *n*-octane, 5% O_2, balance He, total flow 200 $cm^3\ min^{-1}$) at 500 °C. Subsequently, all samples were 'cleaned', *viz.* calcined at 550 °C in 5% O_2 in He for 1 h. *n*-Octane was chosen as a model reductant to simulate a component in a real fuel. NO_x conversions were determined by on-line analysis using a standard chemiluminescence detector (Signal series 4000), with data logged onto a PC at 6 s intervals. CO_2 analysis was performed using a Signal series 2000 IR analyser. No reaction was observed in the absence of a catalyst. H_2 chemisorption was performed in a facility constructed in-house using conditions described elsewhere.[3] Metal particle diameters were calculated assuming a spherical geometry. BET surface areas were determined by standard N_2 adsorption.

Previously much importance has been placed upon the analysis of temperature profiles for $DeNO_x$ catalysts.[4–6] Moreover, such studies have been performed upon 'aged' materials to simulate exhaust catalyst lifetime performance. Conversely, in the present study it was found that profile measurements were not a reliable indication of catalyst activity. Hence isothermal activity profiles of the catalysts were determined using 'clean' samples at temperatures in the region of the hydrocarbon light off (defined as the temperature required for > 20% hydrocarbon combustion, in these studies *ca.* 220 and 195 °C for 0.3% Pt/Al_2O_3 and 1% Pt/Al_2O_3, respectively). By this method it is possible to obtain information on the activity of catalysts in the absence of any surface deposition. This premise is reflected in Fig. 1 which compares the activity of a 0.3% Pt/Al_2O_3 catalyst at 198 °C. Trace 1, in which the catalyst was temperature profiled from 150 °C, exhibits a severe loss of activity *cf.* trace 2 obtained for the 'clean' surface. Thus it is clear that this frequently adopted procedure for evaluating catalysts may seriously underestimate their intrinsic activity.

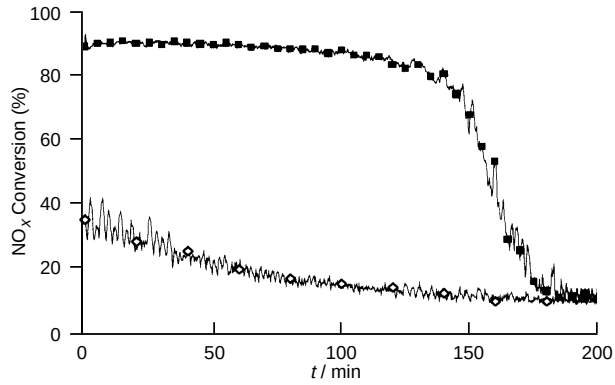

Fig. 1 Effect of surface retention upon activity of 0.3% Pt/Al_2O_3 at 198 °C. **1**, (◇), $DeNO_x$ activity after exposure to reaction mixture at lower temperatures; **2**, (■), $DeNO_x$ activity of 'clean' surface.

Fig. 2 illustrates the response of several 1% Pt catalysts under 'clean' reaction conditions. The data further demonstrate that high $DeNO_x$ activity is possible below the hydrocarbon light-off temperature. In all cases there was an initial period of high activity for NO reduction (> 90% NO_x) and for *n*-octane combustion (100% conversion of *n*-octane to CO_2). The high combustion activity resulted in a marked increase in catalyst temperature (at least 30 °C, as indicated by in-bed thermocouple).

The duration of the initial period of high activity (see Fig. 2) was found to be dependent on the reaction temperature and the choice of catalyst support as summarised in Table 1. Thus, while the SiO_2-supported catalyst exhibited very rapid deactivation below 190 °C, the activity of 1% Pt/ZrO_2 was constant at temperatures as low as 180 °C for > 10 h. Similarly for 1% Pt/Al_2O_3, decreasing the furnace temperature from 180 to 175 °C halved the catalyst lifetime. In all cases the decrease in $DeNO_x$ activity was mirrored by a loss of combustion activity.

Some of these features are attributed to variable metal/support interactions. With SiO_2 there is minimal support interaction and hence the catalysis occurs exclusively on unmodified metal particles. In contrast, both Al_2O_3 and ZrO_2 can interact with the Pt and facilitate surface reactions[7] and hence the reaction is not so constrained. Moreover chemisorption results (Table 1), indicate that both the SiO_2- and Al_2O_3-supported samples contain comparatively small Pt particles. Hence it appears that the combination of a non-interacting support and small Pt particles is responsible for the poor low temperature stability of the ex SiO_2 sample. Conversely the low temperature stability of 1% Pt/ZrO_2 is ascribed to the positive combination of these factors.

To test this hypothesis the 1% Pt/Al_2O_3 sample was subjected to a high temperature treatment in 5% O_2–He (740 °C for 24 h) to induce sintering. This increase in particle size was clearly beneficial to $DeNO_x$ activity (Fig. 3). Comparative studies of

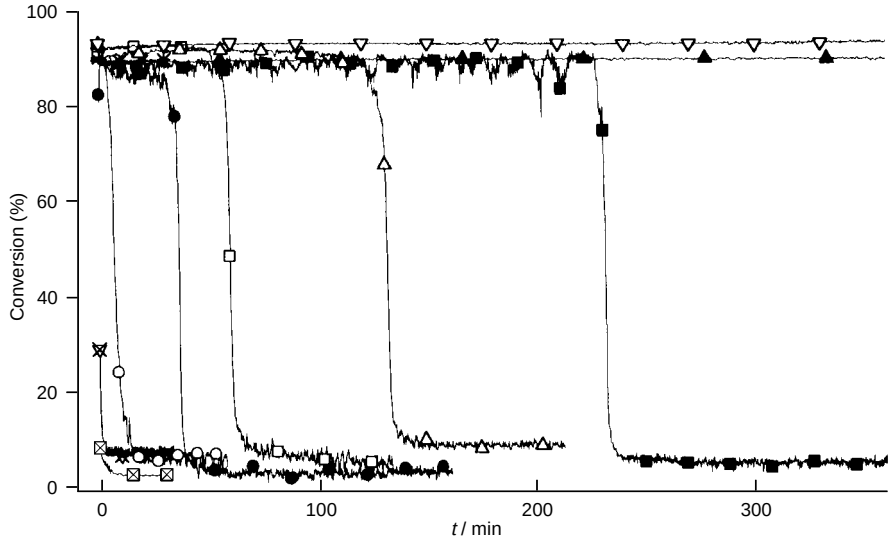

Fig. 2 Effect of the choice of the support and the temperature on the activity of supported Pt catalysts for NO reduction by *n*-octane (100 mg catalyst, 500 ppm NO, 500 ppm *n*-octane, 5% O_2–He, balance He, total gas flow rate was 200 cm^3 min^{-1}). Al_2O_3[c]	12	0.24	160	15	130	∞	∞	∞

[a] Metal surface area (MSA) and Pt particle size determined from H_2 chemisorption. [b] ∞ indicates beyond the end of the experiment. [c] Sample sintered at 740 °C, in 5% O_2–He for 24 h. In all cases lifetime is defined as the period for which NO_x conversion > 80%.

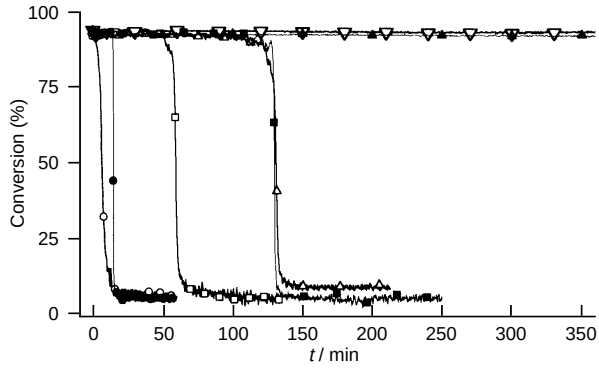

Fig. 3 Effect of sintering on the activity of 1% Pt/Al_2O_3 under standard reaction conditions. Key: (○), 170 °C; (□), 175 °C; (△), 180 °C; (▽), 185 °C; (●), sintered 170 °C; (■), sintered 175 °C; (▲), sintered 180 °C.

the original and the post-sintered samples demonstrated significant improvements in the performance at lower temperatures. The minimum operating temperature for high activity $DeNO_x$ without deactivation was lowered, and the stability of the sintered catalyst was far superior to that of the pre-sintered case with lifetimes at comparable temperatures being more than doubled.

This increased poison tolerance reflects the complex balance in these $DeNO_x$ catalysts owing to the competition for surface sites between the reductant and oxidants, as has been found previously.[8] It further reflects the adverse effects of the retention of reaction intermediates, whether derived from organic compounds or from NO_x, as clearly illustrated in the differences observed in isothermal and temperature-programmed studies. Future work will address the nature of the deposits responsible for deactivation. However at this stage any attempt to identify these poisoning species would be mere speculation and outside the scope of this communication.

These preliminary results have an important technological value concerning the evaluation of the real intrinsic activity of $DeNO_x$ catalysts. Three significant points emerge. First, the intrinsic activity of clean Pt catalysts for NO reduction by higher hydrocarbons may be much higher than would be observed under normal testing conditions because of the rapid and serious deactivation observed at temperatures (*ca.* < 170 °C) below the hydrocarbon light-off region. Second, the lowest apparent activity is observed for supports, such as SiO_2, which do not strongly interact with Pt particles and so perhaps do not provide any resistance to deactivation. Third, the intrinsic activity and stability of large Pt particles is much greater than that of small Pt particles. Hence for a specific support, Pt particle size rather than metal–support interaction seems to be dominant, since the available data suggest that deactivation is initiated at the Pt : support interface. Irrespective of the origin of the enhanced performance it is clear that this information may prove useful in the development of more active catalysts for NO reduction under lean-burn conditions.

We are grateful for financial support for this work through the EU Environment programme, contract number EV5V-CT94-0535.

Hybrid Monte Carlo and lattice dynamics simulations: the enthalpy of mixing of binary oxides

John A. Purton,[a,b] Jon D. Blundy,[a] Mark B. Taylor,[b] Gustavo D. Barrera[b] and Neil L. Allan†[b]

[a] *CETSEI, Department of Geology, University of Bristol, Wills Memorial Building, Bristol, UK BS8 1RJ*
[b] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

We present two novel methods for the calculation of the enthalpies of mixing of oxides; both the sampling of many different configurations and the effects of ionic relaxation, which have been largely neglected in previous studies, are crucial.

Understanding the thermodynamics of solid solutions of oxides and phase stability is essential in many areas of solid-state chemistry and mineralogy, including the fabrication and design of ceramics, solid-state batteries, heterogeneous catalysis and high temperature superconductivity. However, experimental data are difficult to obtain and are often unavailable. This is particularly acute at high temperatures and/or pressures, where thermodynamic behaviour is important for sustained material performance and for the stability of minerals deep within the Earth's interior. The paucity of experimental data has led to possibly severe approximations such as the extrapolation of low temperature data and the assumption that enthalpies of mixing, ΔH_{mix}, are constant over wide ranges of temperature.

Advances in computational procedures are such that atomistic simulations[1] (*e.g.*, Monte Carlo, molecular dynamics, lattice statics and dynamics) are now capable of providing detailed information about the structure and thermodynamics of ordered inorganic materials and minerals over a wide range of *T* and *P*. The vast majority of calculations have studied the properties of perfect crystals, assuming a periodic system in a particular configuration; disorder has largely been investigated theoretically *via* point defect calculations, which refer only to the dilute limit. Such methods are not readily extended to solid solutions or disordered systems containing a finite impurity or defect content. Simulations have been largely restricted to the study of end-member compounds, excluding many industrially important ceramics and naturally occurring minerals.

The key objective of the present work is to show explicitly how (*i*) a modified Monte Carlo technique, that allows an efficient sampling of a large number of different configurations, and (*ii*) direct free energy minimisation *via* lattice dynamics can be used for the study of solid solutions, taking explicit account of relaxation and thermal effects. We do not resort to the use of a parameterised Hamiltonian which averages out local relaxation and cannot readily be extended to include the effects of lattice vibrations and pressure. In this way we remove the major limitations of the existing methods which restrict considerably the contact between experiment and theory, and extend the range of applications that can be tackled to include real rather than model systems.

In this preliminary communication we report results for the enthalpies of mixing of the paradigm system MnO/MgO. We use the ionic model and the set of potential parameters from the work of Lewis and Catlow.[2]

The motivation for our new hybrid Monte Carlo (HMC) approach has been the extensive use made by related techniques in the modelling of polymers and biomolecules.[3–5] During one HMC cycle, one of three options is chosen at random, with equal probability. The first of these is a short NVE molecular dynamics (MD) simulation (15 steps and a timestep of 1.5 fs) in which the last configuration is accepted or rejected by comparing its energy with the energy of the starting configuration and using the standard Metropolis algorithm. If the last configuration is rejected, the original configuration is included in the statistical averaging of thermodynamic properties. In the second, a short MD run follows a random exchange of atoms. Again, the difference in energy between the previous configuration and that immediately after the MD simulation is used in the Metropolis algorithm. This second option allows us to sample efficiently different configurations, while the first mainly takes account of vibrations. At the start of each MD run, velocities are chosen anew at random from a Maxwellian distribution. The third option is a random change of the volume of the box[6] which again is accepted or rejected using the Metropolis algorithm.

In Fig. 1(*a*) we show the values of ΔH_{mix} determined using HMC and a box-size of 216 ions at 1300 K. The enthalpy of mixing at 1300 K is symmetric with a maximum of *ca*. 5.4 kJ mol^{-1} at a concentration of 50% MgO–50% MnO. We have been able to find two sets of experimental data less than thirty years old.[7,8] Agreement with the data of Gripenberg *et al.*[7] is good, but we do not see the asymmetry reported by Raghavan.[8] For comparison we also show values calculated using mean field theory, a common approach to the modelling of solid solutions.[9] In this model, instead of distinct Mg^{2+} and Mn^{2+} ions, a 'hybrid' ion is introduced, for which the non-Coulombic potentials are a linear combination of the potentials for Mn^{2+} and Mg^{2+}, appropriately weighted by the site occupancies. If local relaxation or clustering is important then results from this approach will be poor. Fig. 1(*a*) shows that this is the case even in our relatively simple example, where the Mn^{2+} and Mg^{2+} ions are similar in size.

An alternative approach is to average over a limited set of calculations representing different arrangements of the cations within a supercell. Previous work has often assumed just one (the most regular) arrangement and calculated its energy, with or possibly without relaxation, either using lattice statics/dynamics, or by an *ab initio* method.[10] We have recently developed an efficient method which uses lattice statics and quasiharmonic lattice dynamics (QLD) for the fully dynamic structure optimisation of large unit cells *via* the analytic calculation of the free energy, *G*, and its derivatives with respect to all strains.[11] Given the free energy, G_k, for the relaxed structure of each possible cation arrangement *k* the enthalpy is properly averaged over all arrangements in the Gibbs ensemble using

$$< H >= \frac{\sum_k H_k \exp(-\beta G_k)}{\sum_k \exp(-\beta G_k)}$$

Fig. 1(*b*) shows the enthalpies thus calculated of disordered supercells containing 16, 32 and 64 ions of $Mg_xMn_{1-x}O$ (x = 0, 0.25, 0.5, 0.75, 1). For the 16-ion cell, the average was over all possible cation arrangements, whilst for the larger supercells 32

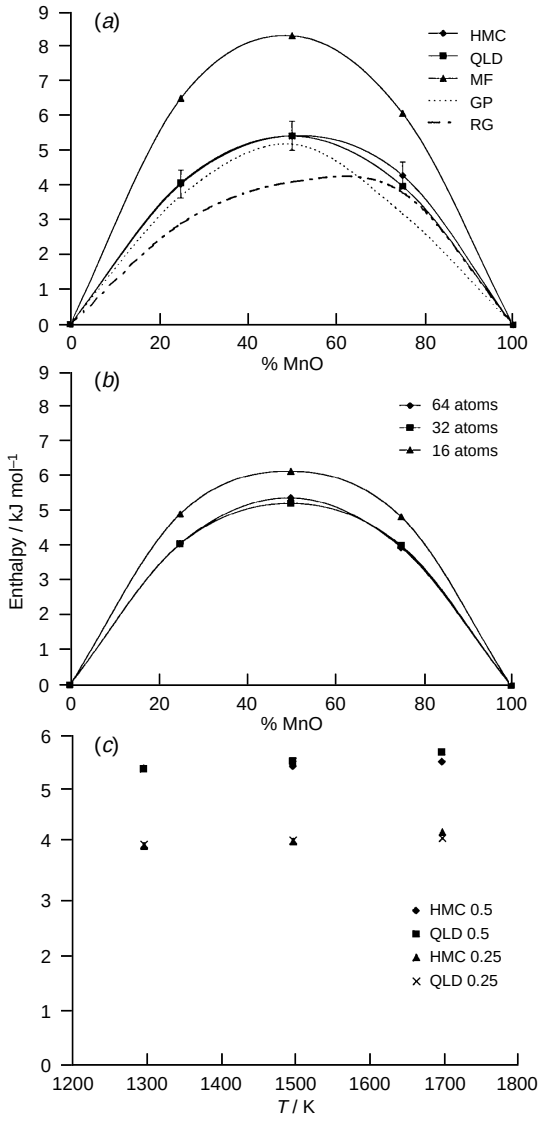

Fig. 1 (*a*) Calculated values of ΔH_{mix} at 1300 K using hybrid Monte Carlo (HMC), mean field theory (MF), and quasiharmonic lattice dynamics (QLD). Two sets of experimental data (GP from ref. 7, RG from ref. 8) are also shown. (*b*) The variation of ΔH_{mix}, calculated using QLD at 1300 K, with supercell size. (*c*) ΔH_{mix} *vs.* T for $Mg_xMn_{1-x}O$ (x = 0.25, 0.5), calculated using QLD and HMC.

arrangements were chosen at random for each concentration. The enthalpies for 32- and 64-ion cells are almost identical and are substantially smaller than those from the 16-ion cell. This highlights once again the importance of allowing for relaxation and clustering. The results for the 64-ion cells are also shown in Fig. 1(*b*) where it is clear that there is excellent agreement between the quasiharmonic lattice dynamics and HMC methods. This result suggests the future use of QLD for enthalpies of mixing at temperatures below the Debye temperature where classical Monte Carlo and molecular dynamics fail due to their neglect of quantum effects. Moreover, the Gibbs free energy can be calculated efficiently and accurately from the QLD, without resorting to lengthy thermodynamic integration.

Fig. 1(*c*) shows the calculated temperature dependence of ΔH_{mix} over the temperature range 1300–1700 K calculated using both HMC and QLD. ΔH_{mix} does not change significantly with temperature, supporting the common assumption that ΔH_{mix} is largely temperature independent.

In summary, we have demonstrated that both the proposed HMC and QLD methods provide an accurate description of the enthalpy of mixing of the binary oxides MgO–MnO. We reiterate that it is essential to take explicit account of ionic relaxation without any averaging out of local effects. The methodology we propose is general, easily extended to other ensembles, and applicable to a wide range of materials and minerals.

This work was funded by NERC grants GR3/09772 and GR9/02621, EPSRC grants GR/K05979 and GR/L31340. GDB's contribution was made possible by means of a grant from el Consejo Nacional de Investigaciones Científicas y Técnicas de la República Argentina.

Conjugated polyrotaxanes containing coordinating units: reversible copper(I) metallation–demetallation using lithium as intermediate scaffolding

A new polyrotaxane containing a conjugated backbone has been synthesized *via* a copper(I) template and electropolymerisation; after decomplexation of Cu^{I}, remetallation is only possible if lithium is present during copper removal, as labile scaffolding able to prevent collapse of the free coordination sites and of the organic matrix.

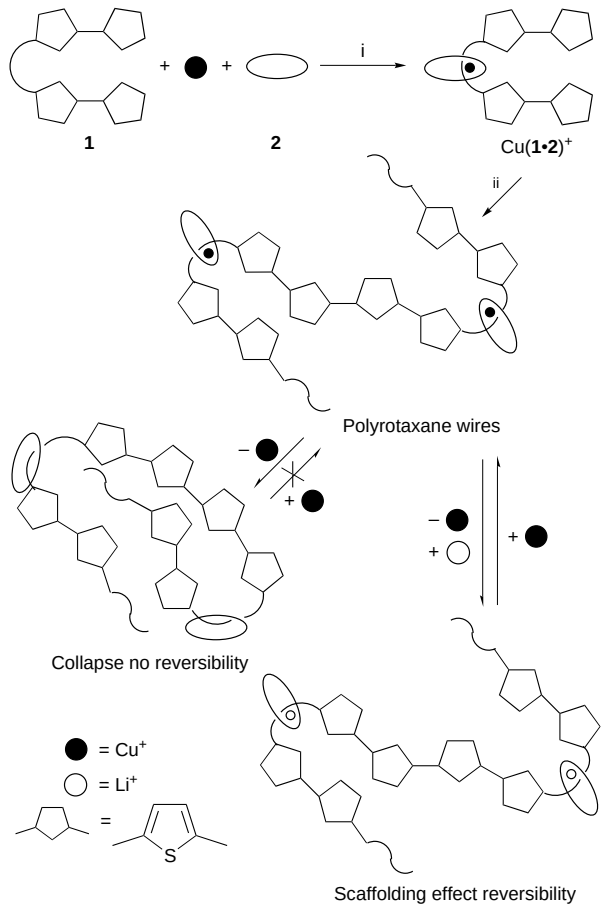
Functionalised conducting polymers obtained by electropolymerisation of pyrrole or thiophene derivatives represent an important family of organic materials.[1] In parallel, rotaxanes have attracted much attention, in relation with photoinduced electron transfer[2] and electro- or photo-chemically driven molecular motions.[3–5]

Recently, the synthesis of a polymetallorotaxane[6] with a conjugated rod threaded through coordinating 30-membered rings has been reported, following a strategy similar to previous works from one of our groups.[7] This report prompts us to disclose our own results and we would like to describe a new coordinating polyrotaxane, with a conjugated –(phen–tph)–$_n$ backbone (phen = 1,10-phenanthroline, tph = thiophene) and its demetallation–remetallation behaviour.

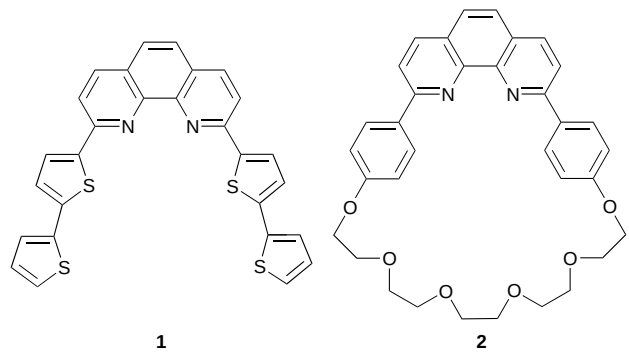
As indicated in Scheme 1, the Cu^{I} template used to assemble the fragments of the precursor could be removed but, interestingly, subsequent remetallation was only possible if lithium was present during demetallation. The function of lithium is assumed to be that of an ionic scaffolding, maintaining the topography of the coordination site after copper removal, though forming a labile complex.

The molecules used are depicted in Scheme 2. The bithienyl-2,9 disubstituted compound **1**† was chosen as the key ligand and the dpphen-containing macrocycle **2**[8] (dpphen = 2,9-diphenyl-1,10-phenanthroline) as its partner for complexation (Scheme 1). The reaction between **2** and a slight deficit of $[Cu(MeCN)_4]BF_4$ followed by addition of **1** in CH_2Cl_2–MeCN at room temperature led to the intertwined heteroleptic copper complex $[Cu(\mathbf{1}\cdot\mathbf{2})]BF_4$ in 95% yield after purification by column chromatography. Analytical and spectroscopic data of this dark red, stable complex confirmed its structure.‡ Cyclic voltammetry (CV) of a 2×10^{-3} mol dm^{-3} complex solution in CH_2Cl_2–0.3 mol dm^{-3} $NBu^{n}_4PF_6$ showed a one electron reversible wave ($E_{1/2}$ = 0.51 V *vs.* 0.01 mol dm^{-3} Ag^+/Ag) corresponding to the redox reaction Cu^{II}–Cu^{I}.§

Electropolymerisation on a platinum electrode (S = 0.07 cm^2, Q = 26 mC cm^{-2}) by continuous cycling of this solution between −0.2 and +1.4 V led to the deposition of a thin red–orange film, characterized by CV measurements [Fig. 1(*a*)]. The presence of the Cu^{I} template is evidenced by the unchanged potential value compared to the monomer. A partial loss of reversibility was observed for this response, but at a slower potential sweep rate (10 mV s^{-1}), the ΔE_p value observed (20 mV) is typical of immobilized electroactive systems. The response between 0.8 and 1.4 V consists of two well defined waves, in agreement with the electrochemical behaviour of end-capped tetrathienylenes,[9] which confirms the electrochemical coupling of the terminal bithienyl units.



Scheme 1 i, Threading step; ii, electropolymerisation



Scheme 2

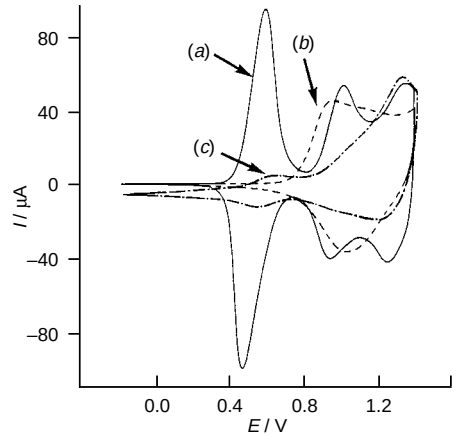


Fig. 1 Cyclic voltammetry in CH_2Cl_2 + 0.3 mol dm^{-3} $NBu^n_4PF_6$ (v = 50 mV s^{-1}) of (*a*) a freshly prepared poly[Cu(**1**·**2**)$^+$] film (solid line), (*b*) after dipping (20 min) in a 0.1 mol dm^{-3} NBu^n_4CN MeCN solution (dashed line) and (*c*) after dipping (4 h) in a 0.1 mol dm^{-3} $[Cu(MeCN)_4]BF_4$ MeCN solution (dot–dashed line)

On treating this film with the strong copper complexing agent CN^-, the signal due to the metallic centre disappeared, whereas those due to the oligothienyl wires dramatically changed with total loss of resolution [Fig. 1(*b*)]. The collapse of the polyrotaxane network was confirmed by the non-reincorporation of Cu^I [Fig. 1(*c*)] or other metallic centers.

Dipping another film freshly prepared under the same conditions in a 0.1 mol dm^{-3} Li^+ + 0.1 mol dm^{-3} CN^- MeCN solution resulted again in complete loss of the copper response but in this case a partial conservation of resolution of the oligothienyl response was observed [Fig. 2(*b*)], which could be attributed to the scaffolding effect induced by Li^+ complexation. Conservation of the topography of the network was spectacularly evidenced by the nearly quantitative reincorporation of Cu^I species [Fig. 2(*c*)] (shown by determination of the ratio of current quantities corresponding respectively to the metallic and the oligothienyl redox systems), probably due to a Li^+/Cu^+ exchange. The strong anodic shift (140 mV) of the electrochemical response of the wire when copper centres are present could be attributed to copper–phenanthroline interactions which induce an electroattracting effect onto the oligothienyl moiety.

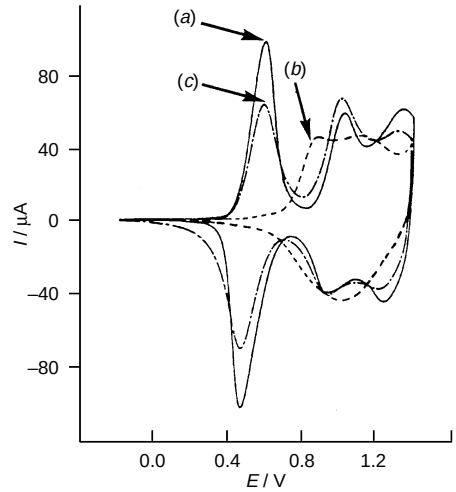

Fig. 2 Cyclic voltammetry in CH_2Cl_2 + 0.3 mol dm^{-3} $NBu^n_4PF_6$ (v = 50 mV s^{-1}) of: (*a*) a freshly prepared poly[Cu(**1**·**2**)$^+$] film (solid line), (*b*) after dipping (20 min) in a 0.1 mol dm^{-3} $LiClO_4$ + 0.1 mol dm^{-3} NBu^n_4CN MeCN solution (dashed line) and (*c*) after dipping (3 h) in a 0.1 mol dm^{-3} $[Cu(MeCN)_4]BF_4$ MeCN solutionn (dot–dashed line)

Reversibility of this demetallation–remetallation process is strongly dependent on the ratio r = $[Li^+]/[CN^-]$ (with $[CN^-]$ = 0.1 mol dm^{-3}) during the demetallation process: for r = 0.1, reincorporation of Cu^I is slower and of 80% compared to the case r = 1, with a loss of reversibility for both the metallic center and the oligothienyl wires, whereas for r = 0.01, collapse of the structure was observed.

In situ conductivity measurements are underway to evaluate the electronic properties of our conjugated structure.

Novel ring-opened reaction of μ-(1–3-η : 4–7-η-cycloheptatrienyl)-tricarbonylirontricarbonylmanganese with aryllithium reagents

Beihan Wang, Ronghua Li, Jie Sun and Jiabi Chen*

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032, China

The reactions of μ-(1–3-η : 4–7-cycloheptatrienyl)tricarbonylirontricarbonylmanganese $[Mn(CO)_3Fe(CO)_3(C_7H_7)]$ 1, with aryllithium reagents, ArLi (Ar = Ph, *o*-, *m*-, *p*-MeC_6H_4), in ether at low temperature, followed by alkylation of the acylmetalate intermediates with Et_3OBF_4 in aqueous solution at 0 °C affords four novel ring-opened polyene complexes $[Mn(CO)_3Fe(CO)_3\{C_8H_7(OEt)Ar\}]$ (Ar = Ph 2, *o*-MeC_6H_4 3, *m*-MeC_6H_4 4, *p*-MeC_6H_4 5), of which the structure of 2 has been established by a single-crystal X-ray diffraction study.

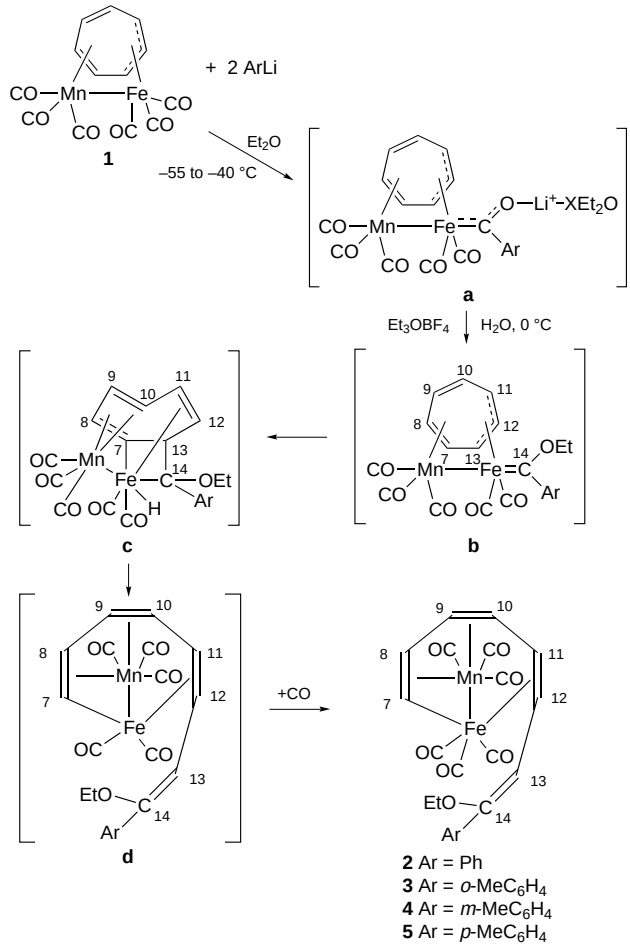
In recent years, alkene-coordinated transition metal carbene and carbyne complexes and/or their isomerized products, as part of a broader investigation of transition metal carbene and carbyne complexes, have been examined extensively in our laboratory. We found that the isomerizations of the alkene ligands and resulting products depend not only on the alkene ligands but also on the central metals.[1–5] For instance, (cycloheptatriene)-tricarbonyliron $[Fe(C_7H_8)(CO)_3]$, reacted with aryllithium and subsequent alkylation with Et_3OBF_4 gave no product containing ethyl group but the novel compound $[(Cl_3C\text{-}cyclo\text{-}C_7H_8)(CO)_2Fe(COC_6H_4Me\text{-}o)]$, in which the Cl_3C group was derived from a metathetical reaction of solvent CH_2Cl_2 molecules aided by iron at Et_3OBF_4, or ring-opened diallyl-like compound $[(CO)_2Fe\{C(OEt)(C_6H_4Me\text{-}o)C_7H_8\}]$ depending on the alkylation conditions.[3] While the cycloheptatrienediiron hexacarbonyl $[Fe_2(C_7H_8)(CO)_6]$, where the two iron atoms are directly bonded to each other, reacted with aryllithium reagents under analogous conditions to yield the novel isomerized bridging carbyne complexes $[Fe_2(CO)_4\{\mu\text{-}\eta^4\text{:}\eta^3\text{-}C_7H_7C(OEt)\text{-}Ar(\mu\text{-}C(OEt)\}]$.[4] In order to further investigate the effect of different binuclear central metals on the isomerizations of the alkene ligands and the reaction products, we chose μ-(1–3-η : 4–7-η-cycloheptatrienyl)tricarbonylirontricarbonylmanganese, $[Mn(CO)_3Fe(CO)_3(C_7H_7)]$ **1**,[6] where the cycloheptatrienyl ligand is η^4 and η^3 respectively bonded to the $Mn(CO)_3$ and $Fe(CO)_3$ units, and the Mn and Fe atoms are directly bonded to each other, as the starting material for the reaction with aryllithium reagents. These reactions led to nucleophilic addition to and cleavage of the cycloheptatrienyl ring to afford novel ring-opened polyene complexes. We report herein these novel reactions and the structures of the resulting products.

$[Mn(CO)_3Fe(CO)_3(C_7H_7)]$ **1**, was treated with 2 molar equiv. of aryllithium reagents, ArLi (Ar = Ph, *o*-, *m*-, *p*-MeC_6H_4), in diethyl ether at −55 to −40 °C for 3–4 h. The acylmetalate intermediates were subsequently alkylated with Et_3OBF_4 in aqueous solution at 0 °C. After removal of the solvent under high vacuum at low temperature, the solid residue was chromatographed on an alumina column at −20 to −25 °C, and the crude product was recrystallized from light petroleum –CH_2Cl_2 solution at −80 °C to afford orange–red crystalline complexes $[Mn(CO)_3Fe(CO)_3\{C_8H_7(OEt)Ar\}]$ **2**–**5**† (Scheme 1) in 47–52% yields.

The mechanism of the reaction (Scheme 1) is as yet unclear, but it could involve unstable alkoxycarbene intermediates **b** and metalcyclobutane intermediates **c**.[7] The latter then gives intermediates **d** upon opening of the ring, as in the reactions of the tetrafluorobenzobicyclo[2.2.2]octatriene tricarbonyliron with aryllithium nucleophiles.[7] Subsequently, such an intermediate **d** can abstract one molecule of CO to satisfy an 18-electron configurational iron and be converted into the stable ring-opened polyene complexes **2**–**5**.

Complexes **2**–**5** are very sensitive to air and to heat in solution but are stable for short periods on exposure to air as solids. Their structures were established by elemental analyses, spectroscopic determination and single-crystal X-ray diffraction.

The X-ray structure of **2** (Fig. 1)‡ shows that the cycloheptatrienyl ring of **1** has been opened by cleavage of the original C(7)–C(13) σ bond, and in **2** the C(13) atom is now linked to the carbon C(14) forming a double bond C(13)–C(14) and the C(7) atom is linked to the iron atom constructing a MnFeC(7) three-membered ring. Along with the formation of the new π bond,



Scheme 1

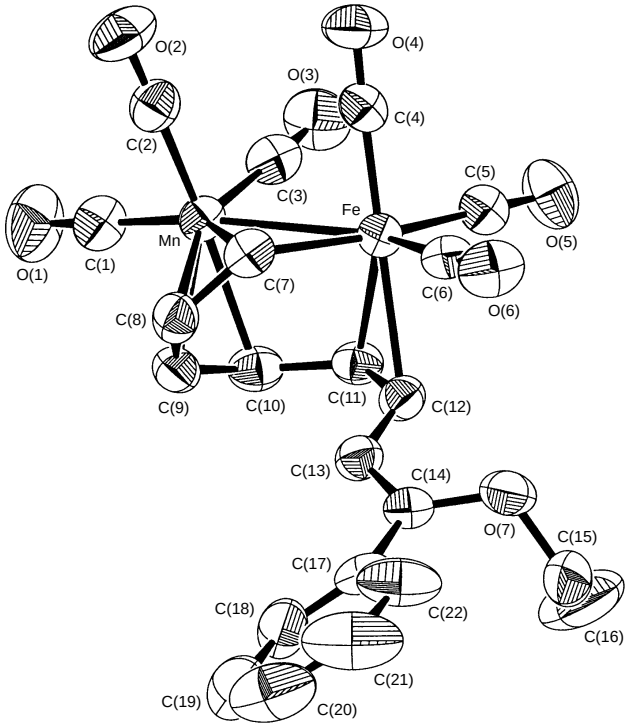


Fig. 1 Molecular structure (bond lengths in Å, angles in °) and labelling diagram for $[Mn(CO)_3Fe(CO)_3\{C_8H_7(OEt)Ph\}]$ **2**: Fe···Mn 2.7216(7), Fe–C(7) 1.967(4), Mn–C(7) 2.130(3), Fe–C(11) 2.211(3), Fe–C(12) 2.260(4), Mn–C(7) 2.130(3), Mn–C(8) 2.160(4), Mn–C(9) 2.144(4), Mn–C(10) 2.234(4), C(7)–C(8) 1.392(5), C(8)–C(9) 1.417(5), C(9)–C(10) 1.392(5), C(10)–C(11) 1.440(5), C(11)–C(12) 1.393(5), C(12)–C(13) 1.441(5), C(13)–C(14) 1.329(5); Fe–Mn–C(7) 45.84(10), Mn–Fe–C(7) 51.0(1), Fe–C(7)–Mn 83.2(1), Fe–C(7)–C(8) 130.3(3), C(7)–C(8)–C(9) 121.8(4), C(8)–C(9)–C(10) 122.7(4), C(9)–C(10)–C(11) 127.4(4), C(10)–C(11)–C(12) 127.3(4), C(11)–C(12)–C(13) 127.3(4), C(12)–C(13)–C(14) 124.9(4).

the alkene ligand became now a conjugated chain octatetraene with the OEt and Ph groups on the terminal carbon atom C(14), and the atomic chains C(7)C(8)C(9)C(10) and C(11)C(12) are coordinated to the orbitals of the Mn and Fe atoms in η^4- and η^2-bonding, respectively, to satisfy the 18-electron rule.

Asymmetric routes to substituted piperidines

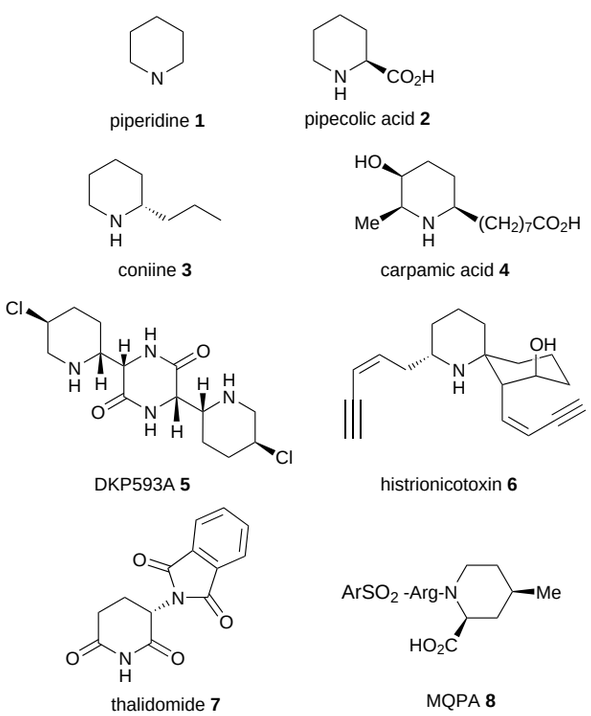
Patrick D. Bailey,† Paula A. Millwood and Peter D. Smith

Department of Chemistry, Heriot-Watt University, Riccarton, Edinburgh, UK EH14 4AS

An overview of the main asymmetric routes to substituted piperidines is presented. A wide range of synthetic strategies have been developed, because of the ubiquitous nature of the piperidine sub-unit in natural products, and because of the biological properties of natural and synthetic piperidine derivatives. This review concentrates on general methodologies that provide enantioselective routes to substituted piperidines, but also includes some specific target syntheses that illustrate the power of the methods that have been developed. The three approaches that have been most successful are: the use of the chiral pool, especially amino acids; the use of reagents that utilise a chiral catalyst; and the use of chiral auxiliaries in the asymmetric formation or derivatisation of the piperidine ring.

Introduction

The piperidine ring system **1** is one of the commonest structural sub-units in natural compounds, as exemplified by structures **2**–**6**. Moreover, piperidine alkaloids (*e.g.* **2**–**6**) and synthetic



analogues (*e.g.* **7, 8**) are the focus of great interest in the pharmaceutical industry because they exhibit an extensive range of biological activities. The importance of this ring system makes short, versatile, stereocontrolled routes to substituted piperidines of tremendous potential value. This review outlines some of the recent developments in the asymmetric synthesis of piperidine systems;[1] it does not include resolution methods, although these are still very important, but focusses on the use of the chiral pool, chiral reagents and chiral auxiliaries. The examples selected are those that, in the view of the authors, offer the most reliable and flexible asymmetric routes to piperidines, and/or have the greatest potential for doing so.

Asymmetry from the chiral pool

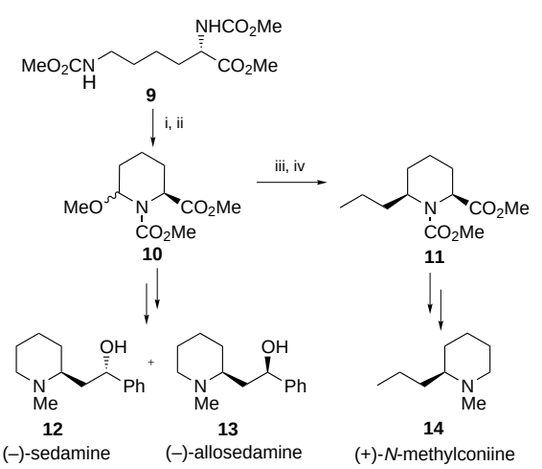
Amino acids

Amino acids are particularly useful precursors for the asymmetric synthesis of piperidine alkaloids for several reasons. Firstly, many amino acids are cheap and homochiral; secondly, they already contain the nitrogen of the alkaloid target; thirdly, they usually lead to 2-substituted piperidines, which is the commonest position for substitution.

Lysine. Lysine is the biosynthetic precursor for many piperidine alkaloids, but there are two main problems with its use in a laboratory synthesis; firstly, the amino groups need to be differentiated and (one of them) converted into a leaving group; secondly, it is not easy to introduce additional substitution (other than the existing carboxylic acid of lysine) into the piperidine ring. Enantiomerically pure forms of pipecolic acid have been prepared from lysine *via* several synthetic pathways. Fujii *et al.* have reported a six step synthesis of L-pipecolic acid in 60% overall yield starting from L-lysine.[2] However, L-pipecolic acid has also been prepared in 39% yield in a one step reaction of L-lysine with disodium nitrosyl pentacyanoferrate(II).[3]

The 6-methoxypipecolate derivative **10**, which is of biological interest, can be synthesised from the lysine derivative **9** by electrochemical oxidation at a platinum electrode.[4] Subsequent conversion of the *cis* isomer into enantiomerically pure (−)-sedamine **12** and (−)-allosedamine **13** was achieved in five further steps as outlined in Scheme 1. (+)-*N*-Methylconiine **14** has also been synthesised from **10** by Shono *et al.*; exclusive formation of the *cis*-disubstituted intermediate **11** was followed by saponification, anodic decarboxylation and reduction to afford the pure enantiomer in good yield (Scheme 1).[5]

Several other methods for the preparation of piperidine derivatives from lysine and various lysine analogues have been

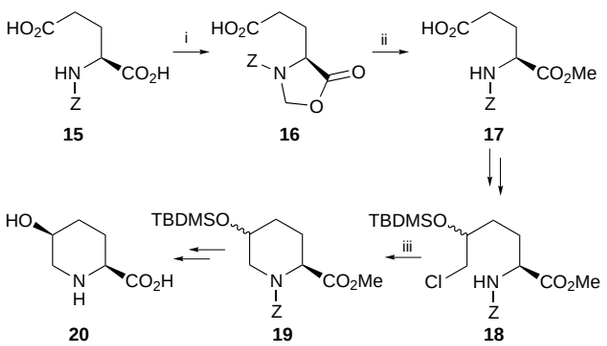


Scheme 1 *Reagents and conditions*: i, −2e⁻, MeOH; ii, MeOH, H_2SO_4; iii, CH_2=$CHCH_2SiMe_3$, $TiCl_4$; iv, H_2, Pd–C

reported,[6,7] including the use of an immobilised analogue of lysine to access piperidine derivatives attached to a polymeric support, providing the opportunity for preparing combinatorial libraries.[8]

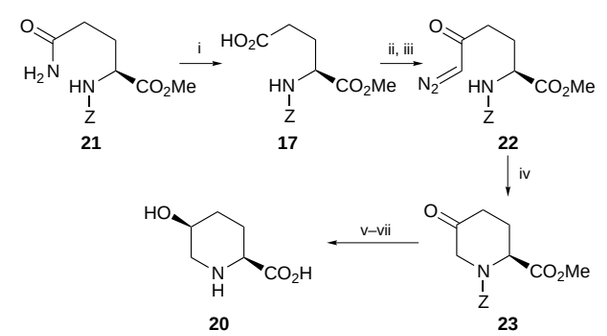
Glutamic acid/glutamine. Glutamic and aspartic acids are attractive chiral building blocks for piperidine targets because the side-chain functionality can be readily derivatised. In both cases, additional carbon(s) need to be introduced, and this can be exploited as a means of introducing additional substituents into the piperidine ring. The side-chain carboxylic acid group is usually retained as a functionalised position, thus providing access to 5-substituted pipecolic acid derivatives in the case of glutamic acid.

For example, Bailey *et al.* have made use of L-glutamic acid in a stereo- and enantio-specific synthesis of the naturally occurring alkaloid, *cis*-5-hydroxy-L-pipecolic acid **20**.[9] The dense functionalisation led to a number of synthetic problems, but treatment of the trialkylsilyl-protected alcohol **18** with NaH in DMF at 85 °C induced an intramolecular cyclisation to form the piperidine unit in 60% yield (Scheme 2).



