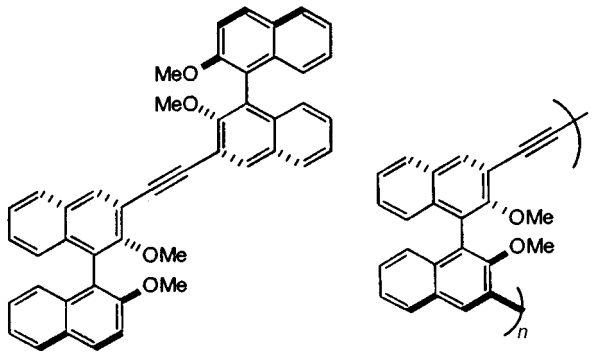
Molecular recognition is a fundamental property of various natural systems and has attracted a significant amount of research interest recently.[1] Such recognition plays a key role in biosynthesis and protein folding. Enantiomeric recognition is a characteristic of many enzymatically catalyzed reactions generating optically active biological molecules and is the basis of asymmetric synthesis.[2] Because chiral amines and related compounds are the basic building blocks of biological systems, the study of enantiomeric recognition of these compounds is of particular significance.[3] Such studies, besides providing an understanding of the functions of natural living processes, also provide useful information for the understanding and design of asymmetric catalysis systems, new pharmaceutical agents[4] and separation materials.[5] Optical sensors have been of great interest in the last decade due to their often simple design and ease of handling. These sensors are increasingly important for biological and environmental analysis[6] as well as for pharmaceutical applications.[7] A promising technique is based on fluorescent probes due to their very sensitive detection ability.[8] These sensors are based on the large changes in their fluorescent properties during interaction with analytes. Recently, Shinkai's group developed a fluorescent molecular sensor that can discriminate D- and L-monosaccharides through their fluorescence response to the binding of guest species.[9] Binding of each enantiomer of the monosaccharides alters the fluorescence intensity to differing degrees, enabling them to be distinguished. More recently, Still and co-workers described small organic fluorescent sensors that detect the presence of unlabeled tripeptides in a sequence-selective manner.[10] Here we report the enantiomeric discrimination of chiral amines using designed receptors that act as sensors by changing fluorescence intensity during host–guest interactions.[11]



1 **2**

The chiral hosts used in our study are dimeric (**1**) and oligomeric (**2**) binaphthol-derivatives that we have previously developed.[12] For the chiral guest amines, we chose D- and L-α-phenylethylamines (**3**), as well as D- and L-phenylalanine methyl esters (**4**). The ^{1}H NMR studies were carried out in a $CDCl_3$ solution of chiral dimer (−)-**1** and D- or L-phenylethylamine (**3**) (host : guest = 1 : 1). Differences in chemical shifts of D- and L-**3** were observed: $\Delta\delta$(D−L) = 0.04 ppm (12 Hz) at δ 1.37 due to methyl-H, 0.04 ppm (12 Hz) at δ 4.2 due to CH of **3**, and 0.01 ppm (3 Hz) at δ 3.7 due to methoxy-H of the host **1**. The results indicated clearly that the complexation of chiral host **1** and the guest chiral amine, as well as enantio discriminations, occurred in $CDCl_3$ solution.

The fluorescence study was carried out in MeCN with the measurements performed on a Hitachi 850 Fluorescent Spectrometer. The experimental procedure is as follows: a solution of the host in MeCN (c 1.4 × 10^{-5} mol ml^{-1}) was titrated with a solution of the chiral amine in MeCN. The fluorescence intensity was measured and the quantum yields determined.[12] The fluorescence quantum yield of the chiral host was assigned as ϕ_0. Upon addition of the chiral guest, the fluorescence quantum yield ϕ of the solution was measured at various concentrations. ϕ/ϕ_0 was plotted against the concentration of the guest. Because most amines do not have a fluorescence chromaphore, an emission wavelength (λ_{em}) at 410 nm, the typical emission of a naphthalene ring, was used to measure the change in fluorescence intensity. Thus, changes in this wavelength can be attributed to the interaction of the guest chiral amines with the chiral host due to host–guest complexation.

It was found that the interaction of the two enantiomers of chiral amines did not have a substantial effect on the emission wavelength. On the other hand, a strong change in fluorescence response intensity was observed with the use of different enantiomers. As illustrated from the plots (Figs. 1 and 2), the dimer and oligomer hosts have different responses to the concentration changes of the guest molecules. When α-phenylethylamine was used as the chiral guest, the following observations were made: at a concentration of (10–15) × 10^{-5} mol dm^{-3}, $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ has a value of 1.13 for the dimeric host and a value of 1.37 for the oligomeric host; whereas at a concentration of (2–5) × 10^{-5} mol dm^{-3}, the $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ values changed to 0.81 for the dimeric and 1.07 for the oligomeric hosts respectively. Thus, in the case of the dimeric host, a change in the concentration of α-phenylethylamine from (10–15) to (2–5) × 10^{-5} mol dm^{-3} reversed the fluorescence

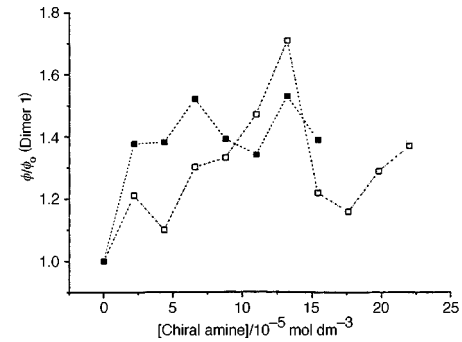


Fig. 1 ϕ/ϕ_0 ratio of fluorescent quantum yield of D- and L-α-phenylethylamine with dimer **1** as the host: (■) D-α-phenylethylamine and (□) D-α-phenylethylamine

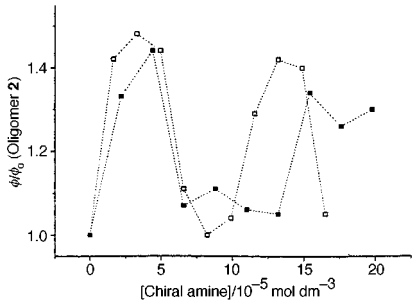

Fig. 2 ϕ/ϕ_0 ratio of fluorescent quantum yield of D- and L-α-phenylethylamine with oligomer **2** as the host: (■) D-α-phenylethylamine and (□) D-α-phenylethylamine

response of the two enantiomers. Such a reversed fluorescence response was also observed during the measurement of phenylalanine methyl ester (Figs. 3 and 4). At a concentration of (7–9) $\times$ 10^{-5} mol dm^{-3}, the $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ has a value of 1.19 for the dimeric host and a vlaue of 1.10 for the oligomeric host; whereas at a concentration of (2–4) $\times$ 10^{-5} mol dm^{-3}, the $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ values changed to 0.97 for the dimeric and 0.98 for the oligomer hosts. Interestingly, the strongest reversal of fluorescence properties for the two enantiomers with the dimeric host was observed at a concentration of 5 $\times$ 10^{-5} mol dm^{-3}, in which the $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ value was measured at 0.86. However, the fluorescence response of the oligomeric host appears relatively constant under the different concentrations of phenylalanine methyl ester. At a concentration of 5 $\times$ 10^{-5} mol dm^{-3}, the $[\phi/\phi_0]_L/[\phi/\phi_0]_D$ value of the oligomeric host was measured at 0.96. As the structure of the hosts has been characterized as having a helical concave structure,[12] we suspect that the chiral amines would clathrate into the chiral host through a π–π interaction between the naphthyl moiety of the host and the phenyl group of the aromatic amine and hydrogen bond. The enantio discrimination could stem from the chiral naphthyl moiety and the main chain chirality of the oligomers. The multiple interacting points and chiral units of the hosts may play different roles during chiral discrimination, which could explain the aberrant response of fluorescence on the concentration of the chiral guest. In conclusion, we have developed two fluorescence sensors for the chiral recognition of chiral amines. The recognition was confirmed by ^{1}H NMR measurement. The fluorescence response of the chiral sensor was found to be markedly influenced by the concentration of chiral amines. Currently, we are developing more selective systems to discrimination among chiral amines on the basis of the present investigation.

$Co_2(CO)_6$-induced deformation of alkynes as a reversible modulator of supramolecular interactions: controlling the synthesis of catenanes

Darren G. Hamilton and Jeremy K. M. Sanders*†

Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW

Complexation of $Co_2(CO)_6$ clusters to the alkyne bonds of a hybrid crown macrocycle alters the dimensions of the macrocyclic cavity such that inclusion complexation and catenane formation by catalytic ring closing metathesis is prevented; since removal of the $Co_2(CO)_6$ 'protecting group' is readily achieved, this procedure provides a general method for modulation of supramolecular interactions.

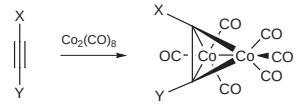
We show here that cobalt carbonyl complexation to alkyne groups provides a simple and reversible method for the modulation of molecular geometry. Since alkynes are popular linker groups that allow the precise spatial positioning of molecular components,[1] this complexation process offers a general approach for the control of supramolecular interactions. We exemplify the principle by controlling the binding properties of macrocycle **1** and hence its ability to act as a template for catenane formation under catalytic ring closing metathesis (RCM) conditions. Complexation of $Co_2(CO)_6$ clusters to the acetylene links of this hybrid crown macrocycle removes its ability to bind electron deficient substrates, while oxidative removal of the clusters restores the macrocycle's original structural form and binding capacity.

The reaction of dicobalt octacarbonyl with acetylene functions has been known for over 40 years (Scheme 1).[2] The complexes were originally of interest as some of the first characterised systems featuring multi-point attachment of an organic molecule to more than one metal atom. Complexation of an acetylene group to a cobalt carbonyl cluster has been used as a protecting group to mask the reactivity of the triple bond,[3] and also as an activating group to promote reactions requiring the stabilisation of an electron-deficient carbon centre.[4]

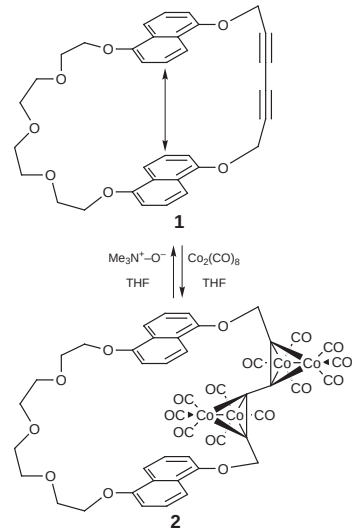
The complexation process is accompanied by a dramatic change in the geometry of the linear acetylenic carbon backbone. Complexation of $Co_2(CO)_6$ to diphenylacetylene reduces the Ph–C–C bond angles from 180 to around 138°;[5] this observation has been exploited in attempts to prepare *cyclo*-C_{18} by temporarily altering the geometry of precursors to favour cyclisation.[6] Of greatest relevance to the present discussion is the structure of the bis-$Co_2(CO)_6$ complex of diphenylbutadiyne (Ph–C≡C–C≡C–Ph).[7] The C–C–C bond angles at the four nominally sp hybridised centres of this complex fall in the range 139–145°. We predicted that if a butadiyne linker were incorporated into a macrocycle then cluster complexation to this host could induce sufficient structural change to inhibit guest binding. Hybrid macrocycle **1** appeared an ideal candidate with which to test this theory since it forms a weak donor–acceptor complex with π-deficient diimides ($K_a \approx 400$ M^{-1}), and has also been employed as a template for [2]catenane formation under kinetically controlled conditions.[8]

Treatment of a THF solution of **1** with excess $Co_2(CO)_8$ (3 equiv. per triple bond) rapidly affords a single complexed product **2** which may be obtained in near quantitative yield after chromatography on silica gel.‡ The ^{1}H NMR spectrum of **2** closely resembles that of **1** save for an aromatic doublet that shifts upfield from around 6.80 to 6.11 ppm perhaps as a result of the greater proximity of the two aromatic components. The ^{13}C NMR spectrum provides rather more information: the methylene carbons adjacent to the complexed butadiyne link are shifted downfield from around 56 to 68–70 ppm (obscured by OCH_2CH_2 resonances). The complexed acetylenic carbons are found at 96 and 93 ppm, downfield shifted from around 72 ppm in free **1**. These shifts are consistent with the introduction of strongly electron withdrawing substituents and previously reported values.[7] The electrospray ionisation mass spectrum of **2** reveals the sequential loss of CO ligands from the bis-$Co_2(CO)_6$ complexed macrocycle (M_r = 1124). Notably, the ^{1}H NMR spectrum of **2** in $CDCl_3$ was unchanged after standing in solution for several weeks; samples stored as dry solids proved similarly robust. Removal of the cobalt clusters could be achieved by treatment of **2** with iron(III) nitrate[3] in EtOH or, more conveniently, with trimethylamine oxide in THF.§ Regeneration of free **1** could be conveniently monitored by TLC. An intermediate, presumably the mono-$Co_2(CO)_6$ complex, could be discerned prior to complete conversion to **1**. Scheme 2 summarises the structural protection and deprotection steps.

We exemplify the application of this idea by controlling the formation of a π-donor/π-acceptor [2]catenane under catalytic ring closing metathesis conditions. The catalytic RCM reaction has become a familiar synthetic tool[9] and has also been employed in templated macrocycle[10] and catenane syntheses.[11] We anticipate that the reversible nature of the RCM bond-forming reaction will facilitate competition and evolution between related interlocked systems and thus provide the 'error-checking' facility necessary for the reliable assembly of higher



Scheme 1 General reaction of a functionalised acetylene with $Co_2(CO)_8$



Scheme 2 Blocking of a cyclophane receptor cavity by temporary structural modification

order interlocked molecular systems. The interlocking procedure also provides an ideal means with which to demonstrate the feasibility of our blocking principle.¶

Exposing a 2 : 1 molar ratio of diimide diolefin **3** and hybrid macrocycle **1** to Grubbs' catalyst (DCM, rt, 3 days) afforded the three isomeric forms of the corresponding [2]catenane **4**; direct hydrogenation of the reaction mixture (H_2, Pd–C) gave a single catenane product **5** in 15% overall yield.‖ Under identical reaction conditions a 2 : 1 molar ratio of diolefin **3** and complexed macrocycle **2** did not undergo interlocking, periodic analysis (LC-MS, TLC) revealing only the stubborn persistence of **2**. After three days 1 mol equiv. of free macrocycle **1** was added to the metathesis mixture and production of [2]catenane **4** commenced: this observation proves that under 'live' metathesis conditions macrocycle **2** is indeed blocked to threading by diolefin **3**. Direct hydrogenation (H_2, Pd–C) of the crude reaction mixture yielded the expected [2]catenane **5** and the protected macrocycle **2**.

The significance of the survival of **2** throughout this sequence of events lies in the realisation that this structural tool provides the means by which to prevent binding at one masked recognition site whilst the chosen reaction conditions act on a binding event elsewhere in the system or, potentially, within the same molecule. Both the olefin metathesis and hydrogenation steps are chemically orthogonal to the deprotection of **2**, the cobalt complexed macrocycle being unaffected by two distinct chemical transformations occurring within the system. We intend to exploit these observations in controlled syntheses of linear [*n*]catenanes.[12] There also exists the possibility of inhibiting a supramolecular interaction within a complex by cluster removal; an alternative view of this process is to regard the cluster as an effector for a particular interaction (Fig. 1). We also note that variations in cluster nuclearity and substitution pattern lead to subtle geometry changes in the resulting adducts, providing a means to fine tune molecular geometry.[13] In summary, it appears likely that both the specific, as described in this work, and general concepts of binding modulation through temporary structural modification will be of use in the area of host–guest chemistry.

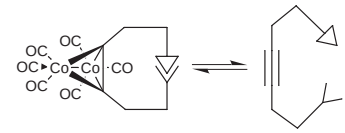


Fig. 1 Inhibition of a supramolecular interaction by cluster removal.

We thank the Engineering and Physical Sciences Research Council (UK) for generous financial support and Professor Phil Parsons (Sussex, UK) for suggesting the use of a trialkylamine oxide as a cluster removal reagent.

Cycloheptyne–cobalt complexes *via* allylation of stabilized γ-carbonyl cations

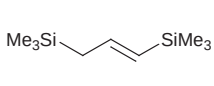
James R. Green*†

Chemistry and Biochemistry, School of Physical Sciences, University of Windsor, Windsor, Ontario, N9B 3P4, Canada

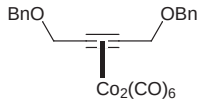
The Bu_2BOTf mediated reaction of stannylsilanes (5 and 9) with γ-methoxy-alkynoate and -alkynone hexacarbonyldicobalt complexes (8), followed by conversion of the organic carbonyl into an acetate and a $BF_3{\cdot}OEt_2$ mediated intramolecular reaction, affords cycloheptenyne hexacarbonyldicobalt complexes (13 and 15).

Cyclic alkynes are compounds of limited stability.[1] The smallest unsubstituted member of the series which can be isolated under conventional laboratory conditions is cyclooctyne; in the vast majority of cycloheptynes and smaller cycloalkynes, the strain of bending the sp hybridized carbon atoms substantially away from 180° has too great an energetic cost. This situation may be ameliorated by resorting to transition metal complexes of cycloheptynes, particularly the dicobalt hexacarbonyl complexes.[2]Alkyne hexacarbonyldicobalt complexes have bond angles which average *ca*. 140° at the alkynyl carbons; the resultant lower angle strain renders the cycloheptyne and cyclohexyne complexes thermally stable.[3]

In addition to the above reasons, cobalt cycloheptyne complexes are of interest due to the potential for applying the rich synthetic utility of cobalt–alkyne complexes[4–6] to seven membered ring systems. This potential is largely unexplored, however, as these systems have been prepared infrequently,[7,8] and their systematic synthesis and study has escaped report. Notably, the attempt to prepare systems of this type *via* a double Nicholas reaction using allyldimetal equivalent **1** and propargylic ether **2** met with complete failure.[9]



1



2

During our recent work involving silver mediated reactions of γ-chloro-alkynoate and -alkynone hexacarbonyldicobalt complexes,[10] we observed striking effects of the presence of an additional oxygen based function on the viability of propargyl alcohol or propargyl ether based Nicholas reactions. As a result, we believed that a stepwise reaction of **1** at the carbon bearing the chloride, manipulation of the carbonyl into a leaving group, and intramolecular allylsilane attack would give a cycloheptenyne complex.‡ Therefore, we tested the reaction of chloride **3** with **1** and $AgBF_4$ (0 °C, CH_2Cl_2), and to our surprise obtained a small amount of **4** as the sole condensation product. Compound **4** most probably results from the preferential loss of the internal trimethylsilyl group from the β-silyl cation intermediate, and allyldimetal equivalents with different electrofuges were investigated for their reactivity with **3**. Stannylsilane **5a**[11] gave more satisfactory results, and allylsilane **6a** was obtained as the major product, contaminated with vinylsilane **7a** (55%, **6a** : **7a** = 78 : 22). In this case the source of the isomeric impurity is believed to be Lewis acid mediated allylic rearrangement of the tin moiety in **5a** to give isomeric allyltin **5a′**;[12] despite this, recovered **5a** showed no evidence of **5a′**. Attempts to use systems with more bulky silyl groups gave improved regiochemical ratios in favour of the allylsilane product, at the expense of a satisfactory chemical yield.

Based on the report from Jacobi's laboratory of the condensation of boron enolates with γ-methoxyalkynoate hexacarbonyldicobalt complexes,[13] we found that Bu_2BOTf (0 °C, CH_2Cl_2) was capable of inducing the condensation between propargyl ether **8a** with **5a** to give **6a**/**7a** (84%, **6a** : **7a** = 78 : 22). While regiochemical impurity **7a** was still present, the use of silylstannane **5b**[14] with **8a** was now possible, and allylsilane **6b** could be prepared in good yield with only a trace of **7b** (63%, **6b** : **7b** = 96 : 4; Table 1). Application of this protocol to phenyl ketone **8b** gave **6c** as the major product, with a more substantial amount of vinylsilane **7c** (73%, **6c** : **7c** = 82 : 18). The methyl ketone **8c** would undergo additional reaction of the alkyl ketone function in the presence of >1 equivalents of Bu_2BOTf, and optimum results for the formation of **6d** were obtained by inverting the order of reagent addition, and by conducting the reaction at −60 °C (39%, 77% based on recovered starting material, **6d** : **7d** = 92 : 8). Finally, silylstannane **9**[15] reacted smoothly with **8a** to give **10** in good yield (83%).

The carbonyl functions in **6** and **10** could be converted into a leaving group by low temperature (−78 °C) reduction with Bu^i_2AlH, and trapping of the resultant alkoxide with freshly distilled acetic anhydride at room temperature, affording acetates **11–12** in excellent yields. In the case of phenyl ketone **6c**, the acylation step was very slow, and the addition of sodium acetate with catalytic amounts of DMAP was required to give useful amounts of **11c**.

12

With the appropriately attached allylsilane and propargylic acetate functions in place, the ability of the substrates to form cycloheptyne complexes was investigated. Slow addition of a CH_2Cl_2 solution of **11** to a 0 °C CH_2Cl_2 solution of excess $BF_3{\cdot}Et_2O$ (final substrate concentration = 1 mM) rapidly afforded cycloheptenyne complexes **13**, as red–violet oils of good thermal stability, in excellent yields (Table 2). In the phenyl and methyl substituted cases **11c** and **11d**, trace amounts of fluorocycloheptyne complexes **14b** (8%) and **14c** (6%), respectively, were also isolated. In the case of substrate **12**, cyclization under these conditions afforded methylenecycloheptyne complex **15a** contaminated with a minor amount of the *endo* double bond isomer **15b** (46%, 87 : 13), along with desilylated fluorocycloheptyne complex **16** (44%). An alternative procedure which employed the slow addition of $BF_3{\cdot}Et_2O$ (5 equiv.) to a solution of **12** (1.5 mM) at 0 °C gave slightly enhanced amounts of **15a** + **15b** (55%, 90 : 10) and a small amount of **16** (8%).

The results demonstrate the facility with which the Nicholas reaction chemistry of cobalt stabilized γ-carbonyl cations can be applied to the preparation of cycloheptyne cobalt complexes. Further work in this area, including that on superior allyldimetal equivalents and one pot, [4 + 3] cycloaddition approaches to the

A new structural type in iron carboxylate cluster chemistry *via* use of bis-bipyridine ligands: $[Fe_6O_4Cl_4(O_2CPh)_4L_2][FeCl_4]_2$

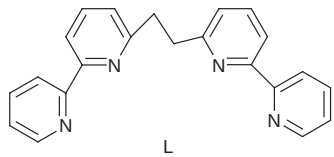
The reaction between $FeCl_3$, NaO_2CPh and L [L = 1,2-bis(2,2′-bipyridyl-6-yl)ethane] in MeCN gives the title complex 1 whose cation contains an unusual $[Fe_6(\mu_3\text{-}O)_4]^{10+}$ core, whereas in MeOH the dinuclear complex $[Fe_2(OMe)_2Cl_2(O_2CPh)L][FeCl_4]$ 2 is obtained; magnetic studies indicate that the cations of 1 and 2 both have $S = 0$ ground states, consistent with the expected antiferromagnetic exchange interactions.

In recent years, the synthesis and study of high-spin molecules (possessing large values of spin S in their ground state) have assumed greater importance as it has been discovered that such molecules represent the source of a new magnetic phenomenon, namely single-molecule magnetism.[1,2] As a result of a large spin and a negative magnetoanisotropy, as reflected in the zero-field splitting parameter D, such a single-molecule magnet (SMM) can be magnetized by an external magnetic field below some critical or blocking temperature. The first SMMs to be identified were $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ (R = Me, Et, Ph, *etc.*) complexes (S = 9 or 10)[1–3] and their one-electron reduced versions in $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^-$ salts (S = 19/2).[2] More recently, the $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ (X = Cl^-, Br^-, F^-, O_2CMe^-, *etc.*; dbm^- is the anion of dibenzoylmethane) complexes with $S = 9/2$[4,5] and $[V_4O_2(O_2CR)_7(L\text{–}L)_2]^z$ salts [L–L = 2,2′-bipyridine (bpy), $z = +1$; L–L = 2-picolinate, $z = -1$] with $S = 3$[6] have also been discovered to be SMMs, as has a $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ salt (tacn = 1,4,7-triazacyclononane) with $S = 10$.[7]

Important to the future of the field of high-spin molecules, and to the possible identification of new SMMs, is the development of synthetic methodologies that can yield new metal clusters, particularly those of Mn^{III} and Fe^{III}. With this in mind, we have been investigating the ability of bis-bipyridine ligands such as L to assemble new cluster types with Mn^{III} and Fe^{III} not available with simpler ligands such as bpy itself. We herein describe access *via* this route to a new Fe_6 structural type, as well as a related Fe_2 species, confirming the potential of this ligand for cluster synthesis in Fe^{III}–Mn^{III} chemistry.



L

The reaction between $FeCl_3$, NaO_2CPh and L (4 : 4 : 1) in MeCN gave a red–brown solution and an off-white solid (NaCl). After 24 h reaction time, the solution was filtered, and the filtrate concentrated under vacuum to half its original volume and layered with Et_2O. Red–brown crystals of $[Fe_6O_4Cl_4(O_2CPh)_4L_2][FeCl_4]_2 \cdot 2MeCN$ **1**·2MeCN slowly grew over 1–2 weeks in 40% yield; dried solid analysed as **1**·MeCN.† The same reaction in a 3 : 3 : 1 ratio carried out in MeOH gave an orange precipitate. This was collected by filtration and recrystallized from warm MeOH–MeCN (1 : 1) to give orange needles of $[Fe_2(OMe)_2Cl_2(O_2CPh)L][FeCl_4]$ **2** in 28% yield.† Note that the use of bpy instead of L in the MeCN reaction gives $[Fe_4O_2(O_2CPh)_7(bpy)_2][FeCl_4]$, the cation of which has been previously reported.[8]

The structures‡ of the cations of **1** and **2** are shown in Figs. 1 and 2, respectively. The centrosymmetric cation of **1** contains an unusual $[Fe_6(\mu_3\text{-}O)_4]^{10+}$ core (6 × Fe^{III}) that can be conveniently described as consisting of three edge-fused $[Fe_2O_2]$ rhombs to which are attached two additional Fe atoms Fe(1) and Fe(1′); the latter are four-coordinate with distorted tetrahedral geometry whereas the other Fe atoms are six-coordinate with distorted octahedral geometry. A side view shows the $[Fe_6O_4]$ core to be nearly planar. The L and central $PhCO_2^-$ groups bridge the Fe(2)/Fe(3) and Fe(2′)/Fe(3′) pairs. An alternative description of the structure is particularly useful: the cation consists of two $[Fe_2O_2(O_2CPh)L]^+$ fragments that are linked by inter-fragment bonds Fe(2)–O(7′) and Fe(2′)–O(7), and this incipient, supramolecular chain formation is terminated by the $[FeCl_2(O_2CPh)]$ caps at each end, whose Fe(1) and O(10) atoms bind to and prevent O(6) and Fe(3) from attaching to another $[Fe_2O_2(O_2CPh)L]^+$ fragment. Note the unusual nearly T-shaped geometry of O(7) and O(7′), with Fe(2′)–O(7)–Fe(3) angles of 159.25(21)°.

The cation of **2** contains a $[Fe_2(\mu\text{-}OMe)_2]^{4+}$ core with bridging L and $PhCO_2^-$ groups, and octahedral geometry at each Fe^{III} completed by terminal Cl^- ions. The dinuclear unit is thus similar to the repeating $[Fe_2O_2(O_2CPh)L]^+$ fragment of **1**, with aggregation blocked by the MeO^--for-O^{2-} substitution at

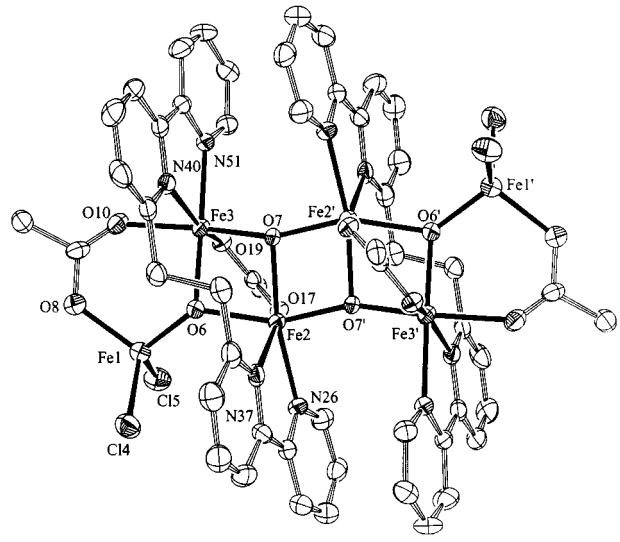


Fig. 1 The structure of the cation of **1**; only the *ipso* C atoms of the Ph rings are shown. Selected interatomic distances (Å) are: Fe(1)···Fe(2) 3.483(2), Fe(1)···Fe(3) 3.357(2), Fe(2)···Fe(3) 2.932(2), Fe(2)···Fe(2′) 3.054(2), Fe(2)···Fe(3′) 3.692(2), Fe(1)–O(6) 1.806(4), Fe(2)–O(6) 1.994(4), Fe(2)–O(7) 2.045(4), Fe(2)–O(7′) 1.889(4), Fe(3)–O(6) 1.965(4), Fe(3)–O(7) 1.864(4). Primed and unprimed atoms are related by the inversion centre.

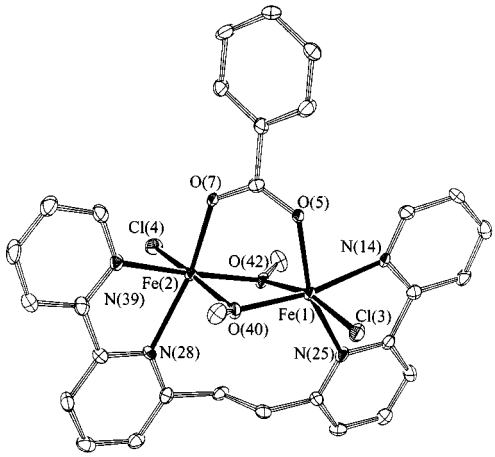

Fig. 2 The structure of the cation of **2**. Selected interatomic distances (Å) and angles (°) are: Fe(1)···Fe(2) 3.088(2), Fe(1)–O(40) 1.981(4), Fe(1)–O(42) 1.993(4), Fe(1)–Cl(3) 2.290(2), Fe(2)–O(40) 2.013(4), Fe(2)–O(42) 1.973(4), Fe(2)–Cl(4) 2.271(2); Fe(1)–O(40)–Fe(2) 101.31(19), Fe(1)–O(42)–Fe(2) 102.29(18).

the bridging position and terminal Cl^- ions on the Fe atoms. The Fe(1)···Fe(2) distance in **2** [3.088(2) Å] is only slightly longer than the Fe(2)···Fe(3) distance in **1** [2.932(2) Å].

Comparison of **1** and **2** shows that L is a binucleating ligand and it adopts the same bridging mode in both complexes with the ethylene bridge forcing the two bpy halves to be essentially parallel. There appears to be no reason why longer chains of $[Fe_2O_2(O_2CPh)L]^+$ repeating units with $[FeCl_2(O_2CPh)]$ caps should not be possible, yielding the supramolecular $[Fe_{2n+2}O_{2n}Cl_4(O_2CPh)_{n+2}L_n]^{n+}$ family of which **1** is the $n = 2$ member. This possibility is currently being investigated by changes in the reagent ratios.

Solid-state magnetic susceptibility data were collected in a 1 Tesla field. The effective magnetic moment μ_{eff} ($\chi_m T$) value for **1** slowly decreases from 10.30 μ_B (13.26 cm^3 K mol^{-1}) at 13.0 K and then decreases rapidly to 6.76 μ_B (5.71 cm^3 K mol^{-1}) at 2.0 K. Subtracting out the expected values for the $[FeCl_4]^-$ anions ($S = 5/2$) shows that μ_{eff} and $\chi_m T$ for the cation decrease to essentially zero at low temperatures, indicating a $S = 0$ ground state. Similarly, μ_{eff} ($\chi_m T$) values for **2** are 9.33 (10.88), 5.90 (4.35) and 5.19 μ_B (3.37 cm^3 K mol^{-1}) at 300, 9.00 and 2.00 K (Fig. 3), respectively. Subtracting out the contribution from the $[FeCl_4]^-$ anion again indicates a $S = 0$ ground state, and fitting of the 13.0–300 K data (lower T data were affected by zero-field splitting in the anion and were omitted) to a Heisenberg exchange model ($\hat{H} = -2JS_1S_2$) gives $J = -10.48$ cm^{-1} with g held at 2.00 (solid line in Fig. 3). This value is as expected from the empirical J *vs.* $2P$ relationship, where $2P$ is the shortest Fe–O–Fe bond distances, which suggests J for **2** should be 10.89 cm^{-1} for $2P = 3.966$ Å.[9] Plots of μ_{eff} *vs.* T and magnetization *vs.* magnetic field for compounds **1** and **2** are available as supplementary information. See http://www.rsc.org/suppdata/cc/1998/1753.

In summary, the use of the bis-bipyridine ligand L has allowed access to a new Fe_6 structural type, as well as an Fe_2 species. The ability of L to provide new high nuclearity Fe and Mn species is under continuing investigation, as is the use of this ligand to access Fe_2 species of biological relevance to the many Fe biomolecules containing a dinuclear oxo-bridged unit.

This work was supported by the National Science Foundation.

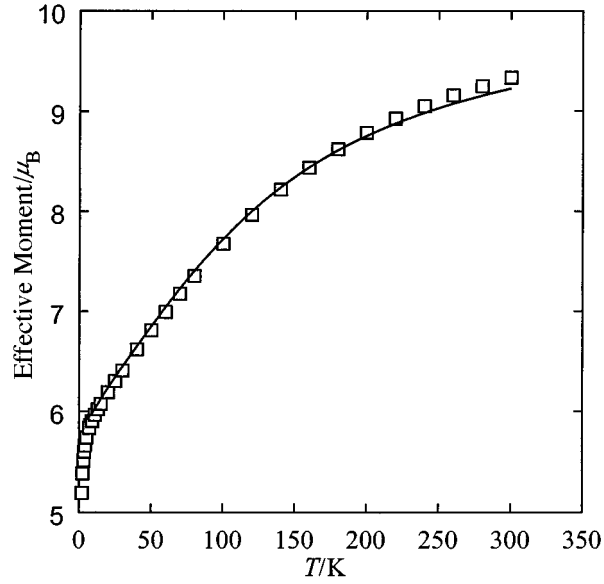

Fig. 3 Plot of effective magnetic moment *vs.* T for complex **2**. The solid line is a fit of the 13.0–300 K data to the appropriate theoretical equation for an exchange-coupled Fe^{III}_2 cation and non-interacting $S = 5/2$ anion. See the text for the fitting parameters.

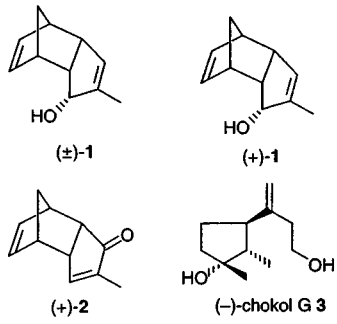
Asymmetric hydrogen transfer protocol for enantiocontrolled synthesis of (−)-chokol G

Regina Mikie Kanada, Takahiko Taniguchi and Kunio Ogasawara*†

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578, Japan

An enantiocontrolled route to the (−)-chokol G, a fungitoxic metabolite from stromata of *Epichloe typhia*, has been devised by employing a Ru^{II}-catalyzed asymmetric hydrogen transfer reaction as the key step.

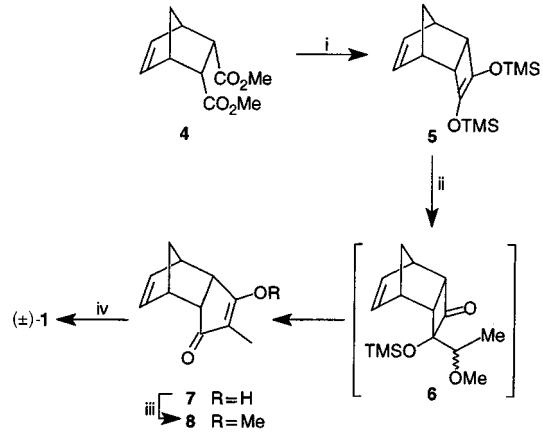
Noyori and co-workers have found that Ru^{II}-complexes of chiral *N*-tosyl-1,2-diphenylethylenediamines are efficient catalysts for the kinetic resolution of racemic aryl and alkenyl alcohols under asymmetric hydrogen transfer conditions in acetone.[1] In general, the reaction proceeds facilely to give highly enantiomerically enriched alcohols with generation of achiral ketones *via* consumption of the enantiomeric alcohols. The reaction, therefore, loses one half of the starting material unless *meso* substrates having a ene-1,4-diol functionality are used. We envisaged that the catalytic asymmetric hydrogen transfer reaction might be carried out without loss of half of the starting material by using substrates having an appropriate structural background. In this regard we chose 2-methylcyclopent-2-enol derivative **1**, having a cyclopentene-3,5-diyl functionality attached to its 4,5-carbons, which does not lose the chirality due to the 4,5-functionality even though its allylic alcohol functionality loses its chirality. We report herein the first example of the asymmetric resolution of racemic allylic alcohol (±)-**1** by asymmetric hydrogen transfer reaction, without formation of an achiral waste product, to give the chiral enone (+)-**2** and the chiral alcohol (+)-**1**, both of which may be converted into (−)-chokol G[2,3] **3**, a fungitoxic metabolite from stromata of *Epichloe typhia*.[2]



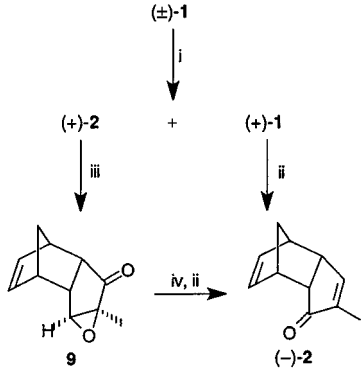
The tricyclic ene-1,2-diol bis-silyl ether[4] **5**, obtained in 90% yield from the diester **4**, was reacted with 1,1-dimethoxyethane in the presence of $BF_3{\cdot}OEt_2$[5,6] to give the aldol product **6**. Without purification, **6** was immediately refluxed in TFA to initiate the ring expansion[5,6] to furnish the β-hydroxy enone **7**,‡ which was treated with Me_2SO_4 in the presence of NaH to give the β-methoxy enone **8** in 56% overall yield from **5**. Treatment of the enone **8** with LAH in refluxing Et_2O afforded in one step the *endo*-allyl alcohol (±)-**1** stereoselectively as a single product in 65% overall yield (Scheme 1).

To carry out the asymmetric hydrogen transfer reaction, the racemic allyl alcohol (±)-**1** was stirred in acetone at room temperature in the presence of a catalytic amount (1 mol%) of the ruthenium catalyst,[1,7] prepared from [{$RuCl_2$(η⁶-mesitylene)}$_2$] and (1*S*,2*S*)-1-*N*-(*p*-tolylsulfonyl)-1,2-diphenylethylenediamine (TsDPEN). The reaction terminated within 5 h to afford the enantiomerically enriched enone (+)-**2**, in 44% yield, leaving the highly enantiomerically enriched allylic alcohol (+)-**1**, $[\alpha]_D^{31}$ +185.4 (*c* 1.1, $CHCl_3$), in 37% yield.§ The enantiomeric purities of the products were determined to be 87 and 98% ee by HPLC using a chiral column (CHIRALCEL OD, elution with 0.1% Pr^iOH–hexane) after converting **1** into the benzoate. When the catalyst, prepared similarly from [{$RuCl_2$(η⁶-cymene)}$_2$] in place of [{$RuCl_2$(η⁶-mesitylene)}$_2$], was used under the same conditions, virtually the same results were obtained to give the enone (+)-**2** in 49% yield with 73% ee and (+)-**1** in 36% yield with >99% ee, although the reaction proceeded at a much faster rate (2 h). The latter alcohol (+)-**1** afforded the enone (−)-**2**, $[\alpha]_D^{27}$ −85.8 (*c* 1.3, $CHCl_3$) [lit.,[8] −85.4 (*c* 1.4, $CHCl_3$)], in 89% yield upon oxidation with manganese(II) dioxide. On the other hand, the former (+)-enone (+)-**2** may be inverted without loss of the original chiral integrity to the enantiomeric (−)-enone **2** in 50% overall yield *via* the epoxide **9** by sequential Wharton rearrangement and oxidation[8] (Scheme 2).

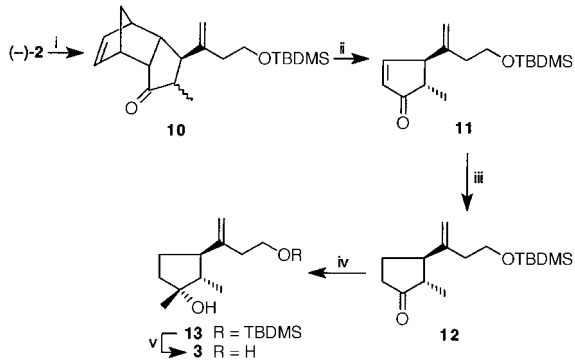
Having established a methodology for the resolution of a particular racemate without losing one enantiomer by employing the asymmetric hydrogen transfer reaction, we next carried out conversion of the resulting enantiomerically pure enone (−)-**2** into (−)-chokol G[3] **3** so as to demonstrate its synthetic potential. The synthesis was commenced by the 1,4-addition reaction of (−)-**2** with 4-*tert*-butyldimethylsiloxybut-2-enyllithium, generated *in situ* by treating 2-bromo-4-*tert*-butyldimethylsiloxybut-2-ene with Bu^tLi,[9] in the presence of lithium 2-thienyl(cyano)cuprate.[9] The reaction furnished the *exo*-addition product **10** in 94% yield as a mixture of the two epimers at the α-methyl center. On thermolysis in refluxing Ph_2O, the mixture afforded the single enone **11**, $[\alpha]_D^{27}$ −97.5 (*c* 1.2, $CHCl_3$), in 87% yield by retro-Diels–Alder reaction and spontaneous α-epimerization to the thermodynamically more stable isomer having *trans*-α,β-configuration. Treatment of **11**



Scheme 1 *Reagents and conditions*: i, Na, TMSCl, toluene, reflux (90%); ii, $MeCH(OMe)_2$, $BF_3{\cdot}OEt_2$, CH_2Cl_2, −78 °C, then TFA, reflux; iii, Me_2SO_4, NaH, DMF–THF (1:1) (56% from **5**); iv, LAH, Et_2O, reflux (65%)



Scheme 2 *Reagents and conditions*: i, [Ru^{II}(η^6-mesitylene)], (1*S*,2*S*)-TsDPEN (1 mol%), acetone, room temp., 4.6 h, [44% and 87% ee for (+)-**2** and 37% and 98% ee for (+)-**1**]; ii, MnO_2, CH_2Cl_2 (89%); iii, 30% H_2O_2, 0.5 M NaOH, MeOH; iv, $NH_2NH_2{\cdot}H_2O$, AcOH (cat.), MeOH, then MnO_2, CH_2Cl_2 [50% from (+)-**2**]



Scheme 3 *Reagents and conditions*: i, CH_2=C(Br)CH_2CH_2OTBDMS, Bu^tLi, 2-thienyl(CN)CuLi, Et_2O, −25 °C (94%); ii, Ph_2O, reflux (87%); iii, DIBAL-H, CuI, HMPA–THF (1:4), −78 °C (92%); iv, MeLi, $CeCl_3$, THF, −78%; v, Bu_4NF, THF [69% from **12** after separation of the epimer (6%)]

with DIBAL-H in the presence of CuI and HMPA[10] in THF allowed 1,4-reduction to give the cyclopentenone **12**, $[\alpha]_D^{29}$ +45.2 (*c* 1.3, $CHCl_3$), in 92% yield. Reaction of **12** with excess MeLi in the presence of $CeCl_3$[3b,11] afforded a mixture consisted of two epimers which, without separation, was exposed to TBAF to give (−)-chokol G[2] **3**, $[\alpha]_D^{29}$ −58.1 (*c* 0.4, MeOH) [natural[2] −43.3 (*c* 0.24, MeOH)], in 69% overall yield as the major product accompanied with the minor epimeric alcohol, $[\alpha]_D^{29}$ −34.2 (*c* 0.3, MeOH), in 6% overall yield. Since the conversion of chokol G **3** into the other congeners, chokols A, B, C, F and K, chokolic acid B, and chokolal A, in the racemic series has been established,[12] the present synthesis formally constitutes the chiral preparation of these natural products.

We thank the Ministry of Education, Science, Sports and Culture of Japan for a scholarship (to R. M. K.).

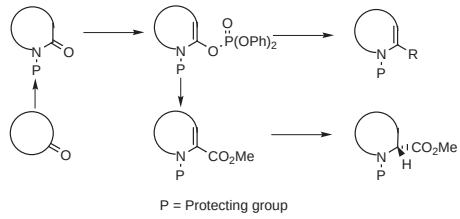
Synthesis of *N*-heterocycles *via* lactam-derived ketene aminal phosphates. Asymmetric synthesis of cyclic amino acids.

K. C. Nicolaou,* Guo-Qiang. Shi, Kenji Namoto and Federico Bernal

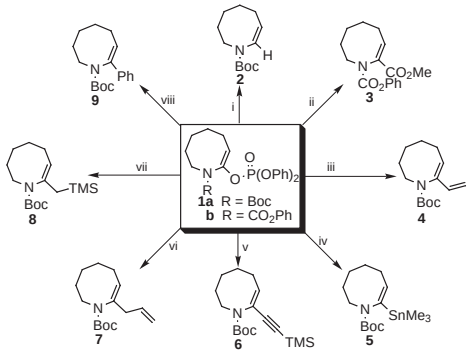
Department of Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037, USA and Department of Chemistry and Biochemistry, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093, USA

A variety of *N*-heterocycles can be synthesized from lactams *via* Pd^0-catalyzed couplings of their corresponding enol phosphates.

Due to the rich chemistry and biology of nitrogen-containing compounds, the synthesis of *N*-heterocycles has been a central and important theme within organic chemistry. The functionalization of lactams to substituted heterocycles *via* the corresponding enol triflates has been reported.[1] However, the triflate-based methodology has been proven cumbersome due to the rather unstable, difficult-to-isolate nature of the triflates and the necessity to use unconventional and expensive triflating reagents. Here we report the synthesis of lactam-derived ketene aminal phosphates[2] and their utilization for the construction of a variety of *N*-heterocycles, including enantiomerically enriched cyclic amino acids. In contrast to their triflate counterparts, these phosphate intermediates enjoy remarkable stability, efficiency of formation and reactivity, as well as easy access and versatility (Scheme 1).[3]



Scheme 1



Scheme 2 *Reagents and conditions*: i, Et_3Al (1 M in hexanes, 2.0 equiv.), $Pd(PPh_3)_4$ (0.05 equiv), THF, 6 h, 92%; ii, CO (1 atm), $Pd(OAc)_2$ (0.1 equiv.), PPh_3 (0.2 equiv.), MeOH (3.0 equiv.), Et_3N (3.0 equiv.), DMF, 60 °C, 4 h, 72%; iii, $Bu_3SnCH{=}CH_2$ (2.0 equiv.), $Pd(PPh_3)_4$ (0.05 equiv.), LiCl (3.0 equiv.), THF, heat, 3 h, 85%; iv, $(Me_3Sn)_2$ (2.0 equiv.), $Pd(PPh_3)_4$ (0.05 equiv.), LiCl (3.0 equiv.), THF, heat, 3 h, 77%; v, $Me_3SiC{\equiv}CH$ (3.0 equiv.), $Pd(PPh_3)_4$ (0.1 equiv.), CuI (0.1 equiv.), Et_2NH–THF (2:1), 25 °C, 4 h, 84%; vi, $Bu_3SnCH_2CH{=}CH_2$ (2.0 equiv.), $Pd(PPh_3)_4$ (0.05 equiv.), LiCl (3.0 equiv.), THF, heat, 4 h, 93%; vii, Me_3SiCH_2MgCl (3.0 equiv.), $Ni(acac)_2$ (0.05 equiv.), Et_2O, 25 °C, 1 h, 88%; viii, PhZnCl (2.0 equiv.), $Pd(PPh_3)_4$ (0.05 equiv.), THF, 50 °C, 1 h, 87%

The synthesis of ketene aminal diphenylphosphates **1a**,**b** is accomplished from the eight-membered *N*-Boc or *N*-CO_2Ph protected lactams *via* their potassium enolates. These compounds proved quite stable at ambient temperatures and to silica gel flash chromatography, entering a variety of coupling reactions with appropriate partners under palladium(0) or nickel(0) catalyzed conditions, (Scheme 2). All of these reactions proceeded smoothly in good to excellent yields, furnishing a variety of products capable of further functionalization.

The generality and scope of the present technology was further illustrated by synthesizing ketene aminal phosphates of different ring sizes, as shown in Table 1. Two useful applications of the newly synthesized dienes[4] (Table 1) are shown in Scheme 3. Thus, diene **4**† enters smoothly into a Diels–Alder reaction with benzoquinone affording, after silica gel-induced tautomerization, hydroquinone **22**, while diene **17** reacted with singlet oxygen to afford endoperoxide **23**. The latter compound was reduced to diol **24** in 57% overall yield upon treatment with aluminium amalgam.

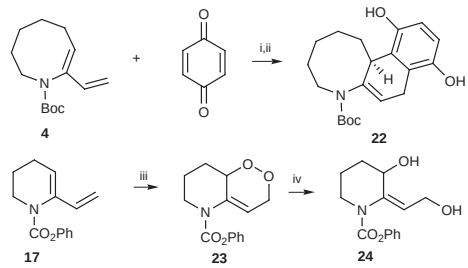
[a] Conditions: $(PhO)_2P(O)Cl$ (1.5 equiv.), KHMDS (1.2 equiv.), THF, −78 °C, 0.5 h; add base to lactam and phosphoryl chloride. [b] Coupling conditions as described in Scheme 2 for compound **1a.** [c] KHMDS (1.0 equiv.) was used.



Scheme 3 *Reagents and conditions*: i, benzoquinone (5.0 equiv.), toluene, heat, 24 h; ii, silica gel, Et_2O, 12 h, 86% (2 steps); iii, O_2, tetraphenylporphine (trace), CCl_4, 500 W halogen lamp, 15 min, ; iv, Al-Hg (excess), THF–H_2O (10:1), 1.5 h, 57%

The chemistry of ketene aminal phosphates was explored further through their Pd-catalyzed carbonylation and subsequent asymmetric hydrogenation. Thus, a series of compounds arising from carbonylation of the ketene aminal phosphates were synthesized in good yields (Table 2). They were then subjected to asymmetric hydrogenation[6,7] in the presence of a catalytic amount of [Rh(COD)-(−)-(*R*,*R*)-(Et-DuPHOS)]OTf.[8] This afforded the corresponding cyclic amino acids in excellent yields and with high enantioselectivities except for the five- and six-membered rings, which resisted hydrogenation under standard conditions and gave low enantioselectivities at high pressures. Inspection of the NMR spectra of the compounds with larger ring sizes (7–16) revealed that the unsaturated esters exist as two rotamers, with rotamer **A** being

Table 2 Synthesis of cyclic dehydroamino acids from carbonylation of ketene aminal phosphates and subsequent asymmetric hydrogenation

Phosphate	Carbonylation[a]	Yield (%)	Hydrogenation[b]	Yield (%)	Ee (%)[c]
10	 **25**	70[d]	 **31**	84	0.4
11	 **26**	78	 **32**	95[e]	26.5

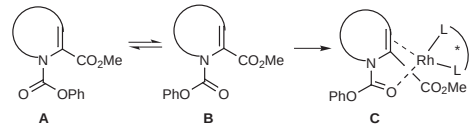
[a] Conditions: CO (1 atm), $Pd(OAc)_2$ (0.1 equiv.), PPh_3 (0.2 equiv.), MeOH (40 equiv.), Et_3N (2.0 equiv.), DMF, 60 °C, 3–6 h; [b] Conditions: H_2 (90 psi), [Rh(COD)-(−)-(*R*,*R*)- Et-DuPHOS)]OTf (0.06 equiv.), MeOH, room temp., 24 h. [c] Determined by HPLC on a Chiralcel OD using hexanes–Pr^iOH (7:1) as eluent (for compounds **31–33**) or an AD column using hexanes–Pr^iOH (97:3) as eluent (for compounds **34–37**). [d] (*R*)-(+)-BINAP (0.1 equiv.) was used instead of PPh_3 (see ref. 5). [e] Reaction performed under H_2 (400 psi) at 70 °C in EtOH. [f] Yield based on 77% conversion.



Scheme 4

the preferred one (Scheme 4). However, the five- and six-membered ring compounds **25** and **26** show the presence of only one rotamer, assumed to be rotamer **A**, in their NMR spectra. Through variable temperature NMR experiments, it was found that the rotamer **B** of **26** appears at around 70 °C. It is, however, rotamer **B** that enables the formation of the requisite chelation complex **C** which could result in asymmetric induction during hydrogenation.[6] This phenomenon can also explain the lack of reactivity of **25** and **26** under standard conditions.

The chemistry described herein demonstrates the potential of cyclic ketene aminal phosphates as substrates for the construction of a variety of *N*-heterocycles, including alkaloid structures and unnatural amino acids through transition metal catalyzed reactions. Multiple applications in synthesis are envisioned for this new synthetic technology.

We thank Professor K. B. Sharpless, Dr L. Gooβen, and Dr K. R. Dress for assistance with chiral HPLC and high pressure equipment. This work was financially supported by the National Institutes of Health, USA (G. M.) and The Skaggs Institute for Chemical Biology.

Notes and References

† *Synthetic procedure* for **4**: To a solution of *N*-CO_2Ph protected 2-azacyclooctanone (1.16 g, 4.7 mmol) and $(PhO)_2P(O)Cl$ (1.46 ml, 7.0 mmol) in THF (80 ml) at −78 °C was added KHMDS (0.5 M in toluene, 14.1 ml, 7.0 mmol). After being stirred at −78 °C for 30 min, the reaction mixture was treated with 1 M aq. NH_3 (80 ml) for 10 min. The organic phase was separated and the aqueous layer was extracted with Et_2O (3× 20 ml). The combined organic phases were dried ($MgSO_4$) and concentrated. The residue was subjected to flash column chromatography (silica gel, 1:1 Et_2O–hexanes containing 2% Et_3N) to give phosphate **1b** (2.18 g, 96%). A solution of **1a** (0.24 g, 0.52 mmol), anhydrous LiCl (66 mg, 1.57 mmol), tri-*n*-butyl(vinyl)tin (0.31 ml, 1.05 mmol) and $Pd(PPh_3)_4$ (53 mg, 0.046 mmol) in THF (20 ml) was heated at 70 °C under Ar for 3 h. The solution was then diluted with Et_2O and filtered through silica gel. The filtrate was concentrated and the residue was subjected to flash column chromatography (silica gel, 1:9 Et_2O–hexanes) to give diene **4** (105 mg, 85%).

Enantioselectivity *vs.* kinetic resolution in antibody catalysis: formation of the (*S*) product despite preferential binding of the (*R*) intermediate

Doron Shabat,[a,b] Hagit Shulman,[b] Harel Itzhaky,[b] Jean-Louis Reymond*[c] and Ehud Keinan*[a,b]†‡

[a] *The Scripps Research Institute, Department of Molecular Biology and the Skaggs Institute for Chemical Biology, 10550 North Torrey Pines Road, La Jolla, California 92037, USA*

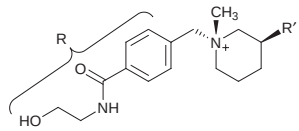
[c] *Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, 3012 Bern, Switzerland*

Antibody 14D9, which catalyzes the stereoselective transformation of achiral enol ethers into the corresponding (*S*)-ketals, resolves a racemic mixture of structurally similar chiral enol ethers by selective conversion of the (*R*)-enol ether into the (*R*)-ketal, raising the possibility that the (*S*) transition state is preferencially stabilized by the antibody despite a better binding of the (*R*) intermediate.

Catalytic antibodies, which are produced by immunization against stable transition state analogs of chemical reactions,[1] offer unique opportunities, not only in expanding the repertoire of synthetic tools available to the organic chemist,[2] but also in studying fundamental aspects of enzymatic catalysis.[3] For example, antibody 14D9, which was raised against the quaternary ammonium hapten **1b**, has taught us a great deal about

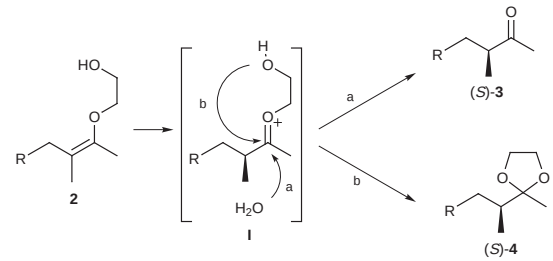


1a R′ = H
b R′ = $CH_2NHCO(CH_2)_3CONH$-carrier protein

synthetic opportunities using catalytic antibodies and also about mechanistic aspects of biocatalysis.[4] This proficient catalyst might be mechanistically related to primordial glycosidase enzymes.[5] Herein we report on a unique property of this catalyst. The antibody catalyzes the enantioselective protonolysis of achiral enol ethers to give the (*S*) product. Yet, evidence from kinetic resolution of chiral enol ethers shows that 14D9 binds the (*R*) oxocarbenium ion intermediate more strongly than the (*S*) intermediate.

The 14D9-catalyzed conversion of enol ether **2** into a mixture of ketone **3** and ketal **4**, which both have an (*S*) configuration (Scheme 1), goes through an intermediate oxocarbenium ion **I**, which is produced in the rate-limiting protonation of enol ether **2**.[6] Partitioning of this intermediate to give the final products **3** and **4** depends on the availability of water molecules in the medium. Ketal **4** does not form in aqueous solutions and is produced exclusively within the antibody binding site. Therefore, the optical purity of **4** provides a direct measure of the enantioselectivity in the antibody-catalyzed reaction. Indeed, the 14D9-catalyzed protonolysis of **2** was found to be highly stereoselective, producing (*S*)-**4** in 99.5% ee.[6]

There is an intriguing question related to the origin of the enantioselectivity in the rate-determining protonation step. Intuitively, one would expect that (*S*) selectivity arises from preferential binding of the antibody to both the (*S*) transition state, (*S*)-TS and the structurally similar (*S*) intermediate, (*S*)-**I** [Fig. 1A]. Nevertheless, we cannot rule out *a priori* the alternative possibility, in which the antibody still binds selectively to (*S*)-TS but binds preferentially to the opposite enantiomeric intermediate (*R*)-**I** [Fig. 1B].



R = $HO(CH_2)_2NHCOC_6H_4$

Scheme 1

This mechanistic issue could be resolved if the affinity of 14D9 to each of the two enantiomeric forms of **I** could be compared. These enantiomeric intermediates occur not only along the reaction pathway leading from **2** to ketal **4**, but also along the similar conversion of the isomeric enol ether **5** to **4** (Scheme 2). Therefore, one could obtain the desired information about the relative stability of (*S*)-**I** and (*R*)-**I** by studying the kinetic resolution of **5** by 14D9. Conversion of (*S*)-**5** and (*R*)-**5** into ketals (*S*)-**4** and (*R*)-**4**, respectively, proceeds *via* the enantiomeric intermediates (*S*)-**I** and (*R*)-**I**. If the antibody catalyzed the protonolysis of (*S*)-**5** preferentially over (*R*)-**5** this would imply that 14D9 binds (*S*)-**I** more tightly than (*R*)-**I**. This would be consistent with the energy diagram shown in Fig. 1(A) for enol ether **2**. Conversely, if catalytic protonolysis of (*R*)-**5** was faster than that of (*S*)-**5**, this would support the alternative energy profile described in Fig. 1(B).

Substrate **5** was prepared from methyl 4-bromomethylbenzoate and ethyl 2-methyl-3-oxobutanoate.[6,7] The initial alkylation product was decarboxylated and the resultant ketone was converted to the corresponding 1,3-dioxolane. The latter was opened with $(Me_3Si)_2NH$ and TMSI to produce a mixture of three isomeric enol ethers in almost equal proportions. These isomers were separated by column chromatography and each was subjected to aminolysis with ethanolamine. The two

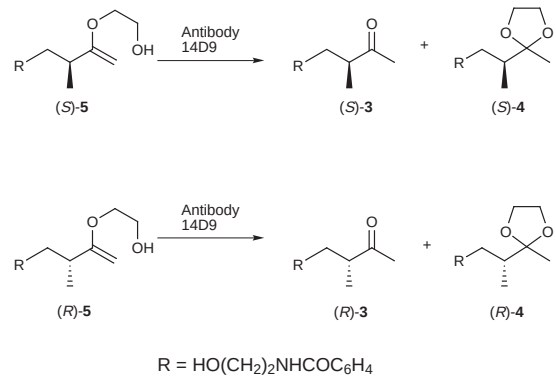

Scheme 2

Table 1 Kinetic parameters for the antibody 14D9-catalyzed hydrolysis of **5**[a]

Substrate	K_M/μM	k_{cat}/min^{-1}	k_{un}/min^{-1}	k_{cat}/k_{un}	K_{TS}/μM
rac-**5**	480 ± 200	(4.3 ±1.9)× 10^{-2}	1.55× 10^{-5}	2760	0.17
(*R*)-**5**	210 ± 70	(4.6 ± 1.5)× 10^{-2}	1.55× 10^{-5}	2990	0.07
(*S*)-**5**	470 ± 230	(3.4 ± 1.7)× 10^{-3}	1.55× 10^{-5}	220	2.14

[a] Reactions were carried out in 100 mM NaCl and 50 mM 1,3-bis[tris-(hydroxymethyl)methylamino]propane (bistris), pH 8.0, 25 °C. Ketal **4** (*ca.* 20%) was formed in all cases.

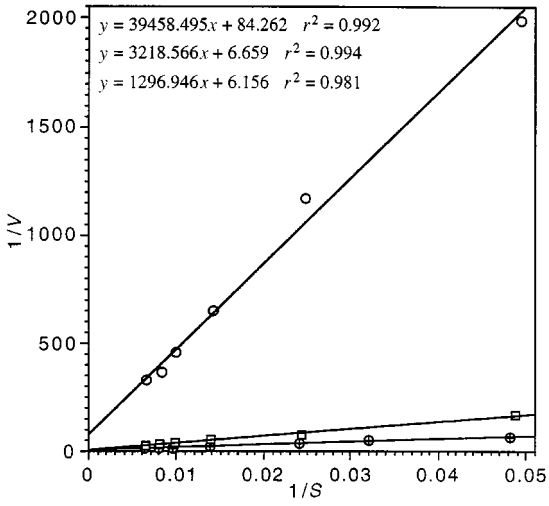

Fig. 2 Lineweaver–Burk plot of reaction rates for the formation of ketone **3** from (□) racemic enol ether **5**, (○) (*S*)-**5** and (⊕) (*R*)-**5**. For the reactions conditions, see Table 1.

enantiomers of **5** were separated by HPLC using a chiral-phase column.[8] Their absolute configurations were determined by converting them to the corresponding ketals and comparing these ketals with authentic samples of (*R*)-**4** and (*S*)-**4**.[6]

Antibody 14D9 catalyzes the protonolysis of racemic **5**, (*R*)-**5** and (*S*)-**5**. In each case catalysis is fully inhibited by the addition of the hapten **1a**, confirming that the reaction occurs within the antibody's combining site. The observation that ketal **4** (approximately 10–20% of the product) is obtained from all three substrates, **2**, (*R*)-**5** and (*S*)-**5**, is consistent with the concept that all of these reactions proceed *via* intermediate **I** within the antibody's combining site.

Interestingly, (*R*)-**5** was found to be a better substrate than (*S*)-**5**, with both a lower K_M and a higher k_{cat} (Table 1 and Fig. 2). A preparative scale experiment with antibody 14D9 using saturating concentrations of racemic **5** (pH 8, 5 μM catalyst and 1 mM racemic **5**) lead to the formation of (*R*)-**4**. Measuring the optical purity of **4**, which is formed exclusively in the antibody-catalyzed process with no background reaction, should allow an unequivocal determination of the degree of kinetic resolution of racemic **5** by 14D9. Under these saturating conditions the enantiomeric purity (63% ee) is consistent with the observed ratio of k_{cat} for each enantiomer of **5**. We calculated the dissociation constants of the transition states,[9] using the equation $K_{TS} = K_M/(k_{cat}/k_{un})$, and found that antibody 14D9 binds the transition state leading from (*R*)-**5** to intermediate (*R*)-**I** ($K_{TS\text{-}5}$ = 7× 10^{-8} M) 31 times more strongly than the transition state leading from (*S*)-**5** to intermediate (*S*)-**I** ($K_{TS\text{-}5}$ = 2.14× 10^{-6} M).

Although this experiment does not measure directly the binding constant of 14D9 to the oxocarbenium ions (*R*)-**I** and (*S*)-**I**, the transition states that lead from (*S*)-**5** to (*S*)-**I** and from (*R*)-**5** to (*R*)-**I** are very closely related to these intermediates. The 31-fold selectivity in the kinetic resolution of **5** suggests that the natural binding selectivity of antibody 14D9 favors intermediate (*R*)-**I**. The (*R*) selectivity in the hydrolysis of **5** stands in stark contrast to the (*S*) selectivity observed in the 14D9-catalyzed hydrolysis of several enol ethers such as **2**, and supports the mechanistic option shown in Scheme 2(*b*).

Earlier experiments indicate that the high catalytic efficiency observed with enol ethers such as **2** (k_{cat}/k_{un} = 10^3–10^4) is caused by a carboxylic acid residue acting as a general acid catalyst within the antibody's binding pocket.[10] Thus, the strong preference for protonation on the *re*-face of enol ether **2** to produce the (*S*) products is the result of the relative positioning of this general acid with respect to the bound substrate.[11] The evidence presented here suggests that 14D9 binds (*R*)-**I** tighter than (*S*)-**I**. It also raises the intriguing possibility that moving the catalytic residue in the antibody binding pocket by mutagenesis could create a new catalyst that will convert prochiral enol ethers to (*R*) products. Moreover, such a modified antibody is expected to be a more efficient catalyst. Future experiments will address this possibility.

Competitive formation of η¹-1-phosphaallene and 1*H*-phosphirene complexes

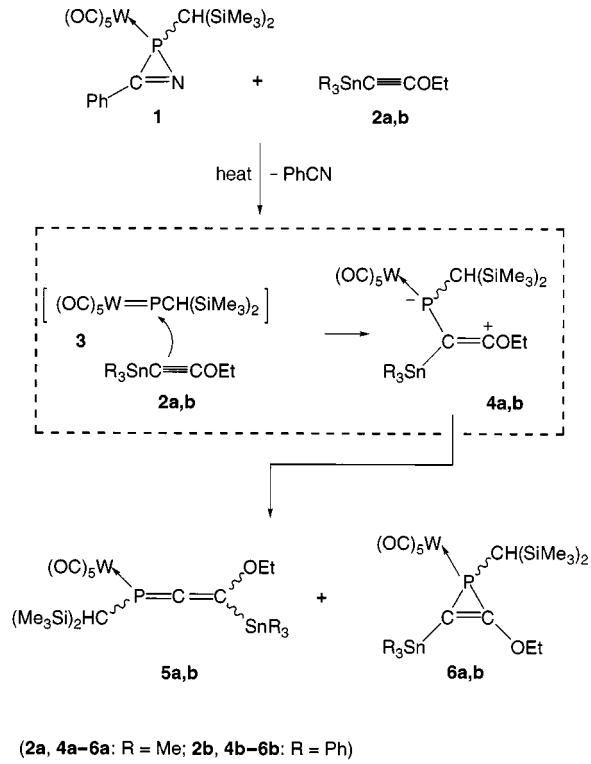
Rainer Streubel,*† Hendrik Wilkens and Peter G. Jones

Institut für Anorganische und Analytische Chemie der TU-Braunschweig, Postfach 3329, D-38023 Braunschweig, Germany

The 2*H*-azaphosphirene complex 1 reacts with triorganostannyl(ethoxy)acetylenes 2a,b to yield bifunctional η¹-1-phosphaallene 5a,b and 1*H*-phosphirene complexes 6a,b; 5a,b and 6a,b are characterized by NMR spectroscopy (^{13}C, ^{31}P) and complex 6b by single crystal X-ray diffraction.

1-Phosphaallenes[1] and their isomers, 1*H*-phosphirenes,[2] and complexes of both,[1,2] have attracted interest because of their synthetic applications in heterocyclic chemistry. At present, there are three main routes to 1-phosphaallenes: elimination of silanolate, reactions of phosphaketenes with phosphoranyl ylides or 1,3-shift reactions of alkinylphosphanes.[1] Despite current research activities, only one example of an η¹-1-phosphaallene complex is known, obtained from a complexation reaction with nickel tetracarbonyl.[3] Furthermore, in contrast to thermally induced rearrangements of cyclopropenes to allenes,[4] related transformations of 1*H*-phosphirene complexes into η¹-1-phosphaallene complexes, or *vice versa*, have not been reported.

We now report the first example of competitive formation of η¹-1-phosphaallene and 1*H*-phosphirene complexes, which has been found to proceed upon thermal decomposition of the 2*H*-azaphosphirene complex **1**[5] in the presence of triorganostannyl(ethoxy)acetylenes **2a**,**b**.[7]



Scheme 1 *Reagents and conditions*: **5a**,**b** and **6a**,**b**: 1 mmol **1** was treated with 2 mmol **2a** at 80 °C for 1.5 h or with 2 mmol **2b** at 70 °C for 2.5 h, respectively. Work-up by column chromatography at low temperature afforded **5a** and **6a** as a mixture, which could not be further separated, and **5b**, **6b**, which have been fully characterized (**5b**: 58%, mp 116 °C; **6b**: 33%, mp 128 °C); the dotted lines indicate the reaction course proposed.

Complex **1** reacts on heating in solution with the acetylene derivatives **2a**,**b** to give the η¹-1-phosphaallene complexes **5a**,**b** and the corresponding 1*H*-phosphirene complexes **6a**,**b** (Scheme 1). The product formation is explained as followed: thermally induced ring-cleavage of the 2*H*-azaphosphirene complex yields benzonitrile, determined by IR spectroscopy, and the phosphanediyl complex [(OC)$_5$W=PCH(SiMe$_3$)$_2$] **3** in the first reaction step. As illustrated in Scheme 1, reaction of **3** with the alkynes **2a**,**b** leads to zwitterionic products **4a**,**b**, which can be regarded as common precursors of the final products **5** and **6**. Furthermore, because the complexes **5b** and **6b** remain unchanged upon heating of pure samples, subsequent rearrangements (**5**–**6** and/or **6**–**5**) can be excluded with reasonable certainty.

The composition and constitution of **5a**,**b** and **6a**,**b** are confirmed by NMR spectroscopic and **5b**, **6b**, additionally, by mass spectrometric investigations.‡ The typical ^{13}C NMR data of **6a**,**b** (**6a**: δ 226.5, $^1J_{PC}$ 90.9 Hz; **6b**: δ 228.2, $^1J_{PC}$ 90.7 Hz) unambigously establish the existence of the 1-phosphaallene moiety in **5a**,**b**. The coordination mode is confirmed by the $^1J_{WP}$ coupling constant values of 262.6 Hz (**5a**) and 265.5 Hz (**5b**), which are in the expected range of η¹-P-coordinated ligands with low-coordinated phosphorus.[7]

In comparison to the related 2-ethoxy substituted 1*H*-phosphirene complex **6c**,[8] the complexes **6a**,**b** show high-field shifted resonances of the phosphorus nuclei at δ −107.4 (**6a**) and −98.2 (**6b**) (*cf.* δ −90.8[8]). Compared to **6c** the carbon-13 resonance values of the three-membered ring in **6a**,**b** are remarkably downfield shifted [C^2: δ 175 ± 3 (*cf.* 158.8), C^3: δ 100 ± 5 (*cf.* 88.1)]. Furthermore, the $^{(1+2)}J_{PC}$ coupling constants of these carbon atoms of **6a**,**b** show greater differences in magnitudes than those observed for 1*H*-phosphirene complex

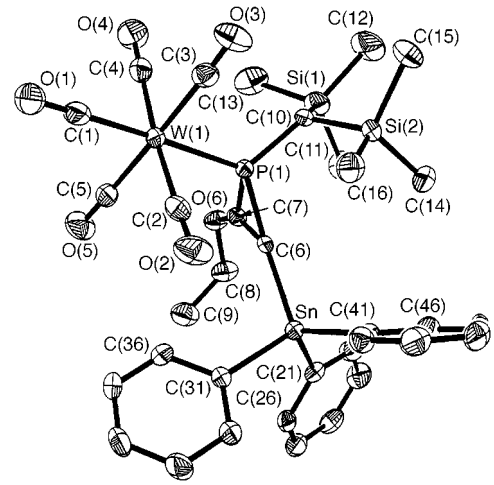


Fig. 1 Molecular structure of complex **6b** in the crystal. Selected bond lengths (pm) and angles (°): W(1)–P(1) 249.83(11), P(1)–C(7) 176.8(4), P(1)–C(6) 182.8(4), P(1)–C(10) 182.2(4), O(6)–C(7) 132.6(5), Sn–C(6) 213.5(4), Sn–C(25) 213.8(4); W(1)–P(1)–C(10) 119.04(14), C(7)–P(1)–C(6) 43.14(19), C(6)–C(7)–P(1) 70.9(3), C(7)–C(6)–P(1) 66.0(2), O(6)–C(7)–C(6) 146.0(4).

6c (**6a**,**b**: C^3: $^{(1+2)}J_{PC}$ 25 ± 3 Hz, C^2: $^{(1+2)}J_{PC}$ ⩽ 3 Hz; **6c**: 4.9 and 2.0 Hz[8]).

The X-ray crystal structure analysis of the complex **6b** confirms the molecular structure (Fig. 1).§ In comparison to the structure [8] of **6c** (values given in square brackets) the endocyclic P–C bond lengths of **6b** are lengthened {P(1)–C(6) 1.828(4) [1.792(8)], P(1)–C(7) 1.768(4) [1.753(8)], C(6)–C(7) 1.323(6) [1.298(11)] Å}, probably because of increased steric strain in **6b**.

We are currently investigating the synthetic potential of this new route to η^1-1-phosphaallene complexes and the reactivity of the complexes **5a**,**b** and **6a**,**b**.

New ammonium carboxylate host compounds screened by combinatorial chemistry

Kazuki Sada,*† Kei Yoshikawa and Mikiji Miyata*‡

Department of Material and Life Science, Graduate School of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka, 565-0871, Japan

Seventeen new ammonium carboxylate host compounds were screened from a combinatorial library of one hundred ammonium carboxylates formed by mixing ten amines and ten carboxylic acids.

The combinatorial library approach has been widely used in the screening of drugs and biological receptors.[1] More recently, this method has been applied to searching for functional compounds in many fields, such as new synthetic reagents,[2,3] superconducting materials,[4] luminescent materials,[5] polymeric materials,[6] artificial molecular receptors,[7] and so on. However, there has been no application of combinatorial chemistry for screening lattice inclusion compounds.

Design of nanoporous materials using organic compounds is now one of the most interesting topics in organic solid-state chemistry.[8,9] However, it is difficult to design inclusion cavities *via* molecular structure. The most promising method for designing molecular cavities relies upon chemical modification of 'leading' compounds that have been found accidentally.[8] We report here seventeen new host compounds *via* application of combinatorial chemistry to finding lattice inclusion compounds.

Ten commercially available amines (**a–j**) and ten carboxylic acids (**1–10**) were used to form the combinatorial salt library. One hundred salts were prepared by mixing stock solutions of the two components in a 1:1 molar ratio. The resulting salt crystals were obtained by filtration or by removal of the solvents, and characterized by IR and ^{1}H NMR analysis. Pr^{i}OH was chosen as the trial guest due to the moderate solubility of the various salts in this solvent. All salts were subjected to recrystallization from Pr^{i}OH, and the resulting crystals were characterized by ^{1}H NMR analysis and X-ray diffraction. Table 1 summarizes the clathrate formation results. Seventeen salts formed inclusion crystals with Pr^{i}OH, fifty four salts yielded guest-free crystals only and twenty salts did not form crystalline materials at all. In some cases, single components crystallized from Pr^{i}OH solution. This result indicates that at least seventeen ammonium carboxylates have inclusion abilities. Testing other guest compounds will yield inclusion compounds with different compositions.

The salts of small carboxylic acids or small amines did not form inclusion compounds with Pr^{i}OH. They formed guest-free crystals or failed to give crystalline materials. On the other hand, the salts of brucine (**j**) formed Pr^{i}OH clathrates. Its complex shell-like molecular structure with tertiary amino groups allows **j** to form molecular cavities in the crystalline state. The inclusion ability and the crystal structure of **3·j**, one of the seventeen host salts, were further investigated.

Complex **3·j** forms inclusion compounds with various organic solvents such as alcohols, ethers, ketones, aromatic esters and aromatic hydrocarbons. Table 2 summarizes the guest compounds and the host–guest ratios. Fig. 1 shows the crystal structure of **3·j** with Pr^{i}OH (1 : 1 : 1).§ The most striking structural feature is the one-dimensional corrugated monolayer structure of the conjugate anions of **3**, which has been observed in molecular complexes[10] or diastereomeric salts.[11] The conjugate cations of **j** bridge the monolayer *via* the salt bridge

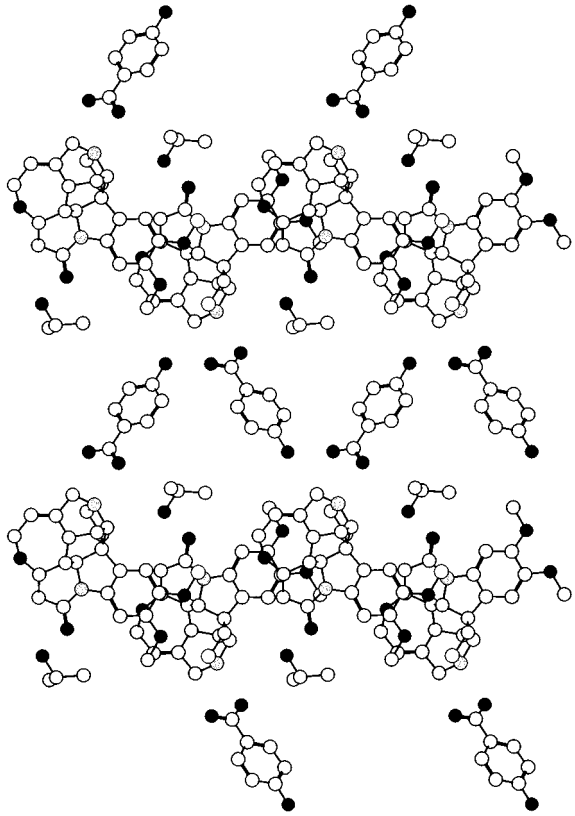

Fig. 1 X-Ray crystal structure of **3·j** with Pr^iOH (1 : 1 : 1)

and the hydrogen bond between them. The corrugated monolayer provides molecular channels that the guest alcohol is included in. The unique shell-like molecular shape of **j** yields the robust monolayer structure *via* van der Waals forces, and the monolayer motif enables **j** to form the Pr^iOH clathrates with various counter carboxylate anions.

In summary, we demonstrated the application of combinatorial chemistry to finding lattice inclusion compounds. Some ammonium carboxylates such as **3·j** form inclusion compounds with various organic compounds. Inclusion compounds of inorganic quaternary salts are already known.[12] However, ammonium carboxylates have been recognized as a source of host compounds.[13] Proper choice of amines and carboxylic acids provides us with various host compounds. Application to chiral recognition by enclathration of salt formation between chiral acid and achiral amines, achiral amine and chiral acid, or chiral acid and chiral amines, is now under investigation.

Room temperature ionic liquids as novel media for 'clean' liquid–liquid extraction

Jonathan G. Huddleston, Heather D. Willauer, Richard P. Swatloski, Ann E. Visser and Robin D. Rogers*†

Department of Chemistry, The University of Alabama, Tuscaloosa, AL 35487, USA

The partitioning of simple, substituted-benzene derivatives between water and the room temperature ionic liquid, butylmethylimidazolium hexafluorophosphate, is based on the solutes' charged state or relative hydrophobicity; room temperature ionic liquids thus may be suitable candidates for replacement of volatile organic solvents in liquid–liquid extraction processes.

Liquid–liquid extraction has often been a favored choice of the process engineer for the development of separation processes.[1] Traditional solvent extraction,[2] however, employs an organic solvent and an aqueous solution as the two immiscible phases and the increasing emphasis on the adoption of clean manufacturing processes and environmentally benign technologies may make such processes seem increasingly anachronistic because of their high usage of toxic, flammable, volatile organic compounds (VOCs). The costs of solvents are high and their safe engineering attracts significant capital costs over and above simple containment. Disposal of spent extractants and diluents will also attract increasing costs through the impact of environmental protection regulations. So much are VOCs the normal media for organic synthetic processes, that current worldwide usage of these materials has been estimated at over 5 billion dollars per annum.[3]

The design of safe and environmentally benign separation processes has an increasingly important role in the development of clean manufacturing processes and in the remediation of sites contaminated by an older generation of manufacturing technologies. Recently, considerable interest has been manifest in the use of room temperature ionic liquids as solvents for industrial catalytic reactions, including polymerizations, alkylations, and acylations.[3–6] This approach appears to allow the controlled production of desired products from reactants with a minimum of waste production through side reactions due to the tendency of ionic liquids to suppress conventional solvation and solvolysis phenomena.[3,4]

Room temperature ionic liquids are liquids that are composed entirely of ions, and in this sense alone resemble the ionic melts which may be produced by heating normal metallic salts such as sodium chloride to high temperature (*e.g.* NaCl to over 800 °C).[3] In fact, ionic liquids can now be produced which remain liquid at room temperature and below (even as low as −96 °C) and appear to be undemanding and inexpensive to manufacture.[3–5] Ionic liquids based on methylimidazolium are favorable species for investigation because of their air and water stability, their wide liquidus range, the fact that they remain liquid at room temperature, and their relatively favorable viscosity and density characteristics.[7,8] In addition, the R group of the cation is variable and may be used to fine tune the properties of the ionic liquid. It is reported that such ionic liquids are able to solvate a wide range of species including organic, inorganic, and organometallic compounds. Miscibility with a number of organic solvents such as benzene and toluene has also been reported.[9]

In view of these developments, it seems likely that the design and implementation of separation processes for product recovery from these media will assume increasing importance. Additionally, it may be apparent that *ionic liquids may in themselves be suitable, and indeed favorable, media for the design of novel liquid–liquid extraction systems.* Some features of these ionic liquid systems, the high solubilities of organic species, the prevalence of high coulombic forces resulting in the practical absence of any significant vapor pressure,[3] and the availability of air and moisture stable, water immiscible ionic liquids (*e.g.* imidazolium salts of PF_6^- or BF_4^-) may recommend such systems as being uniquely suited to the development of completely novel liquid–liquid extraction processes. The data presented here indicate that the partitioning of a number of charged and uncharged aryl organic moieties in a biphasic extraction system comprising the phases butylmethylimidazolium hexafluorophosphate ([BMIM][PF_6]) and water is similar to their partitioning in traditional organic solvent–water systems.

[BMIM][PF_6] was prepared by modification of published procedures.‡ Equal volumes of the ionic liquid and distilled deionized water were contacted in the presence of ^{14}C-labelled tracers of several ionizable and nonionizable substituted aryl molecules. The distribution of the solutes between the heavy, ionic liquid phase and the light, water phase was determined radiochemically.

The distribution data provided in Fig. 1 highlight the relationship between the distribution ratios observed here and similar partitioning in octan-1-ol–water systems (an often used empirical hydrophobicity scale).[10] There is a close relationship between the two systems, although there appear to be differences in detail as is usual in comparing partition between different solvent systems having differing solvation properties.[11,12] The values of the distribution coefficients (*P*) in the octan-1-ol–water system are in general an order of magnitude higher than the corresponding distribution ratios (*D*) for the [BMIM][PF_6]–water system. The reasons for this have not yet

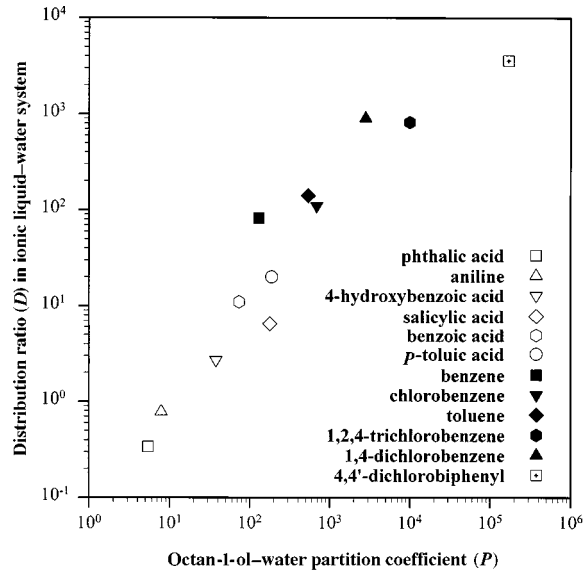

Fig. 1 Correlation of partitioning data between [BMIM][PF_6]–water and octan-1-ol–water biphasic systems

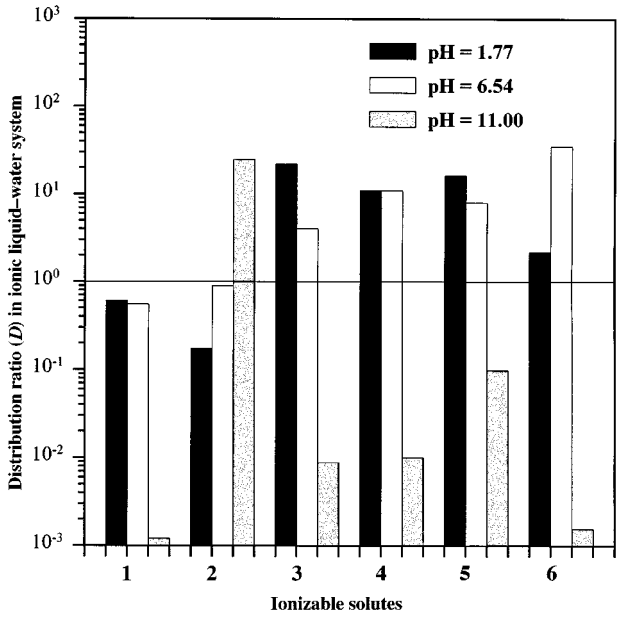

Fig. 2 The solutes studied include: **1** phthalic acid (p*K*1 = 2.89, p*K*2 = 5.51), **2** aniline (pK_b = 9.42), **3** 4-hydroxybenzoic acid (p*K*1 = 4.48, p*K*2 = 9.32), **4** benzoic acid (pK_a = 4.19), **5** salicylic acid (p*K*1 = 2.97, p*K*2 = 13.40), **6** *p*-toluic acid (p*K*1 = 2.27)

been elucidated, but may reflect a generally less hydrophobic character to the [BMIM][PF_6] phase, or may also be due to the strong polar contribution of the relatively high concentration of charged groups present in the ionic liquid compared to the octan-1-ol–water system. These differences do not necessarily imply that ionic liquids represent a 'poorer' extracting phase than octan-1-ol; the distribution values found are adequate for practical applications.[2]

Fig. 1 also shows that for this rather limited set of solute species, those species having charged groups or strong hydrogen bonding moieties (open symbols in Fig. 1) have, in general, much lower partition coefficients than similar neutral or apolar species (filled symbols in Fig. 1). The effect of charge on the distribution of these species was thus investigated further. The ionizable solutes were partitioned in the [BMIM][PF_6]–water system as described above, but with the pH of the aqueous phase adjusted to either pH 1.77 (using concentrated H_2SO_4) or to pH 11 (using concentrated NH_4OH).

The data in Fig. 2 confirm that the distribution coefficient is higher for the uncharged form than for the charged form. For benzoic acid (**4** in Fig. 2) the partition coefficient is higher under acidic or near neutral conditions than in basic solution. For the oppositely charged base, aniline (**2**), the partition coefficient is higher at alkaline pH than in acidified solution. Similar behavior is observed for the other ionizable solutes employed in the study. It is even possible to rationalize differences in solute partitioning at a given pH from the understanding of the predominant charged state in solution (*i.e.* by comparing the pK_a values and the predicted magnitude of the molecule's charge at that pH).

It is worth noting that, in almost all cases, the distribution of these solutes varies from values of *D* greater than 1 to less than 1 depending on the charged state of the solutes. This indicates a change in phase preference between solutes in their charged and uncharged forms. Once again, this is a useful observation and simplification implying that classical techniques of solvent extraction, which are often ideally designed around the fractionating power which may be achieved by the adoption of forward and backward extracting steps,[1,2] may easily be adapted to extractions performed utilizing ionic liquids.

Ionic liquids represent a novel class of solvents and may now also be considered as a novel medium for liquid–liquid extraction. Limited experience with room temperature ionic liquids based on alkylmethylimidazolium hexafluorophosphate suggests that such systems may be easily adapted to conventional liquid–liquid extraction practice.¶ The observation of an approximate correspondence between the distribution of these aryl solutes in the ionic liquid system and their distribution in an octan-1-ol–water system is a useful design criterion. Interestingly, the low vapor pressures of such systems suggest novel methods of solute recovery through evaporative–pervaporative techniques for appropriately volatile solutes. These interesting biphasic systems continue to be actively studied in our laboratories for the development of novel, 'clean' separation technologies.

This research is supported by the Division of Chemical Sciences, Office of Basic Energy Sciences, Office of Energy Research, U.S. Department of Energy (Grant No. DE-FG02-96ER14673).

‡1-Butyl-3-methylimidazolium chloride was prepared by reaction of equal molar amounts of 1-methylimidazole and chlorobutane in a round-bottomed flask fitted with a reflux condenser by heating and stirring at 70 °C for 48–72 h. The resulting viscous liquid was allowed to cool to room temperature and then was washed three times with 200 mL portions of ethyl acetate. After the last washing, the remaining ethyl acetate was removed by heating to 70 °C under vacuum. To prepare the ionic liquid, hexafluorophosphoric acid (1.3 mol) was added (slowly to prevent the temperature from rising significantly) to a mixture of 1-butyl-3-methylimidazolium chloride (1 mol) in 500 mL of water. After stirring for 12 h, the upper acidic aqueous layer was decanted and the lower ionic liquid portion was washed with water (10 × 500 mL) until the washings were no longer acidic. The ionic liquid was then heated under vacuum at 70 °C to remove any excess water.

§ The procedures used in the standard radiochemical assay utilized are described in ref. 13 for similar work investigating aqueous biphasic systems. Standard radiometric assay of equal volumes of the separated phases allows calculation of the distribution ratio as the ratio of the activity in the ionic liquid phase over the activity in the water phase.

¶ Although we were unable to detect water in the ionic liquid by TGA, NMR does indicate the presence of a small amount of water after contact with an aqueous phase. The exact composition and water content of these potential solvents are under active investigation.

The syntheses of $C_6CH_2^{\bullet -}$ and the corresponding carbenoid cumulene C_6CH_2 in the gas phase

Suresh Dua, Stephen J. Blanksby and John H. Bowie†

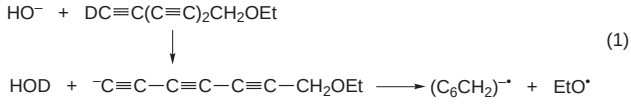
Department of Chemistry, The University of Adelaide, South Australia, 5005, Australia

The ion $(C_6CH_2)^{\bullet -}$ is formed in the gas phase by the process –C≡C–C≡C–C≡C–CH_2OEt → $(C_6CH_2)^{\bullet -}$ + EtO•, and charge stripping of the product radical anion yields the carbenoid neutral C_6CH_2; this can be either a singlet (the ground state), which is best represented as the carbene :C=C=C=C=C=C=CH_2, or a triplet; the adiabatic electron affinity and the dipole moment of the carbenoid neutral are calculated to be 2.82 eV and 7.33 D respectively.

Small cumulenes have been detected in circumstellar gas and dust envelopes which surround red giant stars, in particular, the bright carbon-rich star IRC-10216.[1–3] These include C_n (n = 3 and 5), C_nH (n = 2–8) and C_nH_2 (n = 2–4 and 6), with neutrals where n is even generally being more abundant than those where n is odd.[1–5] The high electron affinities of these neutrals suggests the possibility that the corresponding anions may co-occur with the neutrals in circumstellar envelopes.[6–8] We have reported the syntheses of a number of these anions in the source of a VG ZAB 2HF mass spectrometer [*e.g.* C_5H^-[8] and three isomers of $C_5H_2^{\bullet -}$[9]] and have used collision-induced charge stripping of the anions to effect the syntheses of the appropriate neutrals.[9] Both C_5CH_2 and C_6CH have already been detected in circumstellar envelopes,[3] and it has been suggested that C_6CH_2 should also be present,[10] and that it should be an excellent candidate for detection because of its large dipole moment [calculated to be 7.33 D (Table 1)].[5] The proposed pathways *via* which such hydrocarbons can form in the interstellar environment have been reviewed.[11]

We describe the synthesis and structures of both $(C_6CH_2)^{\bullet -}$ and the corresponding carbenoid cumulene neutral.

The radical anion of C_6CH_2 was synthesised in the source of the ZAB 2HF mass spectrometer as summarised in sequence (1). The reaction between HO^- and DC_6CH_2OEt‡ yields the



(1)

anion $^-C_6CH_2OEt$ which undergoes facile loss of EtO• to yield $(C_6CH_2)^{\bullet -}$. Source formed $(C_6CH_2)^{\bullet -}$ ions are then fired through a collision cell containing O_2 (at 2×10^{-7} Torr; 1 Torr = *ca.* 133 Pa) to produce a beam of neutral C_6CH_2 which then proceeds into a second collison containing O_2 (at 2×10^{-7} Torr) which effects ionisation of the neutral to form a decomposing C_6CH_2 radical cation. The resultant neutralisation reionisation spectrum of $(C_6CH_2)^{\bullet -}$ ($^-NR^+$)[16] is shown in Fig. 1. The observation of a pronounced recovery signal (at *m/z* 86) in the spectrum indicates that the neutral has a lifetime of at least 10^{-6} s, and the similarities between the $^-NR^+$ spectrum and the corresponding charge reversal (CR) spectrum of $C_6CH_2^{\bullet -}$ (listed in the caption to Fig. 1) suggests that the neutral formed has the same connectivity as the radical anion.[17]

Ab initio calculations for both the neutral and radical anion were carried out at the RCCSD(T)/aug-cc-VDZ//B3LYP/6-31G* level of theory using GAUSSIAN94[19] and MOLPRO 96.4.[20] Details are summarised in Table 1. The radical anion and both the singlet and triplet neutrals are best represented as

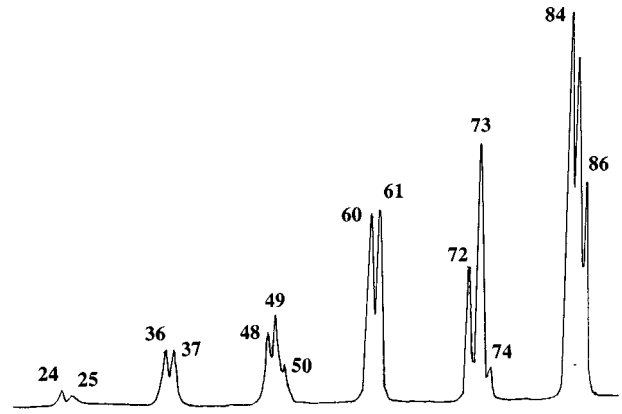


Fig. 1 Neutralisation reionisation ($^-NR^+$) mass spectrum of $C_6CH_2^{\bullet -}$. VG ZAB 2HF mass spectrometer. O_2 in both collision cells (measured pressure outside cells = 2×10^{-7} Torr). CR spectrum of $C_6CH_2^{\bullet -}$ (O_2 in the first collision cell, measured pressure outside cell -2×10^{-7} Torr) as follows [*m/z* (relative abundance)]: 86(49%), 85(88), 84(100), 74(4), 73(57), 72(13), 62(3), 61(43), 60(29), 50(3), 49(19), 48(9), 37(15), 36(9), 25(1), 24(0.5).

$C^6C^7H^8H^9$	180.0	180.0	180.0

[a] RCCSD(T)/aug-cc-p VDZ level of theory including zero point vibrational energy [calculated from vibrational frequencies at the B3LYP/6-31G* level of theory, and scaled by 0.9804 (ref. 18)]. [b] B3LYP/6-31G* level of theory. [c] All other angles along the carbon skeleton are also 180.0°.

simple linear cumulenes. The ground state of neutral C_6CH_2 corresponds to the singlet carbenoid cumulene :C=C=C=C=C=C=CH_2 (*cf.* ref. 21) which has a calculated dipole moment of 7.33 D. The adiabatic electron affinity of this neutral is estimated to be 2.82 eV; thus we propose that $C_6CH_2^{\bullet -}$ as well as the corresponding neutral may be present in the circumstellar environment.

Synthesis and characterization of the new microporous fluorogallophosphate Mu-2 with a novel framework topology

P. Reinert,[a] B. Marler[b] and J. Patarin*[a]†

[a] *Laboratoire de Matériaux Minéraux, ENSCMu., UPRES-A 7016, 3 rue Alfred Werner, 68093 Mulhouse Cedex, France*
[b] *Institut für Mineralogie, Ruhr Universität Bochum, D-44780 Bochum, Germany*

A new three-dimensional microporous fluorogallophosphate whose structure consists of a cubic arrangement of double-four-ring units (D4R) hosting F^- anions was synthesized from a fluoride-containing aqueous medium in the presence of 4-amino-2,2,6,6-tetramethylpiperidine as organic template.

Since 1985, a large number of gallophosphates with microporous frameworks obtained by hydrothermal synthesis have been reported in the literature.[1] The use of the fluoride method[2] led to the discovery of the large pore cloverite, a structure with a three-dimensional 20-membered-ring channel system,[3] the LTA-type $GaPO_4$[4] and several gallophosphates named ULM-*n*.[5] In fact, it was shown that the fluoride anions play a structural role stabilizing the double-four-ring (D4R) units of the structure.[3] This type of secondary building unit was also observed for the gallophosphate Mu-1,[6] which is constituted of isolated D4R units, and the fluorogallophosphate Mu-3[7] whose structure consists of chains of D4Rs. The specific location of F^- trapped within this type of unit was also previously observed for the gallophosphate ULM-5,[8] but in this case F^- is also a component of the framework as it bridges the gallium atoms. Here we report the synthesis and characterization of a new fluorogallophosphate, Mu-2, which was obtained in an aqueous fluoride-containing medium in the presence of 4-amino-2,2,6,6-tetramethylpiperidine as organic template. This organic species was previously introduced into an aluminosilicate gel and led to the crystallization of the precursor of ferrierite.[9] The chain-like fluorogallophosphate Mu-3 was obtained in a quasi-non-aqueous medium in the presence of the same organic template.[7]

Mu-2 was synthesized from an aqueous fluoride-containing mixture in the presence of 4-amino-2,2,6,6-tetramethylpiperidine (R). Typically, the molar composition of the starting gel was $1Ga_2O_3 : 1P_2O_5 : 0.3HF : 1R : 80H_2O$. The gel was prepared by first mixing 0.56 g of the gallium source [an amorphous gallium oxide hydroxide obtained by heating a gallium nitrate solution (Rhône-Poulenc) at 250 °C for 24 h] with 0.58 g of phosphoric acid solution (85% H_3PO_4, Normapur, Prolabo) and the required amount of distilled water (3.4 g). After homogenization 0.04 g of hydrofluoric acid (40% Normapur, Prolabo) and 0.39 g of 4-amino-2,2,6,6-tetramethylpiperidine (Fluka, purum > 97%) were added successively under stirring. The gel was mixed at room temperature for 1 h and transferred to a Teflon-lined stainless-steel autoclave. After heating at 170 °C for 5 days, the solid obtained was washed with distilled water. Mu-2 was easily isolated from the batch by ultrasonication in the form of large rounded truncated cubes with a size close to 100 μm (Fig. 1). This preparation also gives an unidentified phase (probably a layered material) which does not contain fluoride anions.

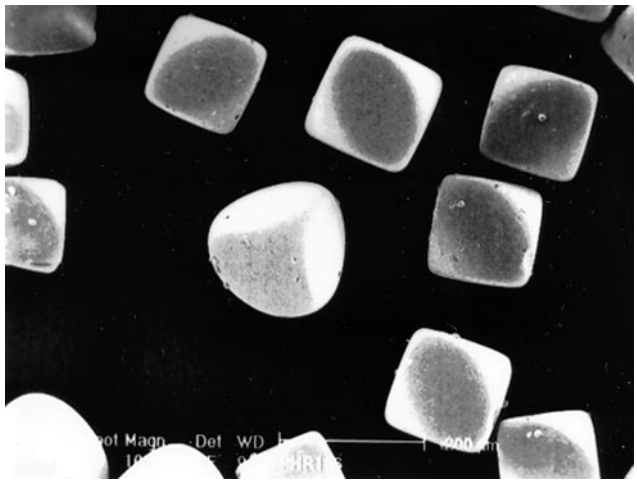

Fig. 1 Scanning electron micrograph of rounded truncated cubes of Mu-2

The X-ray diffraction pattern of Mu-2 was unambiguously indexed with a cubic *I*-centered cell with $a = 16.377(1)$ Å. The elemental analysis of the as-synthesized sample of Mu-2 gave the following composition (wt.%): Ga: 32.9; P: 13.6; F: 1.73; R: 14.4. This analysis is in good agreement with the electron microprobe analysis performed on the rounded truncated cubes. The amount of organic species was confirmed by quantitative ^1H liquid NMR spectroscopy (by dissolution of the sample in 6 M HCl) and 6 molecules were found per unit cell. From the ^{13}C CP-MAS solid-state NMR spectroscopy the amine is occluded in a protonated form (probably monoprotonated according to the structure determination).‡

The TG and DSC curves of as-synthesized Mu-2 were recorded under air on a Setaram TG/DSC111 thermoanalyser.

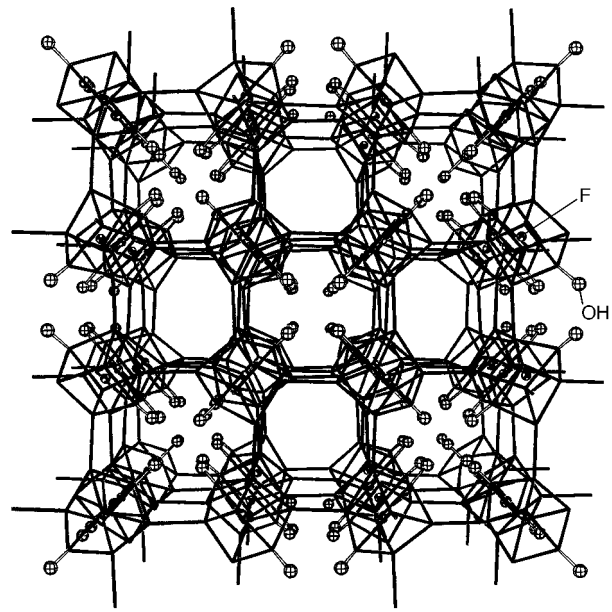

Fig. 2 Perspective view of the framework of the gallophosphate Mu-2 showing the two types of cage-like voids (one without OH group; the other with 8 T-OH groups); the Ga and P atoms are located at the vertices

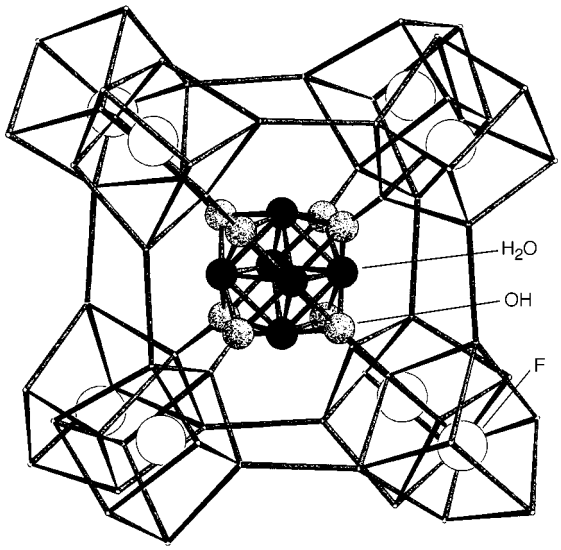

Fig. 3 The $(OH)_8(H_2O)_6$ cluster surrounded by eight D4Rs

Two broad endothermic peaks located at *ca*. 100 and 200 °C are observed. They correspond to the elimination of the physisorbed water molecules, the dehydroxylation of the T-OH groups and the removal of the fluoride anions (mass loss: 7.2%). The second mass loss (*ca*. 14.4%) corresponds to the removal of the organic species (several exothermic peaks on the DSC curve) and is achieved after calcination at 1000 °C. This new gallophosphate shows a low thermal stability. The structure collapses at *ca*. 300 °C and the cristobalite-type gallophosphate crystallizes at 600 °C.

The ^{19}F MAS solid-state NMR spectrum of Mu-2 displays a single signal at −72 ppm (relative to $CFCl_3$). Such a chemical shift value was previously found for the LTA- and CLO-type gallophosphates and is unambiguously assigned to fluoride anions trapped in the D4R units of the structure.

Taking into account all of the results and the density measurement (d_{mes} = 2.48 kg m^{-3}), the unit cell formula of Mu-2 is $Ga_{32}P_{32}O_{120}(OH)_{16}F_6(C_9H_{21}N_2)_6{\cdot}12H_2O$.

The structure analysis based on single crystal and powder X-ray data§ revealed that Mu-2 has a novel framework topology (Fig. 2). The gallophosphate framework of Mu-2 can be completely built from D4Rs as the fundamental building blocks. As observed from ^{19}F NMR spectroscopy, the D4Rs are occupied by a fluoride anion (according to the chemical analysis the occupancy factor is 0.75). Each $[Ga_4P_4O_{15}(OH)_2F]$ building block is interconnected with six other building blocks *via* common oxygen atoms. The remaining two corners of the D4R are T-OH groups (one P-OH and one Ga-OH). The interconnection of the D4Rs forms a three-dimensional but interrupted framework which has a three-dimensional pore system of 8MR pore openings. The framework which shows a strict alternation of phosphorus and gallium atoms at the T sites possesses two types of cage-like voids. The first type of cage (six per unit cell) does not contain any OH groups, whereas the second one (two per unit cell) displays 8 T-OH groups. The protonated 4-amino-2,2,6,6-tetramethylpiperidine occluded into the first type of cage (with a free volume of *ca*. 500 Å^3) is disordered.

An interesting feature of this structure is the $(OH)_8(H_2O)_6$ cluster (Fig. 3) present in the second type of cage. The sixteen T-OH groups of the D4Rs point either to the origin (0, 0, 0) or the center of the unit cell ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$) such that the OH groups are arranged in two $(OH)_8$ cubes [the O–O distance between neighboring hydroxyl groups is 2.85(1) Å]. The six water molecules which are located close to the middle of the cube faces form hydrogen bridges to each other and the hydroxyl groups. The center of the $(OH)_8(H_2O)_6$ cluster, however, is vacant.

‡ For the structure determination 2885 intensities from a twinned single crystal were collected on a four circle Syntex R3 diffractometer in omega scan mode. 1014 reflections remained after merging and were used for the structure analysis based on the SHELXTL program system.[10] The structure was solved by direct methods.

§ The XRD powder data were recorded on a Siemens D5000 diffractometer with a linear 6° position sensitive detector in Debye–Scherrer geometry (Ge monochromator, λ = 1.5406 Å). The Rietveld refinement (2θ range = 7–97°, space group $I23$, number of observations = 3790, number of reflections = 404, number of structural parameters = 40) performed with the XRS-82 program[11] converged to R_F = 0.077, R_{wp} = 0.107 while the statistically expected R_{exp} is 0.113. A detailed description of the structure including the atomic coordinates, displacement parameters, bond lengths and angle of Mu-2 will be published elsewhere.[12] CCDC 182/928.

Formation of isocyanate species on the surface of mordenite-type zeolite catalysts for the reduction of NO by hydrocarbons with H_2O

Moon Hyeon Kim, In-Sik Nam*† and Young Gul Kim

Research Center for Catalytic Technology, Department of Chemical Engineering, School of Environmental Engineering, Pohang University of Science and Technology (POSTECH)/Research Institute of Industrial Science and Technology (RIST), P.O. Box 125, Pohang 790-600, Korea

Surface isocyanate species with IR bands at 2274 and 2325 cm^{-1} play a crucial role for the maintenance of the water tolerance of HM, CuHM and CuNZA catalysts for NO reduction by hydrocarbons in the presence of H_2O.

Several reaction intermediates for the selective reduction of NO by hydrocarbons have been suggested.[1–7] However, their significance during the course of the reaction is still under investigation. Surface NO_x species such as nitrosyls (M–NO), dinitrosyls [M–$(NO)_2$], nitrites (M–NO_2 or M–ONO) and nitrates (M–NO_3 or M–ONO_2) have been found upon the adsorption of NO_x on the surface of zeolite catalysts containing transition metal ions[1–4] and have been regarded as plausible intermediates for this reaction system. The role of organic nitro- and nitrito-species on the catalyst surface was also examined by FTIR studies.[1,4,5] The formation of isocyanate species (–NCO) on Al_2O_3-based catalysts was observed during NO removal reaction with hydrocarbons containing C_3H_6, C_2H_2 or *n*-C_7H_{16}.[6] N-containing surface compounds such as C_2N_2, CN and NCO along with organic nitro-groups are observed over Na- and Ce-exchanged ZSM-5 catalysts.[5] Both surface nitrile and isocyanate compounds were also found over Cu-ZrO_2 catalyst for NO reduction by C_3H_6.[7] However, which of the proposed intermediates plays a major role for this reaction system is still controversial.

Kim *et al.*[8a] recently reported a couple of catalytic systems exhibiting high NO removal activity: HM or CuHM catalyst employing C_2H_4 as a reductant and CuNZA catalyst with C_3H_6. The initial NO conversion of 63% of HM and CuHM catalysts immediately dropped to 20% conversion when 7.3% H_2O was present in the feed gas stream, while a loss of NO conversion of $< 10\%$ was observed for the CuNZA catalyst.[8b] In the present study, it was of interest to examine from the viewpoint of reaction intermediates why the latter catalytic system exhibits stable deNO_x activity maintenance in the presence of H_2O in the feed gas stream while the former does not.

The preparation procedures and physicochemical properties of the mordenite-type zeolite catalysts HM, CuHM and CuNZA employed in this study have been previously described in detail elsewhere.[8] The copper contents of CuHM and CuNZA catalysts are 3.5 (Cu/Al = 0.24) and 2.0 wt.% (Cu/Al = 0.22), respectively. When the reaction mixture including 500 ppm of NO, 1000 ppm of C_2H_4 or 2000 ppm of C_3H_6 and 4.2% of O_2 was admitted onto the self-supporting catalyst wafers pretreated at 550 °C for 2 h in a laboratory designed IR cell, the surface species formed on the catalyst surface during the reduction with or without H_2O at 360 or 400 °C were examined by *in situ* FTIR spectroscopy at room temperature.

Fig. 1 shows IR spectra before and after the reaction in the absence of H_2O. The HM catalyst after reaction exhibited a strong absorption band at 2274 cm^{-1} and broad bands between 2200 and 1950 cm^{-1}. A similar peak at 2275 cm^{-1} was also observed for the CuHM catalyst. However, the IR spectra of the catalyst in the absorption range < 2200 cm^{-1} are clearly different compared to those over the HM catalyst, revealing a distinct peak at 1900 cm^{-1}. The CuNZA catalyst also shows the development of three bands in the wavenumber region 2400–1800 cm^{-1}, with maxima at 2325, 2032 and 1903 cm^{-1}. None of these bands are observed for the catalysts before the reaction.

The formation of isocyanate (–NCO) species has been observed for the reaction of NO and CO over supported noble metal catalysts: at 2270–2250 cm^{-1} for Al_2O_3[9] and 2320–2180 cm^{-1} for SiO_2[9,10] as a support. Prominent IR absorptions at 2270–2230 cm^{-1} of isocyanate species were also observed for NO reduction by hydrocarbons over SCR catalysts.[6,7] Hayes *et al.*[4] tentatively assigned the band at 2260 cm^{-1} observed for the reduction of NO with C_3H_6 over CuZSM-5 catalyst to an organic nitrile species, while Hoost *et al.*[3] suggested isocyanate for a similar band at 2295 cm^{-1}. An unassigned N-containing species containing C, N and O in a 1 : 1 : 1 ratio was formed on Na- and Ce-exchanged ZSM-5 catalysts[5] whereas the adsorption of isocyanic acid (HNCO) on CuZSM-5 catalyst led to a strong absorption peak at 2260 cm^{-1}.[11] With the absorption band at 2298 cm^{-1} for a CuZSM-5 catalyst adsorbing acetone oxime, Beutel *et al.*[12] also observed a similar IR peak at 2271 cm^{-1} when the catalyst was treated with an aqueous NaNCO solution. Moreover, HCN and C_2N_2 chemisorbed on SiO_2 as SiCN and SiNC could be easily converted into SiNCO by heating in an oxygen atmosphere, as previously reported by Morrow and Cody.[13]

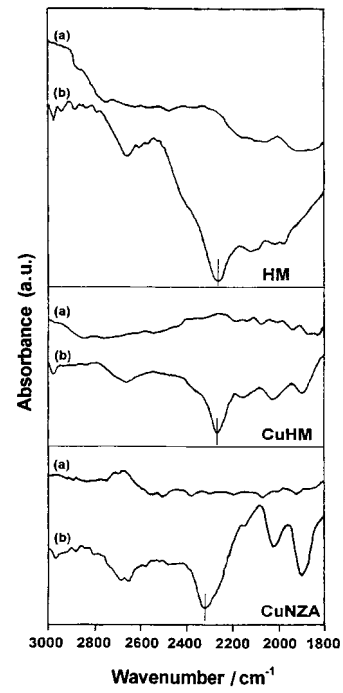

Fig. 1 IR spectra of mordenite-type zeolite catalysts: (a) before reaction; (b) after reaction without H_2O. Reaction conditions: NO 500 ppm, C_2H_4 1000 (HM and CuHM) or C_3H_6 2000 ppm (CuNZA), O_2 4.2% and T = 360 (HM and CuHM) or 400 °C (CuNZA).

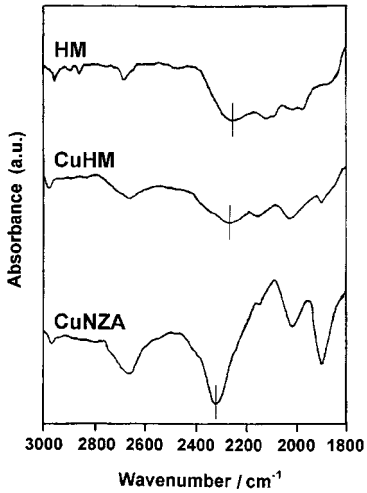

Fig. 2 IR spectra of mordenite-type zeolite catalysts after reaction with H_2O. Reaction conditions: NO 500 ppm, C_2H_4 1000 (HM and CuHM) or C_3H_6 2000 ppm (CuNZA), O_2 4.2%, H_2O 7.3% and T = 360 (HM and CuHM) or 400 °C (CuNZA).

Based upon the previous studies, the absorption bands at 2274 and 2325 cm^{-1} (Fig. 1) may be attributed to isocyanate species formed on the surface of the zeolite catalysts. The same species was also observed over CuZSM-5 catalyst for NO reduction by C_3H_6, but not with C_2H_4.[11] However, its formation on the mordenite-type zeolite catalysts was observed, regardless of the types of reductant employed in the present study, which is also in good agreement with the IR study for NO reduction by C_2H_4 and C_3H_6 over CuZSM-5.[14]

Three major nitrosyl complexes such as Cu^{2+}–NO, Cu^{+}–NO and Cu^{2+}–$(NO)_2$ are commonly observed for Cu-exchanged zeolites upon the adsorption of NO.[2,15] It is generally known that the surface NO_x species on the zeolite catalysts exhibit absorption bands at 1895–1910 cm^{-1}.[2–4,11] Therefore, the peaks at 1900 and 1903 cm^{-1} over CuHM and CuNZA catalysts are primarily due to the formation of NO bonded to isolated Cu^{2+} sites on the catalyst surface. This is clear from the fact that no absorption in this wavenumber region occurred for the copper-free catalyst, HM. The identification of the bands in the region 2200–1950 cm^{-1}, notable at 2148 and 2030 cm^{-1}, is less straightforward; they may arise from carbonyl species formed on the catalyst surface.

To examine the effect of H_2O on the formation of the –NCO species during the reduction of NO by hydrocarbons, the IR spectra of the three catalysts were examined in the presence of 7.3% H_2O, as shown in Fig. 2. The absorption intensity of the –NCO species at *ca*. 2274 cm^{-1} significantly decreased for the synthetic mordenite catalysts, HM and CuHM in the presence of water, while no notable change was found for the CuNZA catalyst. However, the peaks between 2200 and 1950 cm^{-1} still maintain their intensity, regardless of the presence of H_2O in the feed gas stream. Reduction of the –NCO band by H_2O adsorbed on the surface of Al_2O_3-supported Cu–Cs oxide catalyst has also been reported.[6] However, no difference in the peak intensities for the catalyst exposed to gas phase water and for the hydrated catalyst was observed.

HM and CuHM catalysts exhibited a loss of NO removal activity of $>45\%$ with 7.3% of H_2O in the feed gas stream[8b] which is in accord with the dramatic reduction of the absorption band of the –NCO species on the surface of the catalysts. The significant loss of the deNO_x efficiency of the catalysts for the NO removal reaction in the presence of H_2O is primarily due to the competitive adsorption of NO and H_2O on the catalyst surface as well as of hydrocarbons and H_2O.[8b] The alteration of NO removal activity by H_2O however, was apparently negligible for the CuNZA catalyst. It should be noted that the adsorption capacity of NO and hydrocarbons on CuNZA catalyst was also maintained with H_2O in the feed gas stream.[8b] This indicates that the feed of H_2O to the catalyst surface does not suppress the formation of the reaction intermediate on the catalyst surface (see Fig. 2) and may be why the CuNZA catalyst exhibits the strong water tolerance found in the previous study.[8b]

In conclusion, a surface isocyanate species was formed on mordenite-type zeolite catalysts for the reduction of NO by hydrocarbons, regardless of the reductant employed. This indicates that the species plays a crucial role for NO removal reaction with hydrocarbons over the catalysts. The formation of –NCO species on the catalyst surface is also critical for the maintenance of NO removal activity when H_2O is present in the feed gas stream.

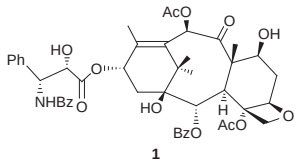
A concise stereoselective synthesis of the C-aromatic taxane skeleton: an application of novel sequential transacetalation oxonium ene cyclization

H. R. Sonawane,*† Dilip K. Maji, G. H. Jana and G. Pandey

Division of Organic Chemistry (Technology), National Chemical Laboratory, Pune-411008, India

A three-step sequence for the construction of the C-aromatic taxane nucleus from easily available A-ring unit 2 and C-aromatic unit 3 is reported; $SnCl_4$ promoted reaction of 4, presumably *via* the diastereoselective oxonium ene cyclisation reaction of 6a formed *in situ*, delivers cyclic ether 5a which on treatment with Bu^{n}Li provides C-aromatic taxane skeleton 8.

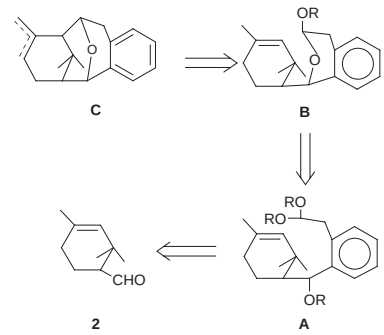
The remarkable chemotherapeutic potential and the unique molecular framework of taxol[1] **1** have stimulated enormous synthetic efforts towards the synthesis of taxane diterpenoids.[2] Although five different total syntheses of **1** have been reported[3] in recent years, interest towards the development of new synthetic methods to acquire potent taxol analogues continues to grow. In this context, one of the long standing problems has been the construction of the sterically congested central eight-



1

membered B-ring. In view of the known difficulties stemming from the high degree of ring strain and the transannular interactions associated with the direct cyclooctane annulation process, a recourse to indirect methods such as fragmentation of bicyclic systems, ring contraction and ring expansion have been developed.[4] For the purposes of construction of the taxane skeleton, particularly *via* C_{10}–C_{11} bond formation as the key step, the methods available are limited to the Heck reaction,[5] the Kishi–Nozaki coupling reaction[6] and the intramolecular nitrile oxide cyclization reaction.[7] Moreover, the application of these methods is severely restricted due to their substrate-specific nature and also the difficulty encountered in deriving the required substrates. In this context, we have initiated a new convergent approach starting with B-*seco*-taxane **A** wherein the critical bond connection between C_{10}–C_{11} was envisioned to arise from the α-alkoxycarbenium ion generated from **B** *via* treatment with a Lewis acid (Scheme 1). This approach was expected to help overcome the known unfavorable entropic and transannular interactions associated with the direct cyclooctane annulation using an acyclic precursor. We report herein our successful preliminary results for the construction of taxane skeleton **8** *via* the oxonium ene cyclisation reaction of **4** as the key step.

The precursor compound **4** was readily assembled by the reaction of aryllithium reagent **3**, prepared *via* the reductive metalation of the diethylacetal of 2-iodophenylacetaldehyde[8] using Bu^{n}Li, with compound **2** (Scheme 2). The utility of chiral A-ring unit **2** derived from α-pinene in the preparation of B-*seco*-taxanes has recently been reported by us.[9] The substrate **4** (75%) was found to be a mixture of **4a** (1*R**,2*R**) and **4b** (1*R**,2*S**) in the ratio of 3.4:1, established from the ^{1}H NMR spectral data.[10] Since the separation of individual diastereomers

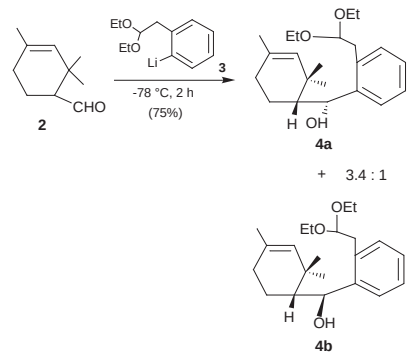


Scheme 1

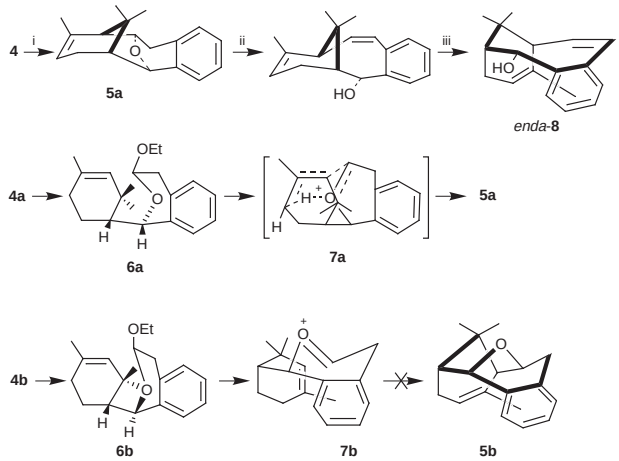
was found to be difficult, it was decided to use the mixture of isomers for the next step.

Addition of $SnCl_4$ (2.5 equiv.) to a stirring solution of **4** in CH_2Cl_2 at −60 °C for 3 h, followed by quenching of the reaction mixture with saturated aqueous NH_4Cl, usual workup and purification *via* silica gel column chromatography, afforded compound **5a** in 32% yield (Scheme 3). The ^{1}H and ^{13}C NMR spectra of **5a** confirmed its structure and indicated that it possessed a complete taxane core incorporating an *endo*-ether linkage connecting C_2 and C_{10} in the central eight-membered B-ring. The structural assignment was further supported by comparing the ^{1}H NMR data from the structurally related C-aromatic *exo/endo* atropisomeric taxanes reported by Shea.[11]

In order to understand the mode of formation of **5a** from **4**, the reaction was also examined using two more Lewis acids, *i.e.* $TiCl_4$ and $BF_3{\cdot}Et_2O$ (Table 1). It was noticed that these Lewis acids are equally effective in promoting the formation of **5a**. For example, the reaction of 1 equiv. of $SnCl_4$ with **4** provided transacetalation product **6** in good yield (65–74%) as a mixture of diastereomers (suggested on the basis of the ^{1}H NMR spectrum). Interestingly, when **6** was separately treated with $SnCl_4$ (1.5 equiv.), it was readily transformed to compound **5a**, thus, revealing the nature of the overall transformation[12] (Scheme 3). The only other report that deals with a similar type of strategy for the construction of the taxane skeleton is from Hitchcock and Pattenden,[13] who demonstrated the efficacy of a



Scheme 2



Scheme 3 *Reagents and conditions*: i, $SnCl_4$ (2.5 equiv.), −60 °C, 3 h, CH_2Cl_2; ii, Bu^nLi, THF, room temp., 7 h; iii, heat

Table 1 Results of Lewis acid-promoted cyclisations

Compound	Lewis acid (equiv.)	*T*/°C	Product	Yield (%)
4	$SnCl_4$ (2.5)	−60	**5a**	32
4	$SnCl_4$ (1.1)	−78	**6**	74
6	$SnCl_4$ (1.5)	−60	**5a**	41
4	$TiCl_4$ (1.1)	−78	**6**	72
4	$BF_3{\cdot}Et_2O$ (1.1)	−78	**6**	65

tandem radical macrocyclization–transannular sequence using an appropriately functionalised A-ring unit.

Initially, the high stereoselectivity observed in the overall cyclization process, *viz.* **4**→**5a**, appeared somewhat intriguing. However, mechanistic considerations along with an examination of the molecular models helped us greatly in increasing our understanding. Mechanistically, in analogy with Overman's proposal,[14] a concerted oxonium ion ene cyclization may well be visualized in the formation of *exo*-**5a** from oxonium ion **7a**, derived from the major isomer **6a** involving a favorable six-membered transition state. The lack of the possibility of such a transition state, due to the unfavorable geometry of the oxonium ion **7b**, from the minor isomer **6b** precludes it from undergoing an analogous type of cyclization that would lead to **5b**.

In order to transform **5a** into a molecule having taxane skeleton **8** it was treated with Bu^nLi[15] at room temperature, which furnished crystalline compound *endo*-**8**[16] (78%; mp 141 °C), instead of the corresponding *exo*-**8**. This observation may possibly be explained by considering a thermal *exo* to *endo* atropisomerization[17] during the work-up stage. The structure and stereochemical assignment of *endo*-**8** follows from a detailed ^1H NMR decoupling experiment and selected coupling constants. Finally, the structure was confirmed by a 2D-COSY NMR experiment.

In conclusion, we have described a facile entry into a functionalized C-aromatic taxane ring system employing an oxonium ene cyclization reaction as the key step for the first time. The potential of this method to construct the ABC system of taxol is under investigation.

We are grateful to Dr M. Vairaman, IICT, Hyderabad, for prompt help in providing HRMS data. D. K. M. and G. H. J. thank CSIR and DST, New Delhi, India, for the award of fellowships and financial assistance, respectively.

Direct synthesis of functionalized mesoporous silica by non-ionic alkylpolyethyleneoxide surfactant assembly

Roger Richer and Louis Mercier*†

Department of Chemistry and Biochemistry, Laurentian University, Sudbury, Ontario, Canada P3E 2C6

The co-condensation of tetraethoxysilane (TEOS) and organotrialkoxysilane [$(RO)_3SiR'$] assembled in the presence of structure-directing non-ionic polyethyleneoxide surfactant micelles provides a convenient neutral pH synthesis methodology for the one-step preparation of organically functionalized mesostructured materials.

The surfactant-directed synthesis of mesoporous molecular sieves, high surface area metal oxides (800–1400 $m^2\ g^{-1}$) with uniform pore sizes (20–100 Å in diameter), have in recent years commanded much attention in the field of materials chemistry.[1–4] Organically functionalized derivatives of such materials were produced by the incorporation or grafting of suitable moieties onto the surface of preformed mesostructured oxides,[5] producing highly effective adsorbents[6,7] and catalysts.[8] Subsequently, an alternate functionalization strategy was reported in which organosilane groups were directly incorporated into the mesostructures by a one-step synthesis procedure,[9–12] allowing the preparation of ordered porous materials with controlled chemical composition by stoichiometric adjustment of the synthesis mixture. Since cationic surfactants were used to prepare these materials, acid leaching was required to remove the templating micelles from the electrically charged frameworks, a treatment which sometimes lead to the structural decomposition of the materials.[11] The use of a non-electrostatic assembly strategy to prepare such functionalized mesostructures may therefore produce an electrostatically neutral framework, allowing the non-destructive removal of the structure-directing surfactant by simple solvent extraction.[13] Here, we report a new synthesis strategy for the one-step preparation of organically functionalized charge-neutral mesoporous silica using non-ionic alkylpolyethyleneoxide surfactants as structure-directing agents, namely Tergitol 15-S-12 $[CH_3(CH_2)_{14}(OCH_2CH_2)_{12}OH]$ and Triton-X100 $[(CH_3)_3C(CH_3)_2CCH_2C_6H_4(OCH_2CH_2)_{10}OH]$.

The non-functionalized mesostructured silicas MSU-1 and MSU-2 were prepared according to previously published assembly techniques,[4] using Tergitol 15-S-12 and Triton-X, respectively, as structure-directing surfactants. Functionalized derivatives of MSU-1 and MSU-2 were synthesized by stirring TEOS and mercaptopropyltrimethoxysilane (MPTMS) in solutions of Tergitol 15-S-12 (0.02 mol l^{-1}) or Triton-X100 (0.027 mol l^{-1}) at 308 K until clear mixtures formed, then NaF was added (the molar composition of each mixture was 0.1 surfactant: $1-x$ TEOS: x MPTMS:0.02 NaF, where x = 0, 0.02 or 0.05). After aging for 24 h, the resulting powders were filtered, air dried and washed by Soxhlet extraction over ethanol for 24 h. The functionalized mesostructures assembled using Tergitol-15-S-12 were thus labeled as MP-MSU-1-2% (x = 0.02) and MP-MSU-5% (x = 0.05), while those prepared from Triton-X100 were designated as MP-MSU-2-2% (x = 0.02) and MP-MSU-5% (x = 0.05). The mesostructures were characterized by powder X-ray diffraction (XRD), N_2 sorptometry, elemental analysis (for S), ^{29}Si MAS-NMR and scanning electron microscopy (SEM). The materials' physical properties obtained from these techniques are given in Table 1.

The low angle powder XRD patterns of the MSU-1 and MSU-2 materials featured dominant first order (d_{100}) diffraction peaks (with d-spacings of 51 and 66 Å, respectively, see Table 1) and broad, low intensity second order (d_{200}) peaks at higher incidence angle. These represent features typical of ordered mesostructured oxides with 'wormlike' pore channel structures, as expected of materials assembled using either neutral[2] or non-ionic surfactants.[3,4] As organosilane moieties are incorporated into the mesostructures, the d_{100} peaks of the materials become shifted to higher diffraction angles, indicating progressive contractions of the lattice d-spacings upon functional group loading (Table 1). Although this effect is slight for the MP-MSU-1 mesostructures (a contraction of only 6% from MSU-1 to MP-MSU-1-5%), significant contraction of the MSU-2 lattice is observed (by 39% from MSU-2 to MP-MSU-2-5%). Moreover, the intensities of the (100) peaks for the functionalized materials were lower in intensity compared to their respective parent mesostructures, and the higher order (200) reflections are no longer detected. Lypophilic interactions between the organosilane molecules and the hydrophobic core of the micelles are likely to result in the deeper penetration of the organosilane molecules within the micelle than do the TEOS molecules. This will cause the micelle structure to 'open-up' and allow TEOS molecules to migrate deeper within the micelle, where they subsequently crosslink with the organosilane functionalities. The perturbations thus caused to the micelle organization thus results in the assembly of more disordered materials with shorter lattice spacings.

The N_2 adsorption isotherms of MSU-1 [Fig. 1(a)] and MSU-2 [Fig. 1(b)] both featured well resolved inflexions at partial pressures between 0.3 and 0.6, demonstrating the existence of uniform mesopore channels with diameters of 32 Å [Fig. 1(c)] and 41 Å [Fig. 1(d)], respectively. No appreciable hysteresis loops were observed in any of the isotherms' desorption

Table 1 Physical characteristics of mesostructures and their functionalized derivatives

Sample	d_{100} lattice spacing/Å	BET surface area/$m^2\ g^{-1}$	Pore diameter/Å[a]	S content/ mmol g^{-1}	Organosilane content (%)[b]
MSU-1	51	1225	32	0	0
MP-MSU-1-2%	50	943	26	0.40	2.6
MP-MSU-1-5%	48	858	22	0.87	5.8
MSU-2	66	1018	41	0	0
MP-MSU-2-2%	50	1176	27	0.47	3.0
MP-MSU-2-5%	40	763	—	1.1	7.7

[a] Measured using the Horvath–Kawazoe pore size distribution model.[14] [b] Percentage of Si atoms present as organosilane with respect to total Si content.

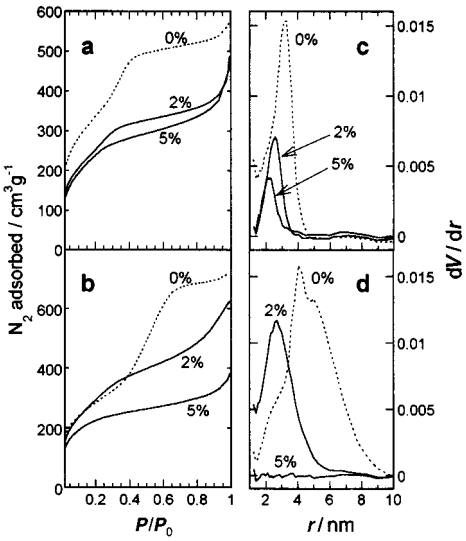

Fig. 1 Left: N_2 adsorption isotherms of (a) MSU-1 (dotted curve) and MP-MSU-1 materials (solid curves), and of (b) MSU-2 (dotted curve) and MP-MSU-2 materials (solid curves). Right: background-substracted Horvath–Kawazoe pore diameter (r) distribution[14] of (c) MSU-1 (dotted curve) and MP-MSU-1 materials (solid curves), and of (d) MSU-2 (dotted curve) and MP-MSU-2 materials (solid curves).

branches, denoting the absence of bottlenecking in the pore channels. The surfactant extraction technique was thus effective in removing the surfactant from the pore channels without damaging the structure of the synthesized materials. The large BET surface areas measured were likewise consistent with the presence of highly porous materials (Table 1). The isotherms of the functionalized derivatives MP-MSU-1-2% [Fig. 1(a)] and MP-MSU-2-2% [Fig. 1(b)] were also indicative of mesoporosity, but the shifts observed in the positions of the inflexions (to between 0.1 and 0.3) show that constrictions in the pore channels have arisen. This can be attributed to both the lattice contractions and to the presence of the mercaptopropyl (MP) moieties which line the pore channel walls, thus reducing the pore diameters and volumes of the mesostructures [Fig. 1(c) and (d)]. Despite pore constriction, the functionalized materials nonetheless retained the very high surface areas characteristic of mesoporous molecular sieves (Table 1). The isotherms of the increasingly loaded MP-MSU-1-5% and MP-MSU-2-5% mesostructures demonstrated an even greater constriction of the pores (Table 1), resulting in further reduction of total pore volume in MP-MSU-1-5% [Fig. 1(c)] and no discernable porosity in MP-MSU-2-5% [Fig. 1(d)]. The significant decreases in surface areas for both of these materials (Table 1) further substantiate these observations. Since all of the functionalized materials are shown to exhibit crystallographic ordering according to their XRD patterns, the incremental featurelessness observed in their N_2 isotherms can be explained by the influence of the increasing amounts of mercaptopropyl groups lining the framework channels, disrupting the uniformity of the pores and reducing their diameters.

The SEM images of the materials revealed aggregates of ultrafine spherical particles with a 'cotton ball'-like morphology. The particles appeared to be quite uniform in size, with diameters averaging about 0.3 μm for all compositions. The minute sizes of these particles creates significant textural porosity within the mesostructure aggregates, resulting in notable sloping of the nitrogen adsorption curves beyond the mesopore inflexions, as well as significant nitrogen uptake observed at relative pressures approaching unity [Fig. 1(a) and 1(b)].

The ^{29}Si MAS NMR spectra of the functionalized mesostructured (recorded with a 600 s pulse delay) denoted the presence of the following Si sites: Q^4 signals at −110 ppm [$(SiO)_4Si$], Q^3 signals at −101 ppm [$(SiO)_3SiOH$] (both corresponding to framework silica derived from hydrolyzed TEOS), and T^2 and T^3 signals (at −60 and −65 ppm, respectively) corresponding to the organosilane (mercaptopropylsilane) silicon atoms.[11] In all cases, the Q^4/Q^3 signal intensity ratios were close to 1.5, while the intensities of the T^2 and T^3 signals increased as a function of organosilane loading in the materials. By comparing the integrations of these NMR signals, in combination with the elemental analysis results (for S content), the functional group content in the mesostructures was deduced and expressed in Table 1 both in terms of S content and organosilane percentage. Although the amount of organosilane incorporated into the MP-MSU-1 materials was found to be close to that expected on the basis of the stoichiometry of the solution reaction mixture, the functional group loading in MP-MSU-2-2% and MP-MSU-2-5% exceeded this content by a factor of *ca*. 1.5 (Table 1). This suggests that preferential assembly of the organosilane molecules has occurred at the interface of the Triton-X micelles, denoting a greater attraction of the organosilane molecules to the surfactant's hydrophobic chain.

The one-step preparation of functionalized mesoporous silica by non-ionic surfactant assembly presents a clear advantage over methodologies involving charged quaternary ammonium surfactants, namely that it does not necessitate the use of potentially destructive acid leaching to remove the framework-bound surfactant from the mesostructures. Moreover, the assembly process described in this paper is achieved under neutral pH conditions, unlike the other direct-synthesis approaches which were performed in alkaline environments.[9–12] This feature connotes the possibility of incorporating organic functionalities that would be unstable or otherwise reactive under non-neutral pH conditions, such as strongly electrophilic functionalities. For example, we have preliminary experimental evidence which demonstrates the successful incorporation of chloroalkyl functionalities into mesostructured frameworks following the synthetic protocol described in this paper.

The authors would like to thank the Ontario Geosciences Centre (Sudbury, Ontario), Dr Allan Palmer (Natural Resources Canada, Nepean, Ontario) and Dr Glenn Facey (University of Ottawa NMR Lab) for providing instrumental support. We also gratefully acknowledge the Laurentian University Research Fund (LURF) for financial support.

Reductive cleavage and related reactions leading to molybdenum–element multiple bonds: new pathways offered by three-coordinate molybdenum(III)

Christopher C. Cummins

Department of Chemistry room 2-227, Massachusetts Institute of Technology, Cambridge, MA, 02139-4307, USA

Three-coordinate molybdenum(III) complexes comprise a new class of reactive-yet-isolable substances. Related to a well known class of metal–metal triple bonded dimers, the monomeric molybdenum(III) complexes supported by sterically-demanding *N-tert*-alkylanilide ligands offer previously unavailable synthetic routes to molybdenum–element multiple bonds. Terminal nitride, phosphide and carbide functionalities have been prepared from reactions with dinitrogen, white phosphorus and carbon monoxide, respectively.

Introduction

Professor Malcolm H. Chisholm of Indiana University has championed the chemistry of compounds containing Mo≡Mo and W≡W triple bonded moieties since the early 1970s.[1] For the most part, the compounds of interest have supporting amide (*e.g.* NMe_2) or alkoxide (*e.g.* OBu^t) ligands. Although chromium(III) does not exhibit a similar tendency to form unbridged metal–metal triple bonds, it was shown in seminal work by Bradley's group that the complex $Cr(NPr^i_2)_3$ **1** exists in discrete monomeric form.[2] Moreover, the compound manifests a trigonal-planar coordination geometry, along with a high-spin (quartet) ground state. Thus an interesting dichotomy arose between the chemistry of chromium(III), on the one hand, and that of molybdenum(III) and tungsten(III) on the other. The successful synthesis of a discrete monomeric molybdenum(III) entity would bridge this gap, and hints that such a species might be accessible *via* implementation of bulky amide ligands can be found in reported attempts at the synthesis of $Mo[N(SiMe_3)_2]_3$ **2**.[3] Note, indeed, that the hexamethyldisilazide ligand is known to support three-coordination for the 3d metals Sc through Co in the 3+ oxidation state, and that the remarkable amide $U[N(SiMe_3)_2]_3$ **3** is a monomer.[4]

Against the foregoing backdrop, we set out to explore complexes of the new amide ligand N(R)Ar [R = $(CD_3)_2CH_3$, Ar = 3,5-$C_6H_3Me_2$], and related derivatives.[5] Use of the $C(CD_3)_2CH_3$ substituent was deemed worthwhile as a ^2H NMR spectroscopic handle, and the choice of substituents was prompted by a desire to (i) avoid β-hydrogens, (ii) combine one roughly spherical substituent with one roughly planar substituent for efficient intramolecular packing, and (iii) use hydrocarbon-only building blocks so as to avoid decomposition pathways to which silylamides are prone, such as cyclometallation or N–Si bond cleavage.[6]

A ready synthesis of deuterated *N-tert*-butylanilides was found to consist of $[^2H_6]$acetone condensation with the desired substituted aniline, followed by treatment of the resulting imine with methyllithium.[5] The most widely successful ligand to date is that derived from deprotonation of *N*-$[^2H_6]$-*tert*-butyl-3,5-dimethylaniline with *n*-butyllithium. Crystallization from ether affords the white etherate $Li[N(R)Ar](OEt_2)$, which is suitable for reaction with transition metal halides.

Synthesis and characterization of three-coordinate complexes

Following the lead of Bradley's synthesis of $Cr(NPr^i_2)_3$ **1** from chromium(III) chloride and lithium diisopropylamide,[2] it was elected to investigate the reaction of $MoCl_3(THF)_3$[7] with $Li[N(R)Ar](OEt_2)$.[5] In this endeavour, the presence of a deuterium label in the ligand led to rapid identification of appropriate conditions for the synthesis of $Mo[N(R)Ar]_3$ **4**, the compound exhibiting a single ^2H NMR peak at δ *ca.* 64.[8] Various conditions were sampled, with the result that a 2 : 1 lithium amide to molybdenum chloride stoichiometry was deemed optimal (ostensibly to speed conversion to products) and that diethyl ether solvent gave the best results. The desired compound, $Mo[N(R)Ar]_3$ **4**, has been obtained in 60–80% isolated yield as a lipophilic orange–red crystalline substance.[9] Other variously substituted anilide ligands including the 'parent' $-N(Bu^t)Ph$,[9] the adamantyl-substituted derivatives –N(1-Ad)Ar and –N(2-Ad)Ar, and the mono-fluorinated derivative –N(R)(4-C_6H_4F)[10] have all provided corresponding three-coordinate tris-anilide complexes of Mo^{III} following the standard protocol developed for **4**.[9]

An important feature of the characterization of **4** is the fact, substantiated by X-ray crystallography,[9] that it exists in the solid as discrete mononuclear complexes with no short intermolecular contacts. As such, **4** and related derivatives constitute the first definitive examples of three-coordinate molybdenum. The geometry at molybdenum is trigonal planar. Thus, although Mo≡Mo triple bonds are known to be *ca.* 80 kcal mol^{-1} (1 cal = 4.184 J),[11] the substituents are sufficiently large in the present case to obviate dimerization.[12] A representative structure[9] is that of $Mo[N(R)Ar]_3$ **4**, shown in Fig. 1.

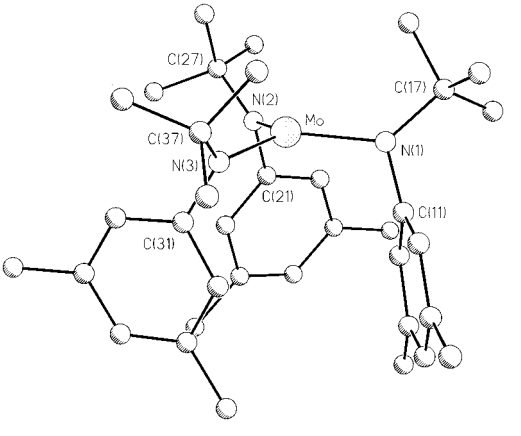

Fig. 1 Ball and stick representation of $Mo[N(R)Ar]_3$ **4**, from X-ray coordinates.[9] The Mo–N distances average 1.967(7) Å, and the sum of N–Mo–N angles is 357.7(3)°.

The X-ray crystallography studies show that the intramolecular packing conformation is one with the three 3,5-$C_6H_3Me_2$ substituents on one side of the trigonal plane and the three Bu^t groups on the other side. Another conformation that would

maximize the in-plane N to Mo π bonding is a 'two-up, one-down' arrangement of substituents; investigation of this alternative by molecular mechanics suggests that it is higher in energy by *ca.* 6 kcal mol^{-1} than the observed conformation.[12] Solution NMR spectra of Mo[N(R)Ar]$_3$ **4** are consistent with preservation of the pseudo-C_3 symmetric structure, with only a single –N(R)Ar environment being observed down to *ca.* −40 °C. EXAFS data collected at 10 K on frozen toluene solutions likewise were consistent with the pseudo-C_3 symmetric conformation.[9]

Also critical to an appreciation of the tris-anilide molybdenum(III) complexes is the fact that they are high spin, with all three d electrons unpaired. This is known from both solution and solid-state magnetic susceptibility studies, with μ_{eff} for the complexes being close to the spin-only value.[9] Symmetry arguments and computational studies[13] agrees that this should be the case, and indicate that the half-occupied orbitals possess σ (d_{x^2}) and π (d_{xz}, d_{yz}) symmetry with respect to the pseudo-C_3 axis. This is an interesting point to be recalled later in the bonding discussion pertaining to very stable nitrido complexes, *e.g.* N≡Mo[N(R)Ar]$_3$ **5**.

With regard to the properties of **4**, it should be noted that despite its coordinative unsaturation no reaction is observed with pyridine, triethylphosphine, or tetrahydrofuran (benzene, 25 °C). Thus, the compound is not a Lewis acid. If this result is to be attributed to electronic effects, then a reluctance to go low-spin (making the d_{z^2} orbital available) can be invoked. Otherwise, it can be suggested that the pyridine, PEt_3, and THF molecules are too large to access the molybdenum center. That more electron-deficient complexes such as Ti[N(R)Ar]$_3$ **6** display an η^3 bonding mode for the N(R)Ar ligand,[14] while the molybdenum complexes display strictly the η^1 bonding mode, can be taken as evidence that the Mo complexes are not overly electron-poor.

Reactions furnishing the nitrido linkage

Theoretical work has placed the N≡Mo bond dissociation enthalpy (BDE) at *ca.* 165 kcal mol^{-1}, nearly 75% of the value for the N≡N triple bond of dinitrogen.[13] This being the case, it is not surprising that many reactions have been found which, in effect, transfer a nitrogen atom to Mo[N(R)Ar]$_3$ **4**, giving rise to N≡Mo[N(R)Ar]$_3$ **5**. Compound **5** can thus be regarded as a thermodynamic sink in systems containing **4** and sources of a nitrogen atom. Also, **4** can be regarded as an example of an 'azophilic' complex, in much the same way that fragments poised to form strong bonds to oxygen [*e.g.* Ta(OSiBu$^t_3$)$_3$] **7** are regarded as oxophilic.[15] The notion of the extreme stability of **5** is further substantiated by electrochemical studies showing that the complex is highly resistant to both oxidation and reduction.

Geometric and electronic structure issues related to diamagnetic **5** are reminiscent of the discussion given above for **4**. A representative structure is that of NMo[N(Bu^t)Ph]$_3$ **8**, shown in Fig. 2.[9] As in the case of **4**, the aryl groups are close-packed on one side of the molecule, while the Bu^t groups now form a protective 'pocket' about the Mo≡N triple bond. The three d electrons unpaired in **4** are involved in **5** in making the σ and π bonds to the nitrido nitrogen, bonds which have the same symmetry as the orbitals (d_{z^2}, d_{xz} and d_{yz}) utilized in **4** for the unpaired electrons. Thus it can be seen that the molybdenum–anilide bonding is essentially unperturbed on going from **4** to **5** (a notion substantiated by bond length considerations), and that the conformation of the Mo[N(R)Ar]$_3$ fragment also remains essentially constant. Little reorganization is required for addition of a nitrogen atom to **4**.

During initial purifications of **4** by recrystallization (OEt_2, −40 °C), it was noted that solutions became purple if under N_2, but retained the orange–red color of **4** if maintained in an argon atmosphere. Solid **4** can be manipulated under N_2 without any observable decompostion, and 0.05 M solutions of **4** stored

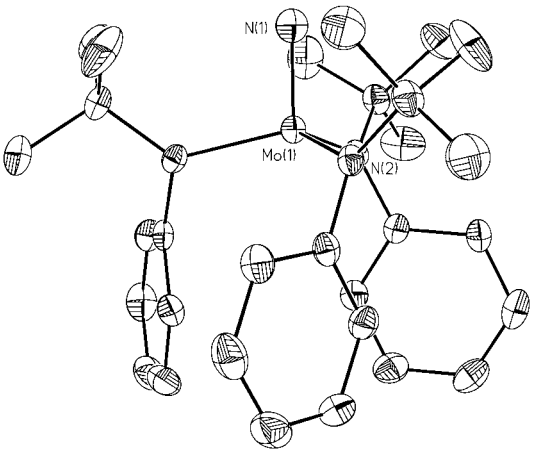

Fig. 2 Thermal ellipsoid representation of N≡Mo[N(Bu^t)Ph]$_3$ **8** from an X-ray study.[9] The Mo–$N_{nitride}$ bond resides on a crystallographic threefold axis. Ellipsoids are at the 35% probability level. The Mo–$N_{nitride}$ bond length is 1.658(5) Å, while the Mo–N_{amide} bond length is 1.979(2) Å.

under N_2 at room temperature degrade only slowly (*ca.* 5% per day). Naturally it was surmised that the purple color was due to N_2 chemistry, favored at low temperature either due to enhanced solubility of N_2 or to other entropic factors. In fact, at the time a purple N_2-bridged dimolybdenum(III) amido complex was already known, namely (μ-N_2)[Mo(Bu^t-Me$_2$SiNCH$_2$CH$_2$)$_3$N]$_2$ **9**.[16] Thus, the purification process for **4** was developed to involve exclusion of N_2. The full details of the reaction of **4** with N_2[9] were not elucidated until after **5** had already been characterized in full in the context of a nitrous oxide N–N cleavage reaction.[8]

Nitrous oxide

The existence of molybdenum(VI) nitrido-tris-amide complexes such as NMo(NPh$_2$)$_3$[17] **10** was an early indicator that **4** should function as an N-atom acceptor. This raised the question: what molecule might serve, with a minimum of reorganization, as a nitrogen-atom donor? One answer that came to mind was nitrous oxide, since loss of its terminal nitrogen atom would yield nitric oxide. The latter, while admittedly reactive, is a viable diatomic gas plausible as a leaving group in an N-atom transfer reaction. A problem with the selection of nitrous oxide as an N-atom donor was that literature precedent showed clearly that reducing metal complexes react with N_2O to give exclusive N–O bond cleavage, liberating N_2 as a stable byproduct.[18] This is why nitrous oxide is sometimes referred to as 'a clean oxidant'. Furthermore, on thermodynamic grounds one expects N–O bond cleavage, given that the N–O bond is the weaker by *ca.* 75 kcal mol^{-1} of the two bonds in the molecule.[19]

Experiments showed that solutions of **4** react smoothly with nitrous oxide (≥4 equiv.), **4** being converted rapidly (≤5 min, 25 °C) to a 1:1 mixture of nitride **5** and the similarly diamagnetic nitrosyl derivative (ON)Mo[N(R)Ar]$_3$ **11** with no observable intermediates [eqn. (1)].[8] Various conditions were

$$\underset{\mathbf{4}}{\text{Mo[N(R)Ar]}_3} \xrightarrow{N_2O} \underset{\mathbf{5}}{\text{N≡Mo[N(R)Ar]}_3} + \underset{\mathbf{11}}{\text{O=N=Mo[N(R)Ar]}_3} \quad (1)$$

sampled, and in no case was the ratio of nitride : nitrosyl perturbed from 1 : 1. Careful analysis of the reaction mixtures ruled out the presence of the (at the time unknown) oxo complex, Mo(O)[N(R)Ar]$_3$ **12**, which would have been produced if **4** has deoxygenated nitrous oxide. (As described below, brown paramagnetic oxo complex **12** can be synthesized independently.[20])

An independent synthesis of nitrosyl **11** was achieved by simple treatment of a solution of **4** with nitric oxide [eqn. (2)].[8]

$$\underset{\mathbf{4}}{\text{Mo[N(R)Ar]}_3} \xrightarrow{NO} \underset{\mathbf{11}}{\text{O=N=Mo[N(R)Ar]}_3} \quad (2)$$

The yellow, diamagnetic compound was produced in high yield, its synthesis being reminiscent of Bradley's classic synthesis of $(ON)Cr[N(SiMe_3)_2]_3$ **13**.[21] The synthesis and characterization of **11** in pure form permitted unambiguous assignment of its contribution to the NMR spectra from the N_2O reactions. Furthermore, the rapid and efficient combination of nitric oxide with **4** raised the possibility that free NO may be involved in the mechanism for nitrous oxide N–N bond cleavage by **4**. A second possibility is that the mechanism involves bimetallic activation of nitrous oxide, an appealing possibility that neatly accounts for the observed 1 : 1 ratio of **5** : **11**. The data in hand, however, are insufficient to pinpoint the mechanism of the splitting reaction. Definitive kinetic data will have to be acquired by stopped-flow techniques in order to settle the issue.

Characterization of nitride **5** was required for a complete interpretation of the data from nitrous oxide reactions with **4**. Interestingly, a clean route to **5** was discovered that involves treatment of **4** with mesityl azide.[8] This reaction, like the N_2O reaction, is unusual in comparison with known reactions of the substrate with reducing metal compounds. Normally, reductants elicit N_2 elimination from organoazides, giving metal imido derivatives.[22] Here, as demonstrated with a ^{15}N-labeling study, abstraction of the terminal nitrogen atom occurred, giving high-yield conversion to pale yellow **5**. As in the case of the N_2O activation reaction, the mechanism of mesityl azide N–N bond cleavage by **4** remains to be elucidated in detail. A key issue here is whether the N–N bond breaks before or after the N–C bond. The issue of a bimetallic activation mechanism is not important for the case of mesityl azide, since no evidence was found for the formation of the putative aryldiazenido complex $MesN{=}NMo[N(R)Ar]_3$. Based on subsequent synthetic studies, the latter is expected to be a stable, diamagnetic complex.

Dinitrogen

Having characterized nitride **5**, $N{\equiv}Mo[(R)Ar]_3$, a more detailed interpretation of the behavior of **4** in the cold under N_2 (1 atm) became possible.[23] Catalina Laplaza noticed that the purple solutions (presumed to contain $(\mu\text{-}N_2)\{Mo[N(R)Ar]_3\}_2$, **14**) lost the purple color upon standing for a couple of hours at 25 °C, and that peaks for nitride **5** were dominant in corresponding NMR spectra. This raised the exciting possibility that **4** was able to directly bind and split N_2, under mild conditions, and in the absence of any added reagents! Accordingly it was found that **4** could be converted in good yield to **14** by storage of a toluene solution under N_2 at −40 °C for 3–5 days. Subsequent warming to room temperature gave quantitative conversion to nitride **5** with the first-order kinetics and a $t_{1/2}$ of *ca.* 30 min.[23]

Subsequent work has included extensive characterization of the intermediate purple dinitrogen complex **14**, with its N–N bond length of 1.19(2) Å (EXAFS) and ν_{NN} of 1630 cm^{-1} (Raman).[9] The dinitrogen ligand bridges the two molybdenum centers in the typical[24] linear, end-on fashion, and the relatively high symmetry of the complex renders it paramagnetic, with a triplet ground state. It exhibits a single ^2H NMR signal at δ *ca.* 14. Isotopic labeling studies with $^{15}N_2$ permitted determination of a temperature-dependent primary kinetic isotope effect on the splitting reaction (conversion of **14** to **5**),[9] the magnitude of which was in accord with predictions based on the observed Raman ν_{NN} of $(\mu\text{-}^{15}N_2)\{Mo[N(R)Ar]_3\}_2$ and the diatomic oscillator approximation.[9]

The mechanism of dinitrogen cleavage by **4** has now also been studied in considerable detail by theoretical methods.[13] The important steps are [eqn.(3)] binding of dinitrogen by **4** to

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} + N_2 \rightleftharpoons \underset{\mathbf{15}}{N_2Mo[N(R)Ar]_3} \quad (3)$$

give the low-spin 1 : 1 adduct, $(N_2)Mo[N(R)Ar]_3$ **15**, [eqn. (4)] trapping of **15** by a second equiv. of **4** to give dinuclear **14**, and [eqn. (5)] unimolecular fission of **14** at the N–N bond *via* a

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} + \underset{\mathbf{15}}{N_2Mo[N(R)Ar]_3} \longrightarrow \underset{\mathbf{14}}{(\mu\text{-}N_2)[Mo\{N(R)Ar\}_3]_2} \quad (4)$$

$$\underset{\mathbf{14}}{(\mu\text{-}N_2)[Mo\{N(R)Ar\}_3]_2} \longrightarrow 2\ \underset{\mathbf{5}}{N{\equiv}Mo[N(R)Ar]_3} \quad (5)$$

zigzag (not linear) transition state to produce 2 equiv. of nitride **5**.

Experimentally we have not yet been able to observe the 1 : 1 adduct **15** directly, and we postulate that the binding of N_2 by **4** is rapid and reversible with only small equilibrium concentrations of **15** being present under 1 atm of N_2. To observe **15** directly, experiments are currently underway wherein **4** is being monitored by NMR and IR under large dinitrogen pressures. Theoretical studies predict that **15** will feature an end-on interaction between Mo and the N_2, and this is in accord with the structure of recently reported $N_2Mo(Me_3SiNCH_2CH_2)_3N$ **16**,[25] which has been shown (in contrast to **15**) not to be labile.

Although the reductive cleavage of dinitrogen to nitride by well-defined transition metal complexes in homogeneous solution was unprecedented prior to 1995,[23] it can be expected that more examples of this remarkable reaction type will eventually come to light. A very recent example comes from the labs of Floriani,[26] and it involves the use of niobium calixarene complexes. It is reasonable to speculate that the development of robust complexes capable of N_2 reductive cleavage will eventually result in applications in catalysis, the ultimate goal being the development of a homogeneous analog of the Haber–Bosch process.[27] The real obstacle to this type of application, currently, rests in the low reactivity of the very stable metal–nitrido functional group—*e.g. ca.* 165 kcal mol^{-1} for the Mo≡N bond in $NMo[N(R)Ar]_3$.[13]

Nitrogen atom transfer

Intermetal nitrogen atom transfer is a reaction type known for less than a decade, and it has the attractive feature of providing a means for breaking a metal–nitrogen triple bond under mild conditions in homogeneous solution.[28] Although such reactions—in which a neutral N atom passes completely from one metal to another with breaking of one M≡N triple bond and formation of a new one—have been proposed to proceed by μ_2-N atom-bridged intermediate complexes,[29] experimental verification of this has come only recently.[10]

A question one might ask concerns the degree to which the spectator ligands in a nitrido metal complex attenuate the affinity of the metal fragment for the N atom. In an experiment[30] designed to compare alkoxides with anilides, $Mo[N(R)Ar]_3$ was treated with Chisholm's alkoxynitride complex, $NMo(OBu^t)_3$, **17**.[31] Reaction of **4** with **17** [eqn. (6)] led to formation of a blue

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} + \underset{\mathbf{17}}{N{\equiv}Mo(OBu^t)_3} \longrightarrow \underset{\mathbf{18}}{(Bu^tO)_3Mo{=}N{=}Mo[N(R)Ar]_3} \quad (6)$$

intermediate, presumed to be $(Bu^tO)_3Mo(\mu\text{-}N)Mo[N(R)Ar]_3$, **18**.[30] Conducting the reaction in benzene at 25 °C in the absence of N_2 led to formation of nitride **5** along with 0.5 equiv. of the well known metal–metal triple-bonded dimer,[11] $Mo_2(OBu^t)_6$, **19** [eqns. (7) and (8)]. Thus, N-atom transfer was sub-

$$\underset{\mathbf{18}}{(Bu^tO)_3Mo{=}N{=}Mo[N(R)Ar]_3} \rightleftharpoons \underset{\mathbf{5}}{N{\equiv}Mo[N(R)Ar]_3} + \underset{\mathbf{20}}{'Mo(OBu^t)_3'} \quad (7)$$

$$2\ \underset{\mathbf{20}}{'Mo(OBu^t)_3'} \longrightarrow \underset{\mathbf{19}}{(Bu^tO)_3Mo{\equiv}Mo(OBu^t)_3} \quad (8)$$

stantiated,[30] and the –N(R)Ar-substituted complex demonstrated a greater affinity for the nitrogen atom than the alkoxide-substituted complex. The reaction is interesting in that it provides precedent for synthesis of a metal–metal multiple bond from a metal nitride, and also in that the observation of a blue

intermediate [eqn. (6)] suggested that more might be learned about the mechanism of this type of N-atom transfer.[30]

An interesting spin on the N-atom transfer reaction occurred when **4** was treated with alkoxynitride **17** under an atmosphere of N_2 (benzene, 25 °C).[30] Under these conditions, formation of the dimer **19** was nearly shut down, while formation of nitride **5** proceeded smoothly. The very slow reaction of **4** directly with N_2,[9] assessed in control experiments to occur to an extent of ⩽5% per day under these conditions,[30] cannot account for the smooth conversion of **4** to **5** in the presence of **17**, suggesting that **17** catalyzes the splitting of N_2 by **4** [eqn. (9)].[30] This

$$\underset{\mathbf{20}}{\text{'Mo(OBu}^t\text{)}_3\text{'}} + \underset{\mathbf{4}}{\text{Mo[N(R)Ar]}_3} \xrightarrow{N_2} \underset{\mathbf{5}}{\text{N}{\equiv}\text{Mo[N(R)Ar]}_3} + \underset{\mathbf{17}}{\text{N}{\equiv}\text{Mo(OBu}^t\text{)}_3} \quad (9)$$

supposition was substantiated by experiments involving reaction of **4** with **17** under an atmosphere of $^{15}N_2$, which resulted in label incorporation into both the alkoxynitride **17** and **5** isolated after the reaction.[30] A mechanistic scenario accommodating the data involves (i) N-atom transfer to generate **5**, (ii) concomitant formation of some form of 'Mo(OBu^t)$_3$', **20**, and N_2 splitting either by **20** alone or *via* a heterodinuclear species such as putative (Bu^{t}O)$_3$Mo(μ-N$_2$)Mo[N(R)Ar]$_3$ **21**. Combining the latter three steps provides a plausible mechanism for the observed result, namely that the splitting of N_2 by **4** is accelerated in the presence of alkoxynitride **17**.[30]

In pursuit of more information regarding the putative N-atom bridged complexes in intermetal nitrogen atom transfer reactions, it was elected to treat **4** and analogues with another nitridomolybdenum amide complex, namely NMo(NMe$_2$)$_3$ **22**.[10] This particular choice was prompted by speculation that an N-atom bridged species might possess greater thermal stability if the two molybdenum fragments involved possess electronically similar ligand sets. Dimethylamide ligands, in addition, were regarded as small enough to permit N-atom transfer. The latter consideration is important in that control experiments[10] showed that no reaction occurs between **4** and NMo[N(Bu^t)Ph]$_3$ **8**, or between **5** and Mo[N(Bu^t)Ph]$_3$ **23**.

A striking teal color was generated upon mixing the three-coordinate complex Mo[N(R)Ar$_{4F}$]$_3$ (**24**, Ar$_{4F}$ = 4-C$_6$H$_4$F) with **22** in toluene or ether [eqn. (10)].[10] The nitride-bridged

$$\underset{\mathbf{24}}{\text{Mo[N(R)Ar}_{4F}\text{]}_3} + \underset{\mathbf{22}}{\text{N}{\equiv}\text{Mo(NMe}_2\text{)}_3} \longrightarrow \underset{\mathbf{25}}{\text{(Me}_2\text{N)}_3\text{Mo}{=}\text{N}{=}\text{Mo[N(R)Ar}_{4F}\text{]}_3} \quad (10)$$

complex (Me$_2$N)$_3$Mo(μ-N)Mo[N(R)Ar$_{4F}$]$_3$ **25** was isolated in good yield and characterized by a variety of techniques including X-ray diffraction (Fig. 3).[10] Although the structure was of marginal quality due to dimethylamide disorder, the nitride nitrogen appeared to be situated equidistant from the two dissimilarly ligated Mo centers.

Although this particular μ-nitride species (**25**) seemed relatively robust, a more fragile analog was generated by treatment of **22** with the 'parent' complex **23** [eqn. (11)].[10] Thus

$$\underset{\mathbf{23}}{\text{Mo[N(Bu}^t\text{)Ph]}_3} + \underset{\mathbf{22}}{\text{N}{\equiv}\text{Mo(NMe}_2\text{)}_3} \longrightarrow \underset{\mathbf{27}}{\text{(Me}_2\text{N)}_3\text{Mo}{=}\text{N}{=}\text{Mo[N(Bu}^t\text{)Ph]}_3} \quad (11)$$

was derived a suitable synthesis of the symmetrical μ-nitride complex (μ-N)[Mo(NMe$_2$)$_3$]$_2$ **26**, by treatment of **23** with 2 equiv. of **22**. The notion is that the unsymmetrical ligated μ-nitride complex (Me$_2$N)$_3$Mo(μ-N)Mo[N(Bu^t)Ph]$_3$ **27** is thermally unstable, and serves as a source of 'Mo(NMe$_2$)$_3$' **28** under the reaction conditions [eqn. (12)]. Trapping of **28** by the second

$$\underset{\mathbf{27}}{\text{(Me}_2\text{N)}_3\text{Mo}{=}\text{N}{=}\text{Mo[N(Bu}^t\text{)Ph]}_3} \rightleftharpoons \underset{\mathbf{28}}{\text{'Mo(NMe}_2\text{)}_3\text{'}} + \underset{\mathbf{22}}{\text{N}{\equiv}\text{Mo[N(Bu}^t\text{)Ph]}_3} \quad (12)$$

equiv. of **22** provides the symmetrically substituted nitride derivative, nitridodimolybdenum–hexadimethylamide [**26**, eqn. (13)]. Using this procedure, thermally sensitive **26** could be

$$\underset{\mathbf{28}}{\text{'Mo(NMe}_2\text{)}_3\text{'}} + \underset{\mathbf{22}}{\text{N}{\equiv}\text{Mo(NMe}_2\text{)}_3} \rightleftharpoons \underset{\mathbf{26}}{\text{(Me}_2\text{N)}_3\text{Mo}{=}\text{N}{=}\text{Mo(NMe}_2\text{)}_3} \quad (13)$$

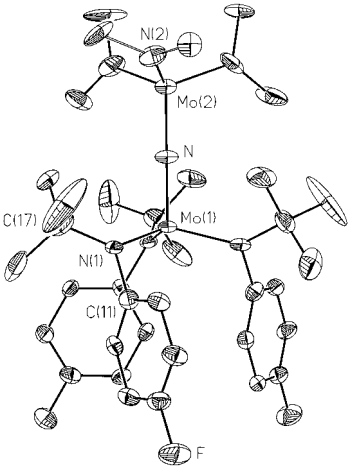

Fig. 3 Thermal ellipsoid representation of (Me$_2$N)$_3$Mo(μ-N)Mo[N(R)Ar$_{4F}$]$_3$ **25**, from an X-ray study.[10] The Mo–N–Mo axis resides on a crystallographic threefold axis; the resulting NMe$_2$ disorder is not shown. Ellipsoids are at the 35% probability level. The Mo(1)=N bond length is 1.82(4) Å, while the Mo(2)=N bond length is 1.83(4) Å.

isolated in pure form by fractional crystallization, and was characterized by X-ray crystallography (Fig. 4). The μ-N atom in **26** resides at a crystallographic center of inversion, with a Mo–N distance of 1.7990(8) Å. This distance is consistent with an Mo–N double bond,[10] the Mo≡N distance in **8** being 1.658(5) Å.[9] A molecular-orbital description of **26** also suggests a bond order of two between both molybdenum atoms and the bridging nitride ligand, the highest-lying three electrons being in a π-symmetry molecular orbital that possesses a node at the bridging nitrogen atom. A compound fascinating in its simplicity, **26** is related to the well known dimer Mo$_2$(NMe$_2$)$_6$ **29**[11] by formal insertion of a neutral nitrogen atom into the metal–metal triple bond. Indeed, thermal decomposition of **26** gives rise to a mixture of **22** and **29**.[10]

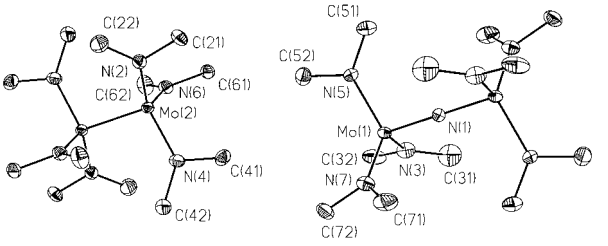

Fig. 4 Thermal ellipsoid representation of (μ-N)[Mo(NMe$_2$)$_3$]$_2$ **26** and Mo$_2$(NMe$_2$)$_6$ **29**, from an X-ray study in which the two occurred together in a 1:1 cocrystal.[10] Ellipsoids are at the 35% probability level. The Mo(1)=N(1) bond length is 1.7990(8) Å, while the Mo(1)–N(5) bond length is 1.953(8) Å.

The molybdenum systems described in this section do much to augment our knowledge of intermetal N-atom transfer reactions. Importantly, as earlier surmised[29] it is now established[10] that N-atom bridged species play an important role as intermediates in the transfer process. Some of the mixed-valence N-atom bridged species have been isolated, such that much can be expected to be gained from a study of their physical properties, decomposition kinetics, and other reaction chemistry. An intriguing aspect of the chemistry is that sources of the reactive, sterically-unhindered fragments 'Mo(OBu^t)$_3$' **20**[30] and 'Mo(NMe$_2$)$_3$' **28**[10] are available *via* N-atom transfer chemistry. Now that N-atom abstractors such as **4** are readily prepared, it is likely that other synthetic applications of N-atom transfer chemistry will result.

Molybdenum–phosphorus chemistry: establishment of the terminal phosphide (M≡P) functionality

The chemistry in this section stemmed from a desire to explore in broad terms the reactivity of **4** and related three-coordinate molybdenum compounds. Having learned about the pronounced stability of the Mo≡N triple bond in **5**,[9] it was of interest to see if the analogy could be pushed to phosphorus, an endeavor which if successful would lead to an unknown functional group: the terminal phosphide, M≡P.[32] As described below, it is indeed possible to draw several analogies between the molybdenum–nitrogen and the molybdenum–phosphorus chemistries.

Activation of white phosphorus

White phosphorus, consisting of tetrahedral P_4 molecules, is the most abundant form of elemental phosphorus.[33] The majority of its transition-metal mediated reactions involve metal carbonyl fragments and cluster chemistry.[34] The closest precedent for the reaction of a three-coordinate molybdenum compound with white phosphorus comes, as so many good things do, from the labs of Malcolm Chisholm. Thus, the dimethylamine adduct of the tungsten dimer $W_2(OCH_2Bu^t)_6$ **30** was treated with P_4 in an attempt to prepare the W≡P functional group.[35] What was obtained instead is the interesting complex, $(\eta^3\text{-}P_3)W(OCH_2Bu^t)_3(HNM_2)$, **31**.[35] The latter can be understood as a P_4 molecule with one vertex replaced by the isolobal tungsten tris-alkoxide fragment.[36]

In contrast to Chisholm's tungsten chemistry, three-coordinate **4** reacts smoothly with P_4 in toluene at 25 °C to afford the desired terminal phosphide derivative P≡Mo[N(R)Ar]$_3$ **32**, [eqn. (14)].[37] The analog stemming from reaction of 'parent'

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} \xrightarrow{P_4} \underset{\mathbf{32}}{P{\equiv}Mo[N(R)Ar]_3} \qquad (14)$$

Mo[N(Bu^t)Ph]$_3$ **23** with P_4, namely PMo[N(Bu^t)Ph]$_3$ **33**, was prepared similarly,[10] and both have been characterized by X-ray diffraction. Compounds **32** and **33** are diamagnetic yellow–gold crystalline solids that dissolve readily in standard organic solvents. They, like their three-coordinate precursors, are readily prepared on 5–10 g scales.

A most intriguing feature of the NMR spectra of the terminal phosphide compounds is that their ^{31}P signal appears downfield of 1200 ppm! The latter phenomenon has been studied in detail by solid-state NMR techniques, and by computational methods.[38] The enormous downfield isotropic signal is interpreted[38] as arising from an unusually large chemical shift anisotropy in the system, consonant with field-induced mixing of the ground state with a paramagnetic excited state. The excited state in question is thought to involve promotion of electron density from an M–P σ bonding orbital into an orbital that is M–P π* in character.[38]

Structurally, phosphide compounds **32** and **33** are similar to nitride **8**, and the respective Mo≡P bond distances 2.119(4) and 2.111(2) Å are of interest (Fig. 5). Triple-bond covalent radii can be estimated for both Mo and P using the reference compounds P_2 and $Mo_2(NMe_2)_6$, giving the prediction of 2.055 Å for an Mo≡P triple bond.[37] Agreement with the experimental values is seen to be quite close.

Triamidoamine-supported[39] molybdenum and tungsten phosphide complexes PMo(Me$_3$SiNCH$_2$CH$_2$)$_3$N **34** and PW(Me$_3$SiNCH$_2$CH$_2$)$_3$N **35** were reported close on the heels[40] of **32**; **35** exhibited a W≡P distance of 2.162(4) Å, with an interesting added twist that the tungsten–phosphorus coupling constant had an unanticipated low value of 138 Hz. Organophosphide and phosphinidene complexes of tungsten exhibit much larger values of J_{WP}.[40] The data may be taken as an indication that the phosphorus 3s orbital participates little in the tungsten–phosphorus bonding, but rather accommodates a rather low-lying lone pair of electrons. Interestingly, compounds **35** and **34** were prepared not *via* a reaction with elemental phosphorus, but rather through treatment of precursor chloro complexes with Li[P(H)Ph] in what must involve a complex sequence of steps.[40] Such methodology was later successful for the preparation of the corresponding terminal arsenide complexes, As≡M(Me$_3$SiNCH$_2$CH$_2$)$_3$N (M = Mo **36**, W **37**), which have been the subject of a force-constant study.[41]

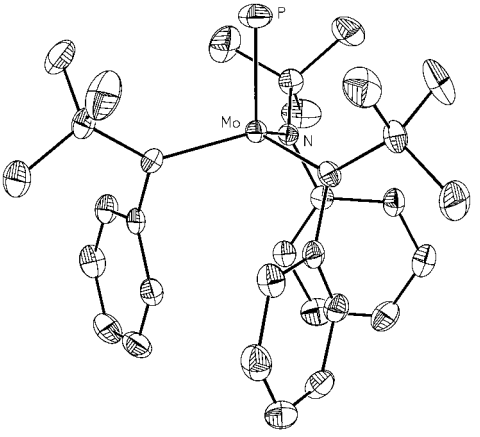

Fig. 5 Thermal ellipsoid representation of P≡Mo[N(Bu^t)Ph]$_3$ **33**, from an X-ray study.[10] The P–Mo bond is coincident with a crystallographic threefold axis. Ellipsoids are at the 35% probability level. The Mo≡P bond length is 2.111(2) Å, while the Mo–N bond length is 1.973(2) Å.

Reactions of terminal phosphide complexes with oxo, sulfur atom, and nitrene donors

First off it should be stated that like nitride **5**, phosphide **32** is not an exceptionally reactive compound. In part, the low reactivity of **32** toward certain reagents (including benzonitrile, benzaldehyde and methyl iodide) can be ascribed to the substantial steric shielding of the M≡P triple bond by *tert*-butyl groups. However, phosphide **32** does undergo some reactions involving addition of a terminal substituent to the phosphorus atom, especially in cases where a cumulene-like moiety Mo=P=X (X = O,[42] S[37] or NMes[37]) with a delocalized π system can arise.

Sulfur atom transfer to the terminal phosphide

The so-called PS complex, S=P=Mo[N(R)Ar]$_3$ **38** was prepared either in 62% yield in a slow reaction of **32** with elemental sulfur [43 h, OEt$_2$, 25 °C, eqn. (15)], or in 50% yield in a rapid reaction with ethylene sulfide [1.5 h, OEt$_2$, 25 °C, eqn. (16)].[37]

$$\underset{\mathbf{32}}{P{\equiv}Mo[N(R)Ar]_3} \xrightarrow{1/8\ S_8} \underset{\mathbf{38}}{S{=}P{=}Mo[N(R)Ar]_3} \qquad (15)$$

$$\underset{\mathbf{32}}{P{\equiv}Mo[N(R)Ar]_3} \xrightarrow{SC_2H_4} \underset{\mathbf{38}}{S{=}P{=}Mo[N(R)Ar]_3} \qquad (16)$$

The purple–red compound exhibits a ^{31}P NMR signal at δ 383, a dramatic upfield shift relative to phosphide **32**. That **38** exists as discrete monomeric units in the solid state was verified by X-ray crystallography (Fig. 6).[42] The Mo–P and P–S bond lengths are respectively 2.100(2) and 1.921(3) Å, and the angle at P is linear. It is a striking observation that the Mo–P distance is not significantly different than in the terminal phosphide species. Since the P–S distance is similar to what has been found for phosphine sulfides, perhaps the best valence-bond description of the 'PS' complex is, in fact, S–P≡Mo[N(R)Ar]$_3$, with appropriate formal charges: positive on P and negative on S. An important point to take into consideration in any analysis of the bonding in the PS complex **38** relative to phosphide **32** is that in the former the phosphorus 3s orbital is necessarily utilized in the σ framework, while in the latter all indications[38] are that it does not participate in the bonding.

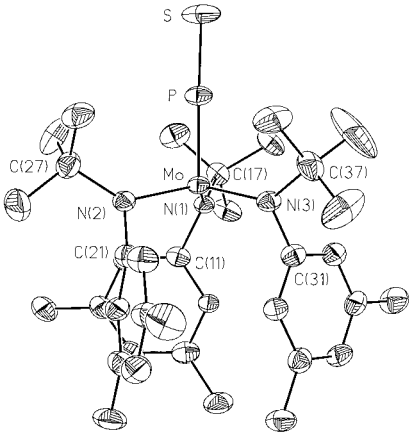

Fig. 6 Thermal ellipsoid representation of $SPMo[N(R)Ar]_3$ **38**, from an X-ray study,[42] Ellipsoids are at the 35% probability level. The P=S bond length is 1.921(3) Å, while the Mo=P bond length is 2.100(2) Å.

Although the importance of the $S{=}P{=}Mo[N(R)Ar]_3$ resonance structure for **38** has not yet been substantiated chemically, the $S{-}P{\equiv}Mo[(R)Ar]_3$ structure being favored by crystallographic data,[42] some support for the former structure comes from reactivity studies on the corresponding oxo derivative.[42] Before leaving the PS complex, however, it should be noted that formation of **38** by sequential addition of the elements phosphorus and sulfur to three-coordinate **4** represents an exceedingly satisfying and simple synthesis of a previously unknown type of cumulene.

Oxo transfer to the terminal phosphide

Underscoring the relatively unreactive nature of **32**, early attempts to synthesize the 'PO' complex, $O{=}P{=}Mo[N(R)Ar]_3$ **39** resulted in no reaction. Reagents employed unsuccessfully include pyridine- and trimethylamine-*N*-oxides and dry oxygen. The harsh and hydrocarbon-insoluble oxidant iodosylbenzene was also treated with **32**, but the reaction resulted in extensive decomposition. Dimethyldioxirane (Me_2CO_2) is a powerful, thermally unstable, hydrocarbon-soluble oxidant that is typically used as 5% solutions in acetone.[43] Treatment of phosphide **32** with the Me_2CO_2 ultimately proved a successful route to the PO complex **39**.[42]

Accordingly, treatment of a gold dichloromethane solution of **32** at −78 °C with the stoichiometric amount of Me_2CO_2 gave rise to an intense purple color [eqn. (17)].[42] It proved necessary

$$\underset{\mathbf{32}}{P{\equiv}Mo[N(R)Ar]_3} + O_2CMe_2 \longrightarrow \underset{\mathbf{39}}{O{=}P{=}Mo[N(R)Ar]_3} + OCMe_2 \qquad (17)$$

to precipitate PO **39** from the reaction mixture by addition of cold acetonitrile. Once pure, the purple, diamagnetic [$\delta(^{31}P)$ 269.8] **39** can be manipulated at 25 °C with minimal decomposition. The most common problem encountered in handling **39** is that, under a variety of conditions, phosphide **32** is regenerated from it.

X-Ray crystallography showed PO **39** to possess an essentially linear angle at P [177.6(8)°], and Mo–P and P–O distances of 2.079(5) and 1.49(2) Å, respectively.[42] Thus, like the phosphorus monosulfide complex **38**, PO **39** exhibits a shorter Mo≡P distance than phosphide **32**! This can indeed be taken as evidence that the $O{-}P{\equiv}[N(R)Ar]_3$ resonance structure is an important contributor, with appropriate formal charges. The P–O distance is essentially the same as for free phosphorus monoxide,[44] tricyclohexylphosphine oxide[45] and some μ_3-PO complexes in clusters.[46]

Some evidence lending credence to the $O{=}P{=}Mo[N(R)Ar]_3$ resonance structure for **39** is available in the form of reaction chemistry.[42] This resonance structure is reminiscent of the resonance structure, $O{=}C{=}ML_n$, invoked for metal carbonyls in describing the classic Fischer carbene synthesis.[47] Thus can be seen the analogy to organic carbonyls, and the fact that nucleophiles add to the complexed CO carbon understood. Likewise, the zirconocene reagent Cp_2ZrMe_2, which possesses nucleophilic methyl groups in conjunction with an oxophilic metal center, reacts with PO **39** with formation of a phosphorus–carbon and a zirconium–oxygen bond.[42] The product, **40**, is the result of insertion of the PO moiety into the Zr–Me bond. Compound **40** is orange–brown and diamagnetic, and structurally can be deemed analogous to $Mo(NMe_2)_4$[48] or $Mo[P(Cyclohexyl)_2]_4$.[49] The Mo–P and P–O bonds in **40** are 2.169(2) and 1.613(5) Å, such that multiple bonding between molybdenum and the trigonal-planar phosphorus center can be invoked.[42] Also, an analogy can be extended to relate compound **40**, with its Zr–O–P–Mo moiety, to 'zirconoxy carbenes' prepared by reaction of zirconocene derivatives with metal carbonyl complexes.[50]

Thus was the first complex containing a terminal PO, or phosphorus monoxide, ligand prepared and characterized.[42] Previous examples of complexes containing PO ligands have involved oxidation of bridging phosphide ligands in multimetallic clusters.[46] The PO molecule has garnered attention as a free species, due to its presence in interstellar space, and as a heavy analog of nitric oxide.[51] It will certainly be of interest to determine the extent of the chemistry of PO as a ligand in coordination chemistry, especially given the analogy with NO. Although information concerning the P–O bond strength in **39** is not yet available, preliminary results show that the complex is readily deoxygenated by triethylphosphine.

Reaction of **32** *with an aryl azide*

In some respects, the reactivity patterns of phosphide **32** are reminiscent of an electron-poor triogranophosphine. One reaction characteristic of triorganophosphines is that with organoazides to produce phosphinimines, a reaction known as the Staudinger reaction.[52] Seeking to push the analogy between **32** and PR_3 compounds, **32** was treated in ether with mesityl azide at 25 °C over a period of *ca.* 22 h [eqn. (18)].[37] The reaction

$$\underset{\mathbf{32}}{P{\equiv}Mo[N(R)Ar]_3} + N_3Mes \xrightarrow{-N_2} \underset{\mathbf{41}}{MesN{=}P{=}Mo[N(R)Ar]_3} \qquad (18)$$

afforded a diamagnetic blue–green product, which turned out to be $(MesNP)Mo[N(R)Ar]_3$ **41**, the product of a Staudinger-like addition of mesitylazide to **32** with loss of dinitrogen. The compound displays a single –N(R)Ar ligand environment according to room-temperature proton and carbon NMR spectroscopies.[37]

X-Ray crystallography showed **41** to possess an essentially linear Mo–P–N angle,[37] and confirmed the molecular connectivity. Interestingly, **41** is a unique phosphorus-monosubstituted aryldiazonium complex; the related 'iminophosphenium' cation $[PNAr^*]^+$ (Ar* = 2,4,6-$C_6H_2Bu^t_3$) is known as a discrete species, having been isolated and characterized as its tetrachloroaluminate salt.[53]

Thus was the reactivity of phosphide **32** confirmed to be related, at least to a degree, to that characteristic of triorganophosphines. It is interesting that, to date, the reactivity of terminal phosphide complexes M≡P is restricted to the addition of groups to the P terminus. No reactions have yet been identified in which the M≡P triple bond engages in cycloaddition reactions, despite the fact that such reactions are prevalent for closely related high-valent terminal phosphinidene complexes.[54] Further developments can be expected for phosphide complexes in this regard, especially if they can be generated in conjunction with a less sterically demanding ancillary ligand coordination sphere.

One-coordinate carbon multiply-bonded to molybdenum: the terminal carbide functionality

Having found that the $Mo[N(R)Ar]_3$ fragment is well suited as a platform for the construction of molybdenum–element multiple bonds, it was only natural to turn attention to some questions in the organometallic genre. A specific question of interest had to do with whether a carbide complex anion, *e.g.* $^{-}[C{\equiv}Mo\{N(R)Ar\}_3]$ **42**, isoelectronic to nitride **5**, could be accessed. Indeed, one-coordinate carbon was known previously only in, for example, carbon monoxide, isocyanides and cyanide ion. The functional group constituted by one-coordinate carbon bonded only to a single metal center was unknown.

To follow the chemistry it was deemed worthwhile to utilize a ^{13}C label for the carbon in question. This was made feasible by the observation that $Mo[N(R)Ar]_3$ **4** readily binds carbon monoxide in an irreversible fashion.[55] Thus, carbonyl $(O^{13}C)$-$Mo[N(R)Ar]_3$ **43** was obtained in 88% yield as a brown paramagnetic species [eqn. (19)].[55] Magnetic susceptibility

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} \xrightarrow{CO} \underset{\mathbf{43}}{OCMo[N(R)Ar]_3} \qquad (19)$$

measurements were consistent with assignment of carbonyl **43** as a low-spin complex of molybdenum(III), an IR band at 1797 cm^{-1} was attributed to ν_{CO} for complex **43**, and the ^2H NMR spectrum of **43** revealed a single –N(R)Ar ligand environment.[55]

Now the problem remained of turning the carbonyl oxygen into a leaving group. A strategy was adopted whereby complex **43** would be (i) reduced to its corresponding anion and (ii) treated with a suitable electrophile. In practice it was observed that treatment of **43** with an excess of sodium amalgam in THF provided the desired anion [**44**, eqn. (20)] which is diamagnetic

$$\underset{\mathbf{43}}{OCMo[N(R)Ar]_3} \xrightarrow{Na/Hg} \underset{Na[\mathbf{44}]}{Na^{+}[^{-}O{-}C{\equiv}Mo\{N(R)Ar\}_3]} \qquad (20)$$

and can be written with a molybdenum–carbon triple bond as in $^{-}[O{-}C{\equiv}Mo\{N(R)Ar\}_3]$. The hope was that anion **44** would behave as a nucleophile in a manner analogous to an alkoxide ion. Although **44** could be isolated as its sodium salt, it was simply generated *in situ* for treatment with electrophiles. Pivalyl chloride was identifed as a suitable electrophile and, accordingly, the neutral diamagnetic 'carbido pivalate' complex $Bu^tC(O)O{-}^{13}C{\equiv}Mo[N(R)Ar]_3$ **45**, was obtained in 82% yield as a beige solid, and was fully characterized [eqn. (21)].[55]

$$\underset{Na[\mathbf{44}]}{Na^{+}[^{-}O{-}C{\equiv}Mo\{N(R)Ar\}_3]} + Bu^tC(O)Cl \xrightarrow{-NaCl} \underset{\mathbf{45}}{Bu^tC(O)O{-}C{\equiv}Mo[N(R)Ar]_3} \qquad (21)$$

But for the great stability of the $-C{\equiv}Mo[N(R)Ar]_3$ core under reductive conditions, the synthesis might have reached a dead end with compound **45**. It was hoped that the pivalate moiety would be removed under reductive conditions, with the desired carbide anion $^{-}[C{\equiv}Mo\{N(R)Ar\}_3]$ **42** perhaps to be obtained directly. Although the situation did not prove to be so simple, it was indeed the case that reductive conditions resulted in removal of the $-O_2CBu^t$ group, albeit less than quantitatively. Subjection of **45** to an excess of solid sodium mirror in THF led [eqn. (22)], according to ^{13}C NMR monitoring, to production of

$$\underset{\mathbf{45}}{Bu^tC(O)O{-}C{\equiv}Mo[N(R)Ar]_3} \xrightarrow{i\ Na^0,\ ii\ MeCN} \underset{\mathbf{46}}{HC{\equiv}Mo[N(R)Ar]_3} \qquad (22)$$

a mixture containing the desired 'sodium carbide' (Na[**42**], identified tentatively as several peaks in the vicinity of δ 500), methylidyne $HC{\equiv}Mo[N(R)Ar]_3$ **46**, and the carbonyl anion **44**. Given the complexity of the mixture, it was opted to attempt protonation of **42** to methylidyne **46**, and to attempt separation of the latter from the salt of **44**. Fortunately, addition of the crude mixture to acetonitrile was found to effect the desired transformation. Being relatively insoluble in acetonitrile, methylidyne **46** was easily separated from the soluble salt of **44**. The isolated yield of **46** was 53%, based on the neutral carbonyl precursor **43**.[55] Methylidyne **46** has a characteristic ^{13}C NMR peak at δ 287, accompanied by a J_{CH} of 157 Hz. A recent single-crystal X-ray diffraction study shows **46** to be a pseudo-threefold symmetric species with an Mo≡C triple bond distance of 1.699(5) Å.

Now the task at hand was to deprotonate **46** and to isolate **42** as a salt with a large cation, this in order to sequester a version of **42** having one-coordinate carbon. Given the interpretation that the preceding chemistry had relied upon deprotonation of acetonitrile by **42**, it was evident that a strong base would be required for deprotonation of methylidyne **46**. Benzylpotassium[56] was chosen, as it can conveniently be weighed out as a solid and because potassium, being a heavier alkali metal, should exhibit a decreased tendency to coordinate to a carbanion (compared with Li or Na), especially if complexed with a suitable crown ether or cryptand complement. Reaction in THF of methylidyne **46** with K(benzyl) led, as desired [eqn. (23)], to production of the potassium salt of carbide **42**, isolated

$$\underset{\mathbf{46}}{HC{\equiv}Mo[N(R)Ar]_3} + K(benzyl) \xrightarrow{-toluene} \underset{K[\mathbf{42}]}{K^{+}[^{-}C{\equiv}Mo\{N(R)Ar\}_3]} \qquad (23)$$

in 69% yield as a solvent-free dimer (X-ray, Fig. 7). In C_6D_6, where K[**42**] presumably retains its dimeric structure, a single sharp ^{13}C signal is observed for the carbide carbon at δ 494.5. A closer look (X-ray) at the structure of dimeric K[**42**] reveals a central K_2C_2 square, with the coordination at K complemented by π complexation of two –N(R)Ar aryl groups per potassium. The structure thus incorporates encapsulation of the potassium cations by lipophilic residues, accounting for the observed good solubility of the compound in C_6D_6, and also for the lack of retention of THF.

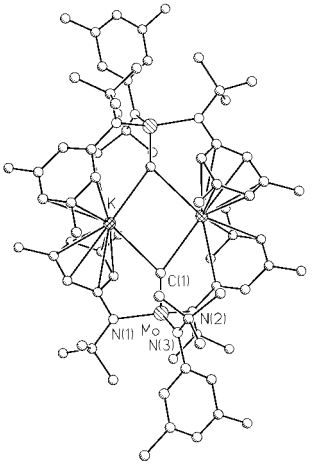

Fig. 7 Ball and stick representation of dimeric potassium carbide $K_2[\mathbf{42}]_2$, from an X-ray study.[55] A crystallographic center of inversion is located at the center of the dimer. The C(1)≡Mo distance is 1.68(3) Å, while the K···C distance is 2.94(2) Å.

Encapsulation of the potassium was achieved in two ways;[55] addition of cryptofix-2,2,2 to a solution of K[**42**] gave [K(2,2,2-crypt)][**42**] [eqn. (24)], whereas when K[**42**] was

$$\underset{K[\mathbf{42}]}{K^{+}[^{-}C{\equiv}Mo\{N(R)Ar\}_3]} \xrightarrow{2,2,2\text{-crypt}} \underset{[K(2,2,2\text{-crypt})][\mathbf{42}]}{[K(2,2,2\text{-crypt})^{+}][^{-}C{\equiv}Mo\{N(R)Ar\}_3]} \qquad (24)$$

treated with 2 equiv. of benzo-15-crown-5, the salt [K(benzo-15-crown-5)$_2$][**42**] was produced [eqn. (25)]. Both salts exhi-

$K^+[^-C{\equiv}Mo\{N(R)Ar\}_3]$ K[**42**] —benzo-15-crown-5→ $[K(benzo\text{-}15\text{-}crown\text{-}5)_2^+][^-C{\equiv}Mo\{N(R)Ar\}_3]$ (25)
$[K(benzo\text{-}15\text{-}crown\text{-}5)_2]$[**42**]

bited low benzene solubility, in contrast to the dimeric precursor K[**42**], suggesting that the new salts consisted of discrete anions and cations. Remarked upon initially as a curious observation was the fact that the carbide ^{13}C signal (THF) for the new salts was rather broad.[55] Thanks in part to a suggestion from Professor Klaus H. Theopold, it has been determined that proton exchange between methylidyne **46** and its conjugate base takes place on the NMR timescale, with rate parameters such that a small percentage of **46** is sufficient to broaden substantially the carbide ^{13}C signal. For [K(2,2,2-crypt)][**42**], the ^{13}C signal in question was reported as δ 482.8, but this parameter is sensitive, of course, to the presence of small quantities of **46**. It is now known that addition of K(benzyl) to a THF solution of [K(2,2,2-crypt)][**42**] results in dramatic sharpening of the carbide ^{13}C signal, presumably due to removal of trace quantities of methylidyne **46**.

X-Ray crystallographic confirmation of the presence of Mo-bound one-coordinate carbon was obtained with the structure of $[K(benzo\text{-}15\text{-}c\text{-}5)_2]$[**42**], which exhibits discrete and separate cations and anions (Fig. 8).[55] An interesting metrical parameter is the Mo≡C distance to the carbido carbon, 1.713(9) Å, which is not significantly different from the corresponding value found for methylidyne **46**. Also noteworthy is the fact that anion **42** displays conformational features very similar to those (described above) for the isoelectronic nitride **5**.[9]

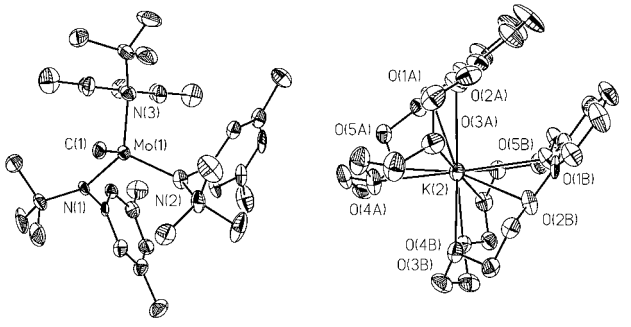

Fig. 8 Thermal ellipsoid representation of carbide salt $[K(benzo\text{-}15\text{-}crown\text{-}5)_2]$[**42**], from an X-ray study.[55] The Mo≡C distance is 1.713(9) Å.

Thus was established one-coordinate carbon as a viable functional group in organometallic chemistry.[55] It is interesting to reflect on the circuitous nature of the compound's synthesis, the carbide carbon arising from carbon monoxide.[57] Much remains to be elucidated with regard to terminal carbide reactivity, and with respect to the issue of synthesis of neutral or even cationic variants. In the present case, anion **42** displays a marked downfield shift for its carbido carbon nucleus, a circumstance likely arising from a large ^{13}C chemical shift anisotropy.[38] More detailed studies should shed light on this interesting finding, in conjunction with information on the M≡C bonding in this unusual species.

Terminal oxo, sulfide, selenide and telluride complexes

In the preceding sections we have seen that $Mo[N(R)Ar]_3$ **4** offers ready synthetic inroads to triple bonds involving Mo and C,[55] N[9] or P.[37] Also, several complexes of the sort Y=X=Mo[N-(R)Ar]$_3$ were described (*e.g.* YX = OP **39**,[42] SP **38**,[42] MesNP **41**[37] and ON **11**[8]) which all are linear cylindrically symmetric 8π systems analogous to CO_2 or N_2O, and thus anticipated to be rather stable. Thus, the triple bonds and the 8π systems can be regarded as the 'sinks' in the chemistry of $Mo[N(R)Ar]_3$ **4**. Especially intriguing in this regard is the observation that the reaction of **4** with N_2O led to exclusive N–N bond cleavage, rather than to formation of the putative oxo species, O=Mo[N-(R)Ar]$_3$ **12**.[8] The latter result runs completely counter to the known chemistry of nitrous oxide, a molecule that prefers to act as an oxo source with liberation of N_2.[18] Our interest piqued by these observations, we set out to prepare oxo **12** by an alternate route. When this endeavor was successful, a further course of action was undertaken involving synthesis of the heavier congeners of **12**, namely E=Mo[N(R)Ar]$_3$ (E = S **47**, Se **48** and Te **49**).[58]

The synthesis of the paramagnetic, chocolate-brown oxo-molybdenum(v) complex **12** proved to be straightforward, involving addition of pyridine-*N*-oxide to an ethereal solution of **4**.[20] Such a procedure [eqn. (26)] led to isolation of **12** in 72%

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} + O{\leftarrow}NC_5H_5 \xrightarrow{\text{–pyridine}} \underset{\mathbf{12}}{O{=}Mo[N(R)Ar]_3} \qquad (26)$$

yield. Characterization of **12** included EPR spectroscopy, magnetic susceptibility measurements, ^2H NMR spectroscopy, and X-ray crystallography.[20]

The structure of monomeric **12** is significant in being of low symmetry relative to its threefold symmetric relatives, of which nitride **5** is representative.[9] The low symmetry of **12** arises from three disparate O–Mo–N–C_{tert} dihedral angles: 40, 3 and 62°;[20] a typical value for threefold symmetric analogues being 35°. Electronic structure arguments indicate that the low symmetry of **12** (and its heavier congeners, described below) is a consequence of the d^1 electron configuration. The unpaired electron resides, according to calculations, in an orbital that has π* character with respect to the Mo=O multiple bond. Since there are two such orbitals, but only one electron to populate them, the complex is subject to a Jahn–Teller distortion involving the disposition of the –N(R)Ar ligands. The latter adopt an orientation that minimizes repulsive interactions between the unpaired electron and the Mo–N π bonds. The heavier chalcogenide complexes **47**, **48** and **49**, which have less ionic character to their Mo=E bonds than in the case of oxo complex **12**, likewise exhibit low-symmetry structures, but these are C_s as opposed to the case for **12**, which in the solid state has C_1 symmetry. Despite the low symmetry of all the E=Mo[N(R)Ar]$_3$ complexes, in solution they are fluxional as judged by their ^2H NMR spectra, which show but a single signal at 25 °C.[20]

Whereas the oxo compound **12** was not amenable to preparation by the direct reaction of $Mo[N(R)Ar]_3$ **4** with dioxygen, the heavier chalcogenide derivatives all could be prepared by interaction of **4** with the respective elemental chalcogen.[20] Thus, S=Mo[N(R)Ar]$_3$ **47** was obtained in 63% yield subsequent to treatment of **4** with S_8 [eqn. (27)]. Reaction

$$\underset{\mathbf{4}}{Mo[N(R)Ar]_3} + \underset{E = S, Se \text{ or } Te/PEt_3}{1/n\ E_n} \longrightarrow \underset{E = S\ \mathbf{47},\ Se\ \mathbf{48},\ Te\ \mathbf{49}}{E{=}Mo[N(R)Ar]_3} \qquad (27)$$

of **4** with elemental selenium gave Se=Mo[N(R)Ar]$_3$ **48** in 80% yield after 11 h in ether at 25 °C. Elemental tellurium reacted only sluggishly with **4**, such that catalytic PEt_3 was employed, to catalyze the reaction *via* the phosphine telluride. The result was the isolation in 73% yield of Te=Mo[N(R)Ar]$_3$ **49**, as a dark brown solid. Characterization of the molybdenum(v) chalogenide complexes by EPR spectroscopy provided increasingly well resolved rhombic spectra on going from E = O to E = Te. Density functional calculations indicated that the covalent character of the Mo=E bond increased as O ≪ S < Se < Te. The Mo=E bond lengths, as determined by X-ray crystallography are E = O, 1.706(2); S, 2.1677(12); Se, 2.3115(6) and Te, 2.5353(6) Å (see Fig. 9 for a representative drawing of telluride **49**).[20]

A very telling set of experiments involved thermochemical measurements made on reactions that lead to oxo **12** and sulfide **47**.[20] For instance, the heat of reaction of **4** with pyridine-*N*-oxide was measured, permitting estimation of the bond dissociation enthalpy D(MoO) as 155.6 ± 1.6 kcal mol^{-1}. This

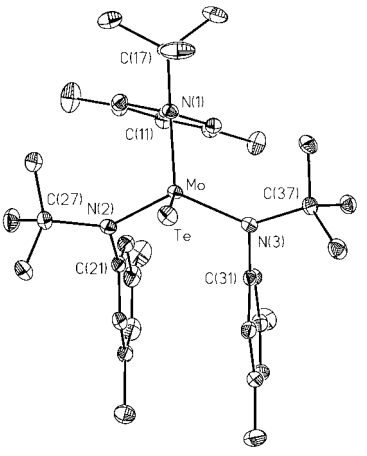

Fig. 9 35% probability level thermal ellipsoid representation of terminal telluride **49**, from an X-ray study.[20] The Te=Mo bond length is 2.5353(6) Å. Reproduced with permission from *J. Am. Chem. Soc.*

measurement indicates that **12** possesses one of the strongest metal–oxo bonds known,[59] and carries the corollary that the result of N_2O reaction with **4** is not a consequence of any thermodynamic bias.[19] Although there is a paucity of data for terminal metal–sulfur bond strengths in the literature, a D(MoS) of 104.4 ± 1.2 kcal mol^{-1} was obtained for **47** from measurement of the heat of reaction of ethylene sulfide with **4**.[20] The latter is an alternative method for preparing **47**, an example of thiirane desulfurization.[60] Although experimental data are not available for the selenide– and telluride–molybdenum bond dissociation enthalpies, density functional theoretical methods predict values of 91 and 71 kcal mol^{-1}, respectively, for **48** and **49**.[20]

Molecular orbital calculations performed for sulfide **47**, as for the other chalcogenide complexes, indicate the SOMO (singly occupied molecular orbital) to be largely Mo–E π* in character. The SOMO is high-lying relative to the highest-lying doubly occupied level, additionally, such that the complexes should be regarded as one-electron reductants.[20] This behavior is manifested both in terms of intermolecular and intramolecular redox chemistry. An example of the former is the ferrocenium triflate or iodine oxidation of **12** to provide salts of the $[O{\equiv}Mo\{N(R)Ar\}_3]^+$ cation. Chalcogenide complexes **12**, **47**, **48** and **49** are all thermally sensitive, with Bu^t radical elimination from the –N(R)Ar ligands occurring at elevated temperatures. Thermolysis (60–80 °C, 5–25 h) of the Mo=E complexes accordingly led to first-order decay, with the products being a new series of diamagnetic molybdenum(VI) chalcogenide complexes, E=Mo(=NAr)[N(R)Ar]$_2$ (E = O **50**, S **51**, Se **52**, Te **53**). The thermal instability of **12** and its heavier molybdenum(V) congeners contrasts sharply with the thermally robust nature of nitride **5**[9] and phosphide **32**.[37] such that although the chalcogenide complexes[20] are isolable and could be characterized, they do not represent 'sinks' in the chemistry of Mo[N(R)Ar]$_3$ **4**.

Concluding remarks

The isolation and characterization of three-coordinate molybdenum(III) complexes has been facilitated by the use of bulky *N-tert*-butylanilide ancillary ligands. The remarkable new complexes, embodied by Mo[N(R)Ar]$_3$ **4**, display a wealth of dramatic new reaction chemistries, and thereby have opened up new areas of inquiry in transition metal chemistry. Accordingly, dinitrogen cleavage to molecular molybdenum nitride **5** has been realized under mild and mechanistically well defined conditions.[9] The same nitride forms in equimolar amounts with nitrosyl **11**, in a highly unusual example of nitrous oxide N–N bond cleavage by **4**.[8] New vistas have opened for intermetal N-atom transfer reactivity; N-atom bridged intermediates have been characterized,[10] and the atom transfer reaction has been coupled with N_2 cleavage and metal–metal bond formation.[30] White phosphorus, with its tetrahedral P_4 molecules, has been harnessed to provide examples of terminal phosphide species,[37] the phosphorus analog of nitride **5**.[9] The sinks in the system have been identified as featuring Mo–element triple bonds or three-membered 8π-electron cumulenes, with Mo[(R)Ar]$_3$ comprising a terminus. These observations have permitted the chemistry to be extended to encompass the terminal carbide functionality (one-coordinate carbon bonded to a single metal),[55] and a molybdenum complex of phosphorus monoxide.[42]

As the reactivity patterns for **4** become more well established, it will be of interest to probe the detailed effects of ligand-induced steric requirements in the system, and to search for routes to related three-coordinate compounds based on other metals, including tungsten. Because Mo[N(R)Ar]$_3$ **4** can be prepared in multigram quantities, and can be prepared inexpensively for synthetic applications without deuterium-enrichment in the –N(R)Ar ligand,[61] it may be expected that the compound will find manifold applications in synthetic chemistry. At the very least, the reaction pathways uncovered in the context of studying **4** and related compounds can serve as a starting point for the mechanism-based design of new reagents or catalyst systems.

