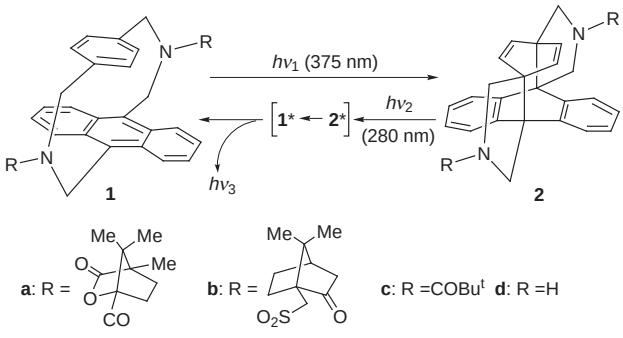
2,11-Diaza[3.3](9,10)anthracenoparacyclophane **1** has been developed as a photochromic material which undergoes photointerconversion with isomer **2**.[1] In the photochromic reaction, we recently found that photocycloreversion of **2** to **1** was chemiluminescent, attributable to the formation of excited **1*** as in the case of non-bridged cycloadducts between benzene and anthracene (Scheme 1).[2,3] Such chemiluminescent photoreactions are attractive as a probe to analyze the potential surface of excited states and as an optical data storage system of read-out by fluorescence.[2–4] We have attempted to introduce a chiral source into the cyclophane system since the chirality may cause circular polarization of both the fluorescence of **1** and the photochemiluminescence of **2** as well as photocontrol of chiroptical properties. Circular polarization of luminescence (CPL) is a useful probe to obtain structural and electronic information in an excited state,[5] and steric and electronic features of the emitting state of the photochemiluminescence may be analyzed by CPL. Here, we report a simple method to introduce molecular chirality into the cyclophane system **1** by modification with a chiral auxiliary, and CPL from the modified **1a** and **2a**.

The cyclophanes **1a** and **1b** were prepared by acylation of the amino derivative **1d** with commercially available (1*S*)-(−)-camphanic chloride and (1*S*)-(+)-10-camphorsulfonyl chloride, respectively. The modified cyclophane **1a** showed circular dichromism (CD) in its absorption bands suggesting the side-chains were fixed in a special conformation inducing molecular chirality (Fig. 1) while **1b** indicated CD only arising from the carbonyl chromophore in the auxiliary camphorsulfonyl groups. As the chiral center in **1b** was separated by one extra methylene group than in **1a**, the camphorsulfonyl group may not restrict the side-chain conformation in **1b**. The conformation of **1a** was analyzed by NOESY spectroscopy. Fig. 2 shows the



Scheme 1

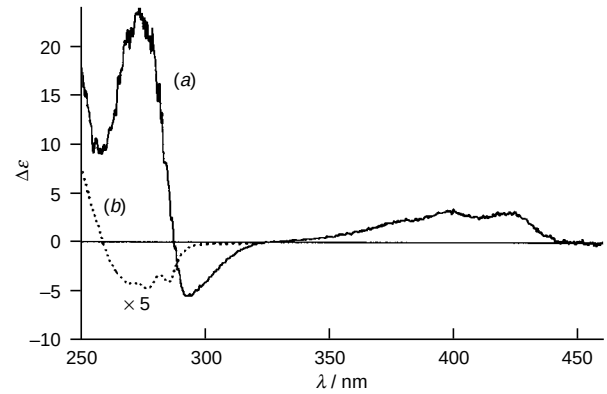


Fig. 1 CD spectra of (*a*) **1a** and (*b*) **2a** in CH_2Cl_2

NOESY spectrum of **1a** in which four cross-peaks important in determining the conformation of **1a** appeared and are correlated by dotted lines. From the spectrum, it is evident that the 7′-Me[1] proton was located close to aromatic protons H_e, H_g and H_j, and

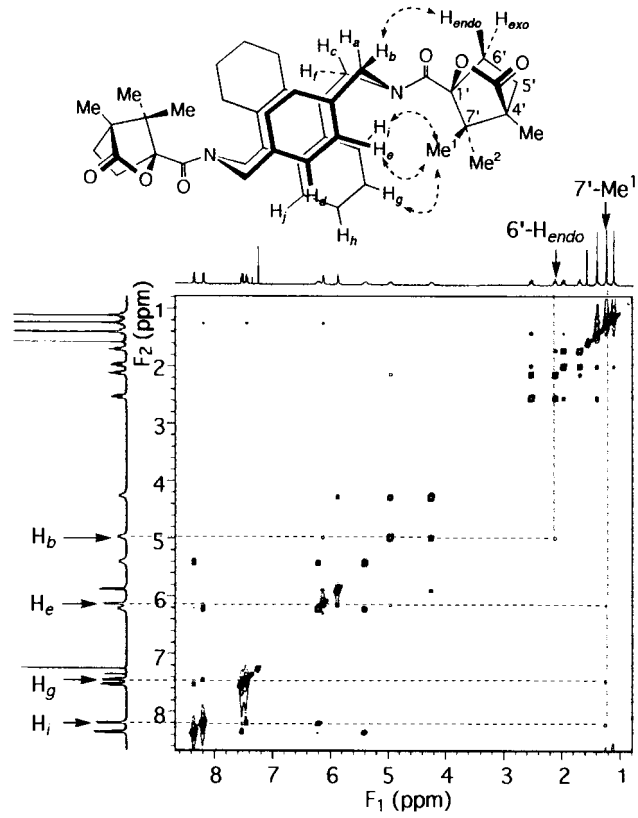

Fig. 2 NOESY spectrum of **1a** in $CDCl_3$ (500 MHz)

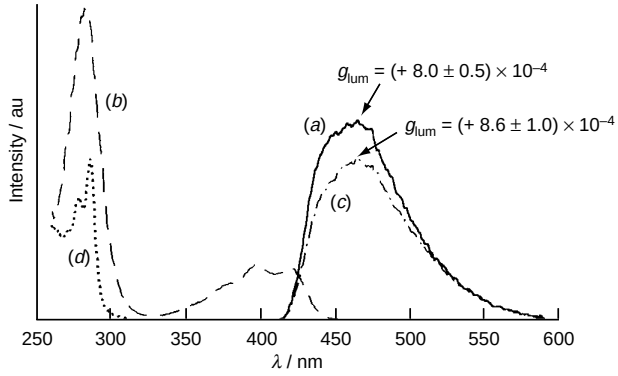

Fig. 3. Fluorescence spectra of **1a** and **2a** (in CH_2Cl_2); (*a*) Emission and (*b*) the excitation spectra of **1a**; (*c*) Photochemiluminescence and (*d*) the action spectra of **2a**. The observed g_{lum} values are shown at the detection wavelength (460 nm).

that 6′-H_{endo} was fixed near by one of the bridge methylene protons H_b. Empirical force field (MM2)[6] calculation showed that **1a** adopted the most stable C_2-symmetrical conformer consistent with the NOESY results .

The cyclophane **1a** underwent photointerconversion with **2a** and a change in CD was detected (Fig. 1). Cyclophane **1a** showed a positive Cotton effect in the longer wavelength absorption band, while **2a** showed a negative Cotton effect in its absorption band centered at 280 nm. The specific rotation of **1a** was $[\alpha]_D^{23}$ ($CHCl_3$) +192° and that of **2a** was $[\alpha]_D^{23}$ ($CHCl_3$) −1.4°.

Compound **2a** underwent chemiluminescent photocycloreversion providing excited **1a*** as in the case of **2** which underwent no conformational restriction such as **2c**.[2] The photochemiluminescence spectrum was the same in profile with that of fluorescence of **1a** (Fig. 3). Fluorescence assignable to **2a** itself was not detected.[3] The action spectrum for the emission of **2a** was identical with the absorption of **2a** showing no contamination with **1a** during the measurement. The quantum yields of fluorescence of **1a** and the photochemiluminescence of **2a** were 0.33 and 0.23, respectively. The decay of both emissions was analyzed as a dual exponential curve and the lifetimes were 7.8 ns (26%) and 18.4 ns (74%) for **1a**, and 6.9 ns (28%) and 16.6 ns (72%) for **2a**.

The fluorescence of **1a** was circular polarized as expected from its structural features. The dissymmetry factor for the fluorescence [$g_{lum} = 2(I_L - I_R)/(I_L + I_R)$; I_L and I_R are intensity of left and right circularly polarized emission, respectively] of **1a** was g_{lum} (+8.0 ± 0.5) × 10^{-4} (λ_{em} = 460 nm, λ_{ex} = 375 nm, in CH_2Cl_2). The CPL for the photochemiluminescence of **2a** was also detected and its g_{lum} value was the same as that of fluorescence of **1a** within experimental error, g_{lum} = (+8.6 ± 1.0) × 10^{-4}(λ_{em} = 460 nm, λ_{ex} = 280 nm in CH_2Cl_2).§ This is the first observation of circular polarization of photochemiluminescence which may enable examination of structural change in an excited state during an adiabatic reaction. The dissymmetry factor for the absorption [$g_{abs} = 2(\varepsilon_L - \varepsilon_R)/(\varepsilon_L + \varepsilon_R)$; ε_L and ε_R are molar absorptivity for left and right circular polarized light, respectively] of **1a** was +6.4× 10^{-4} at 375 nm (in CH_2Cl_2). In the case of **1a**, overlap between fluorescence and long wavelength absorption bands suggested that the fluorescent process was the reverse transition of the absorption [*cf.* Fig. 3, curves (a) and (b)], and the g_{abs} was almost same as g_{lum}. These suggest that the structure of **1a** did not differ largely between the ground and the emitting states. Differently, for **2a**, g_{abs} was −6.3 × 10^{-4} at 280 nm (in CH_2Cl_2) showing opposite sign compared with the g_{lum} of the photochemiluminescence. In the case of **2a**, as the structures of the light absorbing and the emitting species were quite different from each other, the changes of electronic and steric properties during the photoreaction caused inversion of sign between g_{abs} and g_{lum}.

In summary, modification with a chiral camphanic auxiliary induced molecular chirality of the cyclophane **1a** and the photoisomer **2a**. The photoexcited **2a*** rapidly reverted to **1a*** and recalled the electronic and steric features of **1a*** which was the same as those generated on excitation of **1a**.

The authors are grateful to Professor E. W. Meijer of Eindhoven University of Technology for correspondence about CPL and encouragement. The present work was partly supported by the Okayama Foundation for Science and Technology.

‡ Here photochemiluminescence denotes luminescence which is emitted from an electronically excited product formed by an adiabatic reaction of an excited starting molecule ($h\nu_3$ in Scheme 1).

§ In the CPL measurement on **2a**, both the starting **2a** and the photoproduct **1a** were capable of absorbing the excitation light (280 nm), however after the measurement only **2a** was detected in the sample. Thus in the photostationary state **2a** existed preferentially to **1a** and the present CPL observed in photochemiluminescence of **2a** was regarded as that responsible mainly to **2a**.

[LW≡P→$GaCl_3$] 5 [L = $N(CH_2CH_2NSiMe_3)_3$] is prepared by treatment of [LW≡P] with $(GaCl_3)_2$; decomposition of 5 in CH_2Cl_2 affords dimerisation under Me_3SiCl elimination to give a cationic W_2P_2 tetrahedral complex 6; both complexes are structurally characterised.

In 1995 Cummins[1] and Schrock[2] and their coworkers succeeded in the synthesis and the first structural characterisation of complexes **1** and **2**, respectively, containing a metal phosphorus triple bond. Our synthetic goal, however, has been directed towards the alkoxide substituted complexes **3** where the phosphido ligand coordinates additionally to a metal pentacarbonyl fragment.[3] The $^1J_{WP}$ coupling constant was observed to be 554 (**3a**) and 536 Hz (**3b**) for the triple bond and appeared to be in contradiction with the 138 Hz found for the W complex **2a**. To shed light onto this problem we decided to synthesise **2a** (M′ = W) *via* the reaction of [WCl(L)] [L = $N(CH_2CH_2NSiMe_3)_3$] with $Li[P(SiMe_3)_2]$. Subsequent reaction with $[M'(CO)_5(thf)]$ leads to the *trans*-substituted complexes **4**.[4] ^{31}P NMR data (**4a**: δ 679.8, $^1J_{WP}$ 426 Hz; **4b**: δ 728.1, $^1J_{WP}$ 413 Hz) combined with theoretical calculations reveal that the linear coordination of a complex fragment to the phosphido atom is responsible for a dramatic increase of the s character of the triple bond and consequently for the increase of the coupling constant. In further studies it was of interest how coupling constant and triple bond length behave by coordination of a simple σ-acceptor group. Herein we report our results of the reaction of **2a** with group 13 Lewis acids.

The reaction of **2a** with $BH_3{\cdot}SMe_2$ only led to an insoluble solid. Elemental analysis did not indicate the formation of the expected adduct [LW≡P→BH_3]. Even following the reaction by ^{31}P NMR only showed that the starting material disappeared but no new signal could be detected. In the reaction of **2a** with $BF_3{\cdot}OEt_2$ in CH_2Cl_2, however, a ^{31}P NMR signal at δ 607 ($^1J_{WP}$ 478 Hz) could be observed for a short time. Then the reaction mixture became black and insoluble black material precipitated.

Reaction of **2a** with the dimer $[GaCl_3]_2$ in a 2 : 1 ratio in toluene led to the isolation of a yellow crystalline compound **5**, which is sparingly soluble in toluene, thf and CH_2Cl_2.‡ The $^{31}P\{^1H\}$ NMR spectrum of **5** reveals one signal at δ 366 bearing one pair of satellites with $^1J_{WP}$ = 712 Hz. The high field shift as well as the considerable increase of the coupling constant is consistent with those found in **4.** However, the observed coupling constant is one of the largest for these triple bond systems. Almost identical NMR data were detected in the structurally uncharacterised complex $[LW{=}PMe]^+$-$[OTf]^-$ (δ 339, $^1J_{WP}$ = 748 Hz) synthesised by Schrock and coworkers.[5]

The molecular structure of **5** was established by a single-crystal X-ray diffraction study.§ The main feature of the molecular structure of **5** is the entirely linear arrangement of the N_{ax}–W–P–Ga axis (Fig. 1). The Cl atoms of the $GaCl_3$ group are slightly disordered. The orientations of the Cl atoms are slightly eclipsed to the W–N(2) bonds, but staggered to the N(1)–C(1) bond. The W≡P bonding distance is 2.168(4) Å which is only slightly longer than the bond length found in **2a** (2.162 Å). This indicates the replacement of almost the same amount of phosphorus 3p σ-contribution to the W≡P bond in **2a** by 3s-orbital contribution of the former lone pair of the phosphorus, produced through the coordination to a σ-acceptor such as $GaCl_3$. This finds further support from the dramatic increase of $^1J_{WP}$. Owing to the remarkable backbonding ability of the W≡P moiety to the W^0 centre the triple bond length increases from 2.162(4) in **2a** to 2.202(2) Å in **4a**.[4] The most significant difference in bonding distances in comparison to **2a** occurs for the N_{ax}–W bond which is shortened by 0.10 Å. This is probably

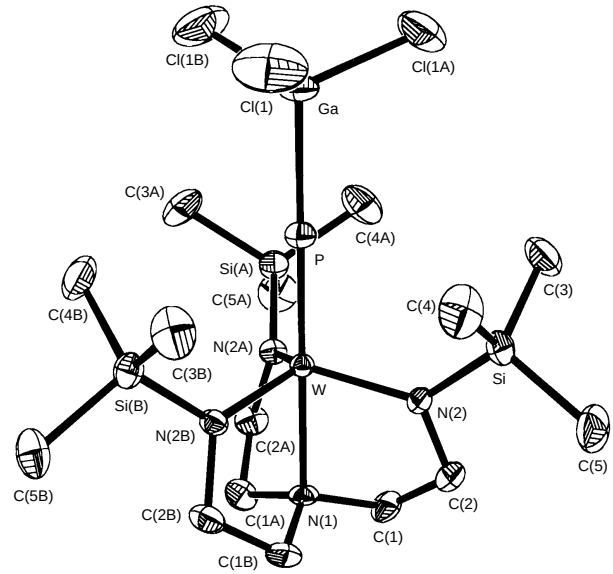

Fig. 1 Molecular structure of **5** (only one position of the Cl atoms is drawn for clarity). Selected bond lengths (Å) and angles (°): W–P 2.168(4), P–Ga 2.335(4), W–N(1) 2.248(10), W–N(2) 1.967(3), Ga–Cl(1) 2.159(11), Ga–Cl(2) 2.186(12), N(1)–W–P 180.0, W–P–Ga 180.0, N(1)–W–N(2) 77.52(8).

due to a reduced electron density at the metal core which results in a higher acceptor ability of the W atom. The Ga–P distance is 2.335(4) Å. This is consistent for Ga–P single bonds as found in *e.g.* $GaCl_3(PMe_3)$ (2.353 Å).[6]

The structural features of **5** were modelled using the B-P86/SVP density functional approximation.[7] The structural optimisation resulted in a molecular shape best described in terms of C_3 symmetry. There is good agreement between the calculated and experimentally observed structural parameters [calc.: d(W≡P) = 2.186 Å, d(W–N_{eq}) = 2.007 Å; exptl.: d(P–Ga) = 2.335(4) Å, d(W≡P) = 2.168(4) Å, d(W–N_{eq}) = 1.967(3) Å]. The only exceptions are the calculated distances for P–Ga and W–N_{ax}, which are longer by 0.1 and 0.2 Å, respectively. For the latter bond, the same effect was found in the calculated and experimental structures of **2a** and **4a**.[4]

Electronic energies, calculated with the B-P86/SVP (B3-LYP/ SVP) approximation, show reaction of **2a** with 0.5 $(GaCl_3)_2$ to be exothermic at −68 (−61) kJ mol^{-1}. The same methods calculated the energies for the reaction of **2a** with BH_3·thf to be −22 (−2) kJ mol^{-1}.[4] In accordance with the experimental observation the formation of a BH_3 adduct seems to be less favoured in comparison with the preferred formation of the $GaCl_3$ adduct **5**.¶

However, a solution of **5** in CH_2Cl_2 appears to be unstable. After a few days the yellow–brown colour of the solution disappears. Red, star shaped crystals of **6** and an amorphous solid precipitated. According to a $^{31}P\{^1H\}$ NMR study the CH_2Cl_2 solution contains no detectable amounts of phosphorus. The red crystalline compound was examined by X-ray diffraction,§ but only a weak data set was obtained. However, it was possible to solve the structure to a reasonable degree. The structure revealed a tetrahedral $[W_2P_2]^+$ moiety, where the W atoms are coordinated by two tren type ligands (Fig. 2). These are linked together by two $GaCl_2$ groups which are in the former position of the $SiMe_3$ moieties. Furthermore, all $SiMe_3$ groups are removed and $[GaCl_4]^-$ and Cl^- occur as counter ions. The W–P bonds are now 2.462(12) and 2.473(10) Å and the W–W bond is 2.585(2) Å. A related nitrido bridged tungsten dimer is $[W_2(\eta^5\text{-}C_5H_4Pr^i)Cl_2(\mu\text{-}NR)(\mu\text{-}C_2Et_2)]$ with an analogous W–W distance of 2.5923(5) Å.[8] Obviously, in the first step of the conversion of **5** the Si–N bond is cleaved to form the thermodynamically stable $SiClMe_3$. The replacement by $GaCl_2$ moieties leads to a rearrangement resulting in the formation of the W_2P_2 complex **6**.

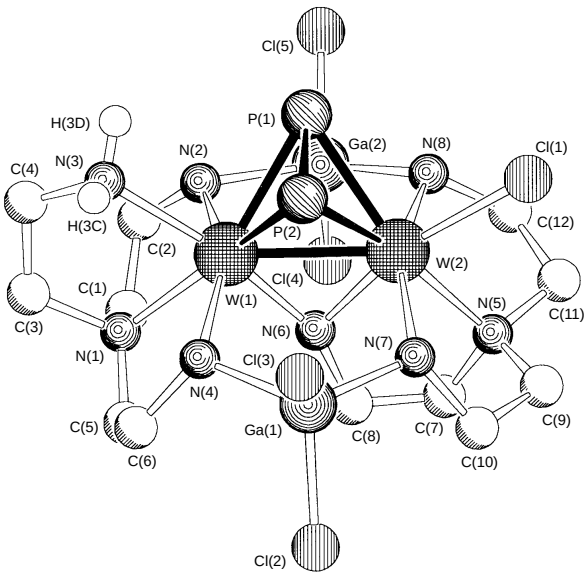

Fig. 2 Molecular structure of **6**. Selected bond lengths (Å): P(1)–P(2) 2.07(2), W(1)–P(1) 2.461(12), W(1)–P(2) 2.473(10), W(2)–P(1) 2.483(11), W(2)–P(2) 2.498(9); Cl(1)–W(2) 2.464(12), W(1)–W(2) 2.585(2), W(1)–N(6) 1.97(3), W(2)–N(6) 2.00(3).

The transformation of **5** into **6** could explain the instability of complexes of the type $[LW{\equiv}P{\rightarrow}EX_3]$ (E = B, Ga; X = H, F, Cl). Loss of $SiClMe_3$ or $SiHMe_3$ decreases the steric protection of the W≡P triple bond which results in arbitrary formation of higher aggregates of unknown composition. Deliberate attempts to remove $SiMe_3$ groups may activate the [LW≡P] complex with their preferred end-on reactivity to undergo side-on reactions. This is a goal for further investigations.

Hydrogenation of butane-2,3-dione with heterogeneous cinchona modified platinum catalysts: a combination of an enantioselective reaction and kinetic resolution

Martin Studer,*[a]† Victor Okafor[b] and Hans-Ulrich Blaser[a]

[a] *Scientific Services, Novartis Services AG, CH-4002 Basel, Switzerland*
[b] *University of the Witwatersrand, Department of Chemistry, Johannesburg, South Africa*

(*R*)-3-Hydroxybutan-2-one was obtained with 85–90% ee albeit in low yield by the Pt/Al_2O_3 cinchona catalyzed hydrogenation of butane-2,3-dione by a combination of enantioselective hydrogenation and kinetic resolution.

Modified heterogeneous catalysts for enantioselective hydrogenation are of interest, both from a theoretical and practical point of view.[1] Up to now only two efficient catalyst systems are known and only a few substrate types can be hydrogenated with enantioselectivities of 90% or higher. Most notable is the tartrate modified Raney-nickel catalyst with an ee of up to 98% for β-keto esters and β-diketones,[2–4] and the cinchona modified Pt catalysts for the hydrogenation of α-keto esters with 95% ee.[5] Even though some progress in expanding the scope of the latter was reported recently,[6–8] none of the new systems had an ee > 60%. Here we describe the enantioselective hydrogenation of butane-2,3-dione **1**, where we obtained (*R*)-3-hydroxybutan-2-one (*R*)-**2** in up to 90% ee by a combination of enantioselective hydrogenation and kinetic resolution using a Pt/Al_2O_3 catalyst modified with 10,11-dihydrocinchonidine (HCd).

Vermeer *et al.*[6] investigated the enantioselective hydrogenation of **1** to **2** and found an ee of 38% when using a 6.3% Pt/silica catalyst modified with cinchonidine in CH_2Cl_2 at 0 °C. We decided to re-investigate this substrate using a catalyst that gave the highest enantioselectivities so far reported for several α-keto esters (5% Pt/Al_2O_3, JMC type 94, pretreated for 2 h at 400 °C with H_2).[5] First, we investigated the effect of several reaction parameters.[9] Modifier type and concentration, as well as the solvent, had a very strong effect on the enantioselectivity, while the influence of H_2 pressure (25–135 bar) and temperature (0–25 °C) were found to be negligible. The best results were obtained with HCd in toluene (ee ≈ 50%). During the course of this investigation we noticed that at conversions > 80% the ee started to rise and the reaction did not stop at **2** but slowly continued to give the corresponding diols **3** (Scheme 1), a fact not described by Vermeer *et al.*[6]

These findings prompted us to investigate the two consecutive hydrogenation steps in more detail. The first step was carried out by hydrogenating 5 ml **1** with 50 mg catalyst, 10 mg HCd and 20 ml toluene in a 50 ml autoclave at 107 bar, stopping the reaction at the time given in Table 1. Because the reaction of **2** to **3** was considerably slower, the second step was carried out by hydrogenating the filtrate of the above described reaction mixture (after 15 min reaction time) with 125 mg catalyst and 25 mg HCd at 107 bar. Again, the reaction was stopped after the time given in Table 2, Figs. 1 and 2.

These results show that as the concentration of **2** declined, the ee of **2** increased from 50 to 85–90%, albeit with a rather low chemical yield of < 30%. We analyzed our data on the basis of the reaction network shown in Scheme 1. For the calculations we assumed that the reactions of **1** or **2** were first order in substrate and in catalyst, leading to equations of the type d[(*R*)-**2**]/dt = [cat]{k_R'[**1**] − (k_{RR}' + k_{RS}')[(*R*)-**2**]} at constant hydrogen pressure. The time dependent concentration of all species was calculated by numerically integrating these equations. The apparent rate constants k_i' at 107 bar H_2 were obtained by minimizing the difference between measured and calculated data points (least-squares, MS EXCEL 7.0 Solver subroutine). The reported k_i values are $k_i = k_i'$/[cat]. In the absence of modifier, the following values were found: $k_R = k_S = 17\ h^{-1}\ g^{-1}$, $k_{SR} = k_{RS} = 3\ h^{-1}\ g^{-1}$, $k_{RR} = k_{SS} = 4$

h^{-1} g^{-1}. For the modified system, we obtained: k_R = 270 h^{-1} g^{-1}, k_S = 110 h^{-1} g^{-1}, k_{SR} = 15 h^{-1} g^{-1}, k_{RS} = k_{RR} = k_{SS} = 4 h^{-1} g^{-1}. Three points are important. First, our model describes the measured data well. Secondly, we confirmed the observation of Vermeer *et al.*[6] that the hydrogenation of **1** is a 'ligand accelerated' reaction as observed for several α-keto acid derivatives.[1] Unfortunately, the enantiodiscrimination is modest, leading to only 50% ee. Thirdly, the increase in the ee of **2** during the second step is due to kinetic resolution because k_{RS} is significantly larger for the modified than for unmodified catalyst, while k_{RS}, k_{RR} and k_{SS} remain virtually unchanged. This leads to a fast disappearance of (*S*)-**2**, and to a predominance of the *meso*-diol **3**. Another consequence is a gradual increase in the ee of the two chiral **3** molecules in favor of the (*R*,*R*)-**3**.

To the best of our knowledge, only two analogous investigations of the enantioselective reduction of diketones were reported. Kitamura *et al.*[10] and Fan *et al.*[11] investigated the hydrogenation of **1** using a homogeneous Ru^{II}–(*S*)-BINAP catalyst. Tai *et al.*[3] and Brunner *et al.*[12] reported results on the hydrogenation of acetylacetone, a 1,3-dione, with a heterogeneous tartrate modified nickel catalyst. The results for both systems are quite different from ours: in both cases, enrichment was found for the diols but not for the intermediate hydroxy ketone. Unfortunately, no enantioselectivities were reported for **2** in refs. 10 and 11. For (*R*,*R*)- and (*S*,*S*)-**3**, both found an ee approaching 100% in favor of (*S*,*S*)-**3**, but a rather high *meso*:chiral ratio of 3. This can be explained assuming a very high enantioselectivity for the first step ($k_S \gg k_R$), and $k_{SR} \cong 3k_{SS}$. Similar to our results, Tai *et al.* found a modest ee of 74% in the first step with acetylacetone as substrate.[3] However, when 70% of the corresponding hydroxy ketone was converted, they obtained an ee of 98% for the chiral diols with the (*R*,*R*)-diol in excess (and only 8% of the *meso* form). They showed that this was due to a high k_{RR} value. The major difference between the two heterogeneous systems is that in the case of the 1,3-dione, the diastereoselective reaction of the major intermediate is faster, leading to enriched diol, whereas in our case the minor intermediate reacts preferentially, leading to an enriched hydroxyketone.

FEATURE ARTICLE

Precious metal polymers: platinum or gold atoms in the backbone

R. J. Puddephatt

Department of Chemistry, The University of Western Ontario, London, Canada N6A 5B7

The synthesis and characterisation of oligomers and polymers containing gold or platinum atoms in the backbone are reported. The polymers range in structure from the conjugated, rigid-rod type containing linear gold(I) centres to hyperbranched or dendrimeric materials containing octahedral platinum(IV) centres.

Introduction

This article gives a personal account of the synthesis and characterization of some new types of oligomers and polymers with either platinum or gold atoms in the chain backbone. These form a small part of the more general field of metal-containing polymers, which are of interest since they might have unusual optical or electrical properties or they might be useful as precursors to other materials or as catalyst precursors. There are several known types of linear-chain polynuclear coordination complexes containing platinum or gold, including the stacked, one dimensional conductors or semiconductors $K_2Pt(CN)_4Br_{0.30}\cdot 3H_2O$,[1] $[Pt(NH_2Et)_4][PtCl_2(NH_2Et)_4]Cl_4\cdot 4H_2O$ and $K_4[Pt_2(P_2O_5H_2)_4X]\cdot nH_2O$ (X = Cl, Br, I),[2] and the simple halogen-bridged gold(I) halides.[3] More recently, rigid rod polymers such as $[Pt(PBu_3)_2(\mu\text{-}C{\equiv}C{-}R{-}C{\equiv}C{-})_n$ **1** (R = aryl spacer group) have been reported.[4] The dialkynyl ligands, and related but neutral diisocyanide ligands, are particularly well suited to the design of rigid-rod polymers and examples are now known with Pt–Pt bonds and even Pt_3 cluster units in the backbone as illustrated by **2** and **3**, PP = $Ph_2PCH_2PPh_2$.[5,6] The first part of this article will describe the further development of this field to include gold-containing rigid-rod polymers.

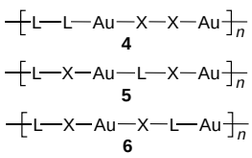
3

Gold-containing oligomers and polymers

Gold(I) tends to have a coordination number of two with linear stereochemistry,[3] so it is well suited to form linear rigid-rod polymers. If neutral polymers are to be formed, one neutral ligand L and one anionic ligand X^- are required for each gold(I) centre. Suitable ligands might then include L–R–X^-, where R is a linear spacer group, and L might be an isocyanide and X^- an acetylide. Alternatively, one ligand L–R–L and $^-$X–R–X^- could be used for each two gold(I) centres. The general types of polymers targetted are then shown as **4**–**6**. Since many of these polymers proved to be insoluble, it has been important to prepare model compounds containing only two gold(I) atoms, by using capping monodentate ligands in combination with one bridging ligand, in order to optimise the synthetic methods and to facilitate characterization of the polymers.



Diisocyanides, diacetylides and isocyanoacetylides

Since the isocyanide functionality is sensitive to bases, the most successful synthetic route to isocyanide(alkynyl)gold(I) complexes is by reaction of oligomeric or polymeric compounds $(AuC{\equiv}CR)_n$, in which the alkynyl ligand bridges by bonding to one gold atom through the σ donor and to a second gold atom using its π electrons,[7] with an isocyanide ligand. Although the explosive Au_2C_2 has been known for many years, the more stable (**CAUTION**: but still potentially explosive) digold diacetylides $(AuC{\equiv}C{-}Ar{-}C{\equiv}CAu)_n$ **7** needed for this work were unknown and were prepared according to eqn. (1), B = base, in which the aryl spacer group Ar = 1,4-C_6H_4, 4,4′-$C_6H_4C_6H_4$ or 1,4-(2,5-$Me_2C_6H_2$).[8]

$$2[Me_2SAuCl] + HCC\text{-}Ar\text{-}CCH + 2\ B \rightarrow 2\ Me_2S + 2\ BH^+Cl^- + \{Au\text{-}C{\equiv}C\text{-}Ar\text{-}C{\equiv}C\text{-}Au\}_n \quad (1)$$

Suitable binuclear gold(I) model compounds [RN≡CAuC≡C–Ar–C≡CAuC≡NR] **8** (R = Bu^t or Xy = 2,6-dimethylphenyl) and [RC≡CAuC≡N–Ar–N≡CAuC≡CR] **9** [R = Bu^t or Ph, Ar = 1,4-C_6H_4, 1,4-(2-MeC_6H_3), 1,4-(2,6-$Bu^t_2C_6H_2$), 1,4-(C_6Me_4), 1,4′-(2,6-$Me_2C_6H_2)_2$], were then prepared as shown in eqns. (2) and (3).[8]

$$1/n\ \{AuCC\text{-}Ar\text{-}CCAu\}_n + 2\ RNC \rightarrow \underset{\mathbf{8}}{[RN{\equiv}C\text{-}Au\text{-}C{\equiv}C\text{-}Ar\text{-}C{\equiv}C\text{-}Au\text{-}C{\equiv}NR]} \quad (2)$$

$$2/n\ \{AuCCR\}_n + CN\text{-}Ar'\text{-}NC \rightarrow \underset{\mathbf{9}}{[RC{\equiv}C\text{-}Au\text{-}C{\equiv}N\text{-}Ar'\text{-}N{\equiv}C\text{-}Au\text{-}C{\equiv}CR]} \quad (3)$$

While eqns. (2) and (3) indicate that the products are molecular in nature, and this is the case in solution, the compounds associate in the solid state either through π stacking between aryl groups of neighbouring molecules[9] or, more commonly, through intermolecular Au···Au bonding.[8] These weak Au···Au interactions, which are known in several other classes of gold(I) complexes, are thought to have strengths of 5–10 kcal mol^{-1}, similar to the strength of hydrogen bonds, and are thought to arise from relativistic London forces.[10] The association present in crystals of [PhC≡C–Au–C≡N$Bu^t_2C_6H_2$N≡C–Au–C≡CPh] comprises both aryl π stacking and Au···Au bonding and is shown in Fig. 1.

It was then possible to prepare polymers **10** containing alternating diacetylide and diisocyanide ligands according to

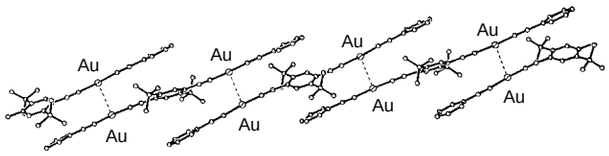


Fig. 1 The intermolecular association present in the solid state structure of [PhC≡CAuC≡NBu^t$_2$C$_6$H$_2$N≡CAuC≡CPh] due to (*a*) π-stacking and (*b*) Au···Au bonding. The Au···Au distance is 3.174(1) Å.

eqn. (4) (Ar and Ar′ are as defined earlier). The polymers are

$$1/n\ \{AuCC\text{-}Ar\text{-}CCAu\}_n + CN\text{-}Ar'\text{-}NC \rightarrow \{\text{-}Au\text{-}C{\equiv}C\text{-}Ar\text{-}C{\equiv}C\text{-}Au\text{-}C{\equiv}N\text{-}Ar'\text{-}N{\equiv}C\text{-}\}_n \quad (4)$$

10

insoluble, which might have been predicted since intermolecular association through π stacking and/or Au···Au bonding will lead to effective crosslinking of the linear rigid-rods into a three-dimensional network. Though each individual interaction is likely to be weak, the combination of many interactions for each polymer chain is likely to give strong crosslinking leading to insolubility. The polymers are therefore characterised only in the solid state by elemental analysis and by comparison of spectroscopic data with those of the well characterised model compounds.[8]

One interesting property of these gold(I) complexes is that they are emissive at room temperature either in the solid state or in solution.[9,11] The emission is strongly red shifted in the solid compared to solution state as illustrated in Fig. 2, particularly

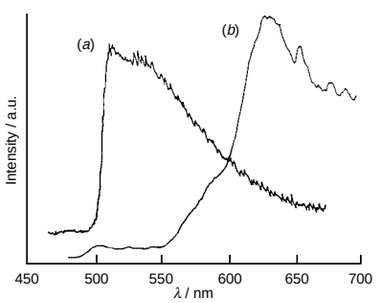

Fig. 2 The emission spectra of XyNC–Au–CCC$_6$H$_4$NO$_2$-4, (*a*) in solution in CH_2Cl_2 and (*b*) in the solid state, showing the red shift in the solid state. In this case the association in the solid state is due to π-stacking.

when Au···Au bonding orπ stacking is present in the solid state structures. In addition, there is a red shift in the emission and a decrease in emission intensity as the molecules increase in size, as illustrated for the solid state spectra shown in Fig. 3, and this

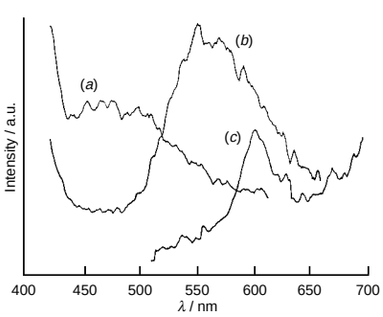

Fig. 3 The solidstate emission spectra of gold(I) complexes showing the red shift with increasing molecular size: (*a*) [Bu^{t}N≡C–Au–C≡CPh], (*b*) XyN≡C–Au–CCC$_6$H$_4$–C$_6$H$_4$CC–Au–C≡NXy] and (*c*) {Au–C≡C–C$_6$H$_2$Me$_2$C≡C–Au–C≡NC$_6$H$_2$Bu^t$_2$)N≡C}$_n$

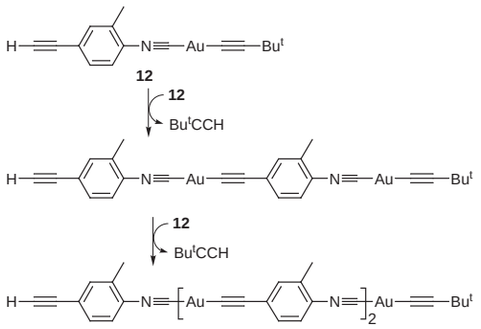
provides evidence for at least some π conjugation in the rigid-rod chains.[9]

The new ligands 4-HC≡CC$_6$H$_4$N≡C and 4-HC≡C–2-MeC$_6$H$_3$N≡C bind readily to gold(I) in forming the complexes such as [4-HC≡CC$_6$H$_4$N≡C–Au–Cl] **11** and [4-HC≡C–2-MeC$_6$H$_3$N≡C–Au–C≡CBu^t] **12**. The acetylide derivatives such as **12** give weak Au···Au bonded association in the solid state [Au···Au 3.479(2) Å] and form oligomeric complexes H–(C≡C–Ar–N≡C–Au–)$_n$–C≡CBu^t **13** by elimination of Bu^{t}CCH on heating as illustrated in Scheme 1.[12] The oligomers tend to precipitate from solution when n = 4–6 and then no further chain growth occurs.