Scheme 2 *Reagents and conditions*: i, $(CH_2O)_n$, TsOH, benzene, reflux (94%); ii, NaOMe, MeOH, reflux (95%); iii, NaH, DMF, 85 °C (60%)

This route has been subsequently improved in two ways. Firstly, the problematic differentiation of the two carboxylic acid groups in glutamic acid has been overcome by selective hydrolysis of glutamine using *tert*-butyl nitrite, and the development of a rhodium(II) catalyzed carbene N–H insertion reaction has led to a short and efficient route to the piperidine ring. The substitution pattern is amenable to the synthesis of 2,5-disubstituted targets such as DKP593A **5**, and the monomer of this compound has been prepared in protected form (Scheme 3).[10]

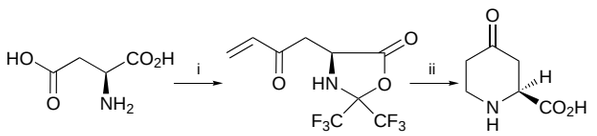


Scheme 3 *Reagents and conditions:* i, Bu^{t}ONO, MeCN, reflux (74%); ii, EtOCOCl; iii, CH_2N_2, Et_2O; iv, $[Rh(OAc)_2]_2$, benzene, reflux; v, $NaBH_4$, MeOH; vi, HO^- (aq); vii, H_2, Pd–C

The α-chiral centre can also be sacrificed after using it to control the stereochemistry elsewhere, such as in the synthesis of (*S*)- or (*R*)-3-hydroxypiperidine from D- or L-glutamic acid,[11] or in the formation of piperidines (and pyrrolidines) from glutamine.[12]

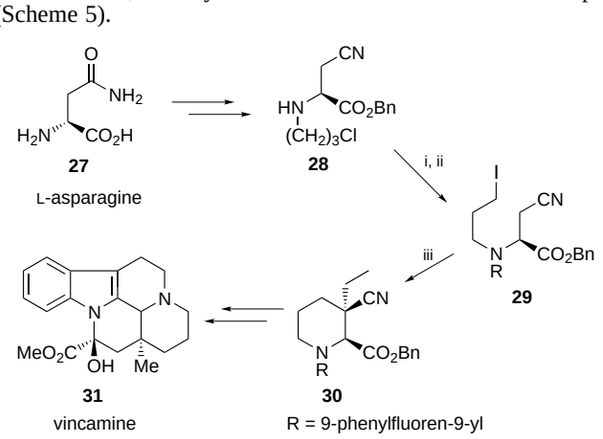
Aspartic acid/asparagine. In the same way that glutamic acid provides a route to 5-substituted pipecolic acids, aspartic acid can be used as a chiral precursor to 4-substituted pipecolic acids. For example, a range of 2,6-disubstituted piperidines can be prepared by extending the side-chain carboxylic acid group of Asp, using the attack of a sulfonamide on a ketone to effect the cyclisation.[12]

Differentiation of the α- and β-carboxylic groups in Asp can be tricky, but they were neatly distinguished in work by Golubev *et al. via* the formation of an oxazolidinone, which could be readily transformed into the hexafluoroacetone protected enone **25**.[13] A Lewis acid catalysed intramolecular Michael addition, followed by deprotection of the vicinal amino and carboxylic functions, gave the 4-oxo-L-pipecolic acid **26** which served as an intermediate in the synthesis of *cis*- and *trans*-4-hydroxy-L-pipecolates (Scheme 4).



Scheme 4 *Reagents and conditions*: i, hexafluoroacetone, then $SOCl_2$, Δ, then CH_2=$CHSnMe_3$, $BnPd(PPh_3)_2Cl$, dimethoxyethane; ii, $BF_3{\cdot}OEt_2$, benzene, Δ, then H_2O–Pr^{i}OH

Using the side-chain of asparagine in a completely different way, Christie converted the amide of asparagine into a nitrile, and used this to construct the piperidine ring in an asymmetric synthesis of vincamine **31**, a known hypertensive agent.[12] Thus, L-asparagine was converted into the iodide **29**, which was cyclised in the presence of LDA and ethyl iodide to afford the piperidine derivative **30** equipped with two chiral centres at positions 2 and 3. Apovincamine, a known precursor to vincamine **31**, was synthesised from **30** in six further steps (Scheme 5).



Scheme 5 *Reagents and conditions*: i, $NaHCO_3$, CH_2Cl_2, 9-phenylfluoren-9-yl bromide, K_3PO_4, $Pb(NO_3)_2$, MeCN; ii, NaI, MeCN, Δ; iii, LDA (excess), EtI (excess), −78 °C

Other amino acids. The amino acids discussed above all utilise the functionalised side-chains to become part of the piperidine ring. It is also possible to use both the α-amino and α-carboxylic acid groups of amino acids to form piperidine rings, in which case the amino acid side-chain becomes a piperidino subsituent. In such cases, the amino acid must be chosen so that the side-chain matches the target molecule. For example, starting from L-alanine, Angle *et al.* completed a nine step synthesis of (+)-monomorine, with the key step in the synthesis involving a Claisen rearrangement.[14]

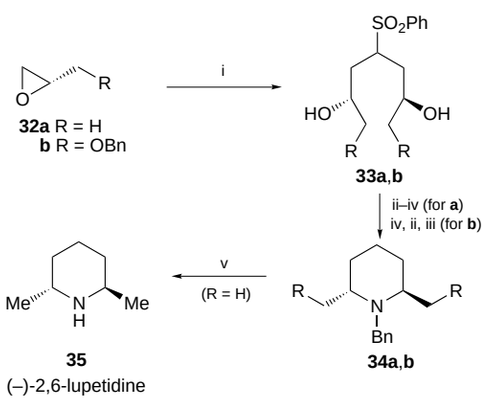
Sugars

Sugars have been used extensively to prepare polyhydroxylated piperidines; these aza-analogues of pyranose sugars often have potent enzyme inhibitory properties, and are thus of medicinal

importance. There is clearly a wide range of sugar building blocks available that might provide much of the functionalisation and stereochemistry, and the one selected depends on the specific target. The major challenge is to successfully differentiate the hydroxy groups so that one of them can be converted into an amino group, and a second one can be converted into a leaving group. This field has been dominated by Fleet's group, and he has developed a number of elegant tactics for achieving the necessary selectivity for the synthesis of polyhydroxylated targets.[15] Less oxygenated targets can also be accessed relatively quickly, as exemplified by the work of Tadano *et al.*[16]

Other chiral building blocks

As many alkaloids incorporate one or more 'isoprene' units within their structure, terpenes are sometimes attractive chiral building blocks. For example, Honda *et al.* developed an efficient stereoselective route to nuphar piperidine alkaloids starting from the readily available chiral monoterpenes, (−)- or (+)-carvone;[17] stereoselective construction of the piperidine ring was achieved *via* an intramolecular aza-Wittig cyclisation. Many other chiral building blocks are specific to the target in question, rather than providing general routes to substituted piperidines; for example, the chiral epoxide **32a** allows a short efficient synthesis of the C_2-symmetric target (−)-2,6-lupetidine **35** (Scheme 6)[18] and elaboration of the oxygenated analogue **34b** might provide access to other C_2-symmetric piperidine derivatives.



Scheme 6 *Reagents and conditions*: i, MesPh–BuLi; ii, TsCl, Py; iii, $PhNH_2$; iv, Na–Hg; v, Pd–C

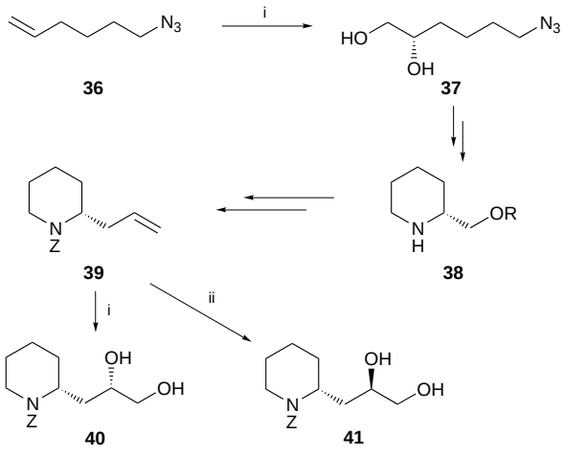
Use of chiral reagents

There are now many chiral reagents that induce asymmetry, and some of these have found widespread applicability in the synthesis of substituted piperidines. In most of the examples below, the reagent utilises a chiral catalyst, with obvious economic advantages.

Sharpless asymmetric dihydroxylation

This procedure has been used quite widely, as exemplified by the asymmetric syntheses of *trans*-2,6-disubstituted piperidines, (+)-epidihydropinidine and (+)-solenopsin A, reported by Takahata *et al.*[19] The asymmetric dihydroxylation (ADH) reaction was exploited even more effectively by Takahata *et al.*, using the ADH reaction to provide access to the piperidine ring, and then employing it again to generate the dihydroxylated targets **40** and **41**; the ADmix control of absolute stereochemistry was able to override any diastereocontrol for dihydroxylation in the penultimate step (Scheme 7).[20]

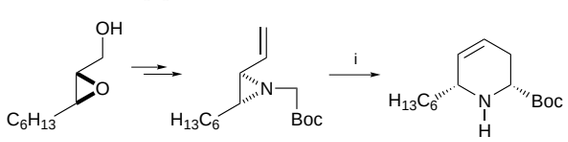
Sharpless's more recent asymmetric aminohydroxylation procedure is certain to be used extensively for the synthesis of piperidine targets.[21]



Scheme 7 *Reagents and conditions*: i, AD Mix-α; ii, AD Mix-β

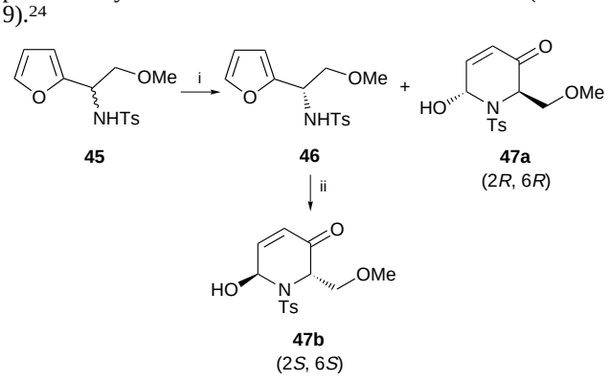
Sharpless asymmetric epoxidation

The Sharpless asymmetric epoxidation reaction is now a well-established and reliable procedure for the epoxidation of allylic alcohols, and there are many asymmetric syntheses of piperidine targets that exploit the reaction. One recent example nicely demonstrates how Sharpless asymmetric epoxidation (SAE) can be used to control (ultimately) the stereochemistry of three substituents on the piperidine ring.[22] A much more general approach is demonstrated by Ahman and Somfai, who prepared the chiral vinylaziridine **43** (> 95% ee) in a straightforward manner from the known epoxy alcohol **42**, itself produced *via* Sharpless asymmetric epoxidation. They showed that these types of vinylaziridines undergo an aza-[2,3]-Wittig rearrangement yielding the corresponding *cis*-2,6-disubstituted tetrahydropyridines **44** as single diastereoisomers (Scheme 8).[23] This methodology has been extended, allowing access to many indolizidine and piperidine alkaloids.



Scheme 8 *Reagents and conditions*: i, LDA, THF

Less conventional is the use of SAE conditions to effect kinetic resolution of the racemic furanyl sulfonamide **45**, which provided asymmetric routes to both enantiomers of **47** (Scheme 9).[24]

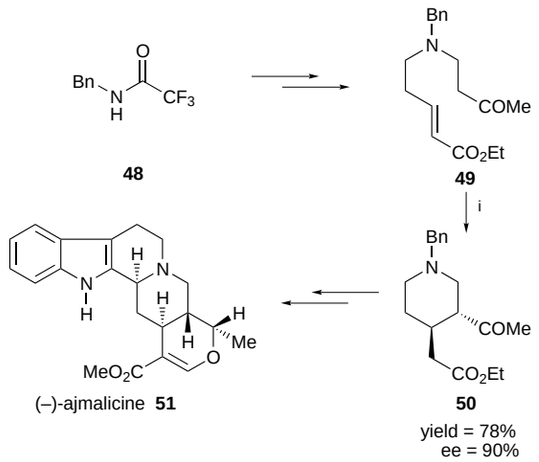


Scheme 9 *Reagents and conditions*: i, $Ti(OPr^i)_4$, L-(+)-DIPT, Bu^tOOH, SiO_2, CaH_2; ii, MCPBA

Chiral bases

Michael reactions using enolate nucleophiles can sometimes occur enantioselectively if triggered by a chiral base. For

example, the readily available achiral compound **49** has been shown to undergo an asymmetric intramolecular Michael reaction with the chiral base, (+)-1-phenylethylamine, to give the optically active cycloadduct **50** in good yield and 80% ee (Scheme 10).[25] This versatile chiral building block has been used in the synthesis of various alkaloids including kainic acid, (−)-tetrahydroalstonine and (−)-ajmalicine **51**.

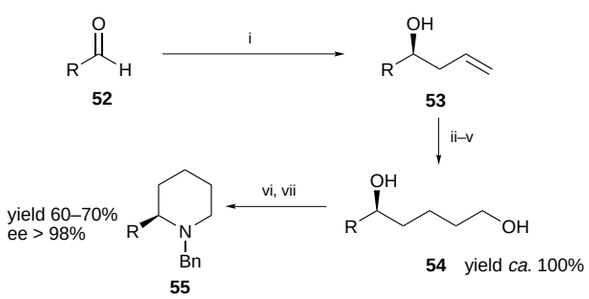


Scheme 10 *Reagents and conditions*: i, (+)-1-phenylethylamine, THF

Chiral boron reagents

The boron reagents developed by Brown are so efficient that their use in the asymmetric synthesis of substituted piperidines was inevitable. For example, the allylB(Ipc)$_2$ reagent can be reacted with a wide range of aldehydes, to provide homoallyl alcohols **53**; these can be elaborated to the diols **54**, from which the 2-substituted piperidines **55** are readily prepared. Not only does this provide a simple route to diverse 2-substituted piperidines, but either enantiomeric series is accessible by use of appropriate chiral boranes (Scheme 11).[26]

The use of chiral borane reagents as catalysts has been only moderately successful, but used in conjunction with a chiral auxiliary, the matched reagents can lead to very high asymmetric induction—see the section concerning Diels–Alder reactions of imines.



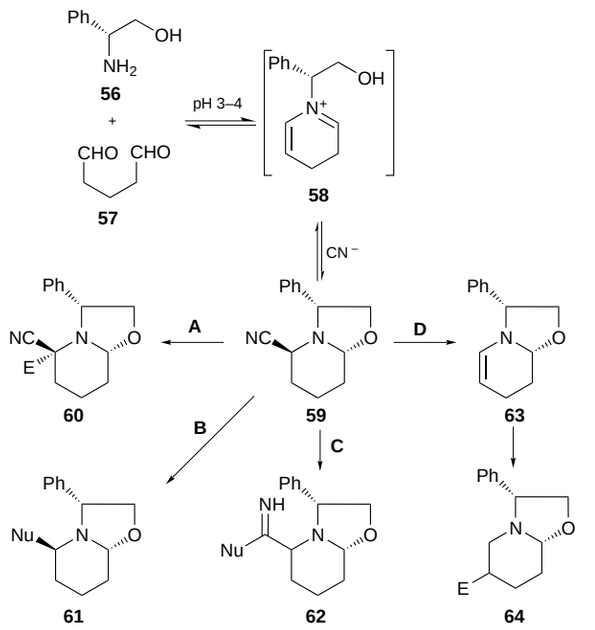
Scheme 11 *Reagents and conditions*: i, Ipc$_2$BAll, −100 °C; ii, BH_3·DMS; iii, MeOH; iv, $BrCH_2Cl$, −78 °C, then BuLi; v, H_2O_2–OH^-; vi, MsCl, NEt_3; vii, $BnNH_2$

Chiral auxiliaries

Chiral auxiliaries have been used with great success in the synthesis of piperidine ring systems. Perhaps the three most general and widely used methods are: the CN(*R,S*) method, the use of chiral lactams, and aza-Diels–Alder methodology.

The CN(R,S) *method*

The CN(*R,S*) method aptly derives its name from the Institut de Chemie des Substances Naturelles du C.N.R.S., where Husson *et al.* developed the use of chiral 2-cyano-6-oxazolopiperidine **59** for the asymmetric synthesis of functionalised piperidines; **59** can be readily obtained from a 'one-pot' condensation reaction between (−)-phenylglycinol, gluteraldehyde and KCN under acidic conditions (Scheme 12).



Scheme 12

The CN(*R,S*) method allows access to a wide range of 2,6-disubstituted piperidines of very high optical purity, exploiting the high functionality and facial selectivity in **59**. It possesses two non-equivalent reactive sites on the piperidine ring system; an α-amino nitrile at the C-2 position and an α-amino ether at the C-6 position. As summarised in Scheme 12, differential chemo- and stereo-selective reactions can be achieved at several positions, allowing access to a wide range of piperidine derivatives: (i) electrophilic attack at the C-2 position (route A); (ii) nucleophilic attack at the C-2 position (route B); (iii) attack at the cyano group (route C); and (iv) electrophilic attack at the C-3 position (route D).

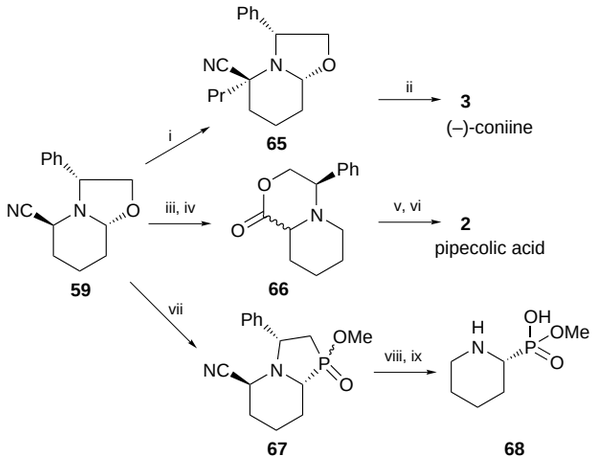
To demonstrate the versatility of the CN(*R,S*) method, Husson *et al.* have completed the syntheses of numerous enantiopure piperidine alkaloids which exhibit biological activity including monomorine, perhydrohistrionicotoxin, various analogues of podophyllotoxin and cephalotaxine.

For example the α-amino nitrile anion, generated by treatment of **59** with LDA, can be alkylated by reaction with alkyl halides. Elimination of the cyano group in the presence of NaH results in the formation of a single diastereoisomer; stereoelectronic effects are responsible for the addition of hydride to the *si* face, so that only *cis* diastereoisomers are formed. This has been illustrated in the synthesis of (−)-coniine[27] (Scheme 13).

Alternatively, the nitrile can itself be incorporated into the target molecule, as in a four step synthesis of (*S*)-(−)-pipecolic acid **2** from the synthon **59**.[28] The cyanide was first converted into the ethyl ester, and reduction with Zn(BH$_4$)$_2$ gave the lactone **66** as a mixture of diastereoisomers. A deprotonation and reprotonation procedure converted **66** into a single diastereoisomer, from which (*S*)-(−)-pipecolic acid was subsequently isolated in 47% overall yield by a simple hydrogenation under acidic conditions (Scheme 20). The phosphonic acid analogue of **2** can also be accessed using the CN(*R,S*) method, as indicated in Scheme 13.[29]

Chiral lactams

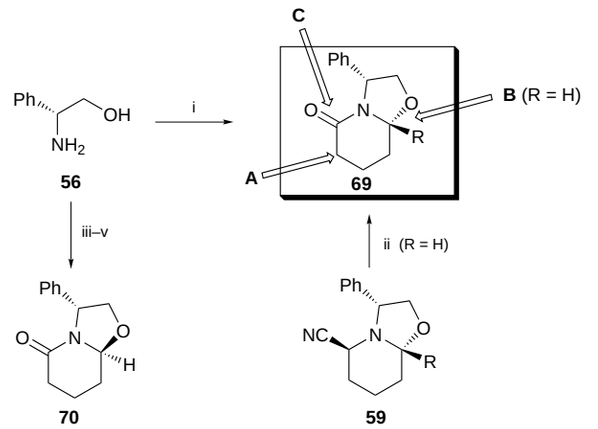
The use of chiral lactams has been developed most effectively by Meyer's group,[30] and this approach has wide applicability to



Scheme 13 *Reagents and conditions*: i, LDA, THF, −78 °C, then PrBr; ii, $NaBH_4$, then H_2SO_4; iii, HCl–EtOH, SiO_2, PhMe; iv, $Zn(BH_4)_2$, Et_2O; v, LDA, THF, AcOH; vi, H_2, Pd–C, HCl–MeOH; vii, $P(OMe)_3$–$SnCl_4$; viii, $NaBH_3CN$; ix, H_2, Pd–C

the synthesis of substituted piperidines, as indicated in Scheme 14. In particular: (i) the enolate of lactam **69** can be alkylated at the 3-position (A); (ii) the *N*-acyliminium intermediate allows introduction of C-6 substituents (B); and (iii) the amide carbonyl can be further functionalised (C). Overall, this provides access to 2,3,6-trisubstituted piperidines with excellent diastereo- and enantio-control.

In the course of their endeavours towards starting materials for the asymmetric synthesis of piperidine derivatives, Royer and Husson were also able to prepare **69** and epimeric **70** from **59**, as shown in Scheme 14.[31]

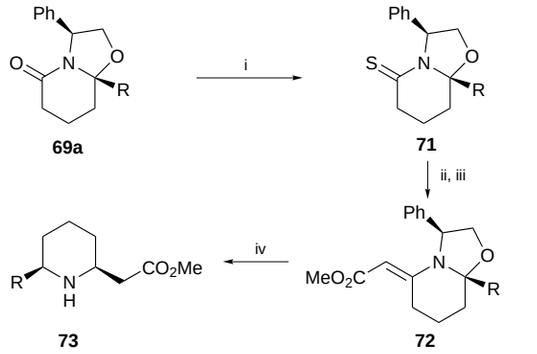


Scheme 14 *Reagents and conditions*: i, $RCO(CH_2)_3CO_2H$; ii, LDA, −78 °C, then O_2; iii, glutaric anhydride, AcCl; iv, $NaBH_4$; v, HCl–MeOH

Meyers has demonstrated the flexibility of his methodology in numerous syntheses.[30] For example, his approach readily allows access to 2,6-disubstituted piperidines (see Scheme 15),[32] whilst reduction of the (thio)lactam clearly provides a simple route to 2-substituted piperidines.

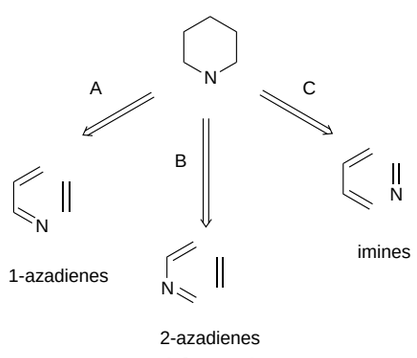
Aza-Diels–Alder reactions

The aza-Diels–Alder reaction has the potential to be a very effective method for the preparation of substituted piperidines.[33] The reaction potentially allows the rapid construction of quite complex piperidines, functionalised or derivatised at various positions, and there is the possibility of regio-, diastereo- and enantio-selectivity in the reaction. The aza-Diels–Alder reaction has therefore provided the key step in numerous syntheses of these compounds. Nevertheless, there



Scheme 15 *Reagents and conditions*: i, Belleau's reagent; ii, $BrCH_2CO_2Me$; iii, $P(OMe)_3$; iv, 3 atm. H_2, $Pd(OH)_2$–C

are problems associated with all of the possible aza-Diels–Alder routes to piperidines, and only recently has substantial progress been made concerning the general applicability of these reactions. The three basic variations of the aza-Diels–Alder reaction that can be used to form piperidine derivatives are shown in Scheme 16. An excellent recent review on 'Asymmetric Hetero-Diels–Alder Reactions' by Waldmann includes a valuable summary of asymmetric aza-Diels–Alder chemistry.[34]



Scheme 16

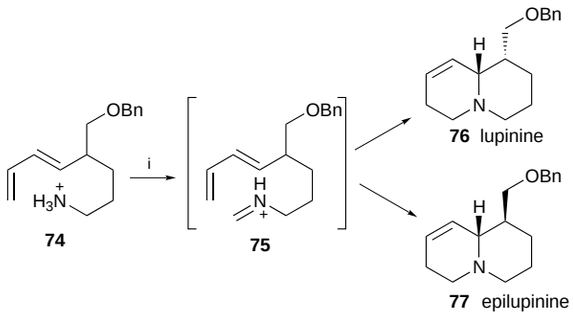
1-Azadienes (route A). 1-Azadienes have proved particularly capricious in (4 + 2)π cycloaddition reactions, with competing imine chemistry often thwarting the intended reaction, and although chiral auxiliaries can be attached to the nitrogen atom, this has not proved to be a major asymmetric route to substituted piperidines.

2-Azadienes (route B). 2-Azadienes have also been extensively studied as starting materials for the synthesis of piperidine-based compounds *via* the Diels–Alder reaction. Unfortunately, general asymmetric versions of these reactions have been elusive, as there is no simple way by which a removable chiral auxiliary can be attached.

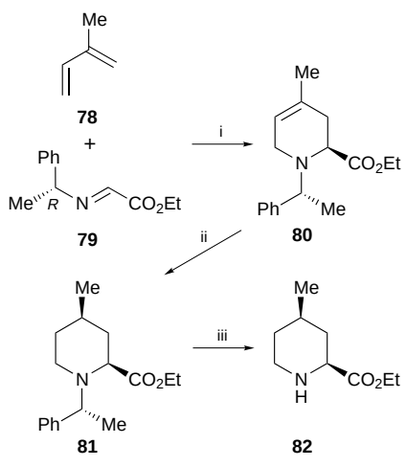
Imines as dienophiles (route C). The Diels–Alder reaction of imines or iminium salts with carbon dienes is probably the most efficient route to substituted piperidines reported to date. Intramolecular cycloadditions of *N*-acyl imines have been particularly useful in the synthesis of several natural products, including lupinine **76** and epilupinine **77** (Scheme 17).[35]

The chiral imine **79** can be readily produced by condensation of ethyl glyoxylate with 1-phenylethylamine, and the Diels–Alder reaction of **79** with a number of dienes has been investigated (Scheme 18).[36]

Bailey *et al.* have proposed a mechanism which explains why catalytic amounts of water are necessary to effect the cycloaddition under acidic conditions. It was suggested that intermolecular hydrogen-bonding between water and the imine formed a seven membered ring complex (Fig. 1) and that the diene approached this π-stabilised iminium intermediate from



Scheme 17 *Reagents and conditions*: i, HCHO



Scheme 18 *Reagents and conditions*: i, DMF, TFA (1 equiv.), H_2O (cat), 25 °C; ii, H_2, Pt–C, EtOAc; iii, H_2, $Pd(OH)_2$–C, EtOH

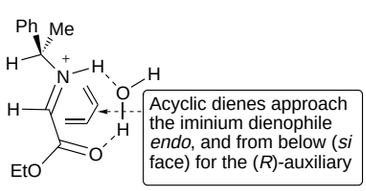


Fig. 1 Predictive model for the outcome of the aza-Diels–Alder reaction between acyclic dienes and **79**

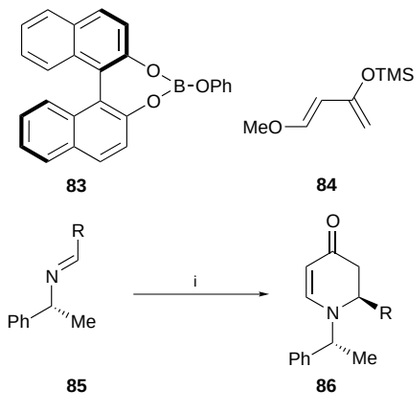
the *si* face due to steric preferences induced by the chiral *N*-auxiliary.[37]

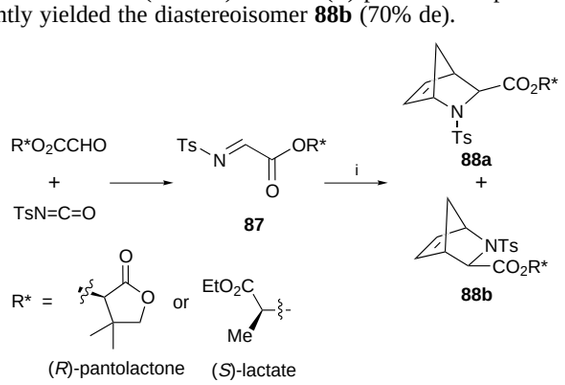
Stella and co-workers devised an alternative set of conditions in which the Diels–Alder reaction proceeded in the presence of TFA and $BF_3{\cdot}OEt_2$ in CH_2Cl_2 at low temperature. Application of these conditions in the cycloaddition of the chiral 1-phenylethylimine of methyl glyoxylate with cyclopentadiene led to total face selectivity and up to 98% *exo* selectivity in the cycloadduct, but extension to acyclic dienes was less successful.[38]

The Diels–Alder reaction of imines with *N*-chiral auxiliaries demonstrates that both high *endo*/*exo* selectivity and asymmetric induction can be achieved to allow access to a range of enantiopure piperidine derivatives. Moreover, the chiral Lewis acid **83**, derived from (*R*)-binaphthol and triphenyl borate, has been shown to catalyse the Diels–Alder reaction between chiral imines and Danishefsky's diene **84** with a very high degree of asymmetric induction (Scheme 19).[39] The use of lanthanide Lewis acid catalysts has been recently published in aza-Diels–Alder reactions of an imine derived from a chiral aldehyde,[40] and the addition of chiral ligands to these reactions has given very encouraging preliminary results—this may well turn out to be one of the most efficient and economical asymmetric routes to chiral piperidines.



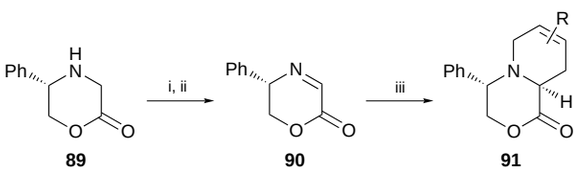
Scheme 19 *Reagents and conditiosn*: i, **83**, **84**, CH_2Cl_2, −78 °C

Holmes has investigated the participation of *N*-*p*-tolylsulfonyl imines **87**, carrying an chiral ester auxiliary, in the aza-Diels–Alder reaction with cyclopentadiene (Scheme 20).[41] The source of chirality on the ester moiety of the imines was from glyoxylate ester derivatives of (*R*)-pantolactone and ethyl (*S*)-lactate, which are known to coordinate Lewis acids in asymmetric cycloaddition reactions. The best results were obtained using Et_2AlCl in toluene at −78 °C. Use of the (*S*)-lactate auxiliary led to the formation of **88a** as the major diastereoisomer (76% de) whereas (*R*)-pantolactone predominantly yielded the diastereoisomer **88b** (70% de).



Scheme 20 *Reagents and conditions*: i, cyclopentadiene, Et_2AlCl, toluene, −78 °C

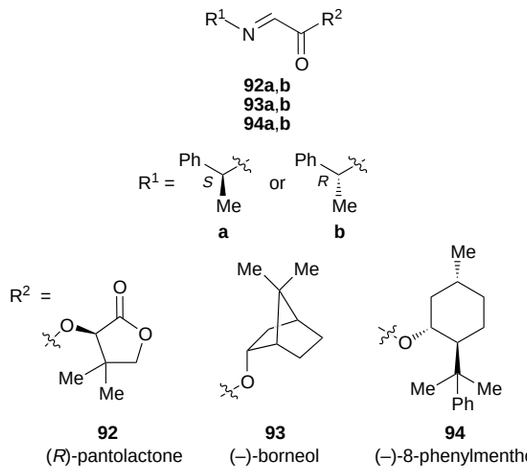
Several groups had sought to prepare the cyclic imines such as **90**, for which Diels–Alder reactions ought to proceed with excellent diastereo- (and hence enantio-)control. Routes in which the imine should have been generated by cyclisation of δ-amino aldehyde derivatives were singularly unsuccessful, but Harwood's group has successfully prepared **90** *via* an oxidative route, and the enantiocontrol in its aza-Diels–Alder reactions is (as expected) superb (Scheme 21).[42] The modest overall yield, and the cost of (unrecoverable) (*R*)- or (*S*)-phenylglycinol are limitations, but this method does provide the highest enantiocontrol from a single auxiliary, and (provided the reaction is sufficiently general) it offers to be a very attractive asymmetric route to a wide range of substituted piperidines.



Scheme 21 *Reagents and conditions*: i, NBS; ii, propylene oxide; iii, substituted butadienes, TFA or AcOH (*ca.* 1.5 equiv.), $BF_3{\cdot}OEt_2$, −78 °C (yield *ca.* 35% from **89**)

Returning to the readily accessed glyoxylate imines, the groups of Bailey and Holmes were able to combine their

auxiliaries and explore the effect of matched and mismatched auxiliaries on the nitrogen and the ester moieties of the imine in aza-Diels–Alder reactions.[43] The imines derived from alcohols (*R*)-pantolactone, (−)-borneol and (−)-8-phenylmenthol in combination with (*R*)- and (*S*)-1-phenylethyl *N*-auxiliaries were studied (imines **92**–**94**) using 2,3-dimethylbutadiene as the 4π partner.



Optimum results were recorded for the Diels–Alder reaction using the imine PhMeCHN=CHCO$_2$PhMen* **94a** bearing matched auxiliaries, and the reaction provided single stereoisomeric products with a range of dienes. The reactions also occurred with complete regiospecificity in all cases, and acyclic dienes added *via* an *endo* transition state, whilst cyclic dienes yielded the *exo* adducts. Detachment of the (recoverable) ester auxiliary was achieved by saponification, and removal of the (cheap) 1-phenylethyl auxiliary could be achieved by catalytic hydrogenation, allowing access to piperidines of known absolute stereochemistry.

Other chiral auxiliaries

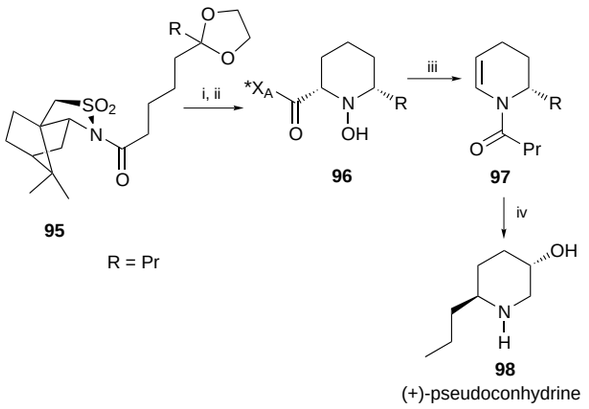
There are many other examples of syntheses involving chiral auxiliaries for the synthesis of piperidines, although most have yet to demonstrate that they are as reliable and versatile as the general methods outlined above. Nevertheless, the wide range of other approaches may provide the best method for a specific target. We have selected a dozen or so examples to illustrate the types of methodology available.

Oppolozer's group has led the way in the use of chiral sultams in asymmetric synthesis, and their methodology provides access to 2,6-*trans*-dialkylated piperidines.[44] Their approach can also be adapted to other substitution patterns, such as the 2,5-disubstituted piperidine (+)-pseudoconhydrine **98**, which has been prepared *via* a versatile deoxygenative decarboxylation–imine trapping route (Scheme 22). In most of the sultam work, the moderately high asymmetric induction can be improved by recrystallization, and the chiral sultam auxiliary can be efficiently recovered part way through the synthesis.

A similar camphor-like auxiliary has been developed by Wanner's group, providing access to 2-substituted piperidines.[45] The key step involves the conversion of an *N*-acyl 2,3-didehydropiperidine into an acyliminium derivative, which is susceptible to nucleophilic attack with high stereocontrol.

Alkylation of acyliminium intermediates has also been achieved, using a C_2-symmetric chiral hydrazone derivative as the source of asymmetry.[46] Hydrazones have also been used by Enders and Jegelka in a further development of RAMP/SAMP methodology, although the approach perhaps lacks generality.[47]

A rather unusual variation of the SAMP/RAMP auxiliary uses a cyclic hydrazine, and involves C–O bond cleavage that is reminiscent of Meyer's chiral lactam work.[48]



Scheme 22 *Reagents and conditions*: i, NaN(SiMe$_3$)$_2$, 1-chloro-1-nitrocyclohexane, H_3O^+; ii, $NaCNBH_3$; iii, NaH, 110 °C, PrC(O)X, base; iv, $BH_3.SMe_2$, THF, then H_2O_2, NaOH, then Pd(OH)$_2$–C, MeOH

The enantiospecific reduction of imines can be used to gain access to piperidines, as demonstrated by Moody's group.[49] The approach should be quite flexible, as a variety of alkyl derivatives could be introduced during the synthesis to yield a range of 2,6-disubstituted piperidines.

Using well-established auxiliaries, several groups have developed quite general asymmetric routes to substituted piperidines. For example, Agami *et al.* utilised an intramolecular ene-iminium cyclisation in which stereoselective control was exerted *via* a morpholinone auxiliary;[50] this gave access to *cis*-2,4-disubstituted piperidines, in which the solvent provided the nucleophile stereospecifically. Using the ephedrine auxiliary, hetero-Diels–Alder chemistry has also been used to gain rapid access to a linear piperidine precursor; although the stereocontrol was modest, the minor diastereoisomer was readily removed, and the second (and final) step provided 5-hydroxy-2-methylpiperidine as a single enantiomer, with full recovery of the auxiliary.[51] The aza-annulation of enamines is another general approach,[52] and asymmetric versions have been developed. In contrast, Jones' imidazoline chiral auxiliary effects complete stereocontrol, and provides access to a wide range of 2-substituted piperidines, but the auxiliary is lost upon final deprotection.[53] Finally, Meyer's formamidine chiral auxiliary, which labilises the proton α to nitrogen, can be used in the synthesis of piperidines.[54]

Conclusions

The huge amount of work on the synthesis of piperidines testifies to their importance. However, there are only a few really concise approaches that provide access to a wide range of substitution patterns. If 2-substituted piperidines are required, then there are many possible synthetic strategies. But for more complex targets, three main options dominate the literature: (i) a tailor-made synthesis using a chiral pool precursor (*e.g.* an amino acid or a sugar); (ii) the construction of a linear precursor using the best asymmetric reagents available (*e.g.* chiral AD-Mix or borane reagents), although such syntheses are often long; and (iii) the use of a chiral auxiliary to control the construction or derivatisation of a piperidine derivative. The last approach offers the potential of short, flexible, highly stereospecific syntheses, despite some limitations. The top methods are the CN(*RS*) approach, the use of Meyers' bicyclic lactam chemistry, and aza-Diels–Alder reactions.

Despite much success, the apparently simple piperidine ring system remains a demanding challenge for synthetic chemists, and there is still enormous scope for improvement. It seems certain the the biological properties of substituted piperidines will ensure that synthetic work on them continues apace.

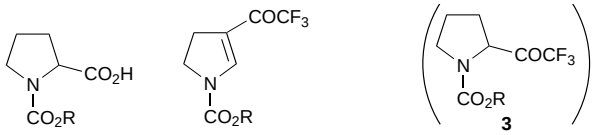
An anomalous Dakin–West reaction of *N*-carbamate substituted prolines and trifluoroacetic anhydride

Masami Kawase,*[a] Michitaka Hirabayashi,[a] Hiromi Koiwai,[a] Katsumi Yamamoto[a] and Hiroshi Miyamae[b]

[a] *Faculty of Pharmaceutical Sciences, Josai University, 1-1 Keyakidai, Sakado, Saitama 350-0290, Japan*
[b] *Faculty of Science, Josai University, 1-1 Keyakidai, Sakado, Saitama 350-0290, Japan*

A novel transformation of *N*-alkoxycarbonylprolines 1 to 4-trifluoroacetyl-2,3-dihydropyrroles 2 was efficiently realized by utilizing trifluoroacetic anhydride, in which probable intermediates were mesoionic 1,3-oxazolium-5-olates B.

The Dakin–West (D–W) reaction of α-amino acids usually produces α-amino ketones.[1] However, treatment of *N*-acyl-*N*-alkyl-α-amino acids or *N*-acylprolines with trifluoroacetic anhydride (TFAA) under the D–W reaction conditions can lead to trifluoromethylated oxazoles,[2] acyloins[3] or morpholines,[4] depending on the nature of the *N*-substituents of the amino acids and/or reaction conditions. In the course of our studies on the reactivities of mesoionic 1,3-oxazolium-5-olates,[5] we have now found that *N*-alkoxycarbonylprolines **1** led unexpectedly, by way of a novel decarboxylative dehydration followed by trifluoroacetylation, to 4-trifluoroacetyl-2,3-dihydropyrroles **2** under the D–W reaction conditions.



1a R = Me

Thus, treatment of **1a** (1 mmol) with TFAA (3 mmol) in MeCN (5 ml) at 80 °C for 5 h gave rise to *N*-methoxycarbonyl-4-trifluoroacetyl-2,3-dihydropyrrole **2a** in 66% yield. In the reaction, the D–W reaction product, *N*-methoxycarbonyl-2-trifluoroacetylpyrrolidine **3** (R = Me), was not isolated.

Reaction variables were briefly examined. Addition of pyridine (3 equiv.) to the reaction reduced the yield (**2c**; 22%). High temperatures (80 °C) were needed to obtain a high yield of **2c**, lower temperatures (60 °C) reducing the yield (**2c**; 46%). Various solvents such as MeCN, DMF, $ClCH_2CH_2Cl$, benzene, $MeNO_2$ and acetone are usable, and among them MeCN and DMF are the solvents of choice for this reaction, while little or no reaction takes place in THF, DME or dioxane. Several urethane-protected prolines **1a**–**f** were reacted in this way and the results are presented in Table 1. Among the *N*-alkoxycarbonyl groups examined, Me, Et and Bu proved to give a good yield of the product **2**. The low yields of **2d**–**f** could be attributable to the ease of cleavage of the alkoxy group in the mesoionic oxazole intermediate **B**. In the reaction of **1f**, *N*-allylacetamide **9a** was isolated in 58% yield as a side product.

Table 1 Reactions of *N*-alkoxycarbonylprolines with TFAA[a]

Entry	Starting material	Solvent	Product (% yield)[b]
1	**1a**	MeCN	**2a** (66)
2	**1a**	DMF	**2a** (67)
3	**1b**	MeCN	**2b** (61)
4	**1b**	DMF	**2b** (53)
5	**1c**	MeCN	**2c** (58)
6	**1c**	DMF	**2c** (68)
7	**1d**	MeCN	**2d** (32)
8	**1d**	DMF	**2d** (27)
9	**1e**	MeCN	**2e** (34)
10	**1f**	MeCN	**2f** (30) + **9a** (54)
11	**1g**	MeCN	**9b** (94)[c]
12	**7**	MeCN	**8** (86)

[a] The reactions were carried out according to the general procedure described in the text. [b] Isolated yields of pure products. All new compounds gave satisfactory spectroscopic data (IR, MS, ^1H and ^{13}C NMR) and analytical (combustion and/or high resolution mass) data. [c] Plus 54% of proline.

The structure of **2** was determined from analytical and spectral data† and was subsequently secured by single-crystal X-ray diffraction analysis of **2d** (Fig. 1).‡

A plausible mechanism for the formation of **2** is suggested in Scheme 1. The existence of the mesoionic oxazole **B** is supported by the following facts. (i) The reaction of Z-proline

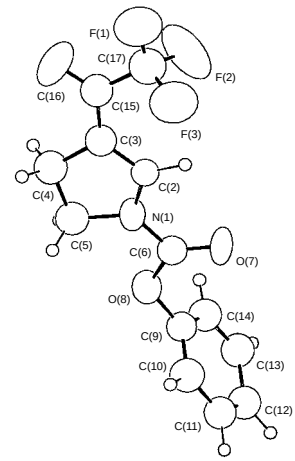

Fig. 1 X-Ray Crystal structure of **2d** (the probability level of the ellipsoids is 50%)

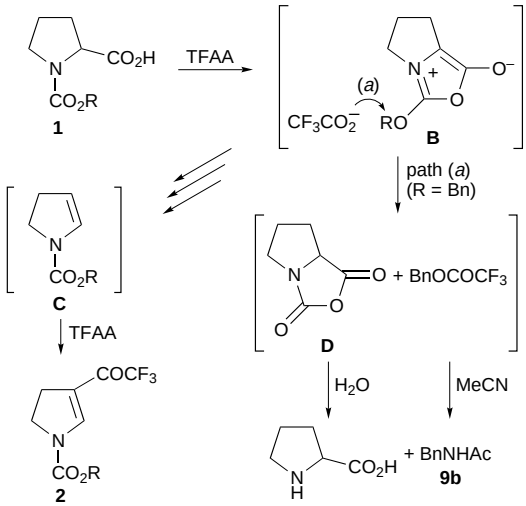

Scheme 1

1g with TFAA afforded proline (45%) and *N*-benzylacetamide **9b** (94%). Formation of proline is presumably due to hydrolysis of anhydride **D**,[6] which was produced by the attack of trifluoroacetate ion on the mesoionic oxazole intermediate **B** *via* path (*a*). *N*-Benzylacetamide **9a** was formed by the Ritter reaction of intermediary benzyl trifluoroacetate and the solvent MeCN. (ii) Treatment of *N*-methoxycarbonyl-*N*-methylphenylalanine **4a** with TFAA in the presence of pyridine gave the D–W reaction product, trifluoroacetyl derivative **5a**, in 93% yield.[7] In the case of *N*-benzyloxycarbonyl-*N*-methylphenylalanine **4b**, trifluoroacetyl derivative **5b** and the anhydride[8] of **6a** *N*-carboxyphenylalanine were obtained in 39 and 43% yields, respectively. (iii) In attempts to form the mesoionic oxazole **A** by treatment of *N*-ethoxycarbonyl-*N*-phenylglycine **4c** with $SOCl_2$, Potts *et al.* isolated the anhydride **6b** of *N*-carboxyglycine and ethyl chloride.[9] This suggests that ring closure to the mesoionic oxazole **A** actually occurred and that it underwent rapid deethylation. However, it is difficult to obtain a definitive explanation for the transformation of **B** to **2**. The existence of intermediary **C** is supported by the reaction of *N*-methoxycarbonyl-2,3-dihydroindole-1-carboxylic acid **7** with TFAA. Thus, the reaction yielded *N*-methoxycarbonylindole **8** in 86% yield and disclosed the probable intermediacy of **C**. Indeed, *N*-methoxycarbonylindole **8** cannot undergo trifluoroacetylation, whereas *N*-methoxycarbonyl-2-pyrroline **C** (R = Me)[10] prepared independently gave the trifluoroacetyl derivative **2a** in 65% yield under the same reaction conditions as described for **1a**. Finally, trifluoroacetylation of **C** leads to the product **2**.

In summary, this work describes the reaction of *N*-alkoxycarbonylprolines and TFAA, which has great practical potential because of the ready availability of the starting materials and reagents and the ease of manipulation. Our method makes novel compounds **2** readily accessible for further study as building blocks for the synthesis of fluorine-containing compounds, in view of the versatility of aminoenones (N–C=C–C=O) in synthetic as well as heterocyclic chemistry.[11] Detailed mechanistic studies and synthetic utilization of **2** as trifluoromethyl building blocks are now in progress.