Finally, the characterization of Mo[N(R)Ar]$_3$ **4**[8] and the initial elucidation[23] and documentation[9] of its reaction chemistry[37] serve as a striking reminder of the riches that surely do remain to be mined within the realm of exploratory synthetic inorganic chemistry.

Acknowledgments

I am indebted to the coworkers from my group whose names appear in the list of references. The hard work, enthusiasm, and skillful laboratory technique of these individuals has brought to fruition the chemistry reported on in this article. I am grateful to Professors Richard R. Schrock and Peter T. Wolczanski for helpful discussions, and for inspiration to study the chemistry of three-coordinate transition-metal complexes. For financial support I gratefully acknowledge the National Science Foundation (CAREER Award CHE-9501992), the Alfred P. Sloan Foundation, the Packard Foundation, 3M, DuPont, Union Carbide, and Monsanto.

Christopher C. Cummins was educated at Cornell University where he carried out research under the direction of Professor Peter T. Wolczanski and received his A.B. degree in 1989. His PhD work, carried out at the Massachusetts Institute of Technology under the direction of Professor Richard R. Schrock, was in the areas of block copolymer synthesis and coordination chemistry with triamidoamine ligands. In 1993 he graduated from M.I.T. and accepted an Assistant Professorship at the same institution. His research has focused on inorganic radical chemistry, the activation by three-coordinate transition metal complexes of small molecules including dinitrogen and the nitrogen oxides, and the development of new synthetic methods for inorganic chemistry. In 1996 he was promoted to the rank of Professor. In 1997 Dr Cummins received the Phi Lambda Upsilon Fresenius Award, and in 1998 he received the Award in Pure Chemistry from the American Chemical Society and the Alan T. Waterman Award from the National Science Foundation.

Synthesis and characterization of the nine-atom, rhena- and tungsta-boranes $(Cp^*Re)_2B_7H_7$ and $(Cp^*W)_2B_7H_9$, $Cp^* = \eta^5\text{-}C_5Me_5$. Molecular mimics of hypoelectronic main-group clusters in Zintl phases

Andrew S. Weller, Mayou Shang and Thomas P. Fehlner*

E-mail: Fehlner.1@nd.edu

Geometric and molecular orbital analyses of the metallaboranes $(Cp^*Re)_2B_7H_7$ and $(Cp^*W)_2B_7H_9$, which display unusual, but identical, core structures and skeletal electron pair counts of $n - 2$, demonstrate a close connection between these molecular compounds and anionic, hypoelectronic main-group clusters found in the solid state.

The chemistry of metallaborane complexes is dominated by two-valence electron fragments of Group 8 and Group 9 metals[1–3] such as $\{Fe(CO)_3\}$ or $\{CoCp\}$, $Cp = \eta^5\text{-}C_5H_5$, in which the metal fragment replaces a boron vertex in the resulting metallaborane.[4] The fact that transition-metal halides, $[Cp^*MCl_n]_m$, $Cp^* = \eta^5\text{-}C_5Me_5$, react with monoboron reagents to yield metallaboranes[5] permits the synthesis of compounds containing earlier transition metals (M = Ta,[6] Cr,[7] Mo[8] and W[9,10]). We anticipated that the lower number of valence electrons and higher frontier orbital energies of such fragments would lead to unusual behavior. Indeed, in small clusters the metal center introduces unsaturation on the bonding network supported, in part, by the relatively higher energy metal functions.[6–8] Alternatively, when more boron atoms are available, highly capped structures result.[9] Moving to Group 7 transition metals[11,12] we now report the synthesis of the first example of a dirhenaborane, which displays an unprecedented nine-atom molecular structure. For support, the nearly isostructural and isoelectronic tungsten analog is also described.

Addition of BH_3·thf to Cp^*ReCl_4[13] at room temperature and subsequent gentle heating affords the pale yellow rhenaborane $(Cp^*Re)_2B_7H_7$ **1** in good yield after chromatographic workup.† Its red, isostructural and isoelectronic partner, $(Cp^*W)_2B_7H_9$ **2** is formed as a minor product during the pyrolysis of $Cp^*WH_3B_4H_8$ in toluene.‡[9] Both compounds **1** and **2** have been fully characterized by single-crystal X-ray diffraction,[11]B and ^{1}H NMR spectroscopy and high-resolution mass spectrometry. The ^{11}B NMR spectra of **1** and **2** display four signals in the ratio 1 : 2 : 2 : 2, distributed over an unusually large[14] chemical shift range of ≈ 100 ppm. In addition to signals due to Cp* and BH_t groups, the ^{1}H NMR spectrum of **2** displays a broad integral two resonance at δ −8.9 in the region associated with μ or μ_3 B–H–M groups while for **1** the high-field region is featureless.

The solid-state molecular structures of compounds **1** and **2** are shown in Fig. 1.§ Both feature similar structural cores, although the structural motif is not one anticipated for a nine-atom cluster *e.g.* tricapped trigonal prism. Compound **1** has effective C_{2v} symmetry, while the presence of the two μ_3 B–H–W hydrogen atoms affords **2** with approximate C_2 symmetry. The metal–metal distances of 2.7875(6) in **1** and 2.9522(8) Å in **2**, both fall in the range associated with their respective M–M single bonds.[15] The seven skeletal electron pairs (sep) associated with **1** and **2** are three less than expected for a normal nine-vertex *closo* cluster.[16] Hence, we have explored the geometric and electronic factors responsible.

Fenske–Hall calculations[17,18] on the Cp analogs of **1** and **2** show a large HOMO–LUMO gap for both compounds consistent with the observed stability and electron count. The respective HOMOs are metal–metal bonding and their unfilled antibonding partners are found to higher energy. Further confirmation of a metal–metal bond is provided by Mulliken overlap populations of 0.12 and 0.13 for **1** and **2**, respectively. Corbett has described examples of hypoelectronic main-group clusters in Zintl phases[19] with accompanying non-standard deltahedral structures. Distortion of the standard deltahedron for a given *closo n*-atom skeleton to that observed leads to a reduced number of low-energy cluster bonding orbitals thereby supporting the low sep count found. In a similar spirit, we note that the observed geometry of **1** (and **2**) may be generated by a 45° rotation of one of the square pyramidal faces of a tricapped trigonal prism around its C_2 axis thereby converting the four

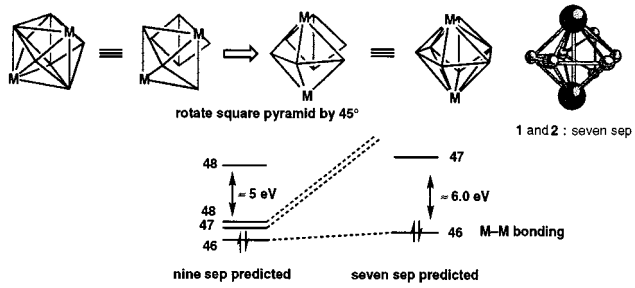

Scheme 1

five-connect vertices of the square base into two four- and two six-connect vertices (Scheme 1). Inclusion of a metal–metal bond generates the observed structure. We have successfully modeled this distortion for **1**. On moving from a hypothetical neutral Re_2B_7 tricapped trigonal prism with a Re–Re bond to the observed structure, two low lying orbitals move to higher energy, thereby accounting for the observed sep count of $n - 2$. Alternatively, the observed structure can be rationalized by inserting a {BH} fragment into a B–B bond of a hypothetical dodecahedral $Cp^*_2Re_2B_6H_6$ cluster. Note that the observed geometry accommodates the electropositive metal centers in high connectivity cluster vertices as well as the propensity for both rhenium and tungsten to form metal–metal bonds.

Compounds **1** and **2** can thus be described as molecular metallaborane counterparts of hypoelectronic main-group cluster Zintl phases. Of course, they possess different properties being neutral (no cations or high cluster charges), molecular (soluble in aliphatic solvents) and modestly air-stable. Full details as well as related chemistry will appear in due course.

The generous support of the National Science Foundation is gratefully acknowledged.

Stereoretentive introduction of (*E*)- and (*Z*)-γ-alkoxyallyl groups into carbonyl compounds *via* light-promoted reaction with γ-alkoxyallylstannanes

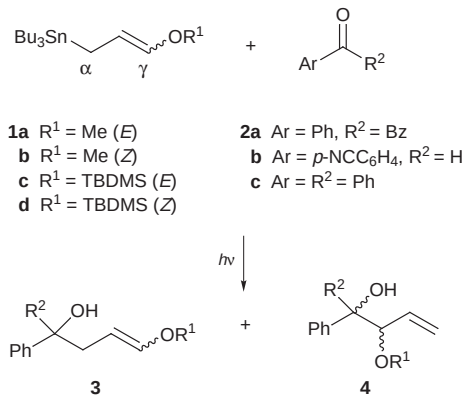
Akio Takuwa,*† Yutaka Nishigaichi, Seiji Ebara and Hidetoshi Iwamoto

Department of Material Science, Faculty of Science and Engineering, Shimane University, Matsue, 690-8504, Japan

The light-promoted condensation between carbonyl compounds and (*E*)- or (*Z*)-γ-alkoxyallylstannanes affords predominantly the linear homoallylic alcohols, with retention of the double bond geometry of the γ-alkoxyallyl moieties.

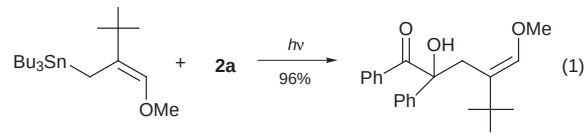
It is well-known that both (*E*)- and (*Z*)-γ-methoxyallylstannanes add to aldehydes at the γ-position in the presence of BF_3•OEt_2 to produce the vicinal diol monomethyl ether (γ-product).[1] The α-ethoxyallylstannane also afforded the γ-product *via* a double allylic shift (one at the reagent level and the second in the addition reaction).[2] In addition, Thomas,[3] Marshall[4] and Gung[5] have reported that α-alkoxy or α-silyloxy substituted crotylstannanes also reacted at the γ-position with aldehydes or ketones under both thermal and Lewis acid-promoted conditions to afford the homoallyl alcohols having an alkoxy or silyloxy group at the terminus of the allylic carbon (*i.e.* vinyl ethers) and that the geometry of the vinyl ether unit in the products is generally *Z* or an *E*/*Z* mixture depending on the reaction conditions and on the substrates. Thus, the stereoretentive introduction of (*E*)- and (*Z*)-γ-alkoxyallyl groups at the α-position of carbonyl compounds has yet to be developed. We[6] and Fukuzumi[7] have found recently that the light-promoted reaction between Group 14 organometallic compounds and electron accepting carbonyl compounds is one of the most useful methodologies for selective carbon–carbon bond forming reactions. In connection with our interest in the light-promoted reaction of allylstannane, we studied the photoallylation of carbonyl compounds with γ-methoxy- and γ-siloxy-allylstannanes. Reported here is the first example of the regioreversed and stereoretentive introduction of (*E*)- and (*Z*)-γ-alkoxyallyl groups *via* light-promoted reaction (Scheme 1).

Irradiation ($h\nu$ > 400 nm) of an MeCN solution containing (*E*)-γ-(methoxyallyl)tributylstannane [(*E*)-**1a**, 24 mmol dm^{-3}] and benzil (**2a**, 20 mmol dm^{-3}) for 2 h at 0 °C gave two addition products. These were identified as the desired α-product (*E*)-**3a** (74%) and the regioisomeric γ-product **4a** (18%) (Table 1, entry 1). Irradiation of the diketone **2a** with the geometrically isomeric tin reagent (*Z*)-**1a** under the same conditions afforded



Scheme 1

the α-product (*Z*)-**3a** (66%) and the regioisomer **4a** (23%) (entry 2). The *E*/*Z* olefin geometry of α-product **3a** could be deduced from the 12.7 and 6.3 Hz coupling constants of the vicinal vinyl protons in the ^{1}H NMR spectrum.‡ Double allylation of the two carbonyl groups in the diketone **2a** did not occurred even under prolonged irradiation. The photoallylation also proceeded even in less polar solvents such as benzene and hexane, but slightly less efficiently. (*E*)- and (*Z*)-γ-[(*tert*-Butyldimethylsiloxy)allyl]tributylstannanes [(*E*)- and (*Z*)-**1b**] also reacted photochemically with **2a** to give again the desired α-products predominantly, with complete retention of the double bond geometry of the allylic moiety of the tin reagent **1b** in both cases (entries 3 and 4). When the γ-methoxyallylstannane had a bulky *tert*-butyl group at the β-position (**1c**), it showed complete α-regioselectivity [eqn. (1)]. Thus, the α-regioselectivity depended upon the steric crowding around the γ-position of the allylic stannanes.



(1)

The photoallylation of *p*-cyanobenzaldehyde **2b** with γ-alkoxyallylstannanes was also examined. Irradiation of the absorption band of aldehyde **2b** in MeCN containing (*E*)- or (*Z*)-**1a** with light of wavelength longer than 320 nm for 5 h at 0 °C gave two regioisomeric homoallylic alcohols in which the γ-methoxyallyl group was again introduced preferentially at the α-position (entries 5 and 7). Similar but higher α-regioselectivity was observed in the photoallyltion with the siloxyallyltin reagents (*E*)- and (*Z*)-**1b**. However, the γ-alkoxyallylic groups in both the tin reagents **1a**,**b** were

Table 1 Light-promoted condensation of (*E*)- and (*Z*)-γ-alkoxyallyltributylstannanes with carbonyl compounds

Entry	1	2	*T*/°C	Products (% yield; *E*:*Z*)[a,b]
1	(*E*)-**1a**	**2a**	0	**3a** (74; 98:2), **4a** (18)
2	(*Z*)-**1a**	**2a**	0	**3a** (66; 2:98), **4a** (21)
3	(*E*)-**1b**	**2a**	0	**3b** (78; 99:1), **4b** (9)
4	(*Z*)-**1b**	**2a**	0	**3b** (74; 1:99), **4b** (14)
5	(*E*)-**1a**	**2b**	0	**3c** (36; 91:9), **4c** (14)
6	(*E*)-**1a**	**2b**	−78	**3c** (37; 96:4), **4c** (13)
7	(*Z*)-**1a**	**2b**	0	**3c** (32; 14:86), **4c** (17)
8	(*Z*)-**1a**	**2b**	−78	**3c** (42; 8:92), **4c** (21)
9	(*E*)-**1b**	**2b**	0	**3d** (39; 88:12), **4d** (8)
10	(*E*)-**1b**	**2b**	−78	**3d** (37; 92:8), **4d** (6)
11	(*Z*)-**1b**	**2b**	0	**3d** (36; 13:87), **4d** (12)
12	(*Z*)-**1b**	**2b**	−78	**3d** (47; 8:92), **4d** (15)
13	(*E*)-**1a**	**2c**	−78	**3e** (52; 96:4), **4e** (15)
14	(*Z*)-**1a**	**2c**	−78	**3e** (46; 9:91), **4e** (19)

[a] *E*:*Z* ratios were determined by ^{1}H NMR analysis of the crude mixture. [b] The γ-products consisted of a 1:1 mixture of *syn* and *anti* diastereomers.

introduced with partial loss of the geometry of the allylic double bond. On the other hand, when the irradiation was carried out at −78 °C in propionitrile, the geometry of the γ-alkoxyallylic group of the tin reagents **1a**,**b** was almost completely maintained in the α-products (entries 6 and 8). Benzophenone **2c** could also be allylated with (*E*)- and (*Z*)-**1a** to give preferentially the α-product with retention of the geometry of the γ-methoxyallyl moiety (entries 13 and 14).

The present allylation is initiated by an electron transfer from the tin reagent **1** to the photoexcited carbonyl compound **2** to give the γ-alkoxyallyltributyltin radical cation (**1**$^{\bullet+}$)-ketyl radical anion pair (**2**$^{\bullet-}$), followed by the dissociation of the (γ-alkoxyallyl) C–Sn bond of **1**$^{\bullet+}$ into a γ-alkoxyallyl radical and a tributyltin cation.[6,7] The resulting γ-alkoxyallyl radical couples with **2**$^{\bullet-}$ preferentially at the less crowded α-position to yield the linear homoallylic alcohol. The configuration of the γ-alkoxyallyl unit is maintained without *E*/*Z*-isomerization during all these processes to give the α-product stereospecifically.

When the $BuSnCl_3$-mediated transmetallation method[8] was employed for the reaction of the tin reagents (*E*)- and (*Z*)-**1a** with aldehyde **2b**, the α-product **3a** was also produced from both the tin reagents, but the olefin geometry of the product **3a** was *Z* regardless of the geometry of the starting tin reagents.§ In addition, it has been reported that alkoxyallyl carbanion reagents (ROCH=CHCH$_2$M: R = alkyl or $SiMe_3$; M = Li) react with electrophiles including carbonyl compounds to afford (*Z*)-linear vinyl ethers.[9]

In conclusion, we have found that the present light-promoted reaction provides the first example of a stereoretentive introduction of (*E*)- and (*Z*)-γ-alkoxyallyl groups from γ-alkoxyallylstannanes into carbonyl compounds at the α-position.

‡ After irradiation, the products were separated into individual regioisomers (**3a** and **4a**) by TLC (SiO_2, hexane–Et_2O, 1:1, v/v). Each geometrical isomer could be purified by carefully repeating the TLC separation (hexane–CH_2Cl_2, 1:2, v/v). *Selected data* for α-product (*E*)-**3a**: oil; δ_H($CDCl_3$, 270 MHz) 2.7 (dd, *J* 7.7, 15.2, 1H), 3.0 (dd, *J* 7.7, 13.2, 1H), 3.4 (s, 3H), 4.1 (s, 1H), 4.4 (ddd, *J* 12.7, 13.2, 15.2, 1H), 6.2 (d, *J* 12.7, 1H), 7.2–7.8 (m, 10H); ν_{max}($CHCl_3$)/cm^{-1} 3534 (OH), 1679 (C=O). For α-product (*Z*)-**3a**: oil; δ_H($CDCl_3$, 270 MHz) 2.9 (dd, *J* 7.0, 14.4, 1H), 3.2 (dd, *J* 7.0, 15.4, 1H), 3.4 (s, 3H), 4.4 (ddd, *J* 6.3, 14.4, 15.4, 1H), 4.5 (s, 1H), 6.0 (d, *J* 6.3, 1H), 7.2–7.8 (m, 10H); ν_{max}($CHCl_3$)/cm^{-1} 3542 (OH), 1673 (C=O). All other compounds gave satisfactory spectral data. The γ-product **4a** consisted of a 1:1 mixture of *syn* and *anti* diastereomers, which supports the proposed reaction mechanism showing the products being formed by the combination of allylic and ketyl radicals.

§ To a solution of the tin reagent (*E*)- or (*Z*)-**1a** (0.3 mmol) in CH_2Cl_2 (6 ml) under N_2 at −78 °C was added $BuSnCl_3$ (0.3 mmol) in CH_2Cl_2 (3 ml). After stirring the mixture at that temperature for 10 min, the substrate **2b** (0.2 mmol) was added slowly and the resulting mixture was stirred for 2 h at that temperature. The reaction mixture was quenched with a 10% aq. KF and worked up as usual. The (*Z*)-α-product was obtained in 19 and 71% yield, respectively, along with a very small amount of γ-product [(*Z*)-**3a**:**4a** = 91:9 from (*E*)-**1a**; 99:1 from (*Z*)-**1a**].

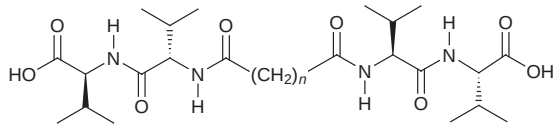
Intralayer hydrogen-bond-directed self-assembly of nano-fibers from dicarboxylic valylvaline bolaamphiphiles

Masaki Kogiso,*† Takeshi Hanada, Kiyoshi Yase and Toshimi Shimizu

National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki, 305-8565, Japan

Dicarboxylic L-valyl-L-valine bolaamphiphiles produced nanoscale fibers with widths of 10–30 nm, *via* proton-triggered self-assembly in water, which are dominated by both intralayer, lateral hydrogen-bond networks between end carboxylic acid groups and parallel β-sheet networks between amide groups.

Carboxylic amphiphiles form a variety of self-assemblies such as micelles, vesicles, fibers, and crystals in water. The formation behavior strongly depends upon hydration states, salt concentrations, and pH conditions in aqueous dispersions.[1,2] In particular, the end carboxy groups exist as carboxylate anions (soap), acid–soaps, acids, or a mixture of these. To date it is still uncertain whether inter- or intra-layer carboxy interactions enforce the crystalline order and whether they dominate supramolecular structures or not.[3] A large number of crystal structures have been reported for fatty acids that form an acid-acid cyclic dimer,[3,4] whereas only one crystallization was achieved for potassium palmitate soap.[3,5] This indicates that no specific interlayer interactions are dominant in the soaps. We have recently demonstrated the formation of rod-like micelles, supramolecular microtubes,[6] and needle-shaped crystals[7] in water from dicarboxylic glycylglycine bolaamphiphiles. In addition to hydrophobic interactions between the alkylene spacers, the predominant forces driving these self-assemblies involve anion-anion, intralayer acid-anion, and interlayer acid-acid interactions, respectively.[8] Here we describe proton-triggered nano-fiber formation from valylvaline bolaamphiphiles **1–3**, which is dominated by intralayer acid-acid and amide hydrogen-bond networks. Furthermore, the separate contributions of the inter- and intra-layer interactions on the supramolecular structures was evaluated using FT-IR analysis.



1 $n = 6$
2 $n = 8$
3 $n = 10$

The dicarboxylic bolaamphiphiles **1–3** with an L-valyl-L-valine moiety at each end were synthesized by condensation of alkane-1,*n*-dicarboxylic acid (n = 6, 8 and 10) with 2 equiv. of *C*-protected L-valyl-L-valine benzyl ester, followed by deprotection of the *C*-terminal.‡

The obtained white powders of **1–3** are sparingly soluble in water (< 0.1 mg ml^{-1} at 23 °C), but become highly soluble (> 50 mg ml^{-1} at 23 °C) after neutralization with alkali hydroxides. When alkaline aqueous solutions of **1–3** (10 mM, 2 equiv. NaOH, pH > 7) were slowly acidified by vapor diffusion of 1–5% AcOH into the solution,[7,8] the bolaamphiphiles **2** (n = 8) and **3** (n = 10) produced a hydrogel in 1–2 weeks. In contrast, the bolaamphiphile **1** (n = 6) with a shorter oligomethylene bridge formed a crystalline solid as a precipitate. We obtained these self-assemblies at pH 3.4, 4.3 and 4.9 for **1**, **2** and **3**, respectively. From pH titration results,[8] the original carboxylate anions of **1–3** proved to be fully protonated at these pH values. Elemental analyses of the crystal from **1** and the dehydrated gels from **2** and **3** are also consistent with the protonated state.§

Energy-filtering transmission electron microscopy (EF−TEM) is a useful tool for observing low-contrast organic and biological samples without staining.[9] Furthermore, unstained TEM observations have the advantage of avoiding awkward microscopic artifacts. EF−TEM of the hydrogel revealed that the gels from **2** and **3** are comprised of a number of fibrous assemblies with micrometers lengths [Fig. 1(a)]. High-resolution EF−TEM images clearly show the presence of nanoscale fibers with widths of 10–30 nm [Fig. 1(b)]. No significant intertwisted fibers, observed for organogels made of N-protected bolaform amides,[10] can be seen. Furthermore, small angle X-ray diffraction analysis of the fibers from **2** and **3** displayed no crystalline Bragg reflections. These findings indicate that the proton-triggered self-assembly provides supramolecular fibers made of the fully protonated bolaamphiphiles **2** or **3**.

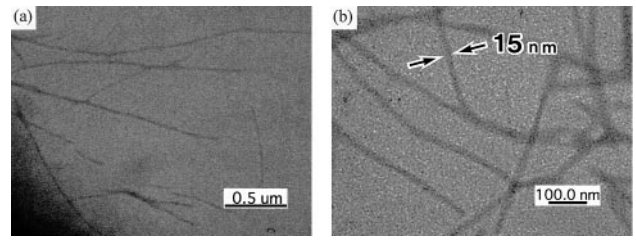


Fig. 1 (a) Energy-filtering transmission electron micrograph of the nano-fibers made of 3. (b) High-resolution image of the same specimen.

FT-IR spectra of the dried self assemblies from **1–3** were measured on a CaF_2 plate. Fig. 2 shows a partial FT-IR spectrum of the dehydrated fibers from **3**. The CH_2 antisymmetric and symmetric stretching bands of **3** appear at 2930 and 2856 cm^{-1}, respectively. The CH_2 scissoring band gives a single sharp peak at 1467 cm^{-1}. These band characteristics

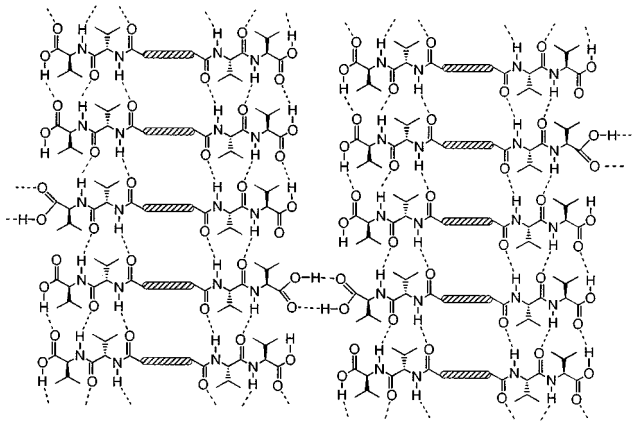

Fig. 4 A possible model for the predominant intralayer hydrogen-bond network within the nano-fibers from **2** or **3**. Interlayer acid-acid hydrogen bonds are partly depicted.

suggest that the alkylene bridge of **3** has a high *trans* conformational population[11] and that its packing mode is triclinic.[12] On the other hand, the presence of a parallel β-sheet network between amide groups can be confirmed by the N–H stretching, with the amide I and II bands at 3296, 1640 and 1549 cm^{-1}, respectively.[13] This is in contrast with the three-dimensional networks of hydrogen bonds found within microtube membranes and crystals of oligoglycine bolaamphiphiles.[7,8] The isopropyl groups of the valine residue enforce two-dimensional hydrogen-bond networks due to steric hindrance.

A broad band due to the carboxylic acids (CO_2H) appears around 1725 cm^{-1}, whereas no carboxylate anion (COO^-) bands can be seen around 1600 cm^{-1}. Fig. 3 shows FT-IR spectra in the CO_2H band region for the dried self-assemblies of **1–3** and their second derivative plots. Curve-fitting analysis also supports the validity of this deconvolution for the CO_2H band. As a result, we found three independent absorption bands at 1741, 1725, and 1711 cm^{-1} for **3**. The absorption bands near 1740 and 1725 cm^{-1} can be assigned to the C=O stretching vibration of the free, non-hydrogen bonded and laterally hydrogen-bonded CO_2H groups, respectively.[14] On the other hand, the bifurcated hydrogen bond of the CO_2H groups, which is commonly observed in the solid state, displays a band around 1710 cm^{-1}. The area ratio of each band for **3** is calculated to be 20:65:15 for the non-hydrogen-bonded:laterally hydrogen-bonded:bifurcated CO_2H groups. The nano-fibers made of **2** also display three FT-IR bands at 1738, 1722, and 1708 cm^{-1} with an area ratio of 15:60:25, respectively. However, the CO_2H band area ratio of **1** is 20:35:45. These results indicate that intralayer, lateral hydrogen-bond networks are of great importance in the nano-fiber formation from **2** and **3**. On the basis of the FT-IR analyses, a possible hydrogen-bond network within the nano-fibers is shown in Fig. 4. Intralayer interactions between the carboxylic peptide head groups enforce an extended molecular sheet. Similar structures were also depicted for the organogel-forming bolaform amides with no interacting end functionalities.[10] On the other hand, interlayer cyclic dimer formation by the CO_2H groups determines the crystalline structure of **1**. The bolaamphiphile **1** probably requires stronger interlayer interactions to compensate for a decrease in hydrophobic interactions.

In conclusion, the FT-IR deconvolution analysis of the CO_2H bands clarified that intra- and inter-layer interactions between the head groups of **1–3** control the formation of supramolecular nano-fibers and the crystalline solid, respectively.

An STM–XPS study of ammonia oxidation: the molecular architecture of chemisorbed imide 'strings' at Cu(110) surfaces

Albert F. Carley, Philip R. Davies and M. Wyn Roberts*

Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB. E-mail: robertsmw@cardiff.ac.uk

The structural characteristics of imide strings formed when a Cu(110) surface is exposed to an ammonia rich NH_3–O_2 mixture at 325 K have been determined by STM. The spacing of the NH units within a string is 5 Å and at complete coverage the strings are separated by 7.2 Å.

Here we provide a detailed insight into the structure of the imide overlayer that results from the oxidation of ammonia at a Cu(110) surface. The experiment was carried out under dynamic co-adsorption conditions where there is no evidence at the surface of either of the two reactants, ammonia and oxygen, and investigated using X-ray photoelectron spectroscopy (XPS) and scanning tunneling microscopy (STM). The combination of STM with *in situ* XPS provides a unique and powerful approach to the study of the mechanism of surface reactions: STM provides structural information at the atomic level and XPS allows chemical identification of the surface species. The dual function ultra high vacuum spectrometer was supplied by Omicron Vakuumphysik.

The formation of a chemisorbed imide adlayer at a Cu(110) surface exposed to an ammonia-rich (30 : 1) mixture of ammonia and dioxygen was first established by us using XPS and high resolution electron energy loss spectroscopy (HREELS).[1,2] Subsequently, Bradshaw *et al*.[3] showed using photoelectron diffraction that the imide species are adsorbed in the short-bridge site on Cu(110). Previous STM studies by Madix's group[4] have concentrated on the reaction of pre-adsorbed oxygen atoms on Cu(110) by ammonia. Chem-isorptive replacement of oxygen occurs primarily at Cu–O chain ends[4,5] leading to a mixed imide–oxygen adlayer.

An STM image of the Cu(110) surface saturated with imide species (Fig. 1) shows close-packed, broad NH(a) 'strings' with a uniform separation between strings of 7.2 Å, which is close to twice the copper lattice spacing in the $<100>$ direction. Since individual NH species are generally not resolved along the strings, STM alone cannot determine the packing density of the imide moieties in the $<1\bar{1}0>$ direction. However, quantification[6] of the observed XP N(1s) spectrum gives a saturation coverage of 2.6×10^{14} cm^{-2}. Population of all the short bridge sites (*i.e*. a 2×1 structure) would lead to a saturation imide coverage of *ca*. 5×10^{14} cm^{-2}. We conclude that the imide species are adsorbed in alternate short bridge sites, with a NH–NH spacing of *ca*. 5 Å. This is in excellent agreement with recent density functional calculations.[7] Whether the imide species are adsorbed in a $p(2 \times 2)$ or a $c(2 \times 4)$ surface structure cannot be determined from the present data.

Corroboration of the intermolecular spacing of the imide molecules comes from an analysis of the string labelled '6' in Fig. 2, observed during the real-time study of the growth of imide strings on the copper surface at 325 K. Unusually, discrete features within the string are resolved in this case, with a spacing of 5.2 Å. We were able to observe this particular feature develop alongside the already completed NH string labelled '5' at approximately the same rate as other NH strings. The feature was stable (as were all the features recorded in this

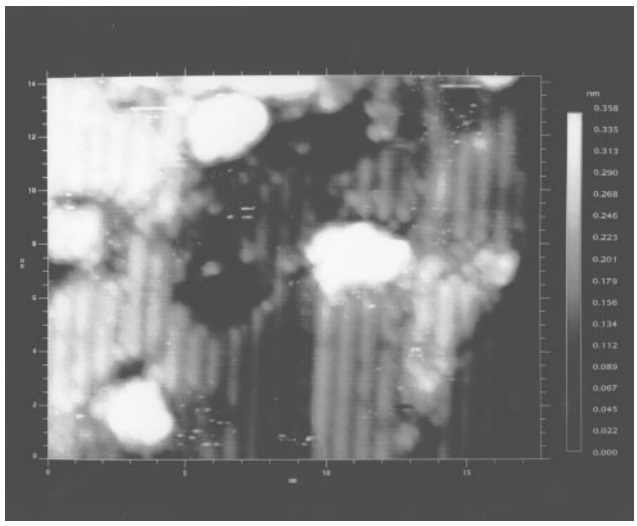

Fig. 1 STM image of a Cu(110) surface saturated with imide species after several hours exposure to the 30 : 1 ammonia–dioxygen mixture. Note the regular spacing of the imide rows. STM imaging conditions: sample bias −0.62 V, tunneling current 0.24 nA, scan speed 215 nm s^{-1}.

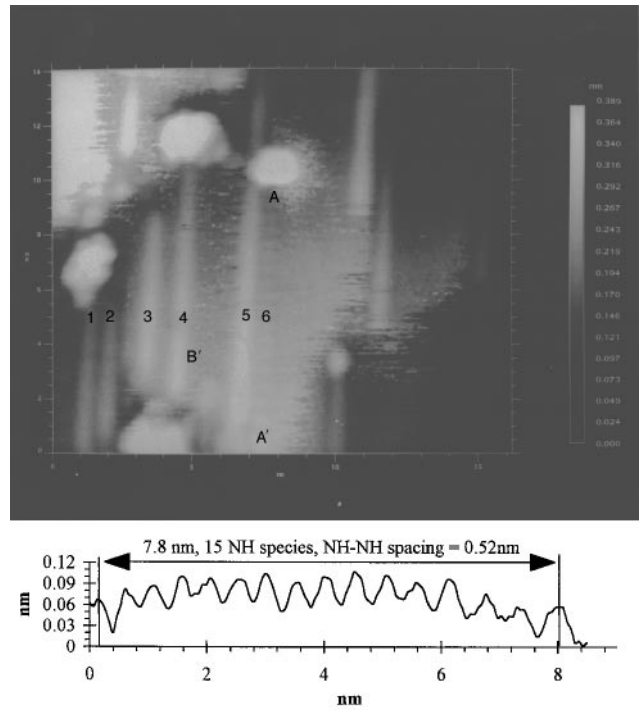

Fig. 2 STM image recorded during exposure of a Cu(110) surface at 325 K to a 30 : 1 ammonia–dioxygen mixture; the image was recorded after 2300 s at a mixture pressure of 1.5×10^{-8} mbar. The characteristically broad imide rows are aligned in the $<1\bar{1}0>$ direction. Selected NH strings are numbered 1–6; the line profile below the image was obtained between the points A and A' and shows a corrugation reflecting the individual imide species in row 6. STM imaging conditions: sample bias −1.00 V, tunneling current 0.25 nA, scan speed 91 nm s^{-1}.

experiment) for at least 40 minutes and was identical in both the forward and the reverse scan. Why the NH molecules should be resolved in this particular feature (and a few others) but not in the majority of cases is not clear. We have already reported[1,2] that XPS shows that only NH is present at the surface, as reflected in an N 1s feature with a binding energy of 397.8 eV, during exposure of Cu(110) to such an ammonia–dioxygen mixture.

It is significant that the NH species form extended strings at the surface, rather than simply adsorbing randomly. We have previously established that under dynamic co-adsorption conditions novel surface chemistry can be observed through the interaction of weakly adsorbed species, possessing a short surface life-time, with reactive co-adsorbates (see the reviews in ref. 8). In this case, NH formation results from the interaction of ammonia molecules (present at immeasurably low coverages under the reaction conditions and undergoing rapid surface diffusion) with transient oxygen species. The NH (possibly radical-like) species then diffuse across the terraces and are trapped at sites adjacent to the ends of NH strings, where they are energetically most stable.[7] We have not however been able to progress further the debate[1,9] as to whether at the Cu(110) surface the reactive oxygen species are atomic [eqns. (1) and (2)] or molecular [eqn. (3)] in nature (s = surface transient; a = chemisorbed species):

$$O_2(g) \rightarrow 2\,O^{\delta-}(s) \quad (1)$$

$$NH_3(s) + O^{\delta-}(s) \rightarrow NH(a) + H_2O(g) \quad (2)$$

$$NH_3(s) + O_2^{\delta-}(s) \rightarrow NH(a) + O(a) + H_2O(g) \quad (3)$$

Both atomic[10] and molecular[11] transient oxygen species have been implicated in the surface chemistry observed at other metal surfaces under dynamic coadsorption conditions.

A further observation that can be made in Fig. 1 is that during the early stages of the development of the NH overlayer, nucleation of NH strings frequently occurs not at the ideal close-packed spacing of 7.2 Å but one lattice spacing further apart giving a spacing of 10.8 Å. (Compare for example the separation between NH strings 1 and 2, and 3 and 4.) This observation is interesting because although these NH strings appear very stable even at 325 K, continual exposure to the ammonia–dioxygen mixture generates a close-packed layer with a uniform 7.2 Å string separation. This can only result from a displacement of some of the NH chains due to lateral interactions between imide species, as newly formed NH groups diffuse to short-bridge sites located between imide chains separated by 10.8 Å.

In summary, the mechanism of the selective oxidation of ammonia at Cu(110), first investigated using X-ray and electron energy loss spectroscopies,[1,2] has been developed through STM to provide a model at the molecular level. Details of the interatomic spacing of the NH units within an imide string and the spacings between the rows of strings have been obtained for the first time.

We are grateful to EPSRC for their generous support of this research.

Short and efficient route to substituted linear triquinanes from 2-methoxyphenols

Day-Shin Hsu, Polisetti Dharma Rao and Chun-Chen Liao*†

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043

Highly oxygenated and substituted *cis,anti,cis* fused linear triquinanes are prepared from commercially available 2-methoxyphenols and cyclopentadiene.

Extensive efforts by synthetic organic chemists during the last two decades towards the synthesis of polyquinane natural products have resulted in the development of several elegant approaches.[1] However, except for a few, most of these approaches are either target oriented or require fairly long sequences of reactions to arrive at the desired carbon framework. Consequently, the search for new methodologies that provide efficient and rapid access to desired quinane skeletons continues.

Masked *o*-benzoquinones **1** bearing an array of functional groups can be easily generated *in situ* by the oxidation of commercially available 2-methoxyphenols with hypervalent iodine reagents such as (diacetoxy)iodobenzene (DAIB) and [bis(trifluoroacetoxy)]iodobenzene (BTIB) in MeOH.[2] Masked *o*-benzoquinones **1**, being the most easily accessible cyclohexa-2,4-dienones, readily undergo Diels–Alder reactions in various modes, *i.e*. they act as dienes and dienophiles in both inter- and intra-molecular reactions.[2–6] We have already made use of these reactions in the synthesis of highly functionalized bicyclo-[2.2.2]octenones,[2] *cis*-decalins,[3,4] linear and angular triquinanes[5] and in the synthesis of several natural products.[6] We herein report the development of a new and simple approach to facilitate stereoselective synthesis of highly substituted linear triquinanes using Diels–Alder reactions of cyclopentadiene with *in situ* generated masked *o*-benzoquinones and oxa-di-π-methane (ODPM) photorearrangement as the key steps.

Accordingly, we have carried out the Diels–Alder reactions of cyclopentadiene with masked *o*-benzoquinones **1**, generated *in situ* by adding a solution of a 2-methoxyphenol **2** (2 mmol) in MeOH (8 ml) to a mixture of DAIB (3 mmol) and cyclopentadiene (50 mmol) in MeOH (6 ml) at reflux during 1 h. It was observed that products **3** were produced exclusively except in the cases of **1d** and **1f** (Scheme 1, Table 1). Masked *o*-benzoquinones **1d** and **1f** produced both the possible adducts, *i.e.* **3d** and **4d** and **3f** and **4f**, respectively. Compound **4d** was isolated in pure form while the thermally unstable compound **4f** was found to rearrange to **3f** rapidly. Then the adduct **4d** was subjected to rearrangement in mesitylene at 160 °C for 10 min. As expected compound **3d** was produced in almost quantitative yield. To simplify the preparation of compounds **3d** and **3f**, the concentrated reaction mixtures obtained individually from the reactions of **1d** and **1f** with cyclopentadiene were heated, without purification, in mesitylene at 160 °C for 10 min to furnish compounds **3d** and **3f** in 86 and 76% yield, respectively. It was also observed that by extending the Diels–Alder reaction time to 6 h for **1d** and 18 h for **1f** the desired products could also be obtained exclusively (Table 1).

The observation of products **4d** and **4f** and their isomerization to **3d** and **3f** respectively suggests that a tandem process involving a Diels–Alder reaction followed by Cope rearrangement is in operation in the formation of the latter compounds which are secondary products at least in part if not all. However, controlled experiments carried out at 0 °C made it clear that there are two competetive Diels–Alder reactions taking place. Importantly, in both the modes these cycloadditions are regio- and stereo-selective. In such cycloaddition reactions of cyclopentadiene,[7] this is the first time that a stable and thoroughly characterized norbornene-type adduct, **4d**, has been isolated.

For the conversion of compounds **3a–g** into triquinanes, they were irradiated in acetone using light of wavelength centered at 300 nm in a Rayonet reactor. While **3a** provided the desired ODPM rearrangement product **5a** in 68%, **3b** furnished the expected triquinane **6b** in 45% yield. In other cases a complex reaction mixture was a regular feature. These results are not unexpected since only in the cases of **3a** and **3b** does the biradical intermediate enjoy resonance stabilization by the methoxycarbonyl group. Treatment of **5a** with Ac_2O and BF_3•OEt_2[8] resulted in the highly oxygenated linear triquinane **6a** (Scheme 2). The overall yield of compound **6a** from **2a** is *ca*. 42%. The stereochemical assignments of the triquinane **6a** were based on NOE studies.

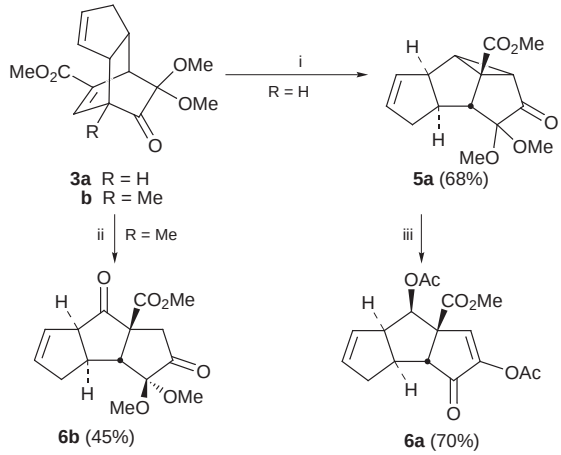
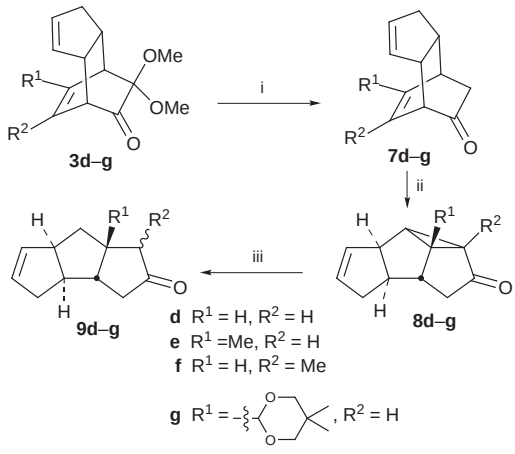


Scheme 2 *Reagents and conditions*: i, *hν* (1% in acetone), 18 h; ii, *hν* (1% in acetone), 10 h; iii, Ac_2O, BF_3•OEt_2, CH_2Cl_2, 60 °C, 3 h

It was anticipated that reductive removal of the ketal group in compounds **3c–f**, which is known to stabilize free radicals, would minimize the undesired photodecarbonylation. Accordingly, the demethoxylation of **3d–g** was achieved by reduction with SmI_2 to produce compounds **7d–g** in excellent yields.[9] Irradiation of compounds **7d–g** in acetone gave the desired products **8d–g** in agreement with our prognostications. Attempted cleavage of the cyclopropane ring of compound **8d** under the conditions previously employed for the transformation of compound **5a** into **6a** proceeded in an undesired fashion. Consequently, the procedure recently developed by Enholm and Jia for the cleavage of analogous compounds was adopted.[10] Thus treatment of compounds **8d–g** with Bu_3SnH and AIBN in refluxing benzene provided the desired linear triquinanes **9d–g** in good yields (Scheme 3, Table 2). A single stereoisomer was obtained in all cases with one exception. Compound **9f** was produced as a 1:10 mixture of epimers.

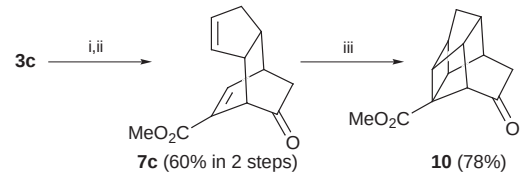


Scheme 3 *Reagents and conditions*: i, SmI_2 (4 equiv.), THF–MeOH, room temp., 10 min; ii, *hν* (1% in acetone), 24 h; iii, Bu_3SnH, AIBN, benzene, reflux

Table 2 Stereoselective synthesis of linear triquinanes (**3**→**7**→**8**→**9**)

Substrate	Product[a]	Yield (%)	Product[b]	Yield (%)	Product[c]	Yield (%)
3d	**7d**	91	**8d**	65	**9e**	70
3e	**7e**	93	**8e**	50	**9f**	81
3f	**7f**	79	**8f**	48	**9g**	83
3g	**7g**	95	**8g**	58	**9h**	93

[a] See ref. 9 for experimental procedure. [b] A 1% solution in acetone was irradiated for 24 h. [c] See ref. 10 for experimental procedure.



Scheme 4 *Reagents and conditions*: i, $HS(CH_2)_3SH$, BF_3•OEt_2, CH_2Cl_2, room temp.; ii, Raney Ni, EtOH; iv, *hν*, acetone

For the removal of the ketal group in compound **3c**, which cannot be affected by SmI_2, it was subjected to transketalization followed by reduction with partially deactivated Raney nickel,[11] to obtain **7c**. Irradiation of compound **7c** in acetone, however, gave [2+2] photocyclization product **10** instead of the desired ODPM rearrangement product (Scheme 4). This is an undesired result and is probably due to the localization of the triplet excited state energy in the α,β-unsaturated ester moiety to give the [2+2] adduct, rather than localization of the triplet excited state energy in the keto group, which is necessary for ODPM rearrangement to proceed.

The stuctures of all the new compounds **3**, **4d** and **5**–**10** were thoroughly established by IR, ^1H and ^{13}C NMR and mass spectral analysis. In the cases of compounds **3a**,**c–f**, H–H COSY spectra assisted in fixing the position of the double bond in the five-membered ring. The stucture of compound **10** was also unambiguously established with the help of a H–H COSY spectrum.

In conclusion the above methodology provides appropriately oxygenated and variously substituted linear triquinane skeletons with naturally occurring *cis*,*anti*,*cis* stereochemistry making use of inexpensive readily available aromatic compounds as starting materials. The present methodology is complementary to the existing related ones such as Wender's approach based on arene-alkene *meta* photoaddition and Singh's methodology based on ODPM rearrangement.[12,13] Application of this methodology to the total synthesis of *Lycopodium* alkaloids of the magellanane group,[14] using compound **9g** as the key intermediate, is in progress in our laboratory.

We thank the National Science Council (NSC) of the Republic of China for financial support. One of us (P. D. R.) thanks the NSC for a post-doctoral fellowship.

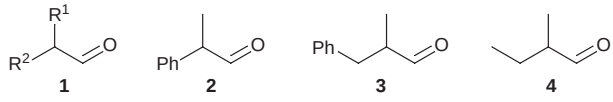
The triisopropylsilyl effect: exceptional Cram-type selectivity in Mukaiyama aldol reactions of a silyl ketene thioacetal

Anthony P. Davis,*† Stephen J. Plunkett and Jayne E. Muir

Department of Chemistry, Trinity College, Dublin 2, Ireland

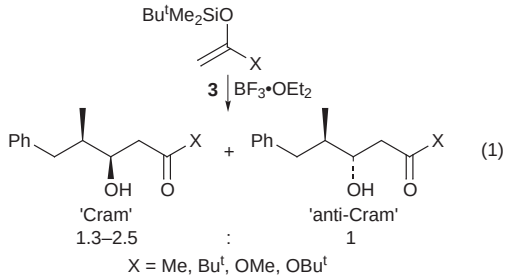
The level of 1,2-asymmetric induction in the $BF_3{\cdot}OEt_2$-promoted addition of silyl ketene thioacetals to α-asymmetric aldehydes is affected by the bulk of the silyl group; unprecedented Cram-type selectivity is given by the triisopropylsilyl derivative 8a.

The optimisation of 1,2-asymmetric induction in additions to aldehydes **1** still presents challenges in stereoselective synthesis. Effective methodology is available for substrates with heteroatom-based substituents,[1] while good 'Cram-type' selectivity can now be obtained with α-aryl aldehydes, or where R^1 and R^2 are alkyl groups of greatly differing steric bulk.[2,3] However, in cases where the α-substituents are more subtly differentiated, it is still difficult to achieve acceptable levels of selectivity. We now describe a variant of the Mukaiyama aldol addition which provides useful Cram-type selectivities with even the most 'difficult' of aldehydic substrates.

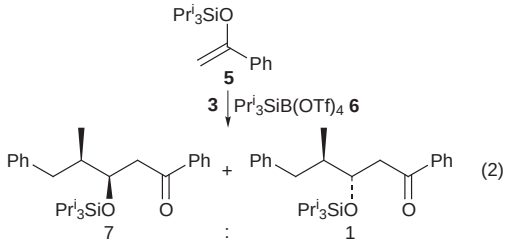


1 **2** **3** **4**

The new method is related to the conventional Mukaiyama addition as explored by Heathcock and Flippin [*e.g.* eqn. (1)],[3a] and to our subsequent development exemplified by eqn. (2).[3f]

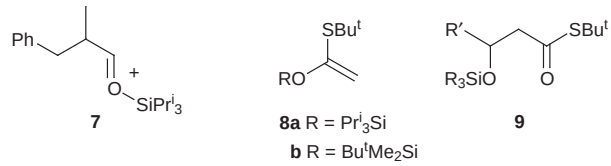


(1)



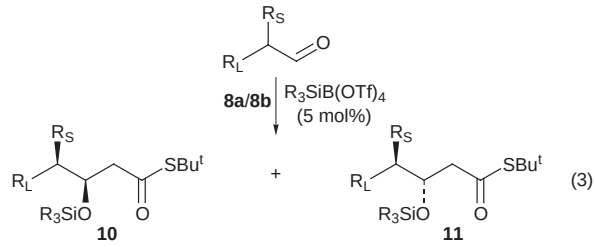
(2)

The Heathcock study yielded good selectivities (up to 36 : 1) with 2-phenylpropanal **2**, but modest results with the more challenging **3**. In our own methodology, use of triisopropylsilyl enol ether **5**, and 'supersilylating agent' **6**[4] gave a selectivity of *ca.* 100 : 1 with **2** and [as shown in eqn. (2)] a useful level of 7 : 1 with **3**. The improvement was thought to be due to the bulk of the Pr^i_3Si group in intermediate **7**, requiring the nucleophile to pass close to the asymmetric centre.[5] Control experiments employing $BF_3{\cdot}OEt_2$ catalysis, and **3** as substrate, gave lower selectivities (*ca.* 3 : 1) that did not depend substantially on the bulk of the silyl group in the enolate.[3f,6]



7 **8a** R = Pr^i_3Si **9**
b R = Bu^tMe_2Si

The present work was aimed at extending the scope of our earlier method, specifically by employing a nucleophile of more general utility than **5**. Silyl ketene thioacetals **8** seemed especially attractive due to the versatility of the thioester groups in aldol products **9**.[3e] Accordingly, we prepared the triisopropylsilyl derivative **8a** and, for comparison, the *tert*-butyldimethylsilyl analogue **8b**, by treatment of *tert*-butyl thioacetate with LDA/THF/DMPU followed by Pr^i_3SiOTf and Bu^tMe_2SiCl respectively.‡ Reaction of **8a**/**8b** with aldehydes **2**–**4**, catalysed by the corresponding supersilylating agents under the conditions reported previously,[3f] gave the expected β-silyloxy thioesters **10** and **11** [eqn. (3), R_L = large, R_S = small] with the



10 **11** (3)

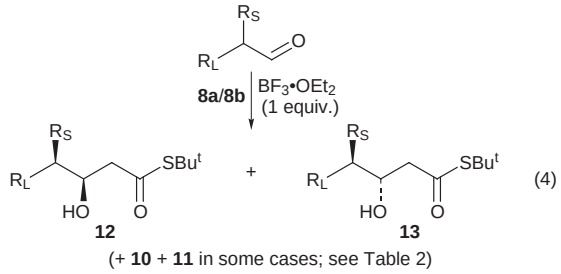
yields and diastereoselectivities shown in Table 1. Although not startling, the results were pleasing in that they generalised the earlier discovery (dependence of selectivity on steric bulk of SiR_3), registered an acceptable selectivity of 5 : 1 for aldehyde **3**, and confirmed that even the exceptionally challenging substrate **4** could be transformed with significant selectivity (3.5 : 1) using reagent **8a**.

Table 1 Additions of silyl ketene thioacetals **8a**/**8b** to α-asymmetric aldehydes **2**–**4** catalysed by $R_3SiB(OTf)$[a]

Aldehyde	Nucleophile	Yield (%)	**12** : **13**[b]
2	**8b**	80	27 : 1
2	**8a**	79	77 : 1
3	**8b**	58	3.6 : 1
3	**8a**	78	5.5 : 1
4	**8a**	88	3.5 : 1

[a] Reaction conditions: $R_3SiB(OTf)_4$ (5 mol%), CH_2Cl_2, −80 °C, 1 h, quenching at low temp. with sat. aq. $NaHCO_3$. [b] Determined by NMR integration. Cram's rule was assumed to hold for all substrates, and was used to assign product stereochemistries.

By contrast, a surprise awaited when, for completeness, we repeated the reactions employing the conventional promoter $BF_3{\cdot}OEt_2$ [eqn. (4)]. On the basis of the earlier results with the



(+ **10** + **11** in some cases; see Table 2)

silyl enol ethers, we expected inferior diastereoselectivity with little dependence on R_3Si. In fact, as shown in Table 2, the method produced *higher* selectivities, which *did* increase with the bulk of the silyl group. The analysis was complicated by small amounts of **10** and **11** which appeared in some cases in addition to the expected products **12** and **13**. However, whether or not these were taken into account, *the discrimination achieved by the triisopropylsilyl reagent* **8a** *was quite outstanding.* For aldehyde **2** the selectivity was raised to the point where the minor isomer was difficult to detect with certainty, while for **3** and **4** the ratios were superior to those achieved in any previously reported additions.[7]

Although some aspects of this behaviour remain mysterious, a partial explanation is possible based on computer-based molecular modelling.[8] Systematic conformational searches on **8a** and **8b** reveal preferred structures in which the bulky Bu^t(S) and R_3Si(O) groups are held above and below the plane of the C=C bond, effectively shielding the nucleophilic carbon from attack by electrophiles (Fig. 1). As both faces are affected, these nucleophiles appear highly hindered and might be expected to react with unusual diastereoselectivity. The R_3Si appears to be the more flexible of the two blocking groups,§ suggesting that attack may occur through the face *anti* to Bu^t(S) and providing an explanation for the sensitivity of the reactions to the steric bulk of R_3Si. In contrast, **5** adopts conformations in which one face of the C=C bond is shielded, but the other is essentially free (Fig. 1). It therefore attacks **3**·BF_3 with moderate selectivity, which does not depend greatly on the bulk of R_3Si. This analysis does *not* explain why catalysis by $R_3SiB(OTf)_4$ does not lead to even greater selectivity with **8**, as it does with **5**. We can only assume that the combination of an exceptionally hindered nucleophile **8** and a similarly hindered electrophile **7** causes a change in mechanism which degrades selectivity.

Table 2 Additions of silyl ketene thioacetals **8a**/**8b** to **2**–**4** catalysed by $BF_3{\cdot}OEt_2$[a]

Aldehyde	Nucleophile	Yield (%)	**12**:**13**[b]
2	**8b**	84	54:1
2	**8a**	76	~130:1
3	**8b**	43 (51)[c]	5.8:1 (5.5:1)[c]
3	**8a**	78 (81)[c]	13:1 (12:1)[c]
4	**8a**	77 (90)[c]	5.4:1 (5.0:1)[c]

[a] Reaction conditions: $BF_3{\cdot}OEt_2$ (1 equiv.), CH_2Cl_2, −80 °C, 30 min, quenching at low temp. with aqueous phosphate buffer (pH 7). [b] NMR integration; see Table 1. [c] Major products **12** and **13** were accompanied by minor quantities of **10** and **11**. Unbracketed figures refer to **12**/**13** only, while bracketed figures include contributions from the silylated products.

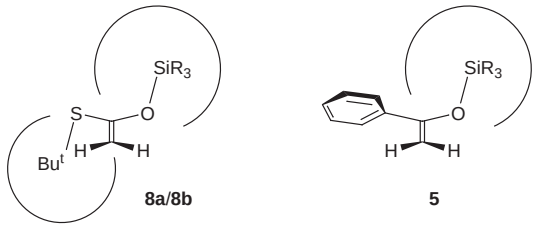


Fig. 1 Schematic views of **8a**/**8b** and **5** in their preferred conformations, as predicted by computer-based molecular modelling

In conclusion, we have discovered an addition to aldehydes which takes place with unprecedented Cram-type selectivity, and gives products which can serve as versatile intermediates for organic synthesis. Our results further highlight the special utility of the triisopropylsilyl group as a tool for directing reactivity through long-range steric intervention.[9]¶

Financial support for this work was provided by Forbairt (the Irish science and technology agency) and the EU Human Capital and Mobility Programme.

‡ Conveniently, the Pr^i_3Si derivative **8a** could be purified by flash chromatography (hexane–Et_2O, 40:1). Substantial losses were incurred when the same technique was applied to **8b**.

§ Conformations in which the silicon atom is roughly in the plane of C=C bond appear at energies ⩾11 kJ mol^{-1} above baseline.

¶ An alternative might be the *tert*-butyldiphenylsilyl group. However, a limited series of experiments indicates that, in this system, its effective bulk lies between that of Pr^i_3Si and TBDMS.

7 For comparison, additions to **4** usually result in *ca.* 1:1 ratios of diastereomers (recent example: J. J. Eshelby, P. J. Parsons and P. J. Crowley, *J. Chem. Soc., Perkin Trans. 1*, 1996, 191). Even a highly hindered lithium α,α-bis(alkylthio) enolate gave a ratio of just 3.5:1 with this substrate [ref. 3(*c*)]. Only the arylthionation-allylation of Heathcock, which is not a simple addition reaction, gives selectivities comparable with the present method (I. Mori, P. A. Bartlett and C. H. Heathcock, *J. Am. Chem. Soc.*, 1987, **109**, 7199).

Electrochemical synthesis of dialkylsubstituted polystannanes and their properties

Mitsutoshi Okano,* Naoki Matsumoto, Makoto Arakawa, Toshiyuki Tsuruta and Hiroshi Hamano

Department of Photo-Optical Engineering, Tokyo Institute of Polytechnics, 1583 Iiyama, Atsugi, Kanagawa, 243-0297 Japan. E-mail: okano@photo.t-kougei.ac.jp

Poly(dibutylstannane) and poly(dioctylstannane) were obtained by electrochemical polymerization of dibutyldichlorostannane and dioctyldichlorostannane, respectively, in a one-compartment cell equipped with a platinum cathode and a silver anode, using tetrabutylammonium perchlorate and DME as the supporting electrolyte and the solvent, respectively.

Polystannanes have attracted the attention of many researchers,[1–4] because heavier atoms in the backbone of σ-conjugated polymers are expected to give larger σ-conjugation, narrower band gaps, and more metallic character.[5–10]

The most frequently employed synthetic pathways to polysilanes and polygermanes, which have been more extensively studied as σ-conjugated polymers, are Wurtz coupling with alkali metals,[11] electrochemical reduction,[12–15] and dehydrogenative coupling.[16] Among these, electrochemical reduction has been said to be the most important pathway as an industrial method. However, for polystannanes, Wurtz coupling[4,17] and dehydrogenative coupling[1,2] reactions, but no electrochemical reduction, have been reported.

The purpose of this communication is to report the electrochemical syntheses of poly(dibutylstannane), $(Bu_2Sn)_n$, and poly(dioctylstannane), $(Oct_2Sn)_n$, and their basic properties.

Dibutyldichlorostannane and dioctyldichlorostannane were purchased from Tokyo Kasei Kogyo and Gelest, Inc., respectively, and vacuum distilled before use. Electrosynthesis was carried out according to the method reported previously,[12] using a Pt cathode, an Ag anode, and a one-compartment cell equipped with a syringe port. Tetrabutylammonium perchlorate (TBAP), precipitated from ethyl acetate–pentane solution and vacuum dried, was the supporting electrolyte and dry DME was the solvent. A constant voltage of 20 V was applied between the two electrodes. The charge passing through the circuit was monitored by a coulometer. Electrolysis was terminated when the charge reached a previously calculated value based on eqn. (1) and the amount of monomer used. Typically, 95% of the

$$n\mathrm{R_2SnCl_2} \xrightarrow{+\,2ne} (\mathrm{R_2Sn})_n + 2n\mathrm{Cl^-} \qquad (1)$$

R = Bu, Oct

theoretically required charge was passed because it was known from previous work[12] that complete electrolysis (electrolysis with 100% of the theoretically calculated charge) tends to give a lower yield and lower molecular weight as a result of backbiting reactions.

Isolation of the dialkyl-substituted polystannane was carried out as follows. As described in detail below, the polystannanes are extremely sensitive to moisture in air. Therefore, all the isolation procedures were carried out under nitrogen atmosphere and using syringe techniques. After electrolysis, most of the polymer was obtained as a precipitate and the rest of the polymer was dissolved in the electrolyte solution. Firstly, all the contents of the electrolysis cell were transferred to a two-necked flask connected to a vacuum line and equipped with a rubber septum. The supernatant solution in the electrolysis cell was transferred to the two-necked flask by a syringe technique. Then, pentane (50 ml) was introduced into the electrolysis cell and the remaining precipitated polymer was dissolved whilst being stirred magnetically. The polymer solution thus obtained was transferred and added to the previously collected supernatant solution in the two-necked flask. Then, all the solvent was removed from the two-necked flask under reduced pressure. Next, the polymer was separated from the supporting electrolyte and low molecular weight compounds as follows. Pentane (30 ml) was introduced into the two-necked flask to redissolve all the polymer. In order to precipitate polystannane and to dissolve the supporting electrolyte and low molecular weight compounds, dry methanol (100 ml) was added. The polymer was obtained by discarding the supernatant solution. The above procedure for the separation of supporting electrolyte and low molecular weight compounds was repeated. Then, the remaining solvent was removed under reduced pressure to obtain the polymer sample. A pure sample was obtained by Soxhlet extraction using pentane as the solvent. Finally, the collected polymer was dried in vacuum. The resulting polymer was a slightly sticky yellow solid regardless of the substituent groups (butyl or octyl).

Typical synthetic data are summarized in Table 1. Yields were 40–60% for $(Bu_2Sn)_n$ and 30–50% for $(Oct_2Sn)_n$. Syntheses were also successful in tetrahydrofuran. Absorption spectra were measured in pentane because pentane dissolves polystannanes well and also because polystannanes were found to be stable in pentane in the dark. Absorption maxima varied from 378 to 381 nm for $(Bu_2Sn)_n$, and were at slightly shorter wavelengths for $(Oct_2Sn)_n$. Devylder *et al*. reported that λ_{max} of $(Bu_2Sn)_n$ reaches a plateau value of 380 nm as its molecular weight increases.[4] Therefore, electrochemically obtained $(Bu_2Sn)_n$ had λ_{max} values as long as those of $(Bu_2Sn)_n$. Molecular weight values should be handled with care for they were measured using tetrahydrofuran as the eluent, in which the polystannanes degraded slowly because of the moisture remaining in THF. Significant amounts of polystannanes may have decomposed during the analysis. However, the molecular weight values seem reasonable. Molecular weights of *ca*. 10000 are as good as electrochemically synthesized σ-conjugated polymers since under the same electrolysis conditions, the authors obtained a M_w of 10 000–25 000 for $(Bu_2Ge)_n$ and 15 000–35 000 for $(Bu_2Si)_n$.

It has been reported that polystannanes are somewhat sensitive to the air.[2] The authors wished to clarify whether

Table 1 Synthetic results

Polymer	Yield/g (%)	C.E.[b]	λ_{max}[c]/nm	M_w ($\times 10^4$)	M_w/M_n
$(Bu_2Sn)_n$	2.22 (56.1)	59.1	381	1.09	2.6
$(Bu_2Sn)_n$	1.83 (46.6)	49.1	379	1.17	2.1
$(Bu_2Sn)_n$[a]	2.01 (50.8)	53.5	378	0.64	1.3
$(Oct_2Sn)_n$	1.20 (27.9)	29.4	378	0.59	1.7

[a] Synthesized in THF. [b] Current efficiency. [c] Measured in pentane. [d] Measured by GPC using THF as the eluent.

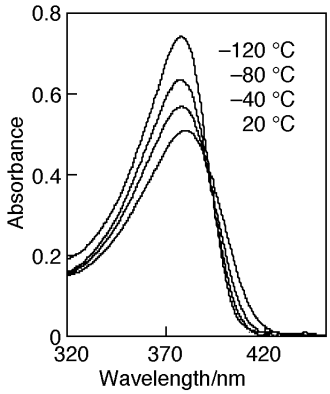

Fig. 1 Absorption spectra of $(Bu_2Sn)_n$ as a function of temperature.

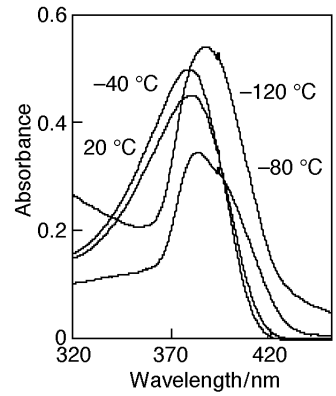

Fig. 2 Absorption spectra of $(Oct_2Sn)_n$ as a function of temperature.

polystannanes are sensitive to oxygen or sensitive to moisture in the air. In order to determine the stability of $(Bu_2Sn)_n$ toward oxygen, oxygen gas was bubbled into the pentane solution of $(Bu_2Sn)_n$. No decomposition was observed. In contrast, it was very difficult to obtain a stable tetrahydrofuran solution of $(Bu_2Sn)_n$. Even in freshly distilled CaH-dried tetrahydrofuran, a $(Bu_2Sn)_n$ solution of a concentration suitable for UV absorption measurements was not stable. Therefore, it was concluded that $(Bu_2Sn)_n$ is stable toward oxygen but extremely reactive to moisture.

The thermochromic behavior of $(Bu_2Sn)_n$ was examined because thermochromic behavior is most frequently discussed as a typical property of σ-conjugated polymers. Polysilanes and polygermanes, which have dialkyl substituent groups larger than butyl, are well known to exhibit so-called discontinuous thermochromic changes. However, $(Bu_2Sn)_n$ did not exhibit discontinuous thermochromic changes in pentane between −120 °C and room temperature (see Fig. 1). It has been said that the thermochromic behavior of σ-conjugated polymers is attributable to conformation changes in the main chains, and that such conformation changes are controlled by side chain interactions. Considering the fact that Sn–Sn bonds are much longer than Si–Si and Ge–Ge bonds, the above-mentioned lack of discontinuous thermochromic changes in $(Bu_2Sn)_n$ is attributable to weak side chain interactions. In contrast to $(Bu_2Sn)_n$, $(Oct_2Sn)_n$ showed discontinuous thermochromic changes (see Fig. 2). The absorption shift was much smaller than those observed for $(Oct_2Ge)_n$ and $(Oct_2Si)_n$. The absorption shift, which can be regarded as a manifestation of changes in effective conjugation length induced by conformation changes, decreased from $(Oct_2Si)_n$ to $(Oct_2Sn)_n$. For further discussions concerning these phenomena, it should be confirmed that the conformation changes of the polymers are of the same kind, *i.e*. all-*trans* and helical-*gauche* conformations.

To conclude, two dialkyl-substituted polystannanes were successfully synthesized by an electrochemical method. Considering the results obtained in the electrochemical syntheses of various polysilanes and polygermanes,[12] syntheses of all kinds of dialkyl-substituted polystannanes are expected to be successful as well. Syntheses of phenyl-substituted polystannanes are the authors' next challenge in this field because syntheses of phenyl-substituted polysilanes and polygermanes are more difficult than the dialkyl-substituted polymers.[12]

3_{10}-Helix stabilization *via* side-chain salt bridges[1]

T. Scott Yokum, Matthew G. Bursavich, Ted Gauthier, Robert P. Hammer*† and Mark L. McLaughlin*

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana, 70803-1804, USA

Decapeptides, Sb-10 (H-Api-Aib-Aib-Glu-Aib-Aib-Glu-Aib-Aib-Api-NH_2) and Ipi-10 (H-Api-Aib-Aib-Lys-Aib-Aib-Lys-Aib-Aib-Api-NH_2), where Aib is α-aminoisobutyric acid and Api is 4-aminopiperidine-4-carboxylic acid, are designed to be amphipathic as 3_{10}-helices; Sb-10 is the first example of a 3_{10}-helical peptide stabilized by side-chain salt bridging or ion pairing.

The 3_{10}-helix (*i*, *i* + 3 hydrogen bonding pattern) comprises 10% of all recognized helical structures in proteins.[2] These helices are commonly found in short stretches of proteins, often as the terminating segment of an α-helix.[2] Interest in the 3_{10}-helix arises because the 3_{10}-helix is thought to participate in receptor binding and may also be a protein folding intermediate to the α-helix.[2,3] *De novo* design studies examining the 3_{10}-helix have primarily focused on peptides rich in α,α-disubstituted amino acids (ααAAs).[4,5] The ααAAs are used extensively because the ϕ and ψ angles of these residues are restricted to those favoring helical structures.[4] Many factors have been reported for the selective formation of the 3_{10}-helix over the α-helix including: placement of ααAAs, percentage of ααAAs, peptide length, and peptide design.[5–7] Unfortunately, most studies exploring these factors have focused on hydrophobic peptides in organic media.[4] The extensive library of methods available for the stabilization of α-helices in aqueous media such as amphipathy, side-chain intra- and inter-peptide salt bridges, and side-chain covalent linkages[8–10] provides an excellent starting point for the stabilization of 3_{10}-helical peptides in aqueous media. The Marqusee–Baldwin peptides cleanly show α-helix stabilization from intra-helical, side-chain ion-pairing that is reduced at high salt concentrations.[9a] The *i*, *i* + 4 positioning of Glu and Lys residues stabilize the α-helix while *i*, *i* + 3 positioning does not. Additional combinations of salt-bridging residues (*i*, *i* + 4) also stabilize α-helical conformations.[9b]

We have reported the synthesis and characterization of a 3_{10}-helical decapeptide with 80% ααAAs (Fig. 1; **Ipi-10**).[7] The high percentage of ααAAs in **Ipi-10** promotes helicity and the peptide was designed to be most amphipathic as a 3_{10}-helix. Herein we report the synthesis and characterization of an analogous amphipathic 3_{10}-helical peptide containing two intra-peptide side-chain salt bridges (**Sb-10**), which are designed to further stabilize the 3_{10}-helix.

Sb-10 has the same sequence as **Ipi-10** with the exception of glutamic acids replacing the lysines. The peptide sequences are: **Sb-10**, H-Api-Aib-Aib-Glu-Aib-Aib-Glu-Aib-Aib-Api-NH_2 and **Ipi-10**, H-Api-Aib-Aib-Lys-Aib-Aib-Lys-Aib-Aib-Api-NH_2, where Aib is α-aminoisobutyric acid and Api is 4-aminopiperidine-4-carboxylic acid. The design results in an amphipathic 3_{10}-helix that places the two Api residues and the two glutamic acids on the same face (*i*, *i* + 3) of the 3_{10}-helix (Fig. 1). The *i*, *i* + 3 placement of the Glu and Api residues potentially introduces ionic interactions that can provide additional 3_{10}-helix stability relative to the alternative α-helix conformations, since *i*, *i* + 3 salt bridges do not stabilize α-helices.[9a]

Sb-10 was synthesized *via* a combination of manual and automated solid-phase peptide synthesis. The first three C-terminal residues were coupled to PAL-PEG-PS (PerSeptive Biosystems) by refluxing the preformed fluoren-9-ylmethoxycarbonyl (Fmoc)-amino acid fluorides (8 equiv.) and Pr^i_2NEt (3 equiv.) in CH_2Cl_2 until quantitative Fmoc cleavage tests[11] showed at least 90% coupling for each step.[12] The remainder of the peptide was synthesized on a PerSeptive Biosystems 9050 peptide synthesizer using preformed Fmoc-acid fluorides.[12] The peptide was purified by RP-HPLC on a C4 column with a H_2O–MeCN–0.5% TFA gradient. Peptide purity was greater than 95% according to an analytical RP-HPLC using C18 column and a similar gradient. Molecular weight was verified by MALDI-MS and amino acid analysis gave the expected amino acid content. Peptide concentrations for circular dichroism (CD) studies were determined by quantitative amino acid analysis.

α- and 3_{10}-Helical peptides have minima centered about 222 (n→π*) and 207 nm (π→π*) in the CD spectra. The ratio, *R*, of the n→π* band over the π→π* band differentiates the α- and 3_{10}-helix.[13] The ratio is near 1 for the α-helix and is approximately 0.4 for a 3_{10}-helix.[13]‡

The CD spectra of **Sb-10** and **Ipi-10** for comparison were taken in 50–100% aqueous–organic solvent mixtures [1:1 MeCN–H_2O, 9:1 MeCN–H_2O, 9:1 MeCN–trifluoroethanol (TFE)]. **Ipi-10** has a CD spectra indicative of a weak 3_{10}-helix only in 100% organic solvent [Fig. 2(A)].§ **Sb-10** exhibits moderate α-helicity in 1:1 MeCN–H_2O and begins to show 3_{10}-helical character in 9:1 MeCN–H_2O. In 9:1 MeCN–TFE,

Table 1 Circular dichroism data and derived structural parameters for **Sb-10**

Solvent	$[\theta]_{\pi\rightarrow\pi^*}$[a,b]	$[\theta]_{n\rightarrow\pi^*}$[a,c]	*R*	Helicity[d] (%)
9:1 MeCN–TFE	−15230	−6579	0.43	71 (3_{10})
9:1 MeCN–H_2O	−12749	−6461	0.50	*e*
1:1 MeCN–H_2O	−8673	−7433	0.85	31 (α)
0.1 M TMAT in 9:1 MeCN–TFE	−15774	−9576	0.61	*f*
0.01 M TMAT in 9:1 MeCN–TFE	−15038	−9235	0.61	*g*
0.001 M TMAT in 9:1 MeCN–TFE	−15333	−6531	0.43	71 (3_{10})

[a] Units for $[\theta]$ are deg cm^2 dmol^{-1}. [b] The minimum for the $[\theta]_{\pi\rightarrow\pi^*}$ band is in the range from 205–209 nm. [c] The minimum for the $[\theta]_{n\rightarrow\pi^*}$ band is in the range from 222–225 nm. [d] The percentage of α-helix is estimated using the equation: α-helix (%) = $-100([\theta]_{n\rightarrow\pi^*}+ 3000)/33000$ and the percentage of 3_{10}-helix is estimated using the equation: 3_{10}-helix (%) = $-100([\theta]_{\pi\rightarrow\pi^*})/21\ 500]$. [e] This peptide probably forms a mixture of α-helical, 3_{10}-helical and coil structures. The percentage of α-helix is estimated at 29% and the percentage of 3_{10}-helix is estimated at 59%. [f] This peptide probably forms a mixture of α-helical, 3_{10}-helical and coil structures. The percentage of α-helix is estimated at 57% and the percentage of 3_{10}-helix is estimated at 73%. [g] This peptide probably forms a mixture of α-helical, 3_{10}-helical and coil structures. The percentage of α-helix is estimated at 54% and the percentage of 3_{10}-helix is estimated at 70%.

the CD spectrum of **Sb-10** has strong 3_{10}-helical character (71% 3_{10}-helicity). The transition of **Sb-10** from an α-helix to a 3_{10}-helix as the solvent dielectric is decreased agrees with the theoretical calculations of the solvent effects on the 3_{10}/α-helix equilibrium.[14] Marshall's calculations predict Aib-rich peptides should favor the α-helix in water and the 3_{10}-helix in less polar media.[14]

The percent 3_{10}-helicity of **Sb-10** is estimated to be higher than that of **Ipi-10** (71 *vs.* 45%[5]) suggesting that the two salt bridges significantly stabilize the 3_{10}-helical conformation. The CD spectral changes upon titration of **Sb-10** with an organic solution (9:1 MeCN–TFE) of tetramethylammonium trifluoroacetate¶ (TMAT, 0.0 to 0.1 M) are consistent with side-chain ionic interactions stabilizing 3_{10}-helical conformation. **Sb-10** makes a transition from a 3_{10}-helix to a partial α-helical structure as the TMAT concentration is increased. The decreasing 3_{10}-helix stability of **Sb-10** as the salt concentration is increased parallels what has been observed for α-helical peptides stabilized by side chain ionic interactions.[9a]

Ipi-10 and **Sb-10** have the same number of residues, the same percentage of ααAAs, and the same amphipathic design. The α-helix forming propensities of lysine and glutamic acid are similar[15] so the additional 3_{10}-helicity of **Sb-10** compared to **Ipi-10** must result from side-chain interactions. The decreasing stability of the 3_{10}-helical conformation of **Sb-10** as salt concentration is increased also supports the idea that *i*, *i* + 3 salt bridging or ion pairing stabilize 3_{10}-helices.

Barkley and M. L. M). M. G. B. was an undergraduate researcher supported by a grant to the Louisiana State University, College of Basic Sciences, from the Howard Hughes Medical Institute.

Notes and References

† E-mail: chammer@chrs1.chem.lsu.edu

‡ This intrepetation of ratio (*R*) of the n→π* and π→π* bands of the CD spectrum has been disputed by Andersen *et al.* (N. H. Andersen, Z. Liu and K. S. Prickett, *FEBS Lett.*, 1996, **399**, 47). Their study used much longer peptides (22 residues) containing low percentages (1/22–5/22) of Aib, which can form highly amphipathic α-helices (but not amphipathic 3_{10}-helices). They find that comparison of NMR (NOE) and CD evidence suggests that these peptides are a mixture of α-helix, 3_{10}-helix (in one case) and random coil. When the CD was corrected for 'disordered' residues, a peptide containing 5/22 Aib residues had $R > 1$, which they argue goes against the findings of Toniolo (ref. 13). We are confident in the case of **Ipi-10** and **Sb-10** that $R \sim 0.4$ reflects a 3_{10}-helix and not some contribution from a random coil spectrum as the CD of **Ipi-10** and **Sb-10** in water or phosphate buffer are essentially baseline ($-[\theta]_{\pi\rightarrow\pi^*} < 50$). This is apparently due to a very weak random coil ('disordered') spectrum of these peptides resulting from the lack of stereogenic amino acids (only 2 L-Lys or 2 L-Glu resides).

§ **Sb-10** shows no concentration dependence of the CD spectrum in 9:1 MeCN–TFE over a 10-fold concentration range (0.02–0.3 mM): $[\theta]_{\pi\rightarrow\pi^*} = -15\ 000 \pm 750$; $R = 0.42 \pm 0.02$. This suggests that **Sb-10** is monomeric under these conditions.

¶ A highly organic-soluble salt, such as TMAT, is required for titration of the **Sb-10** side-chains because strong 3_{10}-helix character is only present in 100 % organic media.

Consecutive catalytic hydroformylation-acetalization of glucal derivatives with rhodium–phosphite and pyridinium toluene-*p*-sulfonate as catalysts: the influence of protecting groups.

[b] *Departament de Química, Universitat de Girona, Girona, Spain*

Consecutive catalytic hydroformylation-acetalization of unsaturated carbohydrates (glucals) to give the dimethyl acetal of 2-*C*-formyl-D-alditol derivatives using the catalytic system [Rh(μ-OMe)(cod)]$_2$/P(O-*o*-Bu^{t}C$_6$H$_4$)$_3$/PPTS is strongly dependent on the protecting groups on the carbohydrate.

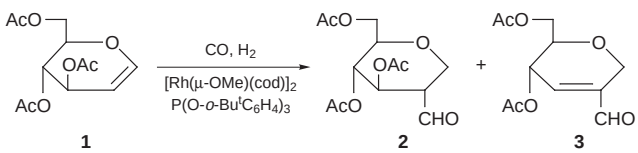
Sequential reactions have emerged as a direct and economic synthesis procedure, because different reactions can be carried out without isolating any intermediates, which means greater economy in solvents and purification.[1] The most popular sequential reactions are the so-called domino[2] (cascade) or tandem[3] reactions, in which several bonds are formed through different intermediates. In the consecutive 'one-flask' reactions, the product of one reaction is the starting material for a second reaction that occurs in the same flask. Although many examples of this methodology have been published, there are few examples of catalytic consecutive reactions which require different catalysts.[1–3]

We have already reported the synthesis of acetals from alkenes by means of a consecutive hydroformylation-acetalization process with rhodium–phosphine and pyridinium toluene-*p*-sulfonate (PPTS) as hydroformylation and acetalization catalysts respectively.[4] Since the catalyst for the hydroformylation process requires the presence of basic phosphine ligands, and the acetalization reaction requires an acid catalyst, the main goal of that process was to find two compatible catalytic systems. The solution was to use phosphonium or pyridinium salts in the presence of phosphine.

Here we show that the consecutive hydroformylation-acetalization of unsaturated carbohydrates (glucals) using rhodium complexes and PPTS as catalysts, respectively, is strongly dependent on the protecting groups in the carbohydrate.

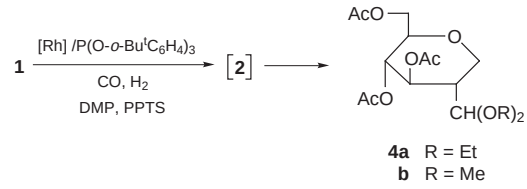
We have previously reported[5,6] the hydroformylation of 3,4,6-tri-*O*-acetyl-D-glucal **1** using the [Rh(μ-OMe)(cod)]$_2$/P(O-*o*-Bu^{t}C$_6$H$_4$)$_3$[7] catalytic system to give a mixture of aldehydes which are the result of introducing the formyl group at position 2 of the sugar ring (Scheme 1). The low selectivity was due to the elimination of AcOH from **2** to give an α,β-unsaturated aldehyde **3**, under the drastic reaction conditions required. In order to prevent this elimination we intend to convert *in situ* the aldehyde function formed in the hydroformylation reaction into the acetal function (Scheme 2). Moreover, this will enable us to deprotect and transform the hydroxy groups and then to take advantage of the reactivity of the acetal or aldehyde function.

Thus, the hydroformylation of **1** was carried out with the catalytic system [Rh(μ-OMe)(cod)]$_2$/P(O-*o*-Bu^{t}C$_6$H$_4$)$_3$, under



1 **2** **3**

Scheme 1



4a R = Et
b R = Me

Scheme 2

standard hydroformylation conditions (50 bar, 100 °C, CH_2Cl_2).[5,6] A mixture of aldehydes **2** and **3** was principally obtained (Table 1, entry 1). When the reaction was performed in $CH(EtO)_3$ under the same reaction conditions, the main compounds obtained were **2** and **3** together with small amounts of several hydroformylation-acetalization products such as the acetal **4a** (entry 2). Adding 60 mg of PPTS per 5 mmol of substrate to the reaction mixture gave a complex mixture, in which the hydroformylation-acetalization product **4a** was predominant, but the aldehydes had not completely disappeared (entry 3). By increasing the amount of PPTS, higher percentages of diethyl acetal **4a** were obtained, although conversion was low (entry 4). When the solvent was $CH(OMe)_3$ conversion decreased, although the selectivity in the dimethoxy derivative **4b**‡ was similar (entry 5). The use of 2,2-dimethoxypropane, another useful reagent for acetal formation, as the solvent did not allow the acetal to form and the elimination product **3** was obtained instead (entry 6). Interestingly, when PPTS was added, acetal **4b** was principally obtained in 66% yield (entry 7). Small quantities of the less reactive α,β-unsaturated aldehyde **3** remained in the mixture.

In the presence of PPTS the acetalization reaction is faster than the elimination of AcOH from **2** to give **3**. Moreover, it is interesting to note that there were fewer secondary reaction products, such as isomeric aldehydes (< 10%) and hydrogenation (< 10%) products, under these slightly acid conditions.

Table 1 Hydroformylation-acetalization of 3,4,6-tri-*O*-acetyl-D-glucal **1** with the catalytic system [Rh(μ-OMe)(cod)]$_2$/P-(O-*o*-Bu^{t}C$_6$H$_4$)$_3$/PPTS[a]

Entry	PPTS/mg	Solvent	Conversion (%)[b]	Products (%)[c] **2**	**3**	**4a**	**4b**
1	—	$Cl_2C_2H_4$	90	54	22	—	—

5 $R^1 = CH_3$, R^2 = Ac	**8** $R^1 = CH_3$, R^2 = Ac	65
6 $R^1 = CH_2OPiv$, R^2 = Piv	**9** $R^1 = CH_2OPiv$, R^2 = Piv	56
7 $R^1 = CH_2OBz$, R^2 = Bz	**10** $R^1 = CH_2OBz$, R^2 = Bz	42
		85
11	**12**	

[a] Standard conditions: glucal (5 mmol), $[Rh(\mu\text{-OMe})(cod)]_2$ (0.05 mmol), $P(O\text{-}o\text{-Bu}^tC_6H_4)_3$ (0.5 mmol), PPTS (0.25mmol), solvent (15 ml), 100 °C, 50 bar, CO/H_2 = 1, 48 h. [b] Isolated yield.

The glucal **5** reacted in similar hydroformylation-acetalization conditions to give the acetal **8** in a 65% yield (Table 2).

When the hydroxy groups in the carbohydrates were protected with other acyl derivatives such as pivaloyl (**6**) or benzoyl (**7**), the hydroformylation-acetalization products **9** and **10** were also obtained as the main products although in lower yields. This was probably because the steric hindrance of these bulkier groups decreases the rate of hydroformylation.

Unexpectedly, benzyl protected glycal **11** gave only the methyl α-glycoside **12** under the hydroformylation-acetalization conditions. As a result, both the rhodium complex and the acidic proton compete to attack the double bond so that when the protecting groups in the hydroxy groups are acyls, the double bond is deactivated. Therefore, the electrophilic attack cannot take place and rhodium coordination is preferred. However, when hydroxy groups are converted to ethers (*e.g.* the benzyl derivative **11**) the double bond is relatively activated and the attack of the acidic proton is faster. The fact that the reactivity of the double bond in the glucal depends on the protecting group can be rationalised as an 'armed-disarmed' effect.[8] This effect has been successfully used in disaccharide synthesis with glycals as glycosyl donors,[9] but to the best of our knowledge this is the first example of this effect being observed in competitive catalytic reactions.

In conclusion, the catalytic system $[Rh(\mu\text{-OMe})(cod)]_2/P(O\text{-}o\text{-Bu}^tC_6H_4)_3$ in the presence of PPTS allows the consecutive hydroformylation-acetalization reaction of glucals, depending on the protecting groups present in the carbohydrate ring. Thus, when hydroxy groups are protected as acyl derivatives the hydroformylation-acetalization leads to the dimethyl acetal of 2-*C*-formylalditol derivatives such as **4a**,**b**, **8**, **9** and **10**. However, when the protecting groups are benzyl, the methyl glycosides resulting from the addition of MeOH to the double bond of glucal are observed, but not the hydroformylation products.

Reactions of metalloalkynes.‡ The reaction of the ethyne-1,2-diyl complex, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}C{\equiv}C)]$, with $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$. An example of $\mu_3,\eta^1\text{-}C{\equiv}C$ coordination of a carbide ligand

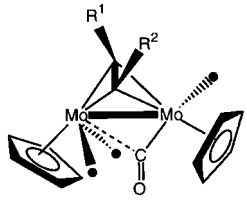
Christopher S. Griffith, George A. Koutsantonis,*† Brian W. Skelton and Allan H. White

Department of Chemistry, University of Western Australia, Nedlands, Perth, WA, Australia, 6907

Reaction of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}C{\equiv}C)]$ with $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$ gave $[MoRu_2(\mu_2\text{-}CO)_3[\mu_3\text{-}C{\equiv}C\{Ru(CO)_2(\eta\text{-}C_5H_5)\}](\eta\text{-}C_5H_5)_3]$ as the major product after chromatography and not the expected dimolybdenum 'alkynyl' adduct; this new complex contains a carbide (C_2) ligand bound, in triply bridging mode to the $MoRu_2$ triangle, through one carbon and the other in a monohapto fashion to the other ruthenium atom.

We are interested in the reactivity of metalloalkynes in so far as their reactivity is similar to that of simple organic alkynes.[1] The dimetalloalkynes, or ethyne-1,2-diyl complexes, are a special class of these complexes and their reactivity has been of particular interest to us.[2–14] Ethyne-1,2-diyl complexes contain the C_2 ligand which is often implicated in catalytic CO hydrogenation mechanisms. Multinuclear homo- and hetero-metallic complexes containing the C_2 molecule offer the opportunity to study and observe the reactivity of such species.[15]

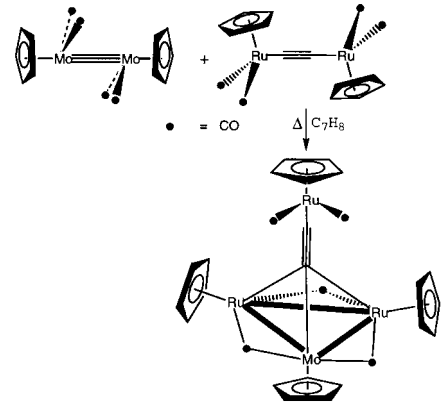
Herein we report the unexpected course of the reaction between $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$ **1** and the dimetalloalkyne, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)_2\}_2(\mu\text{-}C{\equiv}C)]$ **2**. We have recently found[16] that metalloalkynes of ruthenium and iron, *viz*. $[M(CO)_2(\eta\text{-}C_5H_5)(C{\equiv}CR)]$, react readily with complex **1**, giving, in the case of ruthenium, the expected 'alkyne' adduct **A**. The analogous



A: $R^1 = Ru(CO)_2(C_5H_5)$, R^2 = Me or Ph
B: R^1 = H; R^2 = Me or Ph
G: $R^1 = R^2 = Ru(CO)_2(C_5H_5)$

iron compounds underwent Fe–C bond cleavage, by a yet to be determined mechanism, and resulted in the formation of complexes **B** in their reaction with **1**. It is of note that the analogous reaction with an iron congener of **2**, *viz*. $[\{Fe(CO)_2(\eta\text{-}C_5Me_5)_2\}(\mu\text{-}C{\equiv}C)]$, resulted in carbonyl transfer to **1** to give $[Mo_2(CO)_6(\eta\text{-}C_5H_5)_2]$ with decomposition.[2b]

The reaction (Scheme 1)§ in refluxing toluene gave a mixture of products and some unreacted starting material that were readily separated using column chromatography. The major red–black fraction provided a good yield of $[MoRu_2(\mu\text{-}CO)_3[\mu_3\text{-}C{\equiv}C\{Ru(CO)_2(\eta\text{-}C_5H_5)\}](\eta\text{-}C_5H_5)_3]$ **3**, an electron deficient 45-electron cluster considering the $\mu_3,\eta^1\text{-}C{\equiv}C\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ unit as only a two-electron donor. The compound remarkably contains a μ_3-CC fragment bound to the $MoRu_2$ triangle and is, to our knowledge, the only example of this type of coordination to any metal cluster other than those of Cu[17] or Li.[18] Moreover, the bonding mode of the C_2 ligand observed here is also unique in so far as it is surrounded by metals but not 'buried'. The range of bonding modes so far observed for the interaction of four metals with a carbide ligand



Scheme 1

(Fig. 1) implicates the π system of the triple bond more fully in bonding in multi-metallic systems.

The ^{1}H NMR spectrum of **3** comprises two signals at δ 5.26 and 4.90 in a 1 : 3 ratio which are assigned to the Mo(η-C_5H_5) and Ru(η-C_5H_5) moieties, respectively. These signals remain unchanged in the temperature range 296–233 K. This implies that the Mo(η-C_5H_5) and Ru(η-C_5H_5) vertices are undergoing fluxional motion giving rise to an averaged signal for the three Ru(η-C_5H_5) vertices and a separate signal for the Mo(η-C_5H_5) vertex. This fluxionality is also reflected in the ^{13}C NMR spectrum of **3**. This contains two signals for cyclopentadienyl ligands and two signals are observed at δ 234.2 and 232.4 which are assigned to the terminal and bridging CO ligands. The signals observed at δ 308.4 and 87.2 are assigned to the μ_3-C and η^1-C of the carbide ligand, respectively.

These data and those reported in the footnote were insufficient to unequivocally assign the connectivity and as such a room-temperature single-crystal X-ray structure study¶ was undertaken. The structure determination is of limited utility given that the cell obtained in the tetragonal setting *P*4/*m* contains a pseudo-inversion centre, relating two independent molecules in the asymmetric unit, and with a crystallographic mirror plane coincident with the molecular symmetry plane in each of the independent molecules. In addition, the specimen obtained after many attempts was of marginal suitability for the experiment. However, the results are consistent with the

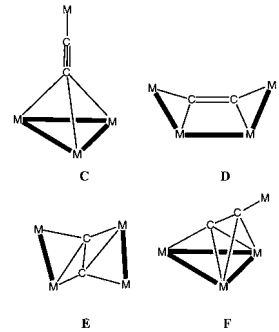


Fig. 1 Bonding modes for a carbide ligand bound to tetrametallic systems

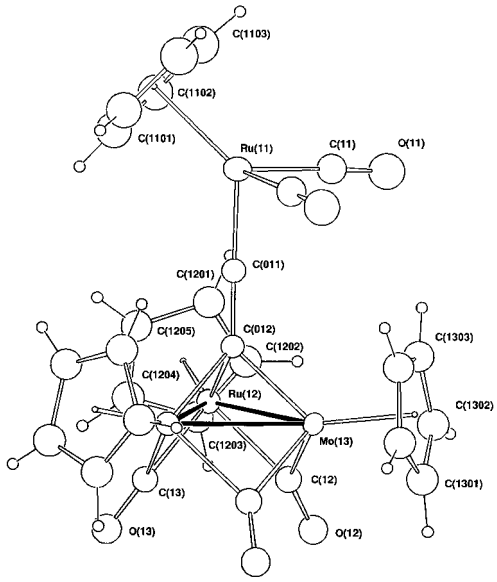

Fig. 2 Projection of one molecule of **3** approximately through the $MoRu_2$ plane. 20% thermal ellipsoids are shown for the metal atoms; other non-hydrogen atoms are shown as isotropic spheres; hydrogen atoms have arbitrary radii of 0.1 Å. Selected bond lengths (Å) and angles (°): Ru(*n*2)–Mo(*n*3) 2.701(2), 2.700(2); Ru(*n*2)–Ru(*n*2′) 2.704(2), 2.710(2); Ru(*n*1)–C(0*n*2) 2.01(1), 1.77(2); C(0*n*2)–C(0*n*1) 1.39(2), 1.46(3); Ru(*n*1)–C(0*n*1)–C(0*n*2) 179(1), 175(2); Ru(*n*2)–Mo(*n*3)–Ru(*n*2′) 60.09(6), 60.24(6); Mo(*n*3)–Ru(*n*2)–Ru(*n*2′) 59.96(4), 59.88(4) for the two molecules (molecule 1, $n = 1$; molecule 2, $n = 2$).

stoichiometry and connectivity as expressed in **3** and Fig. 2, albeit with interatomic parameters of a higher than desired uncertainty. The molecules are best considered as being composed of trinuclear heterometallic $MoRu_2$ triangles with each metal atom coordinated by a pentahapto cyclopentadienyl ligand which is essentially perpendicular to the plane of the triangle. The structure determination cannot rigorously exclude the possibility of scrambling of the molybdenum atom among other metal sites of the triangle in the solid. The metal cores are coordinated from 'above' by the μ_3,η^1-C≡C{$Ru(CO)_2(\eta$-$C_5H_5)$} unit which has its CC axis at right angles to the metal triangles with the μ_3-C symmetrically bridging to each of the metal core atoms. Three bridging carbonyls complete the coordination of the metal core and these are directed 'below' the plane of the core.

The formal electron count gives this substituted triangular cluster 45 cluster valence electrons (CVE) with each Ru atom achieving an 18-electron count and the Mo formally electron deficient with a 16-electron count. In the various bonding modes and their valence bond representations hitherto observed for the carbide ligand bound to four metals (Fig. 1)[19] the CC unit has a formal bond order of three in mode **C** while in mode **D** the bond order is two and in **E** and **F** it is one. Theoretical calculations[19] have been performed that rationalise the bonding observed for **D**–**F** and it is noteworthy that complex **3** (mode **C**) does not adopt mode **F** where the electron deficiency experienced by the Mo atom could be alleviated.

The mechanism operating in this reaction is unclear. However, it is likely that the CC bond of **2** interacts initially with the unsaturated metal–metal bond in **1** to give a structure similar to **G** which presumably undergoes fragmentation, evidenced by the isolation of $[Ru(CO)_2(\eta$-$C_5H_5)]_2$ from the reaction. The reason for this fragmentation is presumably steric.[16] It is possible that **G** undergoes homolytic cleavage of a $Ru(CO)_2(\eta$-$C_5H_5)$ group and that this is the source of the dimer isolated from the mixture; this, however, seems unlikely given the ultimate stoichiometry of the product.

Work is in progress to identify the minor products from the reaction in the hope that they will shed further light on the mechanism operating in this reaction.

We thank the Australian Research Council for supporting this work. C. S. G. is the holder of an Australian Postgraduate Award.

A mild, efficient and selective oxidation of sulfides to sulfoxides

José M. Fraile, José I. García, Beatriz Lázaro and José A. Mayoral*†

Departamento de Química Orgánica y Química Física, Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-C.S.I.C., E-50009 Zaragoza, Spain

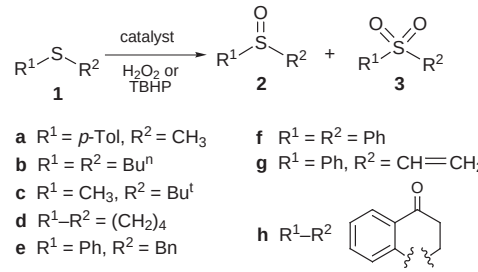
Several titanium derivatives supported on silica have been investigated as catalysts in the sulfide→sulfoxide oxidation; the supported titanium/tartaric acid catalyst is highly suited to reactions carried out with H_2O_2, leading to high yields and high sulfoxide/sulfone selectivities, while small asymmetric inductions (up to 13%) are observed.

The selective oxidation of sulfides to sulfoxides has been a challenge for many years, partly due to the importance of sulfoxides as intermediates in organic synthesis.[1] In recent years selective oxidation of sulfides to sulfoxides has been carried out with a large number of supported reagents.[2] Recently, the use of H_2O_2 has taken on a new importance due to environmental implications, however, a catalyst is necessary to activate this oxidant. TS-1[3,4] and TS-2,[5] promote sulfide oxidation, but the use of bulky sulfides is precluded by their limited access to the Ti active sites. In order to overcome this limitation other molecular sieves have been used.[3–6] Ti-MCM-41 allows the oxidation of bulky sulfides,[6] but with low sulfoxide/sulfone selectivity.

Following a methodology closely related to that used by Shell to prepare $TiCl_4$-modified silica,[7] we have treated silica with $Ti(OPr^i)_4$ and shown[8] that this solid is an efficient catalyst in the epoxidation of alkenes of any size with hydroperoxides. We considered it interesting to test these silica-supported titanium compounds as catalysts in the selective oxidation of sulfides to sulfoxides (Scheme 1).

Firstly we tested the silica treated with $Ti(OPr^i)_4$ (**cat-1**, Ti content: 1.02 mmol g^{-1}) as a catalyst in the oxidation of methyl *p*-tolyl sulfide with TBHP and with H_2O_2 (Table 1, entries 1–4). Although the oxidation is faster with TBHP, a better sulfoxide/sulfone selectivity is obtained with H_2O_2. The recovered catalysts show a similar activity, but the product selectivity increases, mainly in the reaction carried out with H_2O_2, which indicates that the recovered catalyst does not have the same structure. It seems logical that in the presence of a large excess of water (we use 30% H_2O_2), the isopropoxy groups are hydrolysed to hydroxy groups, and that this modification of the Ti environment influences the course of the reaction.

In view of these results we decided to assess the effect of the introduction of polar groups near the titanium and we treated the original catalyst with diethyl (*R*)-tartrate (Scheme 2) to obtain **cat-2** (1.06 mmol Ti g^{-1}). The modification of the catalyst was monitored by IR spectroscopy, which shows the appearance of a broad carbonyl band. The width of this band indicated the presence of several kinds of carbonyl groups, and Scheme 2 shows only one of the possibilities. The catalytic tests (Table 1, entries 4–7) show that the introduction of diethyl tartrate reduces the catalytic activity and increases the sulfoxide/sulfone



Scheme 1

Table 1 Results obtained in the oxidation of methyl *p*-tolyl sulfide **1a** promoted by different supported titanium catalysts[a]

				Yield (%)				
Entry	Catalyst	Sulfide	Oxidant	*t*/h	Total	sulfoxide **2**	sulfone **3**	**2**:**3**

selectivity in the reaction carried out with TBHP, while the catalytic performance is almost unchanged when H_2O_2 is used. The recovered catalyst gives an exceptional sulfoxide/sulfone selectivity (entry 7), which points to a new structure of the catalytic sites after recovery, as shown by the modification of the IR carbonyl band, which suggests the hydrolysis of the ester groups.

In view of this we decided to treat the initial catalyst with (*R*)-tartaric acid and to test the catalytic activity of this solid (**cat-3**, 0.82 mmol Ti g^{-1}). The results obtained with TBHP (entry 8) are very similar to those obtained using the catalyst containing diethyl (*R*)-tartrate (**cat-2**). However, the reactions carried out with H_2O_2 (entries 9 and 10) lead to an excellent sulfoxide/sulfone ratio and a very high selectivity (97%) with respect to the H_2O_2.

(*R*)-Tartaric acid is strongly adsorbed onto silica, thus it is important to assess the modification of the titanium centres and the catalytic role of these centres. The modification of the environment of titanium can be estimated from the amount of Pr^{i}OH lost during the preparation of the catalyst. Although it is not possible to obtain quantitative conclusions, given that some Pr^{i}OH may remain adsorbed on the silica surface, GC analysis shows that 65 ± 5% of the Pr^{i}O groups present in the original solid are lost during treatment. This result agrees with the modification of most of the titanium atoms. The catalytic role of the titanium was confirmed by adsorbing onto silica gel the same amount of (*R*)-tartaric acid used to modify the catalyst and carrying out the reaction in the presence of this solid. The results obtained are the same as those reached in the absence of catalyst, showing that the catalytic activity is related to the presence of titanium.

Although it was not the aim of the present work, the introduction of chiral centers may produce an asymmetric reaction, and so this possibility was considered. The ee of the sulfoxides was determined as previously described,[9] and the absolute configuration was determined by polarimetry.[10] The low ee obtained for the (*R*)-sulfoxide provides additional evidence for the modification of the catalytic centers.

Given that the catalyst obtained by treatment with (*R*)-tartaric acid (**cat-3**) leads to the best selectivity, we tested the effect of using a smaller amount of catalyst. Very good results were obtained, with a sulfide/titanium ratio = 140, by simply increasing the reaction time. In order to test the general scope of this method it was applied to several other sulfides (Scheme 1, Table 1, entries 12–19).

This solid promotes the reaction with a very small amount of catalyst and leads to high yields and selectivities. The methodology is applicable to bulky sulfides and is compatible with the presence of other oxidisable functions, as shown in the last two examples where epoxidation of the double bond (**1g**) or Baeyer–Villiger oxidation of the ketone (**1h**) were not observed.

As far as the mechanism is concerned, either the H_2O_2 may be the oxidation agent, *via* a Ti–OOH intermediate, or a supported peracid intermediate may be formed.

We tested the recovery of the catalyst in the oxidation of dibutyl sulfide **1b** (Table 2). A gradual leaching of titanium takes place. However, this leaching is very slow given that after five reactions each mmol of titanium has been treated with about 5000 mmol of water. Furthermore, even the fifth reaction takes place with reasonable yield and selectivity. The existence of leaching suggests that the reaction can take place, at least in part, in the homogeneous phase. In order to clarify this point we treated **cat-3** with H_2O_2 for 4 h. The solid was separated by filtration and the filtrate used in the oxidation of a corresponding amount of sulfide **1a**. The filtrate promotes the reaction with a 83:17 sulfoxide/sulfone ratio. In another experiment we carried out the reaction of **1a** until 85% conversion (15 min), then the catalyst was separated by filtration and both the solid and the filtrate were used in a new reaction. The sulfide was consumed in both reactions at almost the same rate.

Table 2 Recovery of the catalyst in the oxidation of **1b** with H_2O_2 promoted by **cat-3**

5	9	91	82	9	—
6	—	—	—	—	0.22

[a] Determined by plasma emission spectroscopy.

In our opinion these results indicate the co-existence of the homogeneous and heterogeneous reactions and that a very active homogeneous catalyst is obtained under these conditions. Therefore, it seems that the identification of the homogeneous species and the improvement of the behaviour of the heterogeneous system against leaching are important aims.

These results clearly show that modification of the environment of titanium *via* introduction of organic molecules can modify the performance of the catalysts. This strategy opens the way to the preparation of new families of supported chiral catalysts in which grafting is carried out through the metal instead of through the chiral auxiliary.

This work was made possible by the generous financial support of the C.I.C.Y.T. (Project MAT96-1053).

A novel cyclic formal, 1,3,5,7-tetraoxacyclononane, from the direct reaction of 1,3,5-trioxane and ethylene oxide

J. Masamoto,*[a]† N. Yamasaki,[a] W. Sakai,[a] T. Itoh,[a] N. Tsutsumi[a] and H. Nagahara[b]

[a] *Kyoto Institute of Technology, Matsugasaki, Sakyo, Kyoto 606-8585, Japan*
[b] *Asahi Chemical Industry Co., Ltd. Kojimashionasu, Kurashiki 711-8510, Japan*

A new reaction between 1,3,5-trioxane and ethylene oxide has been observed and a novel cyclic formal, which is the reaction product of 1 equiv. of 1,3,5-trioxane and 1 equiv. of ethylene oxide, has been isolated and identified.

Weissermel and co-workers[1,2] proposed the reaction of formaldehyde with ethylene oxide to form 1,3-dioxolane as the initiation mechanism of the copolymerization of 1,3,5-trioxane and ethylene oxide. Collins *et al.*[3] confirmed that ethylene oxide was converted to 1,3-dioxolane and then from 1,3-dioxolane, 1,3,5-trioxepane was formed. They stated that the direct reaction of ethylene oxide with 1,3,5-trioxane was impossible because of the weak basicity of 1,3,5-trioxane. Weissermel and co-workers[1,2] and Collins *et al.*[3] proposed the formation mechanism of 1,3-dioxolane from ethylene oxide and formaldehyde, and for a long time this was thought plausible for the initiation mechanism of copolymerization of trioxane and ethylene oxide.

We have performed the direct reaction of ethylene oxide with 1,3,5-trioxane, which was thought impossible for a long time, and isolated a novel cyclic formal. From this novel cyclic formal, 1,3,5-trioxepane was formed and then 1,3-dioxolane was also generated. This reaction identified the precise initiation mechanism of the copolymerization of 1,3,5-trioxane and ethylene oxide.

Purified 1,3,5-trioxane (30 g) was melted under an N_2 atmosphere in a glass vessel immersed in an oil bath and held at 70 °C. Gaseous ethylene oxide (4.5 mol% with respect to 1,3,5-trioxane) was introduced into the molten 1,3,5-trioxane which was stirred with a magnetic mixer. A cyclohexane solution of $BF_3{\cdot}OBu_2$ (7×10^{-3} mol% with respect to 1,3,5-trioxane) was introduced into the molten mixture of 1,3,5-trioxane and ethylene oxide through the cap of the glass vessel with a microsyringe. The mixture was stirred using a magnetic mixer in an oil bath to maintain the reaction temperature at 70 °C. The reaction mixture was sampled with a syringe and then poured into PrOH containing a small amount of KOH. The reaction mixture was analyzed by gas chromatography. This showed a 33% yield of the novel compound based on the initial amount of ethylene oxide.

The novel compound was separated using a micro-distillation apparatus (bp 180 °C at 1 atm; mp 8.4 °C and bp 95 °C at 25 torr). Its chemical structure was confirmed using ^{1}H NMR, ^{13}C NMR and mass spectral and elemental analysis.

Fig. 1 shows the ^{1}H NMR pattern of the new compound. The ratio of H^a (proton of formal linkage, δ 5.05) to H^b (proton of formal linkage, δ 4.93) and H^c (proton of ether linkage, δ 3.85) is 1:2:2. Fig. 2 shows the ^{13}C NMR pattern of the new compound, and shows three different types of carbon: C^a (formal carbon, δ 96.9), C^b (formal carbon, δ 97.1) and C^c (ether carbon, δ 70.5). Fig. 3 shows the EI mass spectrum of the new compound, which shows the molecular weight of 134 and composition formula of $C_5H_{10}O_4$, which is in accordance with the molecular weight and composition formula of 1,3,5,7-tetraoxacyclononane (TOCN). The observed elemental analyses are in accordance with the theoretical values (Found: C, 44.76; H, 7.75. Calc.: C, 44.78; H, 7.50%).

The reaction concentration profile is shown in Fig. 4. The profile begins when the initiator (a cyclohexane solution of $BF_3{\cdot}OBu_2$) is injected into the molten mixture of 1,3,5-trioxane and ethylene oxide. At first, as the ethylene oxide concentration (4.5 mol% with respect to 1,3,5-trioxane) decreases, the TOCN concentration increases proportionally. Later, as the TOCN

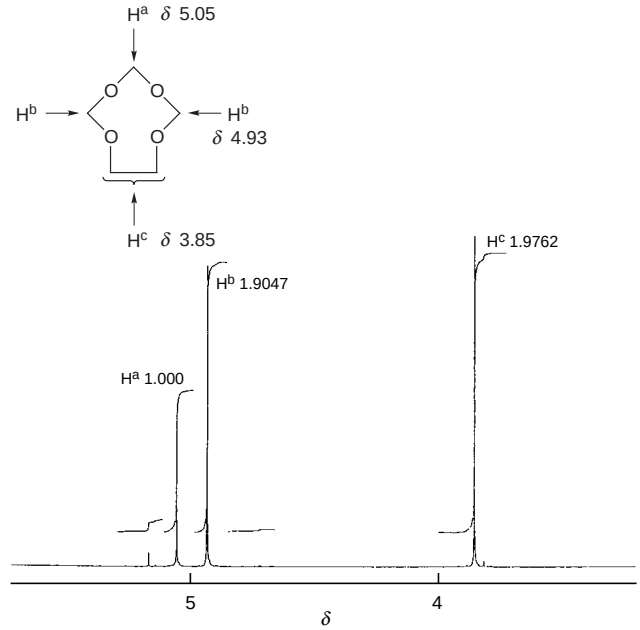

Fig. 1 ^{1}H NMR spectrum of the new compound

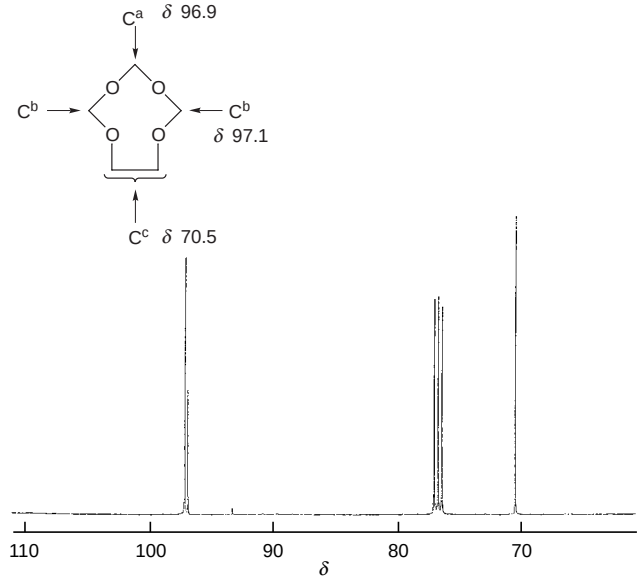

Fig. 2 ^{13}C NMR spectrum of the new compound

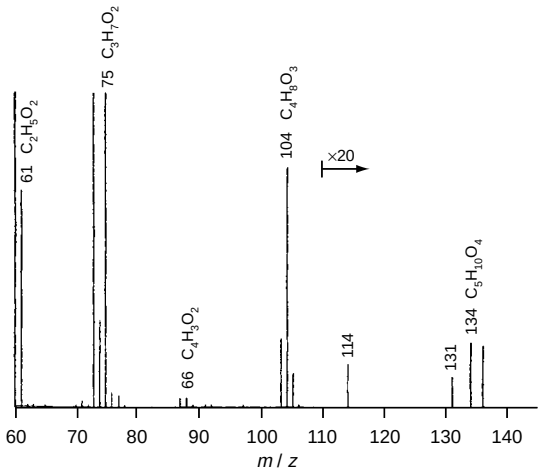

Fig. 3 EI mass spectrum of the new compound

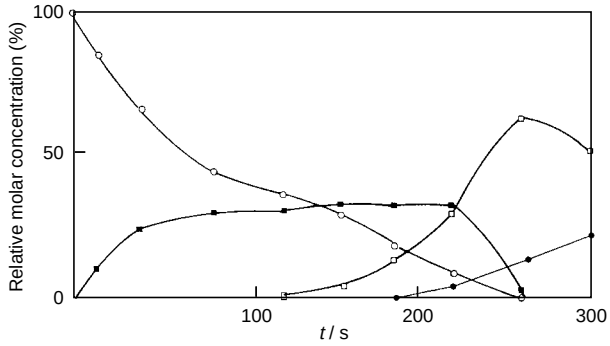

Fig. 4 Profile of reaction of 1,3,5-trioxane and ethylene oxide: (○) ethylene oxide, (■) 1,3,5,7-tetraoxacyclononane, (□) 1,3,5-trioxepane, (●) 1,3-dioxolane. $[EO]_0$ = 4.5 mol% with respect to 1,3,5-trioxane. t = 0 indicates the time at which the initiator is injected into the molten mixture of 1,3,5-trioxane and ethylene oxide. Percentage on the vertical axis indicates the relative molar concentration of ethylene oxide or related compounds to the initial concentration of ethylene oxide.

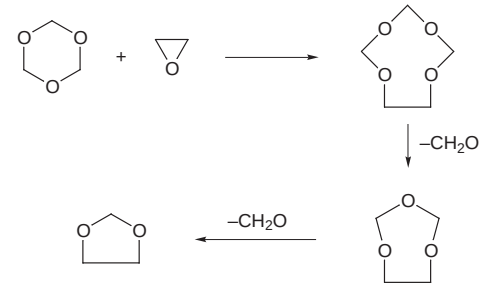
concentration decreases again, the concentration of 1,3,5-trioxepane increases. Soon after the appearance of 1,3,5-trioxepane, 1,3-dioxolane appeares, and with the decrease in concentration of 1,3,5-trioxepane, the concentration of 1,3-dioxolane increases.

Although the equilibrium concentration of 1,3,5-trioxepane and 1,3-dioxolane exist, there is no equilibrium concentration of TOCN. This might be attributed to the higher ring strain energy



Scheme 1

of the nine-membered ring compound of TOCN compared to those of the seven- and five-membered ring compounds. In the case of the cycloalkane, the ring strain energy of the nine-membered ring compound is 27 kJ mol^{-1} higher compared to those of the seven- and five-membered ring compounds.[4]

The newly isolated intermediate, the novel cyclic compound TOCN, identifies a new direct reaction between 1,3,5-trioxane and ethylene oxide, as well as the precise initiation mechanism of the copolymerization of 1,3,5-trioxane and ethylene oxide. First, ethylene oxide directly reacts with 1,3,5-trioxane to produce TOCN (Scheme 1). The 1,3,5-trioxepane is then formed from TOCN, and 1,3-dioxolane is formed from 1,3,5-trioxepane.

Using gas chromatography, we observed compounds of higher molecular weights than TOCN as minor components, which were presumed to be the addition product of ethylene oxide and TOCN. Confirmation of this point will be discussed in the near future.

Enhanced catalytic activity of MCM-41-grafted aluminium isopropoxide in MPV reductions

R. Anwander,*[a]† C. Palm,[b] G. Gerstberger,[a] O. Groeger[b] and G. Engelhardt[b]

[a] *Anorganisch-chemisches Institut, Technische Universität München, Lichtenbergstr. 4, D-85747 Garching, Germany*
[b] *Institut für Technische Chemie I, Universität Stuttgart, Pfaffenwaldring 55, D-70569 Stuttgart, Germany*

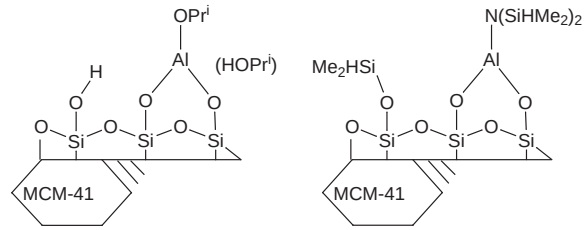
Aluminium alkoxide moieties are grafted onto purely siliceous mesoporous MCM-41 *via* siloxide linkages, producing materials which reveal enhanced catalytic activity in the MPV reduction of cyclic ketones; nitrogen physisorption and ^{27}Al MAS NMR spectroscopy are applied to characterise the catalytically active hybrid systems.

The potential of aluminium reagents, in particular 'Al(OPr^i)$_3$', in Meerwein–Ponndorf–Verley (MPV) reductions and Oppenauer oxidations is well documented.[1,2] Although these transformations formally proceed catalytically, an excess of the aluminium compound is commonly required.[3] Heterogeneously performed MPVO reactions utilising, for example, oxidic or zeolitic materials have also been reported to cope better with catalyst separation.[4,5] Recently, we and others envisaged the mesoporous silicate MCM-41 as a versatile support material for metalorganic moieties.[6,7] As part of this program, we present our preliminary findings on the catalytic MPV reduction of 4-*tert*-butylcyclohexanone mediated by grafted aluminium alkoxide species, including a detailed ^{27}Al MAS NMR study.

MCM-41-supported aluminium isopropoxide **2** was initially prepared according to a one-step solution impregnation by contacting Al(OPr^i)$_3$ and MCM-41 **1** in *n*-hexane.‡,§[8,9]

Assuming a monofunctional surface reaction, a ligand/metal ratio of *ca*. 2.0 can be derived for material **2** from elemental analysis (Table 1). Furthermore, an aluminium surface coverage of *ca*. 1.3 Al nm^{-2} can be calculated from the metal content and the BET surface area of material **1** (1059 m^2 g^{-1}). A considerable amount of unreacted isolated silanol groups is still present after the grafting procedure as indicated by the ν(OH) vibration mode at 3695 cm^{-1} in the IR spectrum. Al(OPr^i)$_3$ immobilisation in the mesopores of material **1** drastically decreases the pore volume and pore diameter as revealed by nitrogen physisorption (Table 1). However, the obtained adsorption/desorption isotherm is still of type IV.

We found that careful drying of the solvent isopropanol (= reductant) significantly increased the catalytic activity of Al(OPr^i)$_3$ in this MPV reduction (Table 2, run 1 *vs.* 2). In contrast, material **2** exhibits dramatically enhanced catalytic activity, producing 86% of the 4-*tert*-butyl cyclohexanol isomers after 5 h even at ambient temperature (run 5). At 80 °C material **2** afforded almost quantitative conversion after 30 min (run 6).¶[10] Hybrid material **2** could easily be separated from the reaction mixture of run 5 by centrifugation. After washing with HOPr^i the catalytic activity of the recovered solid material (**2b**) remained unchanged (run 7). The combined HOPr^i fractions showed no further activity upon addition of new substrate. We also found no catalytic activity for parent material **1** (run 3).



For comparison, recent studies by others revealed that H-MCM-41 and Na-MCM-41 (Si/Al = 15, activation temperature 450 °C) gave only 10% conversion of 4-*tert*-butylcyclohexanone after 6 h at 80 °C.[4] A zirconium hybrid system obtained according to the synthesis sequence: silica + Zr(CH$_2$Bu^t)$_4$ + HOPr^i, showed 75% conversion of cyclohexanone after 20 h at 80 °C.[5]

The efficiency of the MPV reduction is known to depend on the Lewis acidity of the metal center and the ligand exchange ability.[1,2] These factors are markedly affected by the type of (co-)ligand and co-ordination geometry at the metal center. In order to gain further insight into the co-ordination geometry of the catalytically active species, a detailed ^{27}Al MAS NMR study was performed. The ^{27}Al MAS NMR spectrum of Al(OPr^i)$_3$ shows a sharp resonance at 0 ppm typical of octahedral aluminium, accompanied by weak and broad signals

[a] Conditions: 25 g HOPr^i, 0.1 g *n*-nonane, 0.78 g ketone, *ca.* 5 mol% of precatalyst, 25 °C (mol% = 100 $n_{aluminium}/n_{substrate}$). [b] HOPr^i not predried. [c] 0.20 g mesoporous material. [d] 0.20 g SiMe$_3$-silylated material. [e] 80 °C.

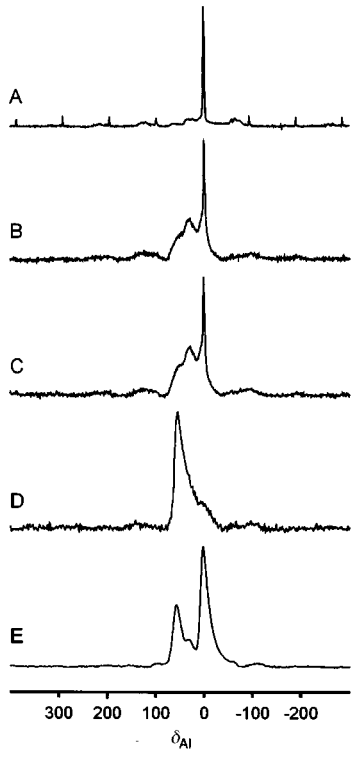

Fig. 1 ^{27}Al NMR spectra: (A) Al(OPr^i)$_3$ as received from Aldrich; (B) material **2**; (C) recovered material **2a**; (D) material **4**; (E) material **2** exposed to air for several days (completely hydrolysed); all hybrid materials were evacuated for 5 h at 25 °C, 10^{-2} Torr prior to measurement

at about 60 and 30 ppm attributable to distorted 4- and 5-co-ordinated aluminium (Fig. 1A).‖[11] In contrast, the spectrum of hybrid material **2** (Fig. 1B) exhibits, besides the sharp resonance at 0 ppm (15%), an intense broad signal pattern in the range of 75 to −25 ppm, clearly indicating the formation of additional aluminium sites. Deconvolution by computer simulation (Bruker WINFIT) yields a Gaussian line at 54 ppm (25%) of regular tetrahedral aluminium sites, and a quadrupolar line shape (δ_{iso} = 49, QCC = 7.5 MHz, 60%), typical of heavily distorted 4-co-ordinated aluminium.[12] Interestingly, this signal pattern did not change after the first catalytic run (material **2a**, Fig. 1C), proving the preservation of the lower-co-ordinated, surface constrained and hence stronger Lewis acidic aluminium centres which are proposed to contribute to the enhanced catalytic activity of material **2**. This is in accord with a previous kinetic study.[13] where the 'melt' form of Al(OPr^i)$_3$ which consists of the predominantly trimeric form with 4- and 5-co-ordinated aluminium centres was found to be 10^3 times more reactive in MPV reductions than the tetrameric form containing 4- and 6-co-ordinated aluminium.

This finding could be corroborated by applying a synthetic approach which exclusively produces lower-co-ordinated aluminium surface species. Novel 4-co-ordinate Al[N(SiHMe$_2$)$_2$]$_3$·thf was reacted with material **1** to yield material **3** *via* a siloxide formation/silylation sequence (*ca.* 0.5 Al nm^{-2}).**[6] Subsequent treatment of hybrid material **3** with a slight excess of HOPr^i afforded material **4** (Table 1). The pore texture of material **4** is roughly comparable to that of material **2**, supporting a disruption of the tetrameric form of Al(OPr^i)$_3$ upon grafting. The ^{27}Al MAS NMR spectrum of material **3** revealed poor signal intensity (not shown in Fig. 1), probably due to the formation of surface-docked alumoxo-silylamide sites in highly distorted co-ordination environments.[14] Upon silylamide/HOPr^i ligand exchange the co-ordination geometry at the aluminium center is markedly relaxed. The resulting ^{27}Al MAS NMR spectrum now features a broad, asymmetric signal with a maximum at 55 ppm, indicating the presence of predominantly 4- and 5-co-ordinated aluminium species (Fig. 1D). Material **4** displayed catalytic activity comparable to that of material **2** (run 8). Although silylated **1** was shown to be catalytically inactive (run 4), the partly silylated surface of material **4** may affect its catalytic performance by hydrophobicity effects.[15] Spectrum E in Fig. 1 shows the ^{27}Al resonances of a completely hydrolysed sample of material **2**. The three overlapping signals of tetrahedral (58 ppm), 5-co-ordinated (34 ppm) and octahedral (0 ppm) aluminium sites are now clearly visible.

We have shown that MCM-41-grafted aluminium isopropoxide is an efficient catalyst in the MPV reduction of 4-*tert*-butylcyclohexanone. A detailed ^{27}Al MAS NMR study revealed that the enhanced catalytic activity can be ascribed to the formation of low-co-ordinated (4-, 5-), geometrically distorted aluminium species. Surface confinement prevents the aluminium alkoxide moieties from self-association, while the silicate material simultaneously acts as an electron-withdrawing matrix.

We thank the Deutsche Forschungsgemeinschaft for generous support.

‡ All manipulations were performed in a nitrogen-filled glovebox (MB Braun MB150B-G-II) as described elsewhere.[6] Purely siliceous MCM-41 was prepared according to the literature and dehydrated at 280 °C, 10^{-5} Torr prior to use. All of the resulting hybrid materials were synthesized in *n*-hexane at ambient temperature in 24 h and subsequently washed several times with *n*-hexane to remove unreacted educt compounds.

§ A similar post-synthetic aluminium incorporation was recently applied to produce mesoporous aluminosilicates.[9]

¶ Although it was shown earlier that addition of Al(OPr^i)$_3$ to alumina significantly enhanced its catalytic activity at 80 °C, this phenomenon was not further explained.[10]

‖ The solution spectrum of Al[(μ-OPr^i)$_2$Al(OPr^i)$_3$]$_3$ in toluene at 25 °C gives a similar spectrum with the very broad signal of the 4-co-ordinated Al disappearing into the base line.[11]

** The formation of both surface bonded metal silylamide '[μSiO]$_x$–Al[N(SiHMe$_2$)$_2$]$_y$' [ν(SiH) = 2102 cm^{-1}], silylated species '≡SiO–SiHMe$_2$' [ν(SiH) = 2151 cm^{-1}] and the consumption of all surface silanol groups was revealed by FTIR spectroscopy.

New paradigms in cycloaddition face-selectivities: remarkable effect of remote substituents in singlet oxygen addition to hexacyclo[7.5.1.0^{1,6}.0^{6,13}.0^{8,12}.0^{10,14}]pentadeca-2,4-diene system

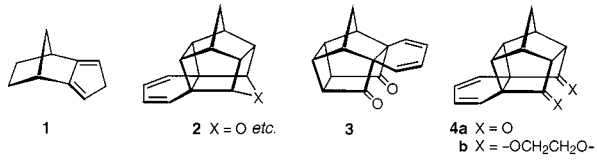
Different modes of direct through-space interactions between remote substituents and an approaching reagent are indicated as important additional controlling factors of face selectivity in singlet oxygen cycloaddition to facially differentiated cyclohexa-1,3-dienes.

Evaluation of stereoelectronic effects that influence π-face selection and control diastereoselectivity in [4+2]-cycloadditions to cyclic dienes continues to be an area of intense scrutiny and new explorations.[1] In this context, substrates in which the 1,3-diene moiety is grafted on to a rigid polycyclic frame to eliminate conformational ambiguities are particularly advantageous, as the facial discrimination and stereoelectronic perturbations can be effected through distal modulation of functionalities.[2,3] In recent years, several polycyclic systems **1**–**4** embodying a cyclic 1,3-diene substructure have been devised and probed for diastereoselection employing a variety of dienophiles, but among these, **4** has been more enduring[3] because of its rigidity, ready accessibility,[4] reactivity and functional group manoeuvrability. In the hexacyclic diene **4**, facial discrimination in the cyclohexadiene moiety is manifested through the interplay of the steric effects of cyclobutyl hydrogens and the electronic interactions of the carbonyl groups. The diastereoselectivities observed in cycloadditions to several derivatives of **4** (obtained through substitutions on the diene moiety as well as modifications of the carbonyl group) have led to the identification of steric effects, filled orbital and electrostatic repulsions, the Cieplak effect and transition state geometrical distortions as the main determinants of face-selectivity.[3] We have now observed that even the simplest derivatisation can lead to a reversal in diastereoselectivity which we interpret in terms of transition state interactions, some of which have not been recognised before as contributors to face selectivity. These subtle effects, though promoted in the present case by the geometry of the hexacyclic system **4** and the relative spatial orientation of the diene unit and the remote functionality, can be operative in other substrates as well and in the absence of other dominant effects, can be the principal determinants of face selectivity; *inter alia* caution must be exercised in extrapolating stereoselectivities, even when seemingly inconsequential functional group changes are effected at distal sites.

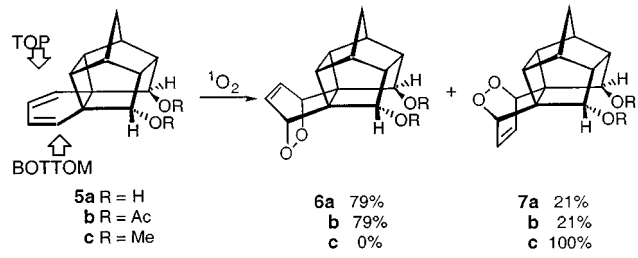


The hexacyclic *endo,endo*-diol **5a**, its diacetate **5b** and dimethyl ether **5c** readily underwent cycloaddition with $^1O_2$ generated in the presence of Methylene Blue (500 W tungsten lamp, O_2, $CHCl_3$, 5–10 °C, 4–5 h) to furnish a diastereomeric mixture of endoperoxides **6a–c** and **7a–c** in 80–85% yield.[5] While the gross structures of both the 'bottom' and 'top' addition endoperoxides **6a**–**c** and **7a**–**c**, respectively, were apparent from the spectral characteristics (^{1}H and ^{13}C NMR), their stereochemistry was unambiguously determined *via* X-ray crystal structure determination‡ of the major endoperoxides **6b** and **7c**. The diastereoselectivities observed in the $^1O_2$ additions (Scheme 1) indicated that while in the *endo,endo*-diol **5a** and diacetate **5b** 'bottom' face addition was preferred, complete reversal occurred in the case of the dimethyl ether **5c** and the 'top' addition product was exclusively obtained. The expectation from earlier studies and interpretations[3] with substrates such as **4b** was that repulsion between *endo*-directed oxygens in **5a**–**c** and the $^1O_2$ reagent should uniformly favour addition from the 'top' face. While the observed selectivity in **5c** was fully in consonance with this reasoning, the unpredicted outcome of diastereoselectivities in the case of **5a,b** suggested intervention of some additional, unrecognized interactions and these needed to be probed through transition state modelling.

The origin of the variations in face selectivities in **5a**–**c** was examined through AM1 calculations[6] on $^1O_2$ addition transition states. Saddle points with vanishing gradients and characterized by a single imaginary vibrational frequency were located for the top and bottom face addition. The possibility of conformational variation in the OR groups was considered by using different initial geometries.

For the methoxy derivative **5c**, two sets of transition structures are obtained, both favoring the top face attack by varying degrees. While the energy preference is marginal (0.2 kJ mol^{-1}) in the structures in which the methyl groups are pointed towards the diene moiety, a strong bias (10.3 kJ mol^{-1}) is predicted when the methyl groups are oriented away from the diene. In the latter, repulsive interactions involving the oxygen lone pairs towards the approaching $^1O_2$ evidently come into play [Fig. 1(*a*)]. Hence the exclusive formation of the top face adduct in **5c** is entirely consistent with electrostatic control of face selection.

For the $^1O_2$ addition to the dihydroxy derivative **5a**, a significant bottom face preference (7.9 kJ mol^{-1}) is computed, qualitatively in accord with the experimental trend. The transition structures for both the top and bottom face approach lack any symmetry (C_1) due to an intramolecular O–H···O hydrogen bond. In the bottom face attack saddle point, an additional hydrogen bonding interaction is evident. The second OH group in the structure interacts with one of the oxygen



Scheme 1

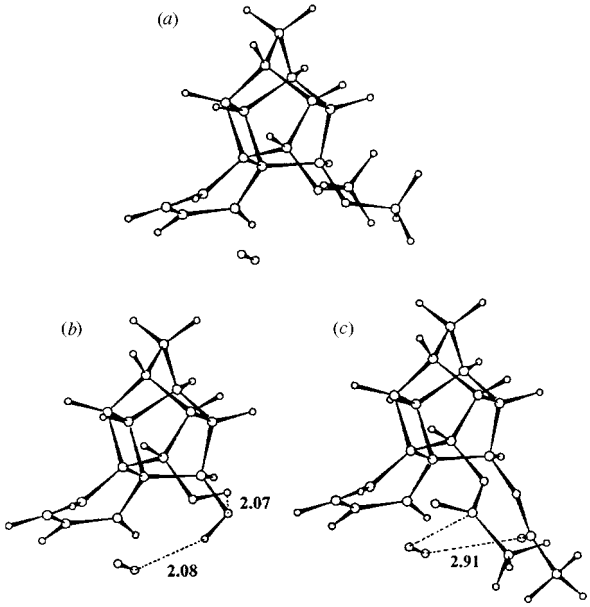


Fig.1 AM1 optimised transition state structures for the bottom face addition of $^1O_2$ to (*a*) **5c**, (*b*) **5a** and (*c*) **5b**

atoms of the approaching dienophile [Fig. 1(*b*)]. The cyclic, cooperative hydrogen bonds seem to provide enough stabilization to overcome electrostatic repulsions noted in **5c**. Additional proof for the role of hydrogen bonding with the singlet oxygen was obtained by computing the energies of transition states with C_s symmetry constraints which led to conformations similar to those of the dimethoxy derivative. The face selectivity calculated in these high energy conformations is revealing. With both the OH groups pointing towards the diene, the bottom face approach of $^1O_2$ is favored by 25.6 kJ mol^{-1}. In this structure, the two OH groups form strong hydrogen bonds with either end of the dienophile. In the alternative transition structures in which the OH groups point away from the diene, an electrostatic preference for top face attack (12.6 kJ mol^{-1}) similar to that calculated for the corresponding conformation of **5c** is obtained.

Transition state energies favoring the bottom face attack for the diacetoxy derivative **5b** are also consistent with experiment. Remarkably, the computed preference (6.9 kJ mol^{-1}) is similar to that obtained in the most stable transition state structures of **5a**. While the latter allows hydrogen bonding between the substituent and $^1O_2$, the origin of the selectivity in **5b** is intriguing. The calculated transition state structure for the bottom face attack suggests a possible mode of stabilisation. The oxygen atoms of the dienophile make fairly short contacts (2.9 Å) with the carbonyl carbon atoms of the symmetrically oriented ester groups [Fig. 1(*c*)]. The O···C=O angles of 91° support the possibility of a favorable interaction between the lone pairs on $^1O_2$ with the π* orbitals on the ester linkages. Similar long range attractive interactions have been recognised,[7] on the basis of several solid state structures, as key factors governing the nature of the reaction coordinate in nucleophilic additions to carbonyl groups. We now propose that such orbital interactions between the reagent and the remote substituent direct the approach of $^1O_2$. The attractive effects are not translated into any reaction at the substituent, but only result in the delivery of the reagent to the nearby diene face. Evidence for this model comes from calculations on a different conformation of the diester groups, with the acyl units pointing away from the diene. While the energy of the transition state for top face addition was virtually unaffected by the conformational change, in the case of the bottom face addition transition state, the ester groups were reorientated to attain the conformation shown in Fig. 1(*c*), implying the stabilizing interactions present in this structure.

In summary, a subtle change of functionality in **5** leads to remarkable variations in the face selectivities of $^1O_2$ additions. Our results indicate that direct through-space interactions between remote substituents and the approaching reagent *via* three distinct modes, *viz.* electrostatic, hydrogen bonding and stabilizing orbital interactions, need to be considered as additional stereoelectronic factors in determining face selectivity.

We thank Mr B. K. Dirghangi and Mr S. Mondal for solving an X-ray structure and DST for support of X-ray facilities at the University of Hyderabad and IACS, Calcutta.

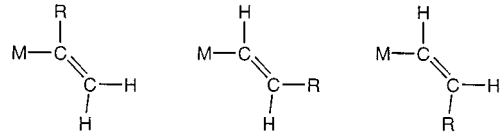
Facile α-β isomerisation of the σ-π phenylethenyl ligand at the diiron centre

Simon Doherty[a] and Graeme Hogarth*[b]†

[a] *Department of Chemistry, University of Newcastle, Bedson Building, Newcastle-upon-Tyne, UK NE1 7RU*
[b] *Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

At 110 °C α-substituted $[Fe_2(CO)_6(\mu\text{-}PhC{=}CH_2)(\mu\text{-}PPh_2)]$ 1 is cleanly converted into the β-isomer $[Fe_2(CO)_6(\mu\text{-}HC{=}CHPh)(\mu\text{-}PPh_2)]$ 2, a process which is accelerated in the presence of arylphosphines; with $P(OMe)_3$ mono- and di-substituted adducts of 1 are isolated at 70 °C, which cleanly isomerise at higher temperatures.

The alkenyl ligand has been proposed as a key intermediate for the Fischer–Tropsch process[1] and as a result, the chemistry of this important ligand has been studied at a variety of metal centres, the emphasis of this work being based on carbon–carbon bond forming reactions.[2–4] Monosubstituted alkenyl complexes can adopt isomeric forms **I**–**III** with the substituent

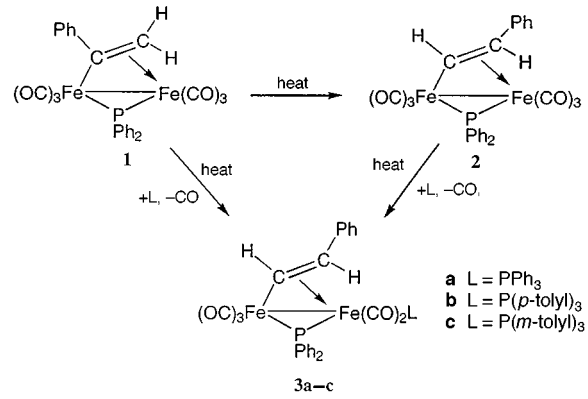


I II III

on either the α- or β-carbon. Interconversion of β-isomers II and III has been noted in a number of instances, and results from rotation about the carbon-carbon bond.[5,6] In contrast, as far as we are aware, and despite the large volume of literature concerning alkenyl complexes, α,β-isomerisation of alkenyl complexes has not been reported. Herein we describe the clean conversion of an α-substituted alkenyl ligand (**I**) to its β-isomer (**II**) at the diiron centre, a process which is accelerated in the presence of arylphosphines.

A convenient route to alkenyl complexes involves the hydrometalation of alkynes, primary alkynes giving both α- and β-substituted isomers depending upon the regioselectivity of the process. Hydrodimetalation of PhC≡CH by $[Fe_2(CO)_7(\mu\text{-}H)(\mu\text{-}PPh_2)]$ is reported to afford a mixture of α-$[Fe_2(CO)_6(\mu\text{-}PhC{=}CH_2)(\mu\text{-}PPh_2)]$ **1** and β-$[Fe_2(CO)_6(\mu\text{-}HC{=}CHPh)(\mu\text{-}PPh_2)]$ **2** substituted isomers in a 4:1 ratio.[7] In our hands, and provided that the temperature is not raised during work-up, the α-isomer **1** is the sole product as shown by ^1H NMR spectroscopy. However, when a toluene solution of **1** was heated at 110 °C for 1 h clean conversion to β-isomer **2** was noted, being isolated in >90% yield after chromatography. Conversion of **1** to **2** is easily followed by ^1H NMR spectroscopy. Under these conditions conversion was quantitative, the appearance of a low-field multiplet being characteristic of the α-proton of an alkenyl ligand. Following the reaction by NMR and IR spectroscopy failed to reveal any intermediates.

In the presence of arylphosphines, alkenyl isomerisation was accelerated. Heating a toluene solution of **1** and PPh_3 to 110 °C for 10 min lead to the quantitative formation of the β-substituted phosphine adduct $[Fe_2(CO)_5(PPh_3)(\mu\text{-}HC{=}CHPh)(\mu\text{-}PPh_2)]$ **3a**.‡ The ^1H NMR spectrum clearly showed that both carbonyl substitution and alkenyl isomerisation had occurred, the α-proton appearing at δ 8.35. Monitoring the reaction by ^{31}P NMR spectroscopy again failed to reveal any intermediates. The acceleration of alkenyl isomerisation was found for other phosphines, including P(*p*-tolyl)$_3$ and P(*m*-tolyl)$_3$ (Scheme 1). In contrast, addition of the more sterically demanding isomer

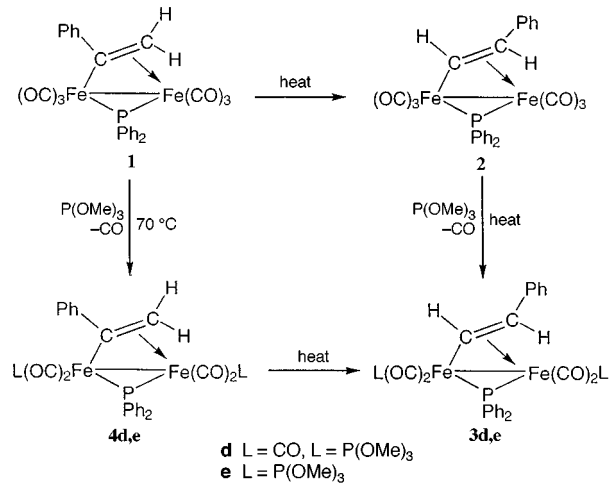


Scheme 1

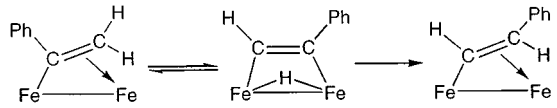
P(*o*-tolyl)$_3$ did not result in accelerated isomerisation, **2** being the sole product, and suggesting that it is carbonyl substitution which accelerates alkenyl isomerisation.

Further insight was gleaned from the reaction of $P(OMe)_3$ with **1** (Scheme 2). This proceeded rapidly (10 min) at 70 °C and led to a mixture of $[Fe_2(CO)_5\{P(OMe)_3\}(\mu\text{-}PhC{=}CH_2)(\mu\text{-}PPh_2)]$ **4d** and $[Fe_2(CO)_4\{P(OMe)_3\}_2(\mu\text{-}PhC{=}CH_2)(\mu\text{-}PPh_2)]$ **4e**.‡ Pertinently, the α-substituted alkenyl ligand is maintained throughout. Warming both **4d** and **e** to reflux in toluene resulted in their rapid (< 10 min) conversion into the β-substituted isomers $[Fe_2(CO)_5\{P(OMe)_3\}(\mu\text{-}HC{=}CHPh)(\mu\text{-}PPh_2)]$ **3d** and $[Fe_2(CO)_4\{P(OMe)_3\}_2(\mu\text{-}HC{=}CHPh)(\mu\text{-}PPh_2)]$ **3e**, respectively, also obtained from the direct reaction of $P(OMe)_3$ with **2**, while reaction of the latter with PPh_3 afforded **3a** in a similar manner.

Conversion of **3** to **4** involves both carbonyl substitution and alkenyl isomerisation. For the arylphosphines utilised to date, carbonyl substitution is rate-determining, being followed by rapid alkenyl isomerisation. In contrast, with the less sterically demanding $P(OMe)_3$, carbonyl substitution is more facile and alkenyl isomerisation becomes rate-determining. While the



Scheme 2



Scheme 3

origin of the rate acceleration of alkenyl isomerisation is not clear, since the β-phenylethenyl ligand is generated in all cases it must be thermodynamically preffered. It is difficult to see how this can be a result of steric effects in the hexacarbonyl complexes and we believe that their must be an electronic preference for the adoption of the β-isomer, while the hydrodimetalation reaction affords the α-isomer preferentially as a result of Markovnikov addition.

The precise manner in which alkenyl isomerisation occurs is as yet unknown. It may simply occur *via* a direct 1,2-proton shift, although it is difficult to see how the rate of such a process would be strongly affected by ligand substitution. A second possibility is that it results from a reversible C–H addition to the diiron centre (Scheme 3). Such a process would afford a hydrido–alkyne intermediate, with the alkyne lying parallel to the diiron vector and acting as a two-electron donor in order to preserve the EAN count of 34. Carbon-hydrogen bond formation from this intermediate would either regenerate the α-isomer or irreversibly afford the thermodynamically favoured β-isomer. Both oxidative addition and reductive elimination are likely to be sensitive to the steric and electronic nature of the other ligands, and this may account for the observed changes in the rate of alkenyl isomerisation.

We are currently investigating whether α–β alkenyl isomerisation is general by studying analogous reactions of other α-substituted complexes $[Fe_2(CO)_6(\mu\text{-}RC{=}CH_2)(\mu\text{-}PPh_2)]$. Further we are trying to gain more mechanistic insight into this transformation *via* reaction of **1** with a wider range of phosphines, phosphites and related reagents, while we are looking for alternative low-temperature routes to phosphine substituted α-alkenyl complexes in order to obtain kinetic information concerning the rate acceleration.

A stereoselective synthesis of a 2-functionalized-methyl-1β-methylcarbapenem key intermediate *via* decarboxylation

Woo-Baeg Choi, Jaemoon Lee, Joseph E. Lynch,*† R. P. Volante, Paul J. Reider and Robert A. Reamer

Process Research, Merck Research Laboratories, PO Box 2000, Rahway, NJ 07065, USA

An efficient synthesis of a key intermediate 2a for the synthesis of 2-functionalized methyl-1β-methylcarbapenem antibiotics 1 has been realized *via* a stereoselective decarboxylation reaction.

The emergence of multiple drug resistant bacteria and the alarming increase in the number of infections resulting from these organisms have clearly demonstrated an urgent need for new antimicrobial agents. Methicillin resistant *Staphylococcus aureus* (MRSA) is one of the more common of these infectious agents and in the early 1990s accounted for about 20% of the bacterial cultures isolated in hospitals.[1] MRSA remains a challenging target of antimicrobial research programs throughout the pharmaceutical industry. 2-Functionalized-methyl-1β-methylcarbapenem antibiotics **1** have drawn much attention due their potent activity against a variety of pathogens including MRSA.[2] However, the lack of an efficient synthesis of these carbapenems has hindered their development as clinical candidates. The 2-hydroxymethyl-1β-methyl ketone **2a** is a key intermediate in the synthesis of **1** and several syntheses of **2a** in variously protected forms have appeared in the literature.[2a,3]

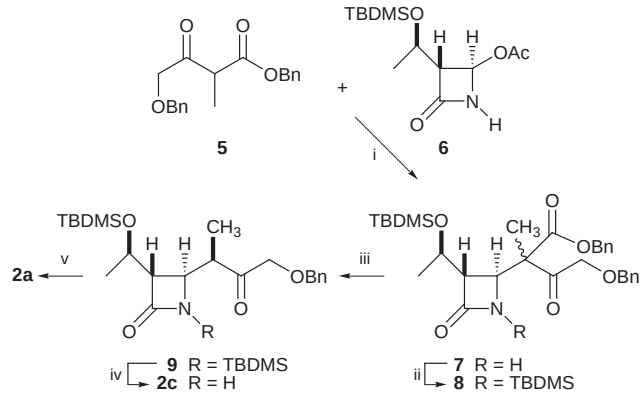
c R = CH_2OBn, R′ = H

Some time ago, we (and others) reported that the malonic acid **3b** underwent a highly stereoselective decarboxylation/protonation to give the 1β-methyl carboxylic acid **2b**.[4a,b] We envisioned that the keto acid **3a** or **3c** should undergo a similar decarboxylation to give **2a** or **2c**, respectively.

After several unsuccessful attempts to generate the requisite β-keto acid **3a** *via* aqueous ester saponification, we adjusted our strategy to allow preparation of a β-keto acid in a nonpolar solvent *via* hydrogenolysis of a suitable benzyl ester. Benzyl 4-benzyloxy-2-methyl-3-oxobutyrate **5** was prepared by the Claisen condensation of benzyl propionate (2 equiv. + 2 equiv. LDA) and methyl *O*-benzylglycolate in 80% yield (Scheme 1). The acetoacetate **5** was then coupled with acetoxyazetidinone **6** (K_2CO_3 in DMF at 45 °C, 1 h) to give *ca*. 2:1 diastereomeric mixture **7** in 85–90% yield. *N*-silylation of **7** was carried out using TBDMSOTf and Et_3N in DMF to give **8** in quantitative yield. In our previous work on the malonic acid series we had



Scheme 1 *Reagents and conditions*: i, K_2CO_3, DMF, 45 °C, 1 h; ii, Et_3N, TBDMSOTf, DMF; iii, HCO_2H, EtOAc, 5% Pd/C, 30 psi H_2, room temp., 1 h; iv, Bu^n_4NF, CH_2Cl_2, 0 °C; v, 10% Pd/C, EtOH, 45 psi H_2

observed a remarkable diastereospecificity in the decarboxylation reaction.[4d] We found that only the (1*R*)-ester **3d** underwent decarboxylation to give **2d**. The (1*S*)-diastereomer underwent decarboxylation only under forcing conditions resulting in ring cleavage and giving **4b** as a major product. We were concerned that such diastereospecificity would be problematic with the 2:1 mixture of diastereomers **8**. We thus separated the two isomers of **8** (silica gel chromatography) and investigated the decarboxylation of each isomer individually. Each benzyl ester **8** was subjected to hydrogenolysis conditions (3 equiv. HCO_2H, 5% Pd/C, 30 psi, room temp., 1 h) in EtOAc. Surprisingly both isomers cleanly gave **9** as a single stereoisomer (> 99:1 β:α).[5] Encouraged by the individual results, the 2:1 mixture of **8** was subjected to hydrogenolysis/decarboxylation to give the desired β-methyl product **9** in 95% yield along with 3–4% of **4a**. *N*-desilylation of **9** was achieved using TBAF in CH_2Cl_2 at 0 °C giving **2c** in 85% yield.[6] Debenzylation of **2c** was accomplished under more vigorous hydrogenolysis conditions in EtOH (10% Pd/C, 45 psi H_2, 1 h) to give **2a** in 90% yield.[7,8]

Although the malonic acid series demonstrated a stereospecific decarboxylation,[4d] this was not an issue in the decarboxylation of **8** (*via* **3c**). This could be due to the greater stability of the enol intermediate and the corresponding lower transition state energy *vs.* the ketene acetal intermediate in the malonic acid series. The greater selectivity in the protonation step may be a result of the lower reaction temperature (20 °C for **2a** *vs.* 80 °C for **2b**) as well as the relative energetics of the two systems.

The Authors thank Dr Mark Greenlee for helpful suggestions during the preparation of this manuscript.

Circular dichroism and absolute conformation of Δ⁴-uronate derivatives: a semi-empirical rule for inherent chiral α-alkoxy acrylates

Iontcho R. Vlahov,[a] Hélène G. Bazin[b] and Robert J. Linhardt*[b]†

[a] *Baker Norton Pharmaceuticals, Inc., 4400 Biscayne Boulevard, Miami, Florida 33137, USA*
[b] *Division of Medicinal and Natural Products Chemistry and Department of Chemical and Biochemical Engineering, University of Iowa, Iowa City, Iowa 52242, USA*

The theoretical basis for using CD spectroscopy to predict the conformation of Δ⁴-uronates is reported.

As part of ongoing research into the chemistry of glycosaminoglycans, our laboratory has been exploring the use of Δ⁴-uronate derivatives as building blocks for the synthesis of heparin. Circular dichroism (CD) spectroscopy was used to study the conformation of these Δ⁴-uronate derivatives in an effort to better understand differences in their reactivity.[1]

Qualitative molecular orbital (MO) theory, frequently used to explain molecular properties (*e.g.* geometry,[2] photoelectron spectra[3] or reactivity[4]) can also help in better understanding CD spectra. Rotational strength (*R*),[5] a substance property, can be defined as the area under a CD band multiplied by a factor [eqn. (1)].

$$R = 0.229 \times 10^{-38} \int (\Delta\varepsilon/\lambda \mathrm{d}\lambda \qquad (1)$$

R is theoretically given by the scalar product of the electronic (μ) and the magnetic (*m*) transition moments for the absorption observed [eqn. (2)].

$$R = \mu m = |\mu|\ |m| \cos\beta \qquad (2)$$

When light is absorbed by the electron cloud of a molecule, electron charge can be shifted in the direction of the electric field vector of the light wave, and it may also be rotated. This first phenomenon corresponds to μ, the latter to *m*. The values of μ and *m* can be determined by identifying the molecular orbitals (MOs) at which the electron excitation mainly occurs. From the cosine term of eqn. (2) it follows that the CD is positive if the angle between μ and *m* is acute ($0 < \beta < 90°$), and negative if the angle is obtuse ($90 < \beta < 180°$). In limited cases the vectors μ and *m* are prependicular to each other, so the scalar product is zero ($\cos 90 = 0$) and the Cotton effect vanishes.

Qualitatively μ and *m* can be determined by multiplying together the two MOs between which the transition occurs (Snatzke MO recipe).[6] The absolute directions of μ and *m* depend on the arbitrary choice of the orbital phases and have no physical meaning.[7] However, their relative orientation determines the sign of the CD. This single CD argument only gives information about the absolute conformation of a molecule (*i.e.* the sign of a torsion angle around a bond) and not about the absolute configuration. A second method is required to correlate the absolute conformation with the determined absolute configuration.

The Δ⁴-uronate derivatives as shown in Fig. 1(*a*) are formally α-alkoxy acrylates. Their C=C–O moiety is locked into the chiral conformation of the dihydropyran ring, making this chromophore inherently chiral[8] [Fig. 1(*b*)]. We propose a semi-empirical rule for predicting the absolute conformation of cyclic α-alkoxy acrylates based on the sign of the Cotton effect. Snatzke has already suggested such a semi-empirical rule for chiral dihydropyrans incorporating an enol ether chromophore, present, for example, in glycals and in many iridoids.[6,7,9]

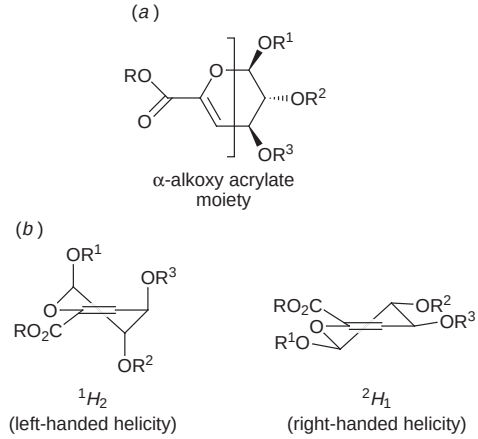

Fig. 1 The structure of (*a*) the α-alkoxyacrylate moiety in Δ⁴-uronate derivatives and (*b*) the half-chair conformers of the Δ⁴-uronate derivatives

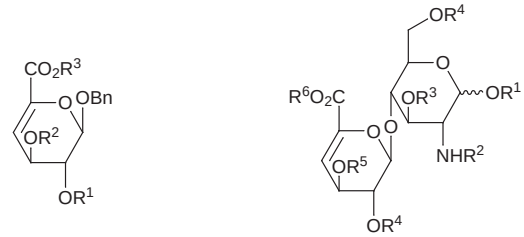
The CD spectra of the Δ⁴-uronates (Fig. 2) show a Cotton effect around 235–240 nm. This band is negative for the compounds **1**–**5**, and positive for compounds **6** and **7**. Since this



1 $R^1 = R^2 = H$, $R^3 = Me$
2 $R^1 = R^2 = Piv$, $R^3 = Me$
3 $R^1 = R^2 = R^3 = Bn$
4 $R^1 = R^2 = TBDMS$, $R^3 = Me$
5 R^1–$R^2 = (Pr^i_2Si)O(Pr^i_2Si)$
6 $R^1 = R^3 = R^5 = R^6 = H$, $R^2 = R^4 = SO_3H$
7 $R^1 = R^3 = R^4 = R^5 = R^6 = H$, $R^2 = Ac$

CD band corresponds to a strong UV absorption, it must come from a $\pi \rightarrow \pi^*$ transition and not from a forbidden $n \rightarrow \pi^*$ transition. Application of the Snatzke MO recipe to such an α-alkoxy acrylate chromophore is shown in Fig. 3. Here the relevant MOs approximate the two possible HOMOs and the LUMO of the isoelectronic 2,3-dimethylbutadiene dianion, although the LCAO coefficients are not identical. The terminal AOs are twisted to reflect the chirality (left-handed twist chosen). The formal multiplications $\pi_a\pi^*$ and $\pi_b\pi^*$ reveal the generation of an electronic transition moment μ. For the $\pi_a \rightarrow \pi^*$ transition, μ is localized nearly exclusively in the achiral part of the chromophore, so this excitation cannot correspond to the strong Cotton effect measured. The latter must then come from the $\pi_b \rightarrow \pi^*$ transition. The translation of charge during the $\pi_b \rightarrow \pi^*$ excitation generates μ. Part of the charge is transferred

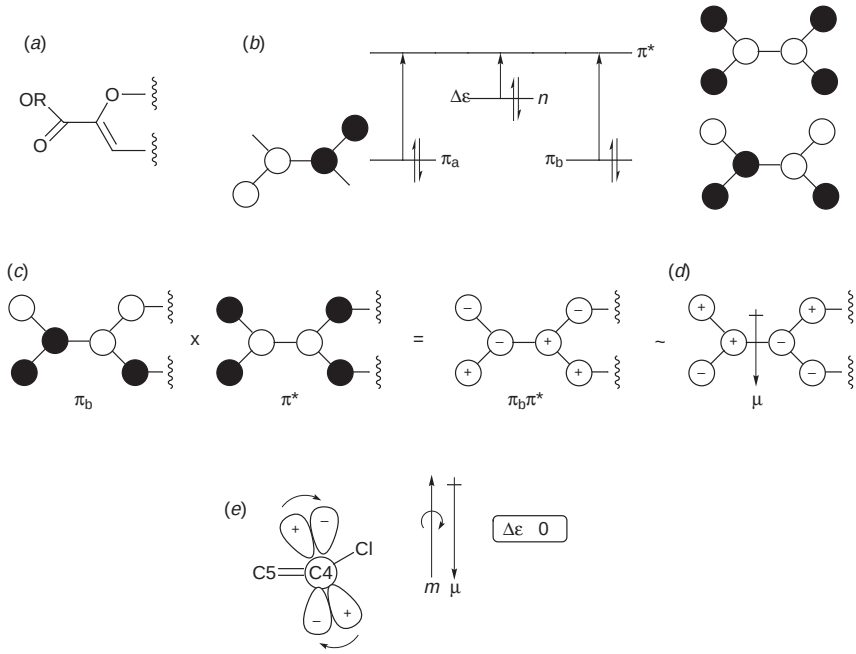


Fig. 3 Application of Snatzke MO formalism to Δ^4-uronates: (*a*) chiral α-alkoxy acrylate chromophore (absolute conformation of the dehydropyran ring is chosen as $^1H_2$; (*b*) relevant MOs of the isoelectronic 2,3-dimethylbutadiene dianion; (*c*) formal multiplication of π_b and π^* giving the electron density; (*d*) charge translation and μ; (*e*) concomitant charge rotation and *m*

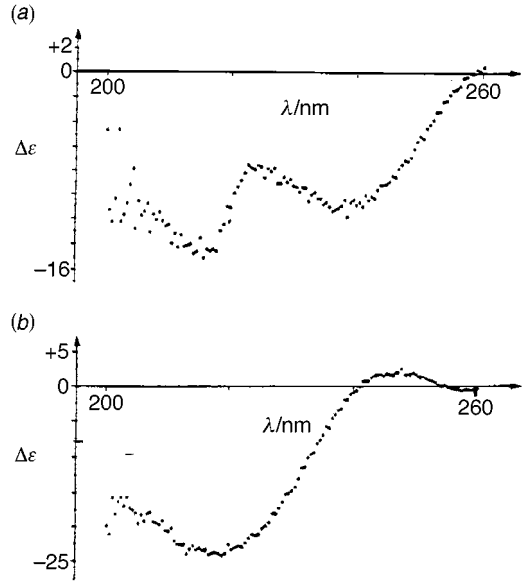

Fig. 2 Superposition of CD curves with (*a*) negative (**1**–**5**) and (*b*) positive Cotton effects (**6** and **7**). These compounds show a single absorption peak at 235–240 nm.

within the dihydropyran ring and this is done for the absolute conformation $^1H_2$ chosen on a left-handed helical path. Such rotation of charge along the line connecting C4–O_{ring} generates *m* which, by the right-hand rule, is oriented antiparallel to μ. The resulting Cotton effect is, therefore, negative and the absolute conformation of the dihydropyran ring in compounds **1**–**5** is $^1H_2$.

For compounds **6** and **7** (a positive Cotton effect measured) the charge is transferred on a right-handed helical trajectory, thus predicting a $^2H_1$ absolute conformation for their ring systems.

The ^{1}H NMR data for the compounds are in full agreement with the prediction of their absolute conformation concluded from this new semi-empirical rule. CD spectroscopy provides the absolute conformation, information that is simply not obtainable using NMR analysis.

We thank Professors Dan Quinn and Lei Geng for their helpful suggestions and the National Institutes of Health (GM38060) for supporting this research.

Molecular recognition using β-cyclodextrin-modified dendrimers: novel building blocks for convergent self-assembly

George R. Newkome,*† Luis A. Godínez, and Charles N. Moorefield

Center for Molecular Design and Recognition, University of South Florida, Tampa, FL, 33620, USA

The synthesis of β-cyclodextrin-based dendrimers 3 and 5 is described; using phenolphthalein as a UV–VIS active probe, it is shown that the binding cavities of these modified receptors retain their molecular recognition properties and can be employed as polyfunctional monomers in self-assembly.

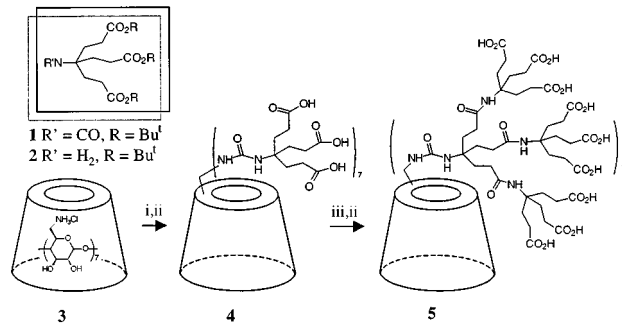
Cyclodextrins (CDs) constitute a popular family of cyclic oligosaccharides whose molecular structures resemble truncated cones.[1] These polyhydroxylated materials have been the subject of numerous investigations in the area of molecular recognition due to their combined solubility in aqueous media and their ability to embrace a wide variety of molecular guests in a well-defined cavity.[2] Also, the *n* primary hydroxy groups at the narrow side of the receptor's cavity exhibit greater reactivity with sterically demanding electrophiles than the *2n* secondary OH groups on the wider, bottom side of the molecule.[1] Therefore, using the appropriate reagents, CDs can be selectively modified to incorporate specific functional groups on the narrow side of the receptor's hydrophobic cavity. Many researchers have capitalized on this property and have subsequently reported the synthesis of modified CDs that have been successfully used as catalysts,[3] receptors for nucleotides[4] and ions,[5] molecular tube precursors,[6] modified electrodes[7] and chemical sensors,[8] to mention but a few applications.[9] Recently, a single CD has been attached to a dendritic surface and investigated with respect to ester hydrolysis activity.[10] β-CDs have also been coordinated to ferrocenyl-terminated dendrimers to study redox characteristics.[11]

As a complementary part of our research program, we are exploring the use of non-covalent interactions and molecular recognition concepts[12] to promote the ordered self-assembly of dendritic structures. These concepts have been eloquently employed by Zimmerman and co-workers.[13]

We herein report the synthesis of two water-soluble dendritic β-CD monomers that retain their molecular recognition properties. These materials therefore belong to a new family of modified receptors that can be envisioned as synthons for convergent, molecular recognition-based assembly of more complex structures and, ultimately, dendritic networks.

Recently, we reported the synthesis of isocyanate[14] **1** and its use in the synthesis of combinatorial-based dendrimers.[15] Attempted treatment of β-CD with triester **1**, under different reaction conditions, afforded no addition products, presumably due to combined steric hinderance. To circumvent this inertness, we prepared 6-heptaamino-β-CD heptahydrochloride[16] **3**‡ (Scheme 1) since isocyanate **1** was known to react with amines under mild conditions.[14] Thus, treatment of heptaamine **3** with 7 equiv. of isocyanate **1** (Pr^i_2EtN, DMF, 25 °C, 5 h) afforded (85%) the first tier polyester dendritic CD monomer. Formic acid hydrolysis (12 h) and dialysis afforded (40%) the polycarboxylic acid **4**, as supported by the ^{13}C NMR spectral data [$\delta(D_2O)$ 158.9 (NH*C*ONH), 178.0 (CO_2).

Construction of the second tier was accomplished by treatment of **4** with 21 equiv. of Behera's amine[17] **2** [DCC, HOBT, DMF–DMSO, 2 d, 25 °C]. Formic acid hydrolysis subsequently afforded (25%) the desired dendritic CD polyacid



Scheme 1 *Reagents and conditions*: i, **1** (7 equiv.), base, DMF; ii, HCO_2H; iii, **4** (21 equiv.), DCC, HOBT, DMF–DMSO

5, whose spectral data supported the conversion [$\delta(D_2O)$158.6 (NH*C*ONH), 179.6 (CO_2).

An important requirement for the synthesis of 'dendrimerized' CDs, that are to be subsequently used as monomers of more complex structures, is that the complexation site, *i.e.* the hydrophobic cavity of the receptor, must remain basically unchanged. In order to verify that CDs **4** and **5** had retained the critical binding locus, displacement experiments, exploiting the well-known association properties of β-CD, were performed.

In moderately basic aqueous medium, phenolphthalein solutions are characterized by a deep purple color that essentially turns colorless upon addition of β-CD.[2b] This dramatic decrease in the UV absorption of the indicator is not

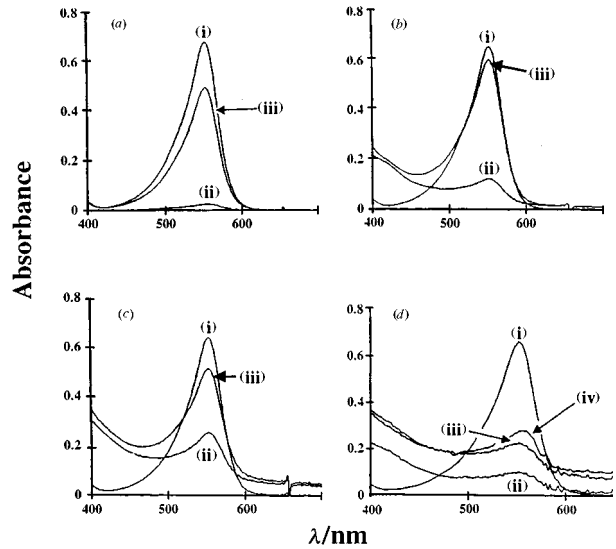


Fig. 1 The effect of CD addition to a 30 μM solution of phenolphthalein pH 10.5 buffer solution (I = 0.6) on the UV spectra for (*a*) β-CD, (*b*) **4** and (*c*) **5**: (i) dye only, (ii) dye and CD (2 mM) and (iii) dye, CD and adamantan-2-amine hydrochloride (5 mM). (*d*) UV spectra of (i) dye, (ii) dye and **4**, (iii) dye, **4** and the bis(adamantane ester) of tetraethylene glycol and (iv) dye, **4**, bis(adamantane ester)and 18-crown-6.

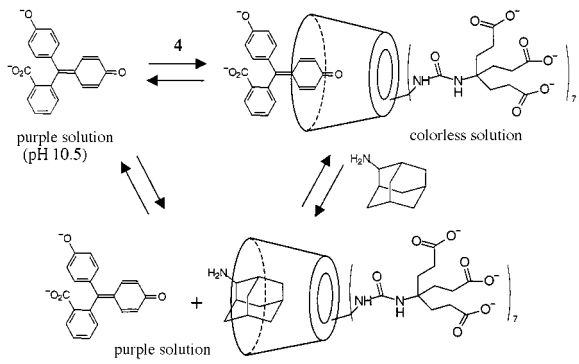
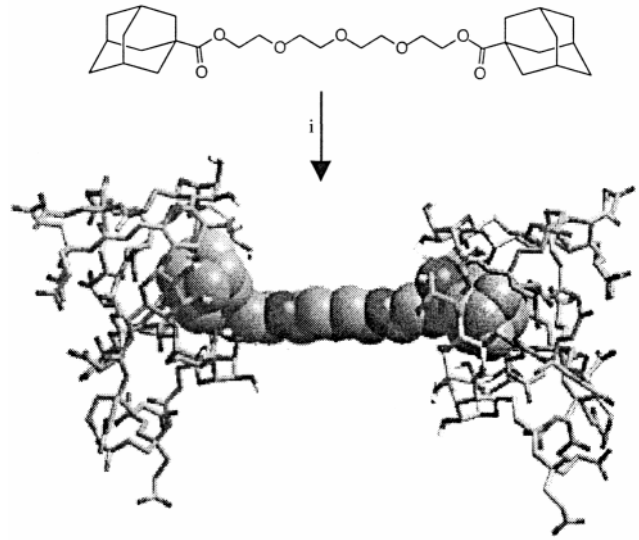
due to a change on the protonation state of the molecule but rather to a specific host–guest inclusion interaction involving hydrogen-bonding, van der Waals forces, and the hydrophobic effect.[18] Complexation of the indicator by inclusion into the β-CD hydrophobic cavity can be thus conveniently followed by UV–VIS spectroscopy. It can be seen in Fig. 1, by comparing spectra (*a*)(i) and (*a*)(ii), that the absorbance at λ = 552 nm of a 30 μM solution of phenolphthalein in a pH 10.5 buffer solution[19] drops dramatically upon the addition of 60 equiv. of β-CD. Consistent with the complexation properties of the unmodified β-CD, spectra (*b*), (*c*) and (*d*) showed similar changes in the absorbance of basic phenolphthalein solutions [spectra (i)] after addition of either CDs **4** or **5** [spectra (iii)]. This decrease in the absorbance of phenolphthalein in the presence of the modified receptors suggests that the indicator is either included in the hydrophobic cavity of the CD or interacting in a similar way with the hyperbranched structure of either **4** or **5**. To rule out the later possibility, we added non-UV-active adamantane derivatives which are known[20] to bind very strongly to β-CD molecules by forming 1:1 inclusion complexes with stability constants on the order of 10^4 M^{-1}.

As observed in Scheme 2, the addition and subsequent inclusion of an adamantane in the CD cavity should promote, if in fact the phenolphthalein is included in the CD cavity, the displacement of the indicator into the bulk of the basic aqueous medium. As a consequence, the solution should become purple



Scheme 2

and the absorbance at λ = 552 nm should increase. Figs. 1(a)(iii), (b)(iii) and (c)(iii), indicate that addition of 2.5 mol of 2-adamantanamine hydrochloride per mol of CD increases the absorption of light of the three aqueous solutions; therefore, as with simple β-CD, the dendritic CDs **4** and **5** retain their binding sites and can incorporate, on the basis of molecular recognition, hydrophobic guests in basic aqueous media. Reappearance of the solution color and absorbance observed in Fig. 1(*d*)(iii), while not as dramatic, was promoted by the addition (0.5 equiv.) of a bis(adamantane ester) of tetraethylene glycol (prepared by the addition of 2 equiv. of adamantanecarbonyl chloride to tetraethylene glycol in the presence of Et_3N). The smaller shift in equilibrium [as compared to Figs. 1(*a*)–(*c*)] to uncomplexed dye in the bulk solution was postulated to arise, at least in part, from Na^+ binding of the polyethylene glycol chain promoting a compact, non-linear structure and thus inhibiting chain elongation and bis-dendrimer assembly. Saturating the solution with 18-crown-6 [Fig. 1(*d*)(iv)] supports this conjecture by further slightly shifting the equilibrium toward displaced absorbing dye and increasing the concentration of the bis-complex (Scheme 3). Another explanation for diminished absorption using the bis(adamantane) could center on other aggregation phenomena as suggested by a heightened spectral baseline. For all cases the percent displacement of dye *via* the addition of adamantane was determined: Fig. 1(*a*), 71.5%; 1(*b*), 89.5%; 1(*c*), 69.5%; 1(*d*), 23%; 1(*d*) with 18-crown-6, 33%.



Scheme 3 *Reagents and conditions*: i, **4**, aq. NaOH–$NaHCO_3$ buffer (I = 0.6) (ref. 19).

An efficient preparation of ditopic receptors based on polyaza[*n*]paracyclophanes

M. Isabel Burguete,[a] Enrique García-España,*[b] Santiago V. Luis,*[a]† Juan F. Miravet,[a] Lorena Payá,[a] Manuel Querol[a] and Conxa Soriano[b]

[a] *Department of Inorganic and Organic Chemistry, ESTCE, University Jaume I, E-12080 Castellón, Spain*

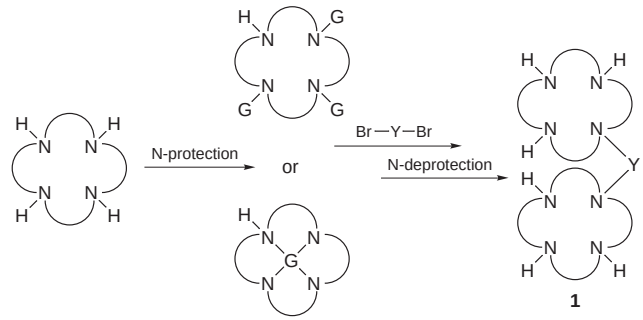
Coordination patterns of tetraaza[*n*]paracyclophanes allow for the selective protection of three out of the four nitrogen atoms *via* the use of simple Zn^{2+} salts; accordingly, a simple method for the preparation of ditopic receptors based on polyaza[*n*]paracyclophanes has been devised.

Ditopic polyaza receptors containing two macrocyclic subunits have become a very important synthetic target, in particular since the discovery of the anti-HIV activity associated to some of those systems.[1] Accordingly, a number of different synthetic strategies have been put forward in recent years to achieve this goal. In this way, several families of receptors having the general structure **1** have been recently prepared.[2]

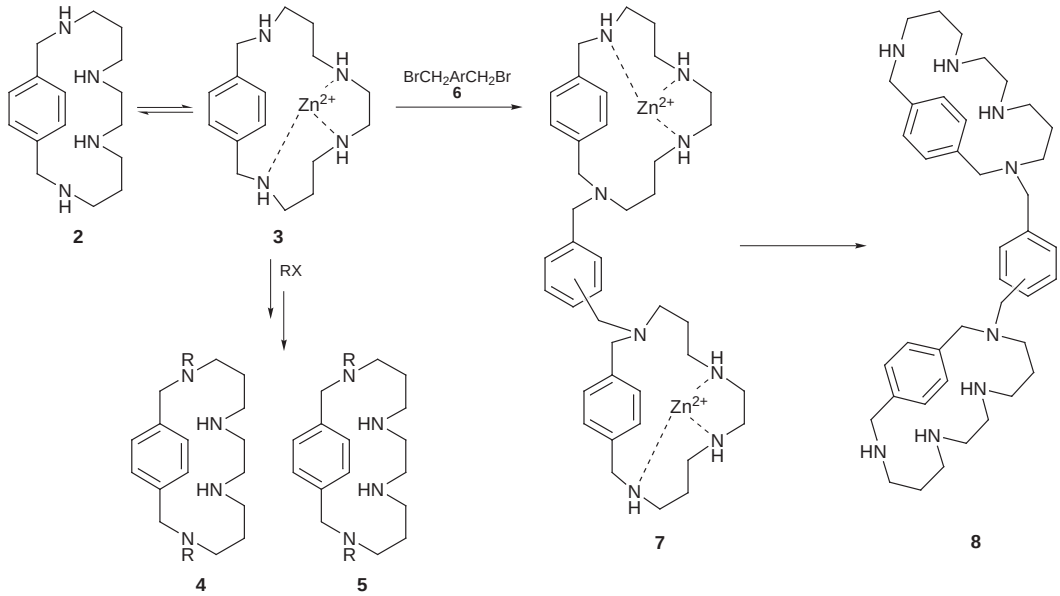
One of the most general synthetic routes for the preparation of this class of compounds is based on the selective protection of the nitrogen atoms in such a way as to leave only one unprotected, reactive nitrogen atom in the macrocycle.[2,3] This intermediate is then reacted with a dihalide to afford, after N-deprotection, the expected ditopic receptor (Scheme 1). As a matter of fact, preparation of ditopic receptors has been one of the central motifs for the development of synthetic strategies for the selective N-functionalization of polyazamacrocycles.

Polyaza[*n*]paracyclophanes **2** represent a very interesting kind of polyaza macrocyclic receptors.[4] One of their most remarkable ligational features is the fact that the presence of the aromatic spacer precludes the simultaneous involvement of all the nitrogen atoms in the coordination to a metal centre (see structure **3**). Thus, for instance, 2,6,9,13-tetraaza[14]paracyclophane **2a** coordinates M^{2+} ions with just three out of its four nitrogen atoms. One of the benzylic nitrogen atoms remains non-coordinated, thus being able to act as a base or as a nucleophile. This property has allowed the development of a simple and novel procedure for selective mono- and di-functionalization of this kind of macrocycle with a variety of reactive alkyl halides, according to the general scheme shown in Scheme 2, to give compounds **4** and **5**.[5] In this way, the otherwise experimentally difficult selective protection of three of the nitrogen atoms can be easily achieved *via* the use of simple metal ions, like Zn^{2+}, without the need of more elaborate reagents or synthetic routes.

This synthetic approach can be further extended to the preparation of ditopic bis-macrocyclic receptors **8** based on



Scheme 1



Scheme 2

Table 1 Results obtained in the preparation of ditopic receptors **8** derived from tetraaza[*n*]paracyclophanes

Starting macrocycle[a]	Alkylating agent[b]	Polyamine:base ratio	*t*/days	Yield[c] (%)
2a	**6a**	1:1	1	30
2a	**6a**	1:1	3	37
2a·4HBr	**6a**	1:5	3	40
2a·4HBr	**6a**	1:7	3	87
2b	**6a**	1:7	3	24

2b·4HBr	**6c**	1:7	3–5	< 10[d]

[a] Compound **2a** (B323): 2,6,9,13-tetraaza[14]paracyclophane; Compound **2b** (D323): 2,6,9,13,tetraaza-16,17,19,20-tetramethyl[14]paracyclophane. [b] Compound **6a**: 1,4-bis(bromomethyl)benzene; Compound **6b**: 1,3-bis(bromomethyl)benzene; Compound **6c**: 1,2-bis(bromomethyl)benzene. [c] Product obtained after chromatographic purification. [d] Estimated from the crude product after the reaction.

polyaza[*n*]paracyclophanes when a bis(halomethyl)benzene is used as the alkylating agent (Scheme 2).

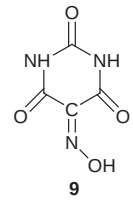
The low coordination of the metal centre in the complexes formed by polyaza[*n*]paracyclophanes **2** has been shown to provide mechanisms for the participation of the coordinated cation in biomimetic catalytic proceses.[4] In this sense, the preparation of ditopic receptors **8** represents an interesting synthetic target.

Results obtained for different macrocycles and aromatic spacers are summarised in Table 1. Careful control of the reaction conditions is required. We used the cyclic polyamines as free bases or as their hydrobromides, and different ratios of macrocycle/base were tested in the range of *ca.* 1 to 10. Best results were obtained when an excess (*ca.* 7:1) of base (anhydrous K_2CO_3) is used and the polyamine is introduced as its hydrobromide. The use of 1,4-bis(halomethyl)arenes gives better yields than the 1,3-substituted analogues. The expected products could not be obtained for 1,2-bis(halomethyl)arenes.‡

The nature of the aliphatic chains between the nitrogen atoms is also very important. Good results were only obtained when propylenic sub-units are present and the expected ditopic receptors could not be prepared starting from cyclophanes containing only ethylenic spacers. This can be related with the different coordination patterns of the macrocycles used.[5b] In this context it is worth mentioning that tetraazacyclophanes containing only ethylenic sub-units have been shown to be able to form dinuclear Cu^{2+} complexes in which all four nitrogen atoms are coordinated.[4b]

Preliminary analyses of the acid-base and coordination tendencies of these compounds have shown some interesting trends. Protonation constants obtained from pH titrations show that in the pH range 2–11 all ligands can take up to seven protons, the eighth protonation not being generally detected under our experimental conditions. At neutral pH values the main species for all ligands are the tetraprotonated ones.§ The high positive charge achieved by these ligands at neutral pH allows us to consider them as potential receptors for anionic species. Thus, for instance, compound **8b** (obtained from **2b** and **6a**) strongly interacts with the barbituric acid derivative 1*H*,3*H*-pyrimidine-2,4,5,6-tetrone 5-oxime (violuric acid) **9** with complexation percentages around 90–100% in a wide pH range (pH < 8).[6]¶

On the other hand, when the interaction with metal cations is considered, compounds **8** revealed the possibility of forming



9

mono- as well as di-nuclear complexes. Thus, for instance, **8d** (obtained from **2b** and **6b**) in the presence of Cu^{2+} salts is able to form both CuL and Cu_2L species with stability constants of $\log K_{CuL}$ = 13.46(3) and $\log K_{Cu2L}$ = 8.8(1). These results also open the possibility for the study of those complexes as potential biomimetic catalysts in aqueous media. Such studies are being presently carried out.

‡ All compounds show the expected spectroscopic data. The most distinctive spectroscopic feature of receptors **2** is the presence in their ^{1}H NMR spectra of three well-defined benzylic singlets at δ 3.4–3.5, 3.6 and 3.7–3.9. *Selected data* for **8a**: $\delta_H(CDCl_3)$ 1.47 (m, 4 H), 1.65 (m, 4 H), 2.34 (t, 4 H), 2.52 (s, 8 H), 2.54–2.66 (m, 8 H), 2.73 (t, 4 H), 3.39 (s, 4 H), 3.62 (s, 4 H), 3.77 (s, 4 H), 7.26 (s, 8 H), 7.39 (s, 8 H); δ_C 26.2, 27.1, 45.3, 46.3, 47.2, 48.4, 48.7, 49.7, 52.7, 59.0, 59.3, 128.7, 129.3, 137.9, 138.5, 139.5.

§ For instance, stepwise protonation constants for receptor **8b**, determined by pH fitrations at 298.1 K in 0. 15 mol dm^{-3}, are: $\log K_{HL}$ = 9.9(2), $\log K_{H2L}$ = 9.53(3), $\log K_{H3L}$ = 8.41(4), $\log K_{H4L}$ = 7.77(4), $\log K_{H5L}$ = 5.95(4), $\log K_{H6L}$ = 4.67(4), $\log K_{H7L}$ = 3.64(4) and $\log K_{H8L}$ < 2. Charges are omitted for clarity.

¶ In the pH range 7–5, the predominant species are H_7LA and H_8LA, obtained by the interaction of the monoanion of violuric acid and the pentaprotonated [log*K* = 4.93(4)] or hexaprotonated receptor [log*K* = 6.18(4)], respectively.

Covalent coupling of an organic chromophore into functionalized MCM-41 mesophases by template-directed co-condensation

Christabel E. Fowler,[a] Bénédicte Lebeau[b] and Stephen Mann*[a]

[a] *Department of Chemistry, University of Bath, Bath, UK BA2 7AY*
[b] *Laboratoire des Matériaux Minéraux, CNRS UPRES-A 7016 - NSCMu, 3 rue Alfred Werner, 68093 Mulhouse Cedex, France*

An ordered organo-silica-surfactant mesophase containing a covalently-linked chromophore was synthesized with MCM-41-type architecture by template-directed co-condensation of tetraethoxysilane and 3-(2,4-dinitrophenylamino)propyl-(triethoxy)silane: a dye-functionalized mesoporous silica with hexagonal order was produced by surfactant extraction of the as-synthesized material prepared under acidic conditions.

The synthesis and properties of ordered mesostructured and mesoporous inorganic-based materials are currently receiving much attention.[1] The ability to prepare these organized materials depends on the use of surfactant,[2,3] block copolymer,[4,5] microemulsion,[6,7] colloidal[8] or bacterial[9] templates which pattern the deposition of the mineral phase by physical and chemical interactions at the inorganic-organic interface. More chemically complex ordered mesophases are being prepared either by post-synthetic grafting[10,11] or *via* direct routes involving the co-condensation of tetraalkoxysilanes and organo-functionalized trialkoxysilanes.[12–16] Such hybrid materials are intrinsically interesting as new forms of organized matter, as well as being of potential technical importance in catalysis[16,17] metal-ion extraction[18] and adsorption processes.[19]

Previously, we have described the synthesis of a range of organo-silica-surfactant mesophases with MCM-41 architectures containing covalently-linked chemically active groups such as alkyl, aryl, allyl, thiol, amino, epoxy, or imidazole moieties.[12,13] Here we extend this approach and show that an intact chromophore can be covalently incorporated into the MCM-41 mesostructure by direct chemical synthesis involving co-condensation of tetraethoxysilane (TEOS) and 3-(2,4-dinitrophenylamino)propyl(triethoxy)silane (DNPTES) in the presence of hexadecyl(trimethyl)ammonium bromide (C_{16}TMABr) micelles. Although a previous report has described the synthesis of phthalocyanine-doped MCM-41, the chromophore was present as an additive within the surfactant micelles.[20] Post-synthetic grafting of a Schiff-base moiety to the surface of MCM-41 silica produced a mesoporous material which showed a characteristic absorption spectrum for the organic ligand.[21] Thus, to the best of our knowledge, the work reported here is the first example of the direct synthesis of an ordered mesoporous silica containing covalently linked organic chromophore functionalities.

A silica-surfactant mesophase was synthesised from either an alkaline or acidic mixture containing the following molar composition, respectively: C_{16}TMABr:NaOH:TEOS:DNPTES:H_2O = 0.12:0.5:0.9:0.1:130 and C_{16}TMABr:HCl:TEOS:DNPTES:H_2O = 0.12:9.2:0.9:0.1:130.‡ In both methods, small-angle X-ray powder diffraction (SAXRD) of the bright yellow as-synthesized materials gave peaks corresponding to hexagonally-ordered organo-silica-surfactant mesophases with unit cell parameters of 4.55 (basic mixture) and 4.31 nm (acidic mixture)§ (Fig. 1). The product prepared under basic conditions showed sharper reflections than the analogous material synthesized at low pH. Acid extraction of the C_{16}TMABr surfactant template from the latter was achieved without loss of the hexagonally ordered MCM-41 structure or contraction in the unit cell parameter (Fig. 1), to produce a dye-functionalized inorganic replica with channel-like mesopores.§ In contrast, similar treatment of the product prepared at high pH resulted in a disordered organo-silica hybrid. TEM images, which showed hexagonal sets of lattice fringes, as well as parallel fringes corresponding to side-on projections of the mesostructure (Fig. 2), were consistent with the long range order parameters determined by SAXRD.

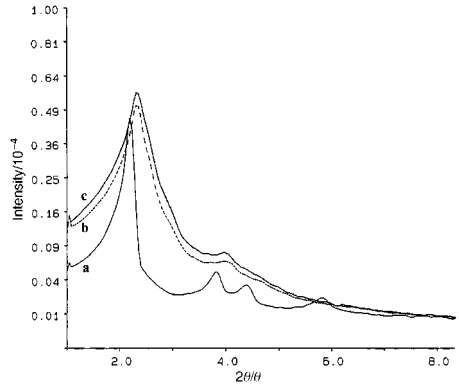

Fig. 1 SAXRD profiles for dye-functionalized ordered silica mesophases: (a) as-synthesized material prepared at high pH, (b) as-synthesized material prepared at low pH, and (c) after surfactant-extraction of material prepared under acidic conditions

Nitrogen adsorption studies confirmed that surfactant extraction of the dye-functionalized material produced under acidic conditions was predominantly mesoporous. A type IV isotherm, with a distinct capillary condensation step that was characteristic of a MCM-41 mesoporous material with a relatively large pore size distribution, was observed. The BET surface area was 760 $m^2\ g^{-1}$, with an average BJH pore diameter of 2 nm. These values are less than those typically reported for pure MCM-41 silicas. As no significant lattice contraction was observed by

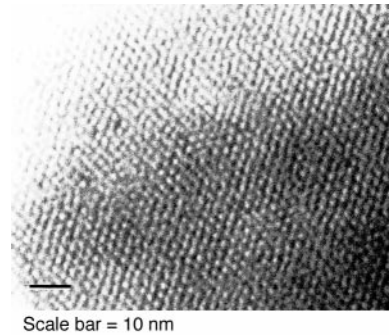

Fig. 2 TEM image of as-synthesized dye-functionalized MCM-41 material showing hexagonally ordered mesostructure. Scale bar = 10 nm.

SAXRD, we attribute this reduced porosity to pendent chromophore moieties that extend into the channel spaces.

^{29}Si DP MAS NMR spectroscopy showed distinct resonances for siloxane [Q^n = $Si(OSi)_n(OH)_{4-n}$, n = 2–4] and organosiloxane [T^m = $RSi(OSi)_m(OH)_{3-m}$, m = 1–3] centres in both the as-synthesized and surfactant-extracted materials.¶ The predominance of T^3 compared with T^2 and T^1 organosiloxane centres indicated that condensation of the organo-functionality in the MCM-41 wall structure was extensive. ^{13}C CP MAS NMR spectroscopy indicated that the dinitrophenylaminopropyl chromophore was covalently linked into the mesophase as an intact unmodified moiety both before and after surfactant extraction.‖ This was consistent with FTIR spectra of the as-synthesised and surfactant-extracted materials which showed characteristic Si–O–Si framework vibrations [1050 (large band), 1200 (shoulder), 480, 750 and 900 cm^{-1}), a Si–C band at 1150 cm^{-1}, as well as vibrations indicative of the chromophore (1338, 1621, 2880–2980, and 3365 cm^{-1}). The intensities of these vibrations were equal in the as-synthesised and surfactant-extracted materials, suggesting no disintegration or loss of the dinitrophenylaminopropyl functionality during the solvent extraction procedure. CHN analysis indicated that *ca*. 20 mol% of the dye functionality was incorporated into the MCM-41 structure.

Diffuse reflectance UV–VIS spectroscopy of the as-synthesised materials showed two broad absorbance bands at 317 and 417nm. These bands were characteristic of the *o*- and *p*-nitro groups, respectively, of the chromophore,[22] and indicated that the optical properties of the dye moiety were maintained when covalently linked into the MCM-41 structure. Extraction of the surfactant resulted in a shift in the position of the band with highest intensity from 317 to 341nm, indicating that the dinitrophenylaminopropyl groups were preferentially located in the pore spaces rather than internalized within the mineral walls. This band was observed at 350 nm for both an acetone solution of non-hydrolysed DNPTES and a sol-gel film of amorphous silica containing hydrolysed DNPTES, suggesting that the blue shift observed for the as-synthesized MCM-41 mesophase was due to specific interactions of the organic moiety with the surfactant micelles. As the infrared spectra of the surfactant-extracted and as-synthesized materials were unchanged, protonation of the chromophore can be ruled out as a cause of the shift in the absorption band.

Our results suggest that it should be possible to incorporate a range of organic chromophores into surfactant-silica mesophases and corresponding mesoporous replicas without extensive modification of the optical properties. Although further work is required, the covalent attachment of dye molecules into ordered or semi-ordered porous MCM-type materials could be of general importance in a number of areas. In principle, the organic moieties can be dispersed and isolated from each other, which for some systems, for example with rhodamine derivatives, should minimize intermolecular quenching of fluorescence properties. Furthermore, the combination of mesoporosity and optical properties should give rise to interesting materials, particularly when host–guest interactions are being examined. Similarly, covalently linked chromophores could be used as sensors in separations technologies to detect molecules within the channel-like pores of MCM-41 phases fabricated in the form of thin membranes. Finally, as the optical properties of the chromophore can be highly sensitive to the local environment, such moieties could be used to probe the internal structure and dynamics of silica mesophases in general.

We thank Dr David C. Apperley at the University of Durham, UK, for solid state NMR data, Dr Christine G. Göltner and Ingrid Zenke at the Max Planck Institute of Colloids and Interfaces, Teltow, Germany, for help with initial SAXRD data, and the University of Bath for financial support.

‡ In a typical preparation under alkaline conditions, C_{16}TMABr (0.40 g, Aldrich) was dissolved in a solution containing 1.0 M NaOH (5.0 g) and distilled, deionised H_2O (17.55 g). TEOS (1.5 g, Aldrich) and DNPTES (0.31 g, Apollo Sci. Ltd) were added, and the mixture stirred for 24 h at room temperature. The solid product was filtered, washed with H_2O and dried for 10 h in air. Extraction of the surfactant was performed by stirring a suspension of the solid product (0.99 g dm^{-3}) in 1.0 M HCl in EtOH at 75 °C for 24 h. The extracted material was filtered, washed with EtOH and dried for 10 h at 100 °C *in vacuo*. CHN analysis gave 6.9% (N), 19.2% (C) and 2.8% (H). For preparations under acidic conditions, TEOS (3.43 g) and DNPTES (0.71 g) were added to acetone (1.34 ml) and co-hydrolysed by addition of 3.85 M HCl acid (0.33 ml) (TEOS:DNPTES:acetone:HCl = 0.9:0.1:1.0:1.0). The mixture was stirred for 15 min at room temperature, and the resulting sol added with stirring to 42.8 ml of a solution of C_{16}TMABr (18.7 mg ml^{-1}; 51.3 mM) in 3.85 M HCl. The final solution was stirred and heated at 90 °C overnight (16 h). The yellow precipitate was filtered, washed repeatedly with distilled H_2O and EtOH, and dried in an oven at 70 °C. Surfactant extraction was performed as described above.

§ SAXRD *d* spacings (*hkl*): DNPTES-MCM (as-synthesized, high pH): 3.95 (100), 2.30 (110), 1.99 (200) and 1.51 nm (210); DNPTES-MCM (as-synthesized, low pH): 3.74 (100), 2.15 (110) and 1.98 nm (200); DNPTES-MCM (surfactant-extracted, low pH): 3.76 (100), 2.20 (110) and 2.00 nm (200). Unit cell parameter, $a = 2d_{100}/\sqrt{3}$.

¶ ^{29}Si DP (direct polarization) MAS NMR data (60 MHz, TMS, 20 °C) for DNPTES-MCM (as-synthesized, high pH): δ −50.9 (T^1, 3.1%), −58.1 (T^2, 4.7%), −66.7 (T^3, 12.5%), −90.3 (Q^2, 7.5%), −98.7 (Q^3, 34.4%), −108.6 (Q^4, 37.9%). For DNPTES-MCM (surfactant-extracted, high pH): δ 58.9 (T^2, 5.0%), −66.9 (T^3, 11.4%), −91.5 (Q^2, 5.9%), −100.6 (Q^3, 37.6%), −109.3 (Q^4, 40.1%).

Formation of triumphene, $C_{60}F_{15}Ph_3$: first member of a new trefoil-shaped class of phenylated [60]fullerenes

Olga V. Boltalina,[a] Joan M. Street[b] and Roger Taylor*[a]†

[a] *The Chemistry Laboratory, CPES School, University of Sussex, Brighton, UK BN1 9QJ*
[b] *Chemistry Department, The University, Southampton, UK SO17 1BJ*

Reaction of $C_{60}F_{18}$ with benzene/$FeCl_3$ during two weeks at room temperature produces the phenylated trefoil-shaped derivative $C_{60}F_{15}Ph_3$; higher reaction temperatures produce $C_{60}Ph_{18}$ from replacement of all fluorines by phenyl groups.

Arylated fullerenes may ultimately constitute the largest class of fullerene derivatives. Many have been made and some fully characterised, *e.g.* $C_{60}Ar_5X$, (X = H, Cl),[1–3] $C_{60}Ph_5OH$ (two isomers),[4] $C_{60}Ph_n$ (n = 2, 4),[5] $C_{70}Ph_n$ (n = 2, 4, 6, 8, 10),[6] $C_{70}Ph_9OH$,[7] $C_{70}Ph_8(OH)_2$,[4] $C_{60}PhH$ and $C_{70}PhH$,[8] a benzo-[*b*]furo[60]fullerene[9] and an isoquinolino[60]fullerene.[10] A number of other derivatives have been identified but so far by mass spectrometry only.[11,12] Most have been made by Friedel–Crafts reactions of fullerenes or halogenofullerenes with the aromatics. They are reasonably soluble and stable, especially towards EI mass spectrometry, and some are luminescent.[6] In $C_{60}Cl_6$, the least accessible chlorine was not readily replaced.[1,2]

Recently we described the formation and characterisation of $C_{60}F_{18}$, a polar crown-shaped molecule, shown in Fig. 1.[13] Fluorofullerenes are very susceptible towards nucleophilic substitution,[14] and fluoroalkanes are the most reactive of the halogenoalkanes in Friedel–Crafts alkylation of aromatics.[15] We now describe the successful isolation and characterisation of the first derivative that results from replacement of fluorine by phenyl, and which shows a unique arylation pattern.

Two samples of $C_{60}F_{18}$ (5 mg) were each added to solutions of anhydrous $FeCl_3$ (*ca.* 5 mg) dissolved in anhydrous benzene (2 ml). One solution was set aside for two weeks, the other was heated to *ca.* 70 °C for 1 h. The mixtures were evaporated to dryness and the resultant solids extracted with CCl_4 (to separate unreacted catalyst). Removal of this solvent under vacuum gave deposits that were dissolved in 1 : 1 hexane–toluene and purified by HPLC using a 4.6 mm × 25 cm Cosmosil Buckyprep column, with a flow rate of 1 ml min^{-1}. From both samples a main fraction of $C_{60}F_{15}Ph_3$ eluted at 49.6 min, and from the heated sample, minor fractions eluted at 14.3 and 17.7 min, these being $C_{60}F_{15}Ph_5$ and $C_{60}F_{15}Ph_7$, respectively. Comparison with the retention time of $C_{60}F_{18}$ (*ca.* 45 min with elution by toluene) shows that replacement of F by Ph reduces the retention time. As in the case of phenylated [60]fullerenes,[12] the retention time is reduced by increasing the phenylation level.

The mass spectrum of the crude extract showed also the presence of $C_{60}Ph_{18}$, but attempted separation resulted in degradation, with a broad peak indicated to be $C_{60}Ph_{18}O(OH)_2$, 2142 amu, eluting at 9.3 min (1 : 1 hexane–toluene, 0.5 ml min^{-1}).

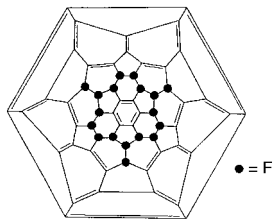

Fig. 1 Schlegel diagram for $C_{60}F_{18}$

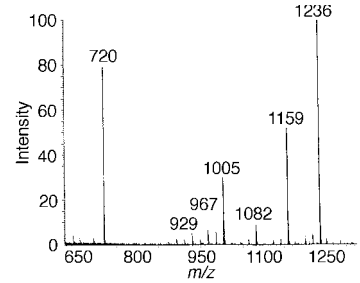

Fig. 2 EI mass spectrum (70 eV) for $C_{60}F_{15}Ph_3$

The mass spectrum (Fig. 2) shows the $C_{60}F_{15}Ph_3$ parent ion at 1236 amu, with peaks at 1159, 1082 and 1005 amu due to successive loss of phenyl groups. The structure of $C_{60}F_{18}$ suggests that the three fluorines which have been replaced by phenyl are the most accessible ones giving a product of C_{3v} symmetry. This is confirmed by the ^{1}H NMR spectrum (Fig. 3) which shows only one set each of the *o*-, *m*- and *p*-hydrogens of the phenyl groups; a spectrum run at −60 °C is identical, proving that the phenyl groups rotate freely and are thus not in a hindered environment.

The structure is further confirmed by the ^{19}F NMR spectrum (Fig. 4) which shows three peaks in a 1 : 2 : 2 intensity ratio at δ −137.22, −138.36 and −145.0, with respective half-height peak widths are *ca.* 12, 12 and 8 Hz respectively. Comparison with the ^{19}F NMR spectrum for $C_{60}F_{18}$ (four peaks in a 2 : 2 : 1 : 1 intensity ratio) shows that it is one of the latter (due to three equivalent fluorine atoms) that is replaced. The 2D-COSY spectrum (inset to Fig. 4), shows that the single intensity fluorine is directly coupled to one of the (adjacent) double intensity peaks. Thus it is the most accessible fluorine that has been replaced, the ease of replacement of the chlorines in $C_{60}Cl_6$.

The structure of $C_{60}F_{15}Ph_3$, which has encouraged us to name it as 'triumphene', is therefore as shown in Fig. 5. The simplicity of preparation suggests that it will be possible to make a large range of other aryl derivatives, the limiting step being only the low availability at present of $C_{60}F_{18}$.

Previously, one of us suggested that nucleophilic replacement of fluorine (in the absence of a catalyst) occurs *via* addition-elimination, because S_N1 substitution (giving a cation on the strongly electron-withdrawing cage) seemed improbable, and S_N2 substitution is impossible.[14] However, if $C_{60}F_{15}Ph_3$

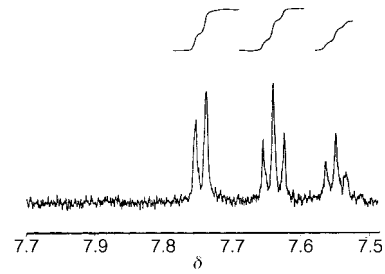

Fig. 3 ^{1}H NMR spectrum for $C_{60}F_{15}Ph_3$

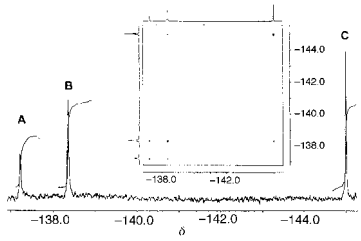

Fig. 4 ^{19}F NMR spectrum for $C_{60}F_{15}Ph_3$ with 2D-COSY spectrum inset. The peak labels correspond to the fluorine atoms identified as in Fig. 5.

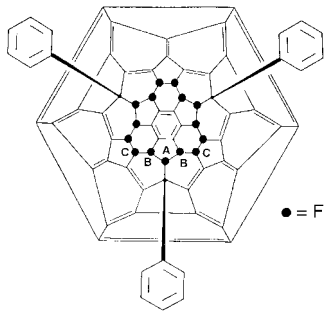

Fig. 5 Schlegel diagram of the structure of $C_{60}F_{15}Ph_3$

was formed by addition-elimination, it could not have C_{3v} symmetry since the phenyl groups would necessarily lie off the symmetry plane of the original $C_{60}F_{18}$. The present work therefore provides unambiguous evidence for direct fluorine replacement in nucleophilic substitution of fluorofullerenes, and is here facilitated by the presence of the Friedel–Crafts catalyst. This reinforces our conclusions concerning replacement of chlorine by phenyl in $C_{60}Cl_6$.[2] Moreover, the reaction of $C_{60}Ph_5Cl$ with $AlCl_3$ produces a free isolable carbocation,[16] and it is clear now that in the presence of these catalysts, substitution in halogenofullerenes takes place *via* an S_N1 mechanism, though necessarily involving frontside attack only.

We have insufficient $C_{60}F_{15}Ph_7$ and $C_{60}F_{15}Ph_5$ at present for full characterisation, but the addition of phenyl groups in pairs suggests that they add across a 6,6-double bond, *e.g.* that which lies on the symmetry plane (the bond across which oxygen adds to give $C_{60}F_{18}O$).[16] One could expect that with longer reaction times, $C_{60}F_{15}Ph_9$ may be observed as a further derivative.

Remarkably, we observed the presence of more volatile $C_{60}Ph_{18}$ (2108 amu) in an early acquisition of the mass spectrum of the crude material (Fig. 6); the mass spectrum shows also the doubly charged $M^+/2$ ions. The spectrum is notable in being less contaminated by the lower phenylated components that we have seen with other phenylation methods.

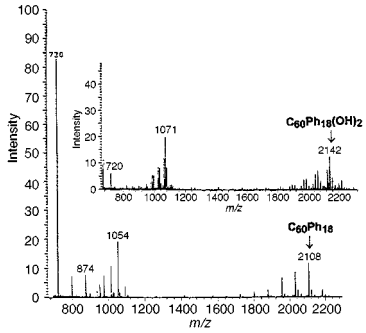

Fig. 6 EI mass spectrum for $C_{60}Ph_{18}$; inset is the mass spectrum for $C_{60}Ph_{18}(OH)_2$ showing also traces of the epoxide derivative

Despite the anticipated steric hindrance, the addition pattern in $C_{60}Ph_{18}$ is likely to be the same as in the fluoro precursor. The mass spectrum shows the presence of a nineteenth phenyl group at much lower intensity. This is due to further phenylation of the cage (well-known to occur with fullerenes and benzene in the presence of Friedel–Crafts catalysts)[11] and indicated in this work by the formation of $C_{60}F_{15}Ph_7$ *etc.* However, the markedly lower intensity of $C_{60}Ph_{19}$ compared to that of $C_{60}Ph_{18}$ provides very strong circumstantial evidence that the eighteen phenyl groups are indeed located at the sites previously occupied by fluorine, giving rise to a fascinating structure of extreme aromaticity.

We have been unable to obtain substitution of F by Ph in $C_{60}F_{36}$ (or in $C_{60}F_{48}$) under the conditions described above.

We attempted also to purify the $C_{60}Ph_{18}$ by HPLC but were unsuccessful because it appeared to oxidise to a diol, $C_{60}Ph_{18}(OH)_2$, and the epoxide derivative, as shown by peaks of 2142 and 2158 amu in the mass spectrum (inset to Fig. 6). Oxygenated derivatives of phenylated fullerenes are prone to form readily.[12]

We thank the Royal Society for a Joint Project Award.