Scheme 1

Diphosphines, diacetylides and phosphinoacetylides

Diphosphines cannot give strictly linear rigid-rod compounds since there will be a tetrahedral angle at each phosphorus atom. The question then arises as to whether these ligands will give polymers at all, since ring formation is also possible.

The digold(I) diacetylides described above can be capped with monodentate phosphine ligands such as PMe_3 to give binuclear model complexes such as [(Me$_3$P)Au–C≡C–C$_6$H$_2$Me$_2$–C≡C–Au(PMe$_3$)] **14** and this forms loose polymers in the solid state by intermolecular Au···Au bonding (Fig. 4).[9,13]

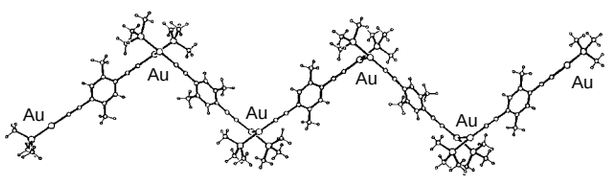


Fig. 4 The intermolecular association through Au···Au bonding in the complex [(Me$_3$P)Au–C≡C–C$_6$H$_2$Me$_2$–C≡C–Au(PMe$_3$)]

The diphosphines Ph$_2$PC$_6$H$_4$PPh$_2$ or Pr^i$_2$PC$_6$H$_4$C$_6$H$_4$PPr^i$_2$ can also give binuclear model complexes such as PhC≡C–Au-Pr^i$_2$PC$_6$H$_4$C$_6$H$_4$PPr^i$_2$–Au–C≡CPh **15** which has the *anti* conformation with respect to the two P–Au vectors as shown in Fig. 5; the bulky Pr^i groups prevent the formation of

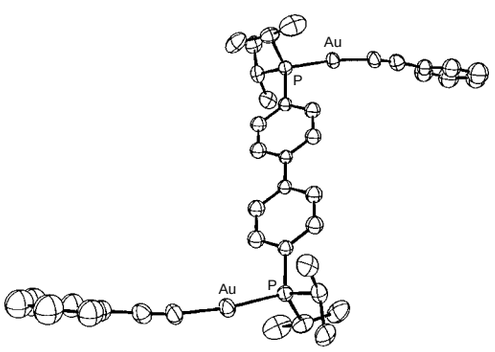

Fig. 5 The *anti* conformation of the two P–Au vectors in [PhC≡C–Au-Pr^i$_2$PC$_6$H$_4$C$_6$H$_4$PPr^i$_2$–Au–C≡CPh] **15**

intermolecular Au···Au bonding in**15**. It is then straightforward to prepare polymers (Au–C≡C–Ar–C≡C–Au–PR$_2$–Ar′–PR$_2$–)$_n$ **16** incorporating both diphosphine and diacetylide bridges. It is likely that the *anti* conformation of the P–Au vectors in **15** is

maintained in these polymers, which are sufficiently soluble when R = Pr^i to allow molecular mass determination by GPC. The improved solubility probably arises because the bulky Pr^i groups prevent crosslinking by intermolecular Au···Au bonding.

It is possible to tailor the system to give rings instead of polymers. Thus, ligands $R_2PCH_2PR_2$ give digold complexes in which the *syn* conformation of the two P–Au vectors is preferred so as to allow intramolecular Au···Au bonding, as for example in $CH_2(PCy_2–Au–O_2CCF_3)_2$ **17** or $CH_2(PPh_2–Au–C{\equiv}CBu^t)_2$ **18** shown in Fig. 6.[14,15] This conformation is

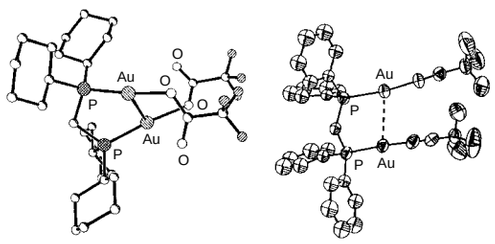

Fig. 6 The *syn* conformation of the two P–Au vectors in $[CH_2(PCy_2–Au–O_2CCF_3)_2]$ **17** and $[CH_2(PPh_2–Au–C{\equiv}CBu^t)_2]$ **18**

maintained on reaction of **17** with rigid-rod bridging ligands and so large rings are formed in $[CH_2(PR_2–Au–C{\equiv}C–Ar–C{\equiv}C–Au–PR_2)_2CH_2]$ **19** or $[CH_2(PR_2–Au–C{\equiv}N–Ar–N{\equiv}C–Au–PR_2)_2CH_2]^{4+}$ **20**. The structure of the complex **20** with R = cyclohexyl and the bridging ligand 1,4-$C{\equiv}NC_6H_4N{\equiv}C$ is shown in Fig. 7.

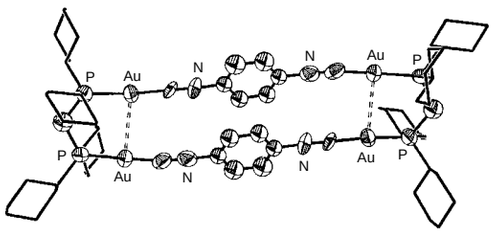

Fig. 7 The structure of the cationic ring complex **20** (R = Cy and Ar = 1,4-C_6H_4)

It is also possible to use mixed phosphine–acetylide donors in forming polymers of gold(I). Thus the ligands $Ph_2PC{\equiv}CH$ and $Pr^i_2PC{\equiv}CH$ form model complexes $HC{\equiv}CPR_2–Au–Cl$ which, on treatment with base, can eliminate HCl to give the polymers $\{R_2PC{\equiv}C–Au–\}_n$ **21**.[16]

Angular diacetylides and triacetylides

In the complexes with diphosphines or phosphinoacetylides, the chains are not strictly linear because of the tetrahedral angle at phosphorus, yet polymers can still be formed in preference to the alternative ring structures. What will happen if an angle is introduced in the diacetylide bridge? The dialkyne 1,3-$(HC{\equiv}C)_2C_6H_3$Me-5 yields digold(I) model complexes 1,3-$(L–Au–C{\equiv}C)_2C_6H_3$Me-5 **22** (L = phosphine, phosphite or isocyanide ligand) which form ribbon structures in the solid state through Au···Au bonding as seen in Fig. 8.[17]

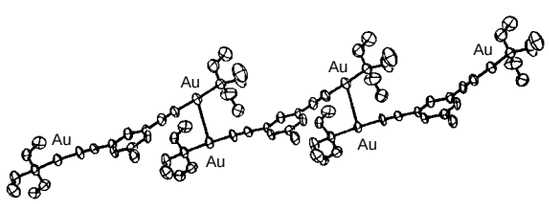

Fig. 8 The intermolecular association through Au···Au bonding in the complex $[1,3\text{-}(L–Au–C{\equiv}C)_2C_6H_3Me\text{-}5]$ [L = $P(OMe)_3$]

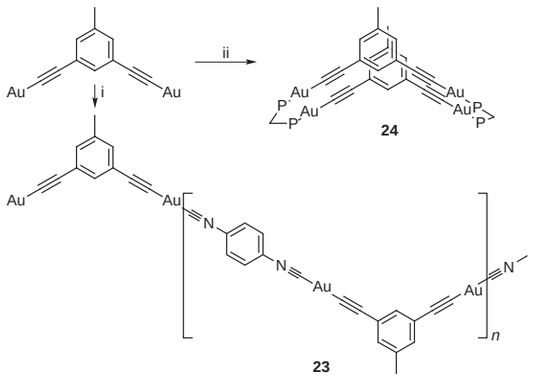
Kinked polymers such as **23** are formed when linear diisocyanide ligands are used but, if the neutral bridging ligand is also non-linear, then ring structures such as **24** are formed instead (Scheme 2).[17]



Scheme 2 *Reagents*: i, $C_6H_4(CN)_2$; ii, $Ph_2PCH_2PPh_2$

If a third acetylide link is added as in 1,3,5-$(HC{\equiv}C)_3C_6H_3$, the gold derivatives can in principle form more complex network polymers either through intermolecular Au···Au bonding or through the use of bridging ligands. The capped complexes 1,3,5-$(L–Au–C{\equiv}C)_3C_6H_3$ **25** are found to form one-dimensional ribbon structures in the solid state with one gold atom not taking part in Au···Au bonding (Fig. 9). With all bridging ligands,

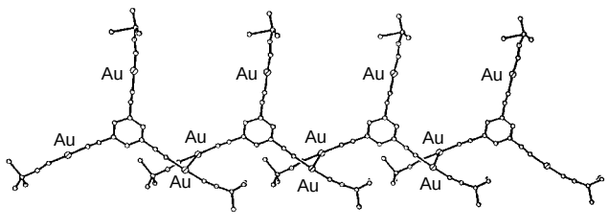


Fig. 9 The intermolecular association through Au···Au bonding in the complex $[1,3,5\text{-}(L–Au–C{\equiv}C)_3C_6H_3]$ (L = $Bu^tN{\equiv}C$)

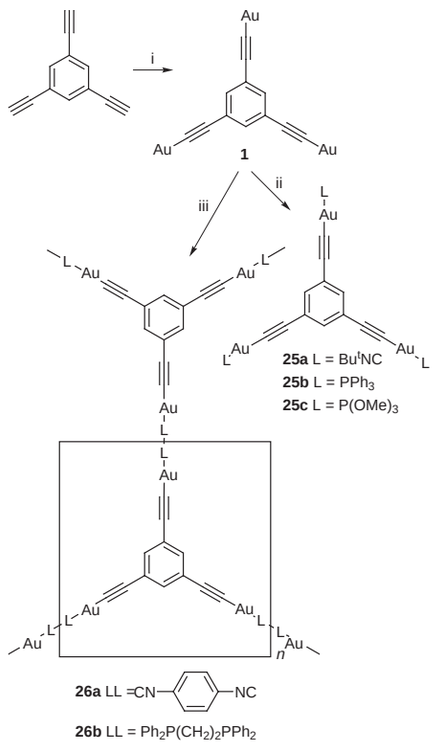
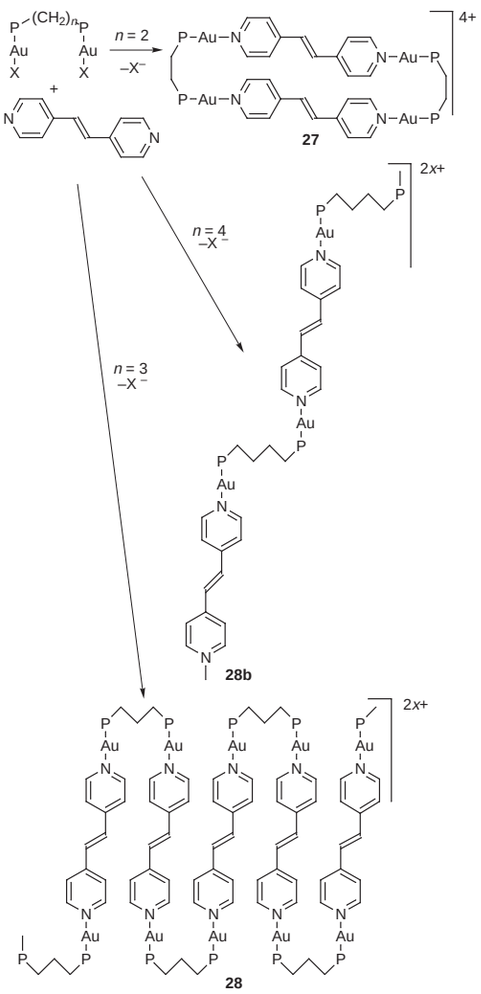
whether the strictly linear diisocyanides or angular diphosphines, insoluble polymers **26** are formed (Scheme 3).[18]



Scheme 3 *Reagents*: i, $[AuCl(SMe_2)]$, NaOAc; ii, 3L; iii, 1.5 L–L

Rings and polymers with diphosphine and bis(pyridyl) ligands

The principles determining if rings or polymers would be formed were now understood in general terms but the detailed structures of the polymers could not be determined since they could not be crystallised. A series of experiments was carried out next using flexible diphosphine ligands $(CH_2)_n(PPh_2)_2$ and a more labile linear bridging ligand *trans*-1,4-bis(pyridyl)-ethene. It was argued that the intramolecular Au···Au bonding interactions would decrease progressively with increasing *n* and so the preferred structure would switch from the large rings to polymers at some point in the series (Scheme 4). Further, the polymers could reversibly cleave to smaller fragments in solution owing the lability of the pyridine donors and this might allow crystallisation and so to full structural characterisation of the polymers.[19]



Scheme 4 X = CF_3CO_2, P = PPh_2

With $(CH_2)_2(PPh_2)_2$, the ring structure $[Au_4(\mu\text{-}Ph_2PCH_2CH_2PPh_2)_2(\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)_2]^{4+}$ **27** is preferred as shown in Fig. 10 but the Au···Au distance of 3.625(3) Å indicates very weak Au···Au bonding and no significant Au···Au attraction is expected for higher values of *n*.[19]

The switch to a polymeric structure $[\{Au_2[\mu\text{-}Ph_2P(CH_2)_nPPh_2](\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)\}_n]^{2n+}$ **28** occurs when $n = 3$ and the polymer **28a** has an interesting sinusoidal conformation as shown in Fig. 11(*a*), since the conformation of adjacent P–Au vectors is *syn*. There is then a switch to the *anti* conformation of P–Au vectors when $n = 4$, such that a more stretched polymer chain is formed in **28b** [Fig. 11(*b*)].[19]

An interesting case occurs when $n = 5$, since three different structural forms have been crystallised (Fig. 12). Two of these

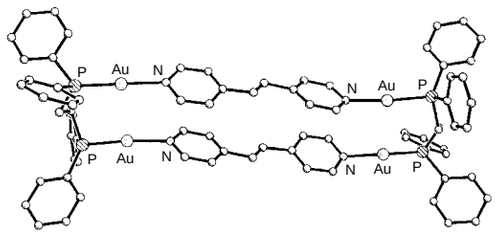


Fig. 10 The structure of the cationic ring complex $[Au_4(\mu\text{-}Ph_2PCH_2CH_2PPh_2)_2(\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)_2]^{4+}$

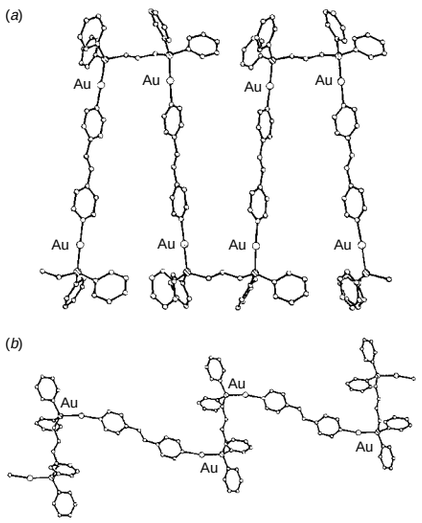

Fig. 11 The structures of the cationic polymer chains $[\{Au_2[\mu\text{-}Ph_2P(CH_2)_nPPh_2](\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)\}_n]^{2n+}$; (*a*) $n = 3$; (*b*) $n = 4$

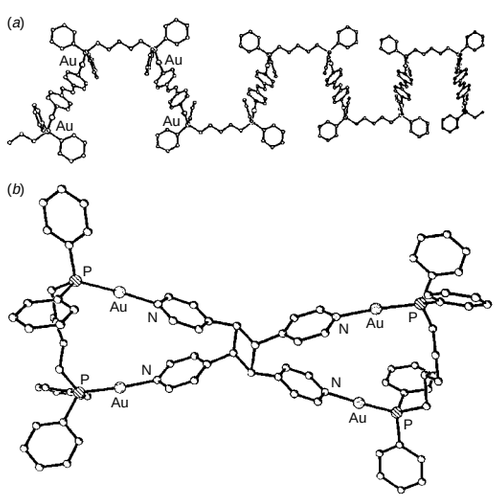

Fig. 12 The structures of the helical (*a*) cationic polymer chains $[\{Au_2[\mu\text{-}Ph_2P(CH_2)_5PPh_2](\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)\}_n]^{2n+}$, and of the cyclobutane ring form (*b*)

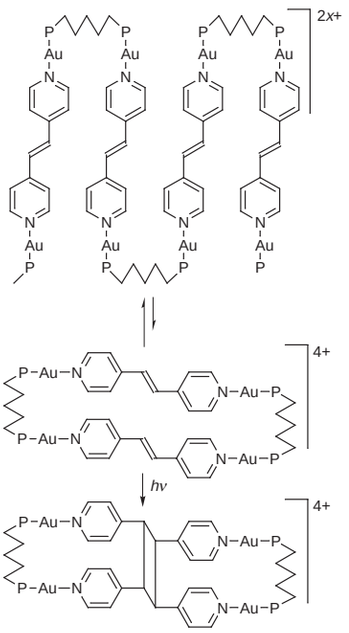
are polymers **28c**, one of which has the sinusoidal conformation as in **28a** but the other has a conformation intermediate between *syn* and *anti* and the resulting chain adopts a helical structure [Fig. 12(*a*)]. In most of the structurally characterised polymers, the chains pack parallel to one another but the helical polymer has chains that cross over one another while running in mutually perpendicular directions. The third structural form with $n = 5$ proved to be a novel ring structure with a central cyclobutane ring formed by a 2 + 2 cycloaddition reaction of two bis(pyridyl)ethylene ligands [Fig. 12(*b*)]. Further study showed

that this form was only obtained when crystallisation was carried out in the open laboratory and it is thought to be formed by a photochemical cyclisation of small amounts of ring structure present in equilibrium with the chain forms as shown in Scheme 5.[16]



Scheme 5 P = PPh_2

The complex with $n = 6$ proved to be a stretched polymer **28d** (Fig. 13) whose structure is similar to that of **28b**, having *anti* conformation of adjacent P–Au vectors but with the long $(CH_2)_6$ chain partly folded back on itself.[16]

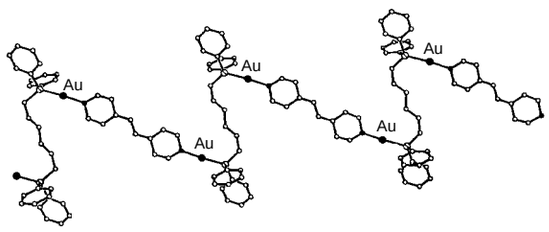


Fig. 13 The structure of the cationic polymer chain $[\{Au_2[\mu\text{-}Ph_2P(CH_2)_6PPh_2](\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)\}_n]^{2n+}$

The polymers **28** are not conjugated since there is a saturated carbon chain in the diphosphine ligands. However, conjugated polymers can be prepared by using the diphosphine ligands *trans*-$Ph_2PCH{=}CHPPh_2$ or $[Fe(\eta^5\text{-}C_5H_4PPh_2)_2]$; the structure of the polymer **29** prepared from the latter ligand is shown in Fig. 14 and has the stretched polymer form with *anti*

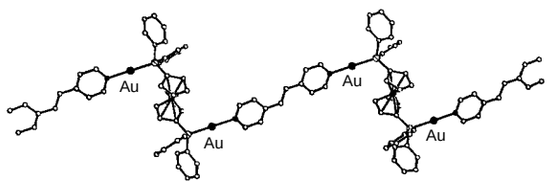

Fig. 14 The structure of the cationic polymer chain $[\{Au_2[\mu\text{-}Fe(C_5H_4PPh_2)_2](\mu\text{-}NC_5H_4CH{=}CHC_5H_4N)\}_n]^{2n+}$

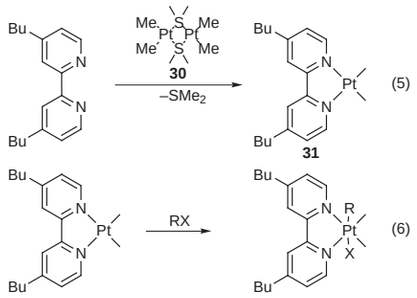
conformation of adjacent P–Au vectors. This polymer, as a pressed disc, converts from being an insulator to a semiconductor when doped with iodine, partial oxidation of ferrocene to ferricenium centres is thought to be a likely rationalisation of this observation.[16]

In conclusion, it is now possible to tailor the structures of gold(I) compounds with bridging ligands to give either rings or polymers. The polymers have interesting structures and preliminary studies indicate the possibility of optical and electronic properties based on the conjugation along the chains.

Platinum-containing oligomers and polymers

The synthesis of oligomers or polymers with platinum atoms in the backbone is based on the two simple reactions shown in eqns. (5) and (6). The first is a ligand substitution of a diimine



ligand such as 4,4′-di-*tert*-butyl-2,2′-bipyridine onto a dimethylplatinum(II) centre by displacement of weakly bound Me_2S ligands from $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ **30** to give **31**,[20] while the second involves oxidative addition of an alkyl halide to the platinum(II) centre of **31**, a reaction which occurs easily for primary alkyl halides and is tolerant to a wide range of functional groups.[21] Both reactions occur in almost quantitative yield and so are ideal for multistep syntheses as described below.

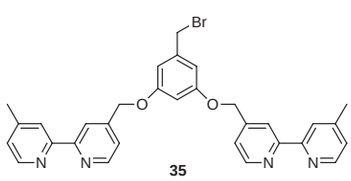
Linear chain platinum polymers

The oxidative addition to platinum(II) of alkyl halides containing polymerisable substituents can lead to polymers with organoplatinum(IV) substituents as side chains,[22] but the key to making polymers with platinum atoms in the backbone is to use alkyl halides with a bipyridine substituent. Thus, the oxidative addition of a bromomethyl derivative of 2,2′-bipyridine, 4-$BrCH_2$-4′-Me-2,2′-$(C_5H_4N)_2$ **32**, to **31** gives a platinum(IV) complex with a free bipyridine group, which can then coordinate to a second dimethylplatinum unit, and repetition of the sequence can give oligomers with platinum atoms in the backbone as shown in Scheme 6.[23]

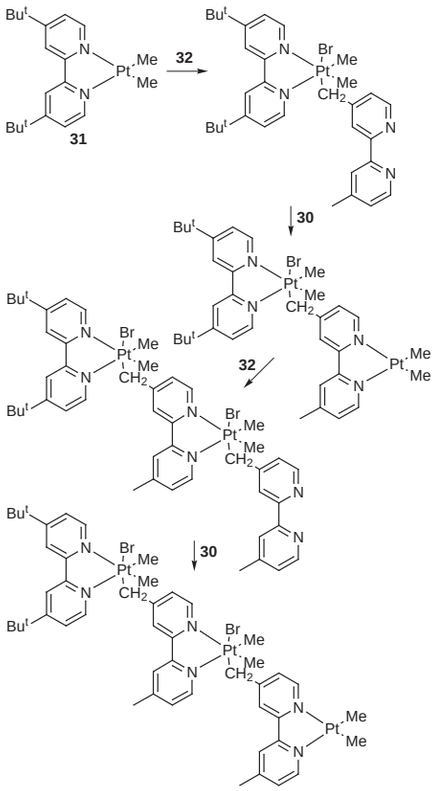
A simple self-assembly of a platinum containing polymer occurs on reaction of **32** with **30** as shown in Scheme 7. Displacement of the Me_2S ligands from **30** gives the platinum(II) monomer **33** which undergoes polymerisation by intermolecular oxidative addition.[23]

Dendrimeric platinum polymers

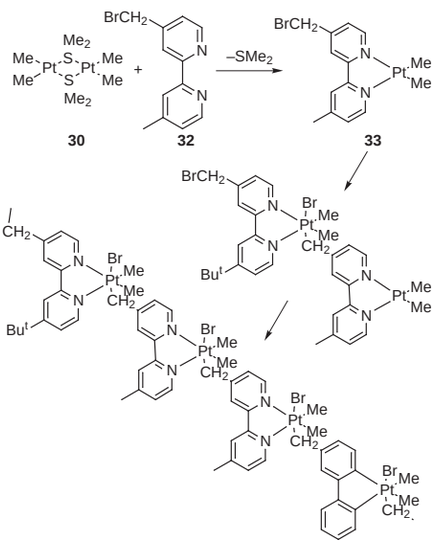
To make a dendrimer, it is necessary to introduce a branch in each generational growth step.[24] This requires at least a trifunctional reagent having two alkyl halide and one bipyridine or one alkyl halide and two bipyridine units as present in **34** and **35** respectively. The first successful synthesis is a convergent



method based on the reagent **34** (Scheme 8). Reagent **34** can add to 2 equiv. of **31** to give the diplatinum(IV) complex **36**, which



Scheme 6

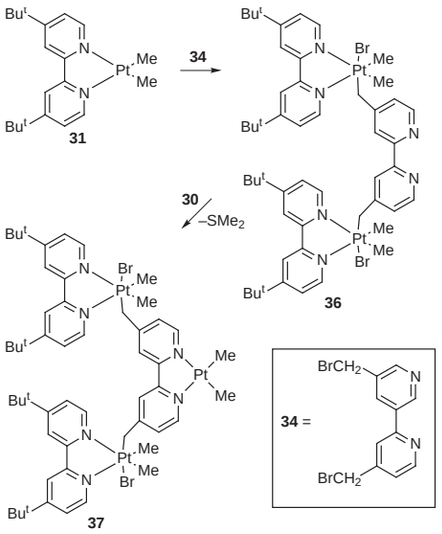


Scheme 7

can then add a dimethylplatinum(II) group to the free bipyridine to regenerate a reactive platinum(II) centre in **37**, whose structure is shown in Fig. 15.[25]

Now repetition of the cycle using **37** and **34** gives a Pt_7 dendrimer **38** (Scheme 9). One more generation can be grown, but the reactive platinum(II) centre, which is formed at the centre of the molecule in a convergent synthesis, becomes increasingly sterically congested with each generation and eventually the oxidative addition step fails.[25]

The self-assembly of a hyperbranched polymer with platinum atoms in the backbone is readily achieved by reaction of **34** with **30**. The first step is ligand substitution to give the platinum(II) complex, which then undergoes polymerisation by intermolecular oxidative addition (Scheme 10).[25]



Scheme 8

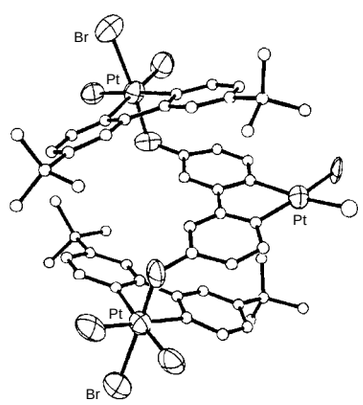


Fig. 15 The structure of the $Pt^{IV}_2Pt^{II}$ complex **37**

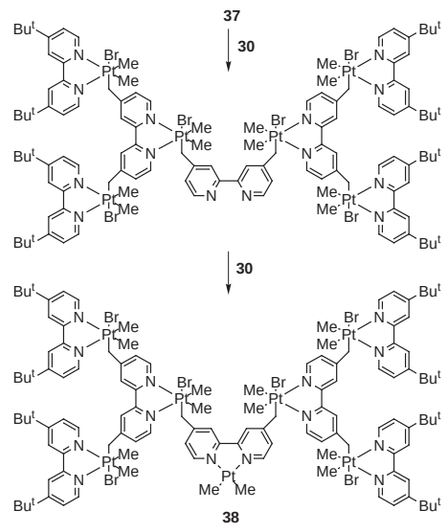
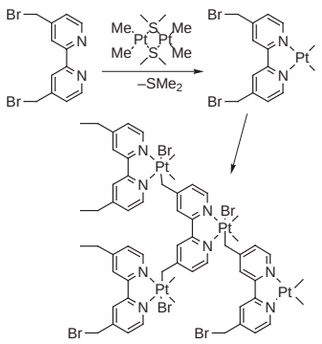


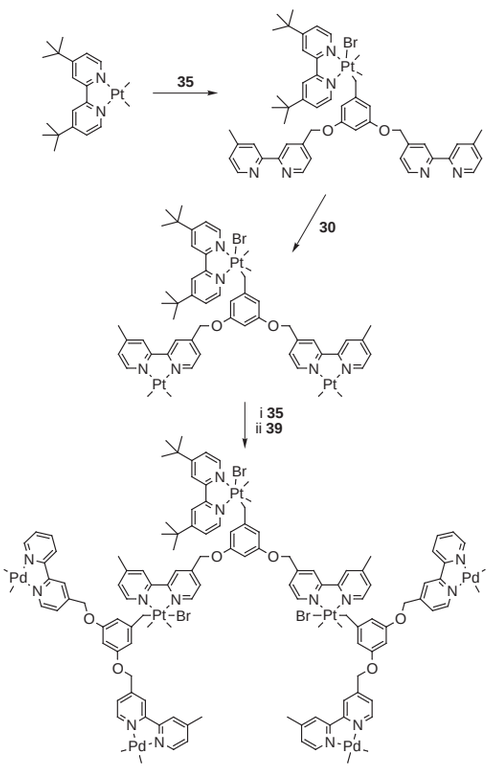
Scheme 9

A divergent method for dendrimer growth is based on the reagent **35**, which contains one bromomethyl group and two bipyridine groups. With this system, the reactive platinum(II)



Scheme 10

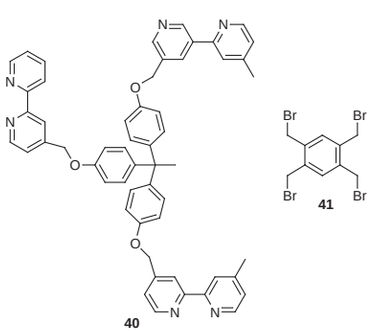
centres are formed at the periphery of the dendrimer and it is easy to introduce a different metal in the outer generation as shown in Scheme 11, using as a source of dimethylpalladium units the complex $[Pd_2Me_4(\mu\text{-pyridazine})_2]$ **39**.[26]



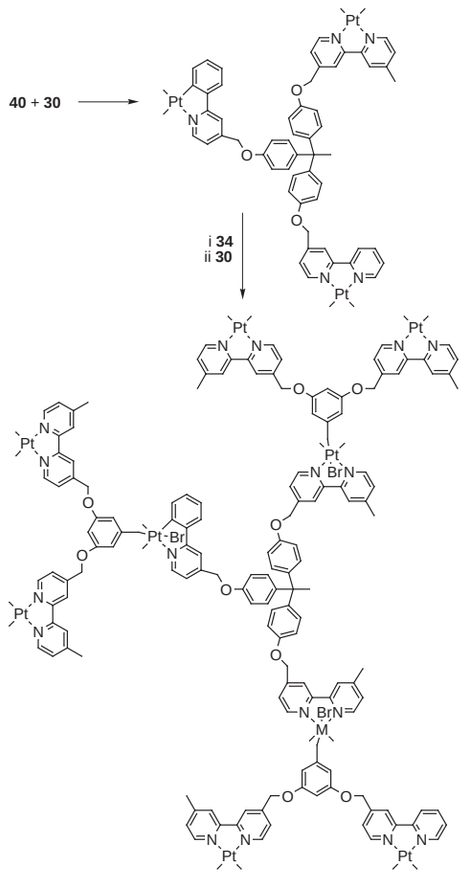
Scheme 11

Stars and exotic molecules based on polyfunctional cores

Polyfunctional cores are useful for facilitating the rapid growth of complex molecules. Two useful core molecules for platinum oligomers are **40** and **41**. The synthesis of a Pt_9 dendrimer by



40 **41**



Scheme 12

use of the core reagent **40** and the dendrimer reagent **34** is shown in Scheme 12.[26]

The core reagent **41** is useful for assembling four molecules which contain one platinum(II) centre each, including simple molecules like **31** or the more complex linear or dendrimeric molecules prepared in Schemes 6, 8 and 9.[23,25,27] An example is shown in Scheme 13 and the most complex example so far prepared is the Pt_{28} dendrimer shown in Fig. 16 and formed by coupling four Pt_7 dendrimer units **38** to the tetrafunctional core.

The X-ray crystal structures of perdeuteriated and protiated enzyme elongation factor Tu are very similar

Serena J. Cooper,[a] David Brockwell,[b] James Raftery,[a] David Attwood,[b] Jill Barber[b] and John R. Helliwell*[a]†

[a] *Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*
[b] *School of Pharmacy and Pharmaceutical Science, University of Manchester, Manchester, UK M13 9PL*

X-Ray structural comparisons show that perdeuteriation does not affect the overall fold or domain arrangement of elongation factor Tu.

Perdeuteriation involves replacing all the non-exchangeable hydrogens in a molecule with deuterium. For proteins this can be achieved by growing a bacterial expression system on a fully deuteriated medium, which is a technique used for protein NMR[1] and has potential for protein neutron scattering studies.[2,3] Whilst the effects of D_2O on proteins are well documented and indeed is a method used in the study of enzyme mechanisms,[4] there is a paucity of structural information on the impact of perdeuteriation. Most of the published information on perdeuteriation derives from the elegant work of the groups of Crespi and Berns in the 1960s.[5,6] Their experiments, as well as more recent data, indicate that perdeuteriation has a destabilising effect on proteins. Conversely biological properties such as ligand binding do not appear to be drastically changed.[7–9] This leads to the possibility of preparing perdeuteriated proteins with similar activities but with modified physical properties relative to the parent protiated protein. As part of a larger study on the effects of perdeuteriation on proteins we compare the X-ray crystal structure of perdeuteriated with that of native *i.e.* protiated, elongation factor Tu (EFTu) from *Escherichia coli*.

Both forms of the enzyme were prepared using an *E. coli* over-expression system, with the perdeuteriated form utilising a deuterium adapted *E. coli* strain, MRE600D.[10] Once cells were grown all further processes were carried out in an aqueous (H_2O) environment, so only the deuterons unable to exchange with the solvent remained attached to the protein. The native and perdeuteriated enzymes were purified identically. Analysis by electrospray mass spectrometry showed that the protein was 95% deuteriated on carbon, and that 78 of the 668 non carbon bound deuterons did not exchange with protium during isolation (*ca.* 24 h).

Crystals of both native and perdeuteriated EFTu were obtained by utilising conditions similar to those of Kjeldgaard and Nyborg.[11]‡ Both forms of the enzyme were subjected to limited cleavage with 1% trypsin for 1 h on ice. In this period a 14 peptide fragment, between Ala45 and Arg58, is excised and no further proteolysis occurs. Cleavage does not affect enzyme activity, as assessed by GDP binding assays. Crystals grew within a few days, to a typical size of $0.3 \times 0.3 \times 0.5$ mm but deteriorated after approximately one week, as determined by visual examination. Within each droplet the crystals displayed a range of (roughly) bipyramidal habits. Protiated crystals were found to diffract to *ca.* 3.5 Å using Cu-Kα radiation from a rotating anode with an R-AXIS IIc area detector. The diffraction resolution was extended to 2.5 Å at station PX7.2 SRS Daresbury.§ Many of the crystals were found to diffract poorly or were twinned. A 4.0 Å data set of a perdeuteriated EFTu crystal was measured on the R-AXIS IIc area detector using rotating anode Cu-Kα radiation.¶ A second perdeuteriated crystal was measured at station PX7.2 SRS Daresbury and although it diffracted to 2.8 Å was subsequently found to be adversely affected by twinning. All the crystals were of space group $P4_32_12$ with small but significant variation in the unit cell dimensions. We are not certain whether this variation is the result of perdeuteriation, but it is most probably simply due to the variety of crystal morphologies, as also observed previously.[11]

We have solved both the 2.5 Å protiated and 4.0 Å perdeuteriated structures by molecular replacement using GDP-EFTu coordinates based on a 2.6 Å analysis, kindly given to us by Professor M. Kjeldgaard of Aarhus University.[11]‖ The native and perdeuteriated models have been refined to *R* factors of 0.230 and 0.217 respectively.** The lower resolution of the perdeuteriated structure deems it unrealistic to draw any very detailed comparisons between the two structures, *i.e.* particularly with reference to differences in bonding distances. However it does readily allow a comparison between the overall domain to domain arrangement, as well as secondary structure. EFTu is an ideal candidate to examine the importance of perdeuteriation on proteins as it is a large (393 amino acid) multiple domain protein, the only other perdeuteriated X-ray structure available to date being a small (149 amino acids) single domain protein.[3] EFTu comprises three domains, and therefore has a large potential for conformational flexibility. The two refined X-ray models were aligned with respect to each other and also to the original Aarhus model,[11] using the program LSQMAN.[12] The rms distance deviations between protein C_α atoms of these alignments are, in ascending order of disagreement: 0.56 Å Aarhus protiated to our protiated; 0.79 Å Aarhus protiated to perdeuteriated and 0.83 Å perdeuteriated to our protiated. The protiated to protiated value of 0.56 Å represents the 'control' rms against which the other two should be compared. The rms overlap value of 0.56 Å between protiated and protiated EFTu models corresponds well with the Luzzati (0.55 Å) and Cruickshank (0.29 Å) estimates for the errors in our protiated model.†† Thus subtle structural differences between perdeuteriated and protiated EFTu cannot be ruled out yet and clearly requires confirmation.