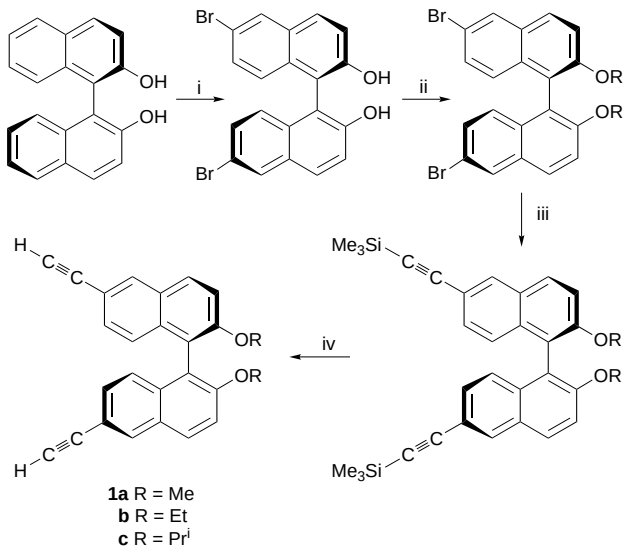
Treatment of C_2-symmetric chiral acetylenes, prepared from (*R*)-1,1′-bi-2-naphthol, with dichlorobis(trialkylphosphine)-platinum or -palladium in the presence of a Cu^{I} catalyst in amine gave high molecular-weight polynuclear complexes, which show a large negative optical rotation.

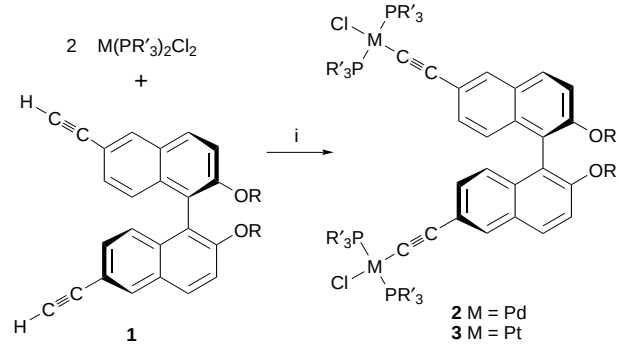
In recent years much attention has been drawn to molecular architecture incorporating coordination chemistry of transition metals.[1] We have been studying the chemistry of transition metal–poly(yne) polymers, in which metal atoms are linked by diynes such as butadiyne or *p*-diethynylbenzene to form rigid rod-like molecules.[2] Recently we showed that our methodology for the synthesis of multinuclear transition metal acetylides in one-dimension can be successfully applied to the synthesis of a three-dimension system giving a platinum–acetylide dendrimer.[3] Now we have expanded our methodology to the synthesis of polymers having a controlled main chain such as a helical structure. Since artificial polymers with a chiral backbone may maintain a stable single-handed helical conformation, they are of interest in view of their potential as new materials.[4] Here we report the first synthesis of a novel optically active poly(yne) polymer possessing a chiral acetylene bridge.

Bridging acetylene ligands **1** were easily prepared from 1,1′-bi-2-naphthol as shown in Scheme 1.[5] When optically active (*R*)-1,1′-bi-2-naphthol (commercially available, >99% ee determined by HPLC using a chiral column) was used as a starting material, optically active acetylenes [**1a**: $[\alpha]_D$ −69 (*c* 0.05, $CHCl_3$); **1b**: $[\alpha]_D$ −29 (*c* 0.05, $CHCl_3$); **1c**: $[\alpha]_D$ −8 (*c* 0.1, $CHCl_3$)] having C_2 symmetry were obtained. X-Ray crystallographic study of **1b** and **1c** showed that the two naphthyl groups make a dihedral angle of 112.8° in **1b** and 105.3° in **1c**, respectively.‡

As a model compound of the polymer we prepared optically active dinuclear complexes possessing a chiral acetylene bridge (Scheme 2). Treatment of **1a** with 2 equiv. of $Pd(PEt_3)_2Cl_2$ in the presence of a CuCl catalyst in Et_2NH at room temperature gave dipalladium complex **2a**. Similarly the reaction of **1b** with $Pd(PEt_3)_2Cl_2$ gave **2b**. Platinum analogs **3** were also prepared in a similar manner but at higher temperature (under piperidine reflux) because proportionation between platinum diacetylides and dichlorides takes place only at high reaction temperature.[2] These complexes were fully characterized by IR and NMR spectroscopy and elemental analysis.§ Yields and optical rotations are summarized in Table 1. The ^{1}H NMR spectrum of **3a** using the chiral shift reagent $Eu(fod)_3$ showed that no racemization took place during the conversion from chiral 1,1′-bi-2-naphthol.¶



Scheme 1 *Reagents and conditions*: i, Br_2, CH_2Cl_2, −78 °C to room temp., 4 h, 91%; ii, RI, K_2CO_3, acetone, reflux, overnight, 85–89%; iii, $Me_3SiC{\equiv}CH$, $Pd(PPh_3)_2Cl_2$, CuI, Et_3N, reflux, overnight, 68–78%; iv, K_2CO_3, MeOH, overnight, 85–87%



Scheme 2 *Reagents and conditions*: i, CuCl, Et_2NH, room temp., 4 h (M = Pd); CuCl, piperidine, reflux, overnight (M = Pt)

Reactions of chiral acetylene **1** with an equimolar amount of $M(PR'_3)_2Cl_2$ in the presence of a CuI catalyst in Et_2NH result in the formation of polynuclear complexes **4** and **5** having high molecular weight (Scheme 3). Experiments using ^{31}P NMR spectroscopy and GPC indicated the formation of dinuclear complexes **2** or **3** at an early stage, which slowly condense with terminal acetylene to propagate a metal–acetylide main chain. Since the resulting polymers are stable and soluble in common organic solvents, purification was performed by column chromatography on alumina followed by reprecipitation from CH_2Cl_2 into MeOH. The regular structures of **4** and **5** were

[a] Determined by GPC using poly(styrene) standards. [b] In 10^{-1} deg cm^2 g^{-1} [*c* 0.05 (R = Me, Et), *c* 0.10 (R = Pr^i), $CHCl_3$ at 25 °C].

confirmed by spectral analyses. For example, the ^{31}P NMR spectrum of **5d** exhibited one singlet signal at δ 3.27 with satellite signals (J_{Pt-P} = 2365 Hz). Only one set of signals, attributed to the naphthyl group, was observed in the ^1H and ^{13}C NMR spectra of **5d**.‖ Yields, molecular weights and optical rotations for **4** and **5** are shown in Table 2. The M_w values for palladium polymers **4** are in the range of 5400–12 000 regardless of the substituent on acetylene and the nature of the phosphine ligands, and are smaller than those of the platinum analogs **5**. A similar trend was observed in *p*-diethynylbenzene-bridged poly(yne) polymers.[2] In contrast, the M_w values of platinum polymers **5** were influenced to a certain extent by the substituent on the naphthyl group of the acetylene bridges and the nature of the phosphine ligands. Thus, the M_w values of ethoxy analogs **5b** and **5d** are much higher than those of the methoxy and isopropoxy variants. Since there is no significant difference in the structure of the bridging acetylene ligands **1b** and **1c** as determined *via* X-ray analysis, it is not clear why the molecular weights of the resulting polymers depend on the bridging acetylene ligands. Tributylphosphine analogs **5c** and **5d** have higher M_w values than triethylphosphine analogs **5a** and **5b**. It should be noted that all polymers prepared here showed larger specific optical rotations than both acetylene ligands **1** and model compounds **2** and **3**, which may indicate that the main chain of the polymers adopts a one-handed helical conformation and induces the helical chirality of the polymers.

In summary, we prepared novel optically active poly(yne) polymers of palladium and platinum possessing C_2-symmetric chiral acetylene bridges, which provide the first organometallic polymer with an optically active backbone, although some optically active organic acetylene polymers, in which chirality is similarly derived from 1,1′-bi-2-naphthol, have been reported very recently.[5]

This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas, 'New Polymers and Their Nano-Organized Systems' (No. 277/08246103), and Encouragement of Young Scientists (No. 09740491) from the Ministry of Education, Science, Sports and Culture, Japan.

Diastereoselective routes to side-chain truncated analogues of *N*-acetylneuraminic acid†

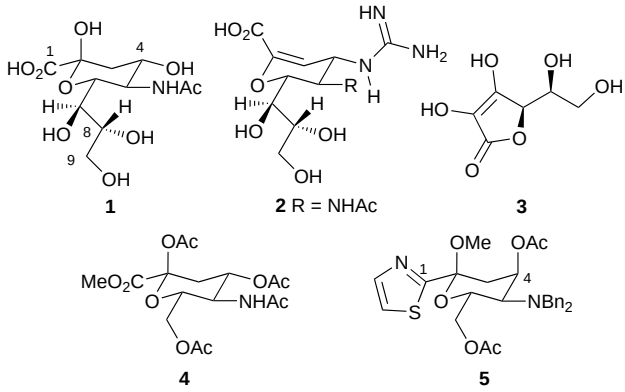
Martin Banwell,*[a]‡ Chris De Savi,[a] David Hockless[a] and Keith Watson[b]

[a] *Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, ACT 0200, Australia*

[b] *Biota Chemistry Laboratory, Chemistry Department, Monash University, Clayton, Victoria 3168, Australia*

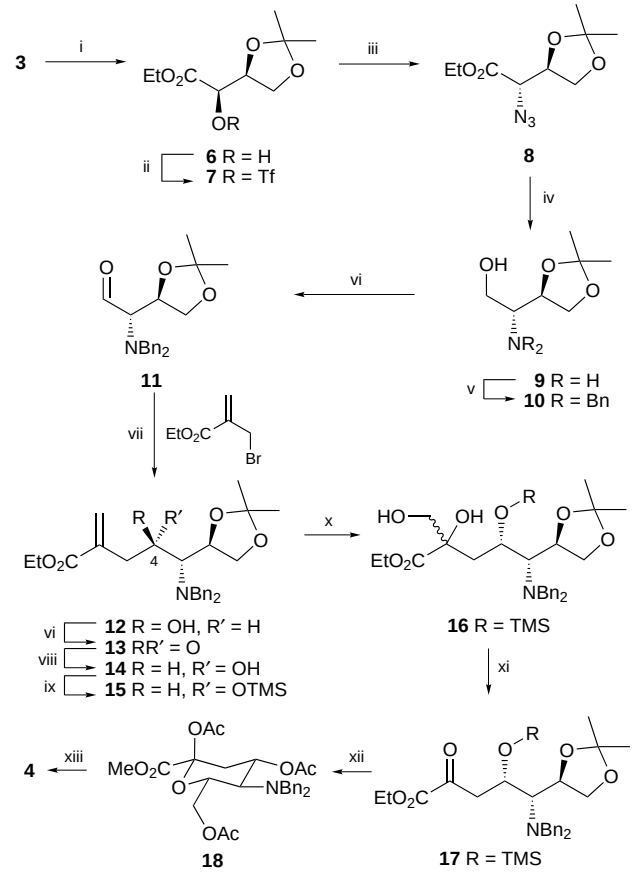
Vitamin C 3 has been converted, in a completely stereocontrolled manner, into the side-chain truncated analogues 4 and 5 of *N*-acetylneuraminic acid 1.

N-Acetylneuraminic acid **1** (Neu5Ac) and other members of the sialic acid class of carbohydrates play fundamental roles in many important biological processes, including cell adhesion and differentiation, immune responses, tumour metastasis and the development of neural cells.[1] In addition, they constitute a ligand commonly recognised by many infectious pathogens such as viruses, bacteria and parasites.[1] Consequently, sialic acids and various derivatives including the potent anti-influenza drug GG167 **2**[2] are assuming increasing importance as pharmacological tools and/or therapeutic agents.[3] In this regard there is now considerable interest[4] in side-chain truncated analogues of Neu5Ac which are currently only accessible *via* degradation of the natural product **1**.[3,4] Therefore, we report herein on the stereocontrolled conversion of abundant vitamin C **3** into compounds **4** and **5**, each of which embodies the sialic



acid core but lacks the C-8/C-9 (side-chain) assemblage associated with the parent system **1**. The reaction sequences used for these conversions offer possibilities for the synthesis[5] of a range of novel sialic acid analogues which can vary in both the nature and stereochemistry of the substituents attached to the pyranose ring.

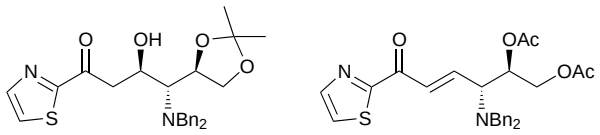
The reaction sequence (Scheme 1) leading to compound **4** starts with a literature procedure[6] for the oxidative degradation of vitamin C **3** to the α-hydroxy ester **6**. The triflate derivative **7** of the latter compound was then prepared in quantitative yield by standard methods[7] and underwent a smooth S_N2 reaction with lithium azide[8] in DMF at room temperature to give the azide **8** {80%, $[\alpha]_D$ −14.7 (*c* 2.6)§}. Reduction of this α-azido ester with LAH afforded the amino alcohol **9** {100%, $[\alpha]_D$ −10.5 (*c* 1.5)} which was immediately protected as its *N*,*N*-dibenzyl derivative **10** {90%, $[\alpha]_D$ +1.2 (*c* 2.1)}. Oxidation of compound **10** using the Swern reagent gave aldehyde **11**[9] {95%, $[\alpha]_D$ +3.9 (*c* 3.8)} which upon reaction with ethyl (2-bromomethyl)acrylate, zinc dust and saturated aq. NH_4Cl[10] in THF afforded the homoallylic alcohol **12** {87%, $[\alpha]_D$ −14.8 (*c* 2.1)} in a completely diastereoselective fashion.[11] Oxidation of the latter compound with the Swern reagent afforded ketone **13** {90%, $[\alpha]_D$ −72.9 (*c* 2.5)} and this was immediately reduced with $NaBH_4$ in EtOH to alcohol **14** {82%, $[\alpha]_D$ −5.9 (*c* 2.3)} which proved to be the only isolable product of the reaction. Attempts to cleave the C=C double bond[12] within this last compound using ozone failed because of competing reaction at the aromatic rings associated with the *N*,*N*-dibenzylamino moiety. Consequently, a somewhat more circuitous method was devised for achieving this end. Thus, compound **14** was



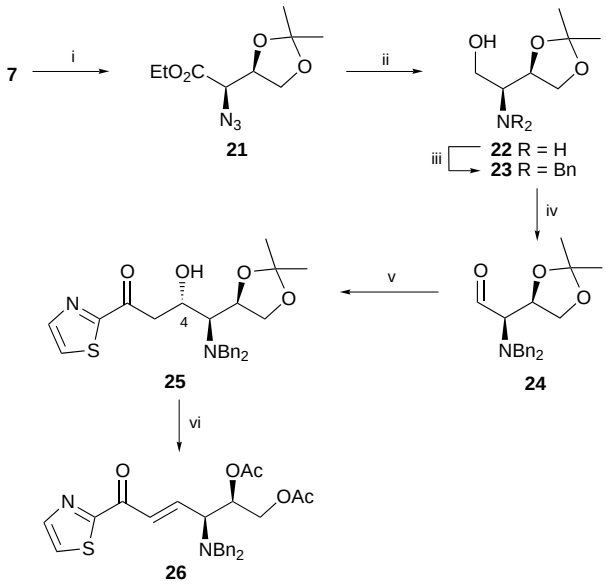
Scheme 1 *Reagents and conditions*: i, see ref. 6; ii, Tf_2O (1.3 equiv.), 2,6-lutidine (1.3 equiv.), CH_2Cl_2, −50 to −10 °C, 0.75 h; iii, LiN_3 (2.5 equiv.), DMF, 18 °C, 3 h; iv, LAH (3.5 equiv.), THF, 18 to 65 °C, 3 h; v, BnBr (2.2 equiv.), K_2CO_3 (2 equiv.), MeCN, 60 °C, 14 h; vi, $(COCl)_2$ (1.2 equiv.), DMSO, CH_2Cl_2, −78 to 0 °C, 1 h, then Et_3N (2.6 equiv.); vii, Zn dust (1.2 equiv.), sat. aq. NH_4Cl, THF, 60 °C, 0.75 h; viii, $NaBH_4$ (6 equiv.), EtOH, −10 °C, 1.5 h; ix, TMSCl (4.0 equiv.), hexamethyldisilazane (4.0 equiv.), pyridine, 0 to 18 °C, 19 h; x, AD-mix-α (2.2 equiv.), Bu^tOH, H_2O, 18 °C, 22 h; xi, $Pb(OAc)_4$ (0.9 equiv.), $CaCO_3$ (11 equiv.), CH_2Cl_2, 18 °C, 0.33 h; xii, 6% w/v HCl in MeOH, 18 °C, 18 h then Ac_2O (10 equiv.), DMAP (trace), pyridine, 18 °C, 20 h; xiii, Pd black, 5% w/v HCO_2H in MeOH, 18 °C, 0.5 h, then Ac_2O (10 equiv.), DMAP (trace), pyridine, 18 °C, 20 h

converted into the corresponding Me_3Si-ether **15** {83%, $[\alpha]_D$ −12.9 (*c* 3.0)} and the C=C double bond within this latter compound was dihydroxylated using AD-mix-α.[13] The resulting 1 : 1 mixture of diastereoisomeric diols **16** (83%) was then cleaved with lead tetraacetate to give the α-keto ester **17** {90%, $[\alpha]_D$ −21.7 (*c* 2.3)}. Treatment of compound **17** with 6% w/v methanolic HCl at room temperature for 18 h and subsequent peracetylation of the crude reaction mixture resulted in formation of the sialic acid analogue **18** {72%, $[\alpha]_D$ −81.3 (*c* 5.7)}. The benzyl protecting groups within this last compound could be removed using palladium black and formic acid[14] in MeOH and the resulting primary amine was acetylated to give the target compound **4** {80% at 80% conversion, $[\alpha]_D$ −97.1 (*c* 1.0)}, the structure of which follows from spectroscopic data.

Extension of this chemistry to the preparation of compound **5** is readily achieved. Thus, aldol condensation of the enolate anion derived from 2-acetylthiazole[15] with aldehyde **11** afforded the β-hydroxy ketone **19** {72%, $[\alpha]_D$ −58 (*c* 0.7)} in a completely stereoselective manner. Reaction of this last compound with 20% w/v methanolic HCl at room temperature for 18 h and subsequent peracetylation of the crude reaction mixture afforded compound **5** {70%. $[\alpha]_D$ −182.1 (*c* 1.0)} together with quantities (30%) of the open-chain dehydration product **20** {$[\alpha]_D$ −154.2 (*c* 0.6)}.



While the reaction sequence just described delivers a sialic acid analogue **5** which possesses the unnatural configuration at C-4, there are some constraints associated with the stereochemical variations that are available. This situation is highlighted by the outcome of the reaction sequence outlined in Scheme 2. Thus, treatment of triflate **7** with sodium azide in DMF at 75 °C for 6 h afforded azide **21** {85%, $[\alpha]_D$ +42.5 (*c* 2.7)} together with minor amounts (*ca*. 8%) of its C-2 epimer **8** which could be removed chromatographically. Reduction of compound **21** with LAH then provided the corresponding amino alcohol **22** {83%, $[\alpha]_D$ + 1.0 (*c* 5.7)} which was converted into the *N*,*N*-dibenzyl derivative **23** {92%, $[\alpha]_D$ −80.0 (*c* 6.8)}. Oxidation of this latter compound afforded the C-2 epimer of α-amino aldehyde **11**, namely compound **24** {88%, $[\alpha]_D$ +58.7 (*c* 7.9)}, which underwent stereoselective aldol condensation with the enolate anion derived from 2-acetylthiazole to give amino alcohol **25** {79%, $[\alpha]_D$ −5.5 (*c* 3.7)}. The stereochemistry at C-4 within compound **25** has not been rigorously proven but is assigned as illustrated on the basis of the well-known[9,11] directing effect of an α-(*N*,*N*-dibenzylamino) substituent on nucleophilic additions to aldehydes. In an effort to achieve a cyclisation reaction, compound **25** was treated with 8% w/v methanolic HCl, then the crude reaction mixture was subjected to exhaustive acetylation. However, no cyclisation products were observed. The only compound obtained was the open-chain dehydration product **26** {70%, mp 123–125 °C, $[\alpha]_D$ +106.3 (*c* 0.7)}, the structure of which was established by spectroscopic and X-ray crystallographic methods.¶



Scheme 2 *Reagents and conditions*: i, NaN_3 (2 equiv.), DMF, 75 °C, 6 h; ii, LAH (3.5 equiv.), THF, 18 to 65 °C, 3 h; iii, BnBr (2.2 equiv.), K_2CO_3 (2 equiv.), MeCN, 60 °C, 14 h; iv, $(COCl)_2$ (1.2 equiv.), DMSO, CH_2Cl_2, −78 to 0 °C, 1 h then Et_3N (2.6 equiv.); v, Bu^tOH (1 equiv.), Bu^nLi (1.2 equiv.), THF, 18 °C, 0.66 h, then 2-acetylthiazole (1.2 equiv.), −50 °C, 2.5 h; vi, 8% w/v HCl in MeOH, 18 °C, 18 h, then Ac_2O (10 equiv.), DMAP (trace), pyridine, 18 °C, 20 h

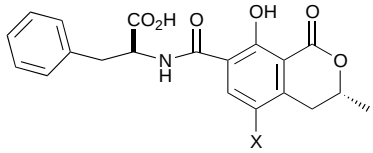
Ochratoxin A acts as a photoactivatable DNA cleaving agent

Ivan G. Gillman, Jennifer M. Yezek and Richard A. Manderville*

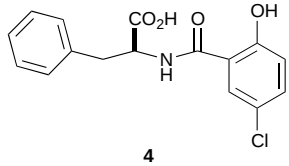
Department of Chemistry, Wake Forest University, Winston-Salem, North Carolina 27109-7486, USA

The ability of ochratoxin A to photoinduce DNA cleavage is described; in the presence of DNA the photoreaction yields the non-chlorinated derivative, ochratoxin B, while a hydroquinone derivative is produced under anaerobic conditions.

Ochratoxin A (OTA, **1**: X = Cl) is a fungal toxin produced by a species of Aspergillus and Penicillium.[1,2] It contaminates a wide range of foodstuffs and is implicated in the disease Balkan endemic nephropathy in which patients suffer from urinary tract tumors.[3] OTA induces single-strand DNA cleavage[4] and DNA adduction *in vivo*;[5] properties that establish a basis for its genotoxicity. However, the mechanism of OTA-induced DNA damage is currently not known.



OTA, **1** X = Cl
OTB, **2** X = H
OTOH, **3** X = OH



4

Despite this, it is known that the chlorine atom is essential[6] and antioxidants inhibit its genotoxic activities.[7] While activation of OTA appears to be oxidative,[3–7] we have found, using fluorescence spectroscopy (λ_{ext} = 380 nm, λ_{em} = 441 nm), that the toxin is particularly susceptible to light and decomposes over time unless a suitable filter is used to suppress light intensity. Since certain halogenated compounds have been shown to efficiently photocleave DNA,[8–10] we hypothesized that **1** may photoinduce DNA damage. Such activity was also expected to provide new insight into the toxin's DNA targeting activities as photoactivatable agents have proven useful as probes of DNA structure,[11] sequence,[12] and mechanism, both in terms of DNA strand-scission[13] and DNA alkylation.[14]

Here we describe our preliminary findings on the photonuclease activity of **1**. While *in vivo* activation of **1** may be mediated by cytochrome P450[15] with subsequent formation of hydroxyl radicals,[16,17] our results show that light can also activate **1** and the products from the photoactivation provide new insight into species that may participate in its *in vivo* DNA targeting activities.

The ability of **1** to facilitate DNA photocleavage was examined using supercoiled plasmid DNA and agarose gel electrophoresis. As shown in Fig. 1, no cleavage resulted in the absence of light (lane 2), highlighting that **1** alone does not induce DNA cleavage. However, in the presence of light, DNA cleavage by **1** occurred in a concentration dependent fashion (lanes 4–7). Table 1 shows the effect of various additives on the extent of photocleavage by **1**. In an ambiently oxygenated atmosphere, inhibition was provided by the oxygen radical scavengers, DMSO, *tert*-butyl alcohol and sodium azide. However, a marked increase in the extent of photocleavage occurred in an N_2-flushed atmosphere, precluding the requirement for activated oxygen species. Inhibition of photocleavage was also provided by copper(II) ions; a metal that binds **1** effectively and quenches its fluorescence spectrum.[18] That both Cu^{II} and O_2 inhibit DNA cleavage suggests that they quench the excited state of **1**.[19]

Additional insight into the mode of photocleavage by **1** was obtained from the finding that the non-chlorinated derivative, OTB (**2**: X = H), and the derivative **4**,† which lacks the dihydroisocoumarin (lactone) ring system of **1**, failed to photoinduce DNA strand-scission (Fig. 2). These findings are remarkably similar to the *in vivo* toxicity of **1** and indicate a requirement for both the chlorine atom[6] and the lactone.[20]

Product analysis from the photoreaction of **1** in aqueous buffered media also provided information regarding the mode of photocleavage by the toxin. In an ambiently oxygenated atmosphere, no products were identified in the photoreaction of **1** alone, even though the toxin was consumed as evidenced by

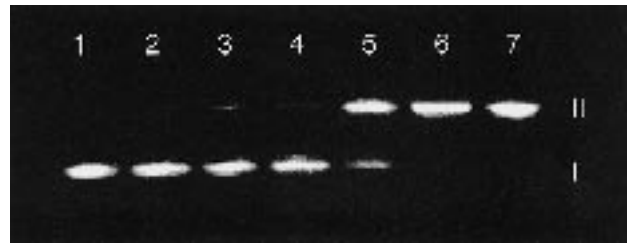


Fig. 1 Cleavage of supercoiled plasmid DNA by **1**. Reaction mixtures (20 μl total volume) contained 400 ng of plasmid DNA in 10 mM MOPS buffer, pH 7.4, and were irradiated on ice through a Pyrex filter with an ILC Technology 300 W Xenon arc lamp. After 5 min, the reaction mixtures were analyzed on a 1.2% agarose gel. Lane 1: DNA alone. Lane 2: DNA + 1000 μM **1**. Lane 3: irradiated DNA. Lane 4–7: irradiated DNA + 40, 200, 400 and 1000 μM **1**, respectively.

Table 1 Effect of additives on the extent of photocleavage of supercoiled DNA (Form 1) by **1**

Conditions[a]	Form I[b] (%)	Form II[c] (%)	Form III[d] (%)
Control	89	11	0
+**1**	27	73	0
+100 mM NaN_3	78	22	0
+1 μl DMSO	66	34	0
+1 μl Bu^tOH	62	38	0
+ SOD[e]	27	73	0
+ catalase[f]	27	73	0
+10 mM $Cu(OAc)_2$	74	26	0
Anaerobic[g]	0	61	39

[a] Reactions were run at pH 7.4 (10 mM MOPS buffer) using 200 μM **1** and 400 ng of supercoiled plasmid DNA in 20 μl total volume, and were irradiated in ice through a Pyrex filter with an ILC Technology 300 W Xenon arc lamp for 5 min. Densitometric quantitation of the gels was performed using a Microtek Scanmaker E_6 equipped with PhotoImpact and UTHSCSA Image Tool software. [b] Supercoiled DNA. [c] Nicked circular DNA. [d] Linear DNA. [e] 1000 units ml^{-1} super oxide dismutase. [f] 1000 units ml^{-1} catalase. [g] Reaction with **1** was purged with N_2 prior to photocleavage.

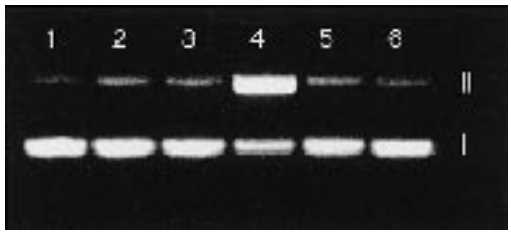

Fig. 2 Structure–activity relationships in DNA cleavage of supercoiled plasmid DNA by **1**. Reactions were carried out for 5 min as described in the caption below Fig. 1. Lane 1: DNA alone. Lane 2: DNA + 200 mM **1**. Lane 3: irradiated DNA. Lane 4: irradiated DNA + 200 μM **1**. Lane 5: irradiated DNA + 200 μM **2**. Lane 6: irradiated DNA + 200 μM 4.

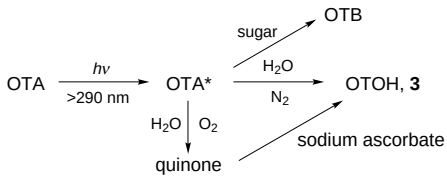

Scheme 1 Summary of the photoreaction of **1**. Excitation by light (> 290 nm) to produce **1*** is accompanied by production of **2** in the presence of a sugar. Under anaerobic conditions (N_2, H_2O) substitution of chlorine by H_2O yields the hydroquinone **3**, which is also produced under reducing conditions in the presence of O_2.

HPLC. However, in the presence of calf thymus DNA or dextrose, photoirradiation of **1** yielded the non-chlorinated derivative **2**.‡ Under anaerobic conditions in the absence of a sugar, photoreaction of **1** produced the hydroquinone derivative, OTOH (**3**: X = OH),§ a finding that we attribute to $S_{RN}1$ displacement[21] of the chlorine atom by H_2O. Interestingly, **3** was also detected in the presence of O_2 when a reducing agent (sodium ascorbate) was added to the photoreaction. This observation suggests that the hydroquinone **3** may have originated from a reactive quinone precursor, in analogy to photooxidation of halogenated phenols that yield benzoquinone derivatives in the presence of O_2.[22,23] The results of these studies are summarized in Scheme 1.

In conclusion, the fungal carcinogen **1** does not facilitate DNA cleavage alone. However, we have demonstrated that light is one way to activate **1** to induce DNA damage. The finding that **2** is a product of **1** photoirradiation in the presence of DNA, suggests that strand-scission is mediated by H-atom abstraction from deoxyribose sugars through initial C–Cl bond homolysis.[8–10] In the absence of a sugar and O_2, **1** is converted in high yield to the hydroquinone derivative, **3**. This species is also formed in the presence of O_2, provided that a suitable reducing agent is added to the photoreaction. This result suggests strongly that photooxidation of **1** produces a reactive quinone derivative, a species that may be responsible for the toxin's DNA adduction properties.[5] Presently, experiments are in progress to identify the cleavage sites and the mechanistic pathways for photocleavage. We are also studying the oxidation of **1** to determine the exact nature of oxidized **1**, its chemical reactivity and lifetime in aqueous buffered media and the potential of such a species to induce DNA adduction.

We thank Dr Fred W. Perrino (Department of Biochemistry, Wake Forest University) for the sample of plasmid DNA. This work was supported by Grant #IRG from the American Cancer Society and Wake Forest University.

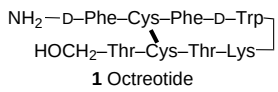
Dihydropyran-2-carboxylic acid, a novel bifunctional linker for the solid-phase synthesis of peptides containing a C-terminal alcohol

Hsing-Pang Hsieh, Ying-Ta Wu, Shui-Tein Chen*† and Kung-Tsung Wang

Institute of Biological Chemistry, Academia Sinica, Taipei, 11529, Taiwan

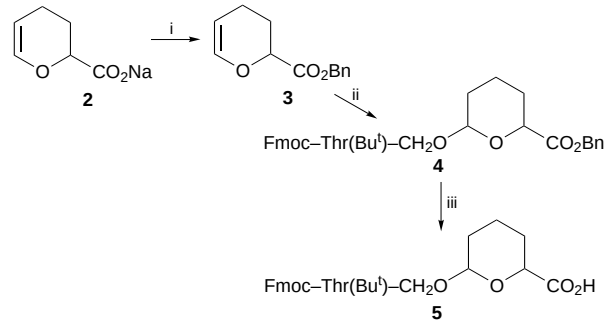
Dihydropyran-2-carboxylic acid, a novel compound used to link an amino alcohol and an amine resin, is utilised for the solid-phase synthesis of peptide alcohols *via* the Fmoc strategy; this bifunctional linker was effectively applied to the synthesis of Octreotide.

Peptides that contain a C-terminal alcohol, such as Octreotide,[1] Enkephalins,[2] Gramicidin[3] and Trichoderma species,[4] have been the focus of recent research, because of these peptides bind with high affinity to their receptors and have a long half-life *in vivo*. Peptides containing a C-terminal alcohol cannot be synthesized by conventional solid-phase peptide synthesis (SPPS), because present protocols require a free carboxy group to attach onto the resin. Octreotide **1**, a metabolically stable somatostatin analog, inhibits the growth of tumor cells by binding to surface somatostatin receptors.[5] Many methods have been reported for its synthesis,[1a,6a,b,c] however[5,6] these methods have drawbacks including low yields and complicated procedures. We describe here a new procedure using dihydropyran-2-carboxylic acid as a bifunctional linker for the synthesis of peptide alcohols by SPPS.



1 Octreotide

Sodium 3,4-dihydro-2*H*-pyran-2-carboxylate **2** was prepared according to established procedures.[7,8] Compound **2** is a key component of the bifunctional linker which easily undergoes self-lactonization under acidic conditions,[9,10] and the carboxy group of **2** must be protected before the dihydropyran portion couples with the amino alcohol. Compound **2** was reacted with BnBr in DMF at 25 °C in the presence of Cs_2CO_3 to form benzyl 3,4-dihydro-2*H*-pyran-2-carboxylate **3**, which was further reacted with Fmoc-Thr(Bu^t)OH[11] in the presence of TsOH in CH_2Cl_2 to yield Fmoc-Thr(Bu^t)-THP-2-CO_2Bn **4**. Selective catalytic transfer hydrogenation to remove the benzyl group of **4** using Pd/C–cyclohexa-1,4-diene yielded Fmoc-Thr(Bu^t)-THP-2-CO_2H **5** (90% yield) without interfering with the other three protection groups. Enzymes such as alcalases and lipases or chemical methods such as K_2CO_3 in THF–H_2O under mild hydrolytic conditions were ineffective for removal of the benzyl ester, due to low reactivity and low conversion. Catalytic hydrogen transfer, however, effectively cleaved the benzyl ester without deprotecting the Fmoc group, while the Fmoc group could be cleaved by hydrogenation over Pd/C or $Pd(OAc)_2$.[12] In a similar manner, Fmoc-Gly-THP-2-CO_2H **6** and Fmoc-Phe-THP-2-CO_2H **7**, the C-terminal amino alcohols of the Grami-



Scheme 1 *Reagents and conditions*: i, Cs_2CO_3, BnBr, room temp., 24 h (80%); ii, TsOH, CH_2Cl_2, Fmoc-Thr(Bu^t)-ol, 12 h (85%); iii, Pd/C, MeOH, cyclohexa-1,4-diene, 2 h (90%)

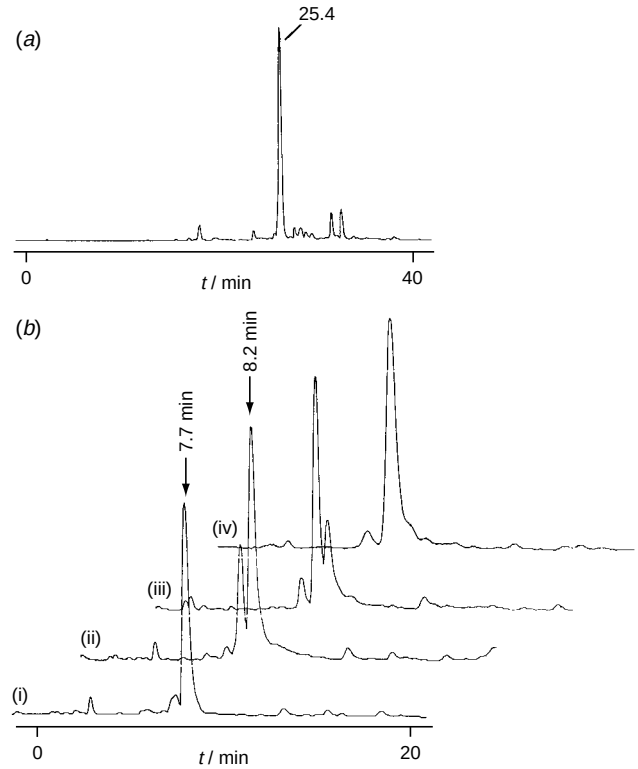


Fig. 1 (*a*) Analysis of reduced Octreotide (retention time 25.4 min) by HPLC. Sample was taken from the aq. AcOH (5%) used to extract the peptide immediately after the elongated peptide was cleaved from the resin. Conditions for HPLC: RP-18 column, 4.6 × 250 mm; gradient 0 → 30 min, 0 → 100% B; 30 → 35 min, 100% B; 35 → 40 min, 100 → 0% B; flow rate 1.0 ml min^{-1}; A = 5% MeCN in water containing 0.1% TFA; B = 90% MeCN in water containing 0.1% TFA; UV detection at 214 nm. (*b*) The time course for the folding of reduced Octreotide: (i) 0, (ii) 8, (iii) 32 and (iv) 46 h. The progress of the peptide folding was followed by analytic reverse-phase HPLC. The retention time for the reduced Octreotide was 8.2 min and for the folded Octreotide was 7.7 min. Conditions for HPLC: RP-18 column, 4.6 × 250 mm; gradient 0 → 20 min, 50 → 60% B; 20 → 25 min, 60% B; 25 → 30 min, 60 → 50% B; flow rate 1.0 ml min^{-1}; A = 50% MeCN in water containing 0.1% TFA; B = 90% MeCN in water containing 0.1% TFA; UV detection at 214 nm.

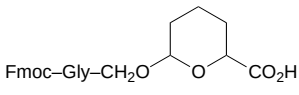
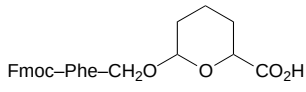


6



7

cidin[3] and Trichoderma species,[4] were also obtained from Fmoc-Gly-ol[13] and Fmoc-Phe-ol[13] in yields of 72 and 78%, respectively (see Scheme 1).

The novel linker was used successfully to synthesize Octreotide. Fmoc-Thr(Bu^t)-THP-2-CO_2H was attached to an amine resin and the peptide Fmoc-D-Phe-Cys(Trt)-Phe-D-Trp(Boc)-Lys(Boc)-Thr(Bu^t)-Cys(Trt)-Thr(Bu^t)-CH_2O-THP-CO-amide resin was synthesized stepwise using an Fmoc protocol. After completion of the peptide synthesis, simultaneous cleavage of Octreotide from the resin and deprotection of the side-chains was performed using the TFA method (TFA–thioanisole–ethanedithiol–H_2O = 0.9 : 0.5 : 0.25 : 0.25). Dilsulfide bond formation was achieved by air oxidation in aqueous phosphate buffer at 25 °C pH 7 for 48 h monitored by HPLC. Pure Octreotide was isolated *via* preparative reverse-phase HPLC (70% total yield). Fig. 1 illustrates the time course of the disulfide bond formation. The reduced form of Octreotide and the final product appeared as major peaks (Fig. 1). The presence of Octreotide was confirmed by amino acid analysis and FAB mass spectrometry (*m*/*z* 1019.5 [M^+ + 1]).

The high yields and purity (Fig. 1) of Octreotide produced using the novel bifunctional linker demonstrate that the linker is stable under basic Fmoc/Bu^t synthetic conditions as well as acid-labile and easily removed from the resin to regenerate the desired C-terminal alcohol. Furthermore, because the DHP-2-CO_2H linker first couples with the C-terminal amino alcohol to form the first residue for SPPS, the linker can more easily couple to any primary, secondary or even tertiary alcohols compared to Ellman's DHP-resin bound system.[6] In conclusion, the novel bifunctional linker can be used successfully in the synthesis of peptide C-terminal alcohols in addition to the preparation and screening of combinatorial peptide and non-peptide libraries *via* solid-phase synthesis techniques.[14]

Support for this research by the National Science Council, Taiwan, is gratefully acknowledged.

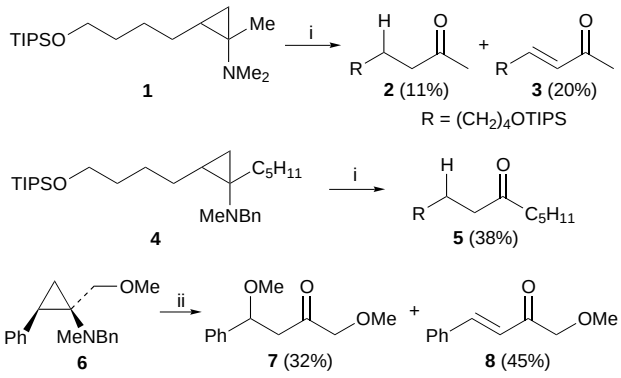
CAN-mediated tandem 5-*exo*-cyclisation of tertiary aminocyclopropanes: novel accelerative effect of an *N*-benzyl group for oxidative ring-opening

Yoshiji Takemoto, Saori Yamagata, Syun-ichirou Furuse, Hiroki Hayase, Tomoki Echigo and Chuzo Iwata*†

Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565, Japan

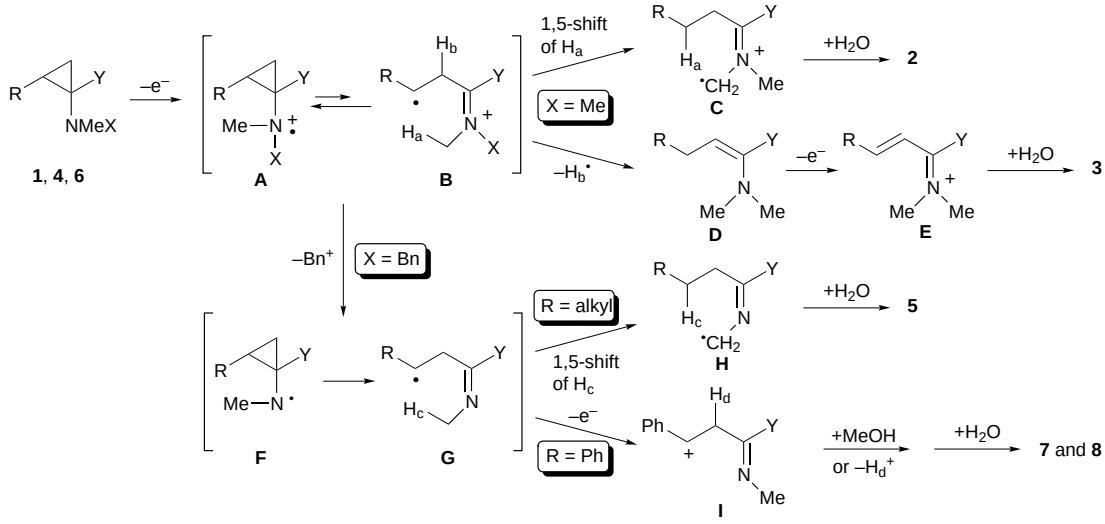
Treatment of tertiary cyclopropylamines with cerium(IV) ammonium nitrate (CAN) gave ring-opened ketones and/or bicyclic secondary amines *via* an oxidative cyclopropane cleavage followed by a hydrogen abstraction or 5-*exo* radical cyclization: an *N*-benzyl group plays a crucial role in these reactions.

Cyclopropylamines have attracted considerable interest from organic and biological chemists as conformationally constrained amino acids[1] and mechanism-based inhibitors of cytochrome P-450 and monoamine oxidase.[2] Thus far many facile preparations of cyclopropyl amines, such as the Simmons–Smith cyclopropanation of enamines[3] and the Ti^{II}-mediated coupling of *N*,*N*-dialkylamides and monosubstituted olefins,[4] have been developed. However, compared with these synthetic methods, few transformations of cyclopropylamines into more versatile synthetic intermediates have been reported.[3,5] Only the enzymatic oxidation of cyclopropylamines to clarify the mechanism for the inactivation of cytochrome P-450[6] and monoamine oxidase,[7] and ethylene formation from 1-aminocyclopropane carboxylic acid[8] have been examined. In these studies, it has been proposed that the ring-opening reaction proceeds *via* cyclopropylamine radical cations, whose existence have been proven by an EPR study.[9] Recently, we developed an efficient synthetic method for cyclic ethers and spirocyclic compounds by a single electron transfer (SET) promoted ring-opening of cyclopropyl sulfides with cerium(IV) ammonium nitrate (CAN).[10] Our recent efforts have been directed to the oxidative ring-opening of the tertiary cyclopropylamines. Herein we report a convenient method for cleaving a cyclopropyl bond‡ and an intramolecular [3 + 2]cycloaddition with a tethered olefin.[11]

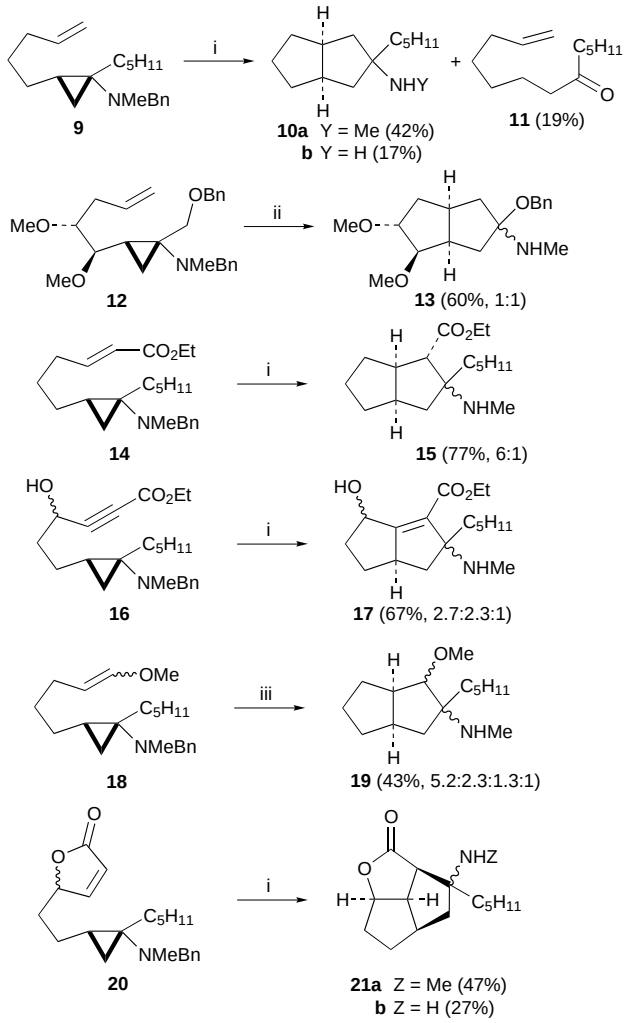


Scheme 1 *Reagents and conditions*: i, CAN, $NaHCO_3$, DMF, room temp.; ii, CAN, K_2CO_3, MeOH, 0 °C

The ring-opening of *N*,*N*-dimethyl- and *N*-methyl-*N*-benzylcyclopropylamines **1**§ and **4**§ was studied as a model reaction (Scheme 1). The CAN-promoted oxidation of **1** proceeded slowly (20 h) in DMF in the presence of $NaHCO_3$ to give the ring-opened ketone **2** and α,β-unsaturated ketone **3** in 11 and 20% yield, respectively. The use of MeOH as solvent in place of DMF slowed the reaction rate, resulting in the recovery of almost all the starting materials. On the other hand, the reaction of **4** under the same reaction conditions proceeded smoothly (2 h), irrespective to the reaction solvent, to give the ring-opened ketone **5** as the sole product in good yield. Although all products seem to be produced by cleaving the most substituted cyclopropyl bond of **1** and **4**, two-electron oxidation occurred simultaneously with single-electron oxidation in the former case. In addition, the oxidation of 2-phenylcyclopropylamine **6** took place only through two electron oxidation, giving the β-methoxy ketone **7** and the α,β-unsaturated ketone **8** in 32 and 45% yield, respectively. These results indicate that the CAN-mediated oxidation of the tertiary cyclopropylamines is affected by substituents on both the nitrogen and the cyclopropane ring. The reaction pathway shown in Scheme 2 clearly explains these phenomena. The SET oxidation of **1** and **4** generates the radical-



Scheme 2



Scheme 3 *Reagents and conditions*: i, CAN, $NaHCO_3$, DMF, room temp.; ii, CAN, $NaHCO_3$, MeOH–THF (5 : 1), room temp.; iii, CAN, $NaHCO_3$, DMF, 0 °C

cation **A**, which is equilibrated to the ring-opened iminium radical **B**. In the case of **1** (X = Me), the following 1,5-hydrogen shift (**B** → **C**) and successive deprotonation and second SET oxidation (**B** → **D** → **E**) might proceed slowly because the equilibrium lies so far to **A**. On the other hand, in the case of **4** (X = Bn), the benzyl group of the radical-cation species **A** and **B** was rapidly lost from the nitrogen atom, giving the aminyl radical **F** and/or iminyl radical **G**. Because the aminyl radical **F** undergoes a very rapid ring-opening to **G**,[12] the next 1,5-hydrogen shift (**G** → **H**) occurs at a reasonable rate to afford **5**. However, in the case of **6** (R = Ph), another SET oxidation of **G** takes place at a rate faster than the 1,5-hydrogen shift due to the stability of the radical, producing **7** and **8** *via* the cation intermediate **I**.