Multiple α-agostic interactions in a metal–methyl complex: the neutron structure of $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$

Jacqueline M. Cole*[a,b]† Vernon C. Gibson,[c] Judith A. K. Howard,[a] Garry J. McIntyre[b] and Gary L. P. Walker[c]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*
[b] *Institut Laue Langevin, B.P. 156, 38042 Grenoble Cedex 9, France*
[c] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*

The neutron structure of $[Mo(NC_6H_3Pr^i_2)\text{-}2,6)_2Me_2]$ reveals two highly distorted methyl ligands; this distortion is due to the presence of multiple C–H···M α-agostic interactions.

Since the formalisation of the three-centre C–H···M 'agostic' interaction by Brookhart and Green in the mid 1980s,[1] these interactions have been found to occur in many coordinatively unsaturated alkyl, aryl and polyhapto hydrocarbon metal complexes.[2] They are relatively readily observed and detected in alkyl derivatives possessing β-hydrogens, either in solution for rapidly averaging agostic hydrogens *via* the effect of isotopic perturbation on C–H coupling constants and chemical shift positions, or in the solid state by X-ray crystallography.‡ Agostic interactions in metal–methyl species have proved more difficult to detect because (1) any isotopic perturbation of the resonance effect is diluted over a greater number of hydrogen environments and (2) in X-ray structure determinations, there are no obvious ligand distortions of the type seen in longer chain alkyls and it is inherently difficult with X-rays to locate the methyl hydrogen atom positions with any accuracy. The only reliable method of establishing the presence of agostic interactions in metal–methyl complexes is *via* diffraction.

To date, the only metal methyl complex to have been characterised by neutron diffraction that shows clear evidence for an α-agostic methyl C–H···M interaction is $[TiMeCl_3(Me_2PCH_2CH_2PMe_2)]$.[3] Here, we describe the neutron structure of the coordinatively unsaturated molybdenum α-agostic dimethyl complex $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$ which was prepared from the reaction of $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Cl_2(dme)]$ with 2 equiv. of methylmagnesium chloride. Full synthetic details will be reported elsewhere.[4] A crystal of dimensions 6.0 × 2.0 × 1.0 mm was grown from a saturated pentane solution at −35 °C. The molecular structure of $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$ is shown in Fig. 1, along with selected bond lengths and angles.

The geometry about the metal centre is best described as distorted tetrahedral with inter-ligand angles in the range 107–114°. The bond distances for the Mo–N and N–C(*ipso*) bonds [1.756(2) and 1.382(2) Å, respectively] in combination with Mo–N–C angles [159.6(1)°] are consistent with linear imido ligands.[5] The two methyl groups are crystallographically equivalent so the following discussion concentrates on only one methyl group. Each methyl group shows a partial positional disorder amongst the hydrogen atom sites, which can be described as resulting from a slight rocking motion about C(13), the pivot atom for a fluxional rotation which, averaged over all possible sites in all unit cells, gives the 'static average' picture shown. H(13A) can be resolved into two positions [(H13A) and (H13′)] with occupancies in the ratio 2 : 1 and these refine independently both isotropically and anisotropically. The latter tends to a distortion and an overlap in the two density distributions, but with derived molecular parameters very close to those reported herein, which result from an isotropic description of the disordered sites.

A large amount of librational motion therefore exists, thus disguising the precise position of the hydrogen atoms. However, despite the librational effects, the average geometry gives conclusive results. The coordination of each methyl group is markedly distorted from regular tetrahedral geometry and of special note are the particularly small angles Mo(1)–C(13)–H(13A) [103.7(4)°] and Mo(1)–C(13)–H(13B) [104.7(3)°] which are consistent with the hydrogen atoms being drawn towards the metal centre. Consequently, the angles, Mo(1)···H(13A)–C(13) (52.6°) and Mo(1)···H(13B)–C(13) (51.8°) are noticeably larger than those corresponding to the hydrogen atoms H(13C) and H(13′) (43.0 and 43.9° respectively).

The Mo(1)···H(13A) and Mo(1)···H(13B) distances [2.585(8) and 2.598(5) Å, respectively] are also significantly shorter than Mo(1)···H(13C) and Mo(1)···H(13′) [2.755(5) and 2.76(1) Å] and the Mo(1)–C(13) bond length of 2.112(2) Å is very short,

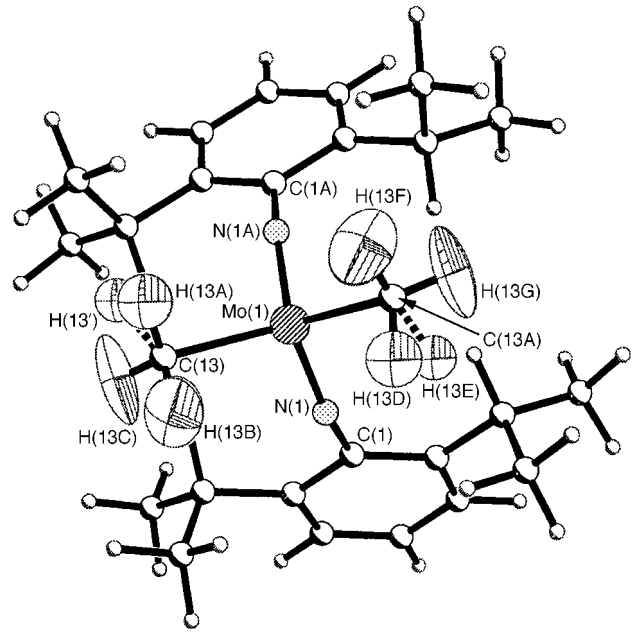

Fig. 1 The molecular structure of $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$ with 50% probability thermal ellipsoids shown on the methyl hydrogen atoms, thus indicating the extent of libration. Selected bond dimensions (Å and °): Mo(1)–N(1) 1.756(2), Mo(1)–C(13) 2.112(2), Mo(1)···H(13A) 2.585(8), Mo(1)···H(13′) 2.76(1), Mo(1)–H(13B) 2.598(5), Mo(1)···H(13C) 2.755(5), N(1)–C(1) 1.382(2), C(13)–H(13A) 1.07(1), C(13)–H(13′) 1.09(1), C(13)–H(13B) 1.068(7), C(13)–H(13C) 1.049(8); N(1)–Mo(1)–N(1A) 112.5(1), N(1)–Mo(1)–C(13) 107.86(7), C(13)–Mo(1)–C(13A) 114.1(2), C(13)–Mo(1)···H(13A) 23.7(2), C(13)–Mo(1)···H(13′) 21.0(3), C(13)–Mo(1)···H(13B) 23.4(2), C(13)–Mo(1)···H(13C) 19.8(2), Mo(1)–N(1)–C(1) 159.6(1), Mo(1)–C(13)–H(13A) 103.7(4), Mo(1)–C(13)–C(13′) 115.1(6), Mo(1)–C(13)–H(13B) 104.7(3), Mo(1)–C(13)–H013C) 117.2(3).

comparing with literature values of 2.554 Å (mean) and 2.189 Å (lower quartile).[6] This short Mo–C distance is also likely to be a consequence of the agostic interactions. All C–H distances are identical within experimental error. Of the two α-agostic hydrogen atoms per methyl group (therefore, four agostic interactions per molecule) both appear strong and of the same strength, judging by their relative geometries.

More than one agostic interaction in $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$ is not unreasonable since this molecule is quite severely coordinatively unsaturated. It is not possible to place a precise electron count on the complex since, for symmetry reasons, the two *cis* imido ligands are in direct competition for one of the metal d_π orbitals. This means that the electron count must be below 16 electrons (the count derived from assuming that both imido ligands can form two π bonds) and formally could be as low as 14 electrons (*i.e.* the count arising from three π-bonds between the molybdenum and the two imido groups). In general, the results described here underscore the notion that agostic interactions will occur whenever a metal centre possesses a suitably oriented and energetically accessible vacant orbital, and that multiple interactions of this kind may occur at a single metal centre. The neutron diffraction study described here shows clear evidence for four α-agostic methyl C–H···M interactions within $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$. It represents the second metal–methyl complex showing α-agostic interactions and the first one to show multiple agostic interactions.

The authors wish to thank the Institut Laue Langevin, Grenoble, France (J. M. C.) and the EPSRC (J. M. C. and G. L. P. W.) for financial support.

‡ It should be noted that the evidence for β-agostic interactions is often derived from other structural parameters such as a low M–C–C bond angle rather than direct location of the agostic hydrogen atom position.

§ *Crystal data* for $[Mo(NC_6H_3Pr^i_2\text{-}2,6)_2Me_2]$: $C_{26}H_{40}MoN_2$, M_r = 475.94, deep orange–red rectangular crystal (6.0 × 1.8 × 1.0 nm), monoclinic, space group *C*2/*c*, a = 20.240(4), b = 6.550(1), c = 19.910(4) Å, β = 103.99(3)°, V = 2561.2(8) Å^3, Z = 4, T = 150.0(2) K, D_c = 1.234 g cm^{-3}, $F(000)$ = 348, μ = 0.233 mm^{-1}, 2110 unique reflections ($6.56 \leqslant 2\theta \leqslant 60.02°$) were measured on the D9 four circle diffractometer at the Institut Laue Langevin (ILL), Grenoble, France in a beam of wavelength 0.8405(2) Å obtained by reflection from a Cu(220) monochromator. Half-wavelength contamination was removed with an erbium filter. The sample was mounted on the cold head of an Air Products closed-cycle refridgerator. Background corrections following Lehmann and Larsen[7] and Lorentz corrections were applied. Cryostat shield and absorption corrections were made using the local program ABSCAN and the DATAP program[8] respectively (transmission range: 0.6477–0.8045). The structure was refined by full-matrix least-squares refinement using SHELXL-93[9] against 2100 reflections. Refinement of 312 positional and anisotropic displacement parameters for all atoms [except for isotropic H(13A) and H(13′)] converged to $R1$ [$I > 2\sigma(I)$] = 0.0467 and wR_2 [$I > 2\sigma(I)$] = 0.0462 [$w = 1/\sigma^2(F_o)^2$] with S = 1.431.

$[Cu_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6\}$, the first discrete Cu^I_8 cubane in which each face of the cube is bridged by a diselenophosphate ligand and has an interstitial selenide ion (Se^{2-}), is reported.

The interests in combining transition metals and main group elements in clusters stem from two possibilities that these compounds could be useful precursors for the synthesis of new materials and provide a search for new coordinations and geometries.[1] We are interested in the synthesis of molecular cubic clusters having an interstitial main-group atom because they are not only extremely rare[2] but also particularly interesting in view of their unusual bonding characteristics.[3] Although there are several examples of metal carbonyls having μ_8-E (E = C,[4] Si,[5] P,[6] S[7] and As[8]) bridges, the metallic frameworks surrounding the interstitial atom are largely tetragonal (square) antiprisms.

In 1990, Fenske and Krautscheid reported a beautiful mega cluster, $Cu_{20}(\mu_8\text{-}Se)Se_{12}(PEt_3)_{12}$ **1**,[9] which consists of an undistorted, selenide centered Cu_8 cube, each of whose edges is bridged by a peripheral copper atom. The resulting 20 copper atom polyhedron is surrounded by twelve selenium ligands which are arranged in such a fashion as to form a near regular icosahedron. The peripheral copper atom is further coordinated by a PEt_3 ligand. The average formal oxidation state of each copper atom of the cluster is 1.3. In 1995, a sulfide centered Cu^I_8 cube, $\{Cu_8(\mu_8\text{-}S)[S_2P(OPr^i)_2]_6\}$ **2**, whose core geometry is analogous to the central portion of Fenske's compound was reported by Fackler.[1] Unlike compound **1** in which each edge of the cube is bridged by a copper atom, **2** is bridged by a sulfur atom of the dithiophosphate ligand. This brings to our attention as to whether a discrete Cu_8 cube with a selenium atom in its center can be isolated.

In order to synthesize a molecule having a selenide centered Cu^I_8 cube, we focused our attention on the ligand dialkyl diselenophosphate, $Se_2P(OR)_2^-$ (dsep). In sharp contrast to many studies on compositions and structures of phosphor-1,1-dithiolato metal complexes,[10] the chemistry of phosphor-1,1-diselenolato metal compounds has received scant attention. Consequently, there are very few papers referring to this ligand.[11] Among these, are the preparation of various dialkyl diselenophosphates and investigations of the spectroscopic properties of several main group and transition metal complexes. Powder X-ray patterns of some of the compounds are also included. Herein, we report the first discrete Cu^I_8 cubane encapsulating a selenide ion (Se^{2-}), $\{Cu_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6\}$ **3**. To our surprise this is also the first phosphor-1,1-diselenolato complex of any element studied by single crystal X-ray diffraction.

Treatment of $NH_4Se_2P(OPR^i)_2$ and $Cu(MeCN)_4PF_6$ in a 2 : 1 ratio in diethyl ether at 0 °C for 4 h results in a pale yellow solution. After chromatographic work-up (silica gel, eluent CH_2Cl_2–hexane = 3 : 2), a yellow material identified as **3** can be isolated in 40% yield. Compound **3** was fully characterized by positive FAB mass spectrometry, NMR† (^1H, ^{31}P) and X-ray diffraction.‡ In the positive FAB mass spectrum, a peak at *m/z* 2429 corresponds to the intact selenide-centered diselenolate Cu^I cluster. Also appearing in the mass spectrum is a peak at *m/z* 2122 which can be attributed to loss of a dsep ligand giving $\{Cu_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_5\}^+$. The ^{31}P NMR spectrum displays a singlet with satellites (J_{PSe} 671 Hz) at δ 73. This clearly implies all dsep ligands of **3** are equivalent in solution.

One and a half molecules of **3** exist in the asymmetric unit with the Se(02) atom located at a crystallographic inversion center. Fig. 1 shows a thermal ellipsoid drawing of one of the two independent molecules of **3**. The copper atoms are arranged at the corners of an almost regular cube. Each selenium atom of the dsep ligand bridges two copper atoms. Thus dsep exhibits a 'tetrametallic tetraconnective'[10f] (μ_2, μ_2) coordination pattern and each occupies a square face of the cube. The average 'bite distance' is 3.784(2) Å, which is *ca.* 0.2 Å longer than that observed for the sulfur analogue.[2a] Each copper atom of the cube is coordinated to three selenium atoms of three different ligands. The averaged Cu–Se(dsep) bond length is 2.447 Å and the Se–Cu–Se bond angles range from 113.15(11) to 118.09(11)°. In addition to the distorted trigonal planar geometry around the copper atom, there is a strong interaction to the central selenium atom. The average Cu–Cu distance of **3** is 2.928 Å, which is *ca.* 0.08 Å shorter than that observed for Fenske's compound. Consequently, the bond length between

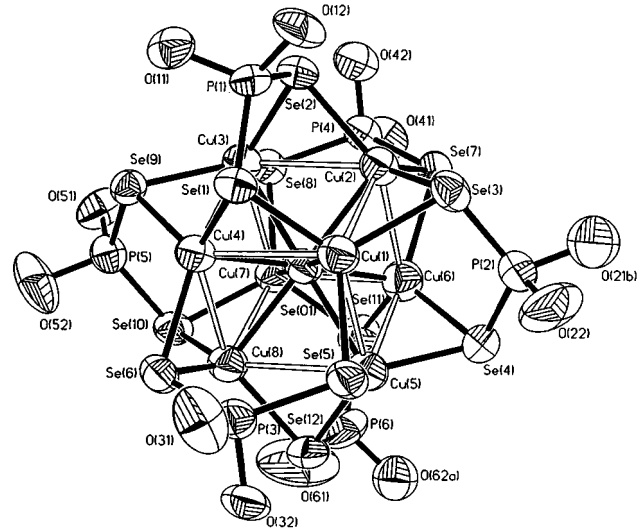

Fig. 1 The thermal ellipsoid drawing (50% probability) of one of the two independent molecules of **3**. The isopropyl groups are omitted for clarity. Selected bond lengths (Å): Se(01)–Cu(1) 2.550(3), Se(01)–Cu(2) 2.524(3), Se(01)–Cu(3) 2.577(3), Se(01)–Cu(4) 2.520(3), Se(01)–Cu(5) 2.546(4), Se(01)–Cu(6) 2.506(3), Se(01)–Cu(7) 2.532(3), Se(01)–Cu(8) 2.532(3), Cu(1)–Cu(2) 2.919(3), Cu(1)–Cu(4) 2.929(3), Cu(1)–Cu(5) 2.921(3), Cu(2)–Cu(6) 2.917(3), Cu(2)–Cu(3) 2.941(3), Cu(3)–Cu(4) 2.974(3), Cu(3)–Cu(7) 2.955(3), Cu(4)–Cu(8) 2.859(3), Cu(5)–Cu(6) 2.920(4), Cu(5)–Cu(8) 2.966(4), Cu(6)–Cu(7) 2.875(4), Cu(7)–Cu(8) 2.966(4).

the central selenide and the peripheral copper atoms ranges from 2.506(3) to 2.577(3) Å and is slightly shorter than that of $[Cu_{20}Se_{13}(PEt_3)_{12}]$, [2.605(3) Å]. Astonishingly the averaged $Cu–Se_{cen}$ bond length, (2.535 Å), in **3** is even shorter than that of the corresponding sulfide analogues (2.694[2a] and 2.585 Å[2b]). Overall owing to the lack of fourfold symmetry, molecule **3** has an idealized T_h point group symmetry. The central selenide atom in conjunction with the twelve selenium atoms of the ligands forms a body-centered icosahedron. Previously this type of geometry has only been observed upon two occasions, for **1** and $Cu_{26}Se_{13}(PEt_2Ph)_{14}$.[12]

Besides Fenske's cluster **1**, compound **3** is the only coordination complex possessing a μ_8-Se bridge. Nevertheless, μ_8-Se bridges do exist in several solid state materials of the type A_2Se (A = Li, Na, and K) with antifluorite structure.[13] It is worth noting that a metal atom in the center of a metallic cube is known for Ni[14] and Pd[15] and a remarkable solid state material, $K_4Cu_8Te_{11}$, in which a potassium ion is encapsulated in the center of a cubic Cu_8 core has also been reported.[16]

The P–Se distances of **3**, [2.144(7)–2.177(6) Å], are slightly shorter than those observed for bridging PSe_2 fragments in the solid state compounds $A_2AuP_2Se_6$ (A = K, Rb) [2.197(6)–2.258(6) Å],[17] $[Cs_2Cu_2P_2Se_6]$ [2.186(4)–2.202(5) Å],[18] and the molecular complexes $[Hg_4(Se_2)_2(PSe_4)_4]^{8-}$ [2.221(5)–2.237(5) Å][19] and $[Fe_2(CO)_4(PSe_5)_2]^{2-}$ [2.214(6)–2.216(6) Å.[20] Observation of a μ_2, μ_2 bridging mode in **3** is unusual and unprecedented for selenophosphate complexes. Three new clusters containing dsep ligands, $Ag_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6$, $Ag_9(\mu_7\text{-}Se)[Se_2P(OPr^i)_2]_8$ and $Ag_{10}(\mu_7\text{-}Se)[Se_2P(OPr^i)_2]_8$ have also been characterized and details will be reported in due course.

The research grant (NSC 87-2113-M-033-003 to CWL, NSC87-2113-M-031-002 to JCW) from the National Science Council of Taiwan is greatly appreciated.

Notes and References

† $^{31}P\{^1H\}$ NMR ($CDCl_3$), δ 73 (J_{SeP} 671 Hz); ^1H NMR ($CDCl_3$), δ 1.37 [d, 72H, $CH(CH_3)_2$], 4.88 [m, 12H, $CH(CH_3)_2$]; $^{77}Se\{^1H\}$ NMR ($CDCl_3$), δ −59 (J_{SeP} 671 Hz). Unfortunately we were unable to detect the resonance frequency of the central selenide ion in the ^{77}Se NMR which might be caused by the long T_1 value. FAB MS, *m/z* 2429 (M^+), 2122 (M − dsep); Anal. Calc. for $C_{36}H_{84}Cu_8O_{12}P_6Se_{13}$: C, 17.80; H, 3.46. Found: C, 17.66; H, 3.34%.

‡ *Crystal data*: $C_{36}H_{84}Cu_8O_{12}P_6Se_{13}$, M = 2429.65; monoclinic, space group $P2_1/n$, a = 13.8341(8), b = 36.969(2), c = 21.9728(12) Å, β = 93.2630(10)°, V = 11219.3(11) Å^3, Z = 6, D_c = 2.158 Mg m^{-3}, $F(000)$ = 6960, T = 298(2) K.

An orange crystal with dimensions 0.20 × 0.20 × 0.40 mm was used for X-ray structural analysis. Intensity data were collected over one quadrant using the ω scan mode on a Siemens SMART CCD diffractometer equipped with graphite monochromated Mo-Kα radiation (λ = 0.710 73 Å). A total of 11 805 unique reflections were measured. The structure was solved by direct methods using SHELXTL-PLUS software package.[21] All Cu and Se atom positions were revealed on the first refinement. Other non-hydrogen atoms were located from subsequent difference Fourier syntheses. Parts of oxygen and carbon atoms of the isopropyl groups (7 out of 18) were found disordered. These disordered atoms were treated in an equal population model. Bond distances were constrained for disordered atoms and atoms connected to the disordered atoms during the structure refinement. These constraints were: P–O = 1.600 Å, O–C = 1.500 Å and C–C = 1.550 Å. The structure was refined by full-matrix least-squares method on F^2. All but disordered atoms and atoms attached to them were refined anisotropically. H-atoms were not included. Refinement converged to $R1$ = 0.0748 [$I > 2\sigma(I)$], $wR2$ = 0.1664 (all data) and S = 1.143 based on 940 variables, 43 restraints, and 11 805 reflections. CCDC 182/947.

The intercalation compound $Li(Mn_{0.9}Co_{0.1})O_2$ as a positive electrode for rechargeable lithium batteries

A. Robert Armstrong, Robert Gitzendanner, Alastair D. Robertson and Peter G. Bruce*

School of Chemistry, University of St. Andrews, North Haugh, St. Andrews, Fife, UK KY16 9ST

By replacing only 10% of the Mn by Co in the layered lithium intercalation compound $LiMnO_2$ the amount of lithium that can be removed and reinserted is increased by 50% corresponding to an increase in the ability to store charge from 130 to 200 mA h g^{-1} at 100 μ A cm^{-2} and rendering this low cost/toxicity material of potential interest as a positive electrode in rechargeable lithium batteries; furthermore the cooperative Jahn–Teller distortion due to localised high spin $Mn^{3+}(3d^4)$ in $LiMnO_2$ appears to be suppressed for $Li_x(Mn_{0.9}Co_{0.1})O_2$; $x < 0.9$ (80% Mn^{3+} assuming Co^{3+}).

First generation rechargeable lithium batteries are now a major commercial success.[1] They utilise the layered intercalation compound, $LiCoO_2$, as the positive electrode from which lithium is removed on charging the cell and reinserted on discharge.[2,3] Only half the lithium may be removed and reinserted reversibly (Li_xCoO_2; $0.5 < x < 1$) limiting the practical capacity to store charge to *ca.* 130 mA h g^{-1}. In order to develop much needed second generation batteries, new lithium intercalation hosts are essential. The challenge facing solid state chemistry is to synthesise lithium intercalation compounds that possess a higher capacity to cycle lithium in a host which is cheaper and less toxic than $LiCoO_2$.[2] Several systems have been extensively investigated including those based on layered $LiNiO_2$ and the spinel $LiMn_2O_4$.[4–11] The former offers improved capacity of *ca.* 170 mA h g^{-1} while the latter (110 mA h g^{-1}) is cheaper and less toxic than $LiCoO_2$. Recently we reported the first synthesis of layered $LiMnO_2$, isostructural with $LiCoO_2$.[12–14] Key to the preparation was the use of a low temperature ion exchange route. Being a manganese oxide it has the potential to deliver a low cost/toxicity electrode. Most of the lithium may be removed on initial charging (> 200 mA h g^{-1} at 100 μA cm^{-2}) but only a proportion of this can be reinserted (*ca.* 130 mA h g^{-1}) rendering this otherwise attractive cathode of less interest. By replacing only 10% of the Mn by Co, a material is obtained, the cost and toxicity of which remain sufficiently low to be of industrial interest and for which the ability to sustain a high capacity on cycling (200 mA h g^{-1} on cycling at 100 μA cm^{-2}) is enhanced.

Synthesis of $Li(Mn_{0.9}Co_{0.1})O_2$ employed the ion exchange method reported previously.[12] $Na(Mn_{0.9}Co_{0.1})O_2$ was synthesised by mixing Na_2CO_3, $Mn(CH_3CO_2)_2{\cdot}4H_2O$ and $Co(CH_3CO_2)_2{\cdot}4H_2O$ in water, drying by rotary evaporation then heating initially at 250 °C for 3 h then 670 °C for 1 h in air. The resulting solid was subjected to ion exchange by refluxing in a 5–10 fold excess of LiBr in hexanol at 150 °C for 8 h. Rietveld refinement using powder neutron data collected on POLARIS (ISIS, RAL, Oxfordshire) confirmed that the structure is layered and isostructural with $LiCoO_2$ (α-$NaFeO_2$ structure). A good fit was obtained between the observed and calculated powder diffraction profiles [R_{wp} = 0.026, rhombohedral cell with lattice parameters a = 2.8750(2) Å and c = 14.3930(8) Å, c/a = 5.006], Fig. 1. The structure is composed of close packed oxide ion layers stacked to yield a cubic close packed arrangement, a sheet of octahedral sites is located between each pair of oxide layers and alternate sheets are occupied by transition metal and lithium ions. The very different scattering lengths of Mn and Co made it possible to refine their occupancies on the shared transition metal sites. Values for Mn and Co of 0.93(1) and 0.07(1) were obtained. We have also synthesised Co substituted compounds up to $Li(Mn_{0.5}Co_{0.5})O_2$ and refinement with neutrons shows a continuous increase of the Co content on the transition metal sites and an associated contraction of the *a*-axis corresponding to shortening of the TM-O distances (TM = transition metal), as expected for a continuous solid solution. The *a*-axis contracton is consistent with replacement of Mn^{3+} by Co^{3+} rather than Co^{2+}/Mn^{4+}. Atomic emission analysis revealed a slightly lithium deficient composition of $Li_{0.85}(Mn_{0.9}Co_{0.1})O_2$ which agrees well with the amount of lithium that can be removed and inserted electrochemically and with the neutron refinement of the Li site occupancy.

Mn^{3+} is a Jahn–Teller active ion and in pure $LiMnO_2$ it results in a distortion from the ideal rhombohedral structure to monoclinic symmetry.[12] The cooperative Jahn–Teller distortion persists on deintercalation giving rise to a two phase mixture of monoclinic $LiMnO_2$ and rhombohedral $Li_{0.5}MnO_2$ until the $Li_{0.5}MnO_2$ composition is reached at which the structure becomes a single rhombohedral phase. At this point only 50% of the transition metal sites are occupied by the Jahn–Teller active Mn^{3+} ion. It appears that a combination of cobalt substitution and slight lithium deficiency is enough in the case of $Li_{0.85}(Mn_{0.9}Co_{0.1})O_2$ to suppress the cooperative Jahn–Teller distortion despite 75% of the transition metal sites being occupied by Mn^{3+} (assuming Co^{3+}). We have inserted lithium into $Li_{0.85}(Mn_{0.9}Co_{0.1}O_2)$ and find that even for $Li_{0.9}(Mn_{0.9}Co_{0.1}O_2)$ (80% Mn^{3+} if Co^{3+}) there is no evidence for a cooperative distortion in the X-ray or neutron data. The Jahn–Teller distortion in $LiMnO_2$ is driven by the localised high spin $3d^4$ configuration of Mn^{3+}. It is interesting that such a low level of Co^{3+} suppresses the distortion. Understanding the electronic structure in detail and particularly investigating the origin of the suppression of the cooperative Jahn–Teller distortion is beyond the scope of this paper and necessitates a subsequent study,

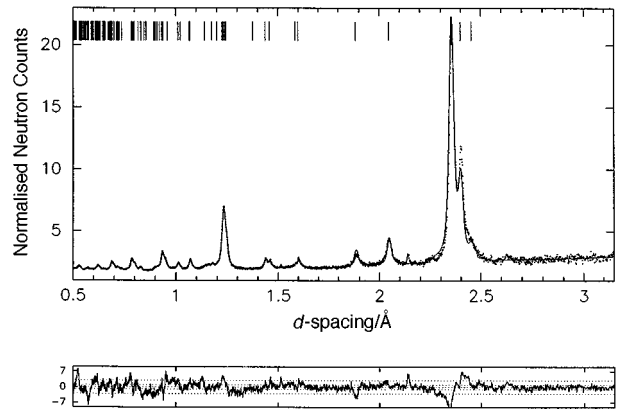

Fig. 1 Powder neutron diffraction data for $Li_{0.85}(Mn_{0.9}Co_{0.1})O_2$. Dots, experimental points points; solid line, fit by a layered structure and lower solid line, difference plot. The peak at d = 2.15 Å arises from the vanadium sample can.

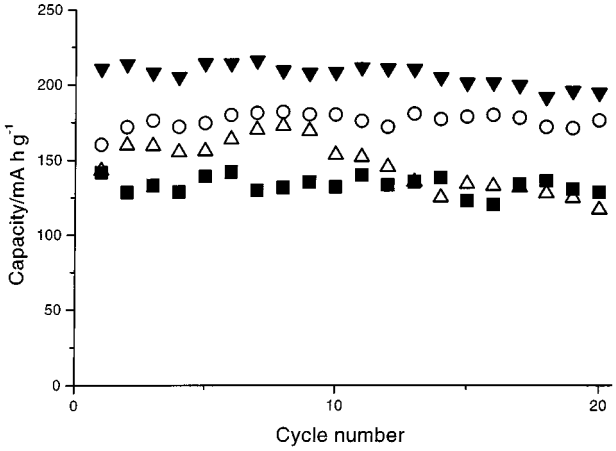

Fig. 2 Variation of specific discharge capacity with cycle number at 100 μA cm^{-2} and 2.6–4.8V; for layered $LiMnO_2$ and three Co doped samples. (△) $Li(Mn_{0.95}Co_{0.05})O_2$, (▼) $Li(Mn_{0.90}Co_{0.10})O_2$, (○) $Li(Mn_{0.85}Co_{0.15})O_2$, (■) $LiMnO_2$.

already underway, which will include establishing the oxidation states of Mn and Co.

The performance of the material as an intercalation electrode in a cell was investigated by forming a composite between the intercalation compound, super S carbon and Kynar Flex 2801 binder (a copolymer based on PVDF) in the weight ratios 85 : 10 : 5. The electrode was cast onto Al foil. Cycling was performed in three-electrode cells (Li counter and reference) in 1 M $LiPF_6$ in EC–DMC (2 : 1) as electrolyte and at a constant current density of 100 μA cm^{-2} (14 mA g^{-1}) within the potential range 2.6–4.8 V, Fig. 2. The discharge capacity on the first cycle is 210 mA h g^{-1} and ranges between this value and 200 mA h g^{-1} up to twenty cycles (the variation between different cells is < 5%), demonstrating a substantial improvement in capacity compared with $LiMnO_2$ and eliminating the capacity loss on the first cycle. Why might this be so?

Cycling lithium in the spinel host $LiMn_2O_4$ over the range $Li_{1+x}Mn_2O_4 (0 < x < 1)$, involves a two phase reaction between cubic $LiMn_2O_4$ and tetragonal $Li_2Mn_2O_4$, arising from the Jahn–Teller distortion which occurs when more that 50% of the octahedral 16d sites in spinel are occupied by Mn^{3+}.[6] As a result, there is an abrupt change in the unit cell volume on Li cycling as one phase converts to the other, leading to disconnection of the particles and the formation of isolated regions in the electrode incapable of storing lithium.[15] A similar first order phase change occurs in the case of layered $LiMnO_2$ within the first cycle. We also know from extensive X-ray and neutron diffraction studies, HREM and electrochemical data that $LiMnO_2$ converts to a spinel phase on cycling.[16] The absence of a Jahn–Teller distortion in $Li_{0.85}(Mn_{0.9}Co_{0.1})O_2$ may be related to the elimination of the abrupt capacity loss suffered by $LiMnO_2$ within the first cycle. Further work will be carried out, including longer term cycling, to better understand the mechanism of intercalation in the Co doped materials and to understanding how a small proportion of Co modifies the process compared with pure $LiMnO_2$.

Results from compositions which neighbour $Li_{0.85}(Mn_{0.9}Co_{0.1})O_2$ are also shown in Fig. 2. The data indicate that the capacity retention is even better for compositions with more than 10% Co, however the overall capacity is somewhat reduced.

Only a proportion of the capacity is delivered above 4 V *vs.* Li^+/Li, Fig. 3. However, the move to 2.3 V electronics in mobile communications and other portable applications coupled with the use of graphite anodes which deliver a large proportion of their capacity at a voltage near that of lithium metal, makes 3 V electrodes attractive for future lithium-ion batteries. The intense current interest in α-MnO_2 and its derivatives, which operate at 3 V, bears witness to this.[17]

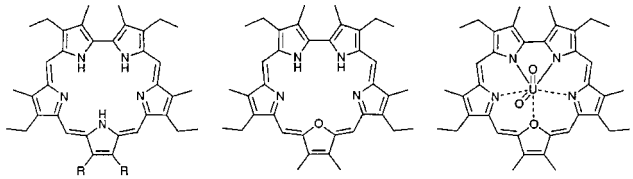
Synthesis and characterization of an oxasapphyrin-uranyl complex

Jonathan L. Sessler,* Andreas Gebauer, Michael C. Hoehner and Vincent Lynch

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712, USA. E-mail: sessler@mail.utexas.edu

Reaction of monooxasapphyrin with uranyl diacetate in the presence of triethylamine leads to the formation of a stable, in-plane aromatic uranyl complex.

Sapphyrin (*e.g.* **1**) is an aromatic 22 π-electron expanded



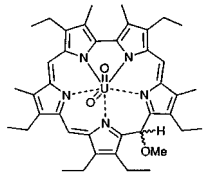
1a R = Me
1b R = Et

2 **3**

porphyrin that has been known for more than 30 years.[1,2] Its pioneering role in expanded porphyrin research[2a–c] and the more recent finding that it[2d] and other related materials[3] bind anions in their protonated forms continues to inspire interest in these pentapyrrolic systems. In spite of this increased attention, the metal coordination chemistry of sapphyrin remains woefully underdeveloped.[2] At first blush this seems surprising since one of the most intuitively appealing aspects of sapphyrin[2a] is that it should act to stabilize complexes with larger cations than those normally coordinated by porphyrins (*e.g.* Gd^{3+}, UO_2^{2+}, *etc.*).

However, efforts to obtain such complexes have so far failed.[2a,4]† Recently, we prepared an organic-soluble, furan-containing analogue of sapphyrin, system **2**,[8] and now wish to report that this monooxa species supports the formation of a stable, in-plane uranyl complex (**3**).

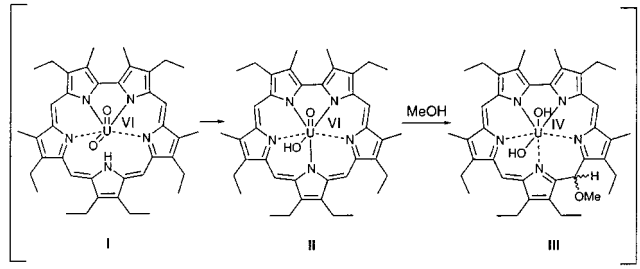
The rationale for using **2** as a possible uranyl chelating ligand derived from an appreciation of what happens when sapphyrin **1b** is treated with UO_2^{2+}. Under most reaction conditions the macrocycle is either returned unchanged or suffers decomposition. However, in the presence of methanol a uranyl complex (**4**) of what is a formally a reduced form of sapphyrin may be isolated.[4] This finding was rationalized in terms of intermediates **I**, **II** and **III** (Scheme 1) playing a critical role in mediating the key nucleophilic attack step leading to the formation of the reduced, methoxy-functionalized product **4**.



4

This led us to consider that a stable, aromatic uranyl complex might be obtainable were the central pyrrole of the tripyrrane 'replaced' by a furan. Such a replacement would also create a ligand that, once deprotonated, would be dianionic and hence well suited to coordinate the uranyl cation on a charge matching basis.

As it transpired, treatment of the bis-hydrochloride salt of **2**, but not **1**·2HCl,[4] with uranyl diacetate dihydrate in acetonitrile containing triethylamine led, after column chromatographic purification, to the formation of a green metallic solid. This material displays a UV–VIS spectrum typical of a sapphyrin



Scheme 1 Proposed intermediates in the formation of **4**

species with one strong Soret band at 483 nm and three weaker Q-type absorption bands at 624, 647 and 708 nm (Fig. 1). The significant bathochromic shift (29 nm) of the Soret band compared to the starting oxasapphyrin bis-HCl salt (Soret band at 454 nm, Q-type bands at 625, 633, 669 and 689 nm), together with the bathochromic shift and different aspect of the Q-type bands (Fig. 1), provided a preliminary 'hint' that (i) the metal insertion process was successful and (ii) the monooxasapphyrin skeleton was still intact.

Proton NMR spectroscopic studies revealed the presence of two sets of peaks at the low field frequencies (*i.e.* 10.37 and 10.78 ppm, respectively) typical of aromatic sapphyrin *meso* protons.[9] On the other hand, no signals ascribable to internal NH protons were observed. Since sapphyrins such as **1** and **2** are known to be quite basic (*i.e.* easily protonated),[2,10] this finding is interpreted as being consistent with the formation of a metal complex wherein the key metal-to-ligand contacts involve, at a minimum, all four of the nitrogens present in the macrocyclic core (*i.e.* structure **3**). The presence of a uranyl moiety was also implied by the identification of a ν(O=U=O) band in the IR spectrum at 936 cm^{-1}. Final proof for the formation of the proposed 1 : 1 uranyl complex then came from an X-ray crystallographic analysis.

Crystals of **3** were grown by allowing a dichloromethane solution of the complex to diffuse slowly into hexanes.‡ As illustrated in Fig. 2(*a*) the uranyl cation is located almost in the center of the sapphyrin. The uranyl-to-nitrogen distances of 2.449(4) Å (U–N1), 2.470(3) Å (U–N5), 2.582(4) Å (U–N2), and 2.587(3) Å (U–N4) are all very similar to one another. By contrast, the oxygen of the sole furan subunit, at a distance of 2.791(3) Å (U–O3), is significantly further away. The ur-

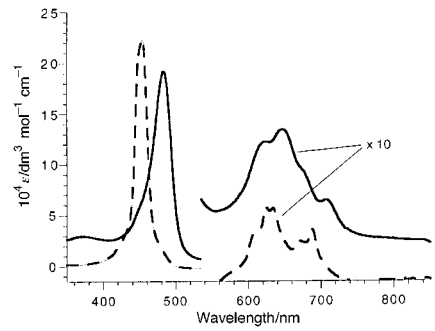


Fig. 1 UV–VIS spectrum of the monooxasapphyrin-uranyl complex **3** (—) as recorded in CH_2Cl_2. Also shown for comparison is the spectrum (---) of the starting monooxasapphyrin macrocycle (**2**·2HCl).

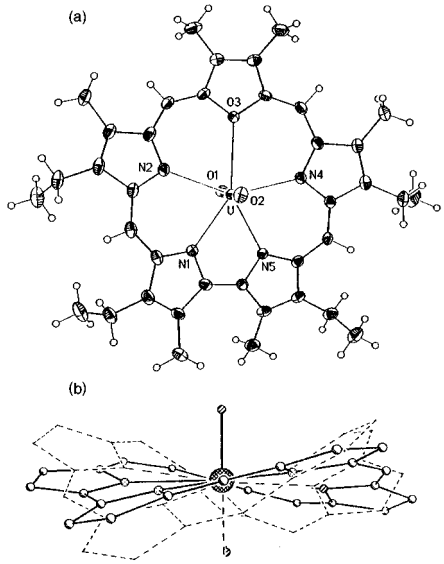

Fig. 2 (*a*) Front view of $C_{38}H_{42}N_4O_3U$ (**3**) showing the heteroatom labeling scheme. Thermal ellipsoids are scaled to the 30% probability level. H atoms are scaled to an arbitrary size. (*b*) Overlay of the side views of **3** (ball-and-stick model) and the pentaphyrin–uranyl complex **5** (dashed lines). The β-substituents of both have been omitted for clarity.

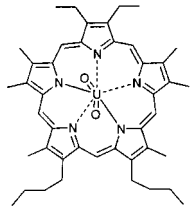
anium(VI) cation is found to sit within a distorted pentagonal bipyramidal ligand environment (the relevant angles are: 75.00(11)° (N1–U–N2), 72.97(10)° (N2–U–O3), 74.18(10)° (O3–U–N4), 74.75(11)° (N4–U–N5), 64.11(12) (N1–U–N5) and 176.29(13) (O1–U–O2), respectively.

Complex **3** possesses a saddle-shaped conformation as illustrated in Fig. 2(*b*). However, the distortion found is much less than that observed in the case of an earlier reported pentaphyrin uranyl complex **5** (*cf.* Fig. 2).[6b] To the extent that



5

the binding core of pentaphyrin is expected to be larger than that of sapphyrin, this comparative finding lead us to suggest that the saddle-shaped distortion of the uranyl pentaphyrin **5**, and to a lesser extent that of the oxasapphyrin complex **3**, is caused by a macrocyclic core that is too big (as opposed to too small) for the uranyl cation. This is reflected in the average N–UO_2^{2+} bond distances; these are 2.522 and 2.541 Å, in the case of **3** and **5**, respectively.

Complex **3** was also studied by cyclic voltammetry.§ Here, one quasi-reversible reduction wave was observed at 0.62 V (100 mV s^{-1}) that most likely belongs to the UO_2^{2+}–UO_2^{+} couple. In addition, one irreversible reduction wave at 1.58 V (100 mV s^{-1}), assignable to a UO_2^{2+} to U^{4+} reduction process, and one irreversible oxidation wave at 0.64 V (100 mV s^{-1}), ascribed to the oxasapphyrin ligand, are also observed. The quasi-reversible wave of the UO_2^{2+}–UO_2^{+} couple is found to fall at a significantly more positive potential than the corresponding uncomplexed UO_2^{2+}–UO_2^{+} couple (E_0 = 0.163 V),[11] as would be expected in light of the favorable bonding interactions present in complex **3**.

Complex **3** was found to be very stable when stored as a solid or in CH_2Cl_2 solution over long periods of time at room temp. in the presence of air. It was also found to be stable, as a CH_2Cl_2 solution, when exposed briefly to aqueous solutions of pH = 2 (70% decomposition after 72 h), or when treated with those of pH = 11 for longer periods (no apparent decomposition after 72 h). By contrast, almost complete decomplexation was observed within a few min when HOAc (10% v/v) was added to a solution of **3** in $CHCl_3$.

In summary, we have described the first example of a stable in-plane metal cation complex of a sapphyrin derivative. It provides a further cogent demonstration of how small changes in ligand structure (in the present instance an O for NH 'replacement') can influence significantly the metal chelation chemistry of a given system.

Support of this research by the National Science Foundation (Grants CHE 9122161 and CHE 9725399 to J. L. S.) is gratefully acknowledged.

Notes and References

† Uranyl complexes of two other pentapyrrolic systems, namely superphthalocyanine[5] and pentaphyrin[6] are known. Also known are sitting-atop η^2-Rh^I and -Ir^I complexes as well as 1 : 1 Zn^{II} and Co^{II} derivatives.[2a,e,7]

‡ *Crystal data* for **3**: dark green crystals, monoclinic, $P2_1/n$, Z = 4, a = 11.990(1), b = 15.351(1), c = 18.954(1) Å, β = 104.53(1)°, V = 3377.1(5) $Å^3$, D_c = 1.65 g cm^{-3}, μ = 48.49 cm^{-1}. 11 387 reflections were measured, of which 9466 were unique [R_{int} (F^2) = 0.021]. The structure was refined on F^2 to a $R_w(F^2)$ = 0.0857 with a goodness of fit = 1.074 for 416 parameters, while the conventinal $R(F)$ = 0.0358. CCDC 182/945.

§ Cyclic voltammetry was carried out (25 ± 2 °C) under dry argon using a Bioanalytic Systems Inc. (BAS) CV-59W version 2 MF9093 voltammetric analyzer. Dry MeCN was the solvent, 0.1 M $NBu^n_4PF_6$ the electrolyte, a 1.6 mm Pt disk the working electrode, and a Pt wire the auxilary electrode. A Ag–AgCl couple, separated from the bulk solution by means of a porous Vycor plug, was used as the reference electrode.

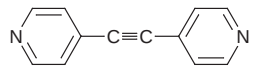
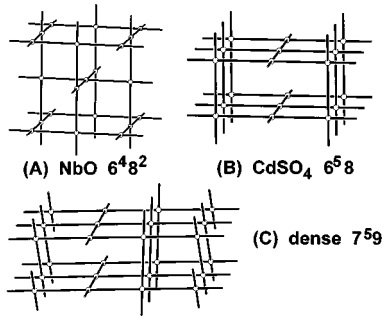
Copper(II) nitrate reacts with 1,2-bis(4-pyridyl)ethyne (bpethy) in ethanol to yield mixtures containing, beside to a one-dimensional ladder-like polymer, a networked [Cu(bpethy)$_2$] species, with a triply interpenetrated chiral frame based on pseudo-square planar metal centres, showing a topology theoretically predicted but never observed before, and containing uncoordinated ligands as guest molecules.

The crystal engineering of networked coordination polymers, of potential utility as zeolite-like materials, has produced in recent times novel interesting assemblies by using suitable bidentate spacer ligands. Among these an important class is represented by ligands containing two 4-pyridyl donor units interconnected by chains or groups of different types, which can afford variated lengths, linear or non-linear geometries, and conformationally rigid or non-rigid molecular skeletons. With the most simple of these ligands, *i.e.* 4,4′-bipyridyl, a variety of architectures have been obtained in the past years.[1] The use of longer bis(4-pyridyl) spacers has afforded very interesting structural motifs, as double helices,[2] double sheets,[3] interpenetrated ladders[4,5] and brick-wall frames,[4] interpenetrated diamondoid nets[6] and other noteworthy species.[7,8] We have studied the self-assembly process of one of these ligands, the rigid linear 1,2-bis(4-pyridyl)ethyne (bpethy), with copper(II) nitrate.



bpethy

The choice of such building elements was performed with the aim to gain some control of the networking process, since the nitrate anions, due to their donor ability, are known to give rise either to T-shaped metal centres (metal to ligand molar ratio 1 : 1.5)[1a,4] or to pseudo-square planar metal centres (metal to ligand molar ratio 1 : 2).[1b] Moreover, in the latter case an array of single sheets of squares, commonly observed with 4,4′-bipyridyl,[1b,9] seemed to us rather unlikely, taking into account the increased length of bpethy (*ca.* 9.8 *vs.* 7.1 Å). Looking, therefore, for a 3D network of square planar centres as the target, besides the prototypical frame of NbO (topology $6^4 8^2$, A in Scheme 1) we have found only two other examples,



Scheme 1

suggested by O'Keeffe,[10] and referred to as the tetragonal $CdSO_4$ (B)† and the so-called 'dense' net (C). In a very recent communication a product from the self-assembly of copper(II) nitrate and 1,2-bis(4-pyridyl)ethane has been described,[11] containing a (twofold interpenetrated) 3D net based on pseudo-square planar copper centres, which has been erroneously ascribed to the NbO topological type (A) but, indeed, belongs to the $CdSO_4$ one (B). We report here the first example of a (triply interpenetrated) coordination network of the third topological type (C). Again a theoretically anticipated topology, of unlike existence within simple inorganic compounds, can be accomplished in the area of coordination polymers. The reactions of $Cu(NO_3)_2 \cdot 3H_2O$ with bpethy afford mixtures of products. On layering over an ethanolic solution of the salt an ethanolic solution of the ligand (molar ratio 1 : 2) the formation of small elongated blue crystals is observed after few days. The product, investigated by single crystal X-ray analysis,‡ corresponds to $[Cu(bpethy)(NO_3)_2] \cdot 0.5EtOH$ **1**. On allowing the solution to concentrate almost to dryness by evaporation, the reaction further proceeds, giving flat hexagonal blue crystals of a second species **2**, also characterized by X-ray analysis,‡ together with other minor unidentified products. Compound **1** consists of one-dimensional linear chains of Cu^{II} ions linked by bpethy ligands, which run in parallel pairs joined by bridging nitrate anions, in a ladder-like fashion. The metal ions exhibit Jahn–Teller distorted octahedral coordinations (2 N atoms of bpethy, 2 O atoms of a chelating nitrate, and 2 O atoms of two asymmetric μ-η^1-anions, see Fig. 1, top). The ladders propagate in two different directions (rotated by 39.6°) as shown in Fig. 1, bottom. Compound **2** is a more complex and interesting species, formulated as $[\{Cu(bpethy)_2(H_2O)_2\}\{Cu(bpethy)_2(NO_3)(H_2O)\}_2][NO_3]_4 \cdot bpethy \cdot 1.33H_2O$. It contains a fascinating tridimensional polymeric architecture consisting of three interwoven nets, each belonging to the topological type C of Scheme 1. A single net (Fig. 2) presents linear –Cu–bpethy–Cu–bpethy– chains both parallel and perpendicular to the trigonal crystallographic ***c*** axis, joined at the square-planar metal centres (Cu···Cu contacts all *ca.* 13.6 Å). The chains perpendicular to

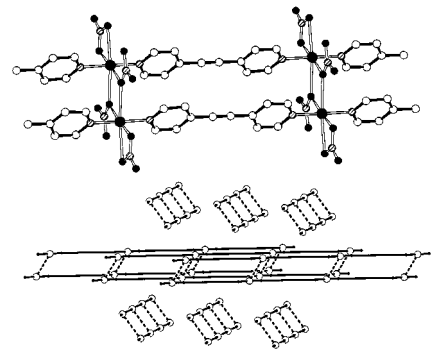


Fig. 1 A view of one mesh of the ladder in **1** (top) and a schematic view of the packing of the ladders (bottom)

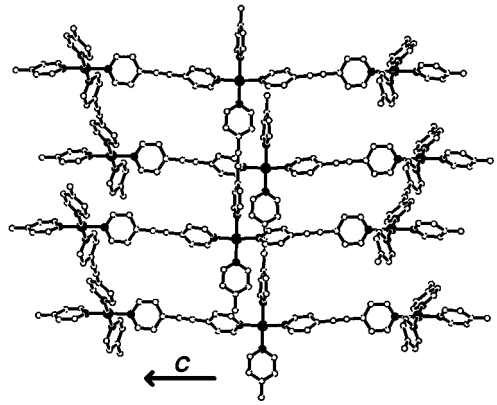

Fig. 2 A view of part of a single dense net C in compound **2**

the ***c*** axis are rotated by 120° about this axis on passing to each successive layer, in a 3_1 helical disposition, thus resulting in a chiral network. The topology of this network exhibits some peculiar features among the known four-connected nets:[10] (i) it is unique in not containing circuits shorter than heptagons; (ii) it has the highest 'topological density'§ (and is thus termed 'dense'); (iii) each metal node is ideally surrounded by eight equidistant neighbours but directly connected only to four of these. The voids present in a single net are too large to be left filled only by the counter ions. Thus three $[Cu(bpethy)_2]$ nets of the same topology interpenetrate as illustrated in Fig. 3.¶ Indeed, the three nets are not identical because of the difference in the coordination of the Cu^{II} ions: the octahedral metal environments show in all cases four equatorial N-bonded pyridyl groups, but the axial (loosely bonded) ligands are two water molecules in one of the three nets (net I, black), and a water molecule and a η^1-nitrate anion in the other two (nets II and III, white and dotted). In spite of the threefold interpenetration there are still voids that contain, besides free nitrate anions, disordered water molecules and uncoordinated bpethy ligands (Fig. 3). These molecules, moreover, form hydrogen

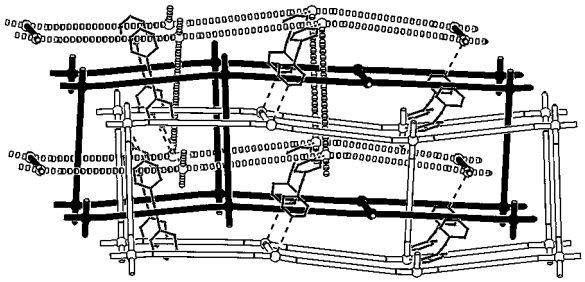

Fig. 3 A schematic view of the three interpenetrated nets C in **2**. Net I (black) is crystallographically independent, while nets II and III (white and dotted) are related by twofold axes. The solvated ligand molecules are also shown with their hydrogen bonds (dashed lines).

bonds involving the two nitrogen atoms and two water molecules coordinated to the copper ions of nets II and III (N···O 2.82 Å), giving rise to hydrogen bond bridges Cu–(H_2O)–bpethy–(H_2O)–Cu, of length 17.59 Å. Taking into accout these interactions nets II and III together can be described as an unique tridimensional five-connected array, interpenetrated by the four-connected net I. Interpenetration phenomena involving different types of nets are quite rare; we have found only one previous example, *i.e*. the interpenetration of two different diamondoid networks in K_2PdSe_{10}.[12] Though the preference of compound **2** for the C type topology, rather than A or B, remains unexplained, the unusual features observed (new topology, interpenetration of different motifs, network chirality, guest molecules anchored to the frame) make this species an interesting solid state rarity, as well as a notewhorty reference structure for the engineering of frames based on square-planar metal centres.

Notes and References

† This net can be sligthly distorted in such a manner to tolerate the presence of tetrahedral centres substituting the square planar centres. This is the case for $CdSO_4$ itself as well as for the coordination polymer $[Ag_2$(hexamethylenetetramine)$][NO_3]_2$; O. M. Yaghi, H. Li and M. O'Keeffe, *Mater. Res. Soc. Symp. Proc.*, 1997, **453**, 127.

‡ *Crystal data*: **1** $[Cu(bpethy)(NO_3)_2]\cdot 0.5EtOH$, monoclinic, space group *C*2/*c* (no. 15), a = 25.540(8), b = 9.186(3), c = 15.482(12) Å, β = 117.08(4)°, V = 3234(3) Å^3, Z = 8, Dc = 1.605 Mg m^{-3}, final R value 0.0933 for 1039 independent absorption corrected (ψ-scan) reflections [$I > 2\sigma(I)$].

2: $[\{Cu(bpethy)_2(H_2O)_2\}\{Cu(bpethy)_2(NO_3)(H_2O)\}_2](NO_3)_4\cdot bpethy\cdot 1.33H_2O$, trigonal, space group $P3_121$ (no. 152), $a = b$ = 13.652(1), c = 40.648(2) Å, V = 6560.9(8) Å^3, Z = 3, D_c = 1.450 Mg m^{-3}, final R value 0.0789 for 3952 independent absorption corrected (SADABS) reflections [$I > 2\sigma(I)$].

The data collections were performed by the ω-scan method, Mo-Kα radiation (λ = 0.710 73 Å), at 293 K on an Enraf-Nonius CAD-4 diffractometer for **1** and at 243 K on a SMART-CCD area-detector diffractometer for **2**, within the limits $3 < \theta < 25°$ (**1**) and $1 < \theta < 26°$ (**2**). The structures were solved by direct methods (SIR97)[13] and refined by full-matrix least squares (SHELX97).[14] Anisotropic thermal factors were assigned in **1** to Cu and the NO_3^- atoms and in **2** to all the non-hydrogen atoms except for a disordered nitrate and a solvated water molecule. The assignment of the absolute structure for **2** was confirmed by the statistics and the refinement of the absolute structure parameter as implemented in SHELX-97, to a value of 0.07(4).[15] All the diagrams were obtained using the SCHAKAL97 program.[16] CCDC 182/953.

§ The topological density has been defined[10] as the cumulative sum of the numbers of topological neighbours for the first ten coordination shells (1186 for A, 1488 for B, 2078 for C and 980 for diamond).

¶ In the one-dimensional helical coordination polymer $[Ag(pytz)](NO_3)$ [pytz = 3,6-di(4-pyridyl)-1,2,4,5-tetrazine][8] the nitrate ions show weak interactions with the metal ions (Ag···O 2.79 Å). We have rationalized that, by assuming these contacts also as bonds, the overall topology is of type C, three-fold interpenetrated; however, given the long Ag···O distances, a one-dimensional chain description is perhaps more appropriate.

Aluminosilicate mesoporous molecular sieves with enhanced stability obtained by reacting MCM-41 with aluminium chlorohydrate

Robert Mokaya* and William Jones

Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: rm140@cus.cam.ac.uk

Aluminosilicate MCM-41 materials prepared by post-synthesis alumination using aqueous aluminium chlorohydrate exhibit remarkably high mechanical and hydrothermal stability and in addition the materials, after steaming at high temperatures, possess stronger Brønsted acid sites compared to the parent material.

Recently, heteroatom substituted mesoporous molecular sieves such as MCM-41 have attracted much interest due to their potential use as hosts, adsorbents or catalysts.[1] Of particular interest are Al-containing materials which may be used as solid acid catalysts.[2,3] The structural stability of such aluminosilicate mesoporous molecular sieves is very important to their application as catalysts. Indeed the thermal and hydrothermal stability of Al-containing MCM-41 has been the focus of much recent research.[3,4] Despite good thermal stability, AlMCM-41 materials generally suffer from poor (and unpredictable) structural ordering and low hydrothermal stability and are easily destroyed by boiling in water or by steaming at high temperatures.[3,4] Studies on the mechanical stability of mesoporous molecular sieves have concentrated on pure silica materials[5] and to the best of our knowledge there is no data on the mechanical stability of silica-alumina materials. The structural stability of mesoporous molecular sieves can be improved by increasing the thickness of the pore walls and/or by enhancing the local ordering of the walls. This may be achieved by post-synthesis treatments such as pore wall grafting[6] or recrystallisation.[7] We have recently discovered that structurally well ordered AlMCM-41 can be prepared by reacting purely siliceous MCM-41 with aluminium chlorohydrate (ACH) solution containing Al polycations. Herein we report on the remarkable stability of the resulting aluminosilicate materials.

The starting material, a purely siliceous MCM-41 (designated PSMCM), was prepared according to ref. 8. AlMCM-41 was prepared by adding 1.0 g of calcined PSMCM to a 50 ml solution of ACH at 80 °C and stirring for 2 h (at 80 °C). The precursor Al-grafted MCM-41 was obtained by filtration and thoroughly washed with distilled water (until free of Cl^- ions), dried at room temperature and calcined in air at 550 °C for 4 h. The physical properties of the purely siliceous material (PSMCM) and AlMCM-41 samples prepared from ACH solutions with Al concentrations of 0.12, 0.30 and 0.48 mol l^{-1} (designated AlMCM2 (Si/Al = 9.7), AlMCM4 (Si/Al = 6.5) and AlMCM5 (Si/Al = 6.1) respectively) are given in Table 1. The *d* spacing of the AlMCM materials is higher than that of the starting PSMCM material and generally increases with the amount of aluminium incorporated. This is consistent with the incorporation of increasing amounts tetrahedral Al into the framework and is in part due to the longer Al–O bond length compared to the Si–O bond. The effect of the incorporation of Al onto the framework is clearly illustrated by the changes in the thickness (calculated by subtracting the pore diameter from the lattice parameter) of the pore walls. At 16 Å the wall thickness of PSMCM is comparable to the largest reported values for MCM-41.[8] On Al incorporation the wall thickness progressively increases up to 23.9 Å (for AlMCM5). The increase in wall thickness is at the expense of pore diameter which reduces from 31.6 Å for PSMCM to 25.8 Å for AlMCM5. The surface area reduces slightly while the pore volume shows a larger decrease. However, the lowest surface area (753 m^2 g^{-1}) and pore volume (0.62 cm^3 g^{-1}) obtained for the most aluminous sample (AlMCM5) is still high.

The mechanical stability of the Al-grafted materials was investigated by pressing the materials in a steel die of diameter 13 mm for 10 min. The effects of compression (external pressures were calculated from the applied force and the die diameter) on the ordering and textural properties of AlMCM4 (Si/Al = 6.5) are shown in Fig. 1 and Table 1. Except for a slight decrease in the *d* spacing, compaction at 185 MPa does not have any significant effect on the XRD pattern of AlMCM4. The retention of structural integrity is confirmed by the minimal decrease in the surface area and pore volume (Table 1). Compaction at 370 MPa resulted in a decrease in XRD peak intensity (with no further decrease in *d* spacing) and was accompanied by a 29% decrease in surface area and 25% decrease in pore volume. After compaction at the higher pressure of 740 MPa the surface area and pore volume reduced by 60%. However, the XRD pattern still indicates retention of some hexagonal symmetry. The mechanical stability exhibited here is remarkable especially in the light of previous studies which have shown that pure silica MCM-41 is essentially destroyed at 224 MPa.[5] It is likely that the stability observed

Table 1 *d* spacing and textural properties of the studied materials

Sample	d_{100}/Å	Surface area/m^2 g^{-1}	Pore volume/cm^3 g^{-1}	APD[a]/Å	a_o[b]/Å	Wall thickness/Å
PSMCM	41.2	887	0.85	31.6	47.6	16.0
AlMCM2	42.0	760	0.69	29.3	48.5	19.2
AlMCM4	42.8	767	0.65	26.5	49.4	22.9
AlMCM4 (185 MPa)[c]		755	0.57	27.4		
AlMCM4 (370 MPa))[c]		547	0.49	28.5		
AlMCM4 (740 MPa))[c]		284	0.26	30.6		
AlMCM5	43.0	753	0.62	25.8	49.7	23.9
ST-AlMCM5)[d]		558	0.45	22.6		
REF-AlMCM5)[e]		834	0.70	24.9		

[a] APD = average pore diameter (determined using BJH analysis). [b] a_0 = Lattice parameter, from the XRD data using the formula $a_0 = 2d_{100}/3$. [c] Sample AlMCM4 compressed at the pressures shown in parentheses. [d] Sample AlMCM5 steamed at 750 °C for 4 h. [e] Sample AlMCM5 refluxed in distilled water for 16 h.

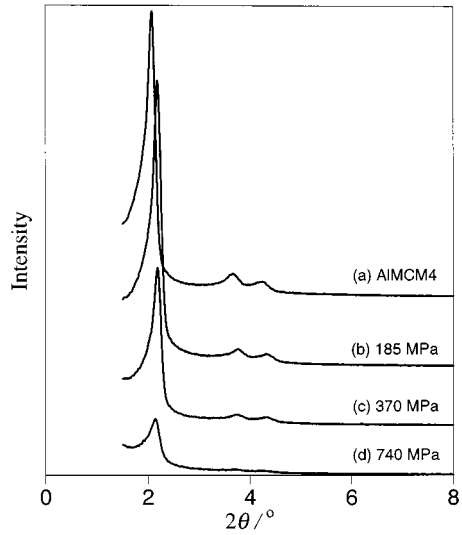

Fig. 1 Powder XRD patterns of sample AlMCM4; (a) original material and after compaction at (b) 185 MPa, (c) 370 MPa and (d) 740 MPa

here is due to the much thicker walls of the Al-grafted sample; a direct (mixed-gel) synthesised Al-MCM-41 material (with a Si/Al ratio of 23 and 11 Å thick walls) was destroyed after compaction at 370 MPa. We also investigated the mechanical stability of the pure silica starting material (PSMCM) and observed good structural integrity (not unlike that of AlMCM4) up to 370 MPa. However, after compaction at 740 MPa the degradation of PSMCM (as indicated by XRD) was much greater than that of AlMCM4.

To investigate hydrothermal stability, the Al-grafted materials were subjected to steaming at 750 °C for 4 h or refluxing in distilled water for 16 h (at a water to sample ratio of 1 l g^{-1}). The effects of these treatments on the ordering and textural properties of AlMCM5 (Si/A/ = 6.1) are shown in Fig. 2 and Table 1. After steaming, the Al-grafted sample exhibits an XRD pattern which indicates retention of structural ordering albeit with reduced peak intensity and lower *d* spacing. This is accompanied by a 3.2 Å reduction in pore diameter and a 25% decrease in both the surface area and pore volume. Previous studies have shown that whereas pure silica MCM-41 is relatively stable to steaming, Al-containing MCM-41 materials

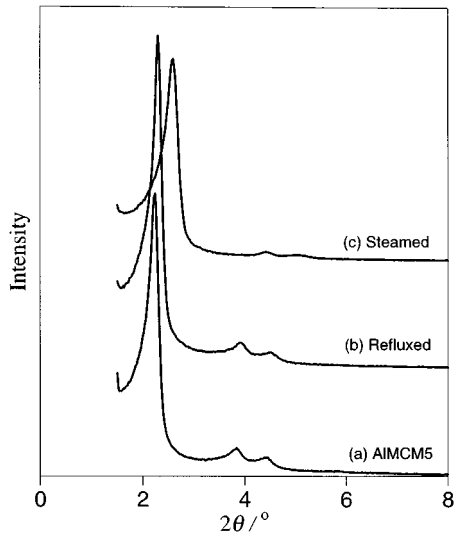

Fig. 2 Powder XRD patterns of sample AlMCM5; (a) original material and after (b) refluxing in water for 16 h and (c) steaming at 750 °C for 4 h

are on the other hand highly unstable.[3] It is therefore noteworthy that the Al-grafted material reported here is able to maintain structural ordering and considerably high surface area and pore volume. To ascertain the effect of steaming on catalytic properties we compared the acid content[2] and activity (for cumene cracking)[2] of AlMCM5 with its steamed analogue (ST-AlMCM5). The acid content of ST-AlMCM5 was 0.257 mmol $H^+ g^{-1}$ compared to 0.605 mmol $H^+ g^{-1}$ for AlMCM5. However, despite a lower acid content, the conversion of cumene was higher for the steamed sample; ST-AlMCM5 had an initial rate (in mmo l g^{-1} h^{-1} and taken at 10 min time on stream) of 1.225 compared to a rate of 0.843 for AlMCM5. This translates to an apparent turnover frequency (TOF) of 4.75 over ST-AlMCM5 and 1.4 over AlMCM5. This results indicate that the acid sites in the steamed sample (though fewer in number due to some dealumination) are stronger than those on AlMCM5. This observations are reminiscent of the behaviour of steam stabilised Y zeolites. To the best of our knowledge, this is the first example of an Al-containing MCM-41 material, which exhibits such stability to high temperature steaming. Indeed a direct (mixed-gel) synthesised Al-MCM-41 material (Si/Al = 23) was destroyed by similar hydrothermal treatment with its surface area decreasing by 75%.

The hydrothermal stability of the Al-grafted materials is further illustrated by their stability in boiling water. Fig. 2 indicates that heating (refluxing) of AlMCM5 in boiling water for 16 h had virtually no deleterious effect on its XRD pattern which suggests excellent retention of structural ordering. This is confirmed by the fact that the surface area and pore volume, far from decreasing, actually increase (Table 1). When subjected to similar treatment the structural ordering of the pure silica starting material (PSMCM) was destroyed and its surface area reduced by 65%. The direct (mixed-gel) synthesised Al-MCM-41 material (Si/Al = 23) was even less stable and was rendered amorphous after refluxing in water for a shorter time of 6 h.

We have demonstrated that Al-containing MCM-41 with good structural stability can be prepared by reacting purely siliceous MCM-41 with aluminium chlorohydrate. The enhanced mechanical and hydrothermal stability of materials reported here may be due to recrystallisation effects, involving the grafted Al, which act to heal defect sites in the structure of the MCM-41 materials. This is likely because the Al is initially grafted onto the pure silica material *via* silanol groups which are known to occur at defect sites. Similar recrystallisation effects are known to occur in zeolites.[9] Stable aluminosilicate MCM-41 materials are expected to find use as solid acid catalysts especially for processes which require catalyst regeneration under severe conditions.

R. M. is grateful to the EPSRC for an Advanced Fellowship.

A manganese-containing molecular sieve catalyst designed for the terminal oxidation of dodecane in air

Robert Raja and John Meurig Thomas*†

Davy Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS

Mn^{III} ions that replace a few percent of the framework Al^{III} sites in a microporous aluminophosphate—number 18, with a pore aperture of 3.8 Å—function as catalytically active centres for the selective oxidation of dodecane preferentially at C_1 and C_2.

The activation and functionalisation of alkanes are notoriously difficult to execute and control—far more so than the processes involved in their complete oxidation (combustion).[1] Taking cues from the general field of redox metallo-enzymes[2–4] that catalyse shape- and regio-selectively the oxidation of hydrocarbons, but also from framework-substituted, transition-metal-ion-incorporated microporous aluminium phosphates (AlPOs),[5–7] we have designed a heterogeneous catalyst that selectively converts dodecane in air, without the need for stoichiometric donors such as alkyl hydroperoxides or H_2O_2.

The catalyst consists of so-called AlPO-18,[8] in which a small fraction, typically 4 atom%, of the Al^{III} ions has been isomorphously replaced, during synthesis,[9] by Mn^{II} ions. Separate experiments, involving combined *in situ* X-ray absorption spectroscopy and X-ray diffractometry[10,11] plus *ex situ* scanning transmission electron microscopy, have established that, in O_2 or dry air, at temperatures up to *ca*. 550 °C, the Mn^{II} ions (like those of isomorphously substituted Co^{II}) are all converted to the +3 oxidation state while remaining tetrahedrally coordinated (*i.e*. coordinatively unsaturated) without loss of structural integrity of the AlPO host or exsolution from it of its embedded transition-metal ions. EXAFS and other analyses show that the individual Mn^{III} active sites are spatially well separated throughout the three-dimensional internal surface of the catalyst. Whereas all these active centres are accessible to small molecules, because of the structural characteristics of AlPO-18 (see Fig. 1) only those situated at the mouths of the pores that emerge at exterior surfaces are accessible to the extremities of the linear dodecane.

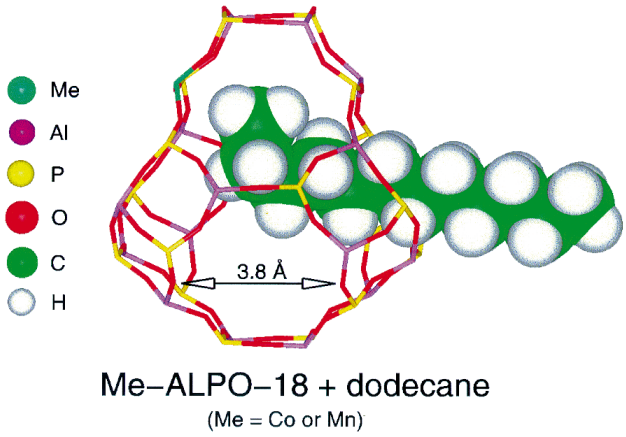

Fig. 1 Energy-minimised configuration adopted by *n*-dodecane at 0 K inside an AlPO-18 framework. The terminal methyl group (C_1) and C_2 of the dodecane are significantly closer to a tetrahedral framework site containing the metal ion (manganese, in this case) than either C_3, C_4 or C_5, implying that the Mn^{III} ions in the framework of the AlPO-18 cage, along with intracage O_2, exert a greater influence on the C_1 and C_2 than on other carbons on the dodecane backbone.

The details of the synthesis of Mn^{II}-containing AlPO-18 are exactly the same as for that of other MeAlPO-18 (Me = Co, Zn, Mg, Mn, *etc*.) catalysts.[6] Briefly, the Mn^{II} ion is introduced to the template-containing precursor gel from which small crystals of phase pure product appear. Upon gentle calcination in O_2, the template (*N*,*N*-diisopropylethylamine) is entirely gasified, leaving the cages of the resulting catalyst empty. In a typical experiment, 0.5 g of catalyst was added to 50 g of dodecane in a stainless steel high pressure catalytic reactor (Cambridge Reactor Design) lined with PEEK (poly ether ether ketone), and equipped with a mechanical stirrer and liquid sampling valve. Removal of samples for analyses during the course of the reaction is possible without perturbing the pressure in the reactor. Dry air was pressurised into the reaction vessel (1.5 MPa) and the reactor was heated to the desired temperature (373 K). Samples were periodically removed, analysed by gas chromatography (GC; Varian 3400 CX} equipped with a BPX5 column (25 m × 0.32 mm) and a flame ionisation detector (FID), and the total conversion and product distribution (estimated in moles and normalised with respect to the GC response factor) were determined as a function of time (using 1,2-dichlorobenzene as internal standard). The acids formed were esterified and analysed as methyl esters.[12] The identity of the products was confirmed by injecting authenticated standard samples. The mass balance was calculated for each run and the estimated error in the analysis arising from handling or sampling loss is less than 6.0 mol%.

Exactly analogous experiments were carried out with another manganese-containing AlPO, MnAlPO-36[13] in which the pore diameter is appreciably larger (6.5 Å × 7.5 Å), thereby permitting much greater access to the dodecane. Fig. 2 and Table 1 summarise the results. It is obvious that the small pore aperture of MnAlPO-18 (and of CoAlPO-18) results in

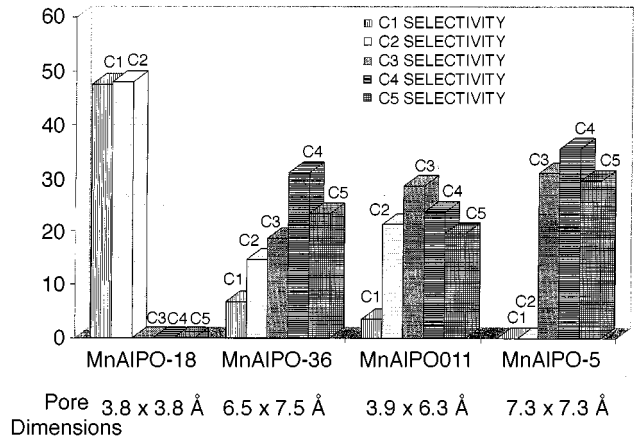

Fig. 2 Bar chart summarising the various degrees of regio-selectivity in the oxidation of dodecane over four microporous MnAlPO catalysts. The regio-selectivity for terminal oxidation with MnAlPO-18 far exceeds that of any of the other three.

Table 1 Oxidation of dodecane[a] in air: comparison of catalysts

Catalyst	Conv./mmol	Product[b] distribution/mmol											
		C_1-ol	C_1-al	Lauric acid	C_2-ol	C_2-one	C_3-ol	C_3-one	C_4-ol	C_4-one	C_5-ol	C_5-one	Others[c]

Mn-ALPO-11 (0.04)	6.82	0.24	—	—	0.91	0.53	0.75	1.19	0.58	1.03	0.43	0.91	0.25

[a] Dodecane = 49.7 g; catalyst = 0.5 g; air = 1.5 MPa; temp. = 373 K; time = 24 h. [b] C_1-ol = dodecan-1-ol; C_1-al = dodecanal; C_2-ol = dodecan-2-ol; C_2-one = dodecan-2-one; C_3-ol = dodecan-3-ol; C_3-one = dodecan-3-one; C_4-ol = dodecan-4-ol; C_4-one = dodecan-4-one; C_5-ol = dodecan-5-ol; C_5-one = dodecan-5-one. [c] Others = mainly CO_2, CO, water and lower olefins/hydrocarbons in the gas phase.

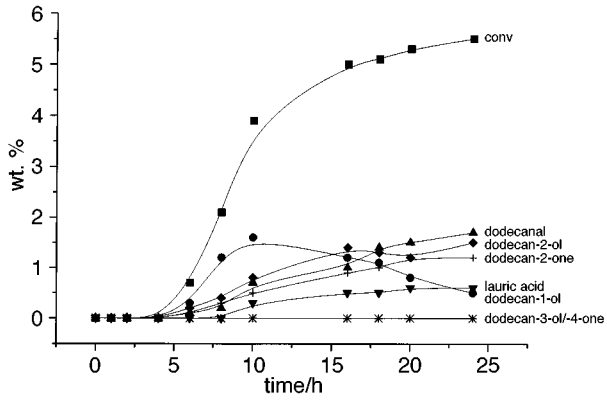

Fig. 3 Typical kinetic plots for the oxidation of dodecane over MnAlPO-18 catalyst under the conditions given in Table 1

oxidation of the dodecane (total conversion = 5.5 wt.%) only at C_1 and C_2, whereas in MnAlPO-36 (possessing essentially the same concentration of the active site) (total conversion = 5.2 wt.%) the oxyfunctionalization occurs at essentially all the carbon atoms of the dodecane backbone, and more predominantly at the C_4 and C_5 positions. The kinetics of oxidation of dodecane using MnAlPO-18 was studied in detail (Fig. 3), and after an initial period of induction (4 h), dodecan-1-ol and dodecan-2-ol were formed simultaneously, and were subsequently oxidised to dodecanal, lauric acid and dodecan-2-one at prolonged contact times. In an identical experiment, the solid catalyst was filtered off (when hot) after 8 h (conversion = 2.4 wt.%) and the reaction was continued for a further 16 h. But, no further conversion was observed, showing that the Mn^{III} ions in the framework of the molecular sieve are solely responsible for the catalysis. (The reaction mixture was independently analysed by ICP analysis and no detectable quantities of Mn or Co were observed.) MnAlPO-18 and CoAlPO-18 (and possibly other transition-metal ion substituted AlPO-18) are therefore good candidates for suitable catalysts in the production of functionalised hydrocarbons required as surfactants and detergents. We know from parallel work[14] that a CoAlPO-18 (total conversion = 7.1 wt.%) catalyst preferentially activates the terminal and secondary methyl groups of *n*-hexane.

We believe that the key to the catalytic activity is the coordinatively unsaturated Mn^{III} ion. Just as with the tetrahedrally coordinated Ti^{IV} ions in TS-1,[15] metallocene derived Ti↑MCM-41[16,17] and especially the Co^{III} ions in CoAlPO-18,[14] expansion of the coordination shell in the transition state is likely to be facile. Moreover, after the departure of the products, the retention of the isolated Mn^{III} ions in the framework of the microporous host favours the regeneration of the catalyst's activity. Its selectivity, however, is solely due to the pore size dimensions that govern access of the hydrocarbon. It should be mentioned that, after the reaction, the catalyst (MnAlPO-18) was washed thoroughly with methanol and activated at 550 °C for 12 h in the presence of dry air. It was then recycled twice without significant loss in catalytic activity (conv. = 15.65 mmol) and selectivity (C_1 = 48% and C_2 = 47.6%).

We thank EPSRC, UK for financial support (rolling grant to J. M. T.), the Royal Commission for the Exhibition of 1851 for a Research Fellowship to R. R., Dr G. Sankar for help in sample preparation and useful discussions and Dr R. G. Bell for computer guidance.

Displacement of a cyclopentadienyl ligand by a crown ether from a lanthanocene(II) [LnCp''$_2$]; crystal structures of the first cationic lanthanoid(II) complexes, [SmCp''([18]-crown-6)][SmCp''$_3$]·0.5C_6H_6 and [YbCp''([18]-crown-6)][Cp'']·3C_6H_6 [Cp'' = η^5-$C_5H_3(SiMe_3)_2$-1,3]

Yurii K. Gun'ko, Peter B. Hitchcock and Michael F. Lappert*†

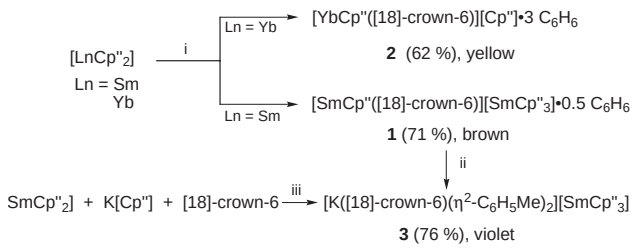
The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ

Treatment of [SmCp''$_2$] or [YbCp''$_2$] with [18]-crown-6 in benzene at ambient temperature yields the X-ray characterised, crystalline salts [SmCp''([18]-crown-6)][SmCp''$_3$]·0.5C_6H_6 1 and [YbCp''([18]-crown-6)][Cp'']·3C_6H_6 2; 1 with K in toluene affords [K([18]-crown-6)(η^2-PhMe)$_2$][SmCp''$_3$], also accessible from [SmCp''$_2$], K[Cp''] and [18]-crown-6 in toluene [Cp'' = η^5-$C_5H_3(SiMe_3)_2$-1,3].

The use of crown ethers to solubilise lanthanoid (Ln) halides or nitrates is well documented.[1] By contrast, the chemistry of (crown ether)Ln organometallic complexes is still undeveloped, although we have recently studied the reactions of some tri(cyclopentadienyl)lanthanoid(III) complexes with potassium in the presence of [18]-crown-6 and an arene, which have yielded the crystalline salts [K([18]-crown-6)(C_6H_6)$_2$][{LaCp'$_2$}$_2$(μ,η-C_6H_6)][2a] and [K([18]-crown-6)(η^2-PhMe)$_2$][(LnCp''$_2$)$_2$(μ,η-PhMe)] [Cp' = η^5-$C_5H_3Bu^t_2$-1,3; Cp'' = η^5-$C_5H_3(SiMe_3)_2$-1,3; Ln = Ce or Pr].[2b]

We now report (*a*) two facile, but diverse, cyclopentadienyl displacement reactions from a lanthanocene(II) [LnCp''$_2$] (Ln = Sm or Yb) by a crown ether, affording (Scheme 1) the crystalline [SmCp''([18]-crown-6)][SmCp''$_3$]·0.5C_6H_6 **1** or [YbCp''([18]-crown-6)][Cp'']·3C_6H_6 **2**; (*b*) the partial redistribution of **2** in toluene into **2** and [YbCp''$_2$([18]-crown-6)]; (*c*) the synthesis from a toluene solution of another crystalline tri(cyclopentadienyl)samarate(II) [K([18]-crown-6)(η^2-PhMe)$_2$][SmCp''$_3$]·0.5PhMe **3** from either **1** and K, or [SmCp''$_2$], K[Cp''] and [18]-crown-6 (Scheme 1); and (*d*) the X-ray structures of **1–3**.‡ Further features of interest are that **1** and **2** are the first examples of cationic lanthanoid(II) complexes, **2** the first lanthanoid salt containing a cyclopentadienide counter-ion, and **1** and **3** are new members of the rare family of salts containing a lanthanate(II) anion.[3]

Each of the crystalline salts **1–3** gave satisfactory microanalytical results, as well as IR and NMR§ spectra. The latter in [$^2H_8$]toluene or [$^2H_6$]benzene for **1** and **3** were complicated by the paramagnetism of the f^6 Sm^{II} causing strongly shifted signals, but were substantially temperature-invariant in the range 0 to +50 °C. The ^{29}Si{^{1}H} NMR spectra of **1** at 25 °C showed two signals at δ 98.50 ([SmCp''([18]-crown-6)]$^+$) and δ −58.59 ([SmCp''$_3$]$^-$) in the appropriate 1 : 3 ratio. By contrast, for the case of the diamagnetic f^{14} Yb^{II} salt **2**, there was partial redistribution in toluene solution, readily monitored, especially by ^{171}Yb{^{1}H} and ^{29}Si{^{1}H} (three signals at δ 44.47, −2.49 and −19.68 in a 1 : 1 : 3 ratio at 25 °C), but also ^{1}H NMR spectra in the same temperature regime; cooling below −10 °C led to crystallisation of **2**. The ^{171}Yb{^{1}H} NMR spectra in [$^2H_8$]toluene revealed two signals at 25 °C: δ −82.46, assigned to **2**, and δ 14.44, assigned to [YbCp''$_2$([18]-crown-6)] {*cf.*[4] δ 0 for [Yb(η^5-C_5Me_5)$_2$(thf)$_2$] in thf at 296 K}; whereas at 50 °C a single broad signal at δ −1.77 was observed, indicative of a fast exchange process between the two species but a decrease in the relative contribution of **2**. Lowering the temperature to −10 °C led to a decrease in relative intensity and shift of the higher frequency signal to δ 30.35, and simultaneously an enhancement in relative intensity and shift of the lower frequency signal to δ −32.43. These data show that in toluene or benzene there is an equilibrium between **2** and the neutral complex [YbCp''$_2$([18]-crown-6)], with the latter favoured at higher temperatures.



Scheme 1 Synthesis of the crystalline cyclopentadienyllanthanoid(II) salts **1**–**3**. *Reagents and conditions*: i, [18]-crown-6, benzene, 12 h, *ca.* 20 °C; ii, K (mirror), toluene, 3 h, *ca.* −30 °C, iii, toluene, 5 h, *ca.* 20 °C.

Crystalline **1** consists of well separated ions, Fig. 1. The cation [SmCp''([18]-crown-6)]$^+$ has a sandwich-like structure; the Sm is located within the cavity of the quasi-parallel Cp'' and the crown ligand, the latter being distorted due to strong O(6) atom deviation. The centroid of the Cp'' ring and the six oxygen atoms of the crown ether form a strongly distorted pentagonal bipyramidal arrangement around Sm. The crown ether is disordered 0.57 : 0.43 over two orientations, approximately related by mirror symmetry, with two carbon positions in common. The Sm(1)–C_{sp^2} distances are in the range 2.828(6) to 2.913(6) Å [to C(5) shortest, to C(3) longest] with Sm(1)–Cp''(centroid) 2.606(6) Å; this compares with 2.553 Å in [Sm(Cp'')Cp'''(thf)] [Cp''' = η^5-$C_5H_2(SiMe_3)_3$-1,2,4)].[5] The average Sm(1)–O distance of 2.714 Å [ranging from 2.571(9) to 2.829(9) Å, to O(5) shortest, to O(3) longest] is *ca.* 0.15–0.2 Å longer than in Sm^{III} crown ether complexes.[1e] The [SmCp''$_3$]$^-$ anion in **1** has the Sm in an almost trigonal planar arrangement with respect to the centroids of the three Cp'' ligands, as in [SmCp''$_3$].[6] The Sm(2)–C_{sp^2} distances are in the range 2.816(6) to 3.092(6) Å [to C(39) shortest, to C(26) longest], with two Sm–Cp''(centroid) distances of 2.701(6) and one of 2.670(6) Å, compared with 2.698(5) to 2.807(5) Å in [SmCp''$_3$].[6]

Crystalline **2**, likewise, has well separated ions, the nearest Yb contact to the anion being 6.58 Å. The sandwich-like nature of the cation [YbCp''([18]-crown-6)]$^+$ resembles that of **1**. The Yb(1)–C_{sp^2} distances, ranging from 2.739 to 2.814 Å [to C(5) shortest, to C(3) longest], as well as *d*[Yb–Cp''(centroid)] 2.508(7) Å, are significantly longer than in [{YbCp''$_2$}$_\infty$], having Yb–C_{sp^2} from 2.654(5) to 2.684(6) with Yb–Cp''(centroid) 2.382 and 2.366 Å.[7] The Yb–O distances range from 2.519(5) to 2.583(6) Å [to O(4) shortest, to O(1) longest]. The anion is such that two Cp' groups lie across inversion centres with the disorder only partially resolved and hence the dimensions are unreliable.

Crystalline **1** and **3** have identical anions. The asymmetric unit contains two cations and two anions and one toluene solvate molecule. The six K–O bond lengths range from 2.72(2) to 2.83(2) Å and the K···C(from η^2-PhMe) contacts are 3.53(3) Å.

A reaction which has some analogy with the formation of salt **1** from [SmCp"$_2$] is that between MgR_2 or Mg(Br)R and a cryptand or an azacrown ether to yield [MgR(macrocycle)][MgR_3] or [MgR(macrocycle)][Mg(Br)R_2], which show fluxionality in [$^2H_6$]benzene involving exchange of R as between cation and anion (*e.g.* R = Bu^i).[8]

The formation of the [SmCp"$_3$]$^-$ counter anion in **1** contrasts with the [Cp"]$^-$ of **2** in the related ytterbium reaction. We suggest that [SmCp"([18]-crown-6)][Cp"] is first formed, but captures a further molecule of [SmCp"$_2$] to give **1**; the lack of reaction between **2** and [YbCp"$_2$] is attributed to steric hindrance, Yb^{2+} being significantly smaller than Sm^{2+}.

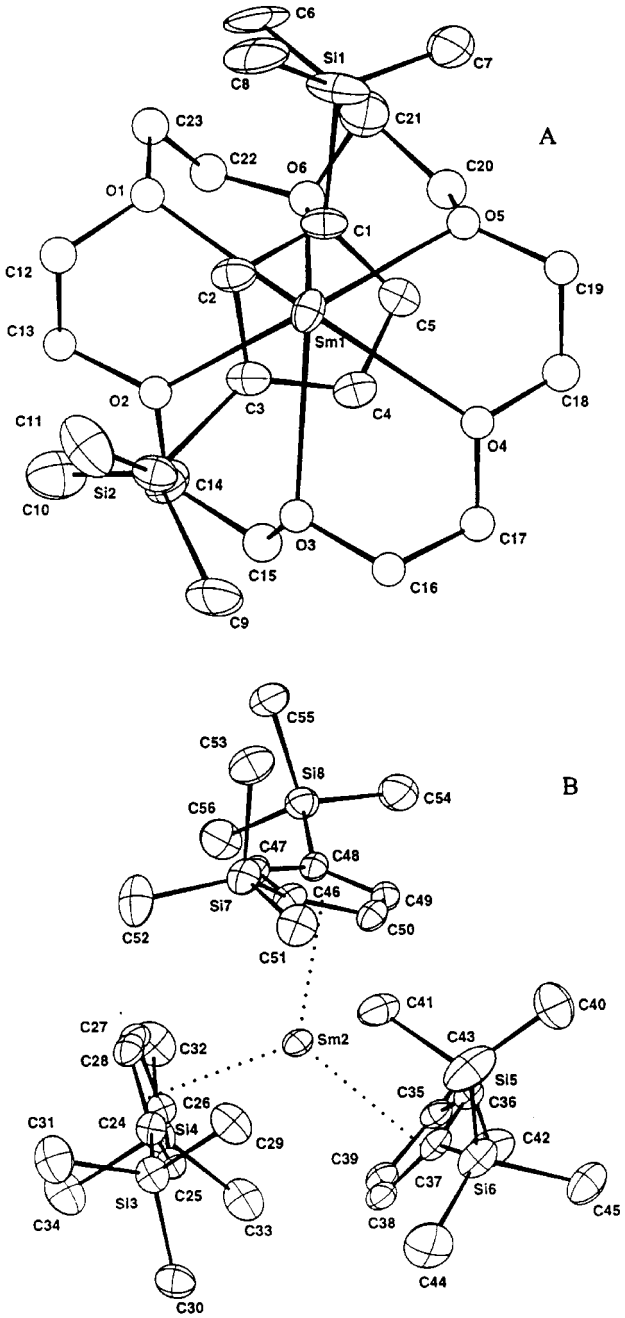


Fig. 1 The structure of cation (**A**) and anion (**B**) in **1**; selected bond lengths and angles are in the text

The results here presented open up a new chapter in organolanthanoid chemistry; the cationic lanthanoid(II) complexes, in particular **1**, are expected to have a rich chemistry. For **2**, we shall replace [Cp]$^-$ by a weakly coordinating anion.

We thank EPSRC for the award of a fellowship to Yu. K. G. and for other support.

Novel intramolecular rearrangement of 3-bromo-3,3-difluoroalanine Schiff bases *via* radical *ipso*-substitution at the aromatic ring

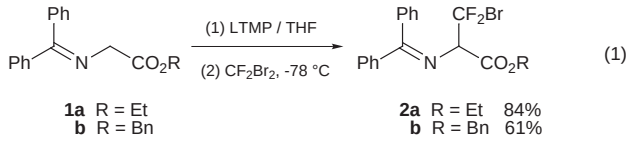
Hideki Amii, Susumu Kondo and Kenji Uneyama*†

Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushimanaka 3-1-1, Okayama 700-0082, Japan

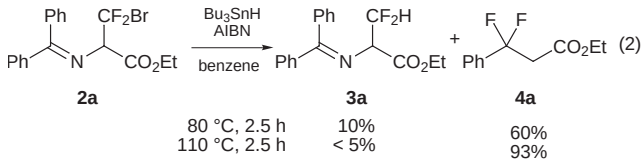
3-Bromo-3,3-difluoroalanine Schiff bases are synthesized by bromodifluoromethylation of the corresponding glycine Schiff bases with CF_2Br_2; their intramolecular rearrangement involving radical *ipso*-substitution at the aromatic ring of the imine moiety provides 3,3-difluoro-3-arylpropanoates in good yields.

Organofluorine compounds are receiving increasing attention in the medicinal, agricultural, and material sciences. In particular, interest in fluorine-containing amino acids and their derivatives has existed for many years, since they have potentially unique biological activities and thus are a current synthetic target.[1] Herein we report a new approach to the preparation of 3-bromo-3,3-difluoroalanine Schiff bases **2** and their intramolecular rearrangement *via* radical *ipso*-substitution at the aromatic ring, which provides β,β-difluoroalkanoates.[2,3]

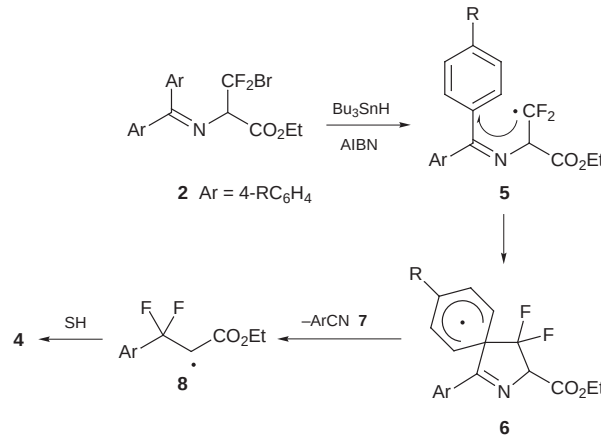
3-Bromo-3,3-difluoroalanine Schiff bases **2** are synthesized using commercially available CF_2Br_2, the simplest CF_2 unit.[4] Appropriate choice of reaction conditions was essential to avoid the decomposition of the bromodifluoromethyl moiety of **2** due to nucleophilic attack of the bases, such as NaH and even LDA. When Schiff base **1** was treated with lithium 2,2,6,6-tetramethylpiperidide (LTMP) in THF at −78 °C followed by CF_2Br_2, difluoromethylene compounds **2** were obtained in good yields [eqn (1)].



3-Bromo-3,3-difluoroalanine Schiff bases **2** are interesting fluorinated synthetic building blocks, and their transformations were examined next. Firstly, we explored Bu_3SnH/AIBN mediated radical cleavage of the carbon–bromine bond in **2**. Treatment of **2a** with Bu_3SnH/AIBN/benzene at 80 °C for 2.5 h gave not only the reduction product **3a** (10%), but also unexpectedly gave ethyl 3,3-difluoro-3-phenylpropanoate[5] **4a** (60%) as the major product [eqn (2)]. Raising the reaction



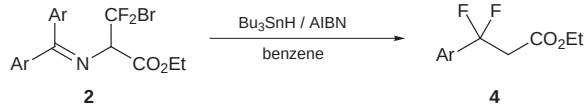
temperature (> 110 °C) favoured the rearrangement (**2a**→**4a**). The formation of **4a** can be explained by assuming the pathway pictured in Scheme 1. Initially, Bu_3SnH/AIBN mediated homolytic fission of the C–Br bond in **2** generates α,α-difluoroalkyl radical species **5**. The resultant α-fluorinated carbon radical **5** undergoes intramolecular *ipso* attack to the aromatic group[6–10] of the imine moiety of **5**, forming the spiro cyclohexadienyl radical **6**. Extrusion of aromatic nitrile **7** from **6** then occurs to furnish the carbon radical **8**.[11] Subsequent hydrogen abstraction gives rise to β,β-difluorocarboxylic acid ester **4** as the final product.



Scheme 1

Other examples of selective formation of **4** are given in Table 1. The Schiff bases **2** which possess either electron-donating or -withdrawing substituents on the aryl ring of the imine moiety provide **4** in high yields. It is noted that the reactions of **2c** and **2d**, which have electron-donating substituents, required more forcing conditions (entries 2 and 3), whereas electron-withdrawing substituents enhanced the reaction rates (entries 4 and 5).

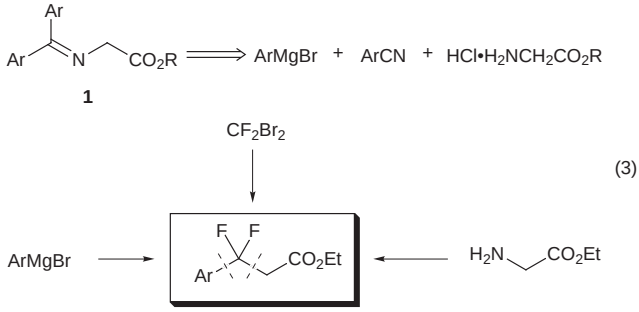
Table 1 Radical rearrangement of Schiff base **2**[a]



Entry	Ar	*T*/°C	*t*/h	Product	Yield[b] (%)
1	Ph	110	2.5	**4a**	93
2	4-MeC_6H_4	130	7.0	**4c**	90
3	4-$MeOC_6H_4$	130	7.0	**4d**	99
4	4-FC_6H_4	110	1.5	**4e**	80 (99)[c]
5	4-$CF_3C_6H_4$	110	2.0	**4f**	90

[a] All reactions were carried out in sealed glass tubes containing **2**, Bu_3SnH (2 equiv.) and AIBN (0.1 equiv.). After the reactions were completed, an equimolar amount of aromatic nitrile was generated (90–95% isolated yield in each case). [b] Reported yields are isolated yields unless specified. [c] The number in parentheses is the yield determined by ^{19}F NMR analysis.

The Schiff bases **1** are easily synthesized in one pot from the corresponding arylmagnesium bromides, aryl cyanides and glycine ethyl ester hydrochloride [eqn (3)].[12] In the net transformation to **4**, aryl cyanides were regenerated after completion of the intramolecular radical rearrangement, as shown in Scheme 1. Thus, the construction of **4** was formally



(3)

achieved by the coupling of three components, *i.e.* ArMgBr, CF_2Br_2 and glycine derivatives.

In conclusion, the synthesis and a novel reaction of 3-bromo-3,3-difluoroalanine Schiff bases were developed, which provide a new route to difluoromethylene compounds *via* intramolecular rearrangement involving radical *ipso*-substitution at the aromatic ring.

We thank to the SC NMR laboratory of Okayama University for ^{19}F NMR analyses and the Ministry of Education, Science, Sports and Culture of Japan for financial support (Grant-in-Aid for scientific research, No. 09305058).

‡ Representive experimental procedures. (i) To a solution of 2,2,6,6-tetramethylpiperidine (106 mg, 0.75 mmol) in freshly distilled THF (1 ml) cooled down to 0 °C under argon atmosphere, 1.53 M BuLi in hexane (0.50 ml, 0.75 mmol) was added dropwisely and then stirred for an additional 30 min. The LTMP solution was cooled to −78 °C, and the solution of glycine Schiff base (0.5 mmol) in THF (1 ml) was added dropwisely to the LTMP solution. After 1 h, CF_2Br_2 (525 mg, 2.5 mmol) was added, and the mixture was stirred at −78 °C for a further 5 h. The reaction mixture was quenched with aq. NH_4Cl, and the organic layer was washed with brine and dried over Na_2SO_4. Purification of the products by recrystalization from hexane gave colorless plates. (ii) A solution of **2a** (19.9 mg, 0.05 mmol), Bu_3SnH (34.9 mg, 0.12 mmol) and AIBN (1.0 mg, 6.0 mmol) in benzene (2 ml) was heated at 110 °C in a sealed glass tube for 2.5 h. The reaction mixture was cooled, reduced in volume, and purified by chromatography on silica gel (hexane–EtOAc) to afford **4a** (10.0 mg, 93%) as a colorless oil.

Photo-induced depolymerization of reversible supramolecular polymers

Brigitte J. B. Folmer, Esther Cavini, Rint P. Sijbesma and E. W. Meijer*†

Laboratory of Macromolecular and Organic Chemistry, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands

The degree of polymerization of supramolecular polymers based on quadruple hydrogen bonding of 2-ureido-4-pyrimidone units is decreased upon the photochemical formation of reversibly interfering end-caps.

Photo-induced processes to control the molecular weight of polymers are well-known and used in many advanced applications, like coatings and photolithography.[1–3] In all of these processes, the photochemical event changes the molecular structure by either polymerization of monomers, the cross-linking of polymers, the depolymerization of polymers or the side-chain modifications of polymers by, for example, the photo-induced formation of initiators or catalysts. The changes in the chemical composition of the material and, hence, in properties like solubility or viscosity, are the result of the breaking or making of covalent bonds of the polymer.

Recently, we introduced the concept of using quadruple hydrogen bonding to prepare reversible supramolecular polymers.[4] Linear polymers **1** (Fig. 1) are formed by the self-assembly of two 2-ureido-4-pyrimidone units, which dimerize strongly in solvents like $CHCl_3$ and in the solid state with dimerization constants (K_{dim}) exceeding 10^6 M^{-1}. The polymers obtained exhibit true polymer properties illustrated by high solution viscosities, shear thinning in the melt and viscoelastic properties of the neat materials. The reversibility of the supramolecular polymers, with degrees of polymerization (DP) of more than 500, is demonstrated by experiments where monofunctional 2-ureido-4-pyrimidone **2** is added as a chain stopper to polymer **1**. A rapid exchange controls the DP, leading to a strong decrease in viscosity upon addition of **2** to **1**. This control of DP resembles the way the DP of condensation polymers is tuned,[5] but now in an unprecedented rapid way under ambient conditions.

Here we report on the photo-induced generation of chain stopper **2**, and how the viscosity of the solution of supramolecular polymer **1** is triggered by a photochemical process (Scheme 1). We designed precursor **3**, being the *o*-nitrobenzyl

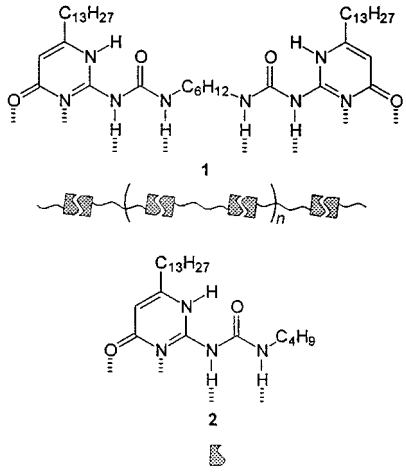

Fig. 1 Difunctional compound **1**, which forms supramolecular polymer chains, and monofunctional compound **2**, which acts as an end-cap

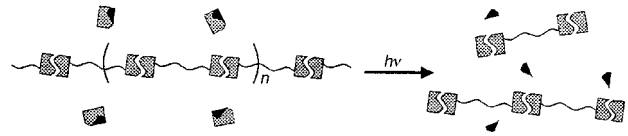


Scheme 1

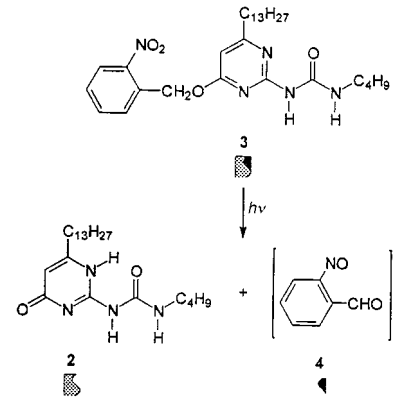
ether protected derivative of chain stopper **2**. This protecting group is well-known for its clean cleavage upon UV irradiation,[6] by which compound **3** is converted into chain stopper **2** (Scheme 2).

Compound **3** was prepared by the reaction of *o*-nitrobenzyl chloride with **2**, that in turn was made by the reaction of butyl isocyanate with the corresponding isocytosine. Bifunctional compound **1** was prepared by the reaction of the same isocytosine and hexane-1,6-diyl diisocyanate following a procedure published previously.[4] When **1** is more than 99.9% pure, a DP of around 700 is obtained and a 40 mM solution of **1** in $CHCl_3$ exhibits a η_{rel} of 13.16.

The photolability of **3** was investigated by UV irradiation of a 9.9 mM solution of **3** in $CDCl_3$.‡ The progress of the deprotection was readily monitored *via* ^{1}H NMR spectroscopy; the H-5 signal of pyrimidine **3** at δ 6.25 decreased in intensity as the upfield H-5 signal of pyrimidone **2** at δ 5.81 increased. Also the characteristic NH signals of **2**, downfield in comparison to the NH signals of **1** due to dimerization, appear upon formation of **2**.

The photogeneration of **2** (0.1 equiv.) in the presence of polymer **1** was monitored *via* viscosity measurements (η_{rel} in $CDCl_3$), as presented in Fig. 2. The addition of 0.1 equiv. of precursor **3** produced a small decrease in the viscosity (η_{rel} went from 13.16 to 10.79) *versus* the enormous drop in viscosity (η_{rel} went from 13.16 to 1.92) upon the addition of 0.1 equiv. of chain stopper **2**. After 2 h irradiation of the mixture of **1** and **3**, the η_{rel} is similar to the η_{rel} of a solution of **1** and 0.1 equiv. of chain stopper **2**. The shape of the plot of the decrease in η_{rel} with time is consistent with the monoexponential formation of **2** from **3** and the way **2** directly affects the DP of **1**.

In order to check for artefacts in the approach used, we have performed a number of reference experiments. A decrease in



Scheme 2

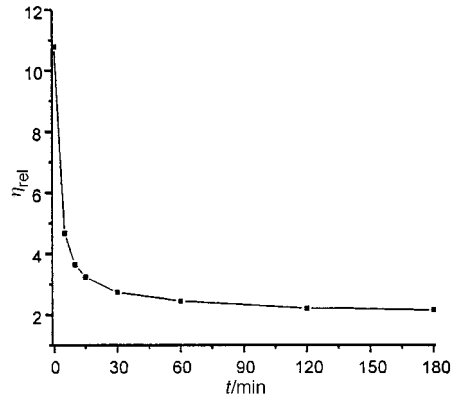


Fig. 2 Relative viscosity of a 40 mM solution of **1** with 0.1 equiv. of **3** in $CHCl_3$ upon UV irradiation

η_{rel} from 13.16 to 12.83 was found after 4 h irradiation of **1** without end-caps. The addition of 0.1 equiv. of *o*-nitrobenzyl ether protected phenol to a solution of **1** in $CDCl_3$ followed by UV irradiation for 3 h resulted in a decrease in η_{rel} from 13.16 to 8.46, while the addition of 0.1 equiv. of phenol to a 40 mM solution **1** in $CDCl_3$, resulted in a relative viscosity of 11.00. Hence, the large decrease in viscosity of the photoactive system is mainly caused by the formation of chain stopper **2**.

In conclusion, we have demonstrated the triggering of the DP of a reversible supramolecular polymer. These experiments also confirm the selectivity and specificity of polymer formation by quadruple hydrogen bonding.

Part of this investigation was supported by The Netherlands Foundation for Chemical Research (SON), with financial aid from The Netherlands Organization for Scientific Research (NWO). E. C. acknowledges the EU for an Erasmus grant.

Novel single molecule precursor routes for the direct synthesis of highly monodispersed quantum dots of cadmium or zinc sulfide or selenide

B. Ludolph, M. A. Malik, P. O'Brien* and N. Revaprasadu

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, SW7 2AY UK. E-mail: p.obrien@ic.ac.uk

Good quality highly mono-dispersed nanoparticles of II–VI binary chalcogenides ME (M = Zn or Cd, E = S or Se) have been prepared in a 'one-pot' synthesis by the thermolysis in tri-*n*-octylphosphine oxide (TOPO, *e.g.* at 200 °C for 45 min, *ca.* 50 Å ± 2.5 Å diameter) of the corresponding bis[methyl(*n*-hexyl)di-thio or -seleno]carbamato {M[E_2CN-Me(C_6H_{13})]$_2$, E = S or Se} complexes; the CdS, CdSe and ZnSe particles have been characterized by electronic spectroscopy, photoluminiscence, X-ray diffraction and electron microscopy (SAED, SEM and TEM).

Compound semiconductors as isolated quantum dots[1–7] are the subject of considerable interest. Cadmium selenide has been extensively studied and is an attractive material because its band gap can be tuned across the visible region by varying the size of the material in the range 400–800 nm. One particularly useful approach to the synthesis of CdSe is the pyrolysis of metal–organic species in tri-*n*-octylphosphine oxide.[8] We have successfully developed a variation of this method in which single molecule precursors, often based on carbamato complexes, have been used. A wide range of quantum dots have been prepared including CdSe, CdS, PbS, PbSe and ZnSe.[9–11]

However, we have now developed some novel air stable precursors based on bis[methyl(*n*-hexyl)diselenocarbamato]-zinc or -cadmium which decompose cleanly in MOCVD to selenides.[12–14] Here, we have used these compounds in a novel 'one pot' synthesis of quantum dots of the II–VI semiconductors ME (M = Zn or Cd and E = S or Se). Highly monodispersed CdSe, CdS, ZnSe, and ZnS with good optical properties can be prepared.

In a typical synthesis,† 1.0 g of the precursor was dissolved in 15 ml trioctylphosphine (TOP). This solution was then injected into hot trioctylphosphine oxide (TOPO) (200 °C) and kept at this temperature for 30–40 min. The resulting solution was cooled to *ca.* 70 °C and an excess of methanol added and a flocculant precipitate formed. The solid was separated by centrifugation and redispersed in toluene. The toluene was removed under vacuum to give TOPO capped ME nanoparticles. The absorption edge of the nanoparticles were calculated using the direct band gap method.[15]‡ The optical absorption edge for CdSe nanoparticles showed a clear blue shift (614 nm, 2.02 eV, fraction 1 to 599 nm, 2.09 eV, fraction 5) as compared to the bulk band gap (716 nm, 1.73 eV). A similar but smaller shift (498 nm, 2.48 eV, fraction 1 to 493 nm, 2.51 eV, fraction 5) was shown by CdS nanoparticles (bulk 512 nm, 2.42 eV).

Accurate measurement of the absorption edge for ZnS nanoparticles (bulk ZnS 340 nm, 3.65 eV) was difficult owing to the overlap with TOPO absorption (300 nm). Different fractions of ZnSe nanoparticles showed a blue shift in the absorption spectra (362 nm, 3.42 eV to 345 nm, 3.59 eV) as compared to the bulk band gap (480 nm, 2.58 eV). The average size of the particles decreases from fraction 1 to 5. The relatively small shift in the absorption edge from fraction 1 to 5 for both CdS and ZnSe samples reflects the relatively narrow size distribution in these samples.

TEM images show well defined, spherical particles with the size range of 53–59 Å (CdS), 54–59 Å (CdSe) (Fig. 1), and 35–42 Å (ZnSe). The XRD patterns for CdSe, CdS (Fig. 1 and 2) and ZnSe show broad peaks typical of small particles. The SAED pattern exhibits broad diffuse rings owing to the small size of the crystallites. The indexing of the lattice parameters patterns of XRD and SAED for CdSe, CdS and ZnSe indicate the formation of the hexagonal phase.§ The EDAX pattern clearly confirmed the presence of the corresponding elements for ME nanoparticles. The strong peak for phosphorus in each case was due to the capping of the particles by TOPO which was further confirmed by shift in the IR band (P=O) for TOPO.

The photoluminescence spectra for CdS nanoparticles show a broad band edge emission from 589 to 504 nm for excitation at 370 nm depending upon the concentration of samples. A shift in luminescence maxima at higher concentration was observed which is due to filtering effects which became important at such concentrations. Near band edge luminescence was observed for CdSe for a excitation wavelength at 465 nm which indicates a fluorescence activation by surface derivation. The maximum of the emission band is gradually blue shifted as the size distribution become weighted with particles of the smaller dimensions. Fig. 3(a) and (b) show the photoluminescence and band edges for CdSe and CdS nanoparticles. The luminescence spectrum of ZnSe nanoparticles showed a broad emission at 440

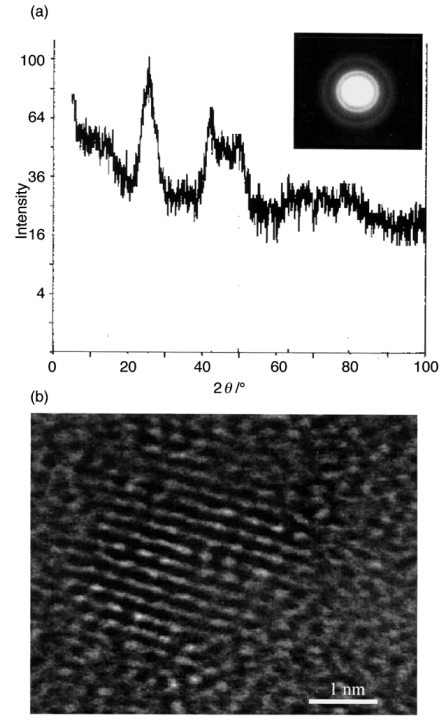

Fig. 1 (a) XRD and SAED pattern for CdSe nanoparticles and (b) HRTEM image of a CdSe Q-dot (diameter: 5 nm)

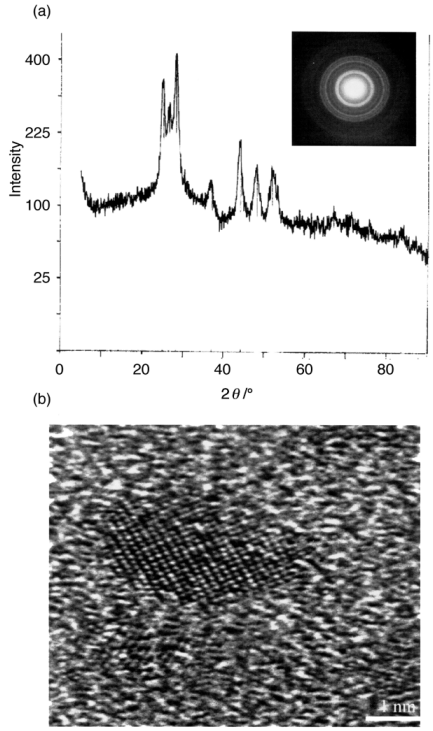

Fig. 2 (a) XRD and SAED pattern for CdS nanoparticles and (b) HRTEM image of a CdS Q-dot (diameter: 5 nm)

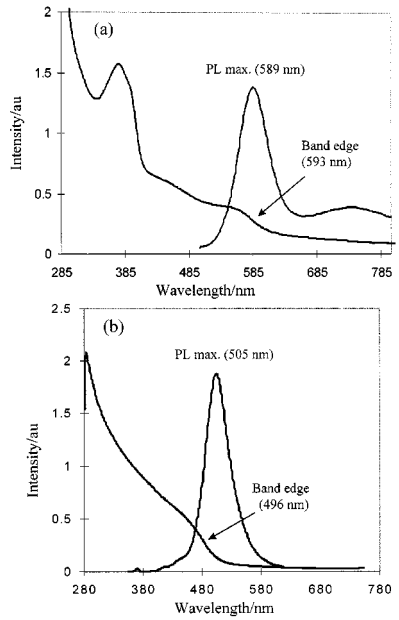

Fig. 3 Optical absorption spectrum and photoluminescence spectrum showing the band edge and emission maximum of (a) CdSe (fraction 3) and (b) CdS (fraction 3)

nm for an excitation wavelength of 345 nm. The emission spectrum is red shifted in relation to the band edge by *ca.* 0.04 eV. As the particle size decreases the surface/volume ratio increases thereby increasing the number of surface traps. These surface states or defects normally associated with semiconductor nanoparticles are passivated by TOPO. Therefore the deep trap emission associated with these states are absent.

In conclusion, good quality highly mono-dispersed nanoparticles of ME have been prepared for the first time by thermolysis in TOPO using $M[E_2CNMe(C_6H_{13})]_2$ type single molecule precursors in a one pot synthesis. These are the first stable, non-air sensitive single molecule precursors which can easily be used to give high yields of TOPO capped quantum dots. The CdS, CdSe and ZnSe particles have been characterized by UV–VIS, PL, EDAX, XRD, SAED and TEM whereas the ZnS particles were characterized by UV–VIS, PL and EDAX only and are being investigated for other properties.

Paul O'Brien is the Royal Society Amersham International Research Fellow (1997/98) and the Sumitomo/STS Professor of Materials Chemistry. We thank the EPSRC for a grant supporting work on single molecule precursors for quantum dots. B. L. was supported by the Socrates program of the EU and N. R. by a Royal Society/FRD development program between ICSTM.

Notes and References

† The compounds were prepared by adaptations of the literature methods[15,16] and fully characterised by NMR, mass spectrometry, microanalysis and IR spectroscopy.

‡ A Philips PU 8710 spectrophotometer was used to carry out the optical measurements, the samples were placed in silica cuvettes (1 cm path length). For photoluminescence spectroscopy a Spex FluoroMax instrument with a xenon lamp (150 W) and a 152 P photomultiplier tube as a detector was used to measure the photoluminescence of the particles. Good spectra were obtained with the slits set at 2 nm and an integration time of 1 s. The samples were placed in quartz cuvettes (1 cm path length). The wavelength of excitation is indicated in the text and was shorter than the onset of absorption of the particular sample being studied. X-Ray diffraction patterns were measured using a Philips PW 1700 series automated powder diffractometer using Cu-Kα radiation at 40 kV and 40 mA with a secondary graphite crystal monochromator. Samples were supported on glass slides (5 cm). A concentrated toluene solution was slowly evaporated at room temperature onto a glass slide to obtain a sample for analysis. A JOEL 2000 FX MK 1 electron microscope operating at 200 kV with an Oxford Instrument AN 10000 EDS analyser was used for the conventional TEM images. Selected area electron diffraction (SAED) patterns were obtained using a JEOL 2000 FX MK2 electron microscope operated at 200 kV. The samples for TEM and SAED were prepared by placing a drop of a dilute solution of sample in toluene on a copper grid (400 mesh, agar). The excess of solvent was wicked away with a paper tip and the sample allowed to dry completely at room temperature. EDAX (energy dispersion analytical X-ray spectroscopy) was performed on the sample deposited by evaporation on glass substrates by using a JEOL JSM35CF scanning electron microscope.

§ The X-ray diffraction pattern of the CdS particles gave peaks with the following observed *d*/Å values (% relative intensity, *hkl*): 3.55 (76, 100), 3.35 (52, 002), 3.16 (100, 101), 2.06 (43, 110) and 1.90 (26, 103) corresponding to hexagonal cadmium sulfide; 3.57 (62, 100), 3.36 (91, 002), 3.16 (100, 101), 2.45 (29, 102), 2.07 (48, 110) and 1.90 (50, 103) (ASTM). CdSe: 3.50 (100, 002), 2.13 (80, 110), 1.84 (50, 112) and 1.48 (10, 211) corresponding to hexagonal phase; 3.51 Å (70, 002), 2.15 (85, 110), 1.83 (50, 112) and 1.38 Å (8, 211) {ASTM}. ZnSe: 3.06 (70, 101), 1.99 (100, 110), 1.24 (35, 105), 1.10 (40, 302) corresponding to hexagonal phase; 3.05 (70, 101), 1.99 (100, 110), 1.22 (40, 105), 1.09 (40, 302){ASTM}.

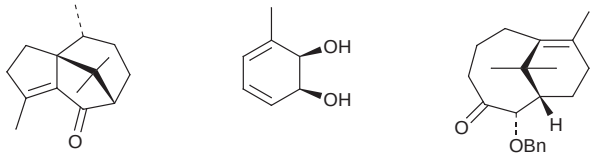
Chemoenzymatic total synthesis of the sesquiterpene (−)-patchoulenone

Martin Banwell*† and Malcolm McLeod

Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, ACT 0200, Australia

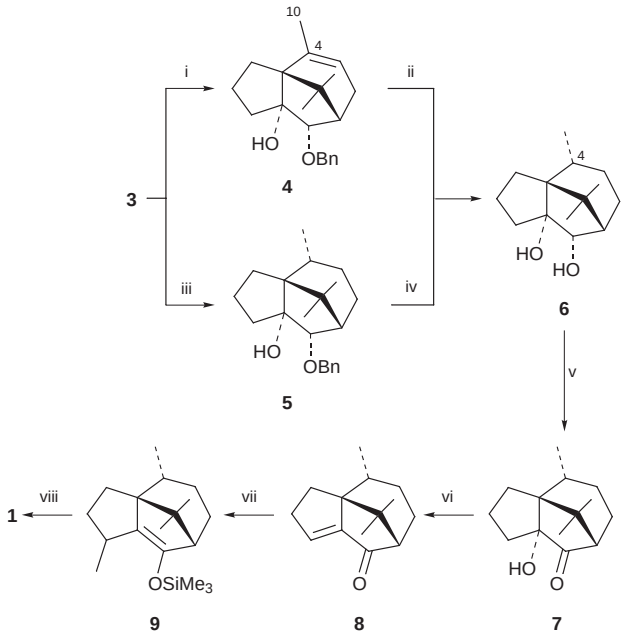
Monochiral *cis*-1,2-dihydrocatechol 2, obtained by microbial oxidation of toluene, has been converted, *via* intermediate 3, into the cyperene-type sesquiterpene 1.

(−)-Patchoulenone **1** is a prominent member of the cyperene class of sesquiterpenes and was first isolated in 1964 from *Cyperus rotundus* Linné (*Cyperaceae*), a plant common in Sudan, India, China, Thailand and Japan.[1,2] The compound has



1 **2** **3**

also been identified as a constituent of, *inter alia*, the root bark of *Uvaria narum* Wall. (*Annonaceae*)[3] and *Piptostigma fugax*.[4] Despite a number of the source plants being used in traditional medicines, only a modest amount is known about the biological properties of (−)-patchoulenone. Thus, compound **1** shows[2] *in vitro* activity (EC_{50} 1.08×10^{-4} M) against the malarial parasite *Plasmodium falciparum*, strong anti-fungal activity against *Rhizoctonia solani* and *Saprolegnia asterophora*,[4] and significant toxicity in a brine shrimp bioassay.[4]



Scheme 1 *Reagents and conditions*: i, $SnCl_2$ (0.25 equiv.), $CHCl_3$, 18 °C, 1 h; ii, H_2 (60 psi), 10% Pd/C, MeOH, 18 °C, 48 h; iii, SmI_2 (1.6 equiv.), HMPA, THF, 0 °C, 0.25 h; iv, H_2 (1 atm), 10% Pd/C, THF, 18 °C, 0.75 h; v, $(COCl)_2$ (3.0 equiv.), DMSO (5.0 equiv.), CH_2Cl_2, −78 °C, 0.25 h, then **6**, 0.25 h then Et_3N (6.0 equiv.) −78 to 0 °C, 0.25 h; vi, $SOCl_2$, pyridine, 40 °C, 1 h; vii, MeLi (10 equiv.), CuBr·DMS (5.0 equiv.), THF, −40 °C, 0.5 h, then **8**, Me_3SiCl (10 equiv.), HMPA, −78 °C, 0.5 h; viii, DDQ (4.0 equiv.), 2,6-lutidine (6.5 equiv.), CH_2Cl_2, 18 °C, 0.1 h

The 1,4,9,9-tetramethyl-2,4,5,6,7,8-hexahydro-3*H*-3a,7-methanoazulene framework associated with the cyperene-type sesquiterpenes has been the subject of a number of synthetic studies[5] and the title compound itself has been synthesised by Hikino *et al*[6] who used (+)-camphor as the starting material. The racemic modification of patchoulenone has also been prepared *via* the Lewis acid catalysed addition of a diazo ketone to a tethered olefin.[7] We now report a quite distinct and chemoenzymatic total synthesis of (−)-patchoulenone which employs the monochiral *cis*-1,2-dihydrocatechol **2**, obtained by microbial oxidation of toluene, as starting material.[8]

In connection with synthetic approaches to taxoids, we have recently described[9] the conversion of compound **2** into the bicyclo[5.3.1]undecenone **3**. As has been observed in a closely related system,[10] the carbon–carbon double-bond and carbonyl group within compound **3** are in close proximity. As a consequence the molecule readily engages in a tin(II) chloride catalysed intramolecular Prins reaction (Scheme 1) to give the tricyclic isomer **4** {97%, $[\alpha]_D$ −32 (*c* 2.0)‡}. Hydrogenation of compound **4** using H_2 at 60 psi and with palladium on carbon as catalyst provided a *ca.* 3:1 mixture of the saturated *cis*-diol **6**§ {59%, mp 209–211 °C (sealed tube), $[\alpha]_D$ −21.4 (*c* 0.6)} and its C4-epimer {21%, mp 207–209 °C (sealed tube), $[\alpha]_D$ +37.2 (*c* 0.7)} which could be separated from one another by flash chromatography. An alternative route to the pivotal compound **6** involved subjecting compound **3** to reductive cyclisation using samarium(II) iodide[11] and a chromatographically separable mixture of **5** {39%, mp 53–54 °C, $[\alpha]_D$ +17.9 (*c* 0.9)} and the $\Delta^{4(10)}$-isomer {54%, $[\alpha]_D$ +65 (*c* 0.4)} of compound **4** was produced. Hydrogenolysis of compound **5** could be achieved under standard conditions and the resulting diol **6** (95%) was oxidised to the acyloin **7** {91%, $[\alpha]_D$ −0.2 (*c* 1.0)} using the Swern reagent. Dehydration of compound **7** to the enone **8** {68%, $[\alpha]_D$ −150 (*c* 0.5)} could be effected using thionyl chloride in pyridine at 40 °C. This latter compound was subjected to reaction with the Gilman reagent derived from methyllithium and copper(I) bromide–dimethyl sulfide (DMS) complex[12] and the ensuing enolate anion trapped with trimethylsilyl chloride to give the unstable silyl enol ether **9**, which was obtained as a single diastereoisomer. Dehydrogenation of compound **9** with DDQ/2,6-lutidine[13] then gave (−)-patchoulenone **1** {77% from **8**, mp 50–51 °C (lit.,[1] 52.5 °C), $[\alpha]_D$ −101 (*c* 0.4) [lit.,[1] −97.1 (*c* 8.0)]}, the ^1H and ^{13}C NMR spectral data for which matched those reported[2] for the natural product.

We thank the Institute of Advanced Studies for financial support including the provision of a Postdoctoral Fellowship to M. M. Drs G. Whited and L. Kwart of Genencor International Inc. (Palo Alto) are thanked for providing generous supplies of the *cis*-1,2-dihydrocatechol **2**.

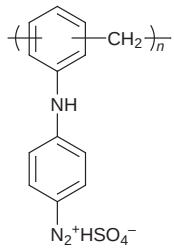
Construction of highly stable covalently attached multilayer films was achieved by UV irradiation of ionic self-assembled multilayer films of diazo-resins and poly(sodium styrene sulfonate).

A layer-by-layer self-assembly technique based on electrostatic interaction as the driving force has attracted much attention in recent years.[1–3] This technique has proved to be a rapid and experimentally very simple way to produce complex layered structures with precise control of layer composition and thickness. However, the stability of such assembled films depends on the nature of solvent and is not always adequate.[4] How to improve the stability of such films is thus still a challenge. Here, we report on photoreactive multilayer films containing diazo-resins as polycations and poly(sodium 4-styrene sulfonate) as polyanions held together by electrostatic interactions. Upon UV irradiation, the adjacent interfaces of the multilayer films react to form a crosslinking structure which greatly improved the stability of the films. These changes were confirmed by UV–VIS and FTIR spectroscopy.

UV–VIS spectra were obtained using a Shimadzu 3100 UV–VIS-NIR spectrophotometer and IR spectra were obtained using a Bruker IFS66V FTIR instrument. The synthesis of the diazo-



DAR

resin, DAR has been reported elsewhere.[5] The fabrication process of multilayer films containing DAR and PSS was conducted in the dark. The freshly cleaned substrate (quartz or CaF_2 slide) was first immersed in 0.9 vol% aqueous cationic poly(diallyldimethylammonium chloride) (PDDA) solution for 20 min. After rinsing with deionized water, the substrate was alternately dipped into aqueous solutions of PSS (1 mg ml^{-1}) and then DAR (1.5 mg ml^{-1}) for 20 min, with intermediate water washing and N_2 drying. Multilayer films can be formed by repeating the last two steps repeatedly.

UV–VIS spectroscopy was used to follow the fabrication process. Fig. 1 shows the UV–VIS absorption spectra for 2, 4, 6 and 8 bilayers of DAR/PSS assembled on a quartz slide. The absorbance at 380 nm is attributed to the π–π* transition of the diazonium group.[6] The linear increase in absorbance at 380 nm with the number of layers indicates a progressive deposition. The assembled films were immersed in a ternary mixture of H_2O–DMF–$ZnCl_2$ (3 : 5 : 2, w/w/w) to investigate their stability. This ternary system was chosen because of the high solubility of the polyelectrolyte complex of DAR/PSS in this solvent. Nearly 30% of the assembled films were dissolved after 5 min immersion according to the decrease of absorbance at 250 and 380 nm, and indicates that this type of ionic self-assembled film is not adequately stable in the ternary solvent.

Owing to the well known reactivity of diazonium and sulfonate groups, the above assembled films containing 8 bilayers of DAR/PSS were irradiated with a 30 W medium power mercury lamp at a distance of 10 cm. Fig. 2 shows the changes in UV–VIS spectra of the films with different time of irradiation, from which, we can clearly see that the absorbance at 380 nm decreases dramatically due to the decomposition of the diazonium group and within 5 min, the decomposition had proceeded completely. We then immersed the irradiated films into the same ternary solvent as for the untreated film and sonicated it for 0.5 h. No detectable damage of the films was observed, according to the absorbance at 250 nm, indicating a much greater stability.

From the change of the stability of the multilayer films before and after UV irradiation, it is proposed that photoreaction takes place between the diazonium and sulfonate groups. First, DAR is converted into its phenyl cationic form after released N_2 upon UV irradiation, then an S_N1 type of nuclear displacement by sulfonate occurs[7] as shown in Scheme 1.

Photoreaction changes the crosslinking structure of the multilayer film from ionic to covalent so that a three dimensional network forms which covers the whole substrate including four side faces. This can explain, despite the interaction between the substrate and the first layer of multilayer films not being covalent, the stability of the films in

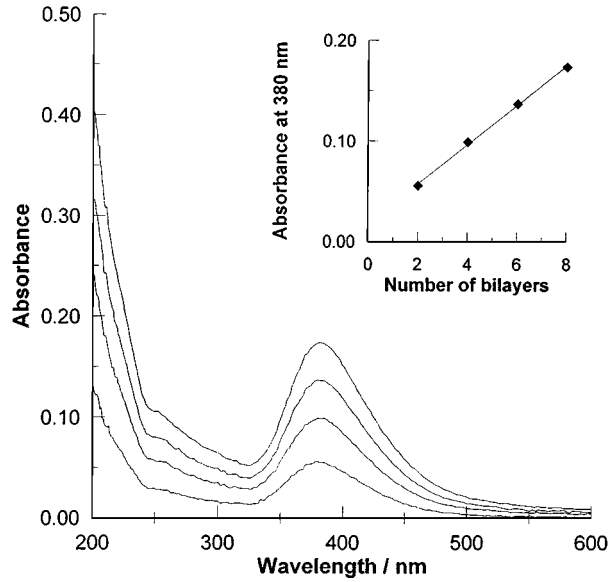


Fig. 1 UV–VIS absorption spectra of multilayer films of DAR/PSS, from the lower to upper, the number of bilayers is 2, 4, 6 and 8. Inset shows the absorption at 380 nm *vs.* the number of bilayers.

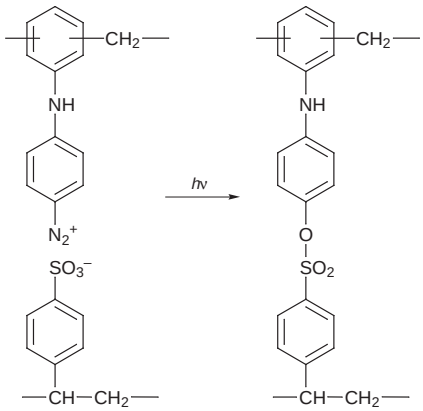

Scheme 1 Photoreaction of DAR and PSS

all solvents, such as MeOH, DMSO, DMF, $CHCl_3$ as well as the ternary solvent described above.

The photoreaction of diazonium and sulfonate groups in multilayer films was further confirmed by IR spectroscopy (for IR spectra see http://www.rsc.org./suppdata/cc/1998/1853). Two absorption peaks at 2166 and 1178 cm^{-1} are observed in the IR spectra of 12 bilayers of DAR/PSS assembled on a CaF_2 substrate before UV irradiation, which originate from the asymmetric stretching of CN_2 and symmetric stretching of SO_3^-, respectively. After UV light irradiation, the absorption at 2166 cm^{-1} disappeared completely, indicating the decomposition of the diazonium group. Meanwhile, a new absorption at 1162 cm^{-1} appears which corresponds to the symmetric stretching of the sulfonate coupled with the phenyl group. In layer-by-layer multilayer films, photoreaction should be facilitated to some extent by the close proximity of the diazonium and sulfonate groups.

In conclusion, a new type of covalently attached multilayer film has been fabricated by exploiting the layer-by-layer technique and then by photoreacting diazonium and sulfonate groups at the interface. Owing to the formation of three-dimensional crosslinking structure based on covalent bonding, the resulting multilayer films are much more stable than those based on ionic interactions. Further studies are in progress to assemble functional semiconductor nanoparticles and organic dye molecules into this covalently attached three-dimensional network.

Anionically induced decomposition of 2-ethoxycarbonylprop-2-enyl peroxides

C. Cramay, R. Ferdinando, M. Degueil-Castaing and B. Maillard*†

Laboratoire de Chimie Organique et Organométallique, associé au CNRS UMR 5802, Université Bordeaux 1, F-33405 Talence-Cedex, France

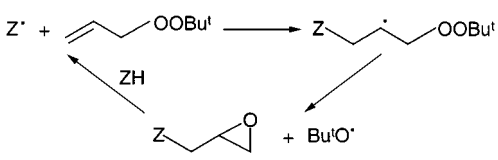
Treatment of 2-ethoxycarbonylprop-2-enyl peroxides with potassium alkylperoxylate, the sodium enolate of diethyl malonate and a primary or secondary amine yields epoxides *via* a two-step process: (i) addition of the nucleophile to the acrylic unsaturated bond and (ii) intramolecular anionic substitution on the peroxidic bond.

2,3-Epoxy esters are useful synthons, in particular for the production of 2-, 3- , 2,3-di-hydroxy and 3-amino-2-hydroxy esters.[1] The general methods of synthesis are the Darzen's condensation[2] and the various epoxidations[2] of 2,3-ethylenic esters. Many years ago the formation of epoxides was identified[3] in the homolytically induced decomposition of allyl *tert*-butyl peroxide. Subsequently, the free radical addition of reactive hydrogen donor solvents to allylic peroxides was used to prepare functionalised epoxides[4,5] (Scheme 1). Such a reaction, applied to acrylic peroxy derivatives, led to the formation of an epoxide with the simultaneous creation of a C–C bond, affording a new method for generation of 2,3-epoxy esters.[6] However, in some cases, synthetic interest in this reaction was limited by the formation of a mixture of several epoxides in low yields. For example, an attempt to prepare 1-ethoxycarbonyl-1-[2,2-bis(methoxycarbonyl)ethyl]oxirane[7] by free radical addition of dimethyl malonate to *tert*-butyl 2-ethoxycarbonylprop-2-enyl peroxide **1** failed mainly for two reasons:[7] (i) both possible radicals were generated from dimethyl malonate by hydrogen abstraction by radicals $Bu^tO\cdot$ and $Me\cdot$ and (ii) inefficient addition of the electrophilic radical $\cdot CH(CO_2Me)_2$ to the electron-poor double bond of the acrylic peroxide.

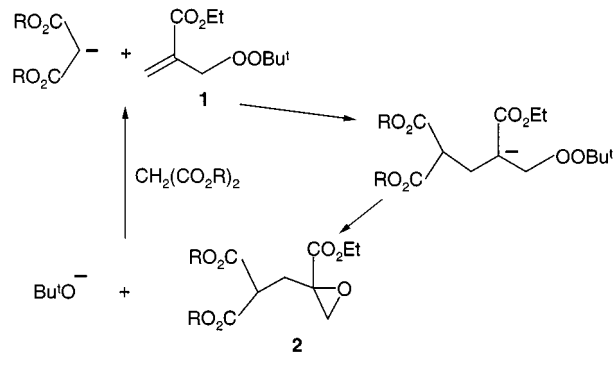
The selective production of the desired radical from dimethyl malonate was brilliantly solved by Roberts *et al.*[8] by application of reverse polar effects resulting from the addition of an aminoborane to the medium in the induced decomposition of allyl *tert*-butyl peroxide. Following the same approach and considering the existence of an *umpolung* effect on changing from the radical (electrophilic) to the anion (nucleophilic)[9] we designed an anionic-induced decomposition of **1** to produce epoxides **2** (Scheme 2). Indeed, the Michael addition[10] of $^-CH(CO_2Et)_2$ to ethyl acrylate suggested a possible addition of this carbanion to the unsaturation of **1**. The formation of an epoxy peroxide as a by-product in the synthesis of **1**[11] has to be considered as a good argument in favor of the feasibility of the intramolecular attack of the O–O bond, even if Yang and Finnegan[12] identified the adduct peroxide in the addition of Bu^tOOH to ethyl acrylate under basic conditions. The capacity of the *tert*-butoxide anion to abstract a proton from malonate would make this anionic-induced decomposition a chain process. The validity of this proposal was verified *via* the formation of **2** (R = Et, yield 60%) by the addition of 1 equiv. of peroxide **1**, at −10 °C, to a THF solution of diethyl malonate, previously treated with 0.1 equiv. of NaOEt.

The success of this reaction, the first synthetic example of an anionic decomposition of an allylic peroxide, prompted us to extend this work to other nucleophiles with the objective of gaining a better knowledge of its mechanism. The possible existence of either a concerted, or a two-step process must be considered. The simple way to prove that the adduct carbanion was a real intermediate was to offer it a chance to take a pathway other than the S_Ni reaction on the *tert*-butylperoxy group. This was arranged in the anionically induced decompositions of peroxide **1** induced by the potassium cumylperoxide anion, with the formation of two different epoxy peroxides, or by piperidine with the simultaneous production of an amino peroxide and an amino epoxide (Scheme 3). In the addition of potassium *tert*-butylperoxide to peroxide **3** the generation of two peroxy epoxides (Scheme 4) confirmed the existence of a general two-step process for the anionic-induced decomposition of unsaturated peroxides.

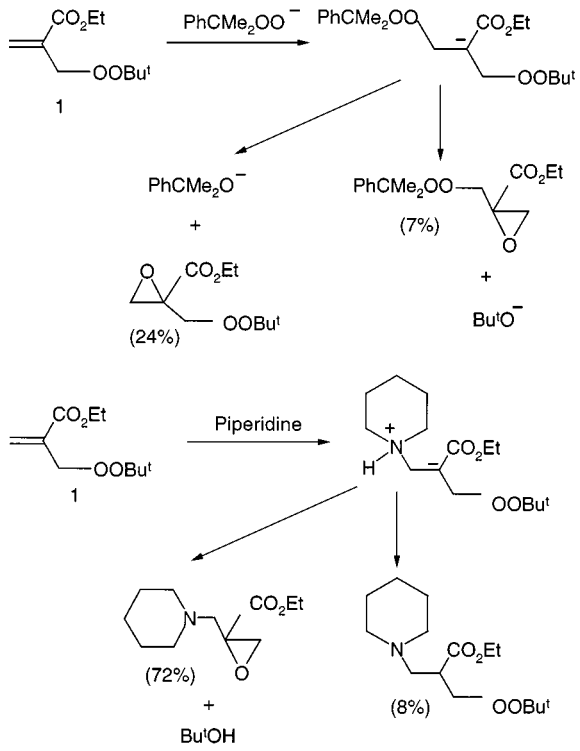
These preliminary results showed that allylic peroxides having an electron-poor double bond can suffer an anionically-induced decomposition consisting of two steps: (i) Michael addition of a nucleophile to the unsaturation and (ii) S_Ni reaction on the peroxidic function. Such steps may be part of a chain mechanism if the eliminated alkoxide is sufficiently basic to regenerate the nucleophile by proton abstraction from NuH, as in the reaction using diethyl malonate or an hydroperoxide; then only catalytic amounts of base are necessary. In the case of amines there is no need for a base because the nucleophile is provided by the lone pair of the nitrogen atom. The third case of interest appears to be when the eliminated alkoxide is not efficient enough to produce the nucleophile: it is then necessary to provide a stoichiometric amount of nucleophile to react with the unsaturated peroxide. This last possible induced decomposition was checked using ethyl 2-methylpropanoate as the precursor of the nucleophile,[13] the base being LDA. The addition at −78 °C of a THF solution of $Me_2C^-CO_2Et$[13] to peroxide **1** afforded after classical treatment the expected epoxy diester in a yield of 74%.



Scheme 1



Scheme 2



Scheme 3

In conclusion, anionically-induced decomposition of unsaturated peroxides having electron-poor double bonds by an addition-S_Ni process was clearly identified for the first time and appears a promising way to obtain oxygenated heterocycles such as epoxides (these reactions are currently under study in our group). This approach complements the homolytically induced decomposition of such unsaturated peroxides according to the *umpolung* effect identified in the replacement of a radical by the corresponding anion.

Biosynthesis of isoprenoids in *Escherichia coli*: The fate of the 3-H and 4-H atoms of 1-deoxy-D-xylulose

José-Luis Giner,[a] Bernhard Jaun[b] and Duilio Arigoni*[b]

[a] *Department of Chemistry, State University of New York - ESF, Syracuse, NY 13210, USA*
[b] *Laboratorium für Organische Chemie, Eidgenossische Technische Hochschule, Universitätstr. 16, Zürich, CH-8092, Switzerland*

The ubiquinone obtained from *E. coli* after feeding of 1-deoxy[3-^{2}H]xylulose shows labeling of the *E*-methyl group in the terminal unit and of all other positions derived from the terminal methylene group of isopentenyl pyrophosphate, whilst label from 1-deoxy[4-^{2}H]xylulose is retained exclusively in the double bond corresponding to the dimethylallyl pyrophosphate starter unit.

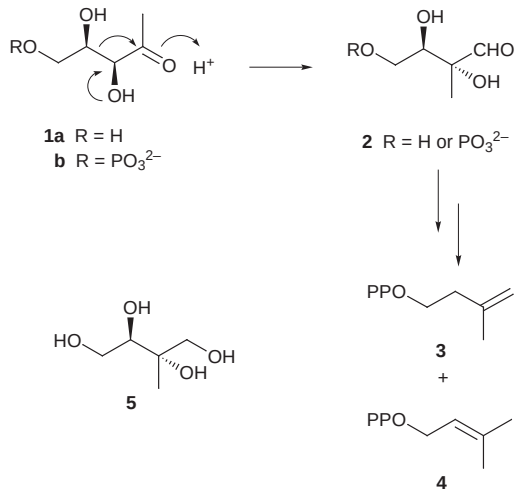
Recent studies have indicated that in *E. coli* the early steps of isoprenoid biosynthesis, *i.e.* formation of isopentenyl pyrophosphate (IPP) **3** and dimethylallyl pyrophosphate (DMAPP) **4**, occur *via* a mevalonate-independent pathway,[1,2] known to be operative also in other bacteria[1] as well as in green algae[3] and higher plants.[4] This alternative route proceeds *via* the intermediacy of 1-deoxy-D-xylulose **1a** (or the corresponding 5-phosphate **1b**) as first demonstrated for the formation of ubiquinone and menaquinone in *E. coli*,[2] and subsequently confirmed for the formation of a variety of terpenes in higher plants.[5]

The first committed step in the formation of IPP and DMAPP from **1a** or **1b** (Scheme 1) is believed to be a rearrangement to the branched aldehyde **2**, as suggested by the labeling patterns observed for the biosynthesis of the related tetrol **5** in *Corynebacterium ammoniagenes*[6] and the demonstration that **1a** indeed serves as a precursor of **5** in leaves of *Liriodendron tulipifera*.[7] Clearly, the overall conversion of **1a** to IPP and DMAPP requires *inter alia* three reductive steps, but the sequence of events remains unknown. To narrow down the number of mechanistic possibilities we have now investigated the fate of the H-atoms at positions 3 and 4 of 1-deoxyxylulose **1a** during the biosynthesis of ubiquinone in *E. coli* by using specifically deuterated forms of the precursor.

The required labeled substrates were prepared by exploitation of a recently described synthetic route centered on the Sharpless asymmetric dihydroxylation of **8** to **9** (Scheme 2).[8] For the preparation of 1-deoxy[3-^{2}H]xylulose **1c**, 1-triphenylphosphoranylidenepropan-2-one **7** was deuterated at the 1-position by deuterium-exchange in CH_2Cl_2–D_2O–CD_3OD (10:1:1) in the presence of 0.1% TFA. The resulting 1-deoxyxylulose was shown to contain 85% deuterium at C-3 and 5% at C-1 by a combination of ^{1}H and ^{2}H NMR spectroscopy of its 5-benzyl ether. The [4-^{2}H]-labeled 1-deoxyxylulose **1d** was assembled from benzyloxy[1-^{2}H]acetaldehyde, itself available from the unlabeled compound **6** through reduction with $LiAlD_4$ (> 99 atom%) and subsequent Swern oxidation of the resulting deuterated alcohol. A deuterium content of 70% was estimated for **1d** by ^{1}H NMR analysis of the corresponding 5-benzyl ether.

Samples of the labeled precursors (640 mg) were fed to 1 l cultures of *E. coli* (K-12 strain). The cells were grown for 24 h at 37 °C in a minimal medium containing 3.0 g l^{-1} glucose.[9] Ubiquinone **10** was obtained in a yield of 2.5 mg l^{-1}, which is twice as high as normally observed in the absence of the precursor. The biosynthetic samples were analyzed by mass spectrometry and NMR spectroscopy.[10]

The ubiquinone produced in the presence of **1c** was shown by integration of the 500 MHz ^{1}H NMR spectrum to contain 31% CH_3 and 69% CDH_2 in the (*E*)-31'-methyl position (signals at δ 1.679 and 1.661, respectively). In addition, integration of the signal cluster at δ 1.91–2.0 also indicated 69% monodeuteration of the CH_2 groups labeled with a square in formula **10**. These data correspond to a specific incorporation rate of 81% per unit derived from added **1c**.† The location of the deuterium was confirmed by peaks at δ 1.976 and 1.689 in the ^{2}H NMR spectrum in a ratio of approximately 7:1; an additional minor peak at δ 1.608 is due to the labeling of the (*Z*)-methyl groups by the small amount of deuterium present at C-1 of the precursor. The retention of deuterium from the 3-position of 1-deoxyxylulose **1c** in the positions arising from the terminal methylene group of IPP was further verified by ^{13}C NMR



Scheme 1

● position of the label from **1d**

analysis. The signal for the (*E*)-31'-methyl group bearing one deuterium was observed as a triplet (J_{C-D} = 19.1 Hz) shifted by −288 ppb from the signal of the unlabeled compound at δ 25.672. Monodeuteration of the labeled methylene positions was evidenced by the appearance of a broad triplet (J_{C-D} = 19.5 Hz) with an α-shift of −385 ppb from the normal signals at δ 39.735 and 39.714. The presence of deuterium at the positions indicated in **10** also resulted in β-shifts of −30 ppb for the adjacent quaternary olefinic carbons (δ 137.6–134.8) and of −72 ppb for the adjacent methylene carbons (δ 26.5–26.8). The signals due to the methyl group at C-3' (δ 16.334) and the other internal methyl groups (δ *ca*. 16.0) displayed γ-shifts of −30 ppb, while a γ-shift of −17 ppb was observed for the (*Z*)-methyl group at C-31' (δ 17.660).

Mass spectral analysis (EI) of the ubiquinone sample from the feeding experiment with **1d** disclosed the presence of an amount of d_1 molecular ions corresponding to *ca*. 45% of the total. From this value an approximate 65% specific incorporation of the label from **1d** into a single C_5 unit of **10** can be estimated. As a first indication that the label was localized at C-30' the same proportion of d_1 ions was observed for the $C_5H_9^+$ fragment expected to originate from the terminal C_5 unit of the isoprenyl chain. In keeping with this, the ^{2}H NMR spectrum displayed a single sharp signal at δ 5.138 and the ^{1}H NMR spectrum showed by integration the loss of *ca*. 0.36 H from the olefinic region, but no diminution of the resolved olefinic signals at δ 4.938 (2'-H) and 5.061. Independent proof for the location of the label came from the ^{13}C NMR spectrum which showed a marked diminution of peak intensity for the signal at δ 124.435. This signal must be assigned to C-30' since a β-shift of −99 ppb was observed for C-31' (δ 131.263) and γ-shifts were observed for the (*E*)- and the (*Z*)-methyl groups at C-31' (−63 and −21 ppb, respectively).‡

Thus, the deuterium label from C-4 of the precursor **1d** is retained in the 30'-position, *i.e.* in the double bond corresponding to the DMAPP starter unit, but not in any of the remaining double bonds generated from IPP in the elongation process. This is in striking contrast to the situation observed for the mevalonate pathway in eukaryotic organisms where the same H-atom of IPP (H_{Re}) is lost both in the isomerization to DMAPP and in the elimination step of the elongation process.[11] An IPP isomerase has been partially purified from *E. coli*;[12] if DMAPP is generated in the organism mainly through the action of this enzyme, then one has to conclude that in *E. coli* different H-atoms are lost from IPP in the isomerization and in the elongation process. The alternative that IPP and DMAPP may be formed independently from a common intermediate of the new pathway seems less plausible but cannot be dismissed on the basis of our results.

The difference in the metabolic origin observed in this study for the olefinic hydrogens of ubiquinone may prove relevant in connection with hitherto unexplained reports based on natural abundance ^{2}H NMR analysis of cyclic monoterpenes from higher plants which had disclosed a substantial relative enrichment of deuterium at the carbon atom stemming from C-2 of the starter DMAPP unit with respect to the other vinylic hydrogen atom of the geranyl pyrophosphate precursor.[13]

We thank Dr Linda Thöny-Meyer (Mikrobiologisches Institut der ETH-Z) for the *E. coli* K-12 wild-type strain, and Dr J. Schierle and Dr H. Keller (Hoffmann-La Roche A.G., Basel) for a sample of ubiquinone. Financial support by Novartis International A.G., Basel, is gratefully acknowledged.

Notes and References

† Mass spectral analysis of the sample of **6** derived from **1c** showed a cluster of M^+ ions corresponding to the addition of up to eight deuterium atoms per molecule.

‡ A β-shift of −108 ppb was also observed for the signal at δ 26.795 which can now be assigned to C-29'; additional shifted signals at δ 134.918 ($\Delta\delta$ = +7 ppb) and 124.292 ($\Delta\delta$ = −6 ppb) are most probably due to the two olefinic carbons of the adjacent C_5 unit.

Observation of ^{18}O solvent-induced isotope shifts in ^{19}F NMR signals

John R. P. Arnold*[a]† and Julie Fisher[b]

[a] *School of Biology, University of Leeds, Leeds, UK LS2 9JT*
[b] *School of Chemistry, University of Leeds, Leeds, UK LS2 9JT*

$H_2{}^{18}O$ solvent-induced isotope shifts, which have differing dependence on the level of ^{18}O-enrichment, have been observed in the ^{19}F NMR signals of F^- and 5-fluorouridine, but are absent in 5-fluorouracil.

The chemical shift of an ^{19}F NMR signal is highly sensitive to its environment, and as such it is well-suited to the observation of the solvent-induced isotope shift (SIIS). This is the shift observed when the solvent is changed to a heavier isotope form, usually by an H to D substitution, and most commonly this is a change from H_2O to D_2O.[1] Fluorine-modified amino acids and heterocyclic bases have been incorporated into biomolecules, and subsequent H_2O/D_2O SIIS measurements have enabled evaluation of the solvent exposure of specific residues in proteins[2,3] and nucleic acids.[4–7] An alternative heavy isotope form of water is $H_2{}^{18}O$. Thirty years ago a study of NaF, made without the benefit of today's high magnetic fields and FT techniques, gave the $H_2{}^{16}O/H_2{}^{18}O$ SIIS (herein the ^{18}O-SIIS) as being '< 0.05 ppm' upfield.[8] The origin of the fluorine H_2O/D_2O SIIS has been considered in terms of hydrogen bonding with the solvent and the different vibrational behaviour of H_2O and D_2O.[9] It has been calculated that an OH bending vibration can account for about 30% of the H_2O/D_2O SIIS observed for F^-.[10] Lower frequency librational modes are also potential contributors to the SIIS, but a failure to detect any ^{18}O-SIIS for 50 mM F^- led to the conclusion that these librational modes do not play a significant role in the SIIS of fluorine.[9] Here we report a re-examination of the ^{18}O-SIIS of fluorine.

We investigated the fluoride ion, which has been used in a number of previous studies of ^{19}F SIIS,[1,8–10] together with 5-fluorouridine and 5-fluorouracil, which represent subunits commonly used to incorporate fluorine into nucleic acids to probe structure and function, as well as being important anti-cancer chemotherapy agents.[11] The experimental arrangement placed fluoride, fluorouridine and fluorouracil in the same sample, so that the solution conditions for each were identical.‡ With the ^{18}O enrichment at 86%, the fluoride and fluorouridine resonances both displayed small but distinct upfield shifts, whilst fluorouracil showed no such effect (Fig. 1 and Table 1).§ On reducing the ^{18}O enrichment to 53%, the fluoride SIIS was reduced whilst the fluorouridine SIIS was *downfield*; with fluorouracil still showing no isotope shift. A further decrease in ^{18}O enrichment to 43% reduced the isotope shifts of F^- and of fluorouridine (still downfield). Further significant reduction of the ^{18}O content was impractical due to the difficulty in measuring the diminishing isotope shifts. Thus the effect of ^{18}O enrichment of the solvent water for F^- is an upfield shift proportional to the level of ^{18}O enrichment (within experimental error). For fluorouridine the effect is more complicated, but can be explained by the observed isotope shift being the sum of one term which is upfield and proportional to the ^{18}O content, and a second term which is downfield and non-linear. The change from an upfield to a downfield isotope shift with decreasing ^{18}O enrichment of the solvent meant that at some point the ^{18}O-SIIS would be zero. This behaviour is illustrated by Fig. 2, where at 66% ^{18}O, the ^{18}O-SIIS was not detectable (*i.e.* being less than the linewidth). Both solvent-induced and intra-molecular isotope shifts are generally upfield on heavy atom substitution.[1] However, a few cases of downfield isotope shifts have been reported,[1,12] and other than where noted above, we know of no previous reports of ^{18}O-induced isotope shifts of ^{19}F, nor of ^{18}O-SIIS for any other NMR-active nucleus.

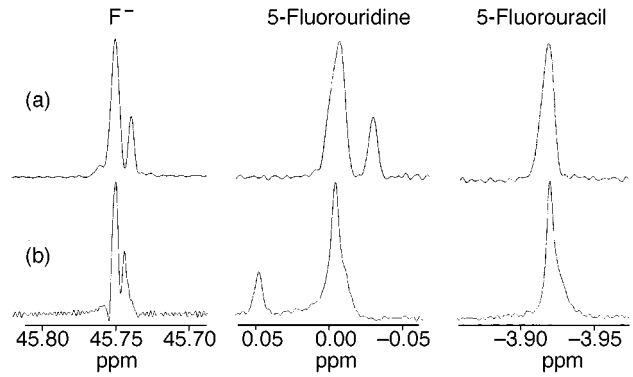

Fig. 1 ^{19}F NMR spectra (^1H-decoupled) of fluoride ion (left), 5-fluorouridine (centre) and 5-fluorouracil (right). Smaller signals are due to ^{18}O-induced shifts. (a) ^{18}O-enrichment in central chamber of concentric tube was 86%, solute concentrations 4 mM fluoride, 1 mM for both fluorouridine and fluorouracil. (b) ^{18}O-enrichment 53%, concentrations 30 mM fluoride, 1 mM for both fluorouridine and fluorouracil.

Table 1 SIIS values for fluoride, 5-fluorouridine and 5-fluorouracil‡§

Solvent system	Concentrations[a]/mM	Enrichment[b] (%)	SIIS[c] (ppm) F^-	5-Fluorouridine	5-Fluorouracil
$H_2{}^{16}O/H_2{}^{18}O$	4, 1, 1	86	−0.0120	−0.0227	0
$H_2{}^{16}O/H_2{}^{18}O$	4, 1, 1	53	−0.0068	+0.0089	0
$H_2{}^{16}O/H_2{}^{18}O$	4, 1, 1	43	−0.0060	+0.0080	0
$H_2{}^{16}O/H_2{}^{18}O$	30, 1, 1	53	−0.0056	+0.050	0
$H_2{}^{16}O/H_2{}^{18}O$	50, 1, 1	53	−0.0040	+0.044	0
H_2O/D_2O	4, 1, 1	100	−2.771	−0.243	−0.199
H_2O/D_2O	50, 1, 1	100	−2.679	−0.255	−0.190

[a] In the order of fluoride ion (as NaF), 5-fluorouridine, 5-fluorouracil, present in the same sample. [b] Enrichment of the heavier-isotope solvent in its chamber of the concentric NMR tubes. [c] Negative values indicate upfield shift for heavier-isotope solvent, positive for downfield shift. ^{18}O-SIIS values have estimated error span of ±0.0005 ppm. H_2O/D_2O SIIS estimated error margin ±0.001 ppm.

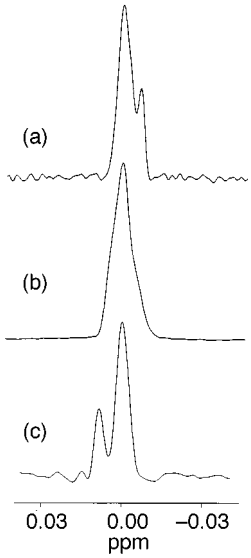

Fig. 2 ^{19}F NMR spectra (^{1}H-decoupled) of 5-fluorouridine (5 mM) with varying ^{18}O-enrichment in the central chamber of concentric tubes: (a) 87, (b) 66 and (c) 44%. ^{18}O-SIIS values are −0.0060, 0 and +0.0084 ppm respectively (all ± 0.0005 ppm).

In order to approach the conditions used in a previously reported study[9] (*i.e.* 50 mM NaF), we increased the flouride ion concentration from 4 to 30 and then 50 mM, whilst using 53% ^{18}O. With this increasing concentration, the SIIS of fluoride ion decreased in an approximately linear fashion so that it was only 0.004 ppm at 50 mM. The combination of lower magnetic field strengths and relatively high fluoride concentration would thus account for the previous negative results.[9] Increasing the fluoride ion concentration also made the SIIS of fluorouridine significantly more pronounced, but did not cause any change to the absence of a perceptible ^{18}O-effect for the resonance of fluorouracil (Table 1 and Fig. 1).

The H_2O/D_2O SIIS values are also given in Table 1; those for F^- are in fair agreement with previous reports.[1,8,10] Values for fluorouridine and fluorouracil have not previously been reported, but 0.39 ppm has been given for closely related 2'-deoxy-5-fluorouridine[6] for 10–100% D_2O (since seperate tubes were used) under different sample conditions. Our value for fluorouridine is some 25% larger than that for fluorouracil. This may be related to the absence of an observable ^{18}O-SIIS for the latter, if the internal vibrations of solvent water make a stronger contribution to the ^{19}F chemical shift of fluorouridine than to that of fluorouracil. Alternatively, for fluorouracil, upfield and downfield contributions to the ^{18}O-SIIS may more consistently balance than would seem to be the case in fluorouridine. Pyrimidine bases have been noted to weakly self-associate in aqueous solution,[13] but with the relatively low concentrations used here the effect of this should be small (*i.e.* in the order of 0.1% of the molecules being associated, based on typical association constants[13]).

We have shown that an ^{18}O-SIIS for ^{19}F is detectable, and can be of relatively significant magnitude. Thus the librational motions within the water molecule cannot be discounted from contributing to the fluorine chemical shift, but clearly other terms are also involved, at least for fluoropyrimidines. The ^{19}F ^{18}O-SIIS may prove to be a useful complement to the H_2O/D_2O SIIS in the study of fluorine-labelled proteins and nucleic acids.

‡ Samples for NMR analysis were prepared as follows: a solution of NaF (4 mM), 5-fluorouridine (1 mM), 5-fluorouracil (1 mM), and EDTA (0.1 mM) in 25 mM sodium phosphate buffer, pH 6.8 was divided into portions which were then lyophilised to dryness. The residues were then re-dissolved in appropriate volumes of 90% $H_2{}^{16}O$/10% D_2O or 90% $H_2{}^{18}O$/10% D_2O. In this way the ^{16}O and ^{18}O portions contained identical concentrations of all solutes. The solutions were placed in an NMR tube containing a concentric insert, with typically 80 µl of ^{18}O-enriched sample in the central chamber, and 330 µl of ^{16}O sample in the outer part. An ^{18}O-shifted signal is thus identified by its size compared to the ^{16}O resonance. Reduction of the ^{18}O enrichment was achieved by diluting with the ^{16}O solution. The concentration of NaF was increased by evaporating to dryness appropriate volumes of NaF solution in H_2O, and then redissolving these in the ^{18}O and ^{16}O solutions. For measurements of H_2O/D_2O effects, lyophilised solutions were redissolved in either H_2O or D_2O, and placed in concentric NMR tubes.

§ All ^{19}F NMR spectra were acquired on a GE-Omega 500 spectrometer at 470.5 MHz using a 5 mm ^{19}F/^{1}H probe. Broadband ^{1}H decoupling was applied by waltz-16 modulation of the decoupler. All spectra were acquired with a sample temperature of 25 °C. FIDs were multiplied by Gaussian functions and zero-filled prior to Fourier transformation. The digital resolution of the ^{19}F NMR spectra were at least 0.12 Hz (0.00026 ppm) per point. Chemical shifts are shown with respect to 5-fluorouridine (in the lighter isotope solvent) as the internal reference.

A new type of rhenium condensed cluster $[Re_9Se_{11}Br_6]^{2-}$ has been synthesized by the reaction of Re_3Br_9 and PbSe at 550 °C and structurally characterised; the structure of $[Re_9Se_{11}Br_6]^{2-}$ contains the bioctahedral rhenium cluster Re_9 which can be considered as the result of progressive uniaxial condensation of three Re_3 clusters.

Condensation of fragments with the formation of polyhedral clusters is one of the most promising methods in synthetic cluster chemistry.[1] The most remarkable examples of the applicability of this method are seen in the syntheses of some octahedral clusters, for example, the zirconium halide cluster $[Zr_6Cl_{12}(PMe_2Ph)_6]$ which is formed from three binuclear complexes $[Zr_2Cl_6(PMe_2Ph)_4]$,[2] or of sulfide and selenide cluster complexes of molybdenum and tungsten $[M_6Y_8(PEt_3)_6]$ by reductive dimerization of two triangular cluster complexes $[M_3S_4Cl_4(PEt_3)_x]$.[3] Recently[4] we have developed a condensation method for the high yield synthesis of the octahedral rhenium cluster chalcobromides $Re_6E_4Br_{10}$ and $Re_6E_8Br_2$ (E = S, Se, Te) using the triangular cluster rhenium bromide Re_3Br_9 and lead or cadmium chalcogenides (PbE or CdE where E = S, Se and Te) as starting compounds. We have found that given condensation reactions can yield not only octahedral clusters but also other cluster complexes.

Here we present the preparation‡ and structural characterisation§ of a new cluster complex $[PPh_4]_2[Re_9Se_{11}Br_6]$ containing the bioctahedral rhenium cluster anion $[Re_9Se_{11}Br_6]^{2-}$. This type of cluster was not known for rhenium previously. It can be considered as the result of progressive uniaxial condensation of three Re_3 clusters.

$[PPh_4]_2[Re_9Se_{11}Br_6]$ crystallises with triclinic symmetry to form dark red prisms. The $[Re_9Se_{11}Br_6]^{2-}$ unit (Fig. 1) is structurally identical to that of $Co_9Se_{11}(PPh_3)_6$[7] and Mo_9E_{11} (E = S, Se) which was found in some ternary molybdenum chalcogenides.[8–14] In the crystal structures of the latter, the metal ion is bonded to six X atoms belonging to the adjacent Mo_9E_{11} cluster units, so $[Mo_9E_{11}X_{6/2}]$ units similar to $[Re_9Se_{11}Br_6]^{2-}$ are formed.

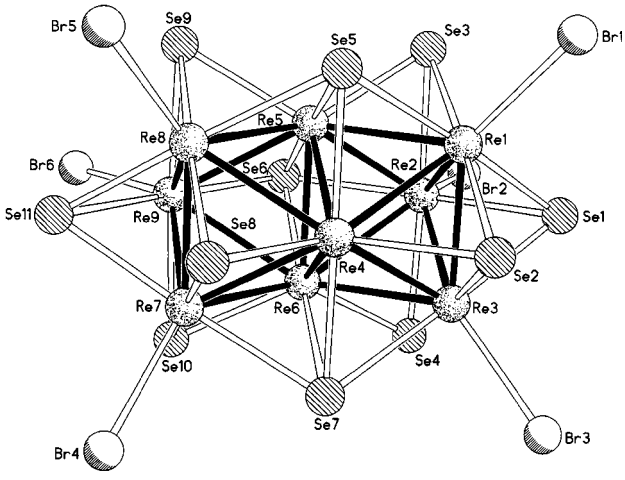

Fig. 1 Structure of the $[Re_9Se_{11}Br_6]^{2-}$ anion showing the atom labelling scheme and highlighting the bioctahedral Re_9 core

The environments of the external Re atoms (Re1–3 and Re7–9) in $[Re_9Se_{11}Br_6]^{2-}$ are similar and consist of four Re atoms, four Se atoms forming a quasi-planar square, and one Br atom. The internal Re atoms Re4–6 are connected to six Re and four Se atoms.

The Re–Re distances within the Re_9 cluster can be classified into three groups. The first corresponds to the distances within the two external Re_3 triangles formed by the Re1–3 and Re7–9 atoms, here the mean distances are 2.596(1) and 2.594(1) Å respectively; these are the shortest Re–Re distances in the Re_9 cluster. The second group is formed by Re4–6 atoms of the internal Re_3 triangle, these Re–Re distances are the longest in the cluster with a mean of 2.687(1) Å. And finally, the third group comprises the Re–Re bonds between these Re_3 triangles (inter-triangle distances) which range from 2.645(1) to 2.663(1) Å. So, in the $[Re_9Se_{11}Br_6]^{2-}$ cluster the two external Re_3Se_3 triangles are compressed whereas the middle Re_3Se_3 triangle is expanded by comparison.

It is well known that the metal–metal distances in octahedral condensed clusters depend on the number of the valence electrons on the metal atom [the so-called valence electron concentration (VEC)], which are available for the metal–metal intracluster bonding.[15] Comparing the Re_9 obtained here and the Mo_9 cluster which is found in some ternary molybdenum selenides,[8–14] we can see that an increased charge on this cluster leads mainly to an increase in the size of the median triangle. For example, going from $In_2Mo_{15}Se_{19}$ to $In_{3.33}Mo_{15}Se_{19}$, the corresponding Mo–Mo distances increase from 2.681 to 2.768 Å[8] showing that the same tendency is found here.

To provide a further strategy for the synthesis of other condensed rhenium clusters, it is interesting to consider the VEC and the stability of related compounds. For example, in the series of condensed clusters $[Mo_9E_{11}]^0$, $[Mo_{12}E_{14}]^{2-}$, $[Mo_{18}E_{20}]^{4-}$, $[Mo_{24}E_{26}]^{6-}$, $[Mo_{30}E_{32}]^{8-}$, $[Mo_{6/2}E_{6/2}]^{2-}$ the number of valence electrons per metal atom (VEC) available for M–M bonding is increased from 3.56, 3.83, 4, 4.08, 4.13 to 4.33, respectively,[16] to allow an increase in the order of the metallic bonding. In other words, the formal oxidation state of metal atoms is lowered. In rhenium cluster chemistry, the situation is the same, namely, the VEC for $[Re_6E_8]^{2+}$ and $[Re_9Se_{11}Br_6]^{2-}$

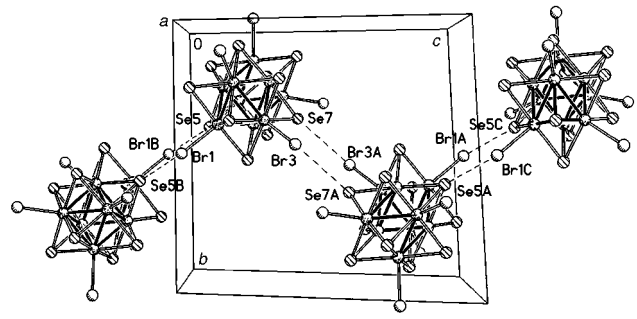

Fig. 2 Intercluster interactions *via* Se···Br short contacts

cluster units is 4 and 4.11, respectively. Here it is interesting to remark that for the hypothetical $[Re_{12}E_{14}Br_6]^{2-}$ dianion (the unknown member from the next step of progressive condensation of Mo_3X_3 units) the VEC would be 4.33, that is the same as in $[Mo_{6/2}E_{6/2}]^{2-}$ clusters.

An interesting feature of the structure is the infinite chains of clusters along the crystallographic *c* axis: each cluster unit $[Re_9Se_{11}Br_6]^{2-}$ exhibits interactions to two neighbours *via* Se···Br short contacts across inversion centres (Fig. 2): Br1–Se5A 3.547 Å, Br3–Se7B 3.840 Å.

We would like to thank the EPSRC for provision of the X-ray equipment and Professor William Clegg for the use of this equipment and associated computing facilities. This work was also supported by Russian Foundation for Basic Research (grant N 96-03-32955).

Notes and References

† Dedicated to Professor Achim Müller on the occasion of his 60th birthday.

‡ *Experimental procedure*: Re_3Br_9, PbSe and KBr in molar ratio 1 : 4 : 6 were heated in an evacuated fused-silica tube at 550 °C for 2 d. The reaction mixture was washed with water and a small amount of boiled HBr. The resulting solid was washed with MeOH to give a dark red solution. An excess of $[PPh_4]Br$ was added to this solution causing precipitation of a brown powder. Recrystallisation from MeCN leads to the formation of two types of crystals, dark red prisms and pyramids. The prism crystals were used for X-ray analysis.

§ *X-Ray structure analysis*: $(PPh_4)_2Re_9Se_{11}Br_6$, dark red prism, crystal dimensions, 0.33 × 0.19 × 0.18 mm, triclinic, space group $P\bar{1}$, a = 13.3335(9), b = 15.3791(11), c = 17.1175(12) Å, α = 84.687(2), β = 73.086(2), γ = 77.672(2)°, Z = 2, V = 3279.1(4) Å^3 [T = 160(2) K]. Chelating diphosphine–palladium(II) dihalides; outstandingly good catalysts for Heck reactions of aryl halides

Bernard L. Shaw* and Sarath D. Perera

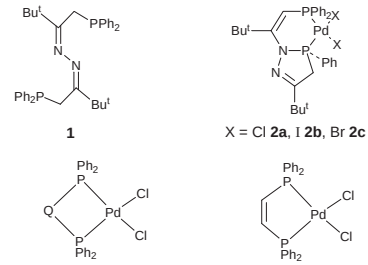
School of Chemistry, University of Leeds, Leeds, UK LS2 9JT

Contrary to previously held views, chelating diphosphine–palladium dihalide complexes are excellent catalysts for Heck reactions involving aryl halides; the undesirability of trying to prepare such catalysts *in situ* is discussed.

The Heck vinylation or olefination reaction [eqn. (1)] is very

important in organic synthesis.[1a–c] A Heck catalyst is frequently generated *in situ* from $Pd(OAc)_2$ and a tertiary phosphine, L = PPh_3 or P(*o*-tolyl)$_3$; commonly 1–5 mol% of Pd is used which means that the maximum turnover numbers are only 100–20. When discussing arylation with aryl halides[1b] Heck stated that 'chelating diphosphines do not give as good catalysts'; this was in comparison with the catalysts commonly used and mentioned above and which are therefore a benchmark for comparing reactivity and performance. Cabri and co-workers[2a] agreed with this statement of Heck and in a review[2b] wrote that his statement 'Chelating diphosphines...in general do not produce useful catalysts' was valid only because aryl halides were used but also wrote 'with bidentate ligands a decrease in reaction rates or sometimes a complete suppression of the reaction is observed'. Ditertiary phosphine–palladium complexes are effective catalysts for Heck reactions with aryl triflates or with aryl halides in the presence of a halide scavenger (Ag or Tl).[1c,2a–c] Overman and coworkers have demonstrated that diphosphine (*e.g.* BINAP)–Pd catalysts promote intramolecular Heck reactions with aryl iodides, with high ee.[2c] However, very large amounts of catalyst, 3–10 mol%, have been used for these reactions. The prevailing belief is that chelating diphosphine–Pd complexes are not good catalysts for the classical Heck reaction [eqn. (1)].

We have now investigated **2a** and **2c** and ditertiary phosphine–palladium(II) dihalide complexes **3a–d** and **4** and find them to be outstanding as catalysts for Heck olefination reactions with aryl iodides and bromides in several respects. Our results are summarised in Table 1. High yields and very high turnover numbers (TONs; up to 225 000) were obtained, with good rates; catalysts were active over the temperature range 50–150 °C, which could probably be extended; in some cases reaction times could probably be reduced, we left some reactions for prolonged times to show that the catalysts were stable; in no case was any metallic Pd produced. The yields were isolated yields and chromatography was not necessary, the Pd being removed by a simple wash with a very small amount of aqueous sodium cyanide solution and the product was then purified by crystallisation. We have used this very effective isolation procedure for Heck reactions catalysed by palladacycles.[3] The very stable complex **2a** can be easily made in high yield, from **1** and $[PdCl_2(NCPh)_2]$[4] by a transannular reaction; we also reported the crystal structure of **2b** and prepared **2c** by metathesis.[4] Treatment of PhI (2.0 g, 10 mmol), styrene and NBu^n_3 with catalyst **2a** (0.044 mg) in dmf at 95 °C for 12 d gave a pale orange solution. This was taken up in CH_2Cl_2 and after a water wash and then a wash with a solution of NaCN (2 mg) in



water the organic layer was essentially colourless. The stability constant for $[Pd(CN)_4]^{2-}$ is about 10^{52},[5] and this wash presumably took the Pd into the aqueous layer. Crystallisation from methanol then gave *trans*-stilbene in 67% yield corresponding to a TON of 101 200. The other reaction mixtures summarised in Table 1 were worked up in an analogous manner, except that for reactions with methyl acrylate the work up was done in diethyl ether. In example 2, with 9 days reaction time at 95 °C, the isolated yield of methyl cinnamate was 92%, TON = 139 000. We also studied catalyst **2a** at higher temperatures, 125 and 150 °C, and shorter reaction time (48 h, entries 4 and 5) with very good yields and excellent TONs (110 200 and 60 400) and no sign of decomposition to metallic Pd. Bromide **2c** was a good catalyst for converting methyl acrylate and iodobenzene into methyl cinnamate (example 3). **2a** catalysed the olefination of 4-bromoacetophenone to acetylstilbene; 91% yield, TON = 27 500. Bases other than NBu^n_3 were used, entries 7–10, *viz*. NaOAc, K_2CO_3 with NBu^n_4Cl, K_2CO_3 or $KHCO_3$, in example 8 a reaction temperature of only 50 °C was used. Reaction 11, with 4-bromocyanobenzene was carried out at 125 °C for 12 h. Products were identified by their proton NMR spectra.

The 4-membered ring chelated dppm complex **3a**[6,7] (0.032 mg) converted PhI (1 g) plus styrene into stilbene at 150 °C/48 h in 87% yield with a TON of 76 300 and no sign of decomposition. **3a** also converted 4-bromoacetylbenzene into 4-acetylstilbene at 125 °C in 88% yield. The 5-membered chelate ring complex catalysts **3b**[8] and **4**[9] gave very good yields (76% to 95%) of stilbene derivatives and **4** gave acetylstilbene in 82% yield, using $KHCO_3$ as base. The 6-membered ring chelate **3c** gave a particularly high TON (224 700) and 80% yield for the conversion of iodobenzene/styrene to stilbene, with reaction conditions 3 d/125 °C; the 7-membered chelate dppb complex **3d** under these conditions gave a TON of 170 300. **3c** and **3d** also catalysed reactions of 4-bromoacetylbenzene with styrene in high yields and with good TONs. We favour a mechanism for the syntheses summarised in Table 1 involving a Pd^{II}–Pd^{IV} cycle similar to those we proposed for Heck reactions catalysed by palladacycles or in the phosphine free systems (Jeffery conditions).[3,10]

Typically, in Heck syntheses involving chelating diphosphines, the diphosphine and the equivalent amount of palladium, *e.g.* palladium acetate, has been added to the mixture of reactants in the belief that a compound of type $[(L–L)PdX_2]$[2b] will form *in situ*. However, there are very good reasons for

Table 1 Selected results of the Heck reactions catalysed by P–P palladium chelates[a]

No.	Aryl halide	Olefin	ArX/olefin mmol/mmol	Catalyst (mmol)	Time (T/°C)	Yield (%) (TON)

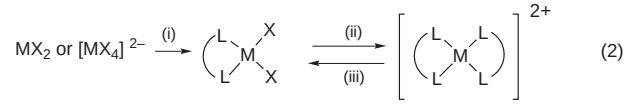
[a] For all except examples 7–10 and 15, 1.2 equiv. NBu^n_3 to the aryl halide were used as base; dmf was used as solvent to dissolve the catalyst, *e.g.* in examples 6, 11, 17 and 19, 1 cm^3 of dmf was used; in examples 1–5, 12, 16 and 18, 2 cm^3; in examples 9, 13, 14 and 15, 5 cm^3; in examples 8 and 10, 10 cm^3. sty = styrene, mac = methyl acrylate, bab = 4-bromoacetylbenzene, bcb = 4-bromocyanobenzene. [b] $NaOAc \cdot 3H_2O$ (2.65 mmol) used as base. [c] K_2CO_3 (25 mmol, base) and Bu^n_4NCl (10 mmol) were used. [d] K_2CO_3 (15 mmol) used as base. [e] $KHCO_3$ (25 mmol) used as base.

thinking that in some cases only a fraction of the Pd will do this. In Pd^{II} and Pt^{II} chemistry, in many cases, on addition of one equivalent of a chelating diphosphine or diarsine to $[MX_4]^{2-}$, half of the Pd^{II} or Pt^{II} is converted into $[M(L–L)_2]^{2+}$, *i.e.* in eqn. (2) half the metal will remain as $[MX_4]^{2-}$.[12a–d] This follows from the very high *trans*-effect (*trans*-labilising effect) of a tertiary phosphine (arsine) compared with a chloride ligand. We showed that a chloride ligand *trans* to a tertiary phosphine such as PEt_3 was substituted by pyridine about 10^4 times faster than chloride *trans* to another chloride ligand,[11] *i.e.* in eqn. (2) the



(2)

rate of substitution (ii) will be much greater than that of substitution (i). Thus a Magnus type salt $[M(L–L)_2][MX_4]$ is formed, which is often of very low solubility. Conversion of such a salt to *cis*-$[(L–L)MX_2]$ is often difficult; boiling it in dmf (bp 153 °C) or with a mixture of hydrochloric acid and ethanol will often effect the conversion[12a–c] but in some cases even such extreme conditions are not sufficient or satisfactory.[12c,d] A satisfactory method of synthesising complexes of type $[(L–L)PdX_2]$ is to treat a compound of type $[PdX_2(NCR)_2]$, *e.g.* the well known $[PdCl_2(NCPh)_2]$, with the chelating diphosphine in a suitable solvent system, *e.g.* CH_2Cl_2 or acetone,[12a–d] and this is the method we have used in the present work. Complexes **3a**–**d** and **4** have been studied extensively[6–9,12a–d] and **3a**–**c** have had their crystal structures determined.[7]

As will be gathered from the above, process (iii) in eqn. (2) may be exceedingly slow and it is not known in detail how it occurs. Palladium acetate is a trimer, the acetate ligand is labile and one might expect that on adding a chelating diphosphine and the equivalent amount of palladium acetate to a mixture of reactants for a Heck synthesis, *in situ*, much of the Pd would be converted into $[Pd(L–L)_2]^{2+}$ but not much $[(L–L)PdX_2]$ (X = OAc *etc*.) would be formed. If so it calls into question some arguments which have been put forward when discussing Heck reactions involving Pd–chelating diphosphine catalysts.[2b,c] It is recommended that catalysts for Heck reactions should be preformed and the source of Pd and the phosphine not added separately to the reactants; this could become especially important when very small amounts of Pd and diphosphine are used.

Even when catalysts are generated from a Pd^0 complex, such as $Pd_2(dba)_3$, the resultant complex(es) will oxidatively add aryl halide to give Pd^{II} complexes which could then participate in a catalytic cycle involving Pd^{II}/Pd^{IV}.

Enzymatic synthesis of a chiral gelator with remarkably low molecular weight

Vassil P. Vassilev, Eric E. Simanek, Malcolm R. Wood and Chi-Huey Wong*†

Department of Chemistry and the Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, CA 92037, USA

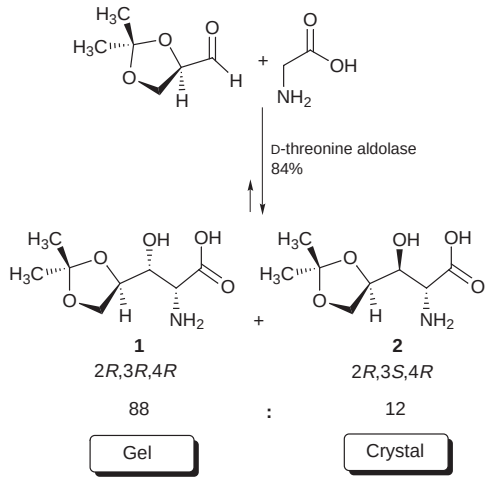
In one enzymatic step, two products of low molecular weight are obtained: one is a gelator of organic solvents, the other crystallizes to form an extended hydrogen-bondednetwork.

One product synthesized during our investigations of the enzymatic synthesis of β-hydroxy-α-amino acids using threonine aldolases was an optically-active, low molecular weight gelator of organic solvents.[1] Compound **1** is remarkably effective: only 0.2–0.4% of **1** is required for gel formation. Herein we report our investigations of **1** and **2** utilizing transmission electron microscopy, single crystal X-ray diffraction, and computation.

The products of the enzymatic aldol reaction between glycine and 2,3-*O*-isopropylideneglyceraldehyde (Scheme 1) are two diasteriomers which differ only in their absolute stereochemistry at C3. While **1** forms a gel in most organic solvents (Table 1), **2** crystallizes. This difference led us to investigate this system further.

While gel formation in aqueous and non-aqueous media by high molecular weight molecules is a well documented phenomenon, the study of low molecular weight gelators is in its infancy.[2] Their potential as nucleating agents for synthetic polymers and in health care products has been recognized.[3–8] All of these molecules contain chiral centers, hydrophobic regions, and groups capable of forming intermolecular interactions such as hydrogen bonds. Beyond such a description, our ability to predict which molecules will form gels in not possible: their discovery occurs serendipitously. In addition to the above cited small molecules, other recently published examples include derivatives of cholesterol,[9] 2,3-bis(*n*-decyloxy)anthracenes,[10] calixarenes,[11] and fluorinated hydrocarbons.[12] A majority of the gelators identified—especially those which give quartenary structure visible in electron micrographs—incorporate large aliphatic (hexadecyl, octadecyl) chains.[13–16]

Due to the low solubility of **1** in organic solvents, a MeOH quench strategy is used to form gels. Gels are obtained by first dissolving **1** in a small volume of MeOH, and then adding the solvent of choice warmed to ~ 40 °C: MeOH is typically present in < 10% v/v. Subsequent cooling of the solution to room or low temperature affords the gel. Excess solvent is removed by allowing the gel to stand at room temperature and decanting. After solvent release is complete, the molar ratio of **1**:solvent can be calculated (Table 1).



Scheme 1

Table 1 Compound **1** forms gels from a variety of solvents

Solvent	Phase formation	**1**/solvent (mol/mol)	**1**/wt%	*T*/°C[a]
H_2O	solution	—	20.5	—
H_2O–EtOH (1:5)	gel	125	4.5	3
MeOH	solution	—	2.4	—
MeOH	gel	117	4.9	3
THF	gel	702	0.4	room temp.
EtOH	gel	509	0.9	3
Bu^nOH	gel	1456	0.2	3
Pr^iOH	gel	1245	0.3	room temp.
MeCN	gel	1251	0.4	room temp.
Et_2O	gel	443	9	3
$PhCH_2CH_2OH$	gel	723	0.24	3
Bu^sOH	gel	1369	0.2	3
$C_5H_{11}OH$	gel	330	0.7	3
Isoamyl alcohol	solution	—	0.16	0
$C_8H_{17}OH$	gel	630	0.25	3
Solketal	solution	—	0.48	0

[a] Refers to temperature at which the solution of **1** in the indicated solvent was left to stand before gel formation was observed: 3 °C indicates a cold room at *ca.* 3 °C; 0 °C indicates an ice bath.

Compound **1** can be visualized by transmission electron microscopy following staining with OsO_4 vapor. At *ca.* 40 °C the gel becomes a viscous solution which can be transferred *via* pipet to a carbon-coated EM grid. After air drying for 5 min, the grid is placed in a sealed chamber next to a vial containing aq. OsO_4. After sitting overnight, the sample is examined in the EM. We observe fibers that are similar in appearance to those observed in related systems. Fig. 1(A) shows a low magnification image of the fibril network obtained. Fig. 1(B) shows a higher magnification image in which the dimensions of individual fibers can be measured. To our eyes, while the fibers all appear to be greater than 1 μm in length, they appear to terminate by forming a larger diameter fiber. Their widths also

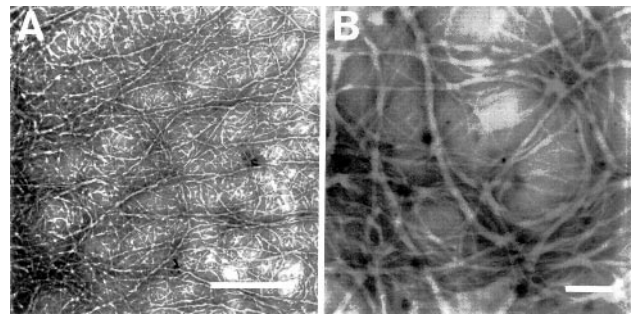


Fig. 1 Transmission electron micrographs of **1**. The scale bars shown represent (A) 2 μm and (B) 200 nm.

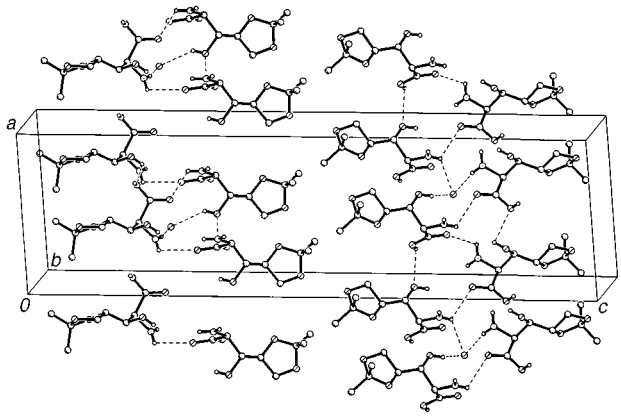

Fig. 2 Packing of **2** occurs with the inclusion of a water molecule (hydrogens omitted). Hydrogen bonds (calculated) are shown as dashed lines.

appear to be well defined. That is, we can identify three distinct sizes: narrow fibers (< 5 nm); medium fibers (20 nm); and wide fibers (> 20 nm). In Fig. 1(A) the wide fibers run from right to left, while medium fibers run between wide fibers. Narrow fibers are difficult to see at this magnification, but are seen in Fig. 1(B). Many of the gel fibers formed by higher molecular weight gelators containing one or more long chain alkanes show quarternary structure within a fibril: they appear woven like a rope. While some of the fibers suggest such a helicity, the images are not as satisfying as those reported by Thierry[3] and Demharter.[16d]

To infer reasonable patterns of intermolecular interactions in **1**, we investigated the crystal structure of **2**, which gave crystals suitable for single-crystal X-ray diffraction from an EtOH–water solution (similar to that in which **1** gives gels).‡ Fig. 2 shows the packing of these molecules in the solid state which contains a hydrophobic domain comprising the isopropylidene ring, and the hydrophilic domain comprising carboxylate, amine, and hydroxy groups. In general, hydrophobic groups of one molecule pack against the hydrophobic groups of neighboring molecules in either an edge-to-edge or face-to-face arrangement.[17] The hydrophilic regions pack to form a 3D network of interactions that are depicted as hydrogen bonds in Fig. 2.[18] Incorporated into the lattice is a highly-coordinated water molecule. All potential hydrogen bonding interactions are satisfied with the exception of the oxygen atoms of the isopropylidene group.

We envisioned that the difference between the gel and crystalline states might arise from the dimensionality of directional intermolecular interactions. That is, in the crystalline state, highly directional hydrogen bonds extend in three dimensions: one dimension is communicated along the hydroxy group at C3. Changing the geometry of this hydroxy group—changing from **2** to **1**—might change directional ordering in the third dimension leading to a gel state. To investigate this possibility we performed Monte Carlo calculations in Macromodel. Unfortunately, we find no conformational preference for the C3 hydroxy group in any of the four diasteriomers.[19]

To better evaluate the structure of the gel, we attempted to prepare gels from acidic or basic solutions of aq. MeOH and *n*-butanol—the solvent which most readily forms gels with **1**.[20]

We observed no gel formation even when *ca.* 10× the amount of **1** required for gel formation from 'pH-neutral' organic solvents was added. It seems very likely that the proton balance must be maintained for hydrogen bonding or ion-pairing to facilitate gel formation.

The molecular basis for the formation of a gel state instead of a crystal state remains unclear. We are pleased, however, that molecules like **1** and **2**—which contain three chiral centers and are available in one enzymatic step—display such interesting properties.

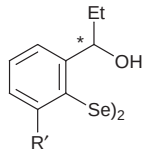
New and efficient selenium reagents for stereoselective selenenylation reactions

Gianfranco Fragale,[a] Markus Neuburger[b] and Thomas Wirth*[a]†

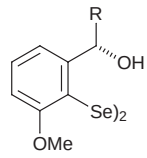
[a] *Institut für Organische Chemie der Universität Basel, St. Johanns-Ring 19, CH-4056 Basel, Switzerland*
[b] *Labor für Kristallographie, Institut für Anorganische Chemie der Universität Basel, Spitalstr. 51, CH-4056 Basel, Switzerland*

The simple substitution of an aryl proton by a methoxy substituent improves the selectivity of the stereoselective selenenylation reaction dramatically, leading to addition products with diastereomeric ratios up to 50 : 1 in the methoxyselenenylation reaction of styrene.

Stereoselective reactions using chiral selenium compounds have been investigated recently by us[1] and other research groups.[2] These reagents can be employed in asymmetric selenenylation reactions or as ligands in metal-catalyzed transformations. For this purpose we have developed readily available chiral diselenides of type **1**. Diselenide **1a** (R' = H),



1



2

which can be synthesized *via* a two-step procedure, has already been used in many stereoselective reactions with good results. We have shown that an oxygen atom in the chiral side chain in close proximity to the selenium is responsible for the efficient transfer of chirality.[3]

C_2-Symmetrical chiral diselenides with an additional chiral side chain at the second *ortho*-position are also very efficient reagents in selenenylation reactions, however, they have to be prepared by multistep synthesis.[2a] Because an additional simple substituent in **1** (R' = Me, CF_3) does not improve the selectivity in the selenenylation reaction,[4] we decided to prepare compounds **2** with heteroatom-containing substituents such as the methoxy group.

Diselenides **2a**,**b** were synthesized from the optically active alcohols **3a**,**b**, respectively (Scheme 1). Alcohol **3a** was obtained by chiral reduction of 3-methoxyacetophenone with (−)-*B*-chlorodiisopinocampheylborane in 97% ee.[5] Through diethylzinc addition to 3-methoxybenzaldehyde catalyzed by (*R*,*R*)-bis{2-[1-(pyrrolidin-1-yl)ethyl]phenyl} diselenide,[6] alcohol **3b** was obtained in 97% ee. The alcohols **3a**,**b** were first deprotonated with Bu^{n}Li in the presence of TMEDA and then lithiated in the *ortho*-position with an excess of PhLi.[7] Successive reaction with selenium and oxidative work-up yields the diselenides **2a**,**b** in 63 and 47% overall yield, respectively.‡

3a R = Me
b R = Et

2a R = Me
b R = Et

Scheme 1 *Reagents and conditions*: i, Bu^{n}Li, TMEDA; ii, PhLi; iii, Se, O_2

From diselenide **2a** crystals suitable for X-ray analysis were obtained. The structure of **2a** (Fig. 1)§ is substantially different from other diselenides bearing heteroatom-containing sidechains. In other structures we found a strong interaction between the heteroatom of the sidechain and the selenium atom. In the structure of **2a** a strong interaction with the oxygen of the methoxy group is observed [Se–O (mean): 2.977 Å] while the distance from the selenium to the oxygen in the side chain (4.22 Å) is clearly greater than the sum of the van der Waals radii (3.40 Å).

As a consequence of these interactions the smallest substituent, namely the hydrogen atom, is placed in the plane of the benzene ring. Because solid state geometries may not be adopted in solution, further structural investigations have been performed.

The structure in solution has been determined through NOE measurements of diselenide **2a** in [$^2H_6$]DMSO. Irradiation at the frequency of the proton in the 5-position (the proton *ortho* to the side chain) showed a strong NOE with the protons of the methyl group and the proton of the hydroxy group. No interaction could be detected with the benzylic proton. Therefore, we suggest that the structure is similar to that in the solid state.

To analyze the substrate efficiency in stereoselective synthesis, we employed these two diselenides in the methoxyselenenylation of styrene. The diselenides **2a**,**b** were transformed *in situ* into the electrophilic triflates **4a**,**b** by bromination and exchange of the bromine ion with AgOTf (Scheme 2). The reaction with **4a** yielded β-methoxy selenide **5a** with a diastereomeric ratio of 50 : 1 in 55% yield.¶ By carrying out the reaction with **4b** bearing an ethyl substituent in the side chain the addition product **5b** was obtained with a diastereomeric ratio of only 11.5 : 1 and 60% yield. This is in

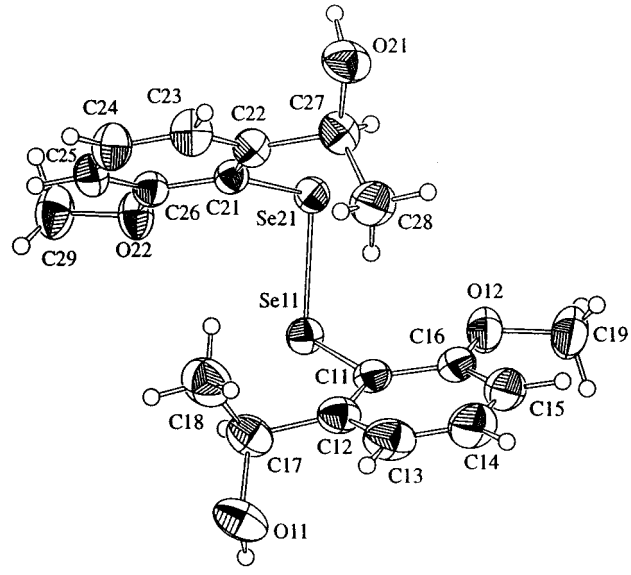


Fig. 1 ORTEP plot of the crystal structure of diselenide **2a**. Thermal ellipsoids are at the 30% probability level.

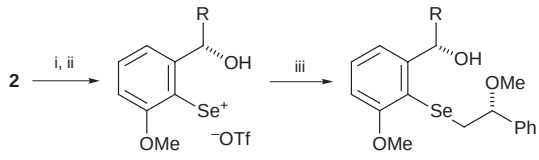

Scheme 2 *Reagents and conditions*: i, Br_2; ii, AgOTf; iii, styrene, MeOH

Table 1 Results of stereoselective reactions with selenium electrophiles generated from diselenides **2a** and **1**

Entry	Alkene	Product	Ratio (% yield) With **4a**	Ratio (% yield) With **6**
1			50:1 (55%)	16:1 (81%)
2			28:1 (45%)	5:1 (49%)
3			12:1 (51%)	9:1 (45%)
4			26:1 (54%)	6:1 (41%)
5			1.5:1 (42%)	1:1 (60%)
6			12:1 (66%)	9:1 (66%)

contrast to our previous observations where diselenides bearing ethyl substituents gave better selectivities than those with methyl substituents. Comparison of these results with those obtained using the arylselenenyl triflate **6** generated from diselenide **1a** (16 : 1) showed that selenenyl triflate **4a** represents a more efficient reagent for stereoselective selenenylation reactions (Table 1).

Encouraged by these results, we carried out further investigations with the electrophilic selenenyl triflate **4a** generated from diselenide **2a**. The methoxyselenenylation reaction of 4-fluorostyrene as well as β-methylstyrene showed increased facial selectivity compared to the reaction with the selenenyl triflate **6** derived from diselenide **1a** (entries 2 and 3). The selenolactonization of the unsaturated carboxylic acid (entry 4) was improved to a ratio of 26 : 1 by using the electrophile **4a**. The product of the cyclization of (*E*)-hex-3-enol and electrophile **6** (entry 5) was isolated as a racemate.[8] Cyclization with **4a** showed a modest facial selectivity of 1.5 : 1 in the resulting product. The stereochemistry of the major diastereomer could not be assigned in this case. The product of the cyclization of a carbamate (entry 6) is obtained with a diastereomeric ratio of 12 : 1. After radical removal of the selenium moiety and deprotection, (*S*)-salsolidine is obtained.[9] The absolute stereochemistry is in all cases the same as that observed with diselenide **1a**.

In summary, we present herein a new, readily available organoselenium reagent bearing a methoxy substituent *ortho* to the selenium. The electrophilic methoxyselenenylation of styrene was performed with a diastereomeric excess of 96%. The increased transfer of chirality is due to the forced interaction of the *ortho*-oxygen atom with the selenium. An X-ray diffraction structure and NOE measurements underline this assumption.

‡ Alcohol **3a** (1.37 g, 9 mmol) and TMEDA (1.86 g, 9.6 mmol) were dissolved in dry pentane (12 ml) under argon, cooled to 0 °C, treated slowly with Bu^nLi (9 mmol, 1.6 M solution in hexane) and allowed to stir for 15 min. Then PhLi (27 mmol, 3.0 M solution in cyclohexane–Et_2O) was added and the mixture was stirred for 14 h. After cooling to 0 °C, selenium powder (54 mmol, 4.32 g) was added. The mixture was allowed to warm up to room temperature and stirred for an additional 5 h, then 1 M HCl (50 ml) was added. After extraction of the resulting mixture with Bu^tOMe (3 × 50 ml) and drying of the combined organic phases with $MgSO_4$, powdered KOH (100 mg) was added. The solvent was removed under vacuum and the residue purified by flash chromatography (silica gel, Bu^tOMe–pentane 1 : 2) and recrystallized from EtOH to yield **2a** (1.37 g, 66%) as orange crystals: mp 146–148 °C (Calc. for $C_{18}H_{22}O_4Se_2$: C, 46.98; H, 4.82. New branched carbohydrate building block from a tandem elimination-Farvorski rearrangement

Mikael Bols*† and Ib B. Thomsen

Department of Chemistry, University of Aarhus, Langelandsgade 140, DK-8000, Aarhus, Denmark

3-Methoxycarbonyl-1,5-anhydro-β-D-*erythro*-pentofuranose 1 was obtained when 2,3,4-tri-*O*-tosyl-1,6-anhydro-β-D-glucopyranose 2 was treated with NaOMe.

Carbohydrates are a rich and cheap source of chiral compounds for use in stereospecific synthesis.[1] One such popular chiral starting material is 1,6-anhydroglucose **3** (levoglucosan),[2] and its decendants the Cerny epoxides **4** and **5**.[3] Compound **4** is routinely obtained from **3** in two steps: conversion of **3** to 1,6-anhydro-2,4-di-*O*-tosyl-β-D-glucopyranose **6** followed by epoxidation of **6** *via* treatment with NaOMe.[4,5] The tritosylate **2** is sometimes obtained as a byproduct in the tosylation of **3**, but can also be converted to **4** in high yield by treatment with base (Scheme 1).[6]

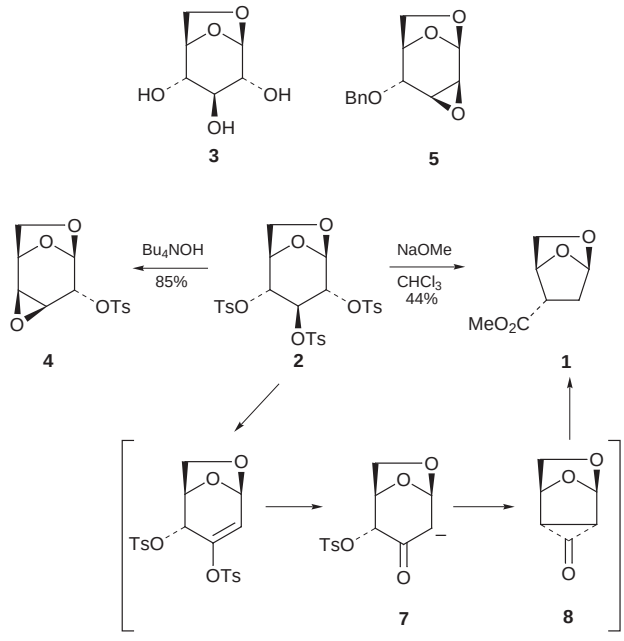
When recently requiring some **4** we tried to obtain it from **2** using NaOMe as base. However, to our surprise, inspection of the reaction product revealed besides small quantities of **2** and **4** a large amount of another compound. After purification the compound could be isolated in 44% yield and identified by ^{1}H, ^{13}C and COSY NMR and EI mass spectroscopy:[7] a mass peak at *m/z* 159 (M+1) corresponded to $C_7H_{10}O_4$; ^{13}C NMR peaks at δ 52 and 178 identified a methyl ester; ^{13}C NMR peaks at δ 38 and 43 and ^{1}H NMR peaks at δ 2.0 and 2.7 were consistent with deoxygenated CH and CH_2 moieties; and COSY correlations showed anomeric C next to CH_2 next to CH. All were consistent with structure **1**. The stereochemistry at C-3 could be determined by comparison with spectra of the four isomeric acetylated 1,5-anhydropentosides. Only the isomers with the 3 substituent *exo* had a J_{45} value of 0 Hz.

The compound **1** was not formed from epoxide **4**, as **4** was completely stable to prolonged treatment with NaOMe. Formation of compound **1** can be explained by a Farvorski rearrangement of an intermediate ketone **7** (or its regioisomer) as outlined in Scheme 1. The ketone can be formed by elimination of a tosylate. Attack by methoxide and ring opening of the intermediate cyclopropanone **8** apparently occur with high regioselectivity.

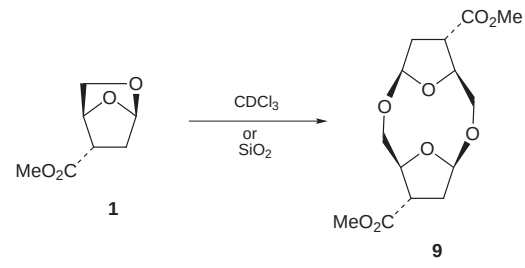
Compound **1** is a highly strained compound. On standing in $CDCl_3$ or when subjected to silica gel chromatography under non-basic conditions, **1** was spontaneously and quantitatively transformed to a new crystalline compound. X-Ray crystallographic structure determination revealed it to be the dimer **9** (Scheme 2). This structure determination also confirmed the structure and stereochemistry of **1**. To avoid the conversion of **1** to **9**, chromatography of the former was carried out with 1% Et_3N present.[8]

The tandem elimination-Farvorski rearrangement of a tritosylate is to the best of our knowledge unprecedented. To investigate its generality we also subjected tritosylarabinoside **10** and methyl 2,3,4-tri-*O*-tosyl-α-L-rhamnopyranoside to reaction with NaOMe. From the reaction of **10** Farvorski products **11** and **12** were isolated in 8 and 5% yield, respectively, together with 22% of epoxides **13** (Scheme 3). From the reaction of the tritosylrhamnoside, 29% of a mixture of Farvorski products was formed. Thus the reaction is apparently general but much less favored in these other cases.

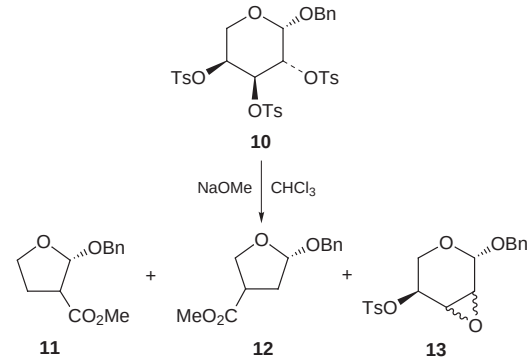
Farvorski product **1** is a useful chiral building block. Although the yield of its formation, as is common for many Farvorski rearrangements, is relatively low this is compensated



Scheme 1



Scheme 2



Scheme 3

for by the fact that branched carbohydrate chains are usually synthesised *via* multistep procedures.

We acknowledge financial support from the Danish National Science Research Council (SNF) grant No. 9502986. We also thank B. O. Pedersen for mass spectra and Rita Hazell for X-ray structure determination of **9**.

8 *Typical procedure*: To tritosylate **2** (2.35 g) in $CHCl_3$ (25 ml) was added a solution of Na (400 mg) in MeOH (3 ml). The strongly exothermic reaction was left for 30 min. and then water (15 ml) and sat. aq. NH_4Cl (3 ml) was added. The phases were separated and the organic layer dried ($MgSO_4$), concentrated and the content chromatographed in EtOAc–pentane (1:4) with 1% Et_3N to give **1** (261 mg, 44%). In another identical experiment no Et_3N was added to the mobile phase during chromatography. This gave **9** in 49% yield (291 mg).

Remarkable acceleration of dimethyl phosphate hydrolysis by ceric cations

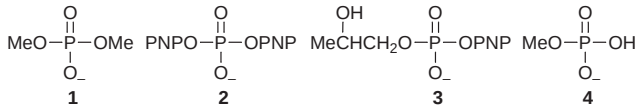
Robert A. Moss*† and Kaliappa G. Ragunathan

Department of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, New Jersey 08903, USA

Ce^{4+} cations in aqueous solution at pH 1.8 and 60 °C reduce the half-life of dimethyl phosphate hydrolysis from 8454 years (pH 7, 60 °C) to 22 min.