To examine possible structural differences in more detail we also aligned each domain individually, *i.e.* our protiated EFTu domains 1, 2 and 3 with perdeuteriated EFTu domains 1, 2 and 3 in turn, and thereby accentuate any domain shifts. The rms distance deviations (for only the C_α atoms within the relevant domains) are; domain 1, 0.76 Å; domain 2, 0.99 Å and domain 3, 0.80 Å. The rms distance deviations for all C_α atoms in the above alignments are; 0.96 Å based on domain 1; 1.15 Å based on domain 2 and 0.99 Å based on domain 3. The greatest deviation is within the loop or turn regions, as can be seen in Fig. 1. However, considering typical temperature factors of $\geqslant$40 for these regions, a coordinate displacement of *ca.* 0.7 Å[2] would be expected in any case. Overall it appears that there are no major domain shifts (*i.e.* none $>$1.5 Å) and both structures have the same fold and global arrangement of domains. Thus the X-ray crystal structure analyses clearly show that perdeuteriation has no effect on the tertiary structure of EFTu. This is a significant finding for structural techniques that utilise perdeuteriated proteins such as NMR and neutron diffraction. It appears that the observed physiochemical differences[7] between protiated and perdeuteriated EFTu are not of an overall structural nature. X-Ray studies are underway on a number of

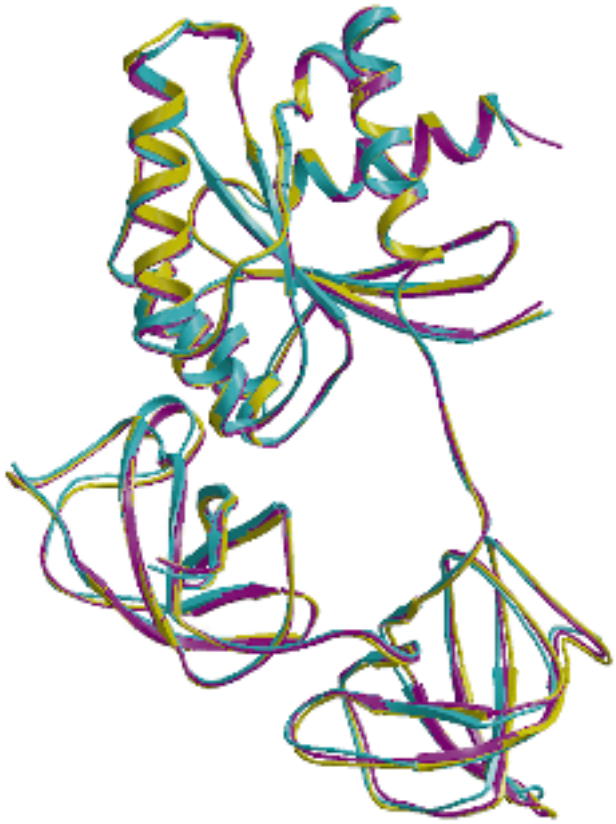

Fig. 1 Overlay of perdeuteriated and protiated EFTus indicating the similarity of the domain domain arrangements. Key: yellow, our protiated structure; magenta, Aarhus protiated structure, reproduced with permission;[11] cyan, perdeuteriated structure. Figure created using MOLSCRIPT.[13]

other proteins and will allow further analysis of the potential structural changes due to perdeuteriation to compare with the EFTu results presented here.

‡ Crystals were grown by vapour diffusion in 20 μl sitting drops, determined by screening as: 10 mM $MgCl_2$, 50 mM Tris-HCl at pH7, 0.5 mM dithiothreitol (DTT), 1 mM NaN_3, 10 mM phenylmethylsulfonyl fluoride (PMSF), 10 mM guanosine diphosphate (GDP) and either 4.7 mg ml^{-1} protiated EFTu with 3.5–4.25% PEG (6000 Da) or 1.9 mg ml^{-1} perdeuteriated EFTu with 3–4.5% PEG (6000 Da). All drops were equilibrated with a reservoir of 200 μl 10% (6000 Da).

§ 2.5 Å data were collected at station PX7.2 Daresbury from a single protiated crystal. A total of 27° of data yielded an R_{merge} of 0.078 for 14 002 reflections with a completeness of 89%, whereby 63% of the reflections have $I \geqslant 3\sigma(I)$. Unit cell dimensions are $a = b = 70.8$ $c = 163.4$ Å.

¶ 60° of 4.0 Å resolution data from a single perdeuteriated EFTu crystal were collected on the Manchester R-AXIS IIc, which yielded an R_{merge} of 0.22 for 5230 reflections, 60% of which have $I \geqslant 3\sigma(I)$, for the strong reflections the merging R is 0.05 and the overall R_{merge} only increases above 0.25 for data higher than 4.2 Å resolution. The data are 97% complete. The unit cell dimensions are $a = b = 69.8$ $c = 160.5$ Å.

‖ Molecular replacements were carried out using AMORE.[14] Both using the 2.6 Å resolution Aarhus coordinates with our X-ray data to 4 Å. The R factors at this stage for the protiated and perdeuteriated are 0.345 and 0.348 respectively.

** Subsequent to molecular replacement both structures were subjected to further rigid body refinement and simulated annealing followed by positional and B-factor refinement using XPLOR.[15] After inspection on the graphics and insertion of the Mg^{2++} and GDP co-factors into the protiated model it was put through further rounds of positional and B-factor refinement using the maximum likelihood method in REFMAC.[14] A round of refinement is defined as positional and B-factor refinement followed by model inspection/rebuilding. The perdeuteriated model was also further refined using REFMAC.[14] A bulk solvent correction was applied. The GDP and Mg^{2++} co-factors were added in the second round of refinement. R_{free}[15] was used as a guide for both protiated and perdeuteriated refinements, final values are 0.341 and 0.335, respectively.

†† The precision of protein model coordinates can be estimated using the Luzzati approach[16–18] and more recently that of Cruickshank,[19] who has considered the various protein cases in detail, including a medium resolution refined model based on initial better resolution coordinates. The Luzzati coordinate error estimates for the protiated and perdeuteriated EFTu models are 0.55 Å (5–2.45 Å) and 0.51 Å (8–4 Å) respectively. Likewise the Cruickshank estimates are 0.29 and 0.72 Å, respectively, with due account taken of the use of restraints in these refinements.

Expected and unexpected outcomes of a heteroborane isomerisation

Shirley Dunn, Georgina M. Rosair, Andrew S. Weller and Alan J. Welch*

Department of Chemistry, Heriot-Watt University, Edinburgh, UK EH14 4AS

Gentle thermolysis of compound 1, an intermediate in the isomerisation of an overcrowded icosahedral carbametallaborane, surprisingly yields two rearranged products, compound 2 (expected from theory) and compound 3 (unexpected).

There is a substantial and continuing interest in the isomerisations of heteroboranes and the mechanisms by which such isomerisations occur.[1] Recently[2] we reported the first experimental isolation of an intermediate in the isomerisation of an overcrowded, notional C_{cage}-adjacent icosahedral metallacarborane. We showed that this species has a closed, non-icosahedral structure which previously had been recognised only theoretically,[3] and we demonstrated that it was a true intermediate by effecting its conversion to a C_{cage}-separated icosahedron on gentle warming.

We now report the results of initial experiments with a system where one boron vertex is tagged with an SMe_2 group, which allows significant new insight into the precise isomerisation mechanism.

Deprotonation of the recently reported carbaborane 7,8-Ph_2-9-SMe_2-7,8-*nido*-$C_2B_9H_9$[4,5] with NaH in thf, followed by reaction with $[MoBr(MeCN)_2(\eta^3\text{-}C_3H_5)(CO)_2]$ at 0 °C, yields the neutral, charge-compensated species **1** in good yield.‡ Compound **1** displays carbonyl stretching bands in the IR spectrum at relatively high frequency (1971 and 1917 cm^{-1}, CH_2Cl_2) which identify it as a potential non-icosahedron. This was confirmed by a crystallographic study§ which revealed the structure shown in Fig. 1. Thus compound **1** constitutes only the second example of a derivative of Wales' hypothetical '1,2-C_2' intermediate[3] in the isomerisation of 1,2-*closo*-$C_2B_{10}H_{12}$ to 1,7-*closo*-$C_2B_{10}H_{12}$. However, the presence of the SMe_2 function attached to B(3) affords the possibility of mapping the movement of that boron atom when **1** is converted to the appropriate analogue of 1,7-*closo*-$C_2B_{10}H_{12}$, thus yielding valuable additional mechanistic information.

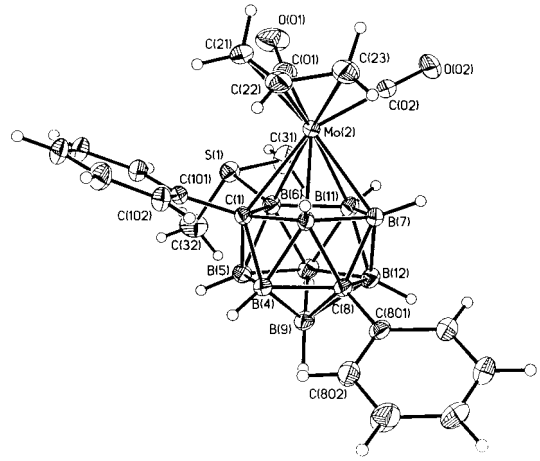

Fig. 2 Perspective view of **2**. Selected bond distances (Å) and angles (°): Mo(2)–C(01) 1.947(3), Mo(2)–C(02) 1.931(3), Mo(2)–C(21) 2.360(3), Mo(2)–C(22) 2.236(3), Mo(2)–C(23) 2.355(3), C(01)–O(01) 1.159(4), C(02)–O(02) 1.155(3), C(1)–C(101) 1.521(3), C(8)–C(801) 1.512(4), B(6)–S(1) 1.937(3); C(01)–Mo(2)–C(02) 77.73(13).

To our considerable surprise, gentle thermolysis (thf reflux) of **1** affords two new carbametallaboranes, compounds **2** and **3**, isolated by thin layer chromatography in reasonable yields.‡ Both display carbonyl stretching IR bands at low frequencies relative to those in **1** (1936 and 1853 cm^{-1} in **2**; 1931 and 1840 cm^{-1} in **3**) as expected for icosahedral compounds. Structural study of **2** and of **3**§ confirmed this prediction. Compound **2** (Fig. 2) has a 1,8-Ph_2-2-(η^3-C_3H_5)-2,2-$(CO)_2$-6-SMe_2-2,1,8-*closo*-$MoC_2B_9H_8$ architecture whereas in compound **3** (Fig. 3) the SMe_2 group is bound to B(7), *i.e.* **3** is 1,8-Ph_2-2-(η^3-C_3H_5)-2,2-$(CO)_2$-7-SMe_2-2,1,8-*closo*-$MoC_2B_9H_8$. The overall reaction scheme is shown in Scheme 1, compound **4**

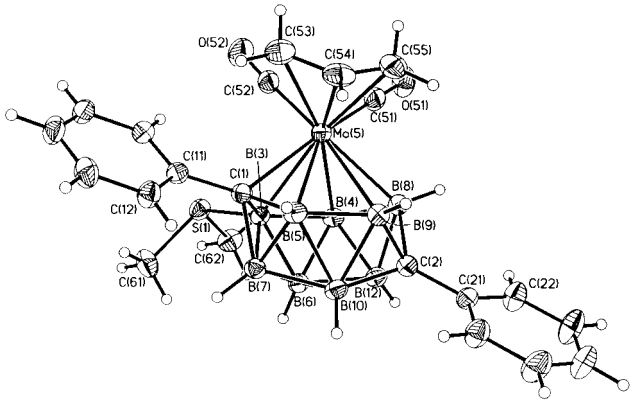

Fig. 1 Perspective view of **1** (numbered as in ref. 3). Selected bond distances (Å) and angles (°): Mo(5)–C(51) 1.973(4), Mo(5)–C(52) 1.989(4), Mo(5)–C(53) 2.374(4), Mo(5)–C(54) 2.243(4), Mo(5)–C(55) 2.362(4), C(51)–O(51) 1.152(4), C(52)–O(52) 1.153(4), C(1)–C(11) 1.506(4), C(2)–C(21) 1.493(3), B(3)–S(1) 1.934(3); C(51)–Mo(5)–C(52) 76.57(14).

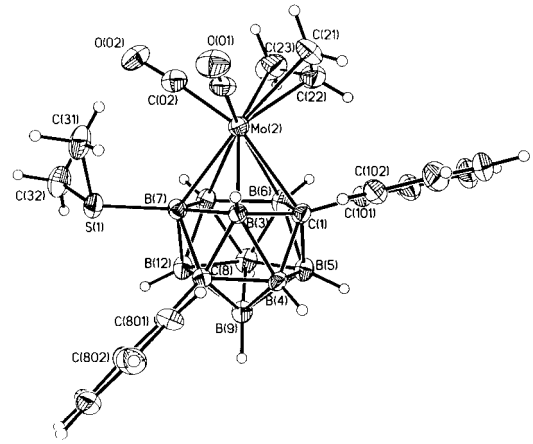

Fig. 3 Perspective view of **3**. Selected bond distances (Å) and angles (°): Mo(2)–C(01) 1.974(8), Mo(2)–C(02) 1.929(9), Mo(2)–C(21) 2.368(9), Mo(2)–C(22) 2.201(9), Mo(2)–C(23) 2.370(9), C(01)–O(01) 1.152(10), C(02)–O(02) 1.170(10), C(1)–C(101) 1.513(9), C(8)–C(801) 1.509(9), B(7)–S(1) 1.936(7); C(01)–Mo(2)–C(02) 85.1(3).

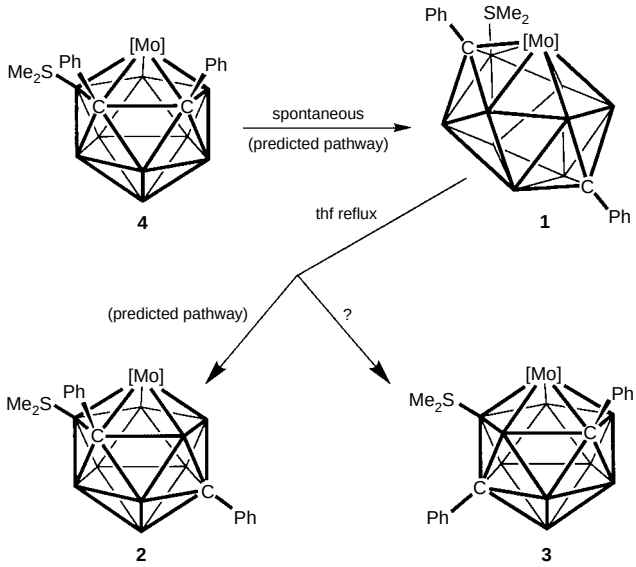

Scheme 1 Reaction scheme for formation of compound **1** from the notional overcrowded precursor **4**, and subsequent tranformation of **1** into both **2** and **3**. The pathways identified as 'predicted' are those which are in agreement with the predictions of ref. 3. [Mo] = $Mo(\eta^3\text{-}C_3H_5)(CO)_2$.

representing the likely non-isolable (overcrowded) initial reaction product. To support the assumption that the B–S bond remains intact under the conditions of gentle thermolysis employed, a sample of 7,8-Ph_2-9-SMe_2-7,8-*nido*-$C_2B_9H_9$ was heated to reflux in thf for 1 h and was recovered unchanged (^{1}H NMR spectroscopy).

As far as the relative positions of the cage carbon atoms is concerned both **2** and **3** are examples of '1,7-I_h' species. According to Wales[3] 1,2-I_h $C_2B_{10}H_{12}$ is predicted to transform to the 1,2-C_2 $C_2B_{10}H_{12}$ intermediate *via* a single route, whereas 1,2-C_2 $C_2B_{10}H_{12}$ can rearrange to 1,7-I_h $C_2B_{10}H_{12}$ *via* two possible routes, all pathways involving low symmetry transition states. We have successfully tracked the transformation of **4** into the isolated intermediate **1**, and one pathway for the subsequent transformation of **1** into **2**, thus providing experimental support for these theoretical predictions. However, the conversion of **1** into the unexpected product **3** must occur *via a* pathway not currently articulated, and clearly demonstrates that further experimental and theoretical work in this fascinating area is warranted.

We thank the EPSRC and the Callery Chemical Co. for support.

Supramolecular assembly of low-dimensional silver(I) architectures *via* amide–amide hydrogen bonds

Christer B. Aakeröy*† and Alicia M. Beatty

Department of Chemistry, Kansas State University, Manhattan, Kansas, 66506, USA

The ligand nicotinamide (L) is used to propagate the linear coordination geometry of AgL_2 into 1-D and 2-D assemblies *via* a combination of coordinate covalent bonds and specific intermolecular hydrogen-bond interactions; the precise nature of the resulting lamellar structures are also influenced by the nature of the counterion.

Some recent efforts in the field of crystal engineering have focused on the predictable assembly of organic molecular solids *via* intermolecular interactions,[1] and it has become clear that certain functional groups *e.g.* carboxylic acids and amides, are reliable, robust connectors for the formation of hydrogen-bonded organic networks.[2] However, relatively little work has been done in constructing predictable assemblies of coordination compounds *via* directional intermolecular interactions.[3] Ordered assemblies of transition metal complexes (*e.g.* 'coordination polymers'[4]) are being studied for their potential as useful conductive, porous and magnetic materials.[5] From a crystal engineering standpoint, the advantage of using transition metals is that the shape of the main building unit can be controlled by using a metal–ligand system that is known to exhibit a desired coordination geometry. A specific geometry can then be propagated throughout the crystal structure by attaching substituents (intermolecular connectors) to the ligands. In order to probe the strength and reliability of various intermolecular connectors, a low-dimensional metal–ligand system is a convenient starting point, as this may allow us to drive the assembly of linear coordination complexes into one or two dimensions in the crystal lattice *via* specific intermolecular interactions. Silver(I) is one of the few metal ions that commonly displays linear coordination, thus AgL_2 complexes of silver(I) with pyridine derivatives provide the required low-dimensional building blocks.[6] The amide functionality is an appropriate intermolecular connector for this study,[7] in part due to its well known ability to form hydrogen-bonding networks in organic molecular solids,[8] and also because it is unlikely that silver(I) ions will coordinate to either the amide carbonyl oxygen or amine nitrogen atoms in the presence of a pyridine nitrogen. In order to also investigate the influence of the steric requirements and hydrogen-bonding ability of the counter ion on the supramolecular assembly, we have initiated a systematic structural study of a family of silver complexes. We now report the X-ray single crystal structures of three new compounds,[9] $[Ag(C_5H_4NCONH_2)_2][O_3SCF_3]$ **1**, $[Ag(C_5H_4NCONH_2)_2][BF_4]$ **2** and $[Ag(C_5H_4NCONH_2)_2][PF_6]$ **3**, which contain infinite low-dimensional architectures, assembled through intermolecular hydrogen bonds.‡

The reaction of silver(I) triflate with nicotinamide leads to the formation of dinicotinamidesilver(I) triflate **1** (mp 183–185 °C), where the cationic complex contains a silver ion coordination to two nicotinamide ligands in a near-linear fashion, L–Ag–L 174.29(8)°. As expected, the coordination to the silver ion is through the ring nitrogen atoms. The 1-D geometry of the complex cation is propagated in the solid state through amide–amide hydrogen bonds [N···O 2.920(3) Å], leading to infinite $C_1^1(12)$ chains.[10] Neighbouring chains are linked through symmetry related hydrogen bonds, r(N···O) = 2.898(3) Å, forming a 'head-to-head' $R_2^2(8)$ motif. These two intermolecular interactions create an infinite ladder-like arrangement (Fig. 1). There are no further hydrogen-bond interactions between adjacent cationic ladders. The anion acts as a cross-link between two cationic ladders *via* weak hydrogen bonds to the two remaining amide hydrogen atoms, r(N···O) = 3.094(3) and 3.179(3) Å. Thus the presence of a triflate ion, which has oxygen atoms readily available as hydrogen-bond acceptors, does not disrupt the formation of the intended ligand–ligand hydrogen bonds, and the amide functionalities propagate a linear assembly of the silver complexes.

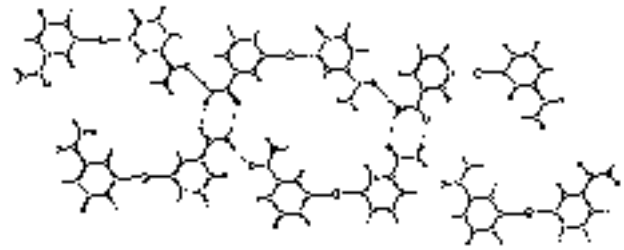

Fig. 1 Infinite 1D ladder motif in **1**, constructed *via* $C_1^1(12)$ and $R_2^2(8)$ hydrogen bonds between linear cationic moieties

Reaction of silver(I) tetrafluoroborate with nicotinamide yields the linear complex, dinicotinamidesilver(I) tetrafluoroborate **2** (mp 217–220 °C), where again the silver ion is coordinated to two ligands in a linear fashion, N–Ag–N [177.3(2)°]. However, in this structure, two unique amide–amide hydrogen bonds, r(N···O) = 2.966(7) and 2.863(7) Å, form two $C_1^1(4)$ chains, which generate infinite two-dimensional sheets (Fig. 2). The anions are sandwiched between cationic sheets, held there by two N–H···F; r(N···F) = 2.979(7) and 3.082(8) Å, and one C–H···F;r(C···F) = 3.138(7) Å, hydrogen bonds. The overall crystal packing displays an ...ABAABA...

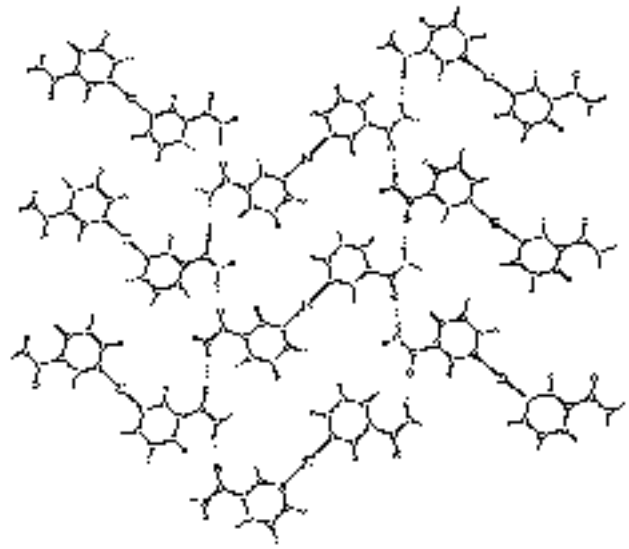

Fig. 2 2D cationic network in **2**, formed by $C_1^1(4)$ hydrogen bonds (the same 2D motif is found in the crystal structure of **3**

Fig. 3 Edge-on view of the lamellar crystal packing in **3**; hexafluorophosphate counter ions are positioned between silver-containing cationic sheets

arrangement, where A is a cationic sheet and B is an anionic layer (Fig. 3). Within ABA units the distance between cationic sheets is *ca.* 3.6 Å, while the separation between ABA units is *ca.* 3.2 Å, with no hydrogen bonds between cationic layers.

The reaction of silver(I) hexafluorophosphate with nicotinamide yields dinicotinamidesilver(I) hexafluorophosphate **3** (mp 234–238 °C), which again contains the expected linear cationic complex, N–Ag–N 173.4(1)°. Neighboring cations are linked *via* two unique amide–amide hydrogen bonds, r(N···O) = 2.943(4) and 2.870(4) Å, leading to a 2D network that is virtually identical to the cationic sheet observed in **2** (Fig. 2). The anions are positioned between sheets through two N–H···F hydrogen bonding interactions, r(N···F) = 3.033(4) and 3.058(4) Å. The crystal structure displays an ...ABAABA... packing (Fig. 3), with cationic sheets separated by *ca.* 3.8 Å within ABA units and *ca.* 3.4 Å between ABA units.

The structures of **1**, **2** and **3** demonstrate that the silver ion provides the desired linear AgL_2 building unit, and neighboring amide functionalities assemble these complexes into either 1-D or 2-D supramolecular architectures *via* intermolecular hydrogen bonds. Although the precise geometries of the hydrogen-bond networks change in this series, amide–amide interactions persist in the presence of anions with widely differing geometries and coordinating abilities. Consequently, we have gained a level of control over the way in which adjacent linear silver(I) complexes are arranged within the 3-D lattice. However, a detailed comparison of the crystal structures of **1** *vs.* **2** and **3** indicates that the counter ion does play an important role in the assembly of these complexes, resulting in the formation of either 1-D or 2-D cationic motifs based on prevailing amide–amide interactions. For example, 2-D cationic sheets are observed in structures where the anion is approximately spherical and with relatively low-coordinating ability ($[BF_4]^-$ and $[PF_6]^-$), whereas cationic ladders arise in the presence of a more anisotropic counter ion with stronger hydrogen-bond acceptors. In the case of the lamellar 2-D assemblies displayed by **2** and **3**, we hope to specifically control inter-layer separations by altering the characteristics of the counterion. Moreover, we are also examining how changes to the position of the amide functionality (*e.g.* 4-carboxamidepyridine *vs.* 3-carboxamidepyridine) and the presence of other substituents on the ligand, influence the nature of the hydrogen-bond networks and the resulting 3-D packing.

The work presented here illustrates that directional hydrogen bonds can be used in assembly of transition-metal complexes even in competition with potentially disruptive counterion interactions. Consequently, we can expect that many principles of crystal engineering that have been developed and tested in organic solid-state chemistry will assume further relevance in supramolecular aspects of coordination chemistry.

V_2O_5 reacts with aqueous NH_3 under hydrothermal conditions to give a novel sinusoidal layered compound $NH_4V_3O_8$; the structure features weak hydrogen bonds between the $V_3O_8^-$ layers and the NH_4^+ cations that occupy the interlayer space.

There has been renewed interest in alkali-metal vanadium oxide bronzes owing to their applications as cathode materials in rechargeable high-energy-density lithium batteries[1] and to their diverse structural chemistry.[2] The common synthetic schemes to produce such compounds include high temperature solid state reactions,[3] redox intercalations[4] or electrochemical methods.[5] Recently, hydrothermal techniques have been demonstrated to facilitate the synthesis and crystal growth of organic-based vanadium oxide bronzes such as α-, β-$(H_2en)_{0.5}V_2O_5$ (en = ethylenediamine)[6] and $(DABCOH_2)V_6O_{14}$ (DABCO = 1,4-diazabicyclo[2.2.2]octane),[7] to name but a few. To a lesser extent, hydrothermal methods are used in the synthesis of alkali-metal vanadium oxide bronzes.[8] We are interested in the chemistry of metastable layered alkali-metal vanadates that can be used as suitable starting materials for *in situ* hydrothermal intercalation/liquid crystal templating reactions that may produce microporous–mesoporous composite materials.[9] Our entry to this chemistry capitalizes on both the unique chemical properties of V_2O_5 and the hydrothermal method. Vanadium pentoxide is slightly soluble in water and forms a pale yellow solution containing dispersed V_2O_5 layers. Such exfoliated layers can react with acids to give the discrete cationic VO_2^+ species as well as react with bases to give a variety of mono-, di- and polyoxometallate anions.[10] By controlling the basicity of the reaction media and by judicious selection of suitable template cations, we have been able to direct the reaction of V_2O_5 with inorganic bases to form new solid state vanadate compounds rather than discrete isopolyvanadate anions. In this report, we wish to describe the synthesis and structural characterization of a novel layered vanadium oxide compound, $NH_4V_3O_8$ **1**, formed by a mild hydrothermal reaction. Compound **1** is distinct from the many layered compounds in the alkali-metal vanadium oxide family in that it contains highly corrugated layers, and all the vanadium ions in the structure are in the +5 oxidation state.

Pure $NH_4V_3O_8$ can be conveniently prepared from the base-induced polymerization/condensation reaction of V_2O_5 with aqueous NH_3 under hydrothermal conditions. Thus, when a sealed thick-walled Pyrex tube containing 100 mg (0.55 mmol) V_2O_5, 30 mg (0.56 mmol) NH_4Cl, 0.1 ml (0.37 mmol) 28% aqueous NH_3 and 0.5 ml of a mixed solvent composed of H_2O–MeOH (1 : 1, v/v) was heated at 110 °C for 4 days, analytically pure orange–brown single crystals of $NH_4V_3O_8$ were obtained in *ca.* 52% yield.‡ It is important to control the molar ratio of V_2O_5 : NH_3 to *ca.* 3 : 2 as excess NH_3 will lead to the formation of NH_4VO_3 as a by-product. However, addition of NH_4Cl to the reaction can increase the yield while suppressing the formation of the by-product. Eqn. (1) is the mass-balanced reaction that describes the formation of **1**:

$$3V_2O_5 + 2NH_3(aq) + H_2O \xrightarrow{\text{hydrothermal reaction}} 2NH_4V_3O_8 \quad (1)$$

The structure of **1** was determined by X-ray single crystal analysis.§¶ The asymmetric unit contains one N, three H, two V and five O atoms. Six atoms, including N, H(1), H(2), V(2), O(2) and O(5), are situated on the crystallographic mirror planes perpendicular to the [010] direction. The $V_3O_8^-$ layer is formed parallel to the *ab* plane, consisting of highly distorted VO_5 square pyramids around V(1) and VO_6 octahedra around V(2). First, every two square pyramids share a common edge. Such two edge-sharing square pyramid units are then linked with one another to form one-dimensional chains along the *b*-direction. Between these chains reside the VO_6 octahedra which share two edges with two neighboring, edge-sharing square-pyramidal units from one chain and two corners with two different square-pyramidal units from the adjacent chain in an alternating fashion. Fig. 1 shows the interconnection of the VO_5 square pyramids and VO_6 octahedra within one $V_3O_8^-$ layer. Five oxygen atoms are engaged in terminal, *i.e.* O(1) and O(2), doubly bridging, *i.e.* O(3) and triply bridging, *i.e.* O(4) and O(5) coordination, respectively. The layers are stacked along the *c*-direction with the NH_4^+ cations occupying the interlayer space. Because of the weak hydrogen bonding between the terminal oxygen atoms in the vanadium oxide layers and the H atoms from the NH_4^+ cations [*i.e.* O(1)–N 3.16 and O(2)–N 2.92 Å], the structure consists of highly corrugated $V_3O_8^-$ sheets arranged as if the layers intended to bend over in order to maximize the hydrogen bonding. As a result, each individual layer appears to have the sinusoid shape, shown in Fig. 2, so that two protons from a NH_4^+ cation can each form hydrogen bonds with two terminal O atoms on the same layer. Otherwise, a flat layer can only allow for a single hydrogen bond between the tetrahedral NH_4^+ ion and a terminal O atom from one layer.

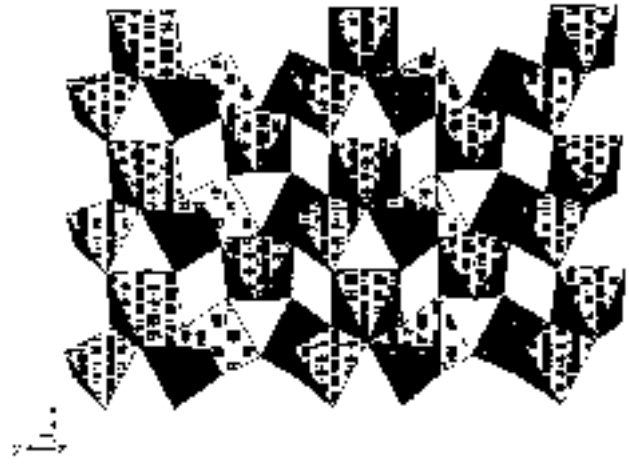

Fig. 1 The structure of one $V_3O_8^-$ layer, showing the interconnection of the VO_5 square pyramids and VO_6 octahedra

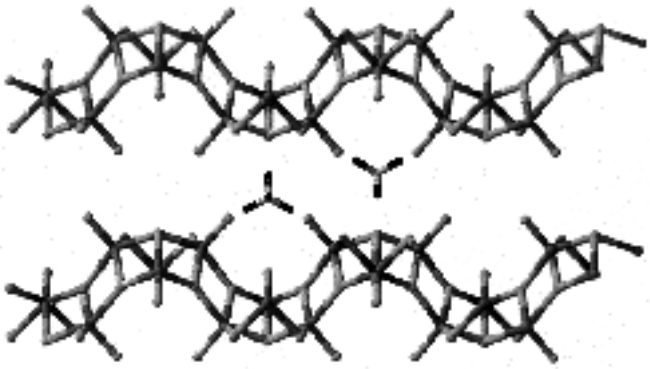

Fig. 2 The structure of layered $NH_4V_3O_8$, viewed down the *a*-direction

Both vanadium ions are in the +5 formal oxidation state as confirmed by the ESCA study.‖ The V–O bond distances within the layer range from 1.605(4) Å, involving the terminal oxygen atoms, to 2.281(6) Å, involving the triply bridging oxygen atoms.

In conclusion, a novel sinusoidal layered compound $NH_4V_3O_8$ has been synthesized and structurally characterized. Recently, Whittingham and coworkers showed that $(NMe_4)V_3O_8$ can be obtained by heating $(NMe_4)V_3O_7$ in air to *ca.* 200 °C.[11] However, the structure of $(NMe_4)V_3O_8$ has remained unknown, and is possibly related to **1**. In the current synthesis, **1** can best be thought of as being formed by reconstructing V_2O_5 layers through a base-induced polymerization/condensation reaction in the presence of the NH_4^+ cation template. To the best of our knowledge, **1** is the first example of a ternary layered vanadium oxide obtained by such a route. This method may open up a new avenue to a potentially large number of novel layered or open-framework materials with the use of other suitable templates.

‡ The product was isolated by water and acetone washing and separated by hand from a small amount of colorless NH_4VO_3 (*ca.* 5–10%) crystals and black $V_3O_{7+\delta}$ (*ca.* 2%) crystals. The unit cell parameters for $V_3O_{7+\delta}$ are: tetragonal, space group *P*4/*mbm* (no. 127), a = 8.9065(6), c = 5.5823(1) Å, U = 442.82(3) Å^3, Z = 2. We have not been able to refine the structure satisfactorily because of severe disorder at two oxygen sites.

§ *Crystallographic data* for **1**: $V_3O_8H_4N$, monoclinic, space group $P2_1/m$ (no. 11), a = 4.993(7), b = 8.423(1), c = 7.849(1) Å, β = 96.426(3)°, U = 328.45(7) Å^3, Z = 2, D_c = 3.022 g cm^{-3}, μ = 4.189 mm^{-1}, T = 295 K, structure solution and refinement based on 480 reflections with $I_o \geqslant 3.0\sigma(I_0)$ converged at R = 0.036, R_w = 0.044 and goodness-of-fit = 1.15. Data were collected on a Siemens SMART diffractometer using Mo-Kα radiation (λ = 0.710 73 Å). An empirical absorption correction based on simulated ψ-scans was applied to the data set. All hydrogen atoms were located from the difference Fourier maps, and were included in the structure but not refined. Further details of the crystal structure investigations of **1** are available from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-407899. CCDC 182/829.

¶ The phase identity and homogeneity of **1** were confirmed by comparing the experimental X-ray powder diffrction patterns of the bulk material with those calculated from the single crystal X-ray data.

‖ Electron spectroscopy chemical analysis (ESCA) gave two overlapping peaks for V2p$_{3/2}$ at 515.37 and 516.68 eV, which is consistent with V^{5+} ions in two different coordination environments. In addition, the binding energies for O 1s are 533.77, 531.95 and 530.21 eV, confirming three different bonding modes of the oxygen atoms in $NH_4V_3O_8$.

A cyano bridged iron(III) linear chain with alternating $Fe(CN)_6$–Fe(cyclam) (cyclam = 1,4,8,11-tetraazacyclodecane) units and unexpected ferromagnetic behaviour

The X-ray crystal structure and magnetic properties of a cyano-bridged iron(III) linear chain containing alternating iron sites and unexpected ferromagnetic behaviour, justified on the basis of the axial distortion from regular octahedral geometry of one of the iron(III) ions, are reported.