To achieve an intramolecular trapping of the presumed radical **G** by a tethered olefin, we next examined the CAN oxidation of *N*-benzyl-*N*-methylcyclopropylamines bearing a suitably situated radical acceptor, typically a double or triple bond (Scheme 3). The oxidation of **9** bearing a terminal olefin was carried out with 5 equiv. of CAN in DMF at room temperature. The reaction was completed in 2 h and gave the bicyclic products **10a** and **10b** in a total yield of 59% along with the ketone **11** as a minor product, while no monocyclic products were obtained.¶ The cyclization of **12** was not influenced by the substituent on the tether, giving the desired products **13** in 60% yield. More interestingly, the α,β-unsaturated ester **14** and the α,β-acetylenic ester **16** cyclized more efficiently to give the corresponding bicyclic products **15** and **17** without the ketones, whereas the oxidation of the methyl enol ether **18** afforded **19** in only moderate yield with several over-oxidation products. The α,β-unsaturated lactone **20** was also investigated to examine whether the chirality of the cyclopropylamine moiety influences the diastereoselectivity of the products obtained by the tandem cyclization. Because the CAN-mediated oxidation of **20** (diasteromeric mixture of 1.1 : 1) gave rise to the tricyclic products **21a** and **21b** in a total yield of 74% as a single isomer, the chirality of the cyclopropylamine moiety of **20** appears to have no effect on the diastereoselectivity of the tandem [3 + 2]-type cycloaddition.[12]

In conclusion, we have developed a novel tandem [3 + 2]-type cycloaddition using the CAN-mediated ring-opening reaction of the cyclopropylamines. This transformation allows for the utilization of aminocyclopropanes as the synthetic equivalents of γ-imino radicals. In addition, the present research demonstrates that the γ-imino radicals possess a totally different reactivity with γ-keto radicals, which can be prepared from cyclopropyl alcohols and α,β-unsaturated ketones by SET oxidation and Bu^n_3SnH-mediated reduction, respectively.[13]

We thank the Research Foundation for Pharmaceutical Sciences for financial support.

Metal-bound chlorine often accepts hydrogen bonds

Gabriel Aullón,[a] Dena Bellamy,[a] Lee Brammer,*[b]† Eric A. Bruton[b] and A. Guy Orpen*[a]†

[a] *School of Chemistry, University of Bristol, Bristol, UK BS8 1TS*

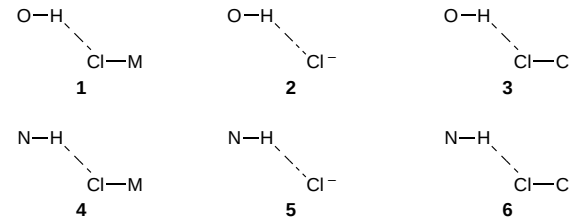
Analysis of 6624 crystallographically characterised hydrogen bonds containing M–Cl, C–Cl or Cl⁻ and either HO or HN groups show that M–Cl moieties are good, anisotropic hydrogen-bond acceptors forming hydrogen bonds similar in length to those of the chloride anion, while C–Cl moieties are very poor hydrogen-bond acceptors.

In a recent article,[1] Dunitz and Taylor showed that the hydrogen bonding capability of the C–F moiety is very poor on the basis of a crystal structure database study and quantum mechanical calculations. The implication of that work is that hydrogen bonding D–H···F–C (D = O, N,*etc.*) interactions are too weak to be of great significance in molecular recognition processes in, for example, biological chemistry or crystal engineering. Here, we show that although C–Cl moieties and C–F have rather similar hydrogen-bonding characteristics, M–Cl moieties (M = transition metal) are much better hydrogen-bond acceptors. The ability of metal halide species to act as hydrogen-bond acceptors has been noted anecdotally by us and others on the basis of one or more crystal structures.[2] Braga, Desiraju and Grepioni and coworkers[3] have shown that ligands in organometallic complexes can be involved in hydrogen bonding. In the systems they have studied the ligands are either rather weak acceptors (*e.g.* carbon monoxide) or behave essentially as their organic analogues do. In the inorganic species studied here (those with terminal M–Cl bonds) the effects of the metal on the hydrogen-bonding ability of the ligand are much more dramatic, in a way not anticipated in recent authoritative texts on hydrogen bonding.[4] Indeed Jeffery states 'while halide ions are strong hydrogen-bond acceptors, there is no evidence from crystal structures supporting hydrogen bonds to halogens.[4a] Here we show that (as Dance has speculated)[5] in contrast, metal bound chlorine is a good hydrogen bond acceptor.

To assess the hydrogen-bonding capabilities of the M–Cl unit, the Cambridge Stuctural Database[6] was used to search for structures containing O–H or N–H fragments as well as M–Cl, Cl⁻ or C–Cl.‡ Our objective was to compare the geometry of D–H···Cl–M interaction in these crystal structures as well as to assess the relative probability of such contacts being formed to chlorine in these three different forms. The intermolecular contacts were categorised as 'short' (≤2.52 Å), intermediate



Scheme 1

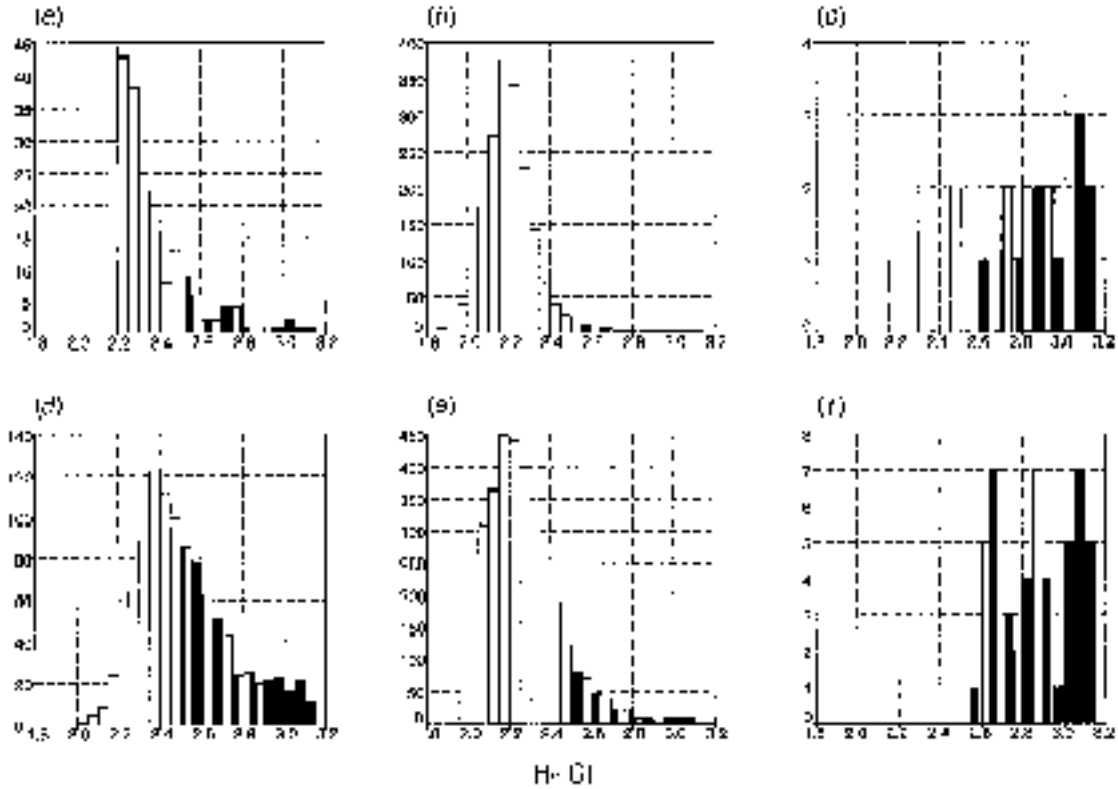


Fig. 1 Histograms of H···Cl distances for (*a*) **1**, (*b*) **2**, (*c*) **3**, (*d*) **4**, (*e*) **5**, (*f*) **6**. Short distances in light grey, intermediate in grey, long in black.

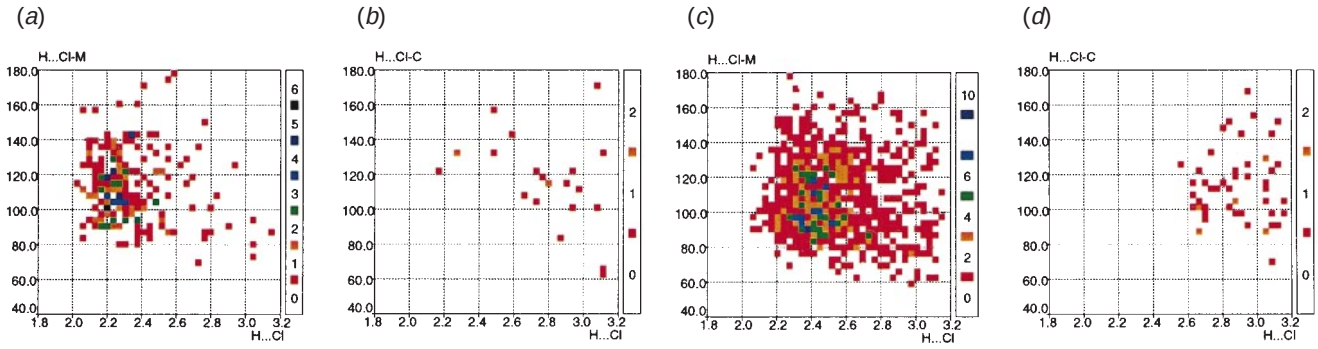

Fig. 2 Scattergrams of M–Cl···H or C–Cl···H angles *vs.* H···Cl distances in systems (*a*) **1**, (*b*) **3**, (*c*) **4**, (*d*) **6**. The number of cases in a given pixel are colour coded.

Table 1 Percentage of hydrogen-bond contacts (H···Cl ⩽ 3.15 Å) which were classified as short (H···Cl ⩽ 2.52 Å)

Interaction	D = O	D = N
D–H···Cl–M	86.5 **1**	57.4 **4**
D–H···Cl⁻	97.2 **2**	90.8 **5**
D–H···Cl–C	22.7[a] **3**	0.0 **6**

[a] Represents five observations (out of a total of 22 O–H···Cl–C contacts ⩽3.15 Å).

(2.52–2.95 Å) and long 2.95–3.15 Å (*cf.* sum of van der Waals radii for H and Cl = 1.2 + 1.75 = 2.95 Å).[7]

The range of H···Cl distances for the cases shown in Scheme 1 are illustrated in Fig. 1. It is clear that Cl^- forms many 'short' Cl···H interactions, as does the M–Cl group, whereas C–Cl moieties form almost no 'short' Cl···H interactions. The correlation of D–H···Cl angles with H···Cl distance (see Supplementary material§) is comparable to that typically observed for the corresponding parameters in both strong and weak hydrogen bonds, and shows a predominance of D–H···Cl angles close to 180° at short H···Cl separations[8]

Fig. 2 shows the spread of M–Cl···H and C–Cl···H angles with respect to H···Cl distance.¶ It is clear from examination of Fig. 2(*a*) that there is a clustering of structures for M–Cl acceptors, particularly in the short distance range, at angles of *ca.* 100–110°, suggesting some directional preference in these interactions. The C–Cl acceptors [Fig. 2(*b*),(*d*)] appear to favour a similar range of angular approaches, through there are fewer data, and almost no stronger, shorter Cl···H interactions.

The percentage of interactions formed that fall in the various categories (in particular the 'short' group, Table 1) may be taken as an indicator of the strength of the interactions of types **1**–**6**. These percentages confirm the expectation that in general O–H is a stronger donor than N–H, and more importantly that the sequence of acceptor strengths is Cl^- > M–Cl ≫ C–Cl.

The clear implication of these observations is that M–Cl containing complexes have the potential to interact with hydrogen-bond donors in both a strong (*i.e.* short) and anisotropic fashion. In the first respect they resemble the chloride ion and in the second organochlorine species. The shortness of D–H···Cl–M bonds presumably derives at least in part from the large negative charge on the chloride in these partially ionic M–Cl bonds. The poor hydrogen-bond acceptor qualities of C–Cl, C–F, *etc.* may in turn be associated with much lower charge accumulation at the halogen atom in these species.[1]

Rheingold, Crabtree and their coworkers showed that the structure of $[HNC_5H_3Ph_2\text{-}2,6][AuCl_4]$ was consistent with greater basicity of chlorine p than sp lone pairs,[2c] since there appeared to be preference for their involvement in the N–H···Cl–M bonds. In this work we have shown that this is not an isolated occurrence and that this phenomenon may be much more general than has hitherto been thought.

These observations may be extended to metal complexes of the other halides, which although less numerous show similar patterns of behaviour in structures in the CSD. We are exploring the application of these observations to the design and synthesis of crystal structures of metal halide complexes, as has been recently reported by Van Koten and coworkers.[10]

We are grateful to Todd Foust for writing utility programs to separate data for simple hydrogen bonds from those for bifurcated examples, and Dr F. H. Allen for useful discussions. We thank the Spanish Ministerio de Educación y Ciencia for an F.P.U. (Becas en el extranjero) grant (to G. A.), an NSF-REU grant (for partial support of E. A. B.), and the Universities of Bristol and Missouri-St Louis for financial support.

Notes and References

‡ All N–H and O–H distances were normalised to standard neutron diffraction determined internuclear lengths, and only those structures containing intermolecular contacts with 1.80 ⩽ H···Cl ⩽ 3.15 Å and D–H···Cl angles ⩾ 110° were included in subsequent analyses. Data for bifurcated hydrogen bonds were removed after the initial search using locally written programs and will be discussed in a later paper.

§ Available upon request from the Authors.

¶ No spatial normalisation corrections[9] have been applied to these scattergrams. Such corrections, although widely recognised as appropriate, are not substantial in this case since there are few fragments for which the E–Cl···H angle (E = M, C) approaches 180°.

Enantioselective palladium catalyzed allylic substitution of acyloxypyrrolinones by alcohols

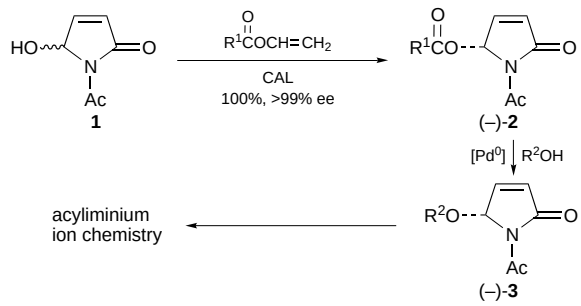
Agnes D. Cuiper, Richard M. Kellogg and Ben L. Feringa*†

Department of Organic and Molecular Inorganic Chemistry, Groningen Centre for Catalysis and Synthesis, University of Groningen, Nijenborgh 4, Groningen 9747 AG, The Netherlands

Chiral non-racemic acyloxypyrrolinones are converted into alkoxypyrrolinones with retention of configuration by a palladium catalyzed allylic substitution; this comprises a key step in a short chemo-enzymatic route to acyliminium ion precursors.

Enantiomerically pure alkoxypyrrolinones have been shown to be facile building blocks for a variety of stereoselective syntheses involving Diels–Alder cycloadditions, 1,3-dipolar reactions, conjugate additions and acyliminium ion intermediates.[1] In particular application in the asymmetric synthesis of alkaloids, based on *N*-acyliminium ion chemistry, is of great current interest.[2] For example, (*R*)-1-acetyl-5-isopropoxy-3-pyrrolin-2-one [compound (−)-**3a** (R^2 = Pr^i) in Scheme 1] has been used by Hiemstra and Speckamp as an intermediate in the synthesis of gelsemine.[3] However, the stereoselective synthesis from (*S*)-malic acid[4] is laborious and more practical routes would be desirable.

Recently we reported simple and efficient enzymatic methodology to obtain enantiomerically pure acyloxypyrrolinones **2** from hydroxypyrrolinones **1**.[5] In this process both enantiomers of an acyloxypyrrolinone can be obtained by the same enzyme (*Candida antarctica* lipase, CAL) using either an esterification (Scheme 1) or a transesterification. Although these compounds have been applied with success in various stereoselective transformations,[6] they are not suitable as acyliminium ion precursors. In order to generate an acyliminium ion the acyl group on nitrogen must be removed.[4] This is possible with an alkoxy group at the 5-position but not with a more sensitive acyloxy group. We now report that the enzymatic method can be combined with a palladium catalyzed allylic substitution to generate optically active alkoxypyrrolinones, which can readily be transformed to acyliminium ion precursors.[4]



Scheme 1

When a solution of (*R*)-(−)-**2a** (R^1 = Me) in Pr^iOH is stirred at room temperature for 7 h in the presence of 0.5 mol% $Pd(PPh_3)_4$, 5-isopropoxy derivative (*R*)-(−)-**3a** (R^2 = Pr^i) is obtained in 99% yield with 95% ee (Table 1, entry 1).‡ The optically active acyloxypyrrolinone is thus converted into optically active alkoxypyrrolinone, *via* Pd^0 catalyzed allylic substitution with Pr^iOH as the nucleophile, with nearly complete *retention of configuration*. An allyl palladium intermediate **5** (Scheme 2) is presumably involved. When the reaction was performed in the presence of $Pd(OAc)_2$ (5 mol%) and PPh_3 (20 mol%) the reaction rate was appreciably lower (90% conversion after 3 d at 20 °C, > 95% ee). An essential feature is that the nucleophile Pr^iOH is also used as a solvent (roughly 13 M). In the presence of an additional solvent like THF (Pr^iOH *ca.* 10^{-1} M) no product was obtained after 18 h at room temp. When the allylic substitution was performed at higher temperatures, the reaction was very fast, but the enantioselectivity decreased in the course of the reaction (Table 2). This depletion of ee might be due either to loss of stereochemical integrity of the allyl palladium intermediate or partial racemization of acyloxypyrrolinone **1** or alkoxypyrrolinone **3**.

The substitution using $Pd(PPh_3)_4$ can easily be performed on a gram scale with equal efficiency (99%) and selectivity (94% ee). A lower rate was observed in the presence of additional PPh_3, probably because the equilibrium for the oxidative addition of the palladium complex is shifted to the left (Scheme 2).[7] The effect on the enantioselectivity is negligible.

When EtOH was used instead of Pr^iOH as a nucleophile the reaction was much faster, probably because of the higher

Table 1 Pd catalyzed nucleophilic substitution of (−)-**2** (> 99% ee)

Entry	R^1	R^2	*T*/°C	Catalyst	*t*/h	Conversion[a] (%)	Ee[b] (%)

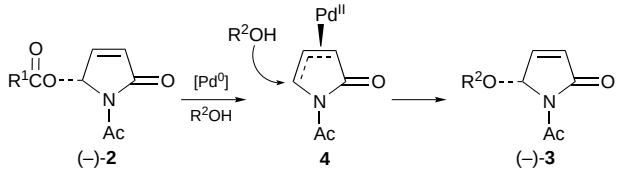
5[d]	C_9H_{19}	Pr^i	20	$Pd(OAc)_2 + PPh_3$ (10%)	63	40	84
6[d]	Bu^t	Pr^i	20	$Pd(OAc)_2 + PPh_3$ (5%)	48	29	95
7[d]	Ph	Pr^i	20	$Pd(OAc)_2 + PPh_3$ (5%)	18	33	93
8	Me	Pr^i	25	$Pd(MeCN)_2Cl_2 + PPh_3$ (5%)	21	100	89
9	Me	Pr^i	25	$Pd(MeCN)_2Cl_2$ (5%)	3	99	> 99
10	Me	Et	25	$Pd(MeCN)_2Cl_2$ (5%)	3	94	99

[a] The conversion was determined by GC. [b] The ee of **3** was determined by chiral GC; > 99% indicates that the other enantiomer could not be detected. [c] (+)-**2** (> 99% ee) was used as starting material. [d] The ee of starting material **2** is unknown.



Scheme 2

Table 2 Pd catalyzed nucleophilic substitution of (+)-**2a** (R^1 = Me) at 70 °C[a]

Entry	*t*/min	Conversion[b] (%)	Ee[c] (%)
1	5	43	90
2	25	91	79
3	40	100	75

[a] $Pd(OAc)_2$ + PPh_3 (5%) was used as catalyst, Pr^iOH was used as solvent. [b] The conversion was determined by GC. [c] The ee of (+)-**3a** (R^2 = Pr^i) was determined by chiral GC.

solubility of the substrate in this solvent. A slight decrease in selectivity (93% ee) was observed (Table 1, entry 3).

This reaction can also be performed with acyloxypyrrolinones with other acyl groups (Table 1, entry 4–7). The optically active starting materials were obtained *via* enzymatic esterification, analogously to our reported procedure.[5] Because a method for direct ee determination of these 5-acyloxypyrrolinones has not yet been found, the palladium catalyzed allylic substitution and subsequent ee determination of the 5-isopropoxy pyrrolinone provides a useful alternative for determination of the ee of the starting materials.

Other palladium catalysts were also examined as the use of $Pd(PPh_3)_4$ did not result in complete stereoselectivity (95–97% ee). $PdBn(PPh_3)_2Cl$ gave, under the same conditions in Pr^iOH, less than 5% conversion in 23 h (71% ee), whereas with $Pd(dppe)_2$ no product was obtained. Palladium(II) complexes such as $Pd(OAc)_2$ were also tested without PPh_3. In this case the reaction did not proceed, but surprisingly when LiCl was added 22% conversion was found after 23 h (42% ee). A mixture of $Pd(MeCN)_2Cl_2$ (5 mol%) and PPh_3 (20 mol%) was also used, but although this reaction was faster than with $Pd(OAc)_2$ and PPh_3 (100% conversion in 21 h), the selectivity was not improved (Table 1, entry 8). A remarkable improvement was achieved when $Pd(MeCN)_2Cl_2$ (5 mol%) was used without PPh_3. With this catalyst the reaction is fast, quantitative and proceeds with complete stereoselectivity (Table 1, entries 9, 10). On 0.5 g scale with 5 mol% Pd^{II} catalyst, 96% yield of (*S*)-**3a** (R^2 = Pr^i, 99% ee) was obtained.

Palladium catalyzed nucleophilic substitution reactions of allylic substrates have found widespread use in organic synthesis and although a variety of nucleophiles has been employed emphasis has been on carbon–carbon bond formation.[8] On the contrary the use of alcohols as nucleophiles in Pd catalyzed allylic substitution is rare, because alcohols are generally considered poor nucleophiles. The few reported examples[9] are often either intramolecular substitutions or make use of derivatives of alcohols. The quantitative and stereoselective Pd catalyzed allylic substitution of 5-acyloxypyrrolinones by alcohols provides a key step in the new catalytic enantioselective, lipase and palladium based methodology for the preparation of enantiopure alkoxypyrrolinones.

We gratefully acknowledge stimulating discussions with Dr A. van Oeveren in the early stages of this work and financial support by the IOP catalysis.

Large variation of the luminescence energy from rhenium(v) complexes with oxo and nitrido ligands

Ueli Oetliker,[a] Carole Savoie,[a] Sandrine Stanislas,[a,b] Christian Reber,*[a]† Fabienne Connac,[a,b] André L. Beauchamp,[a] Frédérique Loiseau[b] and Michèle Dartiguenave[b]

[a] *Département de chimie, Université de Montréal, C.P. 6128, Succ. Centre-ville, Montréal (Québec) H3C 3J7, Canada*
[b] *Laboratoire de Chimie Inorganique, Université P.Sabatier, 118 route de Narbonne, 31062 Toulouse, France*

We observe visible and near-IR luminescence from oxo and nitrido compounds of rhenium(v) with chelating ligands combining soft (P) and hard (O) donors and show that the emitting state energy of the nitrido complexes is higher in energy by a factor of *ca*. two (8300 cm^{-1}) than for the oxo compounds, an unusually large difference.

Complexes of Re^{V} with metal–ligand multiple bonds have received considerable attention due to their reactivity, photochemical and spectroscopic properties.[1–4] We have studied a series of *trans*-dioxo complexes of Re^{V} and Os^{VI} with imidazole, carboxylate and ethylenediamine ligands[5,6] and have discovered near-IR (NIR) luminescence bands that are lower in energy by several thousand wavenumbers than the luminescence maximum of the well known *trans*-$[ReO_2(py)_4]^+$, a representative *trans*-dioxorhenium(v) compound.[7,8] Oxorhenium(v) complexes with low-energy emissions could lead to a novel spin-crossover transition expected for tetragonal 5d^2 complexes.[4]

A detailed comparative study of nitrido and *trans*-dioxo complexes of rhenium(v) reports a difference of 3000 cm^{-1} between the luminescence maxima of related *trans*-dioxo and nitrido compounds.[9] We report here that a significantly larger energy range is accessible to complexes of 5d^2 ions with metal–ligand multiple bonds. We present luminescence spectra of related Re≡O and Re≡N complexes with only one metal–ligand multiple bond and two chelating ligands.

The compounds used for our spectroscopic experiments are shown in Scheme 1. All Re^{V} centers have a triple bond to either an oxo or nitrido ligand and two anionic P–O$^-$ chelating ligands, 2-(diphenylphosphino)phenolate (**2**, **4**) or 1-phenyl-2-(diphenylphosphino)ethanolate (**1**, **3**). The distorted octahedral coordination sphere of the oxo compounds **1**, **2** is completed by chloride ligands.[10,11] The nitrido compound **3** has a triphenylphosphine ligand in its first coordination sphere[10,11] and compound **4** has a square-pyramidal structure, proposed from ^{31}P NMR, IR and elemental analysis data.

The instrumentation for luminescence measurements in the visible and near-IR wavelength range has been described previously.[12,13]‡

Fig. 1 shows low-temperature luminescence spectra of compounds **2**–**4**. Luminescence spectroscopy allows us to directly determine the energy of the lowest energy excited state for each compound. Band maxima and widths of all emission spectra are summarized in Table 1. The spectra of the oxo complexes **1** and **2** are almost identical and only the spectrum of **2** is shown. The band maxima of the oxo compound **2** and the nitrido compound **4** are separated by more than 8000 cm^{-1}, corresponding to emitting state energies that vary by a factor of two. The solid-state emissions are still observed at 200 K, but their integrated intensity decreases by approximately an order of magnitude for the compounds in Fig. 1. The spectrum of the oxo complex **2** shows barely resolved vibronic structure with a separation of *ca*. 800 cm^{-1} between peaks. This progression involves mainly the Re≡O vibrational mode observed at 958 cm^{-1} in the Raman spectrum. The nitrido compounds **3**, **4** do not show resolved structure involving the Re≡N vibrational mode, but their large bandwidths indicate that this high-frequency mode contributes significantly to the bandshape. The nitrido compound **4** shows weak vibronic structure with peaks separated by *ca*. 130 cm^{-1}. Progressions involving similar low-frequency modes have been observed for nitrido complexes of the isoelectronic Os^{VI}.[14]

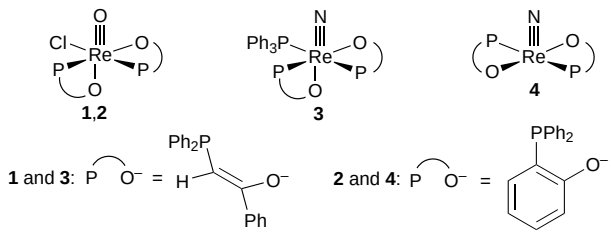
[a] Full width at half height.



Scheme 1 Oxo (**1**, **2**) and nitrido (**3**, **4**) complexes of rhenium(v) used for spectroscopic measurements

The luminescence lifetimes of compounds **3**, **4** are shorter than 5 μs at 20 K, indicating a low quantum yield and important non-radiative relaxation processes even at low temperatures. The NIR luminescences from compounds **1**, **2** are too weak to be detected with fast Ge diodes and no lifetimes could be measured.

Absorption spectra of all compounds were measured in Me_2SO or CH_2Cl_2 solution. The onset of the lowest-energy absorption band occurs at wavelengths close to the high-energy onset of the luminescence spectra in Fig. 1, indicating that the observed solid-state emissions are not originating from deep traps. The molar absorptivities of the lowest-energy bands are low, characteristic for d–d transitions, but higher than those typically observed in *trans*-dioxo systems owing to the absence of inversion symmetry in compounds **1**–**4**. Absorption and Raman data for all compounds are included in Table 1.

We rationalize the observed large variation of the luminescence band maxima by comparing spectra and EHMO calculations based on crystal structures for compounds **1**–**3**.[10,11]§ The molecular *z* axis is chosen to coincide with the metal–ligand multiple bond and the calculations show predominant contributions from the $5d_{xy}$ and $5d_{xz,yz}$ atomic orbitals to the HOMO and LUMO, respectively. The lowest energy electronic transition therefore arises from a $5d_{xy} \rightarrow 5d_{xz,yz}$ orbital excitation, identical to the first electronic transition for *trans*-dioxo complexes of rhenium(V).[4,7] The energy of the HOMO ($5d_{xy}$) orbital depends mainly on the ancillary ligands and varies by less than 400 cm^{-1} within the series of compounds. The different LUMO energies are the most important reason for the variation of the emission energies of oxo and nitrido complexes. The calculated HOMO–LUMO gap for the nitrido compound **3** is 10 621 cm^{-1}, higher by approximately a factor of two than for the oxo complex **2**, where a gap of 4923 cm^{-1} is calculated. These orbital energy differences vary by 5700 cm^{-1}, surprisingly close to the difference of 5850 cm^{-1} between the emission maxima of compounds **2** and **3** given in Table 1. The comparison also indicates that interelectronic repulsions and other physical effects neglected in the EHMO calculations account for the discrepancy between observed transition energies and orbital energy differences. The separation of the $5d_{xz,yz}$ orbitals is calculated to be less than 1000 cm^{-1} for compounds **1**–**3**. These orbitals are degenerate in *trans*-dioxo compounds with D_{4h} symmetry and the small separations calculated for our compounds again underline the close similarity to the *trans*-dioxo systems. The MO calculations therefore confirm our d–d assignment for the lowest-energy electronic transition and are consistent with the spectroscopic data in Fig. 1 and Table 1. In addition, they qualitatively agree with *ab initio* calculations on a series of complexes with metal–ligand multiple bonds.[15]

Electronic spectra and EHMO calculations suggest that the character of the lowest-energy electronic transitions is essentially d–d. We have shown a first example for the large tuning range for the luminescence energies of related oxo and nitrido complexes.

This work was made possible by research grants from the NSERC (Canada) and from the Ministère de l'Enseignement Supérieur et de la Recherche (France).

‡ Luminescence spectra of polycrystalline samples of all compounds were measured in a helium gas-flow cryostat. A Xe lamp and the 488.0 and 514.5 nm lines of an Ar^+ ion laser were used as excitation sources, and the emitted light was dispersed by either a 0.5 m or a 0.75 m monochromator. Photomultipliers and a photon counting system were used to detect the luminescence from the nitrido compounds, the emission from the oxo systems was measured with a cooled Ge detector and a lock-in amplifier, using an acquisition approach developed in our laboratory to minimize noise in the near-IR region.[13] A pulsed excimer laser and a digital oscilloscope were used to measure luminescence lifetimes. Raman spectra were measured with a Spex Ramalog system and Ar^+ ion laser, solution absorption spectra were recorded on a Varian Cary 5E spectrometer.

§ EHMO calculations were made with the program package YAeHMOP (version 2.0) by G. Landrum, 1997. YAeHMOP is available at http://overlap.chem.cornell.edu:8080/yaehmop.html.

Chiral relay auxiliary for the synthesis of enantiomerically pure α-amino acids

Steven D. Bull, Stephen G. Davies,*† Simon W. Epstein and Jacqueline V. A. Ouzman

The Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY

Chiral auxiliary (3*S*)-*N*,*N*′-bis(*p*-methoxybenzyl)-3-isopropylpiperazine-2,5-dione employs a chiral relay network based on non-stereogenic *N*-benzyl protecting groups to enhance diastereocontrol during enolate alkylation.

The structural diversity of non-proteinogenic α-amino acids is reflected by the large number of different methods which have been developed for their asymmetric synthesis.[1] Those approaches that are based on chiral auxiliaries generally rely on alkylation of a masked glycine enolate where diastereofacial selectivity is controlled by an attached homochiral residue.[2] Schöllkopf's auxiliary **1** derived from *O*-methylation of diketopiperazine (DKP) **3** has been widely used in this area but there are problems associated with its use for synthesis (Scheme 1).[3] It is a volatile oil which is difficult to prepare, it exhibits poor diastereoselectivities with a linear or β-branched electrophiles and is also susceptible to acid catalysed hydrolysis.[4] It is known that *N*,*N*′-dialkylpiperazine-2,5-diones are robust, highly crystalline compounds[5] and we wished to exploit these characteristics to create a new chiral auxiliary **4** for the synthesis of enantiomerically pure α-amino acids.

Molecular modelling studies[6] revealed that enolate **5** derived by deprotonation of **4** adopts a conformation which enables the stereochemical information of the (3*S*)-isopropyl group to be relayed through space *via* non-stereogenic benzyl protecting groups. The ring system of enolate **5** is essentially planar with its isopropyl group fixing the conformation of the proximal N4 benzyl *anti*, which in turn directs the distal N1 benzyl group *syn* to the isopropyl group. This arrangement effectively blocks the *Si* face of enolate **5** towards alkylation at C6 (Fig. 1). We predicted that the proximity of the N1 benzyl group to C6 would result in significantly higher alkylation diastereoselectivities for DKP **4** than would be achieved for either Schöllkopf's auxiliary **1** or *N*,*N*′-dimethylated DKP **2** where, in both cases, the stereofacial control is only provided by the C3 isopropyl group.

Highly crystalline (3*S*)-*N*,*N*′-bis(*p*-methoxybenzyl)-3-isopropylpiperazine-2,5-dione **4** ($[\alpha]_D^{23}$ −53.7, *c* 1.0 in $CHCl_3$)‡ was prepared in 85% yield by dropwise addition of *p*-methoxybenzyl chloride to cyclo-[L-Val-Gly] **3**[4] and sodium hydride in DMF (Scheme 1). Enantiomerically pure (3*S*)-*N*,*N*′-dimethyl-3-isopropylpiperazine-2,5-dione **2** ($[\alpha]_D^{23}$ +84.4, *c* 1.0 in $CHCl_3$)‡ was prepared in a similar manner using methyl iodide as the electrophile (Scheme 1). The enantiomeric purities of both **2** and **4** were confirmed by comparison of their ^{1}H NMR spectra with authentic racemic materials in the presence of chiral shift reagent (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol.[7]

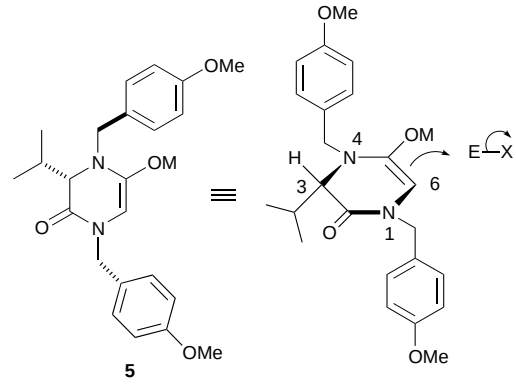

Fig. 1 Electrophile attacks *anti* to both the C3 isopropyl and N1 protecting group

DKP **4** was deprotonated with one equivalent of lithium hexamethyldisilazide in THF at −78 °C followed by addition of four equivalents of methyl iodide to afford a mixture of C6-methylated diastereoisomers **6** and **7** in 93% de (Scheme 2). The diastereoisomers were separated by chromatography [silica, diethyl ether–hexane (1 : 1)] and the configuration of the major diastereoisomer confirmed as *trans*-**7** by direct compar-

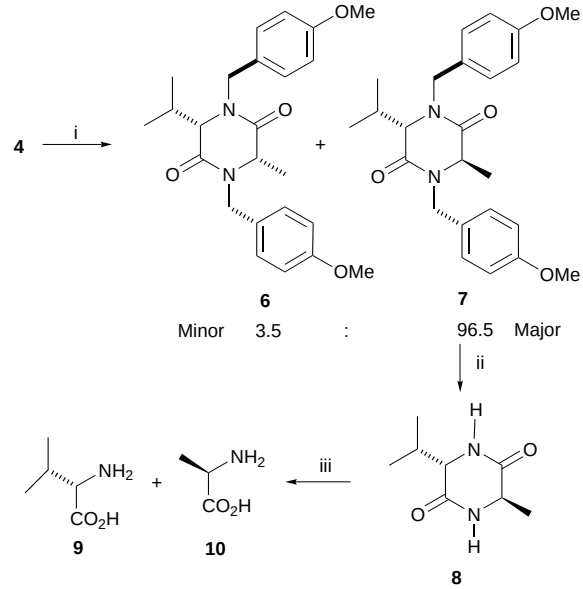


Scheme 2 *Reagents and conditions*: (i) LHMDS, THF, −78 °C; 10 equiv. MeI; (ii) CAN, CH_3CN–H_2O; (iii) 6 M HCl, Dowex 50-XH

Table 1 Comparison of diastereoselectivity and yield for alkylation of auxiliaries **1** and **4**[a]

	De (%)		Yield (%)		
Electrophile RX	**11**	**12**	**11**	**12**	$[\alpha]_D^{23}$ **12** ($CHCl_3$)‡
Methyl iodide	50	93	54	72	+22.5 (*c* 0.98)
Benzyl bromide	91[b]	98	81[b]	88	+58.6 (*c* 0.99)
Allyl bromide	74	94	83[c]	63	+25.8 (*c* 0.99)
Prop-2-ynyl bromide	52[c]	89	70[d]	74	+14.6 (*c* 0.98)
Ethyl iodide	*d*	90	*a*	78	+46.1 (*c* 1.00)
Isopropyl iodide	*d*	96	*a*	90	0 (*c* 1.00)

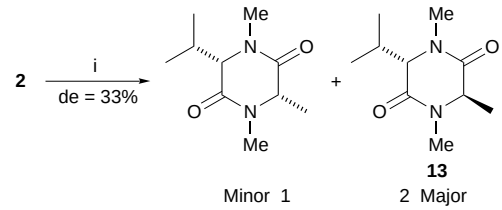
[a] Ref. 13. [b] Ref. 3. [c] Ref. 11. [d] Ref. 12.

ison with an authentic sample prepared *de novo* by *N*-*p*-methoxybenzylation of the piperazine-2,5-dione **8** derived from L-valine **9** and D-alanine **10**.

Deprotection of *trans*-methylated auxiliary **7** was easily achieved *via* oxidative removal of the *p*-methoxybenzyl groups using cerium ammonium nitrate in CH_3CN–H_2O[8] followed by acid catalysed hydrolysis of **8** to afford a mixture of (*S*)-valine **9** and (*R*)-alanine **10**. This mixture was separated by ion exchange chromatography[9] to afford enantiomerically pure (*R*)-alanine, **10** ($[\alpha]_D^{23}$ −14.0, *c* 0.6 M in 1 M HCl)[10]‡ in 86% yield (Scheme 2).

Alkylation of **4** with a range of electrophiles afforded highly crystalline *trans*-alkylated products **12** in > 90% de (Table 1). Simple recrystallisation of the crude reaction product afforded the major *trans*-diastereoisomer pure in good yield. The non-basic character of enolate **5** is particularly noteworthy since reaction with electrophiles that are prone to β-elimination (ethyl iodide or isopropyl iodide) occurred in excellent yield.

It is clear that the alkylation diastereoselectivities observed for the new piperazine-2,5-dione auxiliary **4** compare favourably with those obtained using Schöllkopf's auxiliary **1** (Table 1). Evidence to suggest that the benzylic *N*,*N*′-protecting groups are directly responsible for the improved performance of **4** was obtained by methylating *N*,*N*′-dimethylated piperazine-2,5-dione **2** in which the *N*-methyl groups do not have the capacity to enhance the stereoselectivity *via* the proposed relay mechanism. DKP **2** was methylated under identical conditions



Scheme 3 *Reagents and conditions*: (i) LHMDS, THF, −78 °C; 10 equiv. MeI.

described for **4** to afford *trans*-(3*S*,6*R*)-6-methyl-**13** as the major diastereoisomer in a much reduced 33% de (Scheme 3).

The results obtained for methylation of the enolates of **2** and **4** are clearly consistent with the proposed chiral relay network operating to enhance the diastereoselectivity observed for alkylation of enolate **5**. Further investigations are currently underway to apply the proposed chiral relay concept to enhance stereocontrol in other scenarios.

We thank Zeneca Pharmaceuticals (J. V. A. O.) and Oxford Asymmetry Ltd (S. D. B.) for financial support, and the DTI and EPSRC for a LINK award.

Carboxylate and carboxylic acid recognition by tin(IV) porphyrins

Joanne C. Hawley,[a] Nick Bampos,[a] Raymond J. Abraham[b] and Jeremy K. M. Sanders*[a]†

[a] *Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Department of Chemistry, University of Liverpool, Liverpool, UK L69 3BX*

The scope of carboxylate binding by tin(IV) porphyrins and the solution geometries of the resulting complexes have been explored using ^{1}H NMR spectroscopy; ring current induced shifts and competition experiments indicate the operation of an attractive anthracene–porphyrin interaction; outer sphere carboxylic acid complexes of dihydroxy tin(IV) porphyrins have been characterised, apparently for the first time.

As part of a larger project[1,2] aimed at supramolecular catalysis we have been exploring the ligand recognition properties of tin(IV) porphyrins. We report here on the scope of carboxylate recognition and the solution state geometry of the resulting complexes, demonstrate that anthracene–porphyrin interactions can overcome the usual geometrical preference, and present what we believe is the first direct evidence for hydrogen-bonded carboxylic acid outer sphere complexes.

It has long been known[3,4] that the hard metal centre endows a strongly oxophilic character on tin(IV) porphyrins:‡ carboxylate complexes of acids with p$K_a \leqslant$ *ca*. 5 can be prepared rapidly and effectively quantitatively by mixing a large excess of the free carboxylic acid with dihydroxy tin(IV) porphyrins in non-polar solvents. However, by employing low concentrations of acids, following the reactions by ^{1}H NMR spectroscopy, and exploiting the fact that the ring currents associated with porphyrins lead to large upfield shifts for axially bound ligands, we have uncovered several previously unreported phenomena:

(*i*) The rate and extent of complex formation increases with acid strength: using 5 mM porphyrin and 5 mM propionic acid, complexation is complete in 30 min at room temperature, while carboxylate complex formation with dichloroacetic acid is complete within a few seconds.§ Fig. 1 shows the complexation shifts observed in several dicarboxylate complexes of Sn^{IV}(tpp).¶ The carboxylate complexes are in slow exchange on the NMR chemical shift timescale with any excess carboxylic acid that is present.

(*ii*) With weaker acids or in the presence of < 2 equiv. of stronger acids the monohydroxymonocarboxylate complex is readily observed as the major complex.

(*iii*) Stronger acids generally displace the carboxylates of weaker acids. However, in such competition experiments, anthracene-9-carboxylic acid (p$K_a \approx 3.6$) behaves as if it were intermediate in strength between monochloroacetic acid (p$K_a \approx$ 2.9) and dichloroacetic acid (p$K_a \approx 1.5$). This unusual result is discussed below.

(*iv*) 'Free' carboxylic acid resonances are broadened and shifted upfield unexpectedly: immediately after addition of 1 equiv. of propionic acid to a $CDCl_3$ solution of Sn^{IV}(tpp)$(OH)_2$, the methylene resonance of the added acid was upfield shifted by 1.02 ppm, but as carboxylate complex formation took place over a period of minutes the residual 'free' carboxylic acid signals shifted back towards their normal positions. This observation is consistent with the formation, in fast exchange on the chemical shift timescale, of a weak outer sphere complex between the Sn–OH and carboxylic acid. Such a complex is the first intermediate in the likely mechanism of formation of the final covalent complex (Fig. 2).‖ As the reaction proceeds the concentrations of Sn–OH sites and free carboxylic acids decrease, so the fraction of outer-sphere bound acid molecules also decreases. At low temperatures the formation of the covalent carboxylate complex of adamantane-1-carboxylic acid is slowed sufficiently that it does not interfere with observation of essentially complete formation of the hydrogen-bonded complex (Fig. 3). From analysis of the concentration dependence of shifts we estimate the apparent association constant for this hydrogen-bonded species to be *ca*. 10^4 dm^3 mol^{-1}, while analysis of the ring current-induced shift of H_A indicates a distance of *ca*. 5 Å from the carboxylate oxygen to the Sn centre. To our knowledge, such complexes have never been directly observed previously, although their existence has been

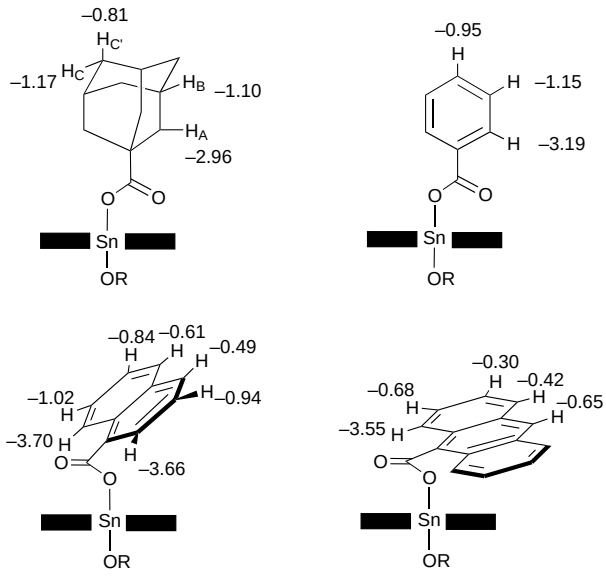

Fig. 1 Porphyrin-induced shifts ($\Delta\delta$/ppm) for some Sn^{IV}(tpp) dicarboxylate complexes. In each case $\Delta\delta = \delta$ (complex) $- \delta$ (free acid).