Dimethyl phosphate **1** (DMP) strongly resists hydrolysis. A recent meticulous study reports $k = 1.6 \times 10^{-13}$ s^{-1} at 25 °C, equivalent to a half-life of ~137 000 years for the pH 7 uncatalyzed cleavage (by Me–O scission) of DMP by water.[1] This extraordinary stability makes the phosphodiester linkage ideal for its role in the backbone of DNA and RNA.[1,2]

The hydrolysis of DMP can be accelerated; below pH 5, acid catalysis is apparent.[1] Bunton *et al.* reported that at pH 1.24 and 100 °C, the P–O$^-$ of DMP was protonated, and hydrolysis of neutral **1** proceeded with $k = 3.13 \times 10^{-6}$ s^{-1} ($t_{1/2}$ = 2.5 days, 78% Me–O scission).[3] More recently, Kim and Chin found that $[(cyclen)Co(OH_2)_2]^{3+}$ at pD 6.3 and 60 °C catalyzed the hydrolysis of DMP (presumably by P–O scission) with $k = 2 \times 10^{-7}$ s^{-1} ($t_{1/2}$ ~40 days).[2]



1 **2** **3** **4**

Various transition metal, lanthanide and actinide cations are known to accelerate the hydrolytic cleavage of phosphodiesters.[4] Our own studies of the metal-ion mediated hydrolysis of phosphodiesters have focused on Th^{4+}, Ce^{4+} and Zr^{4+} cleavage of activated substrates such as bis(*p*-nitrophenyl) phosphate **2** (BNPP) and 2-hydroxypropyl (*p*-nitrophenyl) phosphate **3** (HNPP).[5–7] Rate enhancements $>10^9$, relative to the uncatalyzed hydrolyses, were observed in the Th^{4+} or Ce^{4+} cleavage of BNPP.[5,6] A high value of the charge/cation diameter ratio appears necessary for optimal cation reactivity in phosphodiester hydrolysis.[5–8]

In view of our results with substrate **2**,[6] and the known ability of Ce^{4+} to accelerate the cleavage of DNA (at P–O),[9] we have now examined the Ce^{4+} acidic hydrolysis of DMP. The remarkable kinetic results indicate an acceleration of 2×10^8, relative to the uncatalyzed hydrolysis at 60 °C, and a reduction in $t_{1/2}$ from ~8450 years to 22 min.

Hydrolyses of DMP **1** and of methyl phosphate **4** (MP) mediated by ceric ammonium nitrate (CAN) were followed in D_2O at 60 °C by 400 MHz proton NMR spectroscopy, monitoring the disappearance of the Me signals at δ 3.9, relative to an internal pyrazine standard. Solutions of CAN were not buffered, but were adjusted to pH 1.6 or 1.8 (pD 2.0 or 2.2) by addition of pD 13.4 NaOD solution prior to reaction. The pH typically declined by 0.25 during the reaction. Reactions were followed for two half-lives and the infinity titer was obtained after 24 h at 60 °C. Rate constants were duplicated and agreed to ±7%.

With 1 mM DMP at pH 1.6,‡ the measured hydrolytic rate constants varied from 9.3×10^{-5} s^{-1} at [Ce^{4+}] = 2.5 mM to 4.25×10^{-4} s^{-1} at [Ce^{4+}] = 20 mM. A graphical representation of the dependence of k on [Ce^{4+}] appears in Fig. 1, where 'saturation' behavior is apparent. Michaelis–Menten analysis provides K_m ~0.0105 M and a binding constant of ~95 M^{-1}, with k_{cat} ~6.5×10^{-4} s^{-1}.§ Unfortunately, the fit of the data in Fig. 1 to the Michaelis–Menten equation is not very precise. Although saturation (binding of DMP to Ce^{4+}) is observed, the K_m and k_{cat} are approximate.

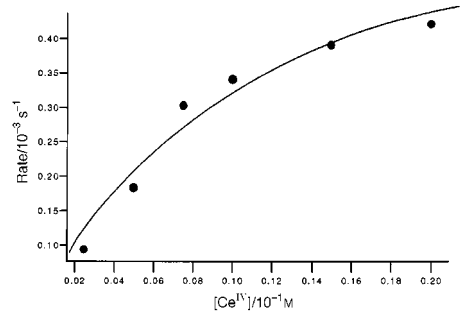


Fig. 1. Pseudo-first order rate constants (s^{-1}) for the hydrolysis of 1 mM DMP by CAN as a function of [Ce^{4+}] at pH 1.6. The points are the experimental values; the solid line is generated from the Michaelis–Menten equation with $K_M = 0.0105$ M and $k_{cat} = 6.48 \times 10^{-4}$ s^{-1}.

Our highest observed rate constant for the cleavage of 1 mM DMP by 10 mM Ce^{4+} was at pH 1.8, 60 °C, where k = $5.28(\pm0.38) \times 10^{-4}$ s^{-1}. At higher pH, precipitation of Ce was apparent.

Comparisons of the hydrolytic kinetics of DMP under neutral,[1] acidic,[3] Co^{3+}-assisted,[2] or Ce^{4+}-mediated conditions appear in Table 1, where the extraordinary acceleration due to Ce^{4+} is manifest. At 200 million, the rate enhancement by acidic Ce^{4+} exceeds those provided by H^+ alone or Co^{3+}-cyclen by factors of 10^3–10^4. The 8454 year 'benchmark' half-life of DMP under neutral conditions at 60 °C is reduced to 22 min by Ce^{4+} at pH 1.8.

The Ce^{4+} cleavage of DMP produces 2 equiv. of MeOH (NMR), so that the reaction is hydrolytic, not oxidative; hydrolysis also occurs in the Ce^{4+} cleavage of deoxyribodinucleotides.[10] Hydrolysis of 1 mM MP **4** by 10 mM CAN at pH 1.8 and 60 °C liberates 1 equiv. of MeOH and proceeds with $k = 6.3 \times 10^{-4}$ s^{-1}, about 1.2 times faster than the corresponding cleavage of DMP. Accordingly, MP does not accumulate during the hydrolysis of DMP. A similar rate ordering prevails during the acid catalyzed hydrolyses of DMP and MP.[3,11]

We briefly examined several other sets of conditions and catalysts for the hydrolysis of DMP. A ten-fold excess of Ce^{3+} at pH 8 (gel) also cleaved DMP at 60 °C, but much more slowly than Ce^{4+} at pH 1.8; the Ce^{3+} hydrolysis was only ~50% complete after 48 h. Surprisingly, Th^{4+} (10 mM) was unreactive toward DMP at pH 3.5 and 60 °C, while Zr^{4+} (10 mM, pH 2.0,

Table 1 Comparison of DMP hydrolyses at 60 °C[a]

Conditions	k_{hydrol}/s^{-1}	k_{rel}	$t_{1/2}$
Neutral[b]	2.6×10^{-12}	1.0	8454 years
H^+, pH 1.24[c]	5.2×10^{-8}	2.0×10^4	154 days
Co^{3+}-cyclen[d]	2.0×10^{-7}	7.7×10^4	40 days
Ce^{4+}, pH 1.8[e]	5.3×10^{-4}	2.0×10^8	22 min

[a] The first two entries are extrapolated to 60 °C from data in the original references. [b] Ref. 1. [c] Ref. 3. [d] Ref. 2; pH 5.9. [e] This work.

60 °C) cleaved DMP slowly ($k \sim 7.6 \times 10^{-6}$ s^{-1}). Addition of 5 mM $PrCl_3$ to 10 mM CAN did not significantly accelerate the cleavage of DMP at pH 2.5, 60 °C; $k = 5.7 \times 10^{-4}$ s^{-1}, comparable to the rate constant with Ce^{4+} alone (Table 1). Rate enhancement due to Pr^{3+}–Ce^{4+} clusters[12] did not occur. Finally, neither added chloride or nitrate ions (120 mM) further enhanced the Ce^{4+} hydrolysis of DMP.

The mechanism of the Ce^{4+}-mediated hydrolysis of DMP is not yet fully defined. The saturation behavior (Fig. 1) implicates binding of substrate P–O$^-$ by Ce^{4+}. The pK_a of the waters of hydration bound to Ce^{4+} is ~0.7,[13] so that the Ce^{4+}-DMP complex will have Ce-bound OH nucleophiles available for attack at the substrate P. One can imagine a P–O(Me) scission mechanistically analogous to that suggested for the Co^{3+}-cyclen/DMP reaction.[2] However, the neutral (> 99.5%)[1] and the acid catalyzed (78%)[3] hydrolyses of DMP occur mainly by O–Me cleavage. Although it seems unlikely that Ce^{4+} complexation of DMP would enhance subsequent H_2O attack at the MeO (rather than the P–O) linkage by the enormous factors observed here, a definitive mechanism requires $H_2{}^{18}O$ studies of the Ce^{4+} hydrolyses of both DMP and MP. These studies, together with comparable examinations of phosphonate monoester hydrolyses, are in progress.

We are grateful to the U.S. Army Research office for financial support.

Notes and References

† E-mail: Moss@Rutchem.Rutgers.Edu

‡ The pK_a of DMP is 1.06 at 60 °C (extrapolated from the data in ref. 3), so that > 77% of the DMP will be in the monoanionic form at pH 1.6, available for binding to Ce^{4+}.

§ From the initial four points of Fig. 1, [Ce^{4+}] = 2.5–10 mM, we can estimate a second order rate constant for the Ce^{4+}/DMP cleavage: $k_2 = 3.5 \times 10^{-2}$ M^{-1} s^{-1} at pH 1.6 and 60 °C. This may be compared with $k_2 = 6.2 \times 10^{-7}$ M^{-1} s^{-1} at pD 6.3 and 60 °C for the Co^{3+}-cyclen/DMP reaction (ref. 2).

A metal-containing synthon for crystal engineering: synthesis of the hydrogen bond ribbon polymer [4,4′-H_2bipy][MCl_4] (M = Pd, Pt)

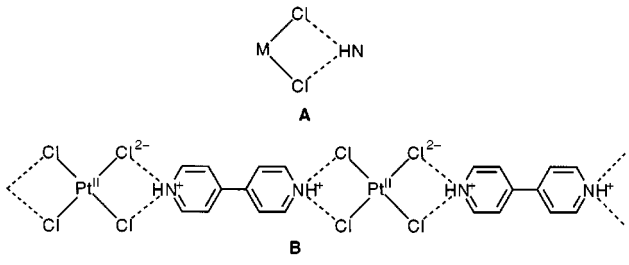
Gareth R. Lewis and A. Guy Orpen*

School of Chemistry, University of Bristol, Bristol, UK BS8 1TS. E-mail: Guy.Orpen@bristol.ac.uk

The utility of the *cis*-MCl_2···HN^+ chelated hydrogen bond as a synthon in preparation of crystalline [4,4′-H_2bipy][MCl_4] (M = Pd 1, Pt 2) is demonstrated; the structure of 2 contains anions and cations linked by hydrogen bonds to form a ribbon polymer.

Desiraju[1] and others[2] have argued persuasively that crystal engineering or synthesis may be a realistic goal for modern chemistry. The means to this goal is the identification and application of reliable synthons which can control molecular aggregation and lead to crystal structures with (partly) controlled structures, containing sheets, ribbons and other desired motifs in the pattern formed. The synthons listed[1,2] and used to date are drawn in the main from the field of organic chemistry and almost all exploit the directionality of hydrogen bonds to afford the desired control of aggregation. The ability to incorporate metals in the structure offers promise of novel functionalities (chemical, magnetic, optical or electronic) which complement those available in purely organic molecular crystals. Here, we show that the metal assisted hydrogen bond affords a new class of synthon, one which may yield both desirable structures and desirable properties.

Recently,[3] we reported a crystallographic database analysis which demonstrated the ability of metal chloride complexes to act as hydrogen bond acceptors, as others had noted in specific examples.[4] Our study showed that these metal-assisted hydrogen bonds typically showed M–Cl···H angles of between 90 and 120°. The geometry at the hydrogen in these systems is normal[5] with all the shorter M–Cl···HE (E = N, O) bonds having E–H···Cl ⩾140°. These geometric preferences are compatible with the formation of acceptor chelate hydrogen bonds in which a pair of *cis*-chloride ligands at a metal form a chelate hydrogen bond with a single H–N moiety (see **A** in Scheme 1). Indeed, such an interaction in [$HNC_5H_3Ph_2$][$AuCl_4$] has attracted attention.[4a]



Scheme 1

We therefore sought to establish the utility of the *cis*-MCl_2···HN interaction (**A** in Scheme 1) as a synthon for the preparation of a hydrogen bonded polymer (**B** in Scheme 1) incorporating both inorganic ([MCl_4]$^{2-}$) and organic ([4,4′-H_2bipy]$^{2+}$) components. The planarity and opposite charges of the component ions led us to expect the formation of planar polymeric ribbons of type **B** shown in Scheme 1.

Reaction of aqueous [MCl_4]$^{2-}$ salts (M = Pd or Pt) with [4,4′-H_2bipy][PF_6]$_2$ leads to instantaneous formation of crystalline precipitates [4,4′-H_2bipy][MCl_4] (M = Pd **1**, Pt **2**).† Single crystal structure analysis‡ of **2** shows the desired structure has indeed been formed (Fig. 1). The component ions have normal, planar geometries with exact C_{2h} symmetry. The N–H···Cl bonds are of dimensions (N–H 0.86 Å, H···Cl 2.51 Å, N···Cl 3.219 Å; N–H···Cl 140°, Pt–Cl···H 95°) similar to those typically observed in our database study.[3] The anion···cation··· anion···cation··· ribbons formed are planar (mean atomic deviation 0.038 Å) and all ribbons lie parallel to one another although they are not coplanar. The ribbons lie perpendicular to the crystallographic mirror planes and extend along $2x - z$. Each ribbon lies 5.81 Å above its face-to-face neighbour and is in closer contact with four other ribbons through edge-to-edge interactions (CH···Cl 2.84 Å, Cl···Cl 3.510 Å, Fig. 2). This apparently efficient packing is presumably facilitated by the planarity of the component ions.

That this synthon may have some general applicability is indicated by the similarity of the structure of **2** and those of [4,4′-H_2bipy][$Cu_2(\mu\text{-}X)_2X_4$] (X = Cl **3**;[6] X = Br **4**[7]). In crystalline **3** and **4**, which were prepared for rather different reasons, hydrogen bonded ribbon motifs are present. In contrast, the structure[8] of [4,4′-H_2bipy][$CoCl_4$] is markedly different with the tetrahedral [$CoCl_4$]$^{2-}$ units forming two-centre

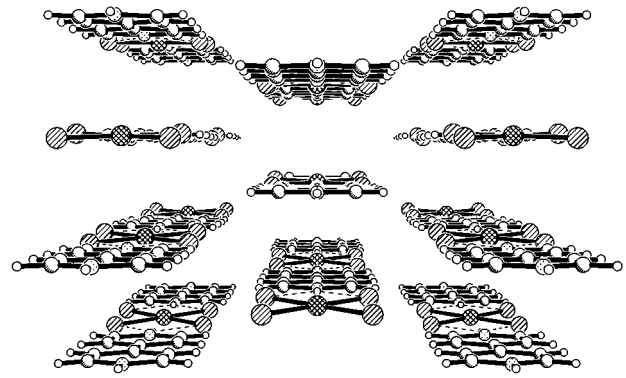


Fig. 2 The crystal structure of [4,4′-H_2bipy][$PtCl_4$] **2**.

Cl···HN interactions in a dimeric cyclic $[4,4\text{-}H_2bipy]_2[CoCl_4]_2$ motif.

The utility of the *cis*-MCl_2···HE (E= O, N) synthon, the effect of the charges and geometry of the component species, the consequent structures formed and their properties are under investigation.

Financial support of the EPSRC is gratefully acknowledged. Our thanks go to Professor W. Clegg and Drs S. J. Cole and S. J. Teat and the EPSRC for use of station 9.8 at the Daresbury SRS and assistance in the data collection for compound **2**. We thank Professor N. G. Connelly for helpful discussions and advice.

Notes and References

† *Synthesis* of $[4,4'\text{-}H_2bipy][MCl_4]$ (M = Pd **1**, Pt **2**): addition of a colourless solution of $[4,4'\text{-}H_2bipy][PF_6]_2$ (156 mg, 0.347 mmol) in H_2O (10 cm³) to a brown solution of $Na_2PdCl_4{\cdot}1/3H_2O$ (101 mg, 0.335 mmol) in H_2O (6 cm³) caused the formation of a light brown insoluble precipitate of **1**. The product was washed with H_2O and dried *in vacuo*, yield 121 mg (88%). Orange crystalline compound **2** was prepared similarly from $[4,4'\text{-}H_2bipy][PF_6]_2$ and $K_2[PtCl_4]$, yield 83%. Both complex salts gave satisfactory microanalytical data.

‡ *Crystal structure analysis* of $[4,4'\text{-}H_2bipy][PtCl_4]$ **2**. The crystal structure of **2** was determined from data collected on a Siemens SMART diffractometer (λ = 0.6978 Å) at 160 K on station 9.8 at the Daresbury SRS. The structure was refined by least-squares against all F^2 data corrected for absorption, and hydrogen atoms were located in difference maps. *Crystal data*: $[4,4'\text{-}H_2bipy][PtCl_4]$, $C_{10}H_{10}Cl_4N_2Pt$, M = 495.09, monoclinic, space group $I2/m$ (no. 15), a = 6.6172(3), b = 11.6264(6), c = 8.0962(5) Å, β = 91.266(2)°, U = 622.76(6) Å³, Z = 2, μ = 12.10 mm⁻¹, 512 unique data, $R1$ = 0.034. Diastereoselective SmI_2-mediated cascade radical cyclisations of methylenecyclopropane derivatives—a synthesis of paeonilactone B

Raymond J. Boffey,[a] Marco Santagostino,[a] William G. Whittingham[b] and Jeremy D. Kilburn*[a]†

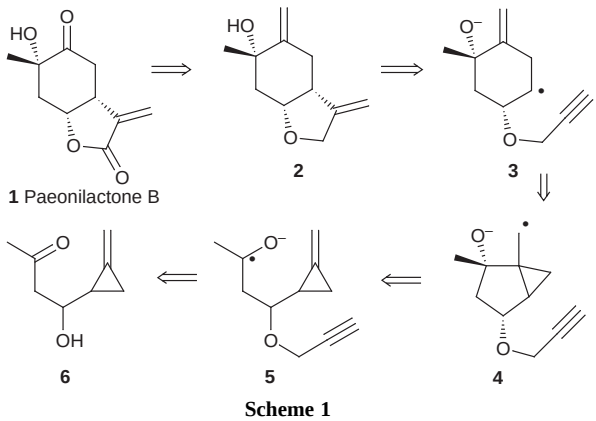
[a] *Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ*
[b] *Zeneca Agrochemicals, Jealott's Hill Research Station, Bracknell, Berkshire, UK RG42 6ET*

The SmI_2-mediated cascade reaction of methylenecyclopropyl ketone 9 proceeds with high diastereoselectivity, which is critically dependent on the presence of HMPA, and provides a short route to paeonilactone B.

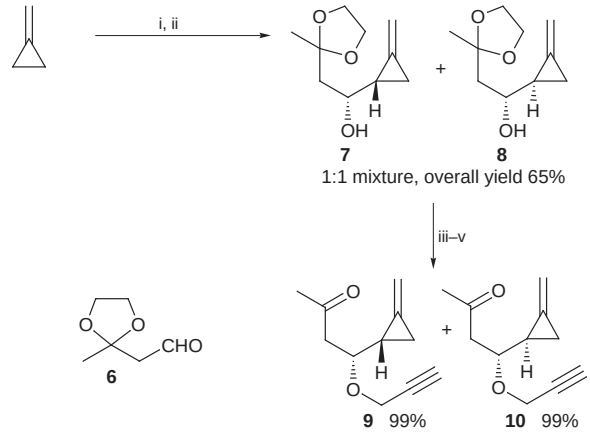
Cascade radical cyclisation reactions have proved to be very popular as a synthetic strategy as they allow the construction of several C–C bonds in one step and can provide elegant synthetic routes to complex polycyclic compounds and natural products.[1] Tandem reactions, initiated in particular by the versatile lanthanide reagent SmI_2, have also been a focus of recent attention.[2] We now report that SmI_2-promoted cascade cyclisations of methylenecyclopropyl ketone derivatives lead to bicyclic products in good yield and with excellent diastereoselectivity. This approach provides a short synthetic route to (±)-paeonilactone B **1**, one of several structurally related monoterpenes isolated from paeony roots,[3] all of which feature a highly oxygenated cyclohexane nucleus.[4]

A retrosynthetic analysis of paeonilactone B (Scheme 1) suggested that the *cis*-fused bicyclic methylenecyclohexane **2** could be prepared by a 5-*exo* cyclisation of methylenecyclohexyl radical **3** onto a pendant alkyne, and **3** could, in turn, arise from cyclisation of ketyl radical **5** onto a methylenecyclopropane unit with subsequent '*endo*' ring opening of **4**.[5] Whether such a sequence would prove to be diastereoselective and provide the correct relative stereochemistry of the tertiary alcohol required for the natural product remained to be tested by experiment.

Addition of lithiated methylenecyclopropane to aldehyde **6**,[6] produced the desired alcohols as a readily separable mixture of diastereoisomers **7** and **8** (Scheme 2).[7] The relative stereochemistry for the two diastereoisomers was established by X-ray crystallographic structure analysis of the *p*-nitrobenzoate ester derived from alcohol **8**.[8] Alkylation of the alcohols gave the corresponding prop-2-ynyl ethers, and subsequent ketal deprotection provided the two diastereomeric cyclisation precursors, **9** and **10** respectively, in essentially quantitative yield.



Scheme 1

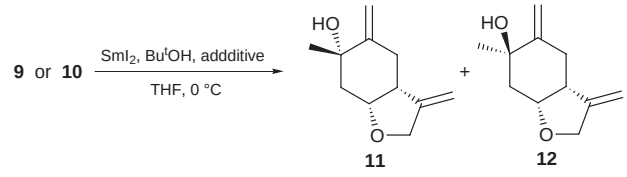


Scheme 2 *Reagents and conditions*: i, BuLi, THF, −78 °C; ii, compound **6**; iii, NaH, DMPU, THF; iv, $HC{\equiv}CCH_2Br$; v, TsOH, acetone, H_2O

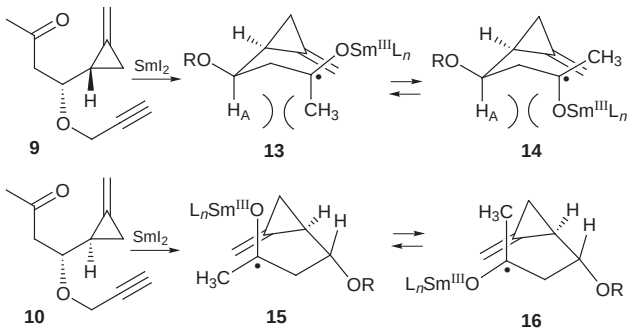
Treatment of ketone **9** with SmI_2, under standard conditions[9] (slow addition of **9** to 2.2 equiv. SmI_2, Bu^tOH, HMPA, THF, 0 °C) gave the desired bicyclic products as a readily separable mixture of diastereoisomers, **11** and **12**, in 57 and 6% isolated yields respectively (ratio **11**:**12** = 10 : 1 by analysis of the ^1H NMR spectrum of the crude reaction mixture) (Table 1). In contrast, treatment of diastereoisomeric ketone **10** with SmI_2, under identical conditions, gave the bicyclic product **12** in 73% isolated yield, and only a trace of the diastereoisomer **11** (ratio **12**:**11** > 30 : 1).

In order to rationalise the observed diastereoselectivity we repeated the cyclisations under identical conditions, but replacing HMPA with the less effective chelator DMPU.[10] These cyclisation reactions gave the bicyclic products with reduced overall yields and required a larger excess of SmI_2 (~6 equiv.) for consumption of starting material.[2b] Notably, for the cyclisation of **9**, the diastereoselectivity was reduced (ratio **11**:**12** = 1.5 : 1), whereas for the cyclisation of **10** the

Table 1 Reaction of **9** or **10** with different additives



Starting material	Additive	Yield (%)	**11** : **12**
9	HMPA	63	10:1
9	DMPU	40	1.5:1
9	—	~20	1:1.3
10	HMPA	79	< 1:30
10	DMPU	62	< 1:30
10	—	0	—



Scheme 3

diastereoselectivity was seemingly unaffected (ratio **12**:**11** > 30 : 1). In the absence of either DMPU or HMPA the cyclisation was, as expected, a poor reaction. Thus **9** gave an overall yield of ~20% of **11** and **12**, but with a reversal of stereoselectivity (ratio **11**:**12** = 1 : 1.3), while cyclisation of **10** yielded none of the desired bicyclic compounds.

The selectivity for the cyclisation of **9** in favour of **11**, in which the tertiary alcohol and ether oxygen are *cis* in the bicyclic product, might be the consequence of chelation control from the weakly basic prop-2-ynylic ether oxygen to the samarium(III) bound to the ketyl radical. However, the decrease in selectivity for the cyclisation of **9** as HMPA is replaced by the weaker chelator DMPU, and reversal of selectivity when neither is present, effectively rules out this possibility. It seems probable that the first step of the cyclisation of **9**, which effectively sets the relative stereochemistry of the product, proceeds through a chair-like transition state, allowing the prop-2-ynyl ether substitutent to adopt a pseudo-equatorial position (Scheme 3). As a consequence of the bond angles of the methylenecyclopropyl group, the alkene appears to be essentially staggered between the ketyl radical oxygen and the ketyl methyl group. Thus the preference for conformer **13** over **14** may largely result from the preference for the bulky $OSm^{III}(HMPA)_n$ moiety to also adopt a pseudo-equatorial position and avoid a 1,3-diaxial interaction with H_A. Replacement of HMPA with DMPU may effectively reduce the steric bulk of the $OSm^{III}L_n$ moiety,[10] leading to a lower selectivity for conformer **13**. In the absence of either HMPA or DMPU the ketyl methyl becomes sterically dominant, leading to a reversal in selectivity.

In contrast, the first step of the cyclisation of **10** may well proceed through a boat-like transition state, since a chair-like transition state would force the prop-2-ynyl ether substituent into a severely hindered axial orientation. In the boat-like transition state the alkene now appears to be largely eclipsed with either the ketyl methyl group (**15**) or the ketyl radical oxygen (**16**). Conformer **15** may now be preferred over **16** since it alleviates the electronic repulsion between the ketyl oxygen functionality and the alkene π-system,[11] and this preference is unaffected by replacing HMPA with DMPU.

Completion of the synthesis of paeonilactone B firstly required protection of the tertiary allylic alcohol as the triethylsilyl ether,[12] followed by oxidation of the allyl ether to the desired α-methylene lactone **17** using CrO_3 and pyridine (Scheme 4).[13] The selective oxidation of the ostensibly more electrophilic cyclohexyl alkene of **17** proved to be impossible with both alkenes reacting rapidly with ozone at −110 °C in EtOH in almost quantitative yield. Even more frustratingly, treatment of **17** with OsO_4 led to dihydroxylation of just the the α-methylene lactone, presumably due to steric congestion around the cyclohexyl alkene. Instead, base-mediated Michael addition of PhSH to **17** gave the thioether which was then successfully ozonolysed to give the desired ketone, with concomitant oxidation of the thioether to the corresponding sulfoxide **18**. Thermal elimination of phenylsulfenic acid[14] then reinstalled the α-methylene lactone and deprotection of the silyl

ether was successfully achieved using pyridine·HF,[15] to give (±)-paeonilactone B, whose structure was confirmed by comparison of its NMR and IR spectroscopic data to those reported previously for the natural paeonilactone.[3]

The reaction of ketene silyl acetals and silyl enol ethers with CCl_4 without a promoter

Michiharu Mitani*† and Hideo Sakata

Department of Chemistry and Material Engineering, Faculty of Engineering, Shinshu University, Wakasato, Nagano, 380-8553, Japan

The reaction of CCl_4 with ketene silyl acetals and silyl enol ethers in the absence of a promoter at ambient temperature or at reflux, or under photo-irradiation, was performed to form products *via* addition of the trichloromethyl group to those silyl substrates.

The reaction[1] of ketene silyl acetals or silyl enol ethers with a variety of carbon nucleophiles, including carbonyl compounds, conjugated enones or organic halides, with promotion by a Lewis acid or in the presence of a desilylative reagent, such as a fluoride compound, is well known to give α-functionalized carbonyl compounds. As with organic halides, while monohalogen compounds such as tertiary, benzyl and allyl halides afford alkylated products in the presence of a Lewis acid, *e.g.* titanium(IV) chloride,[2] zinc(II) chloride[3] or silver(I) perchlorate,[4] polyhalides such as carbon tetrachloride give β-halo-α,β-unsaturated carbonyl derivatives in the reaction catalyzed with copper(I) chloride,[5] triethylborane[6] or a Ru^{II} complex.[7] We have found that ketene silyl acetals and silyl enol ethers react with CCl_4 at ambient temperature or under reflux, or under photo-irradiation conditions, in the absence of a promoter to form products derived from addition of the trichloromethyl group to the ene moieties of those silyl substrates.

A CCl_4 solution of the ketene silyl acetal **1a**[8] from *N*,*N*-dimethylglycine methyl ester was stirred at ambient temperature for 3 h; VPC analysis of the resulting mixture revealed consumption of **1a** and the appearance of one product (Scheme 1). The product was assigned as *N*,*N*-dimethyl(trichloromethyl)glycine methyl ester **2a** *via* its spectral data after isolation (57% yield). Raising or lowering the reaction temperature resulted in the reduction of the yield of **2a** (18 and 27% at 76 and 0 °C, respectively). The ketene silyl acetal **1b**[9] from methyl methoxyacetate in a CCl_4 solution furnished the α-trichloromethyl ester **2b** in 81% yield under reflux conditions; no reaction occurred at ambient temperature. The ketene silyl acetal **1c** from methyl propionate, which lacks a strongly electron-donating substituent like the amino or alkoxy moieties in **1a** or **1b**, afforded the α-trichloromethyl ester **2c** in a good yield (81%) upon photo-irradiation,‡ while **2c** was formed in only low yield (29%) under reflux conditions. The ketene silyl acetals **1d–g** from linear or branched aliphatic esters also gave α-trichloromethylation products **2d–g** upon photo-irradiation. In the case of **1b**, however, photoreaction diminished the yield of **2b** compared with that obtained *via* thermal reaction.

Scheme 2

derived from aliphatic ketones afforded products other than the above-mentioned ones, *i.e.* while 3-trimethylsiloxypent-2-ene **5a** and 4-trimethylsiloxyhept-3-ene **5b**, derived from unbranched ketones, gave the products **6a**,**b** *via* addition of the trichloromethyl group followed by migration of the C=C double bond while retaining the silyl group, 3,3-dimethyl-2-trimethylsiloxybut-1-ene **5c** effected the β,β-dichloro-α,β-unsaturated ketone **7** based on dehydrochlorination after addition of the trichloromethyl group (Scheme 3). These results are collected in Table 1.

Concerning the reaction mechanism, it is postulated that the trichloromethyl radical fragment from CCl_4 attacks the C=C double bond moiety of the silyl substrate to form the product. The spontaneous bond scission of CCl_4 at ambient temperature or under reflux conditions is difficult and thus the formation of **2a**,**b** may be derived from the reaction of the trichloromethyl radical generated *via* single electron transfer (SET) between CCl_4 and the ketene silyl acetals **1a**,**b** bearing strongly electron-donating substituents. Actually, in reactions using either polar (THF) or non-polar (hexane) solvents, the yields of **2a** were better in the former compared with the latter (34 and 2%,

respectively). The reaction of the ketene silyl acetals upon photo-irradiation should also proceed *via* a SET process, as is suggested by the fact that the formation of **2c** from **1c** was enhanced by addition of $LiClO_4$[10] (Table 2). However, the homolytic scission of the C–Cl bond may preferentially operate in the case of the silyl enol ethers, judging from the fact that the formation of the trichloromethylated product **4b** from **3b** was enhanced in a non-polar solvent compared with a polar solvent (77% in hexane; 68% in THF; 51% in MeCN) and suppressed by addition of $LiClO_4$. The reaction of polyhalides other than CCl_4 with ketene silyl acetals and silyl enol ethers is under way.

Three-centre dihydrogen bond with fast interchange between proton and hydride: a very active catalyst for D^+–H_2 exchange†

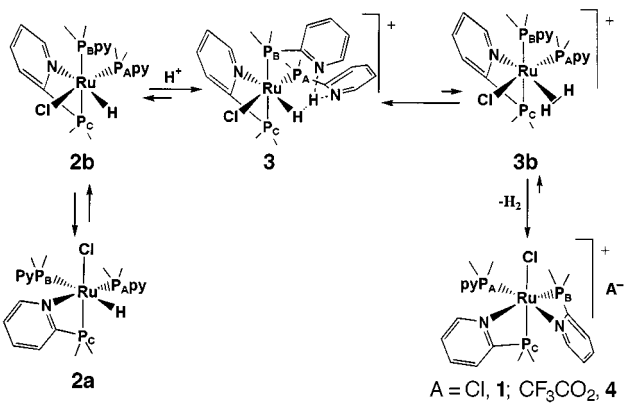
A. Caballero, F. A. Jalón* and B. R. Manzano

Departamento de Química Inorgánica, Orgánica y Bioquímica, Universidad de Castilla-La Mancha, Avda. Camilo José Cela, 10, 13071 Ciudad Real, Spain. E-mail: fjalon@qino-cr.uclm.es

Protonation of a ruthenium hydride containing the hemilabile ligand PPh_2py gave a complex with a three-centre dihydrogen bond (Ru–H···H–Py_2), and this system exhibits a fast proton/hydride interchange and is a very active catalyst for D^+–H_2 exchange.

The term dihydrogen bond[1] was introduced by Crabtree to designate hydrogen bonds in which the proton acceptor is the σ-electron pair of a transition metal hydride. This type of hydrogen bond has now largely been enlightened by intramolecular examples from Crabtree *et al.*[2] and Morris and coworkers,[3] or by intermolecular cases described by Crabtree and coworkers[4] in the solid state and Epstein and coworkers[5] in solution. The study of such chemical bonds is not only of academic importance, but these types of interaction may also be present in intermediates related to hydrogenation, hydrogen transfer and H–D exchange.[3] We envisaged the synthesis of Ru^{II} complexes possessing several PPh_2py ligands. The affinity of the Ru^{II} centre for phosphorus, and the predicted strain of the resulting four-membered cycles when this phosphine is chelated, anticipates its hemilabile behaviour, the easy accessibility of unsaturated species and the presence of basic pyridine groups near the Ru centre, which could operate as efficient proton abstractors from weak acids such as alcohols or hydrogen, could give rise to interesting catalytic properties. We describe the preparation of PPh_2py–ruthenium complexes including an unprecedented three-centre dihydrogen bond that has special properties.

The reaction of $RuCl_2$(bpzm)(cod) or RuClH(bpzm)(cod)[6] [bpzm = bis(pyrazol-1-yl)methane, cod = cycloocta-1,5-diene] with 3 mol equiv. of PPh_2py gives, after the appropriate work up procedure, the new complexes [RuCl(η^1-PPh_2py)(η^2-PPh_2py)$_2$]Cl **1** and RuClH(η^1-PPh_2py)$_2$(η^2-PPh_2py) **2**, respectively. Two isomers of **2** are present in solution, **2a** and **2b** (Scheme 1), and their ratio depends on the solvent and temperature. This supports the existence of an equilibrium in solution between the two species. The facial structure of **1** and **2a** and the mer for **2b** (Scheme 1) are deduced by considering characteristic J_{PP} couplings for the three observed resonances for each compound.[7] The chelating η^2 coordination of some PPh_2py groups, as proposed in Scheme 1, is supported by the characteristic upfield shift of the corresponding ^{31}P NMR signals with respect to the free phosphine ligand.[8] The hydride resonance in the ^{1}H NMR spectrum of **2a** appears at δ −7.46 and shows a distinctly higher H–P coupling constant with one phosphorus, while that of the *mer* isomer **2b** (δ −11.58) exhibits typical *cis* coupling constants to the three phosphorus centres.[7] This chemical shift is characteristic of a hydride in a *trans* disposition to an N-donor ligand,[9a] as has been found in polyphospine derivatives of Ru, and is in contrast with the values expected for analogous compounds with a Cl^- in a *trans* disposition.[9b] The cationic nature of **1** has been confirmed by conductivity measurements in acetone solution.



Scheme 1

In order to investigate the ability of complexes **2b** and **2a** to transfer a proton to the hydride with the formation of a dihydrogen bond, 3 equiv. of CF_3CO_2H were added to a **2b** : **2a** (7 : 2 ratio) CD_3CN solution at −40 °C. Under these conditions both isomers were transformed into a unique cationic compound: [RuClH(η^2-PPh_2py){(η^1-PPh_2py)$_2$H}]CF_3CO_2 **3** (Scheme 1). The identical integration of the hydride and proton resonances of **3** indicates that only one proton has been transferred from CF_3CO_2H. The signal of the newly introduced proton was strongly shifted downfield and appeared at δ *ca.* 20. Such a strongly deshielded resonance has been ascribed to acidic protons in very fast exchange between two basic centres.[9a,10] Consequently, this proton must be in fast exchange between the pyridine fragments of the two monodentate phosphines. The resonance of the surplus acid proton appeared separately at δ *ca.* 5. The chemical shifts of the hydride and phosphorus atoms of **3** were only slightly modified with respect to **2b**[7] and therefore the relative disposition of the ligands must be similar in these two complexes. On raising the temperature, both the pyridinium proton and hydride resonances of **3** broadened. The enormous chemical shift difference between the exchanging resonances (> 9000 Hz) prevented the observation of the coalescence. However, kinetic parameters can be calculated by lineshape analysis in the temperature range below the coalescence. This study was undertaken in $(CD_3)_2CO$ (−90 to −10 °C), which allows lower temperatures than CD_3CN. An E_a value of 13.6 ± 2.7 kcal mol^{-1} was obtained (A = 3.8 × 10^{14}). The exchange between the hydride and the pyridinium proton was also confirmed by spin saturation transfer. The irradiation of the hydride resonance of **3** reduced the pyridinium proton integral by *ca.* 50% at −40 °C. Above room temperature, both in $(CD_3)_2CO$ or CD_3CN solution, H_2 was lost and a new product, [RuCl(η^1-PPh_2py)(η^2-PPh_2py)$_2$]CF_3CO_2 **4** (Scheme 1) was formed with an identical structure to **1**, as deduced from its ^{31}P NMR spectrum.[7]

In order to show the existence of a dihydrogen bond in **3**, the T_1(min) of the hydride group both for **2b** and **3** was determined (300 MHz). CD_2Cl_2 was used as the solvent in order to prevent the possible participation of basic or protic solvents in the relaxation rate of the pyridinium proton and, indirectly, over the exchanging hydride. An addition of exactly 1 equiv. of CF_3CO_2H was performed in order to avoid the relaxation rate average with free protons. Under these conditions, the hydride

of **2b** shows a T_1(min) of 217 ms at −35 °C, whereas the T_1(min) for both the hydride and pyridinium proton of **3** is 85 ms at −20 °C. In the latter complex the T_1 values determined are identical for the pyridinium proton and the hydride over the temperature range studied (−90 to −10 °C). This must be a consequence of the observed exchange between these two protons. We have considered that the excess of the hydride relaxation in **3**, as compared to **2b**, is due to the Ru–H···H–py dipole–dipole interaction. In this relaxation the two ^{14}N pyridinium atoms must also participate because the proton, which is bonded to these two groups, is exchanging with the hydride with a half-life of 0.5, according to the aforementioned magnetization transfer experience. The contribution for each ^{14}N has been estimated to be 1.85 s^{-1}.[11] Hence, the relaxation rate due exclusively to the dipole–dipole interaction with the pyridinium proton is deduced to be 5.30 s^{-1}. Using Morris' approximation,[12] a d_{HH} = 1.70 Å has been calculated, a value that is in the range for a dihydrogen bond and demonstrates its existence in **3**.

Although the phenomenon has been previously described,[2b] the proton–hydride exchange already discussed for a dihydrogen bond is very rare, and Crabtree has postulated the participation of non-classical species as intermediates. Neither Crabtree nor our group have detected this intermediate in solution (**3b** in Scheme 1). However, Chaudret and coworkers[13] have recently reported some examples where an intermolecular exchange between coordinated molecular dihydrogen and weak acid protons has been observed.

The loss of H_2 near room temperature shows the lability of the proposed non-classical species **3b** and this opens up the possibility of interchange with free H_2. Besides, the heterolytic cleavage of an H_2 molecule coordinated in this hypothetical complex would be possible considering the observed higher basicity of the pyridine centres with respect to the hydride in **2**. These two characteristics point to a possible activity of **2** toward D^+–H_2 exchange in protic deuterated solvents.

As a consequence of this possibility, H_2 (1 atm) was introduced at room temperature in a sealed NMR tube in contact with a solution of **2** in CD_3OD as a deuteron source. The evolution of the mixture was monitored by ^{1}H NMR spectroscopy during several hours. The change with time of the relative concentration of H_2 and HD observed in this way is depicted in Fig. 1. The relative concentration of D_2 was calculated accepting the constant concentration of the total dihydrogen isotopomers in solution. According to these results, a very efficient catalyst for D^+–H_2 exchange was present in solution. After 33 min, > 90% of H_2 was transformed. In 18 min the HD concentration reached its maximum and afterwards decreased as a consequence of D_2 formation. An increase in the residual CD_3OD OH signal, and not that of the CHD_2 group, was concomitantly observed. **2a** was the major isomer observed in solution and, surprisingly, during the experience the intensity of the hydride signal due to **2a** was scarcely reduced. Only after 7 days did this signal disappear and [$^2H_1$] **2a** was formed. However, very small signals for **2b** were detected at room temperature (**2a** : **2b** = 30 : 1, 20 °C) before the addition of H_2, and these disappeared instantaneously when the gas was present. Therefore, we propose that, although only small amounts of **2b** are present, this is the efficient catalyst for the process. This example shows a dramatic relationship between structure and reactivity.

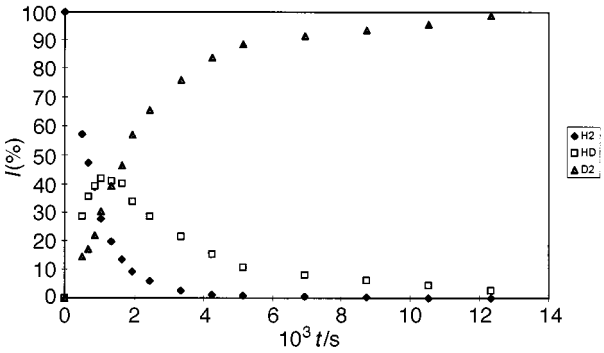


Fig. 1 Relative intensities of the NMR signals of the dihydrogen isotopomers *vs.* time in the D^+–H_2 exchange experiment with **2** CD_3OH; (◆) H_2, (□) HD, (▲) D_2

In conclusion, we present an example where the addition of a proton to the ruthenium monohydrides **2b** and **2a** forms a dihydrogen bond of three centres, and this system shows a fast exchange between the proton and hydride moieties. **2b**, and not **2a**, is extremely active in D^+–H_2 interchange processes. Experiments to assess the catalytic properties of these types of compounds in hydrogen transfer processes are in progress.

We thank to the Dirección General de Investigación Científica y Ténica for financial support (Grant PB95-0901).

Synthesis and structure of pure SiO_2 chabazite: the SiO_2 polymorph with the lowest framework density

María-José Díaz-Cabañas, Philip A. Barrett and Miguel A. Camblor*

Instituto de Tecnología Química, Avda. Los Naranjos s/n, 46071 Valencia, Spain. E-mail: macamblo@itq.upv.es

A SiO_2 material with the lowest framework density (15.4 SiO_2 nm^{-3}) and the largest void volume fraction (nearly 50%) ever reported for crystalline silica polymorphs has been synthesised, and its structure solved by direct methods and fully refined using low-resolution powder X-ray diffraction data.

The synthesis of pure silica polymorphs of decreasing density is a scientific challenge which may result in potential applications, including adsorption and separation of organic molecules but also storage of gases such as H_2 and CH_4. Compared to zeolites of the same structure type pure silica polymorphs may in principle offer (1) a larger void space owing to the absence of counter cations in their pores, (2) distinct adsorption properties, characterised by their extreme hydrophobicity,[1] and (3) a far superior thermal stability. Recent calorimetric measurements[2] and theoretical calculations[3] have shown that the enthalpy of formation relative to quartz is very small and increases only slightly with the decreasing framework density (FD, the number of $SiO_{4/2}$ tetrahedra per nm^3). This suggests the synthesis of low-density materials is not thermodynamically hindered and new phases (though normally considered as still metastable with respect to quartz) could be obtained through a kinetic control of the synthesis process. Actually, the synthesis of microporous SiO_2 polymorphs involves a two-step process: the synthesis of a host–guest compound in the presence of a suitable (normally organic) structure-directing agent (SDA), and its calcination to remove the guest organics. Apparently, the use of SDAs affords the required kinetic pathway and/or the additional stabilisation energy that makes the synthesis feasible. However, until recently only silica phases with a relatively high framework density (above 17 $SiO_{4/2}$ nm^{-3}) have been obtained. We have recently found that a modification of a known method for the synthesis of pure silica materials offers new opportunities for decreasing the framework density of the phases obtained.[4] We illustrate here the success of this strategy which has now afforded the synthesis of a new pure silica polymorph isostructural with zeolite chabazite having the lowest ever reported framework density amongst these materials, 15.4 SiO_2 nm^{-3} (14.6 T nm^{-3} for the type material, structure code CHA).[5]

Pure silica chabazite was synthesised hydrothermally using *N*,*N*,*N*-trimethyladamantammonium (TMAda$^+$) in hydroxide form as the structure-directing agent at near to neutral pH in the presence of fluoride. In a typical synthesis 13.00 g of tetraethylorthosilicate were hydrolysed in 31.18 g of a 1.0 M TMAdaOH aqueous solution and the mixture was stirred to allow the ethanol and water to evaporate to a final H_2O/SiO_2 molar ratio of 3.0. Then, 1.33 g of HF (aq., 46.9%) were added and the mixture, which was homogenised by hand, was transferred to Teflon lined stainless steel 60 ml autoclaves. The autoclaves were heated at 150 °C whilst rotated at 60 rpm. After 40 h crystallisation time (pH = 8.5) the solid product was collected, washed and dried, and recognised as chabazite by powder X-ray diffraction (XRD). Its chemical analysis indicates a composition close to $[C_{13}H_{24}NF_{0.5}]_3[Si_{36}O_{72}(OH)_{1.5}]$ [Anal. Found: C, 17.49; H, 2.98; N, 1.56; F, 1.06. The above composition requires: C, 16.78; H, 2.60; N, 1.51; F, 1.02%]. A charge imbalance between F$^-$ and TMAda$^+$ suggests the presence of connectivity defects in this material (see below), and to maintain electrical neutrality we have included 1.5 OH$^-$ per uc in the above idealised composition.

It is interesting that an aluminosilicate isostructural to chabazite (denoted as SSZ-13) may be prepared using the same structure-directing agent in OH$^-$ medium.[6] However, it appears that in the absence of F$^-$ in alkaline medium aluminium is needed for the synthesis of SSZ-13 to succeed.[6] From our experience in OH$^-$ medium using TMAda$^+$ as the structure directing agent an increase in the Si/Al ratio above 50 favours the crystallisation of either ITQ-1[7] or SSZ-23 (depending on the alkali metal cation present) while higher aluminium contents favours SSZ-13 with the CHA topology.[8]

Thermogravimetric analysis in air (10 °C min^{-1}) shows no weight losses below 260 °C, suggesting no water is occluded as a guest in this material, as expected for a pure silica host. The organics and fluorine are removed in the range 300–650 °C through two overlapping exothermic processes (the first centred at 450 °C). Calcination at 580 °C for 3 h is required to prepare the pure silica host, whose adsorption capacity is exceptionally high. From N_2 adsorption experiments at 77 K a micropore volume of 0.30 cm g^{-1} (calculated by the *t*-plot method or by the amount of adsorbed N_2 at any relative pressure between 0.1 and 0.9), a surface area of 602 m^2 g^{-1} (BET method) and a micropore area of 594 m^2 g^{-1} were calculated. The micropore volume of silica chabazite is by far the largest ever reported for a crystalline pure silica polymorph and exceeds by over 30% those of the beta, ITQ-3 and ITQ-4 materials (0.22, 0.23 and 0.22 cm^3 g^{-1} respectively). The void volume fraction of silica Chabazite is almost 50% (0.46 cm^3 cm^{-3}).

The ^{29}Si MAS NMR spectrum of calcined pure silica CHA (Fig. 1) shows two bands at δ −101.4 and −111.4. The first is assigned to $Si(OSi)_3OH$ defect groups and the second to $Si(OSi)_4$ species. Their relative intensities allow us to quantify the amount of defects in pure silica CHA and shows that an appropriate formulation for this material is $[Si_{36}O_{70.5}(OH)_{2.9}]$. The number of defect groups is relatively small compared to silica materials synthesised in OH$^-$ medium, where the Si–OH concentration is typically about four times larger than the

O(4)	0.26344(19)	0	0	0.0335(10)

amount of occluded cations[9] (this would lead in this case to over 30% Si–OH defects with respect to total Si sites). However, it is noticeable that this defect concentration is much larger than expected for a silica material synthesised at near neutral pH in the presence of fluoride.[10] In view of a plausible control of the defect concentration by the synthesis pH and the pK_a of the condensing silicate species,[11] we have tried to reduce the defect concentration of this material by further decreasing the synthesis pH, but with no success. We are currently trying to understand the unexpected behaviour of this system.

The *Si*$(OSi)_4$ resonance in Fig. 1 is noticeable because of its sharpness (26 Hz), which is probably due to a combination of the absence of Al substitution for Si, the presence of a single Si site in the structure (see below) and the relatively low concentration of defects. We have calculated an average Si–O–Si angle of 148.4° for CHA by applying the equation of Thomas *et al.*[12] to the chemical shift of the *Si*$(OSi)_4$ resonance. This is in excellent agreement with the value obtained by Rietveld refinement (148.0°, see below).

Powder X-ray diffraction (XRD) techniques were used to examine the new pure silica Chabazite material. Laboratory Cu-Kα XRD data were recorded on a freshly calcined sample of the title compound. Inspection of the diffraction pattern and refinement of the unit cell parameters taken from Smith *et al.*[13] verified the phase purity and rhombohedral symmetry (space group $R\bar{3}m$). The high crystallinity of the material after calcination enabled the structure to be solved routinely by direct methods in the program Sirpow[14] using Le Bail[15] extracted intensities from the Mprofil[16] program suite. Subsequent Rietveld[17] refinement of the model produced from direct methods was undertaken in the program GSAS[18] using a manually interpolated background together with a pseudo-Voigt[19] function to describe the peak shape. The refinement proceeded smoothly with no constraints used. The crystallographic data are summarised in Table 1, the final atomic positions in Table 2 with the final Rietveld plot depicted in Fig. 2. The average Si–O bond length (1.603 Å) and average O–Si–O and Si–O–Si angles (109.47 and 148.0°, respectively) are in excellent accord with those expected for zeolite materials. These refinement results clearly verify the formation of a highly crystalline chabazitic material.

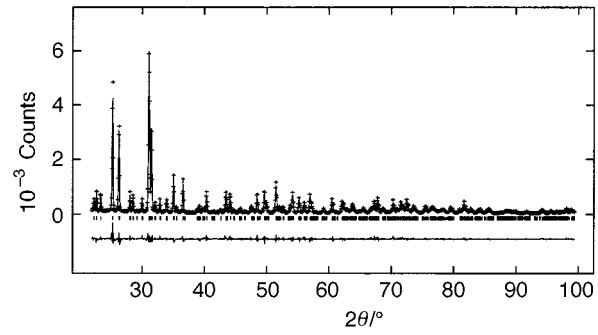

Fig. 2 Rietveld plot for the title compound, observed (+), calculated (solid line) and the difference (lower trace). The tick marks represent the positions of allowed reflections.

Supramolecular self-assembling in mesostructured materials through charge tuning in the inorganic phase

Manuel Roca, Jamal El Haskouri, Saúl Cabrera, Aurelio Beltrán-Porter, Jaime Alamo, Daniel Beltrán-Porter, M. Dolores Marcos* and Pedro Amorós*

Institut de Ciència dels Materials de la Universitat de València (ICMUV), Dr. Moliner 50, 46100-Burjassot (València), Spain. E-mail: loles.marcos@uv.es and pedro.amoros@uv.os

Supramolecular self-assembling of organic CTA^+ micelles and inorganic $[VO(H_2O)PO_4]_n^{q-}$ 2D-anions for the isolation of hexagonal mesostructured materials can be reached by charge tuning in the inorganic phase through the adjustment of the vanadium mean oxidation state.

When researchers of the Mobil company reported the discovery of new mesoporous silica based materials denoted MCM-41,[1] the scientific community imagination was newly stimulated and a large amount of related work was published in a very short time.[2] Originally, the synthesis of mesoporous silica materials was related to a liquid-crystal templating mechanism in which surfactant micelles act as supramolecular templates. However, for low surfactant concentrations another model based on the cooperative organisation of inorganic and organic molecular species has been developed. In that case, the most important point in the synthesis of a mesostructured solid is charge density matching at the organic–inorganic interface.[3]

Although much work has been reported on the influence that variation of surfactant characteristics has in the isolation of mesoporous materials,[4] very little has been done regarding the inorganic counterpart. In contrast with silica based materials, other metal oxides show, in general, shorter progression of their hydrolysis and condensation reactions and hence strong limiting problems related with charge matching at the interface appear. In this sense we present here, to the best of our knowledge for the first time, the possibility of controlling the formation of mesostructured solids by tuning the charge density at the inorganic phase through the adjustment of the metal oxidation state in a mixed-valence system.

We have succeeded in the preparation of mesostructured mixed-valence oxovanadium phosphates with different $V^{IV}:V^{V}$ content (ICMUV-2 materials) using CTAB (cetyltrimethylammonium bromide) as a surfactant directing agent in water. A constant $V:H_3PO_4:CTAB:H_2O$ molar ratio of $1:5:0.1:150$ was always used in the starting reactants and the $V^{IV}:V^{V}$ content was adjusted in a continuous way by adding variable amounts of H_2O_2.

Owing to the complexity of the $V–H_3PO_4–CTAB–H_2O$ system our approach has been based on the independent consideration of the organic and inorganic species present in the mother-liquor. Regarding the organic subsystem, we have used low surfactant concentration to favour a cooperative mechanism in which the charge density matching at the interface must be the leading force to the supramolecular organisation for the preparation of ICMUV-2 solids.

In relation to the inorganic moieties, we have carried out our synthesis at very low pH value since under this condition the oxovanadium cations are present as isolated aqua cations[5] and, in the presence of oxophosphorus anions ($H_2PO_4^-$ at the working pH), should lead to successive hydrolysis and condensation reactions which would lead to the formation of the $[VO(H_2O)PO_4]_n^{q-}$ two-dimensional anions.[6] Supramolecular assembling between organic and inorganic species into a mesostructured solid will take place when the charge density of the inorganic moieties matches with that of CTA^+ micelles. We have calculated an approximate charge density at the rod-like micelles surface of $q = +0.014$ e Å^{-2} presuming a hexagonal close packing of surfactant head groups at the micelle surface and using the micelle diameter (37.5 Å) and the van der Waals radius of the head groups (4.5 Å).[7] From this value and taking into account the bond topology of the $[VO(H_2O)PO_4]_n^{q-}$ moieties,[6] the $V^{IV}:V^{V}$ molar ratio which matches the surfactant micelles charge should be $0.54:0.46$. According to this simple calculation we have experimentally found that it is only possible to obtain hexagonal mesostructured solids when the $V^{IV}:V^{V}$ molar ratio lies between $0.20:0.80$ (sample 1) and $0.61:0.39$ (sample 4), the most crystalline solids being those for which the $V^{IV}:V^{V}$ molar ratio has a value around unity ($0.54:0.46$; sample 3) (see Fig. 1). The existence of a $V^{IV}:V^{V}$ range in which charge density matching must somehow occur, is consistent with the ability of the micelle to change its molecular packing and in this way to accommodate its charge density at the surface to the inorganic phase charge. Hence, the highest crystallinity must correspond to the solid with the most ordered micelles, *i.e.* that with close packing of surfactant head groups at the surface. Also, the $V^{IV}:V^{V}$ matching range can be extended to a greater degree below the best calculated value of 0.54 than above since the micelle can easily adopt a looser packing but not a closer one.

In a typical sample preparation, an aqueous suspension (50 ml) containing V metal (0.226 g, 4.44 mmol), V_2O_5 (1.617 g,

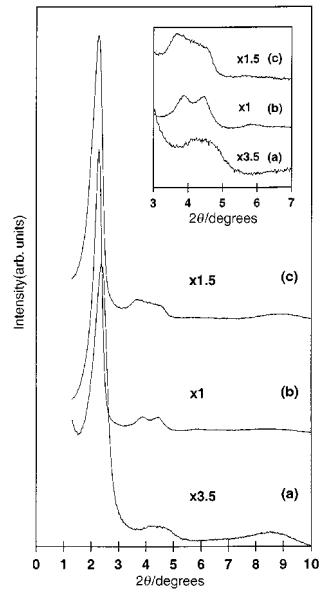

Fig. 1 X-Ray powder diffraction patterns of ICMUV-2 materials having different $V^{IV}:V^{V}$ molar ratios and CTA^+ content; (a) sample 1, (b) sample 3, (c) sample 4

Table 1 Selected synthetic and compositional parameters for ICMUV-2 solids: $[CTA]_x[(V^{IV}O)_y(V^{V}O)_{1-y}PO_4]\cdot zH_2O$

Sample	V^{IV} in solution %	y	x	z
1	35	0.20	0.20	2.01
2	55	0.33	0.33	1.41
3	60	0.54	0.53	1.01
4	85	0.61	0.60	0.65

8.88 mmol) and 7.6 ml of 85% H_3PO_4 was refluxed until complete dissolution. Amounts of V metal and V_2O_5 were adjusted in order to obtain a V^{IV} starting solution and the $V^{IV}:V^{V}$ ratio in the solution was then adjusted by controlled addition of H_2O_2. Subsequently, a 10 ml aqueous solution of CTAB (0.81 g) was added. After stirring for 1 h at room temperature the ICMUV-2 solid was isolated by filtration. Although ICMUV-2 solids can be prepared with slightly higher CTAB concentration (up to $CTAB:H_2O = 0.3:150$) the surfactant concentration used here allows us to obtain the most ordered solids. Table 1 summarises the main synthesis variables and compositional data of selected ICMUV-2 materials. Vanadium oxidation states in the solids were determined by atomic absorption and a redox titration procedure. All the samples were analyzed and characterized by X-ray powder diffraction (Seifert 3000TT diffractometer using Cu-Kα radiation in steps of 0.02° (2θ) for 10 s per step) and TEM on a Philips CM10 instrument operated at 120 kV. Fig. 1 shows the XRD patterns of selected ICMUV-2 materials. Although differences in crystallinity can be observed among solids with different composition, all of them present a similar regular hexagonal array according to TEM analysis and Fig. 2 shows a representative TEM image.

Previously to this work, it was reported the preparation of solids in the V–O–P system which consisted of mixtures of amorphous vanadium and phosphorus oxides[8,9] with a $V:P = 2:1$ molar ratio rather than a genuine vanadyl phosphate. However, in order to obtain an adequate $(VO)_2P_2O_7$ catalyst precursor it is necessary to maintain a $V:P = 1$ molar ratio.[10] In our experiences neither vanadium(V) starting solutions (zero global charged ($[VOPO_4]_n^0$) species, $S^+X^-I^0$ mechanism) nor vanadium(IV) ones ($[VOPO_4]_n^-$ species, S^+I^- mechanism) allowed us to synthesize any kind of solid, only when we reached the necessary charge density matching at the organic-inorganic interface by adjustment of the $V^{IV}:V^{V}$ molar ratio were mesostructured solids obtained. Hence, instead of randomly varying the charge density at the organic phase employed up to now, our approach has allowed us not only a wider range of charge variation when comparing with possible variations offered by changing surfactant characteristics, but a continuous modulation of the charge density at the inorganic phase from $q = 0$ to $q = -1$ per vanadium atom.

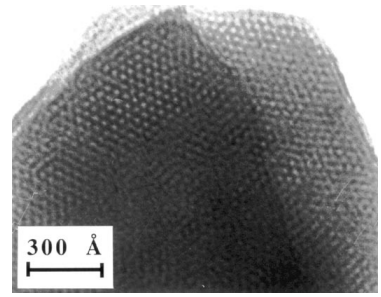

Fig. 2 Representative TEM micrograph of the mesostructured ICMUV-2 materials corresponding to sample 3

The approach reported here suggests that it should be possible to design synthetic strategies for the preparation of hexagonal mesostructured/mesoporous materials for inorganic systems in which different accessible oxidation states are possible for the metallic centre by the simple adjustment of the charge at the inorganic framework.

Reaction of methane with CO or CO_2 in aqueous solution in the presence of O_2 (catalysed by $NaVO_3$) or H_2O_2 (catalysed by $NaVO_3$–pyrazine-2-carboxylic acid) at 25–100 °C affords acetic acid and in some cases also methanol, methyl hydroperoxide and formaldehyde.

The direct conversion of methane, the least reactive representative of the very inert saturated hydrocarbon family, into valuable chemical products under mild conditions is a challenging problem of metal complex catalysis.[1] A very small number of publications have appeared that describe the homogeneous carboxylation of methane in the absence[2a] or in the presence[2b–e] of soluble metal compounds (see also recent works on theoretical study of carbonylation[3a] and carboxylation with the participation of solid metals[3b]).

We have found that heating an aqueous solution of sodium vanadate in the presence of methane, carbon monoxide and air gives rise to the formation of acetic acid, as well as, in smaller amounts, of methanol and formaldehyde (Table 1).† The yield of acetic acid attains 3700% based on vanadium after 50 h at 100 °C, the total turnover number being 49. In the absence of either V^V or CH_4, no products have been detected. When a larger concentration of vanadate (1.0×10^{-3} mol dm^{-3}) was used, in the absence of air, only 0.2×10^{-3} mol dm^{-3} of $MeCO_2H$ was formed after 16 h at 100 °C. While in the course of the reaction with air the solution remains pale yellow, in the case when air is absent the colour of the solution becomes blue indicating the formation of a V^{IV} derivative. Thus it can be concluded that atmospheric oxygen is capable of reoxidizing the V^{IV} species formed in the reaction between methane, VO_3^- and CO. The yield of acetic acid and its relative content in the mixture of the products increases with the increase of partial CO pressure (Table 2). A comparison to Sen's catalytic system ($RhCl_3$/KI), which gives 790% of acetic acid (based on Rh) after 20 h at 80 °C,[2e] shows that the inexpensive sodium vanadate is more active giving a yield of 3300% of acetic acid (based on V) after 25 h at 100 °C.

Table 1 Carboxylation of methane by carbon monoxide in the presence of air catalysed by $NaVO_3$ in aqueous solution[a]

		Products (concentration/10^3 mol dm^{-3})		
T/°C	*t*/h	$MeCO_2H$	MeOH	HCHO
80	5	0.3	0.2	0.03
	15	0.6	0.4	0.1
	25	1.0	0.6	0.5
100	6	2.0	0.9	0.6
	25	3.3	1.1	1.0
	50	3.7	1.9	1.2

[a] Conditions, see Footnote †. Pressures and concentrations: CH_4, 50 bar; CO, 15 bar; synthetic air, 15 bar; $NaVO_3$, 1.0×10^{-4} mol dm^{-3}; initial pH = 7.30.

Hydrogen peroxide can be used instead of molecular oxygen as reoxidizing agent in the carboxylation using pyrazine-2-carboxylic acid (PCA)[4] as a co-catalyst; no products are detected in the absence of PCA. In this case the selectivity of the reaction depends strongly on temperature and CO pressure (Table 3),‡ the carboxylation at room temperature and relatively high CO pressure yielding acetic acid as a sole product. The initial rate of acetic acid accumulation depends linearly on the initial pressure of methane (when this pressure < 50 bar) and on initial concentration of hydrogen peroxide (when $[H_2O_2] < 0.1$ mol dm^{-3}). The role of PCA in aqueous solution is not completely clear; on the basis of preliminary investigations we can assume that PCA stabilises an active vanadium peroxo species, while the protons from PCA simultaneously facilitate the substitution of coordinated water ligands by H_2O_2 in the coordination sphere of vanadium. The reaction of ethane (20 bar) with CO (5 bar) and H_2O_2 (0.1 mol dm^{-3}) in the presence of $NaVO_3$ (1.0×10^{-4} mol dm^{-3}) gave after 2 h at 40 °C propionic acid (3.0×10^{-4} mol dm^{-3}) and acetic acid (3.3×10^{-3} mol dm^{-3}).

Interestingly, the carboxylation of methane also occurs, when carbon dioxide is used instead of carbon monoxide. Under the conditions described in Table 3, the yield of acetic acid is 2000% based on vanadium after 30 h at 40 °C; methanol was also observed (10^{-4} mol dm^{-3}). No acetic acid can be detected, when the reaction was carried out in the absence of either CH_4 or CO_2.

We believe that the reaction involves hydrogen atom abstraction from methane by a radical or radical-like species. In the case of hydrogen peroxide as an oxidising agent, this species could be a hydroxyl radical or vanadium peroxo complex.[4] The vanadate anion (like permanganate or chromate ions) can also add hydrogen from an alkane to one of oxygen atoms reducing V^V into V^{IV}.[5] The methyl radicals thus formed will react[6] with CO to give the radicals RCO$^\bullet$ and then, after interaction with O_2, produce the radicals RCOOO$^\bullet$ and peroxyacetic acid. If carbon dioxide is used as carboxylating reagent, in the first stage CO_2 is apparently reduced into CO by methyl or/and hydroxyl

Table 2 Carboxylation of methane by carbon monoxide in the presence of air catalysed by $NaVO_3$ in phosphate aqueous buffer solution at various pressures of CO[a]

radicals (dry CO_2 reforming of methane in the presence of solid catalyst at high temperatures is well-known process[7]).

We thank BASF, the Russian Basic Research Foundation, and the Swiss National Science Foundation for support. Authors are indebted to Dr Arthur Höhn, Dr Michael Slany (BASF AG, Ludwigshafen, Germany) and Dr Yuriy N. Kozlov (Institute of Chemical Physics, Moscow) for fruitful discussions.

Notes and References

† The oxidations were carried out in a stainless steel autoclave with intensive stirring (volume of the reaction solution = 30 ml and total volume of autoclave = 100 ml). The autoclave was charged with synthetic air (78% N_2, 21% O_2, 1% Ar), and consecutively with carbon monoxide and methane to the appropriate pressures. The reactions were stopped by cooling with ice, and the reaction solution was analysed for $MeCO_2H$ and MeOH by GC (DANI-86.10; fused silica capillary column 25 m × 0.32 mm × 0.25 μm, CP-WAX52CB; integrator SP-4400), as well as by GC–MS (NERMAG R 30-10, capillary column 25 m × 0.32 mm × 0.25 μm, CP-WAX52CB) and ^{1}H NMR (Varian spectrometer, 200 MHz; in D_2O; in this case GC–MS analysis testified partial H–D exchange in methyl groups of $MeCO_2H$ and MeOH formed). The concentration of formaldehyde was measured spectrophotometrically after its transformation into 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine as described previously.[4b]

‡ The reaction was carried out in a glass tube placed into the stainless steel autoclave (100 ml, volume of the solution = 10 ml). (**CAUTION**: the combination of air and H_2O_2 with organic compounds at elevated pressures and temperatures may be explosive!). The resulting solution was analysed by GC (the concentration of MeOOH was measured as concentration of MeOH after reduction of the solution with sodium tetrahydroborate[4]), as well as by GC–MS and ^{1}H NMR.

Synthesis and molecular structure of the first tetranuclear copper(I) silylphosphido cluster $[Cu(CyPSiMe_2PHCy)]_4$

Markus Faulhaber, Matthias Driess*† and Klaus Merz

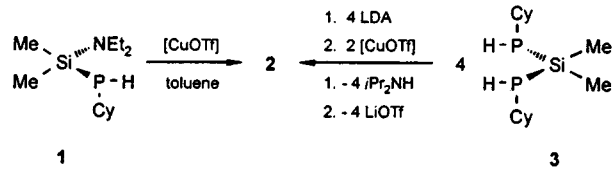
Lehrstuhl für Anorganische Chemie I, Ruhr-Universität, Universitätsstr. 150, D-44801 Bochum, Germany

The reaction of *N*,*N*-diethylamino(cyclohexylphosphino)dimethylsilane 1 with the benzene solvate of copper(I) trifluoromethylsulfonate furnishes the title complex 2, which has been structurally characterized by X-ray diffraction; the same product results on conversion of bis(cyclohexylphosphino)dimethylsilane 3 with copper(I) trifluoromethylsulfonate in the presence of lithium diisopropylamide as an auxilliary base.

Secondary phosphido anions $[RRP]^-$ are of considerable interest as ligands in the coordination chemistry of transition metals and clusters thereof.[1] Such complexes are also attractive as soft nucleophilic transphosphination reagents for selective synthesis of functionalized phosphane ligands. This has recently been shown for oligomeric copper(I) phosphido complexes.[2] Hitherto knowledge of the structural chemistry and the structure–reactivity relationship of copper phosphido aggregates has been relatively scarce and a silylphosphido cluster has not been described. A convenient method for the preparation of phosphido bridged transition metal complexes and clusters is the electrophilic cleavage of Si–P bonds in silylphosphanes through the corresponding metal halides and alkoxides.[3] However, we recently reported on the template synthesis of the first hexaphosphahexasilacyclododecane by the reaction of a triphosphatrisilacyclohexane with copper(I) or silver(I) trifluoromethylsulfonate, where the building up of new Si–P bonds instead of cleavage was observed.[4] In order to extend this building up method for the preparation of acyclic silylphosphane and −phosphido chelate ligands, we are exploring the reactivity of Si-functionalized silylphosphanes toward coin metal(I) complexes.

Here we report on two preparation routes to the first tetranuclear copper(I) silyl phosphido complex **2** (Fig. 1), containing the $[CyPHSiMe_2CyP]^-$ ligand, and we describe its molecular structure which was elucidated by single-crystal X-ray diffraction.

While it was anticipated that the P–H bond in a secondary silylphosphane of the type R_3Si–PH–R would be metalated by copper(I) trifluoromethylsulfonate ([CuOTf]), surprisingly, transphosphination–silylation reactions were observed, leading to a Cu^I silylphosphidophosphane aggregate. Hence the *N*,*N*-diethylamino(cyclohexylphosphino)dimethylsilane **1** reacts with the benzene solvate of [CuOTf] in toluene to give **2** in the form of dark red crystals in 75% yield (Scheme 1).

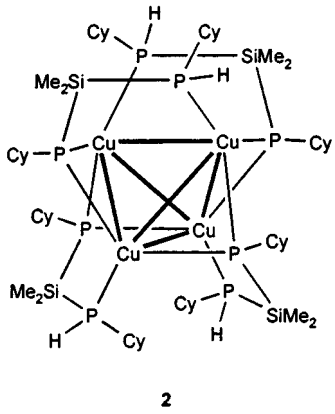


1 3

Scheme 1

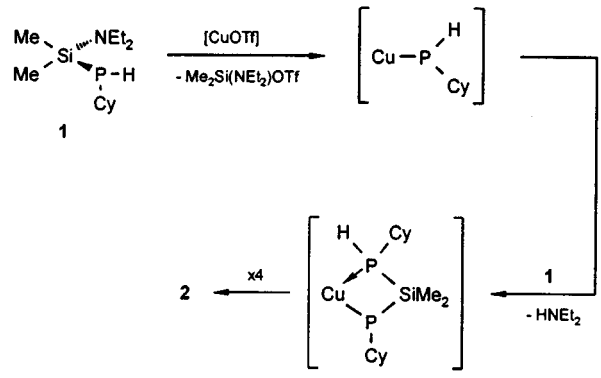
Compound **1** (colourless liquid, $bp_{0.01Torr}$ = 85 °C) is readily accessible *via* a procedure analogous to that for the synthesis of *N*,*N*-diethylamino(methylphosphino)dimethylsilane.[5] The reaction mechanism for the formation of **2** is unknown, but we suggest the stepwise process as outlined in Scheme 2.

Apparently, the first step is the electrophilic cleavage of the Si–P bond in **1** to give the corresponding copper phosphide as intermediate and the corresponding silyl(amino)triflate. The copper phosphide intermediate could then co-ordinate another molecule of **1** and subsequent replacement of the NEt_2 group leads to the PSiP chelate moiety in the co-ordination sphere of the Cu^I centre. Compound **2** (Fig. 2) is also accessible starting from bis(cyclohexylphosphino)dimethylsilane **3** and [CuOTf] in the presence of LDA (lithium diisopropylamide) as base in 70% yield. Compound **3** was prepared through phosphination of dimethyldichlorosilane with $LiAl(PHCy)_4$ (Cy = cyclohexyl).[5] The composition of **2** was confirmed by elemental analysis. As expected, the ^{1}H NMR spectrum of **2** shows two signals at δ 0.3 and 0.4 for the diastereomeric methyl groups of the $SiMe_2$ moiety. The cyclohexyl groups exhibit unresolved multiplets between δ 0.7 and 2.9, and the signal of the chemically equivalent P–H protons is observed as a doublet at δ 3.7 ($^1J_{PH}$ = 267 Hz). The ^{31}P NMR spectrum of **2** shows multiplets at δ −100 and −72, which are relatively broad due to the quadrupole moment of the $^{63/65}$Cu nuclei (I = 3/2) . The P–H stretching vibration is observed in the IR spectrum at 2290 cm^{-1}.



2

Fig. 1 Chelated cluster **2**



Scheme 2

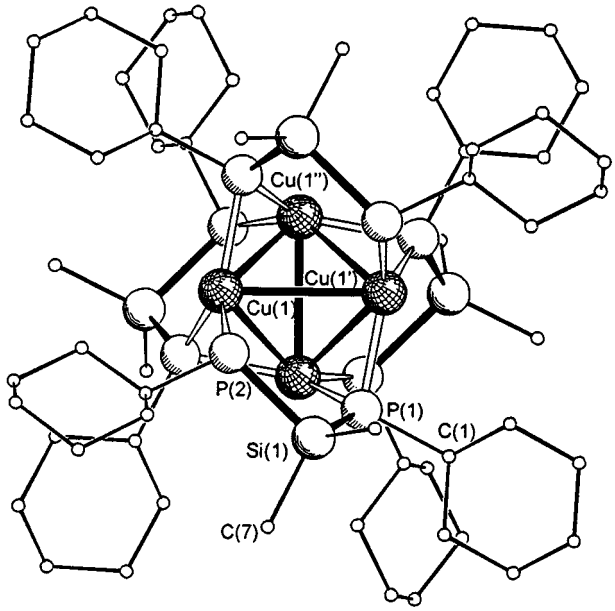


Fig. 2 Molecular structure of **2**. Hydrogen atoms omitted for clarity. Selected distances (Å) and angles (°): P(1)–Si(1) 2.207(5), P(2)–Si(1) 2.263(5), P(1)–C(1) 1.882(9), Si(1)–C(7) 1.890(11), P(2)–Cu(1) 2.261(4), P(1)–Cu(1) 2.270(3), P(1)–Cu(1") 2.235(4), Cu(1)–Cu(1) 3.071(3), Cu(1)–Cu(1") 2.911(2); P(1)–Si(1)–P(2) 98.7(2), Cu(1)–P(1)–Cu(1") 80.5(1), Cu(1")–Cu(1)–Cu(1") 63.67(6).

The X-ray crystallographic analysis‡ proves that **2** exists as a discrete tetramer and its core consists of a distorted Cu_4 tetrahedron. The latter is the result of the chelate property of the ($CyPSiMe_2PHCy$) ligand and, at the same time, of 'metallophilic' dispersion-type interactions between the co-ordinatively unsaturated Cu^I centres. Each phosphane-like P atom is only bonded to one Cu centre while the phosphido-like P atoms are μ_2-co-ordinated. Therefore, two of the six edges of the Cu_4 tetrahedron are not bridged by phosphorus. Accordingly, each Cu center has six neighbouring atoms, three of which are copper and three are phosphorus. The Cu–Cu distances are different: those for the four edges bridged by phosphorus (2.91 Å) are about 0.16 Å shorter than for the two unbridged edges (3.07 Å) of the Cu_4 tetrahedron. Other compounds containing cluster cores of four or more Cu atoms have also been reported. For example, the tetrameric compound $Cu_4I_4[As(C_2H_5)_3]_4$[6] and others with sulfur and nitrogen ligands[7,8] possess a tetrahedral core of Cu^I centres. A structurally related Cu_4 cluster to **2** was reported, where O,O-diisopropyldithiophosphate coordinates *via* η^1 and μ_2 sulfur centres to the Cu centres of the Cu_4 tetrahedron. The Cu–Cu distances in the latter are shorter (2.74 Å for the bridged and 2.95 Å for the unbridged edges of the tetrahedron) than in **2**. The Cu–Cu and Cu–P distances in **2** are within the range observed in other phosphido bridged Cu clusters.[2,7] According to the different co-ordination modes of the phosphino and the phosphido P centres of the ligands, the Si–P distances are not identical: the Si(1)–P(1) distance of the μ_2-coordinating phosphido group (2.207 Å) is about 0.5 Å shorter than the Si(2)–P(1) bond of the η^1-coordinating P atom. The present results underline the value of silylphosphanes for the synthesis of new oligophosphane ligands in the co-ordination sphere of Cu^I centres.

Palladium-catalysed reaction of aryl bromides with metallocenes to produce pentaarylated cyclopentadienes

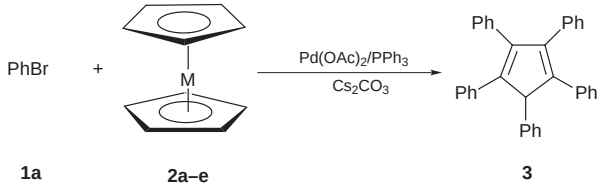
Masahiro Miura,*[a]† Sommai Pivsa-Art,[a] Gerald Dyker,*[b]‡ Jörg Heiermann,[b] Tetsuya Satoh[a] and Masakatsu Nomura[a]

[a] *Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565-0871, Japan*
[b] *Fachbereich 6, Organische/Metallorganische Chemie der Gerhard-Mercator-Universität-GH Duisburg, Lotharstrasse 1, D-47084 Duisburg, Germany*

Aryl bromides can efficiently react with some metallocenes, typically zirconocene dichloride, in the presence of a palladium/phosphine catalyst system and an appropriate base to produce the corresponding pentaarylated cyclopentadienes.

Palladium-catalysed coupling reactions of aryl halides with alkenes, alkynes and organometallic species are now recognized to be highly useful and are widely employed for the preparation of substituted aromatic compounds.[1] It has been recently shown that intermolecular arylation of certain aromatic substrates, such as acenaphthylene,[2a–c] azulene[2a] and 2-phenylphenols,[3a] and a number of five-membered heteroaromatic substrates, including indoles,[4a] furans,[2b,4b] thiophenes[3b,4b] and azoles,[3b,4c] *i.e.* imidazole, oxazole and thiazole derivatives, with aryl halides can also proceed under palladium catalysis without the stoichiometric metalation of the aromatic compounds. In our investigation into the arylation of metallocenes as five-membered aromatic substrates, we observed an unprecedented reaction in which aryl bromides can efficiently react with some of them to produce the corresponding pentaarylated cyclopentadienes in good yields (Schemes 1 and 2), which is reported herein. Note that pentaphenylcyclopentadiene as well as cyclopentadienes having other bulky substituents are known to form stable complexes with various metals, and the synthesis and properties of the complexes have been the subjects of intense study.[5] Recently, the pentaphenyl compound was applied as a ligand of an iron-containing asymmetric catalyst[6] and also as a component of electroluminescent devices.[7] Thus, new, effective methods for the synthesis of its derivatives appear to be of widespread interest. However, only a limited number of the methods have been so far reported.[8–11]

The catalytic reaction was first examined using bromobenzene **1a** (6 mmol) and a number of metallocenes **2** (0.5 mmol) in the presence of $Pd(OAc)_2$ (0.125 mmol), PPh_3 (0.5 mmol), and Cs_2CO_3 (6 mmol) in DMF at 130 °C for 6 h (Scheme 1). From the reaction was obtained pentaphenylcyclopentadiene **3** as the major product; the reaction efficiency was found to be a marked function of the identity of metallocenes: The yields of **3** using **2a**–**e** (M = Fe, Co, Ni, $TiCl_2$, $ZrCl_2$) were < 1, 23, 62, 64 and 70% (based on the cyclopentadiene moiety, *i.e.* 1 mmol = 100%), respectively. Thallium cyclopentadienide was only as effective as **2b**. It should be noted that the use of



1a **2a–e** **3**

2a: M = Fe, **2b**: M = Co, **2c**: M = Ni, **2d**: M = $TiCl_2$, **2e**: M = $ZrCl_2$

Scheme 1

iodobenzene and K_2CO_3 in place of **1a** and Cs_2CO_3, respectively, in the reaction with **2c** significantly reduced the product yield, giving biphenyl as the major product. Analysis of the reaction mixture with **2c** or **2e** after a reaction time of 3 h by GLC–MS confirmed the formation of tri- and tetra-phenylcyclopentadienes together with **3** in comparable amounts, while the peaks of the tri- and tetra-substituted compounds disappeared after 6 h. From the reaction with **2e** using reduced amounts of **1a** (3 mmol) and of palladium acetate (0.0125 mmol) for 20 h, the intermediary products could also be isolated and identified to be 1,2,4-triphenyl- (21%) and 1,2,3,4-tetraphenylcyclopenta-1,3-diene (9%). These results suggest that phenylpalladium species generated in the medium can react with **2c** or **2e** effectively in the initial stages of the reaction, and the cyclopentadienyl moiety is further phenylated in a stepwise manner to the end product **3**.

When the reaction using 4-fluorobromobenzene **1b** in place of **1a** was carried out, contamination by phenyl groups from PPh_3 in the product was observed.[12] Therefore, the applicability of $Pd(OAc)_2/P(o\text{-Tol})_3$ and $Pd_2(\mu\text{-OAc})_2/(P\text{-}C)_2$ [P-C = $o\text{-}CH_2C_6H_4P(o\text{-Tol})_2$], which would avoid the scrambling of aryl moieties,[12] was examined for the reaction of **1a** with **2e**. The latter complex has recently been proven to be an efficient catalyst for the Heck reaction.[12] However, the use of these catalyst systems considerably retarded the reaction and it could not be completed. Consequently, the reaction of **1b** with **2e** was carried out using $P(4\text{-}FC_6H_4)_3$ as ligand. As expected, the corresponding product **4** could be cleanly isolated, although the yield was only moderate (Scheme 2 and Table 1).

One of the possible ways to promote the reaction could be the use of relatively more basic and sterically hindered phosphines.[13,14] It was found that PBu^t_3 can considerably enhance the reaction of **1a** and **2e**: the reaction was completed within 3 h to give **3** in an isolated yield of 77%. Furthermore, in the reactions of **1b** and 4-methyl-, 4-methoxy-, and 3-methylbromobenzenes **1c–e** using PBu^t_3, no incorporation of *tert*-butyl groups in the products was detected, giving the expected compounds **4**–**7**§ in fair to good isolated yields. The use of this phosphine was essential for the reaction of **1d** to take place. Remarkably, under the optimized conditions the amount of palladium catalyst can be reduced to 0.0125 mmol (0.25 mol% per transferred aryl group) while still achieving an acceptable isolated yield of **5** (60%).

In the reaction of a relatively bulky bromide, 2,5-dimethylbromobenzene **1f**, with **2e**, however, PPh_3 afforded a considerably better yield of product **8**§ (70%) compared with PBu^t_3 (31%). While the analysis of **8** obtained using PPh_3 by MS indicated contamination with $C_5H(Ph)(2,5\text{-}Me_2C_6H_3)_4$ (8%), fortunately the purity could be increased to 98% *via* a single recrystallization from MeOH–C_6H_6. The formation of **8** is of special interest, since it should be sterically very crowded. Compound **8** was found to consist of at least six rotamers at room temperature: its ^1H NMR showed six obvious methine proton peaks (three minor ones at δ 4.85, 5.07 and 5.25 and

[a] See also Scheme 2. Reaction conditions: **1** (6 mmol), **2e** (0.5 mmol), $Pd(OAc)_2$ (0.125 mmol), PR_3 (0.5 mmol), Cs_2CO_3 (6 mmol), DMF (10 cm^3), 130 °C. Workup was carried out by adding TsOH (12 mmol) and filtering through a silica gel column, followed by chromatographic purification. [b] Isolated yield based on the amount of cyclopentadiene moiety (1 mmol = 100%). Satisfactory elemental and spectral (^1H and ^{13}C NMR and mass) analyses data were obtained for each compound. [c] Reaction with 0.0125 mmol of $Pd(OAc)_2$ and 0.05 mmol of PBu^t_3. [d] Contaminated with $C_5H(Ph)(2,5\text{-}Me_2C_6H_3)_4$ (8%).

three major ones at δ 5.10, 5.29 and 5.46 in $CDCl_3$) together with more than 20 methyl peaks. This resembles the previously reported spectrum for tetra(2-methylphenyl)cyclopentadienone at a lower temperature of −43 °C.[15] The peaks in the ^1H NMR spectrum of **8** in DMSO-d_6 were still notably sharp even at 100 °C, reflecting its crowded nature, while they were completely broadened at 150 °C.

In summary, we have shown that various homosubstituted pentaarylcyclopentadienes can be prepared *via* the treatment of aryl bromides with metallocenes, typically zirconocene dichloride, under palladium catalysis. This novel synthetic method represents an efficient and straightforward alternative to the rather tedious 'tetracyclone route',[5,8] opening up opportunities for the construction of even extremely sterically crowded pentaarylcyclopentadienes. Its synthetic application as well as the detailed reaction mechanism are currently under investigation.

Enantioselective sulfoxidation mediated by vanadium-incorporated phytase: a hydrolase acting as a peroxidase

Fred van de Velde, Lars Könemann, Fred van Rantwijk and Roger A. Sheldon*†

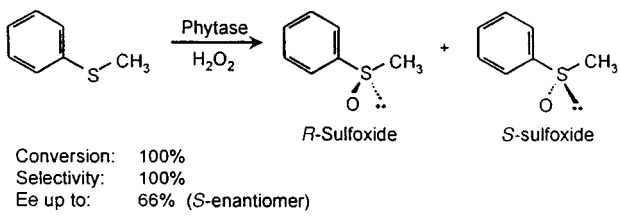
Laboratory for Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands

Phytase (E.C. 3.1.3.8), which *in vivo* mediates the hydrolysis of phosphate esters, catalyses the enantioselective oxidation of thioanisole with H_2O_2, both in the presence and absence of vanadate ion, affording the *S*-sulfoxide in up to 66% ee at 100% conversion.

In the last decade peroxidases, notably chloroperoxidase (CPO; E.C. 1.11.1.10) from *Caldariomyces fumago*, have been shown to catalyse a variety of synthetically useful (enantioselective) oxygen transfer reactions with H_2O_2,[1] including enantioselective oxidation of sulfides.[2] However, a major shortcoming of all heme-dependent peroxidases, such as CPO, is their low operational stability,[3] resulting from facile oxidative degradation of the porphyrin ring. In contrast, vanadium haloperoxidases, such as vanadium chloroperoxidase from *Curvularia inaequalis*[4] are non-heme enzymes and, hence, are much more stable. Unfortunately, the active site of vanadium-dependent haloperoxidases can accommodate only very small substrates, such as halide ion, which severely curtails their utility, although Andersson *et al.*[5] recently found that the vanadium-dependent bromoperoxidase from *Corallina officinalis* mediates the enantioselective oxidation of aromatic sulfides. Recently, it was established[6] that vanadium chloroperoxidases are structurally closely related to the acid phosphatases and the apoenzyme was shown to exhibit phosphatase-like activity. Moreover, vanadate and other transition metal oxoanions are known to be potent inhibitors of acid phosphatases[7] and the related phytases[8] and sulfatases.[9] Hence, we reasoned that incorporation of vanadate ion in these enzymes should produce novel, semi-synthetic peroxidases.

To test this hypothesis we investigated the oxidation of thioanisole with H_2O_2 (Scheme 1) catalysed by vanadium-incorporated phytase (from *Aspergillus ficuum*). At low vanadate concentrations (< 15 μM) we observed quantitative conversion to the sulfoxide, the *S*-enantiomer being preferentially formed in 56% ee. At higher vanadate concentrations (> 25 μM), in contrast, further oxidation to the corresponding sulfone also occurred.

In the standard procedure thioanisole (5 mM) and phytase [30 mg dry weight; 12 mg protein (> 95 % phytase); 0.18 μmol; 1400 U] were dissolved in formate buffer (7 ml; 0.1 M; pH 5.1; containing 0 to 30 μM Na_3VO_4). At this pH vanadate is predominantly present[10] as $H_2VO_4^-$. After 10 min H_2O_2 (5.5 mM) was added and the course of the reaction was followed by chiral HPLC (Chiralcel OD column; Daicel Chemical Industries, Ltd.) using 1,2,3-trimethoxybenzene as an internal standard. Of a wide variety of structurally related enzymes tested (details to be reported elsewhere) only phytase exhibited substantial peroxidase activity.



Scheme 1

We studied the influence of the vanadate concentration on the reaction rate and ee of thioanisole oxidation. As shown in Fig. 1 the reaction rate showed saturation kinetics with respect to the vanadate concentration. From these data we calculated a maximum rate of 120 μmol h^{-1} (which represents a turnover frequency of 11 min^{-1}) and a dissociation constant (K_d) for the vanadate ion of 15.4 μM, which is in the same order of magnitude as its reported K_I value for phosphatases and sulfatases.[9] The ee of the formed sulfoxide increased from 47% to a plateau (from 2.5 to 20 μM) of 56% at room temperature. At 4 °C this value was improved to 66% (see Table 1). At a vanadate concentration of 20 μM the rate of the non-enzymatic reaction was 0.5 μmol h^{-1}. Surprisingly, phytase also catalysed the enantioselective sulfoxidation of thioanisole, giving the

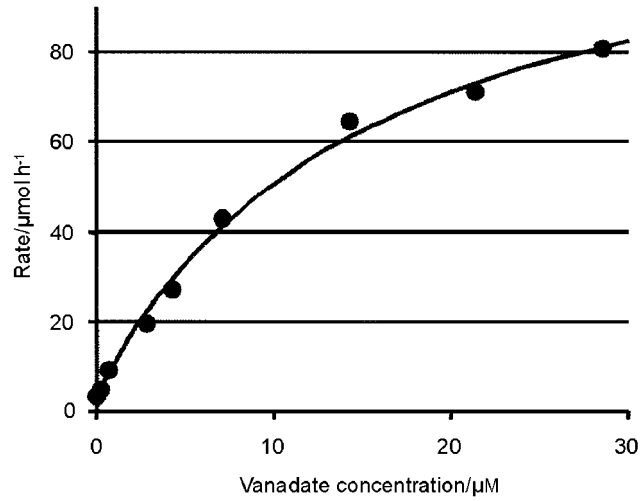


Fig. 1 Influence of the vanadate concentration on the oxidation of thioanisole

S-sulfoxide in 47% ee, *even in the complete absence of vanadium*.

We subsequently studied the metal-free phytase-catalysed sulfoxidation in more detail (Table 1). The conversion and ee increased with increasing enzyme concentration, consistent with the reaction being enzyme catalysed. At room temperature the enzyme activity for the two enantiomers was 0.16 μmol h^{-1} (mg protein)$^{-1}$ and 0.04 μmol h^{-1} (mg protein)$^{-1}$ respectively for the *S*- and the *R*-enantiomer. In consequence, the *intrinsic* enantioselectivity of the enzyme is 58% ee (*S*) at room temperature. In the absence of enzyme, a 34% conversion to racemic sulfoxide was observed in 5 h at 40 °C. Decreasing the temperature from 40 to 4 °C reduced the rate of the blank reaction from 9.52 10^{-8} to 3.42 10^{-9} M s^{-1}, resulting in a corresponding increase in enantioselectivity from 33 to 54% ee.

The highest ees were observed in formate buffer, but a carboxylate buffer was not essential. Ammonium chloride and MES‡ were also effective, giving conversions and (ee values) after 5 h of 74% (35%) and 71% (43%), respectively, in experiments performed at 4 mM H_2O_2. This rules out the *in situ* formation of peroxycarboxylic acids (from the carboxylate buffers) as observed with lipases[11] and metal-free bacterial haloperoxidases.[12] The optimum pH was 5.1 which coincides with that of the natural reaction of phytase. The enantioselectivity decreased from 33 to 18% with increasing H_2O_2 concentration from 5.5 to 20 mM, owing to an increased contribution from the blank reaction at higher H_2O_2 concentrations.

A few experiments were performed aimed at providing insights into the origins of the observed metal-free catalysis. Reactions performed under nitrogen showed no difference with the reactions performed under air. When the reaction was performed with $H_2{}^{18}O_2$ (Campro Scientific) analysis of the sulfoxide product by GC–MS showed that the oxygen (100%) is derived from H_2O_2. Addition of the radical scavenger Trolox™-C,§ a water soluble analog of vitamin E, had no influence on the conversion or enantioselectivity, consistent with hydroxyl radicals not being involved in the enantioselective oxidation.

This leaves us with the question of the origin of the observed oxygen transfer catalysis. It is not metal-based as there is no metal ion in the active site. Although the chelating agent EDTA completely inhibited the enantioselective oxidation this is probably due to removal of calcium ions required for the stability of the enzyme. The crystal structure of phytase from *Aspergillus ficuum* was recently resolved to 2.5 Å, showing that an aspartate residue (Asp339) is located in the active site.[13] Similarly, acid phosphatases are also known to contain aspartate in the active site.[7] Hence, it is tempting to speculate that this aspartate plays a key role in the observed catalysis. Reaction of the free carboxylate group with H_2O_2 would give the corresponding peroxycarboxylic acid which could be the active oxidant. When the reaction was performed with *tert*-butyl hydroperoxide (TBHP) no catalysis was observed consistent with the above proposed formation of peroxycarboxylic acids. Appropriate site-directed mutagenesis studies should be able to confirm the key role of Asp339 in the catalytic mechanism.

In conclusion, we have demonstrated the feasibility of rationally designing a semi-synthetic peroxidase *via* incorporation of vanadium into the active site of phytase by exploiting the structural similarity of vanadate to phosphate. Surprisingly, the metal-free phytase also catalyses enantioselective oxidation and further studies are underway aimed at clarifying the mechanism and exploring the scope of this novel oxygen transfer catalysed by a hydrolase.

We gratefully acknowledge a gift of phytase by Gistbrocades N.V. The financial support of the Dutch Innovation Oriented Program on Catalysis (IOP catalysis; IKA94013) is gratefully acknowledged.

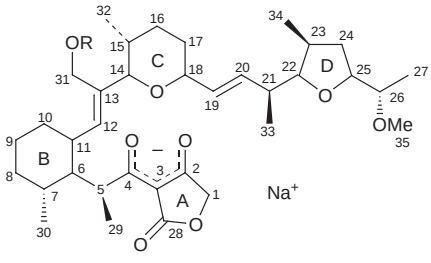
The structure of the ionophoric antibiotic sodium tetronasin (M139603) in chloroform solution has been determined using NMR spectroscopic methods and is shown to contain a water molecule bound to the sodium which is hydrogen bonded to oxygens in the molecule.

The ionophoric antibiotics are an intriguing series of compounds that have widespread biological action.[1] In particular they are efficient mediators of the transport of metal ions and H^+ through the limiting membranes of cells. This property is presumed to be responsible for their biological activity through the dissipation of trans-membrane ion concentration gradients. It is believed that in most cases the transport occurs by the ionophore forming a 1 : 1 complex with the metal ion which then diffuses through the membrane.



1 R = H [Tetronasin (or M139603)]

2 R = 
The discovery of M139603 **1** (subsequently called tetronasin) an ionophoric antibiotic from the aerobic fermentation of *Streptomyces longisporoflavus* NCIB 11426, was announced by ICI in 1980.[2] Its structure is rather different from those of the other common acidic ionophoric antibiotics in that it possesses a biosynthetically rare acid group in the form of an acyl tetronic acid moiety. Tetronasin and several of its derivatives have shown useful properties as coccidiostats and as growth promoters in ruminant animals, reducing methane production and increasing the propionate/acetate ratio in the rumen.[2–4]

A substantial amount of experimental work on the biosynthesis[5] *via* a polyketide mechanism and the synthesis[6–9] of tetronasin has been reported in recent years.

Experiments on the transporting ability of tetronasin for Li^+, Na^+ and K^+ through model biological membranes were performed by Riddell and Arumugam.[10] According to this work tetronasin is one of the faster transporting ionophoric antibiotics for the alkali metal ions. Interestingly, tetronasin displays the fastest association and dissociation rates in the membrane surface yet measured for the sodium salt of an ionophoric antibiotic.

The structure of tetronasin has been determined crystallographically from the 4-bromo-3,5-dinitrobenzoyl derivative **2** of the sodium salt.[11] The sodium ion was observed to be six-coordinated in the solid through five oxygen atoms from the molecule, two of which come from the tetronic acid, and a water molecule which occupies the sixth position. The sodium ion was observed to be at the centre of a very distorted octahedron.

An early report of the NMR spectra of tetronasin[12] suggested that the solution conformation of the ionophore is similar to that determined crystallographically. The solution conformation must, however, differ from that of the solid because ester formation at C(31) removes a hydroxy group which would undoubtedly be involved in hydrogen bonding in the original molecule. It seemed to us that modern NMR methods for the determination of the structure of biomolecules in solution would be appropriate to be applied to the sodium salt of tetronasin. The interest in the solution structure is two-fold. First, it would assist in explaining the rapid association and dissociation rates of the sodium salt during the transport process. Secondly, it might be possible to locate the bound water molecule, observed by crystallography, using NMR methods. Water molecules bound to biologically important molecules are potentially of functional importance and an ability to identify bound water molecules is of considerable significance. Other ionophoric antibiotics whose structures in solution have been solved by NMR methods include sodium salinomycin[13] and sodium monensin.[14]

The assignment of the ^1H NMR spectrum of sodium tetronasin[15] in $CDCl_3$ was straightforward. The resonances for H(12), H(19) and H(20) can readily be identified in the 1D ^1H NMR spectrum. Starting from these resonances the use of COSY and DQF COSY connectivities gave most of the assignments. The region between 1 and 2 ppm is rather crowded and so the chemical shifts of geminal hydrogen pairs were determined by a 2D HSQC experiment at natural abundance. Conformationally relevant scalar couplings were obtained from the 1D spectrum, from a *J*-resolved 2D spectrum and from an E. COSY spectrum.

NOESY spectra were obtained with mixing times of 100, 200, 300, 450 and 600 ms and NOE build up rates proved to be essentially linear in the 0–200 ms range. The NOESY cross peak intensities at 200 ms were used to establish distance restraints. The NOESY spectra contained cross peaks due to exchange between C(31)OH and a broad peak at around 1.77 ppm. At ambient temperature no additional NOESY cross peaks were observed from either of these peaks. However, as the temperature is lowered to −20 and −25 °C additional cross peaks of low intensity were observed from the 1.77 ppm peak which had shifted to 2.20 and 2.28 ppm respectively. Importantly, these cross peaks moved with changes in the position of the diagonal peak. At −25 °C these cross peaks are to $C(31)H_2$ (two cross peaks), C(19)H and $C(29)H_3$. The existence of these cross peaks clearly shows that the broad resonance in the 2.0 ppm region is from a bound water molecule. The absence of these cross peaks at ambient temperature is presumably due to rapid exchange of the bound water molecule.

Starting from the structure derived from X-ray crystallography and employing standard methods[16] including simulated annealing with the use of 49 NOE distance constraints, applied as ±7% of the measured NOE distance, a structure of the molecule was derived without the additional bound water

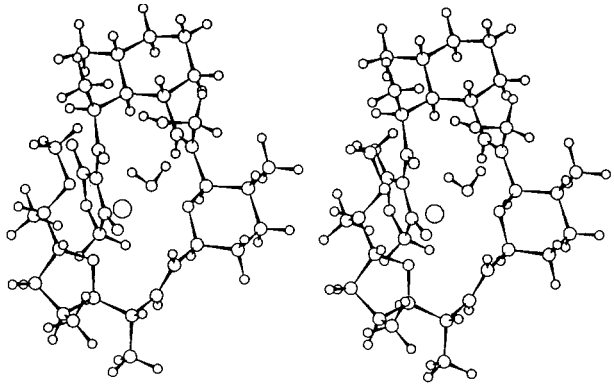


Fig. 1 Stereoview of the finalised structure of sodium tetronasin in solution incorporating the bound water molecule found from molecular modelling and incorporating the NMR distance constraints

molecule. The C(31) hydroxy group is found to hydrogen bond to the C(4) oxygen. The sodium is surrounded by five oxygen atoms. At this point the additional water molecule was introduced which was held close to the sodium with a 5 Å tether. No NOE constraints from the four cross peaks due to the bound water were introduced because the quantification of the NOE intensities was complicated by chemical exchange. The final structure, shown in Fig. 1, emerged after initial minimisation followed by restrained simulated annealing from 400 to 10 K and a final minimisation.

To test the goodness-of-fit a back calculation of the NOE intensities was performed on the model without the bound water molecule, which gave a relative root mean square deviation of 0.16.[17]

Molecular modelling without the NOE constraints led to the molecule unfolding after 100 ps of molecular dynamics at 303 K. A similar calculation on the coupling constants, which had not been used as restraints in the molecular modelling, gave a root mean square deviation of 0.05.[18] The model is thus seen to be in very satisfactory agreement with the experimental data.

The sodium is seen to be at the centre of a distorted octahedron of oxygen atoms with sodium to oxygen distances in the region 2.42 to 2.67 Å. The C(31) hydroxy group remains hydrogen bonded to the C(4) oxygen and the additional water molecule, whose oxygen is 2.67 Å from the sodium, is hydrogen bonded at one end to the C(31) hydroxy group and at the other to the C(26) (methoxy) oxygen.

In contrast to the other ionophoric antibiotics such as monensin, tetronasin has no tail to head hydrogen bond to 'close the circle' within the ligand. The only hydrogen bond involving a hydroxy group occurs across the molecule near the head between the C(31) hydroxy group and the C(4) oxygen. The water forms an additional 'brace' in a 'head to tail' fashion but this is expected to be less strong than a direct hydrogen bond. The C(31) hydroxy group thus has a defined role of structural importance for the sodium tetronasin complex. The design of other ionophoric materials with five oxygen ligands may well require water to be incorporated in the structure in a similar manner to the water in tetronasin. Also, unlike the other ionophoric antibiotics tetronasin takes a water molecule with it into the hydrophobic environment of a chloroform solution and, by implication, into the fatty interior of the membrane. Finally, during the initial series of simulated annealing all of the conformations observed had the acid head group of the molecule close to the sodium ion but in some of these conformations the oxygens remote from the tetronic acid had broken free. These three factors suggest why the on–off rates for sodium with tetronasin are the fastest yet observed for the ionophoric antibiotics. The lack of a direct head to tail hydrogen bond and the presence throughout of one molecule of water will lead to fewer steps in the association/dissociation processes. The lower number of steps in turn could lower the activation energies for these recognition processes.

15 All spectra were obtained at 300 K on a Varian Unity-plus 500 spectrometer operating at 500.3 MHz for ^{1}H, using standard pulse sequences unless otherwise stated.
16 All molecular mechanics simulations were carried out on Silicon Graphics O2, Origin 200 and INDY computers using MSI/Biosym's CDiscover (Discover 95) software package in an Insight II environment. For the energy calculation the extensible Systematic Force Field (ESFF) was used with a 9.5 Å cut off for van der Waals and Coulomb interactions. The effect of solvent was taken into account by application of a distance dependent dielectric constant varying from 1 to an upper limit of 4.5. During the molecular dynamics calculations the velocity Verlet integrator and 1 fs timesteps were used. The temperature was controlled by direct velocity scaling with a 10 K temperature window. Minimisation was applied after every simulated annealing in cascade manner; steepest-descent, conjugate gradient (Fletcher algorithm), Newton method (BFGS algorithm). The iteration limit was 1500 steps, and the final convergence criterion was 0.0001 as maximum derivative.
17 No allowance was made in this unweighted calculation for the relatively larger errors that occur with the smaller NOE observations.
18 The root mean square deviation (rmsd) is here defined as:

$$\text{rmsd} = \sqrt{\frac{\sum_n \left(\frac{J_{(obs)} - J_{(calc)}}{J_{(obs)}} \right)^2}{n}}$$

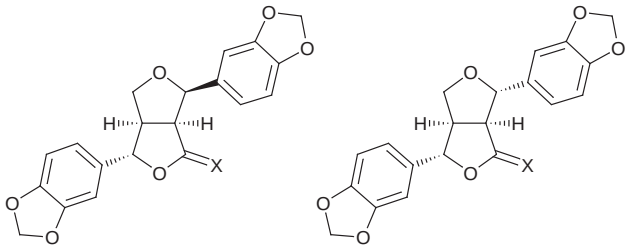
Synthesis of *endo,exo*-furofuranones using a highly diastereoselective C–H insertion reaction

Richard C. D. Brown*† and Jeremy D. Hinks

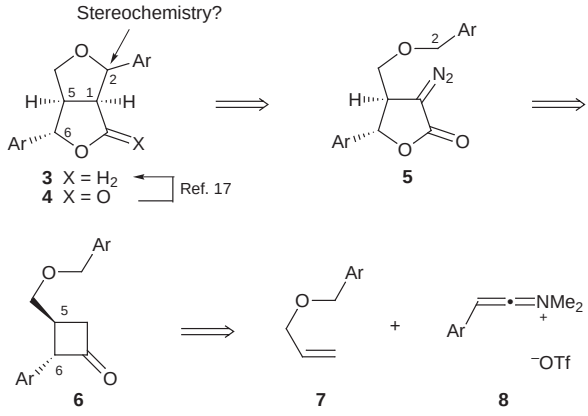
Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ

A highly stereoselective ring closure of α-diazo-γ-butyrolactones to form the 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane ring system is reported; a formal synthesis of the furofuran lignan asarinin 1 is also described.

The 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane ring system is a key structural element in a large sub-class of lignan natural products, the furofuranoids (*i.e.* **1**, **2**, sesamin and aptosimon).[1,2] The electron rich aromatic substituents, which are characteristic of lignans, occupy *endo*- or *exo*-orientations on the 3,7-dioxabicyclo[3.3.0]octane core, which itself may be present at various levels of oxidation. The challenge of correctly establishing the four contiguous stereogenic centres present within the furofuranoids combined with their diverse biological activities has provoked substantial interest in their synthesis.[1–3] Our synthetic interest lay in the possibility of employing a C–H insertion reaction of an α-diazo-γ-lactone to form the 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane ring system. By targeting a furofuranone such as **4** as an advanced intermediate (Scheme 1), we hoped to develop a versatile route which could also be applied to the synthesis of other furofuranoids like asarinin **1** and cinnamonol **2**.



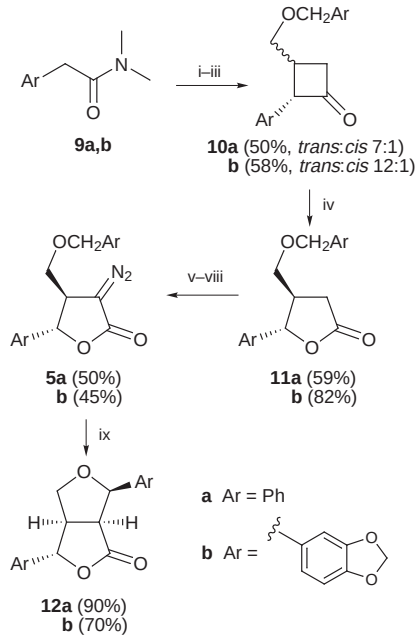
Our retrosynthetic analysis of the furofuranone **4** identified diazolactone **5** as a potential precursor (Scheme 1). Intramolecular C–H insertion into one of the diastereotopic C2–H bonds present in **5** would be expected to provide the furofuranone scaffold. We did not consider that the stereochemistry at the ring junction would be an issue, assuming that the 1,5-*cis*-adduct would be obtained. However, we were more reluctant to predict the stereochemical outcome at C2, hoping that we might control the stereoselectivity at this position through the use of different catalysts and conditions. The *trans*-relationship of the C5 and C6 substituents would be established in the cyclobutanone **6** which would arise from a [2+2] olefin–keteniminium salt cycloaddition reaction between **7** and **8**.



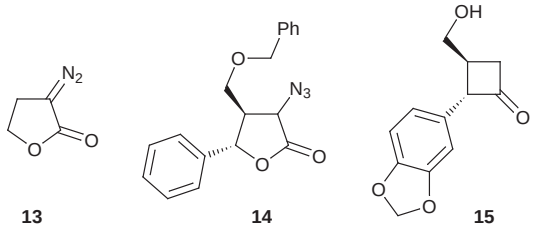
Scheme 1

Initial synthetic studies focused on the synthesis of a simple furofuranone **12a** (Ar = Ph, Scheme 2). According to Ghosez's protocol,[4] amide **9a**[5] was converted *in situ* to the corresponding keteniminium salt which underwent cycloaddition with benzyl allyl ether **7a**.[6] After hydrolysis of the intermediate cyclobutanone iminium salts, a mixture of diastereomeric cyclobutanones **10a** (*trans*:*cis*, 7:1) was obtained which was further enriched in the *trans*-isomer by careful chromatography. Due to the instability of the cyclobutanone **10a** it was immediately oxidised to the γ-lactone **11a**‡ using either MCPBA or H_2O_2 in AcOH.[7]

A search of the literature only revealed one previously reported synthesis of an α-diazo-γ-butyrolactone **13** which does not possess an additional stabilising group adjacent to the diazo functionality.[8] Although the deformylative diazo transfer procedure used to prepare **13** did provide our desired diazolactone **5a**, the yield was very poor, so alternative diazo transfer procedures were investigated. In view of our reluctance to



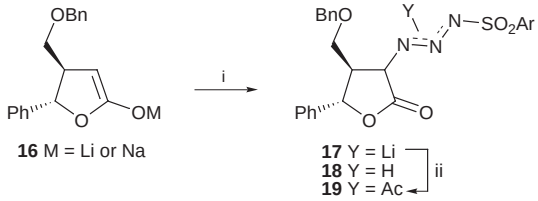
Scheme 2 *Reagents and conditions*: i, Tf_2O, CH_2Cl_2, −20 °C; ii, **7a** or **7b**, 2,6-di-*tert*-butylpyridine, CH_2Cl_2 (followed by 1equiv. K_2CO_3 for **7b**); iii, $NaHCO_3$ (aq.); iv, H_2O_2, AcOH; v, LiHMDS, THF; vi, *p*-$NO_2C_6H_4SO_2N_3$, THF, −78 °C; vii, AcCl; viii, DMAP, THF; ix, 2 mol% $Rh_2(OAc)_4$, CH_2Cl_2, room temp.



13 **14** **15**

pursue other methods of decarbonylative diazo transfer,[9,10] and the existence of encouraging reports of direct diazo transfer to ester and imide enolates, we focused our efforts on the later approach.[11,12]

The conditions reported for direct diazo transfer to ester enolates failed to give satisfactory yields of the diazo lactone **5a**, with azide **14** isolated as the major product. Although disappointing, the isolation of substantial amounts of azide **14** strongly implied that the intermediate triazine anion **17** was being formed efficiently (Scheme 3). An earlier study of the decomposition of triazines had shown that the relative proportions of diazo transfer and azide transfer were influenced by the reaction conditions.[12] In our case the triazine **18** proved to be too unstable to isolate,§ however, treatment of the reaction mixture with AcCl provided a mixture of isomeric *N*-acetyltriazines **19**.[13]¶ When the acetyl triazines **19** were treated with an equivalent of DMAP smooth conversion to a 1:1 mixture of azide **14** and the desired diazo lactone **5a** was observed. The reason for the increased proportion of diazo lactone **5a** are not clear at present although it is tempting to suggest that generation of a metal-free triazine anion, by the nucleophilic deacylation of **19** with DMAP, is important.



16 M = Li or Na

17 Y = Li
18 Y = H
19 Y = Ac

Scheme 3 *Reagents and conditions*: i, *p*-$NO_2C_6H_4SO_2N_3$, THF, −78 °C; ii, AcCl, −78 °C to room temp.

Gratifyingly, the key C–H insertion reaction required to set up the furofuranone framework proceeded extremely cleanly when diazo lactone **5a** was treated with a catalytic amount of $Rh_2(OAc)_4$, providing a single diastereoisomeric product **12a**. The relative stereochemistry of the furofuranone **12a** was assigned as *endo,exo* on the basis of NOE experiments. We were intrigued by the possibility of conducting the same intramolecular C–H insertion reaction under thermal conditions, which might provide altered stereoselectivity. In fact, heating the diazo lactone **5a** in 1,2-dichloroethane cleanly afforded the same cyclised product **12a**, again in excellent yield and stereoselectivity.

Relatively few of the published approaches to the synthesis of furofuranoid lignans have addressed the stereoselective synthesis of the less common *endo,exo* structures.[14–19] To demonstrate the scope of our approach to the synthesis of furofuranoid containing natural products the synthesis of *epi*-aptosimon **12b** was investigated. The conversion of *epi*-aptosimon **12b** to the furofuran lignan asarinin **1** has been reported previously.[17]
Initial attempts to carry out the [2+2] cycloaddition reaction of allyl ether **7b**[6] (Ar = 3,4-methylenedioxyphenyl) with the keteniminium salt derived from amide **9b**[20] failed to provide **10b**. Instead the major isolated product was the alcohol **15** arising from acid-catalysed cleavage of the benzylic ether bond which was assisted by the electron donating methylenedioxy group. The problem was almost certainly due to the formation of di-*tert*-butylpyridinium triflate under the reaction conditions. Fortunately this problem was easily resolved by the addition of anhydrous K_2CO_3 to the reaction mixture, allowing the desired cycloadduct **10b** to be obtained in good yield.

Baeyer–Villager oxidation of **10b** followed by diazo transfer to the resulting lactone **11b** afforded the cyclisation precursor **5b** in a yield of 37% from ketone **4b**. As was the case for the model diazo lactone **5a**, the C–H insertion reaction of **5b** proceeded cleanly to give the known furofuranone (±)-*epi*-aptosimon **12b** in good yield.

In summary, we have achieved a concise and diastereoselective synthesis of the 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane ring system. Significant contributions include: the development of conditions for conducting the keteniminium–olefin [2+2] cycloaddition reaction with alkenes bearing acid-sensitive functionality; and a method for effecting diazo transfer on γ-butyrolactones to provide the α-diazo-γ-butyrolactones **5** in acceptable yield. Finally, (±)-*epi*-aptosimon **12b** has been synthesised using this approach, representing a formal synthesis of the natural product (±)-asarinin **1**.

We thank the Royal Society for a University Research Fellowship (R. C. D. B.). We would also like to acknowledge the use of the EPSRC funded Chemical Database Service at Daresbury.[21]

Fast oxygen uptake/release over a new CeO_x phase

Daniela Terribile,[a] Jordi Llorca,*[b] Marta Boaro,[a] Carla de Leitenburg,[a] Giuliano Dolcetti[a] and Alessandro Trovarelli*[a]

[a] *Dipartimento di Scienze e Tecnologie Chimiche, Università di Udine, via Cotonificio 108, 33100 Udine, Italy. E-mail: trovarelli@dstc.uniud.it*

High-temperature reduction/oxidation cycles promote the oxygen storage capacity of mesoporous ceria; this is associated with the formation during reduction of a hexagonal CeO_x phase which on reoxidation gives amorphous ceria.

Ceria has long been recognized as a key component of catalysts for the treatment of emissions from automobiles. One of the most important functions that it performs is to act as an oxygen buffer, releasing oxygen for CO and hydrocarbon oxidation in a rich environment (excursion on the reducing side of the stoichiometric point) and storing oxygen from O_2 and NO during lean operations (excursion on the oxidizing side of the stoichiometric point).[1] This fast oxygen release/uptake is a consequence of the ease with which ceria can be reduced/oxidized and shift reversibly from the +4 to the +3 oxidation state in accordance with eqn. (1).

$$CeO_2 \rightleftharpoons CeO_x + 0.5(2 - x)O_2 \; (1.5 < x < 2) \qquad (1)$$

Under conditions typically encountered in auto-exhaust catalysis, this reaction occurs easily and reversibly, and CeO_2 is able to accommodate a large number of oxygen vacancies while maintaining its fluorite-type lattice.

The ability to store and release oxygen under actual operating conditions is affected by several parameters, particularly ageing and the consequent loss of surface area, which strongly influences the ability of ceria to perform its action.[2] To partly overcome these problems, much effort has been devoted to the preparation of ceria with enhanced textural and oxygen storage properties. Several strategies have been adopted, including the use of ceria doped with lanthanide or transition metal and/or the development of novel preparation methodologies.[3,4] We have recently described the preparation of mesoporous ceria with enhanced textural properties, demonstrating that by using surfactants as templating agents, CeO_2 with surface area exceeding 200 $m^2\ g^{-1}$ could be obtained.[5] Here, we report the preliminary results on the redox and oxygen storage behaviour of this high-surface area ceria after study of its structural and morphological evolution under a reducing and oxidizing environment. For the first time, a direct relation between the formation of a new reduced phase and fast oxygen uptake has been established. This adds to the basic understanding of the mechanism of oxygen storage in these materials. In addition, a comparison of mesoporous ceria with conventionally prepared CeO_2 will show the importance of the preparation method in the development of materials with novel properties.

High-surface area ceria was prepared according to the methodology previously described.[5] The sample used in this study had a surface area of 194 $m^2\ g^{-1}$ after calcination at 723 K, which compares favorably with the value of 92 $m^2\ g^{-1}$ obtained with ceria prepared by conventional precipitation.

Fig. 1 shows the X-ray powder diffraction pattern of mesoporous ceria ($MSCeO_2$) treated under H_2 at 1373 K for 1 h. For the purposes of comparison, the XRD pattern of conventionally prepared ceria ($CVCeO_2$) subjected to the same treatment under H_2 is also shown. In contrast to the pattern of $CVCeO_2$, the diffractogram of $MSCeO_2$ reduced at 1373 K clearly shows the presence of more than one phase. Peaks belonging to cubic CeO_2 are indicated with an arrow. All the other signals originate from a single reduced 'CeO_x' phase. Careful analysis of the CeO_x phase diffraction peaks enables us to identify a hexagonal unit cell with $a = 9.626(4)$ and $c = 7.076(3)$ Å. This hexagonal phase, which is isostructural with ternary compounds of the type $Pr_8Si_6O_{24}$ or $Sm_4Si_3O_{12}$, has not previously been reported in the phase diagram of non-stoichiometric cerium oxide at this composition range.

The stability of the new hexagonal phase on reheating under air was followed by *in situ* temperature-programmed XRD experiments. As the treatment temperature increases, the relative intensities of all the peaks attributed to the new hexagonal CeO_x phase progressively decrease while maintaining their relative proportions, providing additional evidence that all the indexed lines correspond to the same phase. Increasing amorphization of the CeO_x phase is observed between 673 and 773 K, whereas at 1073 K reoxidation is complete and the CeO_x phase has been totally transformed to cubic CeO_2. Analysis of the shape of the diffraction signals indicates that during this process small CeO_2 crystallites originate from amorphous ceria. The process is fully reversible and subsequent redox treatments alter neither the structural features and morphology of the observed phase nor the dynamics of its formation. The presence of both cubic and hexagonal phases in reduced mesoporous ceria was confirmed by high-resolution transmission electron microscopy and electron diffraction technqiues. Fig. 2 shows an HREM image and the oriented SAED pattern of a near-discrete hexagonal CeO_x phase particle. From the ED pattern it is inferred that the particle belongs to the hexagonal system with lattice parameters $a = 9.62(4)$ and $c = 7.07(1)$ Å. These values are in excellent agreement with those obtained by XRD. Reduction carried out under temperature-programmed conditions (5% H_2 in Ar, 10 K min^{-1}) indicates that the stoichiometry of this phase is CeO_x with x close to 1.66. Reoxidation of the

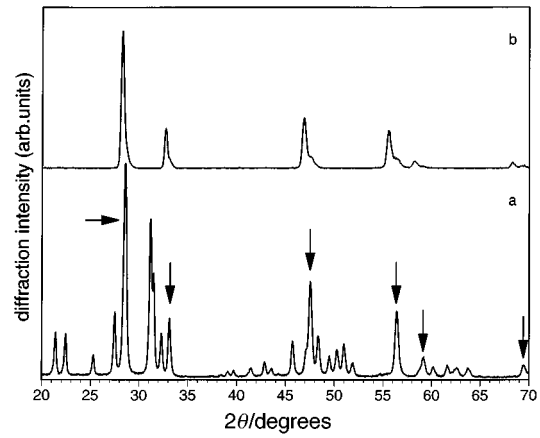

Fig. 1 X-Ray diffraction pattern of $MSCeO_2$ (a) and $CVCeO_2$ (b) treated under hydrogen for 1 h at 1373 K. Before measurements, the samples were cooled at room temperature under hydrogen.

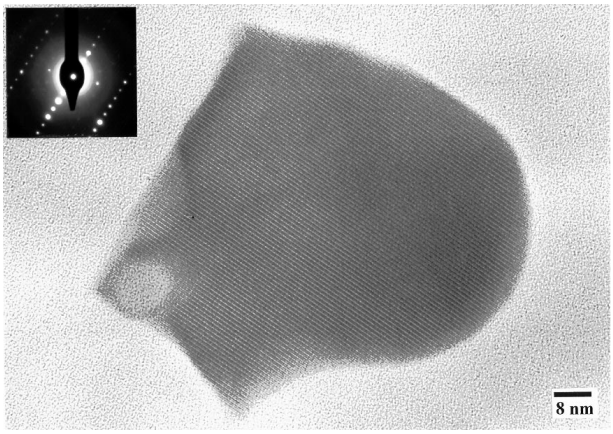

Fig. 2 High-resolution transmission electron microscope image and associated electron diffraction pattern (inset) corresponding to hexagonal CeO_x phase present in reduced mesoporous ceria. The particle is oriented along [$\bar{4}8\bar{4}3$]. Planes close to origin are ($\bar{1}10\bar{4}$) at 1.73 Å and ($\bar{1}010$) at 8.34 Å.

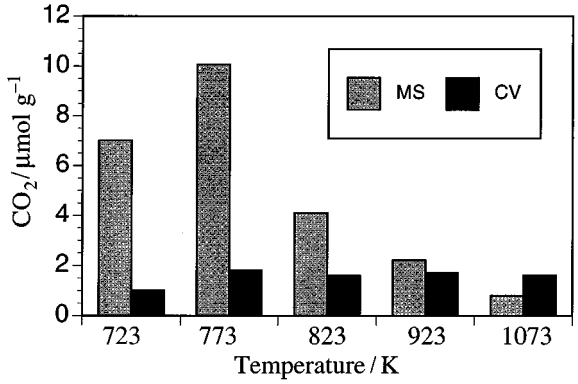

Fig. 3 Oxygen storage capacity of $MSCeO_2$ (gray bar) and $CVCeO_2$ (black bar) measured at 673 K after a redox cycle. Reduction under H_2(5%)–Ar at 1373 K for 1 h and oxidation under air for 1 h at the temperature indicated.

phase (1% O_2 in He, 10 K min^{-1}) occurs slowly at room temperature and complete reoxidation is observed near 800 K. In contrast, oxidation of reduced ceria (obtained from $CVCeO_2$) occurs easily even at room temperature and most of the reoxidation is observed at temperatures lower than 400 K.

The oxygen storage behaviour under dynamic conditions of CeO_2 obtained after oxidation of the CeO_x phase at different temperatures was studied by the method of alternately pulsing O_2 (2% in He) and CO (4% in He) over the catalyst (0.5 ml pulse size) at a temperature of 673 K and following CO_2 evolution.[6] The results, reported in Fig. 3, indicate that there is an optimum temperature for the reoxidation of CeO_x at which the highest conversion to CO_2 occurs. In contrast, reduction and oxidation of $CVCeO_2$ does not produce any variation of oxygen storage capacity. This unique behaviour can be related to the different phases formed in the two samples. Reduction under hydrogen at high temperature causes cubic ceria to lose oxygen and to form non-stoichiometric suboxides which finally give Ce_2O_3. However if the temperature is below 1373 K, only intermediate stoichiometries, which maintain the fluorite structure, are formed from cubic ceria. On reoxidation at room temperature, these oxides easily transform back to CeO_2.[7] In the case of reduced $CVCeO_2$, the fluorite structure is maintained and reoxidation merely fills up the oxygen vacancies. In contrast, the reoxidation of the CeO_x phase to pure CeO_2 in reduced $MSCeO_2$ implies the transformation of a hexagonal phase to a cubic one. This transformation does not occur directly but takes place through the formation of an intermediate amorphous phase whose concentration reaches a maximum in the range 673–773 K. The transformation of amorphous CeO_2 to crystalline ceria originates small CeO_2 crystallites deposited on bulk CeO_2. It is suggested that the presence of this amorphous/crystalline ceria on the top of large CeO_2 crystallites is responsible for enhancement of the oxygen storage capacity in this temperature range for it is known that small CeO_2 crystallites display unusually high defect and transport properties[8] which could enhance surface and bulk ion mobility. consequently increasing the rate of fast oxygen uptake/release over reduced/oxidized ceria. Reoxidation at temperatures higher than 823 K results in the transformation of amorphous or small ceria crystallites into bulk sintered ceria with a loss of oxygen storage. At this point, to recover activity, the material should be subjected to another redox cycle to form hexagonal CeO_x.

One step synthesis of highly active and selective epoxidation catalysts formed by organic–inorganic Ti containing mesoporous composites

Avelino Corma,* José L. Jordá, Maria T. Navarro and Fernando Rey*

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Ti-MCM-41 materials with methylated silicons have been prepared in one step synthesis; the resultant organic–inorganic composites are highly stable and present the highest activity and selectivity ever reported on Ti containing mesoporous catalysts for the epoxidation of olefins using organic peroxides.

The synthesis of molecular sieve mesoporous materials[1] have expanded the possibilities of zeolites and zeotypes, opening new possibilities in the fields of adsorption and catalysis.[2] Postsynthesis treatments devoted to prepared inorganic–organic composites have been carried out by silylating MCM-41 and MCM-48 materials, and in this way their stability, adsorption and catalytic properties have been improved.[3–7] Following the methodology used in sol–gel chemistry to functionalize amorphous silica, organically functionalized mesoporous silicas have been prepared by the co-condensation of tetraethoxysilane and organoalkoxysilanes in the presence of surfactant templates.[8] This method has been successfully extended to the introduction of thiol, amine, epoxide, imidazole and alkyl functionalities.[9] Taking this into account, and the fact that titanium containing molecular sieves increase their activity and selectivity by a postsynthesis silylation,[5,10] prompted us to prepare by direct synthesis, in one step, organic–inorganic self-assembled Ti-MCM-41 materials. Here, we will show that the process is successful, resulting in epoxidation catalysts much more active and selective than any similar materials reported up to now.

The synthesis of organo-silica containing Ti-MCM-41 materials were carried out with gels having the following molar compositions: $(1 - x)$ $Si(OCH_3)_4 : x$ $CH_3Si(OCH_2CH_3)_3 : 0.26$ TMAOH : 0.15 CTABr : 24.3 $H_2O : y$ $Ti(OCH_2CH_3)_4$ where x was varied from 0.15 to 0.35 and y between 0.0166 and 0.0075 (Table 1). Crystallisation was performed at 135 °C for 24 h in Teflon lined stainsteel autoclaves. The final solids were recovered by filtration, washed with water and dried at 60 °C, overnight. The occluded surfactant was removed by a two step extraction procedure. First, the solid was refluxed in a solution of 0.05 M H_2SO_4 in ethanol for 1 h. Then, the remaining occluded surfactant was extracted by refluxing the solid in a 0.15 M solution of HNO_3 in heptane–ethanol (52 : 48) over 24 h. In both steps, a liquid/solid ratio of 50 was used.

[a] TEOS.

The materials before and after surfactant extraction were characterized by XRD, ^{29}Si MAS NMR, UV–VIS, IR spectroscopies and elemental analysis. The catalytic epoxidation of cyclohexene with *tert*-butylhydroperoxide (TBHP) on the Ti organosilica containing MCM-41 catalysts was carried out at 60 °C using an olefin/TBHP molar ratio of 4 and a liquid/catalyst ratio fixed at 20 (m/m). Aliquots of the reaction mixture were withdrawn at different reaction times and analysed by GC.

$Si(OCH_3)_4$ (TMOS) was chosen as the silica source because the structural order of the organo-silica MCM-41 samples obtained by using this precursor is superior to those of samples obtained using $Si(OEt)_4$ (TEOS).

The XRD patterns of samples prepared in the presence of different concentrations of $MeSi(OEt)_3$ (MTEOS) shown in Fig. 1, indicate that there is a limit for the incorporation of organosilica entities in the MCM-41 structure. It was found that the maximum MTEOS/Si ratio, for which a well ordered material is obtained, occurs at a value at 0.35.

Elemental analysis of the samples (Table 1) indicates that the C/N ratio is always > 19, which is the expected value if only CTA^+ filled the pores, and consequently this is an indication that CH_3Si groups are also incorporated into the MCM-41 structure. This assumption has been further established by ^{29}Si MAS NMR and IR spectroscopy. The ^{29}Si MAS NMR spectra of the methyl containing Ti-MCM-41 materials show four signals centred at −110, −100, −90, −65 and −55 ppm that can be assigned, respectively, to $Si(OSi)_4$ [Q_4], $HOSi(OSi)_3$ [Q_3], $(HO)_2Si(OSi)_2$ [Q_2], $MeSi(OSi)_3$ [MQ_3] and $MeHOSi(OSi)_2$ [MQ_2] environments around silicon.[11] The integrated intensity of MQ_2 + MQ_3 signals increases as the MTEOS concentration is increased in the synthesis gel, indicating that there is correspondence between the MTEOS concentration in the gel and the incorporation of CH_3Si groups in the final organosilica material. The presence and stability of CH_3Si

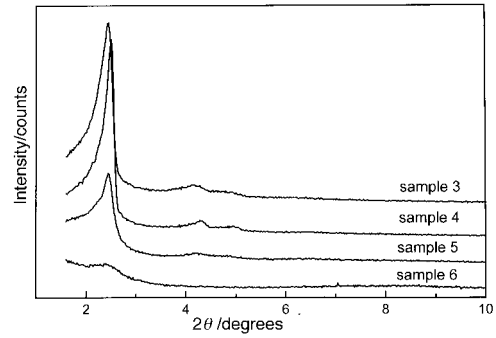

Fig. 1 XRD patterns showing the influence of the concentration of $MeSi(OEt)_3$ on the structural order of the methyl containing Ti-MCM-41 catalysts

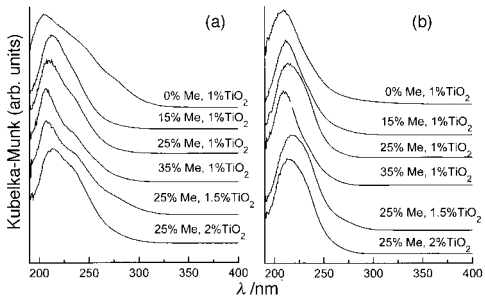

Fig. 2 UV–VIS DRS spectra of the methyl containing Ti-MCM-41 materials of as prepared (b) and extracted (b) samples

groups have been also studied by IR spectroscopy. The IR spectra of the sample heated under vacuum at different temperatures, show bands at 2974 and 1411 cm^{-1}, that can be assigned to methyl groups directly linked to silicon,[12] while, bands appearing at 2956, 2927 and 1464 cm^{-1} can be assigned to the CTA^+ cations located within the pores of the MCM-41 structure.[3] It is observed that the bands attributed to CTA^+ cations decrease in intensity with increased temperature, while bands assigned to methyl groups directly bonded to the silica wall remain nearly unchanged up to temperatures as high as 700 °C, indicating that the Si–C bond in the MCM-41 structure is highly stable to heat.

The UV–VIS spectra of the Ti containing inorganic–organic mesoporous silica materials for the as-prepared and extracted materials containing different methyl group concentrations on the silica walls are shown in Fig. 2(*a*) and (*b*), respectively where a narrow band centred at 220 nm, is taken as proof of Ti incorporation into the silica wall.[14,15] Also, when the UV–VIS spectra of the extracted samples is compared with those of the as-prepared samples, it was found that the 220 nm band is even narrower in the extracted samples than in the as-prepared materials. This indicates that Ti is located in a more distorted tetrahedral environment when the surfactant fills the pores of the MCM-41 structure, similarly to Ti-MCM-41 without any Si–C bonds.

The UV–VIS spectra for samples containing different amounts of Ti [Fig. 2(a) and (b)] in the synthesis gel showed that the 220 nm band becomes broader and a shoulder at 240 nm appears when the Ti content increases. However, after extraction all the samples show a very similar UV–VIS spectra, indicating that during extraction the tetrahedral coordination around the Ti centers becomes more regular.

The catalytic activity of the methyl containing samples for the epoxidation of cyclohexene pass through a maximum when *ca*. 25% of the silicon atoms are methylated. However, the selectivity to the epoxide decreases with increased methyl content, while the efficiency of TBHP increases with level of organic groups on the silica wall [Fig. 3(*a*)–(*c*)].

The production of epoxide calculated after 30 min of reaction was 10.6 mol min^{-1} (mol Ti)$^{-1}$ which gives an initial reaction rate, assuming a pseudo-first order reaction, of 21 mol min^{-1} (mol Ti)$^{-1}$ with a selectivity of 94% to the epoxide at a level of conversion of 98%. These results are, so far, the best ever obtained on Ti-MCM-41 incorporating Ti either by direct synthesis[16] or by anchoring titanocene[17] [0.4 and 2.1 mol min^{-1} (mol Ti)$^{-1}$ respectively], and they are much better than those obtained on titanium–silica cogels[18] [4.7 mol min^{-1} (mol Ti)$^{-1}$].

The inorganic–organic Ti-MCM-41 is highly stable in the presence of water and it represents one step forward in the preparation of epoxidation catalysts.

Supramolecular assembly of well-separated, linear columns of closely-spaced C_{60} molecules facilitated by dipole induction

Leonard J. Barbour, G. William Orr and Jerry L. Atwood*

Department of Chemistry, University of Missouri-Columbia, Columbia, MO 65211, USA. E-mail: atwoodj@missouri.edu

Co-crystallization of C_{60} with *p*-bromocalix[4]arene propyl ether results in a remarkably well packed structure; the calixarene molecules pack with their dipole moments aligned unidirectionally and the unusually close van der Waals contact between the C_{60} molecules is most likely a result of an opposing induced dipole.

Solid-state supramolecular systems involving fullerenes are of interest with regard to the development of novel nanostructures with potentially interesting properties.[1] Although the exploitation of non-covalent interactions is an area of especially intense focus in the field of crystal engineering,[2] this approach cannot be applied effectively to the supramolecular manipulation of fullerenes since these molecules simply lack the necessary functionality. Thus, in order to 'engineer' a desired arrangement of C_{60} molecules in the solid state, one needs to consider their size and shape as the principal structure-directing properties. In addition to optimizing their energies of interaction, molecules will tend to arrange in a manner that makes efficient use of the available space and it is because these two mechanisms cooperate in a subtle manner that crystal structures are generally difficult to predict with accuracy.

Pure C_{60} crystallizes in a face centered cubic (fcc) lattice as a cubic close packed (ccp) arrangement of spheres.[3,4] An array of this type results in the formation of large voids in the lattice (the packing efficiency is only *ca* 74 %) and it follows that co-crystallization with small molecules, or even irregularly shaped larger molecules, may lead to more efficiently packed structures of enhanced stability. Indeed, this statement is supported by several crystal structures of supramolecular complexes of C_{60} that have been reported in recent years.[5] In some cases, it appears that the structure entails only a slight modification of the pure C_{60} structure with small molecules or ions occupying the voids between the spheres, while in other cases, the structure bears little or no resemblance to the pure fullerene phase.

We are currently investigating supramolecular systems composed of co-crystals of calixarenes and fullerenes. The structural chemistry of calixarenes is usually focused on exploitation of their intramolecular cavities for molecular inclusion and in this regard we and other workers have recently reported inclusion complexes of calix[5,6]arene derivatives with C_{60} and C_{70}.[6] In contrast, the calix[4]arenes are not suited to the formation of analogous inclusion complexes with fullerenes because their cavities are relatively small. Moreover the well-known C_{4v} cone conformation of these molecules is usually dependent on the presence of hydroxyl groups at the lower rim (*i.e.* the cone is stabilized by a cyclic hydrogen bonded arrangement), and substitution at this position gives rise to the so-called 'pinched-cone' C_{2v} conformation with an even smaller cavity. Despite the reduced possibilities for the formation of true inclusion compounds, simple calix[4]arene derivatives are similar in dimensions to C_{60} (*ca* 10 Å) and thus co-crystallization of these species may result in interesting and efficiently packed arrangements of the molecules in stoichiometric proportions.

As part of our ongoing study of the interactions between calixarenes and fullerenes, we are currently investigating the effects of substitution at both the upper and lower rims of calix[4]arene (compounds **1**–**4**) on solid-state packing arrangements when co-crystallized with fullerenes.

We now present the results of a remarkably interesting packing mode for a co-crystal of C_{60} with **1**.

Slow diffusion of propan-2-ol into a solution of **1** and C_{60} (5:1 molar ratio) in *o*-dichlorobenzene resulted in the formation of crystals suitable for single-crystal X-ray diffraction analysis.† The molecular structure of the final model is shown in Fig. 1 and the overall packing arrangement of the structure is shown in Fig. 2. The structure is acentric and all the calixarene molecules are arranged in one-dimensional strands (in a head-to-tail arrangement) parallel to [001] such that their dipole moments have the same orientation throughout the crystal. One set of distal propyl groups on each calixarene molecule protrudes down into the small voids between the bromine atoms of the calixarene directly below. The remaining two propyl groups flare out to fill lattice voids associated with the packing of adjacent calixarene strands.

The C_{60} molecules are also arranged in one-dimensional strands running parallel to [001] at 0,0,*z* and $\frac{1}{2},\frac{1}{2},z$. Since the space group symmetry is consistent with an orientationally disordered C_{60} molecule manifesting as a sphere of uniform electron density, the exact positions of the fullerene atoms cannot be determined. However, it is fortuitous that the center···center distance of the fullerenes is represented by the crystallographic *c* axis, which it was possible to determine

	X	R
1	Br	Pr^n
2	Br	CH_2Ph
3	I	CH_2Ph
4	Br	Me

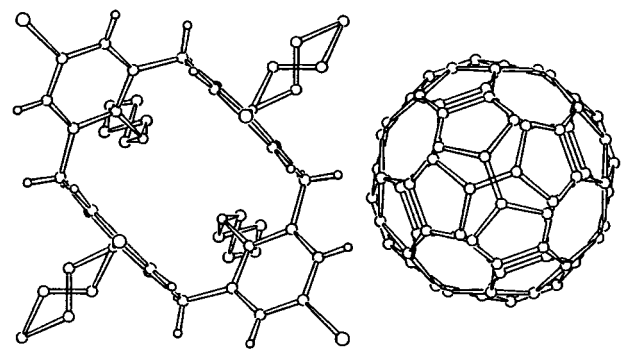

Fig. 1 Projection showing the molecular structure of the calixarene and C_{60} molecules. The calixarene assumes the pinched-cone conformation as a result of substitution at its lower rim. The C_{60} molecule was modeled as being fourfold rotationally disordered with two separate orientations.

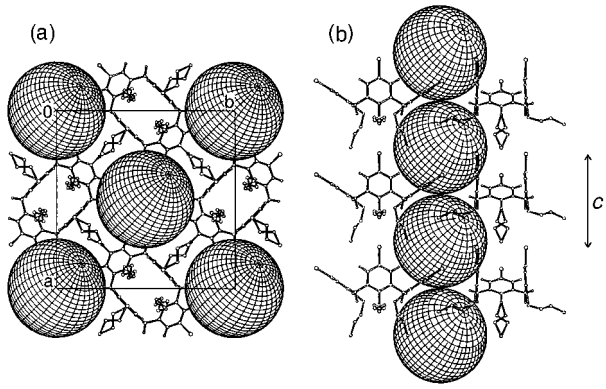

Fig. 2 Packing diagrams (hydrogen atoms omitted) viewed along (a) [001] looking down the linear columns of calixarene and C_{60} molecules, and (b) [−110] showing a side view of the columns and the space-optimization of the calixarene propyl groups.

accurately as 9.8782(5) Å at −100 °C [9.9231(6) Å at room temperature]. In contrast to the close spacing of the C_{60} molecules within the linear strands, the individual nearest-neighbor strands are separated by 12.81 Å (half the diagonal distance of the *ab* unit cell face). Within the linear strands, the $C_{60}\cdots C_{60}$ separation is 0.05 Å shorter than in the structure of pure C_{60}.[3] Taking the mean atom-to-atom diameter of the C_{60} molecule as being approximately 7.07 Å,[3,7] the short $C_{60}\cdots C_{60}$ separation along [001] implies that the shortest possible intermolecular C_{60} C···C distance for a spherically disordered molecule ranges from 2.81 to 3.15 Å. The upper limit compares favorably with previously reported values.[8,9]

The present structure is a striking example of the size–shape complementarity between **1** and C_{60} that allows the formation of an efficiently packed two-component system. This is evidenced by the observation that the crystallographic *c* axis is the repeat distance for both the calixarenes and fullerenes within their respective linear strands as shown schematically in Fig. 3. Although one-dimensional arrangements of C_{60} molecules have been observed in previously reported structures,[10] the complete structural isolation of such strands is unprecedented. Perhaps the most interesting and surprising aspect of the structure is that all the calixarene molecules align themselves in the same direction rather than adopting an overall centrosymmetric arrangement. As a consequence of this polar arrangement, the C_{60} molecules undergo dipole induction and this phenomenon

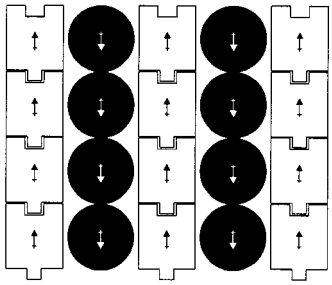

Fig. 3 Schematic representation of the packing arrangement between the calixarene and C_{60} molecules. The view is perpendicular to the *c* axis and the C_{60} molecules are represented by shaded circles. The calixarenes stack in a modular fashion with their dipoles all aligned in the same direction. The calixarene repeat distance exactly matches that for the C_{60} molecules while an opposing polarity is induced in the latter.

satisfactorily accounts for the rather close spacing of the fullerenes within their linear strands.

We are grateful for funding from the National Science Foundation.

Metal-based chirality and spin state change in 16-electron $CpML_2$ systems: a computational study of $CpW(NO)(PH_3)$

Kevin M. Smith,[a] Rinaldo Poli*[a] and Peter Legzdins[b]

[a] *Laboratoire de Synthèse et d'Electrosynthèse Organometallique, Faculté des Sciences 'Gabriel', Université de Bourgogne, 6 Boulevard Gabriel, 21100 Dijon, France. E-mail: Rinaldo.Poli@u-bourgogne.fr*

[b] *Department of Chemistry, University of British Columbia, Vancouver, British Columbia, Canada V6T 1ZI*

Density functional theory calculations indicate that $CpW(NO)(PH_3)$ possesses a planar triplet ground state, a result with significant implications for the inversion of configuration of 16e, d^6 $CpML_2$ species.

Several highly reactive Cp*W(NO)L intermediates (L = PMe_3,[1] PPh_3,[2] =$CHCMe_3$,[3] HCCPh[4–6]) have previously been shown to be generated by reductive elimination of CMe_4 or $SiMe_4$.† These proposed 16 electron, d^6 Cp*W(NO)L species are not observed as they proceed to activate C–H bonds,[1–4] coordinate weak π-acceptor ligands,[7] or engage in coupling and rearrangement reactions[5,6] with available trapping reagents. Previous theoretical studies[8–10] have demonstrated that the geometries and orbital energies of 16e, d^6 $CpML_2$ species are influenced by the bonding properties of their ligands. For example, π-donor ligands enforce a planar-at-metal conformation (*i.e.* the metal sits on the plane defined by the two ligands L and the Cp center of gravity), while pyramidal geometries are preferred for complexes containing either σ-donor (π-neutral) or π-acceptor ligands. However, these studies were carried out using semiempirical methods and so were confined to the spin singlet energy hypersurface. The computational studies that we report here for the $CpW(NO)(PH_3)$ model system indicate that the spin state can play a previously unsuspected yet critical role in 16e, d^6 $CpML_2$ species.

The optimised geometries and relative energies of the singlet and triplet $CpW(NO)(PH_3)$ complexes are shown in Table 1 and Fig. 1.‡ The singlet is pyramidal at W, as expected for a $CpML_2$ species containing π-acceptor and σ-donor ligands.[9,10] However, triplet $CpW(NO)(PH_3)$ is calculated to possess a planar geometry at W, and to be 3.3 kcal mol^{-1} (1 cal = 4.184 J) more stable than the pyramidal singlet species. No significant variation in W–NO bond distance is observed between the two different spin configurations since the W–NO π-bonding orbitals are fully occupied in both cases.[17] There is, however, the expected[18,19] slight overall extension of all bond lengths in the triplet, as well as an increase in CNT–W–P angle.

Table 1 DFT-B3LYP optimized geometries and energies for $CpW(NO)(PH_3)$

	Energy minima		Spin-crossover point	
Parameter	Singlet	Triplet	Singlet	Triplet
φ (N–W–CNT–P)	125.0	180.0	130.0	130.0
W–CNT	2.018	2.093	2.023	2.107
W–P	2.482	2.522	2.481	2.528
W–N	1.791	1.794	1.792	1.795
N–O	1.251	1.252	1.251	1.253
CNT–W–P	121.38	132.82	122.37	129.37
CNT–W–N	128.55	133.55	128.35	133.48
P–W–N	93.33	93.63	95.36	85.64
W–N–O	175.34	176.71	175.37	176.90
Relative energy/kcal mol	0	−3.3	+0.8	+0.8

While triplet $Cp*W(NO)(PR_3)$ complexes have yet to be detected spectroscopically, the intermediacy of such a species where R = Ph is consistent with kinetic measurements of the reaction between $Cp*W(NO)(\eta^2\text{-}PPh_2C_6H_4)H$ and $CNCMe_3$.[7,20] Replacing the Cp and PH_3 ligands of the model complex with bulkier Cp* and PR_3 groups would be expected to enforce a larger CNT–W–P angle and a planar-at-W geometry, thereby further destabilising the singlet state. The steric shielding of the metal centre coupled with the expected reduced reactivity[21] of the high-spin configuration should impart additional stability, making triplet $Cp*W(NO)(PR_3)$ compounds reasonable synthetic targets.§

In order to explore the role of the triplet spin state in the inversion of pyramidal, diamagnetic $CpML_2$ species, further calculations were performed at various values of ϕ for both spin states (Fig. 1). The highest energy singlet conformation is the planar geometry (ϕ = 180°), leading to an inversion barrier of 7.7 kcal mol^{-1} along the singlet spin surface, which compares well with previous studies on other 16-electron systems.[10] The energy of triplet $CpW(NO)(PH_3)$ increases relatively gradually as the geometry is distorted away from the planar-at-W conformation. As a result, the ϕ angle at which both spin states are equal in energy corresponds to a high degree of pyramidalization ($\phi \approx$ 130°), only 0.8 kcal mol^{-1} higher in energy than the singlet ground state.

The one-dimensional energetic situation illustrated in Fig. 1 would suggest a low-energy inversion mechanism for diamagnetic, pyramidal $CpW(NO)(PH_3)$ *via* the spin triplet surface.¶ However, the two geometries at the spin-crossover point are significantly different (Table 1). According to the Franck–Condon principle, both the geometries and the energies must be very similar for the spin flip process to occur. At the crossover

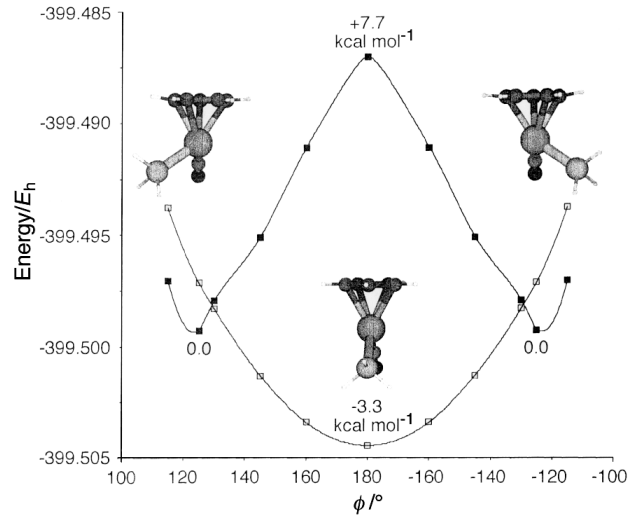

Fig. 1 B3LYP/LANL2DZ energies of optimized singlet (■) and triplet (□) $CpW(NO)(PH_3)$ at various fixed dihedral N–W–CNT–P (ϕ) angles

point (ϕ = 130°), the vertical excitation energies of singlet and triplet geometries (energy of the triplet configuration at the singlet geometry and of the singlet configuration at the triplet geometry) are 6.9 and 8.2 kcal mol^{-1}, respectively. These numbers give an estimate of the upper bound of the spin flip barrier.‖

The energetic proximity of these vertical excitation energies and the inversion barrier along the singlet surface (within *ca.* 1 kcal mol^{-1}) prohibits the definitive identification of the inversion mechanism (two-state *vs.* one-state) for the CpW(NO)(PH_3) species. It is readily apparent, however, that the involvement of the triplet spin state represents a distinct and realistic alternative to a process restricted to the singlet spin surface, the only mechanism which has hitherto been considered for this class of compounds. Further experimental and theoretical work is unquestionably required to explore this possibility for Cp*W(NO)L species, as well as for $CpML_2$ compounds in general.

Several 16e, d^6 Cp*M(PR_3)X species have been invoked in intra- and inter-molecular C–H bond activation reactions (M = Ir, X = CH_3^+;[25] M = Os, X = CH_2SiMe_3;[26] M = Ru, X = CH_2CMe_3;[27] M = Re, X = CO, PMe_3;[28–30] M = W, X = NO[1]). In particular, much recent theoretical, synthetic, and mechanistic work has been focused on the low-temperature alkane C–H bond activation reactions of the Cp*Ir(PMe_3)(CH_3)$^+$ complex,[31–34] but to the best of our knowledge, only one study has addressed the possible involvement of triplet species in this system.[19] The role of the spin state in the reactivity of unsaturated Cp*W(NO)L species is currently under theoretical investigation.[35]

† Cp = η^5-C_5H_5; Cp* = η^5-C_5Me_5; CNT = Cp ring centroid.

‡ Calculations were performed using Gaussian 94.[11] The LanL2DZ basis set was employed to perform geometry optimisations with a density functional theory (DFT) approach. The three-parameter form of the Becke, Lee, Yang and Parr functional (B3LYP)[12] was employed. The LanL2DZ basis set includes both Dunning and Hay's D95 sets for H and C[13] and the relativistic electron core potential (ECP) sets of Hay and Wadt for the heavy atoms.[14–16] Electrons outside the core were all those for H, C, N and O, the 5s, 5p, 5d and 6s electrons for W and the 3s and 3p electrons for P. The mean value of the first-order electronic wavefunction, which is not an exact eigenstate of S^2 for unrestricted calculations on open shell systems, was considered suitable for the unambiguous identification of the spin state. Ground state energies are based on complete geometry optimisations. The singlet geometry for ϕ = 180° was optimised with an imposed mirror plane. For all other values of ϕ, the C_5 ring of the Cp ligand was fixed as a regular pentagon, the degree of pyramidalisation was set at a specific N–W–CNT–P dihedral angle (ϕ), and the geometry was optimised with no other constrained parameters.

The effect of substitution of the C–F group for the C–H group in crystal packing as well as thermal behaviour

Naoto Hayashi,*† Takashi Mori and Kiyoshi Matsumoto*

Graduate School of Human and Environmental Studies, Kyoto University, Yoshida, Sakyo-ku, Kyoto, 606-8501, Japan

The packing motif and/or thermal stability of a crystal is controlled by intermolecular C–F···π interactions.

The C–F group is similar to the C–H group in size. However, when the C–F group is substituted for the C–H group, the crystal structure is generally no longer identical.[1] In a few cases, the change in the packing motif has been explained in terms of C–H···F–C interaction,[2] π–π interaction,[3] *etc*. Here we report the first example of an intermolecular C–F··π interaction which controls the packing motif as well as the thermal stability of the crystal, on the basis of comparison of four crystalline complexes which are composed of triphenylmethanol derivatives, *i.e.* triphenylmethanol (**F0**), (4-fluorophenyl)diphenylmethanol (**F1**), bis(4-fluorophenyl)phenylmethanol (**F2**) and tris(4-fluorophenyl)methanol (**F3**), and MeOH.

By slow evaporation from MeOH solution, **F1** and **F2** afforded 1:1 complexes, as **F1**·MeOH‡ and **F2**·MeOH,‡ respectively, their stoichiometric ratios being the same as that of **F0**.[4] Interestingly, an X-ray analysis revealed that both **F1**·MeOH and **F2**·MeOH are isostructural to **F0**·MeOH;[5] one host and one guest molecule exist in an asymmetric unit, and two hosts and two guest molecules comprise a molecular assembly with the aid of a hydrogen bond (Fig. 1). The fact that none of the fluorine atoms take part in hydrogen bonding with the hydroxy groups is consistent with the reports of Dunitz and Taylor.[6] It is noteworthy that the fluorine atom is disordered in **F1**·MeOH. The disordered fluorines are observed only on two phenyl moieties [*i.e.* plane A and B, in Fig. 1(*a*)], occupancy factors of which are evaluated to be 0.69 and 0.31 for F(A) and F(B), respectively. Disorder of the fluorine atoms is also found in **F2**·MeOH, but it is not identical to that in **F1**·MeOH. The fluorine atoms in **F2**·MeOH are observed on all the three phenyl rings; the occupancy factors are 0.95, 0.80, and 0.25 for F(A), F(B), and F(C), respectively [Fig. 1(*b*)].

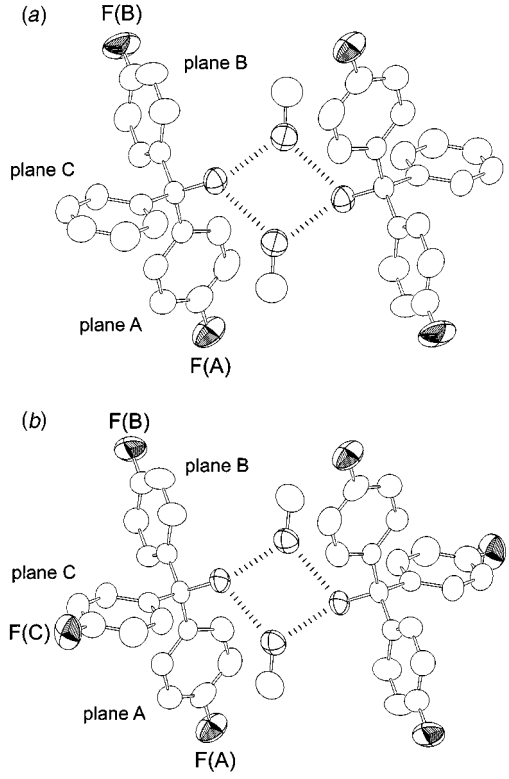

Fig. 1 Perspective views of (*a*) **F1**·MeOH and (*b*) **F2**·MeOH. For clarity, fluorine and oxygen atoms are represented by discriminated ellipsoids, and hydrogen atoms are omitted. Hydrogen bonds are specified by dotted lines.

Despite their isomorphous characteristics, the thermal behaviour of **F0**·MeOH, **F1**·MeOH and **F2**·MeOH upon DSC (differential scanning calorimetry) measurement§ are somewhat different. On heating, the guest molecule in **F0**·MeOH and **F1**·MeOH was lost at very similar temperatures (T_{onset} = 78.5[4] and 76.0 °C, respectively), whereas **F2**·MeOH released the guest at rather lower temperature (T_{onset} = 64.8 °C).

This finding can be explained in terms of C–H··π and C–F··π interactions: Fig. 2 shows that two phenyl rings in **F1**·MeOH, *i.e.* plane C and B, are arranged in an edge-to-face manner. The interplanar angle and centroid-to-centroid distance of the two planes are estimated to be 91.5° and 5.39 Å, respectively. No C–H··π interactions could be observed among the other pairs of phenyl rings. Such a T-shaped arrangement of two benzene rings is known to be energetically favourable.[7] If a fluorine atom is substituted onto plane C in this packing motif, the energetic advantage due to the C–H··π interaction will be lost. This is one of the principal reasons that the disordered fluorine atom in **F1**·MeOH was observed solely on plane A and B. On the other hand, the disordered fluorine atoms, F(A) and F(B), play no role with respect to the thermal stability of the lattice.

In the case of **F2**·MeOH, the disordered fluorine atoms are observed on the plane C as well. It causes the loss of the energetically favorable C–H··π interaction as well as introducing an electrostatic repulsion between the electronegative fluorine atom and the π-electrons. In addition to these, a steric

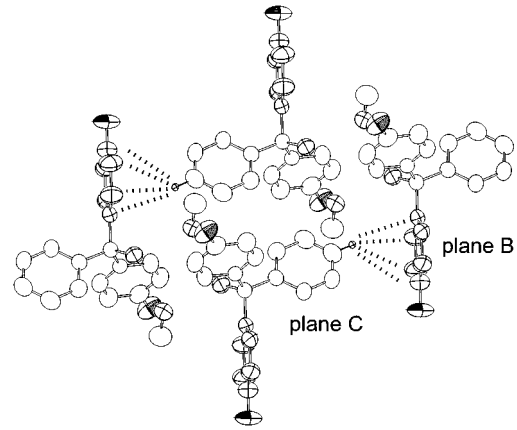

Fig. 2 Projection of the host–guest structure of **F1**·MeOH. Dashed lines represent CH–π interactions.

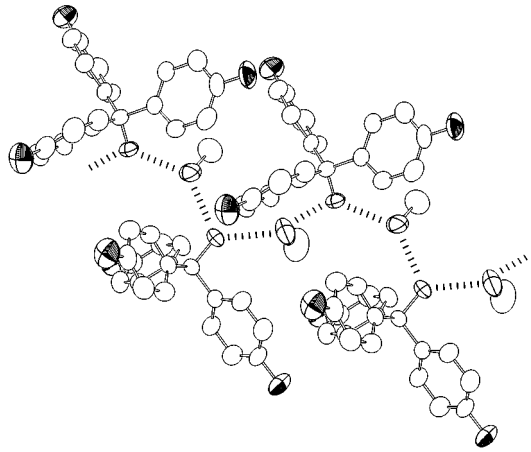

Fig. 3 Perspective view of **F3**·MeOH. For clarity, fluorine and oxygen atoms are represented by discriminated ellipsoids, and hydrogen atoms are omitted. Hydrogen bonds are specified by dotted lines.

repulsion arises, since the distance from the fluorine to the plane B is calculated to be 2.87 Å, which is significantly shorter than the sum of van der Waals radii's of each moiety (F = 1.47, C_{ar} = 1.77 Å).[8] The sum of these factors should lead the instability of the lattice of **F2**·MeOH, so that the guest MeOH is lost more readily than that of **F0**·MeOH and **F1**·MeOH.

Although **F3** also afforded 1:1 complex with MeOH, the crystal structure of **F3**·MeOH‡ is quite different from those of the others. The hydrogen-bonded cyclic network (H–G–H–G) is found in the other complexes, whilst the –H–G–H–G– sequence of an infinite chain of hydrogen bonding is observed in **F3**·MeOH (Fig. 3). Among the four MeOH complexes described here, **F3**·MeOH is thermally most unstable: the guest MeOH was released just at 48.3 °C (onset). The exceptional packing motif of **F3**·MeOH is ascribable to the unfavorable C–F··π interaction again. The C–F··π interaction is not critical in **F2**·MeOH with respect to the packing motif, because only one fourth of the *para* positions of plane C are substituted by fluorine atoms. However, complete occupation would make it too disadvantageous in energy for **F3** to adopt a similar packing motif to the other complexes, so that **F3**·MeOH crystallized in a distinct manner.

These results demonstrate new aspects of a fluorine in crystalline chemistry as well as in medicinal and biological chemistry. Further investigations on the effect of fluorine on crystal structure as well as thermal behaviour are currently underway.

The synthesis of water soluble isoindoline nitroxides and a pronitroxide hydroxylamine hydrochloride UV–VIS probe for free radicals

Damien A. Reid, Steven E. Bottle*† and Aaron S. Micallef

CIDC, School of Physical Sciences, Queensland University of Technology, GPO Box 2434, Brisbane Q 4001, Australia

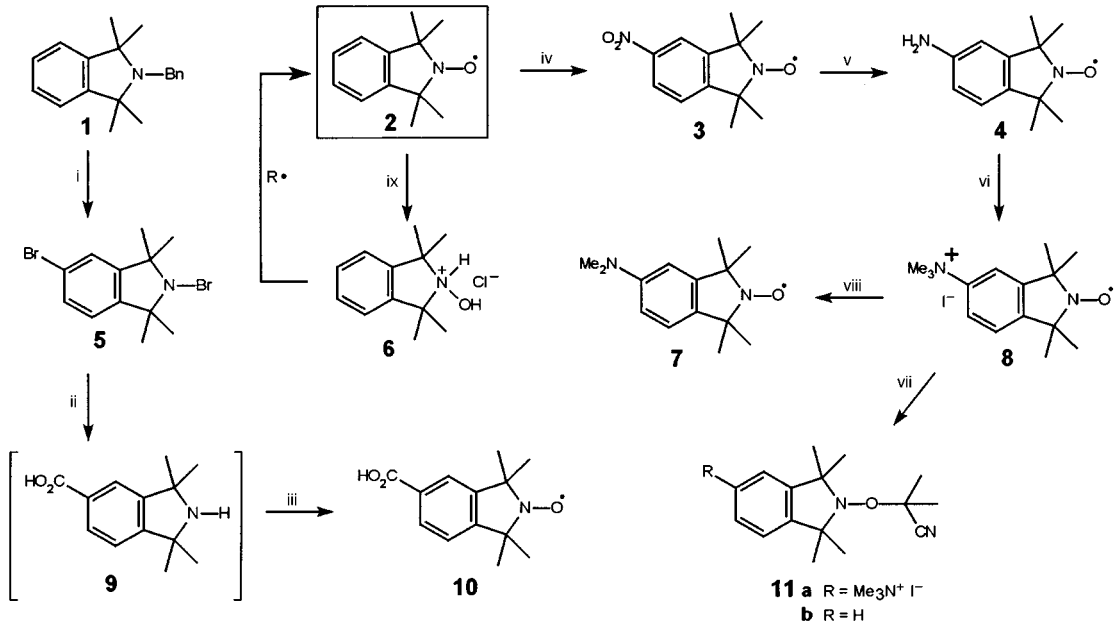
The novel water soluble nitroxides 5-trimethylammonio-1,1,3,3-tetramethylisoindolin-2-yloxyl iodide 8 and 5-carboxy-1,1,3,3-tetramethylisoindolin-2-yloxyl 10 are prepared by nitration of the parent nitroxide 2 and bromination of its amine precursor 1; the stable ($t_{1/2}$ > 580 h in MeOH; *ca* 72 h in physiological saline) pronitroxide 2-hydroxy-1,1,3,3-tetramethylisoindoline hydrochloride 6 was synthesised by treatment of 2 with HCl gas in dry EtOH and reacts with radicals to form 2; the transformation can be followed by UV–VIS spectroscopy.

Nitroxide radicals have long been used as spin labels and probes in biological systems, where, in some cases, their presence also affords protection from oxidative stress and radiative damage.[1–4] However, the 1,1,3,3-tetramethylisoindolin-2-yloxyl (TMIO) nitroxides **2** (Scheme 1) have been largely overlooked for these applications, their main use to date being in spin trapping experiments.[5,6] The TMIO system enjoys a number of advantages over the commercially available nitroxides, the most significant being its excellent thermal and chemical stability and superior EPR linewidths.[7] However, its use in biological systems has been limited because of the near absence of any water soluble derivatives. The sulfonate has been reported,[8] but has not been fully characterised. We here report the synthesis of two water soluble TMIO derivatives, 5-carboxy-1,1,3,3-tetramethylisoindolin-2-yloxyl **10** and 5-trimethylammonio-1,1,3,3-tetramethylisoindolin-2-yloxyl iodide **8**. We also report an alternative strategy for converting the hydrophobic TMIO into a water soluble derivative, with the synthesis of 2-hydroxy-1,1,3,3-tetramethylisoindoline hydrochloride **6**, the first stable water soluble pronitroxide incorporating the isoindoline system.

Compounds **1** and **2** were prepared according to the literature procedures of Griffiths *et al.*[9] Treatment of **1** with Br_2 (6 equiv.) in the presence of $AlCl_3$ (12 equiv.) resulted in oxidative debenzylation and bromination giving 2,5-dibromo-1,1,3,3-tetramethylisoindoline **5** (40%).[10] The slow addition of Bu^nLi (3.6 equiv.) to a solution of **5** in dry THF and quenching gave 5-carboxy-1,1,3,3-tetramethylisoindoline **9** (not isolated) upon aqueous workup [δ_H([$^2H_6$]DMSO) 1.70 (12H, s, Me), 7.45 (1H, d, ArH), 7.88 (1H, d, ArH), 7.94 (1H, dd, ArH), 9.55 (2H, br, NH_2^+); δ_C([$^2H_6$]DMSO) 28.5 (Me), 68.0 (C1, C3), 122.3 (ArC), 123.3 (ArC), 123.7 (ArC), 130.7 (ArC), 143.0 (ArC), 146.8 (ArC), 166.8 (C=O)]. Tungstate oxidation[9] of **9** gave **10** [23% (based on **5**), mp 214–218 °C; $CHCl_3$, g = 2.00585, a_N = 14.45 G (Found: C, 66.57; H, 6.92; N, 6.28; Calc. for $C_{13}H_{16}NO_3$: C, 66.67; H, 6.84; N, 5.98%); *m/z* (EI) 234, 220, 219, 204, 189].

The synthesis of **3** was achieved *via* the quantitative nitration of **2** according to the method of Bolton *et al.*[11] Hydrogenation of **3** (H_2, Pd/C, 10 psi, 4 h) followed by treatment with PbO_2 (0.5 equiv.) to reoxidise to the nitroxide gave **4** as a yellow solid [98%; mp 195–196 °C (from EtOH) (lit.,[12] 198 °C)]. This material possesses substantial synthetic utility, the amine providing a pathway for coupling to amino acids and proteins as well as incorporating into sugars.[13]

The water soluble ammonium nitroxide **8** was prepared *via* basic methylation of **4** (MeI, 120 equiv.; NaH, 10 equiv.) in a sealed vessel (65 °C, 96 h). The product was isolated *via* extraction into water (**CAUTION**: excess NaH) and recovered



Scheme 1 *Reagents and conditions*: i, Br_2, $AlCl_3$, 0 °C, 40%; ii, Bu^nLi, −78 °C, then CO_2; iii, H_2O_2, Na_2WO_4, 23 (from **5**); iv, HNO_3, H_2SO_4, > 95%; v, H_2, Pd, then PbO_2, > 95%; vi, MeI, NaH, 65 °C, 90%; vii, AIBN, 90 °C, 90%; viii, 170 °C, 0.1 mmHg; ix, HCl, EtOH, > 95%

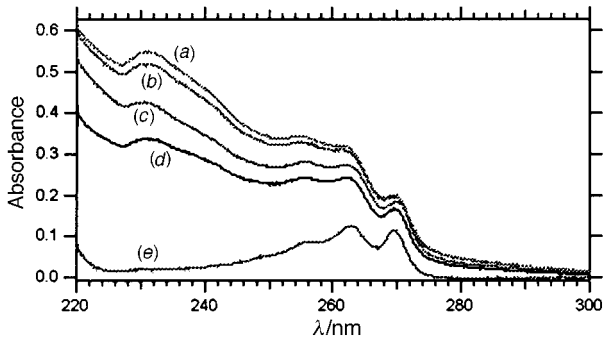


Fig. 1 UV–VIS spectra following the reaction of **6** (2.6×10^{-4} M) with AIBN (0.5 equiv.), 90 °C, in degassed MeOH under N_2 after (*a*) 0.0, (*b*) 1.5, (*c*) 3.0, (*d*) 7.5 and (*e*) 9.0 h. Chromatography confirmed only trace amounts of 2-cyanopropyl adduct **11b**.

by evaporation. The crude solid was taken up in hot EtOH (*ca.* 80 ml) and passed through a short Al_2O_3 column [Al_2O_3 (neutral, act. I), eluent: EtOH–EtOAc (1:4), 700 ml]. Evaporation yielded a yellow crystalline solid **8** [90%; mp 173–174 °C (decomp.) (from H_2O), 175–176 °C (decomp.) (from EtOH, slightly contaminated with inorganics) (Found: C, 46.70; H, 6.58; N, 7.21. Calc. for $(C_{15}H_{24}N_2OI)_2 \cdot H_2O$: C, 46.88; H, 6.56; N, 7.29%); *m/z* (FAB) 248; (EI) 233 ($M - 15$), 142 (MeI^+), 127 (I^+) (accurate to *ca.* 1 ppm)]. The nitroxide **8** has also been characterised by EPR (H_2O, g = 2.00562, a_N = 15.83 G, a_N = 0.204 G), NMR analysis of its 2-cyanopropyl adduct **11a** and by its characteristic thermal decomposition product **7** [mp 126–129 °C (Found: C, 72.10; H, 9.18; N, 11.90. Calc. for $C_{14}H_{21}N_2O$: C, 72.06; H, 9.07; N, 12.01%); *m/z* (EI) 233]. The nitroxide **8** is soluble in water at a concentration of *ca.* 120 mM, exceeding the typical[14,15] solubility requirement for spin probes.

The synthesis of **6** was achieved by bubbling dry HCl into a stirred solution of **2** in EtOH. The reaction was complete when the strong orange colour of the nitroxide had reduced to a faint yellow (*ca.* 0.5 h). Evaporation yielded a white solid **6** [98%; mp 196–198 °C (decomp.) (from MeCN) (Found: C, 63.54; H, 8.05; N, 6.07. Calc. for $C_{12}H_{18}NOCl$: C, 63.29; H, 7.97; N, 6.15%); $\delta_H(CDCl_3)$ 1.79 (12H, s, Me), 7.18 (2H, d, ArH), 7.39 (2H, d, ArH); $\delta_C(CDCl_3)$ 25.5 (Me), 75.9 (C1, C3), 121.9 (ArC), 129.7 (ArC), 139.3(ArC)]. The hydroxylamine hydrochloride **6** is soluble in water at concentrations greater than 1 M.

Hydroxylamines have been used[16] as oxygen sensitive probes in MRI and recently[17] in the determination of reactive oxygen species by EPR analysis with ten-fold greater sensitivities than can be achieved using conventional nitrone spin traps. We have found that the transition from **6** (and its unprotonated equivalent) to **2** can be monitored by UV–VIS spectroscopy and have followed the reaction of **6** with the 2-cyanopropyl radicals generated from the thermolysis of AIBN (see Fig. 1). Blank reactions confirmed this transition did not occur in the absence of AIBN under identical conditions. The ability to observe the formation of a nitroxide spectroscopically, without the use of EPR methods, is quite novel and demonstrates the potential for **6** to act as a UV–VIS probe for free radicals. The hydroxylamine hydrochloride **6** is particulary inert in the solid form and is even stable in solution, having a half life ($t_{1/2}$) > 580 h at 0.26 mM in MeOH exposed to the atmosphere at room temperature (determined by UV–VIS analysis). Treatment with base, however, greatly reduces the stability of **6**, the free hydroxylamine having $t_{1/2}$ < 4 h in MeOH solution. This pronitroxide also possesses significant stability in physiological saline phosphate buffer (pH 6.9) where it has $t_{1/2}$ *ca.* 72 h at 0.26 mM. Notably, when converted to the nitroxide in physiological media this species remains in solution (at this concentration), again demonstrating the potential of **6** as a water soluble radical scavenger.

We thank the CIDC, QUT and the ARC for financial support.

Observation of supramolecular π–π dimerization of a dinuclear ruthenium complex by ^{1}H NMR and ESMS

Eléna Ishow, André Gourdon* and Jean-Pierre Launay

Groupe Electronique Moléculaire, CEMES-CNRS, UPR 8011, BP 4347 29 Rue Jeanne Marvig, 31055 Toulouse, France. E-mail: gourdon@cemes.fr

The dinuclear ruthenium complex of bis{dipyrido[3,2-*f*:2′,3′-*h*]quinoxalo}[2,3-*e*:2′,3′-*l*]pyrene (bqpy) forms dimers in solution maintained only by π–π stacking of the bridging ligand, stable enough to be observed not only by ^{1}H NMR spectroscopy but also by electrospray mass spectrometry at low accelerating cone voltage.

In recent years much attention has been drawn to supramolecular architectures maintained by weak interactions.[1] We report here the first evidence, by ^{1}H NMR and electrospray mass spectrometry, of the supramolecular dimerization of a dinuclear metallic complex only maintained by π-π stacking.

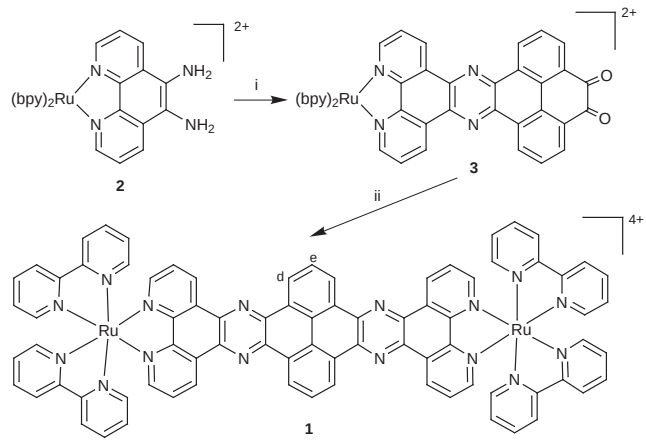
We have recently observed by ^{1}H NMR spectroscopy the supramolecular aggregation in solution of the monometallic complex $[(bpy)_2Ru(tpphz)]^{2+}$ where tpphz is the fully aromatic tetrapyrido[3,2-*a*:2′,3′-*c*:3″,2″-*h*:2‴,3‴-*j*]phenazine.[2] This dimerization by π–π stacking of the tpphz part, was not observed for the dinuclear complex $[(bpy)_2Ru(tpphz)Ru(bpy)_2]^{4+}$. Indeed, the relatively short intermolecular Ru–Ru distance (12.77 Å determined by X-ray diffraction), and therefore the high intermolecular coulombic repulsions, preclude any efficient stacking. Along these lines we have synthesized the dinuclear complex **1** of bis-{dipyrido[3,2-*f*:2′,3′-*h*]quinoxalo}[2,3-*e*:2′,3′-*l*]pyrene (bqpy). In this complex, the calculated intermetallic distance is *ca.* 20 Å, long enough to allow an efficient aggregation of two complexes.

Attempts to synthesize bqpy from 5,6-diamino-1,10-phenanthroline and tetraketopyrene[3] gave only intractable mixtures of insoluble bqpy and by-products. This lack of solubility emphasizes the very important π–π interactions in this type of compound. We have used instead the alternative synthetic route depicted in Scheme 1 which involves successive functionalizations of soluble precursor complexes.† Reaction of 6-amino-5-nitro-1,10-phenanthroline, obtained by nucleophilic amination of 5-nitro-1,10-phenanthroline,[2] with $Ru(bpy)_2Cl_2\cdot 2H_2O$ in refluxing ethanol gave the corresponding amino–nitro complex in 82% yield which was then reduced by hydrazine hydrate over Pd/C to provide the diamino complex **2** in 89% yield. Condensation with tetraketopyrene[3] gave first **3** and then **1** on prolonged heating in acetonitrile–methanol–acetic acid (yield 64%). In contrast to the free ligand bqpy, **1** is soluble in various solvents depending on its counter anions.

As expected by analogy with the mononuclear $[(bpy)_2Ru(tpphz)]^{2+}$ complex, the ^{1}H NMR spectra are very sensitive to concentration.

On one hand, the bqpy protons are clearly the most affected with displacements up to 0.9 ppm between extreme conditions. Their signals are significantly broadened and move upfield with increasing concentration, the most influenced ones being the pyrene protons H^d and H^e; on the other hand, the bpy proton signals are only slightly broadened and move downfield in a smaller extent (maximum 0.1 ppm). We have attributed this concentration effect to the aggregation in solution of dinuclear species by π-stacking of the central bqpy aromatic parts. Consistent with this hypothesis, a temperature increase causes similar effects as dilution. This aggregation, which must be rapid with respect to the NMR timescale, modifies the local electron density and/or the ring current effects in the vicinity of the bqpy ligand. As a matter of fact, the π-stacking localizes the electron density on the central quinoxalopyrene part and decreases the electron density on the ruthenium atoms. These ^{1}H NMR spectra modifications are in agreement with those encountered in some host–guest organic complexes, catenanes and rotaxanes[4] in which inclusion induces shielding and broadening of the aromatic hosts and guest signals. The association constant monomer–dimer has been estimated at 830 M^{-1} by standard curve-fitting to a plot of chemical shift *vs.* concentration (at concentrations below 1.9×10^{-3} M).

This dimerization in solution can also be observed by electrospray mass spectrometry (ESMS). This soft ionisation method[5] has been recently used for the direct characterization of weakly bonded species containing non-covalent interactions such as receptor–ligand,[6] enzyme–substrate,[7] heme–protein complexes,[8] oligonucleotide duplexes[9] and hydrogen-bonded supramolecular assemblies.[10] Moreover, it has also been possible to observe by this technique the formation of multinuclear metal coordination complexes under equilibrium conditions.[11] As low ionisation energies are involved, non-covalent molecular architectures, the stability of which depends on weak interactions, are not destroyed so that ion distributions in the mass spectra reflect with confidence the species arrangement in solution. In our case, we have been able to isolate and discriminate the formation of the supramolecular dimer of **1** only maintained by weak π–π interactions by varying the accelerating cone voltage to control the fragmentation during the ionisation process. The ESMS spectrum recorded at cone voltage of 60 V showed four major peaks at *m/z* 1873, 864, 526 and 359.9 corresponding to pseudomonomolecular ions with the loss of 1, 2, 3, and 4 PF_6^-, and also a fifth intense peak at *m/z* 1200. A state of charge of $\mathbf{3}^+$ was found for this peak by optimizing the resolution of the isotopic pattern. Both values, charge and mass unity, are in total agreement with the formation of the dimeric entity $\{[(bpy)_2Ru^{II}(bqpy)-Ru^{II}(bpy)_2]_2 + 5PF_6^-\}^{3+}$ corresponding to a dimeric neutral



Scheme 1 *Reagents and conditions*: i, ii, tetraketopyrene, MeCN–MeOH–AcOH (20:15:1 v/v), reflux, 4 d, 64%

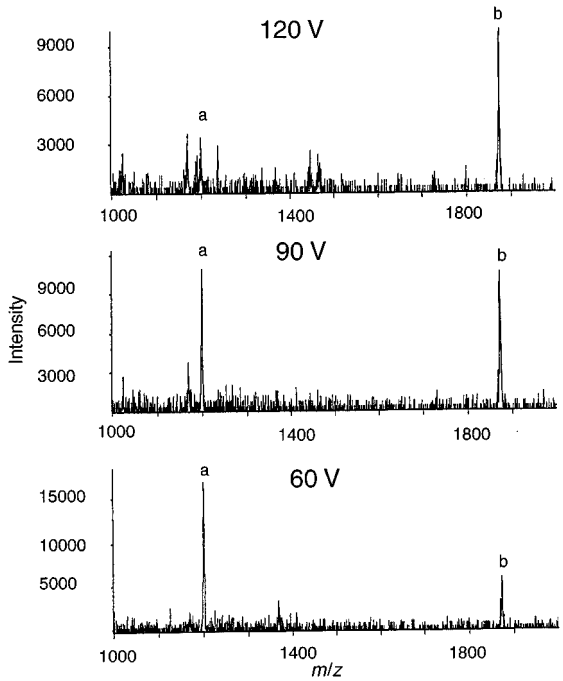


Fig. 1 Detail of the ESMS spectra of **1** in MeCN/H_2O 1 : 1 at cone voltages of 60, 90 and 120 V in the range *m/z* 1000–2000. a refers to the dimeric species $\{[\mathbf{1}_2](PF_6)_5\}^{3+}$ and b to the superimposition of the monomer $\{[\mathbf{1}](PF_6)_3\}^{+}$ and of the dimer $\{[\mathbf{1}_2](PF_6)_6\}^{2+}$. Note the scale change at 60 V.

species $\mathbf{1}_2$ after loss of three PF_6^- counter anions PF_6^-. And likewise, the peak at *m/z* 1873 is also clearly an isotopically resolved overlap of $\{\mathbf{1}\text{-}PF_6\}^+$ and $\{\mathbf{1}_2\text{-}2PF_6\}^{2+}$ species. Moreover, by raising the cone voltage to 90 and 120 V (Fig. 1), this peak intensity decreased and finally vanished, whereas the four other peaks remained nearly unchanged; simultaneously, the voltage increase engendered the partial fragmentation of the dinuclear complex **1** as a novel peak appeared at *m/z* 1169, assigned to the fragmentation product $[(bpy)_2Ru(bpqy)]^{2+}$ with one PF_6^-.

Although the exact geometry of this dimer in solution cannot be determined with accuracy by experimental techniques, some insights can be inferred from theories and experiments on small polyaromatic organic molecules and from molecular mechanics calculations. The steric crowding of the bulky $Ru^{II}(bpy)_2$ extremities imposes a geometry in which the metal–metal axes are more or less perpendicular to each other to allow a quite short bqpy–bqpy distance. In that conformation, both bqpy planes can be either perpendicular (T-shape) or parallel (stacked). On the basis on previous studies,[12] it seems reasonable to assume a stacked geometry for the dimer $\mathbf{1}_2$ in which the ligand bqpy exhibits a large aromatic extension. Stability of such stacked large systems actually results from a compromise between the dominant favourable van der Waals attraction, which seems to be linearly correlated with the number of aromatic moieties, and the repulsive coulombic interactions. In the case of the dimer $\mathbf{1}_2$, these repulsive coulombic interactions are considerably reduced by the strong electron-acceptor ruthenium extremities which decrease the electronic density on the central pyrene-type regions.[13] By positioning two complexes in this perpendicular conformation (Fig. 2), with the bqpy planes parallel at 3.5 Å, the distance between two ruthenium centres belonging to two different molecules is estimated to 14.5 Å which precludes any significant couloumbic repulsion between the metallic moieties.

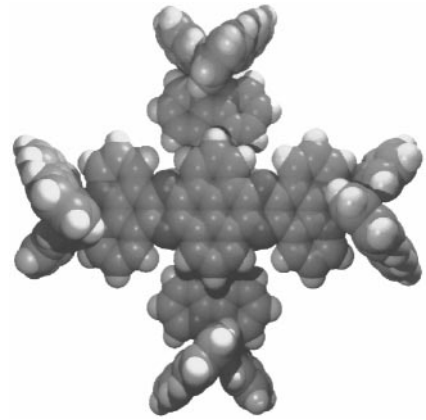

Fig. 2 CPK representation of the dimer $\mathbf{1}_2$

Additionally, such a geometry often exhibits an offset of the aromatic parts from the face-to-face aggregation for the stacked molecules to accommodate with the repulsive coulombic interactions allowed here by the length of the bridging ligand.

Utility of a diene–tricarbonyliron complex as mobile chiral auxiliary: iterative use for constructing contiguous chiral centers

Yoshiji Takemoto,*[a] Yasutaka Baba,[b] Naoki Yoshikawa,[b] Chuzo Iwata,[b] Tetsuaki Tanaka*[b] and Toshiro Ibuka[a]

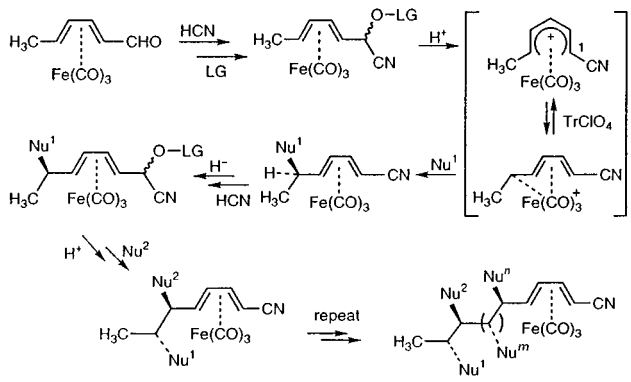
[a] *Graduate School of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: takemoto@pharm.kyoto-u.ac.jp*

[b] *Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565-0871, Japan*

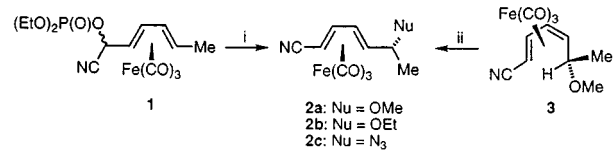
Three stereogenic centers bearing azide, methoxy, and ethylthio groups, have been constructed stereoselectively using the sole chirality of the $Fe(CO)_3$ group with concurrent 1,2-migration of the $Fe(CO)_3$ group and the obtained product was converted to an *anti*-aminoalcohol derivative to determine the absolute stereochemistry.

Nucleophilic attack on coordinated polyenes is an important reaction in π-organometallic chemistry.[1] If reactions of this type occur with predictable regio- and stereo-selectivity, they can be of synthetic utility. For example, the reactivity of acyclic (pentadienyl)iron(1+) cations has been the subject of recent intense investigations.[2] However, compared with cyclic iron(1+) cation complexes,[3] regio- and stereo-selective nucleophilic addition to the acyclic (pentadienyl)iron(1+) cations seems to be difficult due to their configurational flexibility. Thus far, several efficient methods, which skip the isolation of the acyclic (pentadienyl)iron(1+) cations (*in situ* generation), have been developed and applied to natural product synthesis.[4] Previously, we described the regio- and stereo-selective 1,5-nucleophilic substitution of the cyanophosphate $Fe(CO)_3$ complexes with several heteroatomic nucleophiles, giving the 1,2-migrated products of the $Fe(CO)_3$ group with (*E*,*Z*)-configuration.[5] Here, we wish to describe the regio- and stereoselective synthesis of (*E*,*E*)-1,5-substituted adducts and their novel application to construction of contiguous stereogenic centers in acyclic alkenes (Scheme 1).

During our studies on the 1,5-nucleophilic substitution of the cyanophosphate **1**† with methanol, we found that the 1,5-substitution of **1** into the (*E*,*E*)-adducts was catalyzed by trityl perchlorate ($TrClO_4$) in the presence of various nucleophiles. Indeed, treatment of **1** with 10 equiv. of heteroatomic nucleophiles such as methanol, ethanol, and $TMSN_3$ in the presence of 1.1 equiv. of $TrClO_4$ in THF at room temperature gave the desired products **2a**–**c**‡ in moderate yields in all cases (Scheme 2). Furthermore, $TrClO_4$ also promoted the isomerization of the (*E*,*Z*)-adduct **3**‡ to the (*E*,*E*)-adduct **2a**‡ in 81% yield.



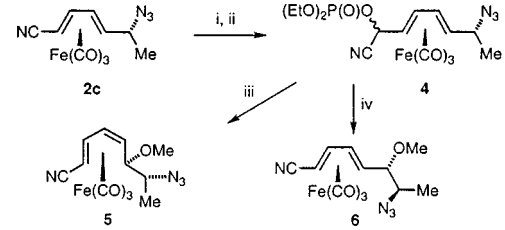
Scheme 1 Utility of an iron–tricarbonyl complex as a mobile chiral ligand



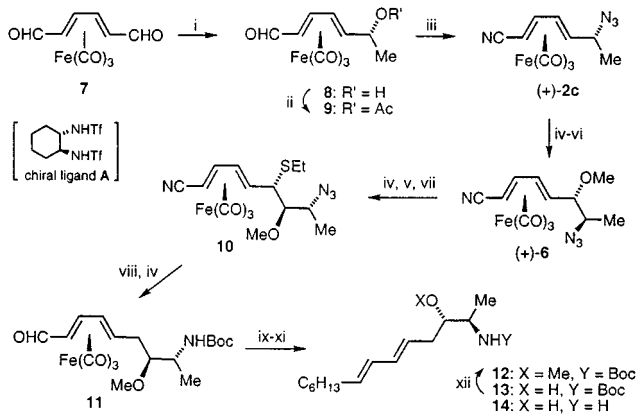
Scheme 2 *Reagents and conditions*: i, NuH (10 equiv.), $TrClO_4$ (1.1 equiv.), THF, r.t., 49% (Nu = MeOH) for **2a**; 41% (Nu = EtOH) for **2b**; 56% (Nu = $TMSN_3$) for **2c**; ii, MeOH (10 equiv.), $TrClO_4$ (1.1 equiv.), THF, r.t., 81%

We next examined the possibility of iterative manipulation of this 1,5-nucleophilic substitution with the obtained azide **2c** (Scheme 3). The requisite cyanophosphate **4** was prepared from **2c** as follows. The reduction of **2c** with diisobutylaluminium hydride (DIBAL-H) was followed by the reaction with diethylphosphoryl cyanide[6] to afford the desired cyanophosphate **4**.† The crude cyanophosphate **4** was subjected to a catalytic amount of $BF_3{\cdot}OEt_2$ in methanol at 0 °C to give rise to the (*E*,*Z*)-1,2-migrated product **5**‡ as a single isomer in 53% yield in two steps (method A).[5] On the other hand, the subjection of **4** to 1.1 equiv. of $TrClO_4$ and 10 equiv. of methanol in THF at room temp. afforded the (*E*,*E*)-1,2-migrated product **6**‡ as a single isomer in 52% yield in two steps (method B). These results indicate that the second nucleophile was introduced regio- and stereo-selectively with the 1,2-migration of the $Fe(CO)_3$ group without influence of the azide group.

In order to determine the absolute stereochemistry of **6** and also to extend this method to the asymmetric synthesis of a natural product such as 2,3-*anti*-aminoalcohol[7] **14** (Scheme 4), we next applied this iterative manipulation to the chiral compound (+)-**2c**. Although we have already reported the efficient asymmetric synthesis of the chiral $Fe(CO)_3$ complexes by the catalytic asymmetric alkylation of *meso*-hexadienal $Fe(CO)_3$ complex **7**, the reaction with dimethylzinc resulted in low yield and poor enantioselectivity.[8] So, we first investigated other reaction conditions to obtain (+)-**2c** enantioselectively. After many experiments, we found that Kobayashi's procedure[9]



Scheme 3 *Reagents and conditions*: i, DIBAL-H, CH_2Cl_2, −78 °C, 78%; ii, $(EtO)_2P(O)CN$, LiCN, THF, r.t.; iii, $BF_3{\cdot}Et_2O$, MeOH, 0 °C, 53%; iv, $TrClO_4$, MeOH, THF, r.t., 52%



Scheme 4 *Reagents and conditions*: i, Me_2Zn, $Ti(OPr^i)_4$, chiral ligand (A), −20 → 0 °C, toluene, 71%; ii, Ac_2O, pyridine, CH_2Cl_2, r.t., 80%; iii, $TMSN_3$, $Sc(OTf)_3$, CH_2Cl_2, r.t., 90%; iv, DIBAL-H, CH_2Cl_2, −78 °C, 88% for **2c**, 77% for **6a**, 78% for **10**; v, $(EtO)_2P(O)CN$, LiCN, THF, r.t.; vi, $TrClO_4$, MeOH (10 equiv.), THF, r.t., 52%; vii, $TrClO_4$, EtSH (10 equiv.), THF, r.t., 61%; viii, H_2 (5 atm), 10% Pd/C, $(BOC)_2O$, MeOH, r.t., 81%, ix, $C_5H_{11}PPh_3Br$, Bu^nLi, toluene, −78–0 °C, 73%; x, H_2 (3 atm), 10% Pd/C, MeOH, r.t., 81% xi, Me_3NO, benzene, 60 °C, 85%; xii, MeI, Ag_2O, MeCN, reflux, 53%

was suitable for the purpose. The reaction of **7** with 1.8 equiv. of dimethylzinc and 1.8 equiv. of titanium(IV) isopropoxide in the presence of the chiral ligand (**A**) in toluene at 0 °C gave rise to monomethylated complex **8** in 71% yield with 96% ee. After acetylation of **8**, an azide group was introduced stereoselectively by the treatment of **9** with $TMSN_3$ and $Sc(OTf)_3$ in CH_2Cl_2 to afford (+)-**2c**.§ Here we undertook the same manipulation developed above (method B) with (+)-**2c** to obtain the *anti*-adduct (+)-**6**‡ in a comparable yield without any racemization. The further introduction of an ethylthio group into (+)-**6** by a similar procedure using $TrClO_4$ and ethanethiol (method B) also proceeded successfully to give the desired (*E*,*E*)-adduct **10**‡ as a single isomer in 61% yield. The hydrogenation in the presence of di-*tert*-butyl dicarbonate and sequential reduction with DIBAL-H of **10** gave the carbamate **11**, which was converted to **12** by a three-step sequence [Wittig reaction, hydrogenation over 10% Pd/C, and decomplexation]. This compound **12** was identical to the synthetic sample which was prepared from the known (2*R*,3*S*)-aminoalcohol derivative **13**[10] by the methylation (MeI, Ag_2O, MeCN, reflux; 53%) in respect of ^1H NMR, IR, mass, and $[\alpha]_D$. Based on these results, it is revealed that all substituents in **6** and **10** would be introduced from the opposite side of the $Fe(CO)_3$ group to give all *anti*-adducts in this iterative manipulation using method B. In conclusion, we have achieved the highly stereoselective synthesis of **12**, a key compound for the asymmetric synthesis of the natural product **14**, by using the (diene)$Fe(CO)_3$ group as a sole and mobile chiral auxiliary. This is the first example in the π-organometallic chemistry that the π-coordinated metal-group controls the contiguous stereogenic centers in acyclic compounds with concurrent 1,2-migration.

Notes and References

† Owing to the instability of **1** and **4** towards column chromatography, these compounds were used as a diastereomixture (2 : 3) without purification.

‡ The relative and absolute stereochemistry of **2a**–**c**, **3**, **5**, **6** and **10** were elucidated from the reported examples[2] and conversion of **10** and the reported product **13** to **12**.

§ Under these reaction conditions, the aldehyde group was converted to a nitrile group.

An alternative interpretation of the HETCOR NMR spectra of poly(lactide)

Khalid A. M. Thakur,*[a]† Robert T. Kean,[a] Mark T. Zell,[b] Brian E. Padden[b] and Eric J. Munson*[b]‡

[a] *Cargill Incorporated, Central Research, PO Box 5699, Minneapolis, MN 55440, USA*
[b] *University of Minnesota, Department of Chemistry, 207 Pleasant St. SE, Minneapolis, MN 55455, USA*

An alternative to the assignments proposed recently by Chisholm *et al.* for the ^{1}H and ^{13}C NMR resonances of poly(lactide) based on their HETCOR spectra is presented; we find that the HETCOR spectra are consistent with older assignments of the tetrad and hexad stereosequence resonances in the ^{1}H and ^{13}C NMR spectra and we believe that the influence of adjacent chiral units on the NMR chemical shift extends asymmetrically and is opposite in the case of ^{1}H and ^{13}C nuclei; this is in contrast to the assumption that the observed chiral repeat unit for any particular stereosequence resonance is the same for ^{1}H and ^{13}C NMR spectra as used by Chisholm *et al.* in their analysis.

NMR spectroscopy has been shown to be an effective method for characterizing the stereosequence distribution in poly(lactide) (PLA) samples.[1,2] Homonuclear decoupled ^{1}H NMR and proton-decoupled ^{13}C NMR spectra have been used to explore the kinetics and predict the stereoisomer composition in PLA.[2–5] Recently, Chisholm *et al* have proposed an alternative set of stereosequence assignments for the ^{1}H and ^{13}C NMR resonances based on heteronuclear correlation (HETCOR) spectra for poly(*rac*-lactide) and poly(*meso*-lactide).[6] The nomenclature for stereosequence assignments of NMR resonances of PLA has been detailed in a number of previous reports.[1,2,6] Fig. 1 reproduces the spectra and assignments obtained for poly(*rac*-lactide) and poly(*meso*-lactide) from one of those reports.[2]

Chisholm *et al.* found cross-peaks between **sis** resonances in the ^{1}H NMR spectra and **isi** and **iss**/**ssi** resonance in the ^{13}C spectra in the HETCOR of poly(*meso*-lactide).[6] In the HETCOR of poly(*rac*-lactide), they found cross-peaks between the **sis** and **iis**/**sii** resonances in the ^{1}H spectra and the **isi** resonance in the ^{13}C spectra. Since these results appeared to contradict the previous assignments, they proposed a new set of stereosequence assignments. However, we believe these are inconsistent with the intensity distribution predicted from simple probability rules. For example, in the ^{13}C NMR spectrum of poly(*meso*-lactide), their assignment of the **isi** and **sis** resonances are reversed such that the **isi** resonance has a higher intensity than the **sis** resonance. The **sis** stereosequence is formed by isotactic addition of two *meso*-lactides, and should have a significantly larger intensity than the **isi** stereosequence, which requires two isotactic additions of three *meso*-lactide monomers. Under polymerization conditions such that no transesterification or epimerization occurs, the **sis** intensity should always be greater than the **isi** intensity.

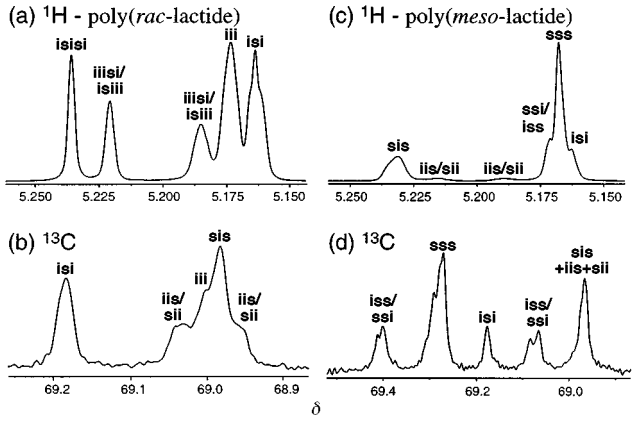

Fig. 1 Methine resonances in ^{1}H and ^{13}C NMR spectra of poly(*rac*-lactide) (a,b), and poly(*meso*-lactide) (c,d). The poly(*meso*-lactide) contained 6% *rac*-lactide as an impurity.

The observed nucleus in a resonance representing a tetrad (or hexad) stereosequence is from one of the two chiral repeat units at the center of the sequence. The tetrad sensitivity arises due to an asymmetrical extent of influence of adjacent chiral repeat units on NMR chemical shifts. If the influence were symmetrical, only triad or pentad stereosequence resonances would be observed in the NMR spectra. The cause of the asymmetrical influence in a tetrad stereosequence resonance in PLA is not known. It may be related to the presence of asymmetric repeat units having a carbonyl on one side and an ester oxygen on the other. It is also possible that the asymmetrical influence on the chemical shift in the ^{1}H NMR spectra is opposite as compared to the ^{13}C NMR spectra. The consequence is that the observed repeat unit for a given stereosequence resonance is not identical in the ^{1}H and ^{13}C NMR spectra, but are adjacent chiral repeat units at the center of the sequence. For example, in the stereosequence –*RRSS*–, represented by **isi**, the observed repeat unit could be either –***R***– or –***S***–. The HETCOR spectra reported by Chisholm *et al*. would result if in case of the ^{1}H NMR spectra the observed nucleus comes from –**R**, and in the case of the ^{13}C NMR spectra, the observed nucleus is from –***S***– (or *vice versa*). Our justification for the analysis of the specific cross peaks present in the HETCOR spectra of poly(*rac*-lactide) and poly(*meso*-lactide), based on the assumption of opposite asymmetrical influence for ^{1}H and ^{13}C NMR, follows.

In poly(*rac*-lactide), –*RR**S**SR*– and –*RR**S**SS*– sequences may be represented as **isi** adjacent to **sis** and **sii**, respectively. If in the ^{13}C spectra the observed repeat unit representing **isi** is –***S***–, this would appear in the ^{1}H NMR spectra as either **sis** or **sii** depending on which repeat unit (*R* or *S*) is adjacent to the **isi** stereosequence. Unfortunately, due to equal probability of occurrence, it is not possible to experimentally distinguish and identify the **iis** resonance from the **sii** resonance.[1,2,6] Hence as observed in the HETCOR, the **isi** resonance in ^{13}C NMR spectrum should have cross peaks with **sis** and one of the **sii**/**iis** resonances in the ^{1}H NMR.

In poly(*meso*-lactide), –*RR**S**SR*– and –*SR**S**SR*– are represented as **isi** and **ssi**, respectively, adjacent to a **sis**. Assuming a similar relationship as above, the –***S***– would appear as a **sis** in the ^{1}H NMR spectrum and either **isi** or **ssi** (not **iss**) in the ^{13}C NMR spectrum. And as observed in the HETCOR, the **sis** resonance in the ^{1}H NMR should have cross peaks with **isi** and one of the **ssi**/**iss** resonances in the ^{13}C NMR spectrum.

Table 1 shows the cross peaks expected to occur if the observed repeat unit in ^{13}C NMR is on the right side and in the ^{1}H NMR it is on the left side of the central two units for poly(*rac*-lactide), and Table 2 shows similar information for poly(*meso*-lactide). It is also possible that the reverse is true, *i.e.* the observed repeat unit in ^{13}C NMR is on the left side and in ^{1}H NMR is on the right side of the central two units. Owing to

Table 1 poly(*rac*-lactide); **ss** not possible

isi	**sis**

limitations in the experimental data and equal probability of asymmetric stereosequences,[1,2,6] it is not possible to determine the direction of the asymmetric influence on ^{13}C and ^{1}H NMR chemical shifts. However, we have clearly shown that the asymmetric influence must be opposite in ^{13}C and ^{1}H NMR, and the observed repeat unit for a given stereosequence resonance is not identical in ^{13}C and ^{1}H NMR.

Further work is in progress to uniquely identify the direction of the asymmetric influence with respect to the molecular coordinates. These and other experiments using ^{13}C labeled PLA to conclusively identify the stereosequence resonances are in progress and will be reported in the near future.

Support for this work was provided by a NIST ATP grant to Cargill Incorporated.

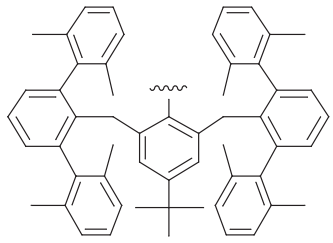
Synthesis and crystal structure of an arenesulfenyl iodide with unprecedented stability

Kei Goto,*† Michel Holler and Renji Okazaki*‡

Department of Chemistry, Graduate School of Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113-0033, Japan

An arenesulfenyl iodide with unprecedented stability was synthesized by oxidation of a thiol bearing a novel bowl-type substituent with iodine, whose monomeric structure was determined by X-ray crystallographic analysis.

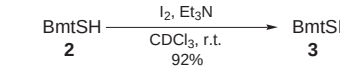
Sulfenyl iodides (RSI) have been suggested to play decisive roles as reaction intermediates in iodination reactions in the human thyroid gland[1] as well as in iodine oxidation of thiols.[2] Although more information concerning simple well defined sulfenyl iodides is desirable, the study of their chemistry has been hampered by their instability resulting from the ready disproportionation reaction ($2RSI \rightarrow RSSR + I_2$), the ΔH value of which is -4.30 kcal mol^{-1}.[3] In the solid state they are much less stable partly because of the large sublimation energy of solid I_2 (14.9 kcal mol^{-1}). Several aromatic acylsulfenyl iodides have been isolated and shown to be stable at room temperature for several hours, but they decompose below 50 °C.[4] The only structural analysis of a sulfenyl iodide was carried out for Ph_3CSI at -118 °C,[5] which is stable in the solid state at -78 °C and in solution in the dark.[6] Thus, no sulfenyl iodide stable at room temperature has so far been structurally characterized.[7] On the other hand, the reported value of the S–I bond dissociation energy is not so small (49.4 ± 2 kcal mol^{-1} for HS–I),[8] suggesting that this species will be stable if the disproportionation process is suppressed. Recently, we reported that a stable arenesulfenic acid can be obtained by direct oxidation of a thiol by taking advantage of a novel bowl-type



1 ≡ Bmt

substituent **1** (denoted as Bmt hereafter).§[9,10] Here we describe the synthesis of an arenesulfenyl iodide with unprecedented stability by iodine oxidation of the corresponding arenethiol, along with its crystal structure.

The sulfenyl iodides isolated so far have been synthesized mostly by halide exchange reaction of the corresponding sulfenyl chloride[6] or oxidation of the corresponding heavy metal thiolates.[4,11] There has been no example of the synthesis of a stable sulfenyl iodide by iodine oxidation of a thiol although this reaction has been considered to involve a sulfenyl iodide as an intermediate and seems to be the most straightforward synthetic pathway to it. Oxidation of thiol **2**[12] bearing the Bmt group with an equimolar amount of I_2 in the presence of triethylamine in $CDCl_3$ resulted in the quantitative formation of sulfenyl iodide **3**, which was isolated by silica gel chromatography as dark brown crystals in 92% yield (Scheme 1).¶ The stability of **3** was remarkable both in the crystalline state and in solution; it showed a melting point at 257 °C and no decomposition was observed even after heating at 80 °C for 12 h in toluene-d_8. It is stable at room temperature in air for more than several months. In the UV–VIS spectrum, **3** showed an absorption maximum at 328 nm in chloroform.



Scheme 1

The structure of **3** was finally established by X-ray crystallographic analysis.‖ An ORTEP drawing of **3** is shown in Fig. 1 with selected bond lengths and angles. The figure clearly shows that the two rigid *m*-terphenyl units surround the S–I functionality like the brim of a bowl, thus preventing the disproportionation process effectively. It was reported that in the crystal structure of Ph_3CSI at -118 °C the molecules are linked *via* short S···I contacts of 3.210(4) Å so that a zig-zag chain is formed.[5] By contrast, the shortest intermolecular S···I distance in **3** is 6.654(2) Å, clearly indicating its monomeric nature. The S–I bond length [2.386(2) Å] is distinctly shorter than that of Ph_3CSI [2.406(4) Å] probably because of the absence of the intermolecular interaction. The S–I moiety is almost perpendicular to the benzene plane [I(1)–S(1)–C(1)–C(2) angle, 87.7(6)°].

In spite of its high thermal stability, sulfenyl iodide **3** undergoes ready reactions with some reagents. Treatment of **3** with butane-1-thiol (8 equiv.) in the presence of triethylamine reduced it to the parent thiol **2** with the formation of a small

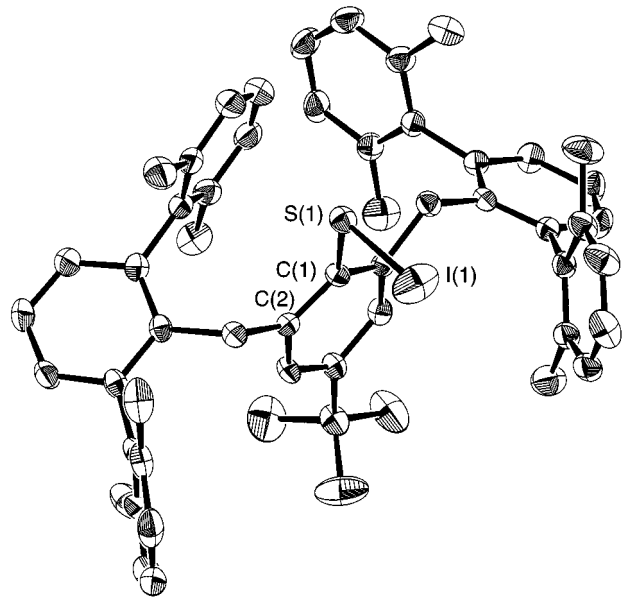


Fig. 1 Crystal structure of **3** (ORTEP drawing; thermal ellipsoids at 30% probability level). Selected bond lengths (Å), bond angles (°), and torsion angle (°): S(1)–I(1), 2.386(2); S(1)–C(1), 1.783(7); I(1)–S(1)–C(1), 101.3(2); I(1)–S(1)–C(1)–C(2), 87.7(6).