The design and elaboration of new systems with original magnetic, optical and/or electrical properties is at the heart of molecular magnetism.[1] In the last few years, there has been a considerable interest in the preparation and properties of molecular magnets.[2] One potential general route to the synthesis of molecular magnets is to make analogues of Prussian blue, in which all the centres are paramagnetic.[3] Following this route, several Prussian analogues have been prepared with the aim of enhancing the ordering temperature by changing the nature of the interaction between the paramagnetic ions through the cyanide bridge. Recently, the room temperature barrier was overcome at 315 K with a $Cr^{III}/[V^{II}–V^{III}]$ compound.[4] Even though these materials can be synthesized by applying the techniques of molecular chemistry and then considered as molecular-based magnets, however, because their magnetic properties can only be tuned by changing the pair of interacting paramagnetic ions, they are close to the ionic magnets. Lately, a hybrid approach has been used in order to obtain molecular-based magnets. It consists of combining $[M(CN)_6]^{n-}$ building blocks with transition metal ion complexes. Following this approach several cyano-bridged bimetallic complexes with 2D[5] and 3D[6] structures have been prepared, which undergo magnetic phase transitions at lower temperature than the Prussian blue analogues. Because they are molecular systems their magnetic properties can be chemically tuned by not only varying the metal ions but also the ligands. By using the same synthetic strategy it is possible to design MM'_6 cyano bridged heptanuclear entities (M = Fe^{III} or Cr^{III}; M′ = Cu^{II} or Ni^{II} and Mn^{II}, respectively).[7] Among them, the $CrNi_6$ and $CrMn_6$ species exhibit high-spin ground states of S = 15/2 and 27/2, respectively. We have now found that from the building blocks $[Ni(cyclam)]^{2+}$ and $[Fe(CN)_6]^{3-}$, two different cyano-bridged complexes can be obtained, depending on the stoichiometric ratio of the reactants. Thus, by dropwise addition of an aqueous solution of $K_3[Fe(CN)_6]$ (1 mmol, 20 ml) to an aqueous solution of $[Ni(cyclam)][ClO_4]_2$ (1 mmol, 50 ml) a brown precipitate is immediately obtained, whose analytical data point to the formula $[Ni(cyclam)]_3[Fe(CN)_6]_2\cdot 6H_2O$. Preliminary magnetic measurements suggest that this compound orders ferromagnetically below 8 K. It is noteworthy that the precipitate dissolves upon addition of a large excess of $[Fe(CN)_6]^{3-}$ (10 : 1 molar ratio), leading to a dark green solution, from which prismatic dark brown crystals of $[Fe(cyclam)][Fe(CN)_6]\cdot 6H_2O$ **1** appear within one week.‡ It is noteworthy that the presence of a large excess of $[Fe(CN)_6]^{3-}$ promotes the substitution of Ni^{II} from $[Ni(cyclam)]^{2+}$ by Fe^{III}. Consequently, complex **1** can also be prepared from cyclam and $K_3[Fe(CN)_6]$. The structure§ of **1** was determined by X-ray analysis (Fig. 1) and it consists of polymeric chains of alternating $[Fe(CN)_6]^{3-}$ and $[Fe(cyclam)]^{3+}$ ions running along the *a* axis, and crystal water molecules. In the chain two CN^- groups of each $[Fe(CN)_6]^{3-}$ unit bridge two iron(III) atoms with Fe···Fe distances of 5.129(1) Å. Both types of iron atoms are located on symmetry elements 2/*m*, and the bridging CN^- ions as well as the C(6) atom of the cyclam ligand lie on the mirror plane. The chains are almost linear as the bond angles for the bridging CN^- group are *ca.* 175°. The Fe–C–N angles for terminal CN^- groups in $[Fe(CN)_6]^{3-}$ do not deviate significantly from linearity. The iron centre in the $[Fe(CN)_6]^{3-}$ unit adopts a minimally distorted octahedral environment, where the *cis*-C–Fe–C angles are close to 90° and Fe–C distances equal for bridging [1.925(8) Å] and terminal [1.936(6) Å] CN^- groups. Owing to coordination of the CN^- groups, the iron centre of the $[Fe(cyclam)]^{3+}$ unit assumes an axially distorted octahedral FeN_6 chromophore. The two axial positions are occupied by the nitrogen atoms of the bridging CN^- groups with Fe–N distances of 2.069(6) Å and the equatorial positions by the N_4 set of donor atoms from the cyclam ligand with Fe–N distances of 1.963(5) Å. The equatorial coordination planes of Fe(1) and Fe(2) are not parallel but form a dihedral angle of 10.7(1)°. In the crystal, the chains are linked by hydrogen bonds involving the lattice water molecules and the N(2) and N(4) nitrogen atoms of the $[Fe(CN)_6]^{3-}$ and $[Fe(cyclam)]^{3+}$ units, respectively, thus leading to a two dimensional layer structure. The donor–acceptor distances range from 2.738(8) to 2.836(7) Å, whereas the nearest Fe···Fe interchain separation is 8.101(1)

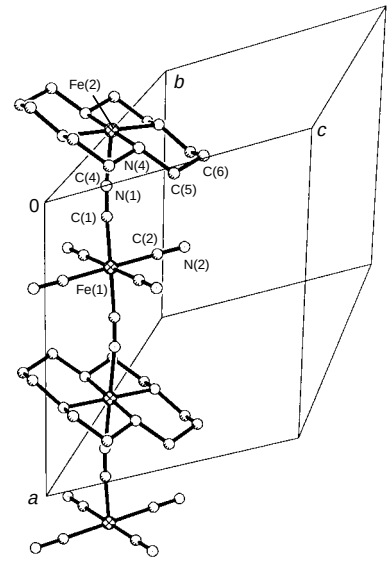

Fig. 1 A perspective view of the chain complex **1**

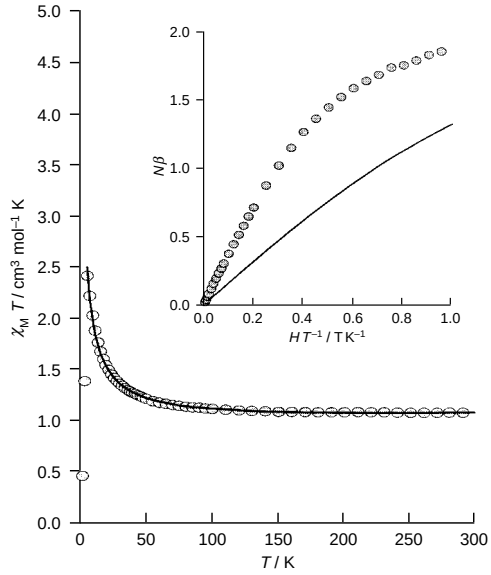

Fig. 2 Magnetic data ($\chi_M T$ *vs.* T) of **1**. Inset: magnetization data ($N\beta$ *vs.* H/T) of **1** (solid line represents the theoretical value of the Brillouin function for $S = \frac{1}{2}$).

Å. It should be noted that, among Fe^{III} polymers, structurally characterized chain complexes are rare and those with alternating iron sites are rarer still,[8] compound **1** being the first example of an iron(III) chain containing alternating iron sites but not alternating bridging ligands.

The temperature dependence of the $\chi_M T$ product per Fe_2 unit in the range 2–295 K is shown in Fig. 2. The $\chi_M T$ product at room temperature, 1.06 cm^3 mol^{-1} K, is significantly larger than the spin-only value of 0.75 cm^3 mol^{-1} K expected for two isolated low spin iron(III) ions ($S = \frac{1}{2}$), assuming $g = 2.00$, probably because of an orbital contribution to the magnetic moment of the low-spin Fe^{III} ions. As the temperature is lowered, $\chi_M T$ remains almost constant until around 100 K, then increases smoothly to reach a maximum of 2.41 cm^3 mol^{-1} K at 6 K and finally decreases sharply to 0.45 cm^3 mol^{-1} K upon cooling to 2 K. Such magnetic behaviour is characteristic of a dominant ferromagnetic coupling within the chain and interchain antiferromagnetic interactions, which are responsible for the decrease of $\chi_M T$ at very low temperature. The experimental magnetization values per Fe_2 unit as a function of the applied field at 5 K (Fig. 2) are greater than those predicted by the Brillouin function for two magnetically isolated iron(III) with $S = \frac{1}{2}$, thus confirming the existence of a ferromagnetic interaction between iron(III) ions. Apparently, **1** is the first example of an iron(III) chain exhibiting ferromagnetic intrachain exchange interactions. For estimating the magnitude of the ferromagnetic coupling, first, the magnetic susceptibility data ($T > 6$ K) were fitted to the Baker's expression[9] for a $S = \frac{1}{2}$ uniformly spaced ferromagnetic chain with the Hamiltonian in the form $H = -J \sum_i^{n-1} S_i \cdot S_{i+1}$.

The best fit parameters were $J = 8.6$ cm^{-1} and $g = 2.27$. The polycrystalline powder EPR spectrum at 100 K seems to be axial with $g_\perp = 2.21$ and $g_\parallel = 2.03$. At first glance, the ferromagnetic behaviour observed for **1** is rather unexpected taking into account the magnetic orbitals involved in the exchange interaction. Low-spin iron(III) ion in octahedral surroundings (t_{2g}^5) has the unpaired electron density on *xy*, *xz* and *yz* d orbitals, which are degenerate. If the Fe(1)–CN–Fe(2) bond is considered to lie along the *z* axis, with the *x* and *y* axes pointing toward the equatorial CN$^-$ groups for Fe(1) and toward the nitrogen atoms of the macrocycle for Fe(2), the *xz* and *yz* orbitals on both iron(III) ions would overlap through the π orbitals of the CN$^-$ group to give rise to antiferromagnetic contributions. A closer examination of the structure of **1**, however, reveals that while the coordination polyhedron of Fe(1) is almost perfectly octahedral (O_h point symmetry), that of Fe(2) is axially elongated along the CN–Fe(2)–NC direction (D_{4h}). For this tetragonal distortion the ground state configuration becomes $(xz, yz)^4(xy)^1$. Then, the ferromagnetic interaction might be the result of the orthogonality between the $(xy)^1$ orbital (b_{2g}) on Fe(2) and the *xz* and *yz* (t_{2g}) orbitals on Fe(1). It is of note that a similar unexpected ferromagnetic coupling has been also observed between two cyano-bridged Cr^{III}[d^3, $(t_{2g})^3$], in the compound *catena*-cyano(phthalocyaninato)chromium(III).[10] Even though no crystal structure determination has been reported for this compound, the Cr^{III} ions in the chain should be in a distorted octahedral surrounding. If so, a similar orbital explanation to that for **1** can be applied to the Cr^{III} compound in order to justify the observed ferromagnetic interaction. In view of these results, more examples are needed of cyano-bridged chain Cr^{III} and Fe^{III} complexes in order to definitively clarify the origin of the ferromagnetic exchange interaction. In this sense, the reaction of $[M(CN)_6]^{3-}$ (M = Cr^{III} and Fe^{III}) toward metal–macrocycle complexes is currently under examination.

Molecular assembly of two-α-helix peptide induced by haem binding

Seiji Sakamoto, Akihiko Ueno and Hisakazu Mihara*†

Department of Bioengineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, Nagatsuta, Yokohama 226-8501, Japan

A designed two-α-helix peptide H2α-17 bound effectively Fe^{III}–mesoporphyrin (haem), and the haem binding simultaneously induced the molecular assembly of the peptide from a monomeric to a tetrameric form.

The self-assembly of polypeptides and functional chromophores, such as chlorophyll and haem, has a significant role in nature, the assembled species displaying highly efficient functions. For example, in the bacterial light-harvesting complex LH2, nine identical units, each consisting of two kinds of α-helical polypeptides and three bacteriochlorophyll *a* (Bchl*a*) units, are combined into a ring-shaped assembly.[1] In the LH2 protein, the orientation and assembly of a large number of Bchl*a* units are regulated by the polypeptide three-dimensional structure in membranes and effective energy-transfer is accomplished. So far, in the field of *de novo* protein design, considerable effort has been devoted to construction of polypeptide three-dimensional structure and conjugation of porphyrin molecules *via* chelation[2–4] or covalent linkage[5–8] with peptides. However, to develop a larger supramolecular system, such as LH2, it will be necessary to construct and regulate self-assembling systems composed of multiple polypeptide units and porphyrin molecules. In line with this aim, we have designed and synthesized a two-α-helix peptide which binds Fe^{III}–mesoporphyrin (haem). Furthermore, we found that the haem-binding simultaneously induced the self-association of the peptide, and that the haem groups were highly oriented in the self-assembled peptides.

17-peptide segment was designed to take an amphiphilic α-helix structure, which was stabilized by two sets of E–K salt bridges (Fig. 1). The two segments were dimerized *via* the disulfide linkage of the Cys^{21} residues. As axial ligands of haem, His was introduced at the ninth position to deploy a haem parallel to the helix. Four Leu residues per helix were arranged around the His to construct a hydrophobic haem-binding site. Even though the hydrophobicity of the sequence may be low, it is expected that the haem binding increases the overall hydrophobicity of the peptide and induces molecular association through hydrophobic interactions. The peptide was synthesized *via* solid-phase methodology using the Fmoc strategy and purified with HPLC to high purity (> 98%). The peptide gave a molecular ion peak at *m*/*z* 4012.2 [(M + H)$^+$] (calc. 4011.7) *via* matrix assisted laser desorption ionization time-of-flight mass spectrometry.

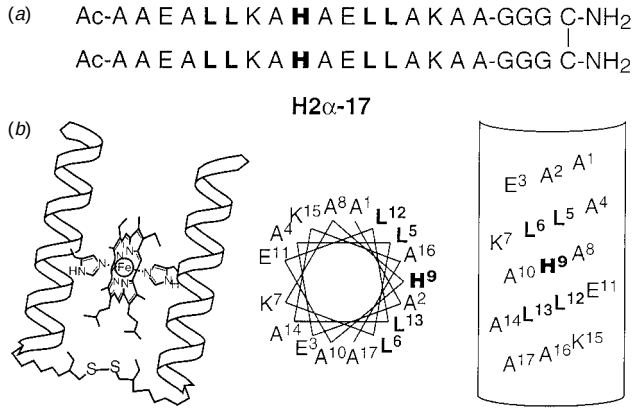

Fig. 1 Structure of the designed peptide, H2α-17. (*a*) Amino acid sequence of H2α-17; (*b*) illustration of the two-α-helix peptide structure bound to the haem, and helix wheel and net drawings of the 17-peptide.

Circular dichroism (CD) studies revealed that the peptide H2α-17 showed a typical α-helical pattern in buffer (pH 7.4) [Fig. 2(*a*)]. From the ellipticity at 222 nm ($[\theta]_{222}$ = −17 100 deg cm^2 dmol^{-1}), the α-helicity was estimated as 54%.[9] Since the monomeric peptide (H1α-17) showed a lower α-helix content ($[\theta]_{222}$ = −6800 deg cm^2 dmol^{-1}, 20%), the two α-helix segments in H2α-17 gathered together by orienting the hydrophobic side-chains inside, resulting in stabilization of the three-dimensional structure. Interestingly, the α-helicity of H2α-17 was increased by the addition of haem ($[\theta]_{222}$ = −26 800 deg cm^2 dmol^{-1}, 85%) [Fig. 2(*a*)]. The addition of an excess amount of cyanide ion (2.5×10^{-2} mol dm^{-3}, 2.5×10^3 equiv.) inhibited the coordination of H2α-17, resulting in a decrease in the α-helicity to the level observed without the haem. Additionally, there was no significant change in the CD spectra by the addition of haem at acidic pH (2.0–6.0). Because the pK_a of imidazole is *ca.* 6.0, the pH effect is attributed to the protonation of the His side chains such that they cannot act as a ligand. Therefore, we concluded that the increase in α-helicity of H2α-17 took place *via* the haem-binding by ligation with His residues. The thermal stability of the peptide in the presence or absence of haem was also examined by CD measurements. H2α-17 showed a midpoint of thermal transition (T_m) at 35 °C [Fig. 2(*b*)]. Similar to the α-helicity, haem binding increased remarkably the T_m value of the peptide to 62 °C. This result indicates that the haem binding increases the stability of the 2α-helix structure.

To further characterize the haem-binding with the peptide, UV–VIS titration of the haem with H2α-17 was carried out in buffer. With increasing peptide concentration, an increase of the Soret band at 405 nm and a decrease of the band at 355 nm of haem were observed (Fig. 3). That is, the UV–VIS spectrum of haem was converted from that of the high spin to the low spin form with an isosbestic point at 390 nm.[8] The UV–VIS spectrum of the haem in the presence of peptide resembles those

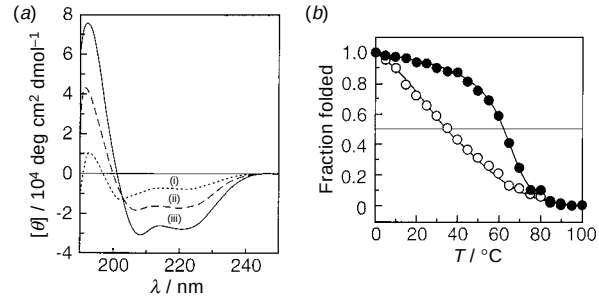

Fig. 2 (*a*) CD spectra of (i) H1α-17 and H2α-17 in the (ii) absence and (iii) presence of haem (1.0 equiv.) in 2.0×10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.4) at 25 °C. [H2α-17] = 1.0×10^{-5} mol dm^{-3} and [H1α-17] = 2.0×10^{-5} mol dm^{-3}. (*b*) Temperature denaturation profiles of H2α-17 in the (○) absence and (●) presence of haem (1.0 equiv.) in the buffer.

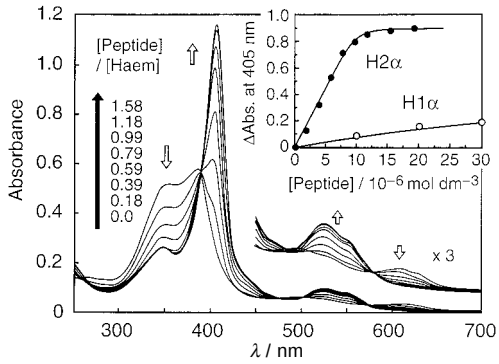

Fig. 3 UV–VIS spectra of haem with increasing H2α-17 concentration in the buffer (pH 7.4) at 25 °C. [haem] = 1.0×10^{-5} mol dm^{-3}. Inset: plots of absorbance at the Soret band of haem as a function of concentration.

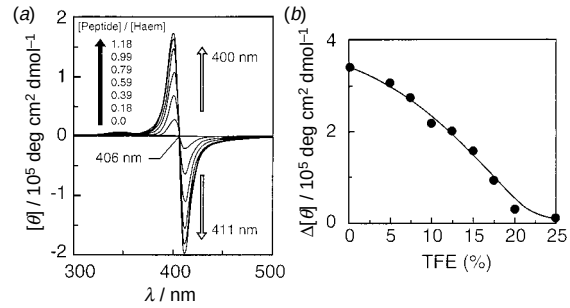

Fig. 5 (*a*) CD spectra of haem with increasing H2α-17 concentration in the buffer (pH 7.4) at 25 °C. [haem] = 1.0×10^{-5} mol dm^{-3}. (*b*) Effect of TFE content on the Soret CD intensity of haem bound to the peptide. $\Delta[\theta] = [\theta]_{max} - [\theta]_{min}$.

of natural cytochromes with six-coordinate iron. The binding constant (K_a) determined from the absorbance change at the Soret band using a single site binding equation,[4] was 1.1×10^7 mol^{-1} dm^3 (Fig. 3, inset). On the other hand, addition of H1α-17 caused little increase of the Soret band, suggesting that the monomeric peptide could not bind the haem effectively in this concentration range. This result implies that the 2α-helix structure and the consequent formation of the hydrophobic pocket are essential for the haem-binding.[4]

To examine the molecular assembly of the peptide in aqueous solution, the peptide samples were passed through a size-exclusion column. In the absence of haem, the peptide showed a sharp single peak [Fig. 4(*a*)]. It is reasonable to conclude that the peptide is in the monomeric form in the buffer, because sedimentation equilibrium studies demonstrated that the peptide existed as the monomeric form [MW_{obs} = 3600 (MW_{calc} = 4010)] under the same conditions. Furthermore, the peptide did not show any concentration dependence of the α-helicity at (0.1–2.0) $\times$ 10^{-5} mol dm^{-3}. When the peptide solution containing the haem (1.0 equiv.) was chromatographed, the haem was co-eluted with the peptide in a sharp peak at a higher molecular weight, suggesting that the haem was tightly bound to the peptide and that the haem-binding gave rise to the formation of a higher self-association state of the peptide [Fig. 4(*b*),(*c*)]. The sedimentation equilibrium studies revealed that the peptide was in a tetrameric form (MW_{obs} = 19 300, 4.2-mer) after haem-binding [Fig. 4(*d*)]. As further evidence supporting the self-association of peptide–haem conjugates, the haem bound to the peptide showed a strong induced CD peak in the Soret region, which was split into a negative peak at a longer wavelength and a positive peak at a shorter wavelength (Fig. 5). The split Cotton effect, *i.e.* exciton-coupling, indicates that the haem groups are highly oriented with respect to each other in close positions in the self-assembled peptides. With increasing percentage volume of trifluoroethanol (TFE), the ellipticity gradually decreased [Fig. 5(*b*)]. Dissociation of the haem from the peptide cannot explain the reduced Soret CD, because the UV–VIS study indicated that the peptide bound the haem with the six-coordinate form below 25% TFE (K_a = *ca.* x 10^7 mol^{-1} dm^3). Thus, the decrease of the Soret CD seems to be attributed to a change of association state of the peptide–haem conjugate from a tetrameric to a monomeric form. This TFE titration study implies that the hydrophobic interaction is important for the self-association of the peptide–haem conjugates. That is, the haem-binding increases the overall hydrophobicity of the amphiphilic 2α-helix peptide and induces the molecular assembly of the peptide–haem conjugates.

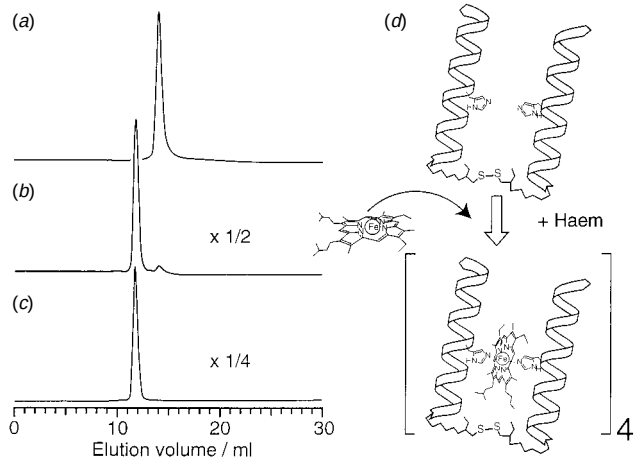

Fig. 4 Size-exclusion chromatograms of H2α-17 (*a*)–(*c*) and the schematic representation of self-assembly of two-α-helix peptide induced by the haem binding (*d*). (*a*) H2α-17 (1.0×10^{-5} mol dm^{-3}) in the absence of haem, detection at 220 nm. (*b*) H2α-17 (1.0×10^{-5} mol dm^{-3}) in the presence of haem 1.0 equiv.), detection at 220 nm. (*c*) H2α-17 (1.0×10^{-5} mol dm^{-3}) in the presence of haem (1.0 equiv.), detection at 405 nm. Column, Superdex 75 HR 10/30 (10 $\times$ 300 mm), 0.1 mol dm^{-3} NaCl/5.0 $\times$ 10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.4) at 25 °C; flow rate, 0.5 ml min^{-1}.

In conclusion, the association and orientation of functional chromophores can be accomplished using an artificially designed polypeptide. These findings could lead to studies applicable to the regulation of haem functions by polypeptide three-dimensional structures and to the development of peptidyl devices with haem functions.

We are grateful to Professor F. Arisaka, Tokyo Institute of Technology, for ultracentrifugation analyses.

An antibody transesterase derived from reactive immunization that utilizes a wide variety of alcohol substrates

Chao-Hsiung Lin, Timothy Z. Hoffman, Yiling Xie, Peter Wirsching* and Kim D. Janda*†

Departments of Chemistry and Molecular Biology, The Scripps Research Institute and the Skaggs Institute for Chemical Biology, 10550 N. Torrey Pines Road, La Jolla, California 92037, USA

A monoclonal antibody obtained from reactive immunization catalyzes transesterifications of alcohol substrates with both broad and unusual specificity.

Reactive immunization has emerged as a new tool for the study of catalysis at the interface of chemistry and biology.[1] Unlike traditional immunization methods that invoke noncovalent interactions to elicit an antibody repertoire, reactive immunization makes use of a chemical reaction to direct the course of the immune response. Powerful applications have resulted in catalytic antibodies that use an enamine mechanism for myriad aldol reactions,[2,3] an alternative pathway for the allylic rearrangement exemplified by Δ^5-3-ketosteroid isomerase,[4] and the enantioselective hydrolysis of a naproxen ester.[5] A tenet which has emerged is that broad substrate specificities, ascribed to the special ontogeny of antibodies induced by immunogens that form covalent bonds within the binding pocket during induction, may be a feature in catalysts derived from reactive immunization.

We discovered that one of our earlier antibodies[1] SPO50C1, derived from immunization with a reactive bis(4-methylsulfonylphenyl) phosphonate, catalyzed the transesterification of *p*-sulfonylphenyl ester **1** by a large number of different alcohols **2** under aqueous conditions (Fig. 1). Therein, our results required the elaboration of the above hypothesis to include not only broad specificity, but also unanticipated or unusual characteristics with regard to substrate tolerance. Notably, alkyl alcohols as substrates in antibody catalysis have not been previously reported. The binding of these alcohols was unexpected, in light of the aromatic and immunogenic nature of the phenolic leaving group, as was their associated reactivities.

The mechanism of the SPO50C1 reaction to yield esters **3** proceeded by way of a covalent acyl–antibody intermediate (species F in the ping-pong notation of Cleland[6]) as substantiated quantitatively by pre-steady-state kinetic analysis of the observed stoichiometric 'burst' formation of phenol **4** upon antibody acylation (k_{obs} = 1.8 s^{-1}).‡ Therefore, as judged from rates of product ester formation (second product Q), deacylation was entirely the rate-determining step. In that SPO50C1 was also a relatively fast esterase with **1** (k_{cat} = 0.56 min^{-1}), alcohols competed effectively with water to partition the acyl intermediate.

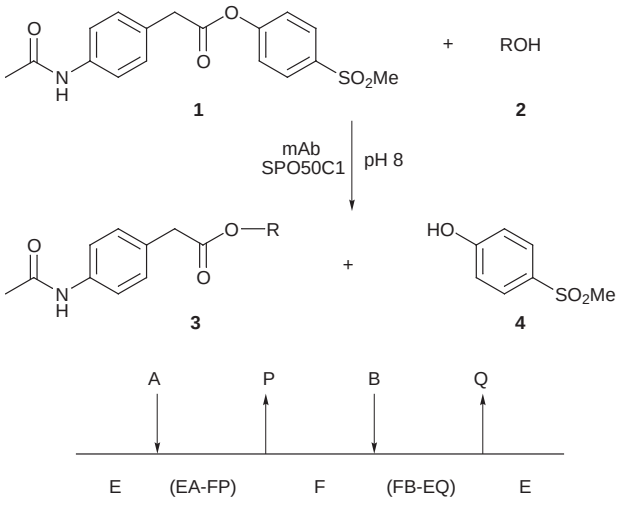

Fig. 1 Reaction catalyzed by SPO50C1

All alcohols were true substrates for the antibody and afforded observed saturation kinetics (Table 1). Significantly, it was shown that even at very high concentrations of some alcohols (*i.e.* 2.43 M for MeOH) the plateau in maximum rates resulted from saturation and not a detrimental 'organic solvent effect' on antibody activity.§ The trend in kinetic data cannot be explained merely in terms of the chemical reactivity of the alcohols, but most likely by a subtle interplay of nucleophilicity, hydrophobic effects and steric interactions.

Correlation analyses[7] of catalysis with Hansch hydrophobicity constants (π), Taft steric constants (E_s) or a multiparameter equation were nonlinear. While decreased K_m values roughly paralleled increased hydrophobicity [$\Delta\log(1/K_m)/\Delta\pi \sim 1$], k_{cat} showed the opposite bias together with breaks and plateaus. The specificity (k_{cat}/K_m) across the entire series of primary alcohols was remarkably similar with K_m becoming dominant and elevating k_{cat}/K_m about 10-fold only at high π values (π = 3.0, 3.5) (entries 10, 11) or with aromatic structures (entries 12, 13). MeOH, as might be predicted due to a low π (0.5), had the highest K_m, and perhaps because of its high nucleophilicity also gave the best turnover. The secondary alcohols were expectedly slower substrates than their primary congeners, however the differences did not reflect the solution reactivities of these alcohols (compare ratios of entries 3 and 4; k_{cat} = 4.4, k_{uncat} = 78.6). Although Bu^nOH (entry 5) and the other primary alcohols could be considered more efficient substrates (k_{cat}/K_m) than Pr^iOH, the latter was comparable or faster under saturating conditions [*i.e.* k_{cat} (entry 4)/k_{cat} (entry 5) = 5.6]. The k_{cat} for Pr^iOH even approached that of BnOH which was 128 times more reactive in solution. Furthermore, Pr^iOH was 10-fold and 100-fold faster than the other secondary alcohols (entries 7, 14), respectively; in addition cyclohexanol (not depicted) showed no detectable activity. Clearly, there was unique behavior associated with Pr^iOH as a substrate for SPO50C1.

The catalysis by SPO50C1 contrasts with the transesterification of some acyl trypsins[8] and esterases[9] where the more hydrophobic alcohols are often better substrates than lower homologs, except MeOH, and secondary alcohols show little or no activity. Also, Bu^nOH (entry 5) was particularly unusual and showed a tangible downward break in both k_{cat} and K_m. It is possible that nonproductive binding modes, as proposed for special substrates of chymotrypsin,[10] were operative. Aromaticity and steric constraints were contributing factors in the SPO50C1 reactions evidenced by the surprising lack of reactivity of cyclohexylmethanol (not depicted) (compare entries 6, 12). Interestingly, phenethyl alcohol was the most specific substrate which might reflect a favorable combination of hydrophobic and/or aromatic interactions and flexibility of the side-chain hydroxy functionality.

Table 1 Kinetic constants[a] for catalytic antibody SPO50Cl transesterification experiments

Entry	Substrate	k_{cat}/min^{-1}	K_m/mM	(k_{cat}/K_m)/ M^{-1} min^{-1}	k_{uncat}/ M^{-1} min^{-1}	Effective molarity/M
1	MeOH	1.4	8.7×10^2	1.7	2.9×10^{-3}	4.8×10^2
2	EtOH	0.19	3.1×10^2	0.60	2.8×10^{-4}	6.8×10^2

[a] Determined at 22 °C in 100 mM bicine, pH 8.0 with 2% MeCN as cosolvent in the presence or absence of antibody. Antibody-catalyzed reactions used 10 μM SPO50Cl and varying concentrations of alcohol in the presence of substrate **1** fixed at 200 μM (close to both the solubility limit and saturation). The mAb has one functional active site (ref. 1). Assays were conducted using reverse-phase (C-18) HPLC (MeCN–H_2O–0.1% TFA eluent) by observing the formation of the ester product at 254 nm. The background rates for entries 4, 6, 8, 9 and 14 were determined at 60 °C and extrapolated to 22 °C by assuming an activation energy of 25 kcal mol^{-1}. The half-life for the spontaneous hydrolysis of **1** at 22 °C under the reaction conditions was 99 min. nd = Not determined (no ester formation was observed at 60 °C). All values have an estimated experimental error of ±10%.

The parameter of 'effective molarity'[11] was used as a measure of the catalytic power of SPO50C1. Although the mechanisms of the antibody-catalyzed and the one-step, base-catalyzed background transesterifications are different, an operational estimate can be made by comparing k_{cat} (min^{-1}) (k_{cat} represents the number of moles of ester product produced per mole of antibody per minute) to k_{uncat} (M^{-1} min^{-1}), the second-order rate constant for alcoholysis. Thus, for example, to achieve the same rate of product synthesis in the uncatalyzed transesterification of **1** by Pr^{i}OH, the concentration of Pr^{i}OH must approach 3600 M (0.050 min^{-1}/1.4×10^{-5} M^{-1} min^{-1}) (Table 1, entry 4). While our previous antibody transesterase, PCP21H3, derived from a transition-state analogue, attained rate enhancements of $>10^6$ M, the alcohol acceptors were restricted to a class structurally congruent to the hapten wherein small changes in binding energy were important.[12]

Our findings here indicated that the influence of structural and electronic factors upon catalysis were not overwhelming. The results refine our view that traditional, inert haptens program complementary binding pockets of somewhat limited scope, whereas reactive immunogens lead to active sites that are more unusual in their substrate tolerance and reactivity. This approach potentially allows one to procure antibodies with the intricate mechanisms of enzymes along with other features useful for biologcal and chemical applications.

This research was supported by NIH Grant GM43858 and The Skaggs Institute for Chemical Biology.

Precise control of RNA cleavage by ribozyme mimics

Andrew T. Daniher and James K. Bashkin*†

Department of Chemistry, Washington University, St. Louis, MO 63130-4899, USA

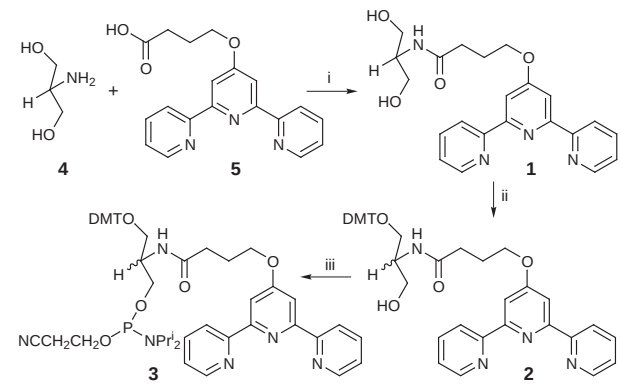
A highly-modified DNA building block, lacking both sugar and base moieties, is synthesized and incorporated into oligonucleotides to form functional mimics of ribozymes.

We demonstrate here that second-generation ribozyme mimics based on a serinol–terpyridine reagent, when incorporated into a DNA oligonucleotide, cleave their target RNA in a sequence-specific manner. Furthermore, the position of cleavage within the target sequence was precisely controlled by the location of the terpyridine within the oligonucleotide. These second-generation mimics function with greatly improved efficiency over our previous terpyridine reagents.[1,2] We attribute the improved cleavage to increased flexibility of the target RNA strand that results when serinol replaces a nucleotide in the DNA sequence: this eliminates a DNA/RNA base-pair near the cleavage site and may lower the barrier for phosphorane formation.

Functional ribozyme mimics consist of an oligonucleotide for molecular recognition and an attached RNA cleavage (transesterification) agent.[3,4] These ribozyme mimics are designed to extend the antisense approach to translation arrest by creating a catalytic cycle independent of any enzyme-mediated RNA cleavage. The antisense method is a gene-specific technique for blocking protein synthesis that inhibits the translation of mRNA into proteins.[5]

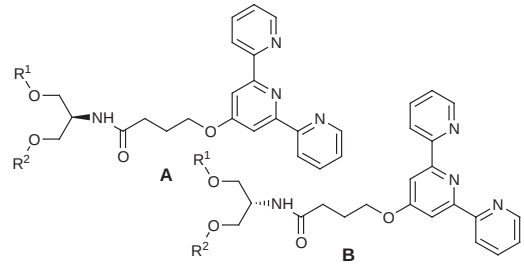
Our group previously reported the first wholly synthetic ribozyme mimic,[1] which was comprised of a 17-mer DNA probe with a pendant terpyridyl (terpy) complex of Cu^{II} incorporated in DNA *via* a thymidine derivative.[2] Aqueous (terpy)Cu^{II} is a known RNA transesterification and hydrolysis agent.[6–8]

We wished to improve cleavage efficiency and the ease of preparation of ribozyme mimics. Here we report greatly improved RNA cleavage and much simpler synthetic routes. The new reagents (Scheme 1) are conjugates of serinol and terpyridine. Serinol, a reduced form of serine, mimics the spacing of the sugar backbone of DNA; it and related compounds have previously been used as building blocks for abasic DNA sites.[9,10] An abasic DNA site eliminates one Watson–Crick base pair in a duplex and increases the conformational flexibility of the double-stranded region. The RNA in an RNA/DNA duplex is relatively inert towards cleavage when compared to its single-stranded form, perhaps because the duplex is a more conformationally rigid structure than the single strand.[11,12] Incorporation of the serinol residue into a DNA sequence allows formation of a duplex with the complementary RNA strand, and increases the flexibility of the RNA in the region opposite the serinol. This flexible RNA region should more readily form the pentacoordinate phosphorane required for transesterification, and should therefore undergo enhanced cleavage compared to a perfectly base-paired sequence.[9]



Scheme 1 *Reagents and conditions*: i, EDC, DMF, room temp., 30 h, 45.5%; ii, Py, Et_3N, DMT-Cl, 30%; iii, Et_3N, CH_2Cl_2, 2-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite, room temp. 20 min, 47%

Derivatizing serinol in an unsymmetrical fashion gave stereoisomers **A** and **B**. Fukui suggested that related compounds, derivatives of the 2*R*,3*R* isomer of L-threoninol, preferentially target the major groove upon incorporation into DNA.[13] Since free rotation can occur in the serinol backbone, both **A** and **B** should be able to reach either groove. This paper describes work on a mixture of stereoisomers **A** and **B**.



The synthesis of **3** is shown in Scheme 1. Serinol, a *meso* compound, possesses the same spacing between alcohols (three carbons) as a normal deoxynucleoside. Serinol **4** was coupled to the terpyridine (terpy) acid **5** with 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), giving **1** (45.5%). Subsequent 4,4′-dimethoxytrilyl (DMT) protection of one of the primary alcohols of **1** gave **2** in 30% yield. Phosphitylation of **2** resulted in the desired phosphoramidite **3** as a mixture of stereoisomers (47%).

Several 17-mer probes designed to target a 159-mer fragment of the HIV *gag* gene mRNA were prepared *via* automated DNA synthesis, using **3** and/or standard nucleoside phosphoramidites. The RNA sequence is shown below, with the 17-mer recognition region underlined.

5′-$^{1(775)}$GGAGAA^{6} AUUUAUAAAA^{16} GAUGGAUAAU^{26} CCUGGGAUUA^{36}
AAUAAAAUAG^{46} UAAGAAUGUA^{56} UAGCCCUACC^{66} CAGCAUUCUG^{76}
GACAUAAGAC^{86} AAGGACCAAA^{96} GGAAC<u>CUUUA</u>^{106} <u>GAGACUAUGU</u>^{116}
<u>AGA</u>CCGGUUC^{126} UAUAAAACUC^{136} UAAGAGCCGA^{146} GCAAGCUUCA^{156}
CAG$^{159(933)}$-3′

The 17-mer DNA probe sequences, in 5′ to 3′ orientations with **X** indicating the serinol–terpy residue, are:

1a 5′-CTACATAGTCTCTAAAG-3′ **1b** **X**TACATAGTCTCTAAAG
1c CTACA**X**AGTCTCTAAAG **1d** CTACATAG**X**CTCTAAAG
1e CTACATAGTC**X**CTAAAG

Derivatives **1b**–**e** of probe **1** differ in the location of the serinol–terpy residue, but all bind to the same region of the RNA target. Control probes for **1b**–**e** [named **1(b**–**e)-ctrl**] were also prepared using **6** (Glen Research) in place of serinol–terpy reagent **3**.