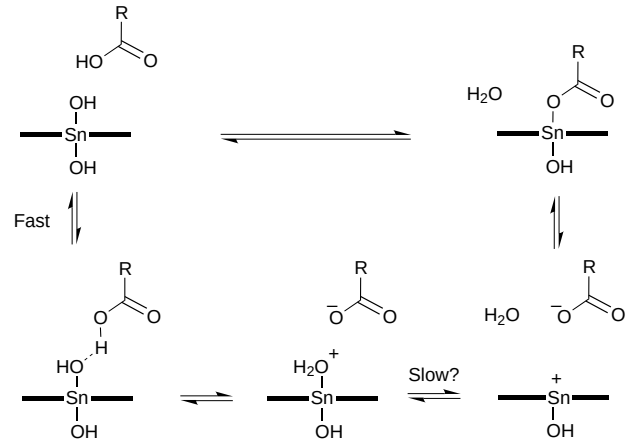

Fig. 2 Presumed mechanism of formation for tin–carboxylate complexes

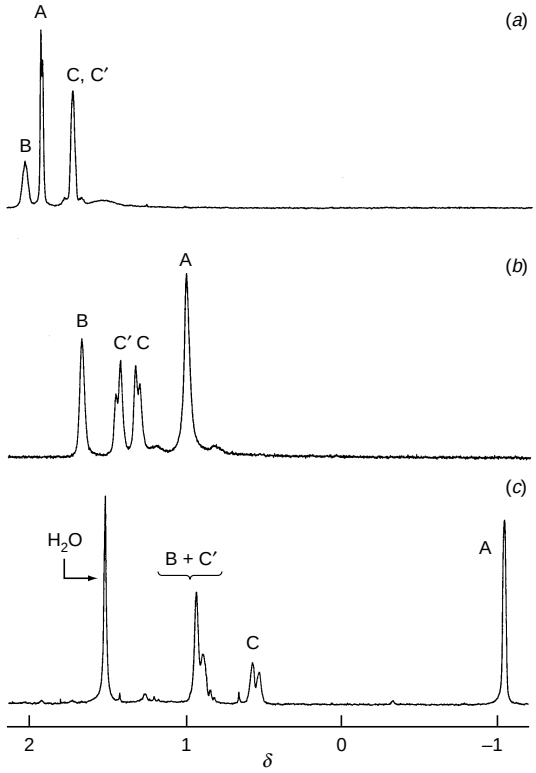

Fig. 3 Partial ^{1}H NMR spectra of adamantane acid (*a*) free, (*b*) hydrogen-bonded to $Sn^{IV}(tpp)(OH)_2$ and (*c*) as dicarboxylate complex. Traces (*a*) and (*c*) were obtained at 250 MHz, 20 °C, and trace (*b*) at 400 MHz, −53 °C.

postulated in connection with tin(IV) porphyrin electrochemistry.[5]

Since the porphyrin ring current is quite well characterised geometrically and has been applied to a range of metallo-porphyrin complexes,[6] we elected to apply the same approach to the tin(IV) systems. In the first instance, the known X-ray[7] structure for the dibenzoate complex was used to parametrise the ring current for our observed solution state NMR shifts in the same complex. With the ring current thus calibrated, the observed $\Delta\delta$ were fitted to give best-fit geometries. While it is not possible to obtain great precision it is clear that simple aromatic carboxylates are bound with their aryl rings effectively perpendicular to the porphyrin plane, with the dihedral angle Sn–O–C–C of *ca*. 180° and with an Sn–O bond length of *ca*. 2.1 Å.

However, the shifts observed in the anthracene complex do not match this geometry: they are consistent only with an arrangement where the Sn–O–C–C angle is reduced to *ca*. 100°, bringing the anthracene ring almost coplanar with the porphyrin as shown in Fig. 1. We attribute this geometry to an attractive π–π or donor–acceptor interaction with the porphyrin ring; this additional interaction also explains the unexpectedly strong binding described above. Naphthoic-1-carboxylic acid, perhaps unsurprisingly, displays a shift (and therefore spatial) behaviour that is intermediate between its anthracene and benzoic homologues (Fig. 1), but we cannot distinguish rapid exchange between 'vertical' and 'horizontal' conformations from a static conformation that is intermediate in geometry.

The exclusive oxophilicity of tin(IV) porphyrins complements perfectly the strong preference of zinc and ruthenium(II) porphyrins for nitrogen ligands. Pyridines do indeed bind to zinc or ruthenium(II) porphyrins in the same solution as carboxylic acids bind to Sn^{IV} porphyrins without mutual interference, so it is possible to construct mixed metal dimers and trimers with completely independent ligand specificities at each site.[9] This greatly expands the repertoire of recognition and catalytic processes that are now available. At a simpler level, $Sn^{IV}(tpp)(OH)_2$ may prove useful as a diamagnetic NMR shift reagent for carboxylates.

We thank Simon Webb for helpful discussions and advice, and the EPSRC and Unilever Research for financial support.

‡ Tin(II) porphyrins bind soft ligands such as S and Se, but their sensitivity to air and moisture renders them unsuitable for routine molecular recognition studies.[8]

§ Detailed analysis of NMR shifts and couplings, and of X-ray structures, reveals that the Sn–O bond length increases slightly but systematically as the pK_a of the carboxylic acid decreases. Details will be discussed in a full paper, but the trends are broadly in line with those expected.[4,7]

¶ H_2tpp = 5,10,15,20-tetraphenylporphyrin.

‖ It is possible that the hydrogen bonding pattern is actually Sn–O–H···O=C rather than as shown. The pK_a dependent behaviour described above is also consistent with the suggested mechanism.

Electrophilic functionalization of a cyclometallated ruthenium complex, an easy entry to new organometallic synthons

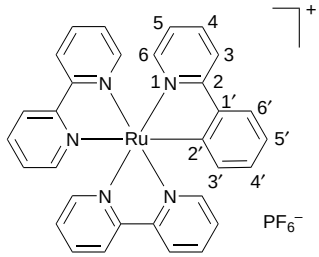
Christophe Coudret,*† Sandrine Fraysse and Jean-Pierre Launay

Molecular Electronics Group, Centre d'Elaboration des Matériaux et d'Etudes Structurales, CNRS UPR 8011, BP 4347, 29 rue Jeanne Marvig, 31055 Toulouse Cedex, France

With the regiospecific halogenation of the complex [Ru(bpy)$_2$L^1]$^+$ (bpy = 2,2′-bipyridine, HL^1 = 2-phenylpyridine) new organometallic starting materials are now available.

Our long lasting interest into dinuclear mixed valence complexes originates from the fact that they are the best chemical models of molecular wires, the basic function of molecular electronics. Indeed, a simple spectroscopic study of the intervalence transition gives directly the ability of the bridging ligand to couple the two metallic centers.[1] Since it is usually achieved by a redox titration, the various species (reduced, mixed valence or oxidized) have to be stable for a long period of time, typically up to 1 h. Ruthenium cyclometallated complexes with a N_5C donor set were found to be among the best metallics ends for such purpose.[2]

In a recent report, the synthesis of such polynuclear complexes involved as 'building block' a brominated cyclometallated RuN_5C complex, which was prepared from a bromine containing ligand.[3] Such a synthesis could be advantageously shortened by a direct and regioselective halogenation of the metallated ligand *i.e.* after the complex is prepared.



1

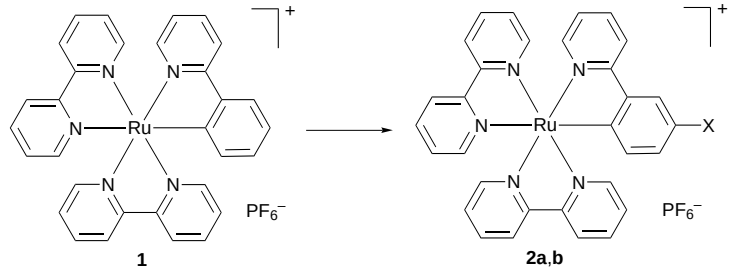
Apart from the typical cathodic shifts of all the redox potentials compared to the RuN_6 family,[4,5] few chemical properties of RuN_5C cyclometallated complexes have been reported. The presence of the C–Ru bond promotes oxidative dimerization,[5,6] but also nitration[3] or chlorination (albeit in low yield).[7] Since the cyclometallated analogue of [Ru(bpy)$_3$]$^{2+}$, *i.e.* [Ru(bpy)$_2$L^1]$^+$, was readily accessible from commercially available chemicals,[4] a systematic study of the electrophilic bromination and iodination of the complex [Ru(bpy)$_2$L^1]PF$_6$ **1** was undertaken on a preparative scale and the reactivity of the resulting complexes under Sonogashira alkynylation reaction was studied. We would like to report here our findings on these points.

Theoretical calculations using extended Hückel theory were first performed in an analogous manner as for [Ru(terpy)(dpb)]$^+$ [dpb = 1,3-bis(2-pyridyl)benzene].[8] As for this complex the HOMO was found to be not only mostly located on the metallated phenyl ring but also having an important coefficient on the C$^{5'}$.‡ Owing to its low oxidation potential (0.5 V *vs.* SCE) and rather high sensitivity to acidic medium, buffered, mildly oxidizing electrophilic conditions were selected.

Upon treatment of the complex with 1.1 equiv. of *N*-bromosuccinimide in MeCN at room temperature[9] and after a hydrazine quench, a single compound was isolated as a PF_6 salt by column chromatography (SiO_2/CH_2Cl_2). It was identified by FABMS as the expected bromo-substituted complex [Ru(bpy)$_2$L^2]PF$_6$ **2a**. Eventually the regioselectivity of the substitution was recognised by ^{1}H NMR spectroscopy since the pattern associated with the very shielded core hydrogen H$^{3'}$ was clearly simplifed. The bromination, easily scaled up, did not require anhydrous or anaerobic conditions to proceed and occurred within 4 to 6 h (Scheme 1).§

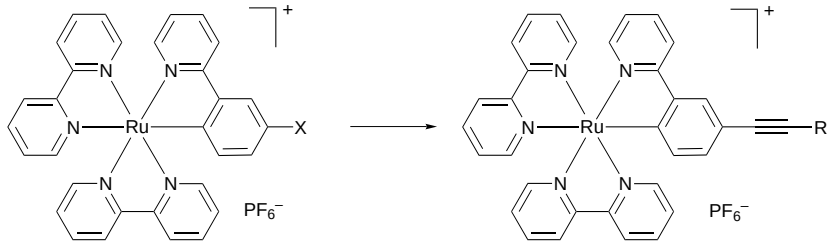
This result prompted us to prepare the iodo analogue, more interesting from a synthetic point of view. Surprisingly NIS[10] was found to be unreactive or lead to complex degradation in MeCN respectively at room or reflux temperature. We found that complex oxidation could be limited by using CH_2Cl_2 as solvent, the best iodinating agent being I_2/PhI(OAc)$_2$, at room temperature for 4 h.[11] Finally, column chromatography purification (SiO_2) after anion exchange using a 'basic eluent' $CHCl_3$–Et_3N–EtOH gave a reproducible isolated yield of *ca.* 50% of [Ru(bpy)$_2$L^3]PF$_6$ **3a**.

As expected, the electron-withdrawing nature of the substituent induced an anodic shift with respect to parent complex **1** for the Ru^{III}–Ru^{II} redox couple of complexes **2a** and **2b** (Table 1). Reactivity of complexes **2a** and **2b** towards Sonogashira's alkynylation [Pd(PPh$_3$)$_4$, CuI, Et_3N, DMF] was then investigated with protected acetylene, *i.e.* trimethylsilylacetylene and 3-methylbut-3-yn-2-ol, as substrates (Scheme 2). In all cases, compounds were isolated as PF_6 salts by column chromatography. A marked difference between **2a** and **2b** was observed



1 **2a**,**b**

Scheme 1 *Reagents and conditions*: X = Br: NBS, MeCN, room temp., 6 h, 95%, **2a**; X = I: PhI(OAc)$_2$, I_2, CH_2Cl_2, room temp., 6 h, 50%, **2b**



Scheme 2 *Reagents and conditions*: i, **2a**, DMF, Et_3N, CuI, $Pd(PPh_3)_4$, 80 °C, 18 h, 80%; ii, **2b**, DMF, Et_3N, CuI, $Pd(PPh_3)_4$, 20 °C, 18 h, 80%

Table 1 Ru^{III}–Ru^{II} redox couples *vs.* SCE (MeCN, 0.1 M $NBu^n_4PF_6$, Pt)

Complex	E^0 (Ru^{III}–Ru^{II})/mV
$[Ru(bpy)_2(L^1)]PF_6$ **1**	464
$[Ru(bpy)_2(L^2)]PF_6$ **2a**	520
$[Ru(bpy)_2(L^3)]PF_6$ **2b**	498

since the iodo complex reacted at room temperature with both alkynes, while the bromo complex required at least heating to 80 °C. Furthermore **2a** did not react with silylated acetylene ($SiMe_3$ or $SiEt_3$). These results, in sharp contrast with a RuN_6 analogue developed by Tzalis and Tor,[12] might indicate that the limiting step is the oxidative addition of the C–Br bond on the Pd^0 complex.

Hence we have shown that, despite the possibility of over-oxidation of the metal center, the presence of the C–Ru bond not only activates the metallated aromatic ring towards electrophilic substitution but also controls its regioselectivity. This *a posteriori* functionalization provides a simple and unique entry to synthetically interesting synthons which would have been difficult to prepare otherwise, especially for the iodo complex **2b**. We are currently studying their reactivity as building blocks in the preparation of more sophisticated architectures such as molecular wires or switches.

‡ Since the HOMO is very close in energy to the two other orbitals belonging to the t_{2g} set of low-spin d^6 Ru^{II}, more complete information is given by the examination of net charges borne by carbon atoms, because they are determined by all occupied orbitals. Thus for carbon atoms *para* to pyridine nitrogens, values near +0.06 are found, while the carbon atom *para* to the C–Ru bond exhibits a −0.09 charge, confirming its better reactivity towards electrophiles. Calculations were performed with the CACAO program (CACAO PC Version 4.0, July 1994. C. Mealli and D. M. Proserpio, *J. Chem. Educ.*, 1990, **67**, 399 using −12.0 eV for Ru 4d energy). A related calculation by the Fenske Hall method has been reported (E. C. Constable and C. E. Housecroft, *Polyhedron*, 1990, **9**, 1939).

Solid state and solution behaviour of novel transition metal containing surfactants

Ian A. Fallis,*† Peter C. Griffiths,* Paul M. Griffiths, David E. Hibbs, Michael B. Hursthouse and Angie L. Winnington

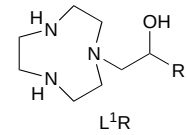
Department of Chemistry, University of Wales Cardiff, PO Box 912, Cardiff, UK CF1 3TB

The micellation properties of first row transition metal containing surfactants derived from aza-macrocyclic ligands is described; the structure of one of the surfactants in the solid state has been determined by X-ray crystallography; the dimensions and morphology of micelles formed by a nickel(II) surfactant have been investigated by small-angle neutron scattering (SANS).

Surfactants containing transition metal ions have only recently begun to be investigated, and to date no attempt has been made at the rigorous determination of their structure–property relationships. Typical cationic amphiphiles, such as cetyltrimethylammonium bromide (CTAB), display surface activity but are essentially 'innocent' in their chemical reactivity. Our interest in this area is ultimately directed towards the preparation and application of surfactants which contain 'non-innocent' transition metal complexes as the head-group. The use of a transition metal ion in the head-group not only imparts charge, but also permits the incorporation of useful properties such as colour (*i.e.* a chromophore), paramagnetism, variable charge and pH sensitivity. However, most importantly, transition metal complexes possess a wide range of reactivity, such as redox behaviour and catalytic activity. Thus transition metal containing surfactants provide a method for localising redox or catalytic activity at an interface.

Here, we report our preliminary results on the synthesis and characterisation of a range of nickel(II) and copper(II) based surfactants. For the purposes of this paper we define the systems under investigation as cationic metallo-surfactants in which a (transition) metal ion forms an integral part of the head-group. Earlier work by other groups on metallo-surfactants has tended to concentrate on the lyotropic phase behaviour of non-labile metal complexes for example a $[Ru^{II}(terpy)_2]^{2+}$ system.[1] An example of micellation in a $[Co^{II}(polyamine)]^{3+}$ system has been reported,[2] but again the metal centre is non-labile. Of systems with kinetically labile metal ions, there has also been an elegant investigation into the micellation of a diaza-18-crown-6 based surfactant (an annelide) in the presence of s-block cations by a range of techniques,[3] and a recent report of a copper(II) cryptand which forms unilamellar vesicles.[4] The work presented here describes the solution and solid state behaviour of a ligand system which produces surface active complexes from non-surface active ligands upon coordination of a labile metal centre.

Initially we sought simple ligand systems in which the various components of the resulting complex amphiphile could easily be modified to accommodate different alkyl chain lengths and numbers, variable head-group size and a range of d- and f-block metal ions. Also we required a ligand system which formed stable complexes in which the metal ion remained strongly bound to the head-group of the amphiphile. This prevents the complication of metal–ligand dissociation affecting the composition of the system. Metal–ligand dissociation would not only increase the ionic strength of the solution but would also lower c.m.c. values by the introduction of the largely hydrophobic free ligand. We therefore prepared the range of ligands L^1R based upon 1,4,7-triazacyclononane ([9]aneN_3). The synthesis of these ligands was achieved in gram quantitites



L^1R

$R = C_nH_{2n+1}$

n = 6, 8, 10, 12, 14, 16

by reacting 20 equiv. of 1,4,7-triazacyclononane with 1,2-epoxyalkanes in ethanol solution. The free ligands were isolated in quantitative yield after removing the excess 1,4,7-triazacyclononane by distillation. To date these ligands represent the first reported examples of aza-macrocycles bearing a single pendant alcohol donor.

The ligands L^1R are poorly soluble in water, but readily dissolve upon the addition of nickel(II) salts to afford blue/purple solutions. The electronic spectra of these solutions indicate that the coordination geometry at the metal centre is octahedral and it is probable that an N_3O_3 (*i.e.* L^1R and two molecules of water) donor atom set is present. The single crystal structure of $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ ($R = C_{10}H_{21}$) was determined.‡ The structure of the cation is illustrated in Fig. 1. This confirms the N_3O_3 coordination sphere at a slightly distorted octahedral metal centre, with the macrocycle in its typical face capping mode and the pendant-arm alcohol also coordinated to the metal centre. The alkyl chain is found to be in the fully extended conformation. The packing diagram (Fig. 2) indicates that a lamellar structure is formed with an antiparallel arrangement of the cations. We have prepared ligands L^1R in both racemic and optically active forms. The structure presented here was prepared with racemic material and the crystal structure contains alternating layers of (*R*) and (*S*) material. It is worth noting that single crystals of the complexes $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ were found to be remarkably easy to obtain by cooling or concentrating stock solutions containing an excess of $NiCl_2$(aq). The facile nature of the crystallisation process is attributed to a Krafft point effect, with the approximate Krafft temperatures for the complex $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ being 35 °C ($R = C_{10}H_{21}$) and 65 °C ($R = C_{16}H_{33}$).

Characterisation of the interfacial behaviour of $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ ($R = C_nH_{2n+1}$, n = 6, 8, 10, 12, 14, 16) has been undertaken to determine its critical micelle concentration, c.m.c. Surface tension measurements were determined by the Du Noüy platinum ring method. A typical plot of surface tension *vs.* concentration is illustrated in Fig. 3 for $[M^{II}(L^1R)(H_2O)_2]Cl_2$ ($R = C_{10}H_{21}$), ($M = Ni^{II}$, Cu^{II}). Using this method,

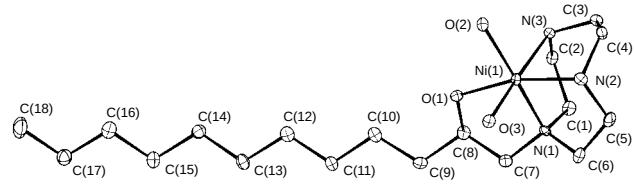


Fig. 1 Structure of the cation in $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ ($R = C_{10}H_{21}$). H-atoms are omitted. Ellipsoids are drawn at 50% probability.

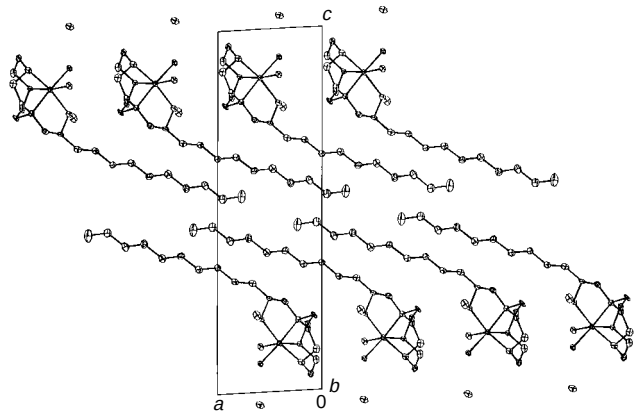

Fig. 2 Packing diagram in $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ (R = $C_{10}H_{21}$). View is along the *b* axis. Ellipsoids are drawn at 50% probability.

the c.m.c.s of the surfactants are 1.5 ± 0.2 mM (M = Ni^{II}) and 0.8 ± 0.1 mM (M = Cu^{II}). The adsorbed amount and hence, area per molecule at the surface, calculated *via* the Gibbs equation, $d\gamma/d \ln c = -\Gamma/RT$ is the same for both surfactants; 50 ± 5 Å^2. The c.m.c. values are lower than expected for a doubly charged amphiphile, which may be explained by noting that the head-group itself contains eight additional carbon centres, and hence reducing the overall hydrophilicity. The lower c.m.c. value of the copper complex is attributed to the tendency for Cu^{II} to adopt five-coordinate geometries. This would result in a marginally smaller head-group. Furthermore, it has been shown[5] that Cu^{II} can increase the acidity of a bound alcohol group so as to permit deprotonation. This process, even if occurring to a limited extent, would reduce the charge on the head-group and permit alkoxide to alcohol hydrogen bonding to occur between head-groups. This interaction between head-groups would reduce the effect of electrostatic repulsion of the head-groups, further lowering the c.m.c. value. Thus it can be seen that a very subtle change in the metal centre from Ni^{II} to Cu^{II} has a significant effect on the micellation properties of these surfactants.

The structures formed in the bulk solution slightly above the c.m.c. have been investigated by small-angle neutron scattering (SANS). The scattering from surfactant systems contains three important terms; the form factor, the structure factor and a constant term, essentially the intensity per micelle. The form factor describes the size and shape of the scattering body. The structure factor describes the spatial distribution of the scattering bodies and is determined by their interaction potential. For dilute cases, the structure factor may be neglected. A full analysis of the comprehensive SANS study will be presented shortly, but some data referring to the $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ (R = $C_{10}H_{21}$) surfactant are presented here.§ A typical set of scattering data and a fit to a spherical micelle model are shown

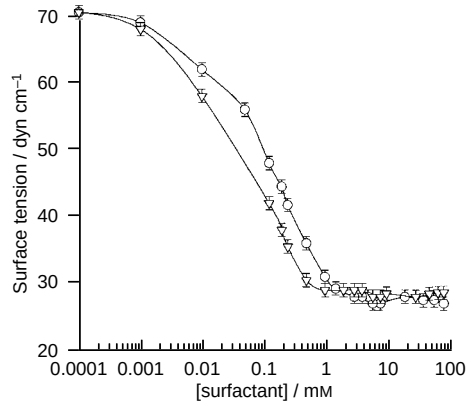

Fig. 3 Surface tension *vs.* concentration for $[M^1(L^1R)(H_2O)_2]Cl_2$(aq) (R = $C_{10}H_{21}$) where M = Ni^{II} (○) or Cu^{II} (▽)

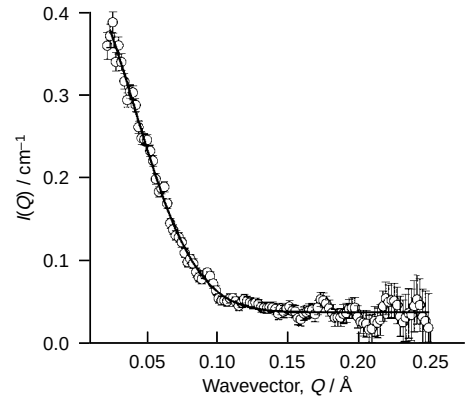

Fig. 4 SANS data for $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ (in D_2O) and the fit to a spherical micelle model. Concentration of $[Ni^{II}(L^1R)(H_2O)_2]Cl_2$ = 10 mM. (The quantity Q is given by $Q = (4\pi/\lambda)\sin(\theta/2)$, and is the modulus of the scattering vector, the resultant between the incident and scattered wavevectors.)

in Fig. 4. Given the resolution of the data, we have made no attempt to break the scattering down into its component 'core' (alkyl tails) and 'shell' (head-group) contributions. The radius of the micelle is found to be 34 ± 3 Å with an aggregation number of 50 ± 10. This radius is somewhat larger than might be expected from a surfactant which has an all-*trans* length of *ca.* 20 Å and it therefore appears that the micelles are either very diffuse in nature or display a degree of non-sphericity. This anomaly is currently the subject of further SANS experiments.

We wish to thank Dr. Stephen M. King (ISIS, Didcot). We also acknowledge the Engineering and Physical Sciences Research Council (P. M. G.) and the Nuffield Foundation (A. L. W.) for financial support.

‡ *Crystal data* for $C_{18}H_{43}Cl_2N_3NiO_3$, M = 479.16, triclinic, space group $P\bar{1}$, a = 7.0430(6), b = 7.4080(8), c = 23.795(3) Å, α = 98.660(14)°, β = 90.670(14)°, γ = 106.010(5) (by least squares refinement of the setting angles for 250 reflections within θ = 2.60–25.13°). U = 1177.9(2) Å^3, Z = 2, D_c = 1.351 g cm^{-3}, T = 150 K, μ(Mo-Kα) = 10.72 cm^{-1}, $F(000)$ = 516, crystal size = 0.24 × 0.18 × 0.16 mm. Data were collected on a FAST TV Area detector diffractometer following previously described methods.[6] From the ranges scanned, 5038 data were recorded ($2.60 < \theta < 25.13°$; index ranges $-7 < h < 7$, $-6 < k < 8$, $-26 < l < 26$) and merged to give 3244 unique (R_{int}) = 0.0726). The structure was solved *via* direct methods[7] and refined on F_o^2 by full matrix least squares[8] using all unique data corrected for Lorentz and polarisation factors. All non-hydrogen atoms were anisotropic. The hydrogen atoms were inserted in idealised position with U_{iso} set at 1.5 U_{eq} of the parent. The weighting scheme used was $w = 1/[\sigma^2(F_o)^2 + (0.0219P)^2]$, where $P = [\text{Max.}(F_o)^2 + 2(F_c)^2]/3$; this gave satisfactory agreement analyses. Final R_1 (F) and $wR2$ (F_o^2) values were 0.0671 and 0.1016 for all 3244 data and 245 parameters. The corresponding R-values were 0.0419 and 0.0978 for 2038 data with $I > 2\sigma(I)$. Sources of scattering factors as in ref. 8. CCDC 182/756.

§ SANS measurements were performed on the LOQ diffractometer at the ISIS Spallation Source, Oxfordshire, UK.

The synthesis and structural characterisation of microporous titanosilicate ETS-10 containing boron in the framework (ETBS-10) are reported.

Microporous titanosilicates known as ETS contain six-coordinate framework titanium atoms and are, thus, fundamentally different from other zeolite-type solids. The framework of ETS-10, the most prominent member of this new family, consists of 'TiO_2' rods, which run in two orthogonal directions, surrounded by tetrahedral silicate units.[1–3] The pore structure consists of 12-rings, 7-rings, 5-rings and 3-rings and has a three-dimensional wide-pore channel system whose minimum diameter is defined by 12-ring apertures. In an attempt to improve the acid characteristics of ETS-10, silicon has been isomorphously substituted by aluminium and gallium on sites which avoid Ti–O–Al(Ga) linkages.[4–6] We now wish to report the synthesis of boron-substituted ETS-10. Establishing the insertion of a light element, such as boron, in the framework of a zeolite-type material is, by no means, a trivial task. In order to gather as much evidence as possible for the substitution of silicon by boron in the framework of ETS-10 we have used a multi-technique approach.

ETBS-10 materials were prepared using a modification of the ETS-10 synthesis.‡ The samples were characterised by bulk chemical analysis (ICP), powder X-ray diffraction (XRD), high-resolution and scanning electron microscopies (HREM and SEM, respectively), FTIR and Raman spectroscopies, ^{29}Si and ^{11}B solid state NMR.

All ETBS-10 samples studied contain a single phase. The HREM images of this phase (not shown) are very similar to those previously reported for ETS-10.[2,3] The powder XRD patterns of ETS-10 and ETBS-10 samples (not shown) are almost identical, the only difference being a slight shift of the ETS-10 reflection at 2θ 24.63° to lower *d*-values when the boron content increases (2θ 24.72° for Si/B = 32). This is a first indication that the smaller boron atom replaces silicon in the structure of ETS-10.

The Raman spectrum of ETS-10 [Fig. 1(*a*)] contains a strong and sharp band at *ca.* 730 cm^{-1} associated with the TiO_6 octahedra. ETBS-10 samples display similar spectra [Fig. 1(*b*,*c*)] but this band broadens and shifts to higher frequency as the boron content increases. Similar effects have been observed with aluminium [Fig. 1(*d*)] and gallium (not shown) substituted ETS-10 samples. Hence, Raman spectroscopy provides further indication of the framework boron insertion.

Fig. 2 shows the ^{29}Si magic-angle spinning (MAS) NMR spectra of ETS-10 and ETBS-10 samples with different boron contents. In ETS-10 there are two types of silicon chemical environments, Si(3Si, 1Ti) and Si(4Si, 0Ti), which give the two groups of resonances at δ −94 to −97 and δ *ca.* −103.7, respectively.[3] The spectrum reveals a further crystallographic splitting of the Si(3Si, 1Ti) site. As the amount of boron in ETBS-10 increases, a new peak grows at δ *ca.* −99 and all the resonances broaden considerably. Owing to this broadening, the ETS-10 line splitting at δ *ca.* −96.5 is no longer resolved. This further suggests that boron has been incorporated into the framework of ETS-10. Indeed, detailed studies on aluminium-substituted ETS-10 have shown that the broadening of the ^{29}Si MAS NMR resonances (and concomitant loss of the δ *ca.* −96.5 line splitting) is due to lattice distortion upon Al incorporation.[3] At present we cannot give a detailed assignment of the ETBS-10 peak at δ *ca.* −99. However, since (*i*) it becomes stronger as the boron content increases and (*ii*) we have found no evidence for the presence in our samples of any other (siliceous) phase, we believe that this resonance is given by Si–O–B environments.

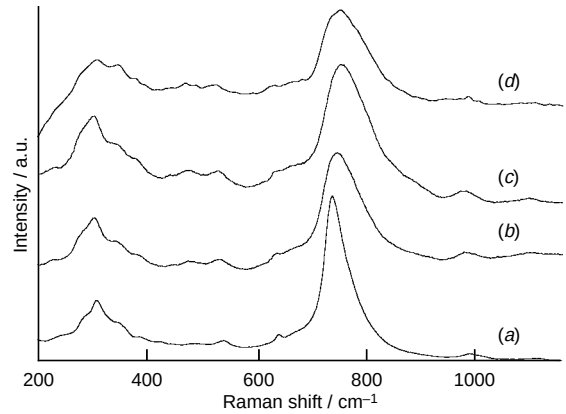

Fig. 1 Stokes shifted Raman spectra of (*a*) ETS-10, (*b*) ETBS-10 (Si/B = 45), (*c*) ETBS-10 (Si/B = 32) and (*d*) Al-substituted ETS-10 (Si/Al = 20). The spectra were measured using a Renishaw Raman imaging microscope model 2000.

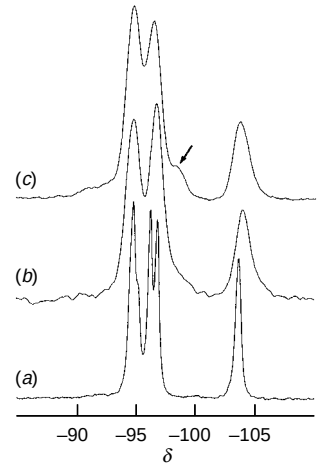

Fig. 2 ^{29}Si MAS NMR spectra of (*a*) ETS-10, (*b*) ETBS-10 (Si/B = 45) and (*c*) ETBS-10 (Si/B = 32). The spectra were recorded at 79.5 MHz on a Bruker MSL 400P spectrometer using 3.0 μs radio-frequency pulses, 40 s recycle delays and spinning rates of 5 kHz.

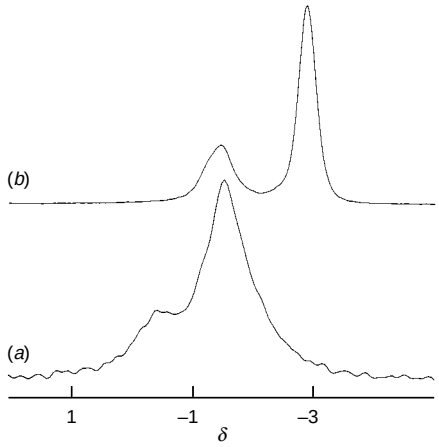

Fig. 3 (*a*) ^{1}H–^{11}B CP MAS and (*b*) ^{11}B MAS NMR spectra of ETBS-10 (Si/B = 32), recorded at 128.4 MHz, using 2 s recycle delays, a contact time of 1 ms and spinning rates of 7 kHz

The ^{11}B MAS NMR spectra [Fig. 3(*b*)] of ETBS-10 samples with different boron contents are similar and contain two groups of very sharp peaks (full width at half maximum, FWHM, *ca*. 78 Hz) at δ *ca*. −1.4 and −2.9. This implies that any electric field gradients created by the electronic cloud at the ^{11}B nuclei are very small and shows that boron is in tetrahedral, rather than trigonal, coordination[7,8] and, most likely, residing in the framework. Indeed, it has been reported that hydrated boron-substituted H-ZSM-5 zeolite gives a single sharp ^{11}B NMR peak at δ −3.[7] On the other hand, the local environment of any extraframework boron would, in principle, be more distorted or, at least, a dispersion of boron sites would occur leading to significantly broader ^{11}B NMR resonances. As prepared hydrated ETBS-10 and dehydrated ETBS-10 (500 °C for 2 h in air) display almost identical ^{11}B and ^{29}Si MAS NMR spectra. The parent gel gives a much broader (FWHM 360 Hz) ^{11}B resonance at δ *ca*. 1.1 (not shown). A second faint and broad peak is seen at δ *ca*. 3.2. The ^{1}H–^{11}B cross-polarization (CP) MAS NMR signal is very weak and the spectrum shown in Fig. 3(*a*) required the accumulation of 30 000 transients (500 for the MAS spectrum). We tentatively assign the two resonances at δ −1.4 and −0.5 to symmetric B–OH environments presumably associated with defect sites or on the surface of the crystallites. Since the former is broader than the δ −1.5 MAS NMR peak it is probably not given by the same boron site.

In order to be absolutely sure that the ^{11}B NMR spectrum of ETBS-10 does contain two separate resonances and that the peaks seen are not part of a second-order quadrupole powder pattern we have further recorded quadrupole nutation (QN)[8] and triple-quantum (3Q)[9] MAS NMR spectra. The latter (not shown) contains two ^{11}B resonances confirming the presence of two main boron sites (the peaks revealed by CP MAS are too faint to be detected). The QN spectrum (not shown) recorded with a radiofrequency, B_1, field of 28 kHz (non-selective excitation) again shows that two resonances are present. A second spectrum, recorded with B_1 = 10 kHz (small deviation from non-selective excitation) suggests that the δ −1.4 resonance has a larger quadrupole coupling constant (C_Q) and, hence, is given by a slightly more distorted boron site. However, both C_{QS} are estimated to be very small (40–80 kHz) confirming that boron is in tetrahedral coordination.

Since ETS-10 contains corner-sharing TiO_6 octahedra and corner-sharing SiO_4 tetrahedra for every framework titanium there is an associated −2 charge. In an analogous way, when SiO_4 is replaced by AlO_4 a −1 charge is introduced. The preferred framework site for silicon substitution by aluminium in ETS-10 has been recently modelled by lattice energy minimisation and semi-empirical quantum chemical calculations on model clusters.[10] The latter technique indicates that, compared to Al–O–Si–O–Ti linkages, Al–O–Ti direct linkages result in enhanced electronic repulsion between neighbouring negative charges associated with the AlO_4 and TiO_6 sites and higher lattice strains. Thus, both electronic and strain factors influence the observed preferential aluminium siting and it is difficult to decide which one plays a more important role. At present, we are performing similar calculations to ascertain whether it is possible to decide or not which one these two factors plays a more important role in the location of boron in ETBS-10.

‡ *Synthesis* of ETBS-10 with Si/B = 45: an alkaline solution was made by mixing 11.32 g sodium silicate (Na_2O 8 mass%, SiO_2 27 mass%, Merck), 4.25 g H_2O, 1.62 g NaOH (Merck), 0.17 g KOH (Carlo Erba), 0.93 KF (Aldrich), 0.34 g KCl (Panreac), 8.96 g $TiCl_3$ (15 mass% solution of $TiCl_3$ in 10 mass% HCl, Merck) and 0.84 g $Na_2B_2O_4{\cdot}10H_2O$ (Panreac). 0.10 g seed of ETS-10 was added to the resulting gel. This gel, with a composition 2.41 Na_2O : 2.18 K_2O : 5.86 SiO_2 : TiO_2 : 0.51 B_2O_3 : 27.1 H_2O, was autoclaved under autogeneous pressure for 2 days at 230 °C. The crystalline product was filtered, washed with distilled water and dried at ambient temperature, the final product being an off-white microcrystalline (2–5 μm) powder. Chemical analysis by ICP of the two samples reported here yielded Si/Ti and Si/B molar ratios of 5.0, 5.2 and 32, 45, respectively, while TG revealed a mass loss from 50 to 350 °C of 13 ± 1%. FTIR spectra of ETBS-10 samples display a shoulder at 990 cm^{-1}, not seen in the spectrum of ETS-10, ascribed to tetrahedrally coordinated boron.

Isolation, structure and iridium-mediated decarbonylation of a sodium fluorenone dianion complex

Zhaomin Hou,*[a]† Akira Fujita,[b] Hiroshi Yamazaki[b] and Yasuo Wakatsuki*[a]

[a] *The Institute of Physical and Chemical Research (RIKEN), Hirosawa 2-1, Wako, Saitama 351-01, Japan*

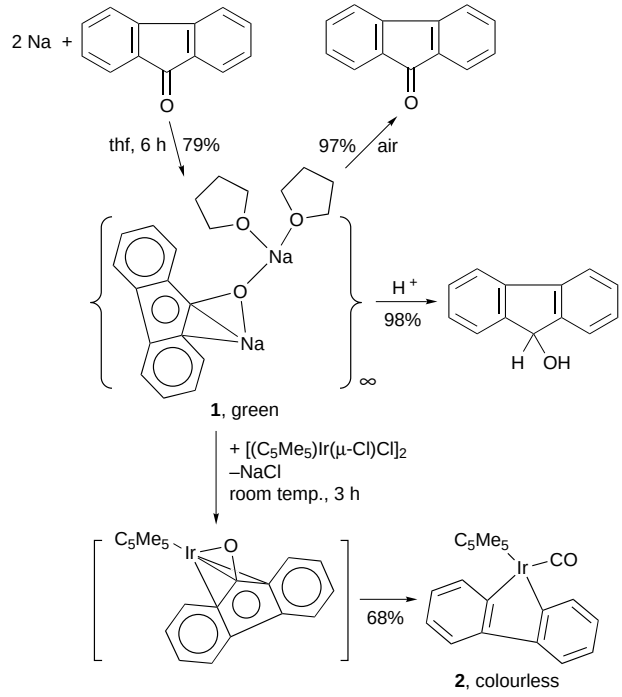
Reaction of fluorenone with 2 equiv. of Na in THF at room temp. gave the polymeric Na–fluorenone dianion complex 1 in 79% isolated yield, which upon reaction with 0.5 equiv. of $[(C_5Me_5)IrCl(\mu\text{-}Cl)]_2$ afforded the decarbonylation product 2; both 1 and 2 have been structurally characterized.

The formation of ketone dianions by two-electron reduction of aromatic ketones with reducing metals such as alkali,[1] low-valent titanium,[2] and lanthanide metals[3] has been known for a long time. These dianionic species as unique nucleophiles have been extensively studied in the area of organic chemistry.[1–3] However, owing to their extreme air- and moisture-sensitivity, which makes them difficult to isolate, structurally characterized examples of this important class of compounds remain very scarce. To date, only two ketone dianion complexes, both of which are limited to those of benzophenone and adopt a dimeric structure, have been isolated and structurally characterized. One is the lithium complex $[Li_2(OCPh_2)(thf)(tmen)]_2$ (thf = tetrahydrofuran, tmen = tetramethylethylenediamine),[4] and the other is the ytterbium(II) complex $[Yb(\mu\text{-}\eta^1:\eta^2\text{-}OCPh_2)(hmpa)_2]_2$ (hmpa = hexamethylphosphoric triamide).[5] Here, we wish to report the isolation and structural characterization of a polymeric sodium fluorenone dianion complex, which constitutes the first example of a structurally characterized fluorenone dianion complex, as well as the first example of a structurally characterized sodium ketone dianion complex. Its reaction with $[(C_5Me_5)IrCl(\mu\text{-}Cl)]_2$ to cause unprecedented decarbonylation of the fluorenone unit is also described.

Reaction of fluorenone with 2 equiv. of fresh sodium chips in thf at room temp. yielded a green precipitate, which upon dissolving in dimethoxyethane (DME) gave a green solution. Evaporation of DME under reduced pressure yielded a green oily residue, which after addition of thf and standing at room temp. for several days afforded green blocks of **1** in 79% yield (Scheme 1).‡ An X-ray analysis has revealed that **1** is a thf-coordinated fluorenonedisodium complex in which one sodium atom [Na(1)] is bonded to the oxygen atom O(1), while the other sodium atom [Na(2)] is bonded to the O(1), C(1) and C(2) atoms of the fluorenone unit (Fig. 1).§ The bond distance of the Na(1)–O(1) bond [2.168(6) Å] is in the 2.14–2.39 Å range of the Na–OR bond distances found in $[NaOBu^t]_6$,[6] $[NaOBu^t]_9$,[6] $[Na\{\mu\text{-}OC_6H_2(CF_3)_3\text{-}2,4,6\}(thf)_2]_2$[7] and $[Na(\mu\text{-}OR)(hmpa)_2]_2$ (OR = fluorenone ketyl),[8] while the bond distances of the Na(2)–C(1) [2.644(7) Å] and Na(2)–C(2) [2.921(7) Å] bonds can be compared with those of the Na–η^{3-5}-Cp bonds (2.620–3.044 Å) found in the sodium fluorenide complexes Na(fluorenide)-$[Me_2N(CH_2)_2N(Me)(CH_2)_2NMe_2]$,[9] $[Na(fluorenide)\{Me_2N(CH_2)_3NMe_2\}]_4$,[9] and $[Na(fluorenide)\{Me_2N(CH_2)_2NMe_2\}]_\infty$.[9] These bond distances are consistent with the fact that **1** is a sodium fluorenone dianion species. The intermolecular interactions between the sodium atoms and part of the fluorenyl ring, the carbonyl unit, and the thf ligands in **1** constitute a unique polymeric structure, in which the fluorenone unit is bonded on one side to a Na atom *via* the Na(2)–η^3-O(1)C(1)C(2) (2.348–2.921 Å) interactions and on the other side to two Na atoms *via* the Na(1′)–η^6-C(8–13) (2.725–2.888 Å) and Na(2′)–η^3-O(1)C(1)C(13) (2.340–3.083 Å) interactions (Fig. 1). The carbonyl moiety interacts with the Na(2) and Na(2′) atoms in a $\mu\text{-}\eta^2$-fashion on two opposite sides (dihedral angle between the Na(2)O(1)C(1) and Na(2′)O(1)C(1) planes = 173°), while the C(13) atom is bonded to both Na(1′) and Na(2′) on the same side [Na(1′)–C(13)–Na(2′) 72.2(2)°]. These structural features are in sharp contrast with those observed in the dimeric benzophenone dianion complexes $[Li_2(OCPh_2)(thf)(tmen)]_2$[4] and $[Yb(\mu\text{-}\eta^1:\eta^2\text{-}OCPh_2)(hmpa)_2]_2$,[5] and apparently result from the planar configuration of the fluorenone unit. The formation of thf bridges in **1** is also noteworthy, since only very few precedents, such as $\{Na(\mu\text{-}thf)[(C_5Me_5)Gd(thf)]_2(\mu\text{-}Cl)(\mu_3\text{-}Cl)_2\}_2$[10] and $[K\{\mu\text{-}OC_6H_2(CF_3)_3\text{-}2,4,6\}(thf)_2(\mu\text{-}thf)]_2$,[7] could be found in the literature. The Na(1)–O(2) [2.371(6) Å] and Na(1)–O(3) [2.391(7) Å] bonds are respectively significantly shorter than the Na(2′)–O(2) [2.440(6) Å] and Na(2′)–O(3) [2.606(6) Å] bonds, showing that the thf bridges in the polymeric structure are unsymmetric, and the intramolecular interactions are stronger than the intermolecular ones. Similarly, the intramolecular Na(2)–C(1) [2.644(7) Å] and Na(2)–C(2) [2.921(7) Å] bonds are respectively much shorter than the intermolecular Na(2′)–C(1) [2.775(7) Å] and Na(2′)–C(13) [3.083(7) Å] bonds, though the Na(2)–O(1) bond distance [2.348(6) Å] is similar to that of the Na(2′)–O(1) bond [2.340(6) Å] (Fig. 1). The bond distance of the C–O bond of the fluorenone unit in **1** [1.379(8) Å] is comparable with those of the benzophenone dianion units found in $[Li_2(OCPh_2)(thf)(tmen)]_2$ (1.406 Å)[4] and $[Yb(\mu\text{-}\eta^1:\eta^2\text{-}OCPh_2)(hmpa)_2]_2$ [1.39(6) Å],[5] and significantly longer than those of free fluorenone [1.220(4) Å][11] and fluorenone ketyl (1.27–1.32 Å).[8,12]



Scheme 1

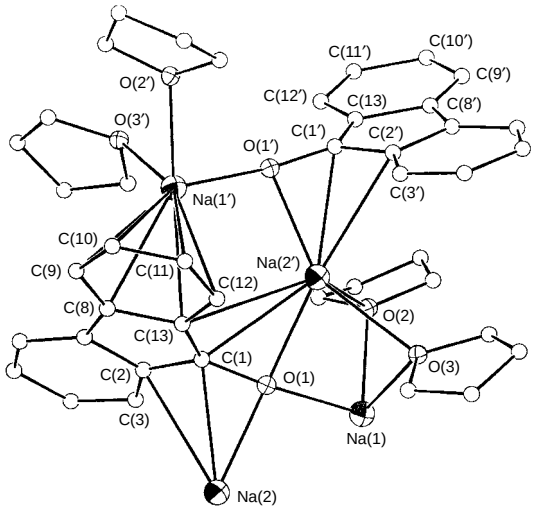


Fig. 1 Extended structure of **1**. Selected bond lengths (Å) angles (°) (′ = 1.5 − *x*, 0.5 + *y*, 1.5 − *z*): Na(1)–O(1) 2.168(6), Na(1)–O(2) 2.371(6), Na(1)–O(3) 2.391(7), Na(2)–O(1) 2.348(6), Na(2)–C(1) 2.644(7), Na(2)–C(2) 2.921(7), Na(2′)–O(1) 2.340(6), Na(2′)–C(1) 2.775(7), Na(2′)–C(13) 3.083(7), Na(2′)–O(2) 2.440(6), Na(2′)–O(3) 2.606(6), Na(1′)–C(8) 2.733(7), Na(1′)–C(9) 2.822(8), Na(1′)–C(10) 2.888(8), Na(1′)–C(11) 2.881(8), Na(1′)–C(12) 2.805(8), Na(1′)–C(13) 2.725(7), O(1)–C(1) 1.379(8); O(1)–Na(1)–O(2) 91.2(2), O(1)–Na(1)–O(3) 86.2(2), O(2)–Na(1)–O(3) 84.5(3), Na(1)–O(1)–C(1) 164.1(5), Na(2)–O(1)–C(1) 86.3(4), Na(1)–O(1)–Na(2) 98.9(2), Na(1)–O(1)–Na(2′) 83.6(2), Na(2′)–O(1)–C(1) 92.9(4), Na(2)–O(1)–Na(2′) 173.4(3), Na(1′)–C(13)–Na(2′) 72.2(2).