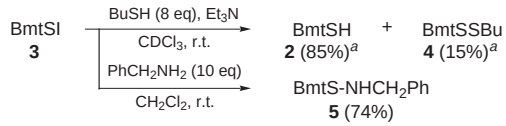
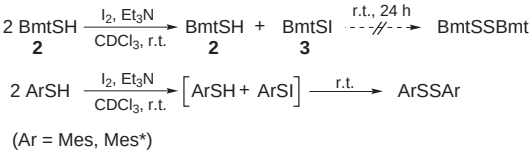


Scheme 2 [a] Estimated by ^{1}H NMR

amount of disulfide **4** (Scheme 2). The reaction of **3** with benzylamine (10 equiv.) readily afforded sulfenamide **5**. On the other hand, **3** was found to be unreactive toward thiol **2** bearing the same substituent. Oxidation of **2** with 0.5 equiv. of I_2 in the presence of triethylamine afforded a 1 : 1 mixture of **2** and **3**, no disulfide formation being detected even after 24 h at room temperature (Scheme 3). These results imply that two species which are otherwise incompatible can be present in the same system with retention of their reactivities toward other reagents when they bear a bowl-type substituent. Under the same conditions, 2,4,6-trimethylbenzenethiol (MesSH) was immediately oxidized to MesSSMes and even 2,4,6-tri-*tert*-butylbenzenethiol (Mes*SH) afforded Mes*SSMes* although the reaction was much slower. Apparently, the bowl-shaped structure of the Bmt group is more effective for prevention of dimerization than a Mes* group, where the functionality is more closely shielded.



Scheme 3 Mes* = $C_6H_2Bu^t_3$-2,4,6

Effects of electron donation into C–F σ* orbitals: explanations, predictions and experimental tests

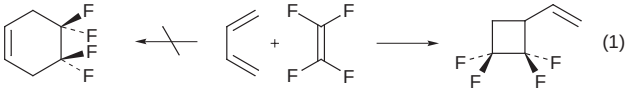
Weston Thatcher Borden†

Department of Chemistry, Box 351700, University of Washington, Seattle, Washington, 98195-1700, USA

The ability of C–F σ* orbitals to act as electron acceptors is shown to be capable of explaining and predicting a wide variety of apparently unrelated phenomena. Among these are (i) pyramidalization of fluorinated radical centers, (ii) the much weaker π-bond in tetrafluoroethylene (TFE) than in ethylene, (iii) the stepwise reaction of TFE with butadiene to form 2,2,3,3-tetrafluoro-1-vinylcyclobutane, rather than the Diels–Alder adduct, (iv) the thermodynamic favorability of replacing C–H with C–C bonds at fluorinated carbons, (v) the preference for disrotatory ring opening and closure of 1,1-difluorocyclopropanes, and (vi) the change from a triplet to a singlet ground state upon substitution of fluorines for the pair of hydrogens at C-2 of cyclopentane-1,3-diyl.

Over the past ten years my research group at the University of Washington has been carrying out computational research on organic molecules containing geminal fluorines. The unifying principle that has emerged from our research is that C–F σ-bonds have low-lying antibonding σ* orbitals, which are capable of accepting electrons from nonbonding p-π AOs, either on the same carbon or on adjacent carbons, and also from σ- and π-bonds on adjacent carbons. We have applied this understanding to explaining otherwise puzzling results, already in the literature, and to making new predictions that we have subsequently verified experimentally.

There is now good evidence, both computational[1a] and experimental,[1b] that the ability of C–F σ* orbitals to accept unshared electron pairs from adjacent carbons (negative hyperconjugation) stabilizes fluorinated carbanions. However, as will be shown in this article, the electron-accepting ability of C–F σ* orbitals is also capable of explaining and predicting a wide variety of additional and apparently unrelated phenomena. Among these are the following: (i) in contrast to methyl radical, trifluoromethyl radical is non-planar and has a high barrier to inversion;[2] (ii) tetrafluoroethylene (TFE) has a much weaker π-bond than ethylene;[3] and, (iii) unlike ethylene, TFE does not undergo a Diels–Alder reaction with butadiene but, instead, forms 2,2,3,3-tetrafluoro-1-vinylcyclobutane [eqn. (1)];[4] (iv)

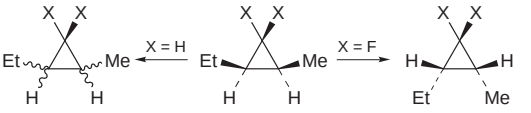


(1)

heats of formation show that transfer of the geminal fluorines from difluoromethane to C-2 of propane [eqn. (2)] is exothermic

$$CH_2F_2 + H_3CCH_2CH_3 \rightarrow CH_4 + H_3CCF_2CH_3 \qquad (2)$$

by 14.5 kcal mol^{-1};[5] (v) although 1-ethyl-2-methylcyclopropane undergoes stereorandom ring opening and closure,[6] replacement of the geminal ring hydrogens by geminal fluorines has been both predicted[7] and found[8] to lead to a very large preference for stereomutation by coupled disrotation of the alkylated ring carbons [eqn. (3)]; and (vi) cyclopentane-1,3-diyl has a triplet ground state;[9] but, as predicted,[10] a derivative of 2,2-difluorocyclopentane-1,3-diyl appears to have a singlet ground state.[11]



(3)

In showing how these diverse phenomena can all be explained by the electron accepting ability of the σ* orbitals of C–F bonds, I will take advantage of the possibility in a review of this type of revealing the intellectual threads that connect what might otherwise appear to be a collection of unrelated research projects. This review is written from a historical perspective and describes how one research project led to another and how each contributed to our understanding of the effects of geminal fluorines on the structure, energetics, and reactivity of fluorinated alkanes, alkenes, radicals, and diradicals.

Why do some radical centers have significant barriers to planarity?

In 1976 I taught a course on MO theory at the University of Washington. The text for the course[12] used second-order perturbation theory to explain the shapes of simple molecules. Bill Cherry, who was a graduate student in the course, saw how this theoretical framework could be used to explain the greater degree of pyramidalization and much higher barrier to inversion in phosphine, compared to ammonia, and why successive replacement of the hydrogens by fluorines in AH_3 molecules with seven or eight valence electrons also increases the barriers to inversion.[13,14] Subsequent conversations between Bill, his thesis adviser, Nick Epiotis, and myself resulted in the three of us coauthoring an article for *Accounts of Chemical Research* on this subject.[15]

The crucial factor in determining how favorable pyramidalization is in a planar AH_3 molecule is the amount of net stabilization provided by the mixing of the nonbonding p_z AO (a_2'') on A with the antibonding $2a_1'$ MO.[13,15] These orbitals are shown in Fig. 1, which also illustrates how their mixing upon pyramidalization transforms the nonbonding p_z AO in planar AH_3 into an MO that consists of a hybridized AO on A whose smaller lobe interacts in a bonding fashion with the three hydrogens.

According to second-order perturbation theory, the amount of net stabilization that arises from mixing between a_2'' and $2a_1'$ is inversely proportional to the size of the energy gap between these orbitals.[12,13,15] Therefore, in two similar AH_3 molecules (*e.g.* NH_3 and PH_3 or CH_3 and SiH_3), the energy lowering caused by pyramidalization and, hence, the amount of pyramidalization at the equilibrium geometry will both be larger in the molecule with the smaller energy difference between the antibonding $2a_1'$ and the nonbonding a_2'' orbitals.

Calculations find that planar AH_3 molecules have much lower-lying $2a_1'$ antibonding MOs when A is a second-row, rather than a first-row atom.[13,15] Consequently, second-order perturbation theory rationalizes the greater pyramidalization and higher barriers to inversion found in phosphines than in

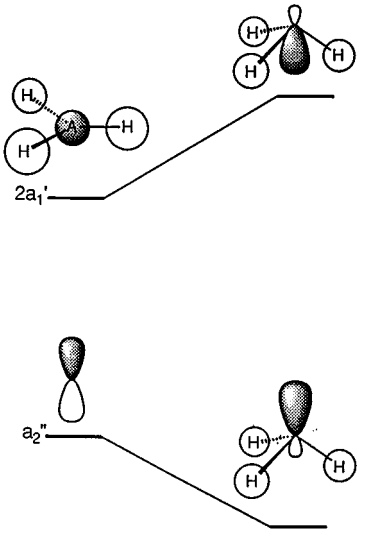


Fig. 1 Effect of mixing the a_2'' nonbonding MO with the $2a_1'$ antibonding MO of planar AH_3 on pyramidalization

amines[16] and in silyl radicals, compared to alkyl radicals.[17] The existence of low-lying $2a_1'$ MOs in planar PH_3 and SiH_3 can be traced to the fact that, unlike the case with 2s and 2p AOs, the maximum density of a 3s AO is significantly closer to the nucleus than that of a 3p AO.[18]

Another way to lessen the energy difference between the nonbonding a_2'' AO on A and the antibonding $2a_1'$ MO in AH_3 is to replace the three hydrogens with more electronegative atoms, such as fluorines.[13,15] The reduction in the energy difference between a_2'' and $2a_1'$ that results from the substitution of fluorine for hydrogen makes mixing of these two orbitals by pyramidalization more energetically favorable.The physical reason that this substitution leads to pyramidalization is that, as shown in Fig. 1, the filled MO that results from mixing of these two orbitals is no longer localized just on A, but is delocalized onto the more electronegative fluorines. Experimentally, it is known that electronegative substituents increase the barriers to inversion at nitrogen[16,19] and, as noted in the Introduction, it has also been found that successive replacement of hydrogens by fluorines results in increased pyramidalizaion and higher barriers to inversion in carbon-centered radicals.[2]

The effect of pyramidalization on the π-bond dissociation energy of tetrafluoroethylene and on the barriers to rotation in fluorinated allyl radicals

In a footnote in our 1977 paper in *Accounts* we pointed out that the favorability of pyramidalization of silyl,[17] cyclopropyl,[20] and fluoroalkyl[2] radical centers should tend to weaken the π-bonds in silenes, methylenecyclopropane, and tetrafluoroethylene (TFE), thus possibly accounting, at least in part, for the high reactivity of these compounds.[15] As illustrated in Fig. 2, if

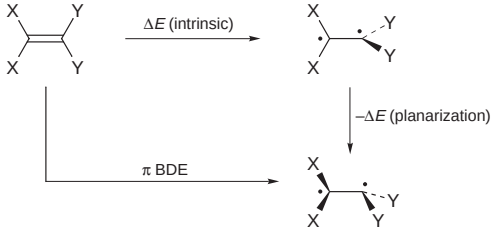

Fig. 2 Thermocycle showing that the π BDE of an alkene is reduced from the intrinsic strength of a π-bond between the planar radical centers by the energy released by their pyramidalization

a π-bond is formed between two radical centers, one or both of which prefer a pyramidal geometry, the π-bond dissociation energy (BDE) will be less than the intrinsic strength of a π-bond formed between the planar radical centers by the amount of energy that is released by their pyramidalization. We have investigated the impact of this effect on the π BDEs of silenes,[21] disilenes,[22] methylenecyclopropane,[23] and tetrafluoroethylene (TFE).[24]

The electronegative substituents attached to each carbon in TFE have a substantial effect on reducing the π-bond strength in TFE from that in ethylene. The strength of the π-bond in ethylene can be obtained experimentally from either the kinetics of *cis–trans* isomerization of 1,2-dideuterioethylene[25] or from the thermodynamics of the reaction shown in eqn. (4).[26] Both methods give a π-bond energy of *ca.* 65 kcal mol^{-1}.

$$H_2C{=}CH_2 + CH_3CH_3 \rightarrow 2\ CH_3CH_2\cdot \qquad (4)$$

Obviously, the kinetics of *cis–trans* isomerization cannot be used to provide an experimental value for the π-bond energy of TFE, but the thermodynamics of the reaction in eqn. (5) with

$$F_2C{=}CF_2 + CF_2XCF_2X \rightarrow 2\ CF_2XCF_2\cdot \qquad (5)$$

X = F has been employed to yield an experimental value of 52 ± 2 kcal mol^{-1} for this quantity.[3]

Computationally, either the barrier to rotation or the energy of the reaction in eqn. (5) can be used. Both types of calculations concur with experiment in finding that the π-bond in TFE is *ca.* 15 kcal mol^{-1}weaker than that in ethylene.[24]

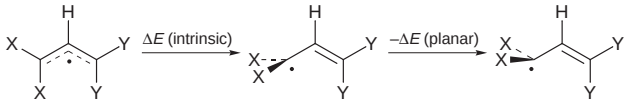
We used *ab initio* calculations to show that the lower π-bond energy in TFE, compared to ethylene, is due entirely to the energetic cost of planarizing the radical centers in TFE. The energy of 18.0 kcal mol^{-1}that is computed to be necessary to planarize the carbons in the singlet diradical transition state for rotation about the double bond[27] is very close to the calculated increase of 18.4 kcal $mol^{-1}$when the energy of the reaction in eqn. (5) is recomputed with the radical center in CF_2XCF_2 (X = H) constrained to planarity.[24] The intrinsic strength of the π-bond in TFE is actually *ca.* 3 kcal mol^{-1} larger than that in ethylene.[27]

Dr Bruce Smart suggested that we investigate whether the much lower barrier to rotation that EPR experiments had found in 1,1,3,3-tetrafluoroallyl radical,[28a] compared to the unfluorinated radical,[28b,c] might have a similar explanation. We found that pyramidalization of the twisted CF_2 group did indeed lower the barrier to rotation in 1,1,3,3-tetrafluoroallyl radical by about 10 kcal mol^{-1}.[29] In the corresponding anion pyramidalization was calculated to provide so much stabilization that a C_s geometry, with one CF_2 group pyramidalized and twisted out of conjugation, was computed to be 17 kcal mol^{-1} *lower* in energy than the planar, conjugated, C_{2v} structure and only 1 kcal mol^{-1} higher in energy than a C_2 structure in which both CF_2 groups are pyramdalized but oriented so that they are in conjugation with the central carbon.[30]

It was known experimentally that 1,1-difluoroallyl radical does not have a particularly low barrier to CF_2 rotation.[28a,b] If CF_2 group pyramidalization were the sole reason for the low barrier to rotation found in 1,1,3,3-tetrafluoroallyl radical, one would have expected 1,1-difluoroallyl to have a similarly low barrier to rotation of the CF_2 group.

In agreement with experiment, our calculations found the barrier to CF_2 rotation to be 6.9 kcal mol^{-1} higher in 1,1-difluoroallyl than in 1,1,3,3-tetrafluoroallyl. The results of our CISD calculations are summarized in Fig. 3.[27]

As shown in Fig. 3, pyramidalization of the rotated CF_2 group actually contributes more to lowering the barrier to rotation in 1,1-difluoroallyl than in 1,1,3,3-tetrafluoroallyl radical. The barrier to CF_2 rotation is higher in difluoro- than in tetrafluoroallyl radical because the intrinsic barrier to rotation of a planar CF_2 group is 9.7 kcal mol^{-1} larger in the former than in the latter radical. The reason for the intrinsically higher barrier to planar CF_2 rotation in difluoroallyl is that, after CF_2 rotation, the $CH{=}CH_2$ π-bond that remains in difluoroallyl is about 10 kcal mol^{-1} weaker than the $CH{=}CF_2$ π-bond that remains in tetrafluoroallyl. A similar difference between the intrinsic



X	Y	ΔE (intrinsic)	ΔE (planar)
H	H	15.4	0.1
F	F	12.6	9.9
H	F	12.3	0.0
F	H	22.3	12.7

Fig. 3 Intrinsic rotation barriers and planarization energies (kcal mol^{-1}) calculated for allyl, difluoroallyl, and tetrafluoroallyl radicals (ref. 27). The net barriers to rotation are given by ΔE (rotation) = ΔE (intrinsic) − ΔE (planarization) − ΔZPE, where the zero-point energy corrections (kcal mol^{-1}) are ΔZPE = −0.9 for X = Y = H, 1.3 for X = Y = F, −0.5 for X = H, Y = F, and 1.3 for X = F, Y = H. The origin of the different signs of the ΔZPE corrections for X = H and X = F resides in the pyramidalization that occurs for X = F in the transition state for rotation (ref. 27).

π-bond energies of ethylene and 1,1-difluoroethylene (DFE) was calculated.[27] This explains why these two molecules have similar π BDEs, despite the fact that the latter contains a CF_2 group, pyramidalization of which is calculated to lower the intrinsic π BDE by 11.4 kcal mol^{-1}.

The origin of the much higher intrinsic π-bond energy in DFE than in either ethylene or TFE is the asymmetric substitution of fluorine on the π-bond in DFE. This allows much better donation of the p-π fluorine lone pairs into the π-bond in DFE than in TFE. The 14.6 ± 1.5 kcal mol^{-1} exothermcity of the reaction in eqn. (6) can be viewed as a specific example of

$$H_2C{=}CH_2 + F_2C{=}CF_2 \rightarrow 2\ F_2C{=}CH_2 \qquad (6)$$

Paulings finding that the reaction, $A_2 + B_2 \rightarrow 2$ AB is always exothermic and that the exothermicity increases with the elecronegativity difference between A and B.[27]

Why does TFE not undergo a Diels–Alder reaction with butadiene?

Although the reaction of ethylene with buta-1,3-diene yields a trace of vinylcyclobutane,[31] by far the major product (99.98%) is cyclohexene, formed by a concerted Diels–Alder reaction. In contrast, as shown in eqn. (1), TFE reacts with buta-1,3-diene to give, as the only isolated product, 2,2,3,3-tetrafluoro-1-vinylcyclobutane,[4] formed *via* a stepwise mechanism involving a diradical intermediate.[32]

Although the π-bond in TFE is considerably weaker than the π-bond in ethylene,[3,27] this fact, by itself, does not explain why a transition state involving formation of a bond to just one carbon of TFE is apparently lower in energy than the transition state for a Diels–Alder reaction, in which bonds are simultaneously formed to both carbons. In fact, our calculations found that, despite the weaker π-bond in TFE, the energy difference between the reactants and the transition state for a concerted Diels–Alder reaction is nearly the same for TFE and ethylene.[33] Moreover, *syn* pyramidalization of TFE to ϕ = 26°, as in the transition state for its Diels–Alder reaction with butadiene, was computed to raise the energy of TFE by 5 kcal mol^{-1} more than the same distortion in ethylene. Presumably, repulsions between the fluorines make pyramidalization of TFE in a *syn* fashion energetically costly, so that CF_2 pyramidalization in the Diels–Alder transition state does not accelerate this reaction.

The prediction that the Diels–Alder reactions of butadiene with both TFE and ethylene have approximately the same activation energy cannot be verified experimentally, because, as noted above, TFE reacts rapidly with butadiene to form a diradical intermediate. The energy of this diradical, relative to the reactants, was calculated to be *ca.* 26 kcal mol^{-1} lower for TFE than for ethylene. Clearly this is why TFE, unlike ethylene, reacts with butadiene by forming just one C–C bond.

As expected, the CF_2 radical center is highly pyramidal (ϕ = 47°) in the diradical; and, of course, the CF_2 group at which the new C–C bond is formed also becomes non-planar. Relief of the 18 kcal mol^{-1} 'strain' that is associated with having two planar CF_2 groups in TFE is obviously the major factor that favors the diradical pathway by 26 kcal mol^{-1} in the reaction of TFE with butadiene. However, this diradical intermediate is apparently stabilized by an additional 8–10 kcal mol^{-1} when it is formed from TFE than from ethylene.

We were able to show that the source of this additional stabilization of the fluorinated, over the unfluorinated, diradical is the greater strength of the C–C bond that is formed in the reaction of butadiene with TFE than with ethylene. This bond is not only stronger, but it is also 0.05 Å shorter in the fluorinated than in the unfluorinated diradical. Our calculations indicated that about 90% of the greater strength of this bond comes from the geminal pair of fluorines on the carbon to which this bond is formed.

Calculations and experimental heats of formation both show the favorability of forming C–C bonds to fluorinated carbons. For example, the reaction in eqn. (7) can be thought of as

$$H_3CCH_2CH_3 + HCF_2CH_3 \rightarrow H_3CCH_3 + CH_3CF_2CH_3 \qquad (7)$$

replacing a hydrogen in 1,1-difluoroethane with a methyl group from propane. Without corrections for ΔZPE, we calculated this reaction to be exothermic by 8.0 kcal mol^{-1} at the MP2 level of theory,[33] which is slightly larger than the value of 6.2 kcal mol^{-1} obtained from experimental heats of formation.[5] An even more dramatic example is provided by the reaction in eqn. (2), in which both hydrogens in difluoromethane are replaced by methyl groups. As noted in the introduction, experimental heats of formation[5] show that this reaction is exothermic by 14.5 kcal mol^{-1}.

Electron delocalization into C–F σ* orbitals in neutral molecules

One possible explanation of the preference for attachment of electronegative elements, such as fluorine[33,34c] and oxygen,[34] to the more highly alkylated of two carbons is that the electrons in the C–H bonds at the β carbons delocalize electrons into the low-lying C–F and C-O σ* orbitals. This would explain not only the energetics of the reactions shown in eqns. (2) and (7), but also why our calculations found that the lengths of C–F bonds increase with increasing alkylation of the carbon to which they are attached, and why the lengths of C–C bonds decrease with the addition of fluorines to one of the carbons.

It is generally accepted that electron delocalization into C–F σ* MOs stabilizes carbanions[1] and is also responsible for the anomeric effect observed when fluorine and a heteroatom with unshared π electrons are attached to the same carbon.[35] However, it is much less clear to what extent delocalization of electrons from C–H bonds into C–F σ* MOs actually is responsible for the energetic preference for attachment of alkyl groups to fluorinated carbons and the accompanying changes in bond lengths. In order to test whether delocalization of electrons into C–F σ* orbitals is of any importance in neutral molecules, we performed additional calculations.[36]

Computational evidence, supporting the delocalization of π-electrons into C–F σ* orbitals, was actually published in 1983 by Greenberg *et al.*[37] Their calculations found the reaction in eqn. (8) to be exothermic by 9.6 kcal mol^{-1}.

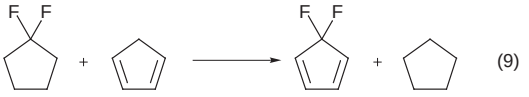
(8)

They attributed the exothermicity to electron donation from the π-bonding orbital of 3,3-difluorocyclopropene into the out-of-phase combination of C–F σ* orbitals. This interaction, which can be represented schematically by the ionic resonance structure shown in Fig. 4, confers a degree of aromaticity on 3,3-difluorocyclopropene. The calculated and observed bond

Fig. 4 Resonance structures for 3,3-difluorocyclopropene. The ionic resonance structure schematically depicts the effect of electron donation from the π-bonding orbital into the out-of-phase combination of C–F σ* orbitals.

lengths and dipole moment of this molecule are consistent with the delocalization of electron density from the π-bond into the C–F σ* orbitals that is depicted in Fig. 4.[36]

The differences in symmetry between the HOMO and LUMO of the ethylene π-bond in cyclopropene and the butadiene π-bonds in cyclopentadiene should make hyperconjugative electron donation from the C–H bonds at C-5 of cyclopentadiene much more stabilizing than delocalization of electron density into the C–F σ* orbitals of 5,5-difluorocyclopentadiene. These hyperconjugative interactions should make cyclopentadiene somewhat aromatic and 5,5-difluorocyclopentadiene somewhat anti-aromatic. Therefore, it is not surprising that our calculations found the reaction in eqn. (9) to be endothermic by 14.1 kcal mol^{-1}.[36]



(9)

Hyperconjugative delocalization into C–F σ* orbitals in 1,3-diradicals

If the C–F σ* orbitals in 1,1-difluorocyclopropene can accept electron density from the π-bonding orbital, they should certainly be able to accept electron density from the in-phase combination of non-bonding p-π AOs in 2,2-difluoropropane-1,3-diyl. Similarly, if the C–H bonds at C-5 of cyclopentadiene can donate electron density into the antibonding butadiene LUMO, they certainly ought to be able to donate electron density into the in-phase combination of non-bonding p-π AOs in propane-1,3-diyl. These hyperconjugative interactions are depicted by the resonance structures in Fig. 5.

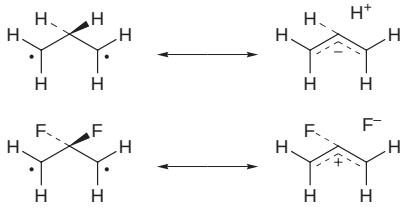


Fig. 5 Resonance structures depicting hyperconjugative electron donation from the C–H bonds of the central CH_2 group into the in-phase combination of p-π AOs at C-1 and C-3 in propane-1,3-diyl and electron donation from the in-phase combination of p-π AOs at C-1 and C-3 into the C–F σ* orbitals at C-2 in 2,2-difluoropropane-1,3-diyl

Thirty years ago Hoffmann analyzed the results of his extended Hückel calculations on propane-1,3-diyl in terms of interaction of the C–H bonds at C-2 with the in-phase combination of p-π AOs at C-1 and C-3.[38] This interaction destabilizes the latter orbital, making it advantageous for the two non-bonding electrons to occupy preferentially the out-of-phase combination of p-π AOs at C-1 and C-3. This combination is the highest occupied MO (HOMO) of the allylic anion in the hyperconjugated resonance structure for propane-1,3-diyl in Fig. 5.

An orbital interaction diagram for 2,2-difluoropropane-1,3-diyl shows that the in-phase combination of p-π AOs at C-1 and C-3 is stabilized by interaction with the C–F σ* orbitals at C-2.[7,36] Therefore, the two non-bonding electrons preferentially occupy the orbital that results from this mixing. This orbital has the same symmetry as the HOMO of the allylic cation in the hyperconjugated resonance structure for 2,2-difluoropropane-1,3-diyl in Fig. 5.

The difference in the symmetry of the HOMO between propane-1,3-diyl and 2,2-difluoropropane-1,3-diyl is predicted to result in a difference in the preferred mode by which these two diradicals are formed from, and undergo closure to, the corresponding cyclopropanes. More specifically, although ring opening and ring closure are predicted to be conrotatory in cyclopropane,[38] they are predicted to be disrotatory in 1,1-difluorocyclopropane.[7,36]

The difference in the symmetry of the HOMOs between unfluorinated and fluorinated diradicals can explain some otherwise puzzling experimental results that were obtained by Dolbier and co-workers[39] and which are summarized in Fig. 6.

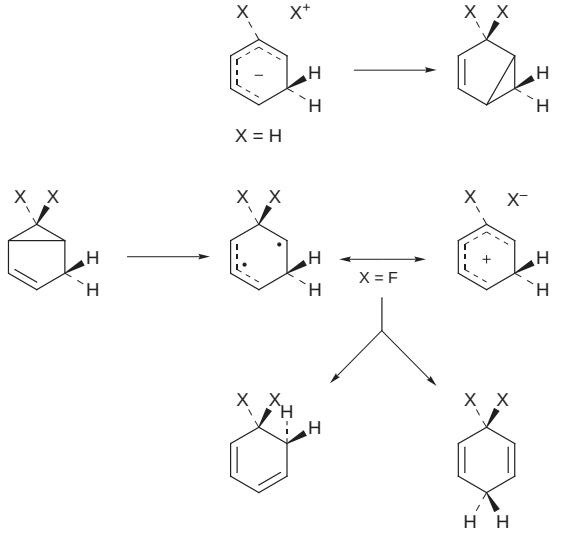

Fig. 6 Rearrangement pathways followed by bicyclo[3.1.0]hex-2-ene and its 6,6-difluoro derivative. The hyperconjugated resonance structure shown for the diradical intermediate formed in each reaction can be used to rationalize the difference between the reaction pathways followed by the hydrocarbon and fluorocarbon (ref. 36).

Derivatives of bicyclo[3.1.0]hex-2-ene (X = H) undergo vinylcyclopropane rearrangements, presumably *via* a diradical intermediate; but Dolbier found that 6,6-difluorobicyclo-[3.1.0]hex-2-ene (X = F) gives no vinylcyclopropane rearrangement product; only the two products of hydrogen shifts in a putative diradical intermediate were detected.

The hyperconjugated resonance structures shown in Fig. 6 can readily account for the different reactions observed for X = H and X = F.[36] Hyperconjugative electron donation from the C–X bonds for X = H gives the diradical intermediate some character of a pentadienyl anion. Disrotation, which is the only stereochemically feasible mode of ring closure in the diradical, is allowed by orbital symmetry for a pentadienyl anion; but the node in the LUMO at the distal CH_2 group makes [1,2]-hydrogen shifts from this carbon symmetry forbidden. In contrast, for X = F, hyperconjugative electron delocalization into a C–X σ* orbital in the diradical confers on it some character of a pentadienyl cation. For such a species disrotatory ring closure is forbidden by orbital symmetry, but the symmetry of the LUMO makes [1,2]-hydrogen shifts allowed.

The hyperconjugated resonance structures for propane-1,3-diyl and 2,2-difluoropropane-1,3-diyl in Fig. 5 also allow one to predict that π-electron donation from alkyl groups at C-1 and C-3 should compete with electron donation from a filled combination of C–H bonding orbitals at C-2. In contrast, it is clear from Fig. 5 that electron donation from alkyl groups at C-1 and C-3 should enhance electron donation into the C–F σ* orbitals of the fluorocarbon. Both predictions have been confirmed by *ab initio* calculations[7,36] and are consistent with the experimental results that are discussed in the next section.

Before discussing the effect on cyclopropane stereomutations of replacing the hyperconjugatively electron-donating CH_2 group in propane-1,3-diyl with the electron-accepting CF_2 group in 2,2-difluoropropane-1,3-diyl, it is important to address the question of whether two hydrogens or two fluorines at C-2 provide more stabilization for the diradical formed by cyclopropane ring opening. After correcting eqn. (10) for the fact that the

$$H_3CCF_2CH_3 + \cdot H_2CCH_2CH_2\cdot \rightarrow \cdot H_2CCF_2CH_2\cdot + H_3CCH_2CH_3 \quad (10)$$

C–H BDE of 2,2-difluoropropane is computed to be 2.4 kcal mol^{-1} larger than that of propane, the CF_2 group in 2,2-difluoropropane-1,3-diyl is calculated to provide 3.2 kcal mol^{-1} more stabilization for this diradical than the CH_2 group at C-2 provides for propane-1,3-diyl.[36]

Stereomutation of cyclopropanes and 1,1-difluorocyclopropanes

The publication of Hoffmann's 1968 paper on propane-1,3-diyl[38] inspired a huge amount of computational and experimental work on the stereomutation of cyclopropane. Our own computational efforts in this area were initially motivated less by an interest in propane-1,3-diyl *per se* than by the desire to have calculations on the hydrocarbon diradical with which we could compare our computational results on 2,2-difluoropropane-1,3-diyl.[7]

The most important results of the computational and experimental studies of the hydrocarbon diradical can be summarized as follows. (i) *Ab initio* calculations predict only a 1–2 kcal mol^{-1} preference for con- over dis- and monorotation,[40] a much smaller preference than was found by Hoffmann's Extended Hückel calculations.[38] (ii) As already noted, *ab initio* calculations also predict that alkyl substituents will greatly reduce the small preference for conrotation that is computed for unsubstituted cyclopropane.[36] (iii) Presumably for this reason, experiments on the stereomutation of substituted cyclopropanes have found no preference for coupled rotation.[6,40]

For cyclopropane substituted only by deuterium, (iv) Berson and co-workers[41a,b] and, later, Baldwin[41c] reported a preference for coupled rotation in their studies of the stereomutation of [1,2-$^2H_2$]cyclopropane. (v) However, Baldwin and co-workers found no evidence for coupled rotation in their subsequent study of the stereomutation of [1,2,3-$^2H_3$, 1-^{13}C]cyclopropane.[41d,e] (vi) Calculations show that isotope effects are incapable of reconciling the results of these two experiments.[40a,b] (vii) The results of reaction dynamics calculations[42] are more consistent with the experimental results for [$^2H_2$]cyclopropane[41a–c] than for [$^2H_3$]cyclopropane.[41d,e]

Since the dynamics calculations predict that the coupled rotation found in [$^2H_2$]cyclopropane consists of not only orbital symmetry-allowed conrotation but also of symmetry-forbidden disrotation, the experimental results on [$^2H_2$]cyclopropane should not be taken as confirmation of Hoffmann's prediction of a preference for coupled *conrotation* in the stereomutation of cyclopropane. There is currently no method available for distinguishing between conrotation and disrotation in the experimental study of the stereomutation of [1,2-$^2H_2$]cyclopropane; so there is no known experimental technique that could disprove the mischievous conjecture of a devil's advocate who asserted that the coupled methylene rotation observed in the stereomutation of [$^2H_2$]cyclopropane consists entirely of disrotation rather than conrotation.

What a difference geminal fluorines make! As already noted, the greater ability of C–F σ* orbitals at C-2 to accept electrons in 1,3-diradicals, compared to the ability of filled C–H orbitals at C-2 to donate electrons, is calculated to make hyperconjugative stabilization of the so-called (0,0) geometry[38] of 2,2-difluoropropane-1,3-diyl larger than that of the same geometry of the hydrocarbon diradical.[36] This should make disrotation much more favorable in the stereomutation of 1,1-difluorocyclopropane than conrotation is in the stereomutation of cyclopropane. The results of *ab initio* calculations on the ring opening of the fluorocarbon show that the transition state for disrotation is, in fact, *ca.* 4 kcal mol^{-1} lower in energy than the transition states for conrotation, monorotation, or cleavage of a ring bond to C-1.[7,36]

As discussed above, 2,3-dialkyl-1,1-difluorocyclopropanes are expected to show an even greater preference for disrotatory ring opening and closure than 1,1-difluorocyclopropanes. As shown in Fig. 7, the calculated preference for ring opening of

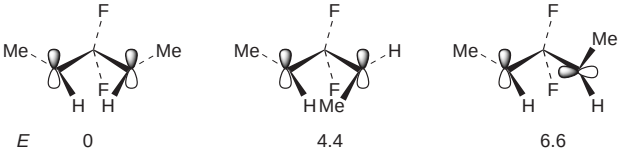

Fig. 7 Relative CASPT2 energies (kcal mol^{-1}) of three conformations of 3,3-difluoropentane-2,4-diyl (ref. 8)

1,1-difluoro-2,3-dimethylcyclopropane to the s-*trans*,s-*trans* (0,0) geometry of 3,3-difluoropentane-2,4-diyl, over rotation of just one methylene group, to form the so-called (0,90) geometry,[38] amounts to 6.6 kcal mol^{-1} when the effects of dynamic electron correlation[43] are included at the CASPT2 level.[8]

As also shown in Fig. 7, ring opening of 2,3-dimethyl-1,1-difluorocyclopropane to the s-*trans*,s-*cis* (0,0) geometry of 3,3-difluoropentane-2,4-diyl is calculated to be more favorable than opening to the (0,90) geometry, but only by 2.2 kcal mol^{-1}.[8] The very large calculated preference of *ca.* 4 kcal mol^{-1} for ring opening to the s-*trans*,s-*trans*, rather than the s-*trans*,s-*cis* geometry of 3,3-difluoropentane-2,4-diyl has been shown to have its origin in the symmetry of the HOMO in this fluorinated diradical.[36]

The large predicted preference for opening of a 2,3-dialkyl-1,1-difluorocyclopropane to an s-*trans*,s-*trans*, rather than an s-*trans*,s-*cis*, geometry can be used to design an experiment to distinguish between conrotatory and disrotatory ring opening.[7,36] If, as predicted, ring opening is disrotatory, the *cis* cyclopropane stereoisomer will open to the preferred s-*trans*, s-*trans* geometry of the 1,3 diradical, whereas the *trans* cyclopropane stereoisomer must open to the s-*trans*,s-*cis* geometry. Therefore, if ring opening is, in fact, disrotatory, an optically active *cis*-2,3-dialkyl-1,1-difluorocyclopropane should racemize faster than its *trans* stereoisomer.

In collaboration with the group of Professor William Dolbier, we prepared optically active *cis*- and *trans*-2-ethyl-3-methyl-1,1-difluorocyclopropane and studied the stereomutations of these two isomers.[8] At 274.5 °C, racemization of the *cis* isomer was found to be 107 times faster than its epimerization to the *trans* isomer by any pathway that effects one-center rotation. At this temperature, racemization was also found to be favored over epimerization in the *trans* isomer, but only by a factor of 6.6. The finding that the ratio of the rate constants for racemization and epimerization is 16.2 times larger for the *cis* cyclopropane than for its *trans* isomer shows that the coupled rotation that is observed in both isomers is disrotation, as predicted.[7,36]

Effect of electron delocalization into C–F σ* orbitals on singlet-triplet energy differences in 1,3-diradicals

Increasing the energy separation between the HOMO and LUMO in a diradical selectively stabilizes the lowest singlet state, relative to the triplet, since in the former state more than one electron can occupy the HOMO, whereas in the latter the HOMO and the LUMO are each occupied by one electron.[44] Thus, either the presence of filled σ orbitals at C-2 that are good hyperconjugative electron donors or unfilled σ* orbitals that are good hyperconjugative electron acceptors can, in principle,

result in singlet ground states for derivatives of propane-1,3-diyl. Therefore, it is not surprising that, although cyclopentane-1,3-diyl has been both calculated[10,45] and found[9] to have a triplet ground state, the ground state of 2,2-difluorocyclopentane-1,3-diyl has been predicted to be a singlet (Fig. 8).[10]

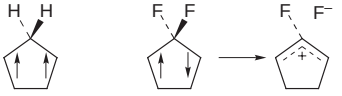

Fig. 8 Cyclopentane-1,3-diyl is known to have a triplet ground state (ref. 9), but electron donation into the C–F σ* orbitals at C-2 is predicted to make 2,2-difluorocyclopentane-1,3-diyl a ground state singlet (ref. 10)

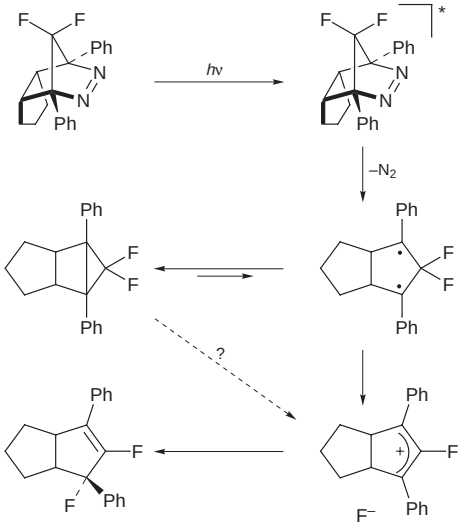
In order to test this prediction, we collaborated with the research groups of Professors Waldemar Adam and Jakob Wirz on the generation and study of the derivative of 1,3-diphenyl-2,2-difluorocyclopentane-1,3-diyl shown in Scheme 1.[11] As



Scheme 1

shown, the diradical was generated by flash photolysis of an azo compound. A strong absorption with λ_{max} = 530 nm appeared with a time constant of τ = 8 ± 1 ps, and in pentane it disappeared with τ = 80 ± 3 ns. In this solvent the diradical reacts to form both the tricyclic difluoride and the bicyclic difluoroalkene. The former was observed by ^{19}F NMR spectroscopy at low temperatures, but at room temperature it rearranges with τ = 225 ± 20 μs to the latter.

The temperature dependence of the rate of disappearance of the diradical was measured and gave log A = 12.8 ± 0.4 and E_a = 7.8 ± 0.5 kcal mol^{-1}. These Arrhenius parameters are very different from those of log A = 6.7 and E_a = 2.6 kcal mol^{-1} measured for disappearance of the hydrocarbon diradical, lacking the geminal fluorines. The fluorocarbon and hydrocarbon diradicals also differ in the rate of their reaction with O_2. The former cannot be trapped by oxygen, making $k_{O2} < 4 \times 10^7$ M^{-1}s^{-1}; whereas, the latter reacts with O_2 with a rate constant of $k_{O2} = 3 \times 10^9$ M^{-1}s^{-1}.

The hydrocarbon diradical gives a triplet EPR spectrum and, like the parent cyclopentane-1,3-diyl, it appears to have a triplet ground state. This accounts for the low values of log A and E_a for the disappearance of the hydrocarbon diradical, since intersystem crossing to a slightly higher energy singlet state is the rate determining step. The reaction of the triplet hydrocarbon diradical with triplet oxygen is fast, because the two triplet species can give a singlet product by forming two C–O bonds in a concerted fashion.

The high E_a for disappearance of the fluorocarbon diradical allowed frozen solutions of it to be studied at low temperatures. At 77 K the red color of the diradical persisted for a day, but no triplet EPR signal was detected. The conclusion that the fluorinated diradical has a singlet ground state is supported by the activation parameters for its disappearance, which are typical of those for a spin-allowed process, and the rate at which it is trapped by oxygen, which was too slow for us to measure. These experimental results[11] are consistent with our prediction that the ability of C–F σ* orbitals to accept electrons is sufficiently large to make the singlet the ground state of 2,2-difluorocyclopentane-1,3-diyls.[10]

Future research

In the course of the theoretical studies described in the previous sections, we moved from explaining phenomena that were already known to predicting new phenomena. Prediction is the ultimate goal of any theory, and the experimental confirmation of our predictions that geminal fluorine substituents should result in disrotatory cyclopropane ring-opening and in singlet ground states for 1,3-diradicals shows that delocalization of electrons into C–F σ* orbitals is a very useful theoretical construct.

If the presence of low-lying empty σ* orbitals at C-2 can stabilize the singlet states of 1,3-diradicals, it follows that high-lying filled σ orbitals at C-2 should have the same effect. Therefore, replacement of the C–H bonds at C-2 of propane-1,3-diyl by weaker bonds to less electronegative elements, for example silicon, should also favor formation of the (0,0) geometries of such diradicals by coupled rotation of the methylene groups in the ring-opening reactions of the corresponding cyclopropanes. The hyperconjugated resonance structure for 2,2-disilylpropane-1,3-diyl in Fig. 9 allows the

Fig. 9 Hyperconjugated resonance structure for 2,2-disilylpropane-1,3-diyl

prediction that ring-opening to form this diradical should be conrotatory.

To the extent that the hyperconjugated resonance structures, like that in Fig. 9, are important, it seems likely that 2,2-disilylcyclopentane-1,3-diyls should, like 2,2-difluorocyclopentane-1,3-dilyls, have singlet ground states. However, since disrotatory closure is expected to be an orbital-symmetry forbidden reaction in 2,2-disilylcyclopentane-1,3-diyls, unlike their difluoro-substituted counterparts, they should be kinetically stabilized against ring closure.

These qualitative predictions have already survived the tests of calculations performed at levels that are deemed to provide quantitatively accurate results.[46,47] It remains to be seen if, as predicted, geminal disilylcyclopropanes will be found experimentally to undergo stereomutation by coupled conrotation[46] and whether 2,2-disilylcyclopentane-1,3-diyls will be found to have singlet ground states and appreciable kinetic barriers to ring closure.[47]

Acknowledgements

I wish to thank my many collaborators, who, over the past twenty years, performed the computational and experimental studies that are described in this article. I am particularly grateful to Dr David A. Hrovat, who was involved to some extent in nearly all the research projects described in this article and who prepared the figure for the cover of this issue. I also thank the National Science Foundation, which generously supported this research. This article is dedicated to the memory of Professor Paul D. Bartlett, in whose physical organic chemistry course at Harvard in 1964 I first learned about the propensity of TFE and other fluorinated alkenes to undergo stepwise cycloaddition reactions.

Weston Thatcher Borden received his undergraduate degree from Harvard in 1964. Following a year spent on a Fullbright Fellowship, studying theoretical chemistry with H. C. Longuet-Higgins, he returned to Harvard and, under the guidance of E. J. Corey, was awarded a PhD in 1968. After another five years on the faculty of the same institution, he joined the Chemistry Department at the University of Washington. His research activities include the synthesis and study of molecules of theoretical interest and the application of qualitative molecular orbital theory and quantitative *ab initio* calculations to the understanding of organic chemistry. He has received fellowships from the Alfred P. Sloan Foundation, the Guggenheim Foundation, and the Japanese Society for the Promotion of Science, and a Humboldt Senior Scientist Award. His non-chemical interests include gardening, hiking, and traditional Japanese arts, such as *chanoyu* and *ikebana*.

Domino reaction of lithiated allenes with nitriles†

Peter Langer,*[a]‡ Manfred Döring[b] and Dietmar Seyferth[c]

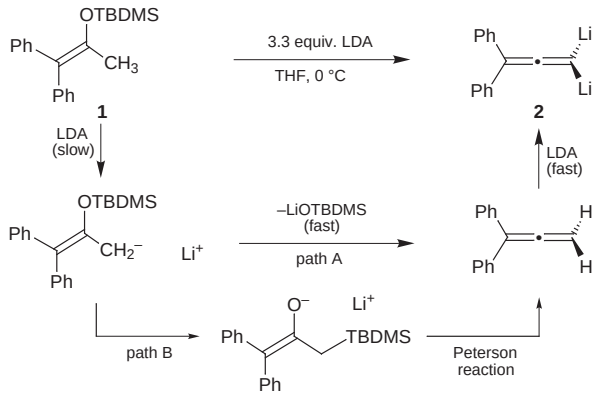
Addition of nitriles to dilithiated allenes results in a unique domino cyclization which involves the so far highest number of nitrile molecules added to an organolithium reagent to form unambiguously characterized oligomers.

The development of domino reactions is of ongoing interest in organic synthesis.[1] Interestingly, although the base-catalyzed polymerization of nitriles has been followed for a long time and the mixtures obtained were among the first organic polymers, only a few structurally unambiguously characterized oligomers derived from multiple addition reactions of nitriles have been reported so far. In contrast, the palladium-catalyzed oligomerization of six isonitrile molecules has recently been reported.[2] Addition of 2 equiv. of a nitrile to an organometallic reagent has been achieved by reaction of 2,3-bis-lithiated methylbutadiene with PhCN,[3a] by 1,4-addition of nitriles to (butadiene)zirconocene[3b,c] and by base-induced oligomerization of glycolonitrile.[3d] Very recently, a domino reaction initiated by addition of a Grignard reagent to a tris-nitrile has been reported.[4a] Herein we report the addition of up to 4 equiv. of a nitrile to dilithiated allenes, a process which we believe includes a novel type of rearrangement reaction.[5]

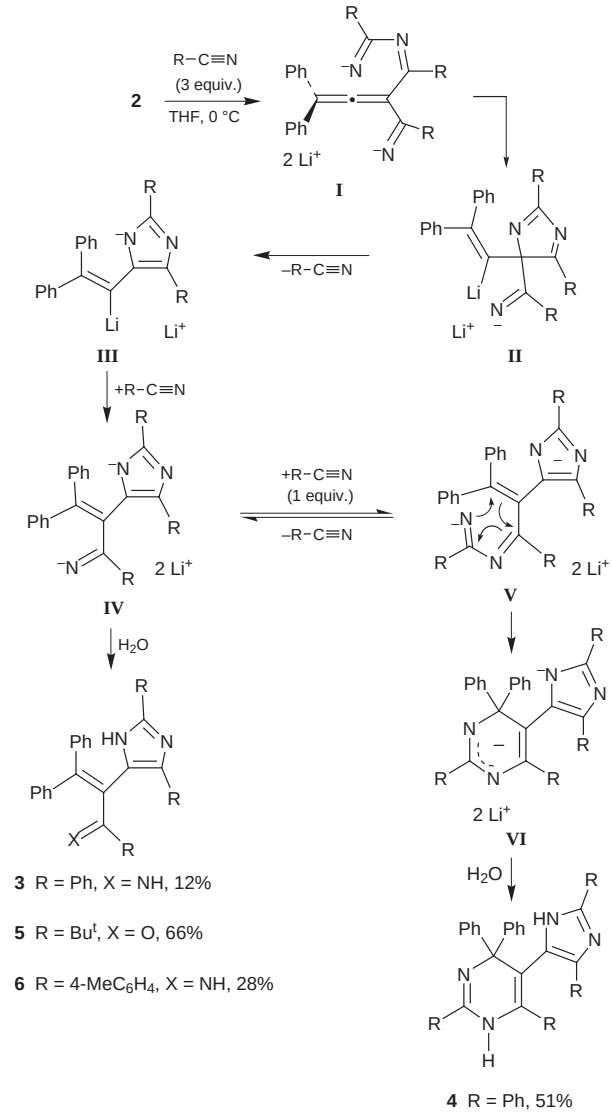
1,1-Diphenyl-3,3-dilithioallene **2** was generated in one pot by treatment of the TBDMS enol ether **1** with an excess of LDA in THF, a reaction recently developed by us.[6] This process presumably proceeds *via* a mechanism involving initial lithiation of the allyl system of the silyl enol ether, elimination of lithium silanolate and lithiation of the 1,1-diphenylallene formed (Scheme 1). The elimination could either occur directly (path A) or proceed *via* a O→C silyl migration/Peterson elimination sequence (path B).

Reaction of lithiated allenes with nitriles was expected to result in formation of allenylimines. Selected examples of these compounds have recently been prepared in moderate yields by reaction of allenic aldehydes with amines.[7] Reaction of **2** with 2.2 equiv. of PhCN resulted in a complex reaction mixture from which two products, **3** (9%) and **4** (14%) (Scheme 2), were isolated by column chromatography in low yields. Much to our surprise, FAB-MS suggested that products derived from reaction of the allene with three and four nitriles, respectively, had been formed. The yield of **4** was significantly improved by use of 4.5 equiv. of the nitrile. Yellow-coloured imidazole **3** and colourless 5-imidazol-5-yl-1,4-dihydropyrimidine **4** were isolated in 12 and 51% yield, respectively.§ Similar results were obtained when 10 equiv. of PhCN were employed. Reaction of dilithioallene **2** with pivalonitrile afforded as the sole isolated product the colourless imidazole **5** (66%). The imine group was hydrolyzed during aqueous work-up to generate an α,β-unsaturated keto group. Reaction of **2** with *p*-tolunitrile gave the orange coloured imidazole **6** (28%).

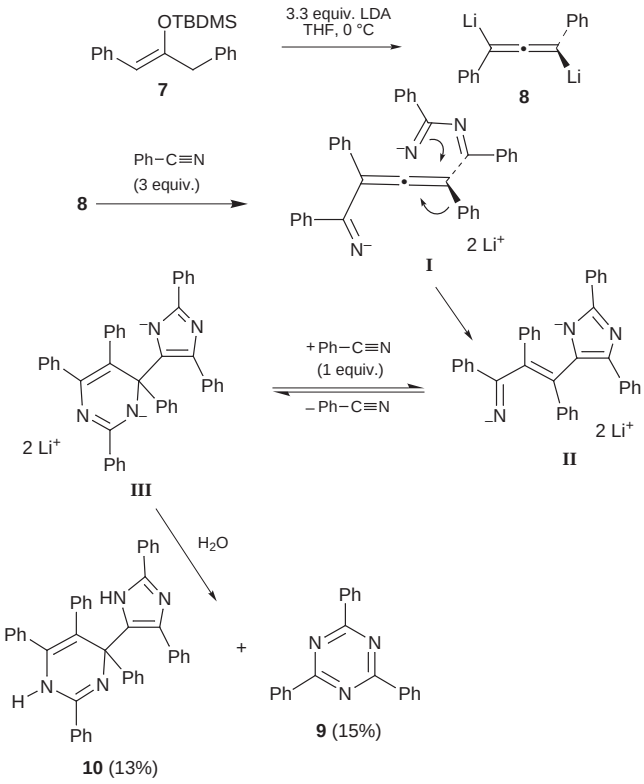
Formation of the sterically crowded imidazoles **3**–**6** can be rationalized by the mechanism shown in Scheme 2. The



Scheme 1



Scheme 2



Scheme 3

terminal carbon atom of the allene dianion **2** initially reacts with two molecules of the nitrile. Presumably, the negative charge will mainly be localized at the nitrogen atoms. A third nitrile molecule is attacked (intermediate **I**) and the amidine anion thus formed attacks the terminal allene carbon atom to give intermediate **II** which contains a five-membered ring and a vinyl carbanion function. An aromatic imidazole anion (intermediate **III**) is generated next by elimination of 1 equiv. of the nitrile. The vinyl carbanion subsequently reacts with the nitrile to give intermediate **IV**. The fourth nitrile molecule is attacked by the imine anion of intermediate **IV** to generate an amidine anion (intermediate **V**). The amidine anion attacks the terminal allene carbon atom bearing the phenyl groups to give a dihydropyrimidine anion (intermediate **VI**). Aqueous work-up furnishes heterocycles **4** and **3** derived from intermediates **VI** and **IV**, respectively.

Reaction of PhCN with the dianion of 1,3-diphenyl-1,3-dilithioallene **8** (formed *in situ* by reaction of silyl enol ether **7** with 3.3 equiv. of LDA) afforded after hydrolytic work-up a mixture of 2,4,6-triphenyltriazine **9**[8] (formed by trimerization of the nitrile) and imidazole **10** (a 1:4 product). The formation of **10** can be explained by a reaction sequence similar to that leading to oligonitrile **4** (Scheme 3). This reaction seems to involve migration of a phenyl rather than a phenylimino group.

It is noteworthy that all carbon atoms of the allene system are involved sequentially in the reaction leading to cyclic oligonitrile **4**. The intramolecular attack of the amidine anion on the terminal (rather than on the central) allene carbon atom and the subsequent rearrangement reaction (**I**→**IV**, Scheme 2) are surprising. However, this process can be explained by the stability of the aromatic imidazole anion formed. Steric hindrance seems to be the reason that no addition of a fourth nitrile molecule takes place for **5** and **6**. Interestingly, treatment of the dianion of 2-methylbenzimidazole or of amide derived dianions with 4.5 equiv. of PhCN resulted in addition of only 1 equiv. of the nitrile to the dianion rather than in formation of an open-chained oligonitrile.[9] This striking difference to the reaction of the allene dianion **2** suggests that the addition of the imine anion to the nitrile is a reversible process which becomes irreversible when the amidine anion generated can undergo a consecutive reaction to form a more stable intermediate (such as **IV** and **VI** in Scheme 2).¶ It is noteworthy that the number of nitrile molecules added to the dianion does not depend on the number of equivalents of the nitrile employed in the reaction. Therefore, there is some relationship between the reaction reported and self-assembly processes.

P. L. thanks Professor A. de Meijere for his support. Financial support from the Fonds der Chemischen Industrie e. V. (award of a fellowship to P. L.) is gratefully acknowledged.

§ *Preparation of imidazole* **4**. To a THF solution (40 ml) of silyl enol ether **1** (1.80 g, 5.6 mmol) was added a THF solution of LDA which was prepared by addition of Bu^{n}Li (1.6 M in hexane) to a THF solution (20 ml) of Pr$^i_2$NH (3.3 equiv.) at 0 °C. The solution was stirred at 20 °C for 6 h during which time the color of the solution became deep red. A THF solution (10 ml) of PhCN (2.58 ml, 4.5 equiv.) was added at 0 °C by syringe. After stirring for 10 h at 20 °C, water (20 ml) was added to the deep purple solution and the colour changed to yellow. The reaction mixture was extracted (Et_2O–THF = 1:1) and the combined organic layers were dried ($MgSO_4$), filtered and the solvent was removed *in vacuo* to give imidazole **4** (1.73 g, 51%) after purification by column chromatography (silica gel, Et_2O–light petroleum = 1:1) as a colorless solid, mp 146–150 °C; δ_H([$^2H_8$]THF, 200 MHz) 6.75–8.20 (m, 30 H, Ar), 8.75 (br, 1 H, NH), 10.68 (br, 1 H, NH); δ_C([$^2H_8$]THF, 50 MHz) 107.20 (C, *C*Ph$_2$), 125.27, 125.76, 125.87, 126.06, 126.26, 127.12, 127.30, 127.50, 128.02, 128.08, 128.17, 128.30, 128.68, 128.90, 129.21, 129.76 129.92, 130.86 (CH, Ph), 132.15, 132.19, 136.43, 136.73, 137.37, 138.19 (C, Ph, =*C*Ph$_2$), 145.67, 148.50, 148.78 (C, C=*C*N), 150.65, 150.78 (C, CN$_2$); ν_{max}(KBr)/cm^{-1} 3495 (br), 3395 (br), 3060 (m), 3029 (m), 2923 (w), 1640 (s), 1598 (m), 1578 (m), 1524 (s), 1496 (m), 1446 (m), 1395 (s), 1370 (m), 1178 (m), 1072 (m), 1028 (m), 697 (s); *m/z* (FAB) 605 (100%, M$^+$+1); Calc. for $C_{43}H_{32}N_4$: C, 85.41; H, 5.33; N, 9.26. Found.: C, 85.17; H, 5.61; N, 9.62%.

¶ The reactions cited in refs. 3(*a*)–(*d*) involve only a single addition of each nucleophilic center to a nitrile molecule since the imine anions formed are intramolecularly trapped to form stable dianionic systems. In contrast, in ref. 4, a second nitrile group is attacked by the initially formed imine anion. Thus, in the third step of the reaction, a stable anion could be formed.

An enantiocontrolled synthesis of a key intermediate to (+)-lactacystin

Sung Ho Kang*† and Hyuk-Sang Jun

Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon. 305-701, Korea

An asymmetric synthesis of a key intermediate 16 to (+)-lactacystin 1 has been established starting from epoxide 2 *via* intramolecular mercurioamidation of allylic trichloroacetimidate 4 and concomitant addition-reduction of ester 13 by Pr^i MgBr, in which reduction of the intermediate ketone proceeded with complete stereoselectivity.

Since neurotrophic factors are responsible for the survival and function of neurons,[1] they might be useful in the treatment of various nerve diseases.[2] Omura *et al*. screened a number of microbial culture samples to isolate the first non-protein neurotrophic agent (+)-lactacystin **1** from *Streptomyces* sp. OM-6519.[3] Its structure, elucidated by NMR spectroscopy and X-ray crystallographic analysis, is composed of (*R*)-*N*-acetylcysteine and a unique pyroglutamic acid *via* a thioester linkage.[4] (+)-Lactacystin inhibits cell proliferation, induces neuritogenesis and increases the intracellular cAMP level transiently in the Neuro 2A neuroblastoma cell line.[3,5] Its intriguing structural features as well as potential therapeutic utility have engendered considerable interest in the fields of synthetic and medicinal chemistry. Here we describe a stereoselective synthetic route to (+)-lactacystin.[6–9] The key steps of our synthesis comprise tertiary amination of the olefinic double bond in allylic trichloroacetimidate **4** *via* mercurioamidation,[10] facile differentiation of the hydroxymethyl groups in **10** by ring formation and diastereoselective derivatization of ester **13** into alcohol **14**.

The known epoxide **2**,[11] $[\alpha]_D^{20}$ −24.7 (*c* 1.15, $CHCl_3$), was treated with LDA to give allylic alcohol **3**, $[\alpha]_D^{21}$ +10.4 (*c* 1.44, $CHCl_3$), in 91% yield (Scheme 1). Only the primary hydroxy group of **3** was functionalized to a trichloroacetimidate. The crude monoimidate **4** was subjected to intramolecular mercurioamidation using mercuric trifluoroacetate with K_2CO_3 to furnish a 1:1 diastereomeric mixture of oxazolines **5** in 92% overall yield after aqueous KBr work-up. Since oxidative demercuration[12] of **5** using O_2 failed under a variety of reaction conditions, it was attempted by exposing **5** to TEMPO in the presence of $LiBH_4$ to provide the oxidized products **6** in 78% yield. The secondary hydroxy groups of **6** were protected with $MeOCH_2Cl$ (MOMCl) and then the silyl groups were removed to afford the corresponding primary alcohols in 84% overall yield. While PDC oxidation of the alcohols in DMF was sluggish, they were efficiently oxidized to carboxylic acids **8** in 78% yield by Swern oxidation[13] followed by $KMnO_4$ oxidation.[14] Complete hydrolysis and the ensuing cyclization were effected by heating **8** at reflux with ethanolic HCl in AcOH. The 2,2,6,6-tetramethylpiperidyl (TEMP) groups of the generated pyrrolidinones **9** were reductively cleaved *in situ* by adding zinc to the hot reaction mixture to produce trihydroxy pyrrolidinone **10**, $[\alpha]_D^{19}$ +9.5 (*c* 0.95, MeOH), in 72% overall yield from **8**.

For the appropriate elaboration of the α-hydoxymethyl groups in **10**, it was chemoselectively reacted with acetone under acidic conditions to give a 7:1 mixture of acetonides **11** and **12** in 95% combined yield (Scheme 2). After chromatographic separation, the primary alcohol **11**, $[\alpha]_D^{20}$ +31.4 (*c* 1.10, $CHCl_3$), was oxidized under Swern conditions and the resulting aldehyde reacted with Pr^{i}MgBr under various reaction conditions to furnish a 1 : 1 mixture of alcohols **14** and **15** along with an appreciable amount of the reduced starting alcohol **11**. Owing to the inefficient Grignard addition, **11** was converted into ester **13**, $[\alpha]_D^{21}$ +57.1 (*c* 1.70, $CHCl_3$), in 90% yield. Subjection of **13** to 1 equiv. of Pr^{i}MgBr provided the corresponding isopropyl ketone in 80% yield, the stereoselective reduction of which was attempted employing several reducing agents such as oxazaborolidine,[15] Ipc_2Cl,[16] sodium triacetoxyborohydride,[17] $NaBH_4$ in the presence of diethylmethoxyborane,[18] and so forth. However, the best stereoselectivity turned out to be 5 : 1 in favor of **14** with $NaBH_4$ in MeOH at 0 °C. Some experimentation revealed that an excess amount of Pr^{i}MgBr reduced the generated isopropyl ketone to the alcohol **14**. Accordingly, **13** was treated with > 2 equiv. of Pr^{i}MgBr to give selectively only the desired diastereomeric alcohol **14**, $[\alpha]_D^{20}$ +40.5 (*c* 1.20, $CHCl_3$), in 91% yield. Acidic hydrolysis of **14** yielded trihydroxy pyrrolidinone **16**, mp 198–199 °C (decomp.), $[\alpha]_D^{20}$ +16.2 (*c* 0.62, MeOH), quantitatively, the spectroscopic data of which are identical to those reported in the literature and which is a known intermediate to (+)-lactacystin **1**.[8,19]

We have developed an enantioselective synthetic route to (+)-lactacystin **1** *via* several crucial steps, including animo hydroxylation of the olefinic double bond in **3**, the hydrolytic cyclization of **8**, and the regio- and stereo-selective functionalization of one hydroxymethyl group in **10**; these should have versatility in the synthesis of its analogues.

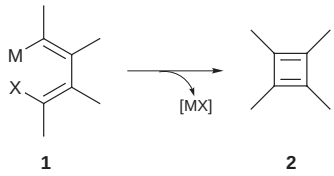
Generation of cyclobutadiene derivatives from 1-metallo-4-halobuta-1,3-diene derivatives

Haruka Ubayama,[a] Wen-Hua Sun,[a] Zhenfeng Xi[b] and Tamotsu Takahashi*[a]†

[a] *Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060, Japan*
[b] *Department of Chemistry, Peking University, Beijing 100871, China*

1-Zircona-4-halobuta-1,3-diene derivatives react in the presence of CuCl to produce cyclobutadiene derivatives which afford their dimers, or Diels–Alder adducts with dimethyl maleate or fumarate.

Cyclobutadiene is one of the most attractive molecules.[1] Several methods have been reported to generate cyclobutadiene derivatives,[1,2] such as (i) irradiation in argon matrix, (ii) preparation from diazo compounds or 3,4-dichlorocyclobutenes or (iii) dimerization of alkynes promoted by metal compounds. A conceptually new and simple method using intramolecular coupling of 1-metallo-4-halobuta-1,3-diene **1** can be considered as a preparative method for cyclobutadiene derivatives, as shown in eqn. (1). However, this simple method has not to the

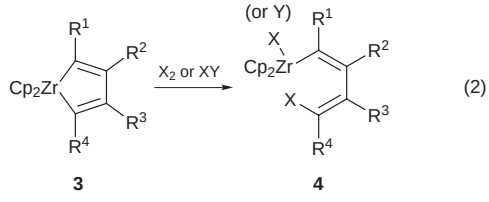


1 **2** (1)

best of our knowledge been reported.

Here we report that 1-zircona-4-halobuta-1,3-diene derivatives afford *in situ* cyclobutadiene derivatives **2** in the presence of CuCl.

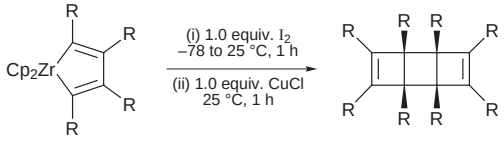
Recently, we reported the highly selective monohalogenation reaction of zirconacyclopentadienes **3** giving 1-zircona-4-halobuta-1,3-diene derivatives **4** [eqn. (2)].[3] Addition of 1 equiv. of



3 **4** (2)

X_2 = I_2; XY = NBS or NCS

CuCl to **4** in THF at room temperature afforded stereodefined tricyclo[4.2.0.0^{2,5}]octa-3,7-diene derivatives **5** within 1 h in good isolated yields (**5a**:‡ R = Et, 72%; **5b**: R = Me, 53%; **5c**:§ R = Pr, 78%) [eqn. (3)]. The ^{1}H and ^{13}C NMR spectra of **5b**



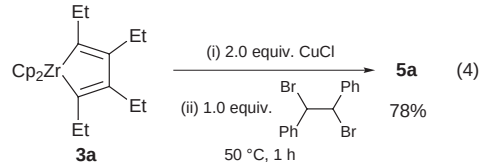
3 (3)

5a R = Et, 72%
b R = Me, 53%
c R = Pr, 78%

were identical with those of authentic *syn*-**5b** prepared according to the literature procedure.[4]

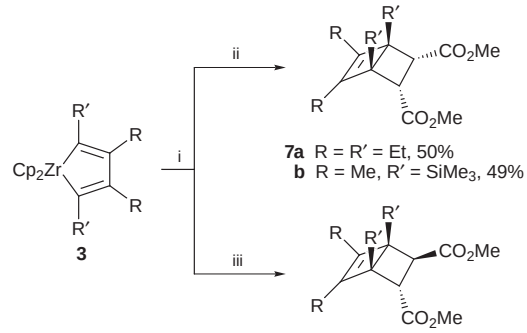
This result indicated that cyclobutadienes were formed *in situ* in this reaction. This reaction can be explained by intramolecular coupling between the 1,4 sp^2 carbon centers of **1** followed by dimerization of cyclobutadienes, as shown in Scheme 2.

Alternatively, addition of 2 equiv. of CuCl to **3a** and monohalogenation of dicopper species **6**[5] formed *in situ* with 1 equiv. of stilbene dibromide also afforded **5a** in 78% yield along with the formation of 98% of stilbene [eqn. (4)].



3a (4)

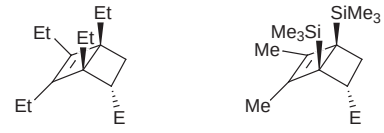
Cyclobutadiene derivatives **2** formed *in situ* by this method were trapped with dimethyl maleate and dimethyl fumarate.[1,2,6] As expected, bicyclic compounds, dimethyl 1,4,5,6-tetraethylbicyclo[2.2.0]hex-5-ene-2-*endo*,3-*endo*-dicarboxylate **7a**[6] and its analogue **7b**, dimethyl 1,4,5,6-tetraethylbicyclo[2.2.0)hex-5-ene-2-*endo*,3-*exo*-dicarboxylate **8a** and its analogues **8b** and **8c**[6] were formed in fairly good yields from dimethyl maleate and dimethyl fumarate, respectively (Scheme 1). The stereochemistry of **7** and **8** was determined by



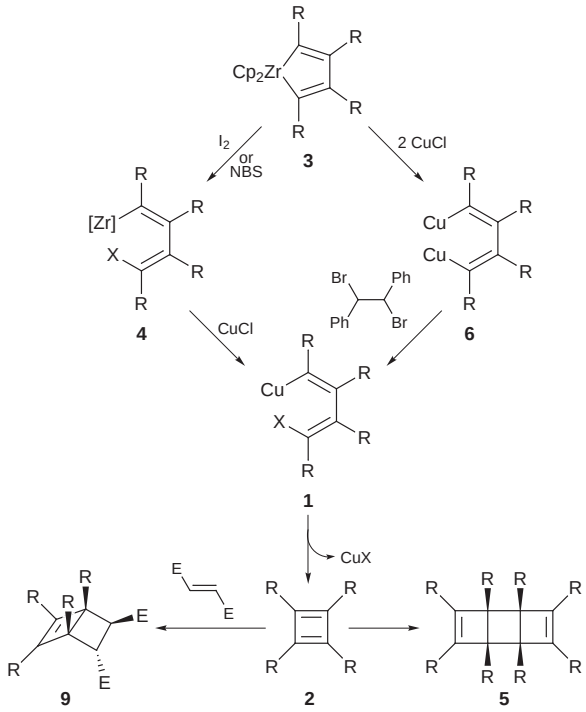
3

Scheme 1 *Reagents and conditions*: i, NBS (1 equiv.), 0 to 25 °C, 1 h; ii, dimethyl maleate (2 equiv.), CuCl (1 equiv.), 0 °C. 12 h; iii, dimethyl fumarate (2 equiv.), CuCl (1 equiv.), 0 °C, 12 h

comparison of their NMR data with those of authentic **7a** and **8c** prepared according to the literature.[6] Other bicyclohexene derivatives **9** were also formed *via* the same procedures as described above.[7]



9a E = CO_2Me, 71%
b E = CN, 61%
9c E = CO_2Me, 50%
d E = CN, 55%



Scheme 2

The formation of **7**, **8** and **9** supports the *in situ* generation of cyclobutadiene derivative **2**.[1,6,7] The reactions described here are summarized in Scheme 2.

Further investigations towards practical application of this simple method in organic synthesis are in progress.

Synthesis and X-ray crystallographic structure of $Ga_4(OH)_6(3\text{-}Bu^tpzH)_{10}I_6\cdot 2MeCN$: a quasi double heterocubane

Paul Hodge and Brian Piggott*

Chemistry Department, University of Hertfordshire, College Lane, Hatfield, Hertfordshire, UK AL10 9AB. E-mail: b.piggott@herts.ac.uk

The reaction of $K[HB(3\text{-}Bu^tpz)_3]$ with GaI_3 resulted in breakdown of the ligand and formation of a novel Ga/O cluster. This compound can be described as four edge-sharing Ga/O,N octahedra or as two face sharing partial Ga/O heterocubanes, *i.e.* a quasi double heterocubane.

In a previous publication we reported the reaction of Na[Me-$Ga(pz)_3$] with $GaCl_3$ to give $Ga_8(pz)_{12}O_4Cl_4\cdot 2THF$, which is based on a Ga_4O_4 core.[1] However, this core contains edge bridging groups and we therefore refer to this and analogous structures as 'non-discrete'. 'Discrete' Ga_4N_4, Ga_4S_4, Ga_4Se_4 and Ga_4Te_4 cubanes are known,[2,3] but to date no 'discrete' Ga_4O_4 cubane has been reported. A similar situation existed in indium chemistry with 'discrete' In_4N_4, In_4S_4, In_4Se_4 and In_4Te_4 cubanes[2,4] and a 'non-discrete' In_4O_4 cubane[5] being known. However, very recently, a 'discrete' In_4O_4 cubane, $In_4O_4(C(SiMe_3))_4$ has been reported.[6]

As an extension of our work on Ga/O cubanes we attempted to synthesise a 'discrete' Ga_4O_4 cubane by replacing Na[Me-$Ga(pz)_3$] with $K[HB(3\text{-}Bu^tpz)_3]$, thus eliminating the possibility of Ga–pz bridging, and $GaCl_3$ with GaI_3, since I^- is a better leaving group than Cl^-. $HB(3\text{-}Bu^tpz)^-$ was chosen in preference to less hindered trispyrazolylborates because of the stabilisation that would be conferred on the cubane by the bulky (3-Bu^tpzH) groups, a known breakdown product of $HB(3\text{-}Bu^tpz)_3^-$.[7] We therefore reacted $K[HB(3\text{-}Bu^tpz)_3]$ with GaI_3 in THF. The clear diamond shaped plate crystals, **1**, isolated from the reaction mixture were subjected to elemental analysis, IR, ^1H and ^{13}C NMR, and mass spectral analysis.† It was not possible to deduce the structure of **1** from this data and so an X-ray crystallographic study was undertaken.‡ The results are shown in Fig. 1 from which the six I^- ions, all the hydrogen atoms and the two molecules of MeCN have been omitted for clarity. From Fig. 1 it is evident that the target compound has not been synthesised but instead $Ga_4(OH)_6(3\text{-}Bu^tpzH)_{10}I_6\cdot 2MeCN$, **1**. The structure of **1** can be described in terms of four, edge sharing, Ga/O,N octahedra. However, given the main thrust of this work we describe it as two face sharing heterocubanes each of which is missing a Ga ion on the long diagonal through the centre of the shared face, an inversion centre. This particular structure is unprecedented in Ga chemistry although $[(CpAl)_6P_4]$[8] and $Al_{10}(OH)_{16}(OSiEt_3)_{14}$[9]

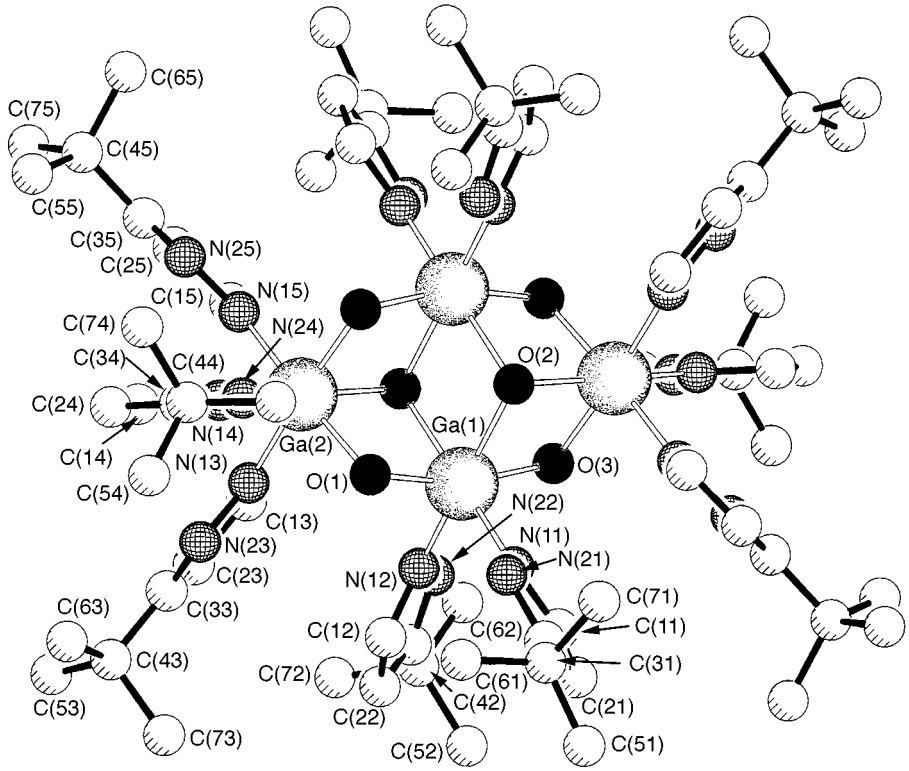

Fig. 1 Structure of **1** with the I^-, H and MeCN removed. Selected bond lengths (Å) and angles (°): Ga(1)–O(1) 1.896(5), Ga(1)–O(2) 2.090(6), Ga(1)–O(3) 1.912(5), Ga(1)–O(2′) 2.106(5), Ga(2)–O(1) 1.963(6), Ga(2)–O(2) 2.021(5), Ga(2)–O(3′) 1.951(5); Ga(1)–O(1)–Ga(2) 106.3(2), Ga(1)–O(2)–Ga(2) 97.4(2), Ga(1)–O(2)–Ga(1′) 101.8(2), Ga(1)–O(3)–Ga(2′) 106.4(2), Ga(2)–O(2)–Ga(1′) 97.1(2), O(1)–Ga(1)–O(2) 77.7(2), O(3)–Ga(1)–O(2) 91.0(2), O(1)–Ga(1)–O(2′) 90.5(2), O(3)–Ga(1)–O(2′) 77.4(2), O(2)–Ga(1)–O(2′) 78.2(2), O(1)–Ga(2)–O(3′) 89.7(2), O(2)–Ga(2)–O(3′) 78.6(2), O(1)–Ga(2)–O(2) 77.0(2). Symmetry transformation used to generate primed atoms: ′ $-x, -y, -z + 1$.

can be claimed to be structurally analogous. Each Ga in **1** attains six coordination by bonding to either two or three 3-Bu^{t}pzH groups and it is thought that the presence of these bulky groups help stabilise the complex. The Ga/O bond lengths and angles that define **1** are given in Fig. 1, from which it can be seen that the corresponding parameters in $Ga_8(pz)_{12}O_4Cl_4\cdot 2THF$ *viz*. Ga_c–O–Ga_c 98.26(6)°, O–Ga_c–O 81.08(6)° and Ga_c–O 2.003(1) Å are within comparable range.[1] Given the reducing properties of HB(3-Bu^{t}pz)$_3^-$,[7] the Ga–Ga distances were examined for evidence of metal–metal bonding. However, since these distances fall within the range 3.089–3.256 Å, whereas the Ga–Ga distances in a series of Ga^I dimers range from 2.34 to 2.54 Å,[8] such bonding is precluded. However, the Ga–Ga distances in **1** are less than the sum of the van der Waals radii of Ga (3.80 Å).[10] Similarly the O–O distances, which are in the range 2.50–2.76 Å, are less than the sum of the van der Waals radii of O (3.00 Å).[10] These observations indicate some degree of strain within the cluster. The corresponding distances in $Ga_8(pz)_{12}O_4Cl_4\cdot 2THF$ are Ga–Ga 3.022 Å and O–O 2.61 Å.[1]

A number of important questions are raised by the structure of **1** with, perhaps, the most important being the origin of the hydroxyl groups. This question was raised in our previous publication with reference to the formation of $Ga_8(pz)_{12}O_4Cl_4\cdot 2THF$, where it was suggested that the source of the oxygen was either air or moisture entering the system on prolonged standing at low temperature.[1] Although dried solvents and Schlenk techniques were used in the synthesis of **1** the conditions for air/moisture exclusion were not the most stringent possible. This was part of the synthetic strategy. However, it is now proposed to repeat this experiment under the most strictly controlled conditions to investigate the method of oxygen inclusion through ^{17}O studies.

Given that, at present, examples of quasi double heterocubanes are extremely rare it would seem that this structural type is an oddity with little relevance to cubane chemistry. However, we do not subscribe to this view and are confident that other examples will be identified thus establishing quasi double heterocubanes as a significant structural type with implications for the synthesis of compounds of higher nuclearity. The reason for this confidence is that we believe the difference between a quasi double cubane and a cubane, in this case $[Ga_4(OH)_6(3\text{-Bu}^t\text{pzH})_{10}]^{6+}$ and $[Ga(OH)_4(3\text{-Bu}^t\text{pzH})_{12}]^{8+}$, is finely balanced sterically and by judicious choice of ligand and control of stoichiometry interconversion can be achieved.

Notes and References

† *Synthesis*: all manipulations were performed under argon using standard Schlenk techniques and all solvents dried prior to use. To a Schlenk tube charged with GaI_3 (1.05 g, 2.33 mmol) was added K[HB(3-Bu^{t}pz)$_3$] (0.98 g, 2.33 mmol) and 60 cm^3 of THF. The pale yellow slurry was stirred for 18 h after which the solvent was removed *in vacuo*. Dichloromethane (60 cm^3) was added to the off-white residue, stirred, and the suspension filtered to remove KI. CH_2Cl_2 was removed *in vacuo* and 60 cm^3 of MeCN was added to the off-white residue. The pale yellow solution was reduced to one third of its original volume and placed in a freezer. After one week clear diamond shaped plates formed which were filtered off and used in the X-ray analysis. Yield: 1.04 g, 75% (Found: C, 33.73; H, 5.35; N, 11.15; Ga, 11.49; I, 34.26. Calc. for $C_{78}H_{132}N_{24}O_6Ga_4I_6$: C, 36.85; H, 5.23; N, 13.22; Ga, 10.97; I, 29.25%). We attribute the poor analysis to solvent dependency. NMR (250 MHz): δ_H 10.42 (br s, NH + OH), 7.70 (br s, H^3), 6.27 (br s, H^4), 5.23 (s, MeCN), 1.38 (s, CMe_3); D_2O addition, δ 7.50 (d, H^3), 6.18 (d, H^4), 4.20 (br s, NH + OH), 1.50 (s, CMe_3); δ_C 156.6 (C^5), 134.9 (C^3), 102.6 (C^4), 30.2 (CMe_3). IR 3197 [ν(NH)], 3100 [ν(CH)], 2966 [ν(CH)], 1495 (ring breathing).

‡ *Crystal data* for **1**: $C_{78}H_{132}N_{24}O_6Ga_4I_6$, M = 2536.31, orthorhombic, space group *Pbca*, a = 16.00(3), b = 25.051(5), c = 26.424(5) Å, U = 10591(4) Å^3, Z = 2, D_c = 1.591 Mg m^{-3}, F(000) = 5008, λ = 0.71069 Å, T = 150 K, μ(Mo-Kα) = 2.811 mm^{-1}. Data were collected on a Delft Instruments FAST TV area detector diffractometer. Of a total of 38 055 collected reflections 8332 were unique. The structure was solved by direct methods. Refinement was by full matrix least squares on F^2. Non hydrogen atoms were refined anisotropically and all hydrogen atoms except those on the hydroxyl groups were included in fixed positions and refined with the riding model. Final R indices [$I > 2\sigma(I)$] $R1$ = 0.0538, $wR2$ = 0.1188. One of the two solvent molecules, MeCN, showed slight disorder but this was not modelled. CCDC 182/951.

Heterogeneous transfer hydrogenation involves pairwise hydrogen transfer from the same position of two molecules of formic acid

Jinquan Yu and Jonathan B. Spencer*†

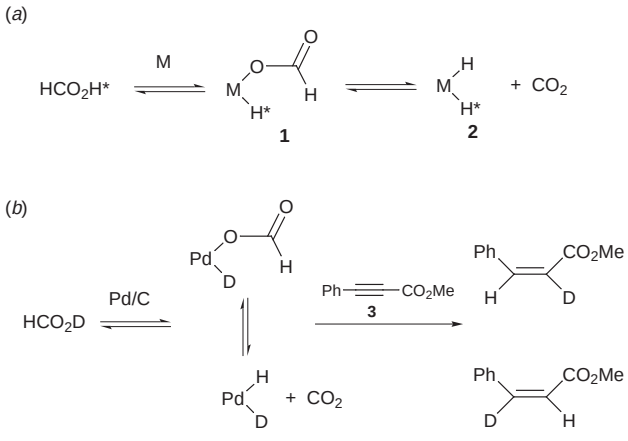
University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW

Using the reduction of an alkyne to *cis*-alkene as a hydrogen trap, differentially deuterium labelled formic acid is shown to deliver a pair of hydrogen atoms either from the formyl or the carboxy position, which suggests that palladium diformate is a key intermediate in heterogeneous transfer hydrogenation.

The oxidation of formic acid to carbon dioxide has been widely used as a source of hydrogen for the reduction of organic compounds.[1–3] This reaction has been shown to be one of the most effective methods for transfer hydrogenation that could potentially replace traditional hydrogenation conditions, such as asymmetric reduction where high pressure is often required.[4] The reverse reaction involving conversion of carbon dioxide to formic acid using catalytic hydrogenation has attracted much interest in recent years because it offers an environmentally friendly approach to the use of carbon resources as a raw material for the chemical industry.[5–8] The advantage of using heterogeneous catalysts in industrial processes has prompted us to investigate the mechanism of this reversible reaction catalysed by palladium on carbon.

A major effort has already been directed to the understanding of the mechanism of this reaction in homogeneous systems with the formato-(hydrido) metal complex proposed as a key intermediate **1** [Scheme 1(*a*)], based on deuterium labelling studies and *ab initio* calculations.[9–11] Recent studies using NMR spectroscopy have provided evidence for the existence of this intermediate,[12,13] however, as discussed by Halpern,[14] such thermodynamically stable compounds may not be the active species on hydrogenation pathways.

It has been proposed that the formato-(hydrido) metal complex **1** collapses to give a metal dihydrido species **2** [Scheme 1(*a*)] which can then carry out the reduction.[9] If this mechanism is operating in heterogeneous systems then the two hydrogen atoms from the same formic acid molecule will always be transferred as a pair in one catalytic cycle. Correspondingly, when the catalytic cycle proceeds from carbon dioxide to formic acid, one hydrogen molecule will provide both hydrogen atoms for the reduction of one molecule of carbon dioxide to give the same intermediate **1**.



Scheme 1

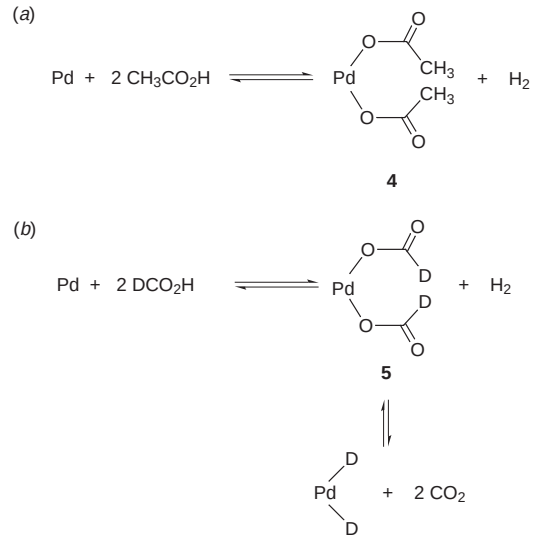
To investigate whether **1** is the active intermediate that provides the hydrogen on the catalytic cycle, the reduction of the triple bond of phenylpropiolate to the *cis*-double bond was employed to trap the hydrogen liberated by the collapse of **1** [Scheme 1(*b*)]. If differentially deuterium labelled formic acid (HCO_2D or DCO_2H) is used then the distribution of deuterium across the *cis*-double bond can determine the origin of the hydrogen transferred to the triple bond. The reduction of a double bond was not used as a reporter molecule for the hydrogen transfer because of the possible additional incorporation of deuterium through isomerization of the double bond before saturation occurs.[15,16]

When the reduction was carried out with HCO_2D the results show that the major product is the *cis*-double bond containing two hydrogen atoms (Table 1), rather than mono-deuterated *cis*-double bond which would be predicted to dominate if both hydrogen atoms came from the same molecule of formic acid as proposed previously for the homogeneous system.[9] It is possible that the major product containing two hydrogen atoms on the double bond could be formed by the preferential donation of hydrogen from the metal surface (H–Pd–D, intermediate **2,** Scheme 1) owing to a favourable kinetic isotope effect. However, when **3** was reduced with an equal mixture of hydrogen and deuterium the results show that there is no

Table 1 Reduction of methyl phenylpropiolate

	Product distribution (%)[a]		
Hydrogen source	H + H	H(D) + D(H)	D + D
HCO_2D[b]	72	10	18
DCO_2H[b]	25	18	57
XCO_2D[c]	28	37	35
$H_2 + D_2$[d]	25	51	24

[a] Errors for the data are ±5%. [b] Labelled formic acids were prepared by treating sodium formate (either DCO_2Na or HCO_2Na) with 1 M HCl or DCl, extracted with Et_2O and dried over anhydrous Na_2SO_4. Distillation of the extracts gave DCO_2H or HCO_2D (99% atom excess as determined by ^1H NMR analysis and mass spectrometry). Pd/C (10%, 38 mg) was added to a mixture of HCO_2D or DCO_2H (235 mg, 5.0 mmol), Et_3N (2.8 g) and phenylpropiolate **3** (80 mg, 0.5 mmol) and vigorously stirred under a blanket of argon. The progress of the reaction was monitored by TLC and stopped at approximately 40% conversion to avoid formation of the fully saturated product. This precaution was taken because the protons α to the carbonyl group of the saturated product can exchange under these conditions and could potentially lead to scrambling of the label. The reaction mixture was filtered to remove the catalyst and evaporated to give residue (81 mg) which was purified by column chromatography (eluted with hexane–Et_2O, 50:1) to afford 25 mg of *cis*-alkene. The distribution of deuterium across the double bond of the *cis*-alkene was determined by ^1H NMR analysis and mass spectrometry. [c] X = a mixture of D and H (2:1). [d] Pd/C (10%, 19 mg) was added to a mixture of Et_3N (2.8 g) and phenylpropiolate **3** (80 mg, 0.5 mmol) and purged with hydrogen and deuterium (1:1). The reaction mixture was stirred at room temperature and stopped at approximately 40% conversion. The isolation and analysis of the *cis*-alkene was carried out as detailed above.

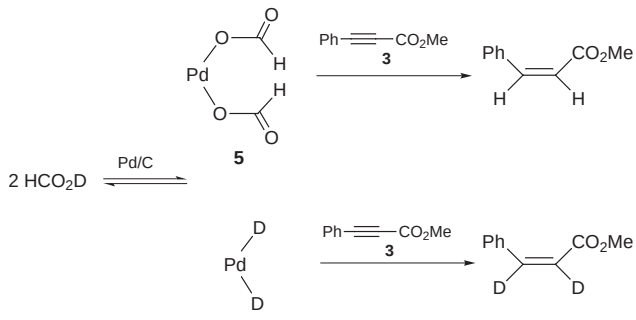


Scheme 2

substantial isotope effect (Table 1), which was also found in an earlier study using a homogeneous catalyst.[17] Furthermore, this mechanism cannot account for the fact that more double deuterated than mono-deuterated *cis*-double bond is formed.

These results would be consistent with a direct pairwise hydrogen transfer from either the formyl or the carboxy position of two different formic acid molecules. It is feasible that two hydro-formato species **1** on the surface of the metal could line up in such a way that the two adjacent formyl groups can donate hydrogen in a pairwise manner. However, palladium is known to react with acetic acid to form palladium diacetate **4** with the liberation of hydrogen from the carboxy position [Scheme 2(*a*)][18] which has prompted us to propose that palladium diformate **5** is formed in a similar manner and is reponsible for pairwise transfer of two formyl hydrogens [Scheme 2(*b*)]. Although palladium diformate has not been isolated, maybe owing to its instability, other metal diformate species have been characterised, such as vanadyl diformate,[19] triarylbismuth diformate[20] and ruthenium diformate.[21] This last example is particularly important because it was identified during the hydrogenation of carbon dioxide using a homogeneous ruthenium catalyst.

The formation of the palladium diformate would give one molecule of hydrogen solely from the carboxy end of the two formic acid molecules that can be used for the reduction of the triple bond (Scheme 3). The palladium diformate can then transfer another pair of hydrogen atoms from the formyl positions to another triple bond. The results with DCO_2H also show that the major *cis*-alkene produced from the alkyne contains two deuterium atoms on the double bond (Table 1). The minor monodeuterated product is probably formed by scrambling of the deuterium label. This could occur either *via* reduction of the carbon dioxide to give formic acid[9] or by collapse of intermediate **5** [Scheme 2(*b*)], if not immediately



Scheme 3

trapped by the triple bond, to give deuterium which can then mix with the hydrogen from the carboxy end to form HD. The formation of HD from hydrogen and deuterium on the surface of the metal has been shown to readily occur in a control experiment (Table 1).

The combined results with HCO_2D and DCO_2H strongly suggests that the hydrogen comes directly from the palladium diformate intermediate **5** rather than intermediate **1**, since this latter species would give the same distribution of deuterium on the double bond in both cases. The high level of pairwise addition of hydrogen from HCO_2D or deuterium from DCO_2H demonstrates the greater reactivity of the formyl position. It is noteworthy that there is a higher incorporation of hydrogen from the formyl position of HCO_2D than deuterium from the same position of DCO_2H, suggesting an isotope effect is involved in the cleavage of the carbon–hydrogen bond of the palladium diformate (Table 1).

The theory was further tested by using a mixture of DCO_2D and HCO_2D in a ratio of 2:1 to reduce the triple bond. The results show that there is a large increase in product containing one hydrogen and one deuterium compared to the product obtained using soley HCO_2D (Table 1). The increase in monodeuterated *cis*-alkene can only be accounted for by pairwise transfer from the formyl position rather than from the formato-hydride intermediate **1** which would be predicted to produce less of the monodeuterated product with the addition of DCO_2D.

The results clearly show that heterogeneous transfer hydrogenation involves the transfer of a pair of hydrogen atoms either from the formyl or the carboxy position of two molecules of formic acid. This provides evidence that palladium diformate is a key intermediate in this reaction and suggests that the reduction of carbon dioxide must also proceed through the diformate intermediate.

We thank the Royal Society for the award of a Royal Society University Research Fellowship (J. B. S.) and the British Council and the Chinese Government for the award of Sino-British Friendship Scholarship (J. Y.).

Self-assembly of a novel nanoscale giant cluster: $[Mo_{176}O_{496}(OH)_{32}(H_2O)_{80}]$†

Chang-Chun Jiang, Yong-Ge Wei, Qun Liu, Shi-Wei Zhang,* Mei-Cheng Shao and You-Qi Tang

Department of Chemistry, Peking University, Beijing 100871, PR China. E-mail: zsw@ipc.pku.edu.cn

Reduction of an acidified solution of $Na_2MoO_4{\cdot}2H_2O$ by iron powder results in the formation of the title compound $[Mo_{176}O_{16}O_{480}(OH)_{32}(H_2O)_{80}]$; the compound is tyre shaped and consists of sixteen $\{Mo_8\}$ subunits being linked by forty-eight MoO_6 octahedra; remarkable features are the size and mass (which is of the order of a protein) and its nano-dimensional cavity of *ca.* 3 nm in diameter.

One of the challenges chemists are facing today is how to synthesize larger mesoscopic molecules from molecular fragments. The aim of such research is not only to improve the understanding of the extreme complexity of natural process, but also to synthesize molecular materials with novel properties, *e.g.* electric and magnetic, which may be anticipated for mesoscopic compounds. Indeed, considerable progress has been made in the field of polymetalate chemistry.[1,2] We have evolved the so-called 'reduction–reconstitution' self-assembly process and synthesized a class of large mixed-valent, nanoscale polyoxomolybdate anions[3–7]‡ constructed of $\{Mo_8\}$ or $\{Mo_{17}\}$ fragments:[2] $[Mo_{36}O_{108}(NO)_4(H_2O)_{16}]^{12-}$ **1**,[3] $[Mo_{57}V_6O_{180}(NO)_6(OH)_3(H_2O)_{18}]^{21-}$ **2**,[4] $[Mo_{57}Fe^{III}_6O_{174}(NO)_6(OH)_3(H_2O)_{24}]^{15-}$ **3**,[5] $[Mo_{57}Fe^{II}_6O_{177}(NO)_6(OH)_2(H_2O)_{22}(MoO)_2]^{18-}$ **4**[6] and $\{\{(H_2O)MoO_{2.5}[Mo_{36}O_{108}(NO)_4(H_2O)_{16}]O_{2.5}Mo(H_2O)\}^{12-}\}_n$ **5**[7] and some of them were also obtained later by Müller's group.[2] By slightly changing the reaction conditions in the same system, Müller *et al.* succeeded in isolating a giant cluster $[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]^{14-}$ **6**.[2,8] Now we have succeeded in synthesizing an even larger nanocompound $[Mo_{176}O_{496}(OH)_{32}(H_2O)_{80}]$ **7** which is also constructed of $\{Mo_8\}$ fragments.

Compound **7** was prepared following the general method leading to 'molybdenum blue'. A solution of $Na_2MoO_4{\cdot}2H_2O$ (5.0 g, 20.7 mmol) in H_2O (50 ml) was adjusted to a pH of *ca.* 1.0 with 36.5% hydrochloric acid. After addition of iron powder (50 mg, 0.9 mmol), the mixture was left to stand for one month to crystallize. The preparation yields blue–black, tetragonal-bipyramidal well defined crystals of **7** in *ca.* 30% yield. Reduction with elemental Al or Zn as well as $N_2H_4{\cdot}2HCl$ yields the same well defined crystals. The compound was characterized by IR and UV–VIS spectroscopy, cerium(IV) sulfate redox titration and elemental analysis,§ as well as by single-crystal X-ray diffraction.¶

The rather intricate single-crystal X-ray structure analysis reveals that the ring-shaped compound **7** consists of 160 MoO_6 octahedral and 16 pentagonal bipyramids of type MoO_7 (Figs. 1 and 2). The structure has approximate D_{8d} symmetry. Sixteen $\{Mo_8\}$ fragments are linked with sixteen Mo atoms in the equatorial plane and another sixteen $\{Mo_2\}$ groups.[2] Each of the sixteen subunits has a pentagonal-bipyramidal MoO_7 center about which seven other MoO_6 octahedral are grouped by corner- and edge-sharing to form an $\{Mo_8\}$ fragment. This $\{Mo_8\}$ fragment also occurs in **1**–**6**, which, however, possess a pentagonal bipyrimidal $Mo(NO)O_6$ centre.

The structure type of **1**–**5** is different from that of **6** and **7**. In **1**–**5** two $\{Mo_8\}$ fragments above and below the equatorial plane are linked through one equatorial Mo atom and are transformed into each other by reflection across the equatorial mirror plane. Thus anion **1** has approximate C_{2h} symmetry and anions **2** and **3** have D_{3h} symmetry. In other words, this kind of linking manner implies that there are $\{Mo_{17}\}$ fragments as building blocks in these anions. By contrast, the arrangement of $\{Mo_8\}$ fragments in **7** (D_{8d} symmetry), which is like that of **6** (D_{7d} symmetry), are twisted relative to each other. This shift means that in **6** and **7** two equatorial Mo atoms are required to link two $\{Mo_8\}$ fragments and so there are sixteen Mo atoms in the equatorial plane in **7** (fourteen in **6**). Two neighbouring $\{Mo_8\}$ fragments on the same side of the equatorial plane are linked

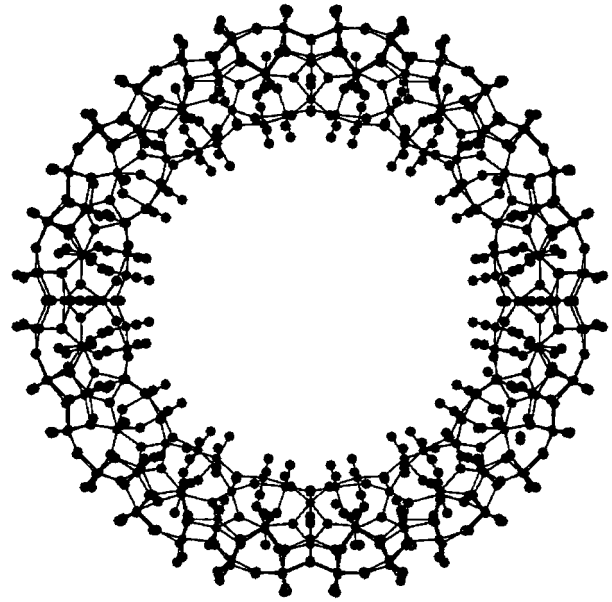

Fig. 1 Ball-and-stick model of the nanoscale cluster (view parallel to the C_8 axis)

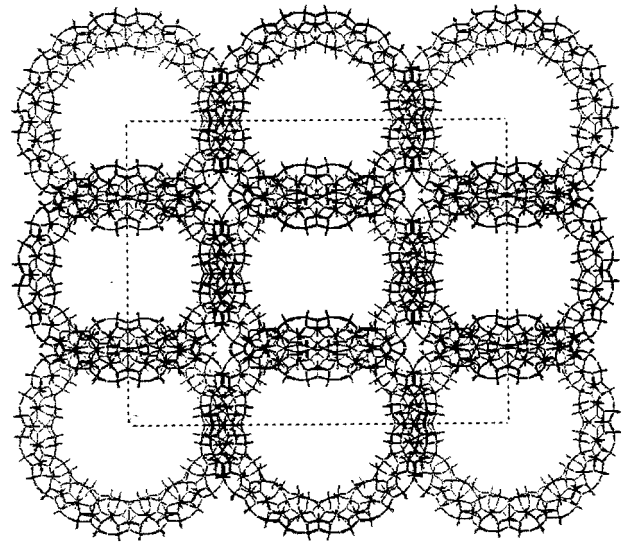

Fig. 2 Packing of the $\{Mo_{176}\}$ molecules in the crystal (view parallel to the *c* axis)

through two Mo atoms (or one $\{MoO_2(H_2O)(\mu_2\text{-}O)\text{-}MoO_2(H_2O)\}$ group) *i.e.* a $\{Mo_2\}$ unit, instead of only one V or Fe center as in **2** and **3**, respectively. However, the central $\{MoNO\}^{3+}$ group of the $\{Mo_8\}$ fragment of **6** is replaced by $\{MoO\}^{4+}$ group in **7**.

Whereas the basic structure of compound can be determined unambiguously, it will probably never be possible to ascertain the exact number of crystallization waters by XRD owing to disorder of the lattice water molecules, the tendency to lose solvent and the weak diffraction of the crystal to X-rays. According to elemental analysis and TGA, the number of water is *ca*. 600 ± 50.

A remarkable feature of **7** is its nanoscale cavity and corresponding host properties. The cavity itself, which is like the inside of a tyre, measures about 3 nm in diameter. A further characteristic of **7** is that it dissolves extremely well in water, ethanol or acetone. This high solubility can be attributed to the large surface built up of a large number of H_2O molecules and OH groups. It is noteworthy that crystals of **7** are obtained from 'molybdenum blue'. 'Molybdenum blue' used to be regarded as amorphous, but recently Müller *et al.* have made some suggestions about its structure[9] and they also succeeded in isolating a compound $Na_{15}\{Mo_{144}O_{409}(OH)_{28}(H_2O)_{56}\}$, *ca.* 250 H_2O **8** from it[10] whose structure resembles **6** apart from some defects in **8**. Now it can be proposed that 'molybdenum blue' is a mixture of compounds which have a similar basic ring-shaped structure.

Polyoxoanions constitute a large class of inorganic compounds,[11] however, the number of different structural types is small. There are indications that **1**–**8** belong to the same kind structural type of compounds as they are all synthesized by a similar method and linked up *via* $\{Mo_8\}$ fragments in different ways. It can be presumed that under suitable reaction conditions, a variety of novel nanoscale clusters with high complexity and multifunctionality could be synthesized by the reduction–reconstruction self-assembly process developed in our laboratory.

Financial support from the National Natural Science Fondation of China No. 29371004 and No. 29733080 is gratefully acknowledged.

Notes and References

† Just before this manuscript was mailed, similar work by Müller *et al.* was published (*Angew. Chem., Int. Ed. Engl.*, 1998, **37**, 1220). However, they prepared their crystals by a different method and solved the structure in space group *Cmcm.*

‡ The charges given here are the values given by Müller *et al.* However, cluster anions with different charges are also obtained in our laboratory.

§ Elemental analysis. Calc. for $[Mo_{176}O_{16}O_{480}(OH)_{32}(H_2O)_{80}]\cdot(600 \pm 50)H_2O$: Mo, 44.9; Found: Mo, 44.0; Na, 0.2; Cl, 0.2%. Characterization of **7**: main IR bands (KBr disc): 1726s, 1618m, 974m, 914w, 668w, 558s cm^{-1}; UV–VIS (H_2O), 750, 220 nm. Cerium sulfate titration: 1 g of **7** reduces 0.830 mmol $Ce(SO_4)_2\cdot2(NH_4)_2SO_4\cdot4H_2O$ corresponding to 32 Mo^V atoms in each molecule.

¶ *Crystal data* for $[Mo_{176}O_{16}O_{480}(H_2O)_{80}(OH)_{32}]\cdot(600 \pm 50)\ H_2O$: M = 36 522.24, orthorhombic, space group *Amm*2 (no. 38), a = 66.628(13), b = 53.760(11), c = 31.775(6) Å, V = 113 816(39) $Å^3$, $F(000)$ = 71 024, Z = 4, D_c = 2.131 g cm^{-3}, Mo-Kα radiation, λ = 0710 69 Å, μ = 1.99 min^{-1}. Intensity data were collected on a Rigaku AFC6S diffractometer at 296 K and a total of 25 975 reflections were collected, of which 12 706 reflections were observed, the structure was solved with direct method and difference Fourier map using SHELXS97 and refined using SHELXL97. Owing to the poor ability of diffraction of the crystal and the limit of the number of reflections, only the Mo atoms are refined anisotropically with $R1$ = 0.1050 for observed reflections and $wR2$ = 0.2685 for all the data.

Preparation and structural characterization of naphtho[2,1-*d*:6,5-*d*′]bis([1,2,3]dithiazole) NT and π-stacked mixed valence salt $[NT]_3[BF_4]_2$

Tosha M. Barclay,[a] Ian J. Burgess,[b] A. Wallace Cordes,[a] Richard T. Oakley[b]† and Robert W. Reed[b]

[a] *Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville, Arkansas, 72701 USA*

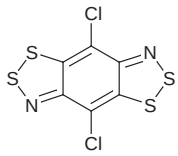
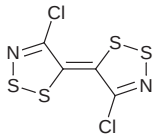
Naphtho[2,1-*d*:6,5-*d*′]bis([1,2,3]dithiazole) NT, prepared by a 'double Herz' condensation of 2,6-diaminonaphthalene with S_2Cl_2, can be electrooxidized to the conductive, π-stacked mixed valence salt $[NT]_3[BF_4]_2$.

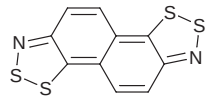
The bis([1,2,3]dithiazoles) **1**[1] and **2**[2] represent the first members of a new family of redox active heterocycles with potential



1



2



3 NT

applications in the design of molecular conductors.[3] While their oxidation potentials are relatively high, the resulting radical cations are extremely stable, forming crystalline 1:1 salts with inorganic counterions. Compound **1** must be prepared by the condensation of diaminobenzenedithiol with sulfur monochloride, as the use of Herz chemistry,[4] *i.e.* a double ring closure of *p*-phenylenediamine with sulfur monochloride, is not effective; the products of this reaction are largely polymeric.[5] We now report that, in contrast to this behavior, the condensation of 2,6-diaminonaphthalene[6] with sulfur monochloride leads, with remarkable regiospecificity and in good yield, to the 'double Herz' cyclocondensation product naphtho[2,1-*d*-:6,5-*d*′]bis([1,2,3]dithiazole) NT **3**. We also describe the structure and redox chemistry of NT, and its use in the formation of the conductive, π-stacked mixed valence salt $[NT]_3[BF_4]_2$.

In contrast to the complex reaction of 1,5-diaminonaphthalene with S_2Cl_2,[7] the condensation of 2,6-diaminonaphthalene with S_2Cl_2 in the presence of pyridine as auxiliary base proceeds *via* electrophilic ring closure at both *peri*-positions[8] to afford what we presume is an oxidized form (radical cation or dication) of the title compound NT **3**. Chlorination of the remaining C–H positions does not occur. In a typical preparation S_2Cl_2 (30 ml) was added to a slurry of 2,6-diaminonaphthalene (3.00 g, 19.0 mmol) in 20 ml of CH_2Cl_2 and the mixture stirred overnight. Pyridine (9.1 g, 115 mmol) in 15 ml of CH_2Cl_2 was then added dropwise and the mixture stirred for another 2 h. The resulting mixture was filtered, and the solid washed with MeCN (3 × 75 ml) to remove pyridine hydrochloride. The remaining solid was slurried in 100 ml MeCN and reduced with Ph_3Sb (6.8 g, 19.0 mmol) overnight. The resulting red–black precipitate was filtered off, washed with 50 ml of MeCN and dried *in vacuo*. This solid was extracted repeatedly with hot chlorobenzene to give deep blue solutions which yielded golden needles of **3** (NT) (2.5 g, 8.9 mmol, 47%) upon cooling. Further purification by fractional sublimation at 180–130 °C/10^{-2} Torr afforded golden blocks, mp 316–320 °C, UV–VIS ($C_2H_4Cl_2$) λ_{max} (log ε) 622 (4.6) nm.‡

Cyclic voltammetry on solutions of NT in THF (with Pt electrodes and 1 M $Bu^n_4NPF_6$ as supporting electrolyte) reveals two reversible oxidation waves with $E_{1/2}$ = 0.41 and 0.66 V *vs.* SCE. These potentials are significantly lower than those observed for **1** (0.93, 1.5 V) and **2** (0.80, 1.25 V),[1,2] and comparable to those found for TTF.[9] Consistently, the intense π–π transition in NT (622 nm) is to longer wavelength of the corresponding absorption maxima in **1** (522 nm) and **2** (565 nm).[1,2] In order to test the potential of NT as a donor for the formation of charge transfer salts we have explored the use of electrocrystallization methods.[10] To date we have found that electrooxidation of NT in a 2:1 mixture of CS_2:$C_2H_4Cl_2$ containing 0.1 M $Bu^n_4NBF_4$ as supporting electrolyte, and using Pt electrodes, currents of 3–5 μA, and growth periods of 10–14 days, affords lustrous black needles of the mixed valence salt $[NT]_3[BF_4]_2$. When dissolved in liquid SO_2, lilac colored solutions of $[NT]_3[BF_4]_2$ exhibit a strong and persistent EPR signal of the $[NT]^+$ radical cation (Fig. 1), with g = 2.0106 and a hyperfine coupling pattern based on a_N = 0.235 mT. Additional coupling to two pairs of hydrogens with a_H = 0.079 and 0.048 mT is also observed.

The crystal structures of both NT and $[NT]_3[BF_4]_2$ have been determined by X-ray diffraction.§ In the structure of NT itself the molecules lie on a center of inversion; the packing pattern consists of slipped π-stacks of NT molecules running in the *x* direction (Fig. 2). In the asymmetric unit of the mixed valence salt $[NT]_3[BF_4]_2$ one NT molecule (A) lies on a center of inversion, while the other molecule (B), along with the BF_4^- ion, adopt general positions. The molecules are packed in layers (Fig. 3) in which the B molecules form dimer units across a center of inversion. These dimers are linked by S···S contacts of 3.407(2) (S3···S5) and 3.250(2) (S4···S6) Å.[11] The B dimers and A molecules adopt an alternating π-stacked arrangement, in which the unique A molecules are slipped relative to the B dimers (Fig. 3). The BF_4^- anions are located between the stacks, bridging B dimers on one side to A molecules on the other.

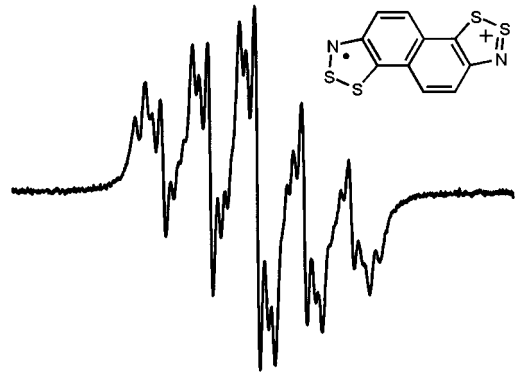


Fig. 1 X-Band EPR spectrum of the $[NT]^+$ radical cation (in liquid SO_2 at 298 K). Sweep width = 2.5 mT.

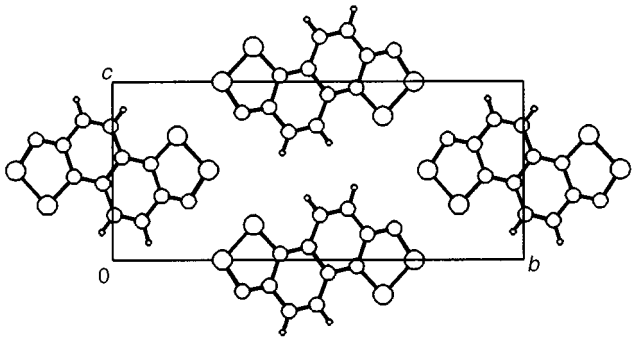

Fig. 2 Crystal packing of NT, viewed along the *x* direction

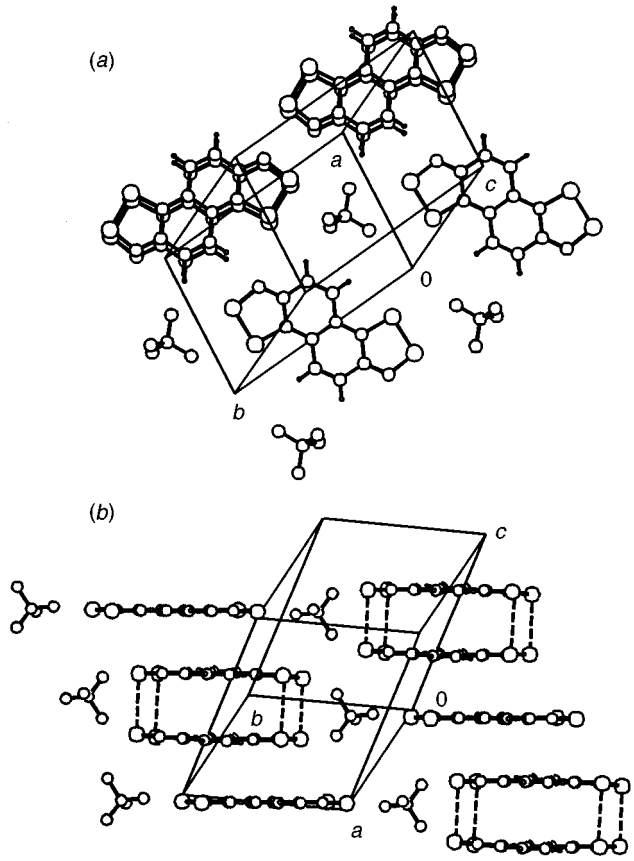

Fig. 3 Crystal packing of $[NT]_3[BF_4]_2$, showing (*a*) layers of neutral molecules and radical cation dimers and (*b*) alternating slipped π-stacks

While the 3:2 stoichiometry of the salt formally implies the presence of a 2/3 positive charge per heterocyclic layer, comparison[12] of the intramolecular distances in NT and $[NT]_3[BF_4]_2$ suggests that the B molecules are nominally oxidized to the radical cation (+1) state, while the A molecules are neutral. The unusual triple-decker[13] stacking pattern found for $[NT]_3[BF_4]_2$ is thus comprised of closed shell ($[NT]_2^{2+}$ and NT) units, and the material is expected to be a semiconductor. Preliminary pressed pellet conductivity measurements on $[NT]_3[BF_4]_2$ nonetheless indicate a relatively high value of σ = *ca.* 10^{-2} S cm^{-1}, indicative of a well developed band structure. More detailed transport property measurements are in progress. Meanwhile, the present results augur well for the use of NT and related bis([1,2,3]dithiazoles) in the design of new conductive charge transfer salts.

Synthesis of porous yttrium aluminium oxide templated by dodecyl sulfate assemblies

Mitsunori Yada,* Masahumi Ohya, Masato Machida and Tsuyoshi Kijima

Department of Materials Science, Faculty of Engineering, Miyazaki University, Miyazaki, 889-2192, Japan.
E-mail: t0a201u@cc.miyazaki-u.ac.jp

An yttrium aluminium oxide dodecyl sulfate mesophase with a hexagonal structure has been synthesized by a homogeneous precipitation method using urea and was converted into a porous material with a specific surface area of 662 m^2 g^{-1} by anion exchange of the surfactant with acetate ion.

Increasing attention has been paid to mesoporous materials, mainly because of their great applicabilities as catalysts, molecular sieves and host materials based on their large internal surface areas and narrow pore size distributions. The first examples of such materials, MCM-41[1] and FSM-16[2] silicas, were synthesized by calcining their mesostructured precursors formed in the presence of a cationic surfactant. This approach has been applied to the preparation of niobium, zirconium and other binary metal oxide-based mesophases.[3,4] Much less study, however, have been reported concerning similar but ternary metal oxide-based materials such as those containing $AlPO_4$[5] and $AlBO_3$[6] as their skeleton.

Our previous studies demonstrated the synthesis of aluminium-based dodecyl sulfate mesophases by the homogeneous precipitation method using urea, in which the surfactant mesophases occurred initially in the layer structure and grew into their hexagonal form with versatile morphologies such as winding-rod, spherical, tubular and funneled shapes depending on the urea concentration.[7,8] A similar observation was made for the gallium-based dodecyl sulfate system.[9] Coincorporation of dodecyl sulfate and alkyl alcohols in the aluminium-based system also led to a lamellar structure with biomimetic surface patterns such as cone-shaped or terraced hollows and domed scales.[10] Recently, we also succeeded in the synthesis of a mesoporous yttrium oxide by the anion exchange method with acetate anion.[11]

Yttrium aluminium oxide is useful as hosts for solid-state lasers such as YAG ($Y_3Al_5O_{12}$) or YALO ($YAlO_3$) and luminescence systems and window materials for a variety of lamps. Therefore, if we could obtain a ordered mesoporous yttrium aluminium mixed oxide, it would be useful not only for adsorbing or separating agents and catalytic bodies but also as a host for the homogeneous dispersion of optically functional species, followed by its post-sintering. The aluminium component combined with yttrium oxide units would also be effective for increasing the solid acidity of the resulting oxide. Here, we report the synthesis of an yttrium aluminium oxide mesophase templated by dodecyl sulfate assemblies with a hexagonal structure and its conversion into a porous material by anion exchange of the surfactant species with acetate ion.

The yttrium aluminium oxide surfactant mesophases with lamellar and hexagonal structures were synthesized by the homogenous precipitation method using urea. Yttrium nitrate hexahydrate [$Y(NO_3)_3{\cdot}6H_2O$] was used as the yttrium source and aluminium nitrate nonahydrate [$Al(NO_3)_3{\cdot}9H_2O$] was used as the aluminium source and sodium dodecyl sulfate [SDS,Me-$(CH_2)_{11}OSO_3Na$] was used as the templating agent. Yttrium nitrate, aluminium nitrate, SDS, urea and water were mixed at a molar ratio of 0.375 : 0.625 : 2 : 30 : 60 and stirred at 40 °C for 1 h to obtain a transparent mixed solution. The nominal Y to Al molar ratio of 3 : 5 corresponds to that for YAG. Urea was used to gradually raise the pH of the reaction mixture since on heating at above 60 °C it is hydrolyzed and releases ammonia. The mixed solution was heated at 80 °C and then kept at that temperature. The pH of the reaction mixture increased from an initial value of 3.6, due to hydrolysis of urea, and precipitation occurred. Immediately after 3 or 20 h, the resulting mixtures were cooled to room temperature to prevent further hydrolysis of urea. After centrifugation, the resulting solids were washed with water a few times and then dried at 60 °C. Powder X-ray diffraction (XRD) measurements were made on a Simadzu XD-D1 diffractometer with Cu-Kα radiation. X-Ray microanalysis (XMA) was conducted with a HORIBA EMAX-5770 instrument. Transmission electron microscopy (TEM) was carried out using a Hitachi H-800MU instrument.

Precipitation at 80 °C commenced when the pH of the reaction mixture reached 6.1 after 1.5 h. Two white solid samples, **1** and **2**, were separated after 3 and 20 h, respectively. The XRD pattern of **1** is characterized by three diffraction peaks at 2θ = 1–7°, along with a halo band near 2θ = 20° [Fig. 1(a)]. The former three peaks are attributable to the 001, 002 and 003 reflections for a lamellar phase with an interlayer spacing of 3.9 nm and the halo band suggests that the short-range arrangement of constituent atoms is completely disordered. According to XMA, the dodecyl sulfate (S) to metal (Al + Y) mole ratio was 0.63, and the Y to Al mole ratio was 0.18. In contrast to the layered mesophase **1**, the XRD pattern of **2** is characterized by a major peak located at $2\theta \approx 2.3°$ and two weak peaks at 2θ = 3–5° along with a halo at $2\theta \approx$ 20°[Fig. 1(b)]. On the basis of a hexagonal unit cell with a = 4.3 nm, these three peaks can be assigned to the 100, 110 and 200 reflections. Thus, these two XRD patterns indicate that the

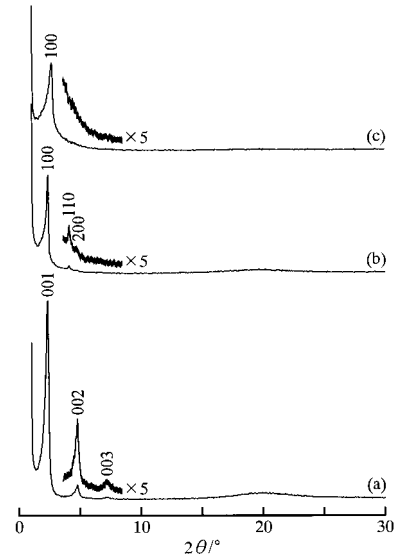

Fig. 1– XRD patterns of yttrium aluminium oxide mesophases templated by dodecyl sulfate assemblies; (a) **1**, (b) **2** and (c) **3**

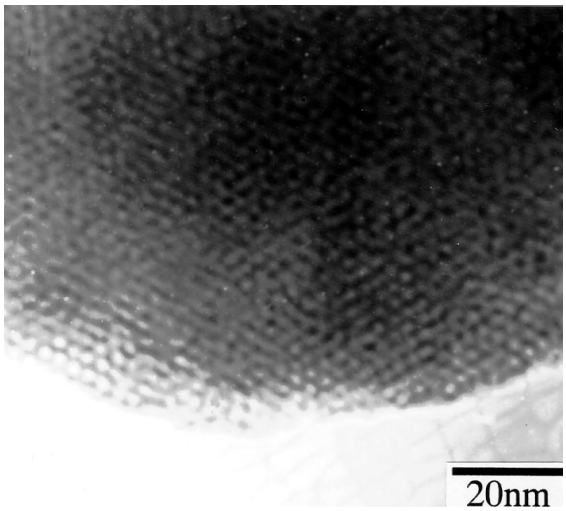

Fig. 2 TEM image of yttrium aluminium oxide mesophase **2** viewed along the axis of the hexagonal channel

yttrium aluminium mixed oxide mesophase undergoes a layer to hexagonal structural transition, as observed in the Al-, Ga- and Y-based systems.[7–11] The unit cell parameter of 4.3 nm for the Y–Al based hexagonal mesophase **2** is equal to that for the Al-based mesophase, but is much less than that for the Y-based mesophase (6.1 nm). A transmission electron micrograph of **2** showed a regular hexagonal array of channels extending for several hundred nanometers or more as shown in Fig. 2. This ordered hexagonal arrangement is similar to the atomic arrangement for the Al-based hexagonal mesophase and MCM-41, but is different from a disordered arrangement observed for the Y-based one. Furthermore, the S to metal mole ratio of 0.31 for the Y–Al based mesophase **2** is close to 0.33 and 0.28 for the Al- and Y-based analogues, indicating that nearly the same amount of surfactant per metal is incorporated in these three mesophases. The Y to Al mole ratio for the Y–Al based mesophase **2** is only 0.34, being nearly half its nominal value. Details for the control of Y to Al mole ratio in the resulting mesophases will be described elsewhere.

A further attempt was made to remove the surfactant species from the hexagonal mesophase **2** by anion exchange with acetate anions in a manner similar to that reported by Holland *et al*. for mesoporous aluminophosphate;[12] the mesophase sample (0.5 g) was mixed with a 0.05 M ethanol solution of sodium acetate (40 ml), and then stirred at 40 °C for 1 h. The centrifuged solid was then washed repeatedly with ethanol. The 100 reflection for the acetate-treated solid **3** shifted slightly to higher angle relative to that of **2**, and the 110 and 200 reflections for the former disappeared, as shown in Fig. 1(c). No sulfur species were detected by XMA of **3**, suggesting the complete removal of dodecyl sulfate species. Since the Y to Al molar ratio of 0.36 for **3** is nearly equal to 0.34 for **2**, the resulting decrease of unit cell parameter *a* from 4.3 to 3.8 nm would be attributable to partial condensation of hydroxide groups induced by the removal of surfactant. Preliminary data suggested that the solid **3** become completely disordered upon calcination at 300 °C for 5 h in air.

Fig. 3 shows an N_2 adsorption isotherm for **3**, measured after heating at 150 °C for 1 h to remove adsorbed water. The rapid adsorption in the range of P/P_0 = 0–0.25 for the sample is due

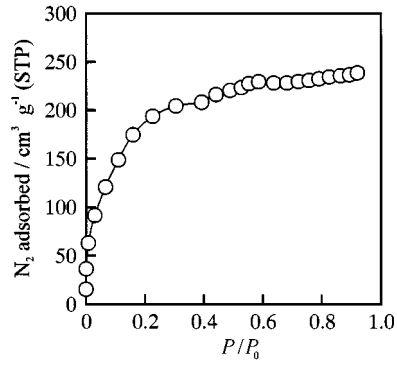

Fig. 3 N_2 adsorption isotherm for **3**

to the monolayer coverage of pores and particle surface and capillary condensation in the pores. The specific surface area determined by the BET method was as large as 662 $m^2\ g^{-1}$ and the pore size determined by Clanston–Inkley method[13] was 1.6 nm. Pre-heating of **3** at 150 °C for dehydration led to a decrease of its crystallinity, as suggested from a slight shift of the 100 reflection from 2.6 to 2.9°. Upon similar acetate-treatment, the Al-based hexagonal mesophase collapsed in structure to yield a specific surface area of only 12 $m^2\ g^{-1}$, whereas the Y-based analogue was converted into a mesoporous solid with a specific surface area of as large as 545 $m^2\ g^{-1}$ without any radial contraction.[11] Thus, the pore structure change observed in the Y–Al mixed system is a result of the stabilization of the inorganic framework due to the combination of yttrium-based species with Al-based structural units.

In conclusion, we have synthesized, for the first time, a hexagonal yttrium aluminium oxide mesophase by a homogeneous precipitation method using urea, and demonstrated its conversion into an acetate-exchanged porous material. The present approach and findings using the homogenous precipitation method will contribute to further development of functional mesostructured ternary or even more complex metal-based oxides.

***Ab initio* Hartree–Fock calculations are performed on the molybdenum and tungsten trioxides and bronzes, obtained by inserting alkali metal atoms or larger species in the MO_3 framework; we examine four known polymorphs and two new structures with a microporous architecture, and characterise their relative stability; we also explore the synthesis conditions under which the microporous polymorphs may be obtained, by designing potential organic templates.**

The structural chemistry of the Mo and W trioxides and bronzes comprises several known polymorphs, such as the perovskite (PV) structure of WO_3, $NaMoO_3$ and $NaWO_3$, the layered (L) α-MoO_3, hexagonal (Hex) $K_{0.33}WO_3$ and pyrochlore (PY) Cs_xWO_3. The bronzes are obtained by inserting extra species into the empty interstices of the host MO_3 lattice, and can be described as comprising an MO_3 framework, in whose pores are located the inserted, or extra-framework, cations.

In the PV, Hex and PY structures, the framework is built entirely of corner-sharing MO_6 octahedra, which connect into 4-membered rings in the PV, and 6-membered rings in the Hex and PY polymorphs. The 6-membered rings form hexagonal channels, which are parallel in the Hex, and intersect in the PY structure; the dimension of the extra-framework voids increases therefore in the order of PV < Hex < PY. In the L polymorph, the MO_6 octahedra connect corner- and edge-sharing in the *bc* plane, leaving a layered structure along *a*. Interstices are present in the interlayer region.

In recent work, we highlighted the importance of the M–O bonding pattern,[1–2] of Coulomb[2] and structural forces,[3] and of steric constraints[4] in the solid state chemistry of Mo and W oxides and bronzes. We now examine the relative stability of the framework structures in the insertion compounds.

A common feature of transition metal oxides (TMOs) are structural distortions due to off-centerings of the metal ions M in their coordination octahedra. In PV materials, the off-centering of M hybridises a set of levels, which in the cubic phase are of M–O non-bonding character, into π M–O bonding (in the valence band) and antibonding (in the conduction band) combinations.[1] When the metal ion has formal electronic configuration d^0, as in MoO_3 and WO_3, only the M–O bonding level is filled, and the distortion is stable; in the bronzes, the inserted atoms ionise and cede electrons to the host lattice, populating the M–O antibonding level at the bottom of the conduction band, which opposes the distortion. The PV-structured W bronzes are stable in the cubic phase.[1] The M–O bonding pattern in the valence and conduction bands is common to all the polymorphs examined, and a partial population of the conduction band will oppose off-centerings of M. Here, we are interested in the insertion compounds A_xMO_3, in which the metal ion has configuration d^x; we shall therefore consider only framework structures in which the M ions are on-centre in their coordination octahedra. We have optimised, under the above constraint, the structure of the four cited polymorphs of WO_3 and MoO_3, using a periodic restricted Hartree Fock Hamiltonian, as implemented in CRYSTAL95.[5] Basis set, tolerances and computational conditions are the same as described in refs. 2 and 3; a convergence criterion of 10^{-6} E_h was used in the geometry optimisation. From the calculated energies, we have constructed a scale of relative stability for the host MO_3 framework; results are summarised in Table 1. We note that the undistorted L polymorph is highly unstable with respect to the other three structures examined, suggesting that insertion compounds based on L-MoO_3 would not be stable following the cation insertion. The relative stability of the other three polymorphs (PV, Hex and PY) parallels their relative density, as higher electrostatic energies stabilise the densest structures.

Moving from the binary oxides to the insertion compounds, the relative stability of the polymorphs is altered; a balance between the Coulomb and steric effects stabilises the structures whose interstices have dimensions comparable with the size of the inserted ions. The experimentally reported crystal structures, for instance of the W bronzes, on increasing the size of the inserted ion, move from the cubic-PV form of $NaWO_3$ towards the Hex K_xWO_3 and Rb_xWO_3, to the PY structure obtained by insertion of Cs and of primary and secondary ammonium salts.[6] The importance of the short-range repulsion between the inserted ion and the MO_3 framework increases with increasing ionic size of the extraframework ion; in ref. 4 we estimated it as 0.52 eV for the relatively small K^+ ion in the hexagonal channels of Hex-WO_3. The energy arising from the short-range repulsion is therefore sufficient to offset the energy difference between the framework structures examined, shifting the stability towards the polymorphs with interstices of the appropriate dimensions. Extraframework ions present during the synthesis of the host MO_3 framework may therefore effectively act as inorganic templates, or structure-directing agents.

The use of organic cationic templates is a standard procedure in the synthesis of microporous aluminosilicates (zeolites), where the correlation between the shape of the organic cation and that of the pore structure obtained is now recognised.[7] The energy difference between the silica polymorphs is in the range of 0.1–0.2 eV per formula unit, much smaller than that we calculated in the Mo and W trioxides (excluding the L polymorph, the energy range of the PV, Hex and PY structures is of *ca.* 0.5 eV per formula unit). We attribute the higher energy difference in the trioxides to two effects: (i) the higher ionic charges, which increases the Madelung field, and (ii) the rigidity of the octahedral framework of TMOs, compared to the more flexible tetrahedral framework of silicates. We note however that the difference in framework energy is still in the range of the steric repulsion, and can be reversed, as confirmed by the different stable structures of the alkali W bronzes. We believe therefore that a template/host approach, similar to that employed in the synthesis of zeolites, can also be applied to obtain novel TMO frameworks. The advantages of TMOs with larger pores are manyfold: for example, such materials would better satisfy the requirement for high ionic conductivity and

Table 1 Relative energy (in eV per formula unit) of the MO_3 frameworks examined

Material	PV	Hex	PY	L	$H^{2\times1}$	$H^{2\times2}$
MoO_3	0.00	0.238	0.607	4.281	0.943	1.128
WO_3	0.00	0.315	0.725	5.471	0.902	1.393

structural stability, necessary in electro- and photo-chromic applications, and in Li batteries. Furthermore, if the pore sizes reach the dimension of small organic molecules, microporous TMOs would allow heterogeneous catalytic applications, and combine the molecular-sieve characteristics of zeolites with the higher acidic strength and redox properties of early transition metal cations.

Attempts to use organic cations, usually quaternary ammonium salts, to template novel TMO frameworks have been reported,[8] but resulted in the formation of inorganic polyanions, the Keggin structures, rather than extensive M–O frameworks. We now examine the topic with a more analytic approach, exploiting the insight that can be obtained from computer modelling to provide information on the relative stability and on the required synthesis conditions for new, microporous structures of TMOs. In particular, we employ a strategy recently developed for the *de novo* design of structure-directing agents in zeolites:[9] given a target microporous architecture, the organic template is gradually grown within the pores, to design molecules which provide optimal space filling and maximum interaction energy with the selected porous system, thus helping to direct the synthesis towards the target structure.

The method requires the knowledge of the porous TMO structure as starting point. This is a challenging task by itself, since microporous structures built up on MO_6 octahedra have so far never been reported; the only exceptions are the OMS sieves based on edge-sharing of $Mn^{IV}O_6$ units,[10] in which the framework has stoichiometry MO_2 and not MO_3 as required for the MO and W oxides. The first problem to solve is therefore that of designing a suitable target structure.

The PV and Hex structures can be imagined as a 2D arrangement, repeated by corner-sharing of the axial oxygens along the third direction; in the design of new structures we retained this 2D approach, as a useful starting point. If we define a new building block, as a chain of *n* aligned edge-shared octahedra, a series of new structures can be obtained from the same connectivity of the PV and Hex phases, replacing single octahedral units with alternating chains of *m* and *n* edge-shared octahedra. Given the method of construction, we denote the new structures $PV^{m\times n}$ and $H^{m\times n}$ (the 1×1 structures reproduce the PV and Hex polymorphs). All the new structures have an MO_3 framework stoichiometry. We have calculated the electronic distribution, geometry and energy of the first two members of the $H^{m\times n}$ series: $H^{2\times 1}$ and $H^{2\times 2}$ (Fig. 1). The new structures represent local minima in the potential energy surface; hence, if synthesised, they would have a non-zero activation barrier towards phase transformations. The calculated internal energy is compared in Table 1 with that of the known polymorphs. The new structures are unstable, as expected; the energy difference has nonetheless the same order of magnitude as that between the known polymorphs and is within the range of the steric energy. It may therefore be possible to overcome this difference with steric effects; given the relative instability of the framework, the template must be selected carefully, and must fit tightly in the porous structure to stabilise these particular polymorphs; which is probably why previous attempts with 'randomly' selected templates failed.

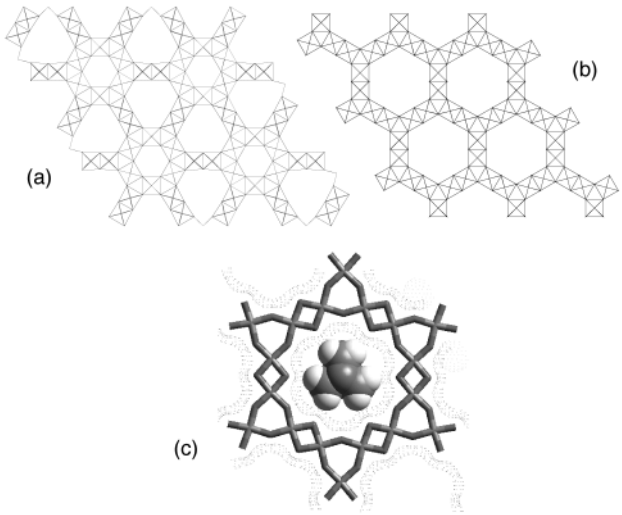

Fig. 1 Disposition of octahedra in the MO_3 framework of the $H^{2\times 1}$ (a) and $H^{2\times 2}$ (b) structures; diazobicyclooctane molecule, as located by the program ZEBEDDE[9] inside the pores of the $H^{2\times 2}$ structure (c)

Finally, we applied the *de novo* method to design templating agents specific for the $H^{2\times 1}$ and $H^{2\times 2}$ structures. The interactions between the framework and the organic template were evaluted *via* interatomic potentials;[11] energy-minimised structures were obtained for each template in a rigid host MO_3 framework, ignoring the M-template terms. Candidate templates are ranked by their calculated binding energy (E_B) with the host lattice: the higher the E_B the more favourable the molecule is considered as a template.[7] The pores of the $H^{2\times 1}$ structure have dimensions comparable to unsubstituted hydrocarbon chains, suggesting that *n*-amines or *n*-diamines, as used in zeolite synthesis may be suitable as templates. The pores of the $H^{2\times 2}$ polymorph have a size comparable to the 12-membered rings in zeotypes, and allow the insertion of more structured organic moieties. Our calculations reveal that adamantane and diazobicyclooctane derivatives are of suitable dimensions, the latter [Fig. 1(c)] having the highest E_B. Future experimental studies will test the prediction of these calculations.

In summary, our computational study has shown the feasibility on energetics grounds of an extensive range of microporous chemistry based on octahedral MoO_3 and WO_3, and has suggested that such structures may be synthesised using a host/guest templating approach.

F. C. thanks ICI Katalco and MSI for funding; the provision of time on the IBM/SP2 computer at the Daresbury Laboratory is gratefully acknowledged. D. W. L. acknowledges funding from the Oppenheimer Trust and the Royal Society.

Transformation of cyclohexene to enantiopure cyclitols mediated by sequential oxyselenenylation with (*S*,*S*)-hydrobenzoin: synthesis of D-*chiro*-inositol and *muco*-quercitol

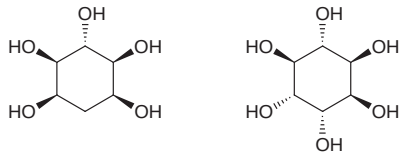
Kwan Soo Kim,*† Jong Il Park, Hoi Kyung Moon and Hann Yi

Department of Chemistry, Yonsei University, Seoul, 120-749, Korea

Oxyselenenylation of cyclohexene with (*S*,*S*)-hydrobenzoin and subsequent oxidation-elimination allows isolation of an allylic ether in which further phenylselenenylation is completely regioselective, thus allowing entry to the cyclitols D-*chiro*-inositol and *muco*-quercitol.

Cyclitols have attracted a great deal of attention from synthetic chemists due to their diverse biological activity and their versatility as synthetic intermediates.[1] Although several methods are available for the synthesis of cyclitol derivatives, there still remains a need for new methodology starting from simple starting materials because the cyclitol derivatives are structurally very diverse and the new methodology could be applied for the synthesis of other highly functionalized cyclic compounds. In this regard, it is noteworthy that cyclohexadiene *cis*-diols obtained from halobenzene by microbial oxidation[2] and from $PhMe_2SiCl$ by reduction and subsequent asymmetric dihydroxylation[3] have been used for the synthesis of cyclitols and other natural products.

Oxyselenenylation of a cycloalkene with an appropriate alcohol and the subsequent oxidation-elimination of the resultant oxyselenide would afford a cyclic allylic alcohol derivative. If a second oxyselenenylation of this cyclic allylic alcohol derivative was followed by oxidation-elimination to give a cycloalk-3-ene-1,2-diol derivative, a correctly protected cyclitol might be efficiently synthesized. However, it has been documented that the oxyselenenylation of both cyclic[4] and acyclic[5] allylic alcohol derivatives usually provides 1,3-diol rather than 1,2-diol derivatives. Therefore, in order to make this serial oxyselenenylation methodology work for the synthesis of enantiopure cyclitols, not only the stereochemistry but also the regiochemistry of the oxyselenenylation must be controlled. We have solved this problem by using a chiral diol, (*S*,*S*)-hydrobenzoin, for the oxyselenenylation of cyclohexene. Herein we report the successful conversion of cyclohexene into various enantiopure cyclitols and the synthesis of important natural cyclitols *muco*-quercitol **1** and D-*chiro*-inositol **2**, which

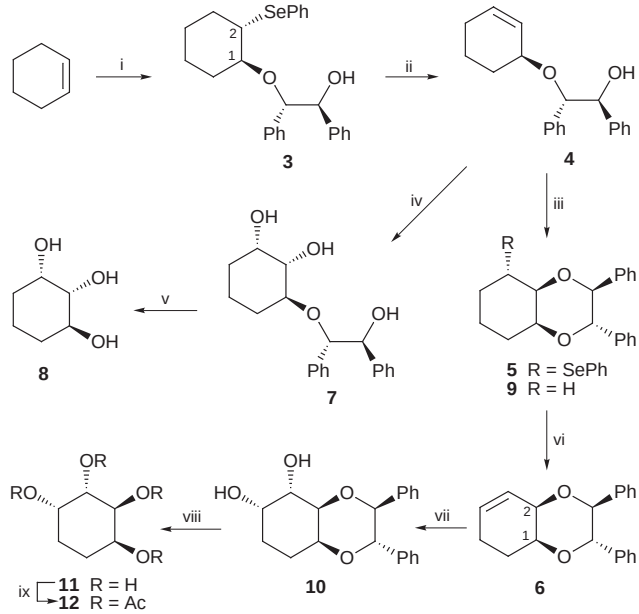


1 **2**

is valuable due to its physiological activity as an insulin mediator[6] and its limited availability.

To a solution of *N*-(phenylseleno)phthalimide (*N*-PSP) (3.44 mmol), (*S*,*S*)-hydrobenzoin (4.13 mmol), and cyclohexene (4.13 mmol) in CH_2Cl_2 (60 ml) was added slowly $BF_3{\cdot}OEt_2$ (0.34 mmol) at 0 °C. Stirring the reaction mixture at room temperature for a further 2 h afforded two diastereomeric oxyselenides [**3** plus the (1*R*,2*R*)-diastereomer; *ca.* 1:1 ratio] in 80% yield (Scheme 1). Although oxyselenenylation with other selenium reagents such as PhSeCl, PhSeBr and PhSeOTf was also possible, they frequently generated the undesired haloselenide or hydroxyselenide. Oxyselenide **3**‡ was separated by column chromatography and converted into olefin **4** {$[\alpha]_D$ −82.3 (*c* 0.7)} by the oxidation with $NaIO_4$ in the presence of $NaHCO_3$ followed by elimination of the resulting selenoxide. Intramolecular oxyselenenylation of **4** using PhSeOTf§ at −78 °C gave only *cis*-fused bicyclic dioxane **5**{$[\alpha]_D$ −34.5 (*c* 0.4)}. Thus, both regiochemistry and stereochemistry were completely controlled in the second oxyselenenylation step. Oxidation of selenide **5** and subsequent elimination provided olefin **6**.

Dihydroxylation of **4** with OsO_4 and NMO and subsequent hydrogenolysis of the resulting **7** afforded triol **8**. The absolute configuration of **8** was assigned on the basis of its ^1H NMR spectrum and by comparison of its specific rotation with that of authentic material {$[\alpha]_D$ +72.8 (*c* 1.0)}.[7] Reduction of selenide **5** with Bu_3SnH gave compound **9**. Dihydroxylation of **6** and subsequent hydrogenolysis of the resulting diol **10** gave tetrol **11**, which, by acetylation, afforded tetraacetate **12**. Examination of ^1H NMR spectrum of **9** and comparison with the ^1H NMR spectra of **12** with that of its known racemate[8] clearly indicated that the relative stereochemistry of compound **6** is *cis*. Consequently, the C1 and C2 configurations of cyclohex-3-ene-



Scheme 1 *Reagents and conditions*: i, (*S*,*S*)-hydrobenzoin, *N*-PSP, $BF_3{\cdot}OEt_2$ (cat.), CH_2Cl_2, room temp., 2 h, 40% of **3** and 40% of its (1*R*,2*R*)-diastereomer; ii, $NaIO_4$, $NaHCO_3$, MeOH–H_2O, room temp., 10 min, then 90 °C 48 h, 92%; iii, PhSeOTf, CH_2Cl_2, −78 °C, 2 h, 68%; iv, OsO_4 (cat.), NMO, acetone–H_2O, room temp., 24 h, 76%; v, H_2, Pd-C (cat.), EtOH, 50 psi, room temp., 12 h, 85%; vi, $NaIO_4$, $NaHCO_3$, MeOH–H_2O, room temp., 10 min, then 90 °C 48 h, 90%; vii, $K_2OsO_4H_2O$ (cat.), NMO, acetone–H_2O, reflux, 20 h, 92%; viii, H_2, Pd-C (cat.), EtOH, 50 psi, room temp., 8 h, 98%; ix, Ac_2O, pyridine, 50 °C, 12 h, 86%

1,2-diol derivative **6** were unambiguously determined to be *S* and *R*, respectively. On the other hand, a ^{1}H NMR decoupling experiment with compound **3** showed *trans* diaxial coupling (8.2 Hz) between H1 and H2 and thus the C1 and C2 configurations of **3** were assigned as *S* and *S*, respectively.

Epoxidation of **6** with MCPBA in CH_2Cl_2 afforded *trans*-epoxide **13** {R_f = 0.30 (silica gel, hexane−EtOAc, 10:1); $[\alpha]_D$ −126.9 (*c* 0.11)} along with its *cis* isomer {R_f = 0.11, $[\alpha]_D$ −112.0 (*c* 0.1)} (*trans*:*cis* = *ca.* 7:3) (Scheme 2). Epoxidation in other solvents gave poorer results. Diaxial opening of the epoxide ring of **13** with PhSeNa gave exclusively hydroxyselenide **14**, whereupon oxidation with 30% H_2O_2 followed by elimination provided allylic alcohol **15** {$[\alpha]_D$ + 3.0 (*c* 0.2)}. Dihydroxylation of **15** occurred on the opposite face to the allylic hydroxy group to afford exclusively triol **16** {$[\alpha]_D$ −50.5 (*c* 0.11)} in 92% yield. Hydrogenolysis of **16** provided *muco*-quercitol **1**, of which the spectroscopic data and physical properties were identical with those of authentic material. Further characterization of **1** was performed *via* transformation to the known pentaacetate **17**.[9]

Protection of the hydroxy group in **15** with the sterically demanding TBDPS group and subsequent epoxidation of the resulting TBDPS ether **18** {$[\alpha]_D$ +17.8 (*c* 1.1)} with MCPBA afforded the desired *trans*-epoxide **19** {R_f = 0.40 (silica gel, hexane–$CHCl_3$–EtOAc, 20:5:1); $[\alpha]_D$ −22.3 (*c* 0.74)} along with *cis*-epoxide {R_f = 0.35; $[\alpha]_D$ −33.2 (*c* 0.80)} (*trans*:*cis* = 3:2). Diaxial opening of the epoxide ring in **19** with PhSeNa afforded exclusively hydroxyselenide **20**, which turned out to be a mixture of two rotational isomers (3:2) about one of the single bonds in the OTBDPS group. The mixture of two stable atropisomers **20** was separated by flash chromatography, and each was converted into allylic alcohol **21,** which was also a stable and separable mixture of atropisomers (3:2). Evidence for the atropisomerism in compounds **20** and **21** could be readily obtained by removal of their TBDPS groups. Thus, treatment of each atropisomer of **20** with TBAF gave the diol **22** which did not show any atropisomerism. Diol **23** {$[\alpha]_D$ +23.0 (*c* 0.10)}, obtained from both atropisomers of **21** by deprotection with TBAF, also showed no atropisomerism.

Dihydroxylation of **23** followed by hydrogenolysis of the resultant **24** {$[\alpha]_D$ − 68.1 (*c* 0.32)} with $Pd(OH)_2$-C (Degussa type) in the presence of a trace amount of conc. HCl gave D-*chiro*-inositol **2**, the physical properties of which are identical with those of authentic **2**.[10] Perbenzoate **25**[11] was prepared for further characterization of **2**. A similar synthesis starting with the (1*R*,2*R*)-diasteromer of **3** would provide L-*chiro*-inositol. The development of the highly diastereoselective oxyselenenylation of cyclohexene with various chiral alcohols including hydrobenzoin derivatives is now in progress.

This work was supported by a grant from Basic Research Institute Program (BSRI-97-3422), Ministry of Education, Korea. Support from OCRC-KOSEF is also acknowledged.

§ Unlike the first oxyselenenylation step, the intramolecular oxyselenenylation proceeded in a reasonable yield only with PhSeOTf, possibly because other selenium reagents, including *N*-PSP, are not reactive enough for the intramolecular oxyselenenylation.

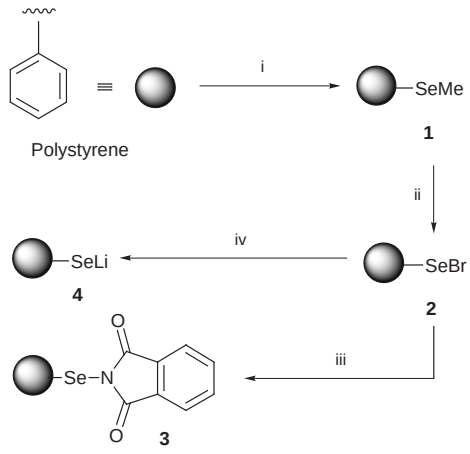
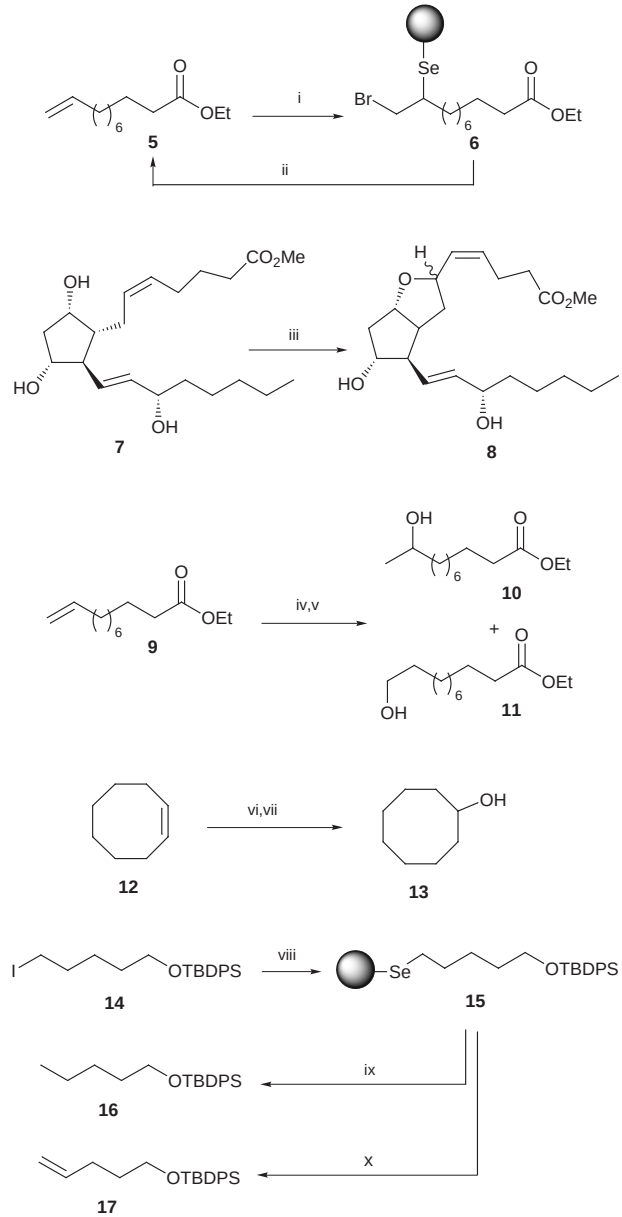
Organoselenium resins 1–4 were prepared from polystyrene *via* lithiation and quenching with MeSeSeMe, and shown to react with a variety of substrates, aiding in useful functionalizations.

Combinatorial chemistry and solid phase synthesis have recently emerged as powerful tools for the drug discovery process.[1] The latter technique is particularly useful for combinatorial library construction due to its adaptability to the powerful and elegant split-pool methods[2] and because of the well recognized purification advantages associated with it. The utilization of polymer-bound reagents,[3] in particular, has gained popularity due to the non-requirement for tethering the substrate to the polymer. Here we describe the preparation of a series of solid-supported selenium resins[4,5] **2–4** (Scheme 1) and their application as linkers and reagents for solid phase synthesis. A distinct advantage of the new reagents is the convenience of handling and their totally odorless nature as compared to the non-bound reagents, whose toxicity and foul smell is often problematic.

Scheme 1 summarizes the preparation of the new resins **2–4** from readily available starting materials. Thus, polystyrene beads suspended in cyclohexane were treated with Bu^nLi–TMEDA[6] and the lithiated species was quenched with MeSeSeMe,[7] furnishing selenium reagent **1** as a pale yellow resin (the loading of selenium was controlled by addition of MeSeSeMe in substoichiometric amounts to the lithiated polystyrene). Exposure of **1** to bromine resulted in quantitative conversion[8] to the polymer-supported selenenyl bromide **2**, which was isolated after filtration and washing as a deep red resin. The selenium

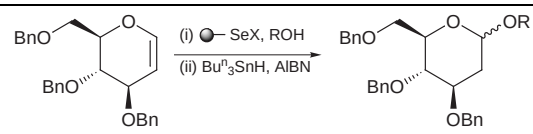


Scheme 1 *Reagents and conditions*: i, Bu^nLi (2.5 M in hexanes, 24 equiv.), TMEDA, cyclohexane, 65 °C, 4 h, then filtration and washing with THF, then dimethyl diselenide (2.0 mmol g^{-1} of polystyrene), THF, 0 °C, 30 min, 100%; ii, Br_2 (0.9 equiv.), $CHCl_3$, 0 °C, 10 min, 100% (based on consumption of Br_2), then filtration and washing, then EtOH, 70 °C, 1 h, > 95%; iii, potassium phthalimide (1.5 equiv.), 18-crown-6 (1.5 equiv.), benzene, 23 °C, 5 h, > 95% yield; iv, $LiBH_4$ (2.0 M in THF, 2.0 equiv.), THF, 23 °C, 1 h, > 95%



Scheme 2 *Reagents and conditions*: i, **2** (1 equiv.), CH_2Cl_2, 23 °C, 30 min; ii, Bu^n_3SnH (4 equiv.), AIBN (0.01 equiv.), PhMe, 110 °C, 6 h, 92% (2 steps); iii, **2** (1.5 equiv), THF, −78 °C, 30 min, then H_2O_2 (30%, 2 equiv.), −78 → 23 °C, 20 h, 94% (2 steps); iv, **3** (0.5 equiv.), H_2O (1 equiv.), CSA (0.05 equiv.), CH_2Cl_2, 24 h; v, Bu^n_3SnH (2 equiv.), AIBN (0.005 equiv.), PhMe, 110 °C, 6 h, 82% (2 steps), **10** : **11** = 2 : 1; vi, **3** (0.5 equiv.), H_2O (1 equiv.), CSA (0.05 equiv.), CH_2Cl_2, 24 h; vii, Bu^n_3SnH (2 equiv.), AIBN (0.005 equiv.), PhMe, 110 °C, 6 h, 80% (two steps); viii, **4** (0.5 equiv.), THF, 23 °C, 12 h; ix, Bu^n_3SnH (2 equiv.), AIBN (0.005 equiv.), PhMe, 110 °C, 6 h, 89% (2 steps); x, H_2O_2 (30%, 1 equiv), THF, 23 °C, 12 h, 78% (2 steps)

Table 1 Polymer-bound selenium promoted synthesis of 2-deoxyglycosides[a]



18 **19**

Entry	ROH	Reagent	Solvent	*t*/h	Yield (%)	Ratio α : β
1	BnOH	**2**	CH_2Cl_2	24	87	2 : 1
2	BnOH	**2**	PhMe	24	96	2 : 1
3	BnOH	**2**	MeCN–CH_2Cl_2 (2 : 1)	24	86	5 : 1
4	BnOH	**3**	CH_2Cl_2	48	68	1 : 5
5	BnOH	**3**	PhMe	48	72	1 : 5
6	BnOH	**3**	MeCN–CH_2Cl_2 (2 : 1)	48	23	1 : 1
7		**2**	MeCN–CH_2Cl_2 (2 : 1)	24	61	8 : 1
8		**3**	PhMe	48	45	1 : 1
9		**2**	MeCN–CH_2Cl_2 (2 : 1)	96	50	20 : 1

[a] All reactions were carried out under an atmosphere of argon in the presence of 4 Å molecular sieves. *Reagents and conditions*: i, (for reagent **2)** ROH (1 equiv.), 2,6-di-*tert*-butyl-4-methylpyridine (1 equiv.), **2** (0.5 equiv.); (for reagent **3)** ROH (1 equiv.), CSA (1 equiv.) and **3** (0.5 equiv.); solvent and time as shown in Table; ii, Bu$^n_3$SnH (2 equiv.), AIBN (0.005 equiv.), PhMe, 110 °C, 8 h.

phthalimide reagent **3** was obtained as a yellow resin from **2** by displacement with potassium phthalimide in the presence of 18-crown-6 (> 95% yield),[9] while the lithium selenide **4** (a pale yellow resin) was prepared by $LiBH_4$ reduction of **2** (95% yield). All new reagents appeared to be quite stable in the air at ambient temperature (inert atmosphere is recommended, however, for their storage and use).

Scheme 2 displays chemistry demonstrating the use of resins **2–4** both as solid phase linkers and polymer-bound reagents. Thus, olefin **5** was quantitatively loaded onto the polymer by treatment with the polymer-bound selenium bromide resin **2** and, subsequently, released reductively under the influence of Bu$^n_3$SnH–AIBN (cat.) to recover the starting olefin **5** in 92% overall yield. The polymer-bound selenium bromide **2** was also shown to be as effective as phenylselenium bromide for the known two-step transformation[10] of $PGF_{2\alpha}$ methyl ester **7** to the PGI_2 analogues **8** (94% yield, *ca.* 2 : 1 ratio of C-6 epimers, Scheme 2). Hydration of an olefin was demonstrated to proceed smoothly with the selenium phthalimide resin **3**.[9] Thus, terminal olefin **9** was converted to the regioisomeric alcohols **10** and **11** in 82% overall yield (**10** : **11** *ca.* 2 : 1 ratio) by the action of reagent **3** and CSA in the presence of H_2O, followed by reductive cleavage from the solid support with Bu$^n_3$SnH–AIBN. Furthermore, cyclic olefin **12** was converted to alcohol **13** in 80% overall yield by the same two-step procedure. The use of the resin **4** was demonstrated as follows. Alkyl iodide **14** was efficiently loaded onto the polymer through mild alkylation conditions in THF. The substrate was then released from the polymer (**15**) by either free radical chemistry to obtain the corresponding alkyl compound **16** (89% overall yield) or oxidative conditions leading to olefinic product **17** (78% overall yield).

Table 1 summarizes applications of polymer-bound selenium bromide **2** and selenium phthalimide[11] **3** to the synthesis of 2-deoxyglycosides.[12] Most noteworthy is the inverse glycosidation stereoselectivity obtained under different reaction conditions. Thus, glycosidation of tri-*O*-benzylglucal **18** with BnOH using the polymer-bound selenenyl bromide reagent **2** (X = Br) followed by Bu$^n_3$SnH–AIBN (cat.) cleavage of the newly formed selenium–carbon bond released the 2-deoxy glycosylated product **19** in 86% yield with 5 : 1 selectivity in favor of the α-anomer (entry 3), whereas the same transformation carried out with the polymer-bound selenenyl phthalimide reagent **2** yielded the product in 72% with a 5 : 1 selectivity in favor of the β-anomer (entry 5).

In conclusion, we have successfully prepared a series of polymer-bound selenium reagents/linkers and demonstrated a number of their uses in organic synthesis. These reagents should find useful applications in solid phase and combinatorial synthesis due to their versatility and ease of handling.

We thank Drs Dee H. Huang and Gary Siuzdak for NMR and mass spectroscopic assistance, respectively. Catalytic oxidation of alkyl aromatics using a novel silica supported Schiff base complex

Ian C. Chisem,[a] John Rafelt,[a] M. Tantoh Shieh,[b] Janet Chisem (née Bovey),[a] James H. Clark,*[a]† Roshan Jachuck,[b] Duncan Macquarrie,[a] Colin Ramshaw[b] and Keith Scott[b]

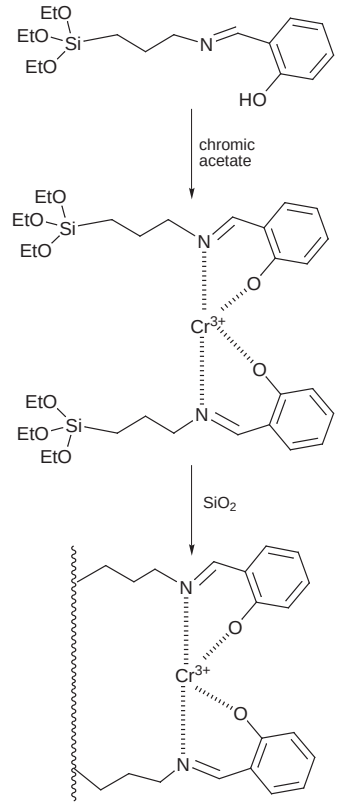
[a] *Department of Chemistry, University of York, Heslington, York, UK YO10 5DD*
[b] *Department of Chemical and Process Engineering, University of Newcastle-upon-Tyne, Newcastle-upon-Tyne, UK NE1 7RU*

A new heterogeneous catalyst based on a chemically modified mesoporous silica gel and possessing immobilised chromium ions has been prepared and successfully applied to the aerial oxidation of alkyl aromatics at atmospheric pressure and in the absence of solvent.

The oxidation of organic substrates provides routes to a wide range of functionalised molecules. Traditional methods involve the use of large quantities of poisonous high oxidation state Cr, Mn and Os reagents.[1] Lower oxidation state metals such as Co^{II}, Mn^{II} and Cu^{II} in AcOH may be used[2] with O_2 as the consumable oxidant. However, the conditions are often harsh, the reagent mixture is corrosive (bromide is used as a promoter), and the chemistry is rarely selective. Environmentally acceptable catalytic oxidations that operate under moderate conditions in the liquid phase with high selectivity are clearly desirable. A range of supported reagents has been used in the liquid phase oxidation of organic substrates. Advantages of supported reagents include ease of handling, use and recovery, low toxicity and the avoidance of solvents. However, in oxidations, supported reagents have generally acted as *stoichiometric* reagents, making their large scale use difficult and expensive. We have proven the possibility of developing genuinely *catalytic* supported reagents which are active in some oxidations.[3,4] More recently, catalysts based on chemically modified silicas, which have higher catalytic site densities, have been prepared.[5,6] We now report a novel heterogeneous catalyst for the liquid phase partial oxidation of alkyl aromatic substrates based on a chemically modified mesoporous silica gel which possesses significantly enhanced activity. The material strongly binds chromium ions and is robust, reusable and active in the oxidation of ethylbenzene and methyl aromatics.

The preparation of the chromium catalyst (CHRISS) is shown in Scheme 1. Salicylaldehyde (1 equiv.) was added to excess absolute EtOH, to which 3-aminopropyl(trimethoxy)silane (1 equiv.) was added. The solution instantly became yellow due to imine formation. Chromium(III) acetate (0.5 equiv.) was then added to the solution, and the mixture stirred for a further 30 min to allow the new ligands to complex the chromium. The silica (Kieselgel 100) was then added and the mixture stirred overnight. The final product was washed with water, EtOH and finally Et_2O until the washings were colourless. Further drying of the solid product was carried out on a rotary evaporator at 70 °C for 2 h. The loading achieved is *ca.* 0.10 mmol g^{-1} [determined by atomic absorption spectroscopy (AAS)]. The catalyst has an average pore size of 100 Å and a particle size of 30–140 μm. The infrared spectrum of the free ligand (*i.e.* prior to complexation with the metal) shows a band at 1642 cm^{-1} attributed to the C=N stretching vibration of the imine. This is reduced to 1593 cm^{-1} upon complexation of Cr^{3+}. Apart from bands in the 250–450 nm region, the diffuse reflectance UV spectrum of the catalyst shows a band at *ca.* 600 nm corresponding to d-d transition for the metal complex. The band is shifted to higher wavelength by about 30 nm from the corresponding band in pure $Cr(OAc)_3$ or $Cr(OAc)_3$ physisorbed on silica, consistent with a change in ligand environment.

The catalytic oxidation of ethylbenzene (used as a model substrate) was carried out in neat substrate using 1.5 g catalyst and air as the consumable source of oxygen. The reaction was performed in a baffled glass reactor with overhead stirring and fitted with a Dean–Stark trap to facilitate the removal of water from the reactor. After a short induction period the conversion rate in the first 5 h of operation was *ca.* 5% h^{-1}, corresponding to a frequency of 1225 turnovers h^{-1} per catalytic site (assuming 0.10 mmol g^{-1} loading of the active site). After the first 5 h, the rate of conversion dropped significantly; this is attributed to the inefficient removal of water from the reaction system, and poor adsorption of ethylbenzene onto the catalyst surface as the acetophenone concentration increases. In addition, catalyst reuse studies were performed by recycling 1.5 g of catalyst twice without any regeneration or conditioning by decanting the liquid from the reactor and adding fresh substrate and then repeating the experiment. The results shown in Fig. 1 demonstrate that the recycled catalyst retains its activity and the catalytic rate is equal to that of the fresh catalyst. Furthermore, the induction period observed with the use of fresh catalyst was eliminated when the catalyst was recycled. This suggests that poor product desorption when the catalyst is not saturated with the product was the cause of the induction periods observed.



Scheme 1

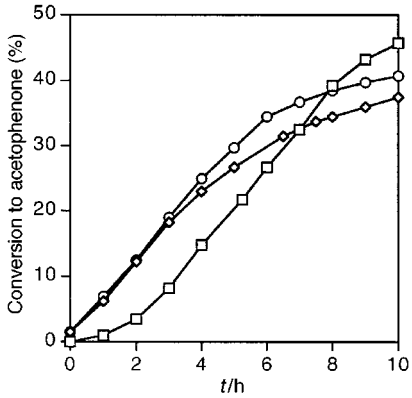


Fig. 1 Production of acetophenone in the oxidation of ethylbenzene using 5 g of the immobilised chromium on silica catalyst: (□) fresh catalyst, (○) first recycle and (◇) second recycle

After 5 h the activity of the recycled catalyst begins to decrease; the effect is more pronounced on the second recycle. The reason for this deactivation is not fully understood. Further reuse studies are in progress, including regeneration and conditioning of spent catalyst.

It is believed that the imprinted method of synthesis allows the chromium to become very tightly bound to the support. To verify that oxidation is occurring due to heterogeneous catalysis, several test reactions were carried out which were designed to encourage the formation of leached chromium. In one test reaction, an unimprinted version of the catalyst was made. Unlike the original catalyst, where the ligands are complexed with the metal and then grafted onto the silica support, the unimprinted version involves the grafting of the ligands before the complexation with the metal ions. This method of production gave a lower loading (0.05 mmol g^{-1} by AAS) and it is likely that the metal–ligand binding is significantly reduced in strength due to the less favourable spatial orientation of the ligands on the surface, leading to a less robust catalyst. In the second experiment, a catalyst based on physisorbed chromium(III) on the silica surface was made. The catalyst was formed by dissolving chromium(III) in EtOH, and stirring with the silica gel. The solvent was then removed by rotary evaporation, leaving a grey solid. The results shown in Fig. 2 indicate that the imprinted version of the CHRISS catalyst is the most active of the species studied. Both the unimprinted and the physisorbed materials show little activity above that of a control reaction, containing no catalyst.

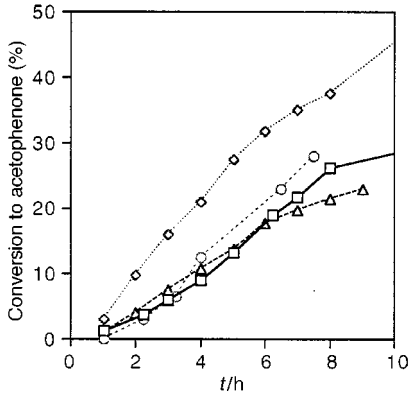

Fig. 2 Production of acetophenone in the oxidation of ethylbenzene using (□) an unimprinted catalyst, (○) a physisorbed chromium(III) catalyst, (◇) the imprinted catalyst and (△) no catalyst

We have successfully extended catalytic chemistry to the commercially important oxidation of methyl aromatics. *p*-Chlorotoluene, *p*-xylene and *o*-xylene all undergo aerial oxidation at atmospheric pressure in neat substrate with the supported chromium catalyst (Table 1). Again it was necessary to prove that the catalysis was not due to leached chromium. Following the method described by Lempers and Sheldon,[7] a *p*-xylene reaction was hot filtered after 1 h (*i.e.* at an early stage of the reaction) to remove the catalyst. The reaction was then restarted without the catalyst, and the product isolated after 24 h. The reaction yielded 15 g of *p*-toluic acid (compared to 166 g from the reaction with CHRISS) which corresponds to the amount formed during an oxidation without the catalyst, *i.e.* the formed product is due to autoxidation. Analysis of the reaction mixture after hot filtration of the catalyst showed < 0.5 ppm of chromium.‡

Table 1 Oxidation reactions using CHRISS[a]

Substrate	*T*/°C	Product(s)	Isolated yield (%)
Ethylbenzene	130	acetophenone	50
p-Xylene	138	*p*-toluic acid	29
		terephthalic acid	5
o-Xylene	145	*o*-toluic acid	7
p-Chlorotoluene	130	*p*-chlorobenzoic acid	12

[a] Reactions were carried out using the supported chromium catalyst (1.5 g) in neat substrate (4.1 mol) with an air feed rate of 800 ml min^{-1} and an agitation rate of 1500 rpm, for a period of 24 h.

The activity of the catalyst is significantly greater than the commercial supported chromium catalyst and other supported reagents based on chemically modified surfaces.[3–6] The fact that we were not able to detect Cr, that experiments with less-robustly held catalysts proceeded at the background rate, and that the reaction after filtration failed to exceed the background rate leads us to believe that the active species is the surface bound Cr complex. The efficiency of the catalytic systems, the use of air as the only consumable source of oxygen and the avoidance of solvent makes them excellent examples of environmentally friendly processes.

The financial support of the EPSRC Clean Technology Unit is gratefully acknowledged. We also thank the Royal Academy of Engineering for a Clean Technology Fellowship (to J. H. C.) and the Royal Society for a University Research Fellowship (to D. J. M.).

The synthesis and aggregation properties of a novel anionic gemini surfactant

Kevin Jennings,[a] Ian Marshall,[a] Helen Birrell,[a] Andrew Edwards,[a] Neville Haskins,[a] Olle Sodermann,[b] Anthony J. Kirby[c] and Patrick Camilleri*[a]†

[a] *SmithKline Beecham Pharmaceuticals, New Frontiers Science Park, Third Avenue, Harlow, Essex, UK CM19 5AW*

[c] *University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

The aggregation of a peptide-based anionic gemini surfactant has been found to be highly dependent on the environment in which this property is measured; dimensions of aggregates varied from those generally observed in micellar species to those in fibrillar material.

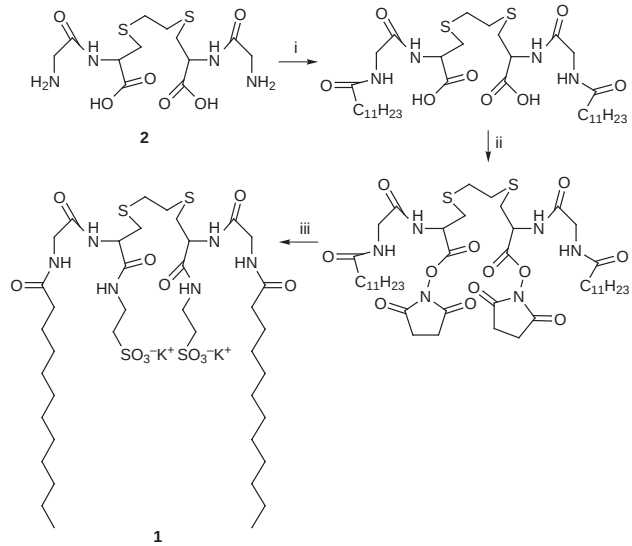
About 25 years ago a rather unusual type of surfactant molecule consisting of dimeric amphiphiles, made up of two long hydrocarbon chains and two ionic groups linked by a spacer, was reported by Bunton *et al.*[1] The name 'gemini' was used by Menger in 1991 to identify these detergents.[2]

The unusual structures of gemini surfactants result in surface and bulk properties that differ from those observed for more conventional single-chain monomeric surfactants having the same number of carbon atoms per polar 'head' group. Thus whereas monomeric surfactants tend to form spherical micelles in dilute solution, geminis usually form thread-like aggregates. Geminis generally have lower critical micelle concentration (cmc) values; their foaming and wetting properties are excellent, resulting in a more efficient lowering of the surface tension of water; they also show unexpected viscosity changes as their concentration is increased.

Most gemini surfactants synthesised over recent years contained bisphosphate or bis(quaternary ammonium) ionic groups linked by spacers ranging from a rigid aromatic group to a more flexible short aliphatic chain. The length of the saturated hydrocarbon tails has ranged from 8 to 18 carbon atoms. The length, flexibility and polarity of the linker group can have a profound effect on the resulting shapes of aggregates formed by gemini surfactants.[2,3]

We have synthesised a peptide-based gemini surfactant **1,** starting from the reaction of L-cysteine with dibromoethane to form the bisthioether. Reaction of the latter with Boc-protected glycine-*O*-succinimide, followed by deprotection, gave compound **2**. This reacted further as shown in Scheme 1 to give **1** as the dipotassium salt. The structure of **1** was confirmed by its ^{1}H and ^{13}C NMR spectra, measured in D_2O. A FAB mass spectrum of **1** in a glycerol matrix, scanning in negative ion mode, gave an isotopic distribution corresponding to the calculated pattern fitting $C_{40}H_{74}N_{6O}O_{12}S_4K$, as shown in Fig. 1.

Gemini **1** was soluble in aqueous media even at neutral pH. The presence of **1** in solutions of the hydrochloride of 1-(1,3-dichloro-6-trifluoromethyl-9-phenanthryl)-3-dibutylaminopropan-1-ol, an anti-malarial drug known as halofantrine and marketed by SmithKline Beecham,[4] caused a substantial change in the fluorescence spectrum of this compound (Fig. 2). From a plot (not shown) of the increase in the intensity of this drug with the increase of the concentration of **1**, an approximate measurement of the cmc was obtained as 10^{-4} mol dm^{-3}. This value is lower than those reported for single hydrocarbon chain surfactants, such as sodium dodecyl sulphate, where the cmc was measured[5] as 7×10^{-3} mol dm^{-3}. Low cmc values have been reported for other gemini surfactants.[2] Fig. 2(*c*) shows that the intensity of the spectrum of halofantrine increases substantially on standing for 24 h, indicating that the organisation of micelles had changed during this period. Electron micros-



Scheme 1 *Reagents*: i, $C_{11}H_{23}COCl$, NaOH, H_2O; ii, *N*-hydroxysuccinimide, DCC, THF; iii, taurine, K_2CO_3, H_2O, THF

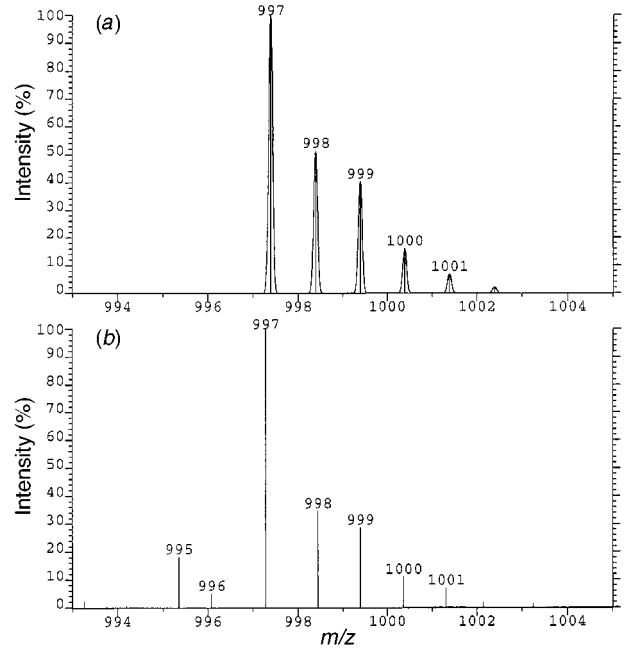


Fig. 1 FAB mass spectrum of **1**: (*a*) calculated and (*b*) experimental isotopic distribution. The spectrum was obtained using a Micromass 70-VSEQ mass spectrometer, negative ionization effected by a primary beam of caesium ions.

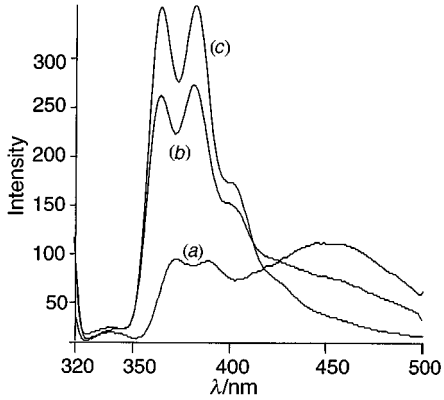

Fig. 2 Emission spectra (λ_{ex} 310 nm) of a 10 μM solution of halofantrine: (*a*) in water, (*b*) in water containing 1 mg ml^{-1} of **1** (fresh solution) and (c) in water containing 1 mg ml^{-1} of **1** (24 h standing). Spectra were recorded on a Perkin-Elmer LS50 spectrofluorimeter.

copy measurements (see later) confirm morphological changes in the organisation of micelles at periods shorter than 24 h.

The diffusion coefficient of **1** was measured as 5.2×10^{-11} m^2 s^{-1} by carrying out diffusion experiments on a sample which was 0.1% (1 mg ml^{-1}) by weight. This value indicated the presence of rather small micelles with a hydrodynamic radius of about 3.5 nm. As the cmc is so low, the diffusion coefficient measured is that of the micelles, with a negligible contribution from the free surfactant.

Attempts to study the morphology of these micelles (1 mg ml^{-1}) in deionised water by transmission electron microscopy (TEM) by negative staining (using 5% w/v ammonium molybdate containing 1% w/v trehalose) at early time points after preparation proved problematic due to surfactant/stain interactions and poor sample spreading; images were obtained that showed discrete globular structures 3 to 5 nm in diameter and globular strings, ~40 nm in length [Fig. 3(A)]. Further analysis of the surfactant solutions after storage at 4 °C for 24 h or longer periods proved easier to prepare by spreading on a grid and staining.

TEM analysis of this aged solution by negative staining gave distinct fibrillar/ribbon structures with periodic 'twist-like' features [Fig. 3(B)]. Fibrils appeared in excess of 10 μm long and ranged between 6 ± 1.5 (n = 23) and 40 ± 13 nm (n = 11) in width. Three populations were identified based on the periodic features exhibited. Low numbers of flat ribbon-like fibrils with irregular spaced twists were seen interspersed among fibrils with 145 ± 23 nm (n = 37) periodicity and a smaller population of shorter 63 ± 8nm (n = 23) period fibrils.

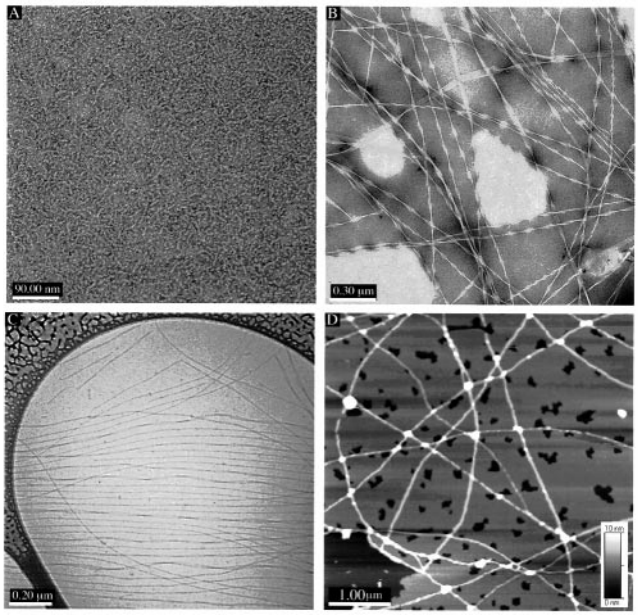

Fig. 3 (A) Negative stained TEM images of **1** immediately after dissolution; (B) negative stained TEM images recorded after 21 h; (C) cryogenic TEM images recorded after 9 days dissolution; and (D) AFM images of surfactant dried onto mica (sample taken from a solution which was 6 h old). TEM and AFM images were obtained using a Hitachi H7100 microscope and a TopoMetrix Explorer microscope, respectively.

Cryogenic transmission electron microscopy (TEM) of samples incubated at 4 °C for 9 days confirmed the presence of fibrils similar to those seen by negative staining after 24 h [Fig. 3(C)]. Fewer fibrils showed periodic features than were seen by negative staining—those present also appeared longer at 211 ± 4 nm (n = 20). Other fibrils (10–20 nm wide) appeared to lack any periodicity. A noticeable inter-fibrillar regular parallel spacing of 20 to 40 nm observed may reflect electrostatic repulsion between surfactant anionic head groups in aqueous solution.

Atomic force microscopy (AFM) images of **1** were also obtained for samples, dried on mica from filtered deionised water, immediately after dissolution and 6 h after dissolution. Images of surfactant immediately after dissolution showed orientated fibrils on top of a relatively flat substructure. Fibrils showed heights of 0.3–0.5 nm above the underlying structure and widths of 37 ± 8 nm. Spreading artefacts due to drying would be expected to result in underestimates of fibril height and overestimates of fibril width (due to tip-sample interactions).

At 6 h after dissolution [Fig. 3(D)] three distinct morphologies were observed by AFM for dried surfactant: sheets, *ca.* 3–4 nm in thickness; globules, 44 nm ± 14 nm (n = 12) in cross-section and 1–5 nm in height; and fibrils, 48 nm ± 10 nm (n = 8) in cross-section and 2–5 nm in height. Fibrils were found to settle predominantly on top of the underlying sheets: areas of exposed mica were largely free of fibrils or contained fibril fragments. This may reflect the strong electrostatic repulsion between the anionic head groups, which would be expected to lie on the outer surface of fibrils in aqueous solution, and the negatively charged mica surface. Approximately 80% of fibrils displayed clear periodicity (mean periodic length = 106 ± 18 nm; n = 8). Periodic features were conserved when the scan direction was rotated through 90° (data not shown) suggesting that it was not caused by a scanning artefact.

The disappearance of smaller fibrils and the appearance of larger, periodic fibrils with time is consistent with a time-dependent aggregation/twisting of early fibrils into larger structures. The fibrilisation phenomena, observed in the TEM and AFM analysis of aggregates of **1,** are reminiscent of those observed in the aggregation of β-amyloid protein (β-AP),[6] which has been implicated in the development of Alzeimer's disease. β-AP contains both hydrophobic and hydrophilic peptide sequences, and has been reported to have micellar properties.[7] Further studies are in progress aimed at identifying the structural features of **1** that lead to the observed aggregation properties.

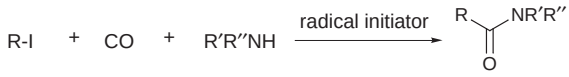
Metal catalyst-free by design. The synthesis of amides from alkyl iodides, carbon monoxide and amines by a hybrid radical/ionic reaction

Ilhyong Ryu,*† Kiyoto Nagahara, Nobuaki Kambe, Noboru Sonoda,‡ Sergio Kreimerman and Mitsuo Komatsu

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565-0871, Japan

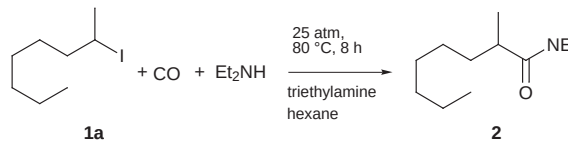
Amides can be synthesized from alkyl iodides and amines in the presence of CO (20–25 atm), without using transition metal catalyst; the radical cascade is initiated thermally using AIBN and allyltributyltin.

Transition metal catalysts facilitate many useful synthetic transformations. However, metal catalyst-free procedures, which do not require complicated techniques for recovering the expensive metals and ligands, would have a distinct advantage.[1] We recently discovered that irradiation conditions enable us to synthesize carboxylic acid esters from alkyl iodides, CO, and ROH.[2] This ester synthesis represents an intriguing example of a reaction which was previously possible only in the presence of a catalyst, but can now be carried out under metal catalyst-free conditions. The role of irradiation was unclear, especially as to whether it was generating an alkyl/iodine radical pair in a non-chain process or simply initiated a radical chain process. Here we report the synthesis of amides from alkyl iodides, CO and amines under thermal initiation conditions [eqn. (1)], expanding the utility of the metal catalyst-free approach and demonstrating the involvement of a radical *chain* transfer step in this hybrid radical/ionic reaction.



(1)

Thermally initiated conditions for the catalyst-free synthesis of amides were examined for the conversion of 2-iodooctane **1a**, diethylamine, and CO into *N*,*N*-diethyl amide **2** [eqn. (2)]. No reaction took place under thermal conditions without a radical initiator. However, the results with conventional radical initiators, such as AIBN and BPO, were disappointing, since only low yields of the desired **2** were obtained. For example, when a hexane solution of **1a** and Et_2NH was heated under 25 atm of CO at 80 °C for 8 h in the presence of AIBN (30 mol%), **2** was obtained in 10% yield. A dramatic increase in the yield of **2** up to 91% was achieved when both AIBN (25 mol%) and allyltributyltin (10 mol%) were used. The combination of AIBN and tris(trimethylsilyl)silane also gave a good result but AIBN–tributyltin hydride gave inferior results. On the other hand, in the presence of 20 mol% of galvinoxyl, the reaction was inhibited, and 81% of iodide **1a** was recovered. These results convinced us that the pathway by which amide **2** is formed includes a radical *chain* transfer.

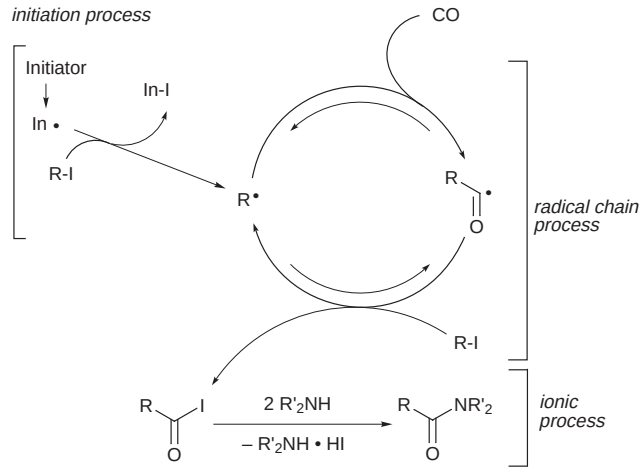


1a **2** (2)

no initiator	0%
AIBN (30 mol%)	10%
BPO (20 mol%)	17%
AIBN (25 mol%), allyltributyltin (10 mol%)	91%
AIBN (25 mol%), allyltributyltin (10 mol%), galvinoxyl (20 mol%)	5%
AIBN (25 mol%), $(TMS)_3SiH$ (20 mol%)	80%
AIBN (30 mol%), Bu_3SnH (30 mol%)	43%

Encouraged by the above results, we then examined the generality of the amide synthesis using AIBN–allyltin as thermal initiator. Table 1 shows that amides can be successfully prepared from RI, medium pressure CO (20–25 atm) and amines.[3] In general triethylamine was added as a base to trap HI, whereas in entry 3, for convenience 2 equiv. of the amine were used as both nucleophile and base. Solvents can be varied, and even in the case where MeOH was used as the solvent, the amide was the only product of the carbonylation reaction (entry 4). Both primary and secondary amines were useful. In general carbonylation of tertiary radicals is relatively inefficient compared with secondary and primary alkyl radicals due to the facile reverse reaction.[4,5] However, the unique radical/ionic cooperation driving the carbonylation/decarbonylation equilibrium in the forward direction could provide an enormous advantage for the carbonylation of tertiary radicals. Using bis(2-ethylhexyl)amine, diamide **8** was prepared (entry 7). On the other hand, when an *o*-aminobenzyl alcohol was treated with **1d**, an *N*-acylated product **10** was obtained (entry 9). In these examples, standard flash chromatography on silica gel was used for the isolation of products, whereas in one case, Renaud's recently reported procedure for removing small amounts of tin residue was tested and found to be convenient (entry 8).[6]

It should be noted that the use of irradiation conditions, which were employed in our previous study,[2] can also be used for the amide synthesis, and are especially useful for the reaction of primary alkyl iodides.[7] Scheme 1 illustrates the three step



Scheme 1

Table 1 Amide synthesis *via* catalyst-free carbonylation of alkyl iodides[a]

Entry	Alkyl iodide	Amine (equiv.)/ solvent/conditions	Product	Yield (%)[b]
1	 **1a**	Et_2NH (0.9) Et_3N (1.3) hexane (0.5 ml) 80 °C, 8 h CO (25 atm)	 **2**	89
2	**1a**	n-$C_6H_{13}NH_2$ (1.1) Et_3N (1.1) hexane (0.5 ml) 80 °C, 8 h CO (20 atm)	 **3**	60[c]
3	 **1b**	Et_2NH (2.3) hexane (0.5 ml) 80 °C, 8 h CO (20 atm)	 **4** (*trans*:*cis* = 85:15)	82
4[d]	 **1c**	piperazine Et_3N (3.0) MeOH (1 ml) 80 °C, 10h CO (20 atm)	 **5**	57
5	 **1d**	$PhNH_2$ (1.0) Et_3N (1.3) MeCN (0.5 ml) 80 °C, 8 h CO (20 atm)	 **6**	96
6	**1d**	Et_2NH (0.9) Et_3N (1.5) hexane (0.5 ml) 80 °C, 8 h CO (20 atm)	 **7**	80
7	 **1e**	bis(2-ethylhexyl)-amine (0.5) Et_3N (1.5) hexane (0.5 ml) 80 °C, 8 h CO (20 atm)	 **8**	97
8	 **1f**	Bu_2NH (1.0) Et_3N (1.3) hexane (0.5 ml) 90 °C, 8 h CO (20 atm)	 **9**	74[e]
9	**1d**	*o*-amino benzyl-alcohol(1.0) Et_3N (1.3) MeCN (0.5 ml) 80 °C, 10 h CO (25 atm)	 **10**	52

[a] In general reactions were conducted on 1 mmol scale with AIBN (20–30 mol%)–allyltributyltin (10%) as initiator. For typical procedure: see ref. 3. [b] Yields after isolation by chromatography on silica gel. [c] *N*-Hexyl-*N*-(1-methylheptyl)amine was formed as a by-product by direct aminolysis. [d] Molar ratio: **1c**:piperazine:Et_3N = 2.5:1.0:3.0. [e] Renaud's NaOH workup (ref. 6) was performed to eliminate tin residues.

mechanism: (i) radical initiation *via* either irradiation or thermal initiator, (ii) radical chain propagation, composed of two reversible type radical reactions (carbonylation and iodine atom transfer), and (iii) ionic quenching to shift the equilibria of the reversible radical reactions.

In this study, we have achieved a new metal-free synthesis of amides from organic iodides, CO and amines using AIBN and allyltributyltin, which previously could only be accomplished in the presence of a transition metal catalyst.[8] We are now examining the applications of this approach to bifunctional substrates which hold promise for the synthesis of a variety of nitrogen heterocycles and designed polyamides.

3 General procedure: A magnetic stirring bar, AIBN (0.3 mmol), hexane (0.5 ml), allyltributyltin (0.1 mmol), alkyl iodide **1a** (1 mmol), triethylamine (1.3 mmol) and amine (1.2 mmol) were placed in a 50 ml stainless steel autoclave with a glass liner. The autoclave was closed, purged twice with CO, pressurized with 25 atm of CO and then heated with stirring at 80 °C for 8 h. Excess CO was discharged at room temperature. Washing the crude mixture with MeCN (10 ml) followed by precipitation of ammonium salts in Et_2O (40 ml), filtration, evaporation of filtrate and column chromatography on silica gel gave pure amide **2**.

Serinal-derived vinyl oxiranes as novel and versatile building blocks for the stereoselective synthesis of D- and L-*erythro*-sphingosines

Christian Hertweck,[a] Helmar Goerls[b] and Wilhelm Boland*[a]†

[a] *Max-Planck-Institute for Chemical Ecology, Tatzendpromenade 1a, D-07745 Jena, Germany*
[b] *Institute for Inorganic and Analytical Chemistry, Friedrich-Schiller-University, Jena, Germany*

Oxazolidine vinyl oxirane 1, a novel and highly versatile building block for the preparation of enantiopure D-(+)-*erythro*-sphingosine and analogues, has been prepared by chloroallylboration of the Garner aldehyde with absolute stereocontrol and in good yield.

Over the last decade, interest in the biological functions of sphingosine, and its derivatives, has increased dramatically. While ceramide has been shown to be an important regulatory component of programmed cell death,[1] sphingosine-1-phosphate (SPP) has been implicated as a secondary messenger in cell proliferation and survival.[2] In addition, sphingosine and its N-methylated derivatives were found to be involved in cell signalling,[3] the induction of cancer cell apoptosis[4] and in the regulation of inflammatory processes.[5] Since the biological activity of these molecules varies substantially with structural modifications of the alkyl side chain,[6] unnatural and functionalized sphingosines are an inviting target for synthesis.

Many protocols for sphingoid base synthesis have been reported.[7] However, a versatile building block, easily accessible in high optical purity, that may be linked to a large variety of functionalized residues has not been available to date. Here, we report the synthesis of such a precursor, vinyl oxirane **1**, that leads directly to isomerically pure protected sphingoid bases, without the need for further synthetic manipulations of the side chain (Scheme 1).

Following the protocol of Oehlschlager, readily available and configurationally stable L-Garner aldehyde **3**[8] was alkylated with an *in situ* formed γ-(*Z*)-chloroallyl-(+)-diisopinocampheylborane **5**[9] to give chlorohydrin **4** in good yield (72% after cleavage of the borinic ester with 8-hydroxyquinoline,[10] 68% after buffered oxidative work-up[11]) (Scheme 2). Subsequent treatment of **4** with a sterically hindered base (DBU) provided vinyl oxirane **1** in high yield under mild conditions.[12] Analyses of ^{1}H and ^{13}C NMR spectra of the crude reaction mixture showed the relative diastereoselectivity to be higher than 97:3 (*anti*:*syn*), which clearly resulted from matched stereochemical bias of the double diastereoselection. With achiral γ-chloroallyl-BBN,[9] similar diastereospecificity was observed, resulting from substrate controlled *si*-facial attack of the allylation reagent. Thus, use of 9-MeO-9-BBN is an inexpensive alternative to the pinene-based borane, provided that a slightly lower degree of diastereoselection (*anti*:*syn* = 95:5), and the formation of *trans*-**1** (4%) as a by-product, is acceptable. Irrespective of the borane used, the entire sequence could be conducted as a 'one-pot' synthesis with an overall yield of 48–57% starting from **3**. Moreover, the protocol does not require tedious purification of any of the intermediates between commercially available serine and the vinyl oxirane building block **1**, and is suitable for multigram synthesis.[8] Upon recrystallisation of the crude product, colourless needles [mp 49–50.5 °C (pentane–Et_2O = 1:1 v/v)]; $[\alpha]_D^{25}$ +40.37 (*c* 1.08, $CHCl_3$)] were obtained and, in all cases, only a single isomer could be detected by NMR spectroscopy. The ORTEP plot (Fig. 1) shows the X-ray structure‡ of vinyl oxirane **1**. The crystal structure shown and semiempirical calculations of the energy minimised conformation of **1** (data not shown) proved to be in good agreement. Both the ORTEP and energy minimised plots

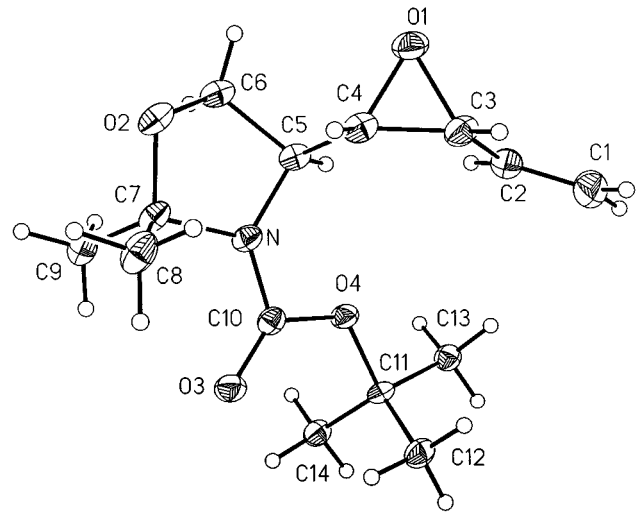

Fig. 1 The molecular structure of vinyl oxirane **1** (ORTEP plot) showing the absolute stereochemistry. Selected bond lengths (Å) and angles (°): C(2)–C(3) 1.472(3), C(3)–C(4) 1.478(3), O(1)–C(4) 1.444(2), O(1)–C(3) 1.461(2); C(4)–O(1)–C(3) 61.1(1), O(1)–C(3)–C(2) 116.0(2), O(1)–C(3)–C(4) 58.8(1), O(1)–C(4)–C(3) 60.0(1), O(1)–C(4)–C(5) 115.3(2); C(1)–C(2)–C(3)–C(4) −159.2(1).

demonstrated that the vinyl oxirane moiety is exposed in such a fashion that nucleophiles, for example lower order or hetero-cuprate reagents, would be predicted to react preferentially *via* a S_N2' type nucleophilic substitution. Electronic and steric factors are expected to determine the initial cuprate–olefin complex, leading to an *anti*-γ σ-allyl cuprate intermediate that suffers reductive elimination to yield the desired S_N2' *E*-configured product.[13]

In fact, excellent selectivity was observed upon treatment of **1** with an *in situ* prepared organocuprate as depicted in general in Scheme 1. Introduction of the alkyl side chain occurred smoothly and proceeded with exclusive formation of the (*E*)-double bond according to ^{13}C and ^{1}H NMR analysis. For the synthesis of native C_{18}-sphingosine,[7] dodecyl bromide was subjected to Br–Li exchange with Bu^{t}Li in Et_2O at −100 °C, followed by transmetallation with CuCN. Coupling of the resulting cuprate with vinyl oxirane **1** provided the protected sphingosine as a single diastereomer in high yield (82%).[14] The free sphingoid base was liberated by mild acid hydrolysis.§ Since cuprates containing sensitive functional groups are readily available by transmetallation of organozinc precursors, this approach promises to be a particularly simple route to a wide range of native and modified sphingosines, under exceptionally mild conditions (*e.g.* for the introduction of isotopes or their attachment on stationary phases for affinity chromatography).

In conclusion, the isomerically pure key intermediate **1** (or *ent*-**1**) is readily available from D- or L-serine on a large scale. This versatile reagent should find general use in the stereoselective synthesis of natural products with special emphasis on D- and L- sphingoid bases and nitrogen heterocycles,[15] which are often difficult and time-consuming to prepare *via* published protocols. Methods for the *syn*-selective chloroallylation of **3** are also under investigation with a view to making the *threo*-series of sphingoid bases equally accessible.

Financial support by the Deutsche Forschungsgemeinschaft, Bonn, and the Fonds der Chemischen Industrie, Frankfurt, is gratefully acknowledged. We thank the BASF AG, Ludwigshafen, and the Bayer AG, Leverkusen, for generous supplies of chemicals and solvents.

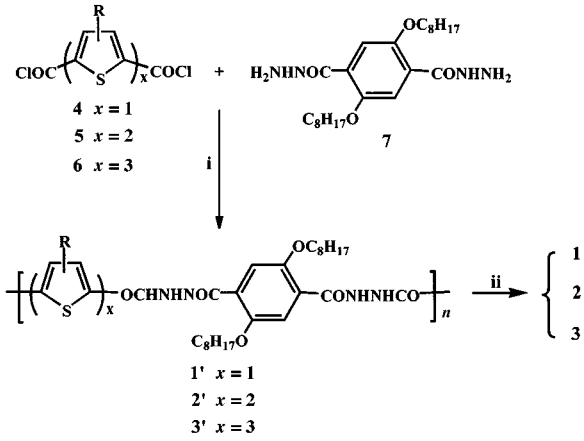
The copolymers of oligothiophenes and 1,4-bis(1,3,4-oxadiazol-2-yl)-2,5-dialkoxybenzene were synthesized with blue, green and orange emissive light depending on the length of the oligothiophene.

In the past few years, π-conjugated polymers have been intensively studied for applications in polymer light-emitting diodes (PLEDs).[1–3] One of the significant advantages of polymer electroluminescent materials is the ease with which the emissive wavelength can be tuned, especially for the realization of blue light.[1] The emissive spectrum of a conjugated polymer basically depends on its π–π* band gap, which can be tailored using different backbone structures.[1,2] For polymers with the same backbone structure, the emissive spectra could also be tuned by attaching different functional groups or/and by controlling the steric conformation of the backbone through synthetic methodology.[4,5] Another effective approach to tuning emissive color is to block the extension of conjugation by inserting non-conjugated groups or other conjugation-blocking groups into the backbone of a conjugated polymer.[6–10] For the conjugation-interrupted approach, thiophene-based polymers have attracted special attention because of the environmental stability of polythiophenes and the ease of synthesis and modification of oligothiophenes. It has been proven that oligothiophenes with different numbers of thiophene rings can emit from blue to red fluorescence.[11] We present here a new synthetic approach to tune the emissive spectra of totally conjugated polymers based on oligothiophenes.

Our new approach incorporates two types of conjugated blocks together to construct a conjugated polymer backbone. One of the two conjugated blocks has a small band gap, while the other has a relatively large band gap. With the fact that head-to-tail regioregular poly(3-alkylthiophenes) may emit light with λ_{max} at around 725 nm,[12] oligomers of 3-alkylthiophene can therefore be used as the smaller band gap blocks in our design. On the other hand, most 1,3,4-oxadiazole-containing conjugated polymers and molecular materials exhibit quite large band gaps (larger than 3.0 eV).[13] Therefore 1,4-bis(1,3,4-oxadiazol-2-yl)benzene was chosen as the larger band gap block in the newly designed polymers **1**–**3**. These polymers may be seen as polythiophene-based polymers, in which the 1,4-bis(1,3,4-oxadiazol-2-yl)benzene group is inserted into the backbone. The extension of conjugation along the backbone of polythiophene is limited or changed, but not interrupted, due to the existence of the 1,4-bis(1,3,4-oxadiazol-2-yl)benzene groups. The conjugated length of the oligothiophenes can be controlled and different functional groups can be attached to the thiophene ring and the benzene ring in the 1,4-bis(1,3,4-oxadiazol-2-yl)benzene moiety, which will result in variation of the emission spectra of the resultant polymers and enhance the solubility of the polymers.

The general synthetic procedure for polymers **1**–**3** is displayed in Scheme 1. The dicarbonyl chlorides **4**–**6** were prepared from the corresponding monomer, dimer and trimer of 3-alkylthiophene, which were synthesized as described in the literature,[14,15] by carboxylation at the α-positions of the thiophene rings with Bu^nLi and dry ice and subsequent reaction with $SOCl_2$.[15] The dihydrazide **7** was prepared from diethyl 2,5-dioctyloxyterephthalate, which was obtained from diethyl 2,5-dihydroxyterephthalate *via* reaction with 1-bromooctane, through a reaction with excess hydrazine monohydrate. The chemical structures and purity of all the compounds were identified by ^1H and ^{13}C NMR, mass and elemental analyses. The polycondensation between the dicarbonyl chlorides and the dihydrazide in *N*-methylpyrrolidinone (NMP) in the presence of LiCl and pyridine afforded the polyhydrazides **1′**–**3′**. The polyhydrazides were isolated by pouring the reaction mixtures into water and then filtering and washing with water and EtOH. The polyhydrazides were converted to the final polymers **1**–**3** by refluxing in $POCl_3$. Pouring the reaction mixtures into water



Scheme 1 *Reagents and conditions*: i, LiCl, pyridine, NMP, 4 h; ii, $POCl_3$, reflux, 6 h

precipitated the final polymers. Polymers **1**–**3** were obtained as gray, yellow and orange powders, respectively, after being washed with water, EtOH and Et_2O and dried under reduced pressure at room temperature. Polymers **1** and **3** are partially soluble in both $CHCl_3$ and THF. Polymer **2** is completely soluble in $CHCl_3$ and partially soluble in THF. However, all the three polymers readily dissolve in a mixture of $CHCl_3$ with a small amount of TFA to give clear solutions. By means of gel permeation chromatography (GPC) using THF as eluent and polystyrene as standard, the molecular weights of the THF soluble parts of the polymers were measured to be M_n = 5419 (M_w/M_n = 1.9) for polymer **1**, 7574 (2.0) for polymer **2**, and 2814 (1.4) for polymer **3**. The actual molecular weights of the polymers should be much higher than these measured values because of the insolubility of the parts with higher molecular weights. The structures of the polymers were confirmed by ^1H and ^{13}C NMR and elemental analyses.‡

The absorption and fluorescence spectra of polymers **1**–**3** as films are shown in Fig. 1. The films were prepared *via* spin-coating on a quartz plate using solutions of the polymers in $CHCl_3$ with a small amount of TFA. The expected gradual bathochromic shift of the absorption spectra is exhibited with the increasing length of oligothiophenes in the polymers. The absorption maximum increases from **1** (λ_{max} = 420 nm) to **2** (λ_{max} = 441 nm) to **3** (λ_{max} = 461 nm). The absorption spectra of all the three polymers are structured, as indicated by the well-defined sub-peaks or shoulders at 360 and 443 nm for **1**, 419 and 471 nm for **2**, and 439 and 494 nm for **3**. It is worth noting that the structures in the spectra become less defined on going from **1** to **3**. This phenomenon implies that the polymers with shorter oligothiophenes have a more regular structure in the solid state. Polymers **1**–**3** in the solid state emit intense blue, green and orange light, respectively, upon UV–VIS excitation (λ > 350 nm). The peak wavelengths in the emission are 489 nm for **1**, 530 nm for **2**, and 579 nm for **3,** respectively. The emissive spectra are much less structured than the absorption spectra. The Stokes shifts were determined to be 69 nm for **1**, 89 nm for **2**, and 118 nm for **3**. The spectral difference among the three polymers could be further ascribed to differences in the internal charge transfer along the backbones of the polymers in their excited states.

Comparing the spectral data with those of alkyl-substituted oligothiophenes and conjugation-interrupted polymers based on oligothiophenes,[8–10, 16–18] polymers **1**–**3** correspond to the effective conjugated length of about three, four to five, and five to six extended thiophene rings, respectively. It is evident that the 1,4-bis(1,3,4-oxadiazol-2-yl)benzene moiety does not play a role as a conjugation-interrupting block in the polymers, but is a part of the whole conjugated structure. Its contribution to conjugation is equivalent to about two to three extended thiophene rings.