6

These probes explicitly test for any enhanced cleavage activity that flexible, abasic reagents might confer on the target RNA.

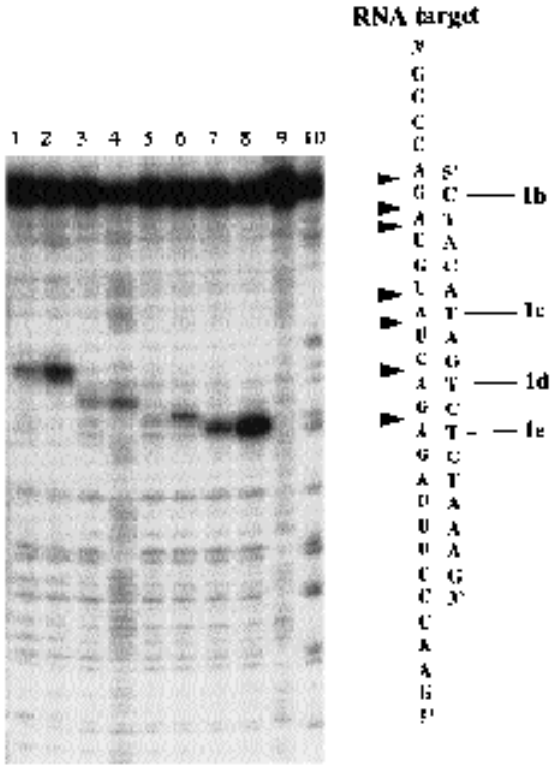


Fig. 1 Site-specific RNA cleavage with serinol–terpyridine probes. Lane 1: **1b**. Lane 2: **1b** + $CuCl_2$. Lane 3: **1c**. Lane 4: **1c** + $CuCl_2$. Lane 5: **1d**. Lane 6: **1d** + $CuCl_2$. Lane 7: **1e**. Lane 8: **1e** + $CuCl_2$. Lane 9: base. Lane 10: RNase T1. Reactions were carried out at 45 °C in a total volume of 10 μl containing the following: 0.1 M $NaClO_4$, 10 mM HEPES (pH 7.5), *ca* 10^{-9} M RNA target, 5 μM probe and 10 μM $CuCl_2$. The probes and $CuCl_2$ were premixed. The reactions were stopped after 24 h with EDTA.

Having prepared the serinol–terpy probes and appropriate controls, we investigated their inherent RNA cleavage abilities. Fig. 1 shows representative results from one set of experiments in which the cleavage of the target RNA was carried out by **1b–e**. To perform these reactions, a solution of a probe (5 μM) was combined with 5′-end labelled RNA (*ca*. 10^{-3} μM) in 10 mM HEPES buffer (pH 7.5), with 0.1 M $NaClO_4$ to control ionic strength. As indicated in Fig. 1, each experiment was done both with and without added 10 μM $CuCl_2$. Reactions were incubated at 45 °C and analyzed by electrophoresis on a denaturing 6% polyacrylamide gel.

Cleavage resulting from the various serinol–terpy-containing probes occurred at the RNA nucleotides opposite the serinol–terpy groups. As the terpy was moved from one internal position to the next, the cleavage followed in a precise manner (Fig. 1). Cleavage occurred whether the terpy was at an internal or external position of the RNA/DNA duplex. No specific cleavage occurred for the unmodified DNA control probe **1a** or the controls **1(b–e)-ctrl** (data not shown). Thus, the flexible, abasic site generated by **6** did not promote cleavage of the RNA target.

The amount and the location of cleavage depended on the serinol–terpy probe used and the temperature. However, the major determining factor was the primary sequence and location of the catalyst. Cleavage sites were identified by comparison with RNase Tl and base hydrolysis lanes (Fig. 1 and Table 1). Generally, cleavage occurred to the 3′- and 5′-sides of the RNA nucleotide opposite serinol, and spanned from one to three positions. Apparent background cleavage is seen in Fig. 1 in those lanes (1,3,5 and 7) corresponding to reactions with no added Cu^{II}. Additional experiments showed that this background cleavage derives from Cu^{II} ion that is scavenged by the terpy-containing DNA probes during synthesis and purification (data not shown). Treating the probes with EDTA prior to reaction eliminated the background cleavage. Adding Cu^{II} (but not divalent Fe, Mg, Pb or Zn) recovered the cleavage activity of the EDTA-treated ribozyme mimics (data not shown).

Table 1 Cleavage results from sequence-specific reactions of ribozyme mimics with the 159-mer target RNA, in the presence of Cu^{II} ion

		% Total cleavage	
Probe	Cleavage Sites	24 h	72 h
1b	G^{118}, A^{117}, U^{116}	18	48
1c	A^{113}, U^{112}	10	35
1d	A^{110}	10	40
1e	A^{108}	48	84

The synthesis of the serinol–terpyridine building block allows the introduction of cleaving agents anywhere within a DNA probe. This approach provides a much more efficient synthetic means of incorporating terpy into oligonucleotides than the preparation of intact nucleoside derivatives. We observed a marked increase in cleavage efficiency compared to our first-generation ribozyme mimics. Our first mimic cleaved 28% of its target after 3 days at 45 °C. Our best second-generation mimic cleaved 84% of its target after 3 days at 45 °C. The serinol backbone may enhance transesterification because it creates an artificial abasic site when incorporated into an oligonucleotide and duplexed to RNA. The RNA site opposite this modified monomer is not base-paired, so it has greater flexibility. This flexibility should allow the terpy ligand to span both the major and minor grooves in the RNA/DNA duplex, and should allow the RNA to adopt reactive conformations. The serinol–terpyridine ribozyme mimics are consistent with our belief that cleavage must occur within the duplex region in order to free the mimic for catalytic turnover.

A pyridazine Schiff-base macrocycle hosts a dicobalt centre in five different redox states: evidence for a mixed valent $Co^{I}Co^{II}$ species

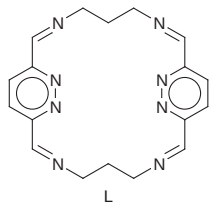
Sally Brooker,*† Robert J. Kelly and Paul G. Plieger

Department of Chemistry, University of Otago, PO Box 56, Dunedin, New Zealand

Electrochemical studies of $[Co^{II}_2L(MeCN)_4][ClO_4]_4$ 1, the first structurally characterised dicobalt complex to be bridged by pyridazine units, reveal two one-electron reductions as well as two one-electron oxidations at high potentials; one-electron reduction generates a mixed valent $Co^{I}Co^{II}$ species which exhibits an intervalence charge transfer band at 965 nm.

Despite intense interest in cobalt(I) complexes as reactive centres for catalytic processes, such as CO_2 fixation and the reduction of water to dihydrogen or as models for vitamin B_{12}, there are relatively few examples of the isolation of such complexes in the absence of the stabilising effects of phosphines or phosphites.[1–4] Notable exceptions to this generalisation include structurally characterised complexes by Creutz *et al.*[3] and by Floriani and coworkers.[4]

We are studying complexes of chelating ligands based on 3,6-diformylpyridazine[5–8] and have found that the resulting dicopper(II) complexes exhibit positive reduction potentials (two well separated one-electron reductions),[7,8] and that dimanganese(II) complexes can be formed and are air stable.[6] These observations clearly indicate that our pyridazine-containing ligands are, as one might expect on the basis of their π-acceptor properties, good at stabilising low oxidation states of transition metal ions. Of these ligands, the macrocyclic ligands are expected to be particularly effective because strong chelation to the metal centres should hinder any subsequent decomposition reactions. Hence we have extended our studies to include a wide range of transition metal ions, with a view to stabilising and isolating unusually low oxidation state complexes.[6–8] Pyridazine- or phthalazine-bridged dicobalt(II) complexes are rare and, to our knowledge, no electrochemical studies have been reported for such complexes.[9] To date, there are no known examples with pyridazine-containing macrocyclic ligands. We report here on an air stable dicobalt(II) complex of the Schiff-base macrocyclic ligand L.



L

Transmetallation of the macrocyclic complex $[Pb_2L'][ClO_4]_4$ {L′ is the (4 + 4) analogue of L}[5,6] with cobalt(II) perchlorate in MeCN yields, after vapour diffusion of diethyl ether into the air stable solution, dark red crystals of $[Co_2L(MeCN)_4][ClO_4]_4$ **1**, in 57% yield.‡ The IR spectrum of **1** shows the presence of an imine absorption and the absence of absorptions due to either amine or carbonyl bonds. The FAB mass spectrum has a cluster of peaks consistent with the presence of $[Co_2L(ClO_4)_3]^+$, thus indicating that the original (4 + 4) Schiff-base macrocycle L′ had ring contracted to the (2 + 2) macrocycle L. This ring contraction, also observed in the case of the dicopper(II) and dimanganese(II) complexes,[6–8] was subsequently confirmed by single crystal X-ray structure analysis of a crystal obtained by slow evaporation of an acetonitrile solution of **1** to which an excess of sodium perchlorate had been added (Fig. 1).§

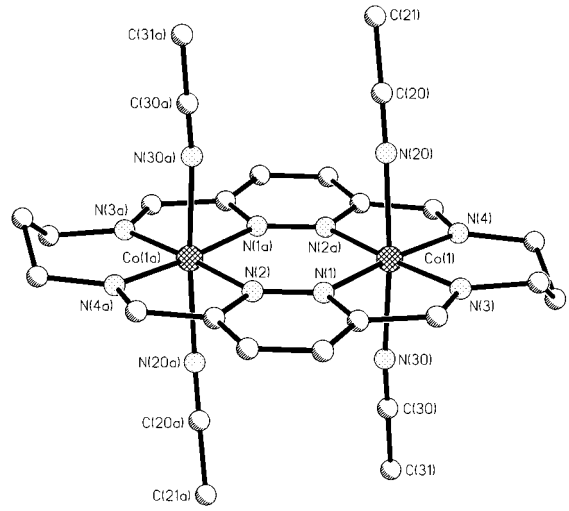


Fig. 1 Perspective view of one of the two independent cations of **1**, $[Co_2L(MeCN)_4]^{4+}$. Selected interatomic distances (Å) and angles (°): Co(1)–N(3) 1.984(4), Co(1)–N(4) 1.964(4), Co(1)–N(2a) 2.005(4), Co(1)–N(1) 2.013(4), Co(1)–N(30) 2.127(4), Co(1)–N(20) 2.135(4), Co(1)···Co(1a) 3.809(1); N(3)–Co(1)–N(4) 94.3(2), N(3)–Co(1)–N(2a) 175.5(2), N(4)–Co(1)–N(2a) 81.2(2), N(3)–Co(1)–N(1) 80.8(2), N(4)–Co(1)–N(1) 174.7(2), N(2a)–Co(1)–N(1) 103.7(2), N(3)–Co(1)–N(30) 92.8(2), N(4)–Co(1)–N(30) 88.8(2), N(2a)–Co(1)–N(30) 87.6(2), N(1)–Co(1)–N(30) 89.4(2), N(3)–Co(1)–N(20) 93.7(2), N(4)–Co(1)–N(20) 90.3(2), N(2a)–C0(1)–N(20) 85.9(2), N(1)–Co(1)–N(20) 92.1(2), N(30)–Co(1)–N(20) 173.5(2).

Cyclic voltammetry was carried out on $[Co_2L][ClO_4]_4$ in dry MeCN and revealed two one-electron reduction waves at remarkably high potentials ($E_{\frac{1}{2}}$ = −0.11 V and $E_{\frac{1}{2}}$ = −0.33 V, *vs.* Ag/0.01 M $AgNO_3$, Fig. 2) plus two one-electron oxidation waves at positive potentials ($E_{\frac{1}{2}}$ = +0.87 V and $E_{\frac{1}{2}}$ = +1.06 V, *vs* Ag/0.01 M $AgNO_3$, Fig. 2). The two reduction waves are tentatively assigned to $Co^{II}Co^{II} \rightarrow Co^{II}Co^{I}$ and $Co^{II}Co^{I} \rightarrow$

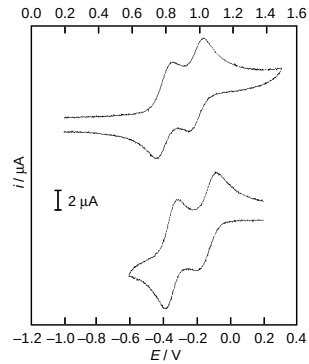

Fig. 2 Cyclic voltammogram of **1** in MeCN (1×10^{-3} M, 0.1 M NEt_4ClO_4, platinum counter electrode *vs.* Ag/0.01 M $AgNO_3$, 200 mV s^{-1}, in this system $Fc–Fc^+$ = +0.09 V).

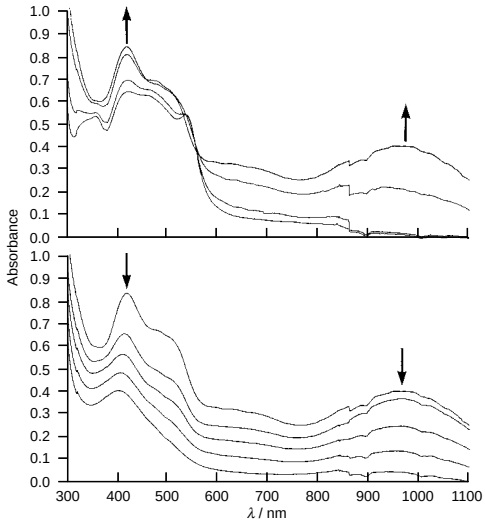

Fig. 3 Spectral changes during two step bulk electrolysis of **1** in MeCN. Top: first one-electron reduction (E = −0.29 V, 0.92 electron equivalents transferred). Bottom: second one-electron reduction (E = −0.60 V, 0.94 electron equivalents transferred).

$Co^{I}Co^{I}$ reductions and the two oxidation waves to be $Co^{II}Co^{II} \rightarrow Co^{II}Co^{III}$ and $Co^{II}Co^{III} \rightarrow Co^{III}Co^{III}$ oxidations.¶

As no electrochemical studies have been reported on the handful of other known 1,2-diazine bridged cobalt complexes, it is not possible to make comparisons with these.[9] However, comparison with the redox properties of other related cobalt complexes, such as those provided by the systematic study of monocobalt complexes of a series of N_4-macrocycles by Busch and coworkers [$-2.21 < E_{\frac{1}{2}}(Co^{II} \rightarrow Co^{I}) < -0.72$ V *vs.* Ag/Ag^+ (0.1 M) in MeCN],[10] confirms that the reductions of **1** are, indeed, occurring at relatively high potentials. In that study the presence of an N_3 pyridine diimine or of two N_2 conjugated diimine groups in the N_4-macrocycle was found to greatly stabilise Co^{I} [$E_{\frac{1}{2}}(Co^{II} \rightarrow Co^{I})$ = − 0.72 V and −0.86 V *vs.* Ag/Ag^+ (0.1 M) in MeCN, respectively].[10] Similarly, as the pyridazine macrocycle L incorporates imine bonds conjugated with pyridazine units an even greater enhancement of stability of Co^{I} results. In fact the observed potentials for **1** fall close to the range normally observed for oxidation of Co^{II} to Co^{III}.[11] For example, in the Busch complexes mentioned earlier the potentials for this oxidation process fall in the range −0.09 to +0.17 V *vs.* Ag/Ag^+ (0.1 M).[10] Again this is in clear contrast with the substantially more positive potentials observed for the oxidation processes of **1**, which presumably result from the build up of positive charge on the complex (+6 on the fully oxidised complex).

It is important to note that in our dicobalt(II) complex the two reductions and the two oxidations all occur in separate one electron steps: in the case of the reductions they are separated by 220 mV ($K_c = 5.24 \times 10^3$) whereas the oxidations are separated by 190 mV ($K_c = 1.63 \times 10^3$). Hence the mixed valent redox products are moderately stable. Preliminary spectroelectrochemical studies of the reduction processes indicate the existence of an intervalence charge transfer band in the mixed valent $Co^{I}Co^{II}$ complex, with the growth of a broad band centred at 965 nm (2790 $dm^3\ mol^{-1}\ cm^{-1}$) as the first electron is added to **1**, followed by bleaching of this band as the second electron is added (Fig. 3).‖ Further work, including solvent and temperature dependence studies, is necessary to confirm this. In contrast, oxidation of **1** does not result in a long wavelength absorption so in this case the mixed valent state appears to be valence localised.

The redox chemistry of the complexes derived from the macrocyclic ligand L is clearly rich: the ability of this ligand to stabilise dinuclear complexes in low oxidation states is very exciting and the reactivity of these complexes is being explored. Further characterisation of all of the redox states by, as appropriate, EPR or NMR spectroscopy, is underway, along with attempts to isolate each species. Finally, these ligands allow us to systematically study the magnetic exchange properties of unique pyridazine-bridged complexes and this feature of **1** is also under investigation.[8]

This work was supported by grants from the University of Otago. We thank Professor W. T. Robinson (University of Canterbury) for the X-ray data collection and B. M. Clark (University of Canterbury) for the FAB mass spectrum. S. B. thanks the University of Otago for the granting of study leave which facilitated the drafting of this paper, Dr E. Bothe and Professor K. Wieghardt (MPI für Strahlenchemie) for stimulating discussions, and also gratefully acknowledges the financial support of the Alexander von Humboldt Stiftung.

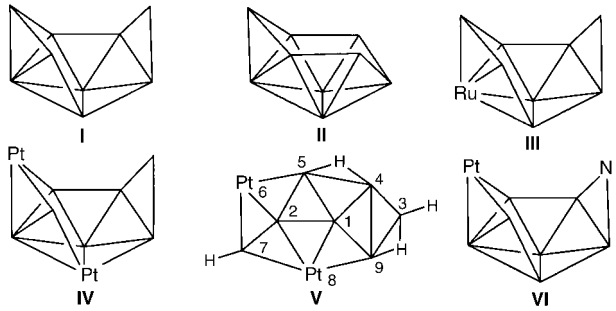
[{(dppe)Pt}$_2$B$_7$H$_{11}$]: An *arachno*-bimetallanonaborane based on the uncommon *n*-B$_9$H$_{15}$ cluster framework

Ramón Macías, Nigam P. Rath and Lawrence Barton*†

Department of Chemistry, University of Missouri-St. Louis, St. Louis, MO 63121, USA

The first bimetallanonaborane, [{(dppe)Pt}$_2$B$_7$B$_{11}$], based on the uncommon *n*-B$_9$H$_{15}$ cluster framework, is prepared and characterized as a final product from the reaction of pentaborane (9) with [PtCl$_2$(dppe)].

The coordination number pattern recognition theory for boranes and carbaboranes, as described by Williams in 1976,[1] requires that in order to generate *arachno*-clusters from *nido* systems, a highest connectivity vertex, adjacent to the open face, is removed. The predicted cluster framework for an *arachno* 9-vertex system is illustrated by structure **I** and recognized as



n-*arachno* B$_9$H$_{15}$. In contrast, the more commonly encountered 9-vertex *arachno*-species are derived by removal of a low connectivity vertex from *nido*-B$_{10}$H$_{14}$ to generate derivatives of what are referred to as *i*-B$_9$H$_{15}$ (structure **II**) and *i*-C$_2$B$_7$H$_{13}$.[2] With the exception of the ruthenanonaborane, [2-(η^6-C$_6$Me$_6$)-2-RuB$_8$H$_{14}$], (structure **III**)[3] reported in trace yields in a preliminary communication in 1986, all the known nine-vertex *arachno*-metallaboranes have structures based on the *i*-B$_9$H$_{15}$ framework.[4] This article describes the synthesis and complete characterization of a diplatinanonaborane whose structure is based on a polyhedral nine-vertex *n*-B$_9$H$_{15}$ *arachno*-cluster type and for which the application of electron-counting rules suggest that the species is another example of the growing list of 'rule-breakers'.

Derivatives of B$_5$H$_9$, in which an electrophilic group has replaced a bridging H atom, are well known.[5] Group 10 derivatives, [2,3-μ-{ML$_n$(X)}B$_5$H$_8$], where M = Ni, Pd, Pt, L$_n$ = (PR$_3$)$_2$, dppe [dppe = (Ph$_2$PCH$_2$)$_2$], X = Cl, Br, are isolated if the reaction between [B$_5$H$_8$]$^-$ and ML$_n$X$_2$ is carried out and worked up at low temperatures.[6] Such species are generally unstable at room temperature in solution, usually resulting in decomposition involving reduction of the metal moiety to elemental metal by the borane moiety. Herein, we describe the results when the reaction mixture, Li[B$_5$H$_8$] and PtCl$_2$(dppe), is allowed to warm to room temperature, dried *in vacuo* for 2 days, exposed to air and separated using TLC on silica gel following filtration through silica gel.[8] Thus [{(dppe)Pt}$_2$B$_7$H$_{11}$] is prepared from [2,3-μ-{(dppe)Pt(Cl)}B$_5$H$_8$], in *ca*. 10% yield as a yellow air-stable crystalline solid, along with [(dppe)PtB$_3$H$_7$],[8a] [(dppe)(BH$_3$)$_2$],[8b] and what appear to be Pt chloride salts. NMR and mass spectral data identified the yellow solid as [{(dppe)Pt}$_2$B$_7$H$_{11}$].[9] This was confirmed by a single crystal structure determination of the diethyl ether sesquisolvate.[10]

The structure of [{(dppe)Pt}$_2$B$_7$H$_{11}$], given in Fig. 1, consists of a nine-vertex *n*-*arachno* framework, obtained by removal of two adjacent vertices of connectivity six and four respectively, from an 11-vertex *closo*-octadecahedron. The {(dppe)Pt} moieties are located at the 6 and 8 positions in the *n*-*arachno* B$_9$H$_{15}$ framework, each replacing a BH group and a bridging H atom. There are bridging H atoms at the B(4)–B(5) and B(3)–B(9) edges and *endo*-H atoms on B(3) and B(7). Only the latter *endo*-H atom is observed from the X-ray structure determination but the presence is clearly confirmed from NMR spectral data. [{(dppe)Pt}$_2$B$_7$H$_{11}$] is shown as structure **IV** and a topological representation, showing the numbering scheme and the *endo*-hydrogens, is given as structure **V**. Bond distances are within the normal ranges for Pt–B, Pt–P and B–B bonding connections. The B(4)–B(9) edge bridged by a BH$_2$ group, at 1.739(13) Å, is similar to that observed for the same cluster interboron connection in *n*-B$_9$H$_{15}$[2,11] and in the ruthenaborane,[3] but it is much shorter than the corresponding B–B interaction in the recently discovered azaplatinaborane, [3,3-(PMe$_2$Ph)$_2$-3-PtB$_7$H$_{10}$-μ-5,6-(NHR)], 1.92(2) Å,[12] in which the B–B edge is bridged by a NHEt group (structure **VI**). NMR data conform to the observed molecular structure for this new biplatinaborane. The ^{11}B spectrum exhibits four resonances of relative

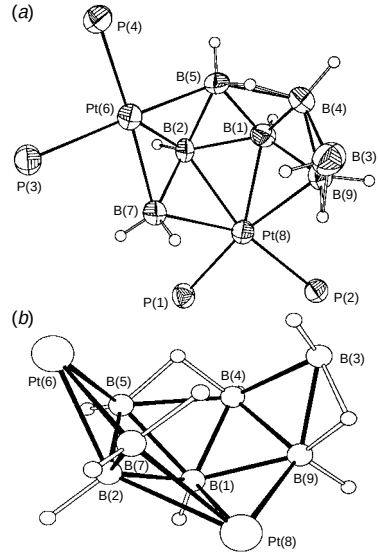


Fig. 1 (*a*) Projection of [{(dppe)Pt}$_2$B$_7$H$_{11}$]], showing only the P atoms of the chelating ligand on Pt. Ellipsoids are drawn at the 50% probability level. In addition to a terminal H atom on each B there is an *exo*-terminal H at position 3, indicated by ^{1}H NMR spectra. (*b*) Alternative representation with the ligands omitted for clarity. Selected interatomic distances (Å): from Pt(6) to P(3) 2.285(2), to P(4) 2.278(2), to B(2) 2.190(9), to B(5) 2.192(0), to B(7) 2.208(9); from Pt(8) to P(1) 2.289(2), to P(2) 2.295(2), to B(1) 2.227(9), to B(2) 2.267(9), to B(7) 2.328(9), to B(9) 2.302(9); interboron values: B(4)–B(9) 1.739(13), B(3)–B(9) 1.80(2), B(3)–B(4) 1.82(2), the other B–B distances are in the range 1.765(13)–1.883(13). Selected angles (°) P(3)–Pt(6)–P(4) 85.83(8), P(1)–Pt(8)–P(2) 84.97(7), P(3)–Pt(6)–B(5) 174.5(2), P(4)–Pt(6)–B(7) 167.6(3), P(1)–Pt(8)–B(9) 170.3(2), P(2)–Pt(8)–B(7) 152.1(2), B(4)–B(3)–B(9) 57.5(5).

intensity 1 : 4 : 1 : 1 and ^{1}H-{^{11}B(selective)} experiments reveal eleven different cage H atoms of which two are bridging and two are *endo*-hydrogen atoms. In addition, ^{31}P NMR spectra exhibit four different resonances of equal intensity; two doublets, an overlapped doublet of doublets that is seen as an apparent triplet, and a singlet. Each signal shows additional coupling to ^{195}Pt. Since P atoms in the same chelating dppe ligand effectively do not couple, we must be observing four-bond $^4J(^{31}P–^{31}P)$ coupling constants. From Fig. 1(*a*), it appears that P(3) and P(4) are effectively *trans* to P(2) whereas P(1) is directed towards the cluster B(1)–B(9) connection. This conformation suggests that the P atoms involved in ^{31}P–^{31}P coupling are P(3), P(4) and P(2). Thus we assign P(2) to the observed apparent triplet, P(3) and P(4) to the doublets and P(1) to the singlet. The cage connectivities of the Pt atoms are different; that for Pt(6) is three whereas that for Pt(8) is four and this appears to be reflected in the differences in ^{195}Pt–^{31}P coupling constants listed in ref. 9. Characterization of [{(dppe)Pt}$_2$B$_7$H$_{11}$] is completed by mass spectral data. The most intense envelope is that for the $[M - BH_3]^+$ ion, suggesting that the connection of the μ-H-BH$_2$ group is quite fragile, perhaps accounting for the preference of *i*-B$_9$H$_{15}$ isomers for nonaboranes and their derivatives.

A final point of note concerning [{(dppe)Pt}$_2$B$_7$H$_{11}$] is that it appears not to conform to the polyhedral skeletal electron pair theory (PSEPT) counting rules.[13] An *arachno* nine-vertex cluster requires $n + 3$ skeletal electron pairs, which for this cluster would be 12 electron pairs. Using the conventional electron-counting methods devised by Wade,[14] [{(dppe)Pt}$_2$B$_7$H$_{11}$] possesses 11 skeletal electron pairs. Such ambiguity has been observed for essentially all clusters containing three-connectivity group 10 metal moieties.[15] Some examples of such systems include [(PPh$_3$)$_2$(CO)Os(PPhMe$_2$)Cl(μ-H)PtB$_5$H$_7$],[15*a*] [(PEt$_3$)$_2$Pt(CMe)$_2$B$_4$H$_4$][15*b*] and [(PPhMe$_2$)$_2$PtB$_8$H$_{12}$].[15*c*] In these systems, the organometallic Pt fragment is best regarded as a square planar 16-electron center that contributes two orbitals and two electrons to the cluster framework. Under this scenario, the metal moiety is not isolobal with a conventional three orbital, two electron conical vertex and the skeletal electron count is two electrons short of the number required for compliance with the PSEPT. In [{(dppe)Pt}$_2$B$_7$H$_{11}$] this feature may be ascribed to the vertex unit [(dppe)Pt] at the 6-position. Apparently in [{(dppe)Pt}$_2$B$_7$H$_{11}$], the two Pt vertices, with different connectivity, contribute differently to the total skeletal electron count for the cluster. The vertex Pt(8), which has connectivity 4 may be considered to be a 'normal' conical vertex conforming to the PSEPT, although in a formal sense each [(dppe)Pt] vertex subrogates a BH(μ-H) moiety. This appears to represent a new example of the so-called rule breakers, and such phenomena warrant further investigation.

We acknowledge support by the Missouri Research Board and the ACS-PRF (grant 31001-AC3). We also acknowledge instrumentation grants from the NSF (No. CHE-9309690 and CHE-9318696), the DOE (Grant No. DE-FG02-92CH10499) and the UM-St. Louis Center for Molecular Electronics. We thank Professor Michael Gross of the Washington University Mass Spectrometry NIH Research Resource (Grant. No. P41RR094) for the mass spectra. Experimental details for the preparation and spectral characterization of [{(dppe)Pt}$_2$B$_7$H$_{11}$], [(dppe)PtB$_3$H$_7$] and [(dppe)(BH$_3$)$_2$] are available upon request from the authors.

Synthesis of verdinochlorins: a new class of long-wavelength absorbing photosensitizers

Andrei N. Kozyrev,[a] James L. Alderfer,[b] Thomas J. Dougherty[a] and Ravindra K. Pandey*[a]

[a] *Chemistry Section, Department of Radiation Biology, Division of Radiation Medicine, Roswell Park Cancer Institute, Buffalo, NY 14263, USA*

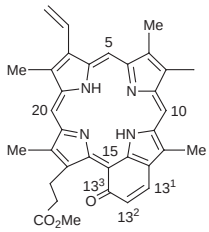
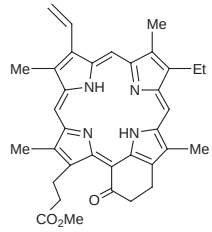
Reaction of 13²-oxopyropheophorbide *a* with CH_2N_2 produced three isomeric methoxyverdinochlorins *via* expansion of the cyclopentanedione ring E; these long-wavelength absorbing verdinochlorins represent the first example of verdins with a reduced pyrrolic ring system, and their structural assignments have been made on the basis of ^{1}H NMR studies; a mechanism of verdinochlorin formation is discussed.

Verdins are a special class of green porphyrins **1** with a fused



1



2

cyclohexenone ring system, which are obtained by the oxidation of the cyclohexanoneporphyrins or rhodins **2** under acidic reaction conditions.[1] Verdin's conjugated exocyclic ring has a strong electron-withdrawing effect and causes a dramatic change in the electronic spectrum, with a prominent absorption near 690 nm.[2] Due to their intense green color, Fischer named this class of compounds as 'verdins' (from Latin *verdo* = green).[1] The chemistry of rhodins and verdins was further explored by Clezy, who prepared a variety of porphyrins with fused exocyclic rings.[3] The utility of this class of compounds as photosensitizers for the treatment of cancer by photodynamic therapy (PDT) was demonstrated by Morgan *et al*.[4]

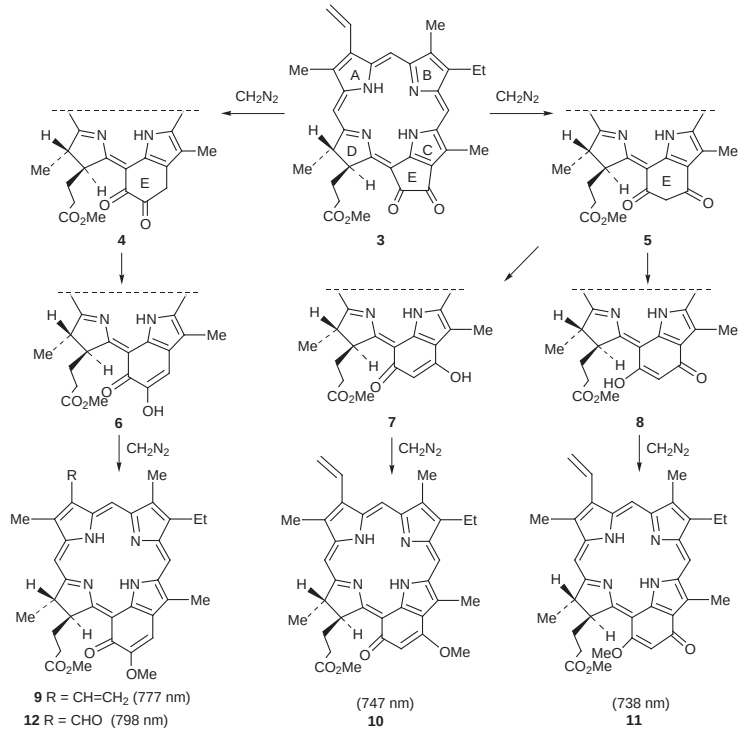
Recently, we have discovered a new and simple method for the preparation of 13²-oxopyropheophorbide *a* **3** by LiOH-promoted allomerization of pyropheophorbide *a*.[5] The oxopyropheophorbide *a* initially obtained as the carboxylic acid was readily converted into the corresponding methyl ester **3** by treating briefly with CH_2N_2. However, if a large excess of CH_2N_2 was used and the reaction mixture was left at room temperature for 4–6 h, a mixture of three main compounds was obtained. These were separated into individual components by preparative TLC. The most mobile orange band had a long-wavelength absorption at λ_{max} 777 nm (29% yield), the second band was red in color (λ_{max} 747 nm, yield: 26%) and the most polar compound was isolated as a green band with λ_{max} 739 nm (yield: 15%) (Scheme 1). Significant bathochromic shifts in the electronic absorption spectra indicated the presence of a conjugated electron-withdrawing exocyclic ring system. Mass spectral analyses of all three products gave the same molecular ion at *m/z* 590. Thus, compared to chlorin **3** an increase in mass by 28 daltons is observed.

It has been shown that CH_2N_2 reacts with cyclic α-diketones,[6] *e.g*. croconic acid, to produce trimethoxy-*p*-benzoquinone by an unusual ring expansion. Under these reaction conditions, we anticipated the possibility of CH_2 insertion into the diketocyclopentane ring of chlorin **3**, which would yield the product(s) with fused cyclohexenone rings, named here as verdinochlorins (*i.e*. verdin with a reduced pyrrole ring).

The structural assignments of the predicted reaction products were confirmed by extensive ^{1}H NMR studies (Fig. 1). The ^{1}H NMR spectra revealed that, compared to starting diketochlorin **3**, all these compounds had an additional signal at δ 4.2, integrating for three protons, along with an additional singlet at δ 6.1 (for the chlorins having absorptions at 738 and 747 nm), and δ 6.85 (for the chlorin absorbing at λ_{max} 777 nm) for the olefinic proton of the cyclohexenone ring, suggesting that all three products were structural isomers. The 2D ROESY NMR data further provided valuable information for the final structural identification. In the NMR spectrum, the orange band (λ_{max} 777 nm) showed the most lowfield shifted signal of the proton at position 13¹ of the cyclohexenone ring, suggesting a closer proximity to the chlorin macrocycle. This was further confirmed by ROESY experiments which clearly showed the through-space interaction of the 13¹-olefinic proton with the resonances of the 13²-methoxy group and the 12-methyl substituent. Upfield shifted resonances for the 17-H proton (δ 5.1) indicated the presence of the neighboring keto group at the 13³-position.[7] Based on these results, the structure for the fast moving band (λ_{max} 777 nm) was assigned as 13²-methoxy-13³-oxoverdinochlorin **9**.

Both the red (λ_{max} 747 nm) and green (λ_{max} 739 nm) verdinochlorin isomers had resonances at δ 6.1 for the protons at the 13²-position. On the basis of the chemical shift of the 17-H, observed at δ 5.3 (similar to **9**), the structure of the red verdinochlorin was assigned as the 13¹-methoxy-13³-keto-isomer **10**. However, for the green isomer, the 17-H resonance was observed at δ 4.7, which suggested the structure to be that of 13³-methoxy-13¹-ketochlorin **11**. In contrast to chlorins **9** and **10**, compound **11** is not a 'true' verdinochlorin, based on the position of the oxo group, and is named as 'isoverdinochlorin'.

The mechanism of the formation of the verdinochlorin isomers seems to be similar to that of the ring enlarged diketone obtained by CH_2N_2 treatment of croconic acid.[8] The insertion of the CH_2 fragment into the cyclopentane dione ring (between the 13/13¹ and 13¹/13² carbon atoms) will produce diketocyclohexane intermediates **4** and **5** (Scheme 1). The enolization of the acidic hydrogens adjacent to the keto function will generate the isomeric hydroxyverdinochlorins **6**–**8**. The hydroxy functions can then react with a second molecule of CH_2N_2 to give the resulting methoxyverdinochlorions **9**–**11**. From the reaction mixture, we did not isolate the cyclohexanone analog in which the keto groups were present at positions 13² and 13³. This indicates that the reactivity of the 13²-keto group in diketochlorin **3** is diminished due to the steric hindrance caused by the substituents attached to the adjacent reduced pyrrolic ring. Thus, CH_2N_2 as nucleophile preferentially attacks the keto group present at the 13¹-position.



Scheme 1

Compared to most of the chlorins, all verdinochlorin isomers **9**–**11** showed a significant red shift of the long-wavelength absorption (Qy-band) in their UV–VIS spectra, which makes them attractive candidates as photosensitizers for photodynamic therapy. It was interesting to observe that the position of the methoxy group in the cyclohexenone ring of verdinochlorins **9** and **10** plays an important role in the shift of the Q_y-band. Thus, compared to chlorin **3**, 13^3-methoxyverdinochlorin **10** gave a red shift of 69 nm, while an even greater shift (99 nm) was observed for the 13^2-methoxy isomer **9**. Both verdinochlorins **9** and **10** had Q_x-bands around 560 nm, while isoverdinochlorin **11** on the other hand showed Q_x-absorption at 600 nm. These absorptions are obviously responsible for their red and green color respectively.