Reflecting the reactivity of a fluorenone dianion species,[1–3] hydrolysis of **1** yielded fluorenol, while air oxidation of **1** afforded fluorenone almost quantitatively. Moreover, when **1** was allowed to react with 0.5 equiv. of $[(C_5Me_5)IrCl(\mu\text{-}Cl)]_2$ at room temp. in DME, the decarbonylation product **2** was obtained as colorless crystals in 68% isolated yield (Scheme 1, Fig. 2).§¶ In contrast, the similar reaction of sodium benzophenone dianion with $[(C_5Me_5)IrCl(\mu\text{-}Cl)]_2$ did not give any C–C bond cleavage product, but instead afforded benzophenone and several unidentified iridium hydride species. These results again demonstrated the difference in behavior between fluorenone dianion and benzophenone dianion. Further studies on the decarbonylation reaction are in progress.

This work was partly supported by a grant-in-aid from the Ministry of Education, Science, Sports, and Culture of Japan.

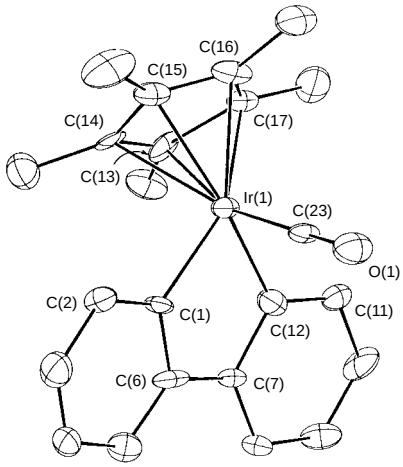

Fig. 2 ORTEP drawing of **2** (only one of the two independent molecules is shown for clarity). Selected bond lengths (Å) and angles (°): Ir(1)–C(1) 2.07(2), Ir(1)–C(12) 2.05(2), Ir(1)–C(13) 2.25(3), Ir(1)–C(14) 2.27(3), Ir(1)–C(15) 2.27(3), Ir(1)–C(16) 2.27(2), Ir(1)–C(17) 2.28(2), Ir(1)–C(23) 1.83(1), O(1)–C(23) 1.14(3); Ir(1)–C(23)–O(1) 179(2).

‡ A typical procedure for the synthesis of **1** is as follows. In a glove box, addition of a thf solution (5 ml) of fluorenone (180 mg, 1 mmol) to freshly-cut sodium chips (48 mg, 2.1 mmol) gave immediately a brown solution, which after being stirred at room temperature for *ca*. 1 h, changed to dark green and yielded gradually thf-insoluble green precipitates. The green mixture was further stirred at room temperature for 5 h. The thf was pumped off and DME (5 ml) was added to give a green solution. Evaporation of DME yielded a green oily residue, which after addition of thf and standing at room temperature for several days afforded thf-insoluble green blocks of **1** (292 mg, 0.79 mmol, 79% yield). Anal. Calc. for $C_{21}H_{24}Na_2O_3$: C, 68.10; H, 6.53. Found. C, 67.80, H, 6.44%.

Biosynthesis of phytyl side-chain of chlorophyll *a*: apparent reutilization of carbon dioxide evolved during acetate assimilation in biosynthesis of chloroplastidic isoprenoid

Kensuke Nabeta,*† Tatsuto Saitoh, Kadzuya Adachi and Kaori Komuro

Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Obihiro 080, Japan

Equal incorporation of either acetyl methyl or carboxy carbons into all carbon atoms of the phytyl side-chain of chlorophyll *via* doubly labelled acetyl CoA, with complete loss of methyl hydrogens, indicated that CO_2 evolved from the carboxy carbon during acetate assimilation through the TCA cycle may be reutilized *via* the reductive pentose phosphate cycle followed by the glycolic pathway, while incorporation of [2-^{13}C]glycerol and [6,6-$^{2}H_2$]glucose into the phytyl chain demonstrated the simultaneous operation of two distinct pathways, both the mevalonate pathway and the 1-deoxy-D-xylulose mediating pathways (non-mevalonate pathway) in isopentenyl diphosphate formation within liverwort chloroplasts.

The labelling pattern of the phytyl side-chain of chlorophyll was determined by incorporation studies using ^{2}H- or ^{13}C-labelled acetates, glycerol and glucose into cultured cells of liverwort, *Heteroscyphus planus*. The most unexpected feature of the labelling pattern was that either acetyl methyl or carboxy carbons were equally incorporated into all carbon atoms of the phytyl side-chain *via* doubly labelled acetyl CoA with complete loss of methyl hydrogens. The labelling pattern of the phytyl side-chain incorporating [2-^{13}C]glycerol and [6,6-$^{2}H_2$]glucose together with ^{2}H- and ^{13}C-labelled mevalonate (MVA)[1,2] revealed the simultaneous operation of two distinct pathways, the classical acetate/MVA (mevalonate) pathway[3] and the novel 1-deoxy-D-xylulose (non-mevalonate) pathway,[4] in isopentenyl diphosphate (IPP) formation within liverwort chloroplasts.

Cell cultures of *Heteroscyphus planus* were grown in MSK-4 medium[5] (6–8 × 75 ml), and fed with sodium [1-^{13}C]-, [2-^{13}C]-, [1,2-$^{13}C_2$]-, [2,2,2-$^{2}H_3$, 1-^{13}C]- and [2,2,2-$^{2}H_3$, 2-^{13}C]-acetate, (> 99 atom%, 0.5 mmol), [2-^{13}C]glycerol (60 atom%, 0.5 mmol in 1 ml of 10% aq. EtOH) and [6,6-$^{2}H_2$]glucose (20 atom%, 11.1 mmol) under continuous light at 25 °C.[6] Chlorophyll *a* was isolated and hydrolyzed, and the isolated phytol was acetylated by the procedure reported previously.

The ^{13}C enrichment [sixteen ^{13}C-enriched peaks with doublets due to ^{13}C–^{13}C coupling (C-1–C-2, C-3–C-20, C-5–C-6, C-7–C-19, C- 9–C-10, C-11–C-18, C-13–C-14 and C-15–C-17) and four intense singlet peaks (C-4, C-8, C-12 and C-16) as shown in Fig. 1 and Table 1] in the phytols incorporating [1-^{13}C]-, [2-^{13}C]- and [1,2-$^{13}C_2$]-acetates was identical, indicating that the doubly ^{13}C-labeled acetyl CoA was formed from either two carboxy carbons of [1-^{13}C]acetate or two methyl carbons of [2-^{13}C]acetate. Transposition of ^{13}C label between the C-4 and C-5 carbons in IPP was also observed. The average intensity of the ^{13}C–^{13}C coupled peaks relative to the intense center peak in phytol incorporating [1,2-$^{13}C_2$]acetate (observed

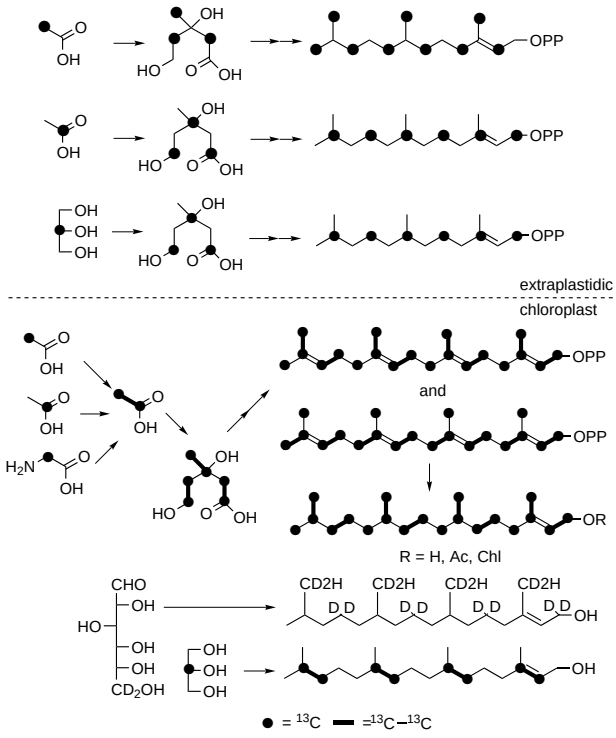

Fig. 1 Labelling patterns of the phytyl side-chain of chlorophyll *a* and sesquiterpenes incorporating ^{13}C labelled acetates, [2-^{13}C]glycerol and [6,6-$^{2}H_2$]glucose in cultured cells of *H. planus*

Table 1 ^{13}C enrichment of phytyl side-chain of chlorophyll *a* incorporating ^{13}C-labelled acetates

	Enrichment (atom% excess)

Average	2.28	1.90	0.89

[a] $J_{^{13}C-^{13}C}$/Hz: C-1–C-2, C-3–C-20, C-5–C-6, C-7–C-19, C-9–C-19, C-11–C-18, C-13–C-14, C-15–C-17 have been previously reported. C-3–C-4 = 34.2, C-7–C-8 = 34.2, C-11–C-12 = 35.4 and C-15–C-16 = 35.4.

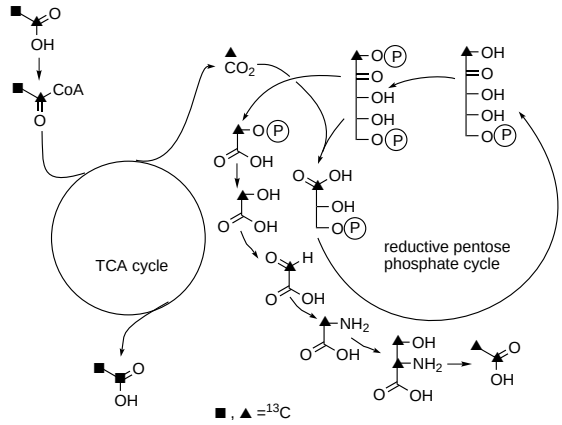

Fig. 2 Pathway for [1,2-$^{13}C_2$]acetate from [1-^{13}C]acetate *via* the TCA cycle, the reductive pentose phophate cycle and the glycollate pathway

relative intensity: 0.185) was much lower (× 4.5) than that estimated (0.82) on the basis of the natural abundance of ^{13}C (1.08%) and ^{13}C enrichment (0.89 atom% excess) indicating that reformed acetate, rather than intact acetate, was incorporated into MVA. The α-^{2}H and β-^{2}H isotopic peaks[6] were not observed in phytol incorporating [2,2,2-$^2H_3$, 2-^{13}C]- and [2,2,2-$^2H_3$, 1-^{13}C]-acetates, respectively, indicating the complete loss of ^{2}H of the acetate during formation of [1,2-$^{13}C_2$]acetate.

The pathway leading to two contiguously labelled acetate (or three contiguously labelled propionate) molecules from [2-^{13}C]acetate, which was detected in a rare actinomycetes, *Actinomadura azurea*,[7] and cell cultures of the vascular plants *Zea mays*[8] and *Morus alba*[9] was reasonably explained by the participation of the tricarboxylic acid cycle (TCA cycle). Formation of doubly labeled acetate from [1-^{13}C]acetate, however, has not yet been reported. The results of this as well as earlier studies in which we examined the incorporation of [2-^{13}C]glycine into the phytyl moiety of chlorophyll *a*[1,2] suggest that the ^{13}C-labelled carbon dioxide evolved during [1-^{13}C]acetate assimilation through the TCA cycle is reutilized *via* the reductive pentose phosphate cycle. Carbon-13 labelled CO_2 was incorporated into ribulose 1,5-bisphosphate at C-1 by the mechanism shown in Fig. 2. The ^{13}C label at C-1 in ribulose 1,5-bisphosphate was further translocated into the methylene carbon (C-2) of glycine *via* the glycolic pathway. The doubly labelled acetyl-CoA was formed from two C-2 carbons of the endogenously formed [2-^{13}C]glycine *via* the glycolic pathway. There is indirect evidence that reassimilation of CO_2 liberated during acetate photoassimilation could be reutilized in glycolate production in *Chlorella*[10] other eukaryotic algae and vascular plants.[11]

Label was detected at C-2, C-3, C-6, C-7, C-10, C-11, C-14 and C-15 of the phytyl side-chain incorporating [2-^{13}C]glycerol, all of which showed $J_{^{13}C-^{13}C}$ coupling ($J_{2,3}$ = 73.2, $J_{6,7}$ = 34.8, $J_{10,11}$ = 34.8 and $J_{14,15}$ = 34.2 Hz). When [6,6-$^2H_2$]glucose was added, the label was incorporated into C-1 (δ_D 4.15) and C-20 (δ_D 1.66) together with three methylene carbons (C-5, C-9 and C-13, δ_D 1.35–1.55, unresolved) and three methyl carbons (C-17, C-18, C-19, δ_D 0.8–0.9, unresolved). The labelling pattern indeed confirmed the operation of the non-mevalonate pathway in biosynthesis of the phytyl side-chain. We found that the phytyl side-chain was also formed from MVA.[1,2] Thus, it is suggested that biosynthesis of all compounds derived from geranylgeranyl diphosphate within liverwort chloroplasts proceeds *via* both the classical mevalonate pathway[1,2,12] and the novel non-mevalonate pathway. The simultaneous operation of the mevalonate and the non-mevalonate pathways has also been detected in microorganisms without organelles.[13]The labelling pattern of β-barbatene, a predominant sesquiterpene hydrocarbon in *H. planus*,[14] incorporating labelled glycerol and glucose revealed that biosynthesis of the cytoplasmic terpenoids proceeds *via* the mevalonate pathway but not *via* the non-mevalonate pathway.

We present here evidence that CO_2 evolved from acetate assimilation is reutilized to biosynthesize isoprenoids in chloroplasts. The enzymes involved in the TCA cycle, the reductive pentose cycle and the glycolic acid pathway are separately localized in mitochondria, chloroplasts and peroxisomes, respectively. Thus reconstruction of acetate in chloroplasts requires consideration of the flux of CO_2 and the intermediates through the TCA cycle in mitochondria.

We are grateful to Dr H. Koshino (The Institute of Physical and Chemical Research) for ^{2}H NMR analyses and to Professors H. Seto (Tokyo University) and K. Kakinuma (Tokyo Institute of Technology) for a generous gift of [6,6-$^2H_2$]glucose. These investigations were supported by the Suhara Memorial Foundation and Grants-in-aid for Scientific Research (A. No. 08306021 and C. No. 08660125) from the Ministry of Education, Science and Culture, Japan.

Synthesis and X-ray crystal structure of a hexanuclear silver(I) complex with non-chelating tri- and tetra-dentate bridging *o*-(diphenylphosphino)benzoate ligands

Wai-Kwok Wong,*[a]† Lilu Zhang[a] and Wing-Tak Wong[b]

[a] *Department of Chemistry, Hong Kong Baptist University, Kowloon, Hong Kong, P.R. China*
[b] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, P.R. China*

Single crystal X-ray analysis of the hexanuclear silver(I) complex $Ag_6[o\text{-}Ph_2P(C_6H_4CO_2)\text{-}O,P]_6$, synthesized by treatment of $Ag(CF_3SO_3)$ with $N(CH_2CH_2NH_2)_3$, 1,3-dicyclohexylcarbodiimide (DCC) and $o\text{-}Ph_2PC_6H_4(CO_2H)$ in 1:1:3:3 molar ratio in ethanol, shows that the complex is centrosymmetric and consists of three independent silver(I) centres linking together *via* non-chelating tri- and tetradentate bridging *o*-(diphenylphosphino)benzoate groups.

We have been interested in the preparation of diimino-, diamino- and diamido-diphosphine ligands and demonstrated that these ligands do indeed exhibit a very rich coordination chemistry.[1,2] Recently, we have extended our study to the preparation of polydentate ligands containing three imino-phosphino groups and show that the heptadentate ligand $\{(o\text{-}Ph_2PC_6H_4)CH{=}NCH_2CH_2\}_3N$ can be prepared *via* template synthesis.[3] Here we report the result of our attempt to extend the template synthetic route for the preparation of the amidophosphino heptadentate ligand.

Treatment of $Ag(CF_3SO_3)$ with $N(CH_2CH_2NH_2)_3$, 1,3-dicyclohexylcarbodiimide (DCC) and $o\text{-}Ph_2PC_6H_4CO_2H$ in 1 : 1 : 3 : 3 molar ratio in refluxing ethanol affords, after work up, white crystals of stoichiometry $[Ag(o\text{-}Ph_2PC_6H_4CO_2)]_6$ **1**‡ in 10% yield. However, compound **1** could not be isolated from the reaction of $Ag(CF_3SO_3)$ with $o\text{-}Ph_2PC_6H_4CO_2H$ and 4-dimethylamino-pyridine (DMAP) in 1 : 1 : 1 molar ratio in the absence of DCC. The structure of **1** was established by X-ray crystallography. Crystals of $\mathbf{1}\cdot 2C_4H_8O\cdot C_6H_{14}$ suitable for X-ray diffraction study§ were grown by slow diffusion of hexane into a tetrahydrofuran solution of **1**. The molecular structure of **1** [Fig. 1(*a*)] shows that the hexameric system is embedded within an outer shell of aromatic rings formed by the phenyl rings of the phosphine and benzoate. The molecule is a centrosymmetric hexanuclear silver(I) complex with three independent Ag atoms linking together *via* the *o*-(diphenylphosphino)benzoate groups forming a $Ag_6[o\text{-}Ph_2P(C_6H_4CO_2)\text{-}O,P]_6$ cluster as shown in Fig. 2. The three independent Ag atoms in the asymmetric unit are four-coordinate and their coordination geometries can be described as highly distorted tetrahedra. The coordination environment of Ag(2) and Ag(3) are very similar. Both silver(I) centres are surrounded by two O atoms and one P atom from three different *o*-(diphenylphosphino)benzoate ligands and have a very long metal–metal distance [Ag(2)–Ag(3) 3.244(2) Å which is significantly shorter than the other two inter-silver distances; Ag(1)···Ag(2) 3.805, Ag(1)···Ag(3) 3.756 Å] between each other. The Ag(2)···Ag(3) distance is much longer than that (2.89 Å) found in metallic silver and is comparable to the long Ag–Ag distance [3.090(4) Å] in $[Ag_6L_2(HL)_2(H_2O)_4]$ (L = pyridine-2,3-dicarboxylate),[4] [3.194(2) Å] in $[Ag(\eta^2\text{-}O_2CMe)(\mu\text{-dppm})]_2$ (dppm = $Ph_2PCH_2PPh_2$),[5] and the inter-chain Ag–Ag distances [3.269(2) and 3.346(2) Å] in $[Ag_2L'_2(H_2O)]_n[ClO_4]_{2n}$ (L′ = trimethylammoniopropionate)[6] indicating a very weak metal–metal interaction. Ag(2) is approximately coplanar with O(1), O(6*) and P(2) [Ag(2)–O(1) 2.185(7), Ag(2)–O(6*) 2.411(8), Ag(2)–P(2) 2.376(4) Å] with a

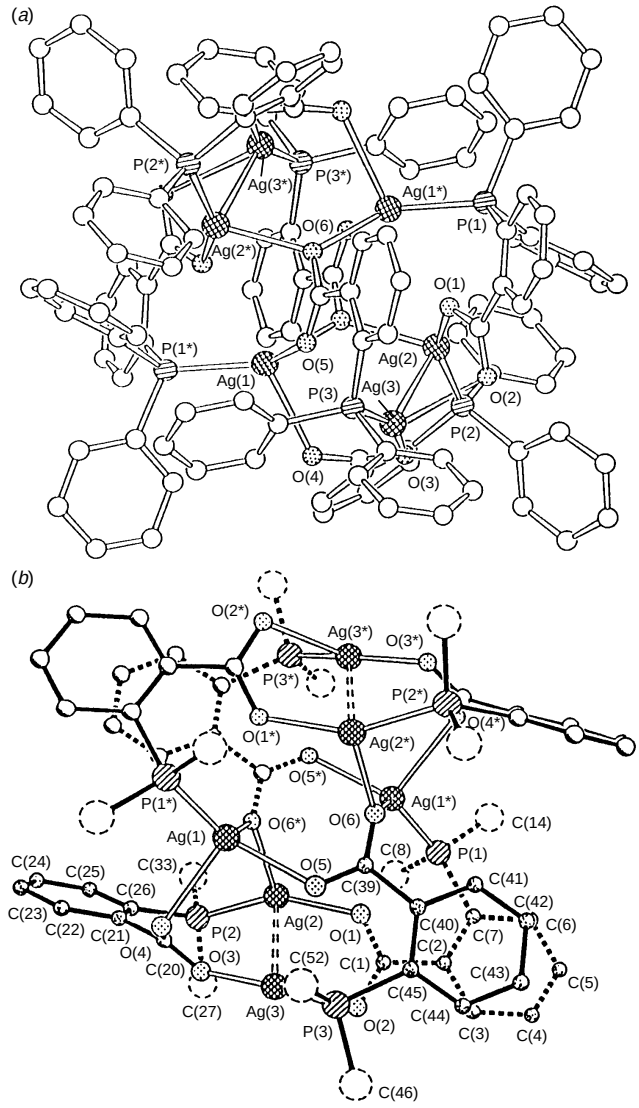

Fig. 1 (*a*) Overall molecular geometry of compound **1**. For clarity, the hydrogen atoms are omitted. (*b*) A perspective drawing of **1** with the phenyl rings of the PPh_2 groups each represented by a circle with broken outline. Selected bond lengths (Å) and angles(°): Ag(2)–Ag(3) 3.244(2), Ag(1)–P(1*) 2.381(4), Ag(2)–P(2) 2.376(4), Ag(3)–P(3) 2.378(4), Ag(1)–O(4) 2.598(9), Ag(1)–O(5) 2.261(9), Ag(1*)–O(6) 2.394(9), Ag(2)–O(1) 2.185(9), Ag(2*)–O(6) 2.411(9), Ag(3)–O(2) 2.619(9), Ag(3)–O(3) 2.176(9), P(1*)–Ag(1)–O(4) 108.8(2), P(1*)–Ag(1)–O(5) 129.5(2), P(1*)–Ag(1)–O(6*) 130.5(2), O(4)–Ag(1)–O(5) 100.4(3), O(4)–Ag(1)–O(6*) 87.9(3), O(5)–Ag(1)–O(6*) 89.9(3), O(1)–Ag(2)–O(6*) 98.6(3), P(2)–Ag(2)–O(6*) 108.0(2), Ag(3)–Ag(2)–P(2) 106.0(1), P(2)–Ag(2)–O(1) 152.8(2), O(2)–Ag(3)–P(3) 93.1(2), O(2)–Ag(3)–O(3) 105.4(3), O(3)–Ag(3)–P(3) 161.2(3), Ag(2)–Ag(3)–P(3), 134.6(1).

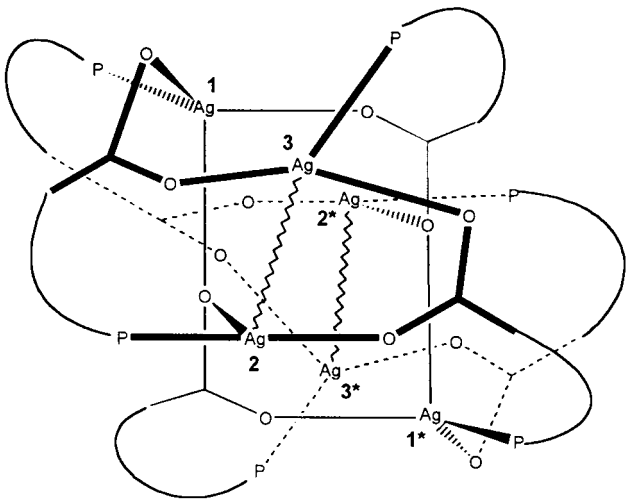

Fig. 2 $Ag_6[o\text{-}Ph_2P(C_6H_4CO_2)\text{-}O,P]_6$ cluster

deviation of 0.108 Å and equatorial bond angles [O(1)–Ag(2)–O(6*) 98.6(3), P(2)–Ag(2)–O(6*) 108.0(2), and P(2)–Ag(2)–O(1) 152.8(2)°] summing to *ca.* 360°. Ag(3) is *ca.* 0.250 Å above the least-squares plane formed by O(2), O(3) and P(3) [Ag(3)–O(2) 2.619(9), Ag(3)–O(3) 2.176(9), Ag(3)–P(3) 2.378(4) Å] with equatorial bond angles [O(2)–Ag(3)–P(3) 93.1(2), O(2)–Ag(3)–O(3) 105.4(3), O(3)–Ag(3)–P(3) 161.2(3)°] summing to *ca.* 360°. However, if one considers the long Ag–O [Ag(2)–O(6*) 2.411(8), Ag(3)–O(2) 2.619(9)] and Ag(2)–Ag(3) distances as insignificant and non-interacting, with the large P(2)–Ag(2)–O(1) [152.8(2)°] and P(3)–Ag(3)–O(3) [161.2(3)°] angles, Ag(2) and Ag(3) may be described as two-coordinate. Ag(1) is surrounded by three carboxylato-O atoms and a P atom from four different *o*-(diphenylphosphino)benzoate ligands [Ag(1)–O(4) 2.598(9), Ag(1)–O(5) 2.261(9), Ag(1)–O(6*) 2.394(9), Ag(1)–P(1*) 2.381(4) Å]. The coordination geometry of Ag(1) is highly distorted from tetrahedral with the Ag atom lying only 0.418 Å above the least-squares plane of O(5), O(6*) and P(1*) and the bond angles ranging from 89.9(3) to 130.5(2)°. The Ag–P distances are normal and comparable to the Ag–P distances [2.363(4), 2.390(4) Å] in $[Ag_2(\mu\text{-}O_2CMe\text{-}O,O')(\mu\text{-}O_2CMe\text{-}O)(dppm)]_2$[5] and [2.342(4)–2.378(5) Å] in $[(C_{12}H_6O_4)_2(Ph_3PAg)_4]$ ($C_{12}H_6O_4$ = 1,8-naphthalenedicarboxylate).[7]

Of the three independent carboxylate groups, two behave as bidentate and one as tridentate ligands. The coordination modes of the two bidentate carboxylate ligands are very similar. Both of them coordinate unsymmetrically to two different silver atoms with a short and a long Ag–O bond in a *syn–syn* bridging mode. For the carboxylato group C(2)C(1)O(1)O(2), the Ag(2)–O(1) distance [2.185(9) Å] is significantly shorter than that of Ag(3)–O(2) [2.619(9) Å] with comparable C–O distances [C(1)–O(2) 1.24(1), C(1)–O(1) 1.28(1) Å]. Similarly, for the carboxylato group C(21)C(20)O(3)O(4), the Ag(3)–O(3) distance [2.176(9) Å] is significantly shorter than that of Ag(1)–O(4) [2.598(9) Å] with similar C–O distances [C(20)–O(3) 1.26(1), C(20)–O(4) 1.24(1) Å]. The carboxylato group C(40)C(39)O(5)O(6) coordinates to three different Ag atoms with Ag–O [Ag(1)–O(5) 2.261(9), Ag(2*)–O(6) 2.411(9), Ag(1*)–O(6) 2.394(9) Å] and C–O [C(39)–O(5) 1.22(1), C(39)–O(6) 1.27(1) Å] distances comparable to those observed in $[Ag_2(\mu\text{-}O_2CMe\text{-}O,O')(\mu\text{-}O_2CMe\text{-}O)(dppm)]_2$ [Ag–O, 2.232(11)–2.485(10), C–O 1.238(21)–1.278(19) Å],[5] resulting a tridentate carboxylato-μ-*O,O′*;μ-*O,O* mode.

Unlike previous reported *o*-(diphenylphosphino)benzoate metal complexes in which the ligand behaves as a bidentate chelating ligand,[8,9] the *o*-(diphenylphosphino)benzoate-*O,P* ligands in **1** do not exhibit chelation with any Ag atom, neither do the carboxylato-*O,O′* groups, instead, both groups connect with different Ag atoms at different coordinating sites.

Thanks are due to the Hong Kong Baptist University, the University of Hong Kong and the Hong Kong Research Grants Council (HKBU 131/94P) for financial support.

§ *Crystal data*: **1**$\cdot 2C_4H_8O\cdot C_6H_{14}$: $C_{114}H_{84}P_6O_{12}Ag_6\cdot 2C_4H_8O\cdot C_6H_{14}$, M_w = 2709.35, triclinic, space group $P\bar{1}$ (no. 2), a = 14.973(2), b = 15.635(3), c = 14.740(3) Å, α = 116.77(1)°, β = 107.71(1)°, γ = 71.87(1)°, U = 2872(1) $Å^3$, Z = 1, $F(000)$ = 1366, D_c = 1.566 g cm^{-3}, μ = 11.46 cm^{-1}. Crystal dimensions: 0.10 × 0.20 × 0.27 mm. Intensity data were collected on a Rigaku AFC7R diffractometer with graphite monochromated Mo-Kα radiation (λ = 0.710 73 Å) using ω–2θ scans ($2\theta_{max} \leqslant 45°$) at room temperature. The data were corrected for Lorentz, polarization effects and absorption correction using ψ-scan method resulting in transmission factors ranging from 0.8482 to 1.0000. A total of 7503 (R_{int} = 0.066) unique reflections were measured; 3183 of these had $I \geqslant 3\sigma(I)$ and were considered to be observed. The structure was solved by direct methods (SIR92)[10] and refined by full matrix least-squares analysis to give R = 0.047, wR = 0.047. Silver and phosphorus atoms were refined anisotropically and the rest of the non-hydrogen atoms were refined isotropically. Hydrogen atoms were generated in their idealized positions (C–H bond fixed at 0.95 Å) and allowed to ride on their respective parent carbon atoms. These hydrogen atoms were assigned appropriate isotropic thermal parameters and included in the structure factor calculations but not in the refinement. All calculations were performed on a Silicon-Graphics computer using program package Texsan from MSC.[11] CCDC 182/774.

Electrochemical dehydrodimerisation of a vinylenylamide ligand: formation of the binuclear group {Mo≡N$^+$CH=CHCH=CHCH=CHN$^+$≡Mo} which displays very strong electronic coupling in the {(Mo^{III})–(Mo^{IV})} mixed-valence state

Yatimah Alias,[a] Marie-Laurence Abasq,[a,b] Frédéric Barrière,[a,b] Sian C. Davies,[a] Shirley A. Fairhurst,[a] David L. Hughes,[a] Saad K. Ibrahim,[a] Jean Talarmin[b] and Christopher J. Pickett*[a]†

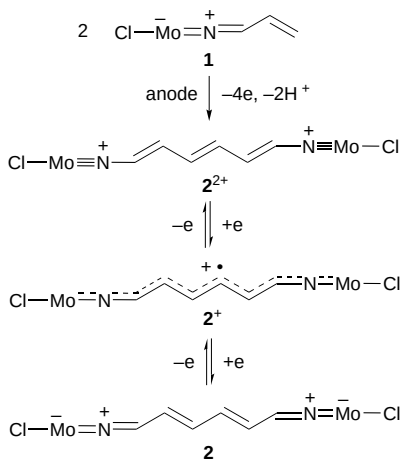
Electrochemical dehydrodimerisation of an {Mo–N=CHCH=CH$_2$} group gives an all-*trans*-{≡N$^+$CH=CHCH=CHCH=CHN$^+$≡} ligand, bridging two Mo^{IV} centres; the {(Mo^{III})–bridge–(Mo^{IV})} mixed-valence state is accessible by electrochemical reduction and exhibits very strong electronic coupling over the 11.7 Å which separates the two metal centres; this accords with EHMO calculations which show that the SOMO has substantial (30%) bridging-ligand character; in its capacity to function as a molecular wire linking two metal centres, the eight-atom hexatriene di(imide) chain {N(CH)$_6$N} compares favourably with C$_8$ chains of acetylenic carbons bridging other metal centres.

An extensive and diverse chemistry of enylamide ligands (–N=CR$_2$; R = H or organic group) is developing, particularly at molybdenum(II) centres.[1] For example, recently it has been shown that incipient carbanionic character at the γ-carbon atom within the {Mo–N=CHCH=CH$_2$} group allows regio- and stereo-specific addition of carbon electrophiles.[2] We now report a new reaction of this vinylenylamide group: anodic dehydrodimerisation to give the hitherto unknown {≡N$^+$CH=CHCH=CHCH=CHN$^+$≡} bridging ligand.

Controlled potential oxidation of *trans*-[MoCl(N=CHCH=CH$_2$)(dppe)$_2$] **1** {dppe = Ph$_2$PCH$_2$CH$_2$PPh$_2$; vitreous carbon; −0.55 V *vs.* ferrocenium–ferrocene (Fc$^+$–Fc); 0.2 M [NBu$_4$][BF$_4$] in tetrahydrofuran(thf)–KOBu^t (2 equiv.)} gives all-*trans*-[Cl(dppe)$_2$Mo≡NCH=CHCH=CHCH=CHN≡MoCl(dppe)$_2$]$^{2+}$ **2**$^{2+}$ in an overall two-electron process, Scheme 1.

Cation **2**$^{2+}$ is formed in *ca.* 70% yield and was isolated from the anolyte as the tetrafluoroborate salt. Recrystallisation from CH$_2$Cl$_2$–EtO$_2$ gave **2**[BF$_4$]$_2$·solvent as dark-orange plates and the structure was determined by X-ray crystallography.‡ This established that the alternate-hydrocarbon bridge has the all-*trans* arrangement as shown in Fig. 1. The *trans*-Cl–Mo–N arrangement at each Mo atom, and the dimensions about the metal atoms, are similar to those found in the molybdenum(IV) methylimide cation *trans*-[MoCl(NMe)(dppe)$_2$]$^+$ **3**$^+$.[3]



Scheme 1

The bridging ligand, which places the two Mo atoms 11.7 Å apart, is unique in that a polyene unit is linked to the metal centres by multiply bonding imide groups. The electronic consequences of this arrangement are considerable. EHMO calcualtions[4] indicate that the LUMO of **2**$^{2+}$ has both metal (30%, 30%) and bridging-ligand π*-character (30%).§ Populating this delocalised orbital by one-electron reduction leads to strong electronic coupling between the metal centres in the mixed-valence ion **2**$^+$ (Robin and Day, Class III behaviour[5]) as is borne out by the following experimental evidence.

Cyclic voltammetry {vitreous carbon; 0.2 M [NBu$_4$][BF$_4$]–CH$_2$Cl$_2$} shows that **2**$^{2+}$ undergoes two successive reversible one-electron reductions with $\Delta E°$ = 320 mV (K_{com} = 2.6 × 10^5) which is indicative of Class II or Class III behaviour, Fig. 2.

Controlled potential electrolysis {vitreous carbon; −1.35 V *vs.* Fc$^+$–Fc; 0.2 M [NBu$_4$][BF$_4$]–CH$_2$Cl$_2$} cleanly generates **2**$^+$ as a stable, paramagnetic solution species (S = 1/2; $g_\perp$ = 1.998, $g_\parallel$ = 1.960; frozen glass, 77 K). The electronic spectrum of electrogenerated **2**$^+$ shows an intense symmetric intervalence charge-transfer (IT) band in the near-IR at 12 820 cm^{-1} which is absent in **2**$^{2+}$.

The IT band-width at half-peak intensity ($\Delta\nu_{1/2}$) can be calculated for Class II systems from ν_{max} using the Hush equation.[6] This gives $\Delta\nu_{1/2}$ (calc.) = 5442 cm^{-1} whereas $\Delta\nu_{1/2}$ (exptl.) = 702 cm^{-1}: IT bands which are considerably sharper than predicted typify Class III character. The intensity of IT bands in Class II complexes are weak with ε_{max} typically in the order of 10^2 dm^3 mol^{-1} cm^{-1}; in addition ν_{max} is solvent dependent. In contrast, Class III complexes display intense solvent-independent IT bands. **2**$^+$ has ε_{max} = 9.5 × 10^4

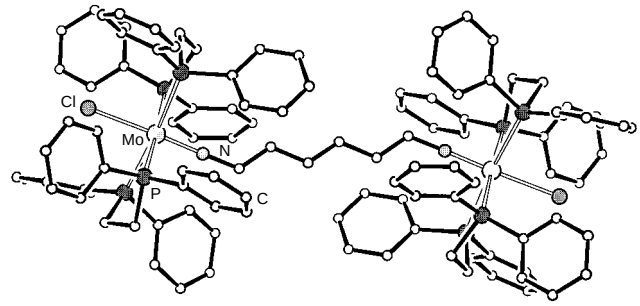


Fig. 1 View of cation [{MoCl(dppe)$_2$}$_2${μ-N(CH=CH–)$_3$N}]$^{2+}$; the two halves are related by a centre of symmetry. Selected molecular dimensions: Mo–Cl 2.521(4), Mo–N 1.752(11), mean Mo–P 2.551(7) Å; Mo–N–C 178.0(10)°.

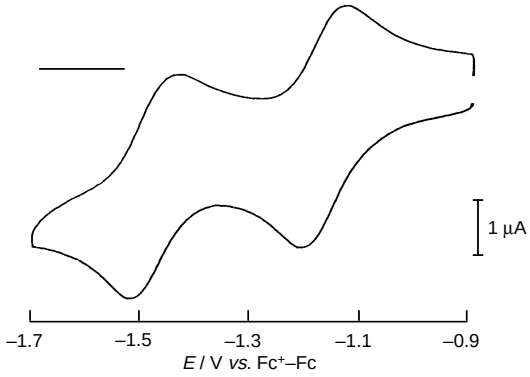

Fig. 2 Cyclic voltammogram at 293 K of $\mathbf{2}^{2+}$ at vitreous carbon electrode in 0.2 M $[NBu_4][BF_4]$–CH_2Cl_2 at a scan rate of 30 mV s^{-1} showing two successive reversible one-electron reductions. Electrode area = 0.0707 cm^2; concentration of complex = 0.26 mM.

$dm^3\ mol^{-1}\ cm^{-1}$ and ν_{max} is solvent independent, again consistent with Class III assignment.

The crystallographic distance between the metal centres, ν_{max} and $\Delta\nu_{1/2}$ can be used to estimate the degree of delocalisation (α^2) in the ground state of a mixed-valence system.[6] For $\mathbf{2}^+$, α^2 is 0.25 which compares favourably with $\alpha^2 = 0.26$ for the Class III system $[(\eta^5\text{-}C_5Me_5)(dppe)Fe{-}C{\equiv}CC{\equiv}CC{\equiv}CC{\equiv}C{-}Fe(\eta^5\text{-}C_5Me_5)(dppe)]^+$; this cation also has eight atoms separating the metal centres which are described as functioning as a 'molecular wire'.[7]

‡ Crystal structure analysis of $[\{MoCl(dppe)_2\}_2\{\mu\text{-}N(CH{=}CH{-})_3N\}][BF_4]_2{\cdot}nCH_2Cl_2{\cdot}mEt_2O$.

Crystal data: $C_{110}H_{102}B_2Cl_2F_8Mo_2N_2P_8{\cdot}CH_2Cl_2{\cdot}C_4H_{10}O$, assuming *n* and *m* are each 1.0, M = 2295.3, triclinic, space group $B\bar{1}$ (equiv. to no. 2), a = 12.533(1), b = 14.733(2), c = 30.206(3) Å, α = 83.818(8), β = 94.801(8), γ = 83.150(8)°, U = 5479.0(9) Å^3. Z = 2, D_c = 1.391 g cm^{-3}, $F(000)$ = 2360, T = 293 K, μ(Mo-Kα) = 5.1 cm^{-1}, λ(Mo-Kα) = 0.71069 Å.

Air-sensitive, thin, deep orange plate crystals. Preliminary photographic examination, then Enraf-Nonius CAD4 diffractometer (with monochromated radiation) for accurate cell parameters (25 reflections, θ = 10–11°) and diffraction intensities (5094 unique intensities (5094 unique reflections to θ_{max} = 20°; 2643 'observed' with $I > 2\sigma_I$).

Corrections applied for Lorentz-polarisation effects, crystal deterioration (*ca.* 14.3% overall), absorption (by semi-empirical ψ-scan methods) and to eliminate negative net intensities (by Bayesian statistical methods). Structure determined by automated Patterson routines; refinement by full-matrix least-squares methods, on F^2 values, in SHELXL.[8] In the cation, non-hydrogen atoms refined anisotropically, hydrogen atoms included with all parameters riding. Anion and solvent regions show disorder and not fully resolved. At conclusion of refinement, wR_2 = 0.182 and R_1 = 0.101[8] for 3881 reflections (with $I > \sigma_I$) weighted $w = [\sigma^2(F_o^2) + (0.0964P)^2]^{-1}$ with $P = (F_o^2 + 2F_c^2)/3$; for the 'observed' data, R_I = 0.068. In the final difference map, the highest peaks (*ca.* 0.67 e Å^{-3}) were close to the Mo centres. CCDC 182/766.

§ EHMO calculations[4] reveal that in $\mathbf{2}^{2+}$ a degenerate pair of occupied orbitals constitute two metal-based HOMOs each with 93% Mo character. Consistent with this, cyclic voltammetry (vitreous carbon; 0.2 M $[NBu_4][BF_4]$–CH_2Cl_2) shows that $\mathbf{2}^{2+}$ undergoes two successive and closely spaced ($\Delta E°$ = 100 mV) reversible one-electron oxidations indicative of a valence-trapped $\{Mo^{V}(bridge)Mo^{IV}\}$ system.

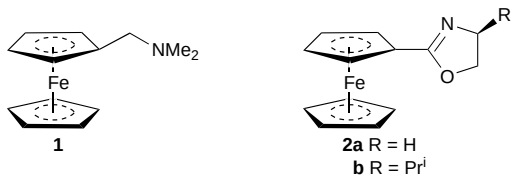
Selective electrochemical magnesium and calcium sensors based on non-macrocyclic nitrogen-containing ferrocene ligands

Antony Chesney, Martin R. Bryce,* Andrei S. Batsanov, Judith A. K. Howard and Leonid M. Goldenberg

Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE

Ferrocene derivatives 1, 2a, 2b and 5 act as electrochemical sensors of Mg^{2+} and Ca^{2+} ions in acetonitrile solution in concentrations as low as 10 mol%: a new redox peak appears in the cyclic voltammogram, anodically shifted by 160–360 mV, with no interference from a large excess of several other metal salts; the single crystal X-ray structure of ligand 5 is reported.

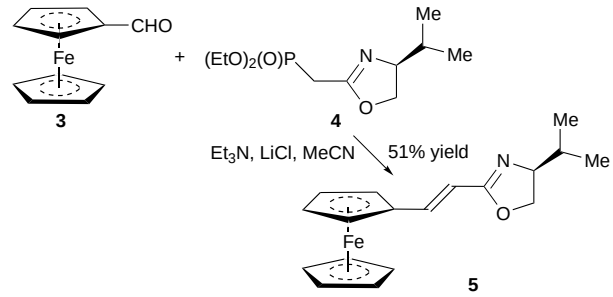
The study of redox-active ligands in which a change in electrochemical behaviour can be used to monitor complexation of guest species is an increasingly important area of molecular recognition.[1] Ferrocene derivatives, most of which are substituted with macrocyclic ligands, have proved successful as ion sensors.[2] However, no selectivity towards magnesium or calcium ions has been reported for these systems: representative derivatives[3,4] show strong affinities for group 1 metals in solution (typically Li, Na or K) and selectivity for Li^+ has been observed for systems which are insensitive to Na^+ or K^+.[5] The electrochemical sensing of Mg^{2+} has been demonstrated in molten alloys[6] and in ferret ventricular muscle tissue,[7] and both fluorescent[8] and fibre-optical[9] devices have proved useful. However, no solution studies on efficient redox-active Mg^{2+} or Ca^{2+} sensors have been reported.



1 **2a** R = H **b** R = Pr^i

We now report the metal-binding properties of nitrogen-containing, non-macrocyclic derivatives of ferrocene. Commercially available (dimethylamino)methylferrocene **1** was employed initially. Titration studies using cyclic voltammetry (CV)† in acetonitrile indicated that compound **1** could detect the presence of Mg^{2+} and Ca^{2+} ions in concentrations as low as 10 mol%: on addition of $Mg(ClO_4)_2$ or $Mg(CF_3SO_3)_2$ a second redox peak appeared in the CV, anodically shifted by *ca.* 230 mV. The observation of approximately equal peak currents for the two redox waves after addition of 0.2 equiv. of $Mg(ClO_4)_2$ (Fig. 1) or $Mg(CF_3SO_3)_2$ suggests the formation of a complex with a ligand : metal ratio of *ca.* 2 : 1. Addition of $Ca(ClO_4)_2$, instead of $Mg(ClO_4)_2$, led to an anodic drift in the redox wave with no clearly defined new peak. Remarkably, the presence of a range of other metal ions in solution [$LiClO_4$, $NaClO_4$, $KClO_4$, $CsClO_4$, $Ba(ClO_4)_2$ and $AgClO_4$] had no effect on the CV, even in concentrations as high as 2500 mol%.‡

We next studied the known oxazolines **2a** and **2b**.[10] The oxygen atom of **2a** and **2b** could act as an alternative chelation site, and **2b** also possesses a potentially sterically demanding isopropyl group α to the nitrogen. Additionally, to assess the importance of the proximity of the binding site to the ferrocene core on the selectivity and strength of binding, the extended oxazoline ligand **5** was prepared from aldehyde **3** according to Scheme 1, utilising reagent **4**, prepared by analogy with the literature procedure.[11] X-Ray crystal structure analysis§ of **5** confirmed the expected *trans* configuration of the alkene bridge (in agreement with ^{1}H NMR data) and the (*S*)-configuration of the chiral centre at C(4) (Fig. 2).