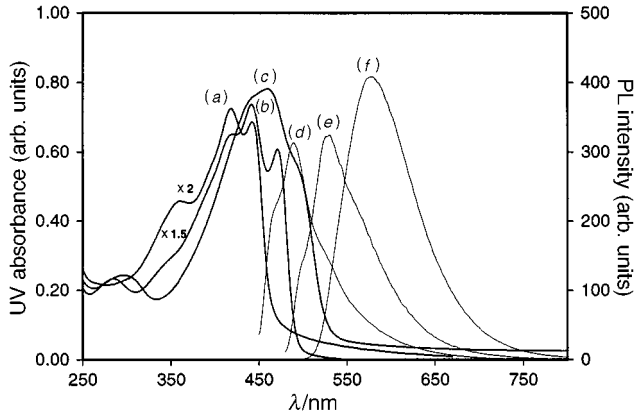


Fig. 1 Absorption [(*a*) 1, (*b*) **2** and (*c*) **3**]and fluorescence [(*d*) **1**, (*e*) **2** and (*f*) **3**] spectra of polymers **1**–**3** in films at room temperature

In conclusion, we have synthesized a new series of totally conjugated copolymers consisting of oligothiophenes and 1,4-bis(1,3,4-oxadiazol-2-yl)-2,5-dioctyloxybenzene. The emissive color of the copolymers could be tuned from blue to green to orange by increasing the number of thiophene ring in the oligothiophene blocks from one to three. The 1,4-bis(1,3,4-oxadiazol-2-yl)-2,5-dioctyloxybenzene block acts as part of the whole conjugated structure and is equivalent to about two to three thiophene rings. Another important aspect of this contribution to electroluminescent polymeric materials is that it might provide an effective approach to the synthesis of n-doped type electroluminescent materials with different emissive colors due to the high electron affinity of 1,3,4-oxadiazole.

Inter-anion O–H$^-$···O$^-$ hydrogen bond like interactions: the breakdown of the strength–length analogy

Dario Braga,[a] Fabrizia Grepioni[a] and Juan J. Novoa[b]

It is demonstrated that inter-anion O–H$^-$···O$^-$ interactions, commonly regarded as strong hydrogen bonds, are not associated with energetically stable anion–anion interactions; inter-anion O–H$^-$···O$^-$ act as a tugboat interaction that control anion aggregation and minimise anion–anion repulsions.

Strength and directionality render the hydrogen bond[1] (HB) the masterkey interaction in supramolecular chemistry[2] and in crystal engineering.[3] Commonly the HB is defined as a stable interaction between an A–H donor and a B acceptor, being A and B electronegative atoms or electron rich groups.[1,4,5] Strong HB are recognised in the solid state by the presence of H···B and A···B separations shorter than van der Waals contact distances and by A–H···B angles that tend to linearity. In these cases the length–strength analogy is believed to hold, *i.e.* the shorter the acceptor–donor distance the stronger the bond. It is customary to distinguish between neutral HB, when both A–H and B belong to neutral fragments, and ionic HB when ions are involved as donors and/or acceptors.[1,4] The case in which both donor and acceptor belong to negatively charged systems, *i.e.* A–H$^-$···B$^-$, falls in this latter category.

In the following we demonstrate, in the prototypical case of inter-ionic O–H$^-$···O$^-$ interactions commonly found in salts of polyprotic acids [such as $KHCO_3$ and KHC_2O_4 (*vide infra*)], that ionic HB are not energetically stable because they are associated with inter-anion electrostatic repulsions.

Experimentally, O–H$^-$···O$^-$ interactions possess the same geometrical properties as neutral O–H···O bonds. The distribution of inter-molecular/ionic O···O distances for neutral O–H···O and O–H$^-$···O$^-$ interactions, as obtained from a search of systems containing carboxylic–carboxylate groups within the Cambridge Structural Database[6] (CSD), are compared in Fig. 1. Inter-anion O–H$^-$···O$^-$ interactions constitute a very well defined subset and are distinct from neutral O–H···O bonds. O$^-$···O$^-$ separations are significantly shorter, both as mean values and as lowest deciles, than O···O distances. Such a decrease in length is traditionally taken as indicative of a substantial increase in HB strength. This observation is in apparent contradiction with another seemingly simple argument: when the charge is delocalised the electrostatic interaction between small anions is repulsive. We face the intriguing question: how possibly the interaction between anions, which are supposed to repel each other electrostatically, can lead to shorter O···O separations than in the corresponding neutral aggregates?

In order to tackle this problem we have used the HF and B3LYP methods with the 6-31 + G (2d,2p) basis set[8] to compute at the *ab initio* level the first-neighbour inter-anion energies[7] for several crystals taken from the CSD sample.[9a–d] Both methods are well suited to deal with the type of ionic interactions discussed herein.[9a,e]

We have chosen to discuss the representative case of potassium hydrogen oxalate, KHC_2O_4.[10] An analysis of the charge distribution on the $[HC_2O_4]^-$ anion shows that the negative charge is delocalised over the whole anion, with a slightly more negative charge on the deprotonated oxygen atom.[11] Fig. 2 allows to rationalise the ion packing in crystalline KHC_2O_4. The $[HC_2O_4)]^-$ anions form chains separated by O···O distances of 2.522 Å. The crystal can be described as a stacking sequence of corrugated layers formed by K^+ cations and by $[HC_2O_4]^-$ chains, respectively (Fig. 2b).

The presence of short O···O separations along the $[HC_2O_4]^-$ chains is the first point to address. The interaction energy computed for two consecutive $[HC_2O_4]^-$ units in the experimental orientation is repulsive [+39 and +46 k cal mol^{-1} (1 cal = 4.184 J) at the HF and B3LYP levels, respectively]. The molecular electrostatic (MEP) map[12] of the isolated anion (Fig. 3) shows that a +1 charge always experiences an attractive interaction except at very short distance from the nuclei. The most negative regions in the $[HC_2O_4]^-$ MEP map are on the oxygens of the deprotonated group, whereas the least negative ones are on the OH region of the protonated group. The absence of positive regions in the MEP map indicates that, irrespective of the relative orientation, two $[HC_2O_4]^-$ anions repel each other electrostatically. The stability of the anionic chain arises from the presence of the K^+ cations. This can be demonstrated by calculating[8] the interaction energy within the subunit $K_2(HC_2O_4)_2$ which is stable against its dissociation into two K^+ and two $[HC_2O_4]^-$ ions (−232 and −334 k cal mol^{-1} at the HF and B3LYP levels, respectively). This indicates that K^+···$[HC_2O_4]^-$ attractive interactions largely predominate over repulsive K^+···K^+ and $[HC_2O_4]^-$···$[HC_2O_4]^-$ terms. In accord with the observed packing, the geometry of the subunit does not

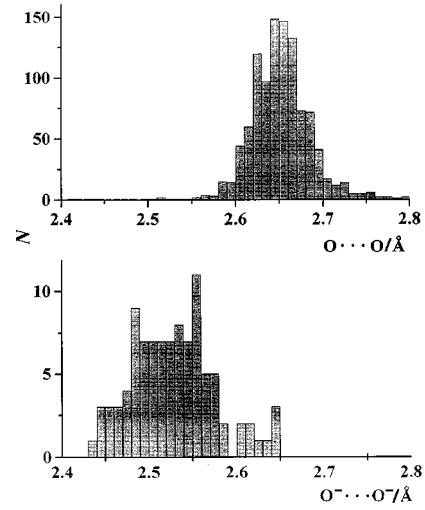

Fig. 1 Histograms of the two populations of O···O separations for neutral O–H···O (top) and inter-anion O–H$^-$···O$^-$ (bottom). Mean values for the O···O separations are 2.652(1) and 2.528(5) and lowest deciles are 2.615 and 2.462 Å, respectively. Intermolecular search on systems containing carboxylic/carboxylate groups based on a cut-off distance of 2.8 Å; duplicate hits manually removed.

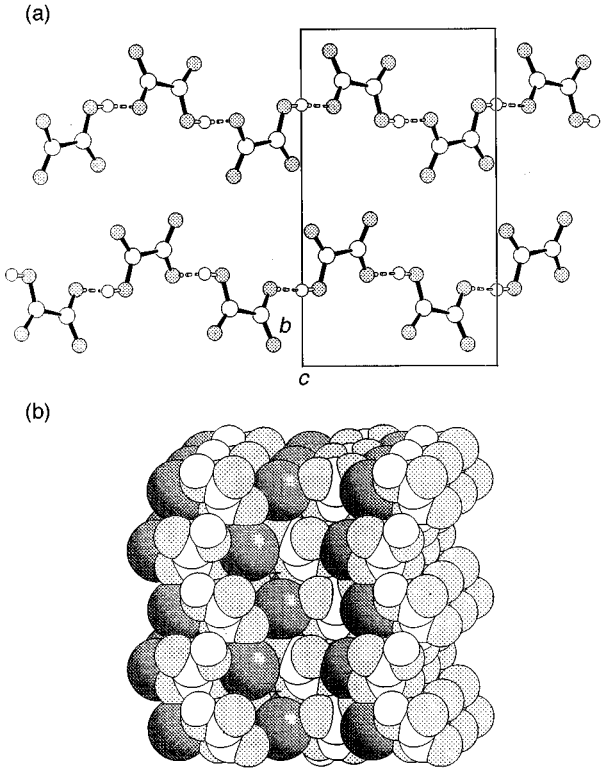

Fig. 2 The experimental packing in crystalline KHC_2O_4. (a) Chains of $[HC_2O_4]^-$ anions. (b) Space filling representation of the ion organisation.

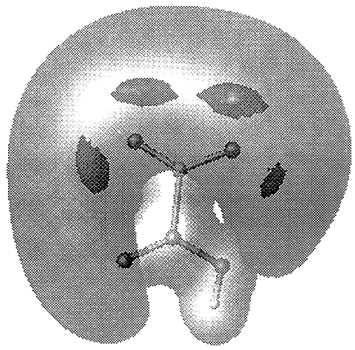

Fig. 3 Molecular electrostatic (MEP) map of an isolated $[HC_2O_4]^-$ anion computed at the HF/6-31 + G (2d,2p) level. Dark regions correspond to -170 kcal mol^{-1}, light grey to -100 kcal mol^{-1}, and light regions around the nuclei to +10 kcal mol^{-1}.

change significantly when fully optimised. To understand why hydrogen bond-like short distances and geometry are maintained on packing $[HC_2O_4]^-$ anions we computed the interaction energy by varying systematically the relative orientation of two $[HC_2O_4]^-$ anions at a fixed distance of 7 Å between the centres of mass. The two most stable (*i.e.* least repulsive) orientations correspond to the chain present in crystalline KHC_2O_4 and to the dimer found in other salts, respectively. Thus the inter-anion HB corresponds to the orientations that favour overlap of the least repulsive MEP regions on the anions. It is important to emphasise that, since $[HC_2O_4]^-\cdots[HC_2O_4]^-$ repulsions are much smaller than $K^+\cdots[HC_2O_4]^-$ attractions, the inter-anion O···O equilibrium distance along the chain is attained at a shorter O···O separation than in neutral HBs. This is a manifest break-down of the widely accepted length–strength relationship in hydrogen bonded solids.

If a bond between two atoms/molecules/ions is taken as anything that requires energy to be broken (whether large or small amount of energy does not matter) then the O–H$^-\cdots$O$^-$ interaction cannot be considered a bond because the ionic chains (or dimers) would 'fall apart' if the cations were removed. Therefore, the O–H$^-\cdots$O$^-$ interaction should be regarded as a *pseudo*-HB because it minimises inter-anion repulsions, but it is not stabilising on an absolute scale.

What is it, then? It is a tugboat interaction, that does not link ions (as an intermolecular chemical bond would do) but rather organises the ions in space, hence conferring directionality to anion–anion electrostatic interactions. The OH group on the anion becomes a probe capable, in the process of crystal nucleation and construction, of exploring the potential energy hypersurface of another anion to find the site of higher nucleophilicity even within the 'thick fog' of a negative field. This understanding has enormous implications in crystal engineering studies, mainly when ionic building blocks are involved,[13] as in organic conductors and superconductors,[14] and in the devise of new synthetic strategies to obtain robust materials.[15] Ionic solids are much more stable than most molecular solids, including those formed of hydrogen bond connected molecules. The inter-anion HB allows the utilisation of molecular synthons within strong ionic fields.

Power ultrasound applied to erosion resistant and mechanically stable free standing highly boron-doped diamond electrodes allows the electrochemical reduction of dioxygen to hydrogen peroxide under conditions of extremely high rates of mass transport and in the presence of cavitation.

The ability to manufacture boron-doped CVD (chemical vapour deposited) diamond routinely is opening the way to the use of this material for technically demanding applications such as a novel electrode material.[1] Advantages of CVD diamond in this new application include its extreme hardness, chemical inertness, and dimensional stability.[2] The electrode material used in this study is in the form of a 5 × 5 × 0.6 mm diamond square with a typical boron-doping level of 10^{20} cm^{-3} corresponding to a B/C atom ratio of 1/1000 which allows a resistivity of 3×10^{-4} Ω m to be achieved. The use of the free standing diamond plate allows problems with substrate interference and adhesion[3] to be overcome. Further, polishing of the electrode surface produces an essentially flat (surface roughness 20–30 nm R_A) and therefore, in the electrochemical sense, ideal electrode surface with properties which are likely to be different to those reported for 'as grown' diamond electrodes.

In sonoelectrochemistry[4] electrode materials are exposed to extreme conditions with mechanical strain induced by pressure waves of some 10 bar amplitude and cavitation induced liquid jets[5] strong enough to cause severe erosion.[6] As an extremely hard material diamond has been extensively characterised *e.g.* for its resistance to water jet erosion.[7] In this test a diamond surface withstands a 0.8 mm diameter water jet with a velocity in excess of 500 m s^{-1}. This compares to a value of 150 m s^{-1} for the erosion of soda lime glass and to jets caused by cavitation in aqueous media with a velocity in the order of 200 m s^{-1}. Therefore diamond appears to be a promising alternative replacing especially the commonly employed carbon based materials graphite and glassy carbon.

An AFM image of the surface of a highly boron-doped and polished diamond plate electrode is shown in Fig. 1. Owing to the polishing the surface is flat down to the nanometer scale and the characteristic faceting typically observed on a 10–100 μm scale for the polycrystalline material has been removed. Raman spectroscopy (excitation wavelength 632.8 nm) reveals this material to be high quality diamond with a strong and sharp signal at 1331 cm^{-1} (FWHM 4.4 cm^{-1}) characteristic for diamond sp^3-carbon.

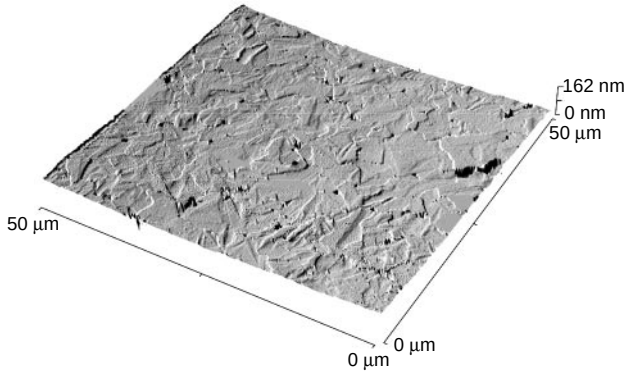

Fig. 1 AFM image of the surface topography of a polished highly boron-doped diamond electrode.

In Fig. 2(a) a cyclic voltammogram† for the one electron reduction of 1 mM $Ru(NH_3)_6^{3+}$ in aqueous 0.1 M KCl is shown [eqn.(1)].

$$Ru(NH_3)_6^{3+} + e^- \leftrightarrow Ru(NH_3)_6^{2+} \quad (1)$$

The well defined voltammetric responses remain symmetric even at fast potential scan rates of up to 1 V s^{-1}. The separation between the peak potentials for the cathodic and the anodic

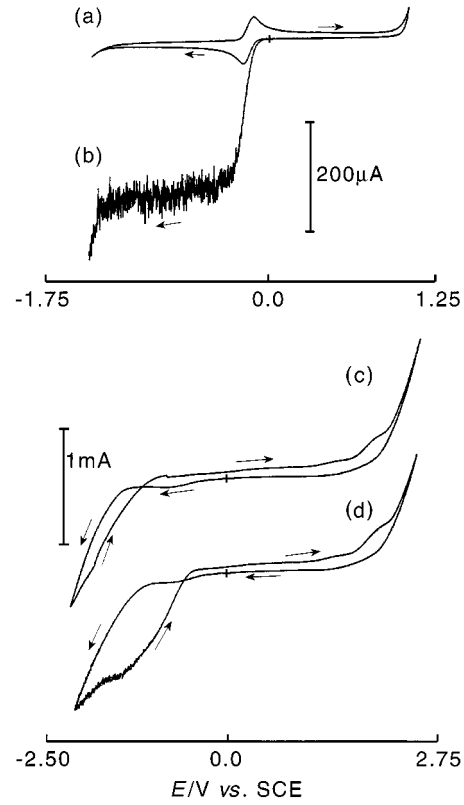

Fig. 2 (a) Cyclic voltammogram obtained for the reduction of 1 mM $Ru(NH_3)_6^{3+}$ in 0.1 M KCl at a polished 5 × 5 mm diamond electrode with a scan rate of 0.1 V s^{-1}. (b) Sonovoltammogram obtained under the same conditions with 90 W cm^{-2} ultrasound intensity and 10 mm electrode to horn distance. Cyclic sonovoltammograms obtained in 0.1 M phosphate buffer at pH = 2 (c) in the absence and (d) in the presence of *ca.* 0.87 mM dioxygen.

Table 1 Electrochemical data obtained from cyclic voltammograms for the reduction of 1 mM $Ru(NH_3)_6^{3+}$ in 0.1 M KCl at a polished highly boron-doped diamond electrode at $T = 20 \pm 2$ °C

Scan rate/ V s^{-1}	$E_{1/2}$[a]/V *vs.* SCE	ΔE_p/mV	$I_{p,cath.}$/ 10^{-6} A	k^{ob}[b]/cm s^{-1}
0.02	−0.18	72	22	9.5×10^{-3}
0.05	−0.18	81	34	9.4×10^{-3}
0.10	−0.18	84	47	11×10^{-3}
0.20	−0.18	96	66	10×10^{-3}

[a] Obtained as mid potential $E_{1/2} = 0.5(E_{p,cath.} + E_{p,anod.})$. [b] Standard rate constant for heterogeneous electron transfer calculated from ΔE_p.[10]

current responses increases with scan rate from 66 mV at a scan rate of 10 mV s^{-1} in agreement with a quasi-reversible electron transfer process with $k° = 0.01 \pm 0.003$ cm s^{-1} similar to standard rate constants for electron transfer observed on other diamond and glassy carbon type materials.[9] Data are summarised in Table 1.

In the presence of power ultrasound the current observed for the reduction of 1 mM $Ru(NH_3)_6^{3+}$ in aqueous 0.1 M KCl is considerably enhanced [Fig. 2(b)]. This mass transport enhanced current response now exhibits 'steady-state' characteristics and the limiting current which can be controlled by changing the ultrasound intensity or the horn to electrode distance may be described by eqn. (2):

$$I_{lim} = n F A D [\text{substrate}] / \delta(D) \quad (2)$$

In this expression the limiting current, I_{lim}, is related to the number of electrons transferred per substrate molecule, *n*, the Faraday constant, *F*, the electrode area, *A*, the diffusion coefficient, *D*, and the diffusion layer thickness, $\delta(D)$, which in aqueous media has been shown[8] to be proportional to $D^{1/3}$. The resulting limiting currents from the sonovoltammetric measurements for the reduction of $Ru(NH_3)_6^{3+}$ with $D = 0.91 \times 10^{-9}$ m^2 s^{-1} may therefore be used for the calibration of the diffusion layer thickness at constant ultrasound intensity and over a range of different electrode to horn distances.

It has recently been shown that the sonoelectrochemical reduction of oxygen at Ni–Cu alloy materials[11] (also known to be very hard and erosion resistant) and at Ti alloy sonotrodes[12] predominantly leads to the 4-electron reduction from dioxygen to water. Sonovoltammograms obtained by scanning the potential over a wide range in the absence [Fig. 2(c)] and in the presence [Fig. 2(d)] of dioxygen in 0.1 M phosphate buffer at pH = 2 at a highly boron doped diamond electrode show some characteristic features different to those previously observed at metal alloy electrodes. A wide solvent window with dioxygen evolution beginning to occur at a potential of +2.2 V *vs*. SCE is observed. Hydrogen evolution commences at a very negative potential of −1.5 V *vs*. SCE. However, after scanning the potential negative and reversing the scan direction the current appears to be increased and a 'crossing' occurs at −1.2 V *vs*. SCE. This feature is a 'tell-tale' sign for a chemical change at the electrode/solution interface, *e.g*. the reduction of surface functional groups of the polished diamond which then cause an increase in the rate of the proton reduction process.

This chemical change on the surface of the polished diamond electrode causes even more pronounced changes in the kinetics for the reduction of *ca*. 0.87 mM dioxygen in aqueous 0.1 M phosphate buffer at pH = 2 [Fig. 2(d)]. After the onset of the reduction process at a potential of −1.2 V *vs*. SCE and reversing the scan direction at −2.1 V *vs*. SCE a sustained limiting current with $I_{lim} = -0.86$ mA can be detected which finally decays with a half wave potential of −0.8 V *vs*. SCE. The calculation of the number of transferred electrons, *n*, per dioxygen molecule based on eqn. (2) and the above calibration procedure with a diffusion coefficient[14] for dioxygen of $D = 1.65 \times 10^{-9}$ m^2 s^{-1} gives $n = 2.1 \pm 0.1$ consistent with the two electron reduction of oxygen to hydrogen peroxide [eqn. (3)].

$$O_2 + 2\,e^- + 2\,H^+ \rightarrow H_2O_2 \quad (3)$$

A colorimetric test reaction with iodide[13] was used to confirm the formation of hydrogen peroxide after a period of 20 minutes electrolysis at an applied potential of −2.0 V *vs*. SCE. In contrast, under the same experimental conditions but without electrolysis the sonolytic formation of H_2O_2 was found to be negligible. The change of the surface properties of the boron-doped diamond electrode which has been reported to be present to a much smaller extent for 'as grown' boron-doped diamond[14] was found to be reversed by scanning into the region of positive potentials and the nature and mechanistic significance of the surface functional groups on the surface of the polished highly boron-doped diamond is currently the topic of a more detailed study by both electrochemical and spectroscopic techniques.

F. M. thanks the Royal Society for the award of a University Research Fellowship and New College (Oxford) for a Stipendiary Lectureship.

Notes and References

† In electrochemical experiments an Autolab PGSTAT 20 system (Eco Chemie, NL) was used for recording voltammetric data in conjunction with a special thermostated three-electrode cell of 25 cm^3 volume which has been described recently.[8] Experimental details for Raman and AFM measurements have been published.[3] Industrially polished boron-doped diamond was treated with oxidising acid in order to remove sp^2 type carbon from the polished surface and has been used as received from De Beers Industrial Diamond Division. Experiments were carried out after degassing with pure argon or dioxygen (BOC) at a temperature thermostated to 20 ± 2 °C.

A highly ordered ferrocene system regulated by podand peptide chains

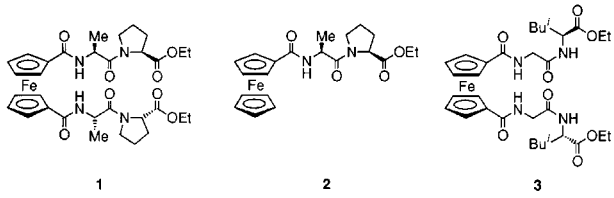
Akihiro Nomoto, Toshiyuki Moriuchi, Shuhei Yamazaki, Akiya Ogawa and Toshikazu Hirao*†

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565-0871, Japan

The ferrocene bearing the podand dipeptide chains, Ala-Pro-OEt, which are aligned parallel in solution by the two rigid intramolecular hydrogen bonds, manifests a novel helically ordered arrangement with one turn of 14.70 Å pitch height in the crystal packing possibly due to the intramolecular hydrogen bonds (the N–H···O=C distance is 2.06 Å) and the hydrophobic interaction of the podand dipeptide chains (the distance between the nearest ferrocene units is 4.54 Å).

Architectural control of molecular assemblies utilizing specific interactions as observed in biological systems is considered to be one of the most convenient approaches to highly ordered supramolecular systems, most of which are expected to exhibit novel functions.[1] In particular, hydrogen bonding has been exploited for the elaboration of regulated supramolecules such as dendrimers[2] and artificial peptides.[3] Crystal engineering has also contributed to a key technique for this purpose.[4] The incorporation of transition metal complexes into such highly structured biomolecules is envisioned to provide new biomaterials and efficient redox systems.[5] Ferrocenes, which possess a reversible redox couple and rotatory cyclopentadienyl moieties, have been regarded as useful organometallic scaffolds for molecular receptors[6] and peptide mimetic models.[7] We have already focused on such properties to demonstrate a unique coordination behavior of the ferrocenes bearing podand *N*-heterocyclic pendant groups.[8] Our system design described here is addressed by an efficient communication of podand peptide chains both intramolecularly and intermolecularly to order the redox-active ferrocene system.

A chiral dipeptide, L-alanyl-L-proline, which is considered to consist of a hydrogen bonding site (Ala) and a hydrophobic moiety (Pro), is incorporated into a redox-active ferrocene scaffold.‡ Ferrocene derivatives **1** and **2** bearing two and one Ala-Pro-OEt chains, respectively, exhibited a reversible oxidation/reduction wave attributable to the Fe(III)/Fe(II) couple at 740 mV and 567 mV *vs.* SCE, respectively, which are indicative of the electron-withdrawing amide function.



1 **2** **3**

X-Ray crystallography studies revealed several interesting structural features. The X-ray crystal structure of **1**§ is depicted in Fig. 1. Surprisingly, the two dipeptide chains of **1**, which have C_2 symmetry, are oriented in the same direction despite the free rotary cyclopentadienyl rings and sterically bulky proline moieites. This structure is considered to be stabilized by two C_2-symmetrical intramolecular hydrogen bonds between CO (Ala) and NH (another Ala) of each podand peptide chain. The N–H···O=C distance of the hydrogen bonds is 2.06 Å. Intermolecular hydrogen bonding was not observed even in the molecular packing. In contrast to the structure of **1**, each molecule of **2**¶ is connected by an intermolecular hydrogen-bonding network, in which the peptide chain is not arranged parallel to the chain of the next molecule. It is also noteworthy that the β-angle of **2** (defined as the angle between the plane of the cyclopentadienyl ring and C(ipso)–CO(bridging) bond) is 24.6° or 23.3°. This value is unexpectedly large compared with those of **1** (5.6°), probably due to the intermolecular hydrogen bonding. The conjugation between the cyclopentadienyl ring and carbonyl group of **2** is disturbed to some extent.

A striking feature is that **1** is found to be packed in a helical molecular arrangement with one turn of 14.70 Å pitch height [Fig. 1(b)], within which the distance between the closest ferrocene units is 4.54 Å. The proline rings and ethyl groups individually form the hydrophobic cores, which are considered to be one of the factors that control the crystal packing and permit the helical assembly. Such an assembly was not observed in the crystal structure of ferrocene **3**‖ bearing podand glycyl-L-leucine chains although the isobutyl group is expected to form

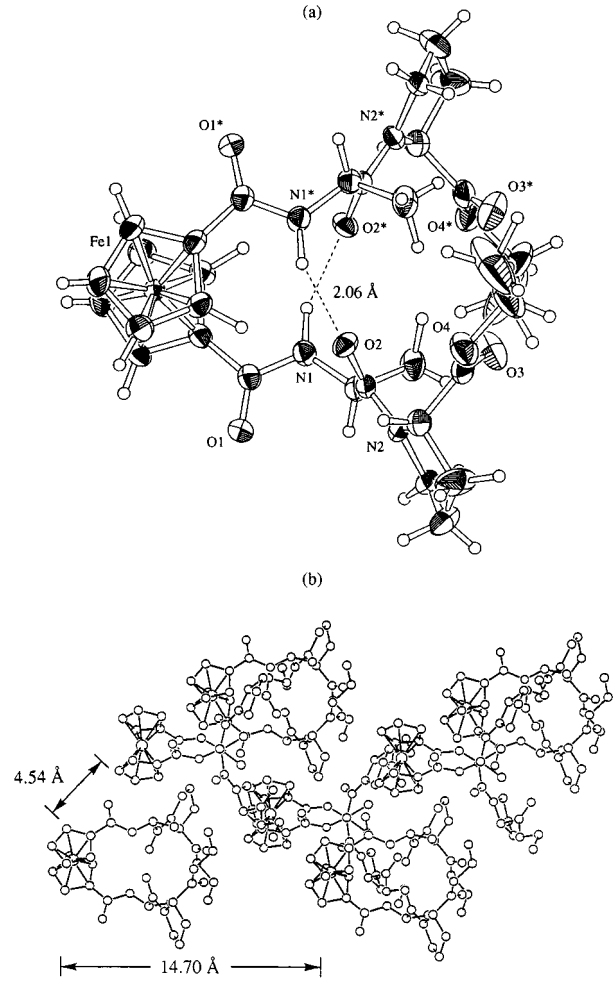


Fig. 1 (a) X-Ray crystal structure of ferrocene **1**. The hydrogen bonds are shown as dotted lines. (b) Crystal packing of ferrocene **1**.

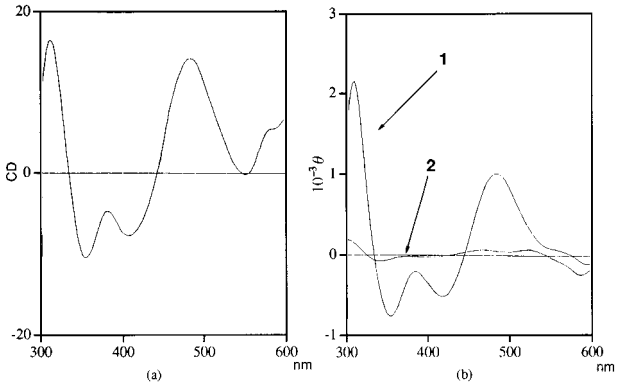

Fig. 2 (a) CD spectrum of ferrocene **1** in the solid state (KBr pellet) and (b) CD spectra of ferrocenes **1** and **2** in CH_3CN (5.0×10^{-4} M)

a hydrophobic core. A helical molecular arrangement is only characteristic of **1**.

The CD spectrum of **1** in the solid state (KBr pellet) showed Cotton effects corresponding to the absorbances of the ferrocene moiety in the UV–VIS spectrum [Fig. 2(a)]. The Cotton effects seem to be caused by the reflection of chirality of the regulated podand peptide chains possessing two rigid intramolecular hydrogen bonds. Furthermore, a similar CD spectrum for **1** was obtained in acetonitrile [Fig. 2(b)] in sharp contrast with the finding that such effects were not observed with **2** in both solid and solution states. This result suggests that the podand peptide chains of **1** are also regulated even in solution by the intramolecular hydrogen bonds.

The ^{1}H NMR spectrum of **1** exhibited only one kind of NH peak at lower field (δ = 8.95, 5.0 mM) as compared with **2** (δ = 6.58, 10.0 mM). These results indicate that the intramolecular hydrogen bonds of **1** are identical in CD_2Cl_2 solution.[7b] Such bonding is also confirmed by the IR spectrum (CH_2Cl_2, ν_{N-H} **1**: 3301 cm^{-1}; **2** 3418 cm^{-1}).[7b]

The oxidation of **1** to a ferrocenium species **1**$^+$ was achieved with CAN [cerium(IV) diammonium nitrate] to show the broad absorption around 657 nm in the UV–VIS spectrum. Interestingly, the Cotton effects were observed even in the CD spectrum of **1**$^+$. A similar oxidative transformation was performed electrochemically, and monitored by *in situ* CD measurement at 1.2 V *vs.* SCE. The Cotton effects of the above-mentioned ferrocenium species are independent of the presence of CAN. These results suggest that the rigid structure of **1** is maintained even in the oxidized form, presumably by the intramolecular hydrogen bonding.

In conclusion, we have designed and synthesized the novel peptide **1** containing a ferrocene unit, in which the podand dipeptide chains (Ala-Pro-OEt) are regulated in both solid and solution states by the two rigid intramolecular hydrogen bonds. Also, a novel helically ordered arrangement is achieved in the crystal packing, where the proline rings and ethyl groups individually form the hydrophobic cores. The present system is likely to be related to helical electron hopping. Studies on the effects of peptide chains and redox-switching properties are now in progress to disclose the scope of an ordered system based on peptide interactions.

‡ Typical procedure for the synthesis of **1**. To a stirred mixture of 1,1′-ferrocenedicarboxylic acid chloride (0.10 mmol) and H-Ala-Pro-OEt·HCl (0.22 mmol) in dichloromethane (2 mL) was dropwise added triethylamine (0.50 mmol) under argon at 0 °C. After stirring at room temperature for 1 h, water (20 mL) was added to the mixture. Extraction with dichloromethane (3×10 mL) followed by evaporation gave the crude ferrocene **1**. Chromatography on an alumina column eluting with dichloromethane and recrystallization from dichloromethane afforded an orange solid in 58% yield. **1**: IR (KBr) 3315, 2991, 1740, 1632, 1544, 1434, 1372, 1336, 1292, 1186, 1026 cm^{-1}; IR (CH_2Cl_2, 1.0 mM) 3301 (N–H) cm^{-1}; ^{1}H NMR (600 MHz, CD_2Cl_2) δ 8.77 (d, 2H, J = 7.6 Hz), 4.85–4.78 (m, 6H), 4.59 (dd, 2H, J = 4.6, 4.3 Hz), 4.45–4.44 (m, 2H), 4.27–4.26 (m, 2H), 4.14–4.05 (m, 4H), 3.89–3.85 (m, 2H), 3.69–3.66 (m, 2H), 2.33–2.27 (m, 2H), 2.12–2.07 (m, 4H), 2.01–1.96 (m, 2H), 1.32 (d, 6H, J = 7.3 Hz), 1.26 (q, 6H, J = 7.0 Hz). **2**: IR (KBr) 3312, 2982, 1743, 1652, 1626, 1535, 1436, 1298, 1183 cm^{-1}; IR (CH_2Cl_2, 1.0 mM) 3418 (N–H) cm^{-1}; ^{1}H NMR (600 MHz, CD_2Cl_2) δ 6.60 (d, 1H, J = 6.9 Hz), 4.83 (quint. 1H, J = 6.9 Hz), 4.69–4.63 (m, 2H), 4.47 (dd, 1H, J = 8.6, 8.2 Hz), 4.35–4.33 (m, 2H), 4.21–4.10 (m, 7H), 3.77–3.73 (m, 1H), 3.66–3.62 (m, 1H), 2.27–2.22 (m, 1H), 2.12–1.94 (m, 3H), 1.42 (d, 3H, J = 6.9 Hz), 1.26 (t, 3H, J = 7.2 Hz). **3**: IR (KBr) 3283, 2959, 1745, 1634, 1552, 1454, 1371, 1304, 1197, 1028 cm^{-1}; IR (CH_2Cl_2, 1.0 mM) 3415, 3320 (N–H) cm^{-1}; ^{1}H NMR (600 MHz, CD_2Cl_2) δ 8.49 (t, 2H, J = 6.1 Hz), 6.48 (d, 2H, J = 10.8 Hz), 4.81–4.79 (m, 4H), 4.63–4.59 (m, 2H), 4.43–4.39 (m, 4H), 4.19 (q, 4H, J = 6.6 Hz), 3.95 (dd, 2H, J = 16.2, 6.1 Hz), 3.87 (dd, 2H, J = 16.2, 6.1 Hz), 1.74–1.57 (m, 6H), 1.28 (t, 6H, J = 6.6 Hz), 1.02–0.97 (m, 12H).

Solid-state solvolysis induced *via* charge-transfer complexation by solid-phase grinding followed by contact with solvent vapor

Motoko Tanaka and Keiji Kobayashi*†

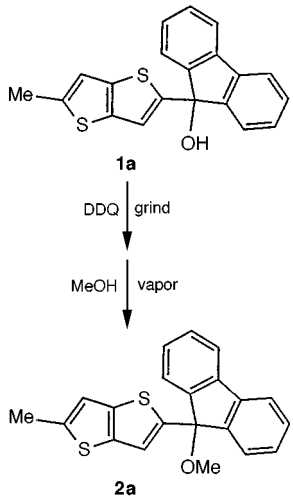
Department of Chemistry, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153-8902, Japan

When 9-thienothienylfluoren-9-ol derivatives were ground together with DDQ then exposed to methanol vapor, solvolysis occurred to yield 9-methoxyfluorenes *via* the generation of a radical cation by solid-state single-electron transfer.

While organic reactions are usually carried out in solvents, solid-state reactions have also been extensively investigated.[1] The solid-state reactions between two different compounds have been realized by grinding a mixture of powdered reactant and reagent[2] or by using co-crystals in which two reactant molecules are preorganized in reactive positions.[3] Both of these methodologies, however, cannot be applied to solvolysis, for which dissolution of substrates in solvents is inevitable. We have recently achieved solid-state photosolvolysis[4] in the crystalline host–guest inclusion complexes with EtOH as a guest component.[5] We now report here on novel solid-state solvolysis by solvent vapor induced by solid–solid contact followed by gas–solid contact, from which a new consequence of solid-state grinding can be deduced.

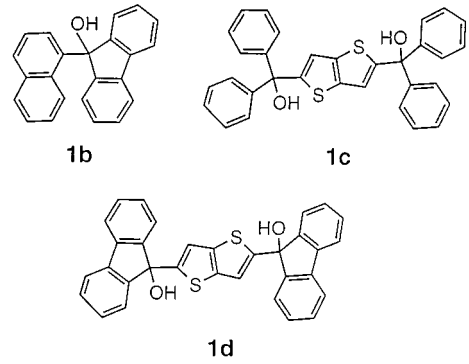
In a typical run, an equimolar mixture of 9-thienothienylfluoren-9-ol **1a** and dichlorodicyanoquinone (DDQ) was ground in a mortal and pestle and the resulting dark green solids were exposed to MeOH vapor below 5 °C for 6 h (Scheme 1). The resulting solids were shown to include a methoxy-substituted product **2a** in 42% yield. DDQ was recovered quantitatively. When substrate **1a** was ground alone and then exposed to MeOH vapor, the reaction did not occur at all, indicating that DDQ acts as a catalyst.[6]

Similarly, ethanolysis and propanolysis were accomplished for **1a** as well as for naphthyl-substituted **1b** and diols **1c** and **1d** to give the corresponding alkoxy derivatives in 5–32% yields. For **1a** and **1d**, tetracyanoethylene (TCNE) also promoted the solvolysis to give the methyl ethers in 70 and 51% yields, respectively, along with 16% of the dimethyl ether in the latter.



Scheme 1

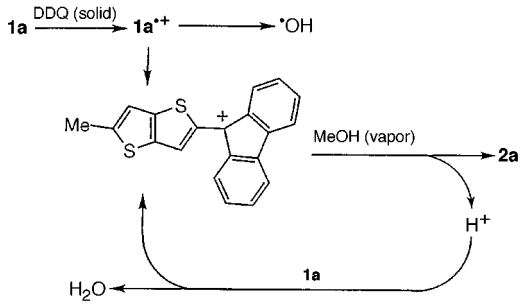
On the other hand, tetracyanoquinodimethane (TCNQ) and *p*-chloranil caused no solvolysis. In all cases, the solid states were retained throughout the procedure of grinding and exposure.



The colored solids obtained by solid-state grinding of **1a** with DDQ exhibited an absorption maximum at 650 nm ascribed to a CT band, as measured by solid-state reflectance spectroscopy. EPR signals were observed for these solid samples.‡ Crystalline charge-transfer complexes were not obtained *via* recrystallization of **1a** and DDQ from MeCN solution. This was also the case for **1b** and **1c**; the charge-transfer complexation was realized only by grinding these compounds with the electron acceptor in the solid-state. The resulting solids exhibited EPR signals and solvolysis occurred upon solid–vapor contact.

For **1d**, a crystalline 1:1 charge-transfer complex was obtained from a highly concentrated colored solution of **1d** and DDQ in MeCN. In sharp contrast to the solids obtained by solid-state grinding, those obtained by recrystallization exhibited no EPR signals and did not undergo solvolysis upon exposure to solvent vapor. Furthermore, the ground mixture of **1d** and DDQ exhibited a charge-transfer band maximum (653 nm) at longer wavelength than the complex obtained by recrystallization (629 nm). All the above observations indicate that the solid-state grinding generates radical ions and that these species are essential to promote the solvolysis by vapor.

Catalytic effects of π-donors in the acetolysis of 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate has been reported,[7] in which the π-donors are assumed to polarize the C-O bond leading to easy heterolytic bond cleavage. The present results appear to be different from such type of catalytic solvolysis in a solution. It has been quite often observed that radical cations generated *via* single-electron transfer undergo the cleavage of a σ-bond.[8] In order to see if such reaction occurs in the radical cation of **1a**, we have carried out the electrochemical oxidation of **1a** in MeOH and ascertained the formation of **2a**. This finding, however, does not settle the mechanism, because the precursor species to **2a** are only slightly generated in the ground solids; the spin concentration of the ground solids is estimated to be only 2% at most from the EPR signal intensity and furthermore **2a** is formed in mear trace amounts when the ground mixture is dissolved in MeOH. Thus the carbocation



Scheme 2

species should be propagated in the solid phase upon gas-solid contact.

As a most plausible mechanism at this stage, we assume that the methoxy substitution occurs in a catalytic chain process initiated by a small amount of the cation generated from the radical cation of **1a**, as depicted in Scheme 2.§ The acid-catalysed ether formation in the solid state was supported by the occurrence of the ethoxy substitution in a crystalline inclusion complex[9] **1d**·$(EtOH)_2$ upon grinding with toluene-*p*-sulfonic acid without solvent.

The reasons why only the ground mixtures of the substrates and acceptors show EPR signals and hence undergo the solvolysis by vapor should be discussed. The substrates used in this work are not planar molecules, and have irregular shape and conformational freedom. For such molecules, close packing in a periodic donor–acceptor arrangement is not easily attained upon recrystallization,¶ as noted already. On the other hand, solid-state grinding would force some of the molecules closer together while still being free from lattice control, and hence permit much stronger charge-transfer interactions than those in crystalline charge-transfer complexes derived from a solution.

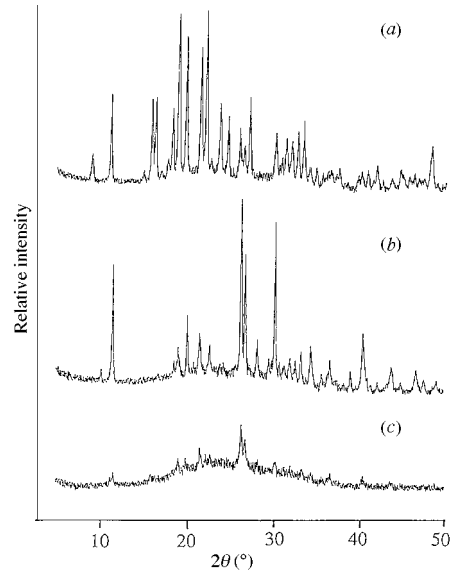


Fig. 1 Powder X-ray diffraction patterns of (*a*) **1a**, (*b*) DDQ and (*c*) a ground mixture of **1a** and DDQ

The above explanation is in line with the results of a powder X-ray diffraction study. The diffraction intensities of the ground solids of **1a** with DDQ decrease significantly as compared with those of each component (Fig. 1), indicating the collapse of the crystalline phase without reorganization into a new charge-transfer crystal phase. Despite the inability of the mixtures to give co-crystal packing, the charge-transfer contacts are strong enough to induce single-electron transfer, which could be partially due to the use of the planar moieties on **1a**. It has been reported that crystalline charge-transfer complexes can be formed by grinding together solid donor and acceptor components.[10] Such behavior has also been encountered for planar donor and acceptor molecules that can also co-crystallize from solution. Thus, it seems reasonable that the reactivity of the present solvolysis system using solvent vapor depends not only on the electron accepting and donating abilities, but also on the molecular shape, of the substrates and electron acceptors.

Notes and References

† E-mail: ckobak@komaba.ecc.u-tokyo.ac.jp

‡ For the ground solids of **1a** and DDQ, an EPR signal occurs at $g = 2.0043$ with a simple profile of a type usually observed for monoradical species.

§ Alternatively the collapse of the radical cation to form H^+ and an alkoxy radical would be possible. In this case also H^+ would give the cation which enters into the chain process.

¶ Most of the substrates in this work act as host species for clathrate crystals, indicating that it is difficult for these compounds to crystallized without incorporation of other guest molecules. See also ref. 9.

Alkane oxidation with manganese substituted polyoxometalates in aqueous media with ozone and the intermediacy of manganese ozonide species

Ronny Neumann*† and Alexander M. Khenkin

Casali Institute of Applied Chemistry, Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

Manganese substituted polyoxometalates (POMs), such as $Li_{12}[Mn^{II}_2ZnW(ZnW_9O_{34})_2]$ were effective catalysts for the oxidation of alkanes to ketones with ozone in an aqueous reaction medium; a green intermediate compound observable by UV–VIS and ESR at −78 °C was postulated to be a reactive manganese ozonide species.

Transition metal substituted polyoxometalates have been studied as oxidatively resistant analogues of metalloporphyrins. The difference between the porphyrin ligand and the oxotungstate ligands when using peroxygen compounds is considerable because with polyoxometalates reaction can occur both at the transition metal center and the tungstate sites.[1] However, 'metalloporphyrin type' formation of stable Cr(v)=O species[2] and manganese catalyzed oxidation of alkenes has been observed using iodosylbenzene as oxidant.[3] A ruthenium substituted polyoxometalate has also been shown to activate dioxygen in a manner similar to a ruthenium porphyrin system.[4] Ozone is an environmentally benign (dioxygen is the co-product), single oxygen donor. The bond cleavage of alkenes with ozone[5] and the facile deactivation of organic ligands such as porphyrins[6] preclude the use of ozone for catalytic epoxidation of alkenes. The oxidative stability of polyoxometalates now presents an ideal opportunity for investigating the oxidation of alkanes with ozone catalyzed by manganese substituted polyoxometalates.

Catalysis with transition metal substituted polyoxometalates is commonly practiced by transferring the polyoxoanion into an organic solvent using a quaternary ammonium cation. With ozone such an approach is unacceptable due to self-oxidation of the counter cation. Use of lithium cations and 40–50% *t*-butyl alcohol–water allows formation of a neutral homogeneous reaction medium. Typically, 10 μmol $Li_{12}[Mn^{II}_2ZnW(ZnW_9O_{34})_2]$ was dissolved in 2.5 mL 40% *t*-BuOH–water and 1 mmol substrate was added. The mixture was cooled to ≈2 °C and ozone as 2.5 mol% O_3/O_2 was bubbled at 30 mmol $O_3\ h^{-1}$ through the solution for 45 min. Ethylbenzene, 82 mol% conversion, yielded acetophenone (major product, ≈85 mol%) and 1-phenylethanol (minor product, ≈15 mol%). Conversion for a control reaction without catalyst was 15 mol% with similar selectivities. Other manganese containing polyoxometalates such as $K_5PMn^{II}W_{11}O_{39}$, $K_6SiMn^{II}W_{11}O_{39}$, $K_6H_6Si-Mn^{II}_2W_{10}O_{40}$ and $K_{10}[Mn_4(PW_9O_{34})_2]$ gave (based on manganese equivalents) similar (±3 mol%) conversions in 50% *t*-BuOH–water. All other polyoxometalates, $K_x[M_2ZnW(ZnW_9O_{34})_2]$ or $K_xSiMW_{11}O_{39}$, with M = Zn^{2+}, Co^{2+}, Cu^{2+}, Ru^{3+}, Cr^{3+} or Fe^{3+} showed essentially *no* catalytic activity. The reaction was general for alkylaromatics, and cyclic and acyclic alkanes as may be observed in Table 1. The reactivity was as expected, *i.e.* alkylaromatics > cyclic alkanes > acyclic alkanes. The selectivity of the oxidation to ketones as the major product is contrary to what has been observed in manganese porphyrin hydroxylations with ozone where 1-phenylethanol is the major product in ethylbenzene oxidation.[6,7] Also notable is the carbon–carbon bond scission in cumene. Oxidation of cyclohexanol yielded only 20% cyclohexanone under identical reaction conditions and both cumyl alcohol and *tert*-butyl alcohol were (< 1% conversion) inert. These results indicate that alcohols were not intermediate products.

Table 1 Oxidation of alkanes with ozone catalyzed by $Li_{12}[Mn^{II}_2ZnW(ZnW_9O_{34})_2]$ in 40% *t*-BuOH–water[a]

Substrate	Product, mol%	Conversion, mol%
Ethylbenzene	Acetophenone, 85 1-Phenylethanol, 15	82 (15)
Diphenylmethane	Benzophenone, > 98	62
Tetrahydronapthalene	α and β-Tetralone,[b] > 98	56
Cumene	Acetophenone, > 98	38
Cyclohexane	Cyclohexanone, > 98	41
Cyclooctane	Cyclooctanone, > 98	38
n-Decane	2-, 3-, 4- and 5-Decanone,[b] > 98	28

[a] Reaction conditions: 1 mmol substrate, 10 μmol $Li_{12}[Mn^{II}_2ZnW(ZnW_9O_{34})_2]$, 2.5 mL 40% *t*-BuOH–water, 45 min, 2 °C. [b] The amounts of ketone were not quantified.

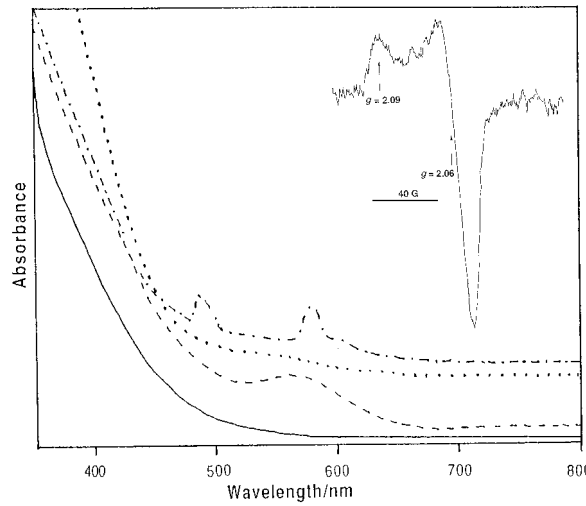

Fig. 1 UV–VIS spectra of various $[Mn_2ZnW(ZnW_9O_{34})_2]^{q-}$ species and the ESR spectrum of the active species. (a) —— $[Mn^{II}_2ZnW(ZnW_9O_{34})_2]^{12-}$, (b) - - - - $[Mn^{III}_2ZnW(ZnW_9O_{34})_2]^{10-}$, (c) ····· brown manganese(v) species, (d) -·-·- green manganese(v)–oxo species. The concentration of $[Mn_2ZnW(ZnW_9O_{34})_2]^{q-}$ was 5×10^{-4} M and the UV–VIS spectra are slightly offset for clarity. Spectra (a) and (b) were taken at ambient temperature, (c) was taken at 2 °C and (d) was taken immediately after removal from −78 °C using a diode array spectrometer. In (d), the optical density is a superposition of the light scattering because of condensation of water on the cuvette and the absorption from the manganese polyoxometalate. The peaks are distorted resulting in a truncated (from the bottom) appearance and with narrow peak widths. The ESR spectrum was taken at 120 K after purging the ozone with N_2.

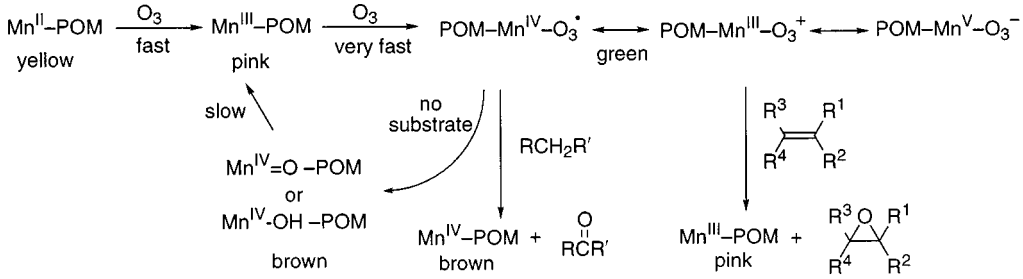
The reactivity of alkanes was further probed by oxidation of *cis*-decalin. Oxidation at the tertiary position yielded a *trans*-decalol–*cis*-decalol ratio of ≈4 : 1 for both the catalysed and non-catalysed reaction.[8] Oxidation of 1 : 1 cyclohexane–cyclo-



Scheme 1

hexane-d_{12} gave a low kinetic isotope effect (KIE), k_H/k_D = 1.2.[9] The findings that cumene selectively formed acetophenone, *cis*-decalin gave *trans*-decalol as the major product and the low KIE in the oxidation of C_6H_{12}–C_6D_{12} all point to an alkyl radical intermediate in the oxidation of alkanes.

The reaction mechanism was further studied by UV–VIS, Fig. 1. The original catalyst, $Li_{12}[Mn^{II}{}_2ZnW(ZnW_9O_{34})_2]$, is yellow. Upon addition of ozone at 2 °C, the solution within a minute turns pink, (Mn^{III}) λ_{max} = 560 nm, as is known for $[Mn^{III}{}_2ZnW(ZnW_9O_{34})_2]$.[9–10] Further addition of ozone turns the solution brown forming a Mn^{IV}–oxo compound.[11] The later was inactive in a stoichiometric reaction with alkenes.[11] The brown compound was not stable slowly reverting within an hour to the pink manganese(III). In a further experiment, a solution of $Q_{12}[Mn^{II}{}_2ZnW(ZnW_9O_{34})_2]$ (Q = trioctylmethyl ammonium) in acetone was cooled to −78 °C and ozone was passed through the solution yielding a green solution, λ_{max} = 486, 580 nm, Fig. 1(d). Further characterization of the green solution by ESR, Fig. 1 (inset), showed an anisotropic spectrum with peaks at $g_{\|}$ = 2.09 and $g_{\perp}$ = 2.06.

After purging the solution of excess ozone with N_2, stoichiometric amounts of alkenes were added. The solution was brought to −40 °C and turned pink after a few minutes. 2,3-Dimethyl-2-butene and cyclooctene, 80 and 63% conversion respectively, reacted selectively to give epoxides as sole products whereas norbornene (74% conversion) gave 94% *exo* epoxide and 6% 2-norbornanone. *cis*-Stilbene was epoxidized 95% stereoselectively with no formation of the cleavage product, benzaldehyde. An identical experiment carried out with stoichiometric addition of ethylbenzene gave a darkish brown solution and yielded (28 mol% based on manganese) acetophenone–1-phenylethanol, ≈20 : 1.

Our interpretation of the results of the catalytic and stoichiometric oxidation reactions, and the UV–VIS and ESR spectra is summarized in Scheme 1. The initial yellow Mn^{II}–POM is first oxidized to the pink Mn^{III}–POM. The catalytic cycle begins by reaction of Mn^{III}–POM with ozone to give the stipulated active intermediate, the green manganese species. Based on the spectra and the reactivity profile, we assign the green compound as a manganese ozonide complex. The ESR spectrum is attributable to an anisotropic oxygen centered radical species[12] formulated here as POM–Mn^{IV}–O–O–O$^{\cdot}$, formed by reaction of Mn^{III}–POM and O_3. Other canonical forms, POM–Mn^{III}–O–O–O^+ or POM–Mn^{V}–O–O–O^- are possible. The UV–VIS spectrum is supportive of this assignment, since peaks at 450–480 nm are typically observed for ozonides.[12] In the absence of a substrate and/or at higher temperatures the compound quickly decays by reduction or disproportionation to a brown manganese(IV) oxo or hydroxy species (a typical ESR spectrum with peaks at g = 2 and 4 was also observed)[11] and then more slowly to Mn^{III}–POM. The formulation of the green species as an ozonide is consistent with the oxidation reaction profiles observed. In alkane oxidation non-catalytic and catalytic reactions showed practically identical selectivity with a preponderance of the ketones as products, a low KIE, formation of acetophenone from cumene and the formation of an equilibrium mixture of *trans*-decalol–*cis*-decalol from *cis*-decalin. This reactivity clearly supports a reaction occuring through a free alkyl radical intermediate[13] as opposed to a oxygen-rebound mechanism often invoked in metalloporphyrin oxidation.[14] Epoxidation of alkenes with retention of stereochemistry is explainable through reaction of the ozonide, POM–Mn^{III}–O–O–O^+ canonical form, as an electrophile with the nucleophilic alkene with co-formation of molecular oxygen and Mn^{III}–POM.

Supramolecular metallocalixarene chemistry: linking metallocalixarenes through imido bridges

Vernon C. Gibson,*[a]† Carl Redshaw,[a] William Clegg[b] and Mark R. J. Elsegood[b]

[a] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*
[b] *Department of Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU*

The synthesis and structures of two novel extended-array metallocalixarenes, derived from the ring-opening of imido–molybdenum precursors, are described.

The ability of calixarenes to act as receptors for a variety of guest molecules is a feature of central importance to their chemistry.[1] The development of supramolecular structures incorporating calixarenes offers an opportunity to extend calixarene host–guest interactions to two- and possibly three-dimensional lattices. Although supramolecular structures have been seen as a result of guest–host interactions,[2] and metal–oxo bridges,[3] clear methodologies for covalently linking metallocalixarenes have not, to our knowledge, been described. Here, we report the synthesis and solid state structures of two novel metallocalixarenes derived from the ring-opening of imido–molybdenum precursors. In one case the metallocalixarenes are linked by hydrogen bonding between pendant amino groups and in the other by a covalent linkage between imido ligands that gives rise to a two-dimensional array of 'cup-to-cup' metallocalixarene units.

Treatment of the tetraimido dimolybdenum complex **1**[4] with two molar equivalents of H_4L (H_4L = calix[4]arene) in refluxing toluene affords, after work-up, the bridged complex {[Mo(NCMe)L]$_2$[3,5-Pr$^i_2$-4-NC$_6$H$_2$)$_2$CH$_2$]} **2** according to Scheme 1.‡ Complex **2** is presumed to form *via* initial displacement of two chloride ligands (per molybdenum), followed by proton transfer to one of the imido ligands to release the *para*-bridged dianiline. Crystals suitable for X-ray diffraction§ were grown from acetonitrile at room temperature. The molecular structure is shown in Fig. 1(a) and selected bond lengths and angles are given in the caption. Each molybdenum possesses a pseudo-octahedral geometry similar to that found in the monometallocalix[4]arene analogue of **1**.[5] The molybdenum atoms are displaced from the O_4 mean planes towards the imido nitrogens of the bridging ligand by 0.246 and 0.247 Å. The molecule has approximate C_2 symmetry, the rotation axis running through the C(13) atom. Significantly, the metallocalixarenes are organised in a 'cup-to-cup' arrangement which gives rise to a calixarene 'socket' [Fig. 1(b)], thus offering the potential for hosting guest molecules in the cooperatively aligned calixarene cavities.

In an extension of this work, we then targetted metallocalixarene species with pendant amino functionalities which we envisaged would allow the linking of metallocalixarene units *via*, for example, amide bonds. Treatment of the chelating bis(imido)molybdenum complex {Mo(OBu^t)$_2$[(2-NC$_6$H$_4$)$_2$-CH$_2$CH$_2$]} **3** with H_4L (one equivalent) in toluene affords, after work-up, the monoimido calixarene complex {[Mo(N-CMe)L][2-NC$_6$H$_4$CH$_2$CH$_2$C$_6$H$_4$NH$_2$-2′]} **4** in which the imido ligand contains a 'free' amino functionality (Scheme 1). Complex **4** is presumed to form *via* loss of two *tert*-butanol ligands followed by transfer of two protons to one of the imido ligands to release the pendant amino group.[5] The IR spectrum of **4** has a strong ν(N–H) stretch at 3165 cm^{-1}, indicative of an

Dediazoniation reactions of arenediazonium ions under solvolytic conditions: fluoride anion abstraction from trifluoroethanol and α-hydrogen atom abstraction from ethanol

Peter S. J. Canning, Katharine McCrudden, Howard Maskill*† and Brian Sexton

Chemistry Department, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU

Arenediazonium salts decompose thermally and photochemically in trifluoroethanol to yield trifluoroethyl ethers and (in part by fluoride abstraction from the solvent) fluoroarenes; the less reactive compounds in trifluoroethanol decompose readily in ethanol to give arenes in a radical reaction involving abstraction of the α-hydrogen from the ethanol.

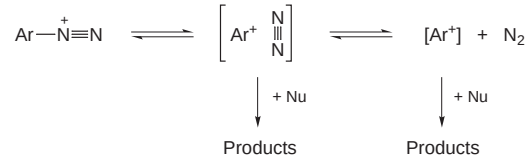
Dediazoniation reactions are amongst the oldest known industrial organic chemical reactions, and their mechanisms are also amongst the earliest to have been investigated.[1] For some years, thermal decomposition of arenediazonium tetrafluoroborates has been used as a route for making fluoroarenes—compounds of increasing importance for the production of pharmaceuticals and agrochemicals. The Balz–Schiemann reaction is one method which involves isolation of the salt and its subsequent thermal decomposition,[2] a potentially hazardous process. Other methods involve decomposition of diazonium salts in liquid hydrogen fluoride,[3] but these also have obvious potential for danger. We have been investigating alternative procedures for decomposing diazonium salts with a view to (i) understanding better the mechanisms involved, and (ii) developing a method more environmentally acceptable and less hazardous than ones currently available. In the course of these investigations, we have discovered that aryl cations (generated by loss of dinitrogen from the arenediazonium ions) are able to abstract fluoride from fluoro alcohols in competition with being captured by the hydroxylic residue of the alcohol. We have also shown that the intermediates involved in the decomposition in ethanol of arenediazonium cations with electron-withdrawing substituents abstract an α-hydrogen from the ethanol. Additionally, we have demonstrated that, under photolysis in trifluoroethanol (TFE), otherwise very unreactive arenediazonium ions react very readily. This product analytical evidence, and the attendant kinetics studies, contribute further to ongoing investigations world-wide of the chemistry of exceedingly short-lived reactive intermediates.

Table 1 Kinetics results[a] for the solvolysis of arenediazonium tetrafluoroborates $XC_6H_4N_2^+ BF_4^-$

Solvent	X	$k_{25}/10^{-6}s^{-1}$	$\Delta H^{\ddagger}$/kJ mol^{-1}	$\Delta S^{\ddagger}$/J K^{-1} mol^{-1}
TFE	*m*-NO_2	0.60	124	54
TFE	*m*-F	1.18	124	59
TFE[b]	H	92.1	114	62
TFE	*m*-OMe	873	103	42
EtOH	*m*-OMe	409	97	14
EtOH	*m*-F	941	64	−87
EtOH	H	232	75	−64

[a] Rate constants at 25 °C were extrapolated using the Eyring equation from average values obtained at other temperatures. Standard deviations on individual rate constants were generally about 1% and reproducibility was better than about 5%. The estimated uncertainty on $\Delta H^{\ddagger}$ is *ca.* 6 kJ mol^{-1} and 12 J K^{-1} mol^{-1} on $\Delta S^{\ddagger}$. [b] Previously reported values (ref. 5): k_{25} = 68.3 × 10^{-6} s^{-1}, $\Delta H^{\ddagger}$ = 114 kJ mol^{-1} and $\Delta S^{\ddagger}$ = 58 J K^{-1} mol^{-1}.

Table 1 gives kinetics results for arenediazonium tetrafluoroborates investigated by our normal UV method.[4,5] In TFE, a solvent which generally promotes heterolytic reactions, we observe high enthalpies of activation and appreciably positive entropies of activation in agreement with previous results.[5,6] Such findings are accommodated by the Zollinger heterolytic mechanism[7] [Scheme 1, where Nu = nucleophile



Scheme 1

(*e.g.* solvent)] except that under our reaction conditions, the first two steps will be essentially irreversible. In accord with earlier workers, we also observe that electron-withdrawing substituents decrease reactivity,[5,6,8] an effect brought about principally through increases in the enthalpy of activation (Table 1). For the *m*-methoxy compound, the most reactive of these compounds in TFE, we note comparable reactivity in ethanol. However, for the much less reactive *m*-fluoro analogue in TFE, we note unexpectedly high reactivity in ethanol, and quite different activation parameters; $\Delta H^{\ddagger}$ is now much lower and $\Delta S^{\ddagger}$ strongly negative, signalling a different mechanism.

In TFE, the products of the thermally induced solvolyses are principally the aryl trifluoroethyl ethers, but between 10 and 35% of aryl fluorides are observed (Table 2). These compounds

Table 2 Product analyses[a] from solvolytic decompositions of arenediazonium salts $XC_6H_4N_2^+ Z^-$ Products (%)

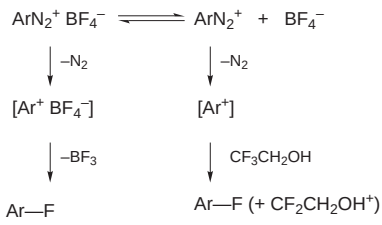
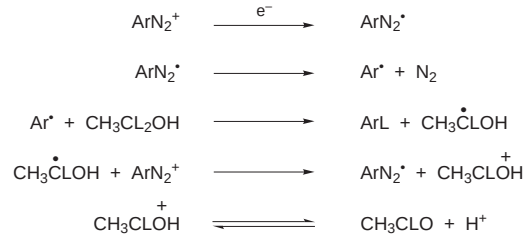
[a] Analyses were carried out by GLC, usually with undecane as internal standard. Each reaction was carried out at least twice, and up to *ca.* six chromatograms were obtained for each reaction. Yields quoted are normalised (total = 100%), absolute recoveries being variable between *ca.* 80–100%. [b] Reaction contained 0.63 mol dm^{-3} $NaBF_4$. [c] This reaction was too slow thermally for a reliable product analysis to be obtained. [d] When the reaction was carried out in CH_3CD_2OH, *m*-$DC_6H_4NO_2$ was isolated by preparative GLC, and characterised by mass spectrometry and ^{1}H NMR spectroscopy.



Scheme 2



Scheme 3

were identified by comparison with authentic samples, and in some cases were isolated by preparative GLC and characterised. If aryl radical intermediates are the source of this fluorine transfer, the same intermediates would also be expected to give some degree of hydrogen transfer. No appreciable yields of reduction product were detected in reactions in TFE, so aryl cations are implicated as the source of fluorine abstraction. Aryl fluorides had previously been detected from reactions of very dilute arenediazonium tetrafluoroborates in aqueous TFE in which the reactants will have been fully dissociated. Since aryl cations are exceedingly short lived,[9] they cannot diffuse through the medium and select very dilute tetrafluoroborate as a reaction partner. Consequently, the TFE component of the solvent was implicated as the source of the fluorine in the product aryl fluorides. This was confirmed by solvolysing benzenediazonium chloride in TFE and obtaining 10% fluorobenzene (compared with 28% from the tetrafluoroborate). We conclude that the fluoroarenes generated from arenediazonium tetrafluoroborates in TFE arise from fluoride abstraction by the aryl cation in part from the solvent and in part from the tetrafluoroborate anion within undissociated ion-pairs (Scheme 2) (where possible involvement of ion-molecule pair intermediates, as in Scheme 1, has been omitted for clarity). In agreement with this proposal, addition of sodium tetrafluoroborate (which will increase the degree of ion-pair association) led to a modest increase in the yield of fluoroarene in TFE. We have no evidence yet regarding the identity of the species remaining after fluoride abstraction from the trifluoroethanol, $(CF_2CH_2OH)^+$, or about whether the fluoride abstractions are concerted or stepwise.

Strongly electron-withdrawing substituents decrease the reactivity of benzenediazonium tetrafluoroborate in TFE, and high temperatures or long times are required for their reactions (Table 1). However, we observed that photolysis using a low wattage UV source at room temperature of a dilute solution in TFE effected complete reaction within minutes; similar observations in liquid hydrogen fluoride have already been reported.[3] Analysis by GLC confirmed that the products (aryl fluoride and aryl trifluoroethyl ether) are the same as in the very slow thermal reaction, and that the yields are rather similar (Table 2). It appears, therefore, that photolysis in TFE involves the same aryl cation intermediates as the much slower thermal reaction.

Analytical results using ethanol as solvent confirmed the kinetics results—the reaction is qualitatively different from that in TFE for compounds with electron-withdrawing substituents. It was already known that ethanol can act as a reducing agent for some arenediazonium ions,[10] and that analogous reactions in methanol involve radical intermediates.[11] Additionally, there is a report that the reaction in methanol involves abstraction of the α-hydrogen.[12] Ethanolysis of *m*-fluoro- and *m*-nitro-benzenediazonium tetrafluoroborates gives high yields of the reduction product, and the former gives a very similar product analysis under photolysis at room temperature. The parent compound (X = H) gives very little reduction and (not surprisingly) very little fluorobenzene under these reaction conditions. The product analysis of the parent compound, therefore, does not provide evidence of a change in mechanism upon transfer from TFE to ethanol intimated by the changed kinetics parameters; at the present we have no ready explanation of this. When *m*-nitrobenzenediazonium tetrafluoroborate was solvolysed in [1,1-$^2H_2$]ethanol (CH_3CD_2OH), [3-^{2}H]nitrobenzene was isolated by preparative GLC and identified by ^{1}H NMR spectroscopy and mass spectrometry. Given the characteristically different kinetics parameters for these arenediazonium salts deactivated in the heterolytic pathway by electron-withdrawing substituents and the different product analytical profiles in ethanol, a different mechanism must be involved. Taking into account the previous evidence for reactions in methanol,[11] and proof that the intermediate abstracts an α-hydrogen from the ethanol, we propose the radical chain mechanism in Scheme 3 based upon earlier proposals by DeTar[13] and Bunnett.[11] The reductant in the initiating step has not yet been identified, but is almost certainly ethanol itself.

We thank the EPSRC for studentships to P. S. J. C., K. M. and B. S., and Zeneca (formerly ICI) for financial support; we also thank Drs J. H. Atherton and D. J. Moody of Zeneca for helpful and stimulating discussions.

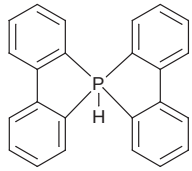
Multiple pathways in the cleavage of benzyl groups from phosphonium salts by lithium aluminium hydride

Neil Donoghue and Michael J Gallagher*†

School of Chemistry, University of New South Wales, Sydney 2052, Australia

Reduction of benzylphosphonium salts by $LiAlD_4$ affords a phosphine and $PhCH_2D$, 2-$DC_6H_4CH_3$ and $PhCH_3$; pathways involving P^V and P^{VI} intermediates are proposed to account for these products.

Benzyl groups are readily removed from benzylphosphonium salts by $LiAlH_4$ in THF to give a phosphine and toluene in good yields.[1,2] The reaction forms the basis of a general method for the preparation of unsymmetrical phosphines[1b] and has found use in the synthesis of cyclic phosphines,[3] but attempts to extend the utility of the reaction to the cleavage of phenyl groups from the more readily accessible arylphosphonium salts have met with limited success,[4] loss of either alkyl or aryl groups or both occurring in an apparently inconsistent way. Reduction of ylides from alkyltriphenylphosphonium salts proceeds exclusively with loss of phenyl[4,5] even when the ylidic carbon is benzylic, establishing that reduction of salts does not proceed *via* ylide formation. Reduction of resolved chiral benzylic salts occurs with partial or complete racemisation at phosphorus,[6] implying that the reaction proceeds *via* a configurationally mobile phosphorane of the type R_4PH. Such compounds have only been observed to form from phosphonium salts in the specialised case of the spirobisbiphenylyl system **1**.[7]

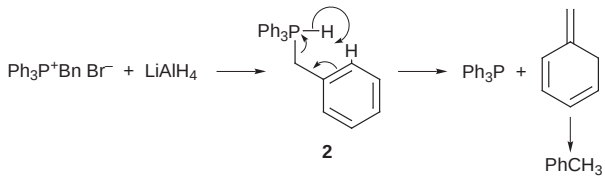


1

Theoretical considerations[8] suggest that the decomposition, shown in eqn. (1), is an allowed concerted process for two

$$R_5P \rightarrow R_3P + RR \quad (1)$$

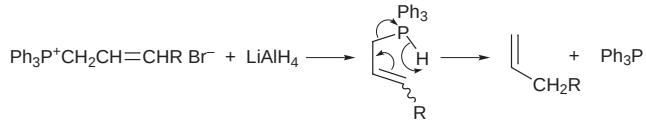
substituents in the equatorial plane of a trigonal bipyramid, suggesting a reasonable pathway for the overall reduction, but it is not obvious why benzyl groups are a favoured leaving group if ionic stability of the leaving group were not an important factor, as had been generally supposed.[2] A possible reason could be a cheleotropic rearrangement of an intermediate phosphorane **2** with transfer of hydrogen from phosphorus to the *ortho* carbon of the benzyl group, followed by aromatisation of the methylenecyclohexa-2,4-diene thus expelled (Scheme 1).



2

Scheme 1

A similar pathway (Scheme 2) can be visualised for allylphosphonium salts and reported reductions of these by



3

Scheme 2

$LiAlH_4$ appear to proceed exclusively with allylic inversion ('S_N2' substitution').[2b] Thus, reduction of (*E*)-cinnamyltriphenylphosphonium bromide with $LiAlD_4$ yields triphenylphosphine and 1-phenyl[1-^{2}H]but-2-ene. Further, these allylic cleavages proceed more rapidly with phosphonium salts than they do with the analogous ammonium salts, which are similarly cleaved but largely without allylic inversion.[9]

We now report that reduction of benzyltriphenylphosphonium bromide with $LiAlD_4$ in refluxing THF (5 h) affords toluene, [α-^{2}H]toluene and [*o*-^{2}H]toluene in a ratio of approximately 1:1:1 as determined by ^{1}H, ^{2}H and ^{13}C NMR spectroscopy; the other product, Ph_3P, showed no deuterium incorporation. The identity of the *o*-deuterated toluene was further confirmed by HSQC 2D ^{1}H/^{13}C{^{1}H} NMR and by comparison with authentic material obtained by quenching 2-$CH_3C_6H_4MgBr$ with D_2O. Analogous comparisons confirmed the absence of detectable amounts of *m*- or *p*-deuterated toluene in the salt reduction. No exchange is observed when toluene is refluxed with $LiAlD_4$ in THF or when the product mixture of toluenes is treated with $LiAlH_4$, indicating that the three hydrocarbons all arise in the reduction process.

We extended the examination to the products from the $LiAlD_4$ reduction of all the phosphonium salts, $Bn_nP^+Ph_{4-n}$ Br^- (n = 0–4) and the results are summarised in Table 1. Ph_4P^+ Br^- cannot, of course, give toluene but under the same conditions it affords a mixture of PhH (21%) and PhD (79%) measured by mass spectrometry.

We have elsewhere presented evidence that the reduction of phosphonium salts with metal hydrides proceeds *via* a number of intermediates,[10] **4–6** (Scheme 3). Clearly, formation of R^-, which subsequently abstracts a proton from THF, could account for the formation of undeuterated hydrocarbon and decomposition of **2** by concerted processes could lead to either α- or *o*-deuterated toluene. Part of the [α-^{2}H]toluene will arise during the conversion of the 6-[^{2}H]methylenecyclohexa-1,3-diene to

Table 1 Yields of toluenes formed by reduction of $Bn_nP^+Ph_{4-n}$ Br^- with $LiAlD_4$

	Yield (%)

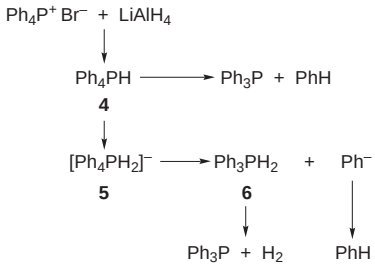

Scheme 3

toluene but there is too much deuterium on the benzylic carbon to be all accounted for in this way, since the ^{1}H–^{2}H isotope effect should ensure that the bulk of the deuterium originally in the *ortho* position, remains there. Therefore, most of the deuterium in $PhCH_2D$ arises by other processes of which there seem to be two, either a concerted loss of deuterium and $PhCH_2$ from **4**, or S_N2 type displacement at the benzylic carbon by hydride ion equivalent. We are unable to determine the relative contributions of these two pathways but we have observed that benzyldimethylphenylammonium bromide exclusively loses $PhCH_2D$ when refluxed in THF with $LiAlD_4$ [eqn. (2)], and,

$$Ph(CH_3)_2N^+CH_2Ph\ Br^- + LiAlD_4 \rightarrow PhNMe_2 + PhCH_2D \quad (2)$$

since an N^V intermediate is very improbable, this presumably goes *via* an S_N2 related process. Also, thermal decomposition of R_5P has resulted in products understandable in terms of concerted loss of two groups [eqn. (1)], *e.g.* the dissociation of PCl_5 to PCl_3 and Cl_2.[11] The exclusive *ortho* selectivity is, we believe, best explained by a concerted intramolecular hydride transfer since an S_N2' attack on the ring might reasonably be expected to give some of the [4-^{2}H]toluene. An alternative process involving radicals, formed by homolysis of P–C (or P–H) bonds, has not been excluded but the exclusive *ortho* deuterium transfer and the absence of the coupling product, 1,2-diphenylethane, lead us to favour a concerted pathway.

We thank the Australian Research Council for support.

Chemical recycling of poly(ethylene) by catalytic degradation into aromatic hydrocarbons using H-Ga-silicate

Yoshio Uemichi,*† Kazuhiko Takuma and Akimi Ayame

Department of Applied Chemistry, Muroran Institute of Technology, Mizumoto, Muroran, 050-8585, Japan

H-Ga-silicate exhibits excellent catalytic activity towards the formation of aromatic hydrocarbons, mainly benzene, toluene and xylenes (BTX), in the degradation of poly(ethylene), indicating its high potential as a catalyst for the advanced chemical recycling of polyolefins.

It is currently very important to recycle waste plastics from the standpoints of environmental protection and conservation of energy. A chemical method that converts plastics into valuable chemical feedstocks or fuels is of great interest because it provides a viable means to contributing to the solution of problems caused by waste disposal. The conversion of plastics can be achieved thermally or catalytically. Since thermal degradation of polyolefins, the main components of waste plastics, is a low selectivity reaction, successful application of catalysts to these conversion processes would be a key step towards the development of the plastic recycling technologies.

Catalytic degradation of polyolefins has mostly been carried out with a view to obtaining valuable hydrocarbon mixtures as fuels.[1–4] There have been only a few reported studies on chemical recycling (otherwise termed feedstock recycling, raw material recycling or tertiary recycling) which aims to yield chemical feedstocks.[5–7] To achieve chemical recycling, polyolefins must be decomposed in high yield into useful feedstocks. This step is usually more difficult than conversion into fuels. In other words, chemical recycling requires cracking catalysts with selectivities much higher than those required for fuel recovery. This is the reason why catalytic chemical recycling of polyolefins has not been developed. Here we report that H-Ga-silicate is highly effective as a catalyst for producing aromatic hydrocarbons selectively in the degradation of poly(ethylene). This successful result means that chemical recycling of polyolefins is now a feasible operation.

Catalytic degradation of low-density poly(ethylene) (Aldrich LDPE, density 0.915 g cm^{-3}) has been carried out using a flow reactor at 400–525 °C, at atmospheric pressure and under a He stream (10 cm^3 min^{-1}). The poly(ethylene) melt, heated at 270 °C, was fed at a feed rate of 0.02 g min^{-1} into the reactor loaded with 0.2 g of catalyst for 15 min. The degradation products were classified into gas (C_1 to C_4), liquid ($>C_5$) and coke (carbonaceous deposit on the catalyst surface). The composition of the gaseous and liquid products was analysed by gas chromatography. The details of the reaction procedures have been given elsewhere.[1] A commercially available H-Ga-silicate (Si/Ga = 25, N. E. CHEMCAT) was pressed into a disk, crushed and sieved to 16–32 mesh granules, and finally calcined at 500 °C for 3 h in air. The Ga catalyst was compared with H-ZSM-5 (Si/Al = 15, N. E. CHEMCAT) and amorphous silica–alumina (Si/Al = 5.4, Nikki Chemical N631L). These alternatives have been extensively used for the conversion of polyolefins into liquid fuels. The acidic properties of the catalysts were evaluated from their catalytic activities for three model reactions: *n*-hexadecane cracking was carried out at 400 °C, using 1 mg of catalyst, cumene dealkylation at 250 °C and 10 mg, and propan-2-ol dehydration at 175 °C and 3 mg. In each case, a pulse reactor loaded with the powdered catalyst was operated under flowing He (30 cm^3 min^{-1}).

Fig. 1 shows the activities of the catalysts for the acid-catalysed model reactions. The highest conversions were shown by H-ZSM-5, followed by H-Ga-silicate. The Ga catalyst was much more active than silica–alumina for the cracking of cumene and *n*-hexadecane, which occurs on strong acid sites, while both catalysts showed almost the same activity for the dehydration of propan-2-ol, which proceeds on weakly acidic sites. It is suggested from these results that H-Ga-silicate is less acidic than H-ZSM-5, but has acid sites that are significantly stronger than those on silica–alumina, which exhibited low cracking activities.

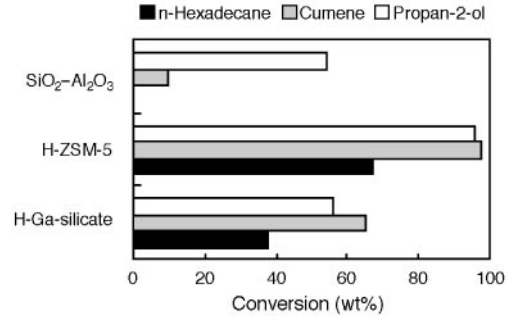

Fig. 1 Catalytic activities for model reactions

The catalysts thus characterised showed quite different activities and selectivities in the degradation of poly(ethylene). The results are summarised in Table 1. H-Ga-silicate is highly effective as a catalyst for the production of aromatic hydrocarbons. A high temperature was favourable to producing the aromatics selectively. A yield of more than 70 wt% was obtained at 525 °C and the liquid product substantially consisted of aromatic hydrocarbons. Benzene, toluene and xylenes (BTX), important raw materials, accounted for most of the aromatics produced. H-ZSM-5 also produced considerable amounts of aromatics at 525 °C. However, the yield was lower than that obtained over H-Ga-silicate at 400 °C. On the other hand, silica–alumina was not suitable for producing aromatics. About 40 wt% yield of aromatics has also been reported in the degradation of poly(ethylene) over metal/carbon catalysts at 526 °C with longer contact times.[5] H-Ga-silicate gives superior results.

Fig. 2 shows the product distributions as a function of carbon number. The products obtained over H-Ga-silicate were distributed over carbon numbers 1–13. The proportion of C_6–C_8

Table 1 Yields of products from degradation of poly(ethylene)

		Yield/wt%				
Catalyst	*T*/°C	Gas	Liquid	Aromatics	BTX	Coke
H-Ga-silicate	400	40.3	59.4	44.1	30.1	0.3
H-Ga-silicate	525	28.0	72.0	71.6	61.8	—[a]
H-ZSM-5	525	58.0	42.0	40.8	33.5	—[a]
SiO_2–Al_2O_3	525	57.2	42.1	9.5	3.7	0.4

[a] Less than 0.05%.

components, mostly BTX, increased with reaction temperature, probably indicating greater aromatisation of the gaseous fractions at higher temperatures. The Ga catalyst showed good stability when reused, as expected from the very small amount of coke deposited on the catalyst surface (Table 1). The ZSM-5-type structure of H-Ga-silicate is likely to resist coke formation.

Ishihara *et al.*[8] reported that the degradation of poly(ethylene) over silica–alumina proceeds as follows: polymer→oligomer→liquid→gas. We believe the consecutive degradation mechanism is applicable to the present work and the aromatics are formed from the oligomer, liquid and/or gas, not directly from the polymer itself. That is, the aromatisation and cracking proceed competitively, and their relative contributions determine the product distributions. Cracking is probably a predominant reaction with H-ZSM-5, over which the liquid hydrocarbons corresponding to the aromatic precursors were converted into gaseous fractions. Thus, the cracking activity of H-ZSM-5 with strong acidity seems to be too high to give a good yield of aromatics. On the other hand, H-Ga-silicate has moderate cracking ability, whilst greatly enhancing aromatisation *via* the catalytic action of Ga species on the catalyst surface.[9,10] Aromatisation would predominate over cracking at high temperature and, hence, the yield of aromatics greatly increased with reaction temperature. It is therefore reasonable to consider that a good balance between cracking and aromatisation activities is the origin of the excellent catalytic performance of H-Ga-silicate. Both aromatisation routes, by direct dehydrocyclisation of the liquid intermediates and by oligomerisation of gaseous fractions and subsequent cyclisation, must be involved in the degradation over the Ga catalyst. The latter should be important at high temperature.

Stabilisation of β-hairpin conformations in a protein surface mimetic using a bicyclic template derived from (2*S*,3*R*,4*R*)-diaminoproline

Marc E. Pfeifer and John A. Robinson*†

Institute of Organic Chemistry, University of Zurich, Winterthurerstrasse 190, 8057 Zurich, Switzerland

A trifunctional template, derived by formal coupling of (*S*)-aspartic acid and (2*S*,3*R*,4*R*)-diaminoproline (available from vitamin C) as a diketopiperazine, was incorporated by solid-phase peptide synthesis into a protein loop mimetic containing the sequence -Ala-Asn-Pro-Asn-Ala-Ala-; this was shown by NMR analysis to adopt a stable β-hairpin conformation in DMSO.

Many proteins exert their biological activity through interactions involving relatively small regions of their exposed surfaces. Small synthetic molecules that mimic surface features of proteins are therefore of potential interest in the design of novel drug candidates. Unlike folded proteins, however, short linear peptides are inherently flexible molecules. To overcome this problem, much attention has been focused recently on the design of templates to constrain peptide chains into biologically relevant secondary and tertiary structures.[1,2] We report here a novel bicyclic template, comprising a diketopiperazine derived from aspartic acid and (2*S*,3*R*,4*R*)-diaminoproline, which was designed to stabilize β-hairpin conformations, as typically found in protein loops connecting adjacent antiparallel β-strands.

In previous work,[3,4] we described the synthesis of template **1**, and its incorporation into the loop mimetic **2**, containing the NPNA (Asn.Pro.Asn.Ala) motif found in a tandemly repeated form in the circumsporozoite protein of *Plasmodium falciparum*.[5] Based on NMR and MD studies, we could show that **2** adopts a stable β-turn conformation within the NPNA motif, while the 4-amido N-atom in the 4-aminoproline moiety of the template prefers a pseudo-equatorial position,[3,6] as depicted in Fig. 1. Here, we set out to introduce an additional amino group in an axial position at the 3-position of the pyrrolidine ring, as in **3**, which could then be used as an anchoring group to more accurately position a peptide loop in a β-hairpin geometry, as in **4**.

A convenient gram-scale synthesis of (2*S*,3*R*,4*R*)-diaminoproline was established by exploiting a known route to the bicyclic β-lactam **5** from vitamin C, which has been implemented already on a multi-kilogram scale in a commercial synthesis of β-lactamase inhibitors.[7] As shown in Scheme 1, **5**

[a] The temperature coefficients for the peptide amides are given; dApro[7] refers to the diaminoproline and Asp[8] to the aspartate moieties, respectively, of the template. Measurements were made in d_6-DMSO in the range 295–320 K. [b] The half-lifes ($t_{1/2}$) of amide resonances were determined by fitting residual peak intensities after dissolution in d_6-DMSO + 10% d_4-methanol to an exponential function. The exchange rates may be classified as: fast [Asp[8] NH and Asn[2]/Asn[4] side chain NHs (data not shown)]; medium (Ala[1], Ala[6]); slow [Asn[2], Asn[4], Ala[5], dApro[7] C(γ)-NH]; and very slow [dApro[7] C(β)-NH]. [c] Measured using 1D and/or E.COSY spectra. [d] For C(β)-NH. [e] For C(γ)-NH

was converted into **6** by a Mitsunobu reaction[8] and exchange of protecting groups, and the β-lactam ring was then opened to yield after esterification the orthogonally protected (2*S*,3*R*,4*R*)-diaminoproline derivative **7**. Thereafter, coupling to Z-Asp(OtBu)-OH, cyclisation to afford the diketopiperazine, and further manipulation of the protecting groups gave **3** in good overall yield.

The template **3** could be incorporated into the cyclic peptide **4** using standard solid-phase methods and Fmoc chemistry.[9] For example, **3** was coupled to Tentagel S-AC resin, and the peptide chain was then elaborated to afford H-Ala-Asn(Mtt)-Pro-Asn(Mtt)-Ala-Ala-Template-Resin. After cleavage from the resin with 1% TFA in CH_2Cl_2, the linear precursor was cyclized using HATU/HOAt‡ in DMF, and all side-chain protecting groups were then removed with TFA in CH_2Cl_2 (35:60) and TIPS (5% v/v). After purification by HPLC, the cyclic peptide **4** was obtained from **3** in 11% yield.

The preferred conformation of **4** was studied in d_6-DMSO (**4** has low solubility in water at pH 5) at 305 K, a temperature at which the amide NH protons are optimally resolved in 1D ^{1}H NMR spectra. A relatively stable β-hairpin conformation in the peptide backbone was indicated in NOESY spectra of **4** by NOEs connecting Ala[1] H(α) as well as Asn[2] NH with Ala[5] NH, which were not observed in earlier studies[3,6] of **2**. A β-turn in the NPNA motif was also indicated, in particular, by a relatively strong Asn[4] to Ala[5] d_{NN} NOE, as well as NOEs between Asn[2] H(β)s and Ala[5] NH, as observed in earlier studies[3,4,6] of **2**. Average solution structures were determined by dynamic simulated annealing§ (SA) using distance restraints derived from NOE build-up curves in a series of NOESY spectra with increasing mixing times. The SA structures showed no major distance restraint violations (*e.g.* >0.2 Å) and revealed a well defined β-hairpin backbone conformation, including a βI turn in the NPNA motif, as in the representative structure **4** shown in Fig. 1.

A critical test of the accuracy of the SA structures is to examine how well they also account for other experimental data, in particular, ^3J coupling constants, relative H/D exchange rates of amide protons, and amide proton chemical shift temperature coefficients. Structure **4** predicts intramolecular hydrogen-bonding across the hairpin, involving the C(β)-NH with O(δ) of the template, as well as Asn[2] NH with Ala[5] CO (indicated by dotted lines in **4** and in Fig. 1). We observe very low amide proton temperature coefficients for these two amide NH groups, as well as relatively slow amide NH exchange rates, measured in d_6-DMSO with 10% v/v d_4-methanol (Table 1), data which indicate the involvement of these NH groups in intramolecular hydrogen-bonding. In addition, the ^3J values for protons in the template, in particular within the diaminoproline moiety, show values consistent with the geometry found in the SA structures, with the C(β)-NH axial, and the C(γ)-NH equatorial. To a first approximation, therefore, the experimental data are interlocking and consistent with the derived SA structures, which indicate a significantly populated β-hairpin conformation in the backbone of **4**. The molecule should not be viewed as rigid, however, and MD simulations may provide a more detailed description of allowed conformational dynamics on the MD time-scale in this system.

Studies are now underway to determine how general this approach is to the construction of conformationally defined β-hairpin loop mimetics of diverse size and sequence. The amino functionality at C(γ) in the template may be useful in this context to allow its attachment to a solid-support for solid-phase syntheses, as well as for coupling to other carrier molecules.

The authors thank the Swiss National Science Foundation for financial support, and Dr Pflieger, F. Hoffmann-La Roche, Basel, for a generous gift of compound **5**.

Unsymmetric dipnictenes—synthesis and characterization of MesP=EC$_6$H$_3$-2,6-Trip$_2$ (E = As or Sb; Mes = C$_6$H$_2$-2,4,6-Me$_3$, Trip = C$_6$H$_2$-2,4,6-Pr$^i_3$)

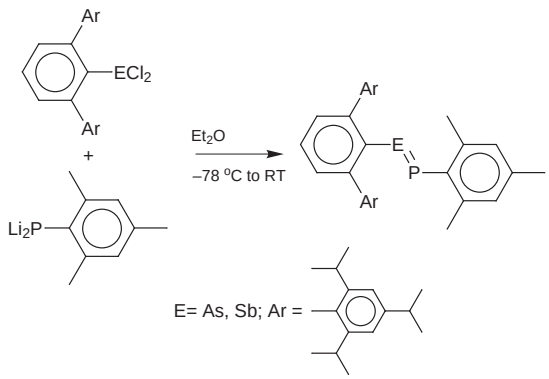
Brendan Twamley and Philip P. Power*

Department of Chemistry, University of California, Davis, California 95616, USA

The use of terphenyl substituents enables the isolation of unsymmetrical dipnictenes with P=As or P=Sb double bonds by a new synthetic route.

The first stable diphosphene Mes*P=PMes* (Mes* = C$_6$H$_2$-2,4,6-Bu$^t_3$) was synthesized by Yoshifuji and coworkers in 1981, *via* the magnesium reduction of Mes*PCl$_2$ in THF.[1] Since that report many further examples of diphosphenes[2] have been synthesized. In contrast, the number of analogous compounds involving double bonds to the heavier pnictogens has remained quite small. For example, there are only two structurally characterized molecules with As–As double bonds,[3] and just one with a P–As double bond.[4] Stable compounds with Sb–Sb[5a] and Bi–Bi[5b] double bonds have only been reported recently. The latter were synthesized by a novel synthetic method involving the deselenation of 1,3,5,2,4,6-triselenatrispnictane (ArESe)$_3$ (Ar = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl, E = Sb or Bi), whereas the related phosphorus or arsenic species, *i.e.* diphosphenes, diarsenes and phosphaarsenes, have usually been prepared *via* reduction with magnesium or sodium naphthalenide or in the case of the unsymmetrical compounds, by the coupling of ArECl$_2$ and Ar′E′H$_2$ in the presence of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene).[4,6,7a] Other methods for synthesizing phosphaarsenes have used Me$_3$SiCl elimination[7b–d] or coupling of the RECl$_2$ (E = P, As) precursors in the presence of Bu^{t}Li.[7e] Currently, there is only one report of a phosphastibene, Mes*P=SbCH(SiMe$_3$)$_2$,[4,6] which was synthesized by the coupling of Mes*PH$_2$ with (Me$_3$Si)$_2$CHSbCl$_2$. However this compound is unstable under ambient conditions and it was characterized by high resolution mass spectrometry and ^{31}P NMR. Using a novel direct elimination method, we now report the isolation of the stable unsymmetric phosphastibene MesP=SbC$_6$H$_3$-2,6-Trip$_2$ (**1**) and phosphaarsene MesP=AsC$_6$H$_3$-2,6-Trip$_2$ (**2**) (Trip = 2,4,6-Pr$^i_3$).

Reaction of the dilithiophosphide Li$_2$PMes[8] in a 1:1 stoichiometry with 2,6-Trip$_2$H$_3$C$_6$ECl$_2$ (E = Sb, As) in Et$_2$O at −78 °C affords the corresponding phosphastibene MesP=SbC$_6$H$_3$-2,6-Trip$_2$ (**1**) and phosphaarsene MesP=AsC$_6$H$_3$-2,6-Trip$_2$ (**2**) (see Scheme 1). Both **1** and **2** were isolated† in low but reproducible yields of 1% and 7% respectively, and their structures were determined by X-ray crystallography (see Figs. 1 and 2).‡



Scheme 1 Synthesis route to unsymmetric dipnictenes

Compound **1** is the first example of a stable species with a P–Sb double bond [P–Sb = 2.335(2) Å]. The molecule has a *trans* configuration with a Sb–C bond distance of 2.174(7) Å and C–Sb–P and C–P–Sb angles of 100.9(2) and 95.7(3)°. There is a torsion angle of 4.2° in the C(37)–P(1)–Sb(1)–C(1) array. The ^{31}P NMR spectrum displays a singlet at 543 ppm which is 77 ppm upfield from Mes*P=SbCH(SiMe$_3$)$_2$ (620 ppm),[4,6] which demonstrates the shielding effect of the bulky terphenyl substituent. In the solid state **2**, which also has a *trans* conformation, has an As–P bond distance of 2.134(2) Å. The As–C bond distance is 1.975(6) and C–As–P and C–P–As angles are 101.4(2)° and 96.7(2)° respectively. These parameters are in reasonable agreement with the only other structurally characterized analogue Mes*P=AsCH(SiMe$_3$)$_2$[4,6] which has an

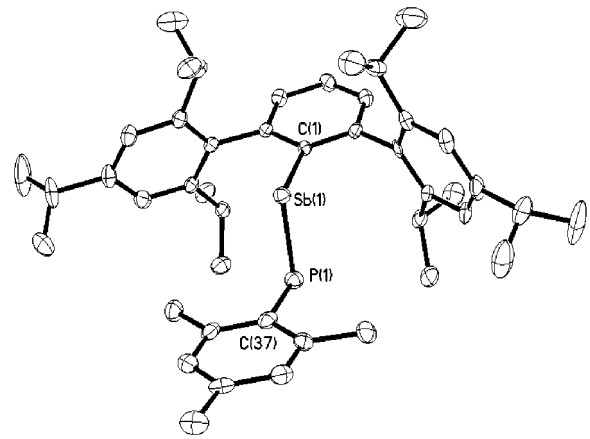


Fig. 1 ORTEP diagram of the structure of **1** (30% probability). H atoms omitted for clarity.

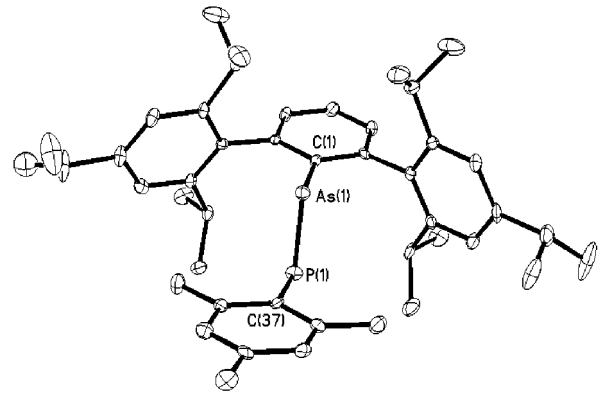

Fig. 2 ORTEP diagram of the structure of **2** (30% probability). H atoms omitted for clarity.

As–P distance of 2.125(1) Å, and C–As–P, C–P–As angles of 101.35(9)°, 96.37(9)°. **2** has a torsion angle of 3.2° for the array C(37)–P(1)–As(1)–C(1). The ^{31}P NMR spectrum of **2** shows a sharp singlet at 534 ppm which is 41 ppm upfield from that of Mes*P=AsCH(SiMe$_3$)$_2$ (575 ppm) and is almost identical to those of (Me$_3$Si)$_2$CHP=AsMes* (533 ppm),[6] and ArP=AsAr (537 ppm) Ar = 2,6-dimesityl-4-methylphenyl.[7a]

The As–P and Sb–P bonds are *ca.* 8% shorter than the calculated covalent single bond distances (2.33 and 2.54 Å)[9] which indicates considerable double bond character. The percentage shortening is comparable to that seen in symmetrical double bonded compounds.[2] In addition **1** and **2** display bond angles of 100.9(2) and 101.35(9)° at antimony and arsenic and narrow angles of 95.7(3) and 96.7(2)° at the phosphorus atoms. The wider angles at arsenic and antimony are somewhat surprising but are probably due to the larger size of the aryl substituents at these atoms. It may be noted that the angles at all the pnictogens are considerably smaller than would be expected for approximately sp^2 hybridization, indicating a concentration of s-character in the lone pair orbitals.

The electronic spectra for **1** and **2** each exhibit two absorption maxima, 512 nm (ε 373), 397 nm (ε 3417) and 467 nm (ε 216), 356 nm (ε 2477) respectively. The spectrum of **2** closely matches those of Mes*P=AsCH(SiMe$_3$)$_2$ [454 nm (ε 280), 353 nm (ε 7500],[4] and ArP=AsAr [463 nm (ε 870), 385 nm (ε 9549) (Ar = 2,6-dimesityl-4-methylphenyl)], [7a] whereas the spectrum of **1** shows a characteristic red-shift for double-bond systems of heavier group 15 elements as seen in *e.g.* ArSb=SbAr,[5a] 599 nm (ε 170), 466 nm (ε 5200) and ArBi=BiAr,[5b] 660 nm (ε 100), 525 nm (ε 4000), where Ar = C$_6$H$_2$-2,4,6-{CH(SiMe$_3$)$_2$}$_3$.

The reaction of 2,6-Trip$_2$H$_3$C$_6$BiCl$_2$ with either Li$_2$PMes or H$_2$PMes with DBU does not lead to the formation of the bismuth analogue MesP=BiC$_6$H$_3$-2,6-Trip$_2$. Instead, the purple symmetrical dibismuthene 2,6-Trip$_2$H$_3$C$_6$Bi=BiC$_6$H$_3$-2,6-Trip$_2$ is formed. The details of this structure as well as those of the corresponding distibenes, diarsenes, and diphosphenes will be reported in the near future.

We thank the National Science Foundation for financial support.

A macrocyclic [60]fullerene–porphyrin dyad involving π–π stacking interactions

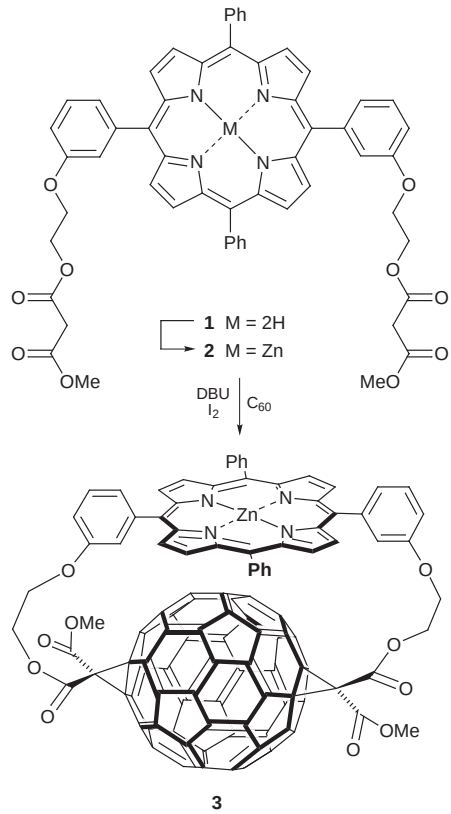
The very regioselective twofold cyclopropanation of C_{60} with a porphyrin bismalonate leads to a C_2 symmetrical [60]fullerene–porphyrin dyad with pronounced electronic interactions between the two π–π stacked chromophores.

In a project aimed at the synthesis of stereochemically defined architectures involving fullerene and porphyrin building blocks[1] we became interested in the development of a model compound with a face-to-face arrangement of the two π-systems and an electronic interaction between the two chromophores. In order to achieve this goal, we decided to restrict the conformational freedom within a dyad by introducing two covalent linkages *via* a tether controlled synthesis[2] with the porphyrin itself being an integral part of the tether.

For this purpose we synthesized the bifunctionalized porphyrin **1** using a mixed aldehyde approach (Scheme 1).[3] Benzaldehyde, 3-[2-(methoxymalonyloxy)ethoxy]benzaldehyde and pyrrole were stirred with $BF_3{\cdot}Et_2O$ as catalyst and Ph_4PCl in CH_2Cl_2 for one hour. After the addition of chloranil the mixture was refluxed for another hour. Separation of **1** from other reaction products required repeated purification with column chromatography (silica gel, CH_2Cl_2–ethyl acetate 20 : 1). The free base porphyrin was converted into the metallated compound **2**† by stirring with $ZnCl_2$ in refluxing acetone. **2** was attached to C_{60} *via* a twofold cyclopropanation achieved by the action of iodine and DBU.[4] This bisaddition proceeds with outstanding regioselectivity, since next to uncharacterized oligomeric material, bisadduct **3** with a *trans*-2 addition pattern (out–out isomer[2]) was formed as the only regioisomer (HPLC) and isolated in 41% yield by flash chromatography (silica gel, toluene–ethyl acetate 9 : 1).



3

Scheme 1

The dyad **3** was completely characterized‡ allowing for an unambiguous structure assignment. The symmetry of **3** is C_2. This is clearly reflected by the splitting of the porphyrin signals to a doublet, for example four signals instead of two observed in **2** for the β-pyrrole C atoms at 131.74, 131.79, 132.03 and 132.08 ppm. Moreover, the C_2 symmetric binding of the tether is revealed by only one signal for the equivalent methoxy protons at 53.87 ppm, two signals for the two different carbonyl groups at 163.49 and 163.53 ppm, two signals for the two different sp^3-C atoms at 70.06 and 70.72 ppm and 26 resolved signals for the 28 different sp^2-C atoms of the fullerene core. Next to the *cis*-**3** and *trans*-**3** adducts (with in–in or out–out bridging and C_2 symmetry) the depicted structure of **3** is the only one consistent with the NMR spectra. The correct structure assignment of **3** as the *trans*-**2** out–out isomer was provided by a combination of molecular mechanics calculations and UV/VIS spectroscopy: (1) the other C_2 symmetric isomers are inaccessible for this tether (MM+ force field), since their strain energy is considerably higher; (2) each addition pattern gives rise to a characteristic electronic absorption spectrum in both the visible and the UV part.[5] The latter is not covered by the absorptions of the porphyrin moiety and therefore the presence of a *trans*-2 addition pattern within **3** is unambiguously revealed by the comparison with the UV/VIS spectra of a variety of series of corresponding bisadducts.[5]

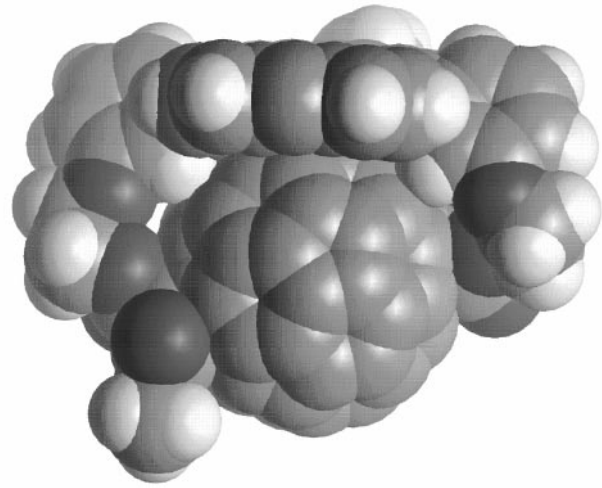


Fig. 1 Space-filling model of the PM3 (Spartan 4.1) calculated structure of **3**. The *meso*-phenyl ring in the front is omitted for clarity.

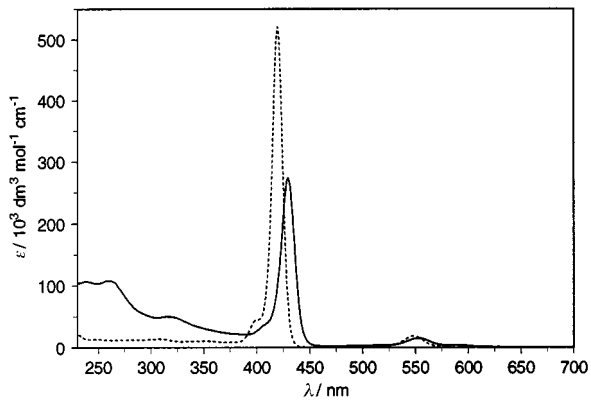

Fig. 2 Electronic absorption spectra of **2** (dashed line) and **3** in CH_2Cl_2 at $c = 3.5 \times 10^{-6}$ mol dm^{-3}.

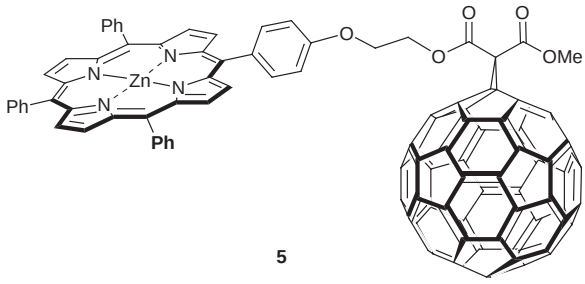
In the MM+ minimized structure of **3** (Fig. 1) the average distance between the four pyrrole N atoms and the Zn atom of the macrocycle and their nearest neighbours on the fullerene moiety is 3.4 Å. The shortest distance between the Zn atom and a fullerene C atom is only 3.0 Å and therefore even shorter than the interplanar distance in graphite.

Electroanalytical investigations on **3** using cyclic voltammetry and differential pulse voltammetry reveal two oxidative and six reductive electron transfer processes which are also present in either the parent porphyrin **2** or the *trans*-2-bis(diethylmalonate) **4**.[5] Only slight shifts, for example of 16 mV, to a more negative potential for the first porphyrin oxidation are detected.§ Compared with **2** the Soret- and Q-bands of **3** show a bathochromic shift and decrease of the molar absorption coefficients indicating a considerable photoinduced interaction between the two chromophores (Fig. 2). Also photophysical analyses of **3** reflect the close proximity and stacking interaction between the corresponding π-systems. Time-dependent luminescence measurements reveal a complete quenching of the typical porphyrin fluorescence with a maximum at about 500 nm which is present in the monoadduct dyad **5**.[1] However, a



5

new luminescence band at 850 nm was found. The luminescence intensity increases with decreasing temperature. The luminescence decay can be fitted double exponentially with the decay times $\tau_1 = 2.84$ ns and $\tau_2 = 0.42$ ns. The relative amplitudes of the decay times were calculated to be 2.12 : 1. This, together with a complete lack of photosensitized $^1O_2$ generation typical for porphyrins,[6] C_{60} and many of its derivatives,[7] suggests an efficient photoinduced energy transfer from the porphyrin to the fullerene.

Detailed comparative investigations on electron and energy transfer processes of **3** and related systems including those with different central metals and additional addends like electron acceptors and dendrimers are currently under way.

We thank the 'Volkswagen Stiftung' for financial support.

Rhodium catalysed diboration of unstrained internal alkenes and a new and general route to zwitterionic [$L_2Rh(\eta^6$-catBcat)] (cat = 1,2-$O_2C_6H_4$) complexes†

Chaoyang Dai,[a] Edward G. Robins,[b] Andrew J. Scott,[c] William Clegg,[c] Dmitri S. Yufit,[b] Judith A. K. Howard[b] and Todd B. Marder*[a,b]

[a] *Department of Chemistry, University of Waterloo, Waterloo, Ontario, N2L 3G1, Canada*
[b] *Department of Chemistry, University of Durham, Durham, UK DH1 3LE. E-mail: Todd.Marder@durham.ac.uk*
[c] *Department of Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU*

Reactions of [L_2Rh(acac)] (L = alkene or phosphine) with B_2cat_3 yield the zwitterionic complexes [$L_2Rh(\eta^6$-catBcat)] and [(acac)Bcat] cleanly; [(dppm)Rh(η^6-catBcat)], the X-ray structure of which is reported, is an excellent catalyst for the diboration of vinylarenes and unstrained internal alkenes *cis*- and *trans*-stilbene and *trans*-β-methylstyrene.

Catalysed 1,2-diborations of alkynes, 1,4-diboration of 1,3-dienes and α,β-unsaturated ketones, as well as additions of B–Si and B–Sn bonds to alkynes, α,ω-diynes and enynes have been the subject of a recent review.[1] These reactions are catalysed by platinum or palladium complexes and usually a single catalytic pathway leads to a single product. In contrast, the catalysed diboration of alkenes can lead to up to nine products owing to the competition between B–C reductive elimination and β-hydride elimination from the L_nM(Bcat)[CHRCHR′(Bcat)] intermediate formed by alkene insertion into the M–B bond. Initially, we examined[2] [(dppb)Rh(η^6-catBcat)], [dppb = $Ph_2P(CH_2)_4PPh_2$] an outstanding hydroboration catalyst,[3] for the addition of B_2cat_2 to 4-vinylanisole and obtained the desired 1,2-diboration product 4-$MeOC_6H_4CH$(Bcat)CH_2(Bcat) in 44% yield. The remaining products included 23% of 4-$MeOC_6H_4CH$(Bcat)CH_3 and 22% of the unusual 2,2,2-tris(boronate) ester 4-$MeOC_6H_4CH_2C$(Bcat)$_3$, both arising from intermediates generated by the β-hydride elimination process. A catalyst system composed of [$AuCl(PEt_3)$] + $Cy_2P(CH_2)_2PCy_2$ gave exclusive formation of the 1,2-bis(boronate) ester; however, catalyst activity and stability were lower than desired. Miyaura and coworkers[4] reported the addition of B_2pin_2 (pin = $OCMe_2CMe_2O$) to terminal alkenes and cyclic alkenes having internal ring strain using a catalytic amount of $Pt(dba)_2$ at 50 °C, but attempts to diborate internal alkenes such as stilbene were unsuccessful. Iverson and Smith[5] reported similar results using $Pt(cod)_2$ or $Pt(norbornene)_3$ as catalyst precursors at ambient temperatures. Clean diboration was observed for norbornene and norbornadiene, but not for other internal alkenes, apparently as a result of complications arising from β-hydride elimination. In addition, neither of the base-free Pt systems is appropriate for modification with chiral ligands. We report herein the first catalyst system capable of diborating internal alkenes including *cis*- and *trans*-stilbene, and *trans*-β-methylstyrene without significant by-products.

Several zwitterionic [$L_2Rh(\eta^6$-catBcat)] complexes had been prepared previously[3] by addition of HBcat to either [$L_2Rh(\eta^3$-2-Me-allyl)] or [L_2Rh(acac)] precursors; however, with L = arylphosphine the reaction had to be carried out under hydroboration conditions (*i.e.* in the presence of excess alkene and HBcat) in order to isolate the [(dppb)Rh(η^6-catBcat)] cleanly. In addition, this approach is obviously inappropriate for L_2 = $(alkene)_2$ or diene. We have now found that reactions (Scheme 1) of [L_2Rh(acac)] with B_2cat_3 yield quantitatively the zwitterionic complexes [$L_2Rh(\eta^6$-catBcat)] [L_2 = $(C_2H_4)_2$ **1a**, $(C_8H_{14})_2$ **1b**, cod **1c**, $(PPh_2Me)_2$ **1d**, dppm **1e**, dppe **1f**, dppp = $Ph_2P(CH_2)_3PPh_2$ **1g**, dppb **1h**, dppf = 1,1-bis(diphenylphosphino)ferrocene **1i**] and (acac)Bcat **2** as evidenced by ^1H, ^{11}B, and ^{31}P NMR spectroscopy, full details of which will be reported elsewhere.

Scheme 1 Synthesis of zwitterionic rhodium complexes

Of particular interest is the fact that 4 mol% of [(dppm)Rh(η^6-catBcat)] **1e**,‡ prepared *in situ* from [(dppm)Rh(acac)] and B_2cat_3 in THF, and whose molecular structure§ is shown in Fig. 1, catalyses the diboration of (addition of B_2cat_2 to) vinylarenes, norbornene and the

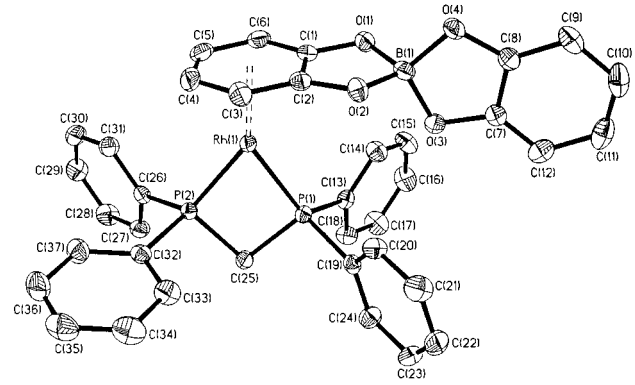

Fig. 1 View of the molecular structure of [(dppm)Rh(η^6-catBcat)] **1e** with ellipsoids shown at 50% probability and H atoms omitted for clarity. Selected distances (Å) and angles (°) Rh(1)–P(1) 2.2332(5), Rh(1)–P(2) 2.2134(5); P(1)–Rh(1)–P(2) 72.938(17).

Table 1 [(acac)Rh(dppm)]/B_2cat_3-catalyzed diboration of alkenes[a]

Entry	Alkene	Product	Time/h	Yield(%)
a			2	87
b			2.5	77
c			1	79
d			6	>99
e			30	>99
f			<72	92
g			<72	>99

[a] All reactions were carried out in THF or [$^2H_8$]THF at room temp. in the presence of 4 mol% catalyst [(acac)Rh(dppm)]/B_2cat_3, and alkene : B_2cat_2 = 1:1; product yields determined by ^1H and ^{13}C NMR spectroscopy.

unstrained internal alkenes *cis* and *trans*-stilbene and *trans*-β-methylstyrene at room temp. (Table 1).¶ *Syn*-addition of the B_2 unit to the alkene was evident in the NMR spectra of the norbornene diboration product (entry d). A crystal structure§ of the *trans*-stilbene diboration product (entry f) is also consistent with *syn*-addition. The disorder observed in the crystal structure results from the apparent superposition in space of the two enantiomers of the racemic compound; attempts to solve the structure based on the *meso*-model gave an unreasonable central C–C bond length. Likewise, in CD_2Cl_2, the signal for the unique benzylic C–H proton at δ 3.71 is distinct from that for the *cis*-stilbene diboration product (entry g) which occurs at δ 3.78 the latter thus being assigned to the *meso* compound. Diboration of *trans*-β-methylstyrene (entry e) proceeds in >99% yield,¶ generating two adjacent and distinct chiral carbon centres.

Significantly reduced hapticity of the π-coordinated catecholate must be required in order to generate vacant sites for alkene and B–B activation. Although reaction times were found to be somewhat longer than in THF, the diborations can also be carried out in less polar C_6D_6 suggesting that complete dissociation into L_2Rh^+ and $[Bcat_2]^-$ is unlikely. The success of the dppm based catalyst system compared with the dppb system indicates that the relative rates of B–C reductive elimination *vs*. β-hydride elimination are a sensitive function of the bite angle of the chelating phosphine ligand.

This is the first report of the catalysed diboration of unstrained internal alkenes and of an efficient phosphine-containing catalyst system for alkene diboration. Further work will examine the mechanism of the reaction, the diboration of other unsaturated substrates and the use of chiral bis(phosphine)-containing zwitterionic Rh complexes for asymmetric diboration reactions.

Catalytic asymmetric Diels–Alder reactions of α-thioacrylates for the preparation of norbornenone

Varinder K. Aggarwal,*[a]† Emma S. Anderson,[a] D. Elfyn Jones,[a] Kerstin B. Obierey[a] and Robert Giles[b]

Cu^{II}–bisoxazoline complexes catalyse the asymmetric Diels–Alder cycloaddition of α-thioacrylates with cyclopentadiene to give the cycloadducts in up to 92% yield, 88% de and >95% ee for the *endo* product; deprotection gives good yields of (1*S*,4*S*)-norbornenone with high enantioselectivity.

The catalytic asymmetric Diels–Alder reaction has been an area of considerable interest over the last two decades and a large number of metals, ligands and dienophiles have been studied.[1–4] The most successful systems have common features associated with them: a bidentate ligand which complexes to the metal and a dienophile which acts as a two point binder to the ligand–metal complex.[5–7] Two point binding of both the ligand to the metal and dienophile to the complex results in limiting the number of accessible conformations of the dienophile bound to the Lewis acid and can result in high enantioselectivity.

We have been interested in developing ketene equivalents for Diels–Alder reactions[8] and have therefore sought dienophiles that could be easily converted to carbonyl compounds. To achieve good levels of enantioselectivity we also needed dienophiles that could act as two point binders to appropriate metals. α-Thioacrylates seemed ideal for our purpose as it was known that α-methylthioacrylates underwent Diels–Alder reactions with cyclopentadiene, for example, and that the adducts could be readily converted into norbornenones.[9–11] Such dienophiles may also act as two point binders to appropriate metals through carbonyl and sulfur coordination. We therefore prepared a range of α-thioacrylates.[12] We chose copper as the metal due to its known propensity to bind to both the sulfide and ester moieties and as ligands we chose bisoxazolines[13,14] due to the success of copper–bisoxazoline complexes in Diels–Alder reactions.[15–25]

Diels–Alder reactions were conducted between cyclopentadiene and the various acrylates[26] using the copper bisoxazoline complex **8**[27] (Scheme 1) and the results are shown in Table 1.

It was found that the selectivity of the Diels–Alder reaction was highly dependent on the nature of the ester and thio substituent. Higher selectivity was obtained with phenylthio- compared to methylthio-acrylates (entries 1 and 3) and higher selectivity was obtained with small or moderately sized ester substituents [Me, Et, Pr^i >> Bu^t (entries 2, 3, 6, 8 and 9)]. The Bu^t ester was much less reactive than the other esters and the reaction had to be conducted at 0 °C (entry 8). This presumably was the cause of the reduction in enantioselectivity. Higher selectivity was obtained at lower temperature (compare entries 3 and 4) and the use of cationic complexes[16] led to high reactivity even at −78 °C (entries 5 and 7) and high *exo*/*endo* selectivity as well as high enantioselectivity. The optimum reagents and conditions required ethyl α-phenylthioacrylate as dienophile, the cationic phenyl-substituted bisoxazoline–cop-

per complex, and reaction at −78 °C in CH_2Cl_2 (entry 5); under these conditions good diastereoselectivity and essentially complete enantioselectivity was observed.

Conversion of the α-phenylthio ester to a carbonyl group was initially problematic. Hydrolysis of the ester to the acid occurred efficiently but attempts to convert the α-phenylthio acid **10** to the carbonyl group using NCS was unsuccessful. This reagent had previously been used to convert an α-methylthio acid to a carbonyl group.[9] We were eventually successful using a different strategy: instead of activating the sulfide we activated the acid and reacted the α-phenylthio acid with diphenylphosphoryl azide[28] and obtained the corresponding ketone **11** directly in high yield and with 88% ee[29] (Scheme 2). The lower enantioselectivity observed for **11** is due to the presence of the *exo* isomer in **10**.

A transition state involving bidentate binding of the dienophile *via* sulfur and the carbonyl oxygen to a square planar Cu^{II} complex[15,16,21,23,24,30,31] may be used to rationalise the enantio- and diastereo-selectivities. However, the high enantioselectivity observed is perhaps surprising as the alkene of the dienophile lies close to the C_2 axis of the metal catalyst where it encounters the minimum steric influence from the phenyl groups of the oxazoline moiety. Indeed, all successful dienophile–metal–oxazoline combinations place the alkene moiety directly over one of the oxazoline substituents where it has maximum influence on the enantioselectivity of the reaction.[32] In our case we believe that the substituent on sulfur plays a major role in controlling enantioselectivity. We believe there is very high diastereoselectivity in formation of the dieneophile–metal–oxazoline complex (only one of the two enantiotopic lone pairs binds to the copper) and it is the orientation of the sulfur substituent which controls the facial attack on the dienophile (Fig. 1). This substituent is forced below the plane of the complex and when this group is large it effectively blocks the *Si* face of the dienophile and therefore forces the diene onto the *Re* face. From analysis of molecular models, the opposite enantiomer would be expected if the dienophile was bound to Cu in a tetrahedral arrangement. This provides further circumstantial evidence for a square planar complex.

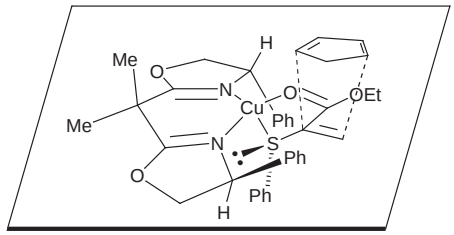

Fig. 1 The dienophile–metal–oxazoline complex

The size of the ester group of the dienophile is critical; an excessively bulky group may prevent the essential two-point binding, as seems to be the case with *tert*-butyl. Equally, the substituent on sulfur of the dienophile is also critical. Although the same discrimination between the lone pairs on sulfur may be observed with the *S*-methyl substituted dienophile, the methyl group is not sufficiently sterically hindering to effectively block the *Si* face to approach of the diene component, resulting in significantly reduced enantioselectivity in this case.

We thank the EPSRC and SB for a CASE award (E. A.), the European Union and Sheffield University for additional support. We thank Ian Davies (Merck) for valuable discussions.

Stereoselective and N-terminal selective α-alkylation of peptides using a pyridoxal model compound as a chiral N-terminal activator

Kazuyuki Miyashita, Hiroshi Iwaki, Kuninori Tai, Hidenobu Murafuji and Takeshi Imanishi*†

Graduate School of Pharamceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565-0871, Japan

Stereoselective and N-terminal selective α-alkylation of peptides is achieved using a pyridoxal model compound as an N-terminal activator which also functions as a chiral auxiliary.

Peptides containing unnatural amino acid(s) are gathering much attention because of their biochemical and medicinal properties. Although such peptides are generally synthesized by sequential coupling of the respective amido acids prepared independently,[1] several methods for the direct modification of peptides have also been reported.[2–4] Most of these methods, however, deal with the alkylation of peptides at sites other than the N-terminal position and seem to lack generality. In addition, their stereoselectivities depend on the stereochemistries of the peptides employed and are not always sufficient.[2,3] In contrast, direct N-terminal modification of peptides appears to be of great utility for the synthesis of peptides including unnatural amino acids, particularly where applied to combinatorial chemistry, as both liquid- and solid-phase peptide syntheses are generally achieved by sequential coupling from a C-terminal amino acid. O'Donnell and co-workers recently reported an interesting method utilizing this idea: direct N-terminal selective α-alkyltion of peptides *via* imine formation.[4] The only serious problem with their method is the lack of stereoselectivity. If the α-alkylation takes place with predictable stereoselectivity, this method would be more useful and versatile. In order for this method to be applicable to the synthesis of various peptides with predictable stereochemistry, it is desirable that the stereoselectivity of the α-alkylation is induced only by an external chiral auxiliary, and is not influenced by the neighbouring chiral centre on the peptide sequence. Here we report a useful method for N-terminal selective and stereoselective α-alkylation of peptides using a chiral pyridoxal model compound bearing an ionophore function.

Taking into account the application of the reaction not only to liquid-phase synthesis but also to solid-phase synthesis, we investigated the benzylation of the aldimines prepared from L-Ala-NHBn and some chiral pyridoxal models under various conditions.‡ As a consequence, we found that the reaction with pyridoxal model **1** having a chiral ansa-structure§ in the presence of $LiClO_4$[5] and DBU was the most effective for the present purpose and stereoselectively afforded the α-benzylated product (*R*)-**4** (X = NHBn) and recovered **1** (79%) after an acidic treatment (run 1 in Table 1 and Scheme 1).

These conditions were employed for the alkylation of peptides **2** (X = AA-OBn) and the results are summarized in Table 1.¶ The peptide-aldimine **3** (X = L-Ala-OBn) prepared from L-Ala-L-Ala-OBn and **1** was also stereoselectively benzylated at the N-terminal position without any detectable racemisation at the C-terminal α-position *via* these sequential reactions (run 2).‖ As expected, the stereochemistry at the N-terminal α-position was not related to the stereoselectivity at all (run 3). In order to examine the influence of the stereogenic centre at the neighbouring C-terminal α-position on the stereoselectivity of the alkylation, dipeptides L-Ala-Gly-OBn, L-Ala-L-Val-OBn, L-Ala-D-Ala-OBn, and L-Ala-D-Val-OBn were chosen as substrates. The reaction of peptides without a stereogenic centre or with a bulkier alkyl group at the C-terminal position similarly gave good *R*-stereoselectivity (runs 4 and 5). Moreover, in the reactions of the peptides having a D-amino acid at the C-terminal position, the same predominantly *R*-configuration was gained with slightly lower stereoselectivity (runs 2 *vs.* 6 and 5 *vs.* 7). It is noteworthy and quite significant that neither the stereochemistry nor the size of the

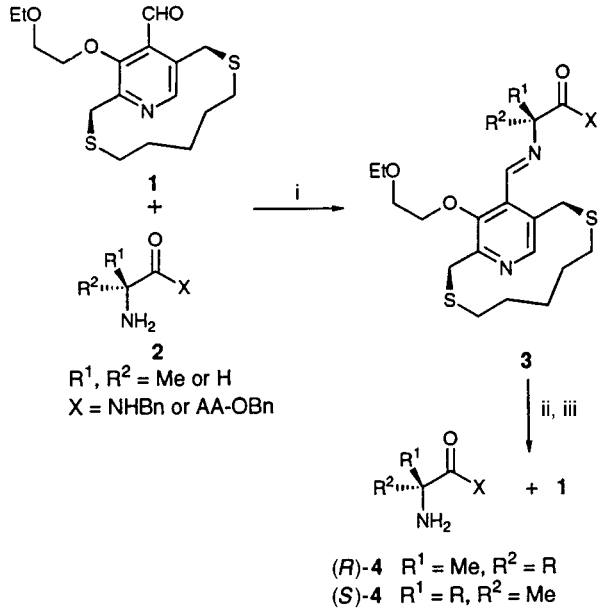
[a] Isolated yield based on substrate **2**. [b] The stereochemistries of the products (*R*)- and (*S*)-**4** (X = L-Ala-OBn) were confirmed by comparing with an authentic sample (*S*)-**4** (X = L-Ala-OBn) prepared from L-Ala and (*S*)-(α-Bn) Ala-OBn, which had been obtained using our previous method (ref. 5). The stereochemistries of other products **4** were assigned as shown from their (*R*)-MTPA amides by comparing their ^1H and ^{19}F NMR data with those of the (*R*)-MTPA amide of authentic (*S*)-(α-Bn)Ala-L-Ala-OBn and (*S*)-(α-Bn)Ala-OBn. Excepting runs 1 and 4, the ratio was determined from the ^1H NMR spectra. In the runs 1 and 4, the ratios were determined from the ^1H and ^{19}F NMR spectra of the corresponding (*R*)-MTPA amides.



Scheme 1 *Reagents and conditions*: i, CH_2Cl_2, room temp.; ii, RBr, $MClO_4$, DBU, MeCN, 0 °C; iii, $TsOH·H_2O$, AcOEt, room temp., 30 min

substituent at the C-terminal α-position of the peptides affected the stereoselectivity. In addition, alkylation with other alkyl bromides proceeded successfully with similar stereoselectivities (runs 8–10). Tripeptide L-Ala-L-Ala-L-Ala-OBn was also stereoselectively benzylated under the same conditions (run 11). These findings show that compound **1** can work as an external chiral auxiliary as well as an N-terminal activator, at least in the synthesis of peptides with neutral amino acids at the neighbouring position.

Interestingly, the reaction without Li^+ or with other alkali metal ions was found to show the reverse stereoselectivity (runs 12–14). Concerning the reaction mechanism, ^1H NMR analysis of the peptide-aldimine **3** in the absence and presence of Li^+ revealed that the rotation of the C4–C4′ bond shown in Fig. 1 was induced only by the addition of Li^+.[5] The stereoselectivities obtained in the absence and presence of Li^+ appear to be attributable to these preferred conformations. Although the detailed mechanism has yet to be determined, predominant attack of the electrophile on the enolates from the side of the ansa-loop (*i.e.* upper side in Fig. 1) in the respective conformations could explain the stereoselectivities.**

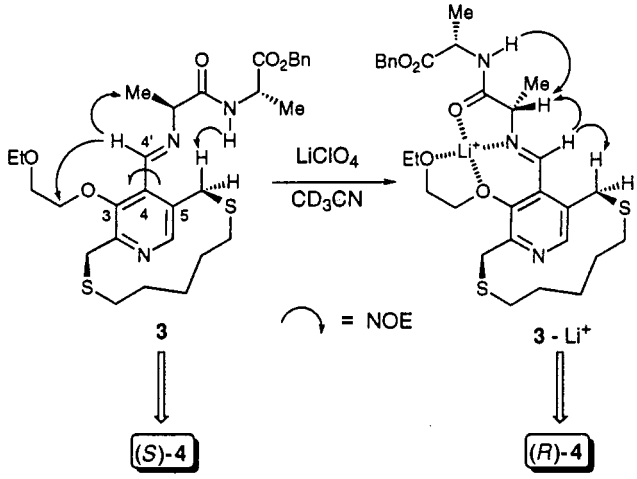


Fig. 1 Selected NOE data for **3** in the absence and presence of Li^+

In the present study, we have demonstrated the first example of stereoselective and N-terminal selective α-alkylation of peptides using a chiral pyridoxal model as an N-terminal activator which also functions as a chiral auxiliary. This α-alkylation reaction could be incorporated into standard sequential peptide syntheses, and could provide a novel method for the stereoselective synthesis of unnatural peptides, in particular, for construction of unnatural peptide libraries.††

‡ Although we first applied the pyridoxal model compound and the reaction conditions which had previously been effective for the asymmetric alkylation of α-amino esters (ref. 6) to this reaction, the desired stereoselectivity was not obtained. Hence, reactions with pyridoxal models having a chiral ionophore chain at C-3 and/or a chiral ansa-structure in the presence of various organic bases and metal ions were examined. Details will be reported in a full article.

§ The pyridoxal derivative **1** was synthesized from the 3-hydroxy derivative (ref. 7) according to the literature procedure (refs. 5, 6).

¶ *General procedure*: The peptide-aldimine was prepared according to the previously described procedure (ref. 5). To a stirred solution of peptide-aldimine **3** (0.10 mmol) and $LiClO_4$ (32.2 mg, 0.30 mmol) in MeCN (1 ml) was added DBU (29.9 μl, 0.20 mmol) at 0 °C. After stirring for 5 min at the same temperature, BnBr (13.2 μl, 0.11 mmol) was added and the mixture was stirred at 0 °C for the period indicated in Table 1. The reaction mixture was diluted with AcOEt (10 ml) and washed with cold water and cold brine. To the organic layer, $TsOH·H_2O$ (38.6 mg, 0.20 mmol) was added and the mixture was stirred for 30 min at room temperature and partitioned with Et_2O and water. The Et_2O phase was worked-up as usual and the residue was purified by SiO_2 column chromatography (AcOEt–hexane = 1 : 2) to give recovered **1** (70–80%). The aqueous phase was basified with $NaHCO_3$ and extracted with AcOEt. Usual work-up and purification with SiO_2 column chromatography (AcOEt) yielded the benzylated peptide **4**.

‖ This was confirmed by the fact that the (*R*)-MTPA amide derived from the benzylated dipeptide was shown to be a mixture of only two diastereomers based on the N-terminal α-position by ^1H and ^{19}F NMR analyses.

** The ansa-loop could push the other substituents out of the side of the ansa-loop and consequently make the other side crowded, which might allow the electrophile to approach from the same side of the ansa-loop. See also ref. 8.

Zirconocene-catalysed cyclobutene formation by reaction of alkynyl halides with EtMgBr

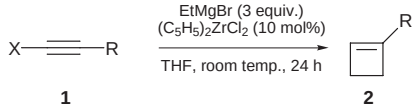
Kayoko Kasai,[a] Yuanhong Liu,[b] Ryuichiro Hara[b] and Tamotsu Takahashi*[b]†

[a] *Department of Chemistry, Miyagi University of Education, Sendai 980, Japan*
[b] *Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060, Japan*

Zirconium-catalysed reaction of alkynyl halides with EtMgBr produced cyclobutene derivatives in which two carbon–carbon bonds were formed on the ethyl moiety of EtMgBr *via* an ethylene group in a catalytic cycle.

The zirconium-catalysed reaction of olefins with EtMgBr was first reported as an ethylmagnesation reaction by Dzhemilev.[1] Recently, we found that the reaction proceeds *via* a zirconocene–ethylene complex and a zirconacycle.[2,3] However, so far the ethyl moiety of EtMgBr has only been incorporated in products as an ethyl group in the catalytic reaction with olefins[1–4] or acetylenes.[5] There has been no example in which two carbon–carbon bonds were formed on the ethyl moiety in the catalytic cycle in the strict sense, even though it is converted into an ethylene group in the cycle. We report here the first example of the formation of two carbon–carbon bonds to the ethyl moiety of EtMgBr in a catalytic cycle.

Typically, when 1 mmol of 1-chlorooct-1-yne **1a** was treated with a catalytic amount of $(C_5H_5)_2ZrCl_2$ (10 mol%) and 3 equiv. of EtMgBr in THF (5 ml) at room temperature for 24 h, 1-hexylcyclobutene **2a** was formed in 61% yield [eqn. (1)].



1 **2** (1)

Table 1 shows the results of cyclobutene formation reactions under the catalytic conditions. The choice of halogen on the terminal carbon of the alkynes was important. 1-Bromo- and 1-iodo-alkynes did not give cyclobutenes under these conditions; only metal–halogen exchange products were formed. The yields were also dependent on the amount of EtMgBr, and the use of 3 equiv. was found to be suitable in all the cases for the catalytic reactions. Interestingly, when a diyne dichloride **1c** was treated under similar conditions, a bridged dicyclobutenyl product **2c** was obtained.

This reaction was interesting due to the fact that an alkynyl chloride and ethylene derived from EtMgBr reacted formally in a [2 + 2] cycloaddition with the loss of halogen. In order to understand this catalytic reaction, we also carried out stoichiometric reactions.[6] The results are shown in Table 2. A typical procedure is as follows. To a solution of $(C_5H_5)_2ZrCl_2$ (0.37 g, 1.25 mmol) in THF (6 ml) was added EtMgBr (1.0 M THF solution, 2.5 mmol) at −78 °C. The reaction mixture was warmed up to −40 °C and stirred for 1 h. To the mixture was added 1-chlorooct-1-yne at −78 °C. The mixture was stirred for 1 h at room temperature. After stirring for 1 h, the reaction mixture was quenched with 3 M HCl and the usual workup gave 1-hexylcylobutene in 80% yield. The same products were obtained under both catalytic and stoichiometric conditions; however, under the latter conditions the reaction proceeded much faster. It is noteworthy that the intermolecular coupling of the chloroalkyne moieties with ethylene derived from EtMgBr

Table 1 Formation of cyclobutenes under catalytic conditions[a]

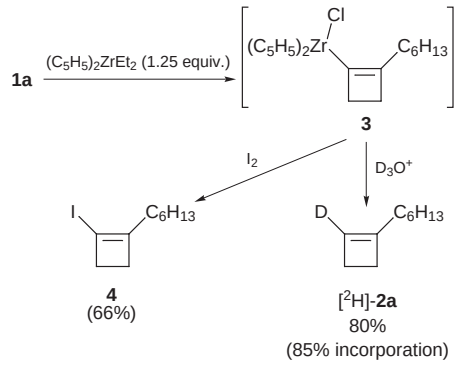
XC≡CR	Product	Yield[b] (%)
1a	 **2a**	61
1b	 **2b**	51
 **1c**[c]	 **2c**	54
 **1d**	 **2d**	50

[a] Unless otherwise noted, $(C_5H_5)_2ZrCl_2$ (10 mol%) and EtMgBr (3 equiv.) were used for the catalytic reactions. Conditions: room temperature, 24 h. [b] Yields were determined *via* GC using hydrocarbons as internal standards. [c] $(C_5H_5)_2ZrCl_2$ (20 mol%) and EtMgBr (6 equiv.) were used.

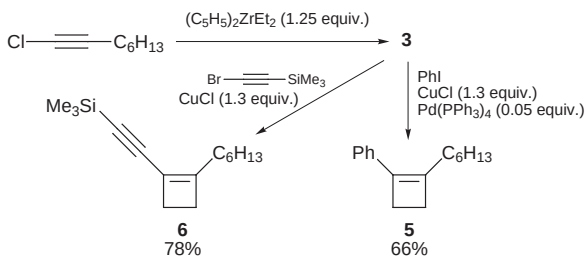
Table 2 Formation of cyclobutenes under stoichiometric conditions[a]

XC≡CR	Product	Yield[b] (%)
1a	**2a**	80 (80)
	**2a**	66
	**2a**	60
1b	**2b**	83
1c[c]	**2c**	89[d] (60)
1d	**2d**	80[d] (50)
 **1e**	 **2e**	40

[a] Unless otherwise noted, $(C_5H_5)_2ZrCl_2$ (1.25 equiv.) and EtMgBr (2.5 equiv.) were used for the stoichiometric reactions. Conditions: room temperature, 1 h. [b] Unless otherwise noted, yields were determined *via* GC using hydrocarbons as internal standards. [c] $(C_5H_5)_2ZrCl_2$ (2.5 equiv.) and EtMgBr (5 equiv.) were used. [d] Yield was determined by NMR analysis. Isolated yields are given in parentheses.



Scheme 1



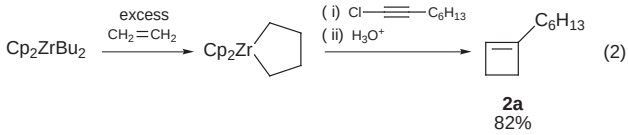
Scheme 2

predominated over the intramolecular coupling of an alkynyl group with an olefin moiety, or the second alkynyl group when **1c**–**e** were used.

Deuterolysis of the stoichiometric reaction mixture gave [^{2}H]-**2a** in 80% yield with 85% deuterium incorporation. Iodinolysis gave a 66% yield of iodocylobutene **4**. These results suggest that the intermediate is cyclobutenylzirconium **3** (Scheme 1).

Since the intermediate **3** contains a zirconium–carbon bond, the further carbon–carbon bond formation reactions of alkenylzirconium compounds were examined (Scheme 2). To a stoichiometric reaction mixture of **1a** and $(C_5H_5)_2ZrEt_2$ prepared *in situ* from $(C_5H_5)_2ZrCl_2$ and 2 equiv. of EtMgBr were added iodobenzene, CuCl (1.3 equiv.) and $Pd(PPh_3)_4$ (0.05 equiv.). The mixture was stirred at 50 °C, and 1-hexyl-2-phenylcyclobutene **5** was obtained in 66% overall yield based on **1a**. Similarly, treatment of **3** with 1-bromo-2-trimethylsilylacetylene and CuCl (1.3 equiv.) gave alkynylcyclobutene **6** in 78% yield. This procedure is a convenient preparative method for various 1,2-disubstituted cyclobutenes.

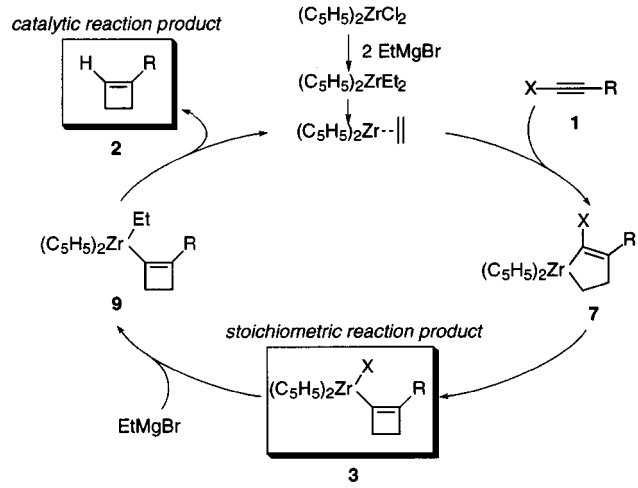
Introducing ethylene gas to a solution of the Negishi reagent (Cp_2ZrBu_2)[7] and subsequent addition of a 1-chloroalkyne also gave cyclobutene **2a** in good yield as expected [eqn. (2)]. This



(2)

clearly showed that ethylene and the ethyl moiety of EtMgBr are equivalent in the carbon–carbon bond formation described above.

A plausible mechanism of the catalytic cyclobutene ring formation is shown in Scheme 3. The zirconocene–ethylene complex reacts with haloalkyne **1** to form α-halozirconacyclopentene **7**, which undergoes a ring-closing reaction to give cyclobutenyl–zirconocene complex **3**. This ring-closing reaction might proceed *via* reductive elimination of



Scheme 3

zirconacyclopentenes[6] and oxidative addition of the alkenyl chloride moiety to zirconocene.[8] The ethylene complex is regenerated by the reaction of **3** with EtMgBr to complete the catalytic cycle.

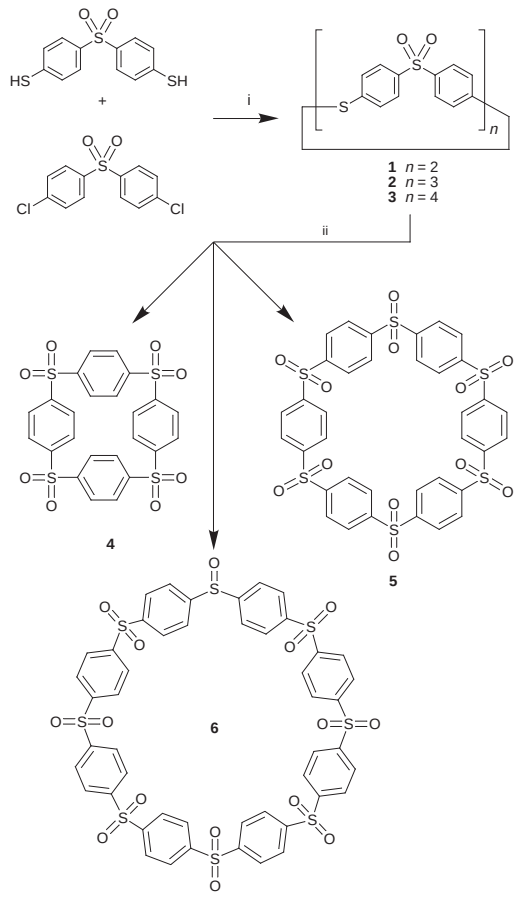
Sulfone-linked paracyclophanes

Ian Baxter,[a] Howard M. Colquhoun,[b]*† Philip Hodge,[c]*‡ Franz H. Kohnke*[c]§¶ and David J. Williams*[a]‖

[a] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*
[b] *Department of Chemistry, University of Salford, Salford, UK M5 4WT*
[c] *Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*

Oxidation of the macrocyclic thioether sulfones $(S\phi SO_2\phi)_n$ (ϕ = 1,4-phenylene; n = 2 or 3) affords sulfone-linked paracyclophanes $(\phi SO_2)_4$ and $(\phi SO_2)_6$; single crystal X-ray analysis reveals the tetramer, $(\phi SO_2)_4$, to be a near-perfect square box, whilst the hexamer, $(\phi SO_2)_6$, adopts a much more irregular conformation; exhaustive oxidation of $(S\phi SO_2\phi)_4$, leads not to the expected octamer, $(\phi SO_2)_8$, but to the heptasulfone sulfoxide $[(\phi SO_2)_7(\phi SO)]$.

The recent discovery of a route to macrocyclic aromatic thioether sulfones containing from four to (at least) 24 aromatic rings has opened up the possibility of converting these, by oxidation, to their all-sulfone analogues (Scheme 1).[1] The strongly electron-withdrawing nature of the sulfone group compared to the electron-donating thioether linkage offers the potential to create a new family of π-electron deficient receptors which, unlike those based on bipyridinium systems,[2] would obviate the need for counterions. Moreover, the exceptionally rigid nature of the diphenyl sulfone unit, coupled with its preferred 'open-book' conformation,[3] should provide a high degree of pre-organisation in any non-covalent complexation process. From a materials perspective, these all-sulfone macrocycles could provide a new approach (ring-opening polymerisation)[4] to the extremely stable but very high-melting and currently unprocessable linear poly(1,4-phenylene sulfone).[5]



Scheme 1 *Reagents and conditions*: i, K_2CO_3, DMA, 150 °C, 48 h; ii, H_2O_2, AcOH, 60 °C

Here we report that peroxide oxidation of the macrocyclic thioethersulfones **1** and **2** in glacial acetic acid does indeed afford the sulfone-linked paracyclophanes **4** and **5** (sulfur analogues of the known [1.1.1.1]paracyclophane and [1.1.1.1.1.1]paracyclophane, respectively).[6] Oxidation of **3** cannot however be driven to completion under these conditions,** the reaction ceasing at the heptasulfone sulfoxide stage (**6**) rather than affording the expected cyclic octasulfone.

The symmetrical aromatic substitution pattern in macrocycles **4** and **5** results in the observation of only a *single* ^{1}H NMR resonance (δ 8.21) for each compound, replacing the AA′BB′ pattern associated with the 1,4 sulfide sulfone substitution patterns of **1** and **2**. However, in keeping with the presence of a sulfoxide linkage in **6**, the ^{1}H NMR spectrum of this material comprises an AA′BB′ system integrating as two aromatic rings, together with a single resonance representing the remaining six rings, at δ 8.21, superimposed on the lower field component. Confirmation that compound **6** is a single oxidation product (rather than a mixture) was provided by the unchanging ratio of the integration values in its ^{1}H NMR spectrum on repeated recrystallisation from DMA, and by MALDI-TOF mass spectrometry of **6** (anthracene-1,8,9-triol matrix, LiBr as cationising agent) which showed a strong parent ion at *m/z* 1111, corresponding to $[(C_6H_4SO_2)_7(C_6H_4SO)Li]^+$.

The solubilities of macrocycles **4** and **6** in conventional organic solvents are very low indeed and, although ^{1}H and ^{13}C NMR spectra of **4** were obtained (with some difficulty) in [$^2H_6$]DMSO solution, a solvent mixture of TFA and CD_2Cl_2 was required to obtain NMR spectra of compound **6**. The cyclic hexamer **5**, in contrast, was easily soluble in a wide range of organic solvents including $CHCl_3$ and acetone.

In order to establish the conformational characteristics of the diaryl sulfone unit as a function of ring size, single crystal X-ray structures were determined for **4** (DMSO solvate), **5** (acetone

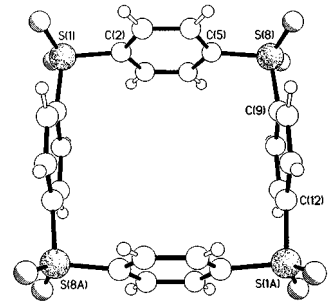


Fig. 1 Molecular structure of the cyclic tetrasulfone **4**. There is a very slight tilting from orthogonality of the aromatic rings with respect to the S_4 plane; the C(2)–C(7) ring is inclined at 86° and the C(9)–C(14) ring at 89° to this plane.

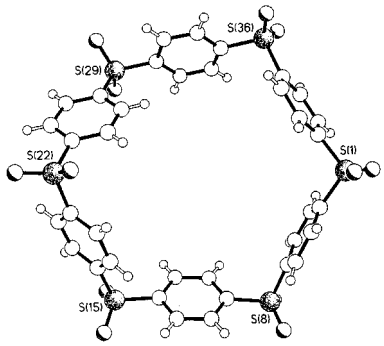

Fig. 2 Molecular structure of the cyclic hexasulfone **5**. Torsion angles about the S–phenyl linkages are in the range 45–88°, with the exception of an 8° torsion angle at S(29).

solvate) and **6** (DMSO solvate).†† The C–S–C bond angles in **5** and **6** lie very close to the conventional unstrained value[3] of 105° but in the effectively *square* cyclic tetramer **4** (Fig. 1) these angles are sharply reduced to an average value of 99.5°. Commensurate distortions are evident in the aromatic ring systems, which in **4** undergo a distinct outward bowing such that 1,4-related C–S bonds, which would normally be co-linear, here subtend angles averaging 10°. In contrast, the aromatic rings of oligomer **5** (Fig. 2) are bowed *inwards*, with the corresponding angle averaging −7.5°.

Remarkably, the structure of compound **6** in fact represents that of the originally-expected octasulfone [(1,4-$C_6H_4SO_2)_8$]. It thus appears that, when oxidation reaches the heptasulfone sulfoxide stage, this compound is able to crystallise *as though it were* the octasulfone, with the 'missing' oxygen atom being disordered over all sixteen possible sites. In keeping with the identification of macrocycle **6** as a *pseudo*-octasulfone, the average crystallographic occupancy of the oxygen atoms in the molecule refined to a value significantly less than one (*ca.* 0.96; *cf.* a calculated value of 0.94 for 15/16 occupancy). Macrocycle **6** adopts a 'figure-of-eight' conformation (Fig. 3) which is essentially strain-free, the two halves of the molecule each approximating the box-like structure of oligomer **4**. Contacts between the sulfone oxygen atoms at S(22) and S(22A) are avoided by a relative shearing of the two sides of the macrocycle, though there is evidence for weak but co-operative C–H···O hydrogen bonding interactions between these sulfone oxygens and transannular C–H groups (Fig. 3).

The cyclic tetramer **4** provides a rare example of a structurally characterised organic molecular square.[7] The mutually orthogonal orientation of the four aromatic rings results in a cylindrical free pathway through the macrocycle (based on van der Waals surfaces) of diameter *ca.* 3.3 Å. The presence of this electrophilic binding site suggests the possibility of complexation with first-row anions such as fluoride or cyanide, and of rotaxane formation with linear, electron-rich species such as the polyalkynes. Complexation studies with **4** are currently in progress.

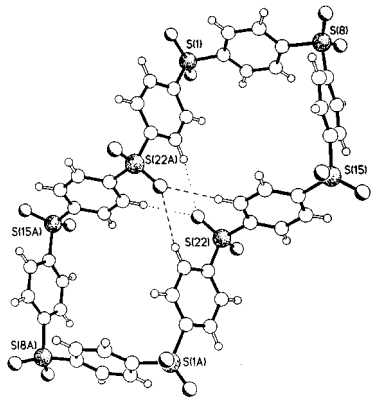

Fig. 3 Molecular structure of the cyclic *pseudo*-octasulfone **6** showing the transannular C–H···O interactions; the two independent sets of C–O and H–O distances and C–H···O angles are: 3.46 and 2.53 Å, 176°; 3.58 and 2.65 Å, 170°

We wish to thank Mr P. R. Ashton of the University of Birmingham for the MALDI-TOF mass spectrometric analysis, and the EPSRC for financial support.

The synthesis of a biotinylated pyrrole and its copolymerization with pyrrole for the purpose of constructing an electronic conducting polymer (ECP) avidin sensor is reported, using fluorescence detection to determine the efficiency of the sensing process.

Electronic conducting polymers (ECP) have many interesting features that make them ideal candidates for sensing devices, and have thus became the subject of many investigations. In addition to their ease of electrodeposition, these polymers can be functionalized by insertion of specific moieties[1] that provide desirable features such as the selective recognition of alkaline cations.[2] The application of ECP in the field of sensors has also been extended to biological species,[3–5] including DNA, peptides and enzymes. The detection of these species is based on the specific recognition between a biological moiety that is inserted in the ECP film, and its complementary target in solution. The subsequent recognition is detected either by radioactive labels,[5] or by a significant change in the electrochemical[3,4] or spectrochemical response[6] of the ECP.

An important aspect of these biosensors is the immobilization of desired biological species in the ECP film. This has been accomplished by the entrapment of the species in the polymer matrix during electrodeposition, and by the use of grafted monomers which are then copolymerized with ungrafted monomers. In the case of the former, the electropolymerization conditions must be compatible with the stability of the biomolecule; in addition for the latter case, specific conditions must be developed for each of the grafted species. These approaches were successfully carried out for the construction of DNA biochips.[7]

A recent approach for immobilization is postpolymerization functionalization. In this case, a two-step chemical procedure is needed. First, starting monomers with an activated ester are grafted onto the polymer that will form the ECP film. Secondly, after electrodeposition the biological species is covalently coupled to the hanging ester *via* a reactive amino group.[8]

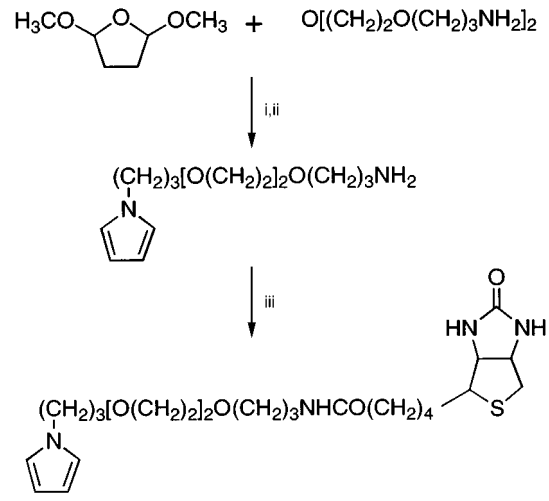
Here we report an original approach for the insertion of biochemical entities in the ECP film *via* the synthesis of a biotinylated polypyrrole. Because of the biotin–avidin affinity, biochemical entities bearing avidin units can bind to the biotin units grafted on the polypyrrole network. This approach allows immobilization of biomolecules on the ECP surface in an easy one-step process, without the use of harsh chemical reagents, since the biotin–avidin system requires only mild immobilization conditions.

The biotinylated polypyrrole film described here is a copolymer electrosynthesized from pyrrole and biotinylated pyrrole, in which the biotin is linked to the nitrogen atom of a pyrrole unit by a hydrophilic spacer arm. The choice of this spacer arm is crucial. It has to be long enough to ensure unrestricted recognition of the biotin by avidin, and a length of eleven atoms or more is deemed necessary.[9] In addition, its chemical composition is important in order to guarantee solubility during the preparation of the active layer, and to achieve good solvation of biotin in order to optimize the recognition. We thus selected a spacer with a hydrophobic/hydrophilic balance originating from three oxygen atoms and ten methylene groups.

The synthesis of the biotinylated pyrrole (Scheme 1) is achieved by coupling an aminoalkylpyrrole and a biotin entity. The aminoalkylpyrrole synthesis was carried out using the reaction pathway described by Jirkowsky and Baudy.[10] While the yields we obtained were consistent with the reported values for the ethanediamine, the equivalents of diamine and the reflux time were increased from 1 to 3 equiv. and 1 to 5 h, respectively. In the second step, the amino group was reacted with the activated ester of biotin to produce the biotinylated pyrrole in 54% yield after purification by column chromatography.

The copolymerization of the film was carried out on microelectrodes (50×50 μm) arrayed on a silicon chip, using different ratios of biotinylated pyrrole to pyrrole monomers (from 5×10^{-3} to 5×10^{-7}). The presence and activity of biotin to avidin was verified by incubating the film with streptavidin–phycoerythrin (Aldrich) and measuring the fluorescence using a microscope equipped with a DCC camera. We used a conjugate between streptavidin and a fluorescent phycobiliprotein, namely R-phycoerythrin, in order to maximize fluorescence and to minimize quenching. The support was previously washed by a phosphate buffer then blocked by Denhardt's reagent‡ in order to avoid non-specific adsorption of the avidin; proteins[11,12] are readily adsorbed onto polypyrrole surfaces without this pretreatment.

The results of these measurements on the microelectrode array are summarized in Fig. 1. The intensity of the fluorescence



Scheme 1 *Reagents and conditions*: i, 4,7,10-trioxatridecane-1,13-diamine (3 equiv.), AcOH, dioxane, reflux, 5 h, 32%; ii, 10% KOH, reflux, 5 h, 65%; iii, D-biotin *N*-hydroxysuccinimide ester (1equiv.), DMF, room temp., 16 h, 54%

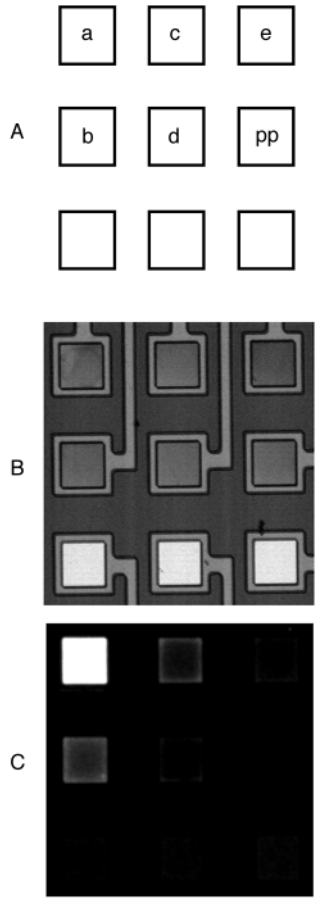


Fig. 1 (A) Pattern of the biotin repartition on the microelectrode array. Electrosyntheses were carried out at 100 mV s^{-1} by repetitive potential scans between −0.35 and 0.85 V *vs.* SCE of 20 mM pyrrole and a decreasing amount of biotin pyrrole with a synthesis charge of 18 mC cm^{-2} (about 60 nm thickness) in 0.1 M $LiClO_4/H_2O$ containing 3% of MeCN on microelectrodes (50 × 50 μm^2) arrayed on a silicon chip. Biotinylated polypyrrole synthesized in presence of (a) 100, (b) 10, (c) 1, (d) 0.1 and (e) 0.01 μM of biotin pyrrole respectively; (pp) = polypyrrole. Each electropolymerization was followed by a thorough washing step and blocking step (see text). (B) Differential interference contrast view of microelectrodes to check the effective deposition of a biotinylated polypyrrole film on the plots. (C) Fluorescence results after a revelation process using a solution of streptavidin–R-phycoerythrin followed by washing in a phosphate buffer.

is related to the amount of biotin involved in the copolymerization reaction and yields the amount of accessible biotin at the surface of the film. The measured fluorescence intensity decreased with a decreasing biotinylated pyrrole to pyrrole ratio. Taking the area marked (a) as the standard, the intensity decreased to 18 and 10.5% of this value when the ratio was decreased to 1:10 and 1:100 [areas (b) and (c)], respectively. In the case of the pure polypyrrole film [without biotin, indicated by region (pp) in Fig. 1(A)], a weak fluorescence was still observed, but only about 2% of the value for (a) and noticeably weaker than the thousand-fold dilution. This indicates that the immobilization of the avidin conjugate on the different dots is specific of the biotin–avidin interaction.

In conclusion, we have reported a simple way of preparing an ECP active layer that is capable of the recognition of avidin conjugates, which would facilitate study of the behavior of many commercial biomolecules. Indeed, this system is very versatile due to the availability of a wide variety of avidin conjugates, which would allow for the elaboration of a large number of biosensors. However, in order to use this sensor on real biological samples, the signal/noise ratio should be increased. In addition, this method has the advantage of miniaturization *via* the use of electrochemical addressing of the electrodeposition.

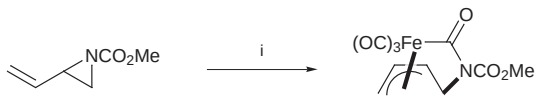
A new route to functionalised π-allyltricarbonyliron lactam complexes from aziridines and their use in stereoselective synthesis and oxidative conversion to β-lactams

Steven V. Ley*† and Ben Middleton

Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW

Aziridinyl enones can be converted in good yield into π-allyltricarbonyliron lactam complexes bearing ketone functionality in the side chain; addition of a variety of nucleophiles into the side chains of these complexes proceeds in good yield and excellent (> 95%) de to afford secondary and tertiary alcohols which on treatment with trimethylamine *N*-oxide form the corresponding β-lactams in good yield.

π-Allyltricarbonyliron lactam complexes have been previously investigated as precursors to stereodefined β- and δ-lactams,[1] and have been utilised in the synthesis of several natural products in our laboratory.[2] Previous preparation of these complexes involved the treatment of π-allyltricarbonyliron lactone complexes with a primary amine[3] or the sonochemical reaction of an alkenyl carbamate with $Fe_2(CO)_9$.[2a] In an isolated example, Aumann has also shown that UV irradiation of the vinyl aziridine **1** in the presence of $Fe(CO)_5$ leads to the formation of a π-allyltricarbonyliron lactam complex **2** in 71% yield (Scheme 1).[4]

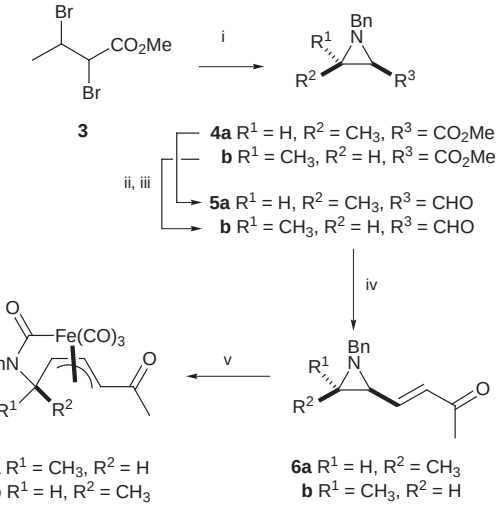


1 **2**

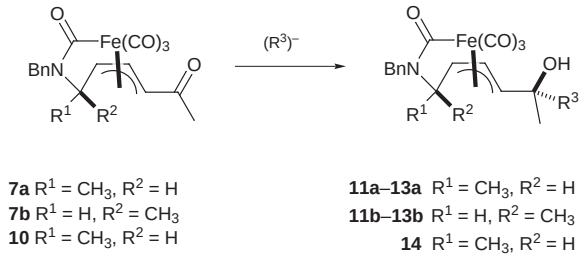
Scheme 1 *Reagents and conditions*: i, $Fe(CO)_5$, benzene, *hν*, 71%

We have additionally demonstrated that ketone functionalised π-allyltricarbonyliron lactone complexes, available from epoxy enone precursors, are versatile chiral templates for organic synthesis.[5] Here we show that the corresponding π-allyltricarbonyliron lactam complexes may be prepared from functionalised alkenyl aziridines by treatment with $Fe_2(CO)_9$ under ultrasonication.[6] This allows the rapid, large scale synthesis of π-allyltricarbonyliron lactam complexes bearing carbonyl functionality in the side chains and facilitates investigation into the potential of these lactam-tethered π-allyltricarbonyliron units as chiral templates. We also show that oxidative decomplexation of the stereodefined alcohols generated by diastereoselective addition of nucleophiles to ketone-bearing π-allyltricarbonyliron lactam complexes can be effected by treatment with trimethylamine *N*-oxide, providing an efficient route to highly functionalised β-lactams.

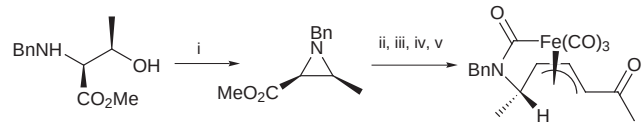
Racemic enones **6a**,**b** were synthesised in a four step sequence from a known common precursor, dibromo ester **3**[7] (Scheme 2). Treatment of **3** with excess $BnNH_2$ in boiling benzene[8] afforded a 1:1 mixture of methyl esters **4a**,**b** which were separated by flash column chromatography. Reduction with $LiAlH_4$ and Swern oxidation[9] of the crude product yielded the aldehydes **5a**,**b**. Horner–Wadsworth–Emmons coupling with diethyl (2-oxopropyl)phosphonate[10] afforded **6a**,**b** respectively in good yield. Sonication of **6a** in benzene in the presence of nonacarbonyldiiron afforded the *exo*-lactam complex **7a** in good yield, with only a small proportion of the chromatographically separable isomeric *endo* complex **7b** being formed (dr 14:1). Similarly, treatment of enone **6b** under the same conditions yielded a 10:1 ratio of **7b** and **7a** in 77% yield.



Scheme 2 *Reagents and conditions*: i, $BnNH_2$, benzene, reflux, 16 h, then chromatographic separation, 35% (**4a**), 35% (**4b**); ii, $LiAlH_4$, Et_2O, 0 °C, 2 h; iii, $(COCl)_2$, Me_2SO, NEt_3, CH_2Cl_2, −70 °C, 3 h, 63% (**5a**), 56% (**5b**) (over 2 steps); iv, $(EtO)_2P(O)CH_2COMe$, NaH, THF, 0 °C, 10 min, 91% (**6a**), 83% (**6b**); v, $Fe_2(CO)_9$, benzene, sonication, 30 °C, 3 h, 68% (dr 14:1) (**7a**), 77% (dr 10:1) (**7b**)



Enantiomerically enriched *exo* complex **10** could be synthesised in five steps from enantiomerically enriched methyl ester **9** (Scheme 3), accessible *via* cyclisation of the known L-threonine derivative **8**.[11] Reaction as above afforded *exo*



Scheme 3 *Reagents and conditions*: i, PPh_3, CCl_4, MeCN, 25 °C, 16 h, 83%; ii, $LiAlH_4$, Et_2O, 0 °C, 2 h; iii, $(COCl)_2$, Me_2SO, NEt_3, CH_2Cl_2, −70 °C, 3 h, 59% (over 2 steps); iv, $(EtO)_2P(O)CH_2COMe$, NaH, THF, 0 °C, 10 min, 83%; v, $Fe_2(CO)_9$, benzene, sonication, 30 °C, 3 h, 68% (dr 18:1)

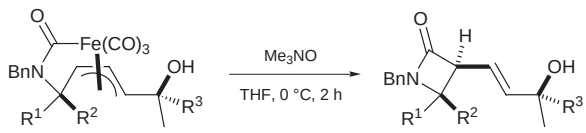
complex **10** in > 95% ee [determined by 200 MHz ^{1}H NMR spectroscopy in the presence of the chiral shift reagent (+)-Pr(hfc)$_3$].[12]

In order that the addition of nucleophiles to the ketone group in the sidechain proceeds with high diastereocontrol, it is necessary that the tricarbonyliron group blocks one face of the carbonyl group, thus forcing approach of the nucleophile to occur from the opposite side, and that the ketone adopts only one reactive conformation. The solution conformation of complex **7b** was investigated by the use of NOE experiments. These results clearly show that the s-*cis* conformation is adopted preferentially (Fig. 1). These results are consistent with earlier studies carried out on π-allyltricarbonyliron lactone complexes.[5a] Reaction of complexes **7a**,**b** with a variety of nucleophiles (Table 1) afforded the addition products **11a–13a** and **11b–13b** in good yield and excellent diastereoselectivity (de > 95%).[13] Reduction of enantiomerically enriched **10** with $NaBH_4$ to form alcohol **14** proceeded in 76% yield without loss of enantiopurity, as determined by 600 MHz ^{1}H NMR analysis of the ester formed with (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride.[14]

Furthermore, it was discovered that treatment of complexes **11–13** with excess Me_3NO in THF at room temperature affords the functionalised β-lactams **15–17** in good yield (Table 2). This result is an improvement over the published method of oxidative decomplexation with ceric ammonium nitrate[3] which



11–13 **15–17**

Table 2 Decomplexation of functionalised π-allyltricarbonyliron lactam complexes to β-lactams

Starting material	R^1	R^2	R^3	Product	Yield (%)[a]

13a	Me	H	allyl	**17a**	54
13b	H	Me	allyl	**17b**	69

[a] Isolated yield after treatment with excess Me_3NO in THF at 0 °C for 2 h, followed by chromatography on Florisil.

has given markedly lower yields of β-lactams with this type of substrate.[15]

In summary, a convenient route to racemic and homochiral π-allyltricarbonyliron lactam complexes bearing ketone functionality in the side chain has been developed. It has been shown that the tethered tricarbonyliron moiety is able to direct nucleophilic attack on an appended methyl ketone group, affording complexes bearing secondary and tertiary alcohol functionality in good yield and with excellent diastereoselectivity. A novel oxidative decomplexation method allows the generation of highly functionalised β-lactams bearing stereodefined secondary and tertiary alcohol centres. These results should extend further the utility of π-allyltricarbonyliron complexes for natural product synthesis.

We gratefully acknowledge financial support from the EPSRC, the Isaac Newton Trust and Zeneca Pharmaceuticals (to B. M.) and the BP Endowment and the Novartis Research Fellowship (to S. V. L.).

UV-induced strand break damage in single stranded bromodeoxyuridine-containing DNA oligonucleotides

Zara A. Doddridge, Jane L. Warner, Paul M. Cullis* and George D. D. Jones*†

Centre for Mechanisms of Human Toxicity and the Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH

Aerobic UVB photolysis of single stranded bromodeoxyuridine (BrdU)-containing DNA oligonucleotides produces immediate and latent strand break products consistent with a specific BrdU base radical-mediated abstraction of the C1′ hydrogen atom from the 5′ neighbouring deoxyribose.

Substitution of genomic thymidine with bromodeoxyuridine (BrdU) renders aerobic cell cultures more sensitive towards the lethal effects of UV and γ-radiation.[1,2] One mechanism proposed to contribute to sensitisation is an increase in the yield of radiation-induced strand breaks caused by the presence of BrdU in DNA.[1,2] From examinations of the duplex structure it was initially proposed that the additional radiation-induced BrdU-mediated strand breakage occurs *via* the formation of reactive uracil(U)-5-yl base radicals, which in turn abstract hydrogen atoms from the 5′ neighbouring deoxyribose.[2,3] Subsequent molecular studies have indeed demonstrated that under anaerobic conditions UV photolysis of BrdU-containing DNA yields both immediate and latent (alkali labile) breaks at the nucleosides 5′ to the site of BrdU.[4–7] To date, however, there have been few definitive molecular studies of BrdU-mediated DNA strand breakage in the presence of oxygen[8] (conditions under which cellular sensitisation is observed) and none in single-stranded DNA.

Here we have examined immediate and alkali-induced strand break products from a 5′- or 3′-^{32}P-end labelled single stranded (*ss*) BrdU-containing DNA oligonucleotide upon UVB photolysis (*ca*. 0.41 mW cm^{-2}), using high resolution denaturing polyacrylamide gel electrophoresis (PAGE). The strand break products were assigned by reference to the products of Maxam and Gilbert reactions,[9] and by enzymatic end-group analysis. Aerobic UVB photolysis of 5′-GCTAGCTATT-BrdU-TTATC-GATCG-3′ **1** results in specific strand cleavage at the nucleoside situated immediately 5′ to BrdU and proceeds with the loss of this 5′-nucleoside. Thus, photolysis of **1** yields a strand break product **6** nine nucleotides in length [Fig. 1(*a*)] together with a strand break product **7** eleven nucleotides in length [Fig. 2(*a*)] (Scheme 1). Co-migration of the photo-induced fragments with products of Maxam and Gilbert reactions implies the presence of phosphate moieties at both termini of the induced breaks. This was confirmed by demonstrating that **6** was a substrate for the 3′-phosphatase activity (+3′P) of T4 polynucleotide kinase (T4PNK), yielding **8** [Fig. 1(*b*)], and that **7** was a substrate for the 5′-phosphatase activity of shrimp alkaline phosphatase (SAP), yielding **9** [Fig. 2(*b*)] (see also Scheme 1).

Piperidine treatment of photolysed **1** yields an approximate five-fold increase in the yield of **6** [Fig. 1(*c*)] suggesting that the majority of BrdU-mediated damage induced at the 5′-nucleotide are alkali labile lesions and not immediate strand breaks.[2,10] This observation of the majority of piperidine-induced breaks occurring at exactly the same location as immediate breaks, and yielding the same 3′-termini, implies a common mechanistic route for both types of strand break at this site. This is consistent with H-atom abstraction occurring from C1′ of the 5′-deoxyribose leading the formation of a deoxyribolactone lesion within the oligonucleotide (**5**)[11] and a small number of direct breaks possessing phosphate termini,[12,13] although the precise mechanism for the direct strand break pathway remains to be elucidated. Structure **5** is sensitive to the strand cleaving effects of alkali and subsequent piperidine treatment would yield further breaks possessing phosphate termini.[11] Interestingly, piperidine treatment of photolysed **1** also appears to produce minor fragmentation about the BrdU moiety possibly the consequence of an induced diffusible species giving rise to piperidine sensitive lesions.

UV illumination under anaerobic conditions yields higher levels of strand breakage plus a markedly different pattern of 3′-termini damage, consisting of both phosphates and other unidentified moieties [Fig. 2(*c*)]. It is known from other studies that generation of a C1′ radical under both oxic and anoxic conditions leads to immediate and latent strand breaks possessing phosphate termini, with release of the undamaged base and the damaged sugar (probably as methylenefuranone **10**).[11–13] The present observation of different end groups following anaerobic photolysis of *ss* BrdU-containing oligonucleotides indicates that, in the absence of oxygen, H-atom abstraction must occur from a site other than (or in addition to) C1′, presumably C2′. These observations are similar to those of Cook and Greenberg[7] for duplexed BrdU-oligonucleotides. On the basis of kinetic isotope measurements these workers

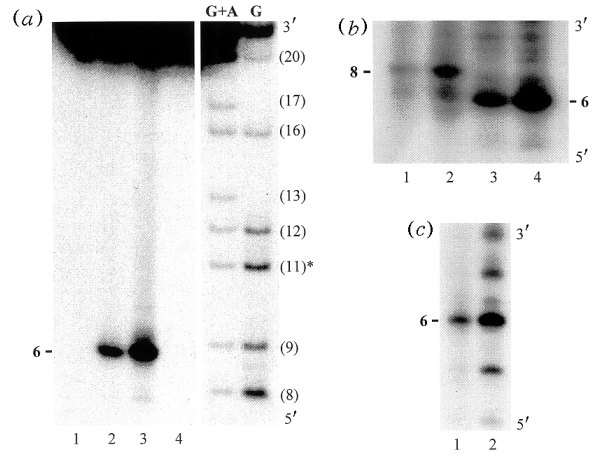

Fig. 1 Autoradiograms of the strand break products of 5′-^{32}P-labelled **1** upon aerobic photolysis and PAGE analysis. (*a*) Photolysis of **1** showing the specific formation of **6** (lane 1: no UV exposure; lane 2: 15 min UV; lane 3: 45 min UV; lane 4: nascent **1** (containing T in place of BrdU), 45 min UV); also shown are the fragment products of Maxam and Gilbert reactions specific for cleavage at G and G+A in 5′-GCTAGCTAGGTGGATCGATCG-3′; the bracketed numbers indicate fragment length with (*) indicating the location of BrdU in the BrdU-oligonucleotides. **(*b*)** Susceptibilty of **6** towards the 3′-phosphatase activity of T4 polynucleotide kinase (T4PNK) to give **8**. In these experiments the released strand break products were 5′-^{32}P-end labelled *after* photolysis using [γ-^{32}P]ATP plus T4PNK either possessing 3′-phosphatase activitity (+ 3′P) (from USB) or T4PNK lacking 3′-phosphatase activity (− 3′P) (from Boehringer Mannheim). {lane 1: 20 min UV + (+ 3′P); lane 2: 45 min UV + (+ 3′P); lane 3: 20 min UV + (− 3′P); lane 4: 45 min UV + (− 3′P)}. **(*c*)** Alkali lability of photolysed **1** revealing an enhanced formation of **6** upon piperidine treatment [lane 1: 15 min UV; lane 2: 15 min UV + piperidine (1 M, 90 °C, 30 min)].

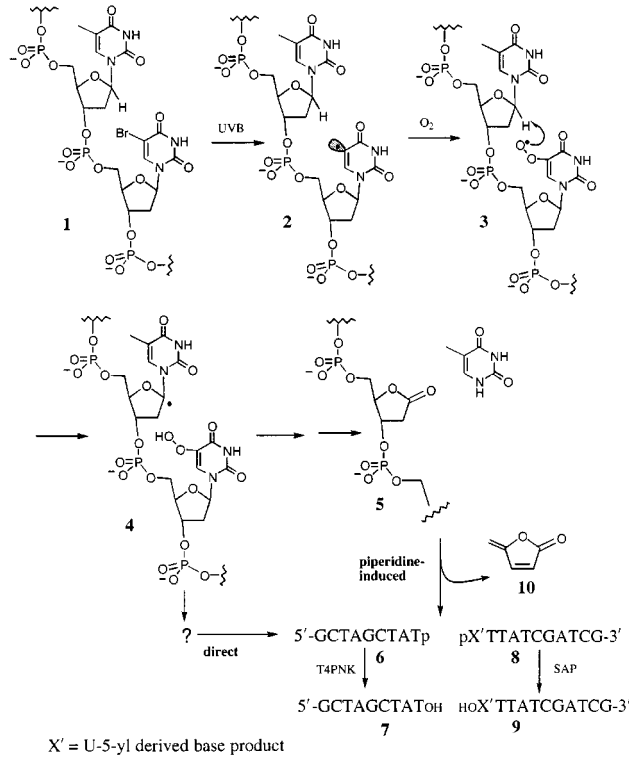
(*c*). Autoradiogram of the strand break products of 5′-^{32}P-labelled **1** upon aerobic or anaerobic photolysis and PAGE analysis. Photolysis of **1** showing the specific formation of **6** plus other unidentified products (denoted as **?**) (lane 1: 45 min UV, aerobic; lane 2: 45 min UV, anaerobic); also shown are the fragment products of Maxam and Gilbert reactions specific for cleavage at G and G+A in **1**; the bracketed numbers indicate fragment nucleotide length with (*) indicating the location of BrdU.



Scheme 1

conclude that under anaerobic conditions U-5-yl radicals abstract the C2′ hydrogen atom of the 5′-deoxyribose, ultimately yielding cleavage products containing 3′-phosphate and a labile 2′-deoxy-3′-ketonucleotide.[7] Clearly, if the anaerobic U-5-yl-mediated abstraction of C2′–H is occuring in our system then specific C2′ abstraction in duplexed BrdU-DNA is not simply a result of conformational effects imposed by the double helix, as it persists in *ss* systems under anaerobic conditions.

It is difficult to rationalise the aerobic abstraction of C1′–H and the anaerobic abstraction of C2′–H by simply evoking U-5-yl as being the sole abstracting species. We therefore propose that under anaerobic conditions it is the initial U-5-yl base radical that abstracts from a site other than C1′ (or a number of different sites), whilst under aerobic conditions the U-5-yl base peroxyl radical (U-5-yl-OO·), formed by the addition of oxygen to the 5-yl radical centre, mediates abstraction specifically from C1′ (Scheme 1).

Support for the above proposal, that in the presence of oxygen abstraction is from C1′, comes from the recent published observation of Greenberg *et al.* that direct strand breaks, mediated by the 5,6-dihydrothymid-5-yl radical in *ss* oligonucleotides in the presence of oxygen, proceed *via* the specific abstraction of the C1′ hydrogen atom by the corresponding base peroxyl radical species.[14] These authors also refer to their preliminary unpublished observations of C1′–H abstraction on photolysis of *ss* BrdU-oligonucleotides under aerobic conditions which directly supports our present observations.[14] Additional support for the specific abstraction of C1′–H by a peroxyl radical comes from calculations of enthalpies for H-atom abstraction in deoxyribose[15] which suggests that the C1′ may be the sole position from which a peroxyl radical could abstract.

Our observations are in broad agreement with those of Sugiyama *et al.*[8] who have demonstrated that under aerobic conditions it is the C1′ hydrogen atom which is predominatly abstracted in duplexed BrdU-containing oligonucleotides; however, they do not propose the base peroxyl radical intermediate as being formed and they propose some abstraction from C2′, both possibly resulting from constraints imposed by the more rigid duplex structure. Our present studies are continuing with examinations of duplexed BrdU-containing oligonucleotides, to investigate the effect of strandidness on BrdU-mediated radical reactions, and to allow for the examination of possible bi-strand lesions leading to double strand breaks and multiply damaged sites.[16]

Unusual results in the liquid phase alkylation of naphthalene with isopropyl alcohol over zeolite H-beta

Changqing He,[a] Zhongmin Liu,[a] François Fajula[b] and Patrice Moreau[b]*†

Unexpected compounds are formed with high selectivity in the liquid phase alkylation of naphthalene with isopropyl alcohol over large pore zeolite H-beta; these have been confirmed to be cyclized products from naphthalene derivatives.

2,6-Dialkylnaphthalenes are valuable compounds for the production of high-quality polyester fibres, plastics and thermotropic liquid crystal polymers.[1] Taking into account that these compounds are manufactured inefficiently by the nonselective alkylation of naphthalene over conventional Friedel–Crafts catalysts[2] or solid silica–alumina catalysts,[3] considerable attention has recently been paid to the development of new processes for the selective preparation of 2,6-dialkylnaphthalenes using environment-friendly zeolite catalysts. Owing to the steric hindrance of naphthalene, medium pore zeolites, such as HZSM-5, show moderate activity in naphthalene alkylation.[4,5] Large pore zeolites, such as Mordenite, beta, Y, and more recently mesoporous aluminosilicates, have been investigated. Alkylating agents bulkier than MeOH, such as isopropyl[5–9] or cyclohexyl derivatives[7,10] and butanol,[11,12] have been also applied successfully to the selective formation of 2,6-dialkylnaphthalenes. Among these studies, substantial advances have been made in naphthalene isopropylation for both the understanding of the alkylation mechanism and the design of catalysts leading to high selectivity in forming 2,6-diisopropylnaphthalenes.[5–9] H-beta has been shown to be more active and selective than HY in the alkylation of benzene with propylene[13] but did not demonstrate selectivity in the alkylation of polyaromatics until recently.[5,9,11,12] Nevertheless, it has been reported that H-beta shows an unexpected high selectivity for *sec*-butylbenzene in the alkylation of benzene with isobutyl alcohol.[14] In our search for suitable catalysts for the selective synthesis of 2,6-dialkylnaphthalenes, we have recently found another peculiar characteristic of H-beta zeolite in the liquid phase alkylation of naphthalene with isopropyl alcohol, in which a series of unexpected compounds were formed with high yield under given conditions. Here we report on the unusual results thus obtained and the identification of the new compounds.

Zeolite catalyst H-beta (Si/Al = 12.5) was obtained from PQ Corporation (CP 810 B-25). HY (Si/Al = 15) was prepared by standard ion-exchange, calcination, steam dealumination and acid leaching procedures from a parent synthetic zeolite. Activation of H forms was achieved by calcination at 773 K for 5 h with a heating rate of 60 K h^{-1} in a flow of dry air. The isopropylation of naphthalene was carried out in a 0.16 dm^3 stirred autoclave reactor (Parr Instrument Company). Under standard reaction conditions, 10 mmol of naphthalene, 20 mmol of Pr^iOH, 10 mmol of undecane as an internal standard sample and 0.1 dm^3 of cyclohexane as solvent were mixed together in the autoclave, and then freshly calcined zeolite (0.5 g) was added. The reaction temperature was set at 473 K and the pressure was maintained at 2 MPa with nitrogen. Samples were withdrawn periodically and analysed on a Varian Series 30 gas chromatography equipped with HP-5 capillary column (25 m) and a FID detector. GC–MS (HP5970) with an OV1 capillary column (25 m) and NMR (Brücker AC200) analysis were used for the identification of the new compounds.

Typical reaction results are listed in Table 1. The activity of H-beta is much lower than that of HY, as shown by the naphthalene conversion which reaches a maximum of 30% under standard reaction conditions, compared with 90% for HY. GC–MS analysis indicates that the new compounds have molecular mass (*m/z*) of 210, 252 and 292, respectively, different from the products usually obtained in naphthalene isopropylation over large pore zeolite catalysts[5–9] which are isopropylnaphthalene (IPN), diisopropylnaphthalene (DIPN), triisopropylnaphthalene (TIPN) and tetraisopropylnaphthalene (TetIPN) with molecular mass of 170, 212, 254 and 296, respectively. As shown in Table 1, H-beta possesses a peculiar catalytic function for the production of the new compounds. After 2 h, the selectivity (around 50 mol%) of total new compounds is higher than that of alkylated derivatives, mainly IPN (43 mol%). DIPN selectivity is unexpectedly low and no TIPN is detected. Such a result is totally different from those obtained by Chu and Chen[5] who used continuous fixed-bed reactor conditions. In agreement with previous results, HY zeolite shows a higher activity and selectivity for DIPN and TIPN than H-beta. It is observed that the new compounds are also formed over HY, but in much smaller amounts than over H-beta. Moreover, the distribution of the new compounds produced over the two zeolites are different. H-beta gives more than 80 mol% of '210' and less '252' or '292', while HY

Table 1 Reaction results of isopropylation of naphthalene over different zeolites at 473 K[a]

			Product distribution (mol%)					New compound distribution (mol%)			
Catalyst	*t*/h	Conv. (%)	IPN	DIPN	TIPN	New	Others[b]	'210'	'252'	'292'	'294'

[a] Reactions conditions: catalyst (0.5g), naphthalene (10 mmol), Pr^iOH (20 mmol), undecane (10 mmol), cyclohexane (100 ml), 2.0 MPa. [b] Others include methyl(isopropyl)naphthalene and ethyl(isopropyl)naphthalene

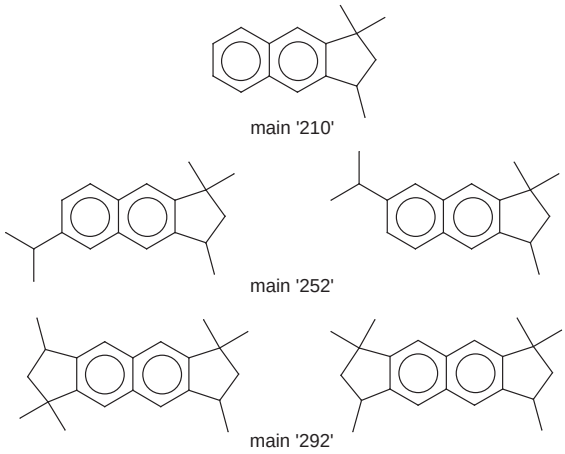

Fig. 1 Proposed structures for the main isomers in new compounds

produces mainly '252' and almost no '210'. There were also many isomers among the new compounds. In fact, there were at least five isomers of '210' and seven isomers of '252' and '292'.

The identification of these new compounds has been made possible by GC-MS and ^{13}C NMR analysis. First, a simple conclusion can be drawn from GC–MS results. Products '210' and '252' could be derived from DIPN and TIPN respectively by removing H_2, and '292' could be produced from TetIPN by removing two equiv. of H_2, suggesting that in a '210' molecule, for example, a branched double bond or an additional hydrocarbon ring might be formed. Second, no dehydrogenated derivative (*e.g. m/z* 168) from IPN (*m/z* 170) is detected, implying that dehydrogenation takes place only between two isopropyl groups, resulting in the cyclization. Therefore, the new compounds are most likely the cyclized products from DIPN, TIPN and TetIPN. That is, one or two additional rings have been formed on naphthalene in the reaction process.

A mixture of the new compounds was isolated by distillation from the products of naphthalene isopropylation over H-beta with the following composition: 79 mol% of '210' (which contains 72% of the main '210' isomer), 9.5 mol% of '252' and 10.6 mol% of '292'. ^{13}C NMR measurements have been applied to this mixture and the obtained spectrum has been compared to those of methyl styrene, indane and tetralin, selected as possible comparable samples, and those of related compounds such as benzocyclobutane, octamethylcyclobutane and dimethylcyclobutanes.[15] The characteristic signals near δ 145.8 in the ^{13}C NMR spectrum of this enriched mixture are similar to those of benzocyclobutane (δ 145.2)[15] or indane (δ 144.3), possibly due to the quaternary carbon atoms of a four- or five-membered ring fused to a benzene ring. This signal position is different in tetralin, where the chemical shift of the corresponding quaternary carbon is at δ 137.4. Therefore, the new additional ring cannot be six-membered. Moreover, the two other signals near δ 45.1 given by the enriched mixture are similar to those obtained with octamethylcyclobutane or 1,1-dimethylcyclopentane for the corresponding quaternary carbon atom.[15] Accordingly, the new ring formed on naphthalene might be five- or four-member. Furthermore, the GC analysis of the products of naphthalene isopropylation over H-beta indicates

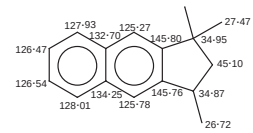

Fig. 2 ^{13}C NMR chemical shifts of the main '210' isomer

that there is one main isomer (72%) among the five '210' species and two main isomers (> 90%) among the seven '252' and '292' species. Such a distribution suggests that the new ring formed in naphthalene is a five-member ring substituted by methyl groups at positions 2',2' and 4', which is the only structure able to give one '210' and two '252' isomers.

Thus, according to the mass, ^{13}C NMR and GC analyses of the new compounds, the structures of the main isomers of '210', '252' and '292' might be consistent with those depicted in Fig. 1, minor isomers possibly resulting from methyl migration and/or ring contraction. The assignment of the ^{13}C NMR chemical shifts of the main '210' isomer (as an example) is indicated in Fig. 2.

Further studies are in progress to elucidate the mechanism and driving force leading to the formation of the new compounds.

The authors thank the France-China PICS-program (No.299) for financial support.

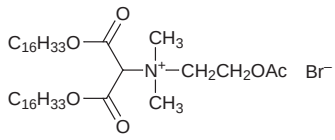
Vesicle–enzyme communication

Fredric M. Menger,* Kingsley H. Nelson and Yingbo Guo

Department of Chemistry, Emory University, Atlanta, Georgia, 30322, USA

Acetylcholinesterase and chymotrypsin are able to catalyze hydrolyses of vesicle-bound substrates at rates that depend upon the ability of the substrates to project beyond the membrane surface.

Pathogenic cells have been identified that produce specific enzymes in excessive amounts. For example, bone cancer has been shown to exude unusually large quantities of alkaline phosphatase,[1] while neuroblastomas generate high levels of acetylcholinesterase.[2] Earlier investigations from our laboratory have exploited this phenomenon in connection with a new and potentially specific mode of drug delivery involving compound **1**.[3] There were two key reasons for synthesizing **1**:



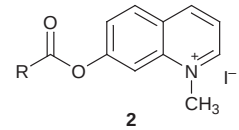
1

(i) It possesses a pair of hydrophobic tails plus a charged headgroup, the components essential for vesicle formation; (ii) It is a substrate for acetylcholinesterase, an enzyme that removes the acetate from the acetylcholine-like moiety. When enzymatic hydrolysis occurs on the 'vesiclized' compound, the freed hydroxy group reacts with one of the ester groups to form a six-membered lactone, thereby eliminating a hydrocarbon tail. But since amphiphiles with a single tail are generally unable to maintain a bilayer structure, the vesicle ruptures and releases its internal contents. The process is enzyme-specific, leading to the possibility of selective release near a cancer cell that overproduces the particular enzyme.

The preceding mechanism presupposes a reaction between a water-soluble enzyme and a vesicle-bound substrate. Somehow, in a manner not yet understood, the substrate within the bilayer membrane is able to find its way to the active site. It seems unlikely that, prior to enzyme binding, a substrate migrates *in toto* from the membrane into the aqueous domain. If this were possible, vesicles would lose and exchange their water-insoluble lipids rapidly, which they do not.[4] A reasonable alternative is that substrates only partially extend themselves beyond the membrane surface. Thus, a lipid molecule might transiently expose its polar moiety (and even portions of its hydrocarbon chains) to the bulk solvent. In this way an enzyme would have an opportunity to grasp the substrate.

An X-ray structure of acetylcholinesterase *(Torpedo californica)* shows that the active site (containing a Ser-His-Glu triad) lies at the bottom of a 'deep and narrow gorge'.[5] Hence, a membrane-bound substrate must seemingly endure a tortuous journey as it leaves the membrane and travels down the cleft to the active site. In actual fact, the journey may not be as difficult as it appears. The cleft is lined with aromatic amino acids that are believed to guide into the active site a substrate molecule reaching the outer rim of the cleft. If this is correct, then one could visualize the escorting of a substrate molecule, which happens to protrude from the membrane, to the active site as soon as a vesicle and a properly oriented enzyme come into contact. It was the purpose of the work reported herein to learn more about such enzyme–vesicle communication.

Substrates in our study consisted of acylated *N*-methyl-7-hydroxyquinolinium iodide derivatives **2**.[6] Acetylcholinester-



2

ase-catalyzed ester hydrolysis leads to a highly fluorescent 7-hydroxyquinolinium salt (λ_{ex} = 400 and 500 nm), allowing kinetics to be carried out spectrofluorimetrically at substrate concentrations of only 5 μM (phosphate buffer; pH 6.0; 25.0 °C), a concentration far too low to cause membrane disruption. Substrates with hydrophobic R groups were incorporated into the vesicle bilayers during their formation. Vesicles, consisting of dilauroylphosphatidyl choline plus 5% dimyristoyl phosphatidic acid (to inhibit floculation),[7] were prepared with the aid of a LiposoFast low-pressure extruder equipped with a 0.1 μm polycarbonate filter.[8] Monodisperse unilamellar vesicles of about 100 nm diameter (dynamic light scattering) at a total lipid concentration of 1.7 mM were thereby achieved. The concentration of acetylcholinesterase (Sigma electric eel, type V-5) added to the vesicular substrates was about 0.7 μM as determined by enzyme titration.[9]

In the absence of vesicles, but otherwise under the conditions specified above, the acetyl form of **2** (called 'C_2') reacts instantly with acetylcholinesterase. Longer-tailed derivatives are slower: the octanoyl, dodecanoyl, and tetradecanoyl esters ('C_8', 'C_{12}' and 'C_{14}') have half-lives varying from 20–60 s. The hexadecanoyl ester ('C_{16}') is not completely hydrolyzed even after half an hour. Although micellization of C_{16} is not a factor in the slow rate (its concentration lies well below the critical micelle concentration), it is quite possible that chain-coiling, as discussed in another context,[10] sterically impedes access to the headgroup by the enzyme.

Introducing vesicles into the system had no effect upon the fluorescence *vs*. time plots for C_2 even at elevated phospholipid concentrations (Fig. 1). Apparently, the hydrophilic substrate fails to bind to the lipid bilayers. C_8 also displays little rate change when co-mixed with phospholipid, a result explainable by either an absence of vesicle binding or by an efficient enzyme catalysis on bound ester. NMR data, given below, strongly favor the latter. In contrast, vesicular substrates C_{10}–C_{16} experience substantial rate inhibitions, the magnitude of which depend on the length of the chain (Fig. 1). Thus, C_{10} has a half-life of 300 s, whereas C_{14} and C_{16} are, for all practical purposes, inert. The C_{14} and C_{16} tails likely serve to anchor the substrates, *i.e.* to impede the ability of the headgroups to project beyond the membrane surface where reactive encounters with the enzyme's cleft become possible. Note that the data in Fig. 1 have practical implications for prodrug design because release of a membrane-bound moiety depends critically upon the structure of the disposable addendum.[11]

NMR spectra in the absence and presence of vesicles leave no doubt that C_8 (and, by inference, all substrate with chains longer

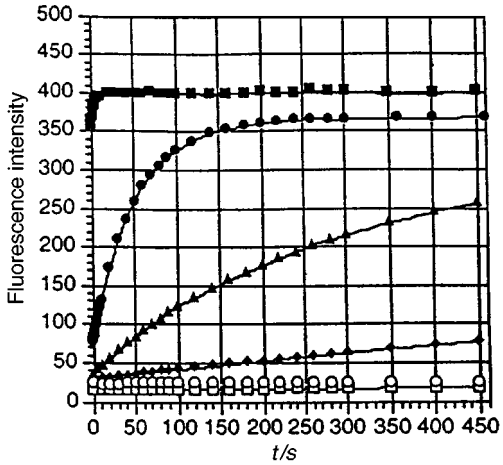


Fig. 1 Change in fluorescence intensity at 500 nm as a function of time in the acetylcholinesterase-catalyzed hydrolysis of vesicular substrates (■) C_2, (●) C_8, (▲) C_{10}, (◆) C_{12}, (□) C_{14} and (○) C_{16} under conditions specified in the text. Note how the reaction rate under standard conditions diminishes with the length of the acyl group.

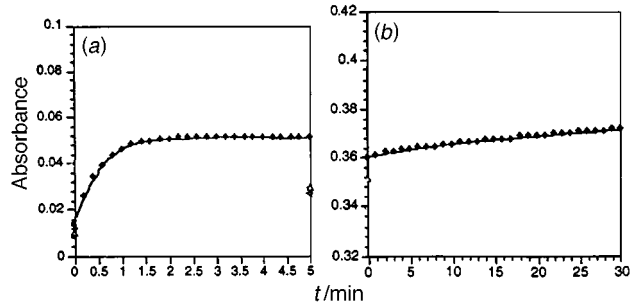

Fig. 2 Change in absorbance at 400 nm as a function of time in the α-chymotrypsin-catalyzed hydrolysis of **3** under conditions specified in the text. (*a*) with no vesicles and (*b*) with vesicles. Absorbance values are higher for the vesicular system owing to scattering by the vesicles.

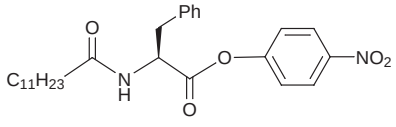
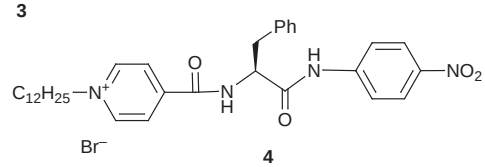
than eight) is substantially vesicle-bound under the experimental conditions.[12] It was found that the sharp aromatic peaks in free solution are obliterated by the vesicles, an observation consistent with substrate immobilization due to bilayer interactions. As would be expected, hydrophilic C_2 was shown to preserve its sharp signals in the presence of vesicles. The results with C_8 prove that an enzyme can maintain a normal rate despite membrane adsorption of its substrate. In terms of our 'protrusion model', the octanoyl group, but not the more hydrophobic tetradecanoyl or hexadecanoyl group, permits escape of the headgroup from the membrane surface into the clutches of the enzyme. The term 'escape' could signify either a dynamic process (in which C_8 rapidly relocates itself in the presence of an enzyme) or a static process (in which C_8 exists in equilibrium among multiple sites regardless of enzyme).

Two additional experiments are relevant to the above conclusions. (i) Tripling the vesicle concentration at a constant 5 μM substrate had little impact on the kinetics. Total binding of the C_{12} and higher substrates is thus assured. (ii) Instead of mixing C_{10} with the phospholipid prior to vesicle formation, C_{10} was added after substrate-free vesicles had been extruded. Since no difference in the kinetics was observed, the substrate in solution must associate with the vesicles rapidly.

To obtain additional information on enzyme–vesicle interactions, we examined a second water-soluble enzyme, chymotrypsin, operating on substrates **3** and **4**. Fig. 2 compares the



3



4

hydrolysis of **3** in the absence of vesicles (phosphate buffer; pH 7.0; 25.0 °C; [substrate] = 5.5 μM; [enzyme] = 0.46 μM) with the hydrolysis of **3** in the presence of vesicles (5.3 mM total phospholipid). A two-order-of-magnitude inhibition by the vesicles is evident. With the goal of further modifying vesicular rates, the 'spacer' between the chain and ester group was extended *via* additional amino acids (*e.g.* dodecanoyl-Gly-Gly-Phe-COOAr) or *via* oxyethylene units (*e.g.* dodecyl-$(OCH_2CH_2)_8$OCO-Phe-COOAr).[13] Unfortunately, the non-vesicular rates were too slow to allow the dependency of rate on spacer length to be systematically examined. Compound **4** behaved well, however, and showed actually a 2.5-fold *faster* initial rate when incorporated into vesicles under our standard conditions. The cationic charge on the pyridinium ring likely positions the ester group into the water away from the membrane surface. Both electric charge (to prevent burying of the reactive headgroup) and spacer rigidity (to prevent looping back of headgroups onto the membrane surface) should favor enzyme–vesicle reactions. These features will be incorporated into future prodrug design.

Vesicle membranes clearly offer an attractive means of controlling enzymatic rates and specificities.

We thank the Army Research Office for supporting this work.

How to circumvent plastic phases: the single crystal X-ray analysis of norbornadiene

Jordi Benet-Buchholz, Thomas Haumann and Roland Boese*†

Institut für Anorganische Chemie der Universität Essen, Universtätsstraße 5-7, D-45117 Essen, Germany

The single crystal structure of the ordered phase of norbornadiene was determined using a new method of growing crystals at low temperatures, *via* an *in situ* technique utilising IR light from a CO_2 laser focused on a capillary filled with an organic solution of a sample that usually forms plastic crystals.

The properties of norbornadiene (bicyclo[2.2.1]hepta-2,5-diene), have been discussed extensively with respect to strain, conjugation and reactivity. The molecular structure has been investigated using spectroscopy,[1] gas electron diffraction[2] and theoretical calculations.[3] However, structural parameters from an X-ray analysis are hithero unknown.

Norbornadiene is a molecule of globular shape[4] and thus tends to form plastic crystals which have in general unusually high melting points and very low entropies of melting (< 21 J K^{-1} mol^{-1}).[4] Such plastic phases are orientationally disordered and do not permit acquisition of detailed structural data. Transitions to ordered low temperature phases are often observed upon further cooling; however, in most of the cases, the plastic crystals shatter during the phase transition. In these cases there are only a few methods available for obtaining a single crystal in the ordered low-temperature phase: (i) sublimation of the sample onto a cold finger cooled below the transition point; (ii) crystallization from a solution of the correct concentration such that saturation is reached at a temperature below the transition point; and (iii) using the shattered crystals of the low temperature phase as seeds and thus grow a single crystal by applying a high temperature gradient in a zone melting procedure. In order to circumvent the above problems, we report here a technique of crystal growth that allows direct access to low-temperature phases.

A DSC[5] investigation of norbornadiene revealed a melting point at −16.02 °C (lit.,[6] −19.1 °C) and a transition temperature at −64.23 °C. In the cooling diagram it solidifies at −19.66 °C and exhibits the phase transformation at −92.79 °C. According to the characteristics of plastic phases, the energy of melting is *ca.* five times lower than that of the phase transition.[7]

X-ray powder diffractograms, taken at different temperatures covering the range of the phase transition,[8] show the characteristics of the high temperature (HT) and low temperature (LT) phases (Fig. 1). The hexagonal lattice symmetry of the HT phase [$a = b = 6.056(7)$, $c = 9.711(12)$ Å, −33 °C] agrees with literature data.[9] The LT phase was indexed for a monoclinic cell [$a = 6.291(2)$, $b = 17.873(7)$, $c = 5.157(3)$, $\beta = 113.95(5)$, −163 °C], in contrast to reported data which assumed a tetragonal cell.[10] The calculated densities for the HT and LT phases are 0.993 and 1.154 g cm^{-3}, respectively. The density of the liquid, 0.906 g cm^{-3}, is close to that of the HT phase and is in agreement with the expected properties for plastic phases.

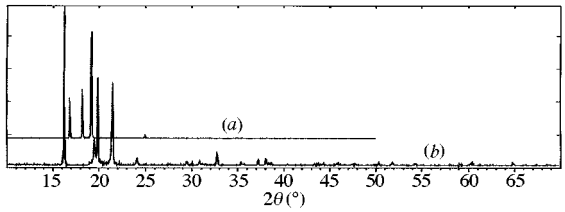

Fig. 1 X-Ray powder diffractograms of norbornadiene at (*a*) −33 and (*b*) −163 °C

In order to evade the HT phase, we modified the *in situ* technique utilizing a focused CO_2 laser beam on a capillary[11] such that, instead of filling the capillary with the neat material, we used an almost saturated solution. The main problems were to find an adequate solvent and an appropriate concentration in order to keep the point of saturation below the transition temperature. A wide variety of different solvents possessing very low melting points and/or low crystallization tendencies as well as good solubility properties were examined. Experiments with common solvents such as pentane failed; however, previous trials to crystallize 1,1-diethenylcyclopropane[12] (mp −131 °C) suggested that this liquid had the desired properties as it remained metastable (oily) down to −193 °C.