In order to achieve a further bathochromic shift, the vinyl group in chlorin **9** (λ_{max} 777 nm) was replaced with a formyl substituent. The corresponding formyl analog **12** showed an unusually large red-shifted long-wavelength Q_y-band in the near-IR region (λ_{max} 798 nm). Owing to their long wavelength absorptions in the red region, these compounds will have definite advantages over Photofrin® (a porphyrin derivative) for treating tumors which are deeply seated.

In conclusion, the new class of chlorins discussed here are the first examples of chlorins with a fused cyclohexenone rings. These compounds are obtained by the ring expansion of the fused cyclopetanedione ring attached to the chlorin system. This methodology has great potential in designing long-wavelength absorbing photosensitizers for PDT, and is currently being explored in our laboratory. The reactions discussed above might also be useful for the preparation of petroporphyrins with cyclohexane/phenyl ring systems. Biological *in vivo* PDT experiments with these compounds are currently in progress and will be published elsewhere.

We thank Professor Kevin M. Smith, University of California, Davis for helpful discussions. This work was supported by grants from Mallinckrodt Medical Inc., St. Louis, the National Institutes of Health (CA 55791), and the Oncologic Foundation of Buffalo. Partial support of the NMR facility by an RPCI Center Support Grant (CA 16056) is also acknowledged.

Star-branched non-covalent complexes between carboxylic acids and a tris(imidazoline) base

Arno Kraft*[a]† and Roland Fröhlich[b]

[a] *Institut für Organische Chemie und Makromolekulare Chemie II, Heinrich-Heine-Universität Düsseldorf, Universitätsstr. 1, D-40225 Düsseldorf, Federal Republic of Germany*

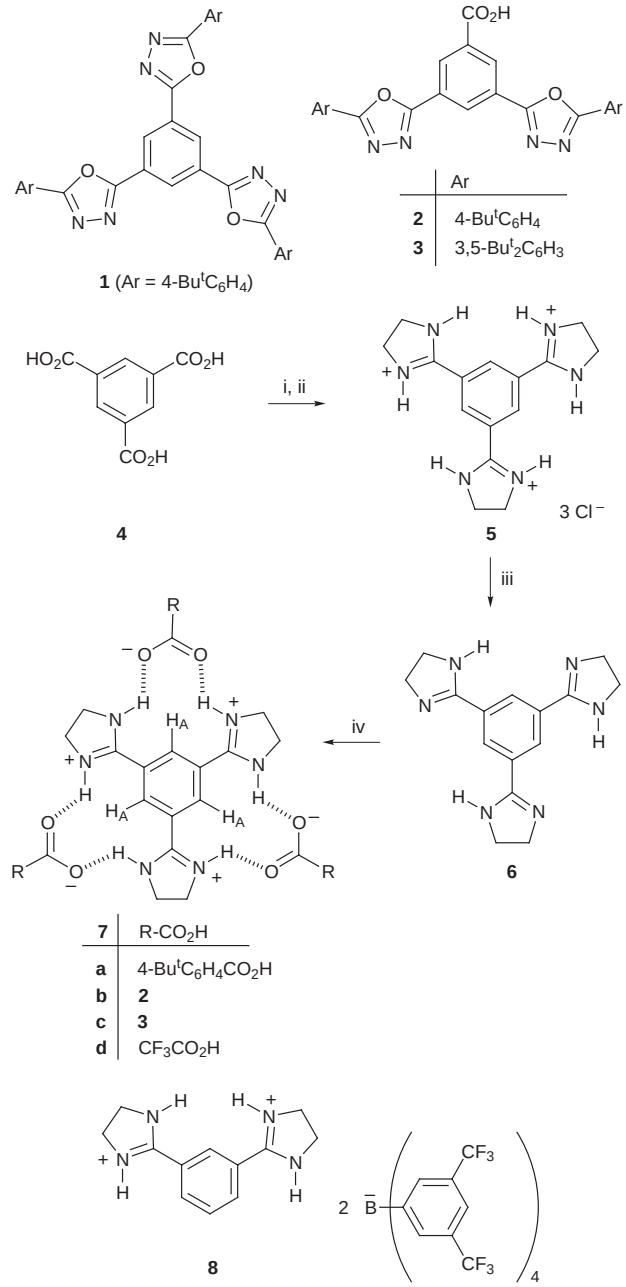
[b] *Institut für Organische Chemie, Westfälische Wilhelms-Universität Münster, Corrensstr. 40, D-48149 Münster, Federal Republic of Germany*

Simple dissolution of 3 : 1 mixtures of aromatic carboxylic acids with suitable solubilising groups and tris(4,5-dihydroimidazol-2-yl)benzene 6 gave branched hydrogen-bonded assemblies 7 that were soluble in chlorinated and aromatic solvents.

Although Nature has perfected the controlled formation of stable hydrogen-bonded aggregates in water, self-assembly of well-defined, non-covalently bonded, high-molar-mass complexes in solution still remains a challenge for chemists.[1] Self-assembly by non-covalent interactions is an elegant approach to many kinds of large defined molecules, circumventing time-consuming chemical syntheses that are often accompanied by enormous purification problems. This can also become crucial in the design of new materials. For example, diaryl-substituted 1,3,4-oxadiazoles have lately received considerable interest as potential electron-transporting materials in electroluminescent devices based on fluorescent dyes and polymers.[2,3] Amongst these, branched structures such as **1** and dendrimers with $\geqslant 3$ oxadiazoles per molecule have the particular attraction of being highly soluble in organic solvents and of forming stable, amorphous, thin films.[3,4] It would be much simpler if such compounds were obtained through an assembly process from smaller components. For this, the non-covalent interaction between carboxylic acids and amidine bases looked very attractive.[5] We decided to use cyclic amidine derivatives which are easier to prepare than unsubstituted amidines and which were already the subject of X-ray crystal structure studies by Hosseini and co-workers who showed that dicarboxylic acids and bis(tetrahydropyrimidine)s or bis(imidazoline)s self-assemble to hydrogen-bonded sheets and networks in the solid state.[6]

A three-star branched structure would result when acids such as **2** or **3** (readily obtained by palladium-catalysed carbonylation of the corresponding aryl iodides)[4] were combined with, *e.g.* a 1,3,5-trisubstituted benzene containing three amidine substituents such as tris(imidazoline) **6**. Although melt condensation of benzene-1,3,5-tricarboxylic acid (**4**) and imidazolidin-2-one was reported to give **6** in modest yield,[7] a modified imidazoline synthesis[8] in solution proved to be more reliable. Hydrochloride **5** was prepared analogously in a single step from **4** and ethylenediamine in boiling ethylene glycol under acid catalysis (Scheme 1). Treatment with aqueous NaOH and sublimation gave the free base **6** in high purity.‡

Salt formation resulted from simple dissolution of a 1 : 3 mixture of **6** and various carboxylic acids in warm $CHCl_3$–EtOH.[9] Upon standing, the salts **7** crystallised from concentrated solutions (usually after evaporation of some of the $CHCl_3$), and one recrystallisation provided analytically pure samples.‡ It was surprising to note that salts obtained from acids with solubilising groups (such as *tert*-butyl derivatives of benzoic acid, **2** or **3**, but not benzoic acid or acetic acid) and **6** are remarkably soluble in non-polar organic solvents, *viz* $CHCl_3$ (**7b**: 40–50 mg cm^{-3}, **7a,c**: >100 mg cm^{-3}) or toluene, although **6** is insoluble in all common non-acidic organic solvents and, for example, acid **2** dissolves only sparingly in $CHCl_3$ (< 1 mg cm^{-3}) or EtOH.



Scheme 1 *Reagents and conditions*: i, $H_2NCH_2CH_2NH_2$, $H_2NCH_2CH_2NH_2 \cdot 2HCl$, TsOH, ethylene glycol, reflux, 3 h; ii, HCl; iii, NaOH, 64%; iv, RCO_2H (3 equiv.), EtOH–$CHCl_3$, reflux, 56–87%

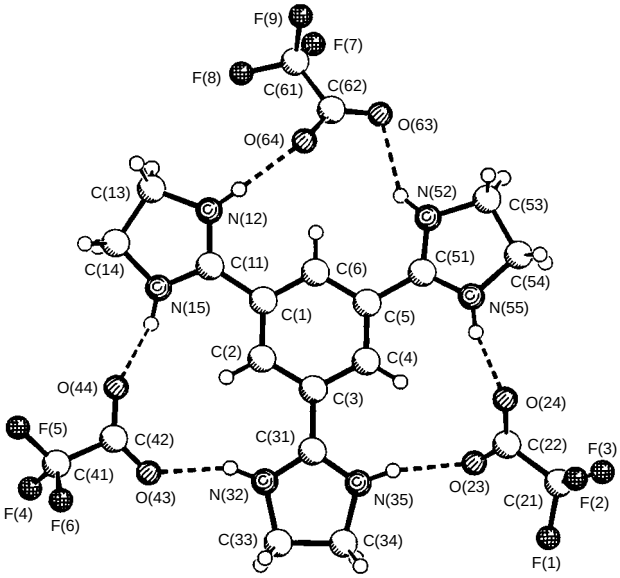


Fig. 1 Crystal structure of **7d**

The ^{1}H NMR spectra of **7a**–**c** in $CDCl_3$ show a broad singlet for the hydrogen-bonded imidazoline NH at δ *ca.* 13. The core's aromatic protons H_A give rise to a diagnostic singlet at an unusual chemical shift of δ *ca.* 10.1. Addition of a polar cosolvent shifts the H_A signal up-field, and in neat [$^2H_6$]DMSO the corresponding resonance is observed at δ *ca.* 8.5. Such a difference of $\Delta\delta$ *ca.* 1.6 for an aromatic proton signal cannot be explained by protonation of **6** alone or simple solvent effects, and must be attributed to the fact that, in the complex, H_A experiences considerable steric pressure. Polar solvents (DMSO, MeOH) cause the complexes to dissociate, whereas in a non-polar solvent each carboxylate forms hydrogen-bonds to two imidazoline NH units, with all non-polar groups facing the outside, probably similar to Hosseini's self-assembled structures.[6] This is further illustrated by the crystal structure of model complex **7d** for which the deviation from C_3-symmetry may be either a consequence of crystal packing effects or an indication that the third carboxylate is less strongly bound than the remaining two (Fig. 1).§

A 1 : 3 stoichiometry of the **6**–carboxylic acid complexes was supported by Job's method of continuous variation. Dilution experiments showed that the ^{1}H NMR chemical shifts of complexes **7a**–**c** in $CDCl_3$ remain unchanged over a concentration range of 10^{-1} to 3×10^{-5} mol dm^{-3} ($\Delta\delta < 0.1$) although the core signals show some line-broadening below 10^{-3} mol dm^{-3}. ^{1}H NMR dilution studies of **8** and tetrabutylammonium benzoate in $CDCl_3$–CD_3OD (97 : 3) gave an association constant of 990 ± 230 dm^3 mol^{-1} for the formation of a simple 1 : 1 complex. Self-association can be excluded unless, as initial experiments have shown, the acid component contains additional functional groups capable of hydrogen bonding, *e.g.* amide groups. Although complexes **7a**–**c** dissociated during column or gel-permeation chromatography (with CH_2Cl_2 as eluent) and mass spectrometry (chemical ionization, fast atom bombardment or matrix-assisted laser desorption/ionisation), vapour-pressure osmometry allowed us to determine the number-average molar mass M_n in solution at concentrations > 5 mmol dm^{-3}: 830 g mol^{-1} (against benzil or **1** as standard) for **7a**, 1810 g mol^{-1} for **7b**, both in $CHCl_3$ at 30 °C, and 2400 g mol^{-1} (against benzil or polystyrene 2000 as standard) for **7c** in toluene at 50 °C. All M_n values are close to the calculated values of 817, 1850 and 2187 g mol^{-1}, respectively, and provide evidence that the complexes are not dissociated under these conditions.

Further investigations towards the use of this simple self-assembly process for the preparation of larger assemblies and ordered supramolecular stacks, and their applicability in electroluminescent devices are in progress.

Synthesis of a potent inhibitor of HIV reverse transcriptase

Chris J. Hamilton,[a] Stanley M. Roberts[b]† and Alexander Shipitsin[c]

[a] *Department of Chemistry, Exeter University, Stocker Road, Exeter, Devon, UK EX4 4QD*

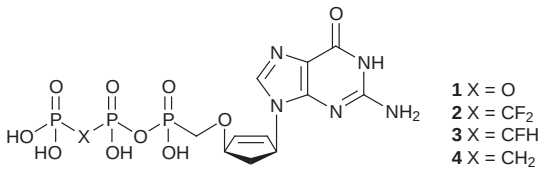
[c] *Engelhardt Institute of Molecular Biology, Russian Academy of Sciences, 32 Vavilov Street, Moscow 117984, Russia*

The newly synthesised P_β,–P_γ-difluoromethylenebisphosphonate analogue 2 of *nor*-carbovir triphosphate is a potent inhibitor of HIV reverse transcriptase; it also exhibits a greatly enhanced stability to dephosphorylation, in foetal blood serum, relative to AZTTP and other nucleoside triphosphates.

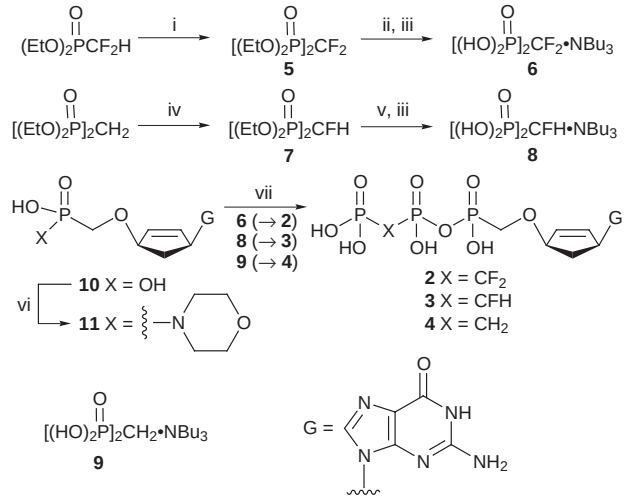
The *in vivo* lability of the P–O–P phosphate ester bonds in nucleoside triphosphates (NTPs) possessing interesting biological activity *in vitro* has prompted the search for more stable analogues. A great deal of effort has centred on the substitution of the phosphate ester oxygen atoms with carbon to give the corresponding phosphonates. These phosphonates are generally more stable to hydrolytic cleavage whilst being isosteric with their parent phosphates. The lower electronegativity of the methylene group, compared to oxygen, leads to a significant decrease in the acid dissociation constants of these phosphonic acids, which is often reflected in a reduction of biological activity. Through the seminal work of Blackburn and co-workers, halogenoalkylphosphonates have been shown to have improved potential as phosphate mimetics, as they more closely resemble the steric and electronic features of their parent units.[1]



We have previously shown that the pyrophosphoryl phosphonate **1** shows potent inhibition of HIV reverse transcriptase (HIV-rt), comparable to that of both AZT and carbovir triphosphates.[2] It is noteworthy that the active compound **1** has an absolute configuration that is the mirror image of that expected for a natural nucleotide.[3] Previous assessments of other such 'unnatural' nucleosides have shown them to exhibit reduced cytoxicity relative to their natural enantiomers.[4]

Further progress in this area would result from structural modifications of the diphosphate unit in **1** to further enhance its stability *in vivo* whilst still retaining good biological activity. To these ends we have prepared a series of bisphosphonates **2**–**4** with progressive fluoro-substitution within the P_β,P_γ-methylene linker group, as described in Scheme 1.

Noteworthy features of the chemical syntheses include the preparation of the tetraethyl difluoromethylenebisphosphonate **5** by coupling diethyl difluoromethylphosphonate with diethyl chlorophosphate,[5] and the preparation of tetraethyl fluoromethylenebisphosphonate **7** using the easy to handle and readily available fluorinating reagent *N*-fluorodibenzenesulfonimide.[6] The tetraesters were hydrolysed using bromotrimethylsilane and subsequently converted into their respective tributylammonium salts **6**, **8** and **9**. The bisphosphonates were coupled to the nucleoside monophosphonate **10** *via* the activated morpholidate **11**.[2,7] Products were purified by anion



Scheme 1 *Reagents and conditions*: i, LDA, THF, −70 °C, 1 h, then $ClP(O)(OEt)_2$, −70 °C, 1 h (34%); ii, Me_3SiBr, room temp., 18 h (83%); iii, NBu_3, EtOH, H_2O, room temp., 90 min; iv, KHMDS, THF, −78 °C, 1 h, then *N*-fluorodibenzenesulfonimide, THF–toluene, −78 °C, 90 min (26%); v, Me_3SiBr, room temp., 72 h (98%); vi, morpholine, DCC, Bu^tOH, H_2O, reflux, 5 h; vii, DMSO, room temp., 0.5–7 days (24–32%)

exchange, followed by reverse phase chromatography, and isolated as their ammonium salts.[8]

The efficacies of **2**–**4** as inhibitors of recombinant HIV-1-rt (Du Pont cat. No. NEI-490) were examined using the Du Pont RT-Detect™ Reverse Transcriptase Assay (cat. No. NEK-070) and the results are shown in Table 1.

Compounds **2**–**4** showed an expected correlation of increased activity with an increase in fluoro-substitution, culminating in the CF_2 analogue **2** being just an order of magnitude less active than the parent compound **1**.

The stability of the CF_2 compound **2** in human foetal blood serum was assessed and compared with AZTTP, some natural nucleoside triphosphates, and the pyrophosphoryl phosphonates' natural enantiomer, **1**-ent (Table 2). Blood serum is an appropriate medium in which to perform this assay as it contains numerous dephosphorylating enzymes and so provides a good model system of the extracellular environment *in vivo*. The half-

Table 1 Relative efficacy of substrates **1**–**4** as inhibitors of HIV-rt[a]

Compound	IC_{50}[b]/μM
1	0.5
2	5.8
3	34.8
4	> 100
AZTTP	1.0

[a] The IC_{50} values shown are the results from enzyme assays carried out in reaction mixtures containing 0.1 units ml^{-1} of HIV-rt, which were incubated at 37 °C for 110 min. [b] IC_{50} = substrate concentration required to inhibit to HIV-rt by 50%.

Table 2 Half-life time in fetal blood serum at 37 °C

Compound	$t_{1/2}$
1-ent	65 min[a]
2	45 h[a]
dGTP	< 30 min[b]
dATP	< 30 min[b]
AZTTP	5 min[b]

[a] As determined by the appearance of the phosphonate **10**. [b] As determined by the disappearance of the nucleoside triphosphate.

life of compound **2** was found to be 90 times greater than those of the natural purine NTPs, dGTP and dATP and also significantly greater than that of the pyrophosphoryl phosphonate **1**-ent. Evidently, the P_β,P_γ-difluoromethylene group greatly enhances the stability of compound **2** towards enzymatic dephosphorylation of the terminal phosphate group. Cleavage of the phosphate ester linkage at the P_α,P_β position could also be reduced as a result of the CF_2 analogue **2** being a poorer substrate for those dephosphorylating enzymes which function to hydrolyse NTPs at this position.

In conclusion, we have shown that it is possible to incorporate two stabilising phosphonate linkages in the 5′-side chain of the 'unnatural' enantiomer of carbovir triphosphate with only a modest compromise in biological activity whilst significantly enhancing biological stability. The use of more lipophilic derivatives of compound **2**, in order to facilitate drug delivery into whole cells, is currently under investigation and will be reported in due course.

We thank the MRC for a research studentship (to C. J. H.) and Wellcome Research Laboratories for the generous donation of AZT, made available through the MRC AIDS Reagent Project.

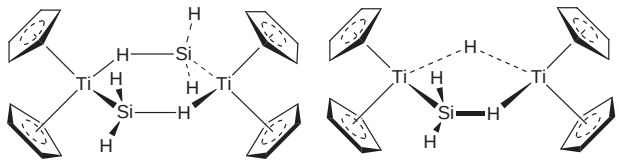
Synthesis and structural characterization of $Cp_2Ti(SiH_3)(PMe_3)$

Leijun Hao, Anne-Marie Lebuis and John F. Harrod*†

Department of Chemistry, McGill University, Montreal, Canada H3A 2K6

The title compound, the first example of a structurally fully characterized, unsubstituted silyl complex of a group 4 element, has been synthesized and showed unusual thermal stability compared to its analog $Cp_2Ti(SiH_2Me)(PMe_3)$.

Very few reports of reactions of SiH_4 with transition metal compounds have appeared, presumably because of the hazards associated with its use.[1]‡ There are also very few examples of structurally well characterised transition metal complexes with SiH_3 ligands.[2] We recently reported the synthesis of compounds **1** and **2** by reaction of SiH_4 with Cp_2TiMe_2.[3] This reaction can



be carried out either with SiH_4 from a cylinder, or with SiH_4 generated *in situ* by catalytic redistribution of $SiH(EtO)_3$. The latter reaction is a convenient procedure for the safe generation of small amounts of SiH_4.[3] Although the structures of **1** and **2** were confidently assigned on the basis of their NMR spectra, we have not been able to obtain either of them in the form of crystals suitable for structure determination by X-ray diffraction. We now report the preparation and structure determination of the related phosphine complex, $Cp_2Ti(SiH_3)(PMe_3)$ **3**, an analog of the organosilyl complexes reported earlier,[4,5] and the first structurally fully characterized, unsubstituted silyl complex of a group 4 metal.

Reaction of Cp_2TiMe_2 with SiH_4 in the presence of PMe_3 in diethyl ether–toluene solution proceeds smoothly to give **3** in 76% yield as square purple plates. Solutions of **3** in toluene or benzene are relatively thermally stable and so could be fully characterized both in solution and in solid state. The structure of **3**, together with some bond parameters, is shown in Fig. 1.§ Of the bond parameters, only the Ti–Si bond length falls outside the range previously determined for $Cp_2Ti(SiHRR')(PMe_3)$ complexes (R = H, R′ = Ph **4**; R = Ph, R′ = Ph **5** or Me **6**).[4] The relevant values are: 2.594(2) **3**, 2.650(1) **4**, 2.652(1) **5** and 2.646(2) Å **6**, indicative of a stronger Ti–Si bond in **3**. The Ti–Si bond distance in **3** is essentially identical to those observed in the phenylsilyl analogue of **1** and in $(Bu^tCH_2)_3TiSi(SiMe_3)_3$.¶ The perspective of **3** shown in Fig. 1 is chosen to show the perfect *gauche* arrangements of the SiH_3 and PMe_3 ligands with respect to the Cp_2Ti unit and the mirror plane symmetry of the molecule. These features are not exhibited by the other organosilyl complexes where the local symmetry of the silyl ligand is lower than C_{3v}.

The spectroscopic data are consistent with the structure revealed by the X-ray analysis. The ^1H NMR spectrum of **1** is consistent with it being a paramagnetic species since only broad resonances were observed and no resonance was observed in the $^{31}P\{^1H\}$ spectrum. Solutions of **3** in toluene give the characteristic EPR spectrum shown in Fig. 2. The doublet of quartets (g = 1.9956) is accounted for by the coupling of the single unpaired electron of Ti^{III} to a single ^{31}P nucleus (a_P = 28.6 G) and to the three Si–H protons (a_H = 4.3 G). Satellites due to coupling to the Ti isotopes [I = 7/2, ^{49}Ti (5.5%); I = 5/2, ^{47}Ti (7.75%)] with a_{Ti} = 7.8 G are also observable. The values for a_P and a_{Ti} are in, or very close to, the ranges observed for **4**, **5** and **6** (28.8–29.9 G and 7.7 to 8.7 G respectively), as is the g value (1.9944–1.9976).[4,5] The value for a_H is somewhat larger than the values for the organosilyl complexes (2.6–3.2 G) which may be a result of the slightly shorter Ti–Si bond in **3**.[4,5]

Solutions of **3** in toluene are stable for several days at room temperature in an argon atmosphere. This stability is unusual and unexpected, given the fact that the compound is a primary silane.[4–6] The closest analog $Cp_2Ti(SiH_2Me)(PMe_3)$ **7**, synthesized from the reaction of Cp_2TiMe_2 and SiH_3Me, generated *in situ* by catalytic redistribution of $SiHMe(EtO)_2$,[3] in the presence of PMe_3 in hexane solution, was stable only for several hours and decomposed to the titanocene(III) hydride **8** and the titanocene(III) silyl compound **9**, as shown in Scheme 1.‖ Similar dehydrocoupling reactions were also observed for other analogous $Cp_2Ti(SiHRR')(PMe_3)$ compounds.[5] We attribute the greater stability of **3** to stronger Ti–Si and Ti–P bonds and a resulting high formation constant for the phosphine complex.

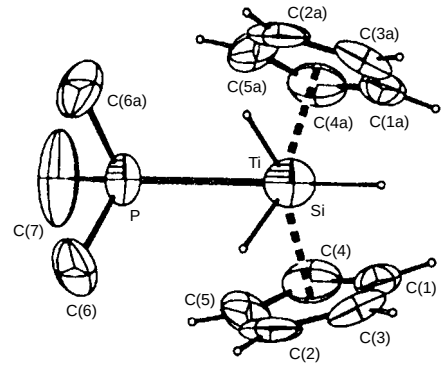


Fig. 1 A view of the structure of **3** down the Si–Ti bond (30% probability ellipsoids). Selected bond lengths (Å) and bond angles (°): Ti–P 2.559(2), Ti–Si 2.594(2), Si–H(av.) 1.53(7); P–Ti–Si 83.91(6), Cp(cent)–Ti = 2.031(3), Cp(cent)–Ti–Cp(cent) 134.2(4).

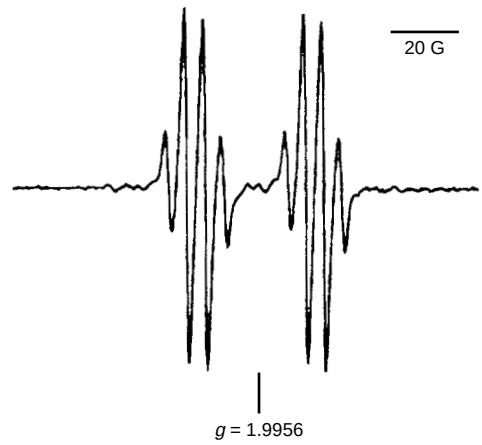

Fig. 2 EPR spectrum of **3** in toluene at room temperature

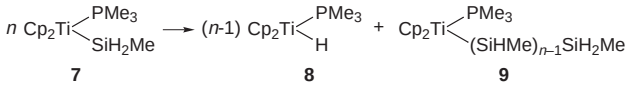

7 **8** **9**

Scheme 1

The consequent suppression of phosphine dissociation to give the coordinatively unsaturated intermediate necessary for reaction of the titanium with Si–H bonds prevents the hydrogen transfer reaction depicted in Scheme 1. In the absence of PMe_3, Cp_2TiMe_2 catalyses the rapid dehydrocoupling of SiH_4 to an insoluble, pyrophoric polymer.

Studies of reactions of SiH_4 with other group 4 compounds are in progress.

We thank NSERC (Canada) and the Fonds FCAR de Québec for financial support, Professor Don Berry for useful discussions, and the Laboratoire de Crystallographie par Rayons X de l'Université de Montréal for access to a diffractometer.

Modified Mg–Al hydrotalcite: a highly active heterogeneous base catalyst for cyanoethylation of alcohols

Pramod S. Kumbhar,† Jaime Sanchez-Valente and François Figueras*‡

Institut de Recherches sur la Catalyse, 2 Av. A. Einstein, 69626 Villeurbanne, France

Modified Mg–Al hydrotalcite (Mg : Al = 3 : 1) prepared by thermal decarbonation followed by rehydration of a conventional Mg–Al hydrotalcite is found to be a highly active, reusable and air stable catalyst for cyanoethylation of alcohols.

Cyanoethylation of alcohols is a widely used reaction for the synthesis of drug intermediates and organic compounds of industrial interest.[1] Acrylonitrile undergoes cyanoethylation with a number of monohydric alcohols to give alkoxypropionitriles which, after hydrogenation, give industrially important amines. The reaction is catalysed by homogeneous base catalysts such as alkali hydroxides[2] and alkoxides[3] and tetraalkyl ammonium hydroxide. However, these catalysts need to be neutralised before purification of the product, resulting in the generation of waste, loss of catalyst and reduced product yields. Alternatively, use of anion exchange resins as heterogeneous catalyst have also been reported.[4,5] Recently, Hattori and Kabashima[6] reported use of alkaline earth oxides, hydroxides and alumina supported KF and potassium hydroxide supported on alumina as heterogeneous catalysts for this reaction. High activities were reported for high temperature activated MgO catalyst (800 °C *in vacuo*). The general reaction scheme for cyanoethylation of alcohols is shown in Scheme 1.

Previously we had reported that modified hydrotalcite, prepared by thermally decarbonating the conventional Mg–Al hydrotalcite followed by controlled rehydration, is highly active for aldol and Knoevenagel condensation reactions.[7,8] The high activity of this catalyst is attributed to the presence of a large number of OH^- groups, generated during rehydration of the thermally activated hydrotalcite, which act as Brönsted basic sites. The use of modified hydrotalcites as heterogeneous Brönsted basic catalysts instead of homogeneous catalysts such as alkali hydroxides and alkoxides has a number of advantages, *viz*. ease of separation, reusability, no waste, and higher activities and selectivities (depending on the reaction).

In continuation of our above mentioned work here we report that the modified hydrotalcites having formula $[Mg_{(1-x)}Al_x(OH)_2](OH)_x{\cdot}yH_2O$ show unprecedented high activity for the cyanoethylation of alcohols with acrylonitrile. The activity of this catalyst is the highest so far reported in the literature for any heterogeneous catalyst. The catalysts were found to be reusable without significant loss in activity. The other interesting aspect of this work is that these catalysts were found to be active even after exposure to air in this reaction, a rare phenomena for a solid basic catalyst.

Mg–Al hydrotalcites having Mg : Al = 3 : 1 was synthesised using the procedure reported by Miyata *et al*.[9] The presence of pure hydrotalcite structure was confirmed by powder X-ray diffraction. The preparation of modified hydrotalcite includes activation of the hydrotalcite in carbon dioxide free N_2 at 450 °C, followed by cooling and hydrating the material in a flow of nitrogen saturated with water at room temperature in a controlled fashion.

Scheme 1

The catalytic reactions were carried out using 10 ml of alcohol and 4 mmol of acrylonitrile. The catalyst after rehydration was transferred to the reactor containing the alcohol followed by addition of acrylonitrile. The samples were analysed by gas-liquid chromatography.

Table 1 shows a comparison of the modified hydrotalcites rehydrated for different periods of time with fresh and calcined hydrotalcites and MgO (from the results of Hattori[6]) for the reaction of acrylonitrile with MeOH in which methoxypropionitrile is the only product. The modified hydrotalcites are much more active than MgO, which also needs a very high activation temperature (800 °C *in vacuo*). The hydrotalcite as such shows only marginal activity as it contains very few basic sites. It is interesting to note that even though the calcined hydrotalcite has a high Lewis basicity, it is only marginally active. This shows that this reaction is catalysed by weak Brönsted basic sites (OH^- sites).

Similar to our earlier results for the aldol condensation reaction,[7] for cyanoethylation the catalytic activity also depends upon the rehydration time. In the present case optimum activity is observed for the catalyst rehydrated for 6 h (catalyst = 0.1 g, water saturated N_2 flow = 80 ml min^{-1}).

The reusability of the catalyst was studied by using the same catalyst after allowing the catalyst to settle, decanting the supernatanat reaction mixture and continuing the reaction by introducing fresh reactants (acrylonitrile and MeOH). The results are sumarised in Table 2. The catalyst was found to be reusable without appreciable loss in activity.

The study was further extended to other monohydric alcohols such as EtOH, Pr^iOH, BuOH and Bu^tOH. The results are summarised in Table 3. Except for Bu^tOH, the catalysts are found to be highly active for all the alcohols, which is in agreement with the results for the homogeneous catalyst. The selectivity for the corresponding alkoxypropionitrile was 100%,

Table 1 Comparison of various catalysts for cyanoethylation of acrylonitrile with MeOH[a]

Catalyst	Conditions for activation of the catalyst	*t*/min	Conversion of acrylonitrile (%)
Mg–Al Hydrotalcite	used as was	120	2.5
Mg–Al Hydrotalcite	N_2 flow at 450 °C	120	20
Modified Mg–Al Hydrotalcite	N_2 at 450 °C rehydration for 3 h in wet N_2 at room temp.	90	98
Modified Mg–Al Hydrotalcite	N_2 at 450 °C rehydration for 6 h in wet N_2 at room temp.	45	99.8
Modified Mg–Al Hydrotalcite	N_2 at 450 °C rehydration for 12 h in wet N_2 at room temp.	45	100
MgO[b]	800 °C *in vacuo*	120	98.7

[a] Reaction conditions: acrylonitrile (0.04 mol), MeOH (10 ml), 50 °C, Catalyst (0.1 g). [b] Results from ref. 6.

Table 2 Reusability of modified Mg Al hydrotalcite catalyst (rehydrated for 6 h) for cyanoethylation of acrylonitrile with MeOH[a]

Cycle	Conversion (%)
1	99.8
2	98.0
3	96.0

[a] Reaction conditions as in Table 1.

except for Pr^{i}OH, in which case the selectivity for β-isopropoxypropionitrile was 80%.

Normally, solid basic catalysts are highly sensitive to air and loose their activity due to carbonation when exposed, preventing them from being used industrially. To check this an experiment was carried out to see if the catalyst remained active when exposed to air. To our surprise we found that the modified hydrotalcite catalyst, even after exposure to air (1 h), showed the same activity as a sample not exposed (100% conversion in 45 min). This result makes this catalyst attractive for practical use.

Table 3 Cyanoethylation of various monohydric alcohols with acrylonitrile over modified Mg–Al hydrotalcite (rehydrated for 6 h)[a]

Alcohol	*t*/min	Conversion of acrylonitrile (%)
EtOH	25	100
Pr^{i}OH	90	95.6
BuOH	20	100
Bu^{t}OH	120	10

[a] Reaction conditions as in Table 1.

In summary we have shown that modified Mg–Al hydrotalcite is a highly active, reusable and air stable catalyst for cyanoethylation of monohydric alcohols.

Germyl anion species-promoted formation of cyanofluoromethylene compounds: first and efficient synthesis of fluorinated homoallylic and homoprop-2-ynylic cyanides

Yasuo Yokoyama*† and Kunio Mochida‡

Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171-8588, Japan

Various fluorinated homoallylic and homoprop-2-ynylic cyanides could be synthesized from 2-fluoro-2-phenylthio-2-phenylacetonitrile and some allylic or prop-2-ynylic chlorides in excellent yields by use of a germyl anion species.

Recently, fluorine-contained organic compounds have attracted wide attention among scientists in the fields of agrochemicals, pharmaceuticals and material sciences. Various antiviral, antitumor and antifungal agents and advanced materials have been synthesized in which fluorine substitution plays a significant role in their biological activities and physical properties.[1] Thus, the formation of an organofluorine compound is a most important reaction in organic synthesis. Particularly, synthetic methodology for a monofluorinated compound ($R^1R^2R^3CF$)[2] is a very attractive target of study, because it is difficult due to the chemical lability of the foregoing compound in some cases. Concerning this problem, we focused on the synthesis of the cyanofluoromethylene compound [$R^1R^2C(CN)F$] as an easy and effective formation of a monofluorinated product. This compound has cyano and fluoro substituents on the same carbon, and could be employed as a useful fluorine-containing building block, because the cyano group is easily transformed to other substituents.[3] Moreover, this molecule is important from the viewpoint of the multifunctional carbon structure.[4] There are two strategies which give the foregoing molecule. One is a stepwise introduction of cyano and fluoro groups,[5] and the other is introduction of a cyanofluoromethylene unit to a substrate. In particular, the latter method is suitable for the synthesis of cyanofluoromethylene compounds because the target molecule can be formed more straightforwardly. However, only a few synthetic examples have been reported at the present time.[6] In this regard, we have developed the germyl anion species-promoted synthesis of a cyanofluoromethylene compound by use of 2-fluoro-2-phenylthio-2-phenylacetonitrile as the cyanofluoromethylene source. Herein we report the first and efficient syntheses of fluorinated homoallylic and homoprop-2-ynylic cyanides.

Some selected data of reactions of 2-fluoro-2-phenylthio-2-phenylacetonitrile with (*E*)-3-chloro-1-phenylprop-1-ene (cinnamyl chloride) in the presence of various activators are summarized in Table 1.

As expected, some germyl anion species were found to give fluorinated homoallylic cyanides (entries 1–3). The yield of the desired compound was affected by the nature of the counter cation. When germyl anions having Li^+ and K^+ were used, the yield of the target product was low. Many unidentified by-products were obtained, whereas the starting cyanide was consumed completely (entries 1 and 3). On the other hand, 2-fluoro-2-phenylthio-2-phenylacetonitrile could be activated effectively by Et_3GeNa to give the active intermediate. This species reacted with cinnamyl chloride to give the corresponding compound quantitatively (entry 2). Other group 14 element-containing anions, such as Me_3SiNa,[7] Et_3SnNa§ and Bu^nLi were not useful for this type of reaction (entries 4–6). In addition, the starting cyanide was transformed to the desired homoallylic cyanide in low yield when lithium naphthalenide (LN), which is well known as a strong one-electron reducing agent,[9] was applied (entry 7). These facts suggested that only Et_3GeNa was suitable for the synthesis of the fluorinated homoallylic cyanide. The reason why Et_3GeNa was favorable for the activation and the cleavage of a sulfur–carbon bond¶ is unclear, but this phenomenon is probably due to the thiophilicity of the germanium atom and the stability of the active intermediate.