Scheme 1

Ligands **2a**, **2b** and **5** all demonstrated a selectivity towards Mg^{2+} and Ca^{2+} over other metal ions, similar to that observed for amine **1** and Mg^{2+} with a second redox peak emerging in the CV arising from ligand–metal complexation. This 'two-wave' behaviour is diagnostic of a large value ($> 10^4$) for the equilibrium constant for cation binding by the neutral (electrochemically unaltered) ligand.[12] Data comparing the redox behaviour of these systems in the presence of Mg^{2+} and Ca^{2+} ions are collated in Table 1. These ligands showed a significant binding enhancement[12] in the presence of Mg^{2+} and Ca^{2+} ions‡ and these data are quantitatively similar to those reported by Beer for the interaction of cations (Na^+, Li^+) with a macrocycle,

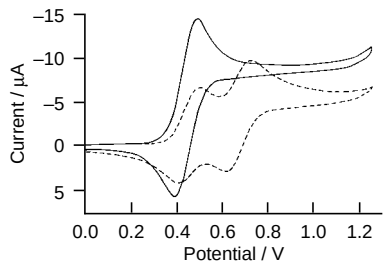


Fig. 1 Cyclic voltammogram of **1** in MeCN (———) and after the addition of $Mg(ClO_4)_2$ (0.2 equiv.) (- - - -)

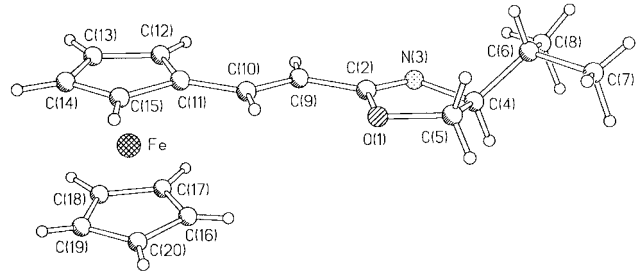

Fig. 2 X-Ray molecular structure of **5**

Table 1 Cyclic voltammetric data

Ligand/ M	$E^{\frac{1}{2}}_{free}$/ mV	$E^{\frac{1}{2}}_{complex}$/ mV	ΔE/ mV	min. equiv. M^{2+} [a]	max. equiv. M^{2+} [b]	K_1/K_2 [c]
1/Ca	490	—[d]		0.1	0.5

5/Mg	650	840	190	1	15	1.6×10^3

[a] Minimum equiv. of metal ClO_4^- salt required to produce a detectable second redox peak. [b] Equiv. of metal salt required for complete disappearance of original ligand redox peak (E free). [c] Binding enhancement for the complexation of a metal cation calculated using the equation in 12(*b*). The equilibrium constants K_1 and K_2 correspond to the complexation processes by the neutral and oxidised forms of the ligand. [d] A second redox peak was not observed; instead, an anodic drift occurred upon addition of Ca^{2+} which ceased when *ca.* 0.5 equiv. had been added. This behaviour is diagnostic of weak binding of the metal and the neutral ligand[12] and prevented the calculation of a binding enhancement.

monitored by changes in the cathodic electrochemistry of an appended anthraquinone substituent, although such systems do not often exhibit significant selectivity in the presence of other metals.[2a] Notably, compounds **1** and **2a** showed an identical affinity for Mg^{2+}, whereas only **2a** showed a strong affinity for Ca^{2+}. The presence of the isopropyl group in **2b** slightly increased the strength of binding of both Mg^{2+} and Ca^{2+} still further, presumably for electronic rather than steric reasons, whilst the amount of Mg^{2+} required to achieve a response was increased by a factor of 10 over that observed for **2a**: recognition of Ca^{2+}, however, suffered no such problem. For compound **5**, there was a considerably reduced anodic shift in the new redox peak and a lowering of the binding enhancement. The observed shift (160–190 mV) is consistent with the transmission of cation binding through a conjugated alkene link, with no contribution from a through-space effect.[3] System **5** required a considerably higher concentration of Mg^{2+} (15 equiv.) than the other ligands before the original ferrocene redox peak was lost.

Cation binding by systems **2a**, **2b** and **5** was also detected by changes in the UV–VIS spectra: on addition of Mg^{2+} or Ca^{2+} a new absorption peak appeared at lower energy. This was most striking for compound **5** which possesses an extended chromophore. Upon addition of $Mg(ClO_4)_2$ (1 equiv.) to a solution of compound **5** (10^{-3} M) in acetonitrile, the solution changed from pale yellow to purple, and the absorption peak of **5** at λ_{max} 449 nm entirely disappeared and was replaced by a new peak at λ_{max} 528 nm. For compounds **2a** and **2b** the colour change was less striking. For example, the absorption peak of **2b** at λ_{max} 446 nm in acetonitrile shifts to λ_{max} 472 nm on addition of $MgClO_4$ (1 equiv.): addition of more $Mg(ClO_4)_2$ gives no significant change in the spectra. A UV titration experiment suggested the formation of a complex of stoichiometry ligand : cation = 2 : 1. We presume that the electrochemical and spectrophotometric response observed for systems **2a**, **2b** and **5** arises from Mg^{2+} or Ca^{2+} coordination to the nitrogen atom of the substituent. The ligands can be recovered unchanged in *ca.* 60% yield from solutions containing the metal salts by aqueous workup.

We have discounted the fact that the electrochemical and spectrophotometric response is due to adventitious protonation or hydration of the ligands. The CV and UV–VIS spectra of ligands **2a** and **2b** in MeCN were unchanged by the addition of water to the solution. Protonation of the ligands (achieved by the addition of perchloric acid to the solution) was monitored by the appearance of a new redox wave at $E^{\frac{1}{2}}$ +680 mV (compound **2a**) and +980 mV (compound **2b**) which are decisively different potentials from those assigned to the metal complexes (Table 1). Moreover, ^{1}H NMR spectroscopic data supported these conclusions.¶

Oxazoline derivatives **2b** and **5** are chiral which may enable chiral recognition of magnesium-containing species, and may also offer a method for electrochemically modifying asymmetric reactions in which magnesium coordination plays a pivotal rôle.[13]

This work was funded by EPSRC (A. C.), Royal Society (L. M. G.) and the Leverhulme Trust (A. S. B.). We thank Dr C. J. Richards for details of the synthesis of **2a** and **2b** prior to publication of ref. 10(*c*).

† Experiments used the ligand (10^{-3} M) and $NBu^n_4ClO_4$ (0.1 M) in HPLC grade MeCN, *vs.* Ag/AgCl with a platinum working electrode. Sequential additions of aliquots of 0.1 or 0.5 equiv. of 10^{-2} M solutions of the appropriate metal salt in MeCN were monitored by CV.

‡ In the presence of 1–4 equiv. of Zn^{2+} [$Zn(ClO_4)_2$ or $ZnCl_2$] an anodic drift (maximum 60 mV) in the redox potential for compounds **1**, **2** and **5** was observed. Addition of traces of Mg^{2+} ions to these mixtures resulted in the immediate appearance of the second redox peak listed in Table 1.

§ *Crystal data*: $C_{18}H_{21}FeNO$, M = 323.21, orthorhombic, space group $P2_12_12_1$ (no. 19), a = 5.8828(4), b = 10.948(1), c = 24.274(2) Å, U = 1563.4(3) Å^3, Z = 4, T = 150 K, μ = 9.6 cm^{-1}, $2\theta \leqslant 55.8°$, 8017 total data, 2840 unique, 2569 observed [$I \geqslant 2\sigma(I)$]; R_{int} = 0.052 before, 0.038 after numerical absorption correction (seven faces, T_{min} = 0.81, T_{max} = 0.93); $wR(F^2)$ = 0.061; $R(F$, obs. data) = 0.028; residual $\Delta\rho_{max}$ = 0.18, $\Delta\rho_{min}$ = −0.25 e Å^{-3}; absolute configuration was determined by Flack parameter, x = −0.01(2). CCDC 182/757.

¶ The data for ligand **2b** are representative; the most diagnostic protons are those at the chiral centre (H_a), the methylene group adjacent to oxygen (H_b) and the unsubtituted Cp ring (H_c). For the free ligand in CD_3CN these protons appear at δ 3.97, 4.08 and 4.24, respectively. Addition of $KClO_4$ to this solution led to no change in the spectrum, whereas on addition of $Mg(ClO_4)_2$ (2 equiv.) the peaks shifted to δ 4.38, 4.81 and 4.46. ^{1}H NMR titration curves, monitoring the shifts of H_a, H_b and H_c upon addition of $Mg(ClO_4)_2$ support the UV–VIS and CV data in suggesting a stoichiometry of 2 : 1. The spectrum in the presence of Mg^{2+} was different from that of protonated **2b**.

2,2′-Dimethylbiphenyl-6,6′-dicarboxylic acid enforces two attached valine molecules to form up a chiral host lattice

Claus Weigand[a] Martin Feigel*[a]† and Claudia Landgrafe[b]

[a] Institut für Organische Chemie and [b] Institut für Analytische Chemie, Ruhr-Universität Bochum, Universitätsstr. 150, D-44780 Bochum, Germany

Crystals of (*R*)-valyl 2,2′-dimethylbiphenyl-6,6′-dicarboxylate 3 and (*S*)-valyl 2,2′-dimethylbiphenyl-6,6′-dicarboxylate 4 are stabilised by a network of inter- and intramolecular hydrogen bonds; together with the space requirement of the biphenyl core, structures result which contain cavities filled by THF (3) or EtOH molecules engaged in hydrogen bridging (4).

The regular structural motifs of proteins, β-strands and α-helices have been imitated using artificial amino acids. β-Sheets, β-turns or unusual helices have been targets of recent research.[1] Other examples are cyclic peptides of alternating chirality which aggregate to dimers in the form of antiparallel or parallel β-sheets.[2] We used an organic dicarboxylic acid as spacer to provide the optimal geometry for a parallel β-sheet.[3] However, the active centers of natural peptide oligomers as the enzymes or catalytic antibodies[4] are often located in regions of irregular peptide conformations. While it may be very difficult to design such active centers from scratch it is promising to study organic spacer units which hold attached peptide chains in divergent directions so that regular sheets or helices cannot be formed by self-association. Here, we report the synthesis and the solid state structure of two small peptides where biphenyldicarboxylic acid **2** is used as nucleation point of an irregular peptide structure.

Methyl 2-iodo-3-methylbenzoate **1** was prepared from *m*-toluic acid.[5] The biaryl coupling forming the dimethyl ester of **2** was achieved in high yields using a specially activated copper catalyst (Scheme 1). (*S*)-**2** was isolated from the brucine salt of the carboxylic acid. The peptide coupling of (*S*)-**2** with 2 equiv. of (*R*) or (*S*)-valine methyl ester yields **3** and **4** (after hydrolysis of the valine ester groups) in almost quantitative yield. Diethyl cyanophosphonate was used for the sterically demanding peptide coupling.[6]

Crystals of **3** and **4** were grown from THF–EtOH and from EtOH. They contain THF and EtOH guest molecules. The X-ray determined solid state structures‡ of **3** and **4** shows that the attachment of four substituents in the *o*,*o*′-positions of the biphenyl core results in a divergence of the two peptide chains by almost 90° (Fig. 1).

The unit cell of **4** contains two different molecules with slightly different orientation of the valine side-chains. The dihedral angles ϕ in the peptide chains A and B of **3** and **4** [A(**3**): ϕ = 112.2°, B(**3**): ϕ = 121.7°, A(**4**)/A′(**4**): ϕ = −67.3/−93.4°, B(**4**)/B′(**4**): ϕ = −116.8/−137.4°] belong to regions of the Ramachandran diagram were extended and helical peptide structures have been located[6] (note the change in sign with the chirality of the amino acid). The biphenyl core obviously does not enforce energetically disfavoured geometries in attached peptides.

In both structures, an intramolecular hydrogen bond is formed between the Val-NH proton of one peptide chain (A) and the biphenylic-carbonyl oxygen of the other chain B. The chains A and B are however identical in the NMR spectra of **3** and **4** in DMSO at 30 °C. Even low temperature spectra of the corresponding dimethyl esters in $CDCl_3$ (−40 °C) contain only one set of signals for both peptide chains. So it can be assumed

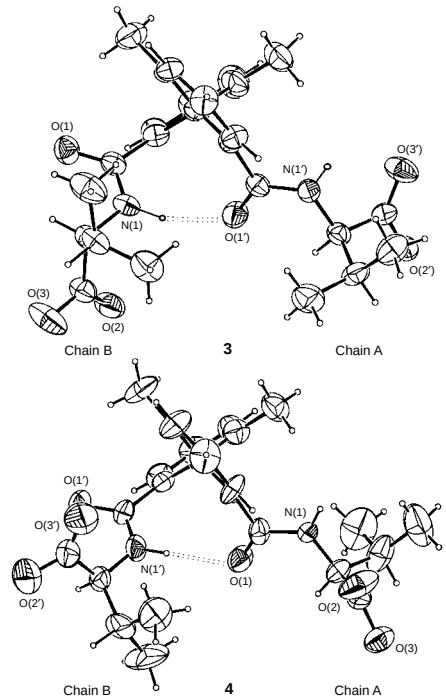

Fig. 1 ORTEP plot of the molecules **3** and **4** in the solid state. Both compounds develop the same intramolecular hydrogen bond, but the orientation of the valine side-chains is different.

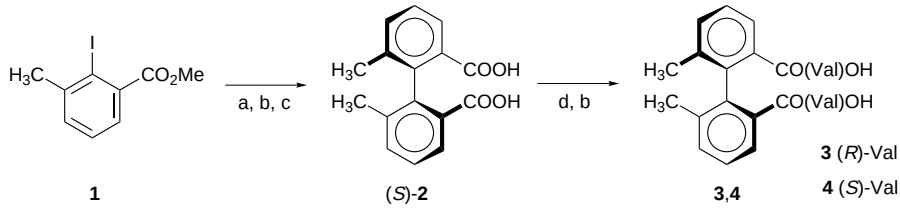

Scheme 1 *Reagents and conditions*: (*a*) **1** (10 g), dendritic copper (Aldrich, 3 μ, 6 g), DMF (20 ml), 150 °C; distill. 92%: (*b*) KOH, EtOH, H_2O (60 °C) then HCl, quant.: (*c*) acetone, MeOH, brucine, 40% (*S*)-**2**, see ref. 5: (*d*) D (or L)-valine methyl ester, diethyl cyanophosphonate, triethylamine, DMF, 90–92%

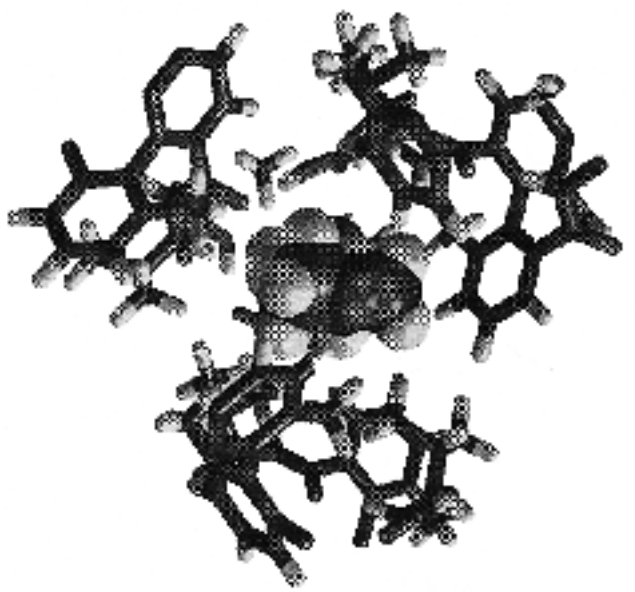

Fig. 2 Coordination of THF (drawn as CPK model) in the solid state structure of **3** (drawn as tubes). A second disordered THF molecule can be seen behind the THF in front.

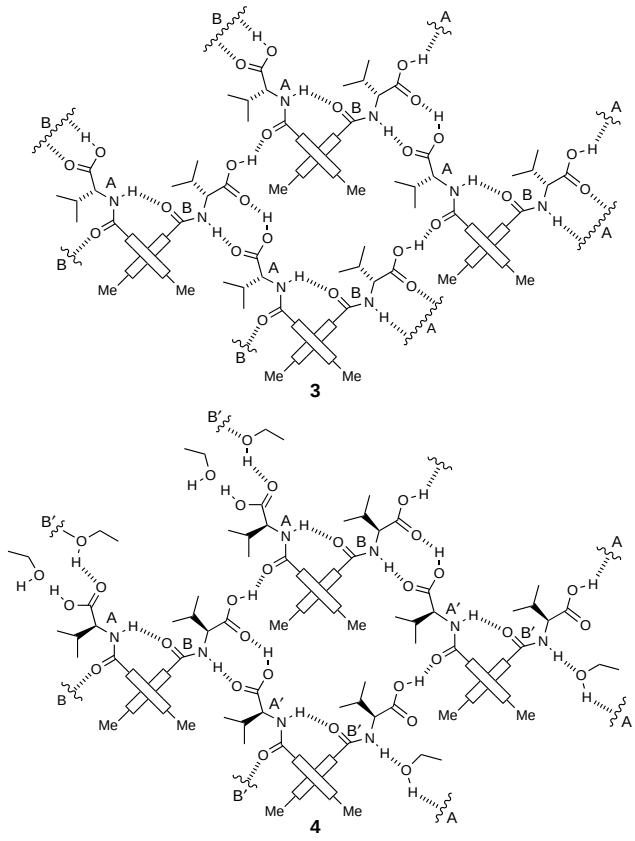

Fig. 3 Schematic two dimensional drawing of the hydrogen bond network in the solid state structure of **3** and **4**. The structure of **4** contains an EtOH molecule disordered over two sites.

that the chains A and B interconvert rapidly on the NMR timescale if the solid state conformation persists in solution.

The crystal lattice of **3** encapsulates THF molecules at two different positions. The THF guests are surrounded by a lipophilic environment of aromatic CH groups and CH_3 groups of valine and of the biphenyl unit (Fig. 2) One of the THF molecules is disordered (site occupation factor = 0.5) and fills only every second position available.

Whereas the conformations of the peptide chains differ in **3** and **4** (see above and Fig. 1), both molecules have an almost identical network of intermolecular hydrogen bonds (see Fig. 3). The carboxylic groups do not form carboxylic acid dimers but are engaged in hydrogen bonding to the amide groups. The carboxylic OH group of chain B is in contact with the CO group at the biphenyl core of chain A building an infinite structure of hydrogen bonded molecules (in **3** and **4**). The carboxylic group of chain A uses the HN–Cα–CO unit of chain B to build up another strand of hydrogen bonds almost orthogonal to the first one. Compound **4** uses EtOH molecules to complete this second strand of hydrogen bonds.

The biphenyl core **2** serves as a molecular cross for attached peptides. The intra- and inter-molecular hydrogen bonds found in the solid state structure of **3** and **4** do not resemble the common β-sheets or helical structures of peptides. Biaryl diacids are known to form inclusion complexes with several organic guests.[8] The peptides in **3** and **4** obviously do not reduce this tendency and may be ideal tools to alter the properties of these cavities. We are looking forward to synthesising host–guest lattices of biphenyl peptides containing longer peptide chains.

Single-feed one-step block copolymerization of *n*-octyloxyallene with phenylallene using π-allylnickel as initiator

Koji Takagi,[a] Ikuyoshi Tomita[b]† and Takeshi Endo*[a]

[a] *Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta 4259, Midori-ku, Yokohama, 226-8502 Japan*

[b] *Department of Electronic Chemistry, Interdisciplinary Graudate School of Science and Engineering, Tokyo Institute of Technology, Nagatsuta 4259, Midori-ku, Yokohama, 226-8503 Japan*

The π-allylnickel initiated block copolymerization of *n*-octyloxyallene and phenylallene takes place in one step from a single-feed mixture of the two monomers.

The living polymerization technique is the most prominent method to obtain well-defined block copolymers.[1] Generally, two monomers are fed stepwise as the polymerization progresses, except in a few examples. Saegusa *et al*. reported the 'one-shot block copolymerization' of 2-alkyl-2-oxazoline with 2-perfluoroalkyl-2-oxazoline,[2] which involves the change of the propagating species from the ionic to the covalent form. Feast *et al*. also reported the successful one-shot block copolymerization of *syn*- and *anti*-7-methylnorbornene using a Schrock molybdenum alkylidene initiator,[3] where the large difference in polymerizability of the two monomers assisted the block copolymerization.

Herein, we describe the π-allylnickel complex initiated block copolymerization of *n*-octyloxyallene **2** with phenylallene **3** in one step from a single-feed mixture of the two monomers[4,5] (Scheme 1).

A mixture of **2** and **3** (50 equiv. each) was added to a toluene solution of $[(\pi\text{-allyl})NiOCOCF_3]_2$ **1** and the polymerization was performed for 12 h. As a result, a copolymer (M_n = 20 100, M_w/M_n = 1.15) was obtained in 94% yield, whose composition was poly(**2**):poly(**3**) = 49 : 51 (determined by ^{1}H NMR spectroscopy) in good accordance with the monomer feed ratio. The monomer conversion, determined by GC, gave interesting information on the copolymerization process (Fig. 1).†

The specific consumption of **2** took place at the initial stage of the polymerization, meanwhile **3** was not converted at all. However, when **2** had been consumed completely, the slow polymerization of **3** started to give a copolymer with a high block sequence. By quenching the copolymerization of **2** with **3** (50 equiv. each) in the initial stages (*i.e.* at 0 °C for 10 min) by pouring the reaction mixture into large amount of MeOH–H_2O (1 : 1), a polymer (M_n = 9450, M_w/M_n = 1.15) was obtained in 54% yield, which was composed solely of a poly (**2**) segment (determined by ^{1}H NMR spectroscopy).[6] This experiment also supports the efficient formation of a block copolymer.

The unexpected formation of the block copolymer cannot be explained fully by the difference in polymerization rate of the two monomers [k_{obs} (**2**) = 9.94×10^3 and k_{obs} (**3**) = 0.14×10^3 l mol^{-1} h^{-1}; k_{obs} (**2**)/k_{obs} (**3** = *ca.* 70]. The observed kinetic coefficient of **2** is not influenced by **3**, because k_{obs} (**2**) in the early stage of the copolymerization (9.94×10^3 l mol^{-1} h^{-1}) is comparable to that in the homopolymerization of **2**. The result clearly indicates that the concentration of the active species (most probably the nickel complex coordinated with **2**) is not affected by **3**. Namely, it can be taken to mean that the coordination equilibrium of the nickel complex with the monomers is shifted considerably to coordinated with **2** in the copolymerization, which promotes the specific polymerization of **2** in the initial stages. Further work on the copolymerization of various monomer combinations and a mechanistic investigation are in progress.

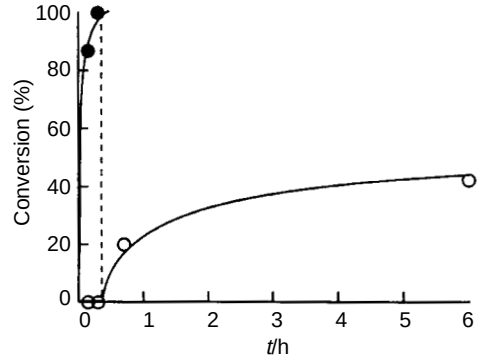

Fig. 1 Time *vs*. conversion curves for (●) **2** and (○) **3** in the copolymerization by **1** at 0 °C ($[\mathbf{2}]_0 = [\mathbf{3}]_0 = 5.0 \times 10^{-2}$ M, [Ni] = 1.0×10^{-3} M)

Notes and References

† E-mail: itomita@res.titech.ac.jp

‡ Estimation of the kinetic coefficients (typical procedure): The copolymerization of **2** with **3** ($[\mathbf{2}]_0/[Ni] = [\mathbf{3}]_0/[Ni]$ = 50, [Ni] = 1.0×10^{-3} M) by **1** was performed at 0 °C in toluene containing *n*- tetradecane (2.0×10^{-3} M) as an internal standard. After designated reaction periods, a small portion of the reaction mixture was sampled with the syringe (*ca.* 10 μl) and the monomer conversions were estimated by GC analysis.

Dioxygenase-catalysed *cis*-dihydrodiol formation in the carbo- and hetero-cyclic rings of quinolines

D. R. Boyd,*[a]† N. D. Sharma,[a] J. G. Carroll,[a] J. F. Malone,[a] D. G. Mackerracher[a] and C. C. R. Allen[b]

[a] *The School of Chemistry, The Queen's University of Belfast, Belfast, UK BT9 5AG*
[b] *The QUESTOR Centre, The Queen's University of Belfast, Belfast, UK BT9 5AG*

Evidence of enzyme-catalysed *cis*-dihydroxylation in the pyridine (3,4-bond) and benzene rings (5,6- and 7,8-bonds) of quinoline and 2-substituted quinolines is examined in light of the isolation of a heterocyclic *cis*-diol derivative of 2-quinolone, as a single enantiomer of opposite absolute configuration to that found for the enantiopure carbocyclic *cis*-diol metabolites from quinolines.

Dioxygenase-catalysed *cis*-dihydroxylation of arenes to yield the corresponding carbocyclic *cis*-dihydrodiol metabolites is well-established in the mono- and poly-cyclic aromatic hydrocarbon series.[1] Recently the first *cis,trans*-dihydrodiol metabolites from a heterocyclic aromatic ring, *e.g.* thiophene, benzothiophene and benzofuran, were isolated using the toluene-dioxygenase (TDO) system present in a mutant strain of the bacterium *Pseudomonas putida* UV4.[2,3] To date, however, no direct evidence for the formation of a *cis*-dihydrodiol metabolite from a pyridine ring has been reported. Indeed, the mechanism of bacterial metabolism of pyridine rings is not clearly understood.[4]

As part of an earlier study of the bacterial metabolism of bicyclic azaarenes using *P. putida* UV4, *cis*-dihydroxylation of the carcinogen quinoline **1** was observed to occur at the carbocyclic ring to yield *cis*-dihydrodiols **2** and **3** in very low yields (Scheme 1).[5] The major metabolites formed in the pyridine ring of **1** were 3-hydroxyquinoline and anthranilic acid. The phenolic metabolite was postulated to be derived from the initially formed unstable *cis*-dihydrodiol **5** of unknown absolute configuration,[5] while anthranilic acid could have been derived from either **5** or **4**. Previous studies[6] of the metabolism of **1** with different strains of *P. putida, P. fluorescens* and a *Rhodococcus* species did not indicate the formation of any *cis*-dihydrodiols, *e.g.* **2** or **3**, but reported oxidation of the pyridine ring to yield **4**.

Encouraged by the recent isolation of *cis*-dihydrodiol metabolites of five-membered aromatic heterocycles[2,3] and of 3-hydroxyquinoline (from bacterial metabolism of **1**),[5] a new approach to obtain direct evidence of *cis*-diol formation in a pyridine ring was sought. It was assumed that our earlier, unsuccessful, efforts to isolate the *cis*-diol **5** from **1** was due to its instability, and to competition from oxidation at position 2 in the pyridine ring yielding **4** and anthranilic acid. To test this assumption the alternative approach of using 2-substituted quinolines **7** and **10** as substrates was adopted. It was hoped that the chloro and methoxy groups present at the 2-position might be readily replaced by OH groups as a result of spontaneous hydrolysis of the initial unstable *cis*-dihydrodiol metabolites **13** and **14**, respectively, to yield the more stable *cis*-diol **6** (Scheme 1). Furthermore it was anticipated that substitution would block oxidation at the 2-position and formation of **4**, thus increasing the yields of other metabolites. Oxidation at C-2 is a common initial step in the bacterial metabolism of quinoline *via* either the 'coumarin' or '*meta*-cleavage' pathways.[4,6]

Addition of **7** to growing cultures of *P. putida* UV4 yielded two carbocyclic *cis*-dihydrodiols **8** (R_f 0.3, 8%) and **9** (R_f 0.45, 30%) as major metabolites (Scheme 1) which were separated using PLC (MeOH–$CHCl_3$, 7 : 93). Formation of the cyclic boronate derivatives using (*S*)-(−)- and (*R*)-(+)-2-(1-ethoxyethyl)phenylboronic acid (MPBA)[7] and their ^{1}H NMR analysis proved that *cis*-dihydrodiols **8** and **9** were both enantiopure, *i.e.* ⩾98% ee. The absolute configurations of the *cis*-dihydrodiols **8** (5*R*,6*S*) and **9** (7*S*,8*R*) were established by comparison of CD spectra and by stereochemical correlation with the corresponding *cis*-dihydrodiols **2** and **3** of known configuration[5] (Table 1).

On the basis of NMR, mass and IR spectroscopy and elemental microanalysis, the least abundant (2%) and most polar metabolite **6** (R_f 0.14) proved to be a *cis*-diol ($J_{3,4}$ = 3.7 Hz) within a δ-lactam ring. The enantiopurity (⩾98% ee) of diol **6** was determined by formation of a monocamphanate derivative from esterification of the hydroxy group at C-4. The structure, relative configuration and absolute configuration of

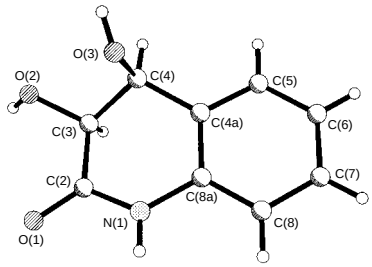

Fig. 1 Crystal structure of metabolite **6**

cis-diol **6** was established by X-ray crystal structure analysis.‡ The preferred conformation of **6** in the crystalline state (Fig. 1) contains the OH groups at C-3 and C-4 in pseudo-equatorial and -axial positions, respectively. The (3*S*,4*S*) absolute configuration deduced from the X-ray study was confirmed by stereochemical correlation with **15** (Scheme 1) which, in turn, has been correlated to the known configuration of the 2-methoxy-2-trifluoromethyl-2-phenylacetate (MTPA) ester derivative **16**.[8] In solution the OH group at C-3 could not be readily converted to a TBDMS ether or camphanate ester derivative, suggesting that *intramolecular* H-bonding to the amide C=O might be present. In the solid state, however, only *intramolecular* H-bonding was observed, each molecule being involved in a total of six H-bonding interactions to three different neighbours. Diol **6** proved to be remarkably stable compared with *cis*-dihydrodiols **2**, **3**, **8** and **9**. Thus while the latter compounds were found to aromatise under acidic conditions (dilute HCl), **6** remained unchanged. An earlier report on the bacterial metabolism of **7** described only the formation of a single *cis*-dihydrodiol **9** in the carbocyclic ring of unspecified ee and absolute configuration.[9]

Addition of **10** as substrate to *P. putida* UV4 also yielded two carbocyclic *cis*-dihydrodiols, **11** (R_f 0.30, 2%) and **12** (R_f 0.4, 7%) (Scheme 1). Similar stereochemical analysis methods to those used for **8** and **9** (NMR and CD spectroscopy) again showed that single enantiomers of configuration indicated in Table 1 [(5*R*,6*S*) and (8*R*,7*S*), respectively] had been formed. The more abundant (13%) and more polar *cis*-diol metabolite from **10** was found to be of identical structure, ee and absolute configuration [(3*S*,4*S*)] to **6** derived from **7**. The optical rotations and absolute configurations of **6**, **8**, **9**, **11** and **12**, and the derived monol **15**, are shown in Table 1.

The formation of the stable (3*S*,4*S*) enantiomer of *cis*-diol **6** as a bacterial metabolite from both **7** and **10** may be explained by a metabolic sequence involving (i) stereoselective *cis*-dihydroxylation to yield the unstable diols **13** and **14**, respectively, and (ii) hydrolysis to yield the stable diol **6** [Scheme 1, path (*a*)]. However, past work on the dioxygenase-catalysed *cis*-dihydroxylations of a range of carbocyclic and five-membered heterocyclic arenes had shown an exclusive or marked preference for the opposite absolute configuration (*e.g.* *cis*-diols **8**, **9**, **11** and **12**), which could be considered as the normal absolute configuration for arene *cis*-diols.

Based on several additional observations an alternative sequence involving partial hydrolysis of substrates **7** and **10** to yield **4**, followed by dioxygenase-catalysed *cis*-dihydroxylation to yield *cis*-diol **6**, appears to be more plausible [Scheme 1, path(*b*)]. Thus, traces of **4** were detected (using GC–MS and ^{1}H NMR analysis) during the biotransformation of **10**, and when **4** was added to *P. putida* UV4 under the normal biotransformation conditions, *cis*-diol **6** (10% isolated yield) of identical ee and absolute configuration to that obtained from **7** and **10** was isolated as a metabolite.

The (3*S*,4*S*) absolute configuration of *cis*-diol **6** derived from the TDO-catalysed dihydroxylation of the pyridine ring in **4**, **7** and **10** seems to be abnormal when compared with that found during TDO-catalysed *cis*-dihydroxylation of arenes in general. The opposite absolute configuration had been observed for the *cis*-diol metabolites of a series of benzocycloalkenes, *e.g.* 1,2-dihydronaphthalene, and the heterocyclic analogues, *e.g.* chromene and thiochromene, using the TDO biocatalyst.[1] The (3*S*,4*S*) configuration of *cis*-diol **6** would be expected if the substrates **7** and **10** were to undergo partial hydrolysis to yield **4**, and if it were to be accepted as a benzocycloalkene-type substrate by the TDO system.

Enzyme-catalysed oxidation of pyridine rings containing alkyl,[4] aryl[8] and thioalkyl substituents[10] has generally been found to occur at the exocyclic substituents, indicating that *cis*-dihydroxylation of a pyridine ring is not a preferred metabolic step, and hence the formation of the *cis*-diol **6** appears to be unusual. Although the formation of compound **6** is still consistent with either TDO-catalysed *cis*-dihydroxylation of the 2-substituted quinoline substrates **7** and **10** [Scheme 1, path (*a*)] or the derived 2-quinolone **4** [Scheme 1, path (*b*)], the currently available evidence is strongly in favour of the latter pathway.

We thank the BBSRC (N. D. S.) and the Queen's University Environmental Science and Technology Research (QUESTOR) Centre (C. C. R. A., J. C.) for financial support, and Eric Becker (Mannheim) and David Clarke (QUESTOR) for valuable assistance with the biotransformations.

Synthesis of pentaarabinofuranosyl structure motif A of *Mycobacterium tuberculosis*

Hari Babu Mereyala, Srinivas Hotha and Mukund K. Gurjar

Indian Institute of Chemical Technology, Hyderabad 500 007, India

The first synthesis of motif A, the branched chain arabinofuranosyl pentasaccharide [t-β-Ara*f*-(1 → 2)-α-D-Ara*f*]$_2$-3,5-α-D-Ara*f*-(1 → 5) which constitutes the major humoral immunological epitope in the arabinogalactan cell wall of *Mycobacterium tuberculosis* is described.

Tuberculosis (TB) continues to affect developing countries as 8 000 000 new cases and 3 000 000 deaths occur every year.[1] As a consequence of the HIV epidemic, the occurrence of TB particularly in developed countries has risen sharply. The etiological agent, *Mycobacterium* (*M.*) *tuberculosis* has been extensively investigated and Fig. 1 represents a schematic diagram of macro structural motifs (A–E) of cell wall arabinogalactan.[2a] The fine structure of the cell wall of mycobacteria allows us to understand drug and solute impenetrability, antigen processing and presentation by accessory cells, and aspects of immunopathogenesis. The structurally unusual and biologically significant arabinofuranosyl residue of motif A (**1**, Fig. 1) is responsible for the antigenicity of arabinogalactan.[2a] It is speculated that, in part or complete, structural motif A is the major humoral immunological epitope of arabinogalactan *vis a vis* whole mycobacteria.[2d] Our interest in the chemistry of compounds derived from *M. tuberculosis* has previously resulted in the synthesis[3] of oligosaccharide fragments of glycolipids and glycopeptide cell wall segments. In this report, we communicate the first synthesis of the branched chain arabinofuranosyl pentasaccharide [t-β-Ara*f*-(1 → 2)-α-D-Ara*f*]$_2$-3,5-α-D-Ara*f*-(1 → 5) which forms the crucial part of structural motif A of the *M. tuberculosis* cell wall.

Synthesis of **1a** was initiated from D-arabinose which was transformed into 5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-(propane-2,2-diyl)-β-D-arabinofuranose (**2**) in two steps.[4] Subsequent desilylation using Bu$^n_4$NF in THF at ambient temperature gave 1,2-*O*-(propane-2,2-diyl)-β-D-arabinofuranose (**3**).[5] Reaction of **3** with NaH–BnBr in DMF protected both the hydroxy groups to afford the 3,5-di-*O*-benzyl derivative **4**. Conversion of **4** into the *n*-pentenyl glycoside was effected with pent-4-en-1-ol in the presence of TsOH to obtain a 1 : 1 anomeric mixture of α,β-*n*-pentenyl glycosides (**5** and **6**) which were separated by silica gel column chromatography (Scheme 1). In another sequence,

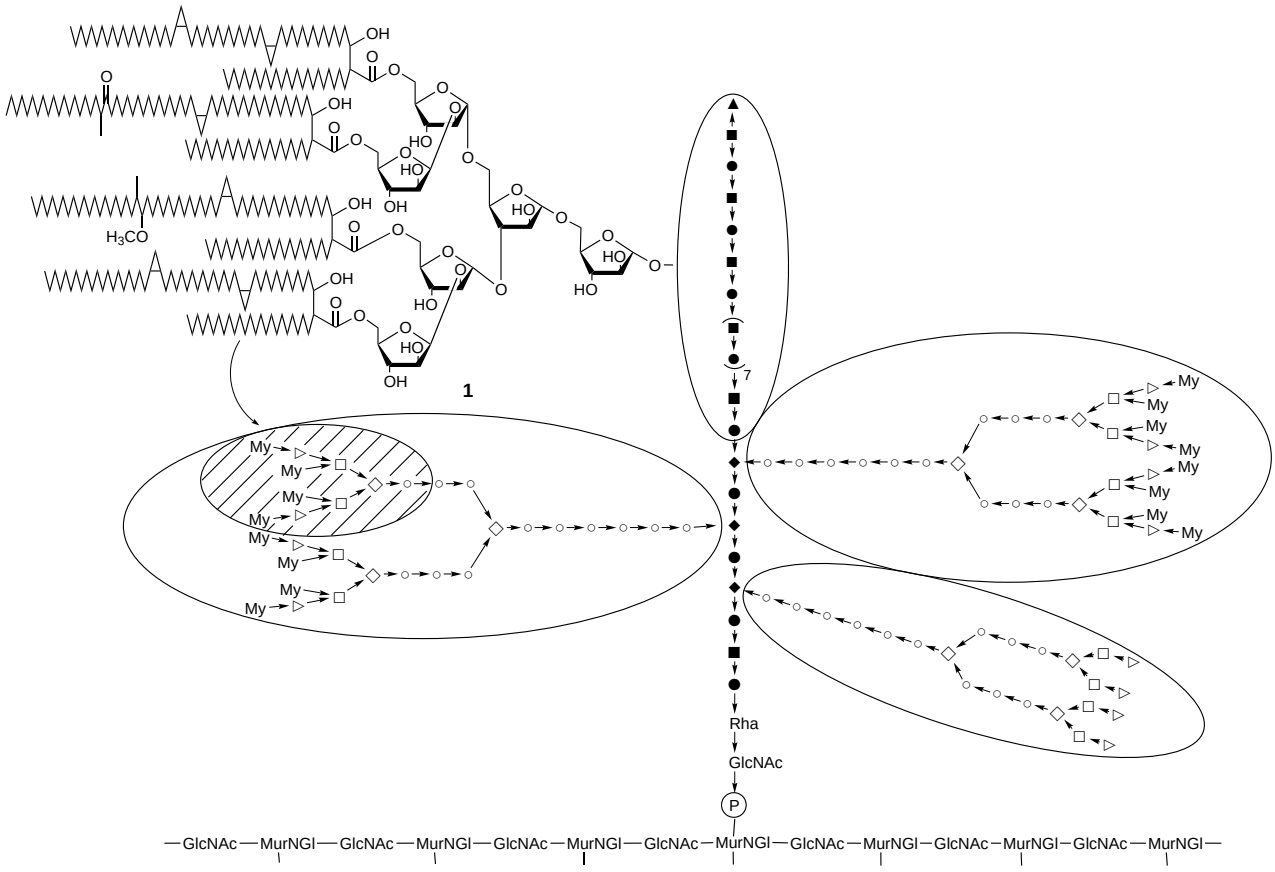

Fig. 1 Schematic diagram of the proposed illustration of the macro structural motifs of the cell wall arabinogalactan. My, Mycolic acid; (▼) t-β-D-Ara*f*; (□) 2-α-D-Ara*f*; (◇) 3, 5-α-D-Ara*f*; (▲) t-β-D-Gal*f*; (■) 6-β-D-Gal*f*; (●) 5-β-D-Gal*f*; (◆) 5,6-β-D-Gal*f*; GlcNAc, *N*-acetylglucosamine; Rha, rhamnose; MurNGl, *N*-glycolylmuramic acid.

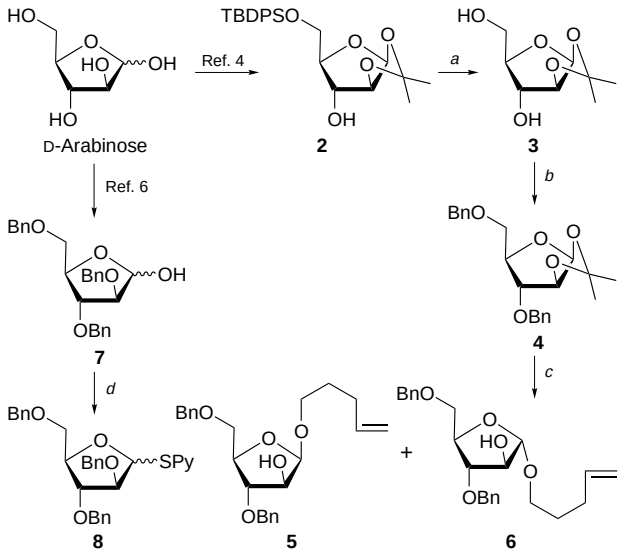
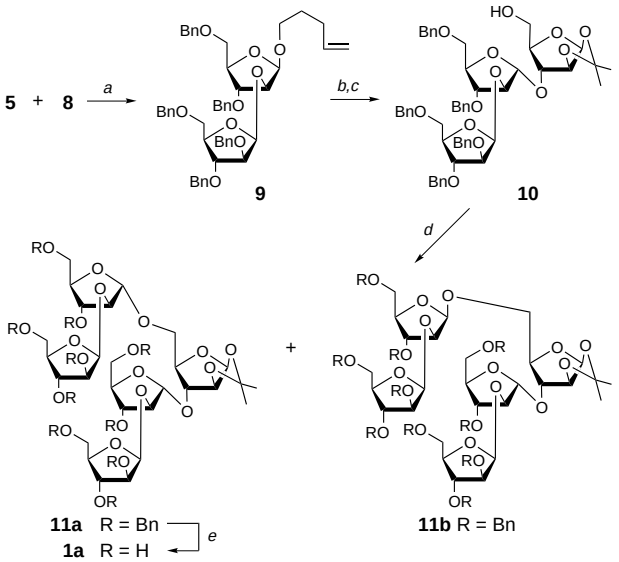


Scheme 1 *Reagents and conditons*: (*a*) Bu^n_4NF, THF, room temp., 2 h, 96%; (*b*) NaH,BnBr, DMF, 0 °C–room temp., 83%; (*c*) Pent-4-en-1-ol, TsOH, CH_2Cl_2, 60 °C, 2 h, 85%; (*d*) PySSPy, Bu^n_3P, CH_2Cl_2, room temp., 30 min, 98%

2,3,5-tri-*O*-benzyl-α,β-D-arabinofuranose (**7**)[6] was transformed into the corresponding *S*-(2-pyridyl)-1-thiofuranoside **8** by reacting with 2,2′-dithiodipyridyl and Bu^n_3P in CH_2Cl_2.[7]

The coupling reaction of **5** with **8** was promoted[8] by the protocol developed in our laboratory, according to which 5% MeI in dry CH_2Cl_2 was used as an activator to give the β-disaccharide **9**. Its structure was confirmed by ^1H and ^{13}C NMR spectroscopy (Scheme 2).

The *O*-glycosylation of **2**[4] with the above formed *n*-pentenyl disaccharide **9** was induced in the presence of iodonium dicollidine perchlorate (IDCP)[9] in CH_2Cl_2, followed by desilylation of the coupled product with Bu^n_4NF in THF, resulted in the isolation of the trisaccharide **10** whose newly formed glycosidic linkage was confirmed as having an α-configuration by the ^1H NMR spectrum. For example, the characteristic resonances due to H-1′ was located at δ 5.05 as a singlet, whereas H-1 and H-1″ protons appeared as doublets at δ 4.90 and 5.75, respectively, as expected for β-anomeric configurations. In addition, the ^{13}C NMR spectrum of **10** showed resonances due to anomeric carbons at $\delta_{C\text{-}1}$ 100.1, $\delta_{C\text{-}1'}$ 105.3 and $\delta_{C\text{-}1''}$ 105.5.



Scheme 2 *Reagents and conditions*: (*a*) 5% MeI in CH_2Cl_2, 57 °C, 4 Å MS powder, 15 h, 69%; (*b*) IDCP CH_2Cl_2, 4 Å MS powder, 24 h, 62%; (*c*) Bu^n_4NF, THF, room temp., 3 h, 95%; (*d*) I(*s*-Collidine)$_2ClO_4$, CH_2Cl_2, 4 Å MS powder, 12 h, 70%; (*e*) $Pd(OH)_2$/C, MeOH,H_2, room temp., 12 h, 97%

The OH group at C-5 of compound **10** was glycosylated again with donor **9** under the conditions reported above. However, in this reaction, a 3 : 2 mixture of α- and β-pentasaccharides (**11a** and **11b**) was formed. The major α-anomeric product (**11a**) was isolated by silica gel column chromatography, hydrogenolysis of which over $Pd(OH)_2$/C at normal temperature and pressure for 12 h gave the required pentasaccharide **1a**. The structure of **1a** was fully characterised by ^1H, ^{13}C NMR and FABMS analysis.[9]

In conclusion it is pertinent to mention that resistance to the current regime of anti-TB drugs is developing rapidly and therefore there is a constant need to discover new drugs. It is reported that (*S*,*S*)-ethambutol inhibits arabinan biosynthesis and therefore the arabinan segment of the cell wall provides an attractive target for development of new drugs because of the xenobiotic status of the human host. The present synthesis of the pentaarabinofuranoside of structure motif A of *M. tuberculosis* cell wall opens a new vista in this direction.

S. H. thanks CSIR, New Delhi, for a Junior Research Fellowship.

Catalytic selective cleavage of a strong C–C single bond by rhodium in solution

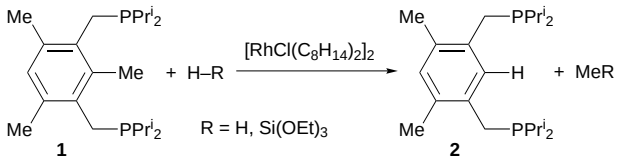
Shyh-Yeon Liou, Milko E. van der Boom and David Milstein*†

Department of Organic Chemistry, The Weizmann Institute of Science, Rehovot 76100, Israel

Reaction of $[RhCl(C_8H_{14})_2]_2$ with an excess of the diphosphine 1,3-bis(diisopropylphosphinomethylene)mesitylene 1 in dioxane under mild H_2 pressure (25 psi) or with an excess of $HSi(OEt)_3$ results in catalytic selective cleavage of a strong C–C single bond.

Activation and functionalization of strong C–C single bonds by soluble transition metal complexes is of considerable current interest.[1–6] Most challenging is the search for the underlying mechanisms and homogeneous catalysis based on such relatively inert bonds. While several examples of homogeneous catalytic activation of C–H bonds of hydrocarbons are known,[2] the few reports of catalytic C–C bond activation in solution are limited to weak C–C bonds α to a carbonyl group,[3] strained systems,[4] or a combination of both.[5] Selective transition metal insertion into a strong, unstrained C–C single bond in solution and details related to the mechanism were reported by us only recently.[6] We report here on the catalytic hydrogenolysis and hydrosilylation of a strong sp^2–sp^3 C–C bond. This rhodium catalyzed process is unprecedented, occurs under homogeneous reaction conditions and is highly selective.