Gratifyingly, a 2:1 mixture of norbornadiene–1,1-diethenylcyclopropane produced a single crystal at −163 °C after a few refinement cycles, *i.e.* moving the CO_2 laser beam focus along the capillary over 12 h. The structure was determined by standard procedures.[13]

The most important geometrical parameters are given as mean values, based on the molecular symmetry C_{2v}, in Fig. 2(*a*). Librational corrected data[14] together with a comparison of the experimental structural data and theoretical calculations are given in Table 1. The best agreement with the X-ray data is found for the MP2/6-31G(d) *ab initio* level[15] and the MW data.[1] Most remarkable are the lengths of the single bonds C1–C2, C1–C6, C3–C4 and C4–C5 [1.536(1) Å]; a value of 1.510 Å[16] would be expected for an sp^2–sp^3 carbon bond. The same holds

for the sp^3–sp^3 bonds between C1–C7 and C4–C7 [1.555(1) Å]; the expected value is 1.544 Å.[16]

In norbornadiene two different types of intramolecular interactions are assumed: homoconjugation, as a through space interaction between the two π-systems, and hyperconjugation, as a through bond interaction between the π-systems and the σ-frame.[17] The latter effect may explain the elongation of the single bonds because the filled π-orbitals of the double bonds have a destabilizing effect on the filled σ-orbitals of the opposite positioned single bonds. The double bonds [1.337(1) Å], however, are close to standard bond lengths (1.335 Å).[16]

Multipole refinements[18] with this data set permitted the production of two-dimensional experimental static electron density maps [Fig. 2(*b*) and (*c*)]. The double bond region in the plane intercepting the double bonds and C7 [Fig. 2(*b*)] shows the typical elliptic distortion. The section through the atoms C1, C7 and C4 [Fig. 3(*c*)] demonstrates the strain produced by the small angle at the bridgehead atom (see Table 1) as the maxima of the electron density of the bent bonds at C1–C7 and C4–C7 are clearly shifted from the internuclear lines. This is emphasized by the dashed interconnective lines [Fig. 2(*c*)]. Another interesting feature in Fig. 2(*c*) is the residual electron density at the internal part of the molecule (marked with an arrow). This electron density is similar to that found in the center of a cyclopropane molecule and which is attributed to σ-aromaticity and rehybridization by angular strain.[19]

Over the last 30+ years various theories have been introduced to describe the high reactivity and the *exo*-selectivity of bicyclo[2.2.1]alkenes compared to similar non-cyclic molecules. A reasonable explanation is the pyramidalisation of the double bonds.[20] The amount of pyramidalisation is described by the interplanar angle β between planes C1–C2–C3–C4 and H2–C2–C3–H3 H. The atoms at the double bonds are displaced to the *endo*-region of the molecule. The X-ray analysis gives β = 4.5(2)° (Table 1). This value agrees well with the theoretically calculated (3.7°) and experimentally determined (4.0°, by microwave and NMR spectroscopy) values.

Houk *et al.*[21] suggested the high frame strain as a cause for the pyramidalisation. An explanation for the direction of the pyramidalisation is not only strain alone, but also a contribution from a torsional interaction.[21] The results from our investigation suggest an additional repulsive effect of the hyperconjugation as the main cause for the pyramidalisation of the double bonds in the direction of the '*exo*' area. The effect of the pyramidalisation is expected to be even stronger for norbornene for which the *ab initio* calculations [MP2/6-31G(d)] predict an angle β of 7.9°.

In summary, molecular and crystal structures for a wide range of orientationally disordered materials should now be accessible with this new method. Crystal growth of the low temperature phase of similar molecules which form plastic crystals in the high temperature phases are in progress.

We thank Dr Sergei Kozhushkov (Universität Göttingen) for the preparation of 1,1-diethenylcyclopropane.

Organic–inorganic composite oxide phases: one-dimensional molybdenum oxide chains entrained within a three-dimensional coordination complex cationic framework in [{Cu_2(triazolate)$_2$(H_2O)$_2$}Mo_4O_{13}]

Douglas Hagrman and Jon Zubieta

Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA. E-mail: jazubiet@syr.edu

The hydrothermal reaction of MoO_3, $CuSO_4{\cdot}5H_2O$, 1,2,4-triazole and H_2O produces a 50% yield of [{Cu_2(triazolate)$_2$(H_2O)$_2$}Mo_4O_{13}], a material constructed from {Mo_4O_{13}}$_n^{2n-}$ chains entrained within the three dimensional framework provided by the {Cu_2(triazolate)$_2$(H_2O)$_2$}$_n^{2n+}$ polymeric complex.

Inorganic oxides constitute a vast family of materials which are ubiquitous as both naturally occurring and synthetic materials[1] and are endowed with a range of physical properties giving rise to applications in areas as diverse as heavy construction, sorption, catalysis, biomineralization and microelectronics.[2,3] The recent elaboration of the chemistries of zeolites,[4] mesoporous materials of the MCM-41 class,[5] biomineralized materials,[6] and organically templated transition metal phosphates[7] has led to an appreciation of the dramatic influence of organic components on the microstructures of inorganic oxides.

We have recently described a fifth major class in which organic materials exert a significant structural role in controlling the architecture of the inorganic oxide: the organically templated molybdenum oxides.[8–13] A subclass of these new materials was inspired by the diversity of topologies adopted by metal–dipodal organonitrogen ligand complexes,[14] whose variability of channel dimensions suggested that metal oxide anionic units could be incorporated into the void space of the cationic skeleton. This strategy has provided a variety of novel molybdenum oxides coexisting with mononuclear, binuclear, trinuclear, and one- and two-dimensional coordination complex cations, of which [{Cu(4,4′-bpy)}$_4$$Mo_{15}O_{47}$],[8] [Cu(4,4′-bipyridylamine)$_{0.5}$$MoO_4$], and [Cu{1,2-*trans*-(4-pyridyl)ethene}-MoO_4][15] are representative examples. However, in no instance of a dipodal ligand was a three-dimensional cationic framework observed for the molybdate family of composites, despite introduction of M^{II} sites with octahedral coordination preferences. Recent studies on crystal engineering of three-dimensional frameworks[16] suggested that tripodal or higher denticity ligands with appropriate donor group orientation may favor three-dimensional architectures, although the coordination preferences of the M^{II} site and interactions with the oxide substructure may also influence the structure. Inspired by these results, 1,2,4-triazole was introduced as the organic component for a copper molybdate phase. The expectation of a three-dimensional cationic framework was realized in the isolation of [{Cu_2(triazolate)$_2$(H_2O)$_2$}Mo_4O_{13}] **1**.

The hydrothermal reaction of MoO_3, $CuSO_4{\cdot}5H_2O$, 1,2,4-triazole and H_2O in the mole ratio 1 : 1 : 1 : 1817 for 72 h at 200 °C yielded blue crystals of **1** as a monophasic material in *ca*. 50% yield. The IR spectrum of **1** exhibited a strong band at 954 cm^{-1} ascribed to ν(Mo=O) and a series of bands in the 720–920 cm^{-1} region characteristic of ν(Mo–O–Mo).

As shown in Fig. 1, the structure† of $\mathbf{1}^+$ consists of one-dimensional {Mo_4O_{13}}$_n^{2n-}$ chains entrained within the three-dimensional framework of the {Cu_2(triazolate)$_2$(H_2O)$_2$}$_n^{2n+}$ polymeric coordination cation. There are two unique copper sites in the cationic framework. One site Cu(A) is effectively square pyramidal {CuN_4O} through ligation to four triazolate nitrogen donors, one from each of four triazolate ligands and to a terminal oxo-group of the molybdate chain. The second site Cu(B) is octahedral {CuN_2O_4}, exhibiting coordination to two *trans* disposed triazolate nitrogen donors, two aquo ligands, and two terminal oxo-groups of the molybdate chains. The organic moiety adopts the anionic triazolate form in a three connect ligation mode. The resulting cationic framework is constructed from undulating chains of Cu(A) sites bridged through the 1,2-nitrogen donors of the triazolate ligands and linked to adjacent chains through the Cu(B) centers which coordinate to the remaining 4-nitrogen donors of the triazolate ligands (Fig. 2). This connectivity pattern produces a honeycomb network when viewed along the crystallographic *c* axis. Furthermore, the disposition of bridging triazolate ligands about a chain results in linkage to four adjacent parallel chains (Fig. 1) giving rise to large tunnels which are occupied by the molybdate chains.

The undulating molybdate chain, Fig. 3, is constructed from edge-sharing molybdenum octahedra and tetrahedra. It is noteworthy that the polyhedral connectivity within these {Mo_4O_{13}}$_n^{2n-}$ chains is distinct from that reported for other one-dimensional molybdenum oxides: $K_2Mo_3O_{10}$, $(NH_4)_2Mo_3O_{10}$, $(H_3NCH_2CH_2NH_3)Mo_3O_{10}$, $[H_3N(CH_2)_6NH_3]$-Mo_3O_{10}, $Na(NH_4)Mo_3O_{10}$ and [{Cu(4,4′-bpy)}$_4$$Mo_{15}O_{47}$].[8] The chain structure conforms to the constraints imposed by the copper–triazolate framework and the coordination requirements of the Cu^{II} sites of the framework.

The title compound demonstrates that the structural variability of the cationic scaffolding constructed from appropriately linked transition metal sites extends to 3-D coordination polymers as well as 1-D and 2-D types, with tunable void volumes, providing a domain for the formation of low dimensional metal oxides. The synthetic approach appears to provide a facile method for modification of the structures of metal oxides, employing a 'ship in the bottle' approach, and

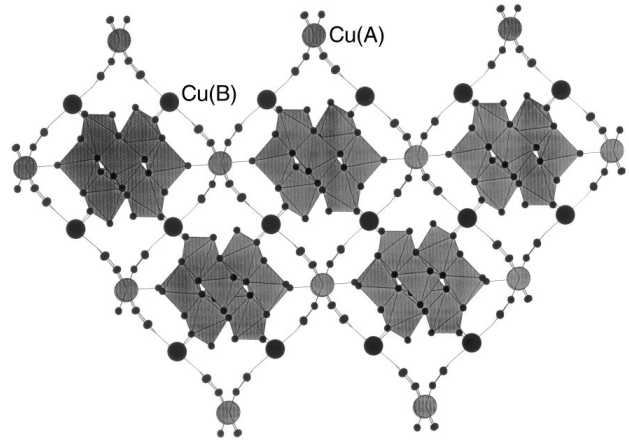

Fig. 1 A view parallel to the crystallographic *b* axis and to the molybdenum oxide chain of the structure of **1**. The molybdate chain is depicted in polyhedral form. The large lighter spheres are the Cu(A) sites, the smaller darker spheres are the Cu(B) sites.

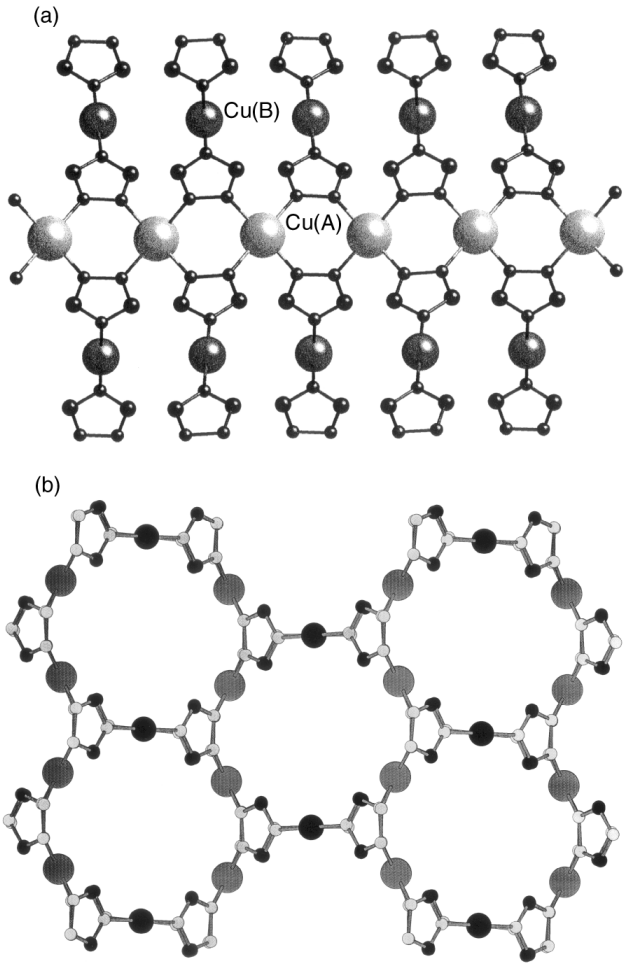

Fig. 2 (a) A view parallel to the crystallographic *a* axis of the chain formed by triazolate bridged Cu(A) sites (large, lighter spheres) and the linkage through Cu(B) centers (large, darker spheres) to adjacent chains. (b) The honeycomb pattern of the $\{Cu_2(triazolate)_2(H_2O)_2\}_n^{2n+}$ framework when viewed parallel to the crystallographic *c* axis. The bonding of the copper sites to the oxide substructure has been omitted for clarity. Selected bond lengths (Å): Cu(A)–N(×4) 1.993(5), Cu(A)–O(10) 2.343(4), Cu(B)–N(×2) 1.947(5), Cu(B)–O 2.000(5)(×2) 2.328(4)(×2).

ultimately for tuning of electronic, magnetic and optical properties of these phases.

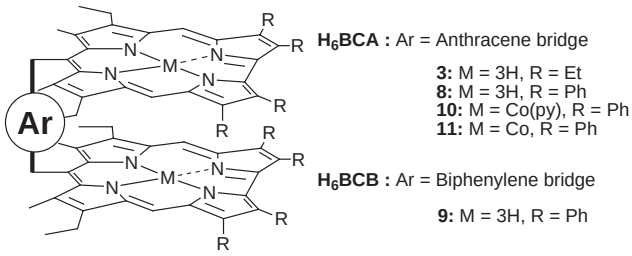
First synthesis of sterically hindered cofacial bis(corroles) and their bis(cobalt) complexes

François Jérôme, Claude P. Gros, Catherine Tardieux, Jean-Michel Barbe and Roger Guilard*†

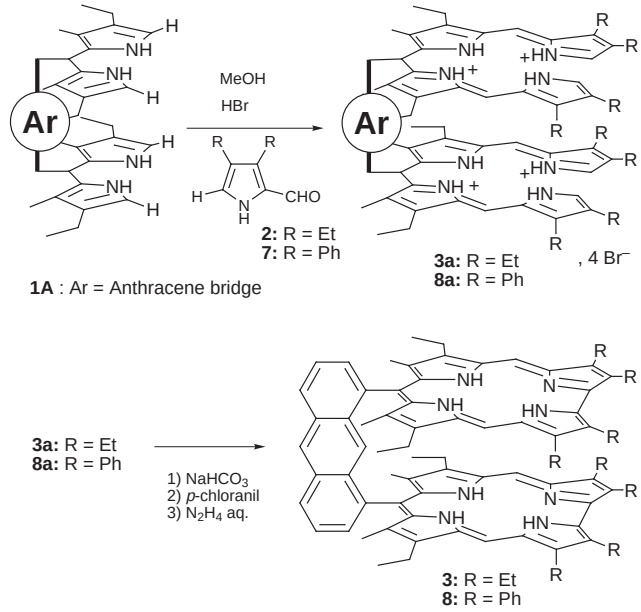
Laboratoire d'Ingénierie Moléculaire pour la Séparation et les Applications des Gaz (L.I.M.S.A.G.), U.M.R. 5633, Faculté des Sciences 'Gabriel', 6, boulevard Gabriel, 21000 Dijon, France. E-mail: Roger.Guilard@u-bourgogne.fr

Syntheses of face-to-face bis(corroles) exhibiting electronic interactions between the two chromophores.

During the past few decades, numerous research has been devoted to the synthesis of dimeric and higher order porphyrins and, to a lesser extent, other macrocyclic tetrapyrroles covalently linked by rigid linkers.[1,2] Bis(porphyrins) with a gable or face-to-face spatial arrangement are effective catalysts for the four-electron reduction of dioxygen to water[3] and the oxidation of organic substrates.[4] A few years ago, 'Pacman' porphyrins achieved the microscopic reverse of dinitrogen fixation.[5] As a result of these significant data, many bisporphyrins and higher oligomers have been prepared with a wide variety of linking units.[6] Except for a few examples,[7] most of these rigidly linked dimeric and higher order oligomeric systems have consisted of porphyrin subunits. At the same time, corrole macrocycles were gaining considerable attention due, in part, to their very rich chemistry and to their ability, compared to porphyrins, to stabilize higher oxidation states of certain coordinated metals.[8] Very recently, symmetrical and unsymmetrical linear bis(corrole) and porphyrin–corrole dyads possessing *para*-phenyl linking units have been described.[7b] Herein, we wish to report the first synthesis of cofacial bis(corroles) **H_6BCA** and **H_6BCB**[9] as well as their bis(cobalt) complexes in order to study metal–metal interactions.

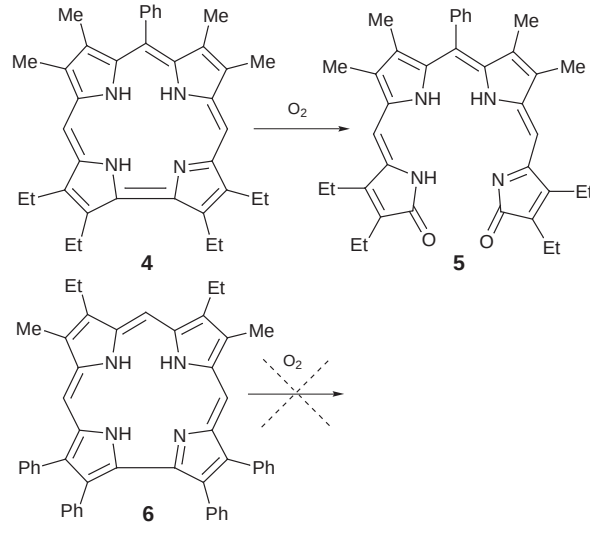


In the course of our work on the syntheses of cofacial bis(porphyrins),[10] it occurred to us that the conjugate addition of a 3,4-disubstituted-2-formylpyrrole to a face-to-face bis(dipyrromethane) followed by a cyclization step should represent a versatile method for new cofacial bis(corroles) formation. Indeed, reaction of compound **1A**[10] with 4 equivalents of **2** in methanol and in the presence of 30% hydrobromic acid in acetic acid led in a first step to the bis(*a*,*c*-biladiene) salt **3a** (Scheme 1), the progress of the reaction being monitored by UV–VIS spectroscopy. *In-situ* addition of sodium hydrogencarbonate and *p*-chloranil followed by addition of 50% hydrazine in water gave **3** as a crude compound after solvent removal. Final purification by chromatography on basic alumina afforded **3** in 5.5% yield. The proton NMR spectrum of the C_2 symmetric derivative **3** exhibits the characteristic patterns of two corrole units cofacially linked by an anthracenyl bridge.[11a] Compound **3** displays a pseudo-molecular peak at *m/z* = 1163 $[M + H]^+$, a Soret band at 402 nm and three Q bands at 510, 548 and 598 nm. Unfortunately, the free-base bis(corrole) **3** was found to be too



Scheme 1

unstable for a full characterization. Indeed, when left in solution in the presence of air and light, **3** readily decomposed over a period of a few minutes into a small amount of less-polar compounds, along with a large amount of base-line materials presumably due to the decomposition reaction with dioxygen of the free-base bis(corrole) which acts as a sensitizer. Such an instability has been pointed out for 10-monophenyl corrole **4** (Scheme 2).[11b] Indeed, compound **4** (as a free-base) was found to be air-sensitive when left in solution and one of its



Scheme 2

decomposition products was identified as an open chain tetrapyrrole structure **5**.[11b] To our knowledge, this is the first example of molecular oxygen oxidation of a corrole macrocycle to a biliverdin structure. Our data led to a possible reaction mechanism involving addition of dioxygen at the 1,19-double bond of the corrole derivative followed by bond cleavage giving two amide groups as terminal functions. In order to prevent oxidative attack of the corrole ring and cleavage of the 1,19-double bond, the four β-pyrrole positions (positions 2,3,17 and 18) were substituted by phenyl groups. As expected, free-base corrole **6**[11b,12] is far more stable than its alkyl-substituted counterpart **4** as the presence of the bulky phenyl groups prevent dioxygen oxidation of the 1,19-double-bond. Indeed, the decomposition of **6** in solution in the presence of air and light only occurred over a period of a few days.

According to these results, we were able to synthesize a stable free-base bis(corrole) **8** (Scheme 1) by reacting first **1A**[10] with **7**,[13] and then by cyclizing the bis(*a*,*c*-biladiene) intermediate **8a**, using *p*-chloranil as an oxidant. The free-base derivative **8**[14] was isolated in 12.5% yield. Starting from 1,8-diformylbiphenylene as a spacer and using the same experimental procedure, compound **9**[15] was obtained in 12% yield. LSIMS mass spectra confirms the dimeric structure of **8** and **9** (*m/z* 1549 $[M + H]^+$ and 1523 $[M + H]^+$, respectively). Cofacial bis(corroles) **8** and **9**, containing phenyl rings at eight β-pyrrole positions, are really more stable than the unprotected one **3**. Indeed, when **8** and **9** are exposed in solution to air and light, no major decomposition is observed after a period of 48 h. Interestingly, the UV–VIS absorptions of **8** and **9** show that the spectra are not simply superpositions of the absorptions of the two corrole chromophores. In particular, the Soret bands of **8** and **9** are red-shifted with respect to those of the simple corrole possessing the same substitution patterns due to the electronic interactions occurring between the two corrole units in **8** and **9**. It is also worthy to note that no electronic interaction has been observed in the recently published linear dimers.[7b]

Standard procedures were employed to metallate the corrole core with cobalt acetate.[16] Compound **8** was heated at 80 °C in pyridine with 2.5 equivalents of $Co(OAc)_2$, the metallation reaction being monitored by UV–VIS spectroscopy. Completion of the reaction occurring within 1–2 h was indicated by the complete disappearance of the absorption at 607 nm and the appearance of a Q band at 597 nm; the Soret band being simultaneously slightly red-shifted (λ_{max} 414 and 435 nm). After purification, the homobimetallic $BCA(Co)_2(py)_2$ derivative **10** was isolated in 23% yield. Interestingly, the two axial pyridine ligands can easily be removed under vacuum (20 mmHg, 50 °C) to yield quantitatively **11**. The electronic absorption spectra of **11** shows a 37 nm blue-shift of the Soret band [λ_{max} (ε/dm^3 mol^{-1} cm^{-1}) = 377 (117 000), 398 (144 000), 529 (47 900) nm] compared to **10**. In LSIMS mode, the molecular peak for the **BCA** complex is observed at *m/z* = 1660 $[M + H]^+$ (100%). It is also worthy to note that **11** decomposes rapidly in the absence of coordinated axial ligands.

In conclusion, these cofacial bis(corroles) can be easily prepared in four steps (starting from the bridging unit) and on a large scale. Moreover, the synthesis of **8** and **9** described here integrate well for the development of coordination chemistry of cofacial bis(corroles) on a broad basis; work is currently underway in these directions.

Stabilisation of an endiolate by co-ordination to vanadium(IV)

Mahin Farahbakhsh, Hauke Schmidt and Dieter Rehder*

Chemistry Department, University of Hamburg, D-20146 Hamburg, Germany. E-mail: rehder@Xray.chemie.uni-hamburg.de

The redox reaction between $[VCl_2(tmeda)_2]$ (tmeda = *N,N,N′,N′*-tetramethylenediamine) and benzil yielded the non-oxo V^{IV} benzoin complex $[V(tmeda)\{Ph(O)C{=}C(O)Ph\}_2]\cdot thf$ (C_2 symmetry), the first structurally characterised vanadium–endiolate complex.

V^{II} is a versatile reducing agent which has been used to effectively reduce, *inter alia*, nitrogen to ammonia,[1] protons to hydrogen,[2] bromoalkanes to alkanes[3] or sulfidophenylsulfanylethane to ethylene and thiocatecholate.[4] V^{II} is also the active intermediate in many reductive hydrogenation and C–C coupling reactions carried out in the presence of the catalyst system VCl_n–H^+–Zn.[5–8] In an effort to establish general pathways leading to non-oxo vanadium-(IV) and -(V) complexes, we have now exploited the reducing potential of V^{II}, stabilised in the form of $[VCl_2(tmeda)_2]$, to reduce benzil to 1,2-dihydroxyethylene and to concomitantly coordinate this tautomeric form of benzoin to vanadium. The use of $[VCl_2(tmeda)_2]$[9] allows the reaction to be carried out in solvents which, unlike water or alcohols, do not straight away provide an oxo group which would otherwise give rise to the formation of the favoured vanadyl [oxovanadium(IV)] moiety. Non-oxo (sometimes also termed 'bare') complexes of high-valent vanadium are of interest in the context of amavadin, a molecular compound of V^{IV} isolated from mushrooms of the genus *Amanita*,[10] and of vanadium nitrogenase, which presumably contains a $\{V(\mu\text{-}S)_3(his)(homocitrate)\}$ coordination site.[11]

Non-oxo complexes of vanadium in its oxophilic oxidation states +IV and +V are still scarce. Examples include [V(salen)(benzilate)],[12] [V(tben)] [H_4tben = *N,N,N′,N′*-tetrakis(2-hydroxybenzyl)ethylenediamine],[13] and [V(salhan)] [H_2salhan = bis(salicylaldehyde-2-hydroxyanil)].[14] Nor has the chemistry of vanadium complexes containing 1,2-diolates as ligands[15–18] yet been developed to a great extent, although this class of complexes is of some interest with respect to model compounds for the physiologically relevant interaction of vanadium with sugars and sugar derivatives such as nucleotides and nucleosides. One such complex, a dimeric adenosyldioxovanadate, has recently been structurally characterised.[19] In contrast to simple α-hydroxycarbonyl compounds, the equilibrium between enediol and the α-hydroxycarbonyl form may be in favour of the former in the case of sugars. Complexes containing the enediol tautomeric form of an α-diketone bound to a vanadium centre have so far not been described. They are known in the dinuclear systems $[W_2X_6(O_2C_2R_2)_2]$ (X = Cl, OR′)[20] and $[Mo_2O_5(O_2C_2Ph_2)_2]$.[21] Vanadium coordination to enolate[22a] and ynolate[22b] has also been reported.

$[V(tmeda)\{Ph(O)C{=}C(O)Ph\}_2]$ forms on addition of benzil to $[VCl_2(tmeda)_2]$ (molar ratio 1:1) dissolved in refluxing, absolute thf. Black, crystalline material of $[V(tmeda)\{Ph(O)C{=}C(O)Ph\}_2]\cdot thf$,† suitable for the X-ray structure determination, is obtained as *n*-pentane is allowed to diffuse into the saturated thf solution within a few days. Since the conversion of benzil to benzoin is a two-electron reduction, half of the vanadium is lost in a side-reaction, the nature of which has not yet been revealed. The exclusive formation of the *Z* isomer of the enediol tautomeric form of benzoin hints at a reaction mechanism where benzil is associated with and thus activated by the V^{II} centre prior to reduction. The coordination of bidentate oxo-functional ligands such as β-diketonates[23] and β-diolates[24] to V^{II} has been noted before (*cf.* also ref. 9).

An ORTEP drawing of $[V(tmeda)\{Ph(O)C{=}C(O)Ph\}_2]\cdot thf$‡ is shown in Fig. 1. The overall geometry is distorted octahedral. V, N1, N1A, O2 and O2A form an approximate plane (deviations: V 0.000, O2 +0.240, O2A −0.240, N1 −0.265, N1A +0.265 Å), O1 and O1A are in the axis, which is slightly bent; the angle O1–O1A amounts to 169.77(8)°. The point symmetry is C_2, with the twofold axis bisecting the angles O2–V–O2A, N1–V–N1A, and the ethylene backbone of the tmeda ligand. Distorted octahedral geometries have also been reported for other non-oxo vanadium complexes,[12–14] while the trigonal-prismatic or distorted trigonal-prismatic arrangements are realised in $[V(hazb)_2]$ [H_2hazb = bis(2,2′-dihydroxyazobenzene],[25] and in non-oxo vanadium(IV) complexes containing ONS donor sets.[26] The carbon–carbon bond length [1.369(3) Å] and the bond angles (average 120°) at the carbons forming the benzoin backbone clearly indicate that the enediol form (sp^2 hybridisation at both carbons) prevails. The V–O bond lengths [1.896(1) and 1.922(1) Å] exceed those of V–O(alkoxide) with a sp^3 hybridised carbon of the alkoxo group (typically 1.77–1.81 Å[12,15a,16–18]); they compare to V–O(phenolate) (1.87–1.91 Å) and V–O(enolate)[22a] [1.928(2) Å], and also to the V–O bond lengths to the non-bridging sugar alkoxides in $[VO_2(\mu\text{-adenosine})_2]^{2-}$ [1.939(2) and 1.916(2) Å];[19] but they are exceeded by V–O(β-diketonate) bond lengths (1.98–2.02 Å).[27]

The +IV state of vanadium has further been established by EPR spectroscopy and cyclic voltammetry.§ The CV exhibits a reversible one-electron reduction step ($V^{IV} \leftrightarrows V^{III}$) at $E_{1/2}$ = −1.080 V, and an irreversible oxidation ($V^{IV} \rightarrow V^{V}$) at +0.27 V *vs.* SCE. The EPR parameters (g_0 = 1.962 , A_0 = 89.0 G; in thf) compare to those commonly found for V^{IV} complexes with a coordination environment dominated by oxygen functionali-

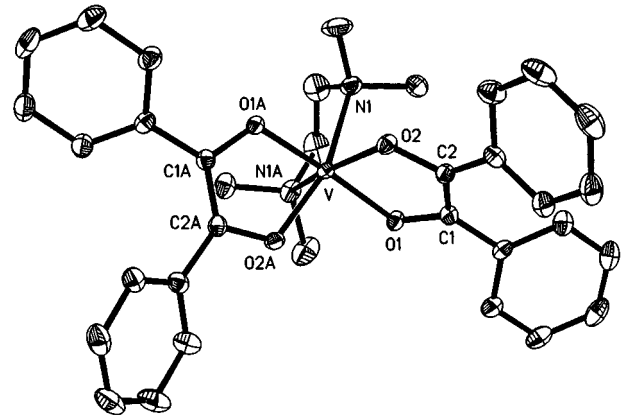

Fig. 1 ORTEP drawing, showing the 50% probability ellipsoids, and numbering scheme for $[V(tmeda)\{Ph(O)C{=}C(O)Ph\}_2]$. Selected bond distances (Å) and bond angles (°): V–N1 2.204(2), V–O1 1.896(2), V–O2 1.921(2), C1–C2 1.369(3), O1–C1 1.342(2), O2–C2 1.354(2), C1–C10 1.474(3), C2–C20 1.472(3); N1–V–N1A 80.35(11), O1–V–O2 79.19(6), O1–V–O1A 169.80(9), O2–V–O2A 108.93(9), N1–V–O1 100.29(7), N1–V–O2 87.10(7) O1–C1–C2 113.3(2), O1–C1–C10 116.4(2), C2–C1–C10 130.3(2).

ties.[28] The BVS analysis, using the parameters provided by Carrano *et al*.,[29] leads to a valence state for vanadium of 3.9.

We are presently expanding this novel route to non-oxo V^{IV} complexes by redox-interaction between a low-valent vanadium centre and a 'pre-ligand' system that serves as the oxidising agent and, in its reduced form, a ligand to the oxidised vanadium.

Notes and References

† [V(tmeda){Ph(O)C=C(O)Ph}$_2$]·thf was prepared in 44% yield. A satisfactory microanalysis was obtained. The ν(C=O) bands are at 1610 and 1588 cm^{-1} (KBr pellet).

‡ *Crystal data* for [V(tmeda){Ph(O)C=C(O)Ph}$_2$]·thf, $C_{38}H_{44}N_2O_5V$, M = 659.69, orthorhombic, space group *Pccn*, a=27.887(10), b = 8.916(2), c = 14.154(6) Å, Z = 4, V = 3519(2) Å^3, D_c = 1.245 g cm^{-3}, μ = 2.71 mm^{-1}, an absorption correction (DIFABS) was applied. Data were collected at 173(2) K on an Enraf Nonius CAD4 diffractometer (Cu-Kα irradiation, λ = 1.541 78 Å, graphite monochromator) in the 2θ scan mode, θ = 3.17–76.35°. Measured reflections 3716, independent reflections 3680 (R_{int} = 0.0152); refined parameters 234. The solution of the structure (SHELXS 97) and refinement (SHELXL 97) converged to a conventional [*i.e.* based on the $I > 2\sigma(I_0)$ criterion] $R1$ = 0.0454 and $wR2$ = 0.1284. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were calculated into ideal positions and included in the final FMLS refinement. Maximum and minimum residual electron densities were 0.540 and −0.637 e Å^{-3}. Only one half of the structure, including one complete enediolate ligand, is crystallographically unique. The thf of crystallisation was treated with a 1:1 disorder model, as required by the crystallographic C_2 axis (symmetry transformation $-x + 1, -y, -z + 1$). CCDC 182/955.

§ X-Band EPR spectra (Bruker ESP 300E) were obtained at 9.74 GHz in *ca.* 1 mM solutions. CV measurements (Princeton Applied Research potentiostat 273A; working electrode: Pt foil, counter electrode: Pt wire) were carried out in *ca.* 1 mM DMF solution with 0.2 M TBAP as conductance salt. The potentials are referenced against SCE. The same crystalline material used for the X-ray structure determination was employed for the EPR and CV studies.

Observing and modelling energetically close α- and β-carbon–hydrogen agostic interactions in an isopropyl tris(pyrazolyl)boratoniobium complex

An equilibrium between α- and β-agostic interactions has been observed in Tp*Nb(Cl)(CHMe$_2$)(PhC≡CMe) 1 [Tp* = hydridotris(3,5-dimethylpyrazolyl)borate] while only α-agostic interactions have been observed for the analogous ethyl complex; calculations using the hybrid QM/MM method IMOMM (B3LYP:mm3) methodology properly account for the experimental results, and suggest that steric effects are responsible for the presence of distinct minima in the isopropyl complex.

Agostic interactions have been found to play an important role in the olefin polymerization reactions and also in the isomerization and dynamics of alkyl groups.[1–5] One of the central issues has been the competition between α- and β-agostic interactions. While theoretical studies have suggested that the two situations could correspond to stable minima, the β-agostic interaction has always been calculated to be energetically favored.[6] To our knowledge, the two types of agostic interactions have never been observed in any single system, since fast rotation of alkyl chain makes characterization of secondary minima unlikely on the NMR time scale. We report here the first observation of an equilibrium between α-C–H and β-C–H agostic forms of an isopropyl group in the formally d^2 complex Tp*Nb(Cl)(CHMe$_2$)(PhC≡CMe) **1** [Tp* = hydridotris(3,5-dimethylpyrazolyl)borate]. We have previously shown that *n*-alkyl complexes such as Tp*Nb(Cl)(CH$_2$R)(PhC≡CMe) exhibit only α-agostic interaction.[7]

The isopropyl complex Tp*Nb(Cl)(CHMe$_2$)(PhC≡CMe) **1** has been isolated in 75% yield from the reaction of Tp*NbCl$_2$(PhC≡CMe)[8] with 1 equiv. of (CHMe$_2$)MgCl.[9] X-Ray diffraction[10] on a single crystal at 160 K reveals a β-agostic structure as shown in Fig. 1. Interaction of one β-H with Nb results in a pronounced distortion of both the alkyl ligand and the metal coordination sphere. An acute Nb–Cα–Cβ angle, a shortened Cα–Cβ bond, a close Nb–Hβ contact and a markedly obtuse Cα–Nb–Cl angle are noteworthy data.[1] The conformation of the isopropyl group is such that the non-agostic Me sits in the wedge formed by two *cis*-pyrazole rings, as do the R groups in Tp*Nb(Cl)(CH$_2$R)(PhC≡CMe) complexes, all of which exhibit α-agostic structures.[7] NMR studies on **1**, however, reveal a more complex situation in solution.

The ^{1}H NMR spectra of **1** in CD$_2$Cl$_2$ indicate dynamic behavior due to an unprecedented equilibrium between a β- and an α-agostic form, **1β** and **1α** respectively (Scheme 1). In the slow exchange regime (193 K), the equilibrium constant measured as the ratio **1β** : **1α** is 3.9 ($\Delta G°_{193}$ = −2.2 kJ mol^{-1}). **1β** is characterized by isopropyl methyls at δ 1.29 and 0.05 (both d, *J* 7 Hz) and a methine proton at δ 2.10. The 'in-plane' rotation of the agostic Me is not frozen out as observed in other β-agostic complexes of the early transition metals. Evidence for the β-agostic interaction thus comes from the ^{13}C NMR data which are consistent with the rehybridization of Cα towards sp^2(δ 72.0, $^1J_{CH}$ 141 Hz). Spectroscopic data for **1α**, including a shielded Hα at δ −1.13 and a broad deshielded Cα at δ 126.4

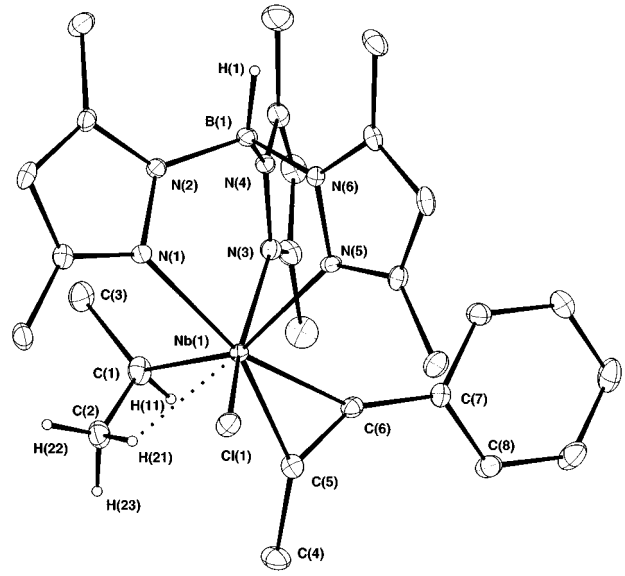

Fig. 1 Plot of the molecular structure of **1**. Located and refined H are shown. Selected bond lengths (Å): Nb(1)–C(1), 2.228(4); Nb(1)···C(2), 2.608(4); C(1)–C(2), 1.476(7); C(1)–C(3), 1.535(6); Nb(1)–H(21), 2.17(5). Selected bond angles (°): Nb(1)–C(1)–C(2), 87.0(3); Nb(1)–C(1)–C(3), 121.2(3); Cl(1)–Nb(1)–C(1), 122.1(1); C(2)–C(1)–C(3), 115.3(4); Cl(1)–Nb(1)–C(1)–C(2), 5.3; Nb(1)–C(1)–C(2)–H(21), 2.4.

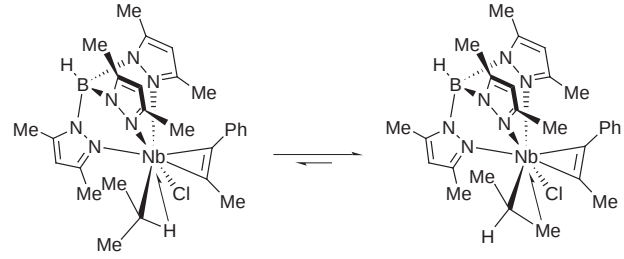
with a reduced $^1J_{CH}$ (100 ± 5 Hz), testify to the α-agostic interaction. Significantly, there is no NMR evidence for a putative third Nb–C rotamer, which might or might not have a β-agostic interaction, namely that with Hα in the wedge formed by the two *cis* pyrazole rings (see discussion of the X-ray data).

The synthesis of Tp*Nb(Cl)[CH(CD$_3$)$_2$](PhC≡CMe) (**1**-d_6), selectively deuterated at the isopropyl methyls, has been achieved.[9] Owing to the preference for H rather than D to occupy an agostic position,[1,11] a thermodynamic isotope effect



Scheme 1

should lead to an equilibrium shift towards the formation of **1α**-d_6, *i.e.* to a smaller equilibrium constant. An isotopic perturbation of the equilibrium is indeed observed. At 193 K the ratio **1β**-d_6 : **1α**-d_6 is 3.2 ($\Delta G°_{193}$ = −1.9 kJ mol^{-1}), which translates to a $\Delta\Delta G°_{193}$ of 0.3 kJ mol^{-1} in favor of **1α**, giving further evidence for the proposed equilibrium between β- and α-agostic forms of the isopropyl group.

The electronic structure of the isopropyl complex **1**, along with that of the ethyl complex,[7b] were examined using the integrated molecular orbitals and molecular mechanics (IMOMM) methodology,[12,13] which has recently been used successfully to model agostic interactions.[15] Only one minimum was located for the ethyl complex, corresponding to the structurally characterized α-agostic isomer.[7b] In contrast, two minima are obtained for the isopropyl complex, one corresponding to the β-agostic structure described above, and the other, 9.3 kJ mol^{-1} higher in energy, to an α-agostic isomer related to the first by rotation of 120° about the Nb–CH(CH$_3$)$_2$ bond. All three minima show features typical of agostic interactions, namely short Nb···H distances (2.35–2.58 Å), long agostic C–H bonds (1.112–1.116 Å), obtuse Cl–Nb–Cα angles (110.8–126.9°) and angles substantially less than 109.5° (86.3–92.4°) between the Nb–Cα bond and the agostic group (H or CH$_3$).

The location of two distinct minima for the isopropyl system, lying very close in energy, raises the question of the origin of the barrier to rotation about the Nb–C bond. The absence of a β-agostic minimum for the ethyl complex suggests that the barrier is not caused by the intrinsic stability of the agostic interactions themselves. The hindered rotation may be thus caused by the steric constraints of the Tp* ligand. The most sterically favorable conformation for the alkyl chain places one Me group along a wedge defined by two *cis*-pyrazole rings, where the pendant methyl groups of Tp* present a significant barrier to rotation about the Nb–C bond. This 'locking' of the non-agostic Me group leaves an α-C–H bond and a Me group to compete for the electron deficient Nb centre in the isopropyl complex, but only two α-C–H groups in the ethyl analogue, thereby accounting for the presence of two distinct isomers in the former, but only one in the latter.

Thanks are due to Bruno Donnadieu and Francis Lacassin for collecting the X-ray data and operating the AMX 400 NMR machine, respectively. J. J. is grateful to the Ministère de l'Enseignement Supérieur et de la Recherche for a fellowship, J. E. M to the European Community for a Marie Curie Fellowship (Grant number ERBFMBICT 971985) and F. M. to the C.N.R.S for a position of Research Associate.

13 IMOMM calculations were performed on the experimental complex replacing Ph of alkyne by H. The QM part of the calculation was performed on the model system [Nb(NH=CH$_2$)$_3$Cl{CH(CH$_3$)$_2$}(HCCH)]$^+$ with Gaussian 92/DFT,[14a] using the B3LYP density functional. A pseudopotential was used for the internal electrons of niobium, and a valence double-ζ basis set for all atoms, with the addition of a polarisation d shell on Cl. The positive charge in the QM part, which arises because the negatively charged Tp* ligand is replaced by three neutral NH=CH$_2$ groups, should not influence the relative energies of the two minima. The molecular mechanics (MM) part was performed using mm3(92).[14b]

Synthesis and characterization of a chelating 2-dimethylsilylpyridine complex of titanocene(III)

The complex $Cp_2Ti[2\text{-}SiMe_2(C_5H_4N)]$ 1, the first example of a chelating silyl, and a tertiary silyl complex of Cp_2Ti(III), is prepared by reaction of $2\text{-}SiHMe_2(C_5H_4N)$ with Cp_2TiMe_2, and its X-ray structure, EPR spectrum and reactions with C_5H_5N and PMe_3 are reported.

Titanocene silyl complexes have been implicated as intermediates in a number of catalytic reactions of hydrosilanes.[1–3] Although several such complexes with primary, secondary and unsubstituted silyl ligands have been synthesised and characterised, they still remain quite rare.[4–8] To our knowledge, only two titanocene complexes with tertiary silyl ligands have been reported, both of which are titanocene(IV) compounds.[9,10] We report here the first example of a tertiary silyl titanocene(III) complex in which the silyl group is part of a chelating ligand.

Reaction of Cp_2TiMe_2 with 2-(dimethylhydrosilyl)pyridine (2.2 equiv.) in hexane resulted in a slow evolution of CH_4, identified by the characteristic rotational fine structure in its gas phase infrared spectrum, and a color change of the solution from orange to purple over a period of 2 to 3 days. Upon cooling to −20 °C for 24 h, deep purple crystals of **1** precipitated and were isolated in 63% yield. In solution ([$^2H_8$]toluene), **1** gave no discernible ^1H or ^{29}Si NMR resonances, as is often the case with strongly paramagnetic Ti(III) complexes. The EPR spectra of **1** (Fig. 1) in solution at both low (−20 °C) and room temperature exhibit a well resolved triplet at g = 1.9872 with a_N = 1.9 G, due to coupling of a single unpaired electron to the ^{14}N nucleus (I = 1) in the pyridine, and satellites due to hyperfine interactions with Ti nuclei [I = 7/2, ^{49}Ti (5.5%); I = 5/2, ^{47}Ti (7.75%)] with a_{Ti} = 8.8 G.

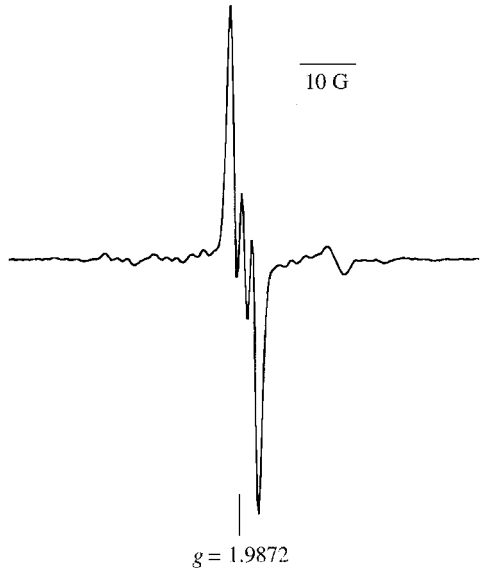

Fig. 1 EPR spectrum of **1** (−20 °C; toluene)

The single crystal X-ray structure of a molecule of **1** shows that this complex is mononuclear (Fig. 2).† The geometry about the titanium center is very similar to those found in the analogous non-chelating silyl(tertiaryphosphine) complexes with the exception of the very acute N–Ti–Si angle of 64.72(7)° compared to the P–Ti–Si angles [84.8(1) to 86.2(2)°] in the latter complexes.[4] The bonding parameters are close to those observed for other titanocene(III) silyl complexes.[4]

Solutions of **1** are air sensitive, but relatively stable at room temperature under inert atmosphere. They decompose slowly over a period of days to give an unidentified paramagnetic product (broad single EPR resonance; g = 1.9778). Such a signal is often observed in the decomposition products of titanocene(III) complexes.[1] The enhanced thermal stability of the chelating tertiary silylpyridine complex **1** is in sharp contrast to the analogous non-chelating silyl(tertiarylphosphine) complexes $Cp_2Ti(PMe_3)(SiHRR')$ (R = H or Ph, R′ = Ph) which are stable only for minutes at ambient temperature.[4,5] We attribute the unusual stability of **1** to the absence of the Si–H hydrogens for further dehydrocoupling reactions.[5]

The pyridine ligand in **1** is labile and can be replaced by other donor ligands as shown in eqn. (1). Solutions of **1** treated with excess PMe_3 in toluene give **2a** [eqn. (1)] identified by its characteristic EPR spectrum which displayed a simple doublet at g = 1.9936 with a_P = 29.3 G, a_{Ti} = 7.7 G (*cf.* ref. 4) and observed by a color change of the solution from purple to bright violet. This reaction is reversible. Removal of the solvent along with the volatile PMe_3 by pumping, followed by redissolution of the residue, gave the starting complex **1**. Similarly, reaction of **1** with excess pyridine gave the silyl(pyridine)titanocene complex **2b**.‡

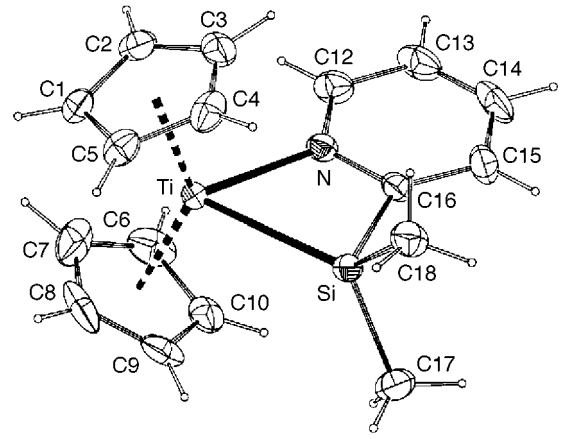

Fig. 2 A view of the structure of **1** (30% probability ellipsoids). Selected bond lengths (Å) and bond angles (°): Ti–N 2.229(2), Ti–Si 2.651(2), N–C(12) 1.340(4), N–C(16) 1.360(4), Si–C(16) 1.922(3), Si–C(17) 1.901(3); N–Ti–Si 64.72(7), Cp(cent)–Ti–Cp(cent) 137.2(1), Ti–N–C(16) 110.0(2), Ti–Si–C(16) 79.64(9), N–C(16)–Si 105.6(2).

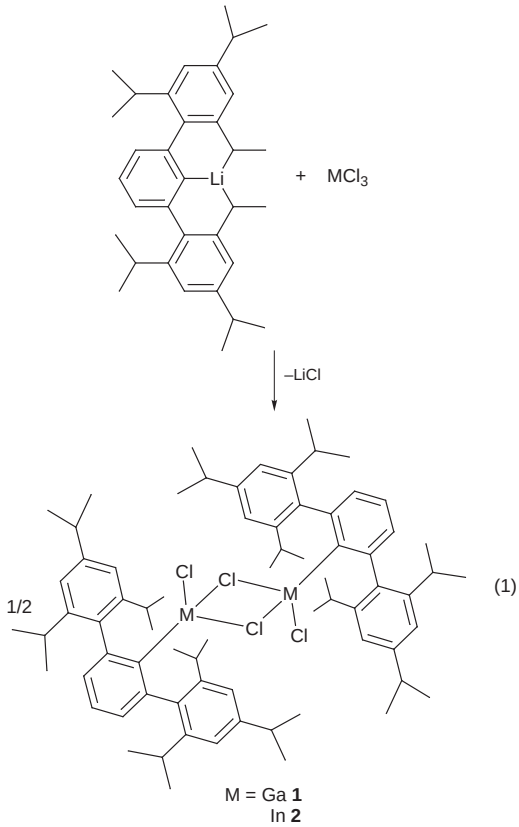
2,6-Bis(2,4,6-triisopropylphenyl)phenyl as an extraordinarily bulky ligand in organometallic chemistry. Synthesis and molecular structure of $[(Mes^*_2C_6H_3)MCl_2]_2$ (M = Ga, In; Mes* = $C_6H_2Pr^i_3$-2,4,6)

Jianrui Su, Xiao-Wang Li and Gregory H. Robinson*

Department of Chemistry, The University of Georgia, Athens, GA 30602-2556, USA. E-mail: robinson@sunchem.chem.uga.edu

Gallium chloride or indium chloride interacts with 2,6-bis(2,4,6-triisopropylphenyl)phenyllithium, $(Mes^*_2C_6H_3)Li$ (Mes* = $C_6H_2Pr^i_3$-2,4,6), affording $[(Mes^*_2C_6H_3)MCl_2]_2$ (M = Ga 1, In 2), interesting group 13 organometallic crystalline dimers, characterized by elemental analyses, ^1H and ^{13}C NMR spectroscopy, and single-crystal X-ray diffraction.

The utilization of bulky ligands in organometallic chemistry is a proven means to compounds which may be particularly sensitive, reactive, or otherwise unstable. This practice has achieved great prominence in the organometallic chemistry of the heavier group 13 elements, particularly where aryl ligands are concerned. The simplest aryl derivatives, triphenylaluminium and triphenylgallium, have been known for decades while the bulkier trimesityl derivatives of aluminium[1] and gallium[2] were first reported in 1986. Herein we report the synthesis† and molecular structure‡ of gallium (**1**) and indium (**2**) derivatives of the very sterically demanding 2,6-bis(2,4,6-triisopropylphenyl)phenyl ligand, $Mes^*_2C_6H_3$ (Mes* = $C_6H_2Pr^i_3$-2,4,6),[3] $[(Mes^*_2C_6H_3)MCl_2]_2$, isolated from reaction of $(Mes^*_2C_6H_3)Li$ with the respective metal chloride [eqn. (1)].



The title compounds, characterized by elemental analyses, ^1H and ^{13}C NMR spectroscopy and single-crystal X-ray diffraction, are noteworthy as they represent interesting organometallic group 13 halide derivatives of the sterically demanding 2,6-bis(2,4,6-triisopropylphenyl)phenyl ligand. The molecular structure of $[(Mes^*_2C_6H_3)MCl_2]_2$ (M = Ga **1**, In **2**) is shown in Fig. 1.

Sterically demanding arylgallium dihalides have been shown to play a critical role in the preparation of novel low-valent organometallic gallanes containing Ga–Ga bonds. For example, 2,6-dimesitylphenylgallium dichloride, upon alkali metal reduction, has been shown to afford Ga_3^{2-} three-membered dianionic metalloaromatic rings.[4–7] Conversely, the gallium dichloride of 2,6-bis(2,4,6-triisopropylphenyl)phenyl, $(Mes^*_2C_6H_3)_2GaCl_2$, prepared *in situ* and allowed to interact with sodium, has recently been shown by this laboratory to give an unprecedented gallium–gallium triple bond in $Na_2[Mes^*_2C_6H_3Ga{\equiv}GaC_6H_3Mes^*_2]$—the first gallyne, a dianionic organogallium congener of acetylene.[8,9] That adjusting the steric demands of an arylgallium halide may afford such interestingly

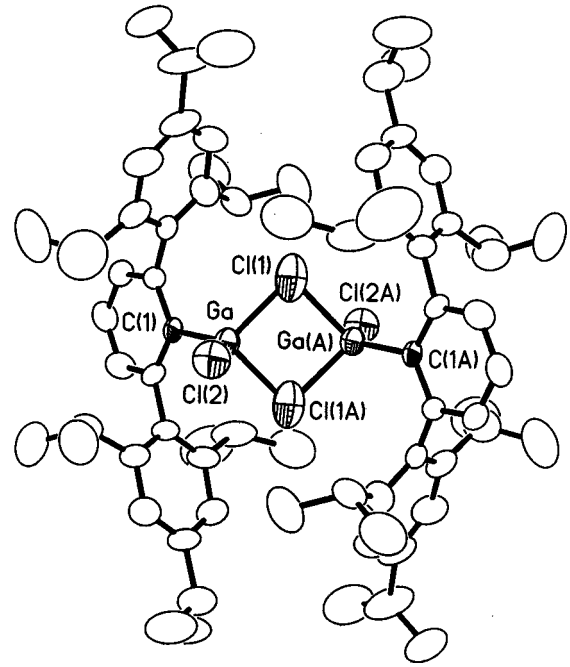


Fig. 1 Molecular structure of **1**. Selected bond distances (Å) and angles (°): for **1**: Ga–C(1) 1.949(8), Ga–Cl(1) 2.196(5), Ga–Cl(1A) 2.201(5), Ga–Cl(2) 2.230(3), Ga(A)–Cl(1) 2.201(5); C(1)–Ga–Cl(1) 112.3(3), C(1)–Ga–Cl(1A) 114.0(3), Cl(1)–Ga–Cl(1A) 90.3(2), C(1)–Ga–Cl(2) 127.3(3), Cl(1)–Ga–Cl(2) 104.0(2), Cl(1A)–Ga–Cl(2) 102.3(2), Ga–Cl(1)–Ga(A) 89.7(2). For **2** (the atom numbering scheme is the same as that for **1**): In–C(1) 2.129(5), In–Cl(1A) 2.233(4), In–Cl(1) 2.236(4). In(A)–Cl(1) 2.233(4); C(1)–In–Cl(1A) 115.3(2), C(1)–In–Cl(1) 114.0(2), Cl(1A)–In–Cl(1) 81.6(2), C(1)–In–Cl(2) 130.7(3), Cl(1A)–In–Cl(2) 103.2(2), Cl(1)–In–Cl(2) 100.7(2), In–Cl(1)–In(A) 98.4(2).

diverse products is sufficiently intriguing to warrant examination of the structural dynamics of this sterically demanding aryl with group 13 metal halides.

Compounds **1** and **2**, soluble in diethyl ether, hexane, and aromatics, assume isostructural dimeric structures possessing two μ_2-bridging chlorine atoms. The bridging chlorine atoms and the metal atoms constitute a planar four-membered M_2Cl_2 ring about a center of symmetry with the two aryl ligands and the two terminal chlorine atoms residing alternately above and below this ring. The environment about the metal centers may be described as distorted tetrahedral as the bond angles about gallium range from 90.3(2) to 127.3(3)°. Considering the steric bulk of the given ligand it is somewhat surprising that these complexes are not monomeric. The most convenient comparison relative to the title compounds concerns the respective 2,6-dimesitylphenyl derivatives. Although the structure of **1** compares with the bis[(dimesitylphenyl)gallium dichloride] derivative, $[(Mes_2C_6H_3)GaCl_2]_2$,[10] it is noteworthy that in **1** the $Ga–Cl_{bridging}$ bond distances [2.196(5) and 2.201(5) Å] are shorter than the $Ga–Cl_{terminal}$ bond distance [2.230(3) Å]. By contrast, for $[(Mes_2C_6H_3)GaCl_2]_2$, the $Ga–Cl_{bridging}$ bond distance [2.334(5) Å] is considerably longer than the $Ga–Cl_{terminal}$ distance [2.172(5) Å]. This trend is also observed for **2** wherein the $In–Cl_{bridging}$ distances [2.236(4) and 2.233(4) Å] are shorter than the $In–Cl_{terminal}$ bond distance [2.448(7) Å]. In $[(Mes_2C_6H_3)InCl_2]_2$[11] the situation is just the opposite with the $In–Cl_{bridging}$ bond distances [2.519(2) and 2.514(2) Å] being considerably longer than the $In–Cl_{terminal}$ bond distances [2.344(3) Å]. Thus, it is interesting to note that for both gallium and indium the bridging M–Cl bonds are shorter than the terminal M–Cl bonds where the sterically more demanding ligand is involved. Indeed, it is noteworthy that the bridging In–Cl distance in **2** of 2.233(4) Å appears to be the shortest In–Cl distance on record. Lastly, it is significant that **2** represents only the third example of a dimeric organoindium halide: $[(Mes_2C_6H_3)InCl_2]_2$ and $[Mes_2InCl]_2$[12] being the other two examples.

We are grateful to the National Science Foundation (G. H. R.: CHE 9520162) and to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for support of this work.

Notes and References

† *Syntheses*: in a dry box a 100 ml flask was charged with $GaCl_3$ (0.88 g, 5 mmol) or $InCl_3$ (1.11 g, 5 mmol) and ether (30 ml). To this solution at −78 °C a diethyl ether solution (30 ml) of $(Mes^*_2C_6H_3)Li·OEt_2$ (2.81 g, 5 mmol) was added dropwise with vigorous stirring. The mixture was stirred for 3 h at this temperature and then allowed to warm slowly to room temp. After stirring for one day the solvent was removed from the mixture *in vacuo*. The residue was extracted with hexane (60 ml) and the white precipitate (LiCl) was separated by filtration. The volume of the colorless filtrate was reduced and placed in a freezer (−20 °C) for 2 days to give cubic colorless crystals. Both **1** and **2** crystallize with one unit of hexane in the unit cell. For **1**: 2.2 g, 65% yield; melting point, 256 °C; Anal. Calc. (found) for $C_{72}H_{98}Cl_4Ga_2$ (E + R Microanalytical Laboratories, Corona, NY): C, 69.50 (68.69); H, 7.90 (8.43%). ^{1}H NMR (300 MHz, 297 K, C_4D_8O), δ 0.89 [d, 12H, CH_3 (Pr^i)], 1.03 [d, 12H, CH_3 (Pr^i)], 1.09 [d, 12H, CH_3 (Pr^i)], 1.22 [d, 12H, CH_3(Pr^i)], 1.26 [d, 12H, CH_3 (Pr^i)], 1.42 [d, 12H, CH_3 (Pr^i)], 2.81 [m, 12H, CH(Pr^i)], 6.61–7.37 [m, 6H, CH (aromatic)], 6.94 [s, 4H, CH (aromatic)], 6.99 [s, 4H, CH (aromatic)]. ^{13}C NMR (300 MHz, 297 K, C_4D_8O), δ 27.67, 33.58, 33.98, 34.12, 37.85, 38.29 (Pr^i); 123.3, 123.9, 130.1, 131.2, 131.6, 150.2, 150.3, 151.7 (aromatic). For **2**: 2.66 g, 75% yield; melting point, 233 °C; Anal. Calc. (found) for $C_{72}H_{98}Cl_4In_2$: C, 64.80 (62.20); H, 7.40 (7.87%). ^{1}H NMR (300 MHz, 297 K, C_4D_8O), δ 0.90 [d, 12H, CH_3(Pr^i)], 1.04 [d, 12H, CH_3(Pr^i)], 1.09 [d, 12H, CH_3(Pr^i)], 1.22 [d, 12H, CH_3 (Pr^i)], 1.27 [d, 12H, CH_3(Pr^i)], 1.43 [d, 12H, CH_3(Pr^i)], 2.82 [m, 12H, CH(Pr^i)], 6.63–7.39 [m, 6H, CH (aromatic)], 6.96 [s, 4H, CH (aromatic)], 7.01 [s, 4H, CH (aromatic)]. ^{13}C NMR (300 MHz, 297 K, C_4D_8O), δ 28.15, 34.03, 34.46, 34.59, 38.31, 38.77 (Pr^i); 123.8, 124.4, 130.5, 131.8, 132.1, 150.6, 150.8, 152.3 (aromatic). The solvent present in the crystal lattice contributes to the less than ideal elemental analyses.

‡ *Molecular structures*: crystals were mounted in glass capillaries under an atmosphere of nitrogen and sealed. X-Ray intensity data were collected at 22 °C on a Siemens P4 diffractometer (Mo-Kα radiation; λ = 0.710 73 Å) using ω-scan technique to a maximum 2θ value of 45°. Both structures were solved by direct methods using the SHELXTL 5.0[13] system of programs. Non-hydrogen atoms were refined anisotropically while the hydrogen atoms were placed in ideal positions with their coordinates and thermal parameters riding on the attached carbon atoms. These two crystalline compounds are isostructural: monoclinic, space group $P2_1/c$ (no. 14). The asymmetric unit contains one half $[(Mes^*_2C_6H_3)MCl_2]_2$ (M = Ga, In) and one half hexane molecule situated on inversion centers, thereby generating the other half molecules.

Crystallographic data: $[(Mes^*_2C_6H_3)GaCl_2]_2$ **1**: a = 13.863(8), b = 15.775(9), c = 18.02(1) Å, β = 106.04(4)°, V = 3789(4) Å^3, Z = 2, R = 0.077, $wR2$ = 0.235 for 2613 [$I > 2\sigma(I)$]. $[(Mes^*_2C_6H_3)InCl_2]_2$, **2**: a = 14.273(3), b = 15.671(3), c = 18.048(3) Å, β = 106.45(1)°, V = 3872(1) Å^3, Z = 2, R = 0.039, $wR2$ = 0.122 for 3226 [$I > 2\sigma(I)$]. A slight disorder was observed for the terminal chlorine [Cl(2)] atom in **2**. CDCC 182/959.

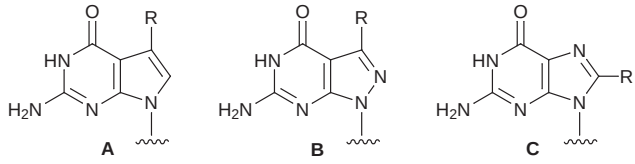
Stabilisation of duplex DNA by 7-halogenated 8-aza-7-deazaguanines

Frank Seela*† and Georg Becher

Laboratorium für Organische und Bioorganische Chemie, Institut für Chemie, Universität Osnabrück, Barbarastr.7, D-49069 Osnabrück, Germany

Oligonucleotides containing 7-halogenated 8-aza-7-deaza-2′-deoxyguanosine ($c^7z^8G_d$) derivatives such as d($Br^7c^7z^8$ G-C)$_4$ 8 (T_m = 88 °C) and d($I^7c^7z^8$ G-C)$_4$ 9 (T_m = 84 °C) are significantly more stable than d(G-C)$_4$ 5 (T_m = 59 °C).

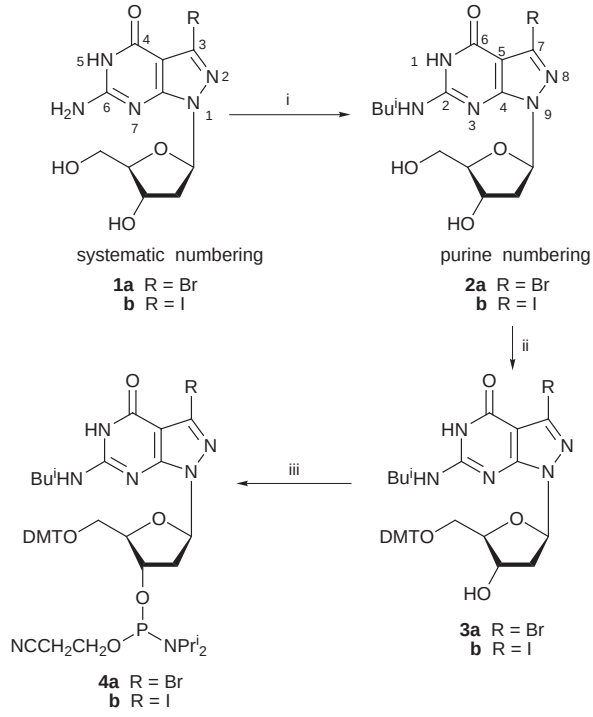
The introduction of 7-halogenated 7-deazapurines (pyrrolo-[2,3-*d*]pyrimidines **A**) into oligonucleotides reveals that these residues are well accommodated in the major groove of the duplex DNA. Furthermore, this modified DNA is stabilised and the particular DNA structure is retained.[1,2] Consequently, the 7 position of 7-deazapurines is an ideal site for the introduction of functional residues into the DNA which can serve later as reporter groups, cleaving agents or residues useful in sequencing by mass spectrometry or by atomic force microscopy.[3] In the series of modified nucleobases related to purines, the 8-aza-7-deazapurines (pyrazolo[3,4-*d*]pyrimidines **B**) depict another heterocyclic system which can be derivatised at the same position while retaining the Watson–Crick recognition site of a purine base (**C**), but not showing the unfavourable properties of 8-substituted purine residues.[4]



Regular pyrazolo[3,4-*d*]pyrimidine nucleosides have already been incorporated into oligonucleotides.[5–7] Also, the monomeric 7-bromo and 7-iodo derivatives of 8-aza-7-deaza-2′-deoxyguanosines (**1a**,**b**) have been synthesised.[8] As we wanted to prove whether compounds **1a**,**b** show the same favourable properties as the corresponding 7-deazapurines, building blocks for oligonucleotide solid-phase synthesis were prepared. For this purpose the isobutyryl residue was introduced as an amino protecting group yielding the protected nucleosides **2a** (64%) and **2b** (66%) (Scheme 1). The protecting group stability was determined UV spectrophotometrically at 300 nm in conc. NH_3 at 40 °C. The half-lives of 7-bromo-8-aza-7-deaza-2′-deoxyguanosine **2a** ($Br^7c^7z^8G_d$; 38 min) and 7-iodo-8-aza-7-deaza-2′-deoxyguanosine **2b** ($I^7c^7z^8G_d$;41 min) were similar to that of the parent 8-aza-7-deaza-2′-deoxyguanosine ($c^7z^8G_d$; 37 min).[7] Subsequently, 4,4′-dimethoxytrityl (DMT) groups were introduced under standard conditions furnishing the 5′-protected compounds **3a** and **3b** (74 and 71% yield), respectively. They were then converted into the phosphoramidites **4a** and **4b** (80 and 76%). All monomeric compounds were characterised by ^{1}H, ^{13}C and ^{31}P NMR spectra as well as by elemental analyses.[9]

Next, the self-complementary hexanucleotides d($Br^7c^7z^8$G-C)$_3$ **13** and d($I^7c^7z^8$G-C)$_3$ **14** as well as the octamers d($Br^7c^7z^8$G-C)$_4$ **8** and d($I^7c^7z^8$G-C)$_4$ **9** were prepared using the building blocks **4a**,**b**. The oligonucleotides were removed from the solid support (conc. aq. NH_3), deprotected and purified on OPC cartridges.[10] Their purity was proven by ion-exchange chromatography on a 4 × 50 mm NucleoPac PA-100 column (DIONEX), and MALDI-TOF mass spectra[11] were obtained. Their base composition was confirmed by enzymatic hydrolysis. Furthermore, their thermodynamic stability was determined by temperature dependent UV–melting profiles. Table 1 summarises T_m values as well as thermodynamic data (MeltWin[12]) of the duplex formation of the self-complementary oligonucleotides **5**, **7**–**9** and **12**–**14** as well as of the corresponding oligomers containing 7-deazaguanine (c^7G_d) (**6**, **10** and **11**).[2]

According to Table 1 it is apparent that the 8-aza-7-deazaguanine moiety which has no 7-substituent stabilises the oligonucleotide duplex [d(c^7z^8G-C)$_4$] **7** (T_m = 72 °C) compared to the parent 2′-deoxyguanosine [d(G-C)$_4$] **5** (T_m = 59 °C, ΔT_m = 13 °C), while the 7-deaza-2′-deoxyguanosine in [d(c^7G-C)$_4$] **6** shows a destabilisation (T_m = 53 °C, ΔT_m = −6 °C).[2] These findings are in agreement with earlier observations made on other oligonucleotides as well as on polynucleotides.[13–15] The octanucleotides with halogenated 8-aza-7-deazaguanine residues [d($Br^7c^7z^8$G-C)$_4$] **8** (T_m = 88 °C) and [d($I^7c^7z^8$G-C)$_4$] **9** (T_m = 84 °C) show considerable duplex stabilisation. The stability of these duplexes was even higher than those of the related oligomers with the 7-halogenated 7-deazaguanine residues (**10** and **11**). Due to the high T_m values of **8** and **9** it was not possible to obtain a complete melting profile, which is necessary to determine the thermodynamic data. Therefore, a set of hexanucleotides was measured showing *ca*. 15 °C lower T_m values. Again, the iodo compound **14**



Scheme 1 *Reagents and conditions*: i, HMDS, Bu^i_2O, DMF, room temp., 13 h, 64% (**2a**), 66% (**2b**); ii, DMTCl, py, room temp., 4 h, 74% (**3a**), 71% (**3b**); iii, (Pr^i_2N)($NCCH_2CH_2O$)PCl, THF, room temp., 30 min, 80% (**4a**), 76% (**4b**)

Table 1 T_m values and thermodynamic data of duplex formation of oligonucleotides[a,b]

Compound	T_m/°C	ΔH/kcal mol^{-1}	ΔS/cal K^{-1} mol^{-1}	ΔG_{298}/kcal mol^{-1}
d(G-C)$_4$·d(G-C)$_4$ **5·5**	59	−67	−179	−11.9

d(Br^{7}c^{7}z^{8}G-C)$_3$·d(Br^{7}c^{7}z^{8}G-C)$_3$**13·13**	73	−70	−181	−14.3
d(I^{7}c^{7}z^{8}G-C)$_3$·d(I^{7}c^{7}z^{8}G-C)$_3$ **14·14**	71	−63	−162	−12.9

[a] Oligonucleotide conc. is 10 μM. [b] Measured in 10 mM Na cacodylate, 10 mM $MgCl_2$, 0.1 M NaCl. [c] Not measurable.

exhibits a somewhat lower T_m value than the bromo derivative **13** (Table 1). When comparing the thermodynamic data of the duplexes **13·13** and **14·14** with the unmodified duplex **12·12** it is apparent that a more favourable enthalpy term leads to duplex stabilisation. This effect was much more pronounced in the series of oligonucleotides containing 7-halogenated 8-aza-7-deazaguanine than in those containing halogenated 7-deazaguanine.

From the chromatographic behaviour of the 7-halogenated nucleosides **1a**,**b** on RP-18 HPLC (Fig. 1) as well as of the corresponding oligonucleotides **8**, **9**, **13** and **14** it is apparent that the halogen substituents make the compounds more hydrophobic. Thus, the major grooves of such DNA duplexes become hydrophobic and water molecules, normally being present in these grooves, are expelled. This can influence both the enthalpy and the entropy of duplex formation. However, enthalpic changes play the major role.

Another difference which is observed for the 7-halogenated 8-aza-7-deazaguanine nucleosides compared to the non-halogenated compounds is the change of the pK values of deprotonation (7-deaza-8-aza-2′-deoxyguanosine = 9.3; compounds **1a**,**b** = 9.0). This effect also increases the N-glycosylic bond stability[8] and is most likely explained by the electron-withdrawing effect caused by the 7-substituents. As a result, the hydrogen bonds within the G-C base-pair are strengthened and the duplex becomes stabilised. It was also shown that the triphosphates of 8-aza-7-deazaguanine nucleosides are efficiently incorporated into DNA using DNA polymerases;[16] they are useful for introducing reporter groups into a sterically unproblematic position of the DNA molecule.

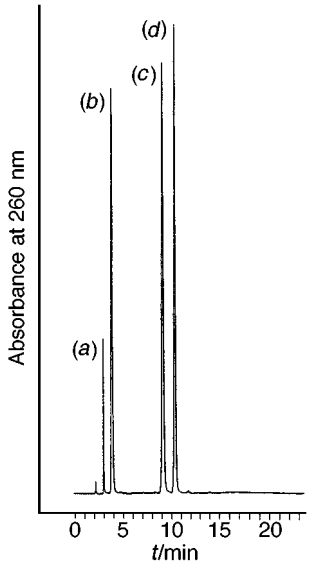

Fig. 1 HPLC profile of (*a*) 6-amino-1*H*-pyrazolo[3,4-*d*]pyrimidin-4(5*H*)-one, (*b*) 8-aza-7-deaza-2′-deoxyguanosine, (*c*) **1a** and (*d*) **1b** on a RP-18 (200 × 10 mm) column. The following solvent systems were used: 0.1 M (Et_3NH)OAc (pH 7.0)–MeCN (95:5) (A) and MeCN (B). They were used according to the following profile: 20 min 5–20% B in A, 35 min 20–50% B in A, 35 min 5% B in A.

We thank Dr N. Ramzaeva for helpful discussions. Financial support by the Bundesministerium für Bildung, Forschung und Technologie (BMBF) is gratefully acknowledged.

Chameleon catches in combinatorial chemistry: Tebbe olefination of polymer supported esters and the synthesis of amines, cyclohexanones, enones, methyl ketones and thiazoles

Christopher P. Ball,[a] Anthony G. M. Barrett,*[a]† Alain Commerçon,*[b] Delphine Compère,[a] Cyrille Kuhn,[a] Richard S. Roberts,[a] Marie L. Smith*[a] and Olivier Venier[a]

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[b] *New Lead Generation, Rhône-Poulenc Rorer, Vitry, France*

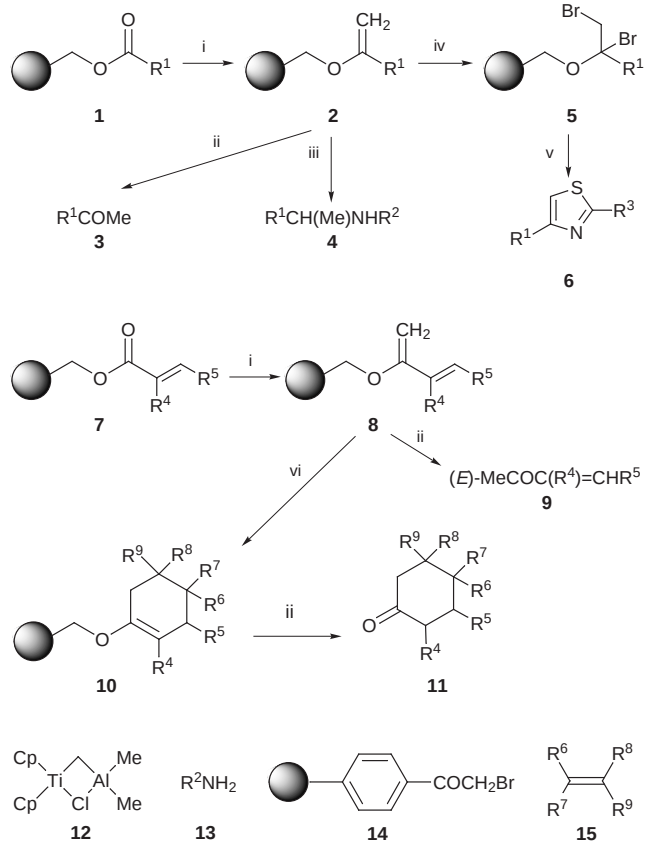
Tebbe olefination of supported esters $R^1CO_2CH_2$–polymer gave the corresponding vinyl ethers $R^1C(=CH_2)OCH_2$–polymer which were released, under acidic conditions, to produce methyl ketones R^1COMe; by reductive amination, to produce amines $R^1CH(Me)NHR^2$; by bromination and reaction of $R^1CBr(CH_2Br)OCH_2$-polymer with thioureas to produce thiazoles; or, for supported dienyl ethers derived from α,β-unsaturated esters, by Diels–Alder reaction and acid mediated cleavage to produce cyclohexanone derivatives.

Solid phase synthesis is invaluable for the construction of libraries of small organic compounds for biological evaluation.[1] Such bioassay is frequently carried out in solution using an appropriate enzyme or receptor. The method of attachment and detachment of the requisite substrates to the resin is critical. In many solid phase syntheses, the substrates are conveniently attached to the polymer support through a carboxylic acid function. This is readily achieved using supports including Merrifield, Wang and Tentagel resins *etc*.[2] Following substrate modification, cleavage affords a carboxylic acid, ester, amide or, *via* reductive cleavage, a primary alcohol. Methods that allow for the cleavage of resin bound carboxylate derivatives yet which access alternative and variable functionality would be extremely desirable. Herein we report the conversion of supported esters into enol ethers,[3] with subsequent on-resin functionalisation and detachment with amplification of diversity.

Methylenation of the resin bound esters **1**‡ with the Tebbe reagent[4] **12** (PhMe–THF 25 °C, 12 h) gave the corresponding vinyl ethers **2** (Scheme 1). The reaction mixtures were quenched with 15% aq. NaOH and the resin washed consecutively with THF, H_2O, EtOAc, EtOAc–MeOH (1:1) and MeOH followed by removal of solvent *in vacuo*. In this reaction, commercial Tebbe reagent (Aldrich) proved to be superior to either **12** generated *in situ*,[5] where premature cleavage from the support was a problem, or the Petasis reagent (Cp_2TiMe_2).[6] Hydrolysis (1 M H_2SO_4 in DMF or 1% TFA in CH_2Cl_2) of ethers **2** brought about cleavage from the resin and gave the corresponding ketones **3**§ (41–92%). Alternatively, acid mediated hydrolysis and reductive amination[7] using amine **13** and $NaBH(OAc)_3$ gave the corresponding amines **4**¶ (13–89%).

The ethers **2** were found to be useful intermediates for further transformations prior to detachment from the resin. Thiazoles, important pharmacophores with diverse biological activities,[8] are available from α-bromo ketones *via* the Hantzsch thiazole synthesis. Thus reaction of the vinyl ether **2** (R = Bn) with Br_2 (1 M in CH_2Cl_2, 2 equiv., 1 h) and washing (CH_2Cl_2) gave the corresponding supported dibromide **5** as indicated by the disappearance of the enol ether (IR), gel phase magic angle spinning ^1H NMR [400 MHz; $CDCl_3$: δ 4.25(CH_2Br)] and elemental analysis (loading 0.65 mmol g^{-1}). Reaction of the dibromide **5** (R = Bn) with thiourea (4 equiv., MeOH at reflux, 12 h), neutralisation (K_2CO_3), filtration with MeOH and evaporation gave thiazole **6** (R = Bn) contaminated with excess thiourea. This impurity was removed by reverse phase HPLC or, more simply, using the polymer supported α-bromo ketone scavenger **14**[9] (200–400 mesh, 0.96 mequiv.g^{-1}, 2 equiv.). Using either of these purification methods, thiazole **6** (R = Bn) was obtained in 40% yield based on the loading of the Merrifield resin (1.0 mmol g^{-1}) to which the phenylacetic acid had been attached. This methodology, which has been extended to a range of thiazoles **6**,‖ has the major advantage of starting from readily available carboxylic acids rather than less diverse commercial α-bromo ketones.

Tebbe methylenation of the resin bound α,β-unsaturated esters **7**[10]‡ (ν_{max}/cm^{-1} 1720–1740) gave the corresponding supported dienyl ethers **8** (1635–1650 cm^{-1}) which could be either hydrolysed (1% TFA in $CDCl_3$) to provide the enones **9**** or converted into the Diels–Alder adducts **10**. The diene



Scheme 1 *Reagents and conditions*: i, **12**, PhMe, THF, 25 °C; ii, 1% TFA, CH_2Cl_2, 25 °C; iii, 1 M H_2SO_4, DMF, then **13**, $NaBH(OAc)_3$, 25 °C; iv, Br_2, CH_2Cl_2 (1 M, 2 equiv.), 25 °C; v, R^3CSNH_2 (4 equiv.), MeOH, reflux, then **14** (2 equiv.), MeOH, reflux; vi, **15**, PhMe, 25 °C (maleimide) or 80–100 °C (other dienophiles)

resins **8** may be stored for up to six months without loss of activity but were generally used directly. Diels–Alder reaction with *N*-methylmaleimide (PhMe, 25 °C) or 2-chloroacrylonitrile, methyl vinyl ketone, dimethyl fumarate or 2-ethylacrolein (PhMe, 80–100 °C) gave the immobilised cyclohexene derivatives **10**. Subsequent cleavage from the resin (1% TFA in CH_2Cl_2) gave the corresponding cyclohexanone derivatives **11**.†† We observed high *endo*-selectivity with *N*-methylmaleimide consistent with the solution phase reactions of 2-silyloxy dienes with maleimides[11] and in contrast with Diels–Alder reactions of resin bound 4-substituted 2-aminobutadienes.[12]

In summary, we have developed a novel detachment method for the removal of substrates from a solid support which allows for the concomitant introduction of further diversity. This strategy using chameleon‡‡ catches should be applicable to the generation of diverse libraries from polymer supported carboxylic esters. Further reactions of the supported enol ethers will be reported in due course.

We thank Rhône-Poulenc Rorer for the most generous support of our programmes on parallel and combinatorial syntheses under the auspices of the TeknoMed project. In addition we thank GlaxoWellcome Research Ltd. for their endowment (to A. G. M. B.), the Royal Society for a Dorothy Hodgkin fellowship (to M. L. S) and the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

‡ The supported esters **1** and **7** were prepared from Merrifield resin (200–400 mesh, 1.0–1.7 mequiv. g^{-1}) (Cs_2CO_3, KI, DMF, 80 °C) [the Tebbe olefination chemistry in this paper has also been carried out on Wang resin (200–400 mesh, 0.7–1.13 mequiv. g^{-1})]. For an alternative synthesis of supported α,β-unsaturated esters see ref. 12. All syntheses in this paper were carried out both manually, using single bead FT-IR spectroscopy to follow reactions (**1** 1720–1740, **2** 1635–1645, **7** 1720–1740, **8** 1635–1650 cm^{-1}) and in a parallel fashion on a Nautilus™ 2400 Organic Synthesizer (Argonaut Technologies, Inc.). All the products were at least 90% pure (HPLC, GC–MS). All yields were determined with respect to the original loading of chloride for Merrifield resin.

§ The ketones **3** [R^1 (%)] were isolated by filtration and evaporation: $Me(CH_2)_6$ (87%); Ph (62%); 4-BrC_6H_4 (41%); 4-IC_6H_4 (71%); 4-$MeOC_6H_4$ (92%); 3-$MeOC_6H_4$ (56%); 2,4,6-$(MeO)_3C_6H_2$ (47%); 4-$MeOC_6H_4CH_2$ (74%); 4-PhC_6H_4 (65%) and 3-indolyl–CH_2CH_2 (74%).

¶ The amines **4** [R^1, R^2 (%)] were isolated by filtration, partition between Et_2O and 1 M NaOH, drying ($MgSO_4$) and evaporation: $Me(CH_2)_6$, Pr (13%); $Me(CH_2)_6$, cyclopropyl (19%); $Me(CH_2)_6$, allyl (27%); 4-$MeOC_6H_4CH_2$, Pr (89%); 4-$MeOC_6H_4CH_2$, cyclopropyl (85%); 4-$MeOC_6H_4CH_2$, allyl (89%); 3-indolyl–CH_2CH_2, Pr (65%); 3-indolyl–CH_2CH_2, cyclopropyl (61%); 3-indolyl–CH_2CH_2, allyl (79%).

‖ The thiazoles **6** [R^1, R^3 (%)] were isolated following purification using scavenger **14**: Ph, NH_2 (40%); Ph, NHMe (15%); Ph, NHBn (10%); Ph, Me (14%); 3-$MeOC_6H_4$, NH_2 (23%); 3-$MeOC_6H_4$, NHMe (15%); 3-$MeOC_6H_4$, NHBn (13%); $Me(CH_2)_6$, NH_2 (15%); $Me(CH_2)_6$, NHMe (10%); $Me(CH_2)_6$, NHBn (12%).

** The enones **9** [R^4, R^5 (%)] were quantified by cleavage (1% TFA in $CDCl_3$) and ^1H NMR with a $(Me_3Si)_2O$ reference: H, Ph (50%); H, Me (28%); H, Et (31%); H, Pr (33%); H, $Me(CH_2)_6$ (48%); $(CH_2)_4$ (53%).

†† The cyclohexanones **11** [R^4, R^5, dienophile, (%, diastereoselectivity)] were quantified by cleavage (1% TFA in $CDCl_3$) and ^1H NMR with a $(Me_3Si)_2O$ reference: H, Ph, *N*-methylmaleimide (30%, 97:3); H, Me, *N*-methylmaleimide (30%, 97:3); H, Et, *N*-methylmaleimide (18%, 97:3); H, Pr, *N*-methylmaleimide (27%, 97:3); H, $Me(CH_2)_6$, *N*-methylmaleimide (35%, 7:3); $(CH_2)_4$, *N*-methylmaleimide (51%, 97:3); H, Ph, (*E*)-$MeO_2CCH{=}CHCO_2Me$ (17%, 1:1); H, Ph, $H_2C{=}CClCN$ (23%, 7:3); H, Ph, $H_2C{=}CEtCHO$ (21%, 5:3); H, Ph, $H_2C{=}CHAc$ (44%, 7:3); H, Me, $H_2C{=}CHAc$ (11%, 5:3); H, $Me(CH_2)_6$, $H_2C{=}CEtCHO$ (19%, 3:1); H, $Me(CH_2)_6$, $H_2C{=}CEtAc$ (22%, 4:1); $(CH_2)_4$, $H_2C{=}CEtCHO$ (20%, 2:2:1:1); $(CH_2)_4$, $H_2C{=}CHAc$ (43%, 3:2).

‡‡ For other chameleons see refs. 13 and 14. Petasis has mentioned the possibility of the olefination of polymer supported peptides using Cp_2TiMe_2 but has yet to report any details: *Fifth Chemical Congress of North America*, Cancun, Mexico, November 13, 1997.

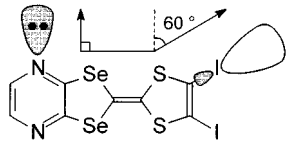
A unique hexagonal system based on an organic π-donor has been tailored by the *strong* and *directional* I···N intermolecular interaction, and its highly symmetrical structure including two types of channels and high conductivity are reported.

The development of highly symmetrical systems is always of interest in materials science as in the cases of molecular conductors based on fullerenes,[1,2] and the introduction of a characteristic intermolecular interaction is necessary to construct a unique molecular-based crystal system. One of the major techniques for controlling solid-state molecular assemblies is the use of the hydrogen bond,[3] however, it is not always enough to fix the direction of the interaction. Recently, we have found that the *strong* and *directional* I···X (X = CN, S or halogen atoms) type cation···anion interaction is useful to control the molecular arrangement of organic conductors.[4] An example of the above I···N interaction is the impressive one-dimensional chain structure in the crystal of *p*-iodobenzonitrile.[5] In the course of our study to extend and generalize the new I···N architecture for molecular-based materials, we have designed diiodo(pyrazino)diselenadithiafulvalene (DIPS, **1**; Scheme 1) which contains two interaction sites, the iodine atom and the nitrogen atom on the edges of the skeleton. Here we report the synthesis, structure and physical properties of a unique hexagonal system with high conductivity and two types of channels tailored by the strong and directional I···N intermolecular interactions.



1

Scheme 1 Schematic view of molecular structure of a new iodine-bonded π-donor **1** and directions of lone pair on the pyrazine ring and σp LUMO on the C–I bond (see text)

Synthesis of **1**† was achieved by the cross-coupling reaction of 4,5-diiodo-1,3-dithiole-2-one[6] and pyrazine-fused 1,3-diselenole-2-one.[7] Long rod-like single crystals (average size 1 mm long, 0.1 mm diameter) of $(\mathbf{1})_3(PF_6)(solv.)_x$ [solv. = chlorobenzene, dichloromethane or trichloroethane] were obtained by the galvanostatic oxidation (1.0 μA) of a solution (20 ml) containing **1** (*ca.* 8 mg) and tetrabutylammonium hexafluorophosphate (*ca.* 20 mg) as a supporting electrolyte. Single crystals were grown on the anode within a few days and the hexagonal section of the rod is in accordance with the hexagonal crystal system (Fig. 1). Elemental analyses indicate that the donor-anion ratios of the salts are 3 : 1 and the solvent used in the crystallization is included in the crystal.‡

Temperature dependences of the conductivity for the salts were measured by the standard four-probe method. They are all semiconductive from room temperature, however, the room temperature conductivity is rather high ($\sigma_{rt} \approx 10$ S cm^{-1}) and the activation energy is small (*ca.* 50 meV).

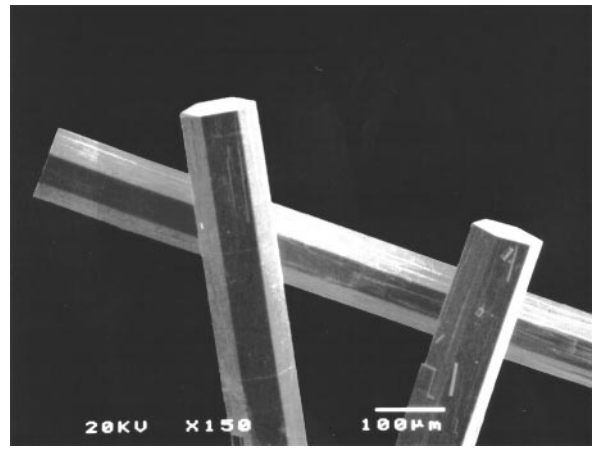


Fig. 1 Photographic SEM image of single crystals for $(\mathbf{1})_3(PF_6)(chlorobenzene)_{1.15}$

X-Ray structural analyses were performed on the single crystals and all salts crystallize into a hexagonal $P6_3/mcm$ space group and are isostructural.§ Fig. 2 shows the unit cell of the PF_6–chlorobenzene salt and there are two types of triangular units of the donor molecules within the *ab* plane, ordered clockwise and anticlockwise, respectively. The hexagonal lattice is constructed by the alternating repetition of these triangular units. The shortest intermolecular I···N distance is 2.879(6) Å and it is almost 20% shorter than the sum of the van der Waals radii (3.53 Å; Bondi[8]). This characteristic I···N contact is much shorter than that of the above-mentioned *p*-iodobenzonitrile crystal (3.18 Å)[5a] and indicates the existence of a very strong intermolecular I···N interaction. The value of the C–I···N angle is almost linear [178.3(2)°] and it is in good agreement with the direction of the pσ LUMO along the carbon–iodine single bond and the lone pair on the pyrazine ring

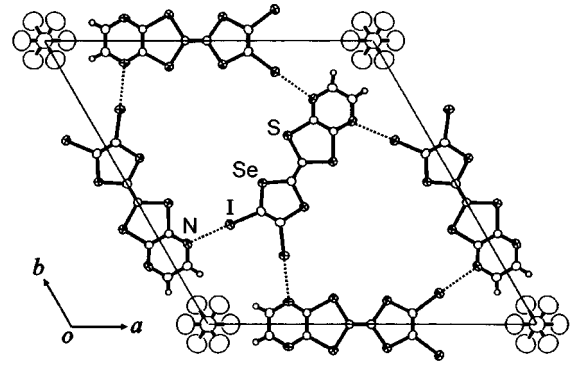

Fig. 2 Crystral structure of $(\mathbf{1})_3(PF_6)(chlorobenzene)_{1.15}$ viewed along the crystallographic *c* axis. Chlorobenzene molecules are omitted for clarity. The shortest I···N intermolecular distance (dotted line) is 2.879(6) Å.

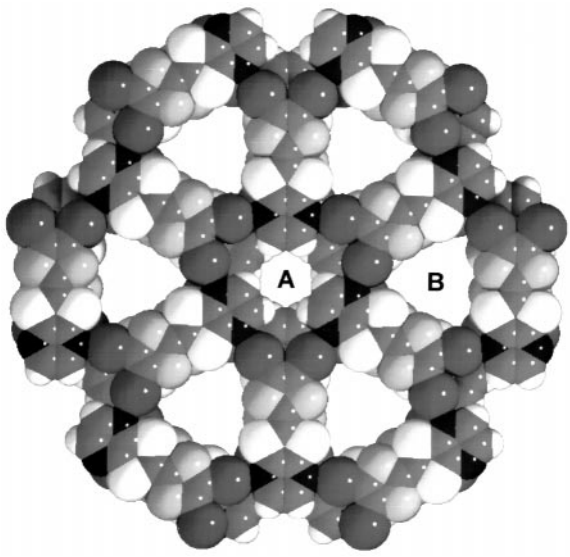

Fig. 3 Extended hexagonal donor-column arrangement of the $(\mathbf{1})_3$(anion)-(solv.)$_x$ crystal system

(Scheme 1). The donor molecule also forms a one-dimensional column along the *c* axis within the head-to-tail mode, this is the regular manner for unsymmetrical π-donors. The topology of the donor network should be recognized as the combination of: (i) characteristic I···N intermolecular interaction parallel to the molecular plane, and (ii) columnar stack perpendicular to the molecular plane.

Fig. 3 shows the extended donor network projected onto the *ab* plane and we can see that there are two types of channels along the *c* axis. One is hexagonal and surrounded by the edges of donor molecules (channel site A, *ca.* 4 Å diameter) and the other is an equilateral triangle surrounded by the sides of donor molecules (channel site B, side length *ca.* 7.5 Å). The PF_6 anion is in channel site A and the phosphorus atom is on the crystallographic special position. The included solvent is in channel site B and is highly disordered due to the low symmetry of the molecule compared with the crystallographic symmetry. Comparing the structures of the salts including different solvent molecules, the whole crystal system is not affected by changing of the solvent and the hexagonal arrangement is identical. The guest-independent channel structure is similar to those of the inorganic 'zeolite' systems[9] and it would be promising to introduce functionalized guest molecules to obtain multi-functionalized materials. Preliminary thermogravimetric experiments indicated that the PF_6–dichloromethane single crystals began to release the included solvent around 80 °C. The decrease in the sample weight had stopped after annealing at 110 °C for 5 days in the case of the powdered sample and the amount of weight loss (*ca.* 6% *vs.* initial weight) is in accordance with the calculated weight percent of dichloromethane included in the crystal.

We thank Professor R. Kato for the use of his conductivity measurement apparatus, and the Material Design and Characterization Laboratory of ISSP (University of Tokyo) for the use of their X-ray diffractometers and SEM-EPMA. This work was partially supported by Grant-in-Aids for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

Ozone-cleavable gemini surfactants, a new candidate for an environmentally friendly surfactant

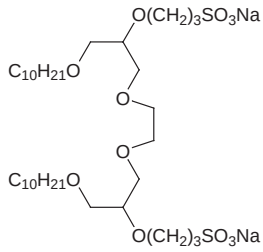
Araki Masuyama,*† Chikara Endo, Shin-ya Takeda and Masatomo Nojima

Department of Materials Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565-0871, Japan

Three types of gemini surfactants bearing carbon–carbon double bond(s) showed excellent surface-active properties, and readily decomposed into non-surface-active fragments and/or single-chain surfactants with different surface-active properties upon exposure to ozone in water.

Surfactants are one of the representative chemical products which are consumed in large quantities every day on a world-wide scale. Special regard concerning environmental safe-guards should be paid to the development of the next generation of new surfactants. Application of ozone in waste water treatment is noted as a modern key technology for the environmental protection of rivers and lakes.[1] Many sewage treatment plants in which an ozonation process is incorporated are operating around the world.

We herein propose a new design of novel surfactant featuring 'environmentally-friendly' characteristics. The concept is based on the following two points: (i) lowering the quantity of surfactant used will contribute greatly to reducing the load on the natural purification system, and (ii) breaking down the original surfactant molecules into smaller fragments after they have fulfilled their original applications will assist the waste water treatment process. Concerning the first point, double-chain surfactants bearing two hydrophilic ionic head groups, generally called 'gemini surfactants',[2] are an attractive motif



1

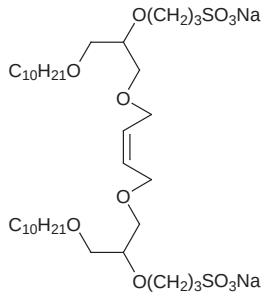
3



4

because many types of gemini surfactants, such as **1**,[3] have very small CMC (critical micelle concentration) values and have the ability to significantly lower surface tension, both of which properties cannot be achieved *via* simple modification of the structure of conventional single-chain monoionic surfactants.[4] The second point is connected with 'chemocleavable' or 'destructive' surfactants, which are one of the stimulating targets of research in the chemistry of amphiphilic compounds.[5] Taking into account these backgrounds, we have recently designed and prepared three types of gemini surfactants bearing carbon–carbon double bond(s) in their lipophilic chains and/or the connecting part (**2**–**4**). Ozonation is applied as a trigger for the destruction of these unsaturated gemini surfactants in water. In connection with our latter approach, Piasecki and co-workers have investigated the reactivity of long-chain alkyl-substituted cyclic acetals toward ozone in water.[6]

Preparation of the target compounds **2**–**4** was achieved according to the established method.[3] Thus they were synthesised by the reaction of 1,2:9,10-diepoxy-4,7-dioxadecane (for preparation of **2**) or (*Z*)-1,2:11,12-diepoxy-4,9-dioxadodec-6-ene (for **3** and **4**) with (*Z*)-dec-4-en-1-ol (for **2** and **3**) or decan-1-ol (for **4**) in the presence of base, followed by sulfopropylation of the resulting double-chain diols with propane-1,3-sultone.‡ Table 1 summarises the data for their CMC, γ_{CMC} (the surface tension at CMC, as an indication of the effectiveness of adsorption at the air/water interface)[7] and pC_{20} (the efficiency of adsorption)[7] values, which were obtained from respective surface tension *vs*. concentration (on a log scale) curves measured by the Wilhelmy method. The corresponding data for the gemini surfactant **1**[3] and the single-chain sulfonate $[C_{10}H_{21}O(CH_2)_2SO_3Na]$ **5**[7] are also included in Table 1 as reference amphiphiles.

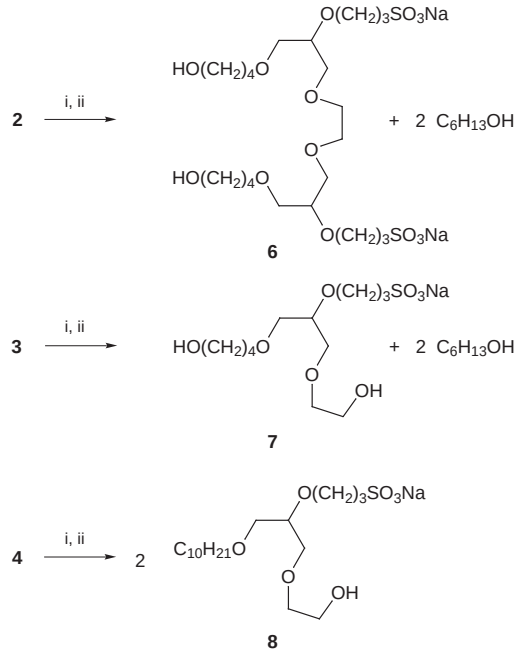
The CMC of a surfactant bearing carbon–carbon double bond(s) in its lipophilic chain is generally higher than that of the corresponding saturated compound.[7] This is also the case for the CMC of gemini surfactants **1**–**3**. It should be noted, however, that the CMC values of **2** and **3** are two orders lower than that of the conventional single-chain analogue **5**. Interestingly, the CMC of the gemini surfactant **4** is very similar to that of the corresponding saturated gemini surfactant **1**, indicating that the CMC is not affected by an unsaturated bond in the connecting part of these gemini surfactants. In summary, both effectiveness and efficiency of adsorption on the surface for a series of gemini surfactants **1**–**4**, regardless of the presence or the absence of double bond(s) in the molecule, are much higher than those for the single-chain surfactant **5**.

Ozonolysis of gemini surfactants **2**–**4** was easily accomplished by passing ozone through their micellar aqueous solutions (1×10^{-2} mol dm^{-3}) at room temperature. Subsequent treatment of the reaction mixture with $NaBH_4$ afforded

Table 1 Interfacial properties of surfactants **1–5** measured by the Wilhelmy method at 20 °C in water

Surfactant	CMC/mol dm^{-3}	γ_{CMC}/mN m^{-1}	pC_{20}
1[a]	3.2×10^{-5}	30.0	5.2
2	9.0×10^{-5}	34.0	5.1
3	1.0×10^{-4}	33.5	5.2
4	2.5×10^{-5}	33.0	5.7
5[b]	1.6×10^{-2}	41.0	2.1

[a] Ref. 3. [b] Ref. 7.



Scheme 1 *Reagents and conditions*: i, **2**, **3** or **4** in water (1×10^{-2} mol dm^{-3}), O_3 (10 equiv.), room temp.; ii, $NaBH_4$ (1.5 equiv.), 5 min., room temp.

the corresponding degradation products, as shown in Scheme 1.§ These products could be extracted as a mixture in each case with $CHCl_3$–MeOH (3:1, v/v). Their structures were confirmed by comparison of their ^1H and ^{13}C NMR data with those of hexan-1-ol and authentic samples of **6**–**8**.¶ Judging from the TLC results of the extracted mixtures and their ^1H NMR spectra in D_2O, other degradation products were not observed and compounds **6**–**8** were found to be produced almost quantitatively.

After ozonolysis and successive reduction of micellar solutions of gemini surfactants **2** and **3**, oil droplets (*i.e*. hexan-1-ol) appeared in the solutions; stable foams were not observed, even immediately after shaking the solutions. Stable foams were generated, however, by shaking solutions containing ozonolysis product **8**. Compound **8** was still surface-active and its surface-active properties were: CMC = 8.0×10^{-4} mol dm^{-3}; γ_{CMC} = 35 mN m^{-1}; pC_{20} = 3.8. Thus the interfacial properties of the parent gemini surfactant **4** and the single-chain surfactant **8** are quite different. Thus, surfactant **4** is categorised as a second generation type of cleavable surfactant.[8]

In summary, the readily accessible gemini surfactants **2**–**4** possess considerable potential as high-performance surfactants. Fragmentation of **2**–**4** in water smoothly takes place on exposure to ozone, followed by reduction with $NaBH_4$ under mild conditions. Studies on various surface-active properties of a homologous series of gemini surfactants and their biodegradability are now in progress.

This work was supported in part by the Fund for Environmental Protection Research from the Nihon-Seimei Foundation.

Note and References

‡ All new compounds gave satisfactory spectroscopic and microanalytical data.

§ A suitable reductant is required to give stable degradation products in water because the corresponding unstable α,α′-dihydroxy peroxides are formed by ozonolysis of the substrates. $NaBH_4$ was chosen because it is an inexpensive industrial reductant and can be used in water.

¶ Authentic compound **6** was prepared by the reaction of $THPO(CH_2)_4OH$ (THP = tetrahydropyranyl) with ethylene glycol diglycidyl ether, followed by sulfopropylation with propane-1,3-sultone and successive deprotection of the THP group by treatment with sulfuric acid. The reaction of $THPO(CH_2)_4OH$ with mono-THP-protected ethylene glycol glycidyl ether, or the reaction of decyl glycidyl ether with mono-THP-protected ethylene glycol, followed by sulfopropylation and successive deprotection afforded authentic compounds **7** and **8**, respectively.

Carbonyl propargylation or allenylation by 3-haloprop-1-yne with tin(II) halides and tetrabutylammonium halides

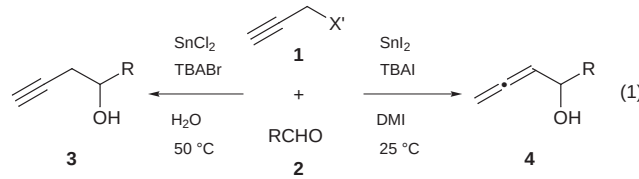
Yoshiro Masuyama,*† Akihiro Ito, Mamiko Fukuzawa, Kohji Terada and Yasuhiko Kurusu

Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102-8554, Japan

3-Bromoprop-1-yne causes carbonyl propargylation with tin(II) chloride and tetrabutylammonium bromide in water to produce 1-substituted but-3-yn-1-ols, while 3-chloroprop-1-yne causes carbonyl allenylation with tin(II) iodide and tetrabutylammonium iodide in 1,3-dimethylimidazolidin-2-one to produce 1-substituted buta-2,3-dien-1-ols.

Carbonyl propargylation or allenylation by 3-haloprop-1-yne with tin(II) chloride is one of the most convenient methods for introduction of propargyl (prop-2-ynyl) or allenyl functions.[1–3] The propargylation or allenylation is promoted by NaI or LiI; it has been presumed that the actual starting material, which reacts with tin(II) chloride, is 3-iodoprop-1-yne derived from the *in situ* reaction 3-bromoprop-1-yne with NaI or LiI.[1,3] We have found that carbonyl allylation by allylic acetates, allylic bromides, allylic chlorides and vinyl epoxides with rin(II) halide can be promoted by tetrabutylammonium bromide (TBABr).[4–8] A lack of reaction with TBABr might suggest that LiI is required to form the intermediate 3-iodoprop-1-yne.[3] Tetrabutylammonium halide (TBAX‴) probably reacts with tin(II) halide (SnX''_2) to form tetrabutylammonium trihalostannate, which is more nucleophilic than SnX''_2. We thus envisioned that TBAX‴ would promote carbonyl propargylation or allenylation by 3-haloprop-1-yne with SnX''_2.[9,10] We here report that using different halogens in SnX''_2 and TBAX‴ affects the selectivity between carbonyl propargylation and allenylation by 3-haloprop-1-yne; carbonyl propargylation occurs with $SnCl_2$ and TBABr, while carbonyl allenylation occurs with SnI_2 and TBAI.

The reaction of 3-haloprop-1-yne **1** and benzaldehyde (**2**, R = Ph) with SnX''_2 and TBAX‴ was investigated under various conditions. The results are summarized in Table 1. The reaction of 3-bromoprop-1-yne (**1**, X′ = Br) with $SnCl_2$ and TBABr at 50 °C in water led to carbonyl propargylation to produce 1-phenylbut-3-yn-1-ol (**3**, R = Ph) (entry 7, Method A), while the reaction of 3-chloroprop-1-yne (**1**, X′ = Cl) with SnI_2 and TBAI at 25 °C in 1,3-dimethylimidazolidin-2-one (DMI) led to carbonyl allenylation to produce 1-phenylbuta-2,3-dien-1-ol (**4**, R = Ph) (entry 13, Method B) [eqn. (1)]. TBAX‴ accelerated



(1)

the carbonyl propargylation or allenylation; > 0.1 equiv. of TBAX‴ was required (entries 5–8). In the propargylation the use of $SnCl_2$ and TBABr (or TBACl) is superior to other combinations of reagents, while SnI_2–TBAI is the best combination of reagents for the allenylation. 3-Chloroprop-1-yne (**1**, X′ = Cl) did not react under the same conditions as those of the propargylation with **1** (X′ = Br). Water is a more effective solvent in the propargylation than some organic polar solvents, such as DMI and THF, in which both organic substrates and $SnCl_2$ are soluble (entries 1, 2 and 8). The by-product produced during the propargylation, 4-phenylbut-3-en-2-one (**5**, R = Ph), was probably formed by the hydration of allenylated product **4** (R = Ph).[3] The reaction of **1** (X′ = Cl) and **2** (R = Ph) with SnI_2–TBAI did not occur in water, and proceeded with lower selectivity for the allenylation in DMI–water (entry 14). Thus, water is unsuitable for the allenylation, in which DMI is a better solvent than DMF or THF (entries 11–13).

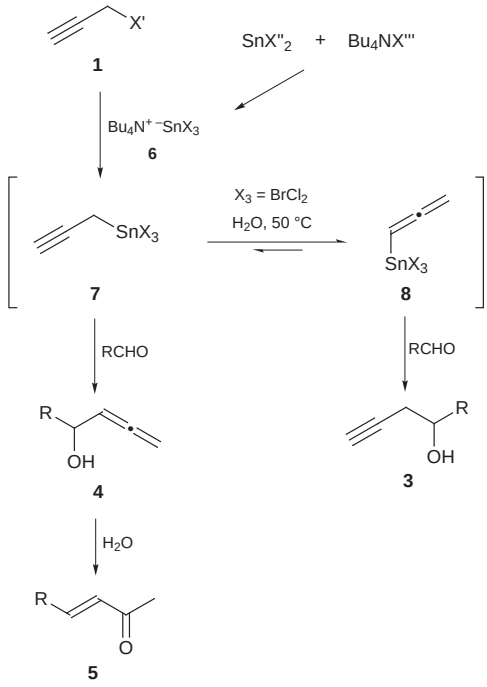
[a] Method A: Entry 7 in Table 1. Method B: Entry 13 in Table 1. [b] Yields of a mixture of **3** and **4**. The ratio in parentheses was determined by ^{1}H NMR analysis (JEOL GX-270 or Λ–500). [c] Isolated yields. [d] The reaction was carried out at 0 °C.



Scheme 1

The propargylation (Method A) and allenylation (Method B) of various aldehydes by 3-haloprop-1-yne **1** was carried out under the conditions which gave the best results for benzaldehyde, as summarized in Table 2. Aromatic aldehydes bearing an electron-donating or −withdrawing group and aliphatic aldehydes can be used to afford the corresponding 1-substituted but-3-yn-1-ols **3** using the $SnCl_2$–TBABr/water system or the corresponding 1-substituted buta-2,3-dien-1-ols **4** with the SnI_2–TBAI/DMI system in moderate yields.

A plausible mechanism was illustrated with Scheme 1. The difference between propargylation using the $SnCl_2$–TBABr/water system and allenylation using the SnI_2–TBAI/DMI system may be due to the Lewis acidity of the tin, reaction temperature and reaction medium. ^{1}H NMR (JEOL Λ–500) observation in [$^2H_7$]DMF at 25 °C revealed that prop-2-ynyltriiodotin (**7**, X = I) was first formed *via* the reaction of 3-chloroprop-1-yne (**1**, X′ = Cl) with SnI_2 and NaI. Prop-2-ynyltriiodotin (**7**, X = I) probably proceeded *via* γ-addition to the aldehyde (carbonyl allenylation), without isomerizing to propa-1,2-dienyltriiodotin (**8**, X = I), in dry polar solvents such as DMI and DMF to produce buta-2,3-dien-1-ols **4**.‡ In contrast, the isomerization of prop-2-ynylbromodichlorotin (**7**, X_3 = $BrCl_2$), derived from reaction of 3-bromoprop-1-yne (**1**, X′ = Br) with $SnCl_2$ and TBABr at the organic–aqueous interface, to propa-1,2-dienylbromodichlorotin (**8**, X_3 = $BrCl_2$) probably occurred more rapidly at 50 °C than carbonyl allenylation by **7** (X_3 = $BrCl_2$).§ The carbonyl propargylation by **8** (X_3 = $BrCl_2$) at 50 °C in water thus produced but-3-yn-1-ols **3**.¶

Notes and References

† E-mail: y-masuya@hoffman.cc.sophia.ac.jp

‡ The carbonyl allenylation by **7** (X = I) seems to have proceeded *via* an acyclic antiperiplanar transition state, because of the weakly Lewis acidic tin in **7** (X = I). See ref. 7 and 8.

§ It was shown by ^{1}H NMR analysis (JEOL Λ–500) that prop-2-ynyltriiodotin (**7**, X = I), derived from 3-chloroprop-1-yne (**1**, X′ = Cl) *via* reaction with SnI_2 and NaI in [$^2H_7$]DMF, isomerized easily to propa-1,2-dienyltriiodotin (**8**, X = I) at 50 °C; J. A. Marshall, R. H. Yu and J. F. Perkins, *J. Org. Chem*., 1995, **60**, 5550.

¶ The carbonyl propargylation by **8** (X_3 = $BrCl_2$), which has a strongly Lewis acidic tin, seems to have proceeded *via* a usual six-membered cyclic transition state.

Unexpected regioselectivity in the coupling of π-coordinated tritylallene with an amido ligand in molybdenum complex

Bor-Chen Huang, Ying-Chih Lin,* Yi-Hong Liu and Yu Wang

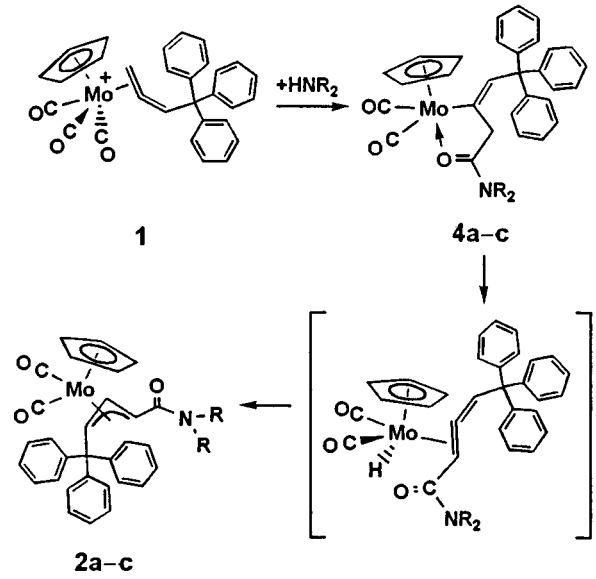
Department of Chemistry, National Taiwan University Taipei, Taiwan 106, Republic of China. E-mail: yclin@mail.ch.ntu.edu.tw

Coupling of π-coordinated tritylallene with an amido ligand was unexpectedly found to take place at the terminal carbon in the reaction of $[Cp(CO)_3Mo(\eta^2\text{-}CH_2{=}C{=}CHCPh_3)][BF_4]$ 1, with three secondary amines (dimethylamine, piperidine, morpholine).

The synthesis and reactivity of organometallic complexes containing η^3-allyl,[1] η^1-allenyl[2] and η^1-propargyl[3] ligands have attracted a great deal of attention owing to their wide applications in organic synthesis. We recently reported distinctive regiospecificity of C–C bond formation in the reactions of tungsten allenyl and propargyl complexes. In the allenyl system,[4] reactions with amines and with alcohols afforded high yields of azametallacycles and oxametallacycles, respectively. The C–C bond formation takes place solely at C_α of the allenyl ligand in both cases. By contrast, the corresponding propargyl complex afforded exclusively the β-coupled allylic complex, the latter regiospecificity was assumed to proceed *via* a η^2-allene intermediate.[5] In a particular system, the η^2-tritylallene complex $[Cp(CO)_3M(\eta^2\text{-}CH_2{=}C{=}CHCPh_3)][BF_4]$, (M = Mo **1**, M = W **1′**, Cp = η^5-C_5H_5) could be isolated and displays coupling reactivity with the expected regiospecificity in reactions with alcohols and some amines.[6] However, when we studied more reactions of **1** with amines, three amines were found to display different regioselectivity. Herein we report the unexpected regioselectivity in the reaction of **1** with these three amines, yielding the α-amido substituted allylic complex as the major product and the β-amido allylic complex as the minor product.

Reaction of **1** with neat piperidine at room temperature for 1 h afforded two amido-substituted allylic products. The major product $Cp(CO)_2Mo[\eta^3\text{-}CH(CONC_5H_{10})CHCHCPh_3]$ **2a**,† has a surprising α-amido-substituted geometry, and the minor product $Cp(CO)_2Mo[\eta^3\text{-}CH_2C(CONC_5H_{10})CHCPh_3]$ **3a**, a normal β-amido-substituted geometry (Scheme 1). The two isomers can be separated by chromatography over silica gel. Complexes **2a** and **3a** were collected as orange–yellow and light-yellow microcrystalline powders upon re-crystallization from hexane–CH_2Cl_2 in *ca.* 65 and 17% yields, respectively. Similar results were found with morpholine and dimethylamine to yield the α-amido-allylic complexes **2b**, **c**† respectively as the major product and the β-amido-allylic complexes **3b**, **c** as the minor product and an X-ray analysis was carried out on a crystal of **2b**.‡ An ORTEP drawing of **2b** is shown in Fig. 1. The most salient feature of the molecule is the presence of an amido-substituted tritylallyl ligand. The amido substituent is attached to the α-carbon C(5) of the allyl ligand with a geometry *syn* to the central hydrogen and the trityl moiety is in an *anti* configuration.

Two possible mechanisms are proposed to account for the formation of **2a**. In both cases, it is necessary to consider nucleophilic attack of amine to the terminal carbonyl giving the amido ligand. Deprotonation[7] of the tritylallene ligand in the presence of amine may result in formation of an allenyl ligand and coupling of the amido ligand with the α-carbon of the σ-allenyl followed by protonation would give the major product.[8] Alternatively, coupling of the amido group with allene leading to C–C bond formation may precede hydrogen migration and the selectivity would be controlled by the presence of the trityl group. To better understand the detail and with the hope to see an intermediate the reaction was monitored



Scheme 1 HNR_2 = piperidine **a**, morpholine **b** or dimethylamine **c**

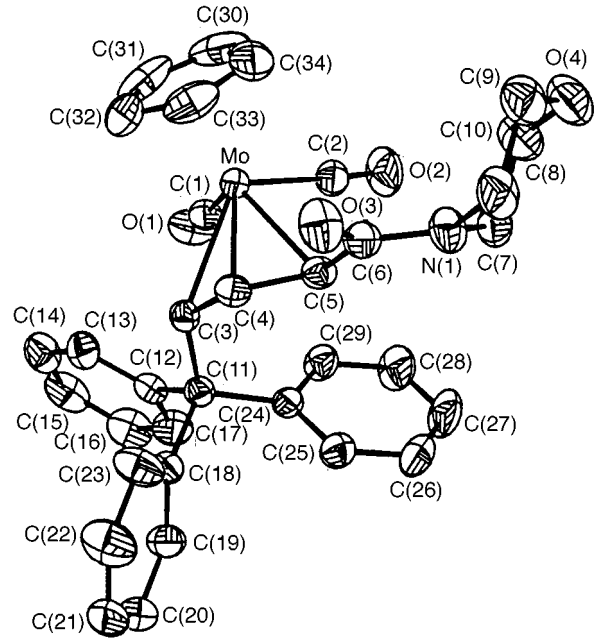


Fig. 1 ORTEP drawing of **2b** with thermal ellipsoids shown at the 50% probability level. Selected bond distances (Å) and angles (°): Mo–C(3) 2.379(2), Mo–C(4) 2.212(2), Mo–C(5) 2.359(2), C(3)–C(4) 1.417(3), C(4)–C(5) 1.409(3), C(5)–C(6) 1.500(3), C(6)–N(1) 1.356(3), C(6)–O(3) 1.228(3); C(4)–C(3)–C(11) 125.1(2), C(4)–C(5)–C(6) 115.4(2), C(1)–Mo–C(2) 77.13(11).

spectroscopically. When the reaction was carried out at −60 °C, an intermediate was indeed observed. Upon addition of piperidine at −60 °C, the light yellow complex **1** dissolved and the solution turned deep red, to give a mixture of an unstable intermediate **4a** as well as **3a**. In the IR spectrum of the mixture the intermediate displays two peaks at 1927 and 1828 cm^{-1} as well as one amido CO stretching absorption at 1577 cm^{-1}. The latter suggested the presence of O-coordinated amido carbonyl.[9] Complex **4a**† transforms to **2a** in 1 h at room temperature but at lower temperature this process is slowed and the structure of **4a** can be assigned on the basis of the spectroscopic data of the mixture obtained at −60 °C. In the ^{1}H NMR spectrum, two doublet resonances at δ 2.28 and 2.74 with J_{HH} 22.4 Hz indicate the presence of a CH_2 group while a singlet resonance at δ 6.55 is assigned to the =CH– group for **4a**. Two-dimensional HSQC[10] data confirms the CH_2 ^{13}C resonance at δ 47.2 and ^{13}CH group at δ 147.5. In the HMBC[11] spectrum, the cross-peak between the CH_2 (δ_H 2.28, 2.74) and the CON (δ_C 180) groups[12] indicate C–C bond formation at the terminal CH_2 group. These observations imply that the intermediate could be a vinyl[13] complex, (Scheme 1) and the first mechanism is thus ruled out. Hydrogen migration of **4a** may proceed through β-elimination to give the metal hydride allene followed by coupling of the hydride at C_β of the allene to give the final product **2a**.

Reactions of **1** with other amines such as methylamine, ethylamine, propylamine, phenylamine, benzylamine, diethylamine, diisopropyl amine, di-*sec*-butylamine, diisobutyl amine and hydrazine gave only the β-coupled product. The p*K*a values of the three unique amines (8.30 for morpholine, 10.90 for Me_2NH and 11.20 for piperidine) giving the α-coupled product are in the range of regular amines (4.69 for aniline to 11.1 for diisopropyl amine) while no striking steric effect is seen for these three amines. While we cannot explain their different reactivity, this is the first case where coupling at the α-position of a η^2-allene has been found. A detailed mechanism for this unusual coupling, the reactivity of compound **1** with other nucleophiles and the corresponding reaction for the tungsten system is currently under investigation.

We are grateful for support of this work by the National Science Council, Taiwan, the Republic of China.

Electrospray mass spectrometric studies of the rhenium hydroxy and methoxy carbonyl complexes $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ (R = H, Me)

Chenghua Jiang,[a] William Henderson,*[b] T. S. Andy Hor,*[a] Louise J. McCaffrey[b] and Yaw Kai Yan*[c]

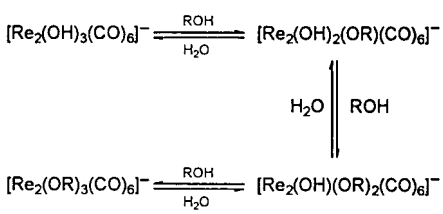
[b] *Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand*
[c] *Division of Chemistry, National Institute of Education, Nanyang Technological University, 469 Bukit Timah Road, Singapore 259756. E-mail: yanyk@nievax.nie.ac.sg*

Exchange reactions of $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ (R = H, Me) with alcohols and phenol have been established by electrospray mass spectrometry (ESMS); dehydration of $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$ and the β-hydride elimination reaction of $[Re_2(\mu\text{-}OMe)_3(CO)_6]^-$ have also been observed under ESMS conditions.

Transition-metal carbonyl hydroxides and alkoxides have been proposed as intermediates in a number of important reactions, such as metal-catalysed hydrogenation of CO,[1] the water–gas shift reaction,[2] and carboalkoxylation of alkenes.[3] Although the syntheses of the complexes $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ (R = H, Me, Et, Pr^i) were reported more than two decades ago,[4] the chemistry of these complexes have received relatively little attention.[5] This is perhaps due to the perceived limited scope of reactivity of these compounds. Simpson and Bergman recently reported the facile alkoxide-exchange reactions of the terminal-alkoxo complexes *fac*-$[Re(\eta^1\text{-}OR)(L)_2(CO)_3]$ (L = phosphine or arsine, R = Me, Et, Pr^i) with alcohols and phenols.[6] It is of interest to investigate the feasibility of analogous exchange reactions involving the bridging-alkoxo complexes $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$, which have in principle three exchangeable alkoxide or hydroxide ligands. Such exchange reactions have been briefly alluded to in the literature[4b,7] but no systematic study has been carried out on them.

The study of the alkoxide exchange reactions of the tris-alkoxo-bridged complexes is expected to be complicated by the formation of singly, doubly and triply-exchanged species which exist in equilibrium with each other (Scheme 1). Identification of these inter-converting species in solution by IR or NMR spectroscopy is expected to be very difficult, especially when the R group (*e.g. n*-octyl) gives a complex ^{1}H NMR spectrum.

We wish to report here that electrospray mass spectrometry (ESMS) is a very convenient yet informative technique that is appropriate for the study of the exchange reactions of the complexes $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$ **1** and $[Re_2(\mu\text{-}OMe)_3(CO)_6]^-$ **2**.† Ionic species existing in equilibrium in solution are transferred intact into the gas phase in the spectrometer and can be directly identified by their *m/z* values, regardless of their rate of inter-conversion on the NMR timescale. Thus, the various exchanged species arising from the reactions of **1** and **2** with different alcohols can be unambiguously identified in the mass spectra and the relative abundance of these species at different times after addition of alcohol can be monitored.



Scheme 1

At a cone voltage of 5 V, solutions of complex **1** in MeCN (typically 0.1 mg ml^{-1}) give a clean strong signal of the parent ion at *m/z* 591/593, together with a weak ion signal at *m/z* 879 corresponding to $[Re_3(OH)_4(CO)_9]^-$.[8] The latter ion is most probably a side product during the synthesis of **1**.[5] This impurity can be converted to **1** simply by adding a drop of aqueous NaOH to the ESMS solution.[9]

About 1 min after addition of a few drops of methanol to the ESMS solution of **1**, the spectrum showed low intensity peaks at *m/z* 605/607, 619/621 and 633/635, corresponding respectively to the singly, doubly and triply (OH → OMe) exchanged species. The peaks of the exchanged species rapidly grew in intensity with respect to that of the parent ion $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$ over 10 min. (Fig. 1), although the exact relative intensities of these peaks at 10 min showed some variability between experiments. On standing the solution overnight (16 h) the main ion observed was $[Re_2(\mu\text{-}OMe)_3(CO)_6]^-$, with the bis- and mono-methoxy ions still present in successively lower abundance, and no parent ion remaining. A clean intense peak of the permethoxylated ion was obtained on letting the solution stand for two weeks, with trace peaks of only the bis-methoxy species remaining. It is also noteworthy that throughout the experiment, the trirhenium ion $[Re_3(OH)_4(CO)_9]^-$ appeared to be unaffected by methanol. These results indicate that (OH → OMe) exchange is quite facile on complex **1**, with all three hydroxy ligands being replaceable.

The (OH → OMe) exchange is readily reversible, as indicated by the ESMS detection of small amounts of $[Re_2(\mu\text{-}$

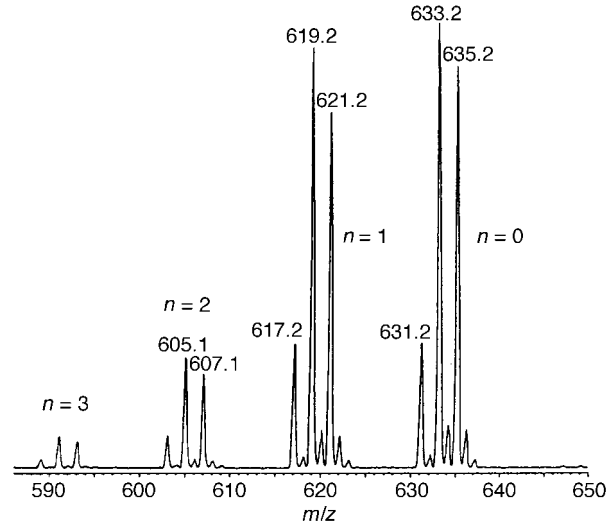


Fig. 1 High-resolution negative ion electrospray mass spectrum of a solution of complex **1** in MeCN, 10 min after addition of MeOH (cone voltage 5 V), showing the presence of the ions $[Re_2(OH)_n(OMe)_{3-n}(CO)_6]^-$ (n = 0–3)

Table 1 Exchange reactions of complexes **1** and **2** with various reagents

Complex	Reagent	Maximum number of OH/OMe groups exchanged
1	*tert*-Butanol	1
1	Methanol	3
1	Ethanol	3
1	*n*-Octanol	3
1	Phenol	3
1	*p*-Toluenethiol, MeC_6H_4SH	3
1	Benzeneselenol, PhSeH	2
1	$FcCH_2PH_2$ (Fc = ferrocenyl)	0
1	$H_2C(CN)_2$	0
2	Water	3
2	Ethanol	3
2	Phenol	3

$OMe)_2(\mu\text{-}OH)(CO)_6]^-$ even in a freshly made solution of complex **2** in MeCN (not rigorously dried). Other than this hydrolysis product, the spectrum contained only the strong signal of the intact **2** ion at *m/z* 633/635. On adding two drops of water to the ESMS solution, hydrolysis occured over a period of minutes to generate a mixture of mono-, bis- and tris-hydroxy complexes, and after 35 min the dominant ion was $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$. Addition of four drops of methanol to this solution quickly (within 1 min) removed $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$ and regenerated $[Re_2(\mu\text{-}OMe)_3(CO)_6]^-$ as the most abundant ion. These results suggest that (OH → OMe) exchange is more facile than (OMe → OH) exchange, possibly due to the greater steric accessibility of the {Re(μ-OH)Re} unit compared to its methoxy analogue.

Exchange reactions of **1** and **2** with other protic compounds have also been investigated by ESMS, as summarised in Table 1. The results are consistent with an exchange mechanism that involves proton transfer to the hydroxy or methoxy ligands as the first step, since compounds with very weakly acidic protons such as malononitrile and ferrocenylmethylphosphine[10] do not displace the OH and OMe ligands. In this context, it is noteworthy that the electrospary mass spectrum of a solution of a 1 : 1 mixture of **1** and **2** in alcohol-free MeCN showed no OH/OMe scrambled species even after 24 h. Steric factors also play an important role in determining facility of reaction, as indicated by the ability of complex **1** to exchange for only one *tert*-butoxide group.

By themselves, complexes **1** and **2** also exhibit interesting fragmentation behaviour at higher cone voltages. Dehydration of **1** begins to occur at 20 V, when a low abundance peak due to $[Re_2(O)(OH)(CO)_6]^-$ (*m/z* 573/575) appears in the mass spectrum. At 40 V, this is the most abundant ion, with very little parent ion remaining. Decarbonylation of the dehydrated species begins to occur at a cone voltage of 60 V, as indicated by the presence of the ions $[Re_2(O)(OH)(CO)_n]^-$ (n = 3–5). Decarbonylation without dehydration apparently does not occur, since ions such as $[Re_2(\mu\text{-}OH)_3(CO)_n]^-$ (n = 3–5) are not detected throughout. This result clearly indicates that dehydration of complex **1** is energetically much more favourable than decarbonylation.

Dehydration does not occur with complex **2**, which fragments *via* β-hydride elimination instead, at a cone voltage of 50 V. The parent ion eliminates formaldehyde to form $[Re_2(H)(OMe)_2(CO)_6]^-$ (*m/z* 603/605), $[Re_2(H)_2(OMe)(CO)_6]^-$ (*m/z* 573/575), and finally the known species[4b] $[Re_2(H)_3(CO)_6]^-$ (*m/z* 543/545). Decarbonylation of the β-eliminated species also occur at 50 V to give $[Re_2(H)(OMe)_2(CO)_5]^-$ (*m/z* 575/577) and $[Re_2(H)_2(OMe)(CO)_5]^-$ (*m/z* 545/547). The peaks of these decarbonylated ions overlap with the peaks at *m/z* 573/575 and 543/545 respectively to give characteristic 'triplet' patterns. Confirmation of these ions was achieved by deuterium labelling, the species $[Re_2(OCD_3)_3(CO)_6]^-$ being generated by addition of excess CD_3OD to **1**. At high cone voltages, the expected mass shifts corresponding to the ions $[Re_2(D)_n(OCD_3)_{3-n}(CO)_6]^-$ (n = 0–3) were observed. Elimination of acetaldehyde also occurs in an analogous fashion from the ion $[Re_2(OEt)_3(CO)_6]^-$, which was generated by addition of ethanol to **1**. As far as we are aware, β-hydride elimination from coordinated alkoxide ligands has not been observed by ESMS previously.

In conclusion, this study has shown that the complex anions $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$ **1** and $[Re_2(\mu\text{-}OMe)_3(CO)_6]^-$ **2** undergo facile exchange reactions with alcohols and phenol. The feasibility and extent of these reactions can be conveniently and unambiguously determined by electrospray mass spectrometry. The results also suggest that complex **1** can be used as a versatile starting material for the synthesis of a wide range of analogous $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ and $[Re_2(\mu\text{-}SR)_3(CO)_6]^-$ complexes, by simple reaction of **1** with an excess of the appropriate alcohol or thiol. Other protic or electrophilic compounds can also be investigated for their reactivity with **1**, simply by adding the compound to a solution of **1** and recording the electrospray mass spectrum of the solution. Thus, ESMS can be used as a quick but accurate technique to screen for potentially useful reactions. The prospect of **1** showing interesting biological activity *via* interaction with the OH, SH and NH functional groups of biomolecules is also attractive and is currently being investigated in our laboratories.[11]

We thank the National University of Singapore (NUS) (RP 950695), the University of Waikato, the National Institute of Education, Singapore (RP 15/95 YYK) and the New Zealand Lottery Grants Board for financial support. The award of an NUS research scholarship to C. J. is also gratefully acknowledged, together with a travel grant (to W. H. and L. McC.) from the Asia 2000 Foundation.

Notes and References

† Electrospray mass spectra were obtained in the negative-ion mode with a VG Platform II quadrupole mass spectrometer using HPLC-grade MeCN as the mobile phase. The samples (in MeCN solution) were injected *via* a Rheodyne injector fitted with a 10 μl sample loop, and delivered to the spectrometer source (60 °C) at 0.01 ml min^{-1}. Nitrogen was used as the drying and nebulising gas, and the capillary voltage was 3.5 kV. Cone voltages were typically varied between 5 and 80 V in order to investigate the formation of fragment ions.

Complexation of triosmium clusters to pyridyl functionalised metalloporphyrins gives heterometallic derivatives that possess the overall recognition and spectroscopic properties of the porphyrin fragment, while incorporating the electronic and structural characteristics of the cluster.

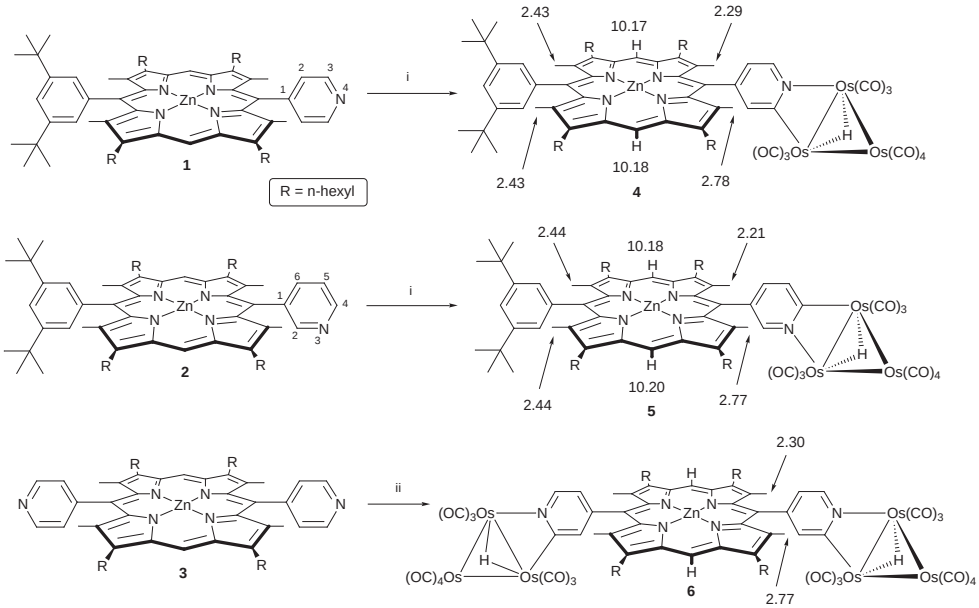
In recent years a range of porphyrin complexes incorporating numerous metal centres have been prepared as components for molecular-scale devices,[1] conjugated porphyrin polymers,[2] supramolecular systems[3] and light harvesting models.[4] These designs exploit the ability of the metal centre to control the manner in which a supramolecular assembly is constructed, and therefore dictate the properties of the final arrangement. Here we report on the preparation and characterisation of a series of triosmium cluster zinc porphyrin derivatives.

The porphyrin monomers **1**–**3** were synthesised by routes analogous to those previously reported.[5] Their key feature is the incorporation of one or more peripheral pyridyl groups available for metallation by an osmium cluster.[6] The pyridyl ring nitrogen is situated in either the 3-position, from which we might expect two cluster substitution products, or the 4-position from which only one product is possible. Treatment of **1** or **2** with $Os_3(CO)_{10}(NCMe)_2$ (1.1 equiv.) in dichloromethane at room temperature affords, after purification by preparative TLC (SiO_2, hexane : chloroform : ethyl acetate, 20 : 1 : 1), the metallated products **4** and **5** in 42% (R_f = 0.28) and 31% (R_f = 0.32) yields respectively (Scheme 1). Under similar reaction conditions, the bis-coordinated cluster compound **6** was isolated in 35% yield from the reaction of $Os_3(CO)_{10}(NCMe)_2$ (2.2 equiv.) with **3** after preparative TLC (SiO_2, hexane : chloroform : ethyl acetate, 10 : 1 : 1, R_f = 0.29).†

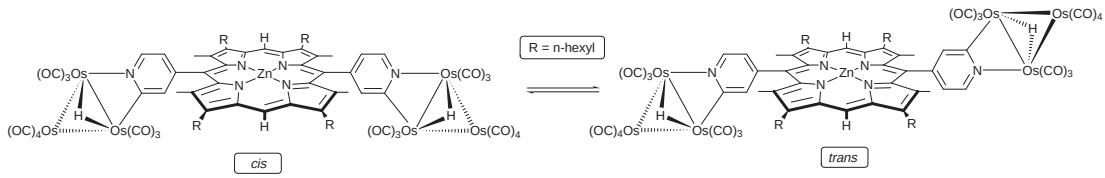
Single crystals of **4** and **5** suitable for X-ray crystallographic analysis were obtained by slow solvent diffusion of methanol into a toluene solution at room temperature.‡ The molecular structure of **4** is as expected: the pyridyl ring of the porphyrin is orthometallated and bridges one edge of the Os_3 triangle to afford a four membered ring containing Os, Os, C and N with the hydride ligand bridging one Os–Os edge. This is consistent with the structure of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-}NC_5H_4)]$.[6] The molecular structure of **5** is isostructural with **4**, the Os_3 unit residing on the 3- and 4-positions on the pyridyl ring (Scheme 1). The unoccupied site nearest to the porphyrin ring (2-position) is presumably inhibited to metallation on steric grounds.

The ^{1}H NMR spectra of **4** and **5** are consistent with the unsymmetrical nature of the molecule: in the spectrum of **4** we observe the porphyrin ring methyl groups as three singlets in a 1 : 2 : 1 intensity ratio. The peripheral methyl groups nearest to the appended cluster are inequivalent, appearing as two singlets because the cluster is not symmetrically disposed about the pyridine ring. However, the furthest methyl groups are unaffected by the presence of the cluster and are effectively equivalent, giving rise to one singlet. The protons of the first methylene group of the hexyl side chains are diastereotopic; additionally two equal intensity *meso* proton resonances are observed. Both of these observations are consistent with the expected slow rotation on the NMR chemical shift timescale about the cluster substituted aryl–porphyrin bond. Since complex **5** follows the same cluster coordination mode as **4**, the spectrum of **5** exhibits similar resonances to **4**.

For **6** the coordinated clusters can be *cis* or *trans* to one another (relative to the porphyrin plane) as shown in Scheme 2.§ At ambient temperature the ^{1}H NMR spectrum of **6** exhibits one



Scheme 1 *Reagents and conditions*: i, 1.1 equiv. $Os_3(CO)_{10}(NCMe)_2$, CH_2Cl_2, RT, 3 h; ii, 2.2 equiv. $Os_3(CO)_{10}(NCMe)_2$, CH_2Cl_2, RT, 4 h. Selected chemical shifts for complexes **4**–**6**.



Scheme 2 Exchange between the *cis* and *trans* isomeric forms of **6**

meso resonance which splits into a 1 : 2 : 1 multiplet at 280 K indicating the presence of at least two species (*cis* and *trans* isomers). A NOESY experiment at 280 K shows NOE cross-peaks for the outer signals, H_a and H_b, of the 1 : 2 : 1 multiplet only with the central resonance, H_c indicating that the *cis* and *trans* isomers are interconverting on the NOESY timescale. For the methyl groups at room temperature two equal intensity resonances are observed, which remain essentially unchanged at 280 K. The NOESY spectrum at 280 K reveals that these methyl resonances exhibit exchange cross-peaks with each other; in addition the bridging hydride shows a strong NOE cross-peak to the methyl resonance at 2.30 ppm, and a weak NOE cross-peak to the resonance at 2.77 ppm due to magnetisation transfer (Fig. 1). The above observations show that the *meso* protons are sensitive to the overall symmetry of the molecule, while the methyl resonances are only sensitive to the local environment dominated by the orientation of the clusters.[7]

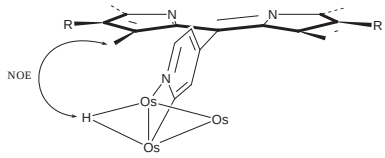


Fig. 1 The orientation of the coordinated cluster relative to the peripheral methyl groups. The CO ligands of the cluster have been omitted.

The absorption spectra of **4**–**6** were similar to **1**–**3**, except for a hypochromic shift of 4, 3, and 7 nm of the Soret band respectively and an increase in absorption between 220 and 420 nm where the cluster absorption bands are evident. More pronounced changes were observed in the luminescence spectra of **4**–**6**. At both room temperature and 77 K the fluorescence spectra intensities and excited state lifetimes of **4**–**6** were somewhat quenched compared to **1**–**3**.¶ Excitation spectra acquired at room temperature at 590 nm, where the fluorescence of the porphyrin is observed, indicate the absence of the cluster bands. In addition, the phosphorescence bands of **4**–**6** compared to **1**–**3** at 77 K show an increase in intensity and a decrease in the triplet lifetime. Collectively, these observations suggest that the quenching observed can be ascribed to a heavy atom effect arising from the cluster rather than to energy- or electron-transfer processes between the cluster and the porphyrin.

The mild preparation and spectroscopic eloquence of complexes **4**–**6** provide potential for the development of functional and structural derivatives. Variation in the nature of the appended cluster, and the porphyrin periphery can be envisaged.

We thank the Engineering and Physical Sciences Research Council, Singapore Government and Università di Bologna (Funds for Selected Research Topics) for financial support.

For **5**: $C_{77}H_{91}N_5O_{10}Os_3Zn$, 0.12 × 0.10 × 0.10 mm, T = 180(2) K, M = 1882.5, triclinic, space group $P\bar{1}$, a = 18.135(5), b = 19.048(6), c = 12.739(5) Å, α = 103.55(3), β = 108.74(3), γ = 102.88(3)°, U = 3833(2) Å^3, Z = 2, D_c = 1.63 Mg m^{-3}, λ = 0.71069 Å, F(000) = 1852, μ = 5.324 mm^{-1}, R_1 = 0.0615 [36807 reflections with $I > 2\sigma(I)$], wR_2 = 0.1624 for 13666 independent reflections and 832 parameters. The crystal data for **5** were collected on a R-Axis IIc diffractometer. All non-hydrogen atoms except the disordered carbons of the hexyl chains are anisotropic in both crystals. CCDC 182/989.

§ Each cluster has the possibility of the hydride bridges being *cis* (*i.e.* both at the back or front) or *trans*, with one at the front and one at the back (Scheme 2). Presumably both the *cis* and *trans* isomers of **6** consist of a mixture of front/front and front/back forms, but the distance between the clusters is so great that the two isomers are spectroscopically indistinguishable.

¶ The fluorescence lifetimes at 298 K were 0.76, 0.70, 0.76, 0.30, 0.37 and 0.21 ns for **1**–**6** respectively.

A concise enantio- and diastereo-controlled synthesis of (−)-quinic acid and (−)-shikimic acid

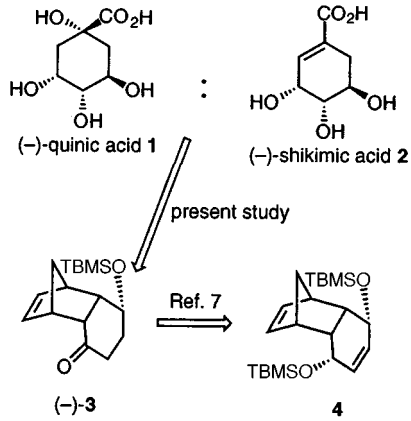
Kou Hiroya and Kunio Ogasawara*†

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578: Japan

(−)-Quinic acid and (−)-shikimic acid, both recognized as the key intermediates in the shikimate pathway in plants and microorganisms, have been synthesized concisely in an enantio- and diastereo-controlled manner starting from a synthetic equivalent of (*R*)-4-hydroxycyclohex-2-enone.

Both (−)-quinic acid **1** and (−)-shikimic acid **2** occur widely in both plants and microorganisms in which they have been recognized as the pivotal biogenetic precursors in the biosynthesis of a variety of aromatic natural products in the biogenetic pathway known as the shikimate pathway.[1] Since the shikimate pathway is only operative in plants and microorganisms, development of a flexible synthetic procedure for both (−)-quinic acid **1** and (−)-shikimic acid **2** as well as a variety of their derivatives is of great importance in biogenetic studies as well as in the search for herbicidal, antifungal or antibacterial agents that do not affect mammals.[1,2] Although a number of procedures including enantiocontrolled approaches have been developed for the construction of (−)-shikimic acid[3,4] **2**, only three racemic[5] and one chiral[6] procedures have been reported for the synthesis of (−)-quinic acid **1** to date. To explore a unified enantiocontrolled route to both (−)-quinic acid **1** and (−)-shikimic acid **2**, we selected the enantiomerically pure tricyclic ketol silyl ether[7] **3**, obtained from the catalytic asymmetrization[7,8] of the *meso* tricyclic ene-1,4-diol bis-silyl ether **4** and which serves as a synthetic equivalent of (*R*)-4-hydroxycyclohex-2-enone,[9] as the starting material. We describe here a diastereoselective conversion of (−)-**3** into both (−)-quinic acid **1** and (−)-shikimic acid **2** in a concise manner in good overall yields (Scheme 1).

Ketol silyl ether[7,8] (−)-**3** (>99% ee) was treated with $OC(OMe)_2$ in THF in the presence of NaH to afford in good yield the β-keto ester which existed in the single enol form‡ **5**, $[\alpha]_D^{29}$ −191.0 (*c* 1.71, $CHCl_3$). On hydroxylation in DMSO containing KF and $P(OEt)_3$,[10,11] the enol **5** gave diastereoselectively the α-hydroxy-β-keto ester **6**, $[\alpha]_D^{30}$ −59.8 (*c* 1.09, $CHCl_3$), as a single stereoisomer. As expected, NOE experiments indicated the *exo*-stereochemistry of the hydroxy functionality, which was confirmed by the later conversion.

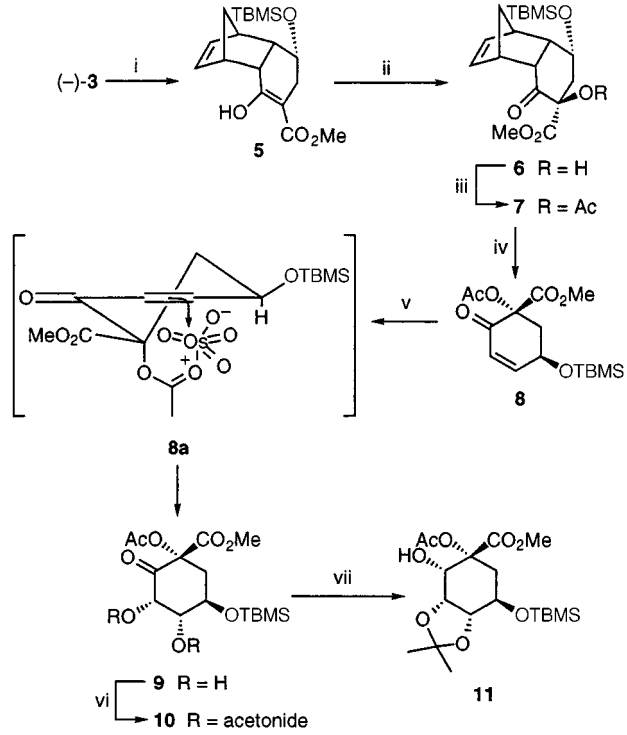


Scheme 1

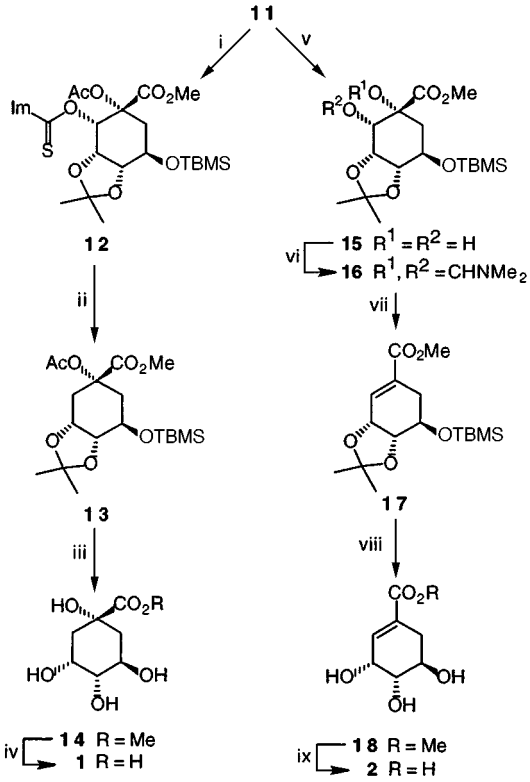
After acetylation, the resulting tertiary acetate **7**, $[\alpha]_D^{30}$ −61.3 (*c* 1.17, $CHCl_3$), was subjected to thermolysis in Ph_2O (*ca.* 280 °C) to give the cyclohexenone **8**, $[\alpha]_D^{29}$ +83.5 (*c* 0.53, $CHCl_3$), by retro-Diels–Alder reaction.

Although the stereochemistry of the catalytic osmylation of (+)-**8** could not be predicted, the reaction gave a readily separable 15 : 1 mixture from which the *cis*-diol **9**, $[\alpha]_D^{28}$ +82.8 (*c* 1.22, $CHCl_3$), having *syn* configuration to the acetoxy group, was obtained in 86% yield as the major product. The observed high diastereoselectivity may be due to the axially disposed acetoxy group in the molecule, which directs the stereochemistry of the dihydroxylation by interaction with OsO_4 forming a complex such as **8a**. After protection of the *cis*-diol functionality of **9** *via* reaction with $(MeO)_2CMe_2$ in the presence of PPTS,[12] the resulting acetonide **10** was reduced with $NaBH_4$ in MeOH at low temperature to give diastereoselectively the single alcohol **11**, $[\alpha]_D^{30}$ −15.5 (*c* 1.23, $CHCl_3$), which served as the common intermediate for (−)-quinic acid **1** and (−)-shikimic acid **2**. The overall yield of **11** from (−)-**3** was 57% (Scheme 2).

To obtain (−)-quinic acid **1**, **11** was first transformed into the imidazo-1-ylthiocarbonate[13] **12**, which then was treated with Bu_3SnH[13] to give the deoxygenated product **13**, $[\alpha]_D^{30}$ −23.2 (*c* 1.39, $CHCl_3$). Removal of the three oxygen protecting groups



Scheme 2 *Reagents and conditions*: i, NaH, $OC(OMe)_2$, THF, room temp., 23 h (86%); ii, O_2, KF, $P(OEt)_3$, DMSO, room temp., 22 h (90%); iii, Ac_2O, pyridine, room temp., 38 h (100%); iv, Ph_2O, reflux, 1 h (100%); v, OsO_4 (cat.), NMO, THF–H_2O (2 : 1), 0 °C, 72 h (86% 15 : 1 de); vi, $Me_2C(OMe)_2$, PPTS (cat.), 65 h; vii, $NaBH_4$, MeOH, −78 °C, 1.5 h (85% from **9**)



Scheme 3 *Reagens and conditions*: i, thiocarbonyl-1,1′-diimidazole, 50 °C, 14 h (100%); ii, Bu_3SnH, toluene, reflux, 9 h (80%); iii, CBr_4, MeOH, reflux, 19 h (86%); iv, NaOH, H_2O, roo temp., 13 h (100%); v, DBU, MeOH, −20 °C, 20 h; vi, $(MeO)_2CHNMe_2$, room temp., 23 h; vii, Tf_2O, Pr^i_2NEt, toluene, 50 °C, 1 h (80% from **11**); viii, 2% HCl–MeOH, room temp., 40 h (95%); ix, NaOH, THF–H_2O (1 : 1), room temp., 1 h (96%)

was carried out in one step by refluxing **13** with CBr_4 in MeOH[14] to give methyl quinate **14**, $[\alpha]_D^{30}$ −31.6 (*c* 1.45, MeOH), which was identical with authentic material derived from natural (−)-quinic acid **1**. Finally, **14** was hydrolyzed with NaOH to give (−)-quinic acid **1**, mp 167–168 °C, $[\alpha]_D^{30}$ −43.6 (*c* 2.03, H_2O) {lit.,[15] 162–163 °C, −42 to −44 (H_2O)}.

On the other hand, to obtain (−)-shikimic acid **2**, **11** was first deacetylated to give the *cis*-1,2-diol **15**, which afforded the cyclohexene **17**, $[\alpha]_D^{29}$ −19.7 (*c* 1.12, $CHCl_3$), *via* the cyclic amino acetal **16** on treatment with *N*,*N*-dimethylformamide dimethyl acetal followed by Tf_2O.[16] Exposure of **17** with dilute HCl in MeOH allowed spontaneous desilylation and removal of the acetonide group to give methyl shikimate **18**, $[\alpha]_D^{29}$ −130.0 (*c* 0.91, EtOH), which was identical with authentic material.[4] Finally, **18** was hydrolyzed with NaOH to give (−)-shikimic acid **2**, mp 184–185 °C, $[\alpha]_D^{25}$ −164.0 (*c* 0.59, H_2O) {lit.,[4] 184–186 °C, −163.7 (*c* 0.59, H_2O); lit.,[17] 184–186 °C, −170 (*c* 0.86, H_2O)} (Scheme 3).

Spermine and thermine conjugates of cholic acid condense DNA, but lithocholic acid polyamine conjugates do so more efficiently

Andrew J. Geall, Dima Al-Hadithi and Ian S. Blagbrough*†

Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY

Polyamine amides have been prepared from cholic and lithocholic acid by acylation of tri-Boc protected spermine and thermine and their binding affinities for calf thymus DNA were determined using an ethidium bromide fluorescence quenching assay; these polyamine amides are models for lipoplex formation with respect to gene delivery (lipofection), a key first step in gene therapy.

Amongst polyamine-containing natural products,[1] polyaminosteroids form a novel, small group whose members and their analogues display a variety of interesting biological activities. Following DNA binding studies with synthetic polyaminosteroids such as dimer **1**, up to four structural features contribute to the strength and type of DNA interactions: total number of positive charges, cation type, regiochemical distribution of the ammonium groups, and steroid hydrophobicity.[2–4] Recently, a so-called molecular umbrella **2** has been constructed from cholic acid **3** and spermidine, creating structures that can mask an attached agent (dansyl as a drug mimetic) from the surrounding environment.[5] Polyamino-steroid squalamine, isolated from liver and gallbladder tissues of the dogfish shark, *Squalus acanthias*, is a spermidine-containing sterol sulfate which displays antimicrobial and fungicidal properties, and induces osmotic lysis of protozoa.[6–8] Walker and co-workers have recently reported the DNA binding affinity and *in vitro* gene delivery potential of various polyamines conjugated to cholic and lithocholic acids **3** and **4**.[9] Although most of their transfection agents contained a cationic head group attached to a hydrophobic tail (*e.g.* cholic and lithocholic acid derivatives **5** and **6**), the more hydrophilic bile acid conjugate **7** had the greatest transfection activity.[9]

11 R = OH R′ = spermine

As part of our continuing studies on polyamine-mediated DNA condensation,[10–12] we have synthesized polyamine conjugates of cholic and lithocholic acids **3** and **4** in order to investigate the effects of changes in hydrophobicity on their binding affinity to DNA. Cholic acid **3** is a sterol nucleus with a hydroxylated hydrophilic surface and an all-hydrocarbon hydrophobic surface, possessing the 5β-cholane ring structure (a *cis*-fused A,B-bicycle). The binding of polyamines to DNA is not a trivial process,[2–4,11–13] spermine and spermidine may bind preferentially to GC-rich major groove and to AT-rich minor groove regions.[11] Structure-activity relationships for the binding of polyamines to DNA, and the subsequent condensation of DNA, indicate that polyammonium ions are suitable for use as gene delivery systems.[10–14] Covalent attachment of a lipid moiety, such as an aliphatic chain or a steroid, further enhances polyamine-mediated DNA condensation. The mechanism by which these compounds cause lipofection is poorly understood.[12–15] Therefore, it is important to determine their physicochemical properties for the design of lipoplexes capable of efficient lipofection.[12,16]

Herein we report the design and synthesis of polyamine amides of lithocholic acid **4**, using our orthogonal protection strategy with polyamines thermine (1,11-diamino-4,8-diazaundecane, norspermine, 3.3.3) and spermine (1,12-diamino-4,9-diazadodecane, 3.4.3) affording **8**‡ and **9** respectively, and the corresponding cholic acid amides **10** and **11**.[10–12] The ^{1}H NMR spectra ([$^2H_6$]DMSO) of their poly-TFA salts all displayed broad ammonium signals at δ 8.00, 8.79 and 8.98 (exchanged with ^2H_2O). In addition, signals at δ 7.20 (1:1:1 t, ^1J = 51 Hz, ^{14}N-^{1}H) were observed for these ammonium ions which we interpret as due to the symmetry of the $R^{14}NH_3^+$ cations.[17] The DNA binding affinities of these polyamine bile acid conjugates were determined using calf thymus DNA and a fluorescence quenching assay based upon ethidium bromide exclusion.[18] The pK_a values of these compounds were assumed to be similar to their 3-cholesteryl carbamate analogues.[12] In our hands, all members of this series of polyamine amides **8–11** were water soluble (at 1 mg ml^{-1}).[9] The binding affinities of these polyamine conjugates have been critically compared as a function of the charge ratio at which 50% (CR_{50}) of the ethidium bromide fluorescence was quenched (measured in 20 mM NaCl). Lithocholic acid conjugates **8** and **9** displayed CR_{50} values of 0.5 and 0.7 respectively (Fig. 1), and these results compare favourably with those obtained using the 3-cholesteryl carbamate of spermine (CR_{50} = 0.62).[12] However, cholic acid conjugates **10** and **11** have significantly weaker binding affinities, displaying CR_{50} values of 5.4 and 5.9 respectively, comparable with spermine (> 4.0) (Fig. 1). Applying the calculation of Burrows and co-workers,[2] and using 330 Da as the mean weight per nucleotide,[16] the C_{50} values of **8**, **9**, **10** and **11** are 3.5, 5.4, 42.0 and 45.9 μM respectively. The poly-

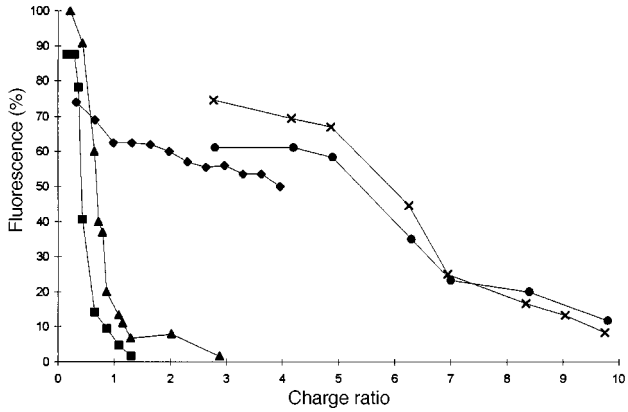

Fig. 1 Ethidium bromide exclusion assay results (calf thymus DNA, [DNA base-pair] = 3.0 μM, 1.3 μM ethidium bromide, 20 mM NaCl, excitation λ = 260 nm, emission λ = 600 nm) showing (◆) spermine, (■) lithocholic acid-thermine conjugate **8**, (▲) lithocholic acid-spermine conjugate **9**, (●) cholic acid-thermine conjugate **10** and (×) cholic acid-spermine conjugate **11**

electrolyte theory of Manning[19] predicts that when 90% of the charge on the DNA is neutralized, condensation will occur.[13] DNA condensation is clearly an efficient process with lithocholic acid polyamine amides **8** and **9** and with 3-cholesteryl carbamates (CR_{50} < 1.0), however an excess of positive charges is required for cholic acid polyamine amides **10** and **11** and for free spermine (CR_{50} > 4.0) to condense calf thymus DNA, reflecting their significantly weaker binding affinities for DNA. Whilst hydrophobicity is important for minor groove recognition,[20] DNA condensation is dependent upon hydrophobicity and distance between positive charges,[21] as well as total number of charges.[13] These data give support to our hypotheses that DNA binding and DNA condensation are also a sensitive function of the lipid attached to the polyamine, as well as a function of the positively charged polyamine moiety.

We thank the EPSRC and Celltech Therapeutics Ltd, for a CASE studentship (to A. J. G.). We acknowledge useful discussions with Dr Richard J. Taylor and Dr Michael A. W. Oxygenation of alkynes to α,β-acetylenic ketones with dioxygen catalyzed by *N*-hydroxyphthalimide combined with a transition metal

Satoshi Sakaguchi, Tomoyuki Takase, Takahiro Iwahama and Yasutaka Ishii*†

Department of Applied Chemistry, Faculty of Engineering and High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan

Alkynes were successfully converted into α,β-acetylenic carbonyl compounds through radical-catalyzed aerobic oxidation using *N*-hydroxyphthalimide (NHPI) combined with a transion metal under mild conditions.

α,β-Acetylenic carbonyl compounds, ynones, are highly valuable precursors in the preparation of a variety of heterocyclic compounds,[1] α,β-unsaturated ketones,[2] cyclopentenones,[3] *C*-nuclosides[4] and chiral pheromones.[5] The conjugated ynones are usually prepared by a coupling reaction of acetylenides with activated acylating reagents such as acid chloride[6b] or anhydrides.[6c,d] Although the oxygenation of prop-2-ynylic C–H bonds is straightforward in the preparation of ynones, only a limited number of methods are available for this purpose. For instance, some chromium complexes are reported to oxidize internal alkynes to conjugated ynones in moderate yields,[7] while the oxidation of alkynes by $Th(NO_3)_2$,[8a] OsO_4,[8b] permaganates[8c] or RuO_4[8d] results in ketones and/or cleaved products such as carboxylic acids as major products. Using electrophilic oxidants such as dimethyldioxirane[9a,b] or H_2O_2,[9c] alkynes are converted into conjugated enones or diketones rather than ynones.

For the synthesis of ynones, one candidate methodology is thought to be the direct introduction of oxygen into a prop-2-ynylic C–H bond *via* a free-radical process, since the abstraction of the hydrogen atom from alkynes by a radical would occur at the energetically favorable prop-2-ynylic position. Recently, we have developed a mild generation method of an active radical species, phthalimide *N*-oxyl radical (PINO), which can readily abstract a benzylic hydrogen atom from toluene, from *N*-hydroxyphthalimide (NHPI) under the influence of dioxygen. Thus, toluene and ethylbenzene could be oxidized to benzoic acid and acetophenone, respectively, under a dioxygen atmosphere (1 atm) at room temperature.[10] Since the bond dissociation energy of the prop-2-ynylic C–H bonds of alkynes (87.3 ± 2 kcal mol^{-1} for pent-2-yne) is approximately equal to that of the benzylic C–H bond of alkylbenzenes (88.0 ± 1 kcal mol^{-1} for toluene),[11] our interest was directed toward the NHPI-catalyzed oxidation of alkynes.

Here we report the first successful catalytic aerobic oxidation of alkynes to conjugated ynones under mild conditions.

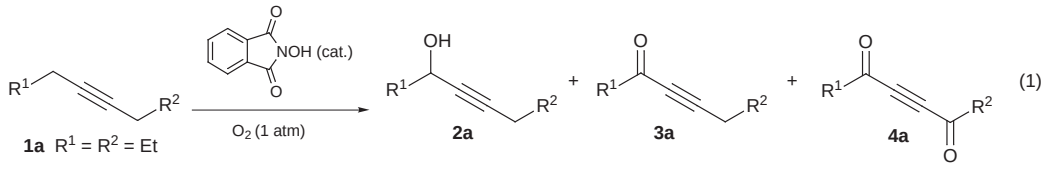
Oct-4-yne **1a** was chosen as a model substrate and allowed to react with dioxygen in the presence of a catalytic amount of NHPI and a transition metal [eqn. (1), Table 1]. Surprisingly, the oxidation of **1a** with molecular oxygen (1 atm) under the influence of NHPI (10 mol%) at room temperature produced oct-4-yn-3-one **3a** (69%) along with oct-4-yn-3-ol **2a** (23%) at 34% conversion (run 1). In analogy with the aerobic oxidation of alkylbenzenes by NHPI,[10b] the oxidation of **1a** was found to be significantly accelerated by adding a transition metal such as $Co(acac)_2$. Thus, the oxidation of **1a** catalyzed by NHPI (10 mol%) in the presence of $Co(acac)_2$ (0.5 mol%) gave **3a** (75%) and **2a** (20%) with 70% conversion (run 2).‡ The same oxidation using $Cu(acac)_2$ (0.5 mol%) in place of $Co(acac)_2$ (0.5 mol%) afforded **3a** with 77% selectivity together with **2a** (22%) at 69% conversion (run 3). However, no reaction took place when $Mn(acac)_2$ was employed in place of $Co(acac)_2$ under these conditions. When the reaction of **1a** with NHPI/$Co(acac)_2$ was carried out at elevated temperature (50 °C), the oxidation was almost complete after 6 h to give **3a** with 72% selectivity along with a small amount of a cleaved product, butanoic acid **5a** (run 6). Similar results were also obtained in the oxidation with NHPI/$Cu(acac)_2$. In the oxidation of **1a** using the NHPI/$Mn(acac)_2$ system at 50 °C, **3a** was formed with 62% selectivity at 63% conversion.

It is reported that dodec-5-yne, upon treatment with Bu^tOOH in the presence of SeO_2 catalyst, leads to the acetylenic alcohol dodec-5-yn-4-ol rather than the ynone dodec-5-yn-4-one.[12] However, the present aerobic oxidation of **1a** by the NHPI catalyst formed ynone **3a** in preference to ynol **2a**. In a previous paper, we showed that the NHPI-catalyzed oxidation of alcohols affords ketones in good yields.[10d] In fact, treatment of oct-1-yn-3-ol under dioxygen in the presence of NHPI and $Cu(acac)_2$ gave oct-1-yn-3-one, with 95% selectivity at 57%

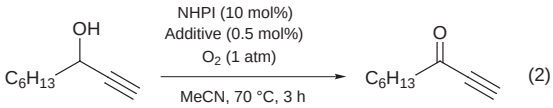
Table 1 Aerobic oxidation of **1a** catalyzed by NHPI under selected conditions[a]

			Selectivity (%)[b]			
Run	Metal	Conversion (%)	**2a**	**3a**	**4a**	**5a**
1	–	34	23	69	< 1	< 1
2	$Co(acac)_2$	70	20	75	< 1	< 1
3	$Cu(acac)_2$	69	22	77	< 1	< 1
4	$Mn(acac)_2$	no reaction				
5[c]	–	48	18	63	< 1	< 1
6[c]	$Co(acac)_2$	85	2	72	2	2
7[c]	$Cu(acac)_2$	83	5	70	2	3
8[c]	$Mn(acac)_2$	63	4	62	3	5

[a] Compound **1a** (2 mmol) was allowed to react under O_2 atmosphere (1 atm) in the presence of NHPI (10 mol%) and a metal species (0.5 mol%) in MeCN (5 cm^3) at room temperature (25 °C) for 30 h. [b] Selectivity of the products was determined by GC analysis using an internal standard. [c] The reaction was carried out at 50 °C for 6 h.



conversion, but in the absence of $Cu(acac)_2$ oct-1-yn-2-ol was converted into the ynone in low yield [eqn. (2)]. This shows that



(2)

$Cu(acac)_2$ plays an important role in the conversion of ynol into ynone.

Conventionally, oxidation of alkynes with molecular oxygen is carried out at higher temperatures, *i.e.* 110–150 °C. Under such conditions the reaction results in undesired over-oxidation products such as oxidatively cleaved carboxylic acids.[13] For instance, the oxidation of dodec-6-yne under 70 atm of air at 110 °C is reported to lead to cleaved products such as hexanoic acid and pentanoic acid as principal products.

It is noteworthy that the NHPI-catalyzed oxidation of alkynes with molecular oxygen could be achieved at room temperature, since undesired side reactions arising from high reaction temperatures could be suppressed.

The present successful conversion of alkynes into ynones is believed to result from the fact that the phthalimide *N*-oxyl radical (PINO) can be generated from NHPI under the influence of dioxygen and **1a** at room temperature. Thus, EPR analysis of PINO formed from NHPI under atmospheric dioxygen in the presence or absence of alkyne **1a** at room temperature was performed. As expected, the EPR signal attributed to PINO was observed in the presence of **1a** after 14 h, but in the absence of **1a** no EPR signal was observed. At this stage, we cannot make an accurate assessment of the interaction between NHPI and the alkyne **1a**. The generation of PINO from NHPI in the presence of alkyne **1a** may be facilitated by the weak coordination of NHPI, which is a weak acid having pK_a = 7.0,[14] to the acelylenic π-bond of the alkyne.

Table 2 summarizes the results for the NHPI-catalyzed oxidation of a variety of alkynes in the presence of $Co(acac)_2$ or $Cu(acac)_2$ under oxygen atmosphere. The conversions of substrates were generally high except for terminal alkynes, and the corresponding α,β-acetylenic carbonyl compounds were obtained in moderate to good yields. Symmetric alkynes such as hex-3-yne **1b** and dodec-6-yne **1c** were oxidized into conjugated ynones hex-3-yn-2-one **3b** and dodec-6-yn-5-one **3c**, respectively, in good yields, (runs 1–3). Unsymmetrical alkyne, oct-3-yne **1d** gave a 1:1 mixture of the corresponding conjugated ynones, **3d** and **3d′** (run 4), although the oxidation of dec-3-yne with Bu^tOOH catalyzed by CrO_3 produced only dec-3-yn-2-one.[7c] Under the same conditions, oct-2-yne **1e** afforded oct-2-yn-4-one **3e** with high regioselectivity (run 5). The terminal alkyne oct-1-yne **1f** was oxidized to oct-1-yn-3-one **3f** with high selectivity, although the conversion was moderate (50%) (run 6). On the other hand, for oct-2-yn-1-al **1g**, the aldehyde moiety was selectively oxidized rather than the prop-2-ynylic C–H bond, giving oct-2-ynoic acid **6g** (run 7).

Table 2 Aerobic oxidation of several alkynes catalyzed by NHPI combined with $Co(acac)_2$ or $Cu(acac)_2$[a]

Run	Substrate	Product	Conversion (%)	Selectivity (%)[b]
1[c]	EtC≡CEt **1b**	AcC≡CEt **3b**	93	81
2[d,e]	EtC≡CEt **1b**	AcC≡CEt **3b**	96	75
3[e]	$C_5H_{11}C{\equiv}CC_5H_{11}$ **1c**	BuC(O)C≡CC_5H_{11} **3c**	89	75
4[c]	BuC≡CEt **1d**	PrC(O)C≡CEt **3d** BuC≡CAc **3d′**	92	70[f]
5[e]	$C_5H_{11}C{\equiv}CMe$ **1e**	BuC(O)C≡CMe **3e**	94	70
6[c,e]	$C_6H_{13}C{\equiv}CH$ **1f**	$C_5H_{11}C(O)C{\equiv}CH$ **3f**	50	80
7[c,e]	$C_5H_{11}C{\equiv}CCHO$ **1g**	$C_5H_{11}C{\equiv}CCO_2H$ **6g**	43	74[g]

[a] Substrate (2 mmol) was allowed to react under O_2 atmosphere (1 atm) in the presence of NHPI (10 mol%) and $Cu(acac)_2$ (0.5 mol%) in MeCN (5 cm^3) at 50 °C for 6 h. [b] Yields of the products were determined by GC analysis using an internal standard. Other products were α-alkynyl alcohols (~5%) and cleaved products such as carboxylic acids (~3%) except for run 7. [c] 20 h. [d] $Co(acac)_2$ was used instead of $Cu(acac)_2$. [e] 70 °C. [f] A 1:1 regioisomeric mixure was obtained. [g] Isolated yield.

In conclusion, various alkynes were converted into α,β-acetylenic carbonyl compounds by aerobic oxidation using NHPI combined with Co^{II} or Cu^{II} complexes. The present method provides a facile method for preparing conjugated ynones from alkynes.

‡ *Typical procedure* for the aerobic oxidation of alkyne: To a solution of NHPI (0.2 mmol, 10 mol%) and a transion metal complex (0.01 mmol, 0.5 mol%) in MeCN (5 cm^3) was added alkyne (2 mmol), then the flask was flushed with oxygen and equipped with a balloon filled with O_2. The reaction mixture was stirred at 25 °C for 30 h. The solvent was evaporated under reduced pressure. The products were purified by column chromatography on silica gel [hexane–EtOAc (10:1 to 3:1)], and characterised by ^1H and ^{13}C NMR, GC–MS and IR spectroscopy.

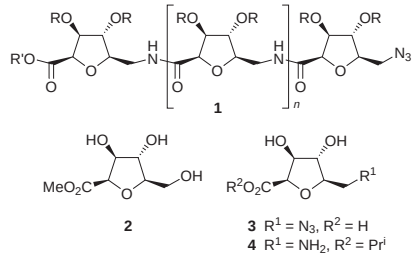
An acid catalysed ring rearrangement of a triflate derivative of D-mannono-γ-lactone 6 is the key step in the synthesis of the *C*-glycosyl sugar amino acid derivatives 3 and 4, examples of carbohydrate amino acid building blocks with specific conformational preferences suitable for incorporation into combinatorial amide libraries; homo-oligomerisation *via* solution phase coupling procedures affords furanose carbopeptoids 1 which adopt novel solution state secondary structures.

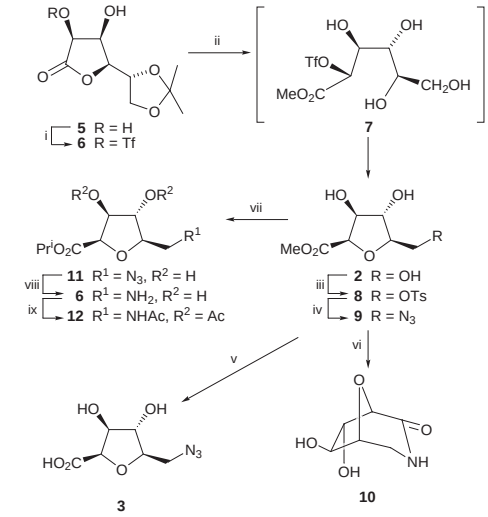
Carbohydrate amino acids are attractive building blocks for the routine incorporation of carbohydrate moieties into combinatorial libraries by standard peptide coupling techniques.[1] The conformational influence of the sugar backbone on peptide chains has been exploited in the rational design of non-peptide peptidomimetics.[2] Homo-oligomeric sugar amino acids ('carbopeptoids'[3]) based upon a pyranose template have been prepared by solution[4] and solid[5] phase approaches, though to date there are no furanose[6] analogues. Here we describe the synthesis of a *C*-glycofuranosyl sugar amino acid analogue and its oligomerisation to materials which adopt a well-defined secondary structure.



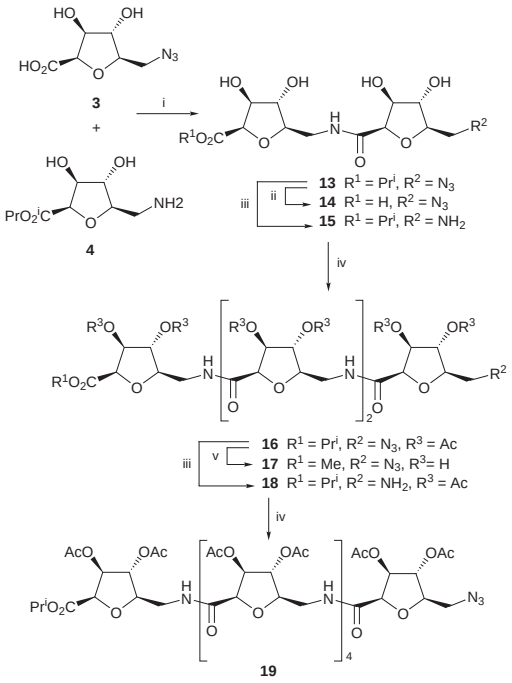
2-*O*-Triflates (trifluoromethanesulfonates) of γ- and δ-lactones in basic[7] or acidic[8] MeOH give good to excellent yields of highly substituted tetrahydrofurancarboxylates. Such a procedure has recently been utilised for the synthesis of *C*-glycosides of glucofuranose,[9] which have provided scaffolds for the generation of glucofuranose libraries. For the synthesis of the *C*-arabinosyl derivative **2**, the triflate **6** is required; in order to effect esterification at C-2, it is necessary to protect the primary hydroxy group at C-6 in D-mannonolactone as its kinetic monoacetonide **5**, easily accessible in 74% yield from the diacetonide of D-mannose.[10] Treatment of the diol **5** with Tf_2O in CH_2Cl_2 in the presence of pyridine caused highly regioselective esterification of the hydroxy group at C-2 to give the stable triflate **6**, which may be isolated in 85% yield; **6** has previously been described but in a significantly poorer yield.[11] Treatment of the crude triflate **6** with HCl in MeOH gave the required ester **2** in 84% yield from **5**, providing multigram quantities of **2** in an overall yield of 62% from D-mannose. The key transformation of **6** to **2** by treatment with acidic MeOH involves hydrolysis of the side chain acetonide, methanolysis of the lactone, followed by intramolecular S_N2-like closure of the resulting open chain hydroxy triflate **7** with inversion of configuration at C-2 (Scheme 1). Although it is possible that intermediates such as **7** could undergo alternative closure to a tetrahydropyran, resulting from attack by the C-6 rather than the C-5 hydroxy group, no *C*-glycopyranosides were isolated; ring closures to *C*-glycopyranoses by nucleophilic displacement at C-2 of a sugar are rare.[12]

The strategy adopted for the synthesis of carbopeptoids **1** utilises well-established peptide bond forming methodology. For the synthesis of sugar amino acid building blocks **3** and **4**, it is necessary to introduce nitrogen at C-6. Selective esterification of **2** with toluene-*p*-sulfonyl chloride in pyridine (to give the 6-*O*-tosyl derivative **8**) and subsequent displacement of the sulfonate ester with NaN_3 in DMF at 90 °C gave the azide **9** in 72% yield over two steps.[13] Hydrolysis of the methyl ester with aq. NaOH and purification by ion exchange chromatography afforded the carboxylic acid **3** in quantitative yield. Catalytic hydrogenation of the methyl ester **9** gave the bicyclic lactam **10** *via* a non-isolable amine; a more hindered ester is required to enable isolation of the required 6-amino component **4**. Accordingly, transesterification of the methyl ester **9** with K_2CO_3 in Pr^iOH gave the isopropyl derivative **11** in 79% yield.[14] Hydrogenation of the azide **11** in the presence of Pd-C in Pr^iOH afforded the amine **4** as the major product together with an unidentified and inseparable minor component; the highly polar amine **4**, characterised as its triacetate **12**, (90% yield from **11**),was used without purification in all further reactions.

Coupling of **4** and **3** was then performed using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDCI) in DMF in the presence of 1-hydroxybenzotriazole (HOBt). This reaction allowed the isolation of the dimeric compound **13** in 74% yield (from the azide **11**) as an easily handled solid (Scheme 2). No protection of the secondary hydroxy groups is necessary during the coupling procedure. Iteration of the coupling procedure gave ready access to the tetramer **1** (n = 2) and the hexamer **1** (n = 4). The dimer **13** was treated with aq. NaOH and purified by ion exchange chromatography to afford



Scheme 1 *Reagents and conditions*: i, Tf_2O, Py, CH_2Cl_2; ii, 1% HCl in MeOH; iii, TsCl, Py; iv, NaN_3, DMF; v, 0.5 M aq. NaOH, dioxane, ion exchange; vi, H_2, Pd, EtOH; vii, K_2CO_3, Pr^iOH; viii, H_2, Pd, Pr^iOH; ix, Ac_2O, Py



Scheme 2 *Reagents and conditions*: i, EDCI, HOBt, Pr^i_2NEt, DMF; ii, 0.5 M aq. NaOH, dioxane, then Amberlite IR-120 (H^+); iii, H_2, Pd, Pr^iOH; iv, **14** (1 equiv.), EDCI, HOBt, Pr^i_2NEt, DMF, then Ac_2O, Py; v, NaOMe, MeOH, then Amberlite IR-120 (H^+)

the free acid **14** in quantitative yield. Additionally the *N*-terminal azide in **13** was reduced with H_2 in the presence of Pd-C to afford the amine **15**. Coupling of the dimeric building blocks **14** and **15** was performed using EDCI in DMF in the presence of HOBt. The reaction mixture was treated with Ac_2O in pyridine to facilitate isolation of the tetramer **16**[15] (55% from **13**) from which the acetate groups can be removed with NaOMe in MeOH to afford the deprotected carbopeptoid **17** in quantitative yield. Hydrogenation of the tetramer **16** in the presence of Pd gave the *N*-terminal amine **18** which was coupled crude to the dimeric acid **14** using EDCI in DMF in the presence of HOBt. Treatment of the reaction mixture with Ac_2O in pyridine gave the hexamer **19** in 68% yield from the tetramer **16**.

The ease with which highly functionalised tetrahydrofurans, such as **4**, can be synthesised is likely to offer opportunities for the production of a range of carbohydrate amino acid building blocks with specific conformational preferences suitable for incorporation into combinatorial amide libraries. The diversity of possible structures afforded by a carbohydrate template in terms of backbone stereochemistries and protecting group manipulations allows formation of hydrophobic or hydrophilic—and thus water soluble—derivatives. Efficient unprotected oligomerisation to give compounds with well-defined secondary structure emphasizes the versatility of the sugar amino acid building block and alludes to the possibility of a more rational design tailored to specific applications. The following paper provides evidence for conformational preferences of the hexamer **19** and the tetramer **16**; NMR and molecular dynamics indicate that both adopt a well-defined secondary structure based around a repeating β-turn mimic stabilised by intramolecular hydrogen bonds.[16]

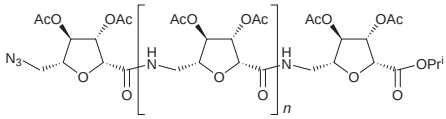
Short oligomeric chains of tetrahydrofuran amino acids exhibit a novel repeating β-turn type secondary structure in solution stabilised by hydrogen bonds and provide clear evidence that carbopeptoids will allow control of conformation in peptidomimetics.

Secondary structural elements such as α-helices and β-sheets are involved in the processes leading to the folding of proteins into functional conformations. The design and synthesis of novel materials which are predisposed to fold into these ordered structures has been an area of intense interest in recent[1] years as they may have interesting catalytic or selective recognition properties. Oligomers[2] based upon a range of templates have been shown to form helices in solution and the solid state. Our approach involves the use of carbohydrate-like frameworks bearing both an amino and a carboxylic acid functionality[3] which have been proposed as non-peptide peptidomimetics[4] by virtue of their rigidity and conformational influence on peptide backbones. Oligomers of pyranose sugar amino acids[5] ('carbopeptoids'[6]) have been synthesised by solution[7] and solid phase[8] methods, but there are few reports of their conformational preferences.[9] Here we describe oligomers of sugar amino acid derivatives based upon a β-D-*arabino*-furanose scaffold which adopt a novel repeating β-turn type structure stabilised by intramolecular hydrogen bonds in solution.

An efficient synthesis of the tetrameric **2** and hexameric **3** carbopeptoids utilising solution phase coupling procedures is reported in the previous paper.[10]



1 *n* = 0, dimer
2 *n* = 2, tetramer
3 *n* = 4, hexamer

Solution conformations in $CDCl_3$ were investigated by ^1H NMR spectroscopy. All resonances were unambiguously assigned by a combination of 2D NMR techniques. Proton spin systems within each residue were identified *via* DQF-COSY and T-ROESY[11] spectra, with the configuration within each sugar ring being confirmed by the observed NOE correlations (cross peaks in NOESY spectra were positive but rather weak, indicating the molecular correlation time, τ_c, to approach the $\omega_o\tau_c$ = *ca*. 1 condition). NOE data also allowed the sequential placement of each residue from the observation of $H2^i$ to HN^{i+1} interactions. To confirm that these were indeed sequential, rather than longer-range correlations brought about by folding of the molecule, semi-selective gradient-enhanced HMBC experiments[12] of the carbonyl region were used to establish unambiguous through-bond ^1H–^{13}C connectivities between adjacent residues *via* correlations with the carbonyl carbons (in particular, $H2^i$ to CO^i and CO^i to $H6^{i+1}$). Finally, the NOE data were further used to establish the solution conformation of the molecule in which tetramer **2** appears to adopt a novel repeating 'β-turn' type structure stabilised by (*i*, *i* − 2) inter-residue hydrogen bonds (Fig. 1). Each repeating tetrahydrofuran unit can be considered as a dipeptide isostere with each H-bond

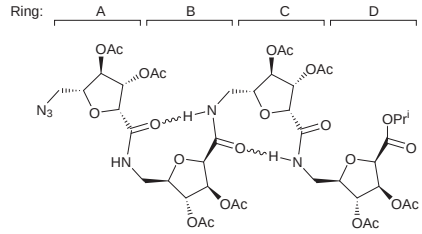


Fig. 1 Representation of the observed solution secondary structure of the tetramer **2** indicating ring labelling. Rings are identified by labelling each residue alphabetically from 'A' at the N-terminus.

completing a turn that is structurally reminiscent of a conventional peptide β-turn.[13]

Proton chemical shift dispersion of **2** is high despite the repeating unit, which is itself suggestive of a well defined solution structure. The ^1H NMR spectrum of the amide region for tetramer **2** and its hexameric homologue **3** is shown in Fig. 2. The chemical shifts of amide protons are sensitive to the presence of hydrogen bonding; a decrease in diamagnetic shielding due to the population of hydrogen bonded states should result in a high-frequency δ_{NH} shift:

For the tetramer **2**, such a shift is observed for two of the three amide protons (δ_H 8.19 and 8.03), subsequently identified as NH^D and NH^C, whose shifts are therefore indicative of involvement in hydrogen-bond formation. The remaining amide (NH^B) resonates at significantly lower frequency (δ_H 6.91), characteristic of an amide which experiences little or no hydrogen-bonding. This shift is similar to that observed for the dimeric unit **1** (δ_H 7.18) which is itself unable to form the inter-residue hydrogen-bond proposed herein for the higher homologues. An equivalent pattern is observed in the hexameric analogue **3** which exhibits four high-frequency amide protons and one again at lower frequency (Fig. 2). The chemical shifts of all three amide protons of the tetramer are, in contrast, similar in DMSO (Table 1), indicating similar solvent hydrogen-bonding interactions for all three. However, temperature coefficients of the amide protons of the tetramer **2** in DMSO indicate that NH^D and NH^C experience greater shielding from these solvent interactions than does NH^B (Table 1) and correlates with the higher chemical shifts of NH^D and NH^C observed in $CDCl_3$.

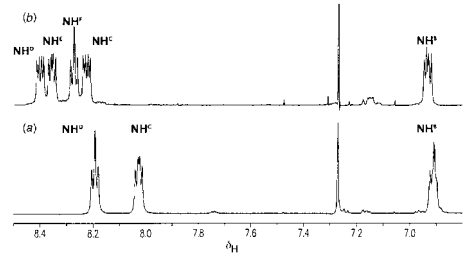

Fig. 2 Amide regions of the ^1H NMR (500 MHz) spectrum of (*a*) tetramer **2** and (*b*) hexamer **3**. Proton assignments are indicated. The spectra were recorded on a Bruker AMX-500 spectrometer at 298 K in $CDCl_3$ and referenced to residual solvent at δ 7.27.

Table 1 Amide proton temperature coefficients and chemical shifts for the tetramer **2**

	$\Delta\delta$([$^2H_6$]DMSO)/ ppb K^{-1}	δ_H([$^2H_6$]DMSO)/ ppm	δ_H($CDCl_3$)/ ppm
NH^D	4.3	8.20	8.19
NH^C	3.9	8.29	8.03
NH^B	5.3	8.12	6.91
H_2O	5.1	—	—

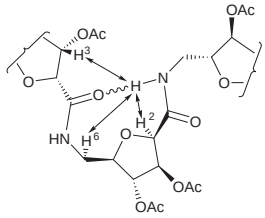

Fig. 3 Representation of the significant inter-residue NOE enhancements observed for each 'turn'. Relevant protons are numbered individually.

The pattern of deshielded *vs.* shielded amide protons for **1–3** is consistent with a repeating structural unit, rather than simply the formation of hydrogen bonds between amide protons and acetate groups on the same or adjacent residues, as is further supported by the NOE data. With only one exception ($H3^A$ to $H6^C$-*pro-S*), all NOEs that were observed *between* residues involved the amide protons and no inter-residue ring–ring interactions could be detected. Significant inter-residue NOEs were NH^i to $H2^{i-1}$, NH^i to $H6^{i-1}$ (stereospecifically) and NH^i to $H3^{i-2}$ (Fig. 3) as observed from both NH^D and NH^C, and are suggestive of the proposed (i, $i-2$) inter-residue hydrogen bonds.

Using these data, molecular dynamics simulations[14] utilising NOE derived distance constraints were performed for the tetramer (Fig. 4). This resulted in the generation of five low energy structures, all of which exhibit the anticipated geometry (backbone atom RMS deviation between the five structures is 0.6 Å). Superposition of these structures [Fig. 4(A)] shows the expected fraying at the C-terminus, which does not participate in hydrogen bonding. The conformer which most satisfies the distance restraints is shown in Fig. 4(B)). This structure is consistent with the lack of ring–ring NOEs and reflects the strong conformational preferences from each sugar ring stereochemistry.

In conclusion, we have shown that short oligomeric furanose sugar amino acid chains—even a tetramer—can adopt well-defined novel secondary structures stabilised by intramolecular hydrogen bonds; this is the first example of a 'carbopeptoid' of *any* length in which secondary structure has been experimentally demonstrated. The ease of synthesis of a wide range of structures such as the tetrahydrofuran **4** is likely to give flexibility and control in the design and applications of peptidomimetics with well-defined secondary structure, low molecular weights and thus good bioavailablity.

The support of the EPSRC is gratefully acknowledged.

The cyanate ion as a bridging ligand between lanthanide and transition metals. Formation of one-dimensional extended arrays $\{(DMF)_6Ln_2Ni(NCO)_8\}_\infty$ (Ln = Sm, Eu) and monomeric complexes $(DMF)_8Ln_2Ni(NCO)_8$ (Ln = Sm, Eu) with three bridging cyanate ligands

Jianping Liu, Edward A. Meyers, James A. Cowan* and Sheldon G. Shore*

Department of Chemistry, The Ohio State University, Columbus, Ohio 43210, USA. E-mail: shore1@osu.edu

Syntheses and molecular structures of the first cyanate bridged lanthanide-transition metal complexes, $(DMF)_8Ln_2Ni(NCO)_8$ and $\{(DMF)_6Ln_2Ni(NCO)_8\}_\infty$ (Ln = Sm, Eu) with three bridging cyanate ligands are reported; magnetic properties of $(DMF)_8Ln_2Ni(NCO)_8$ (Ln = Sm, Eu) complexes are described.

The cyanate ion[1] $[NCO]^-$ offers features as a bridging ligand that have not yet been adequately exploited by linking metal ions through two types of bonding modes: terminal N-bonding, 1,1-μ-N (**I**)[2–7] and both ends-bonding, 1,3-μ (**II**).[8–10] Complexes that have been reported, with two exceptions, are molecular entities that form a single cyanate or a double cyanate bridge between two metals. Exceptions are a silver cyanate complex, a chain-like array with single cyanate bridges[4] and a copper 2,4-lutidine cyanate complex, a chain-like array with two cyanate bridges.[5]

I

II

Here we report syntheses and molecular structures of the first examples of cyanate bridged complexes with three bridging cyanate ligands between a lanthanide and a transition metal. These are the monomeric complexes $(DMF)_8Ln_2Ni(NCO)_8$ (Ln = Sm **1**, Eu **2**) that can be converted into one-dimensional, extended arrays $\{(DMF)_6Ln_2Ni(NCO)_8\}_\infty$ (Ln = Sm **3**, Eu **4**).

The complexes $(DMF)_xLn_2Ni(NCO)_8$ (x = 6 or 8; Ln = Sm, Eu) were synthesized quantitatively by the reaction of 2 : 1 : 8 molar ratios of $LnCl_3$, $NiCl_2$, and K(NCO) in DMF at ambient temperature over a two day period.† Under slightly different crystallization conditions, two unique types of crystals, monomeric complexes $(DMF)_8Ln_2Ni(NCO)_8$ (Ln = Sm **1**, Eu **2**) and one-dimensional, extended arrays $\{(DMF)_6Ln_2Ni(NCO)_8\}_\infty$ (Ln = Sm **3**, Eu **4**) were obtained.† Both **1** and **2** as well as **3** and **4** are isomorphous. The molecular structures of **2** and **4** are shown in Figs. 1 and 2.‡

In complex **2**, the formula is $[(DMF)_8Eu_2Ni(NCO)_8]$. Since the Ni^{2+} ion is located on the crystallographic inversion center, the formula of the asymmetric unit is one-half the molecular formula. The Eu^{3+} and Ni^{2+} ions are linked together by three bridging cyanate ligands to form a slightly distorted trigonal bipyramidal $Eu(\mu\text{-}N)_3Ni$ unit. Interestingly, the distance between Ni^{2+}–Eu^{3+} [3.256(1) Å] is approximately equal to the sum of their atomic radii (3.20 Å),[11] which is probably a result of the three bridging $[NCO]^-$ groups. The forth cyanate ion is a terminal ligand bonded to an Eu^{3+} center. In addition, four DMF molecules are coordinated to the Eu^{3+} ion through their oxygen atoms. Compound **4** is very similar to compound **2**, except that in complex **2** one DMF molecule around Eu^{3+} is replaced by a cyanate ion thereby resulting in the formation of the extended array complex **4**. In complex **4** two cyanate ions form two cyanate bridges to link another Eu^{3+} and a one-dimensional infinite array is formed. The distance between the two adjacent $Eu(1)^{3+}$ and $Eu(2)^{3+}$ centers is 4.081(1) Å. The distances of Ni^{2+}–$Eu(1)^{3+}$ [3.231(1) Å] and Ni^{2+}–$Eu(2)^{3+}$ [3.235(1) Å] are similar to that observed in complex **2**.

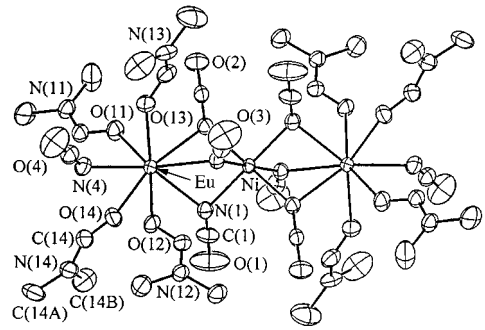

Fig. 1 Molecular structure of $(DMF)_8Eu_2Ni(NCO)_8$ with 50% thermal ellipsoids showing the atomic labelling scheme. DMF hydrogen atoms were omitted for clarity. Selected bond lengths (Å) and angles (°): Eu–O 2.384(5)–2.435(5), Eu–N 2.422(6)–2.563(6), Ni–N 2.081(6)–2.114(6); N–C 1.14(1)–1.18(1) Å, C–O 1.18(1)–1.20(1); N–Ni–N 84.1(2)–85.4(2), Ni–N–Eu 88.4(2)–89.5(2), C–N–Ni, 127.5(6)–142.3(6), C–N–Eu, 127.4(5)–137.8(6), N–C–O 177(1)–179(1).

In complexes **1**–**4**, only nitrogen atoms in the cyanate ligands are coordinated to the metal centers; oxygen atoms remain free. During the structure refinements assignments for N and O peaks on the difference map were interchanged. Assignments shown in Fig. 1 and 2 gave the lowest wR_2 which provides support that nitrogen and oxygen atoms in the $[NCO]^-$ groups are properly identified. Infrared studies of these complexes in the $\nu_{CN} + \nu_{CO}$, ν_{CN} and δ_{NCO} regions are consistent with those observed in complexes[2,3,12,13] for which only M–NCO bonding is claimed.

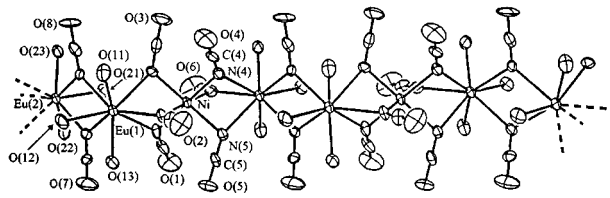

Fig. 2 Molecular structure of $\{(DMF)_6Eu_2Ni(NCO)_8\}_\infty$ with 50% thermal ellipsoids showing the atomic labelling scheme. Only oxygen atoms in DMF were shown for clarity. Selected bond lengths (Å) and angles (°): Eu–O 2.366(9)–2.411(9), Eu–N 2.476(10)–2.517(9), Ni–N 2.096(10)–2.139(9) N–C 1.15(2)–1.20(2) C–O, 1.17(2)–1.21(2); N(7)–Eu–N(8) 69.6(3)–69.8(3), N–Ni–N 178.1(4)–179.2(5), N–Ni–N 82.8(4)–97.4(4), Ni–N–Eu, 88.3(4)–89.5(4), Eu–N–Eu 110.3(4)–110.3(4), C–N–Ni 118.3(8)–129.0(9), C(1,6)–N(1,6)–Eu 142.0(9)–151.4(9), C(7,8)–N(7,8)–Eu 121.0(9)–128.7(9), N–C–O 177(2)–179(2)°.

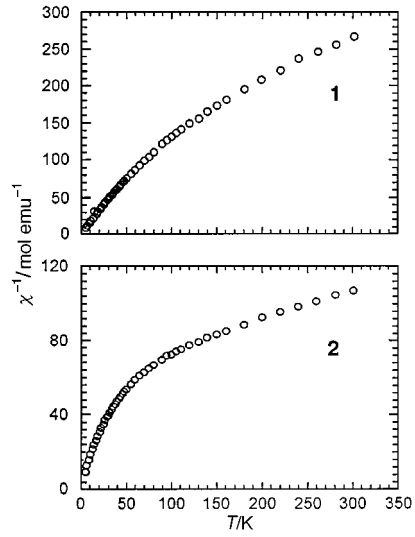

Fig. 3 Plot of $1/\chi$ *vs.* T for complexes $(DMF)_8Sm_2Ni(NCO)_8$ **1** and $(DMF)_8Eu_2Ni(NCO)_8$ **2** at 500 G

Six $[NCO]^-$ groups coordinate to a Ni^{2+} ion through the nitrogen atoms to form an approximately octahedral geometry around Ni^{2+} in both **2** and **4**. The coordination geometry around the Eu^{3+} center is a slightly distorted square antiprism in both **2** and **4**. In **2**, four nitrogen atoms from the $[NCO]^-$ groups and four oxygen atoms from the DMF molecules are coordinated to Eu^{3+}. In **4**, five nitrogen atoms from the $[NCO]^-$ groups and three oxygen atoms from the DMF molecules are coordinated to Eu^{3+}. Bridging $[NCO]^-$ groups between $Eu(1)^{3+}$ and $Eu(2)^{3+}$ ions share an edge of one antiprism base which is the cornerstone for the formation of the one-dimensional infinite chain.

Magnetic properties of **1** and **2** were studied.§ The complexity of the magnetic systems precludes a detailed theoretical analysis at this time, however, several significant observations were made. Both complexes show approximately Curie behavior below 30 K, and deviations at higher temperatures that are manifest as increased susceptibilities (Fig. 3). The deviations normally expected from Curie behavior at low temperature are small relative to the deviations shown at higher temperature for these compounds. Therefore it is the larger effect at higher temperature on which we focus our attention. Ground terms of $^6H_{5/2}$ and $^3F_4$ are assumed for the Sm^{3+} and Ni^{2+} centers in complex **1**, respectively.[14] For Sm^{3+} the first electronic excited state is typically too high in energy to contribute to the magnetic behavior, and so the magnetic properties may arise from antiferromagnetic coupling of the Ln^{3+} and Ni^{2+} ions with population of higher magnetic states at elevated temperature. For Eu^{3+} in complex **2**, a ground state term of $^7F_0$ is assumed. Since the ground state of Eu^{3+} is diamagnetic, the deviation from Curie behavior above 30 K requires a significant contribution from antiferromagnetic coupling of the low lying first excited electronic state of Eu^{3+} to be considered, although the coupling phenomenon may be more complex than the case of Sm^{3+}. Consistent with such a scheme, the low temperature magnetic moment of the europium complex **2** is approximately that of the free Ni^{2+} ion.

We thank the National Science Foundation to support this work through Grant CHE94-09123 and CHE97-00394. We thank Professor Susan M. Kauzlarich and Julia Y. Chan of the University of California at Davis for collecting SQUID data and Professor Samaresh Mitra for helpful comments.

Notes and References

† Preparation of **2** and **4** are described here. Complexes **1** and **3** were prepared in a similar manner. In a dry box, $EuCl_3$ (258.3 mg, 1.0 mmol), $NiCl_2$ (64.8 mg, 0.50 mmol), K(NCO) (324.5 mg, 4.0 mmol), and DMF (*ca.* 15 ml) were placed in a flask and the mixture was stirred for 2 days at ambient temperature under N_2. Filtration separated the KCl precipitate from the deep blue solution. DMF was removed from the filtrate under dynamic vacuum. After 12 h, colorless crystals of $(DMF)_8Eu_2Ni(NCO)_8$ were collected. Yield: nearly quantitative. IR (KBr pellet, cm^{-1}): $\nu_{CN} + \nu_{CO}$: 3518w, 3487w, 3463w, 3397w, 3391w; ν_{CN}: 2188vs, 2180vs, sh, 2122m, (unresolved), δ_{NCO}: 679s, 645w, 631m, 625m, sh, 621m; the remainder of absorption bands belong to DMF: 2940w, 2813vw, 1649s, 1500w, 1440m, 1420w, sh, 1376m, 1251w, 1115m, 1066w, 1015vw, 866vw, 661m. IR (DMF solution, cm^{-1}): $\nu_{CN} + \nu_{CO}$: 3516w, 3491w, 3369w, ν_{CN}: 2194s, sh, 2177vs, ν_{CO}: 1326w, 1260w, δ_{NCO}: 677s, 632m, 619m. Anal: Calc. for $C_{32}H_{56}N_{16}O_8Eu_2Ni$: C, 29.94; H, 4.40; N, 17.46. Found: C, 29.93; H, 4.30; N, 17.50%.

When the filtrate was pumped on for a longer period of time, a viscous oil was formed. After 12 h, colorless crystals consisting of both $(DMF)_8Eu_2Ni(NCO)_8$ and $\{(DMF)_6Eu_2Ni(NCO)_8\}_\infty$ were collected.

‡ Diffraction data were collected with an Enraf-Nonius CAD4 diffractometer using Mo-Kα radiation. All data were corrected for Lorentz and polarization and empirical absorption effects. Crystallographic computations were carried out using SHELXTL program,[15] with trial structures obtained by direct method.

Crystal data: $(DMF)_8Eu_2Ni(NCO)_8$ **2** (−60 °C), monoclinic, space group $P2_1/c$, a = 11.199(2), b = 17.581(7), c = 13.492(6) Å, β = 110.34(2)°, V = 2490.6 Å^3, M = 1283.56, Z = 4, D_c = 1.712 g cm^{-3}, μ = 2.940 mm^{-1}, $F(000)$ = 1284.0, R_1 [3569 independent reflections with $I > 2\sigma(I)$] = 0.0484 ($R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$), wR_2 (4684 reflections measured) = 0.1496 [$wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$). $\{(DMF)_6Eu_2Ni(NCO)_8\}_\infty$ **3** (−60 °C), monoclinic, space group $P2_1$, a = 9.404(2), b = 21.060(8), c = 10.915(5) Å, β = 96.41(3)°, V = 2148.1(3) Å^3, M = 1137.37, Z = 2, D_c = 1.758 g cm^{-3}, μ = 3.391 mm^{-1}, $F(000)$ = 1124.0, R_1 [3486 independent reflections with $I > 2\sigma(I)$] = 0.0340 ($R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$), wR_2, (4209 reflections measured) = 0.0886 [$wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$). CCDC 979.

§ DC magnetization data were obtained with Quantum Design MPMS Superconducting Quantum Interference Device (SQUID) magnetometer with a 5.5 Tesla superconducting magnet. Data were collected and analyzed with the Magnetic Property Measurement System (MPMS) software supplied by Quantum Design. All samples were measured in zero field and then field cooled. Temperature dependent magnetization data were obtained by first measuring the zero field cooled (ZFC) magnetization in the field while warming from 5 to 300 K, then measuring magnetization while cooling back to 5 K with the field applied to obtain the field cooled (FC) data.

Glow discharge synthesis and molecular structures of perchlorofluoranthene and other perchlorinated fragments of buckminsterfullerene

Su-Yuan Xie, Rong-Bin Huang,*† Li-Hua Chen, Wei-Jie Huang and Lan-Sun Zheng

State Key Laboratory for Physical Chemistry of Solid Surfaces, Department of Chemistry, Xiamen University, Xiamen 361005, China

A series of perchlorinated fragments of buckminsterfullerene were prepared by glow discharge using chloroform vapor; their structural features are of significance in understanding the formation mechanism of fullerenes.