Various allylic and prop-2-ynylic chlorides could be also used as substrates instead of cinnamyl chloride under the same reaction conditions (Table 1, entry 2). In Table 2, the results of application of this reaction for some substrates are presented. When 3-chloroprop-1-ene was used as an electrophile, the desired simple homoallylic cyanide was obtained in excellent yield (entry 1). When 1-chlorobut-2-ene (*E*:*Z* = 73:27) was employed, the *E*-isomer of the target compound was obtained predominantly (entry 2, *E*:*Z* = 73:27). Some *E*-allylic chlorides, such as (*E*)-1-chlorohex-2-ene, (*E*)-1-chlorooct-2-ene, (*E*)-1-chlorononon-2-ene and (*E*)-1-chloro-3,5-dimethylocta-2,6-diene could be transformed to the desired products having *E*-configuration in excellent yields (entries 3–6). These results suggested that no isomerization of the olefin occurred under these reaction conditions. Other primary allylic chlorides were also employed as electrophiles (entries 7 and 8). On the other hand, when secondary allylic chloride (3-chlorobut-1-ene) was used, the desired compound was obtained in moderate yield (76%, *syn*:*anti* = 64:36, entry 9). An *E*-isomer of entry 2 was obtained which was formed by the attack of a nucleophile at the γ-carbon as a by-product (24%), because the intermediate was sterically hindered. Furthermore, 1-chlorohexa-2,4-diene and some prop-2-ynylic chlorides could react with the active intermediate to give the corresponding fluorinated cyanides in excellent yields without decomposition of the starting chlorides (entries 10–12). In these cases, products formed by attack of the nucleophile to the γ-position (or ε-position) of chlorides could not be detected at all, except in the case of entry 9. These results revealed that the presented method was applicable to the

synthesis of many types of fluorinated homoallylic and homoprop-2-ynylic cyanides.

A typical procedure is as follows. To a THF solution (20 ml) of 2-fluoro-2-phenylthio-2-phenylacetonitrile (377 mg, 1.55 mmol) was added an HMPA solution of Et_3GeNa[11] (4 ml, 0.42 M) slowly at −60 °C. After stirring for 0.25 h at −60 °C, the temperature was lowered to −80 °C, and cinnamyl chloride (355 mg, 2.32 mmol) was added. The mixture was stirred for 0.5 h at −80 °C and then was passed through a short column of silica gel and eluted with Et_2O. Concentration of this eluate followed by column chromatographic purification afforded 380 mg (98%) of the corresponding compound (Table 1, entry 2).

In conclusion, we have developed the first syntheses of fluorinated homoallylic and homoprop-2-ynylic cyanides. This reaction proceeded smoothly to give the corresponding product in excellent yield under mild reaction conditions. The efficient synthesis presented here can presumably be employed in fluorine chemistry as a useful method for monofluorinated compounds. Further investigation of applications of this reaction and a mechanistic study are now in progress.

Stereoselective Michael/aldol tandem reaction triggered by thiolate anion or analogues

Akio Kamimura,*[a]† Hiromasa Mitsudera,[a] Shigeru Asano,[a] Akikazu Kakehi[b] and Michihiko Noguchi[a]

[a] *Department of Applied Chemistry, Faculty of Engineering, Yamaguchi University, Ube 755-8611, Japan*
[b] *Department of Material Engineering, Faculty of Engineering, Shinshu University, Nagano 380-8553, Japan*

A combination of a *tert*-butyl α,β-unsaturated ester, an aldehyde and lithium thiophenolate in CH_2Cl_2 undergoes a one-pot Michael/aldol tandem reaction to give a condensation adduct of the three components, an α-phenylthiomethyl-β-hydroxy ester, in good yield with high *syn*-selectivity.

The Michael addition is one of the most powerful methodologies in organic synthesis.[1] Thiols are frequently used as good nucleophiles for the reaction with α,β-unsaturated esters, ketones or nitriles to give the corresponding Michael adducts quantitatively. The reaction is regarded as generating a β-thioenolate intermediate as a result of nucleophilic attack of the thiolate at the β-carbon of the Michael acceptor;[2] the intermediate is then protonated to give the Michael adduct. If the β-thioenolate intermediate was able to be used for the aldol reaction, a new Michael/aldol tandem reaction[3] could be developed and might provide a useful methodology for the construction of carbon skeleton since sulfur functionality is convenient for further transformation to other functional groups. There have been several similar examples of this type of reaction with carbon,[4] nitrogen[5] and silicon nucleophiles.[6] Although thiolate and its analogues have also been used in a similar way, good examples are limited to α,β-unsaturated ketones,[7] and the same sequence for α,β-unsaturated esters contains many problems.[7a,d,8] Additionally, the stereochemical outcome of the reaction with esters has not been clear so far. Here, we report a novel one-pot three-component condensation of thiolate, an α,β-unsaturated ester and an aldehyde with high *syn*-stereoselectivity.

The reaction procedure was quite simple; lithium thiophenolate was generated from thiophenol on treatment with butyllithium at −78 °C in CH_2Cl_2 to give a white precipitate, most of which remained undissolved following addition of acryrate esters at −78 °C. To the heterogeneous mixture, aldehyde was added at the same temperature; the reaction mixture then became a homogeneous pale yellow solution. The solution was maintained at −50 °C for 7 h and the three-component condensation adducts **3** were obtained (Scheme 1). To our surprise, no S_N2 product from CH_2Cl_2 and lithium thiolate was observed. The results are summarised in Table 1.‡

The reaction exhibited several interesting features. Firstly, choice of reaction solvent was quite important; CH_2Cl_2 or Et_2O were the only suitable solvents to perform the reaction. Other coordinative solvents such as THF or propiononitrile were not useful; only the simple Michael adduct of thiol and acrylate was formed. The counter cation was also important; use of lithium thiophenolate was essential. The reaction of methyl or ethyl acrylate gave the three component adducts **3a** or **3b** in 62 or 64% yield, respectively, but neither of their diastereomeric ratios were satisfactory (entries 1 and 2). The stereoselectivity was significantly improved when *tert*-butyl acrylate was used instead; the tandem adduct **3c** was obtained in 80% with 92 : 8 *syn*-selectivity (entry 3). The present stereoselectivity is much higher than the analogous aldol reaction of ester enolates generated from *tert*-butyl propionate with LDA, in which the reported *syn* : *anti* ratio was almost 1 : 1.[9] The tandem adducts **3**, starting from other aromatic and α,β-unsaturated aldehydes, were prepared in similar yields with high *syn*-selectivity (entries 4–6). Aliphatic aldehydes also gave the adduct in moderate yield, along with formation of the self-aldol product of the aldehyde (entry 7).

We also examined analogues of thiolate for the reaction. Lithium phenylselenolate,[10] which was generated from diphenyl diselenide and methyllithium,§ was found to be effective for the reaction; again the *syn*-enriched adduct **4a** was isolated in 63% (entry 8). The diastereoselectivity and yield of **4** for the reaction with aromatic aldehydes were slightly less than those for the reactions promoted by thiolate in CH_2Cl_2 (entries 8–10). The reaction with an aliphatic aldehyde, however, gave **4d** in only poor yield (entry 11). Phenoxide was too unreactive to promote the reaction (entry 12). We also tried to apply the present sequence to methyl vinyl ketone with thiolate and benzaldehyde, but only trace amounts of the corresponding tandem adduct were formed.

The stereochemistries of **3** and **4** were determined in the following way (Scheme 2); the phenylseleno group in compound **4a** was replaced by hydrogen on treatment with Bu_3SnH. Diastereomeric ratios of **4a** (85 : 15) and **6** (82 : 18) were almost the same within experimental error. The NMR spectrum of the

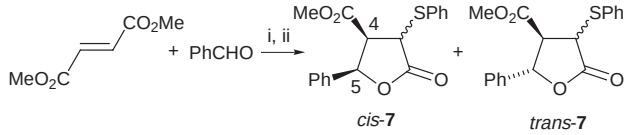
minor isomer of **6** was found to be identical to the known *anti*-diastereomer,[11] and we concluded that the major isomers of **4a** and **6** had *syn*-configuration. The stereochemistries of the other thio analogues **3** were determined on the basis of comparison of their ^{1}H NMR spectra and HPLC patterns.

The present methodology is useful for the preparation of γ-butyrolactone from lithium thiophenolate, fumarate ester and aldehyde. For example, reaction of the three components in CH_2Cl_2 at −50 °C for 5 h resulted in the formation of γ-butyrolactone **7** along with the β-hydroxy ester. The mixture was then treated with PPTS in refluxing toluene to give lactone **7** in 64% yield (Scheme 3). NOE measurements and HPLC analysis revealed that the 4,5-*cis* isomer was formed as the major isomer in an 80 : 20 ratio.



cis-**7** *trans*-**7**

64%; 4,5-*cis*:4,5-*trans* = 80:20

Scheme 3 *Reagents and conditions*: i, PhSLi, CH_2Cl_2, −78 °C, then −50 °C, 7 h; ii, PPTS, toluene, 110 °C, 2 h

Due to the heterogeneity of the mixture of acryrate and thiolate, the mechanism of the reaction and origin of the stereoselectivity are not clear; attempts to trap the β-thioenolate intermediate have so far been unsuccessful. Indeed, since most of the white precipitate of lithium thiophenolate in CH_2Cl_2 is undissolved in the presence of the acrylate esters, the concentration of the β-thioenolate intermediate in the absence of aldehyde should be very low. We assume that the active intermediate is formed with assistance due to coordination of the aldehyde to the lithium cation. Further investigation and application of the reaction will be reported in due course.

We thank Ube Industries Ltd. and Sumitomo Chemical Industry Ltd. for their financial support.

‡ All new compounds were fully characterised by spectroscopic analysis and microanalysis or HRMS.

§ Although lithium phenylselenolate should be generated from selenol and butyl lithium, we wished to avoid using the selenol formed from diselenide due to its toxicity and evil odour. After exploring several potential routes to lithium selenolate, we found that it was generated directly from a solution of diselenide *via* addition of methyl- or butyl-lithium. Although half of the selenium source is wasted as alkyl phenyl selenide, the present method was advantageous because anhydrous selenolate anion with no proton source was generated directly from commercially available diphenyl diselenide; the yellow colour of the diselenide disappeared when an equimolar amount of alkyllithium had been added.

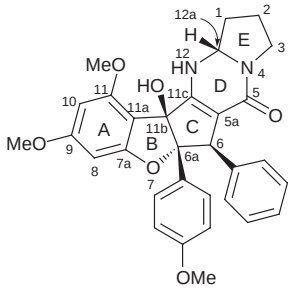
Total synthesis of (±)-aglaiastatin, a novel bioactive alkaloid

Takumi Watanabe,[a] Shiho Kohzuma,[b] Tomio Takeuchi,[a], Masami Otsuka[c] and Kazuo Umezawa*[b]†

[a]*Institute of Microbial Chemistry, 3-14-23 Kamiosaki, Shinagawa-ku, Tokyo 141, Japan*
[b] *Department of Applied Chemistry, Faculty of Science and Technology, Keio University, 3-14-1 Hiyoshi, Kohoku-ku, Yokohama 223, Japan*
[c] *Faculty of Pharmaceutical Sciences, Kumamoto University, 5-1 Oe-Honmachi, Kumamoto 862, Japan*

The first total synthesis of aglaiastatin has been accomplished using pyrrolopyrimidinone construction by simultaneous nucleophilic attack of a nitrogen unit at the carbonyl group and the acyl iminium ion.

We recently isolated aglaiastatin **1**, a novel alkaloid, from the leaves of the tropical plant *Aglaia odorata*; it acts as an agent that induces normal morphology in K-*ras*-transformed fibroblasts.[1] It was shown to be a specific inhibitor of protein synthesis, and the alkaloid displayed potent growth inhibition against various tumor cell lines (*e.g.* IC_{50} value for K-*ras*-NRK cells: 1.67 ng ml^{-1}).



aglaiastatin **1**

Aglaiastatin consists of five fused rings (indicated as A, B, C, D, and E rings for convenience). Related benzofurocyclopentane systems (rings ABC) can be seen in the structures of other natural products such as rocaglamide,[2] and rocaglaol,[3] however, the five-ring system in **1** is rare and has not been reported, except in the case of an unnamed alkaloid.[4] Rocaglamide has been synthesized,[5] but aglaiastatin and the unnamed compound containing the pyrrolopyrimidinone system have never been synthesized.

Since construction of the ABC ring system had already been reported by several groups, development of methodology to construct the CDE ring system was the most challenging task. For the synthesis of aglaiastatin, an ABC ring system with a side chain at the C-5a position as a DE ring precursor was expected to be a promising intermediate for this synthesis. Starting from this substance, E ring formation and subsequent closure of the D ring could afford aglaiastatin. We anticipated that these reaction steps to form the DE ring system could be performed in one synthetic operation. Scheme 1 shows our strategy for the synthesis. At first, we planned to introduce a protected aminobutyraldehyde into the ABC ring prepared according to the reported procedure.[5b] Hydrolysis of the acetal should cause nucleophilic addition of the amide nitrogen to the aldehyde to afford the desired five-membered ring corresponding to the E ring. We anticipated that an acyl iminium ion should be generated by dehydration under acidic conditions. With this compound thus accessible, simultaneous nucleophilic addition of one nitrogen unit to two electrophilic groups, the ketone on the C ring and the acyl iminium moiety on the E ring, would form the D ring. Use of an ammonium salt as the one nitrogen unit for double nucleophilic reaction has been reported in some synthetic studies.[6]

Scheme 2 shows the protocol for the synthesis, which was begun by a coupling between commercially available 4-aminobutyraldehyde diethyl acetal and carboxylic acid **2** by use of the BOP [benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate] reagent[7] to give amide **3** in excellent yield. Starting material **2** (racemic form) is an intermediate formed in Taylor's procedure for the total synthesis of rocaglamide[5b] and was prepared as an epimeric mixture at the C-2 carboxy group ($\alpha:\beta$ = 55:45). The subsequent oxidation step was unexpectedly problematic. Swern oxidation and Dess–Martin oxidation of **3** could not afford the desired ketone **4** reproducibly. Then, we turned our attention to SO_3·pyridine oxidation.[8] However, the reaction rate under the standard procedure was very sluggish. After optimization of the reaction

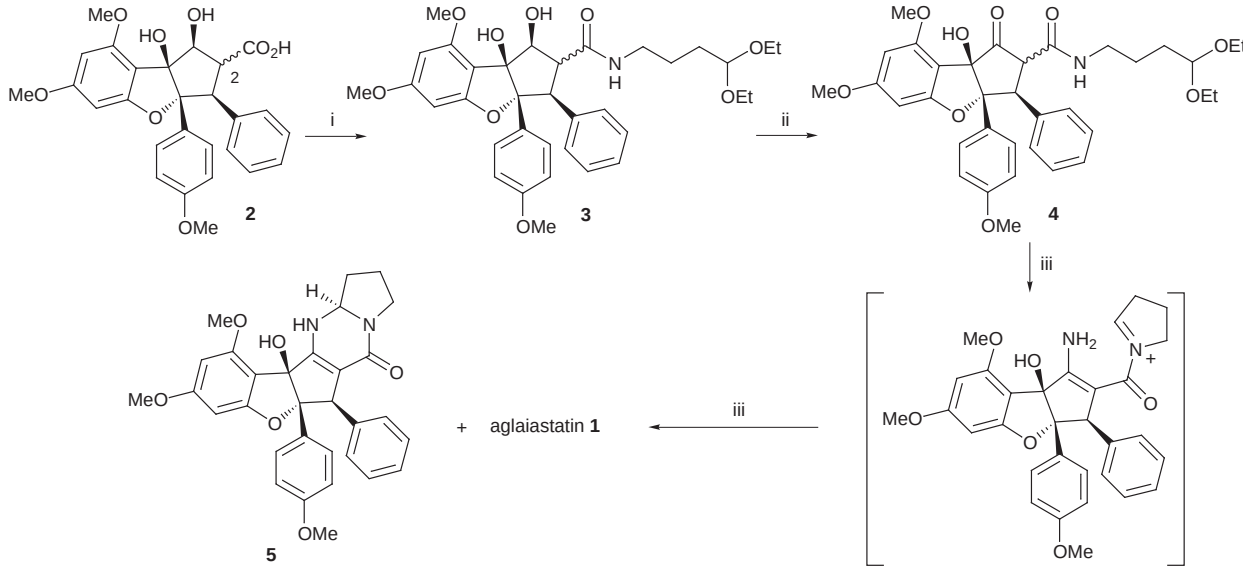
Scheme 1



Scheme 2 *Reagents and conditions*: i, $H_2N(CH_2)_3CH(OEt)_2$, BOP reagent, Et_3N, room temp., CH_2Cl_2, 95%; ii, SO_3·pyridine, Et_3N, room temp., DMSO, 97%; iii, 1 M HCl, THF, then HCO_2H, HCO_2NH_4, room temp., MeOH, 70% for two steps (**1** : **5** = 2 : 1). The yield of **1** and **5** after chromatographic separation was 40 and 19%, respectively.

conditions, the use of a large excess of reagent finally gave satisfactory results. When the reaction was conducted for 1 h using 30 equiv. of SO_3·pyridine, the required ketone **4** was obtained in 97% yield. Prolonged reaction time or heating resulted in contaminating by-products. Although the α : β distribution about the amide group at C-2 varied in every trial, the β isomer was obtained predominantly. For the final pyrrolopyrimidinone formation, hydrolysis of the acetal with HCl and concomitant cyclization would have given the *N*-acyl hydroxypyrrolidine intermediate (not isolated) depicted in Scheme 1. After the usual workup, the crude material was treated with 99% formic acid in the presence of a large excess of ammonium formate (*ca.* 100 equiv.) in MeOH for 4 days. As a consequence, the desired (±)-aglaiastatin was obtained as a mixture of diastereomers at C-12a in high combined yield (70%). Fortunately, aglaiastatin was the predominant product [aglaiastatin (**1**) : diastereomer (**5**) = 2 : 1 determined by ^{1}H NMR]. Selectivity in the formation of **1** *versus* **5** would be explained by nucleophilic attack of the NH_2 group in the convex structure of ABC ring at the downward facing surface of the E ring. The iminium ion would probably be facing upwards due to steric hindrance. These stereoisomers could be easily separated by silica gel column chromatography to give pure **1** and **5** in 40 and 19% yield, respectively. Thus, we accomplished the first total synthesis of (±)-aglaiastatin.

The spectral properties (^{1}H and ^{13}C NMR, FABMS, IR) of the synthetic aglaiastatin, were indistinguishable from those of the natural aglaiastatin, except for optical rotation. Further, optically active aglaiastatin was obtained by separation with semi-preparative scale chiral HPLC (Daicel Chiralpak AD). One of the separated samples of synthetic aglaiastatin showed nearly the same value {$[\alpha]_D^{23}$ + 148.1 (*c* 0.1, MeOH)} as natural aglaiastatin [+151.2 (*c* 0.1, MeOH)]. It also displayed identical growth-inhibitory activity toward K-*ras*-NRK cells (IC_{50} value: 1.49 ng ml^{-1}) to that of the authentic sample (IC_{50} value: 1.67 ng ml^{-1}).

In conclusion, we have accomplished the first total synthesis of the novel protein synthesis inhibitor aglaiastatin. In the process, we developed a new methodology for pyrrolopyrimidinone construction using one nitrogen unit for the ring closure. Attempts to utilize this synthetic scheme for the synthesis of structurally related analogs and enantiomeric synthesis of aglaiastatin are under way.

The authors thank Dr Y. Nishimura and Mr N. Matsumoto, Institute of Microbial Chemistry, for valuable suggestions, and Dr H. Naganawa, Dr R. Sawa and Mr I. Momose, Institute of Microbial Chemistry, for spectroscopic analysis.

Heats of Lewis base complexation, deaggregation and stabilization by α-silicon in a family of primary alkyllithiums

Robert F. Schmitz, Marius Schakel, Marcel Vos and Gerhard W. Klumpp*†

Scheikundig Laboratorium Vrije Universiteit, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands

For primary alkyllithiums, enthalpies of Lewis base induced tetramer → dimer and dimer → monomer conversion, intramolecular Li–NMe_2R complexation and stabilization by α-$SiMe_2R$ are given.

Any understanding and control of σ-organolithium (RLi) reactivity requires extensive knowledge of each of the various forms in which RLis occur: aggregates R_mLi_m (m = 2,4,6), complexes of aggregates with Lewis bases [LB (R_2O, R_3N)] $R_mLi_m{\cdot}n$LB (m, n = 2,4; 4, 1–4) and, in relatively rare cases, monomer complexes RLi·nLB (n = 2,3).[1] Nevertheless, fundamental data, such as enthalpies of transfer of RLi from one aggregation state into another, are scarce: BuLi/THF, ΔH(complexed tetramer → complexed dimer) ≈ −2 kJ (mol RLi)$^{-1}$;[2] Bu^tLi/cyclopentane–Et_2O, ΔH(uncomplexed tetramer → complexed dimer) ≈ −38 kJ (mol RLi)$^{-1}$;[3] neopentyllithium/Et_2O, ΔH(complexed dimer → complexed monomer) ≈ −3 kJ (mol RLi)$^{-1}$.[1] For a family of intramolecularly amine-complexed (trimethylsilyl)methyllithium derivatives $LiCH_2Si(Me)_2CH_2$–Z (**1**–**3**, Z = $N(CH_2X)CH_2Y$, see Fig. 1)[4] and for the parent (trimethylsilyl)methyllithium (**4**, Z = H),[5] we now present relative stabilities of exhaustively complexed monomer, dimer and tetramer, respectively, as well as uncomplexed tetramer. Inclusion in our study of 3-(dimethylamino)propyllithium (**5**),[6] the analogue of **3** in which $SiMe_2$ is replaced by CH_2, provided a measure of RLi stabilization by α-silicon.

In Fig. 1, heats of protonation of **1**–**5** by Bu^sOH [ΔH, kJ (mol RLi)$^{-1}$, benzene, 25 °C]‡ are given together with the monomer (**1**), dimer ($\mathbf{2_2}$) and tetramer [$\mathbf{3_4}$, $\mathbf{4_4}$, $\mathbf{5_4}$ (**a** : **b** = 6 : 4)] structures in which **1**–**5** prevail under the conditions of experiment.

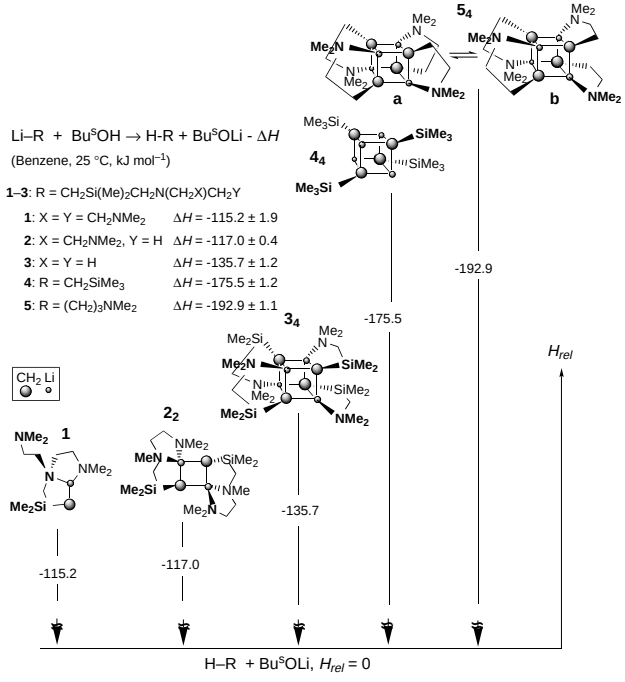

Fig. 1 Heats of protonation by Bu^sOH [ΔH/kJ (mol RLi)$^{-1}$, vertical arrows)] and relative stabilities [H_{rel}/kJ (mol RLi)$^{-1}$]

The protonation products (H–R, Fig. 1) of **1**–**5** are assigned equal *relative* enthalpies since they are devoid of special interactions.§ On this basis, negative differences of heats of protonation equal differences of relative enthalpies (stabilities) of RLi species. We also assume that in **1**–**4**, variation of Z is of minor influence, if at all, on the nature of C–Li.¶ Thus, $\Delta H(\mathbf{3_4}) - \Delta H(\mathbf{2_2}) \approx -19$ kJ (mol RLi)$^{-1}$ indicates that for type-**4** RLi species, amine complexation induced deaggregation of complexed tetramer into dimer is of considerable exothermicity. Further deaggregation of complexed dimer into monomer is nearly thermoneutral: $\Delta H(\mathbf{2_2}) - \Delta H(\mathbf{1}) \approx -2$ kJ (mol RLi)$^{-1}$. $\Delta H(\mathbf{4_4}) - \Delta H(\mathbf{3_4}) \approx -40$ kJ (mol RLi)$^{-1}$ gives the average strength of an N–Li bond in a tetrameric type-**4** RLi complexed by four NMe_3-type nitrogens.‖ $\Delta H(\mathbf{5_4}) - \Delta H(\mathbf{3_4}) \approx -57$ kJ (mol RLi)$^{-1}$ provides an experimental measure of the practically[8] and theoretically[9] important carbanion stabilization by silicon. Parenthetically, the close similarity of $\Delta H(\mathbf{5_4})$, −193 kJ (mol RLi)$^{-1}$, and ΔH of tetrameric 3-methoxypropyllithium under the same conditions [−190 kJ (mol RLi)$^{-1}$][10] testifies to the very similar lithium complexation propensities of –OMe and –NMe_2.

The energetics found in this study for LB induced tetramer → dimer and dimer → monomer conversion, respectively, are in accord with the results of quantum mechanical calculations on MeLi which indicate the latter to be rather more difficult,[11] although, as the present and the previous experiments show, actual values depend on the nature of R and LB (*cf.* ref. 1). Likewise, as expected,[9] the value found for the energy of stabilization of tetrameric primary RLi by α-$SiMe_2R$ [57 kJ (mol RLi)$^{-1}$] is in between those calculated[9] for $LiCH_2SiH_3$ (39 kJ mol^{-1}) and for $^-CH_2SiH_3$ (104 kJ mol^{-1}). The similarity found for –OMe and –NMe_2 as complexing groups of RLi agrees with the very similar capacities of R_2O and R_3N for acceleration of RLi reactions[12] and suggests that the above amine data also approximate those for ethers.

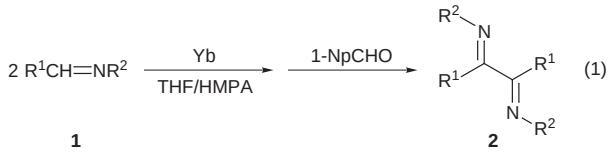
Preparation of vicinal diimines: a new dehydrogenative coupling reaction of aldimines mediated by ytterbium metal

Wu-Song Jin, Yoshikazu Makioka, Yuki Taniguchi, Tsugio Kitamura and Yuzo Fujiwara*†

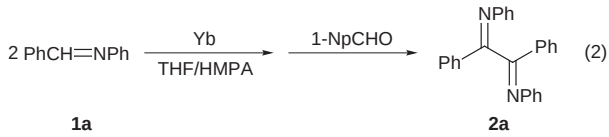
Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, 6-10-1 Hakozaki, Higashiku, Fukuoka 812-8581, Japan

Dehydrogenative coupling takes place to give vicinal diimine compounds in the reaction of aromatic aldimines with ytterbium metal followed by treatment with aromatic aldehydes such as 1-naphthaldehyde (1-NpCHO) as a hydrogen acceptor.

Lanthanide metals have been utilized for various transformations of organic functional groups or C–C bond formations *via* coupling reactions.[1] Previously, we have demonstrated that ytterbium metal causes the coupling reaction of carbonyl and thiocarbonyl compounds,[2] and that imines undergo a similar reaction to give 1,2-diamines or α-amino acids.[3] Imamoto and Nishimura and others reported that samarium(II) compounds are also capable of the coupling of imines to give 1,2-diamines.[4] Recently, a triphenylimine dianion complex [Yb(η^2-Ph_2CNPh)$(HMPA)_3$] has been successfully isolated from the direct reaction of ytterbium metal and triphenylimine and characterized by X-ray analysis.[5] In a continuing study of the reactions of aldimines and ytterbium metal, we have found that the reaction of aromatic aldimines and ytterbium metal followed by addition of oxidants produces the corresponding vicinal diimine compounds [eqn. (1)]. Here we report these new results.



First, *N*-benzylideneaniline (**1a**) was reacted with 0.5 equiv. of ytterbium metal at room temperature then an oxidant was added and the mixture was stirred for 2 h to give the dehydrogenative coupling product, *N*,*N*′-diphenyl-1,2-diphenylethane-1,2-diimine (**2a**) in 81% yield [eqn. (2)].‡ The effects



of various oxidants toward the dehydrogenative coupling reaction of **1a** are summarized in Table 1. From the data in Table 1 one can see that aromatic aldehydes (entries 1–4) are the best compared with others. In particular when 1-NpCHO is used, the best result is obtained, whereas the yield of the product is only 7% when an aliphatic aldehyde is used (entry 5). In addition, it is apparent that $CuCl_2$, peroxides and Bu^tNO_2 give inferior results (entries 6–9) and that only 17% yield is obtained in the case of O_2 (entry 10). The presence of HMPA as an additive is necessary in this reaction since the reaction of **1a** and ytterbium metal cannot proceed in THF alone.

The reaction also occurred with various aromatic aldimines as well as **1a**. The representative results for the dehydrogenative coupling reaction of other aldimines **1** are listed in Table 2. When the substrates are non-substituted, *p*-methyl- and *p*-methoxy-substituted aromatic aldimines **1a**–**d**,**f**,**g**, the reactions proceed smoothly to afford **2a**–**d**,**f**,**g** (entries 1–4 and 6, 7) in good to high yields. On the other hand, the yields of **2** were low in the reactions of *p*-cyano- and *p*-chloro-substituted aldimines **1e** and **1h** (entries 5 and 8). Thus, the electron-donating substituent on the benzene ring is profitable to the reaction. In the reaction of the *o*-methyl-substituted aldimine **1i** at room temperature, only small amounts of **2i** were formed, and the hydrogenation product (o-$MeC_6H_4CHNHPh)_2$ was formed as the main product. This is due to the steric hinderence of the diazametallacyclopentane intermediate toward dehydrogenation with 1-NpCHO (*vide infra*). However, **2i** could be obtained in a moderate yield at reflux temperature (entry 9). The reaction did not occur in the case of C_6H_5CH=$NCMe_3$ (**1j**), and **1j** was recovered (entry 10), due to it's lower reactivity towards ytterbium metal.

Table 1 Effect of various oxidants on the dehydrogenative coupling reaction of aldimine **1a**[a]

Entry	Oxidant	mmol	Yield of **2a**[b] (%)

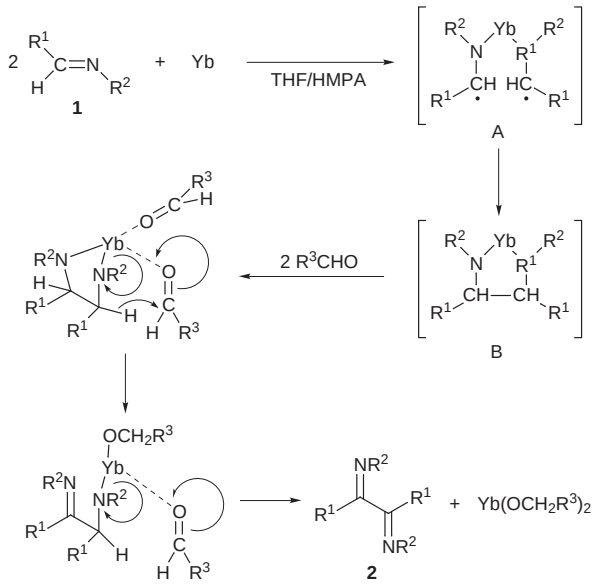

Scheme 1

Although the reaction mechanism is not yet clear, a possible reaction mechanism is shown in Scheme 1. First, one atom of ytterbium metal reacts with two molecules of aldimine **1** *via* two-electron transfer from ytterbium to give a diazametallacyclopentane intermediate B, probably *via* formation of an intermediate A.[6] Subsequent treatment with an aldehyde would cause the coordination and double hydrogen transfer, as in a similar manner to the Meerwin–Pondorf–Varley reduction/Oppenauer oxidation,[7] to give **2** and ytterbium alkoxides, which gives an alcohol R^3CH_2OH after hydrolysis.

In summary, ethane-1,2-diimines **2** can be prepared from the reaction of aromatic aldimines **1** with ytterbium metal followed by treatment with aromatic aldehydes. To the best of our knowledge, this is the first example of metal mediated dehydrogenative coupling of aldimines. Further mechanistic investigation and extension of this reaction are in progress.

‡ Typical procedure for the dehydrogenative coupling of **1** with Yb metal: THF (2 ml), HMPA (0.5 ml) and methyl iodide (2 μl) were successively added to a mixture of **1c** (211 mg, 1.0 mmol) and ytterbium (87 mg, 0.5 mmol) under argon, which was stirred for 2 h at room temperature. Then, 1-NpCHO (156 mg, 1.0 mmol) was added to the mixture. The resulting mixture was stirred for an additional 2 h at room temperature. Usual work-up followed by a silica gel column chromatography (*n*-hexane–ethyl acetate) gave 119 mg (57%) of the desired compound **2c**.

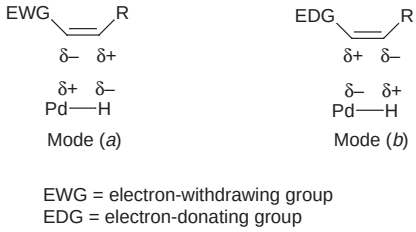
Discovery that quinoline and triphenylphosphine alter the electronic properties of hydrogenation catalysts

Jinquan Yu and Jonathan B. Spencer*†

University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW

Quinoline and triphenylphosphine are found to influence the polarisation of the palladium–hydrogen bond in heterogeneous hydrogenation; this provides a possible explanation for why the addition of these compounds increases the selectivity of the semi- reduction of alkynes.

The selective reduction of alkynes to *cis*-alkenes using heterogeneous catalysts, such as palladium on carbon, is a key reaction in organic chemistry.[1,2] Quinoline and triphenylphosphine have been widely used as additives in heterogeneous hydrogenation to improve the selectivity of this reaction.[3] There has been great interest in rationalising how these compounds alter the properties of the palladium to achieve superior selectivity. Several theories have been put forward, including the selective blocking of sites that cause the side reactions and promoting the rearrangement of the surface structure.[4–6] It has not been possible, however, to probe whether quinoline and triphenylphosphine, both potentially strong ligands, could alter the electronic properties of the metal catalyst. Recently we have devised an approach to achieve this by determining which electronic mode [mode (*a*) $M^{\delta+}$–$H^{\delta-}$ or (*b*) $M^{\delta-}$–$H^{\delta+}$, Scheme 1] of hydrometalation is promoted by the catalyst.[7,8]



Scheme 1

When *cis*-enol ether **1** is isomerised to the *trans*-isomer **2** using deuterium and palladium on carbon the location of the deuterium on the double bond reports which mode of hydrometalation takes place (Scheme 2). The result with unmodified palladium on carbon (Fig. 1) is that the deuterium is incorporated almost entirely at position I, which shows that mode (*b*) ($M^{\delta-}$–$H^{\delta+}$) is dominant; this is a consequence of the polarisation of the palladium–hydrogen bond being induced by the electronic dipole of the substrate.[7,8] Remarkably, when this reaction is carried out in the presence of quinoline, mode (*a*) ($M^{\delta+}$–$H^{\delta-}$) is significantly enhanced (Fig. 1). This suggests that the quinoline, being a strong electron-donating ligand, is capable of stabilising the electron-deficient metal centre in mode (*a*) ($M^{\delta+}$–$H^{\delta-}$). The enhancement of mode (*a*) is found to be dependent on the concentration of quinoline (Table 1). No further enhancement of mode (*a*) occurs when the quinoline concentration is increased above 100 mM, suggesting saturation of the surface by quinoline at this concentration.

The same experiment has been carried out with triphenylphosphine, another electron-donating ligand, and this is found also to promote mode (*a*) ($M^{\delta+}$–$H^{\delta-}$) to a similar extent (Table 1). These results prompted us to propose an explanation for origin of the selectivity of these catalysts for triple bonds over

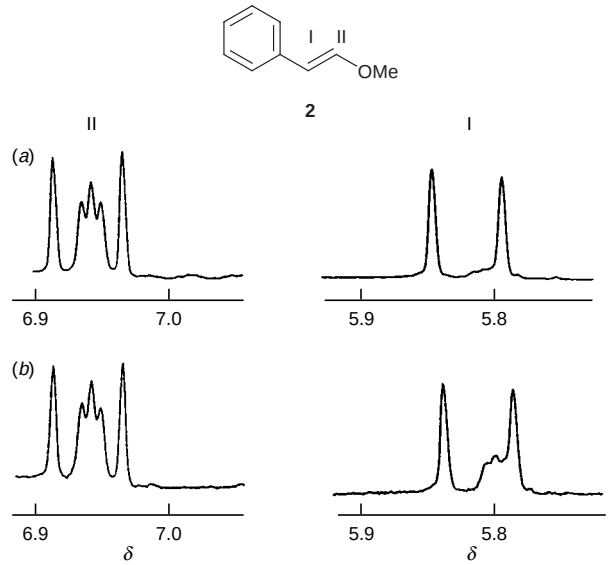


Fig. 1 Part of the ^{1}H NMR spectrum (250 MHz) (double bond region) for compound **2** (in $CDCl_3$) formed by the isomerization of the corresponding *cis*-isomer using D_2 and (*a*) Pd/C or (*b*) Pd/C with 50 mM quinoline. The triplets observed inside the doublets arise from deuterium hydrogen coupling in the labelled compound.