Reaction of $[RhCl(C_8H_{14})_2]_2$ (C_8H_{14} = cyclooctene) with 50 equiv. of the phosphine substrate **1** under mild H_2 pressure (25 psi; 1 psi ≈ 6.894757×10^3 Pa) in dioxane at 180 °C for one day leads to catalytic formation of the demethylated phosphine **2** and CH_4 (Scheme 1; 16 turnovers based on rhodium and 32% yield). The CH_4 was collected by standard vacuum line techniques and was identified and quantified by GC. Compound **2** was identified spectroscopically by various NMR and MS techniques and by comparison with an added authentic sample.[6b] Reactions were also performed in [$^2H_8$]dioxane to record ^1H, $^{13}C\{^1H\}$, ^{13}C-DEPT-135 and $^{31}P\{^1H\}$ NMR spectra. Formation of product **2** is highly selective, the other two arylmethyl groups remaining unaffected and no other organic products were formed. Addition of another 50 equiv. of **1** to the reaction mixture and applying the same reaction conditions resulted in another 15 turnovers, demonstrating that the catalyst remains active. Similar results were obtained by performing the reaction for two days with 100 equiv. of **1** (31 turnovers and 31% yield). Using 500 equiv. of substrate **1** leads to 106 turnovers after three days. The hydrogenolysis proceeds also at lower temperatures (150 °C), but it is much slower, leading to only 15 turnovers after one week.

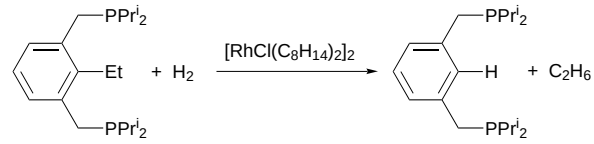


1 **2**

Scheme 1

To probe the possibility of catalytic hydrosilylation of a C–C single bond, we used an excess of $HSi(OEt)_3$ instead of H_2. Reaction of $[RhCl(C_8H_{14})_2]_2$ with 50 equiv. of **1** and an excess of $HSi(OEt)_3$ in dioxane (or toluene) at 150 °C for two days resulted in 10 turnovers to form **2** and $MeSi(OEt)_3$ (Scheme 1), which were unambiguously characterized by ^1H, $^{13}C\{^1H\}$, ^{13}C-DEPT, $^{29}Si\{^1H\}$ NMR and by GC–MS.[6b] Thus, catalytic transfer of a CH_2 group from an arene to a silane was observed. Again the reaction is completely selective.

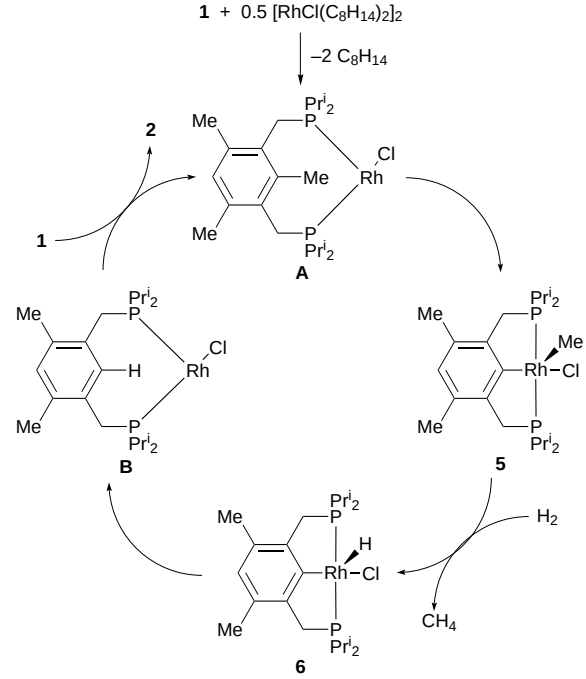
Reaction of 50 equiv. of the ethyl aromatic phosphine **3** with $[RhCl(C_8H_{14})_2]_2$ at 180 °C under mild H_2 pressure in dioxane for 3 days resulted in formation of compound **4** and C_2H_6, although only 4 turnovers were obtained (Scheme 2). Compound **4** was fully identified by comparison with an authentic sample. The expected amount of C_2H_6 was observed by GC analysis of the gas phase. Control reactions showed that **1** and **3** were stable under the same reaction conditions in the absence of rhodium.



3 **4**

Scheme 2

A postulated catalytic cycle is outlined in Scheme 3. The high selectivity of the catalytic processes, only one alkyl group being affected, provides strong evidence that both phosphines are coordinated to the metal centre prior to the C–C bond activation. Intermediates such as **A** have been observed with platinum and ruthenium.[7] At this stage competitive C–H and C–C oxidative addition might occur.[6f] C–H activation would result in the reversible formation of a benzylic rhodium species.[6] Metal insertion into the strong Ar–C bond was observed in a stoichiometric reaction of **1** (0.031 mmol) with 0.5 equiv. of $[RhCl(C_8H_{14})_2]_2$ in [$^2H_6$]benzene (2 ml) in a sealed tube for 2 h



Scheme 3 Proposed catalytic hydrogenolysis cycle for **1** with rhodium

at room temperature. ^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR analysis of the reaction solution showed the formation of **5** in 75% yield. The Rh–Me group is clearly observed in the ^{13}C{^{1}H} NMR at δ −4.3 [dt, ^1J(RhC) 30.2, ^2J(PC) 6.4 Hz] and the *ipso* carbon at δ 166.7 [dt, ^1J(Rh, C) 33.6, ^2J(PC) ≈ 1.0 Hz]. An isostructural rhodium(III) complex was recently fully characterized by X-ray analysis.[6f]

Subsequently, complex **5** reacts with H_2 to yield complex **6**. Indeed, reaction of **5** with H_2 (25 psi) at 80 °C for 1 day and analysis by ^{1}H, ^{31}P{^{1}H}, ^{13}C{^{1}H} NMR, IR and GC analysis showed the quantitative formation of complex **6** and CH_4.§ This reaction may proceed through a rhodium(V) intermediate or *via* σ-bond metathesis. Complex **6** can also be used as catalyst under the same reaction conditions. Release of the aryl phosphine **2** from **6** probably proceeds *via* **B**, which undergoes phosphine exchange with substrate **1** giving back **A**. This is likely to be the rate-determining step. Such a process was demonstrated by treating a dioxane solution of complex **6** with 20 equiv. of PEt_3 at 80 °C overnight, which resulted in formation of the PCP ligand **2** and $RhCl(PEt_3)_3$ by phosphine exchange. Replacement of a cyclometalated terdentate diamino ligand of a ruthenium(II) complex by a phosphorus analogue was reported very recently.[7b] The liberated arene **2** most probably strongly competes with substrate **1**, slowing down the catalytic process. It is well known that α,α′-diphosphine-*m*-xylenes such as **2** and **4** undergo readily Ar–H oxidative addition with rhodium forming thermally stable, isolable complexes such as **6**.[6c,8]

In summary, a novel catalytic process has been presented using simple diphosphine substrates. For the first time, an unstrained, strong Ar–C bond is selectively activated by a metal centre in solution in a catalytic fashion. Moreover, catalytic transfer of a methylene group to a primary silane has been observed using a rhodium complex. Stoichiometric reactions involved in the catalysis were directly demonstrated. Although the catalytic reactions were not optimized and the reactions are at present slow, more than one hundred turnovers were observed.

The research was supported by the US-Israel Binational Science Foundation, Jerusalem, Israel. D. M. is the holder of the Israel Matz Professorial Chair of Organic Chemistry.

‡ Catalytic hydrogenolysis of an unstrained C–C single bond. A [$^2H_8$]dioxane solution (1.5 ml) of substrate **1** (106 mg, 0.278 mmol) was added dropwise to a [$^2H_8$]dioxane solution (1.5 ml) of $[RhCl(C_8H_{14})_2]_2$ (2 mg, 0.00278 mmol), loaded into a 90 ml Fischer porter pressure bottle equipped with a stirring bar and pressurized with H_2 (20–25 psi) (toluene can be used as well). After heating the reaction solution at 180 °C for 1 day, the gas phase was collected by standard vacuum line techniques and analyzed by GC using a molecular sieve column. The formed CH_4 was identified and quantified using authentic samples (13.6 turnovers). ^{31}P{^{1}H} NMR of the reaction mixture shows two signals at δ 5.6 (s, 2 P, **1**) and 3.20 (s, 2 P, **2**). The ratio of the signals (100 : 54) indicated 17.5 turnovers and a yield of 35%. Addition of trioctylphosphine oxide to the reaction mixture as an internal standard indicated 15.3 turnovers and a yield of 31%. The addition of authentic samples **1**, **2** to the reaction mixture resulted in overlap of resonances in ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR.[6b] The same reaction conditions and analysis of the reaction mixture were used for substrate **3**. Similar reaction conditions were applied for the catalytic hydrosilylation, only an excess of $HSi(OEt)_3$ (91 mg, 0.556 mmol) was used instead of H_2.

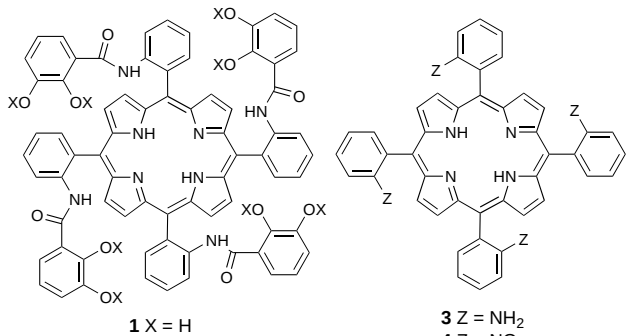
High yield syntheses of all four atropoisomers of the *meso*-tetrakis(*o*-catecholamidophenyl)porphyrin has been achieved; all four atropoisomers were isolated and characterised by NMR spectroscopy; for the methyl protected $2_{\alpha\beta\alpha\beta}$ and $2_{\alpha 4}$ atropoisomers obtained as water and chloroform solvates respectively, X-ray analysis was used to assign their structure.

Porphyrins, used in chemistry, biology, medicine and material science, are among the most fascinating organic molecules. These tetradentate macrocycles bind a large variety of metal cations and exhibit interesting redox as well as photochemical properties. Furthermore their functionalisation either at the β-pyrrolic or *meso* positions has been well established. The porphyrin backbone may be used as a preorganised complexing core for the elaboration of di- and poly-nucleating ligands. Examples of porphyrins bearing neutral bidentate ligands such as bipyridine and phenanthroline have been reported.[1] So far, two examples of porphyrins bearing dianionic bidentate catecholate units have been published.[2,3] Whereas in the first case, two catechols were directly incorporated at the meso positions,[2] in the second example, the porphyrin was functionalised by one to four *m*-catecholamidophenyl units at the *meso* positions.[3] On the other hand, diaza-,[4] triaza- and tetraaza-macrocycles[5] as well as a calix[4]arene derivative[6] bearing pendant catechol units have been also reported.

In our search for polynuclear complexes, we thought that one could take advantage of atropoisomerism,[7] previously elegantly used for the preparation of picket fence porphyrins,[8] for the design of new polynucleating ligands. Thus, the *meso*-tetrakis(*o*-catecholamidophenyl)porphyrin atropoisomers appeared to be interesting targets. Indeed, owing to high rotational barriers, one would expect four atropoisomers designated as



1 X = H
2 X = Me

3 Z = NH_2
4 Z = NO_2

$\mathbf{1}_{\alpha 4}$, $\mathbf{1}_{\alpha 3\beta}$, $\mathbf{1}_{\alpha 2\beta 2}$ and $\mathbf{1}_{\alpha\beta\alpha\beta}$ for the *meso*-tetraphenylporphyrin bearing bulky catecholamido groups at the *ortho* position on the phenyl groups (Fig. 1).

Whereas the $\mathbf{1}_{\alpha 4}$ atropoisomer may lead to heterodinuclear complexes by simultaneous binding of transition and lanthanide cations, the $\mathbf{1}_{\alpha 2\beta 2}$ and $\mathbf{1}_{\alpha\beta\alpha\beta}$ isomers may form homo- or heterotrinuclear species with transition metals. Furthermore, for the $\mathbf{1}_{\alpha\beta\alpha\beta}$ atropoisomer, the formation of infinite coordination polymers with metals adopting octa-coordination around cubic arrangements may also be envisaged. Here, we report the synthesis and structural analysis of the above mentioned ligands.

The synthesis of all four protected atropoisomers $\mathbf{2}_{\alpha 4}$, $\mathbf{2}_{\alpha 3\beta}$, $\mathbf{2}_{\alpha 2\beta 2}$ and $\mathbf{2}_{\alpha\beta\alpha\beta}$ was first achieved by condensation of a statistical mixture of the *meso*-tetrakis(*o*-aminophenyl)-porphyrin **3** isomers with the acyl chloride derivative of the methyl protected catechol[9] in THF in the presence of NEt_3. **3** was obtained as a statistical mixture by reduction of the nitro compound **4** prepared from *ortho*-nitrobenzaldehyde and pyrrole.[8] Although the condensation reaction proceeded quantitatively, the separation of the mixture appeared to be extremely tedious. Indeed, whereas based on TLC analysis [SiO_2, CCl_4–ethyl acetate (1/1)], the separation of atropoisomers could have been straightforward, because of their low solubility, the purification on a preparative silica column yielded, after at least three passages, only small quantities of the pure isomers. The separation of the zinc complexes, obtained by treatment of the mixture by zinc acetate, was as difficult as for the free prophyrin derivatives. Attempts to reach better results using chromatotron or preparative HPLC also failed. An alternative strategy, consisting of the separation of all four atropoisomers of **3**[8] and then condensation with the acyl chloride derivative of the methyl protected catechol, was followed to avoid the purification difficulties mentioned above. In order to minimise the atropoisomerisation, the reactions were carried out at −15 °C in THF and in the presence of NEt_3. Again, the condensation reaction proceeded with almost quantitative yields. After chromatography on silica and crystallisation from $CHCl_3$–ethyl acetate mixtures, the protected atropoisomers $\mathbf{2}_{\alpha\beta\alpha\beta}$ [CH_2Cl_2; CH_2Cl_2–AcOEt (96 : 4); $CHCl_3$], $\mathbf{2}_{\alpha 2\beta 2}$ [CH_2Cl_2; CH_2Cl_2–AcOEt (96 : 4); $CHCl_3$], $\mathbf{2}_{\alpha 3\beta}$ [toluene–$CHCl_3$–MeOH (25 : 5 : 5)] and $\mathbf{2}_{\alpha 4}$ [toluene–$CHCl_3$–AcOEt (25 : 5 : 5)–

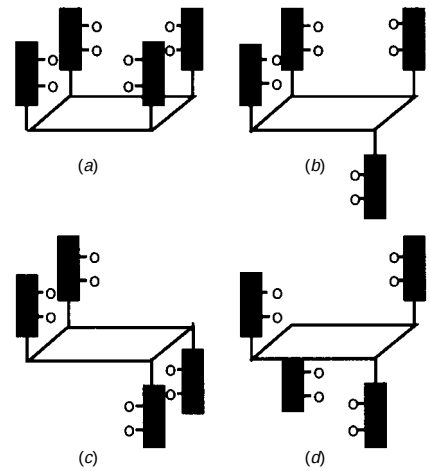


Fig. 1 Schematic representations of α_4 (a), $\alpha_3\beta$ (b), $\alpha_2\beta_2$ (c) and $\alpha\beta\alpha\beta$ (d) atropoisomers of the porphyrins **1**–**4**

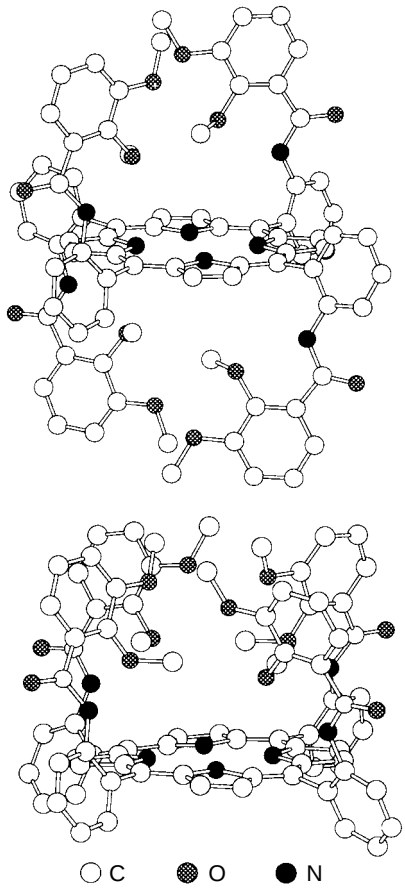

Fig. 2 X-Ray crystal structures of $\mathbf{2}_{\alpha4}$ (top) and $\mathbf{2}_{\alpha\beta\alpha\beta}$ (bottom); solvent molecules as well as H atoms are not shown for clarity. In both cases, the core of the porphyrin was almost planar, the amide groups were in *trans* configuration and the catechol units were found to be oriented in a convergent manner.

(25 : 10 : 5)] could be obtained in 57, 63, 70 and 60% isolated yields, respectively.

Based on symmetry, the ^{1}H NMR signals for $\mathbf{2}_{\alpha3\beta}$ (C_s) could be unambiguously assigned. For the other three $\mathbf{2}_{\alpha4}$ (C_{4v}), $\mathbf{2}_{\alpha\beta\alpha\beta}$ (D_{2d}) and $\mathbf{2}_{\alpha2\beta2}$ (C_{2h}) atropoisomers, only the latter could be identified by the observation of two singlets for the β-pyrrolic protons, whereas for the remaining atropoisomers the assignments could not be achieved without taking into account their polarity. In order to confirm the structural assignment, both $\mathbf{2}_{\alpha4}$ and $\mathbf{2}_{\alpha\beta\alpha\beta}$ atropoisomers were studied by X-ray diffraction (Fig. 2).‡ In both cases, suitable monocrystals were obtained as water and chloroform solvates respectively upon slow liquid–liquid diffusion of MeOH into a chloroform solution of either $\mathbf{2}_{\alpha4}$ or $\mathbf{2}_{\alpha\beta\alpha\beta}$. The X-ray analysis revealed the following common features: (*i*) the core of the porphyrin was almost planar, however, owing to steric reasons, the deformation was slightly greater for $\mathbf{2}_{\alpha4}$; (*ii*) the amide groups were in *trans* configuration with NH hydrogen atoms inwardly oriented towards oxygen atoms belonging to the catechol units and the CO groups oriented in divergent fashion towards the periphery of the porphyrin backbone; (*iii*) both in the case of $\mathbf{2}_{\alpha4}$ for which all four protected catechol units were localised on the same face of the molecule [Fig. 2(top)] and of $\mathbf{2}_{\alpha\beta\alpha\beta}$ for which the two sets of two protected catechols were localised below and above the mean plane of the porphyrin [Fig. 2(bottom)], the catechol units were found to be oriented in a convergent manner. Dealing with the $\mathbf{2}_{\alpha3\beta}$ isomer, although its structure was also established by X-ray analysis which revealed the same common features as for the above two isomers, the data are not reported because of rather low resolution.

The deprotection of $\mathbf{2}_{\alpha4}$, $\mathbf{2}_{\alpha3\beta}$, $\mathbf{2}_{\alpha2\beta2}$ and $\mathbf{2}_{\alpha\beta\alpha\beta}$ atropoisomers at −78 °C using the classical BBr_3–CH_2Cl_2 method[10] afforded the desired compounds $\mathbf{1}_{\alpha4}$, $\mathbf{1}_{\alpha3\beta}$, $\mathbf{1}_{\alpha2\beta2}$ and $\mathbf{1}_{\alpha\beta\alpha\beta}$ as the hydrobromide salts after several precipitations from MeOH–ethyl–ether mixtures. Whereas in the solid state all four atropoisomers were stable, in solution the protonated $\mathbf{1}_{\alpha4}$, $\mathbf{1}_{\alpha3\beta}$ and $\mathbf{1}_{\alpha2\beta2}$ isomers were found to undergo atropoisomerisation. Interestingly, probably due to steric reasons, all three isomers were converted into the lowest energy atropoisomer $\mathbf{1}_{\alpha\beta\alpha\beta}$ under heating at 50 °C for 48 h. This observation is not unprecedented since it has been previously reported for another porphyrin derivative[11] that the protonation of the porphyrin core induces considerable deformation[12] leading to thermal atropoisomerisation.

In summary, high yield syntheses of all four atropoisomers $\mathbf{1}_{\alpha4}$, $\mathbf{1}_{\alpha3\beta}$, $\mathbf{1}_{\alpha2\beta2}$ and $\mathbf{1}_{\alpha\beta\alpha\beta}$ of *meso*-tetrakis(*o*-catecholamidophenyl)porphyrin was achieved and their structures assigned based on X-ray and NMR analysis. Furthermore, it has been established that all three protonated $\mathbf{1}_{\alpha4}$, $\mathbf{1}_{\alpha3\beta}$, $\mathbf{1}_{\alpha2\beta2}$ atropoisomers may be converted into the most stable $\mathbf{1}_{\alpha\beta\alpha\beta}$ isomer upon heating. The formation of the bi- and tri-nuclear complexes using different atropoisomers of **1** with a variety of transition metal cations as well as the formation of coordination polymers are under current investigation.

We thank Dr. R. Ruppert for the initial preparation of the mixture of protected atropoisomers, Dr. I. Huc for his help with the HPLC separation, the Institut Universitaire de France (IUF), and the CNRS for financial support.

Reaction of ketones with the organotitanium oxide [{TiCp*(μ-O)}$_3$(μ$_3$-CMe)] *via* the hydride–vinylidene [{TiCp*(μ-O)}$_3$(μ-C=CH$_2$)(H)] intermediate‡

Mikhail Galakhov, Miguel Mena*† and Cristina Santamaría

Departamento de Química Inorgánica de la Universidad de Alcalá, E-22871 Alcalá de Henares, Madrid, Spain

Thermal and/or photochemical treatment of [{TiCp*(μ-O)}$_3$(μ$_3$-CMe)] 1 (Cp* ≡ η^5-C$_5$Me$_5$) with organic ketones affords the new oxo derivatives [{TiCp*(μ-O)}$_3$(μ-C=CH$_2$)(OCHRR′)] (R = R′ = Me 2, Ph 3; R = Ph, R′ = Me 4, Et 5); these reactions take place by insertion of the ketones CO group into the Ti–H bond of the *in situ* formed [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(H)] intermediate.

We have reported the unprecedented oxotitanium complexes, [{TiCp*(μ-O)}$_3$(μ$_3$-CR)] (R = H, Me),[1] possessing a μ$_3$-alkylidyne sp^3-carbon similar to that found for the early-transition-metal clusters [M$_3$(μ$_3$-CR′)(OR)$_9$] (M = Mo, W)[2] and in contrast with the sp-hybridized alkylidyne carbon of the species as [Co$_3$(μ$_3$-CR)(CO)$_9$].[3] The chemistry of these μ$_3$-alkylidynetrimetal clusters have been extensively explored.[3a,4] Meanwhile, to our knowledge, the [{CrCp(μ-Cl)}$_3$(μ$_3$-CH)],[5] [{TiCp*(μ-O)}$_3$(μ$_3$-CR)][1] and [{TiCp*}$_4$(μ$_3$-CH)$_4$][6] complexes are the only reported examples of μ$_3$-alkylidyne units supported on trinuclear cores without metal–metal bonds and their reactivity is, as yet, practically unknown.[7] This chemistry might be of great current interest, imitating the behaviour of the alkylidyne groups attached to metal or metal oxide surfaces and establishing a clear connection between organometallic and solid surface systems.[8] Here, we report the surprising reactivity of diverse ketones and the μ$_3$-ethylidyne group on an organotitanium oxide.

Treatment of [{TiCp*(μ-O)}$_3$(μ$_3$-CMe)] **1** with 1 equiv. of RCOR′ (R = R′ = Me, Ph; R = Ph, R′ = Me, Et) in toluene or hexane, heating at temperatures between 100 and 120 °C or irradiating with a sunlamp for several days, leads to the formation (46–77% yield) of blue–violet complexes characterised as [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(OCHRR′)] (R = R′ = Me **2**, Ph **3**; R = Ph, R′ = Me **4**, Et **5** (Scheme 1).§

The IR spectra of these complexes show a weak band at 1580 (**2**) and 1598 cm^{-1} (**3**, **4**, **5**) assigned to the *ν*(C=C) of the μ-vinylidene moiety, as in the case of the bimetallic systems [Ru$_2$(CO)$_3$Cp$_2$(μ-C=CH$_2$)] (1586 cm^{-1})[9] and [ClNi(μ-dppm)$_2$(μ-C=CH$_2$)NiCl] (1580 cm^{-1}).[10] The NMR spectra (Table 1) are consistent with the proposed structure and reveal the presence of the characteristic signals for μ-vinylidene, alkoxide and Cp* ligands.

[Ti] = Ti(η^5-C$_5$Me$_5$)

R = R′ = Me **2**, Ph **3**
R = Ph; R′ = Me **4**, Et **5**

Scheme 1

The ^{13}C NMR spectra of **2**–**5** reveal triplets at δ_{av} 317.5 (^2J 5 Hz) attributed to the C$_\alpha$ resonance of the bridging vinylidene fragment >C$_\alpha$=C$_\beta$H$_2$, which are very similar to those found for other known vinylidene complexes.[11] The terminal moiety (=C$_\beta$H$_2$) of this fragment appear, in both ^{1}H and ^{13}C NMR spectra, in the typical range for organic alkenes. The NMR spectra also display the clear presence of the OC*H*RR′ signals whose chemical shifts and multiplicity depend on the nature of the ketone substituents (Table 1) and the values of $^1J_{CH}$ ≈ 142 Hz are according to the proximity of the oxygen atom. Additionally, the NMR spectra of **4** and **5** show signals for three different Cp* ligands in 1 : 1 : 1 ratio and AB spin systems for the vinylidene protons due to the chiral carbon atoms of the alkoxy groups.

A plausible pathway for these reactions involves initial β-hydrogen elimination in the μ$_3$-ethylidyne ligand to generate the intermediate [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(H)]. Similar conversion of μ$_3$-alkylidyne complexes to vinylidenes has been found for many trinuclear clusters[11a] and may be responsible of the H/D exchange reactions in ethylidynes on metal surfaces.[8a,c] Interestingly, we have also observed that the complex **1** incorporate deuterium in the μ$_3$-ethylidyne group when a C$_6$D$_6$ solution of **1** is heated above 200 °C,¶ and this H/D exchange is easy to explain if we assume the participation of the above mentioned hydride intermediate.[12] Finally the insertion of the ketones into the Ti–H bond of [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(H)] takes place (Scheme 2).[13]

Table 1 Selected NMR data (*δ*, *J*/Hz) for complexes [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(OCHRR′)] (R = R′ = Me **2**, Ph **3**; R = Ph, R′ = Me **4**, Et **5**)[a]

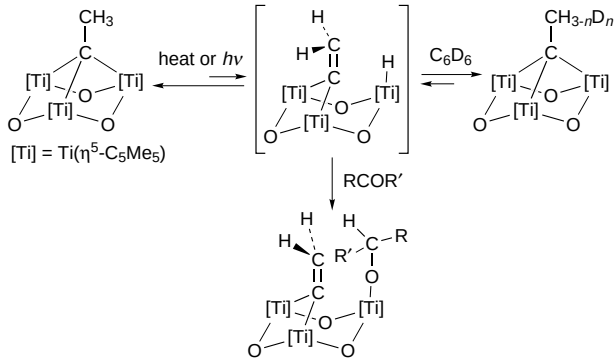

Scheme 2

Thus the incorporation of the ketones onto the organometallic titanium oxide [{TiCp*(μ-O)}$_3$(μ$_3$-CMe)] can be best interpreted in terms of an insertion process of the carbonyl groups into a Ti–H bond of the hydride–vinylidene species [{TiCp*(μ-O)}$_3$(μ-CCH$_2$)(H)]. Further studies are required in order to determine the behaviour of other carbonyl derivatives and unsaturated molecules against these μ$_3$-alkylidyne complexes.

We wish to thank the DGICYT (project PB93-0476) and the Universidad de Alcalá for financial support of this research. C. Santamaría also thanks the MEC for a Predoctoral Fellowship.

‡ Dedicated to Professor Pascual Royo on the occasion of his 60th birthday.

§ *Preparations*: **2**: a solution of **1** (0.50 g, 0.80 mmol) and acetone (0.06 ml, 2.40 mmol) in toluene (50 ml) were transferred by cannula to a Carius tube (volume 100 ml), cooled to −78 °C, and flame-sealed. This tube was heated at 100 °C for 12 h to obtain a blue–violet lather (0.42 g, 77%). EI mass spectrum: *m*/*z* 624 (M$^+$ − MeCOMe, 9%), 613 (M$^+$ − MeCHMe − C$_2$H$_2$, 25%). **3**: this derivative was obtained analogously to **2** from 0.80 g (1.28 mmol) of **1** and 0.23 g (1.28 mmol) of benzophenone heating at 125 °C for 24 h to obtain a blue–violet crystalline solid (0.73 g, 71%). EI mass spectrum: *m*/*z* 624 (M$^+$ − PhCOPh, 6%), 613 (M$^+$ − PhCHPh − C$_2$H$_2$, 28%). **4**: acetophenone (0.16 ml, 1.33 mmol) diluted in 15 ml of hexane was added to a solution of **1** (0.80 g, 1.28 mmol) in hexane (100 ml). The reaction mixture was irradiated at room temp. for 45 h with a sunlamp. The solution was concentrated and a crystalline blue solid was obtained at room temp. (0.50 g, 52%). EI mass spectrum: *m*/*z* 624 (M$^+$ − PhCOMe, < 1%), 613 (M$^+$ − PhCHMe − C$_2$H$_2$, 3%). **5**: the preparation of this complex is similar to **4** from 0.80 g (1.28 mmol) of **1** and 0.17 ml (1.33 mmol) of ethyl phenyl ketone irradiating for 68 h with a sunlamp; 0.44 g (46%) of a blue solid was obtained. EI mass spectrum: *m*/*z* 624 (M$^+$ − PhCOEt, 5%), 613 (M$^+$ − PhCHEt − C$_2$H$_2$, < 1%).

Full NMR and analytical data for the new compounds **2**–**5** can be acquired as supplementary material upon request from the authors.

¶ In the ^{1}H NMR spectra we have detected the presence of μ$_3$-CCH$_2$D and μ$_3$-CCHD$_2$ isotopomers.

Direct conversion of perfluoroalkanes and perfluoroarenes to perfluoro Grignard reagents

Christopher M. Beck, You-Jung Park and Robert H. Crabtree*†

Yale University, Department of Chemistry, 225 Prospect Street, New Haven, CT 06511, USA

Magnesium anthracene selectively reduces C_6F_{12} or C_6F_6 and $CF_3C_6F_{11}$ or $CF_3C_6F_5$ to C_6F_5MgF and $CF_3C_6F_4MgF$, respectively

Magnesium anthracene[1] $MgC_{14}H_{10}$ **1**, has found a wealth of applications in organic chemistry.[2] This compound is believed to act as a soluble, activated form of magnesium metal,[2a,b] and is often the compound of choice for the preparation of Grignard reagents that are difficult or impossible to obtain directly from magnesium metal.[2] Here, we describe the use of **1** in new synthetic routes to perfluoroaromatic Grignard reagents from both perfluoroaromatic compounds as well as from the less costly analogous saturated fluorocarbons.

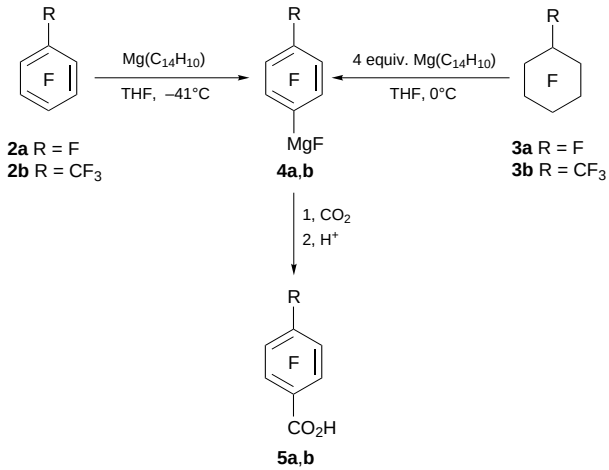
Rare cases are known in which perfluoro Grignard reagents have been synthesized from perfluoroaromatic compounds (but not from perfluoroalkanes) and magnesium by entrainment with a more reactive organic bromide, with[3] or without[4] transition metal catalysis. Important work by Richmond and Pez and their coworkers has shown that transition metal compounds[5] and arene anions[6] can reduce saturated perfluorocarbons in solution but never previously to give such useful species as Grignard reagents.

We now find that hexafluorobenzene **2a** reacts cleanly with 1 equiv. of the orange species **1** in THF solution at −41 °C to afford a solution, the blue color of which is believed to be associated with the anthracene monoanion. Treatment of this solution with CO_2 followed by acid work-up, yielded pentafluorobenzoic acid **5a** in moderate yield (34%), along with unreacted **2a**. The reaction appears to proceed *via* net insertion of a Mg atom into the aromatic C–F bond, forming a Grignard reagent which subsequently reacts with CO_2 to form the carboxylic acid (Scheme 1). Since **1** exists in a temperature dependent equilibrium with anthracene and magnesium metal,[1b] it is unclear if the formation of the Grignard reagent occurs directly or by prior production of a highly active form of magnesium metal.

The reaction of perfluorotoluene **2b** with 1 equiv. of **1** at −41 °C produced perfluorotoluic acid **5b**‡ exclusively as the *para* isomer but in low yield (8.5%). The yields did not change significantly between −78 and 0 °C or in the presence of an excess of **1**. Perfluoronaphthalene gave no identifiable organic products in the presence of **1** at −78 °C. For comparison, Mg powder (Aldrich Co., 50 mesh) was exposed to **2a** or **2b** under analogous conditions. In this case, no reaction was observed between the perfluoroarene and magnesium, further illustrating the necessity for using **1** in Grignard synthesis.

Our success with these perfluoroarenes led us to look at the corresponding perfluoroalkanes. When a THF solution of 4 equiv. of **1** at 0 °C was treated with perfluorocyclohexane **3a**, the initial orange solution rapidly turned dark brown. Subsequent work-up with CO_2, then acid, followed by extraction with dilute base afforded dark brown solids after removal of the solvent. Direct sublimation of these solids at 115 °C *in vacuo* afforded white crystals which proved to be an inseparable mixture of $C_6F_5CO_2H$ and 2,3,5,6-$C_6HF_4CO_2H$§ by ^{19}F NMR spectroscopy in 14 and 4% overall chemical yield based on fluorocarbon. This result is consistent with initial reduction of perfluorocyclohexane to hexafluorobenzene which would then be expected to react with an additional equivalent of **1** to yield the corresponding Grignard reagent. Similarly, perfluoromethylcyclohexane **3b** upon treatment with 4 equiv. of **1** yielded **5b** in 5.7% yield, exclusively as the *para* isomer. As in the case of the perfluoroarenes, no products were observed when commercial Mg powder was treated with **3a** or **3b** in an analogous manner. These transformations constitute, to our knowledge, the only known conversions of perfluoroalkanes directly to Grignard reagents. **CAUTION**: Fluorinated Grignards can spontaneously explode;[8] appropriate care must therefore be exercised.

The authors are grateful to the Department of Energy and the 3M corporation for financial support.



Scheme 1

Table 1 Yields of **5** and reaction temperature for the reactions of **2** and **3** with **1**[a]

Fluorocarbon	*T*/°C	Yield (%)
2a	−41	34.3
2b	−41	8.5
3a	0	14.0[b]
3b	0	5.7

[a] Fluorocarbon was added to a pre-cooled THF solution of **1** and allowed to stir for 15–40 min. Dry CO_2 was introduced for *ca*. 40 min at the reaction temperature and allowed to warm to room temperature under a CO_2 flow. The mixture was then quenched with dilute H_2SO_4 and the THF removed *in vacuo*. The product was extracted with Et_2O, and then extracted by shaking with 1 M (aq) KOH. The basic extracts were acidified with dilute H_2SO_4 and extracted with Et_2O to yield the product. Yields reported here are for the doubly sublimed, analytically pure solids. [b] Isolated as a mixture which also contained 2,3,5,6-$C_6HF_4CO_2H$ in 4% yield based on fluorocarbon.

Photochemistry and magnetic resonance spectroscopy as probes of supramolecular structures and migration pathways of organic molecules and radicals adsorbed on zeolites

Nicholas J. Turro,*[a]† Xuegong Lei,[a] Wei Li,[a] Ann McDermott,[a] Lloyd Abrams,[b] M. Francesca Ottavianai[c] and Hege Støgård Beard[d]

[a] *Chemistry Department, Columbia University, New York, NY 10027, USA*

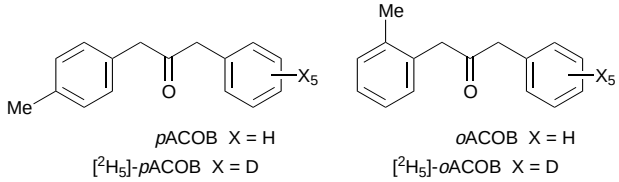
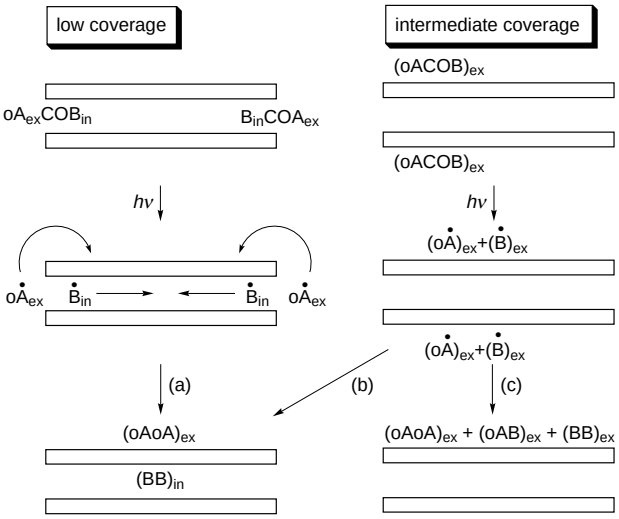
[c] *University of Florence, Department of Physical Chemistry, Via Gino Capponi, 9, 50121 Florence, Italy*
[d] *Chemistry Department, University of Oslo, Oslo, Norway*

Magnetic resonance, surface area measurements and computational techniques have been integrated to elucidate the supramolecular photochemistry of two isomeric ketones adsorbed on two MFI zeolites (silicalite and ZSM-5) and to demonstrate that common factors proportional to the available external surface area operate to determine the measured parameters in each case.

We report here examples of supramolecular photochemistry[1,2] of ketones adsorbed on molecular sieve zeolites (possessing MFI topology). The systems employed are two isomeric ketones, *o*ACOB and *p*ACOB, whose molecular photochemistries are essentially identical,[3] but whose supramolecular photochemistries[4] (Scheme 1) are a strong function of supramolecular composition, structure and dynamics.



As shown in Scheme 1, the external surface of ZSF-5 zeolites[5] possesses two sites for binding of *o*ACOB molecules: (i) the holes on the external surface (*ca.* 30% of the external surface area) and (ii) the remaining 'solid framework' of the external surface (*ca.* 70% of the external surface area). As ketone is loaded, a monolayer of ketone will form at some point and loading of ketone beyond this point will cause the formation of multilayers.



Scheme 1 Schematic description of the supramolecular photochemistry of *o*MeDBK/MFI complexes and *p*MeDBK/MFI complexes at loadings corresponding to less than a monolayer. The holes are filled first (left) and then the solid framework.

According to the paradigm[4] of Scheme 1, the products of the photochemistry of *o*ACOB adsorbed on MFI zeolites will depend both on the initial siting of the ketone and on the dynamics of the radicals produced by photolysis of *o*ACOB adsorbed at these sitings.

The photolyses of *o*ACOB and *p*ACOB adsorbed on two MFI zeolites,[5] silicalite (surface area = 5 m^2 g^{-1})[6] and ZSM-5 (surface area = 16 m^2 g^{-1}),[6] were investigated as a function of loading of ketone in the range *ca.* 0.1 to *ca.* 5% w/w. Fig. 1 summarizes the results of the 'cage effect'[7] as a function of loading. The product mixture from the photolysis of the *p*ACOB/zeolite sysem was found to exhibit a strong positive cage effect (CE)[7] *over the entire loading range* investigated for both silicalite and ZSM-5. In contrast, the product mixture from the photolysis of the *o*ACOB/zeolite system depends strongly on the loading, exhibiting a strong negative cage effect[7] at low loadings, and an increasingly positive cage effect[7] reaching a

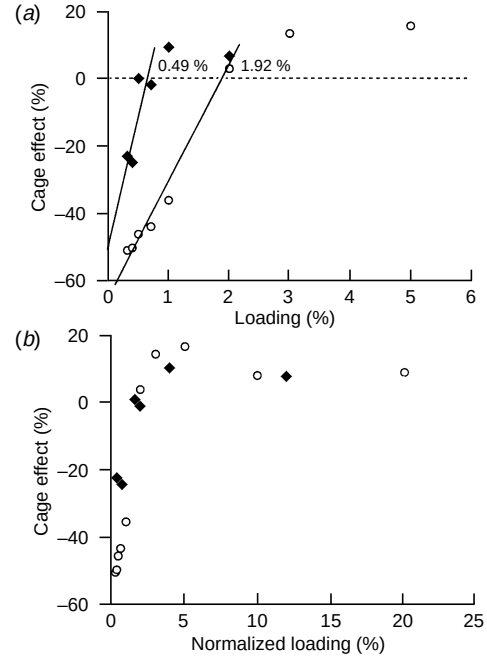


Fig. 1 (*a*) Loading and (*b*) normalized loading dependence of the cage effect for the photolysis of *o*MeDBK on (○) 25M-5 and (◆) silicalite zeolites

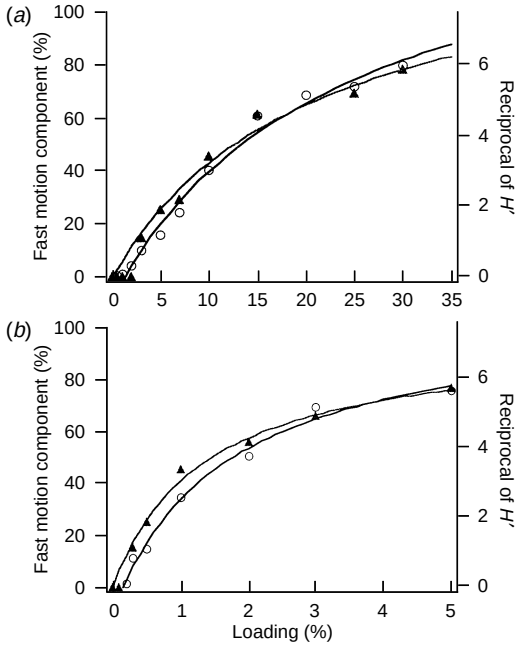

Fig. 2 Values for (*a*) ZSM-5 and (*b*) silicalite zeolites of (○) the reciprocal of H' from ^{2}H NMR spectra and (▲) the fast motion component extracted from EPR spectra, as a function of loading of *o*ACOB

maximum and progressing towards a limiting cage effect of zero at the highest loadings [Fig. 1(*a*)].

For low loadings (conditions for which the surface area and number of holes determine the CE), a linear fit of the data in Fig. 1 yields values of 0.49 and 1.92% for the loadings at which a CE of *ca.* 0% is achieved (assumed to correspond approximately to the formation of the monolayer). The ratio of these loadings is 3.9 and is strikingly similar to the observed ratio (3 : 2) of the experimentally measured surface areas of the two zeolite samples.[6] These results demonstrate that the external surface area is a key parameter in understanding the results.

The reciprocal of the half width of the signal ($H' = 1/\Delta H_{1/2}$) in the solid state ^{2}H NMR of [$^2H_5$]-*o*ACOB was determined as a function of loading (Fig. 2). The values of H' are related to the motion[8] of ring B. If the ring is plugged in a hole on the external surface, its motion is expected to be more constrained than when it is adsorbed on the solid external surface.[8] Finally, if the ring is in a liquid-like multilayer, the motion is expected to be effectively isotropic and unconstrained.

For the lowest loadings, the values of H' for both zeolite samples are small (motion constrained) and constant, as expected if the ketones first occupy the holes on the external surface. The value of H' begins to increase, and then plateau as expected if the ketones begin to occupy a liquid-like environment.

The form of the graph of the ^{2}H NMR data in Fig. 2 may be described by a Langmuir expression such as eqn. (1), where Y is

$$Y = M(k)x/(1 + kx) \quad (1)$$

the value of a parameter proportional to coverage, x is the loading of *o*ACOB (w/w), M is the maximum value of Y [computed from fitting the data to eqn. (1)], and k is related to the equilibrium constant for adsorption of the ketone on the external surface.

If we assume that the motion of the adsorbed *o*MeDBK molecules is directly related to the external surface coverage, then the reciprocal of the half-widths[8] of the ^{2}H NMR data serves as parameter Y in eqn. (1). At loadings below 0.3% the ^{2}H NMR signal is relatively broad and constant, implying that the first *o*ACOB molecules adsorbed are more tightly bound to the holes than subsequently adsorbed molecules which bind to the solid external surface.[9] However, for values of H' plotted as a function of loadings greater than *ca.* 1%, the data fit eqn. (1) within experimental error (solid curves in Fig. 2). Values of $k = 0.041 \pm 0.010$ and 0.56 ± 0.50 for ZSM-5 and silicalite, respectively, are evaluated from the fit to eqn. (1). The data for both zeolite samples overlap within experimental error if the data for silicalite are scaled by a factor of *ca.* 5, which is of the order of the ratio of the measured external surface area of the two zeolites and the ratio of the linear portions of the slopes of the photochemical data in Fig. 1(*a*).

A second experiment employing EPR spectroscopy confirms indirectly the results of the photochemical and ^{2}H NMR experiments. In these experiments 4-oxo-TEMPO (T) was employed as an EPR probe of binding of *o*ACOB to the external surface. A small amount (0.1%) of T was added to the zeolite samples and the influence of the addition of *o*ACOB on the EPR signal of the probe was observed. In the absence of *o*ACOB, the EPR spectrum consists of only a broad signal characteristic peak, a strongly motion-constrained (slow component) probe bound to the external surface. Addition of ketone causes the conversion of the broad signal to a sharp, three line signal (fast component) characteristic of a mobile probe displaced by the ketone to a weaker binding region of the external surface. The resulting spectra could be simulated[10] as the sum of a fast and slow component. Under the assumption that the ketone is displacing the constrained probe, the percent of fast component is proportional to the adsorbed ketone. Fig. 2 shows a plot of the percent of fast component as a function of loading for the two zeolites examined.

A plot of the percent of fast component as a function of loading fits eqn. (1) within the experimental error [Fig. 2(*a*)]. Values of $k = 0.048 \pm 0.010$ and 0.76 ± 0.11 for ZSM-5 and silicalite, respectively, are evaluated from the fit to eqn. (1). Strikingly, these values are experimentally indistinguishable from the k values evaluated from the ^{2}H NMR data ($k = 0.041 \pm 0.010$ and 0.56 ± 0.50 for ZSM-5 and silicalite, respectively). Furthermore, the EPR data in Fig. 2 for the two zeolites overlap the data for the ^{2}H NMR data of Fig. 2 when the data for silicalite are scaled by the same factor (*ca.* 5) which corrects for the different surface areas of the two zeolites.

The authors at Columbia thank the National Science Foundation for its generous support of this research and Dr Zhi Liu for performing preliminary ^{2}H NMR experiments. X. G. L. and W. L. thank the Kanagawa Academy of Science and Technology for funding.

^{2}H NMR, EPR, computational and product analyses of the photolysis of 2,4-diphenylpentan-3-one (DPP) adsorbed on MFI size/shape selective zeolites are consistent with supramolecular structural changes as a function of surface coverage that provide a novel method for the generation of persistent diffusing organic free radicals.