Although there have been a great many achievements in the experimental and theoretical investigation of fullerenes, their formation mechanism is still a puzzle to chemists and physicists.[1] Various schemes have been put forward to explain the formation of fullerenes.[2–7] Each of these schemes rationalise the available experimental evidence. None of them, however, can explain the formation process of the mid-sized intermediates (about 20–30 carbon atoms) and none show the formation of five-membered carbon rings that is known to be critical for fullerene formation. In order to understand the process, there has also been tremendous interest in the trapping of intermediates.[8,9] In our laboratory, a series of perchlorinated polycyclic compounds with a five-member ring and various six-member rings, such as perchloroacenaphthylene ($C_{12}Cl_8$), perchlorofluoranthene ($C_{16}Cl_{10}$) and perchlorocorannulene ($C_{20}Cl_{10}$), have been synthesized *via* discharge in liquid $CHCl_3$ rather than *via* conventional organic synthesis. These compounds were characterized as perchlorinated fragments of fullerene, so the work is helpful in understanding the formation mechanism of fullerenes.[10] Recently, we extended the discharge reaction to the vapor phase, and detected fullerenes and other larger perchlorinated fragments among the products. We were able to obtain single crystals of perchloroacenaphthylene and perchlorofluoranthene, and their structures, determined by X-ray diffraction, may provide more information about the formation mechanism.

The synthesis‡ described here was carried out using a typical procedure developed by this group in recent years. After separation procedures, the pure products were collected, and single crystals of high enough quality for X-ray diffraction analysis were obtained after four months growing in solution. The crystals were characterized as perchloroacenaphthylene ($C_{12}Cl_8$) and perchlorofluoranthene ($C_{16}Cl_{10}$) by X-ray diffraction.§ As shown in Fig. 1, octachloroacenaphthylene is a flat molecule, with all its carbon and chlorine atoms effectively located in the same plane. In contrast, perchlorofluoranthene is a very crowded molecule. If it were planar, some of the intramolecular Cl···Cl distances between neighboring chlorine atoms would be about 2.5 Å, whereas the sum of their van der Waals radii is 3.6 Å; the shortest Cl···Cl distances found in similar compounds are about 3.0 Å, as in perchloronaphthalene (3.032 Å),[11] perchloropyrene (3.003 Å),[12] perchlorophenanthrene (3.037 Å)[13] and 1,10-dichloro-3,8-dimethyl-4,7-phenanthroline (3.082 Å).[14] Thus, 3 Å is likely to be the shortest possible distance between chlorine atoms in this kind of overcrowded perchlorinated polycyclic compound. The structural data§ shows that the mean planes of the benzene and naphthalene rings are not in a same plane, and the dihedral angle between the planes is 26.09(5)°. Distortion of the molecule is due to the steric effects of its component chlorine atoms and mainly involves its five-member ring, so the molecule bends with the axis through its five-membered ring. Compared with the sandal structure of perchloropyrene,[12] one isomer of perchlorofluoranthene which has four six-membered rings but no five-membered ring, the twisted structure of perchlorofluoranthene is distorted more severely. The difference can also be found from comparison of another pair of isomers, fluoranthene and pyrene. The structure of the former is non-planar,[15] but the latter is nearly planar.[16] Obviously, formation of the five-membered ring makes the molecule more flexible, so that it can relieve the strain caused by the steric effect of the chlorine atoms. In fact, the five-membered ring is also found in the structures of other perchlorinated polycyclic compounds synthesized in the experiment.

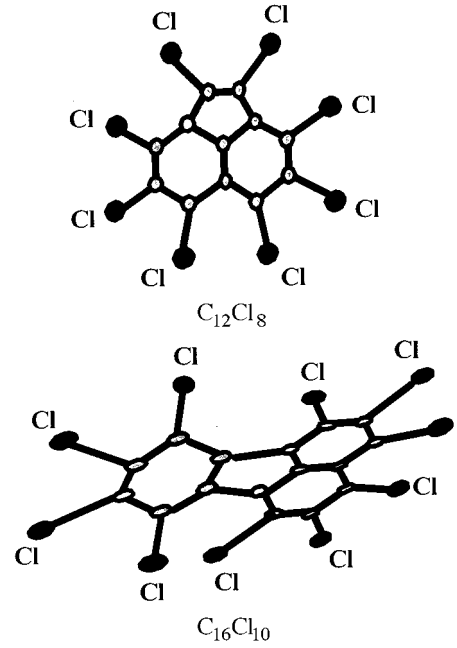

Fig. 1 Molecular structures of perchloroacenaphthylene and perchlorofluoranthene

Formation of the cage structure of the fullerenes also involves the five-membered rings. In fact, C_{60} and other fullerenes were also produced in the glow discharge experiment and were detected by laser-desorption mass spectrometry (Fig. 2). In the mass spectrum, in addition of various fullerene products, some larger perchlorined fragments, such as $C_{22}Cl_{10}$ and $C_{24}Cl_{10}$, are also observed. Although the fullerene products were not seperated, they can be characterized by their particular size distribution.

Products from discharge reactions were expected to be very complicated. However, the products from the discharge reaction of $CHCl_3$ are quite selective: The products were either fullerenes or their perchlorinated fragments. The distorted structure of perchlorofluoranthene suggests that it is the steric effects of the chlorine atoms that limits the possible number of the products and favors the formation of the five-membered ring. Although $CHCl_3$ only contains a single carbon atom, in the

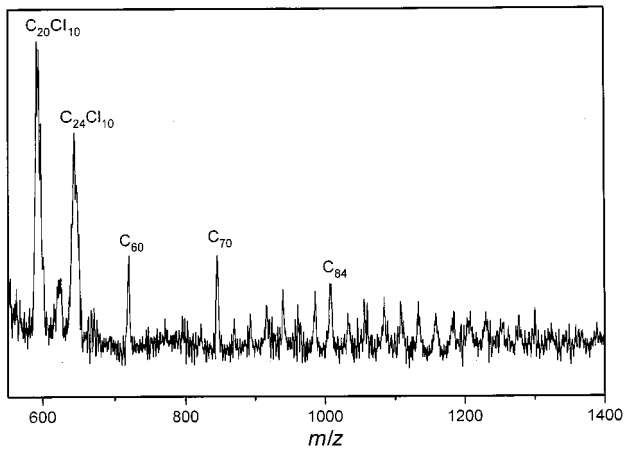

Fig. 2 Laser desorption mass spectrum of fullerenes and other products synthesized from the glow-discharge reaction of $CHCl_3$

discharging reaction it serves as a C1 building block for aggregation into fullerenes or their perchlorinated fragments.

‡ *Typical procedure*: $CHCl_3$ was evaporated from a flask containing 100 ml liquid $CHCl_3$ into a quartz tube with a diameter of *ca*. 40 mm and a length of *ca.* 250 mm; a pair of copper pipes, which acted as both electrodes and a gas passageway, were mounted at the two ends of the tube. When the vacuum pressure of the tube was reduced to less than 300 Pa and an ac voltage of > 10 kV with 25 kHz frequency was applied to the electrodes, a stable glow discharge emerged in the gap between the two electrodes which could be maintained by adjusting the gap. After reacting for several hours, *ca*. 5 g of black deposit was collected, followed by sublimating at 160 °C to separate hexachlorobenzene and the other volatile matter. The residue was extracted with toluene and separated *via* chromatography (Al_2O_3, light petroleum); the third (yellow) component part was perchlorofluoranthene, the fourth (red) component part was perchloroacenaphthylene, and the remainder were other larger perchlorined fragments, C_{60} and other fullerenes products.

§ *Crystal data* for perchloroacenaphthylene: $C_{12}Cl_8$, M = 428, monoclinic, $P2_1/a$, a = 7.079(5), b = 22.396(5), c = 10.661(5) Å, β = 93.046(5)°, U = 1687.8(15) Å^3, T = 298 K, Z = 4, λ = 105418 Å, μ(Cu-Kα) = 24.687 cm^{-1}, $F(000)$ = 532, red crystals with dimensions 0.16 × 0.17 × 0.79 mm. Data were collected on a Enraf-Nonius CAD-4 diffractometer in the ω–2θ scan mode, and corrected for absorption by ψ. A total of 3768 independant reflections were collected in the range 4 < 2θ < 75°, of which 1628 reflections with $I > 2\sigma(I)$ are considered observed.The SIR92 and SHELXL93 program packages were used to solve and refine the structure, respectively. The final deviation factor R_w = 0.0749, wR = 0.1955.

Crystal data for perchlorofluoranthene: $C_{16}H_{10}$, M = 546.66, triclinic, space group $P\bar{1}$, a = 7.4590(7), b = 11.4920(7), c = 11.8800(8) Å, α = 112.346(5), β = 90.858(6), γ = 106.277(6)°, U = 895.60(12) Å^3, T = 298 K, Z = 2, D_c = 2.02 Mg cm^{-3}, λ = 1.5418 Å, μ(Cu-Kα) = 24.68 cm^{-1}, $F(000)$ = 532, orange crystals with dimensions 0.04 × 0.07 × 0.075 mm. Data were collected on an Enraf-Nonius CAD-4 diffractometer in the ω–2θ scan mode, and corrected for absorption by ψ. A total of 3889 independent reflections were collected in the range 4 < 2θ < 75°, of which 2111 reflections with $I = 2\sigma$ were considered observed. The SIR92 and SHELXL93 programme packages were used to solve and refine the structure, respectively. The final deviation factor R_w = 0.064, wR = 0.1362. CCDC 182/981.

Is Ti(η⁸-pentalene)$_2$ a 20-electron complex? A theoretical investigation of a pseudo electron-rich molecule

Karine Costuas and Jean-Yves Saillard*

LCSIM-UMR 6511, Université de Rennes 1, 35042 Rennes Cedex, France. E-mail: saillard@univ-rennes1.fr

DFT calculations confirm the D_{2d} conformation of the title compound proposed by Jonas *et al*; only 9 of the 10 combinations of the π-type ligand orbitals interact with the metal atom: the remaining one, of a_2 symmetry, does not match with any metal orbital and therefore the title compound is not a 20-electron system, but a regular 18-electron complex; calculations predict that the 18-electron [Ti(η⁸-pentalene)$_2$]$^{2+}$ cation should also be attainable.

Jonas and coworkers recently synthesised and characterised a very interesting series of transition metal complexes of V, Ti, Zr and Hf which exhibit a new type of coordination mode of pentalene (C_8H_6).[1–3] In these compounds, exemplified below

1 **2**

by CpV(C_8H_6) **1** and Ti(C_8H_6)$_2$ **2**, the pentalene ligand is folded in such a way that all its carbon atoms are bonded to the metal. Considering the η⁸-bonded pentalene ligand in **1** as being formally a dianion, it is expected to provide the metal centre with its 10 π electrons, leading to a V^{III} 18-electron complex. A similar reasoning leads to the surprising count of 20 electrons in the case of **2**. Such an electron-rich situation generally corresponds to a Jahn–Teller instability due to the presence of two electrons in one (or two) antibonding orbital(s). Unlike **1** and other CpV systems, there is no X-ray characterisation published so far for **2** or related complexes. Its D_{2d} conformation was established on the basis of NMR data.[2] Simple symmetry considerations are fully consistent with the 18-electron count of **1**. Indeed, there is a perfect match between the five empty frontier orbitals of the CpV fragment (four of d-type and one sp-type hybrid)[4] and the five occupied π-type orbitals of $(C_8H_6)^{2-}$,[5] leaving two electrons in a dσ non-bonding level. On the other hand, of the ten occupied π-type combinations of the two $(C_8H_6)^{2-}$ ligands in the D_{2d} complex **2**, only nine have the correct symmetry to match with the nine vacant orbitals of the Ti^{IV} atom. The remaining one, being of a_2 symmetry, cannot overlap with the metal and should remain non-bonding. Thus, symmetry and frontier orbital theory predict an 18-electron count for the D_{2d} conformation of **2**.

Our current interest in transition metal sandwich complexes which do not obey the 18-electron rule[6] as well as in the coordination variability of pentalene with respect to electron count[5] prompted us to perform density functional theory (DFT) calculations[7] on **2**, in order to predict its structure (D_{2d} or less symmetrical), rationalise its electron count and understand its bonding. A full geometry optimisation carried out without any symmetry constraint confirmed the D_{2d} structure (see Fig. 1). The pentalene optimised folding angle is 149°, a value larger than that reported in **1** and related V and Ti complexes (119–127°).[1,2] As a consequence, the Ti–C(pentalene) distances are somewhat larger than those reported for the CpTi(pentalene)

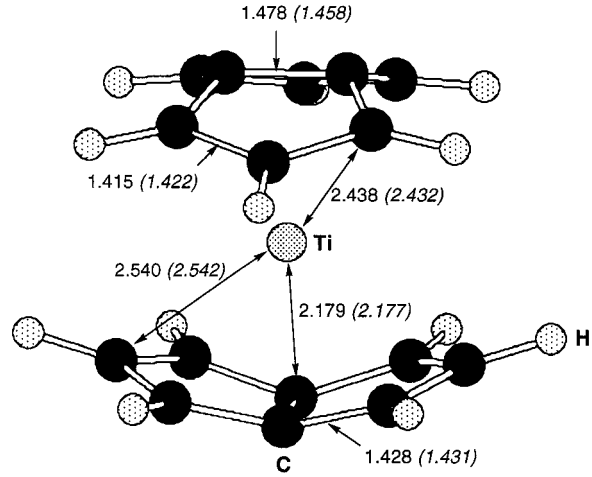

Fig. 1 DFT optimised molecular structure of **2** and **2**$^{2+}$. The values in parentheses correspond to **2**$^{2+}$.

derivatives.[1,2] The MO diagram of **2** is shown in Fig. 2, based on the interaction of the $(C_8H_6)^{2-}$ ligands with the Ti^{IV} center. With an a_2 HOMO deriving from the π-type orbitals of pentalene, it shows clearly that the symmetry-based predictions are correct.[11] The significant HOMO–LUMO gap computed agrees with the stability of these diamagnetic species. The existence of an even larger energy gap below the HOMO suggest that **2**$^{2+}$ or isoelectronic species should also be stable diamagnetic compounds.[12] The optimised geometry of **2**$^{2+}$, for which a HOMO–LUMO gap of 1.93 eV was computed, is very similar to that of **2**. The major metrical data are given in Fig. 1. The folding angle of pentalene is also 149°. Since the a_2 HOMO of **2** has no metal participation, its depopulation in **2**$^{2+}$ has no effect on the Ti–C separations. Since this a_2 orbital derives from

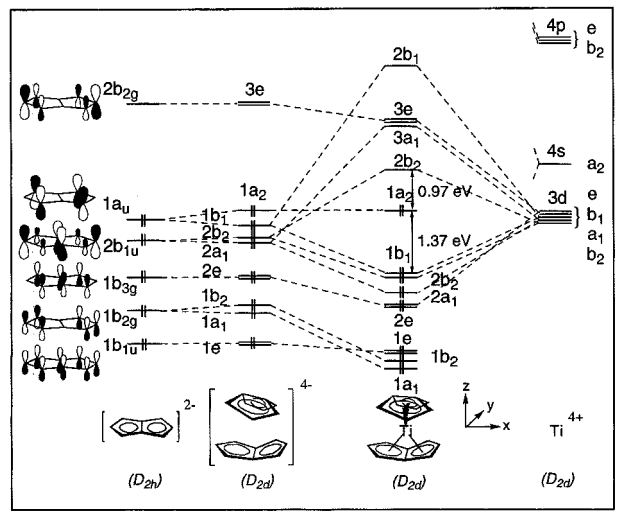

Fig. 2 MO interaction diagram of **2**

the C–C non-bonding $1a_u$ HOMO of $(C_8H_6)^{2-}$ (Fig. 2), there is also little difference between the ligand geometries of **2** and $\mathbf{2}^{2+}$. The shortening by *ca.* 0.02 Å of the central C–C bond upon oxidation is probably due to the σ/π mixing within the non-planar ligands. The smaller folding of pentalene in **2** and $\mathbf{2}^{2+}$, as compared to **1**, is consistent with the fact that in the bis-pentalene systems each ligand [$(C_8H_6)^{2-}$ in **2** and $(C_8H_6)^{-}$ in $\mathbf{2}^{2+}$] is a 9-electron donor whereas in **1** $(C_8H_6)^{2-}$ is a 10-electron donor.

In order to check the possibility of extending the peculiar bonding mode of pentalene in **2** to other ligands, we are currently investigating the electronic structure of hypothetical sandwich complexes of fused conjugated rings such as indacene and naphthalene.

The authors thank the Centre de Ressources Informatiques (CRI) of Rennes and the Institut de Développement et de Ressources en Informatique Scientifique (IDRIS-CNRS) of Orsay for computing facilities.

7 The calculations were carried out with the ADF program[8] developed by Baerends and coworkers,[9] using non-local exchange and correlation corrections.[10] The standard ADF STO basis set IV, of triple-ζ quality for the valence orbitals (except for the single-ζ 4p orbitals), was used for Ti. The other atoms were treated with the standard basis set III, of double-ζ quality for the valence orbitals. The frozen-core approximation was considered.

The first synthesis of promothiocin A

Christopher J. Moody*† and Mark C. Bagley

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD

The first total synthesis of the naturally occurring macrocyclic thiopeptide promothiocin A 1 is described.

Promothiocin A **1**, isolated from *Streptomyces* sp. SF2741, is a member of the thiopeptide family of antibiotics.[1] These natural products, which inhibit protein synthesis in bacteria, are characterised by their complex structure in which an array of heterocyclic rings is incorporated into a macrocyclic peptide framework. Despite the fascinating biological activity of the thiopeptide antibiotics, little synthetic work has been carried out to date, although the synthesis of the pyridine fragments of the micrococcins, sulfomycin and nosiheptide has been addressed,[2–5] and very recently micrococcin P has yielded to synthesis.[6] In continuation of our interest in the synthesis of heterocyclic natural products,[7] we now report the first total synthesis of promothiocin A **1**, thereby confirming the structure and stereochemistry.

The structure of promothiocin A **1** was established by NMR spectroscopy, although the stereochemistry of the natural product was not reported.[1] Therefore we have assumed that the three stereocentres result from natural amino acids (see Fig. 1) and could be incorporated from suitable derivatives of (*S*)-alanine and (*S*)-valine. The overall plan, indicated by the arrows in Fig. 1, was to form the macrocycle by two peptide coupling reactions (1 and 2), followed by introduction of the dehydroalanine side chain (3).

The starting point was the synthesis of the two oxazoles **2** and **3** from (*S*)-alanine and glycine, respectively. This was readily achieved using our previously published method;[8] thus rhodium(II) acetate catalysed reaction of the *N*-protected amino acid amides with methyl 2-diazo-3-oxobutanoate resulted in clean insertion of the metallocarbenoid into the amide N–H bond. Cyclodehydration of the resulting keto amides using the Wipf protocol (Ph_3P, I_2, Et_3N)[9] gave the required oxazoles **2** and **3** in 56 and 49% overall yield respectively (Scheme 1). The glycine derived oxazole **3** was deprotected to give the 2-aminomethyloxazole **4** for subsequent coupling, whereas the alanine derived oxazole **2** was converted into the oxazole-thiazole-pyridine fragment **5** using our previously developed method,[10] based on the Bohlmann–Rahtz pyridine synthesis.[11]

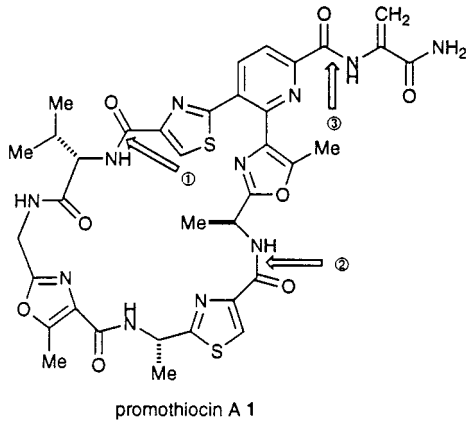

Fig. 1 Promothiocin A **1** and proposed disconnections

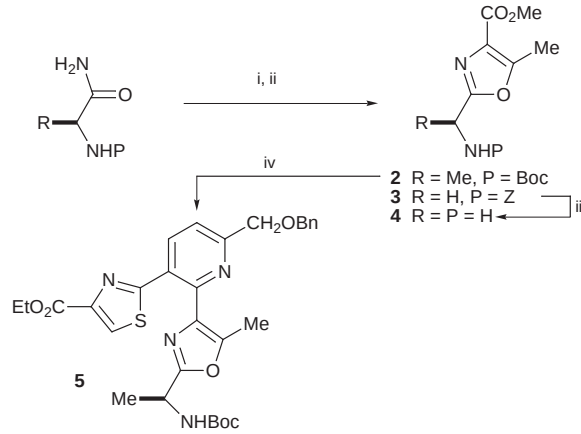
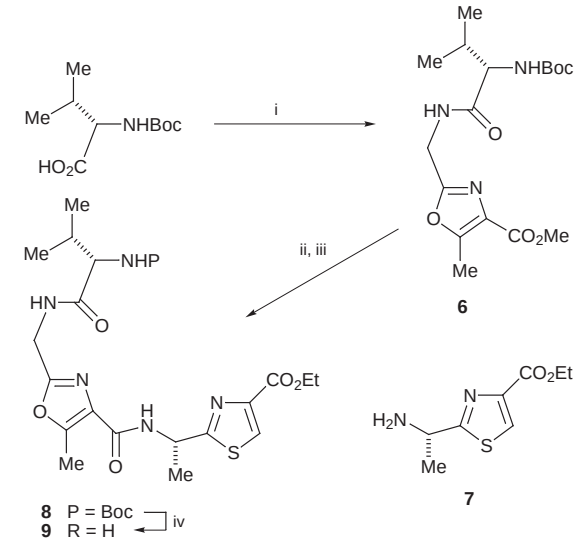
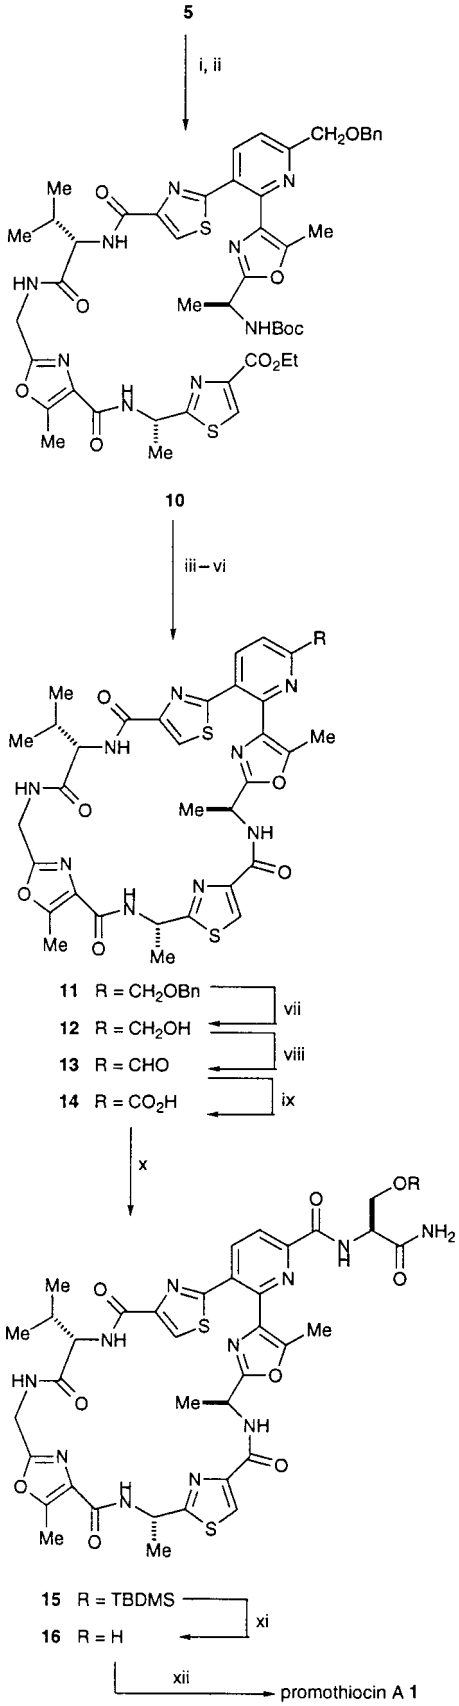


Scheme 1 *Reagents and conditions*: i, methyl 2-diazo-3-oxobutanoate cat. $Rh_2(OAc)_4$, $CHCl_3$, heat (80% for **2**, 76% for **3**); ii, Ph_3P, I_2, Et_3N, CH_2Cl_2 (70% for **2**, 64% for **3**); iii, H_2, Pd-C, MeOH (100%); iv, see ref. 10

The lower valine-oxazole-thiazole fragment **9** was obtained as shown in Scheme 2. Thus *N*-Boc-valine was coupled to the aminomethyloxazole **4** in high yield by mixed anhydride methodology using isobutyl chloroformate and *N*-methylmorpholine (NMM) to give the oxazole **6**. The alanine derived thiazole **7** was obtained from the known *N*-Boc derivative, prepared using the modified Hantzsch reaction,[12] the standard conditions leading to extensive racemisation, and coupled to the carboxylic acid derived by hydrolysis of the ester **6** to give the valine-oxazole-thiazole **8** in excellent yield (Scheme 2). Finally



Scheme 2 *Reagents and conditions*: i, Bu^iO_2CCl, NMM, THF, then **4** (87%); ii, LiOH, aq. THF (93%); iii, Bu^iO_2CCl, NMM, THF then **7** (84%); iv, AcCl, EtOH (100%)



Scheme 3 *Reagents and conditions*: i, LiOH, aq. THF (94%); ii, Bu^iO_2CCl, NMM, THF, then **9** (69%); iii, LiOH, aq. THF (97%); iv, C_6F_5OH, EDCI, CH_2Cl_2 (100%); v, 4 M HCl in dioxane, then aq. $KHCO_3$; vi, Et_3N, $CHCl_3$ (55% over 2 steps); vii, $BCl_3{\cdot}SMe_2$, CH_2Cl_2 (39%); viii, IBX, DMSO (81%); ix, $NaClO_2$, KH_2PO_4, 2-methylbut-2-ene, aq. Bu^tOH (70%); x, *O*-TBDMS-serinamide, EDCI, CH_2Cl_2 (50%); xi, TBAF, THF (57%); xii, MsCl, Et_3N, CH_2Cl_2, then Et_3N (59%)

deprotection of the *N*-terminal Boc group with ethanolic HCl gave the free amine **9** for subsequent coupling.

The coupling of the lower and upper fragments of the promothiocin macrocycle was achieved using mixed anhydride methodology (Scheme 3). Hydrolysis of the ester group in the oxazole-thiazole-pyridine **5** was followed by activation with isobutyl chloroformate/NMM and coupling with the amine **9** to give the terminally protected 'linear peptide' **10** in good yield. Although there are several methods available for macrolactamisation, we have found the Schmidt protocol,[13] used in our recent synthesis of nostocyclamide,[7] to be particularly reliable. Hence the ester group in **10** was hydrolysed and converted into the corresponding pentafluorophenyl ester by coupling with pentafluorophenol in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDCI). The pentafluorophenyl ester was not purified but underwent deprotection at the *N*-terminus on treatment with HCl in dioxane. Work-up and treatment with triethylamine resulted in lactamisation to give the promothiocin macrocycle **11** in 55% yield. The synthesis was completed by elaboration of the dehydroalaninamide side chain, although these final steps proved far from trivial. Deprotection of the benzyl ether to give the pyridine-2-methanol derivative **12** was followed by conversion to the aldehyde **13** using *o*-iodoxybenzoic acid (IBX) in DMSO,[14] and further oxidation with sodium chlorite[15] to give the desired acid **14**. Coupling of the acid **14** with the *tert*-butyldimethylsilyl ether of (*S*)-serinamide using EDCI gave the amide **15**; deprotection of the serine side-chain with TBAF was followed by dehydration (MsCl, Et_3N) to give promothiocin A **1** (Scheme 3). The synthetic material had 400 MHz ^1H and 100 MHz ^{13}C NMR spectra identical to those reported for the natural product,[1] and its specific rotation of $[\alpha]_D^{23}$ + 87.3 (*c* 0.34, $CHCl_3$–MeOH, 1 : 1) [lit.,[1] +79.2 (*c* 0.69, $CHCl_3$–MeOH, 1 : 1)] strongly implies that the natural product does indeed have the stereochemistry indicated in Fig. 1. Thus we have completed the first total synthesis of the thiopeptide promothiocin A **1**, and established the stereostructure of the natural product.

We thank the EPSRC and the Leverhulme Trust for support of our research, Claire Hesketh for preliminary experiments, and Dr Vladimir Sik for detailed NMR experiments.

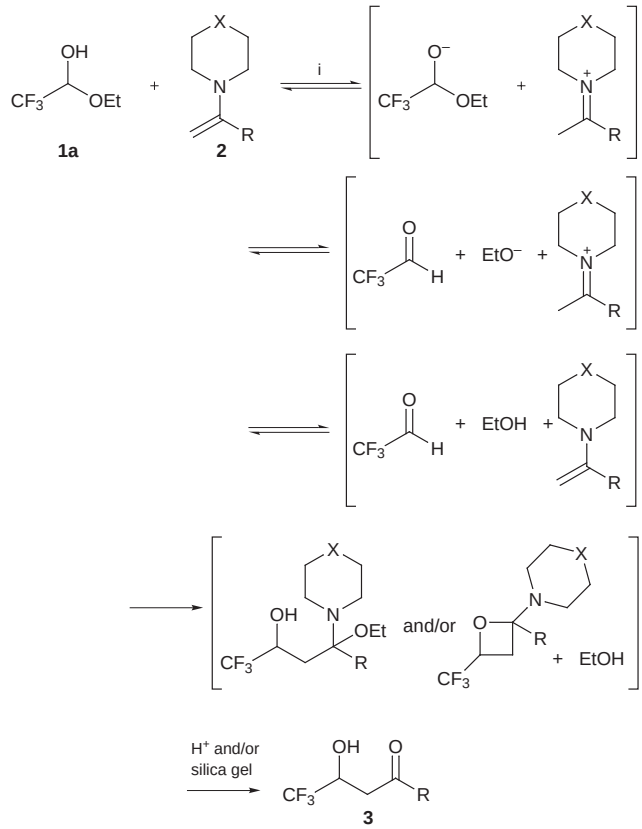
Enamine-assisted facile generation of trifluoroacetaldehyde from trifluoroacetaldehyde ethyl hemiacetal and its carbon–carbon bond forming reaction leading to β-hydroxy-β-trifluoromethyl ketones

Kazumasa Funabiki,*† Miwa Nojiri, Masaki Matsui and Katsuyoshi Shibata*

Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu, 501-1193, Japan

Trifluoroacetaldehyde ethyl hemiacetal 1 readily reacts with various enamines 2 in hexane at room temperature for 1 h to give the corresponding β-hydroxy-β-trifluoromethyl ketones in good yields.

Much attention has been recently addressed to trifluoromethylated compounds, since they are widely used for the construction of new types of biologically active compounds and liquid crystals. In connection with these circumstances, the development of new strategies and methodologies for the efficient synthesis of trifluoromethylated molecules has become the subject of growing interest.[1] Among the many approaches to such compounds, trifluoroacetaldehyde is one of the most useful compounds, and is employed for the construction of functionalized trifluoromethylated components *via* reaction with a number of reagents, such as metal enolates,[2] ketene silyl acetals[3] (phenylthio)bis(trimethylsilyl)methyllithium,[4] aromatic compounds,[5] olefins[3,6] and dienes.[7] In previous methods for the generation of trifluoroacetaldehyde, however, there exist serious disadvantages, including high reaction temperatures and the use of an excess amount of concentrated H_2SO_4.[8] In addition, trifluoroacetaldehyde is gaseous (bp −18 °C) and very miscible with water, and therefore it must be carefully handled.



Scheme 1 *Reagents and conditions:* i, room temp., 1 h

Here we describe for the first time the enamine-assisted facile generation of trifluoroacetaldehyde under extremely mild conditions from trifluoroacetaldehyde ethyl hemiacetal,‡ and its carbon–carbon bond forming reaction with enamines in the absence of additives, which permits highly efficient and convenient access to β-hydroxy-β-trifluoromethyl ketones.

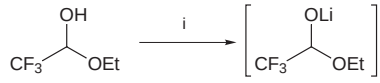
When hemiacetal **1a** was allowed to react with an equimolar amount of enamine **2a**, prepared from acetophenone with morpholine, in hexane at room temperature for 1 h, the corresponding β-hydroxy-β-trifluoromethyl ketone **3a** was obtained in 88% yield (Scheme 1 and Table 1, entry 1).

The use of other solvents, such as dichloroethane, THF, PhMe and MeCN, gave comparable yields of **3a**, irrespective of their polarities (entries 2–5). It is noteworthy that the reaction of **1a** proceeded smoothly to furnish the product **3a** in satisfactory yield in the presence of water (entry 6). The substituents on the nitrogen atom of the enamines did not influence the yields of **3a** (entries 1 and 7). Various enamines bearing aromatic and heteroaromatic substituents could successfully participate in the reaction to afford the corresponding β-hydroxy-β-trifluoromethyl ketones **3** in good to excellent yields (entries 8–11, 14–15). The reaction with enamine **2f** carrying a nitro group on the aromatic ring was very sluggish, producing **3e** in only 13% yield because of the lower solubility of **2f**, which could be improved by replacing hexane with toluene as solvent (entries 12 and 13). The electronic character of the aromatic ring has little influence on the rate of the reaction, according to the yields of **2** for the same reaction time (*p*-NO_2 < 2-thienyl =

Table 1 Reactions of trifluoroacetaldehyde ethyl hemiacetal with enamines[a]

Entry	Enamine	X	R	Solvent	Product	Yield (%)[b]
1	**2a**	O	Ph	hexane	**3a**	88
2	**2a**	O	Ph	$ClCH_2CH_2Cl$	**3a**	78
3	**2a**	O	Ph	THF	**3a**	73
4	**2a**	O	Ph	PhMe	**3a**	88
5	**2a**	O	Ph	MeCN	**3a**	75
6	**2a**	O	Ph	hexane–H_2O (40:1)	**3a**	68
7	**2b**	CH_2	Ph	hexane	**3a**	86
8	**2c**	O	*p*-MeC_6H_4	hexane	**3b**	87
9	**2c**	O	*p*-MeC_6H_4	PhMe	**3b**	87
10	**2d**	O	*p*-$MeOC_6H_4$	hexane	**3c**	72
11	**2e**	O	*p*-ClC_6H_4	hexane	**3d**	86
12	**2f**	O	*p*-$O_2NC_6H_4$	hexane	**3e**	13
13	**2f**	O	*p*-$O_2NC_6H_4$	PhMe	**3e**	52
14	**2g**	O	*o*-MeC_6H_4	hexane	**3f**	87
15	**2h**	O	2-thienyl	hexane	**3g**	75
16[c]	**2i**	O	Pr^i	hexane	**3h**	25

[a] All the reactions were carried out with trifluoroacetaldehyde ethyl hemiacetal (1 mmol) and enamine (1 mmol) in solvent (4 ml) at room temperature for 1 h. [b] Isolated yields of analytical pure products. [c] A mixture of enamines **2i** and **4** (29:71) was employed.



1a **1b**

Scheme 2 *Reagents and conditions:* i, Bu^{n}Li (1.5 equiv.), hexane, 0 °C, 15 min

p-Cl = *p*-H = *p*-Me = *p*-MeO). The reaction of **1a** with the mixture of aliphatic enamines **2i** and 4-(3-methylbut-2-en-2-yl)morphorine **4** (29:71) (1 equiv.) resulted in the exclusive formation of **3h** in 25% yield, and none of the product derived from enamine **4** was detected in the reaction mixture (entry 16). According to these results, the steric effect of the substituents at the β-carbon of the enamines is more important for the the reaction than the electronic effect of the substituents at the α-carbon.

The formation of **3** can be explained by assuming the mechanism shown in Scheme 1. It is significant that the reaction requires only an equimolar amount of enamine, which may act as a base, counter ammonium cation and carbon nucleophile.

More significantly, the reaction of lithium alcoholate **1b**§ with the enamine **2a** did not proceed at all; the acetophenone was recovered in quantitative yield (Scheme 2). According to this result, the ammonium cation, which is generated *via* protonation of the enamine, plays a very important role in the effective generation of trifluoroacetaldehyde in the reaction.

In conclusion, we have demonstrated the enamine-assisted *in situ* generation of trifluoroacetaldehyde and its reaction with enamines, producing the corresponding β-hydroxy-β-trifluoromethyl ketones **3** in high yields. The present method can serve as a synthetically useful entry to β-hydroxy-β-trifluoromethyl ketones, with simple manipulations and high yields of the products. Application of the present methodology to stereoselective synthesis using asymmetric secondary amines or β-monosubstituted enamines is currently in progress in our laboratory.

We thank Dr H. Muramatsu for valuable discussions.

‡ Recent reports have presented the coupling reaction of trifluoroacetaldehyde ethyl hemiacetal, which is considered as an equivalent of trifluoroacetaldehyde. These methods, however, require the use of an excess amount of reagents and/or of limited solvents, the formation of by-products, and relatively low yields of the products, see ref. 9.

§ Kitazume and Yamazaki reported that the tetrahedral form of **1b** is too stable to be converted to trifluoroacetaldehyde due to the strong electron-withdrawing effect of a trifluoromethyl group, see ref 10.

Synthesis of fluorine-containing cyclic amino acid derivatives *via* ring closing olefin metathesis

Sergey N. Osipov,*[a] Christian Bruneau,[b] Michel Picquet,[b] Alexey F. Kolomiets[a] and Pierre H. Dixneuf*[b]†

[a] *A. N. Nesmeyanov Institut of Organoelement Compounds, Vavilov st. 28, Moscow, V334, GSP-1, 117813, Russia*
[b] *UMR 6509 CNRS Université de Rennes, Laboratoire de Chimie de Coordination et Catalyse, Campus de Beaulieu, 35042 Rennes, France*

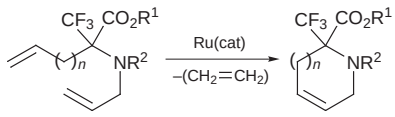
New N-protected α-CF_3 amino esters with two alkene chains (1,7-dienes 3 and 1,6-dienes 5) were reacted with the ring closing metathesis catalyst Ru=CHPh$(Cl)_2(PCy_3)_2$ to give the α-CF_3 dehydropipecolinate and prolinate derivatives 6 and 7.

Among various classes of fluorine-containing biologically active compounds, fluorinated amino acids attract considerable attention. They are especially useful candidates for peptide modification, and β-fluoro-containing amino acids offer potential as irreversible inhibitors of pyridoxal phosphate dependent enzymes.[1] A major drawback of peptide drugs is their rapid degradation by proteases, low lipophilicity and high conformational flexibility and the lack of transport systems to direct peptides into cells.[2] The incorporation of α,α-disubstituted amino acids into key positions in peptides is an efficient strategy to retard proteolytic degradation and to stabilize secondary structures.[3,4] Due to the unique properties of the CF_3 group (high electronegativity, lipophilicity and steric hindrance), α-trifluoromethyl amino acids are a special class of α,α-disubstituted amino acids that can profoundly improve the above mentioned characteristics of peptides.[5]

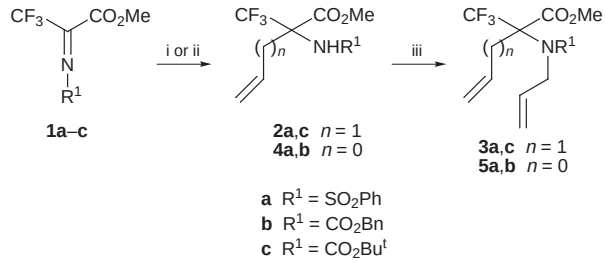
The preparation of rigidified α-amino acids to effect conformational constraints in peptides has played an important role in drug design and development.[6] An efficient access to α-difluoromethyl and α-trifluoromethyl substituted α-amino acids from electrophilic imines of type $XF_2CC(=NPG)CO_2R$ has recently been reported.[7,8] This reaction enabled the direct synthesis of α-fluoromethyl α-amino acids, but the restriction of their conformational flexibility by incorporation into an N-heterocycle was necessary. However, one possible approach is based on intramolecular Ring Closing Metathesis (RCM). The use of olefin metathesis has expanded tremendously in recent years, with applications including the construction of carbo- and hetero-cycles, macrocycles in peptides and other systems.[9] Especially useful are metathesis catalysts based on ruthenium, which have demonstrated remarkable tolerance towards oxygen, protic solvents, and a variety of functional groups.[10]

We now disclose a new effective synthesis of α-trifluoromethyl substituted derivatives of dehydropipecolinic acid and dehydroproline, from α-trifluoromethyl α-amino esters containing two terminal alkene chains, using ring closing olefin metathesis (RCM), according to Scheme 1.

Several imines with different protecting groups on nitrogen, including $PhSO_2$, Boc and Z groups, were successfully applied for the synthesis of α-CF_3 containing α-amino acid derivatives.[11,12] Thus, the preparation of α-CF_3 amino acid derivatives **3** and **5** with two alkene chains was achieved *via* a two-step



Scheme 1



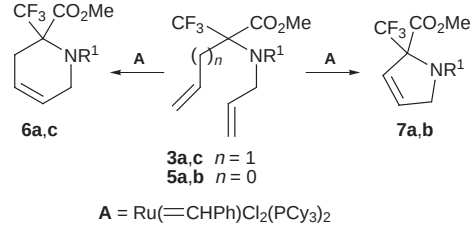
Scheme 2 *Reagents and conditions*: i, CH_2=$CHCH_2MgBr$, THF, −100 °C (1 h) to room temp. (2 h), then aq. HCl (1 M); ii, CH_2=$CHMgBr$, THF, −90 °C to room temp., then aq. HCl (1 M); iii, NaH, DMF, 0 °C, then allyl bromide, 10 h, room temp., then H_2O

procedure starting from the electrophilic imine **1**. The imine **1a** smoothly reacts with allylmagnesium bromide in THF to give the amino acid derivative **2a** in 75% yield. The latter is transformed on deprotonation with NaH and subsequent reaction with allyl bromide into the 1,7-diene derivative **3a** (72%). Similarly, imine **1a** reacts with vinylmagnesium bromide at −90 °C to give **4a** (69%). *N*-Allylation of **4a** *via* successive treatment with NaH and allyl bromide affords the 1,6-diene **5a** (81%) (Scheme 2).

Following the same procedure but starting from the Z and Boc N-protected imines **1b**,**c**, it was possible to isolate in two steps the 1,6-diene **5b** (65%) and the 1,7-diene **3c** (55%) *via* **4b** and **2c**, respectively.

The intramolecular ring closing metathesis reaction was attempted from the 1,7-diene **3a** in CH_2Cl_2 at room temperature in the presence of 10 mol% of the Grubbs catalyst Ru=CHPh$(Cl)_2(PCy_3)_2$ **A**.[9a] The cyclisation of **3a** took place and was completed within 10 h to give the dehydropipecolinate derivative **6a**[13] in high yield (93%) (Scheme 3). The RCM reaction with catalyst **A** (10 mol%) applied to **3c** led to the formation of the six-membered heterocycle **6c** which, after 10 h of reaction, was isolated in 98% yield.

Special interest in α-CF_3 proline derivatives is connected with the fact that proline is known to be unique among the natural amino acids in its abilities to induce β-turns and initiate the folding of an α-helix. Because of these structurally important properties, proline is often suggested as the primary contributor to the biological activity of several proteins, as well as having a key role in biological recognition phenomena.[14]



Scheme 3

Dehydroproline derivatives have also found use as starting materials for kanic acid derivatives.[15]

Recently, attempts to prepare dehydroproline derivatives *via* ring closing metathesis from a $BocN(CH_2CH{=}CH_2)CH(CO_2Me)CH{=}CH_2$ precursor have been made and failed. In the presence of $Ru{=}CHCH{=}CPh_2(Cl)_2(PCy_3)_2$ **B** as catalyst, the acyclic α,β-unsaturated ester $\{BocN[C(CO_2Me){=}CHMe]CH_2CH{=}\}_2$ has been obtained.[9a] This is likely due to the high lability of the vinylglycine α-proton of the precursor.

The absence of an acidic α-proton in the vinylglycine structure of compounds **5** was crucial to the suucessful first formation of the desired dehydroprolinates **7**. Under standard RCM conditions in the presence of 11 mol% of catalyst **A**, at room temperature, **5a** (0.23 mmol) was slowly cyclised into **7a**.[13] However, full conversion of **5a** could not be achieved even after 60 h (conversion ~55%) and derivative **7a** was separated from the starting product **5a** by chromatography over silica gel and isolated in 46% yield.

The benzyloxycarbonyl derivative **5b** (0.2 mmol) was also reacted with 10 mol% of catalyst **A** and after 50 h at room temperature the separation of the starting material **5b** by chromatography led to the isolation of 50% of **7b**.

To the best of our knowledge, the above results show the first use of ruthenium-based RCM catalysts for access to α-CF_3 containing heterocycles (the six- and five-membered cyclic α-CF_3 substituted α-amino acid derivatives). Based on known transformations of amino acid derivatives this direct access should open a route to a variety of fluorine-containing substrates.

The authors thank the E.U. INTAS Programme No. 96-1176 for financial support.

New sulfide-bridged heterocubanes $[M^{VI}(S)Re^{I}_3(CO)_9(\mu_3\text{-}S)_4]^-$, M = Mo or W, with transition metals in very different oxidation states

Fridmann M. Hornung, Karl Wilhelm Klinkhammer and Wolfgang Kaim*†

Institut für Anorganische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70550 Stuttgart, Germany

The cluster anions $[M^{VI}(S)Re^{I}_3(CO)_9(\mu_3\text{-}S)_4]^-$, M = Mo or W, contain three six-coordinate tricarbonylrhenium(I) fragments, held together by one μ_3-sulfide ion and by one reducible and charge transfer-active μ_3-$M^{VI}S_4^{2-}$ unit.

The coordinative versatility of the tetrathiometallates has given rise to a vast number of oligonuclear cluster compounds with intact or altered MS_4^{n-} units (*e.g.* M = Mo or W, *n* = 2; M = Re, *n* = 1) as essential constituents.[1–4] However, there are not many kinds of heterocubanes containing the MS_4^{n-} motif except for species $[MS(M'L)_3(\mu_3\text{-}S)_4]^{n-}$ with four-coordinate centres M′ = Cu^I or Ag^I and L = PR_3 or halogen.[4,5] Heterocubanes with the $MM'_3(\mu_3\text{-}S)_4$ core are generally of interest because of their relevance as models for cluster sites in proteins or on surfaces of industrial catalysts.[6–8]

Herein we present first examples of organometallic heterocubanes with a tetrathiometallate (Mo or W) corner and three six-coordinate low-valent metal centres, *i.e.* rhenium(I) stabilized by three facially arranged carbonyl ligands. The compounds $[M(S)Re_3(CO)_9(\mu_3\text{-}S)_4](NEt_4)$, M = Mo **1** or W **2** were obtained from $Re(CO)_5(CF_3SO_3)$,[9] Li_2S and $(NEt_4)_2MoS_4$ or $(NEt_4)_2WS_4$.‡ Both compounds were crystallised and analysed by X-ray diffraction.§ Fig. 1 illustrates the molecular structure of the cluster anion by example of compound **2**.

Compounds **1** and **2** crystallise in isomorphous fashion with channel structures (Fig. 1). The molecular anions show heterocubane arrangements with fairly ideal tetrahedral MoS_4 or WS_4 and approximately octahedral $ReS_3(CO)_3$ entities. The rigidity of the tetrahedral MS_4 core has been demonstrated recently in the species $(CH_3CN)(OC)_3M'(S_2WS_2)M'(CO)_3(NCCH_3)$, M = Mn or Re.[10] The main differences between **1** and **2** concern the M–S bond lengths in an otherwise qualitatively similar C_{3v} symmetric setting (Fig. 1). Apart from the distortion brought upon the heterocubane by the close to tetrahedral μ_3-MS_4 units (*ca.* 109° angles for S–M–S) there are slightly widened angles of about 95° for Re–S–Re and (μ_3-S1–S3)–Re–(μ_3-S1–S3) but generally compressed bond angles M–S–Re and (μ-S1–S3)–Re–S5 (Fig. 1). All Re···Re distances lie above 3.74 Å whereas the M···Re distances are significantly smaller between 2.93 and 2.97 Å.

The combination between three $(OC)_3Re^+$ groups and a tetrathiometallate(VI) acceptor[2,10–12] function causes a narrowing of the frontier orbital gap as evident from electrochemistry and absorption spectroscopy (Fig. 2). Whereas even the first oxidation occurs irreversibly at +0.48 V (**1**) and +0.45 V (**2**) *vs.* ferrocenium–ferrocene in acetonitrile–0.1 mol dm^{-3} Bu_4NPF_6, cyclic voltammetry at 200 mV s^{-1} revealed reversible first one-electron reduction processes at −1.24 V (**1**) and −1.61 V (**2**). The corresponding values for $(NEt_4)_2MS_4$ at −2.94 V (M = Mo) and −3.16 V (M = W)[10–12] illustrate the effect of tetrathiometallate coordination by $\{(\mu_3\text{-}S)[Re(CO)_3]_3\}^+$.¶ Accordingly, the long-wavelength ligand-to-metal charge transfer $(LMCT_1)^2$ absorption bands ($t_1 \rightarrow 2e$) at 562 nm (**1**, Fig. 2) and 458 nm (**2**) in acetonitrile are lower in energy when compared to the 472 nm for $(NEt_4)_2MoS_4$ and 397 nm for $(NEt_4)WS_4$. Similar shifts were observed for the $LMCT_2$ transitions ($3t_2 \rightarrow 2e$) at 331 nm (**1**, Fig. 2) and 310 nm (**2**). Additional long-wavelength absorption bands at 408 nm (**1**,

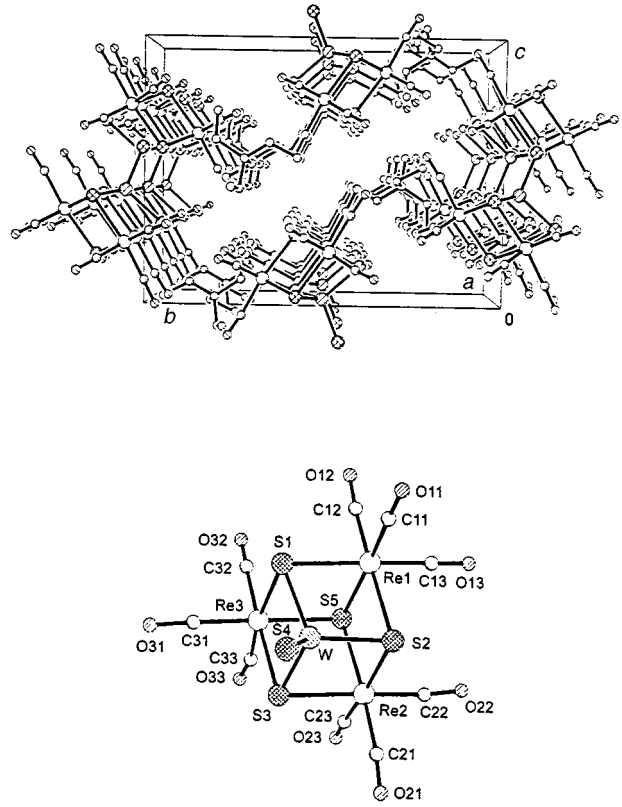

Fig. 1 Crystal structure (top, view along *a* axis) of **2** and molecular structure of the cluster anion. Selected bond lengths (Å) and angles (°) for isomorphous **1** and **2** (in parentheses): M–S4 2.131(8) [2.110(5)], M–(μ_3-S) 2.262(7)–2.285(7) [2.258(5)–2.263(4)], Re–(μ_3-S) 2.502(7)–2.515(7) [2.502(5)–2.522(5)]; S4–M–(μ_3-S) 107.4(3)–110.3(3) [107.3(2)–110.1(2)]. ‡ *Synthesis (general procedure)*: 1 equivalent of lithium sulfide and 3 molar equivalents of $Re(CO)_5(CF_3SO_3)$[9] were reacted under argon in dichloromethane–THF (5 : 1) for 6 h at room temperature. After filtration and removal of the solvent from the filtrate the remaining residue were redissolved in CH_2Cl_2 and treated with 1 equivalent of $(NEt_4)_2MS_4$ (M = Mo or W), dissolved in acetonitrile. After brief reflux the dark-brown solutions were reduced to dryness, the residue redissolved in CH_2Cl_2–CH_3CN (9 : 1) and chromatographed on a silica gel column. The eluted dark brown (**1**) or red fraction (**2**) was collected, the solvent removed under vacuum, and the dark purple (**1**, 10%) or orange–red (**2**, 34%) product crystallised from acetonitrile at −20 °C. Correct C, H, N analyses. ^{13}C NMR ([$^2H_8$]THF): δ = 7.4 (CH_3), 52.8 (NCH_2), 193.0 (CO_{ax}), 197.6 (CO_{eq}). IR (CH_3CN): ν_{CO} = 2049, 2017, 1961, 1926 cm^{-1} (**1**); ν_{CO} = 2050, 2017, 1961, 1926 cm^{-1} (**2**).

§ *Crystallography*: single crystals were obtained from acetonitrile solutions at −25 °C. Crystals were poured into degassed Nujol and transferred into a capillary. This was sealed and immediately brought into the cold gas stream of a Siemens P4 diffractometer (graphite monochromator, Mo-Kα radiation (λ = 0.71 073 Å)) equipped with low temperature device (183 K). Unit cell dimensions were derived from the least-squares fit of the angular settings of 25 reflections. Crystal and refinement data for **1** (**2**): $C_{17}H_{20}MoNO_9Re_3S_5$ ($C_{17}H_{20}NO_9Re_3S_5W$), M = 1197.18 (1285.09), crystal size 0.30 × 0.25 × 0.25 (0.30 × 0.30 × 0.20) mm, monoclinic, space group $P2_1/n$ (no. 14), a = 11.595(4) [11.593(3)], b = 18.226(5) [18.188(3)], c = 13.527(4) [13.460(3)] Å, β = 95.80(2) [95.89(2)]°, U = 2844.1(14) [2823.1(11)] $Å^3$, D_c = 2.796 (3.024) g cm^{-3}, μ(Mo-Kα) = 13.569 (17.297) mm^{-1}, F(000) = 2192 (2320), ω scans, 5836 (8269) measured reflections, 5569 (6814) independent reflections, $wR2$ = 0.194 (0.164) for 5323 (6437) reflections with $I > -\sigma(I)$, $R1$ = 0.090 (0.068) for reflections with $I > 2\sigma(I)$. Due to the failure of finding appropriate reflection for ψ scans, the data were corrected in both cases using the DIFABS program. The structures were solved using direct methods (SHELXS 86). Site and displacement parameters were refined by full-matrix least-squares techniques (SHELXL 93) based on F_o^2 values. All non-hydrogen atoms were treated anisotropically. The hydrogen atoms were treated isotropically, their sites riding on the appropriate carbon atom with fixed C–H lengths and H–C–H angles. CCDC 182/969.

¶ A second reversible reduction occurs at −1.86 V (**1**) and −1.82 V (**2**), respectively. Attempts to characterise the one-electron reduced forms by EPR were unsuccessful even at 3.5 K, probably due to rapid relaxation. Anodic peak potentials for the second irreversible oxidation are at +0.66 V (**1**) and +0.74 V (**2**), respectively.

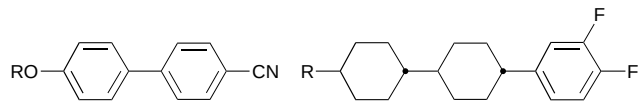
The term liquid crystal is often associated with fascinating compounds that exhibit unusual melting or solubilisation properties, however, it also represents a unique collection of mesophases that exist between the solid state and the amorphous liquid. As such, this unique state of matter can be accessed by a wide variety of materials from low molar mass to polymeric systems. In this Feature Article we describe some recent studies concerning the liquid-crystalline behaviour of 'in-between' materials that have discrete molecular structures, and which are oligomeric but not low molar mass or polymeric systems. Thus, these materials could be described as having supermolecular architectures. We examine some of their mesophase properties and their abilities to form supramolecular assemblies. The development of liquid crystals that have large molecular structures or consist of large scale assemblies is one step towards creating novel self-organising systems which are of a similar dimension to certain biological materials, such as proteins.

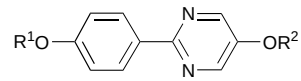
Introduction

Over the past two and a half decades low molar mass liquid crystals (LMMLCs) have been the quintessential molecular electronic materials. The invention of the twisted nematic display (TNLCD) in the early 1970s coupled with Gray and Harrison's development of stable room temperature nematogens based on cyanobiphenyls, **1**, ensured that liquid crystals would be synonymous, across the world, with flat-panel, low voltage visual display units (VDUs).[1] This association has continued with the invention and development of surface stabilised ferroelectric smectic C* displays (SSFLCDs)[2,3] which are near to commercialisation, and the recent extension of this work to device configurations utilising antiferroelectric materials.[4] All devices based on liquid crystal technology are, of course, non-emissive and depend on the reflection of incident light or an artificial light source for viewing. As a consequence, however, materials designed for, and utilised in, LCDs are not usually subject to optical damage. In addition, in-plane switching devices such as SSFLCDs, AFLCDs and bistable nematic displays possess wide viewing angles making them ideal candidates for exploitation in large area, high pixel density devices.

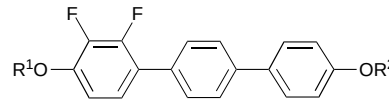
Ever more so, therefore, has the development of materials for use in display devices become a challenge of 'precision' molecular engineering.[1,5] Materials, thus, need to be designed to be chemically and optically stable, possess wide temperature ranges for their liquid crystal phases, have low melting points, low viscosities, suitable birefringences, desirable dielectric properties, low conductivities—in fact the demands on the quality and properties of organic liquid crystals approach those placed on conventional inorganic and semi-conductor materials used in the electronics industry. As a consequence, the design of nematogens is now focused on creating materials based on fluorinated systems because they have low conductivities and viscosities, and suitable positioning of fluoro-substituents allows them to have appropriate dielectric anisotropies for applications,[1,5] see **2**. Similarly, the development of ferroelectric materials is centred on the creation of materials with low viscosities, wide mesophase temperature ranges and low melting points.[6] The design of fast switching low viscosity materials has therefore become akin to the utilisation of aerodynamics in the design of fast sports cars, *i.e.* narrow, stiff, rod-like molecules being the most suitable, *cf.* the phenyl



1 **2**



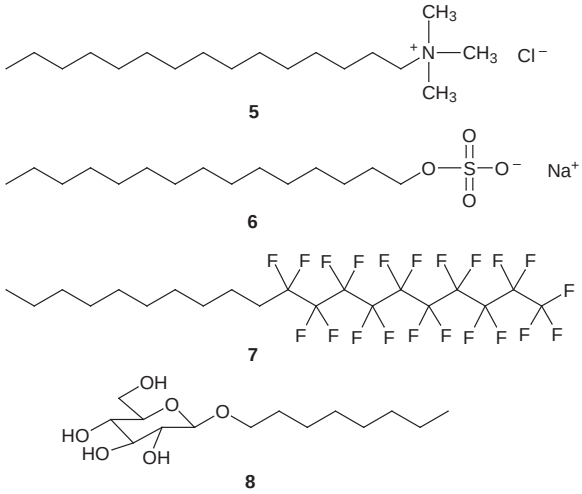
3



4

pyrimidines **3** and the difluoroterphenyls **4**.[7] Although high technology applications of liquid crystals tend to catch the eye, it should be noted that by far and away the highest consumption of liquid crystals is by the soap and detergents industry,[8] followed by that of companies involved in the production of structural polymers (PLCs), for example, poly(*p*-phenylene terephthalamide) is used commercially as the basis for spinning fibres such as Kevlar® (Du Pont) and Twaron® (Akzo).[9] Cationic, anionic, and non-ionic surfactants (*e.g.* **5**–**7**) have been shown to be capable of exhibiting either thermotropic[10] or lyotropic mesophases,[11] and in some cases materials have been shown to exhibit both forms of mesophase, thereby making them amphotropic. Glyco- and phospho-lipids, akin to those found in cell membranes, provide numerous examples of compounds that self-assemble to form lyotropic liquid crystals and self-organise to form thermotropic phases. Octyl 1-*O*-β-D-glucopyranoside, **8**, which is a commercially available non-ionic detergent (Sigma) exhibits a smectic A* phase upon heating, and lamellar, cubic and hexagonal lyotropic phases on progressive addition of water,[12] for example see Fig. 1.

Liquid crystals thus have many wide and varied applications apart from high profile uses in displays. However, because there is such a short amount of time between discovery/innovation



and application in this field there is an impression that liquid crystals are primarily of technological importance. Conversely, the prevalence of many applications of liquid crystals is mainly due to the fact that liquid crystals offer a unique and delicate collection of phases of matter that are precariously balanced between the organised solid state and the amorphous liquid, and which can be accessed by all types of materials, and not just organic compounds. Thus, inorganic, ionic, metal–organic complexed, organic complexed, zwitterionic, elastomeric, dendrimeric, and oligomeric systems, to name a few, have been shown to exhibit mesomorphism.[13]

However, given that much of the research into liquid crystals has been concerned with their potential applications, there still remain two large windows of opportunity for innovation and design of novel materials. Firstly, the gap between conventional low molar mass systems and polymers is relatively unexplored. Little has been reported on large, but discrete, molecular systems, *i.e.* from dimers to trimers to oligomers and dendrimers. When the molecular structures of such systems are well defined, then the materials can be classed as supermolecular entities with clearly defined and unique physical properties. Secondly, the self-assembly of materials to form clusters, aggregates, and complexes *etc*., and then their self-organisation to give mesophases has scarcely been investigated.[14] Both super- and supra-molecular systems are scientifically intriguing and challenging because they involve the rational design and development of large scale structures leading on towards molecular materials of similar dimensions to those of complex systems found in nature, *e.g.* proteins, enzymes, *etc*.

Molecular shape dependency

A primary factor in the formation of liquid crystal phases is the overall, or gross, molecular shape of a compound.[15] Three separate species can be defined where the molecules have the following rotational volumes; spheroid, ellipsoid and discoid. Spheroid mesomorphic materials generally give rise to plastic crystals, ellipsoid or rod-like molecules give rise to calamitic liquid crystals, which include nematic and smectic liquid crystals, and discoid molecules produce nematic–discotic and columnar liquid crystals. Molecules with combinations of these shapes can also be mesomorphic. For instance molecules that possess both disc- and rod-like attributes can exhibit nematic, smectic and columnar phases. Such materials often have polycatenar structures, *i.e.* they possess more than two terminal aliphatic chains (usually four, five or six). Depending on the relative proportion of aliphatic to non-aliphatic regions in the molecular structure, tetracatenar materials can exhibit both

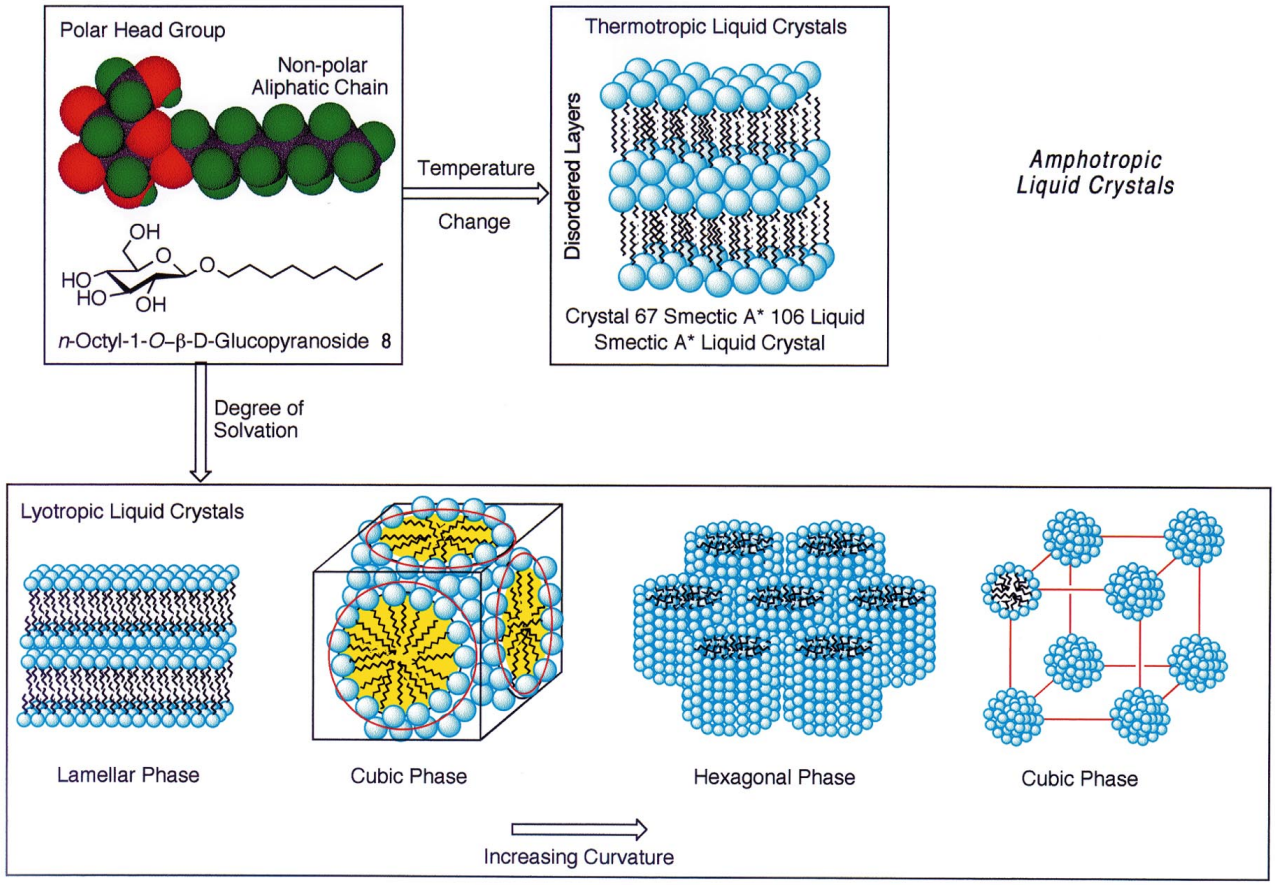


Fig. 1 The phase behaviour of octyl 1-*O*-β-D-glucopyranoside, **8**, when heated to give a thermotropic smectic A* phase, and on addition of water to give lyotropic lamellar, cubic and hexagonal phases. Compound **8** is therefore amphotropic.

smectic/nematic and columnar phases, whereas hexacatenar materials tend to exhibit columnar phases.[16] Similarly molecular structures that combine the features of both discs and spheres can have bowl-like shapes and can produce bowlic or pyramidal mesophases. In most cases, the lowest energy static molecular shape defines mesophase type/formation, however, dynamical variations in molecular structure, such as conformational and geometrical changes, can also impinge on mesomorphic behaviour, particularly if the changes occur as a function of temperature or concentration of solvent.

When a large number of mesogenic units, be they spheroid, ellipsoid or discoid in shape, are linked together they form polymeric liquid crystals. Polymer systems, however, usually have associated problems of dispersity (γ) and degree of polymerization (DP) which impinge on their physical properties. A material that possesses more than one mesogenic unit but with a defined DP and a dispersity of one, *i.e.* a discrete molecular system, could be considered as a supermolecular system. The simplest architectural form of a supermolecular liquid crystal then is a dimer. Dimers may have a number of structural variants, for example the mesogenic units may be joined end to end, side to side, or they may be joined together as Siamese twins.[17] Luckhurst and Imrie,[18] in particular, have made many detailed investigations of dimeric systems, but principally of those where the mesogenic units are linked end to end. Trimers on the other hand can have their mesogenic units joined together in a linear chain, or they may be tethered to a central point, or they may be part of a cyclic system. From these simple examples it can be seen for a system which has available a defined number of structural moieties/units to be used in molecular construction, that a limited variety of molecular topologies are possible, see Fig. 2. However, once a supermolecular architecture has been defined, conformational, geometrical, and configurational factors have to be taken into account in the way a mesophase is formed and stabilised. In this Feature Article, the mesomorphic behaviour for systems that possess restricted molecular topologies and limited molecular flexibilities will be discussed; the first examples involve supermolecular mesogens where the mesogenic units are linked to a central focal point thereby limiting the molecular geometry and conformational structure.

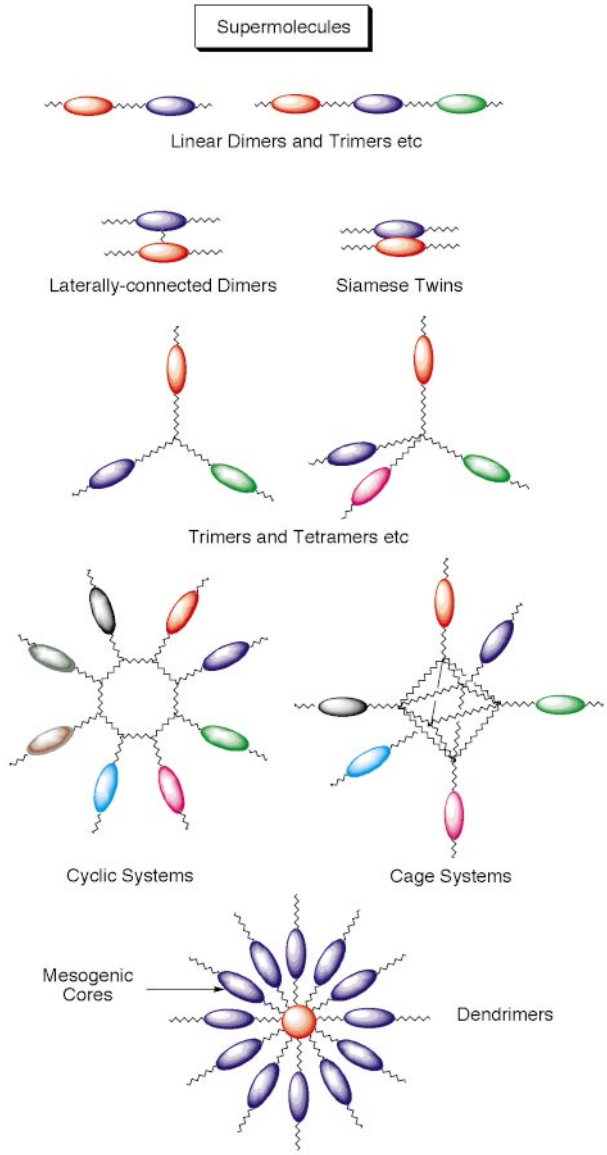

Fig. 2 Various molecular scaffolds for the design of large discrete supermolecules

Materials with defined molecular topologies

The possibility of creating liquid crystals that have large discrete molecular structures with defined molecular topologies is an intriguing prospect because the materials might be expected to exhibit unusual physical properties. For example, on paper an oligomeric material possessing mesogens tethered to a central point could be designed to have a spherical shape with its mesogenic units spread symmetrically about that point. However, if such a material were constrained in a liquid crystal environment, molecular distortion would be expected to occur in order to allow the mesogenic units to pack together.

Examples of simple model tetrahedral systems with cubic symmetry were created by reacting tetrakis(dimethylsiloxy)silane with a variety of alkenyloxy-cyanobiphenyls,[19] thereby generating a set of tetrahedrally substituted mesogenic supermolecules, *e.g.* **9a**–**c**, where four mesogenic units are tethered to a central point. Although such a molecular shape would be expected to disfavour mesophase formation, Table 1 shows that the tetramers exhibit smectic A liquid crystal phases. It is also interesting to note that smectic A phases are preferred over the nematic phase exhibited by the mesogenic monomers themselves. In this sense, these supermolecules are similar in

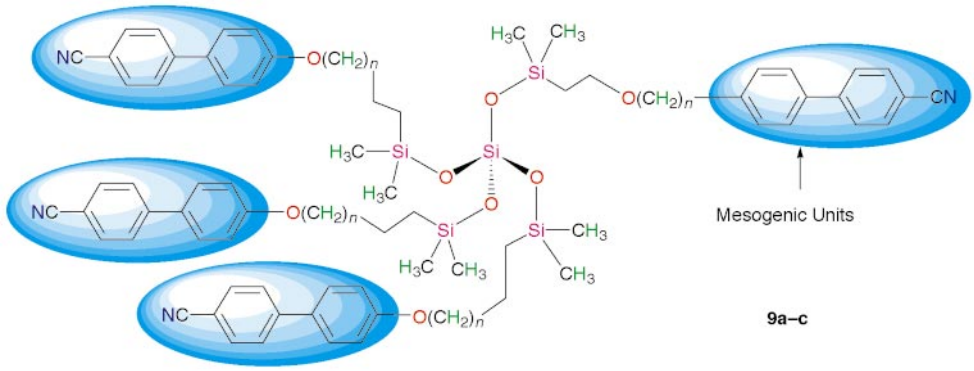

Table 1 Transition temperatures (°C) for the tetramers of structure **9a–c**

Compound	*n*	tg	SmX–SmA	SmA–Iso Liq
9a	2	−9.6	—	88.7
9b	4	−14.7	—	118.7
9c	9	−6.3	38.7	129.7
Cyclic	6	57	—	118.0

mesophase behaviour to conventional side-chain liquid crystal polysiloxanes which have cyanobiphenyl moieties as the mesogenic side group.

In general the smectic A phase has a structure where rod-like molecules pack in diffuse layers where there is no positional ordering of the molecules in the plane and out of the plane of the layers.[15] The only way in which the tetramers can form such a phase is by molecular distortion away from a spherical shape

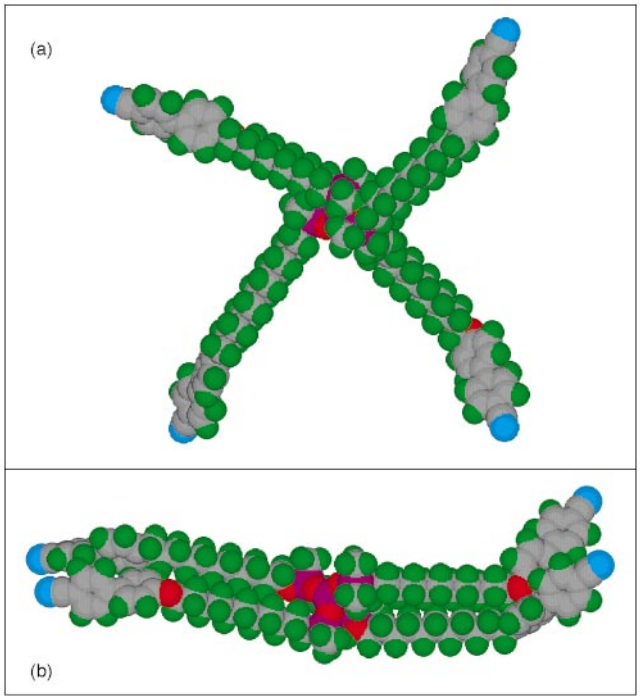

Fig. 3 The molecular shape of tetramer **9c**, (a) shows the shape of the molecule where the four arms were symmetrically positioned about the core; (b) shows the minimised structure in the gas phase at absolute zero using a Silicon Graphics system operating with Quanta and CHARMm software

[see Fig. 3(a)] to give a rod-like conformational structuring. Molecular modelling studies reveal that, even in the gas phase at absolute zero, the conformation where the mesogenic side-chains are aligned is the more energetically favoured conformation [Fig. 3(b)], thereby allowing the supermolecules to achieve rod-like molecular shapes.

Materials **9a** and **9b** exhibit only a smectic A phase, whereas **9c** shows, upon heating, a transition to an additional unidentified phase at 38.7 °C. When the number of methylene units is increased, the isotropization temperatures increase accordingly. Furthermore, the isotropization temperatures of the materials were found to be comparable with those of cyclic siloxanes bearing four side-chains of a similar structure.[20] However, the solidification temperatures of the tetrahedrally substituted systems were found to be much lower. For example, the cyclic analogue of compound **9b** exhibits a glass transition or recrystallisation well above room temperature (*ca.* 50–60 °C), whereas the tetrahedrally substituted equivalent material produces a non-crystalline material that has a low solidification temperature (−14.7 °C). Thus the symmetrically substituted systems show low melting behaviour and primarily glass formation on cooling. This effectively widens the relative temperature ranges of the liquid crystal mesophases.

X-Ray diffraction shows that the trichotomous nature of the tetramers allows for different packing characteristics to exist for the molecules in the smectic A phase. Thus, the separate interactions of the mesogenic units, the alkyl spacers and the silicon cores have to be considered in the formation of the A phase. For the shorter methylene spacer lengths, **9a** and **b**, internal phase separation leads to the smectic A phase being described as a smectic A_d phase with respect to the mesogens and a monolayer smectic A_1 phase with respect to the silicon cores, see Fig. 4. In the smectic A_d phase the mesogenic units are partially interdigitated giving a layer spacing d, where $l < d < 2l$, and l is the molecular length. The smectic A_1 phase is a disordered layered phase where the layer spacing is approximately equal to the molecular length. For the longer methylene spacer lengths, **9c**, the co-existence of smectic A_d and smectic A_2 phases is probable (the smectic A_2 phase is a bilayer system where the layer periodicity is twice the molecular length). The occurrence of these structures can be explained by the presence of biphasic or incommensurate smectic A phases, or even a smectic A anti-phase.

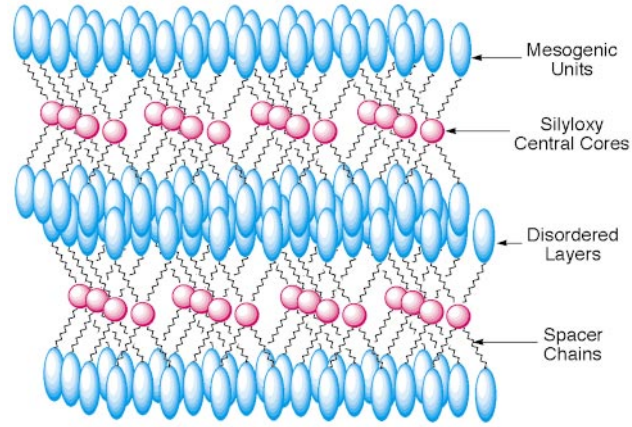

Fig. 4 The structure of the interdigitated smectic A_d phase of tetramers **9a** and **b**. The mesogenic units form an interdigitated bilayer, whereas the silyloxy cores have a monolayer arrangement.

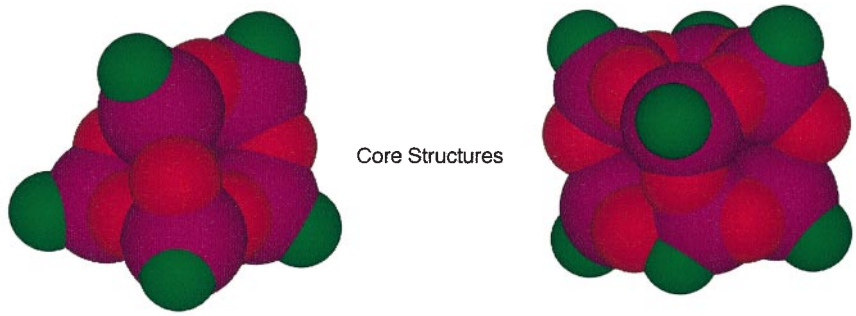
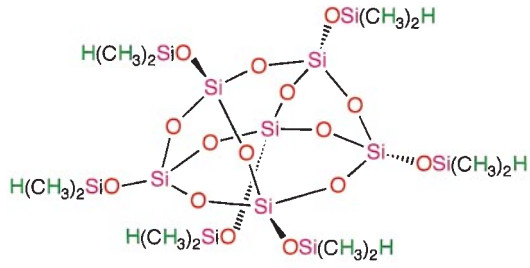
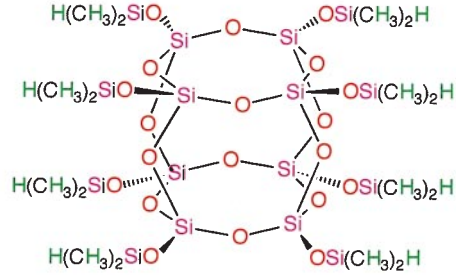
For the tetramers there is adequate free volume for the cyanobiphenyl 'mesogenic arms' to rotate so as to give a distorted rod-like molecular shape. Increasing the number of mesogenic units attached to the central point, however, has the effect of reducing the free volume for the packing of the mesogenic groups, which in turn reduces their freedom of movement and suppresses the ability of the supermolecular system to generate a rod-like conformational form. Increasing the number of mesogens attached to a central point is difficult to achieve without moving in the direction of dendrimer formation, but the substitution of polyhedral core units with mesogenic groups can provide an alternative route to packing a larger number of mesogenic units about a central focal point. The use of various polyhedral siloxane-substituted systems as the central cores of the supermolecular systems allows for meaningful comparisons to be made as the free volume available to the mesogens is reduced as the degree of substitution about the polyhedral core is increased.[21]

The hexakis(dimethylsiloxy)silsesquioxane, **10**, and octasilsesquioxane, **11**, core systems are caged polyhedral units, where silicon atoms are situated at the corners of the cage and oxygen atoms in between. The hexakis-core can be substituted with up to six mesogenic units, whereas the octasilsesquioxane core can be substituted with up to eight mesogenic groups. Comparative materials with similar mesogenic cyanobiphenyl side chains have been prepared. In both cases the cores are not much different in size to the tetrakis(dimethylsiloxy)silane core discussed in the synthesis of the tetramers, optical microscopy shows that, on cooling from the amorphous liquid, smectic A





10



11

liquid crystal phases are formed for the hexakis(dimethylsiloxy)silsesquioxane and octasilsesquioxane systems. Table 2 shows that for the octasilsesquioxane based systems, compounds **12a**–**c**, the clearing temperatures are in a similar temperature regime to those found for the tetrahedrally substituted materials **9a**–**c**. However, the rise in the clearing temperatures, with increasing spacer length, was less steep.[22]

Table 2 Transition temperatures (°C) for the octamers **12a**–**c** based on the octasilsesquioxane core unit

Compound	*n*	tg	Cryst–Sm3	Sm2–Sm3	Sm3–SmA	Sm1–SmA	SmA–Iso Liq
12a	4	11.0	—	—	—	—	93.9
12b	6	3.0	—	—	—	22.5	116.5
12c	11	−7.5	34.4	54.6	64.5	—	128.5

As with the tetramers, the mesogenic arms of the octasilsesquioxane based materials again rotate so that they lie parallel to one another. This creates a rod-like structure where the supermolecules can pack together in layers to form a smectic A phase. Molecular simulations in the gas phase at absolute zero serve to reinforce this point of view. Fig. 5 shows the minimised structure of the cyanobiphenyl substituted octasilsesquioxane

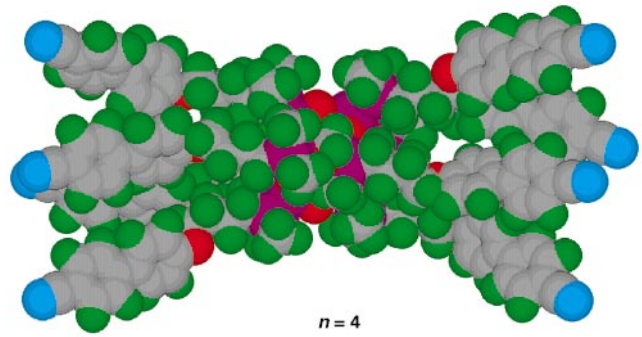


Fig. 5 The minimised structure of the octamer **12a** in the gas phase at absolute zero using a Silicon Graphics system operating with Quanta and CHARMm software

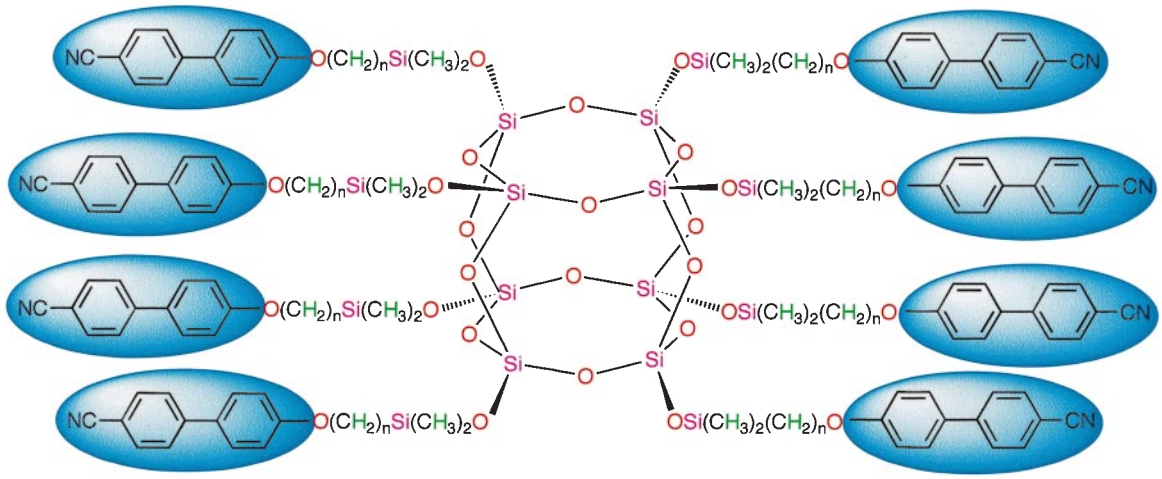
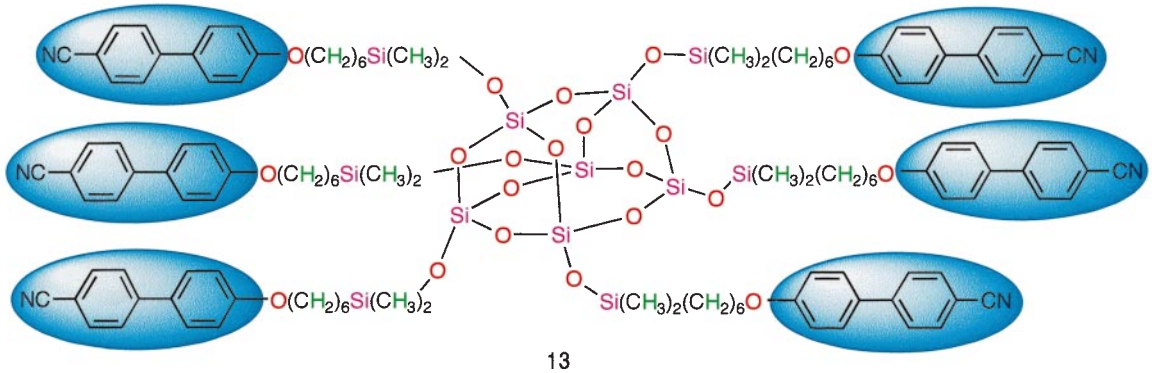


12a-c



13

with a tetramethylene spacer unit. In this structure the cyanobiphenyl 'mesogenic arms' pack together in a parallel arrangement thereby producing a supermolecular system that has a rod-like gross shape which is conducive to the formation of smectic A phases.

Similar results are obtained for systems based on the hexakis(dimethylsiloxy)silsesquioxane core system, **13**. Again smectic A phases are formed indicating that the molecules must adopt a rod-like structure. Mehl and Saez[21] have reported several other variants of liquid crystals based on polyhedral core units, and where cyanobiphenyl moieties were used as the source of mesogenic units smectic A phases were found. Kreuzer *et al*.[23] have reported that silsesquioxane cores with six, eight and ten mesogenic units, with structures based on that of cholesterol, still appear to exhibit smectic A phases, thus demonstrating the power of the mesogenic environment to inflict conformational changes on the supermolecules so as to distort their shapes from being spherical to being tactoidal, and preventing the formation of nematic, or in the last example from Kreuzer *et al*.[23] chiral nematic phases.

Substitution of the silsesquioxane cores with mesogenic groups that are more conducive to smectic mesophase formation, as with the other systems described above, yields supermolecular materials that as expected exhibit smectic phases. However, for the many cases studied, the formation of smectic phases and mesophase temperature ranges are considerably enhanced. For example the use of the 4′-(2-methylbutylbenzoyloxy)biphenyl-4-carboxylate mesogenic unit, which favours the formation of orthogonal smectic A and tilted smectic C, I and F phases, results in the preference for tilted smectic C phases, see compounds **14** and **15**. For compound **14** the smectic C phase is present from 11.5 to 191.5 °C, *i.e.* a temperature range of over 180 °C, whereas it is only present over a temperature range of 22–23 °C for the mesogenic monomer unit. The coupling of the potential stability of the smectic C phase with chirality built into the mesogenic units allows for the possibility of synthesising supermolecular ferroelectric materials which may have interesting non-linear physical properties, *e.g.* antiferroelectric, pyroelectric and piezoelectric properties.

Table 3 shows a comparison of the mesomorphic behaviour for a variety of materials that combine the 4′-(2-methylbutylbenzoyloxy)biphenyl-4-carboxylate mesogenic unit with siloxy moieties based on the tetramer, octasilsesquioxane, cyclic siloxane and polysiloxane systems. It can be seen from the table that in all cases for the supermolecules and the side chain polymer, considerable stabilisation of the liquid crystal properties, and in particular the tilted smectic C phase, is found. However, although the polymer version exhibits similar phase behaviour to the supermolecular systems, its viscosity is very much higher. Conversely, the viscosities of the supermolecular materials are similar to low molar mass liquid crystals.

Further increase in the number of mesogenic units positioned around a central core unit can be achieved only *via* the synthesis of dendrimers. Examples of liquid crystalline dendrimers, however, are surprisingly scarce. The first thermochromic liquid crystalline dendrimer was reported by Percec and Kawasumi for a hyperbranched polyether structure that consists of an AB_2 monomer.[24] Recently, however, the groups of Shivaev and Frey reported simultaneously the synthesis of liquid crystalline carbosilane dendrimers,[25,26] which are similar in structure to the silsesquioxane liquid crystals described above. Some of the reported dendrimers combine a flexible, dendritic carbosilane inner core with an outer region that is functionalised on the surface with cyanobiphenyl mesogenic groups, see Fig. 6. As discussed previously this structural concept appears to be at odds with the formation of liquid crystal phases at first sight, because the rod-like mesogenic units are attached to a molecular scaffolding of globular geometry. Thus, it might be expected that the densely packed mesogenic groups in the outer shell of the dendrimer would ensure a spherical disposition of the supermolecule. However, the dendrimers formed exhibit smectic A phases which again requires that the giant molecules must have conformational rod-like shapes which pack in disordered layers. This suggests that the shapes of the dendritic molecules must be deformed by being in a liquid crystal environment. The possibility of being able to control molecular deformation could lead towards novel applications.

Supermolecules with reduced molecular flexibility

So far the materials discussed have had structures where there is reduced flexibility caused by the tethering of the mesogens to a central point and filling the space about this point with mesogenic groups. Internal flexibility, however, can also be reduced by increasing the number of bridging chains between the mesogenic units; which have so far been limited to one in the above discussion. Fig. 7 for example shows the architectural situation for dimers. When one flexible chain links two mesogenic units together, the odd or even parity of the chain can affect the orientation of the mesogenic units relative to one

another. For an odd number of methylene units the mesogenic groups will lie at an angle to one another, whereas for an even number of methylene units they will be in line with one another. Thus, the transition temperatures for the even members will be much higher than those of the odd because the even members will have approximately a linear shape rather than a bent one.[18] This effect on molecular shape is particularly important for shorter spacer lengths where the flexibility of the spacer chain is less and the dependency of liquid crystal properties on shape is more pronounced. For dimers where two bridging chains are used to link the mesogenic groups together the degree of flexibility around the centre of the supermolecular structure is further reduced. For instance, if carbocyclic ring systems are introduced between the mesogenic groups, as shown in the middle part of Fig. 7, they will be able to bend in and out of the page, but not so easily in the plane of the page. Carbocyclic rings that are appropriately substituted with mesogenic groups are difficult to synthesise, however, for the purposes of producing model systems it is easier to prepare liquid crystals where two mesogenic groups are attached to a macrocyclic aza-crown ether ring as shown in Fig. 7. Tuffin has taken this approach forward in such a way that she has been able to replicate all forms of liquid crystal behaviour in materials that possess a macrocyclic ring.[27]

When a macrocyclic ring is inserted between two mesogenic units, then the liquid crystal groups do not need necessarily to be symmetrically positioned on the ring, and they can be located asymmetrically. This allows control of molecular shape so that bent or linear systems can be produced. Materials with bent structures will of course exhibit different mesophase properties to those of linear systems.[28] For example compounds **16** and **17** have identical mesogenic groups, but linear compound **16** exhibits a nematic phase, whereas **17** has an additional smectic C phase, and interestingly, because **17** is bent ferroelectric or antiferroelectric properties become a possibility.

Not only can the position of the substituents be varied on the central ring, but so too can the flexibilty of the aza-crown ring. For instance, by increasing the size of the aza-crown ring the degree of flexibility can increased, and as a consequence the mesogenic units become increasingly decoupled from one another.[29] Table 4 clearly demonstrates the effect of increasing the size of the macrocyclic ring. For small ring sizes, nematic phases predominate because the macrocyclic ring acts as part of the rigid central core of the mesogen. As the material 'thinks' it is a 'seven ring' mesogen, high transition temperatures are obtained. When the ring is increased in size the aromatic mesogenic groups start to become decoupled, and smectic phases are introduced. As the ring size is increased further to the extent that the macrocyclic ring can flex and bend more easily, and the mesogenic groups become further decoupled from one another, the smectic phases become destabilised. At this point the motions and orientations of the mesogenic units are relatively independent of one another and the material 'thinks' it is now a quasi-dimer. The flexibility was increased further by substituting oxygen for sulfur in the macrocyclic ring unit, and slightly lower clearing points were obtained and further destabilisation of the smectic state occurred. NMR studies in dilute solution as a function of temperature confirm that the macrocyclic moiety can bend and flex easily about its middle. At low temperatures the molecules were shown to have linear rod-like structures, however when the temperature was raised the population of molecules with hair-pin shaped conformational structures grew.[27] Preliminary X-ray diffraction experiments on the neat mesophases exhibited by a selection of the

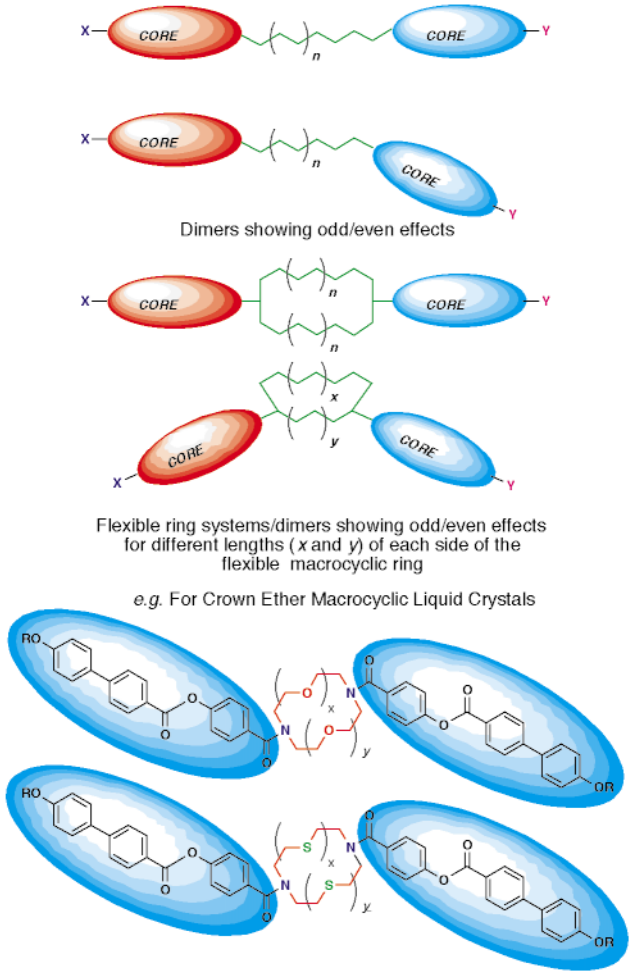

Fig. 7 Schematic representation of mesogenic dimers containing either identical or different mesogenic groups. The linking units between the mesogenic moieties can be either single methylene chains or macrocyclic units. The macrocyclic ring can be an aza-crown *etc*., and the mesogenic groups need not be positioned symmetrically on the ring, *i.e.* $x \neq y$.

materials confirm the presence of a number of sub-phases which have structures based on either linear or bent molecular conformations. Bilayer phases based on molecules that have bent conformational structures, and monolayer phases where the molecules have fully extended rod-like structures were observed, see Fig. 8. In addition, phases where the long axes of the molecules are either orthogonal (SmA_1 and SmA_2) or tilted (SmC_1 and SmC_2) with respect to the layer planes were found, and in the case of bent molecular conformations even 'antiferroelectric-like' phases (SmCalt) were detected.

Supramolecular assemblies of supermolecules

The shapes of the above systems can be varied further by increasing the number and lengths of terminal aliphatic chains attached to the mesogenic aromatic cores. By varying the number and the length of the peripheral aliphatic chains, hair-pin shaped molecular structures can be advantaged over stretched-out conformational structures. Table 5 shows the transition temperatures for a series of compounds based on the tetracatenar macrocyclic liquid crystal structure **18**.[30] It can be seen from the table that as the terminal aliphatic chain length is increased lamellar smectic phases give way to disordered columnar mesophases, and for the hexadecyl homologue, at least, both calamitic and columnar phases are exhibited by the

same material. How then can this be rationalised in terms of molecular shape? One possibility is that clusters of rod-like molecules in their most extended conformations come together, usually in numbers of three, to form disc-like clusters, as postulated for hexacatenar materials.[16] The supramolecular disc-like clusters aggregate and stack in a disordered way to form a columnar architecture. Alternatively, as noted earlier, it is possible that compounds of general structure **18** bend to give hair-pin gross molecular shapes. The bent molecules can

18a–d

effectively assemble together in clusters to give quasi-discs which are the basis for column formation. Thus, in this case we have a supermolecular system, where the conformational structure can change from being linear to being bent in order to support the formation of supramolecular assemblies, which in turn generate a columnar mesophase,[30] as shown in Fig. 9. It is not necessary that the molecules cluster to form flat discs, and in fact the molecules probably remain disordered along the column axes. In this arrangement of the molecules there will be 'pores' running down the column axes, thereby indicating the possibility that such systems might act as ion channels. This arrangement is not too dissimilar to the one proposed previously by Percec *et al*. for synthetic mimics of tobacco mosaic virus.[31]

At the centre of each supermolecular mesogen, of course, is a cavity associated with the aza-crown macrocyclic unit. This cavity is capable of accepting a guest ion, and such resulting guest–host systems have remarkably different phase behaviour to the host system. The guests tested included various metal ions associated with a number of different counter ions.[27] From these studies it is possible to compare the effects produced on sequentially changing the metal ions, *e.g.* Li^+, Na^+, K^+ *etc*., with respect to a common counter ion, such as triflate. Similarly it is also possible to maintain the same metal ion but vary the counter ion. Table 6 shows the variation in mesophase types and transition temperatures for 1 : 1 mixtures obtained in doping studies on the tetradecyloxy tetracatenar material **18b**, and Fig. 10 shows a schematic representation of the structure of the self-assembled columnar phase of **18b** when doped with K^+. The results for the transition temperatures show a strong dependency on the metal ion (and although not shown here, the counter ion). The transition temperatures are markedly affected by the addition of guests, and in some cases mesophases were found to be introduced where other phases exist for the pure host material. The full phase diagrams show there is a strong dependency of phase type and transition temperatures on concentration of the dopant, and therefore these systems could be used as qualitative or quantitative sensors for certain dopants.

Table 6 Dependency of the transition temperatures (°C) on the nature of the metal ion in 1 : 1 mixtures of compound **19a** with the listed metal triflates

Packing of V-shaped molecules into disc-shaped aggregates and columns

Fig. 9 Self-assembly of folded macrocyclic materials can lead to the formation of disc-like structures which in turn self-organise to give columns. The molecules are disordered along the column axes.

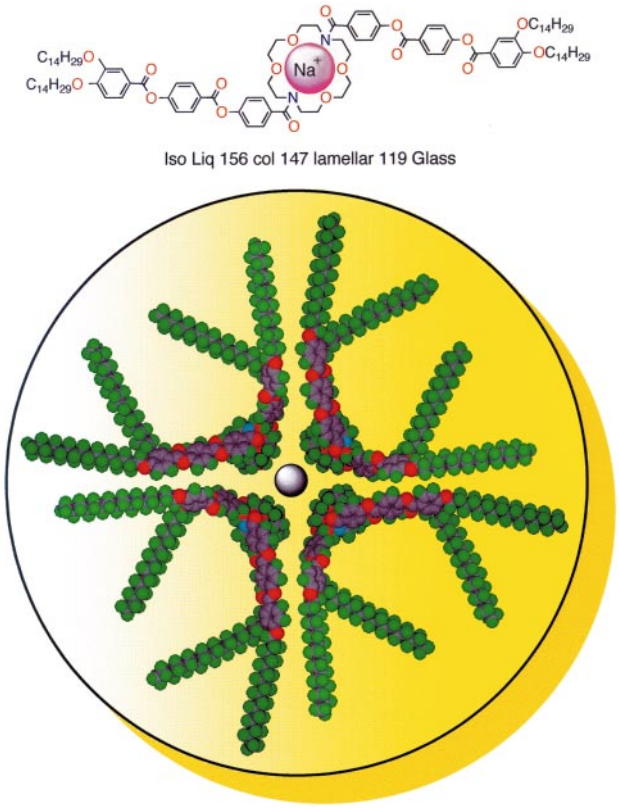

Fig. 10 The self-assembly and self-organisation of folded macrocyclic materials into columns. The inclusion of metal ions stabilises the structure and increases the clearing point of the mesophase.

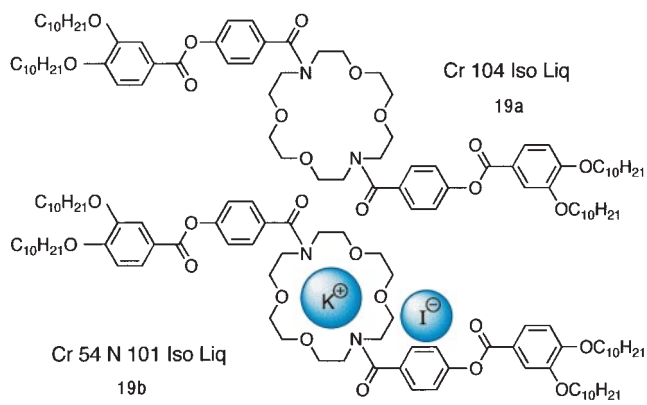
For some macrocyclic systems mesomorphic properties can be injected into guest–host systems where for the host material alone no liquid crystal properties are found. Tetracatenar compound **19a** exhibits no liquid crystal phases because the aromatic groups responsible for inducing mesomorphic properties are too short, however the material will still have latent tendencies to produce liquid crystal phases. Upon the addition of potassium triflate, the resulting guest–host supramolecular system, **19b**, exhibits a nematic phase.[27] One explanation for such remarkable behaviour is that the host tetracatenar material has a folded or globular structure that is not conducive to mesophase formation because the rigid aromatic cores are too short. However, upon inclusion of potassium ions into the cavities of the macrocyclic unit the molecular structure of the host either unfolds to give a combined guest–host assembly which is much longer and narrower than that of host, or else it forms a rod-like hair-pin complex, see Fig. 11. Either way, the guest–host assembly is now much more rod-like in shape and now more capable of supporting mesomorphic phase behaviour. Thus, as with the other systems described above, this potential guest–host assembly could be used as a sensor because the introduction of liquid crystal properties are sensitive to the concentration of the ionic guest species.



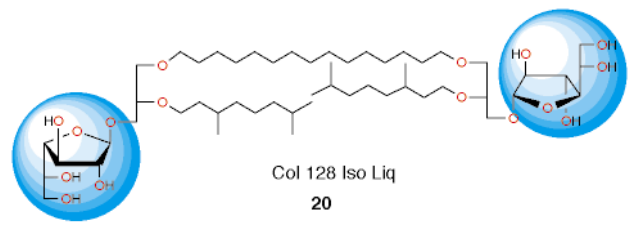
Chiral macrocyclic systems which exhibit chiral nematic phases have also been investigated. The resulting chiral nematic liquid crystals have the property of being able to selectively reflect light of a relatively narrow wave band, *c.f.* non-invasive LC thermometers,[5] and it has been found that when chiral macrocyclic hosts are doped with chiral ionic species, such as amino acids, the wavelength of the reflected light and the degree of circular polarization is dependent on the concentration and spatial configuration of the dopant. Hence the macrocyclic liquid crystal is capable of distinguishing qualitatively and quantitatively between certain types of enantiomers.

Biological systems

Molecular self-assembly and self-organization are becoming increasingly significant in the elucidation of life processes, and to the generation of new supramolecular structures/ensembles and molecular materials.[32–40] As a consequence, the most important inspirations for the conceptual development of such structures and materials are those provided by biological cells, which exemplify the assembly of a variety of microstructures of different sizes and functions. Archaebacteria, with their resistance to extreme conditions, are one class of organisms that have been found to provide a rich source of inspiration. Of particular interest to our studies on molecular topology are lipids derived from thermophilic Archaea. These molecules are characterized by a bipolar architecture with two polar heads linked together by two C_{40} polyisoprenoid chains which are thought to span the membrane, and therefore determine the lipid layer thickness. Although such lipids are classified as bolaphiles, in relation to the glycolipids discussed earlier (and shown in Fig. 1) they are essentially dimers. A unique feature of tetraether-based lipids lies with (i) the high proportion of glycosylated lipids in the membranes of both methanogenous and sulfur depending thermophiles and (ii) the occurrence of unusual carbohydrate moieties, *i.e.* β-D-galactofuranosyl units.[41–43] These structural units may further stabilise the membrane structure through cooperative inter-glycosyl hydrogen bonding, *i.e. via* the formation of supramolecular assemblies.[44,45]

However, in spite of growing attention to archaeal glycolipid structure and function, very few studies have been performed so far to elucidate the relationships between the molecular structure of the glycolipids and the architecture of their supramolecular aggregates. This is in part due to the difficulty of obtaining sufficient amounts of chemically pure compounds from natural sources or by synthetic methods. Some synthetic mimics, however, have been prepared[46] and their self-assembling properties investigated. For instance, compound **20** is a typical representative member of a number of quasi-macrocyclic bolaphiles that have prepared by Auzély-Velty.[47] This material is very similar in structural design to those found in the membranes of archaebacteria and in essence it is an amphotropic dimer.

When the thermal properties of compound **20** were investi-



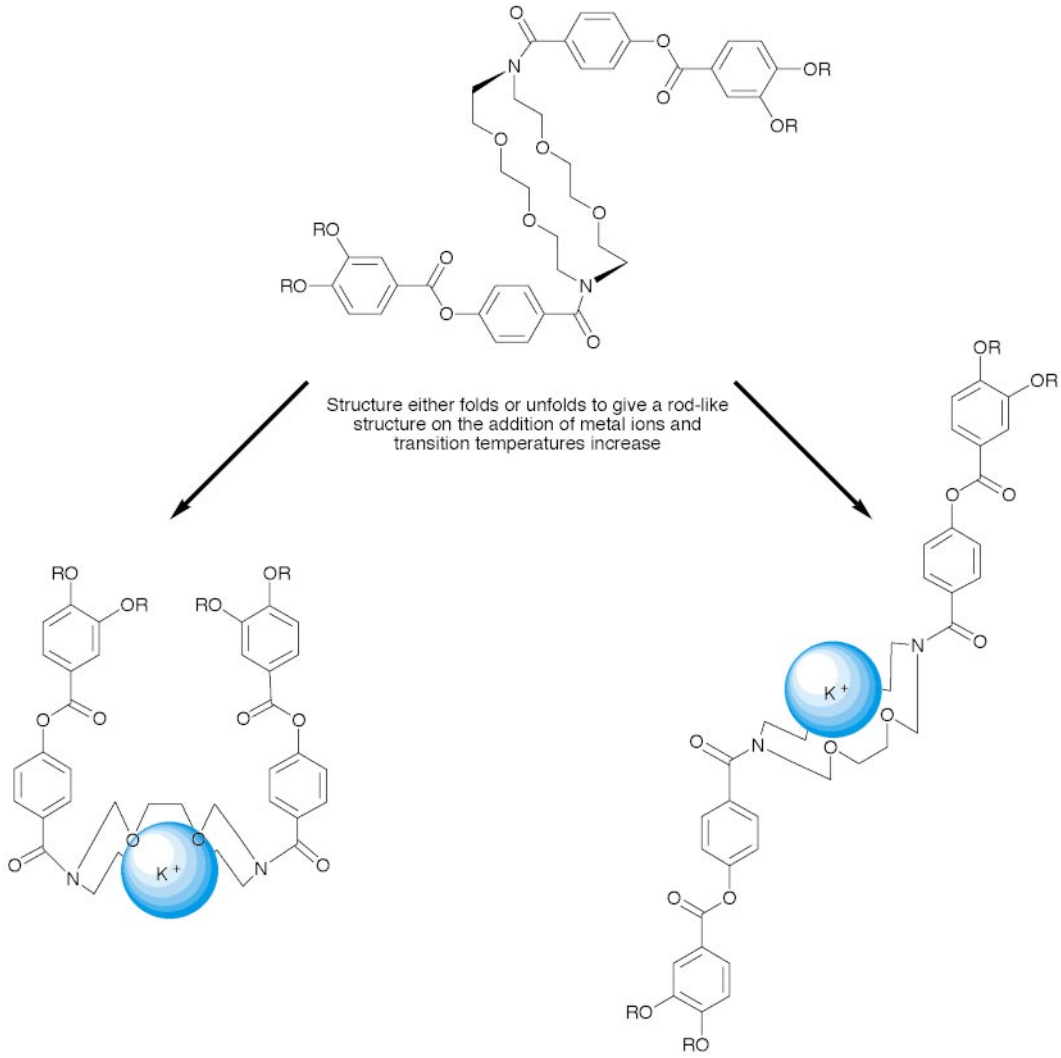


Fig. 11 A globular shaped macrocyclic system undergoes conformational changes upon inclusion of a metal ion. The resulting complex is rod-like in shape and hence the complex is mesomorphic and exhibits a nematic phase.

gated, the material was found to melt just above room temperature from a glassy state directly into a liquid crystal phase which persisted up to a temperature of 128 °C before the isotropic liquid was formed. Upon cooling from the liquid state, the liquid crystal phase was retained *via* supercooling to temperatures well below 0 °C (and under certain conditions down to −50 °C). Thermal cycling served to demonstrate the stability of the mesophase. Thermal optical microscopy showed that the mesophase formed had a columnar structure, Fig. 12(a). The addition of water to the material, plus heating from room temperature, revealed the formation of a lyotropic hexagonal mesophase, Fig. 12(b). The fact that the hexagonal columnar thermotropic phase was found not to be continuously miscible with the hexagonal lyotropic phase indicates that the two columnar structures are not the same. A model for the thermotropic phase based on mixture studies is shown in Fig. 13. In this model the aliphatic chains are on the outside of the columns and the polar head groups are on the inside. This implies that the bolaphiles, just like the macrocycles described earlier, must bend in the centre so that the polar head groups of each end of the glycolipid can interact with one another through hydrogen bonding. Again the hair-pin shaped molecules, just like those shown in Fig. 9 for the macrocyclic systems, cluster together to form quasi-discs which pack in columns (in fact Figs. 9 and 13 could be easily interchanged). In addition, the molecules have no positional order along the column axis. Much the same situation applies for the lyotropic phase structure except for the probability that the columns are composed of double layers with head groups positioned on the outside and on the inside of the columns in order to allow access of water through the system.

In addition to forming thermotropic and lyotropic liquid crystals these bolaphiles also form large scale aggregates on sonication in water, *i.e.* they form vesicles and tubules. These structures are on a much larger scale than those of the columnar structures of lyotropic and thermotropic liquid crystals, however, their existence serves to demonstrate that the process of self-assembly can extend far beyond the level of simple one on one intermolecular interactions.

Conclusions

In conclusion, we have shown that oligomeric materials with unusual discrete large scale molecular structures can exhibit mesomorphic phase behaviour. In order to exhibit such properties molecular deformation takes place. In certain

(a)

(b)

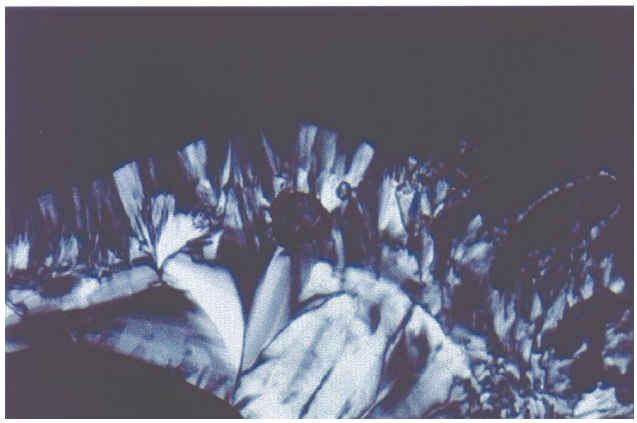

Fig. 12 The defect texture of (a) the thermotropic columnar mesophase and (b) the hexagonal lyotropic mesophase formed by compound **18** (×100)

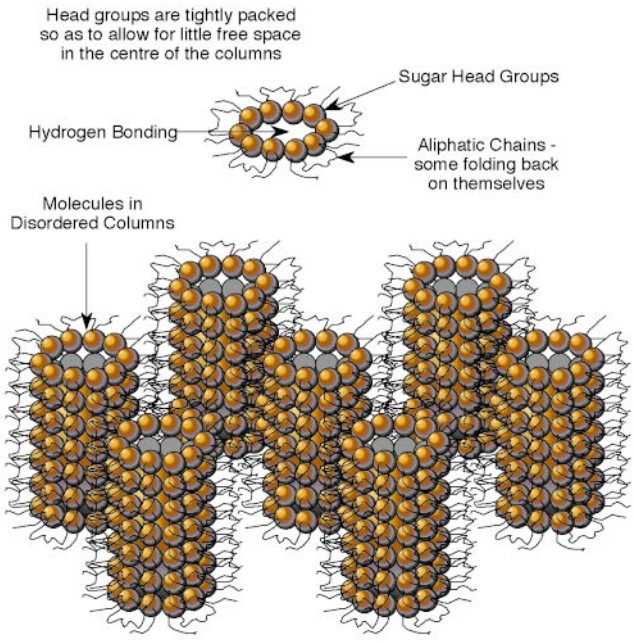

Fig. 13 The disordered hexagonal columnar structure formed by bolaphiles that mimic those found in archaebacteria. The bolaphiles fold in half so that the sugar residues can hydrogen bond. Clustering leads to the formation of disc-like complexes which then self-organise to give a columnar mesophase.

circumstances molecular deformation stabilises the formation of mesophases through a clustering process where the molecules form supramolecular assemblies. The so-formed assemblies self-organise to give mesophases of various types, for example molecules with rod-like molecular structures can fold in the middle to give wedge-shaped conformers which in turn can self-assemble into discs that self-organise into columns. Thus it is possible that materials of this type will have unique properties and hence applications.

Visualising intermolecular interactions in crystals: naphthalene *vs*. terephthalic acid

Joshua J. McKinnon, Anthony S. Mitchell and Mark A. Spackman*†

Division of Chemistry, University of New England, Armidale NSW 2351, Australia

A recently-devised scheme for partitioning crystal space into smooth molecular volumes is used to visualise intermolecular interactions in the crystal structures of naphthalene and terephthalic acid.

The detailed description and classification of intermolecular interactions in molecular crystals is of considerable current interest in crystal engineering,[1] *ab initio* crystal structure prediction,[2] and studies of polymorphism.[3] We have recently described[4] a remarkable new way of exploring molecular crystals by isosurface rendering of smooth, non-overlapping molecular surfaces arising from a partitioning of crystal space based on Hirshfeld's stockholder scheme.[5] These molecular Hirshfeld surfaces partition space in the crystal into regions where the contribution from the sum of spherically-symmetric electron distributions for atoms in the molecule (the promolecule) exceeds the contribution from the corresponding sum over the crystal (the procrystal). Following Hirshfeld, a weighting function $w(\mathbf{r})$ is defined by eqn. (1).

$$w(\mathbf{r}) = \sum_{a\varepsilon molecule} \rho_a(\mathbf{r}) / \sum_{a\varepsilon crystal} \rho_a(\mathbf{r}) = \rho_{promolecule}(\mathbf{r}) / \rho_{procrystal}(\mathbf{r}) \quad (1)$$

The Hirshfeld surface for the particular molecule is defined by $w(\mathbf{r}) = 0.5$, and the volume occupied by the molecule in the crystal is that region where $w(\mathbf{r}) \geqslant 0.5$. For a given crystal structure and set of spherical atomic electron densities, the isosurface defined by $w(\mathbf{r}) = 0.5$ is unique. The first quantitative applications of this partitioning scheme, including measures of molecular size and shape as well as 3D isosurface pictures of these Hirshfeld surfaces, have recently been reported[6] for a variety of van der Waals and hydrogen-bonded crystals.

In a recent article[1a] Desiraju highlighted the way in which crystal engineering is presently at 'an exciting intersection of structural and supramolecular chemistry' and outlined three broad areas in which progress is needed if designer crystals are to become a reality. One of these is the visualisation of a crystal structure in its entirety, rather than focusing on assumed important interactions. This objective recognises the increasingly evident one-upmanship of nature in thwarting attempts to engineer structures for specific purposes,[7] and points to a compelling need for new tools to explore and analyse molecular crystals, taking into account all manner of forces and interactions, strong and directional as well as weak and isotropic. Desiraju gave an example of such a tool, NIPMAT,[8] an interaction display program which produces a pictorial grey-scale matrix from the deviation between all close intermolecular atom-atom contacts in the crystal and the sum of their van der Waals radii, thereby summarising all of the intermolecular interactions simultaneously. In that work, Desiraju demonstrated the application of NIPMAT to two dissimilar molecular crystals: naphthalene and terephthalic acid [see Fig. 6 of ref. 1(*d*)]. Inspired by this example, we decided to apply our Hirshfeld surface partitioning to the same molecular crystals, in the process demonstrating the potential for Hirshfeld surfaces to provide detailed information on all intermolecular interactions at the same time, as well as the relationship between Hirshfeld surfaces in crystals and more conventional representations of molecular surfaces: fused van der Waals spheres and surfaces of constant electron density.

Fig. 1 shows Hirshfeld surfaces for the two molecules, and close examination of them confirms how elegantly and beautifully these surfaces summarise the utter difference between intermolecular packing patterns in these two crystals.‡ The Hirshfeld surface for naphthalene reflects the weak and largely non-directional forces in the crystal, with smoothly varying curvature over the entire surface, and the edge-to-face C–H··π interaction evident as a broad depression above the plane of one ring, in much the same way as seen for benzene.[6] In contrast to this, the Hirshfeld surface of terephthalic acid is characterised by abrupt changes of curvature, especially in the vicinity of the O–H···O hydrogen bonds where the surface is extremely flat, and above and below the molecular plane, where the surface is essentially flat, but with subtle undulations which echo the packing of neighbouring molecules. From Fig. 1 it is evident that naphthalene does not pack in a planar arrangement, while terephthalic acid utilises hydrogen-bonded ribbons which pack slightly offset to, and on top of, one-another.

Fig. 2 illustrates the relationship between the Hirshfeld surfaces in the crystal (mesh in this case) and space-filling representations of the isolated molecules as fused van der Waals spheres. The van der Waals representation of naphthalene fits snugly within the Hirshfeld surface, leaving ample room within this volume in all directions. The same pattern is also seen for terephthalic acid in the vicinity of the phenyl C–H bonds, but the regions around the carboxy groups are dramatically different. Here, as expected, the van der Waals spheres for O and H clearly protrude well beyond the Hirshfeld mesh surface at the ends of the molecule. More subtle is the way in which the oxygen spheres and one H sphere just protrude beyond the Hirshfeld surface on the side of the molecule, corresponding to close C–H···O contacts in the crystal.

Fig. 3 superimposes the Hirshfeld surfaces of these two molecules (mesh) on surfaces of constant electron density on which the molecular electrostatic potential has been colour

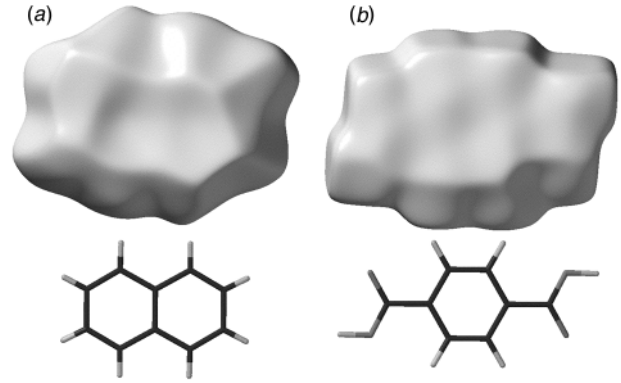

Fig. 1 Hirshfeld surfaces for (*a*) naphthalene and (*b*) terephthalic acid beside stick molecular models. Models and surfaces are all drawn to the same scale.

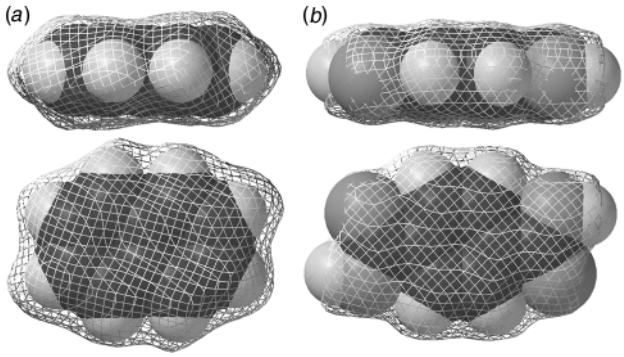

Fig. 2 Front and side views of Hirshfeld surfaces (mesh) for (*a*) naphthalene and (*b*) terephthalic acid superimposed on fused van der Waals sphere representations [van der Waals radii: 1.40 (H), 1.70 (C) and 1.50 Å (O)]

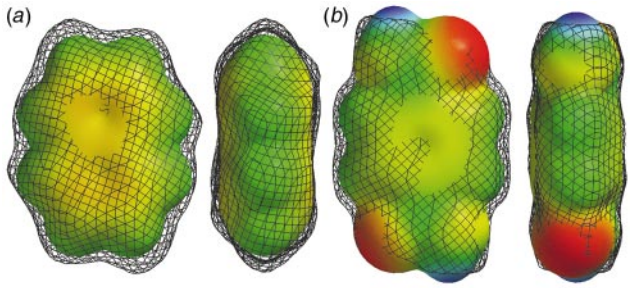

Fig. 3 Front and side views of Hirshfeld surfaces (mesh) for (*a*) naphthalene and (*b*) terephthalic acid superimposed on surfaces of constant electron density (0.002 au) for the isolated molecules, upon which the molecular electrostatic potential has been colour-coded. Colours range from red (–190 kJ mol^{-1} for a unit charge) to blue (+370 kJ mol^{-1}); the same colour range has been used for both molecules.

coded.§ The slightly polar nature of naphthalene (green around the C–H bonds, yellow above the rings) contrasts with the highly localised nature of polarity in the carboxy group of terephthalic acid, and the protrusion of O and H atoms in the latter is evident. A new feature seen in Fig. 3 is the way in which the Hirshfeld surface dips below the surface of constant electron density above the benzene rings for the isolated molecules, just perceptibly in the case of terephthalic acid, but far more so for naphthalene, where it is strikingly evident that, whereas the two rings are essentially equivalent in the electron density surface for the isolated molecule, there is a much closer C–H$\cdots\pi$ contact to one ring than the other in the crystal structure. The C–H$\cdots$O contacts on the edge of the terephthalic acid molecule are also more obvious here than in Fig. 2

We believe that the information on intermolecular interactions which is implicitly contained in an accurate crystal structure analysis is reliably encoded on these Hirshfeld surfaces. The illustrations in this article show how, in a very qualitative manner, this appears to be the case, while at the same time highlighting how the Hirshfeld surfaces, defined as they are for molecules in the crystal, differ fundamentally from representations of isolated molecules. Curvature of the Hirshfeld surface seems to be intimately related to the nature and strength of intermolecular interactions for all examples we have investigated so far, and our future lines of inquiry with these intriguing surfaces will explore this connection further.

Notes and References

† E-mail: mspackma@metz.une.edu.au

‡ Our calculations used the same crystal structures as Desiraju (CSD: NAPHTA10, TEPHTH) with details of the computational method given in ref. 6. Global descriptors of size indicate that the Hirshfeld surfaces of these two molecules are surprisingly similar, with similar volumes (V_H = 172.3 and 169.3 Å^3 for naphthalene and terephthalic acid, respectively), surface areas (S_H = 176.0 and 179.3 Å^2) and packing ratios (P_H = 0.970 and 0.969). As for shape, results for globularity (G = 0.851 and 0.825), a measure of the degree to which the surface area differs from that of a sphere of the same volume, suggest that naphthalene is marginally more spherical than terephthalic acid, while anisotropy ($\sqrt{\Omega}$ = 0.354 and 0.435) confirms that the surface for naphthalene is markedly more isotropic than that for terephthalic acid.

§ These results obtained with the SPARTAN package (see ref. 9); electron density surfaces are at ρ(r) = 0.002 au, from a Hartree–Fock SCF calculation on the isolated molecule with a 6-31G* basis set, at the same geometry as the molecule in the crystal; electrostatic potentials for both molecules utilise the same gradation of colour, with red electronegative and blue electropositive.

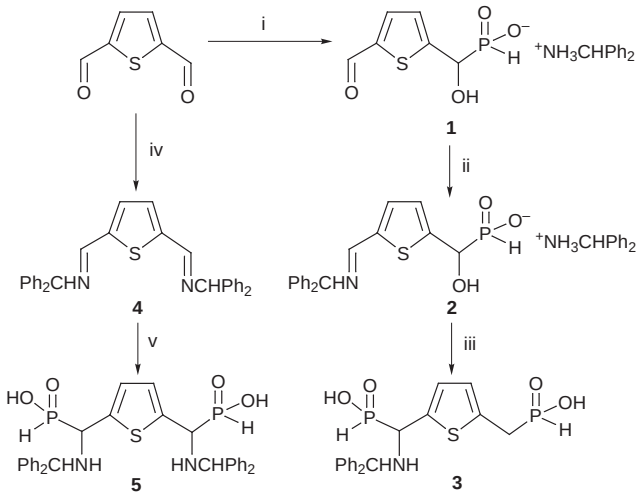
Synthesis of novel α-functionalized phosphinic acid derivatives of thiophene and the first crystal structure of an α-hydroxyalkylphosphinate

S. W. Annie Bligh,*[a]† Carlos F. G. C. Geraldes,[b] Mary McPartlin,[a] Mahesh J. Sanganee[a] and Thomas M. Woodroffe[a]

[a] *School of Biological and Applied Sciences, University of North London, Holloway Road, London, UK N7 8DB*
[b] *Department of Biochemistry and Centre of Neurosciences, University of Coimbra, 3000 Coimbra, Portugal*

Reaction of 2,5-diformylthiophene with Ph_2CHNH_2 and hypophosphorus acid yields novel α-hydroxy- or α-aminomethylphosphinic acid derivatives depending on reaction conditions; the X-ray structure analysis of diphenylmethylammonium 5-formyl-2-thienyl(hydroxy)methylphosphinate provides the first direct structural information on the α-hydroxyalkylphosphinate class of compounds.

Compounds containing an α-aminoalkylphosphinic acid functional group are of considerable importance because of their anti-bacterial,[1] herbicidal[2] and fungicidal[3] activities. Protonation studies of α-aminomethylphosphinic acids [$R_2NCH_2P(H)O_2H$] have shown that the nitrogen atom is very weakly basic compared to those of α-aminomethylphosphonic acids ($R_2NCH_2PO_3H_2$) and α-aminocarboxylic acids ($R_2NCH_2CO_2H$), and that the phosphinic acid group is strongly acidic.[4] In contrast to the widely studied α-aminoalkylphosphinic acid derivatives, relatively few papers have been reported on the chemistry of α-hydroxyalkylphosphinic acids, although there is evidence that α-hydroxyalkylphosphinate esters are pharmaceutically active.[5] Many effective methods for the preparation of α-aminoalkylphosphinic acids have been developed,[6] but few synthetic routes to α-hydroxyalkylphosphinic acids have been reported and these involve prolonged heating of hypophosphorous acids with aldehydes or ketones,[7] or reaction of ketones with bis(trimethylsilyloxy)phosphine.[8] Here we have successfully prepared both types of α-functionalised phosphinates (Scheme 1); of particular importance is the isolation for the first time of the α-hydroxyalkylphosphinate compound using relatively mild reaction conditions, and the first characterisation by X-ray crystallography of this class of compound.



Scheme 1 *Reagents and conditions*: i, Ph_2CHNH_2, 50% aq H_3PO_2, 30%; ii, Ph_2CHNH_2, DMSO, 88%; iii, H_3PO_2, 1,4-dioxane, 26%; iv, Ph_2CHNH_2, MeOH, 51%; v, H_3PO_2, 1,4-dioxane, 72%

The reaction of 2,5-diformylthiophene (prepared as described in ref. 9) with Ph_2CHNH_2 and aqueous hypophosphorous acid (50%) gives an unexpected mono(α-hydroxyalkylphosphinate) derivative **1** rather than the bis(α-aminoalkylphosphinate) derivative **5**. The remaining thiophene carbonyl group is not electrophilic towards the addition of a second water molecule to form the intermediate *gem*-diol; all attempts to prepare the bis(α-hydroxyalkylphosphinate) derivative proved unsuccessful.

The presence of the α-hydroxy group in **1** was confirmed by X-ray structure analysis‡ of the (diphenylmethyl)ammonium salt and the structure of the ions, linked by a hydrogen bond between one of the phosphinate oxygen atoms and a proton of the ammonium cation [O(2)···H(1N) = 1.86 Å] is shown in Fig. 1(*a*). The remaining two protons of the (diphenylmethyl)-ammonium counterion are also involved in hydrogen-bonding to phosphinate oxygen atoms of adjacent symmetry related anions [O···H(N) = 1.72–1.90 Å], resulting in a complicated spiral hydrogen bonded chain of alternating cations and anions running parallel to the *b* axis of the crystal [Fig. 1(*b*)]. Along this helix, adjacent anions (separated by the *b* axis length) are linked by hydrogen-bonding between the α-hydroxy group of one and a phosphinate oxygen of the next [H(1O)···O(3) = 1.98 Å] as can also be seen in Fig. 1(*b*).

In order to prepare the bis(α-aminoalkylphosphinate) derivative **5** from the dialdehyde a two stage process was required. The carbonyl groups were first converted to the imine functions by condensing the dialdehyde and Ph_2CHNH_2 in MeOH to give **4**, and addition of hypophosphorous acid (100%) to **4** in 1,4-dioxane gives a diastereoisomeric mixture of **5** in good yield. However, the addition of hypophosphorous acid (100%) to the mono-imine derivative **2** readily converts the imine to the α-aminoalkylphosphinate, and the presence of excess hypophosphorous acid reduces the α-hydroxy functional group to yield **3**. Attempts to remove the Ph_2CH protecting groups have proved difficult. The new compounds **1–5** give satisfactory elemental analysis and their ^1H, ^{13}C and ^{31}P NMR data§ agree with the structures proposed. Both compounds **1** and **2** have been tested in the antibacterial screen and showed no activity.

Compound **1** is the first example of an α-hydroxyalkylphosphinate as a substituent of a heterocyclic ring. The ability to derivatize only one of the two aldehyde groups to afford the mono(α-hydroxyalkylphosphinate) opens up the possibility that the remaining carbonyl can be used in further reaction with an amine [*e.g.* Scheme 1(ii)]. This availability of an additional active carbonyl in an α-hydroxyalkylphosphinate derivative is thus potentially beneficial for its coupling to biological macromolecules or to polymers for selective metal complexation applications.

Preparation of novel HIV-protease inhibitors

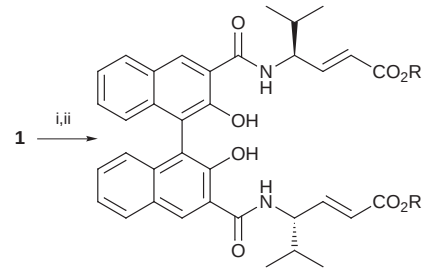
Manfred T. Reetz,*† Claudia Merk and Gerlinde Mehler

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim/Ruhr, Germany

The synthesis and biological properties of new HIV-1-protease inhibitors involving amino acids or dipeptides attached to binaphthol, biphenol or embonic acid are described.

Inspite of recent progress in the development of therapeutics for the treatment of AIDS, a number of problems persist.[1] A well-known approach concerns the design and synthesis of HIV-protease inhibitors. The HIV-protease is a well characterized viral enzyme consisting of two units, each composed of 99 amino acids, which join together to form the C_2-symmetric active homo-dimer. Consequently, one strategy has been to prepare C_2-symmetric inhibitors in the form of peptide mimetics, one family of active compounds being C_2-symmetric 1,2-diols flanked by short peptide units.[2] The hydroxy moities have been shown to participate in the interaction with the HIV-protease *via* H-bonding, the configuration at the two stereogenic centers of the diol playing an important role with respect to the degree of binding. We speculated that similar compounds based on chiral binaphthol or biphenol units in place of the traditional diols could constitute a new class of HIV-1-protease inhibitors, specifically because the enhanced acidity of such moieties would be expected to lead to stronger H-bonding. Here we present the initial results of this strategy.

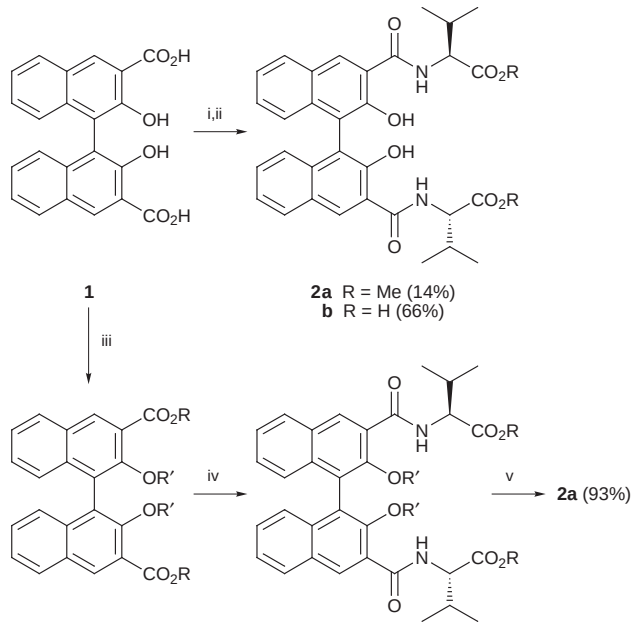
We first envisioned peptides of the type **2b** and **5b** based on racemic 2,2′-dihydroxy-1,1′-binaphthyl-3,3′-dicarboxylic acid **1**. Direct coupling with valine methyl ester resulted in a 14% yield of the desired diastereomeric dipeptide esters **2a**, which were hydrolyzed to the acids **2b**. In order to improve the synthesis, the hydroxy functions of **1** were first protected by benzyl groups (Scheme 1). The diastereomeric mixture of **2b** was separated by HPLC to provide analytically pure (*R,S,S*)-**2b** and (*S,S,S*)-**2b**. In the case of the dipeptide **5b** with two vinylogous amino acid residues, only direct coupling was carried out (Scheme 2).



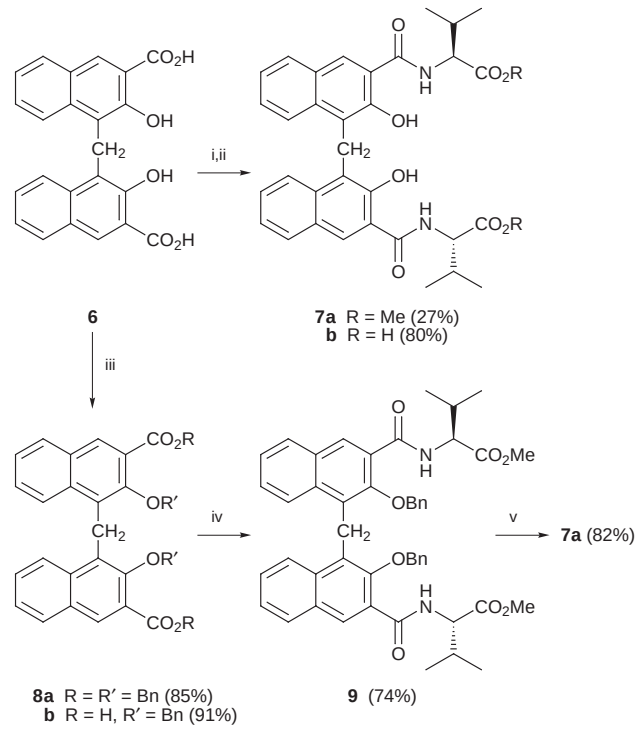
5a R = Et (17%)
b R = H (65%)

Scheme 2 *Reagents*: i, NaOH, NHS, DCC; NEt_3, L-$HCl{\cdot}H_2NCHPr^iCH{=}CHCO_2Et$; ii, LiOH, H_2O

Although there is a limited degree of rotational freedom with respect to the axis going through the two naphthyl units, the C_2-symmetric dipeptides **2b** and **5b** are in fact fairly rigid. In order to introduce more conformational flexibility, we prepared dipeptide **7b** based on embonic acid **6** (Scheme 3). Although the



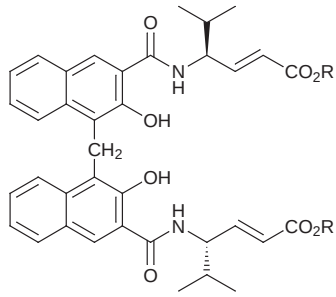
Scheme 1 *Reagents*: i, NaOH, *N*-hydroxysuccinimide (NHS), DCC, L-$H_2NCHPr^iCO_2Me$; ii, LiOH, H_2O; iii, BnBr, K_2CO_3; iv, NHS, DCC, L-$H_2NCHPr^iCO_2Me$; v, $Pd(OH)_2$, cyclohexene



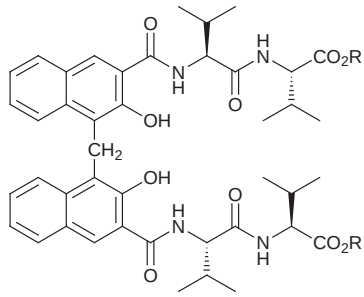
Scheme 3 *Reagents*: i, NaOH, NHS, DCC, L-$H_2NCHPr^iCO_2Me$; ii, LiOH, H_2O; iii, BnBr, K_2CO_3, KOH, H_2O; iv, NHS, DCC, L-$H_2NCHPr^iCO_2Me$; v, $Pd(OH)_2$, cyclohexene

latter is achiral, conformational enantiomers (or diastereomers in the case of **7b**) are likely, especially upon binding to the C_2-symmetric HIV-protease. The dipeptide **10b** incorporating vinylogous valine was synthesized analogously.

In order to test the biological effect of extending the peptidic side-arms, the tetrapeptide **11b** was prepared in a direct manner by NHS–DCC-mediated coupling of **6** with L-valinyl-L-valine ethyl ester. Here, as in all previous cases, the compounds were purified by HPLC and characterized by standard spectroscopic and analytical means.

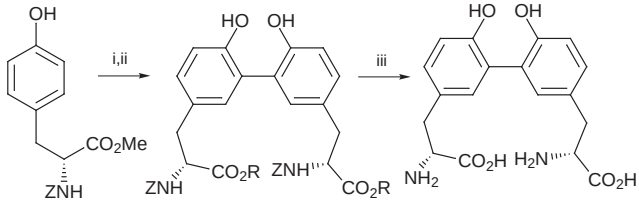


10a R = Me (32%)
b R = H (80%)



11a R = Et (46%)
b R = H (16%)

Finally, the biphenol derivative **13** was prepared by oxidative coupling[3] of *N*-benzyloxycarbonyl-L-tyrosine methyl ester **12**. Deprotection delivered the dipeptide **14** (Scheme 4).



12 (Z = benzyloxycarbonyl) **13a** R = Me (52%) **b** R = H (94%) **14** (90%)

Scheme 4 *Reagents*: i, VOF_3; ii, LiOH, H_2O; iii, H_2, Pd-C

In order to screen the ability of the compounds to inhibit the HIV-1-protease, the IC_{50} values were measured using standard procedures.[4] Table 1 shows that several compounds have activities similar to a number of other HIV-protease inhibitors which have been reported in recent years.[2] It is interesting to note that in the case of **5b** (but not **2b**) the absolute configuration of the binaphthol backbone plays a significant role in the degree of HIV-protease inhibition. Specifically, the (*R*,*S*,*S*)-compound is considerably more active than the (*S*,*S*,*S*)-diastereomer. However, the conformationally more flexible compounds based on embonic acid **6** are more active, especially the tetrapeptide **11b**.

Theoretically, the mode of action of the above compounds can either be due to active-site inhibition of the HIV-protease or to a possible inhibition of dimerization of the two 99-amino acid

Table 1 Properties of synthesized compounds

Compound	Solubility/μM	IC_{50}/μM
(*R*,*S*,*S*)-**2b**	> 65	47
(*S*,*S*,*S*)-**2b**	> 65	48
(*R*,*S*,*S*)-**5b**	> 50	46
(*S*,*S*,*S*)-**5b**	> 50	13
7b	> 100	40
10b	~ 30	8
11b	> 10	2.8
13b	> 100	24
14	> 100	240

units (*i.e*. prevention of homo-dimer formation). In order to shed some light on these aspects, kinetic studies using the model of Zhang were carried out on select compounds, *i.e*. dissociative inhibition constants (K_i) and competitive inhibition constants (K_c) were measured.[5] Accordingly, in the case of the most active compound **11b**, the K_i and K_c values turned out to be 6.9 and 2.0 μM, respectively. This means that active site (competitive) inhibition dominates, although dissociative inhibition plays some role. Mixed inhibition also pertains to the related dipeptide **7b** (K_i = 15.8 μM; K_c = 6.2 μM). In contrast, the mechanism of action of the tyrosin derivative **13b** appears to be based primarily on the inhibition of dimerization of the monomeric HIV-protease units (K_i = 6.8 μM; K_c = 229 μM). This still needs to be studied more closely, *e.g*. using light scattering. However, preliminary molecular modelling is in line with these conclusions.

In summary, we have designed and prepared new HIV-1-protease inhibitors based on naphtholic and phenolic units to which amino acids or dipeptides are attached. Although the respective activities are lower than those of the most potent drugs currently known,[1,2] the discovery of these new lead structures allows for the (combinatorial) synthesis of analogs which may show improved performance.

We thank H.-J. Schramm, J. Büttner and T. Wenger (group of R. Huber at Max-Planck-Institut für Biochemie, Martinsried) for help in the determination of IC_{50} values and kinetic data and for stimulating discussions.

Diphosphonites as highly efficient ligands for enantioselective rhodium-catalyzed hydrogenation

Manfred T. Reetz,*† Andreas Gosberg, Richard Goddard and Suk-Hun Kyung

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim/Ruhr, Germany

Chiral ligands with achiral backbones such as ethano- or ferroceno-bridges linking two phosphonites derived from chiral diols such as binaphthol (BINOL) have been prepared; the corresponding Rh complexes are excellent catalysts in the hydrogenation of prochiral olefins such as itaconic acid dimethyl ester or 2-acetamido methyl acrylate, the ee values being 90–99.5%.

Although a number of chiral diphosphanes and diphosphinites have been shown to be effective ligands in transition metal catalyzed asymmetric reactions,[1] the search for new types of chiral auxiliaries continues.[2] Surprisingly, very little is known concerning chiral diphosphonites as ligands in these reactions.[3] Perhaps this is due to the fact that in all cases reported so far the enantioselectivity is poor (ee = 0–32%).[3] We speculated that chelating diphosphonites derived from a proper combination of an achiral backbone and a chiral diol might constitute useful and easily accessible ligands.[4]

Using ferrocene and (*R*)- or (*S*)-BINOL as cheap building blocks,[5] the diphosphonite **1** was easily assembled in three steps (Scheme 1).[6] **1** is an orange–brown crystalline compound, which in the solid state‡ shows some interesting features (Fig. 1). In spite of their different environments, the two independent molecules in the unit cell have almost identical conformations [P1–Cp1–Cp2–P2 −9(1)°, P3–Cp3–Cp4–P4 −7(1)°; Cp, centroid], with the two P atoms in each molecule situated close to one another [P1···P2 3.506(3), P3···P4 3.428(3) Å].

The ethano-bridged analog **2** was also readily synthesized (Scheme 2).

In order to prepare hydrogenation catalysts, the ligands were treated with $Rh(cod)_2BF_4$ under standard conditions,[7] affording the corresponding complexes (*R*,*R*)-(**1**)Rh(cod)BF_4 or (*R*,*R*)-(**2**)Rh(cod)BF_4, which were characterized by NMR, ESI-MS and IR spectroscopy. Thus far it has not been possible to obtain crystals suitable for crystallographic investigations. Two different types of olefins were chosen as substrates for asymmetric

hydrogenation, namely itaconic acid dimethyl ester **3** and 2-acetamido methyl acrylate **5**, leading to the products **4** and **6**, respectively. The results of the hydrogenation experiments with formation of the *R*-configurated products **4** and **6** are remarkable in several ways (Table 1).

Table 1 Enantioselective hydrogenation of dimethyl itaconate (**3**) and 2-acetamido methyl acrylate (**5**)[a]

Entry	Ligand	Substrate	S/C[d]	Yield (%)[e]	ee (%)[e]
1	**1**	**3**	1000	100	> 99.5
2	**1**	**3**	2000	100	> 99.5
3[b]	**1**	**3**	5380	100	> 99.5
4	**2**	**3**	1000	100	97–99
5	**2**	**3**	2000	100	97–99
6[c]	**1**	**5**	1000	100	99.5
7[c]	**2**	**5**	1000	100	90

[a] Hydrogenations were carried out under the following general conditions: 1.3 bar H_2, dichloromethane, r.t., 20 h, *c*(substrate) = 0.1 mol l^{-1}, catalysts prepared *in situ* with Lig/Rh = 1.1 (4 runs each). [b] Using preformed (*R*,*R*)-(**1**)Rh(cod)BF_4. [c] Lig/Rh = 1.0. [d] Substrate to catalyst ratio. [e] Determined by GC analysis.

In the case of substrate **3** both catalysts afford essentially enantiomerically pure product **4**. However, in the hydrogenation of **5** pronounced differences in enantioselectivity were observed (Table 1). Thus, the ferrocene-based catalyst (*R*,*R*)-(**1**)Rh(cod)BF_4 leads to complete enantioselectivity for both substrates (ee > 99.5%). Although experiments directed towards elucidating mechanistic and structural aspects need to be carried out, the present study shows that catalyst (*R*,*R*)-(**1**)Rh(cod)BF_4 is not only readily accessible, but also highly effective. It remains to be seen how well ligand **1** performs in other hydrogenation reactions and in C–C bond forming processes, metals other than rhodium constituting further possibilities.

A well-defined metallocene catalyst supported on polystyrene beads

Anthony G. M. Barrett* and Yolanda R. de Miguel

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY

A spacer-modified polystyrene support with alcohol functionality was prepared using solid-phase organic reactions, and this resin was further derivatised to give a supported peralkylated titanocene which was active in ethylene polymerisation.

The rapid growth in combinatorial chemistry[1] has generated interest in the development of novel polymers, spacers and linkers for the adaptation of well-known solution methodologies to the solid phase. Transition metal catalysts anchored onto insoluble supports have also received much attention[2] as they are of great use in industrial scale processes, facilitating purification and catalyst recycling. So far, the use of supports for the latest generation of olefin polymerisation catalysts has mainly involved preadsorption of metallocenes on MAO-coated silica[3] or MCM-41.[4] The silica-based catalysts have been successfully used in large scale processes and the polymers obtained appear to be enlarged replicas of the original grains. However catalyst leaching can occur and neither are ideal supports for these unstable catalysts which are subject to facile deactivation. New ways to covalently attach metallocenes and to characterise the resulting complexes are needed, so that superior catalysts may be developed. The recent report by Frechet *et al.*[5] on the preparation of polyolefin spheres and related earlier studies prompts us to report our own work on supported metallocene catalysts.

The objectives of our investigations were to develop a new support **3** for solid-phase chemistry (Scheme 1) that would contain a spacer covalently attached to the resin *via* a stable C–C bond, with an alcohol end group, and to convert it into a well-defined supported titanocene **7**. Grubbs *et al.* have previously reported[6] polymer immobilised Ti-centred metallocene species, but have used these only as the basis of alkene hydrogenation catalysts.

The synthesis of the spacer unit was carried out in solution by sequential monoprotection of tetraethylene glycol (TEG) and monoalkylation with excess 1,5-dibromopentane (Scheme 1). The resulting bromide was attached onto the gel polystyrene support, by alkylation with polystyryllithium, prepared from *p*-bromopolystyrene (Fluka; 1.2–1.3 mmol g^{-1}, 100–400 mesh, 2% DVB) and *n*-butyllithium.[7] The loading level of the desired alcohol resin **3** was estimated during removal of the protecting group from **2b** using UV spectroscopy. FT-IR microspectroscopy, microanalysis and gel phase MAS NMR spectroscopy were used to fully characterise the alcohol resin product **3**.† The derivatisation of this alcohol support **3** was also studied and compared to that of some commercial supports. The nosylate derivative **4** was successfully prepared by treatment with excess 4-nitrobenzenesulfonyl chloride twice. Single bead FT-IR microspectroscopy and microanalysis (%N) were used to determine the extent of conversion. The reaction of the nosylate resin **4** with the tetraalkyl cyclopentadienyl anion was easily monitored by FT-IR and microanalysis (0%N), and gave the peralkylated cyclopentadienyl ligand **5**. The loading level of the cyclopentadienyl resin **5** was estimated by derivatisation with Cookson's reagent,[8] and %N analysis and FT-IR microspectroscopy of the resulting Diels–Alder adduct **6**.

The polymer-supported ligand **5** was converted into the titanocene complex **7** by deprotonation and reaction with cyclopentadienyltitanium trichloride. The titanium content of the beads was determined using inductively coupled plasma-atomic emission spectroscopy. The diffuse reflectance far-IR spectrum of the resin-bound catalyst **7** showed new sharp peaks in the region of 200–400 cm^{-1}, which are typical for Ti–Cl

stretches.[6] X-Ray photoelectron spectroscopy of a single bead gave a peak for the Ti 2p binding energy (at 457.5 eV) which is identical to that reported for other titanocene dichloride complexes.[9] This was good evidence that the structure of the species on the polymer was indeed analogous to that of the homogeneous catalyst. Scanning electron microscopy showed that the overall condition of the beads **7** (Fig. 1) was excellent. The chemical composition of the beads was also confirmed by X-EDS (X-ray energy dispersive spectroscopy) of clusters of beads. Analysis of the sample showed the presence of chlorine (Cl-Kα line = 2.6 keV) and titanium (Ti-Kα line = 4.5 keV) and the Cl : Ti ratio was roughly 2 : 1; in agreement with the catalyst structure.

This resin-bound complex **7** was tested for polymerisation activity by treatment with MAO (10^3 equiv.) and ethylene gas. The activity per bar per hour was estimated to be 41 g polyethylene per mmol catalyst, which was not as high as expected, probably due to diffusion problems into the active sites within the bead. The resulting noodle-like polyethylene chains emanating from the beads could be directly observed by scanning electron microscopy (SEM; see Fig. 2).‡ Kaminsky's work[10] on the coating of cellulose also described noodle-like morphology and it has been suggested that this only formed on very active catalytic centres. The high local activity of these centres on the polystyrene beads **7** could be due to site-isolation of the active species.

In conclusion, we have successfully prepared an active polymer-bound metallocene catalyst for olefin polymerisation. The full characterisation of this catalyst was made possible by the use of many new analytical techniques for on-the-bead characterisation as well as some novel monitoring methods for solid-phase reactions.§

We thank Professor Vernon C. Gibson and Brian Kimberley for carrying out the catalytic assay of **7** in their laboratories. We would also like to thank BP for financial support (fully-funded PhD studentship).

Note added at proof: Subsequent to the submission of this manuscript, Gibson and co-workers have reported the use of a polystyrene imidovanadium catalyst system for the polymerisation of ethylene: M. Electrogenerated poly(thiophenes) with extremely narrow bandgap and high stability under n-doping cycling

Said Akoudad and Jean Roncali*†

Ingénierie Moléculaire et Matériaux Organiques, CNRS UMR 6501, Université d'Angers, 2 Bd Lavoisier, 49045 Angers Cedex, France

The synthesis of a poly(thiophene) polymer with an extremely narrow bandgap is described.

The synthesis of narrow bandgap (E_g) conjugated polymers[1] has been a focus of considerable interest, motivated by their high visible transparency, their ability to be p- and n-doped, allowing their use in electrolytic supercapacitors[2] or dual polymer electrochromic devices,[3] and by the ultimate aim of synthesizing zero bandgap polymers with metallic conduction.

Various routes have been developed to synthesize low bandgap polymers with increased quinoid character in the conjugated backbone,[4] alternating electron-releasing and electron-withdrawing groups[5] or covalent rigidification of the conjugated backbone.[6] Based on a combination of the two first strategies, Yamashita *et al*. have synthesized polymers with the smallest bandgaps known to date ($E_g \approx 0.50$ eV) by electropolymerization of precursors based on three-ring systems with a median pro-quinoid acceptor such as thieno[3,4-*b*]pyrazine (TP) or benzo[1,2-*c*:4,5-*c*′]bis[1,2,5]thiadiazole and two external thiophene or pyrrole rings.[7]

We report here preliminary results on a new electrogenerated small bandgap polymer derived from a bithiophenic precursor involving 3,4-ethylenedioxythiophene (EDOT) and TP. This precursor structure combines the superior polymerizability of bithiophenic structures over more conjugated ones,[8] the solubility imparted by dihexyl chains on the TP system,[9] the high HOMO level of EDOT and the well-known stability of its polymers,[10] and the possibility of achieving an alternating sequence of EDOT and TP units in the polymer.

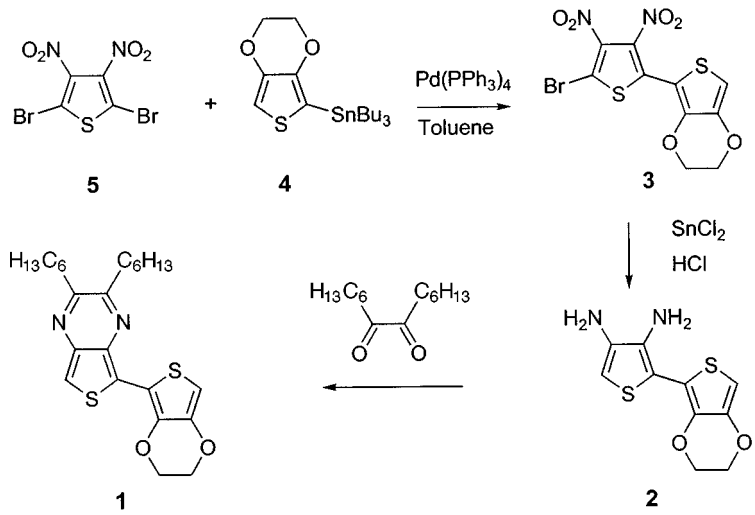
The synthesis of **1** is depicted in Scheme 1. A Stille coupling between 2,5-dibromo-3,4-dinitrothiophene **5**[11] and 2-tributylstannyl-3,4-ethylenedioxythiophene **4** gave the bromodinitro compound **3** in 17% yield. Reduction of **3** with concomittant dehalogenation using $SnCl_2$ in HCl afforded diamine **2** (33% yield) which was then condensed with tetradecane-7,8-dione to give the target compound **1** in 57% yield.‡

Compound **1** has its absorption maximum at $\lambda_{max} = 456$ nm; the 237 nm red shift compared to the EDOT dimer[12] underlines the effect of the TP moiety on the HOMO–LUMO gap of the molecule.

The cyclic voltammogram of **1** shows an anodic peak potential at 0.72 V. This low oxidation potential results from the incorporation of EDOT in the structure. Consequently electropolymerization can be readily achieved at unusually low applied potential, under either potentiostatic or potentiodynamic conditions. Another interesting point is the very low substrate concentration needed for electropolymerization. Thus; application of recurrent potential scans between −0.50 and +0.60 V to a 5×10^{-4} M solution of **1** in MeCN leads to rapid growth of a new redox system centered at −0.10 V (Fig. 1). The CV of the polymer in a monomer-free electrolytic medium shows a redox system corresponding to the doping process with anodic and cathodic peak potentials at 0.10 and −0.16 V. These values lead to a redox potential *ca*. 0.60 V lower than that of the parent polymer derived from a thiophene–TP–thiophene precursor.[7b] The n-doping system shows cathodic and anodic peaks at −1.12 and −1.30 V (Fig. 1). The potential difference between the onset for oxidation and reduction leads to an estimated bandgap of *ca*. 0.50–0.60 V.

Preliminary stability tests under redox cycling in an oxygen-free medium shows that poly(**1**) retains 80% of its electroactivity after 1000 reduction cycles between −0.20 and −1.50 V at a scan rate of 500 mV s^{-1}, or after 250 full cycles of both oxidation and reduction at 100 mV s^{-1} between +0.60 and −1.50 V. These results contrast with the limited cyclability generally observed for small bandgap polymers.[7a,13]

Electrodeposition of poly(**1**) on indium-tin oxide (ITO) coated glass electrodes gave free-standing films which were



Scheme 1

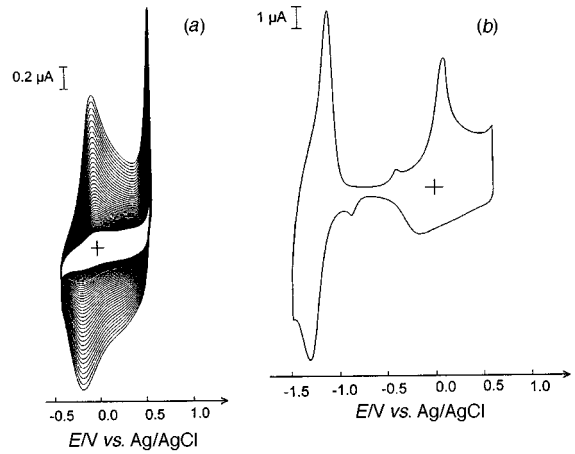


Fig. 1 (*a*) Potentiodynamic electropolymerization of **1** on Pt, t × 10^{-4} M substrate in 0.10 M Bu_4NPF_6–MeCN, scan rate 100 mV s^{-1}. (*b*) Cyclic voltammogram of poly(**1**) in 0.10 M Bu_4NPF_6–MeCN, Pt electrodes, scan rate 100 mV s^{-1}.

submitted to electrochemical reduction followed by immersion in aqueous ammonia over two days. The optical spectrum of neutral poly(**1**) on ITO shows a single absorption band with a maximum at 0.86 eV (1430 nm) and a weak shoulder at *ca*. 1.25 eV (Fig. 2). Unlike the spectra of most of the known small bandgap polymers, this spectrum exhibits a small width at half maximum of the absorption band (0.72 eV) and low absorbance in the whole visible range. These characteristics are consistent with a well-defined polymer structure with a narrow distribution of conjugated chain lengths. Extrapolation to the baseline of the low energy absorption edge crosses the ITO absorption wall and leads to an optical bandgap of 0.36 eV, which is to the best of our knowledge the lowest ever reported for a conjugated polymer. Poly(**1**) shows negligible solubility in CH_2Cl_2 and in hot chlorobenzene it is limited to a few percent. The resulting

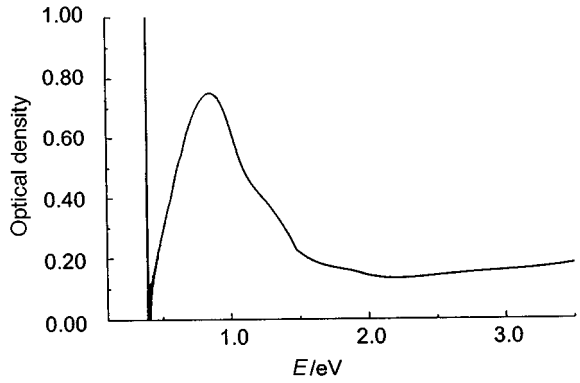

Fig. 2 Optical spectrum of neutral poly(**1**) on ITO (the straight line at 0.40 eV is due to ITO absorption)

solutions show λ_{max} at 800 and 1000 nm, respectively. While this limited solubility might be due to insufficient length in the alkyl substituents, the expected rigid quinonoid structure of the neutral polymer[14] probably contributes to limit the solubility. The improvement of solubility by attachment of longer alkyl chains on both components is presently under investigation.

To summarize, we have shown that a dimeric precursor combining dihexyl-TP and EDOT allows the efficient electrosynthesis of a well-defined polymer with extremely narrow bandgap and excellent stability under n-doping redox cycling. These attractive properties make poly(**1**) an interesting electrode material for various applications, in particular in electrolytic supercapacitors, and work in this direction is now underway.

A novel polynuclear palladium(II) complex with asymmetric coordination of palladium atoms

Rong Cao,*[a] Weiping Su,[a] Maochun Hong,*[a] Wenjian Zhang,[a] Wing-Tak Wong[b] and Jiaxi Lu[a]

[a] *State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Fuzhou, Fujian 350002, PR China. E-mail hmc@ms.fjirsm.ac.cn or rcao@ms.fjirsm.ac.cn*

[b] *Department of Chemistry, The University of Hong Kong, Pokfulan Road, Hong Kong*

The oxidation of $[Pd_2(dppm)_2Cl_2]$ with selenium in the presence of $NaSCH_2Ph$ in DMF gives rise to a novel polynuclear complex $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-}dppm)_2Cl_2]$; a single crystal X-ray diffraction analysis shows that all the palladium atoms in the compound are tetra-coordinated with distorted square-planar geometry, of which two are asymmetrically coordinated with selenium, sulfur, chlorine, and phosphorus atoms.

Bis(diphenylphosphine)methane (dppm), as a constraining ligand, prefers to lock together two metal atoms in close proximity and favors unusual oxidation states; thus, most palladium complexes containing dppm are binuclear complexes doubly bridged by dppm and related ligands, such as $[Pd_2(\mu\text{-}dppm)_2X_2]$ (X = halogen, **1**),[1–4] and the oxidation state of palladium is mainly +1. Many studies have been carried out on the insertion of small molecules, such as CO, SO_2, RCN *etc*., into the Pd–Pd bond in **1** to yield the so-called A-frame complexes with the maintenance of the oxidation state of palladium.[5] Studies on the insertion of an S or Se bridge into **1** to give rise to complexes $[Pd_2(\mu\text{-}E)(\mu\text{-}dppm)_2X_2]$ (E = S, Se; X = halogen) with a change of the oxidation state of palladium from +1 to +2 have also been reported,[6] whilst reports on the palladium complexes with mixed thiolate and diphosphine ligands, especially those having a palladium formal oxidation state of +2 and containing both dppm and thiolate ligands, are very scare. Very recently, Usón and co-workers have characterised octanuclear $\{[Pd(\mu\text{-}SC_6F_5)(\mu\text{-}dppm)Pd](\mu\text{-}SC_6F_5)\}_4$, in which the oxidation state of palladium remains +1.[7] We have been interested in the chemistry of metal–thiolate–diphosphine complexes and a series of complexes, such as $[Co\{Ph_2P(CH_2)_3PPh_2\}(SPh)_2]$,[8a] $[Co_2(SPh)_4(dppx)]$,[8b,c] and $[Pd(SR)_2(dppx)]$ [dppx = $Ph_2PCH_2PPh_2$, $Ph_2P(CH_2)_2PPh_2$][9] have been isolated. Herein we report the synthesis, crystal structure, and properties of a novel tetranuclear palladium(II) complex with asymmetric coordination of palladium atoms, $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-}dppm)_2Cl_2]\cdot 2DMF$ **2**.

In DMF solution, $[Pd_2(dppm)_2Cl_2]$ was reacted with Se and $NaSCH_2Ph$ giving rise to **2**.† In this reaction, Pd(I) was oxidised to Pd(II) and an Se atom was inserted into the binuclear complex to form the A-frame complex $[Pd_2(dppm)_2Cl_2(\mu\text{-}Se)]$; one of the dppm ligands in the A-frame complex was oxidised to dppmSe by excess Se and was cleaved in the presence of $NaSCH_2Ph$, one of the Cl^- ligands was removed and the A-frame complex was then condensed into the tetranuclear complex **2** through forming μ_3-Se and μ-SCH_2Ph.

$$[Pd_2(dppm)_2Cl_2] \xrightarrow{Se} [Pd_2Se(dppm)_2Cl_2] \xrightarrow[NaSCH_2Ph]{Se} [Pd_4Se_2(SCH_2Ph)_2(dppm)_2Cl_2] + dppmSe + NaCl$$

A crystallographic analysis‡ reveals that the complex is a tetranuclear neutral complex. As shown in Fig. 1, two kinds of palladium environments are present: two of the four palladium atoms are each surrounded by two selenium, one sulfur, and one phosphorus atom forming a distorted square-planar arrangement; the other two are each asymmetrically surrounded by one selenium, one phosphorus, one sulfur, and one chlorine atoms in a highly distorted square-planar arrangement. The sulfur atom of each thiolate ligand is shared by two Pd atoms forming a μ-bridge, while each selenium acts as μ_3-bridge linking three palladium centres. The four palladiums form a zigzag chain with a Pd–Pd distance of 3.191(3) Å, much longer than that in $Pd_2(SCH_2CH_2S)_2(PPh_3)_2$ [3.038(2) Å],[10a] but shorter than that

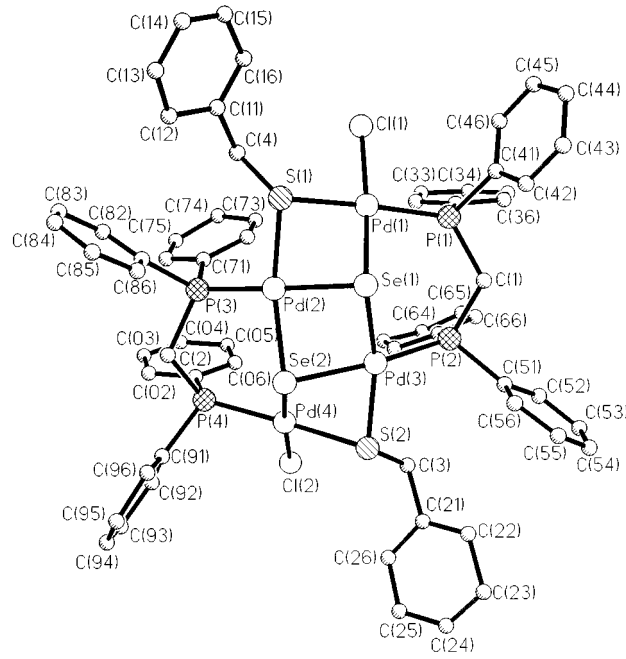

Fig. 1 Molecular structure of $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-}dppm)_2Cl_2]\cdot 2DMF$ with solvent molecules and H atoms omitted. Selected bond lengths (Å) and bond angles (°): Pd(1)–Pd(2), 3.181(3), Pd(2)–Pd(3) 3.228(3), Pd(3)–Pd(4) 3.166(3), Pd(1)–Se(1) 2.387(3), Pd(1)–Cl(1) 2.339(7), Pd(1)–P(1) 2.261(7), Pd(1)–S(1) 2.374(6), Pd(2)–Se(1) 2.432(4), Pd(2)–Se(2) 2.397(3) Pd(2)–P(3) 2.263(7), Pd(2)–S(1) 2.331(6), Pd(3)–Se(1) 2.383(4), Pd(3)–Se(2) 2.446(3), Pd(3)–P(2) 2.262(6), Pd(3)–S(2) 2.326(7) Pd(4)–Se(2) 2.393(4), Pd(4)–Cl(2) 2.345(8), Pd(4)–P(4) 2.264(7), Pd(4)–S(2) 2.381(8); Pd(1)–Pd(2)–Pd(3) 77.9(1), Pd(2)–Pd(3)–Pd(4) 77.0(1), Se(1)–Pd(1)–Cl(1) 173.1(2), Se(1)–Pd(1)–P(1) 94.7(2), Cl(1)–Pd(1)–P(1) 91.1(2), Se(1)–Pd(1)–S(1) 79.5(2), Cl(1)–Pd(1)–S(1) 94.5(2), P(1)–Pd(1)–S(1) 173.3(2), Se(1)–Pd(2)–Se(2) 83.7(1), Se(1)–Pd(2)–P(3) 171.7(2), Se(2)–Pd(2)–P(3) 97.8(2), Se(1)–Pd(2)–S(1) 79.4(2), Se(2)–Pd(2)–S(1) 157.4(2), P(3)–Pd(2)–S(1) 101.1(2), Se(1)–Pd(3)–Se(2) 83.7(1), Se(1)–Pd(3)–P(2) 96.8(2), Se(2)–Pd(3)–P(2) 169.6(2), Se(1)–Pd(3)–S(2) 159.1(2), Se(2)–Pd(3)–S(2) 79.8(2), P(2)–Pd(3)–S(2) 101.7(2), Se(2)–Pd(4)–Cl(2) 174.6(2), Se(2)–Pd(4)–P(4) 95.5(2), Cl(2)–Pd(4)–P(4) 89.4(3), Se(2)–Pd(4)–S(2) 79.8(2), Cl(2)–Pd(4)–S(2) 95.2(3), P(4)–Pd(4)–S(2) 173.8(2), Pd(1)–Se(1)–Pd(2) 82.6(1), Pd(1)–Se(1)–Pd(3) 115.2(1), Pd(2)–Se(1)–Pd(3) 84.2(1), Pd(2)–Se(2)–Pd(3) 83.6(1), Pd(2)–Se(2)–Pd(4) 112.5(1) Pd(3)–Se(2)–Pd(4) 81.7(1), Pd(1)–S(1)–Pd(2) 85.1(2), Pd(3)–S(2)–Pd(4) 84.5(2).

in $Pt_2\{SCH_2CH_2C(CH_3)=CH_2\}_2(PPh_3)_2I_2$ [3.539(1) Å].[11] The average Pd–S–Pd angle [98.6(2)°] is much more obtuse than that in $Pd_2(SCH_2CH_2S)_2(PPh_3)_2$ [80.63(6)°][10*a*] and the average Ni–S–Ni angles in $Ni_2(SCH_2CH_2S)_2(PPh_3)_2$ (82.41°)[10*b*] and $Ni_2\{SCH(CH_3)CH_2S\}_2(PPh_3)_2$ (81.11°).[10*c*] The average Pd–P bond length of 2.291(6) Å is similar to those reported in the Pd–S–P complexes.

^{31}P NMR spectra of the complex show two peaks at 18.595 and 14.493 ppm. It is clear that the P nucleus is deshielded to downfield, indicating that the electrons are transferred from phosphorus atoms to the metal atoms to cause the P nucleus to be deshielded to downfield and the chemical shifts increased.

† *Synthesis* of $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-}dppm)_2Cl_2]\cdot 2DMF$: $NaSCH_2Ph$ (0.42 g, 3 mmol) and selenium powder were dissolved in 15 cm^3 of DMF and the solution was stirred for 12 h. A suspension of $[Pd_2(dppm)_2Cl_2]$ (1.52 g, 6 mmol) in 15 ml of DMF was then added to the solution which turned gradually red-brown with a small amount of black precipitate. The final reaction solution was filtered and the dark-red filtrate was kept at 4 °C. After two weeks, red plate crystals of **2** were collected and washed with distilled water and acetone(yield 22%). Found: C, 45.90; H, 4.12; N, 1.58. Calc. for $C_{70}H_{72}N_2O_2P_4S_2Cl_2Se_2Pd_4$: C, 46.30; H, 4.00; N, 1.54%. IR(KBr): 445(m), 426(m), 375(w), 340(w), 318(w), 300(w), 270(w) cm^{-1}.

‡ *Crystallographic data:* crystal dimensions: 0.25 × 0.30 × 0.30 mm, $C_{70}H_{72}N_2O_2P_4S_2Cl_2Se_2Pd_4$, M = 1815.7, space group $P\bar{1}$ (no. 2), a = 11.203(2), b = 14.928(2), c = 22.354(3) Å, α = 82.27(2), β = 86.86(2), γ = 74.62(2)°, V = 3890(1) $Å^3$, μ = 2.091 mm^{-1}, Z = 2, $R(R_w)$ = 0.086(0.097). Cell dimension measurements and data collections were performed on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-Kα radiation at 23 ± 1 °C. Intensity data were obtained in the range $3.0 \leqslant 2\theta \leqslant 50.0°$ by using the ω scan technique. The data reductions were performed on a Silicon Graphics computer station with Smart CCD software. For the structural analyses, all calculations were performed on an HP/586 computer using SHELXL-PC. The positions of all the palladium, selenium, sulfur, and phosphorus atoms were determined by direct methods, and successive difference electron density maps located the remaining non-hydrogen atoms. All non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were generated geometrically (C–H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their respective parent C atoms before the final cycle of least-squares refinement. One phenyl ring exhibiting disorder was fixed as an idealized rigid group. The final anisotropic refinement of all non-hydrogen atoms on F_o for 5438 observations [$F \geqslant 4.0\sigma(F)$] and 593 variables led to convergence. CCDC 182/985.

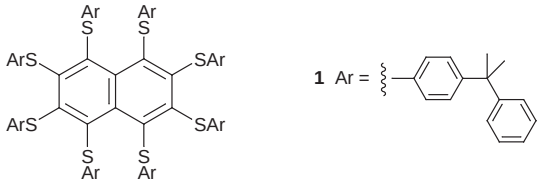
In its stoichiometric 1:1 clathrate with acetone, studied by X-ray diffraction at 123 K, the title host molecule possesses a unique abbbabbb conformation with six side-chain units anti-parallel to the other two; the guest acetone's conformation exhibits non-crystallographic C_2 symmetry, and the observed lowering in symmetry from C_{2v} in the vapour is accompanied by a significant opening of the guest's C–C–C angle, in accord with a key theoretical prediction in the literature (*J. Chem. Phys.*, 1993, 98, 2754).

In the design of new spider host molecules, suitably per-substituted naphthalenes, a challenging goal is to establish the precise way in which the structure of the side-chain unit of a given host controls its ability to form crystalline inclusion compounds.[1] For this host series we have stressed the critical role of the host's molecule conformation; this is well illustrated in the case of octakis(3,4-dimethylphenylthio)naphthalene which, in the course of its self-assembly to form nano-scale cavities capable of trapping diverse guest species,[2] adopts an exactly D_2-symmetric **aabbaabb** conformation, (**a** and **b** denoting side-chain units projecting, respectively, above and below the aromatic core). We now report the synthesis of the new spider host octakis[4-(2-phenylpropan-2-yl)phenylthio]-napthalene **1**, possessing a more extended side-chain unit,



which was initially characterised by ^{1}H NMR, ^{13}C NMR and microanalytical data.‡ The new host **1**, contrasting with the broad inclusion spectrum found for its above-mentioned counterpart, appears to be specific[3] to acetone alone, suggesting the efficiency with which this guest is embedded in the host lattice of **1**. A strictly 1:1 crystalline inclusion compound was formed on recrystallisation of unsolvated **1** from neat acetone.

A low-temperature (123 K) X-ray diffraction analysis was undertaken to determine the host conformation, the conformation of the acetone guest, and the nature of host–guest interactions in this unique adduct of **1**. The 1:1 acetone adduct of **1** is triclinic, space group *P*1, with two host and two acetone guest molecules per unit cell.§ The striking host conformation of **1**, illustrated in Fig. 1(*b*) (the enantiomeric form is also present in the centrosymmetric crystal), is of the previously unknown **abbbabbb** type, with six of the eight side chain units projecting in the opposite direction to the other two. The conformation is close to C_2-symmetric, with the non-crystallographic two-fold axis running normal to the mean plane of the naphthalene core, and bisecting its central carbon–carbon bond. The naphthalene core is markedly non-planar, but almost exactly C_2 in character; corresponding displacements form the ten-carbon mean plane are C(1), C(5), −0.22, −0.23; C(2), C(6), −0.25, −0.25; C(3), C(7), 0.07, 0.08; C(4), C(8), 0.31,

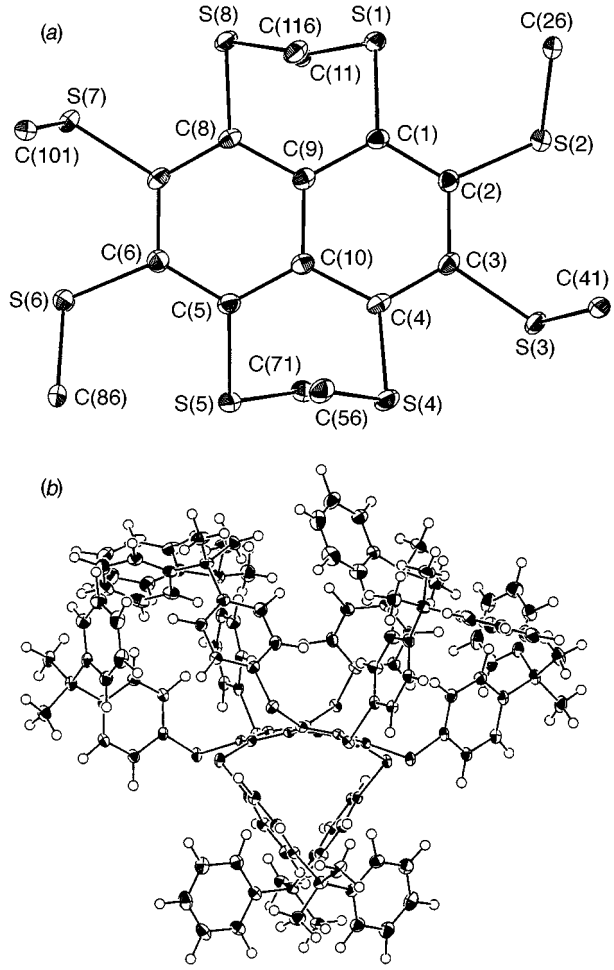


Fig. 1 (*a*) Atomic numbering scheme for the central region of **1** in its acetone clathrate; (*b*) a view illustrating the structure and conformation of the host molecule **1** in its 1 : 1 triclinic adduct with acetone. The host molecule's non-crystallographic C_2 axis is vertical in this view. The distribution of bond lengths (Å) about the naphthalene core is: C(1)–C(2), 1.386(3); C(3)–C(4), 1.386(3); C(5)–C(6), 1.393(3); C(7)–C(8), 1.388(3); C(2)–C(3), 1.424(3); C(6)–C(7), 1.424(3); C(1)–C(9), 1.442(3); C(4)–C(10), 1.439(3); C(5)–C(10), 1.444(3); C(8)–C(9), 1.439(3); C(9)–C(10), 1.427(3). The core bond angles (°) are C(9)–C(1)–C(2), 120.4(2); C(1)–C(2)–C(3), 119.3(2); C(2)–C(3)–C(4), 120.9(2); C(3)–C(4)–C(10), 119.8(2), C(10)–C(5)–C(6), 120.0(2); C(5)–C(6)–C(7), 119.5(2); C(6)–C(7)–C(8), 120.7(2); C(7)–C(8)–C(9), 120.0(2); C(10)–C(9)–C(1), 118.7(2); C(8)–C(9)–C(10), 117.0(2); C(8)–C(9)–C(1), 124.2(2); C(9)–C(10)–C(5), 118.4(2); C(4)–C(10)–C(9), 116.8(2); C(4)–C(10)–C(5), 124.5(2).

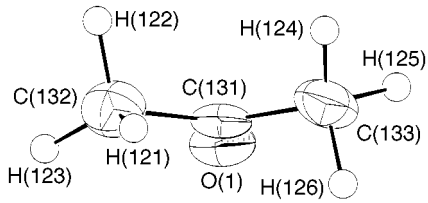

Fig. 2 The near C_2-symmetric conformation of acetone in its 1:1 adduct with host **1** as viewed at a narrow angle to the C=O bond direction

0.30 Å. The average esd for the carbon displacements is 0.002 Å. The corresponding displacements for S(1), S(5); S(2), S(6); S(3), S(7); S(4), S(8): −0.92, −0.89; −0.78, −0.76; 0.18, −0.05; 1.03, 1.00 Å [for other structural data, see caption to Fig. 1(*b*)].

The acetone guest molecule, which also occupies a general position in the unit cell, is shown in Fig. 2. As for the host molecule **1**, all hydrogen atoms were located and, again, the molecule possesses non-crystallographic C_2 symmetry. The non-hydrogen atoms of the guest are exactly coplanar, the angles being C(132)–C(131)–C(133) = 118.3(3), O(1)–C(131)–C(132) = 120.7(3) and O(1)–C(131)–C(133) = 121.0(3)°. The bond lengths are similar to those found for acetone in the vapour phase from a combined analysis of microwave and electron diffraction data[4] [given in parenthesis, for comparison]: O(1)–C(131) = 1.211(3) [1.210(4)], C(131)–C(132) = 1.499(4) [1.517(3)] and C(131)–C(133) = 1.498(4) [1.517(3) Å].

The acetone *conformation* in host **1**, subject to a number of weak host–guest hydrogen–hydrogen interactions (*vide infra)*, is distinct from the C_{2v} equilibrium symmetry situation in the vapour phase, where the in-plane methyl hydrogens eclipse the oxygen atom. It is interesting to note that Smeyers and coworkers[5] have predicted that methyl group rotation, away from the above C_{2v} conformation, will lead to an increase in the C–C–C bond angle. This is in keeping with observation; the C–C–C bond angle for the C_2 guest conformation, 118.2(3)°, is indeed significantly opened compared to the value, 116.0(3)°, for this angle in the C_{2v} vapour phase conformation of acetone. It must be said, of course, that the guest acetone's skeletal geometry may be subject to other host–guest influences, in addition to conformational control by the host lattice.[6] The acetone guest molecule experiences no strong host–guest interactions, and is present in an environment of low polarity. There are no fewer than 17 hydrogen–hydrogen host–guest contacts in the range 2.340–2.959 Å. The closest contact between the host molecule **1** and acetone is of the C–H···O type[7] and has length 2.320 Å. In all, there are five intermolecular contacts between O(1) and hydrogen atoms of **1** and these span the distance range 2.320–2.912 Å.

We thank the EPSRC (UK) for support (to G. A. D.).

‡ Compound **1** was prepared by persubstitution of perfluoronaphthalene with an excess of the appropriate thiolate nucleophile in dipolar aprotic solvent, the required thiol, 4-(2-phenylpropan-2-yl)benzenethiol, being prepared from the corresponding phenol by a general literature method (M.S. Newman and H.A. Karnes, *J. Org. Chem*., 1966, **31**, 3980), and having mp 43–44 °C (Calc. for $C_{15}H_{16}S$: C, 78.90; H, 7.02. Found: C, 78.78; H, 7.15%). Perfluoronaphthalene (0.26g, 0.96 mmol) and sodium 4-(2-phenylpropan-2-yl)benzenethiolate (3.74g, 15.3 mmol), prepared from the above thiol and sodium in absolute ethanol, were stirred in dry, degassed 1,3-dimethylimidazolidin-2-one (DMEU) (40 ml) for 3 h at ambient temperature, under N_2. The red–orange reaction mixture was then added to toluene (200 ml), washed with water (10 × 250 ml), and evaporation of the solvent gave a red oil, from which compound **1** was obtained by column chromatography (silica, hexane–EtOAc) as a orange–red microcrystalline material, 1.51g (81%), mp 161–162 °C. *Selected data* for **1**: δ_H(200 MHz, $CDCl_3$) 1.51 (s, 24H), 1.54 (s, 24H), *ca*. 6.6–6.9 (two AA′BB′ spectra, 32H), *ca*. 7.0–7.3 (m, 40H); δ_C(50 MHz, $CDCl_3$) 30.6, 30.7, 42.6, 42.7, 125.6, 125.7, 126.6, 126.7, 126.9, 127.4, 127.5, 128.0, 128.1, 128.9, 134.8, 135.7, 139.6 (overlapping resonances), 143.7, 148.4, 148.9, 150.1, 150.5 (Calc. for $C_{130}H_{120}S_8$: C, 80.57; H, 6.20. Found: C, 80.52; H, 6.29%).

§ *Crystal data* for **1**·$(CH_3)_2CO$: $C_{133}H_{126}O_1S_8$, M_r = 1996.82, triclinic, space group *P*1, a = 19.299(9), b = 20.235(11), c = 16.338(5) Å, α = 92.15(4), β = 104.71(3), γ = 118.47(4)°, U = 5330(4) Å^3, Z = 2, ρ_{calc} = 1.244 Mg m^{-3}, $F(000)$ = 2120, μ = 0.221 mm^{-1}, T = 123(1) K. Crystal dimensions, orange prism, 0.80 × 0.38 × 0.22 mm. Mo-Kα radiation (0.71069 Å), θ_{max} = 25.02°, 19 349 reflections collected, 18 743 unique reflections R_{int} = 0.0216, 15 294 reflections observed [> 2$\sigma(I)$]. Final R (on F using observed data) a *wR*2 (on F^2 using all data) were 0.0372 and 0.1044 respectively for 1279 parameters. Final GOF = 1.002. Maximum and minimum residual density 0.416 and −0.415 e Å^{-3} respectively. Data were collected on a Rigaku AFC7R diffractometer equipped with an Oxford Cryosystems cryostream cooler (ref. 8). The structure was solved using direct methods (SHELXS-86) (ref. 9) and refined on F^2 using all unique data by full-matrix least-squares (SHELXL-93) (ref. 10). All non-hydrogen atoms have anisotropic displacement parameters. All hydrogen atoms were located in difference syntheses, these were assigned a common temperature factor and included in the model but not refined. CCDC 182/983.

6 With regard to the crystalline state, 1109 X-ray crystal structure analyses have been reported for systems in which acetone is present as a ligand component coordinated to a metal (*e.g*. R. Amstutz, J. D. Dunitz, T. Laube, W. B. Schweizer and D. Seebach, *Chem. Ber*., 1986, **119**, 434; M. Hoyer and H. Hartl, *Z. Anorg. Allg. Chem*., 1992, 612) or is 'anchored' in the lattice by one or more hydrogen bonds (*e.g*. C. P. Brock and G. L. Morelan, *J. Phys. Chem*., 1986, **90**, 5631). Both these situations tend to attenuate thermal motion, favouring direct observation of the acetone's hydrogen atoms, but represent relatively strong host–guest interactions. When such motion-reducing interactions are absent, the acetone molecule normally exhibits high thermal motion and/or disorder, however, see for example, A. Dietrich, K. A. Fidelis, D. R. Powell, D. van der Helm and D. L. Eng-Wilmot, *J. Chem. Soc., Dalton Trans*., 1991, 231; A. Avdeef and W. P. Scheafer, *J. Am. Chem. Soc*., 1976, **98**, 5153. Interestingly, no X-ray results from the molecular crystal of acetone itself have yet appeared in the literature.

A new and easy method for making micrometer-sized carbon tubes

Chien-Chung Han,*† Jyh-Tsung Lee, Reen-Woei Yang, Hua Chang and Chein-Hwa Han‡

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan, ROC

Highly crystalline and single-walled micrometer-sized carbon tubes several centimeters in length have been prepared *via* the pyrolysis of composite fibers consisting of a thermally stable polypyrrole skin layer and a thermally degradable PET core fiber.

Studies on the formation and growth mechanism[1] of nano-size carbon tubes have attracted a lot of research interest in recent years, due to their potential in applications like electron field emitters,[2] nanowires,[3] catalytic micro-reactors and natural gas storage. Various methods have been reported for the preparation of carbon tubes; these include carbon-arc discharge,[4] laser ablation,[5] condensed-phase electrolysis,[6] and the catalytic pyrolysis of hydrocarbons on various substrates such as porous anodic aluminium oxide,[7] fine metal particles[8] and patterned cobalt layers.[9] Regarding nano-tubes, their potential as micro-reactors might be significantly limited due to their relatively small inner diameters, which could preclude the entry of large reactive species or reactants. However, for micrometer-sized carbon tubes, with their relatively larger inner diameter, it would be easier to perform inner surface modifications *via* treatment with various chemicals and render the inner surface active, thus enabling selective separation (or extraction) of interested compounds. Likewise, it would also be easier to embed desired transition metal complexes (with sizes often larger than 2–3 nm) on the inner surface of micrometer-sized tubes, to impart specific catalytic functions. It is envisaged that, with their larger inner tube diameter, the throughput of micrometer-sized tube micro-reactors should be acceptable for practical applications. Similarly, it should also be relatively easier to activate chemically both the inner and outer surfaces of micrometer-sized tubes to facilitate the formation of micro- or meso-porous features, making them suitable for natural gas storage. Although hollow carbon fibers of sub-millimeter size, with 0.4 mm inner diameter and 0.6 mm outer diameter, had been prepared *via* the carbonization of spun poly(acrylonitrile) hollow fibers,[10] there is still a lack of a feasible and reliable method for making thin-walled carbon tubes with diameters in the range of 1–100 μm.

Here, a new and feasible method for the preparation of micrometer-sized single-walled carbon tubes is proposed. The method also enables convenient control of both the diameter and wall thickness of the resultant carbon tubes. Tubes several centimeters in length and pre-organized in one- or two-dimensional matrices have been obtained experimentally.

These carbon tubes were prepared from polypyrrole (PPy)-coated poly(ethylene terephthalate) (PET) fibers by heating the composite fibers at 1000 °C for 3–6 h under an N_2 atmosphere. The PPy coatings were applied *via* a typical reaction-coating approach,[11] by suspending commercially available PET fibers in an aqueous pyrrole solution that contained 2 equiv. of toluene-*p*-sulfonic acid, followed by the addition of oxidants to initiate the polymerization of pyrrole. The resulting PPy thus formed presented itself as a homogeneous black coating on the surface of the PET fibers. The thickness of such PPy coatings could be controlled by altering the pyrrole concentration of the reaction solution, and by the number of reaction-coating treatments conducted. The resulting PPy-coated PET fibers were then slurry-washed with copious amounts of de-ionized water and air-dried for 48 h. The PPy/PET composite fibers, as shown in Fig. 1(*a*), were then placed in a quartz oven and heated from room temperature to 1000 °C at a heating rate of 10 °C min^{-1} under an N_2 atmosphere. An annealing time of between 3 to 6 h was employed after the temperature reached 1000 °C. During the heating and annealing process, some white solid sublimed out of the oven and was identified as a mixture of terephthalic acid and 4-(vinyloxycarbonyl)benzoic acid.§ Most of this solid was collected at between 400 and 500 °C, consistent with the decomposition temperature of the PET fibers. All the carbon fibers obtained after the thermal treatment were found to be hollow tubes with uniform diameters and wall thicknesses, as illustrated by the SEM micrographs in Fig. 1. The wall thickness of such carbon tubes was found to be directly proportional to the thickness of the original PPy coating layer. For example, composite fibers with PPy layer thicknesses of 1.2 (±0.2), 1.5 (±0.3) and 2.0 (±0.3) μm yielded carbon tubes with an average wall thicknesses of 0.38 (±0.05), 0.63 (±0.08) and 1.3 (±0.2) μm, respectively. The electron micrographs of these carbon tubes are illustrated in Fig. 1(*b*)–(*d*). Thermogravimetric analysis of the same composite fibers also showed similar trends on mass retention, with composite fibers having thicker PPy layers displaying higher mass retention after annealing at

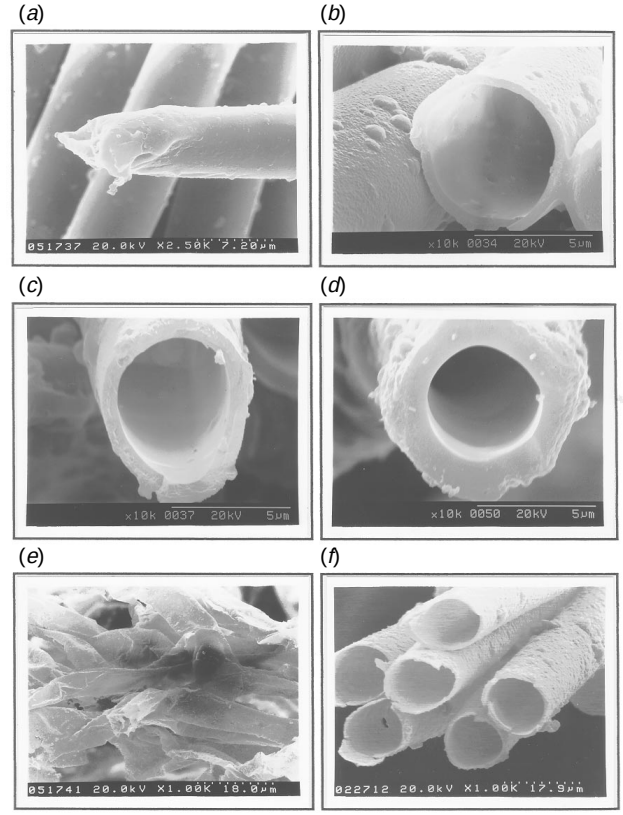

Fig. 1 SEM micrographs for (*a*) PPy/PET composite fibers, (*b*)–(*d*) resultant carbon-tubes of similar diameter (*ca.* 7.5 μm), but with different wall thickness, (*e*) collapsed thin-walled carbon tubes and (*f*) carbon tubes of *ca.* 15 μm diameter

1000 °C. Interestingly, it was found that a minimum thickness of the PPy layer was required to provide sufficient mechanical strength to keep the tubes intact and maintain their round shape during the carbonization process. Fig. 1(*e*) illustrates that, when the PPy layer was less than *ca*. 100 nm in thickness, all the resulted carbon tubes collapsed. Carbon tubes of different sizes can also be prepared from PET fibers with different diameters. For example, carbon tubes with 15 μm in inner diameter [Fig. 1(*f*)] were prepared from PET fibers with a diameter of 16 μm.

All the carbon tubes prepared by the present method were found to be rich in carbon. Elemental analysis results indicated that these tubes consisted essentially of pure carbon, accompanied by small amount of N (< 3 wt%) and H (< 1 wt%). Similar results were obtained by scanning auger microscopy (SAM). A typical SAM spectrum for the outer wall of the carbon tubes clearly reveals that only the C peak at 275 eV is present. The N peak of the original PPy layer at 388 eV had almost completely disappeared. The reduction in N was probably caused by de-nitrogenation of the PPy coating during thermal treatment. Similar de-nitrogenation phenomena had also been reported for the thermal carbonization treatment of poly(acrylonitrile) at *ca.* 800 °C.[12] The de-nitrogenation reaction for the carbon tubes in this study appeared to have taken place throughout the entire tube, as indicated by the SAM spectra for the cross-section and the inner wall of the tubes. Furthermore, the SAM spectrum for the inner wall of the tubes showed hardly any sign of the O peak at 514 eV due to PET core fiber. This suggested that the PET core fiber had decomposed completely, and the tube wall was essentially converted from the original PPy skin layer of the composite fiber.

The use of single-pulse magic-angle-spinning solid-state ^{13}C NMR showed that the carbon of these tubes was unsaturated in nature, with its spectrum showing a complicated broad band between δ 70–160 and a maximum at *ca.* δ 120. The unusual peak broadening may be attributed to the slightly different chemical environment of each carbon atom in the network and its corresponding pair of spinning side-bands. No saturated sp^3 carbons in the range δ 0–70 nor any significant amount of carbonyl carbons between δ 160–300 were observed. The infrared spectra of ground-up carbon tubes as KBr pellets were completely featureless, probably due to the highly symmetric bonding nature of the tubes, as in the case of a carbon matrix with an extensive network. The Raman spectrum for the ground-up carbon tubes showed two bands at *ca.* 1354 and 1584 cm^{-1}, similar to those bands for graphite.

The most intriguing finding in the present study is that, although the carbonized product of PPy powder [annealed at 1000 °C for 3 h] was totally amorphous, the carbon tubes prepared in this study from PPy/PET composite fibers were highly crystalline. The X-ray diffraction spectrum for the ground-up carbon tubes, obtained using a Shimadzu X-ray diffractometer XD-5 with a Cu-Kα radiation source, showed two rather strong and sharp peaks at 2θ = 21.4 and 23.8°, equivalent to a *d*-spacing of 4.15 and 3.74 Å, respectively. Although the X-ray diffraction results indicated the presence of highly crystalline carbons in the tube wall, the lattice structure appeared to be different from the sheet-like morphology of graphite,¶ as the strongest diffraction peak for graphite is at 2θ = 26.6°. Further exploration of the crystalline nature of these carbon tubes with high resolution transmission electron microscopy (TEM) is in progress. It is believed that the surface of the highly stretch-oriented PET fibers might have acted as a template for the arrangement of deposited PPy chains during the polymerization coating process. The formation of more ordered and pre-arranged PPy matrices could increase the possibility of crystalline carbon formation during the carbonization process. The formation of induced structural order in carbon layers on fibres has also been observed for resin-based matrices in carbon–carbon composites.[13]

Using the present new method, carbon tube bundles several centimeters in length have been prepared with little difficulty, and SEM inspection of tubes thus prepared confirmed that they were completely hollow. Similarly, a two-dimensional matrix of carbon tubes has also been successfully prepared for the first time *via* the carbonization of a PPy-coated PET cloth.

A possible carbon tube formation mechanism is suggested as follows. The core PET fibers first melt at *ca.* 254 °C when the crystalline melting point of PET is reached. The PET then decomposes into terephthalic acid and 4-(vinyloxycarbonyl)-benzoic acid by-products *via* intra-chain β-elimination of the ester group between 400 to 500 °C.‖ The resultant by-products then sublime at these elevated temperatures, forming the hollow cores.** Meanwhile, the PPy skin layer also starts to decompose at its decomposition on-set temperature (*i.e.* 310 °C for undoped PPy powder), with the resulting active intermediate species very likely to induce efficient cross-linking of the highly π-bond-conjugated PPy, thus setting up the three-dimensional network of carbon tubes.

The characterization of valence tautomeric cobalt complexes with an array of four states, each with different optical and magnetic properties, is reported and it is shown that they can interconvert reversibly between the four states either thermally or by redox processes.

Complexes of the composition [Co(3,5-DTBCat)(3,5-DTBSQ)(NN)], where 3,5-DTBCat^{2-} and 3,5-DTBSQ^{-} refer, respectively, to the catecholate (Cat^{2-}) and semiquinonate (SQ^{-}) forms of 3,5-di-*tert*-butyl-*o*-quinone, and NN is a chelating diiminium ligand such as 2,2′-bipyridine (bpy, complex **1**) or 1,10-phenanthroline (phen, complex **2**), exhibit valence tautomerism.[1,2] These complexes can be interconverted in solution or in the solid state by means of different external stimuli such as temperature, pressure or irradiation between a high-spin [Co^{II}(SQ)$_2$(NN)] (*hs*-Co^{II}) or a low-spin [Co^{III}-(Cat)(SQ)(NN)] (*ls*-Co^{III}) form with appreciable changes in their electronic absorption spectra and magnetic ground states.[3–6] In solution, the equilibrium in eqn. (1) can be induced by variations of temperature and monitored by UV–VIS spectroscopy.

$$[Co^{III}(SQ)(Cat)(NN)]\ (ls\text{-}Co^{III}) \rightleftharpoons [Co^{II}(SQ)_2(NN)]\ (hs\text{-}Co^{II}) \quad (1)$$

At low temperatures, there is a band at ≈600 nm characteristic of the *ls*-Co^{III} tautomer. As the temperature of the solution is increased the intensity of the 600 nm band decreases and a band at ≈770 nm characteristic of the *hs*-Co^{II} tautomer increases in intensity. Here we report how this valence tautomerism equilibrium may be converted into an array of four states with different magnetic and optical properties that interconvert reversibly between them, where the additional switching capacity results from an electrochemical process.

The reversible redox characteristics of complexes **1** and **2** were employed to develop the square array shown in Fig. 1. A CH_2Cl_2 solution of complex **1** at 273 K with 0.1 M $NBu^n_4PF_6$ as a supporting electrolyte is mostly in the **1**,*ls*-Co^{III} form, as determined by UV–VIS spectroscopy. The CV of **1**,*ls*-Co^{III} under these conditions exhibits a reversible reduction at E_0 = −0.34 and a reversible oxidation at +0.25 V *vs*. a Ag wire (E_0 of ferrocene under the same experimental conditions is +0.36 V). Previous studies of different *o*-quinone metal complexes have shown that the redox processes occur at the quinone ligands.[7] Therefore, the first process at −0.34 V for complex **1**,*ls*-Co^{III} involves the reduction of the semiquinonate ligand to the catecholate form, whereas the second process involves the oxidation of the catecholate ligand of **1**,*ls*-Co^{III} to the semiquinonate ligand form. A CH_2Cl_2 solution of complex **2** at 305 K with 0.1 M $NBu^n_4PF_6$ as a supporting electrolyte is mostly in the **2**,*hs*-Co^{II} form. The CV of **2**,*hs*-Co^{II} exhibits a reduction process at E_0 = −0.2 V *vs*. a Ag wire. This process corresponds to the reduction of both semiquinonate ligands to catecholate ligands. Examination of the scan rate (υ) dependences for the processes observed for both tautomers showed a linear dependence of the peak current with respect to $\upsilon^{1/2}$, indicating that these redox processes are diffusive. Constant-potential electrolysis experiments have confirmed the reversibility of the different processes. Thus, both of the valence tautomers in eqn. (1) can be reduced reversibly. This allowed us to establish the square array shown in Fig. 1.

Treatment of complex **1**,*ls*-Co^{III} in CH_2Cl_2 at 273 K with 1 equivalent of $Co(Cp)_2$ yielded [Co(Cp)$_2$][Co^{III}(3,5-DTBCat)$_2$(bpy)] (**3**,*ls*-Co^{III}) as a dark-green polycrystalline solid (70% yield).† The S = 0 ground state was confirmed by variable-field magnetization data collected at 2.3 and 5.0 K. The presence of two catecholate ligands was also confirmed by an increase (relative to complex **1**) in the intensity of the characteristic catecholate C–O IR bands seen at ≈1250 cm^{-1}. Our interest in complex **3** was considerably enhanced when it was found that the electronic absorption spectrum of this complex in acetone exhibited a temperature dependence consistent with the following valence-tautomeric equilibrium:

$$[Co^{III}(Cat)_2(bpy)]^-\ (\mathbf{3},ls\text{-}Co^{III}) \rightleftharpoons [Co^{II}(SQ)(Cat)(bpy)]^-\ (\mathbf{3},hs\text{-}Co^{II}) \quad (2)$$

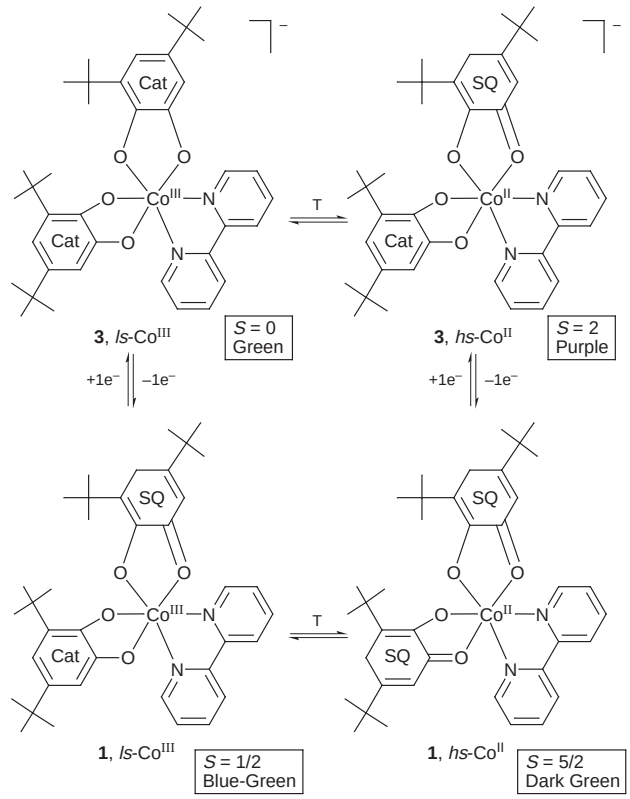

Fig. 1 Diagram of a dual-mode switching array. Complexes **1** and **3** each undergo a valence tautomeric interconversion and the tautomers of complex **3** are obtained reversibly by one-electron reduction of the tautomers of complex **1**. An array of four different states with different optical and magnetic ground states is then obtained.

As shown in Fig. 2, at low temperatures there is an intense band at 405 nm and a second less intense transition at 610 nm, where both bands are characteristic of the (**3**,*ls*-Co^{III})$^-$ isomer. Increasing the temperature converts this *ls*-Co^{III} tautomer to the [Co^{II}(3,5-DTBSQ)(3,5-DTBCat)(bpy)]$^-$ tautomer, identified as (**3**,*hs*-Co^{II})$^-$. The acetone solution changes from green at low temperatures to purple at higher temperatures. Two isosbestic points are seen at 360 and 470 nm, indicating that there are two species in equilibrium. When the sample was cooled, the spectrum characteristic of the (**3**,*ls*-Co^{III})$^-$ form was recovered. The cycle was repeated several times, confirming the reversibility of the interconversion although a gradual decrease of the absorbance was observed due to decomposition of the *hs*-Co^{II} form that reacts even with traces of oxygen. A toluene solution of complex **1** at high temperatures is mostly in the **1**,*hs*-Co^{II} form as confirmed by UV–VIS spectroscopy. Therefore, direct reaction of a toluene solution of complex **1** with 1 equivalent of $Co(Cp)_2$ was used to directly give [$Co(Cp)_2$][Co^{II}(3,5-DTBSQ)(3,5-DTBCat)(bpy)] (**3**,*hs*-Co^{II}) as a purple precipitate obtained after filtration from the solution (20% yield).† This solid is highly air-sensitive, however, it was characterized by variable-temperature magnetic susceptibility, electronic absorption and EPR spectroscopies. The value of μ_{eff} varies gradually from 4.24 μ_B at 320 K to 4.04 μ_B at 70.0 K, whereupon there is an increase to 5.14 μ_B at 20.0 K, followed by a decrease to 3.07 μ_B at 3.0 K. These results are consistent with a *hs*-Co^{II}(S = 3/2) complex with one S = 1/2 semiquinonate ligand, where there is a weak ferromagnetic exchange interaction between the ligand and the metal. Dissolution of **3**,*hs*-Co^{II} in acetone gave the same reversible temperature dependence in the UV–VIS electronic spectrum as shown in Fig. 2 for (**3**,*ls*-Co^{III})$^-$, confirming the existence of the valence tautomeric equilibrium **3**,*ls*-Co^{III-} ⇌ **3**,*hs*-Co^{II-}. X-Band EPR spectra showed the eight-line cobalt hyperfine splitting characteristic of Co–quinone systems [A(Co) ≈ 12 G]. Finally, it must be emphasized that additional constant-potential electrolysis experiments confirmed the reoxidation of the anionic complexes to the neutral species demonstrating the validity of the array detailed in Fig. 1. Thus, an array of four states is controlled by two temperature-controlled valence tautomeric equilibria and two reversible redox processes. The possibility of entering the cycle at each state and advancing through the square array in a clockwise and counter-clockwise direction was also established.