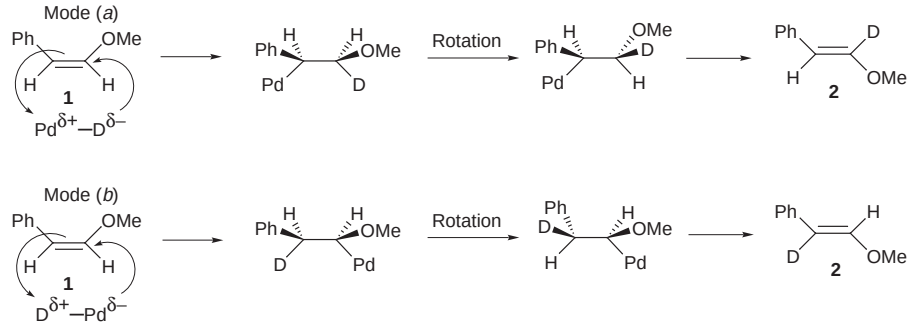

Scheme 2

Table 1 Dependance of reaction mode on ligand[a]

Ligand	Concentration (mM)	Deuterium distribution[b] (%)		Relative ratio of deuterium (%)	
		I	II	I	II
Quinoline	0	56	1	98	2
Quinoline	50	50	19	72	28
Quinoline	100	36	27	57	43
Quinoline	150	36	27	57	43
PPh_3	25	30	22	58	42

[a] A typical example of the procedure: to a solution of *cis*-β-methoxystyrene (134 mg, 1 mmol) in 3 ml of benzene was added 20 mg 10% Pd/C and 39 mg of quinoline (0.3 mmol). The mixture was degassed and refilled with D_2 through a balloon. The reaction mixture was stirred for 2 h at room temperature under 1 atm of D_2 followed by removal of the catalyst by filtration. The filtrate was evaporated to give a mixture of quinoline and the product (162 mg) which was determined by ^{1}H NMR spectroscopy to consist of 40% reduced product, 48% *cis*-isomer and 12% *trans*-isomer. The pure form of the *trans*-isomer was obtained by column chromatography eluting with hexane, and the incorporation of the deuterium at each position on the double bond was determined by integration of the respective ^{1}H NMR signals, using the methyl group as an internal standard. For the experiment performed using 100 mM quinoline samples were taken over the whole course of the reaction. The deuterium distribution across the double bond was found not to vary with reaction time. [b] Errors for the data are ±5%.

double bonds. The main side reactions in the reduction of alkynes to *cis*-alkenes are the further reduction and isomerisation of this product. It is well-documented that a triple bond is more vulnerable to nucleophillic attack than a double bond,[9] therefore, an increase in nucleophility of the metal hydrogen species should improve the selectivity for reduction of the triple bond. The shift from purely mode (*b*) ($M^{\delta-}$–$H^{\delta+}$) towards mode (*a*) ($M^{\delta+}$–$H^{\delta-}$), brought about by the modification of the catalyst with electron-rich ligands, clearly indicates that the metal hydrogen species is made more nucleophilic and hence provides a clue to the origin of the improved selectivity.

Interestingly, promotion of mode (*a*) ($M^{\delta+}$–$H^{\delta-}$) was previously found for the Lindlar catalyst (palladium modified with lead acetate) when it was compared to palladium on carbon.[8] The Lindlar catalyst also gives better selectivity for the reduction of alkynes to *cis*-alkenes, again suggesting that it is the change in the electronic properties of the palladium that is responsible for its improved reactivity.

This study establishes that quinoline and triphenylphosphine act as ligands for heterogeneous palladium and alter the electronic properties of the metal. This provides a new insight into how quinoline and triphenylphosphine may improve the selectivity of palladium catalysts for the semi-reduction of alkynes.

Halogen to metal π-donation in metalloporphyrins

Zeev Gross,* Atif Mahammed and Claudia M. Barzilay

Department of Chemistry, Technion-Israel Institute of Technology, Haifa 32000, Israel

The ^{1}H NMR analysis of the paramagnetic *trans*-dihalogeno-ruthenium(IV) and osmium(IV) porphyrins reveals that the halides have a pronounced effect on both the magnitude and the direction of charge transfer between the metal and the porphyrin, that the degree of covalency of metal–halide bonds increases in the order of Mn^{III} < Ru^{IV} < Os^{IV}, and that the relative strength of halogen-to-metal π-donation is Cl < Br < I.

The relative π-donation strength of halides has become a matter of dispute in recent years. While both early and recent *ab initio* calculations suggested that π-donation increases down the group, F < Cl < Br < I,[1] the conclusions from NMR chemical shift analysis of halomethyl cations (^{13}C) and boron halides (^{11}B) are opposite.[2] A similar conflict seems to exist for halogeno-coordinated metalloporphyrins. The ^{1}H NMR spectra of halogeno-coordinated manganese(III) porphyrins were originally analyzed in terms of competition for π-donation to the metal by the halide (X → M CT) and the porphyrin (P → M CT), and the π-donation ability was proposed to decrease in the order of I < Br < Cl < F.[3] But, much more recent investigations of Mn^{III} and Fe^{III} porphyrins have shown that their metal–ligand bonds are predominantly charge rather than orbital controlled.[4,5] For (*trans*-dihalogeno)ruthenium(IV) tetraphenylporphyrins, the monotonic trend of decreasing upfield isotropic shifts of pyrrole-H down the halide group,[6] opposite to that in (halogeno)manganese(III) porphyrins, led to the conclusion that the order of π-donation ability is Cl < Br < I.[7] But, while Ke *et al*. analyzed the isotropic shifts in terms of P → M CT, M → P CT was indicated by investigation of a (*trans*-dibromo)ruthenium(IV) porphyrin.[8] Obviously, without a definite conclusion about the direction of the CT process in these complexes, the relative π-donation ability of the halides cannot be determined.

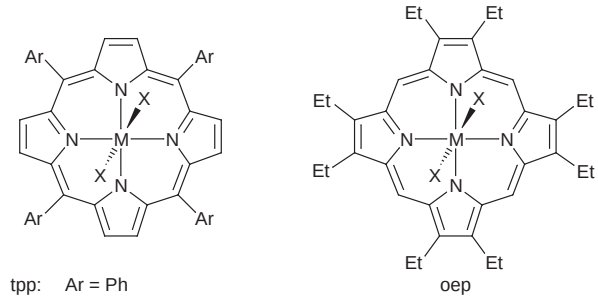
The contradictory NMR analyses of the *trans*-dihalogeno-ruthenium(IV) tetraphenylporphyrins calls for the examination of a larger range of porphyrin structures, as well as of the analogous osmium(IV) complexes.[9] These tetragonally distorted octahedral complexes are exceptionally well suited for the current investigation owing to their stability, high symmetry, well resolved NMR spectra, and because the metal ion is confined to the porphyrin's plane and only the d_π orbitals are singly occupied.[10] Accordingly, we have prepared a large series of dihalogeno-ruthenium(IV) and -osmium(IV) complexes with both pyrrole-unsubstituted and *meso*-unsubstituted porphyrins (Scheme 1),[11] taking advantage of our recently introduced synthetic method for their preparation.[12] The detailed ^{1}H NMR analysis leads to the conclusion that the relative π-donation ability of the halides is Cl < Br < I for all metalloporphyrins, and that the main difference between the metal complexes is an icnrease of σ-covalency of their bonds with axial ligands in the order of Mn^{III} < Ru^{IV} < Os^{IV}.

The first concern in the NMR analysis is the separation of the isotropic shifts into contributions from dipolar (pseudocontact, through field) and contact (through σ and/or π orbitals) shifts.[3b] Examination of Table 1 clearly shows that the *meso*-aryls of the (por)$Os^{IV}X_2$ complexes experience only dipolar shifts, as all isotropic shifts are shifted downfield and they decrease as a function of their distance from the metal exactly as predicted by eqn. (1), which is relevant for purely dipolar shifts.[3b]

$$(\Delta H/H)_i^{dip} : (\Delta H/H)_j^{dip} = [(3\cos^2\theta - 1)/r_i^3] : [3\cos^2\theta - 1)/r_j^3] \quad (1)$$

$$(\Delta H/H)_i^{iso} = (\Delta H/H)_i^{dip} + (\Delta H/H)_i^{con} \quad (2)$$

The results of eqn. (1) were also used in eqn. (2), which allows the calculation of the contact shifts at the pyrrole protons,



tpp: Ar = Ph
ttp: Ar = C_6H_4Me-4

X = I	−4.06	2.64	10.33	−1.96	1.53	−32.55	54.12	5.18	−28.61

[a] Referenced against the diamagnetic dioxoruthenium(VI) complexes. An isotropic shift of −0.95 ppm was reported for *meso*-H of (oep)RuF_2: C. Sishta, M. Ke, B. R. James and D. Dolphin, *J. Chem. Soc., Chem. Commun.*, 1986, 787.

and a fair estimate of its contribution to the *meso*-H and pyrrole-CH_2CH_3 isotropic shifts in the (oep)$Os^{IV}X_2$ complexes. Large and alternating contact shifts of protons (−16.18 ppm) and methylene groups (+12.38 ppm) attached to the β-pyrrole carbons together with the relatively small downfield shifts at *meso*-H (+4.19 ppm) are clearly evident from Table 1. This pattern is fully consistent with π-contact shifts due to P (3e, filled) → M (d_π, singly occupied) CT, but not with M → P (4e, LUMO) CT.[3b] We may safely conclude that the decrease of P → M CT in the order of I < Br < Cl, as reflected by the pyrrole-H contact shifts of δ −16.8, −18.6, and −19.4, respectively, is a result of an increase in X → M CT, *i.e.* the relative π-donation ability in the (por)$Os^{IV}X_2$ complexes is I > Br > Cl.

The spectral analysis of the ruthenium(IV) complexes is less straightforward, since large contact shifts mask any possible contribution by the dipolar shift, even at the aryl protons. This is evident from the alternation of the isotropic shifts for the *meso*-aryl substituents (*ortho- vs. meta- vs. para*-H, as well as *ortho*-H *vs. ortho*-Me, and *para*-H *vs. para*-Me) and the exceptionally large pyrrole-H and *meso*-H shifts (Table 2). The large upfield shifts of both pyrrole-H and *meso*-H are consistent only with a simultaneous action of P → M (upfield pyrrole-H) and M → P (upfield *meso*-H) π charge transfer mechanisms. This explains the earlier mentioned contradictory analyses about the direction of the CT process in the *meso*-substituted (tpp)$Ru^{IV}X_2$ complexes. The most illuminating observation is that the relative importance of M → P CT clearly changes from very low in the dichloro complexes (small shifts of the *meso*-H and *meso*-aryls) to highly significant in the diiodo complexes [$\Delta\delta$(*meso*-H) ≈ $\Delta\delta$(pyrrole-H)]. This phenomenon suggests a π-donation strength series in the order of I > Br > Cl, since as more electron density is transferred from the axial ligand to the metal, M → P CT should indeed increase at the expense of P → M CT.

Finally, we suggest that the relatively small isotropic shifts and the lack of M → P CT in the osmium(IV) porphyrins reflect the well known phenomenon of increased σ-covalency of metal–ligand bonds in post-lanthanide transition metals relative to their 4d analogs.[13] This proposal is supported by the exceptionally large substitution inertness of the (por)OsX_2 complexes.[14] An additional consequence is that halogeno–metal bonds in osmium(IV) porphyrins are not expected to be unusually short, in contrast to the analogous ruthenium complexes with their very strong π-bonding component.[7] Comparison of the bond lengths in (tmp)OsI_2 (Os–I 2.655 Å, this study)[11] and (ttp)Os(Cl_2 (Os–Cl 2.294 Å)[9c] with EXAFS data for *trans*-dihalogeno osmium(IV) complexes of a non-porphyrinic ligand (Os–I 2.627 Å, Os–Cl 2.227 Å),[15] clearly supports this prediction. We conclude that the binding of axial ligands to d^4-metalloporphyrins changes from predominantly covalent for Os^{IV} through intermediate in Ru^{IV} to predominantly ionic in Mn^{III}.[4] In all cases, the extent of P → M CT is a sensitive probe of the energy difference between the singly occupied d_π orbitals and the low-energy 3e orbitals of the porphyrin. In the ionic halogeno–Mn^{III} bonds, the energy of the d_π orbitals is reduced as the bond lengths increase (Mn–I > Mn–Br > Mn–Cl).[16,17] However, the decrease of P → M CT in the order of I < Br < Cl for the osmium(IV) and ruthenium(IV) porphyrin clearly reflects an increase in the energy of the d_π orbitals due to X → M CT, *i.e.* the relative π-donation ability is I > Br > Cl.

We thank Dr S. Cohen from the Hebrew University of Jerusalem for the determination of the X-ray crystal structure of (tmp)OsI_2. This research was supported by the United States–Israel Binational Science Foundation.

Formation and X-ray structure of a novel water-soluble tertiary–secondary phosphine complex of ruthenium(II): $[Ru\{P(CH_2OH)_3\}_2\{P(CH_2OH)_2H\}_2Cl_2]$

Lee Higham, Annie K. Powell, Michael K. Whittlesey,*† Sigrid Wocadlo and Paul T. Wood*

School of Chemical Sciences, University of East Anglia, Norwich, UK NR4 7TJ

The novel secondary–tertiary hydroxymethylphosphine complex, all-*trans* $[Ru\{P(CH_2OH)_3\}_2\{P(CH_2OH)_2H\}_2Cl_2]$, is formed by the room temperature reaction of excess tris(hydroxymethyl)phosphine, $P(CH_2OH)_3$, with either $RuCl_3\cdot H_2O$ or $[Ru(PPh_3)_3Cl_2]$; the X-ray crystal structure of the complex shows extensive intra- and inter-molecular hydrogen bonding consistent with the high water solubility of the complex.

The need for separation and recovery of expensive transition metal catalysts from organic products has led to the well known concept of aqueous/organic biphasic catalysis in which a catalyst that is selectively soluble in the aqueous phase is used to effect the transformation of reactants to products that are themselves selectively soluble in the organic phase.[1] Aqueous transition metal phosphine catalysts have largely been based on di or tri-sulfonated arylphosphines, such as $P(m\text{-}C_6H_4SO_3Na)_3$ (TPPTS). While highly active water-soluble analogues of triphenylphosphine complexes are known, many useful catalysts incorporate alkylphosphines and hydrophilic analogues of these are highly sought after. Tris(hydroxymethyl)phosphine (THMP), $P(CH_2OH)_3$, was initially studied by Chatt *et al.*, but after the disappointing results on the catalytic activity of rhodium complexes, this ligand was largely ignored.[2] There has recently been an upsurge of interest in THMP[3] (and related bi- and tri-dentate alkyl phosphines[4]) with the preparation of a range of complexes with applications in medicinal chemistry as well as catalysis.[5] The report that ruthenium complexes bearing the related water-soluble 1,3,5-triaza-7-phosphaadamantane (PTA) derivative[6] catalysed the reduction of aldehydes to alcohols in a biphasic organic/aqueous medium in the presence of sodium formate prompted us to synthesize tris(hydroxymethyl)phosphine complexes of ruthenium to look for similar properties. We report here that the reaction of $RuCl_3$ with excess THMP does not lead to straightforward coordination of the ligand, but rather results in the formation of a novel tertiary–secondary hydroxymethylphosphine metal complex resulting from the elimination of formaldehyde from THMP.

Addition of a fourfold excess of $P(CH_2OH)_3$ in ethanol to an ethanolic solution of $RuCl_3\cdot H_2O$ at room temperature results in the immediate formation of a green solution. The $^{31}P\{^1H\}$ NMR spectrum shows no remaining free phosphine (δ −24), but does show signals corresponding to THMP oxide (δ 45)[7] and the cation, $[P(CH_2OH)_4]^+$, at δ 24. There is a single ruthenium containing compound, **1**, which gives rise to two triplets in an A_2B_2 pattern at δ 13.5 and 9.7. The same products may be obtained upon stirring an aqueous solution of THMP with a dichloromethane solution of $[Ru(PPh_3)_3Cl_2]$ in a biphasic reaction. Removal of the solvent and recrystallisation of the resulting oil from methanol–hexane yielded yellow crystals of **1** suitable for X-ray crystallography.

The crystal structure shows that **1** is the octahedral ruthenium complex, $[Ru\{P(CH_2OH)_3\}_2\{P(CH_2OH)_2H\}_2Cl_2]$, (Fig. 1)‡ in which two of the tris(hydroxymethyl)phosphine groups have eliminated formaldehyde to give the secondary phosphine ligand $P(CH_2OH)_2H$. The asymmetric unit of the crystal structure corresponds to half a complex molecule with the ruthenium atom positioned on an inversion centre in space group $P2_1/c$. This gives rise to the all-*trans* stereochemistry for the three different ligand types. The phosphorus atom of the tertiary phosphine, P(2), is bonded to ruthenium and the carbon atoms of three hydroxymethyl groups with bond angles in the range 99.2(3)–119.2(2)°. The atom P(1) of the secondary phosphine is bonded to ruthenium, two hydroxymethyl groups and a hydrogen atom and shows a greater degree of distortion from tetrahedral geometry with bond angles in the range 105.7(3)–122.0(2)°. There is a significant difference between the two Ru–P lengths with the distance to the secondary phosphine being about 0.1 Å longer [2.414(2) *cf.* 2.318(2) Å]. The X-ray structure also shows the presence of extensive intra- and inter-molecular hydrogen bonding interactions with a total of 14 contacts per molecule in the range 2.75–3.25 Å (Fig. 2). This has also been observed for other crystallographically characterised complexes containing hydroxymethyl phosphine ligands, notably $[Pd(THMP)_4]\cdot MeOH$,[5a] which has a number of hydrogen bonds shorter than 2.8 Å.

The spectroscopic data for **1** in solution are consistent with the solid state structure.§ The higher field triplet resonance in the $^{31}P\{^1H\}$ NMR spectrum is assigned to the secondary phosphine ligand because of the large P–H coupling (J = 253 Hz) observed in the proton-coupled spectrum. The ^1H NMR spectrum shows two broad singlet resonances (δ 4.53 and 4.48) in a ratio of 1 : 0.6 due to the methylene groups in the tertiary and secondary phosphine ligands. The IR spectrum of **1**

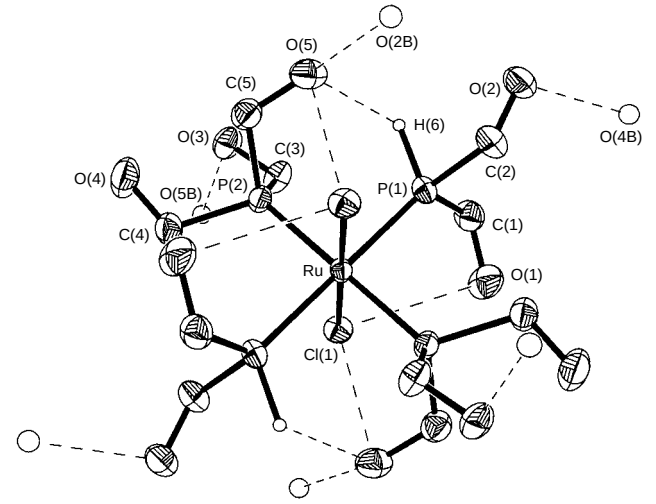

Fig. 1 View of **1** showing the atom numbering scheme and the intra- and inter-molecular hydrogen bonds (30% probability ellipsoids). Hydrogen atoms with the exception of H(6) have been omitted for clarity. Selected bond distances (Å) and angles (°): Ru–P(1) 2.414(2), Ru–P(2) 2.318(2), Ru–Cl(1) 2.450(1), P(1)–C(1) 1.813(6), P(1)–C(2) 1.898(7), P(2)–C(3) 1.856(6), P(2)–C(4) 1.890(6), P(2)–C(5) 1.832(6), C(1)–O(1) 1.407(7), C(2)–O(2) 1.427(7), C(3)–O(3) 1.387(6), C(4)–O(4) 1.389(7), C(5)–O(5) 1.443(8); P(1)–Ru–P(1A) = P(2)–Ru–P(2A) = Cl(1)–Ru–Cl(1A) 180.0, P(1)–Ru–P(2) 85.58(6), P(1)–Ru–Cl(1) 93.12(5), P(2)–Ru–Cl(1) 86.68(5)°. Selected hydrogen bonding distances (Å): O(1)···Cl(1) 3.142(8), O(2)···O(4B) 2.709(8), O(3)···O(5B) 2.777(8), O(5)···Cl(1A) 3.226(7), O(5)···O(2B) 3.067(8).

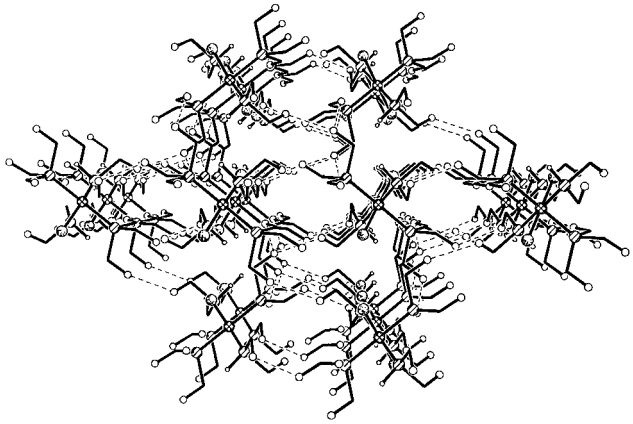

Fig. 2 View of the packing in **1** down the crystallographic *c* axis showing the hydrogen bonding

recorded in KBr shows a band at 2374 cm^{-1} which is assigned to ν(P–H).

The mechanism by which **1** is generated is not clear at present. There is no evidence for formation of the THMP complex $[Ru\{P(CH_2OH)_3\}_4Cl_2]$ nor for free secondary phosphine $P(CH_2OH)_2H$, although the elimination of formaldehyde accounts for the formation of the phosphonium cation observed by ^{31}P NMR.[8] There have been two reports of deprotonation of THMP to give metal alkoxide complexes,[9] but we can find no precedence for the formation of the secondary phosphine. This present facile route into water soluble metal complexes containing a reactive P–H bond offers great scope for further ligand functionalization.

We thank EPSRC for a studentship (L. H.), Johnson Matthey plc for the loan of ruthenium trichloride and Albright and Wilson Ltd. for a gift of $[P(CH_2OH)_4]Cl$. M. K. W. thanks UEA for financial support.

Diastereoselective asymmetric cyclopropanation of (*S*)-(+)-α-(diethoxyphosphoryl)vinyl *p*-tolyl sulfoxide

Wanda H. Midura,[a] Jerzy A. Krysiak,[a] Michał W. Wieczorek,[b] Wiesław R. Majzner[b] and Marian Mikołajczyk*[a]†

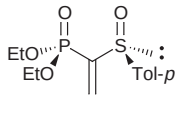
[a] *Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Department of Organic Sulfur Compounds, 90-363 Łódź, Sienkiewicza 112, Poland*

[b] *Institute of General Food Chemistry, Technical University of Łódź, 90-924 Łódź, Stefanowskiego 4/10, Poland*

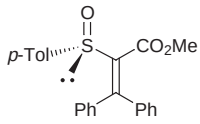
The title sulfoxide 1 reacts with fully deuterated dimethylsulfoxonium methylide, diphenylsulfonium isopropylide and diphenyldiazomethane to form the corresponding cyclopropanes 4 as single diastereoisomers; the chirality of the cyclopropane (+)-4c obtained from 1 and diphenyldiazomethane is (S_S,S_C) as determined by X-ray diffraction analysis; based on experimental data, the steric course of the asymmetric cyclopropanation is proposed.

α,β-Unsaturated sulfoxides have been widely used in asymmetric synthesis as versatile chiral reagents with the sulfinyl group playing the role of a chiral auxiliary.[1,2] Since α,β-unsaturated sulfoxides having no additional electron-withdrawing substituents on the double bond exhibit low reactivity, we recently designed a new type of activated chiral vinyl sulfoxides, namely α-phosphorylvinyl *p*-tolyl sulfoxide **1** and its β-substituted (Me, Ph, Bu^n) analogues.[3,4] The phosphoryl group in **1** activates not only the C=C bond but also makes possible further reactions such as, for instance, the Horner–Wittig reaction. The chiral sulfoxides **1** were found to be good Michael acceptors as well as Diels–Alder dienophiles. They were also used as key reagents for the construction of monocyclic- and condensed carbo- and hetero-cycles *via* tandem Michael addition/intramolecular Horner–Wittig reaction. However, the asymmetric induction in these reactions was not very high.

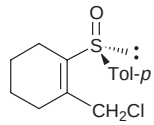
Now we extend our work in this area by reporting a fully diastereoselective, asymmetric cyclopropanation of the sulfoxide (*S*)-(+)-**1**. The present study on asymmetric cyclopropanation was stimulated by the fact that a wide variety of natural products and currently-used insecticides contain the cyclopropane ring in a chiral environment.[5] Moreover, to the best of our knowledge, there are only two reports describing asymmetric cyclopropanation using enantiopure vinylic sulfoxides as chiral reagents.[6,7] Thus, Hamdouchi[6] reacted the sulfoxide (*S*)-(+)-**2** with dimethyl(oxo)sulfonium methylide and obtained a mixture of two diastereoisomeric cyclopropanation products in a 5.9 : 1 ratio. On the other hand, the reaction of the cyclic vinylic sulfoxide **3** with allylmagnesium bromide was found by Iwata[7] to give the corresponding cyclopropane as a single diastereoisomer, however, accompanied by the side coupling product.



1

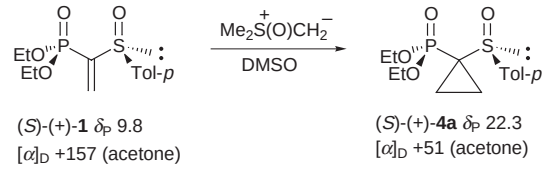


2



3

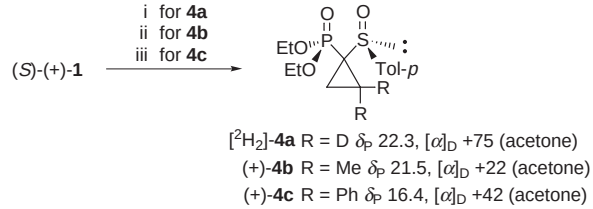
In our preliminary experiment (*S*)-(+)-α-(diethoxyphosphoryl)vinyl *p*-tolyl sulfoxide **1** was treated with an excess of dimethyl(oxo)sulfonium methylide in DMSO at room temperature and gave the expected cyclopropane (*S*)-(+)-**4a** as the only product [eqn. (1)], isolated by flash chromatography on silica gel in 90% yield. The asymmetric version of the reaction was realized by using fully deuterated dimethyl(oxo)sulfonium methylide as the CD_2 transfer agent (Scheme 1). Although the chirality at the newly formed quaternary α-carbon atom is due to isotopic substitution (CH_2 *vs.* CD_2), the ^{31}P NMR spectrum of the crude cyclopropane [$^2H_2$]-**4a** formed revealed only one sharp signal at δ_P 22.3, strongly suggesting that only one diastereoisomer was formed. The deuterium decoupled ^{1}H NMR spectra (500 MHz) of the pure product isolated in 92% yield confirmed its full diastereoisomeric purity (the cyclopropane methylene protons appeared in the spectrum as doublets of doublets at δ 1.26 and 1.38 with $^2J_{H–H}$ = 4.8 and $^3J_{H–H}$ = 9.8 and 14.0 Hz).



(1)

Similarly, treatment of (*S*)-(+)-**1** with diphenylsulfonium isopropylide (prepared according to the procedure described by Corey[8]) in THF at room temperature yielded the corresponding cyclopropane (+)-**4b** which was isolated in a pure state by flash chromatography in 65% yield. To our delight, also in this case the cyclopropanation reaction resulted in the formation of a single diastereoisomer, as evidenced by the ^{1}H and ^{31}P NMR spectra of the product.

In addition to sulfur ylides, in the course of these studies the behaviour of the vinylic sulfoxide (*S*)-(+)-**1** towards diazomethane and diphenyldiazomethane was investigated. Whereas the reaction of the former dipole was found to give rise to 3-diethoxyphosphorylpyrazole *via* transient formation of the corresponding 1,3-cycloadduct, elimination of toluene-*p*-sulfenic acid and tautomerization,‡ the latter reacted with (*S*)-(+)-**1** affording a single diastereoisomeric cyclopropane (+)-**4c** as indicated by the ^{1}H and ^{31}P NMR spectral analysis of the crude product.§ After flash chromatography, pure (+)-**4c** (mp 89–91 °C) was obtained in 86% yield. To provide an unequivocal proof of the full asymmetric induction occuring in this reaction, the cyclopropane (+)-**4c** was oxidized by MCPBA to the



Scheme 1 *Reagents and conditions*: i, $(CD_3)_2S(O)CD_2$, [$^2H_6$]DMSO; ii, Ph_2SCMe_2, THF; iii, Ph_2CN_2, Et_2O

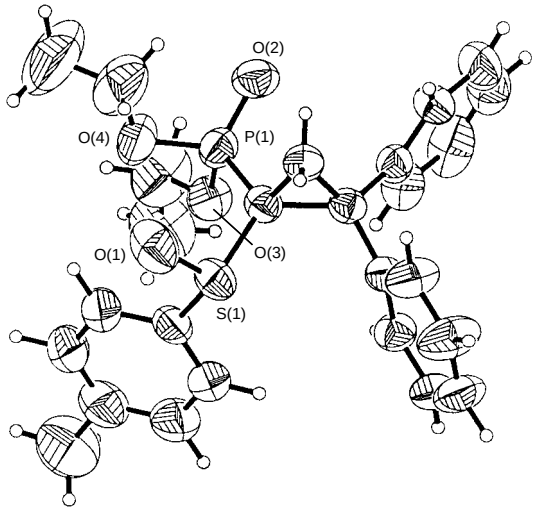


Fig. 1 X-Ray structure of (+)-**4c**. Ellipsoids are shown at the 50% probability level

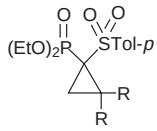
optically active sulfone (+)-**5c**. Its ^{1}H NMR spectrum recorded in the absence and in the presence of (*R*)-(+)-*tert*-butylphenylphosphinothioic acid as a chiral solvating agent[9] showed only two doublets of doublets for the cyclopropyl methylene protons (δ 2.67 and 2.83; $^2J_{H–H}$ = 6 and $^3J_{P–H}$ = 7.1 and 8.4 Hz, respectively), while in the spectrum of the racemic sulfone (±)-**5c** prepared in an independent way in the presence of a



(+)-**5b** R = Me δ_P 21.7, $[\alpha]_D$ 8.5 (acetone)
(+)-**5c** R = Ph δ_P 15.1, $[\alpha]_D$ 25.0 (acetone)

chiral phosphinothioic acid, all the signals of the appropriate protons were doubled. In a similar way, the full enantiomeric purity of the sulfone (+)-**5b** obtained from (+)-**4b** was also confirmed.

In order to rationalize the steric course of the above described fully diastereoselective cyclopropanations of the sulfoxide (*S*)-(+)-**1**, we determined the crystal and molecular structure of the cyclopropane (+)-**4c** by X-ray diffraction (Fig. 1).¶ It turned out that the absolute configuration of the newly formed chiral centre at the α-carbon atom is *S*. Moreover, both polar sulfinyl

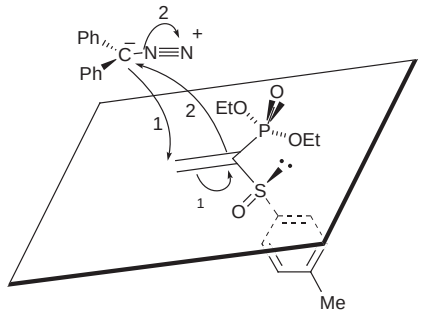


Fig. 2 The proposed steric course of the reaction of Ph_2CN_2 with the sulfoxide (*S*)-(+)-**1**

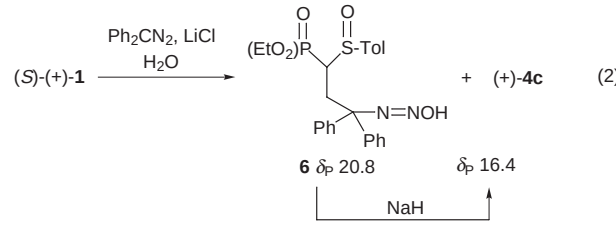
and phosphoryl groups in **4c** are in *anti*-like orientation [the torsional angle S(1)–O(1)···P(1)–O(2) is equal to 93.3 (±0.1)°]. Therefore, it is reasonable to assume that (*S*)-(+)-**1** adopts a similar conformation, and nucleophilic addition of diphenyldiazomethane to the vinylic β-carbon atom of **1** (step 1) and subsequent ring closure (step 2) occur exclusively from the less-hindered diastereotopic face occupied by the electron lone pair at sulfur, as schematically depicted in Fig. 2.

A two-step mechanism for cyclopropanation was supported by isolation of the intermediate adduct **6** which was formed together with the cyclopropane (+)-**4c** when the reaction was carried out in the presence of LiCl [eqn. (2)]. Its subsequent



cyclization to (+)-**4c** was found to occur in the presence of NaH.

In summary, we have described the fully diastereoselective asymmetric synthesis of a new type of optically active cyclopropane **4** which is geminally substituted with two different heteroatoms. The specific reactivity of each heteroatomic centre provides interesting possibilities for further transformations of the cyclopropane **4** into optically active cyclic and acyclic derivatives.

Electrochemically active threading intercalator with high double stranded DNA selectivity

Shigeori Takenaka,*[a]† Yoshihiro Uto,[b]‡ Hideki Saita,[b] Makoto Yokoyama,[b] Hiroki Kondo[b] and W. David Wilson[c]

[a] *Department of Chemical Systems and Engineering, Kyushu University, Fukuoka, 812-8581, Japan*

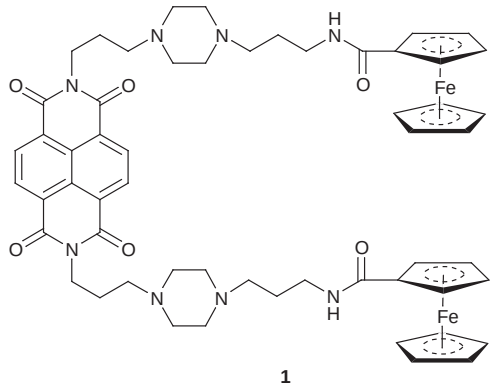
A naphthalene diimide threading intercalator carrying ferrocenyl moieties as its termini can discriminate double stranded DNA from single stranded counterparts owing to a difference in their dissociation rates.

Discrimination of double stranded nucleic acids from single stranded ones is of utmost importance in basic and applied molecular biology. Hybridization of DNA with its complementary DNA or RNA is based on this discrimination and one has to discriminate single stranded RNA of such viruses as HIV from double stranded human chromosomal DNA when targeting the former. Single and double stranded nucleic acids may be discriminated by intercalators but none is known to achieve this feat with a high margin. Recently, threading intercalators were developed in which their substituents can penetrate between the base pairs of double stranded DNA when bound to it.[1,2] This type of intercalator, *e.g.* naphthalene diimides, forms a very stable complex with double stranded DNA, and they dissociate much more slowly from double stranded DNA than do classical intercalators.[1–3] When electrochemically active groups are attached to a threading intercalator, the resulting molecule will serve as a double stranded DNA selective electrochemical probe.[4,5] This idea was substantiated with a naphthalene diimide **1** carrying two ferrocenyl moieties at its ends.



1

Naphthalene diimide **1** was prepared by a reaction of the corresponding amino derivative with *N*-hydroxysuccinimide ester of ferrocenecarboxylic acid and purified by silica gel chromatography (MeOH) followed by recrystallization from water (yield, 25%).

Compound **1** undergoes hypochromic and bathochromic shifts of the absorption band of the naphthalene diimide chromophore upon binding to sonicated calf thymus DNA, which is indicative of DNA intercalation. Sodium dodecyl sulfate-driven dissociation experiments[3] carried out with the complex of **1** and intact or denatured calf thymus DNA§ showed that the dissociation rate constant (k_d) of **1** from the intact DNA was 0.06 s^{-1} at 20 °C, whereas that of **1** from the denatured DNA was 4.2 s^{-1}. These magnitudes of dissociation rate constant are one of the smallest for synthetic intercalators. The ratio of 70 in k_d suggests that single and double stranded DNA can be discriminated kinetically by **1**. Note that these magnitudes are minimal estimates, since 'the denatured' DNA is not necessarily composed of single stranded DNA alone. To test whether compound **1** can discriminate single and double stranded DNA on the electrode surface, the following experiments were carried out.

A DNA-immobilized electrode was prepared by a reaction of mercaptohexyl dT_{20} oligonucleotide on a gold electrode with an area of 2.0 mm^2.[7] HPLC experiments revealed that 64 pmol of mercaptohexyl oligonucleotide was immobilized on this electrode. Then 2 μl of a solution containing appropriate amounts (0–70 pmol) of target dA_{20} oligonucleotide were placed on this modified electrode and kept at 25 °C for 20 min to allow hybridization with the immobilized probe dT_{20}. After this reaction, 2 μl of a 1 mM solution of **1** were placed on the

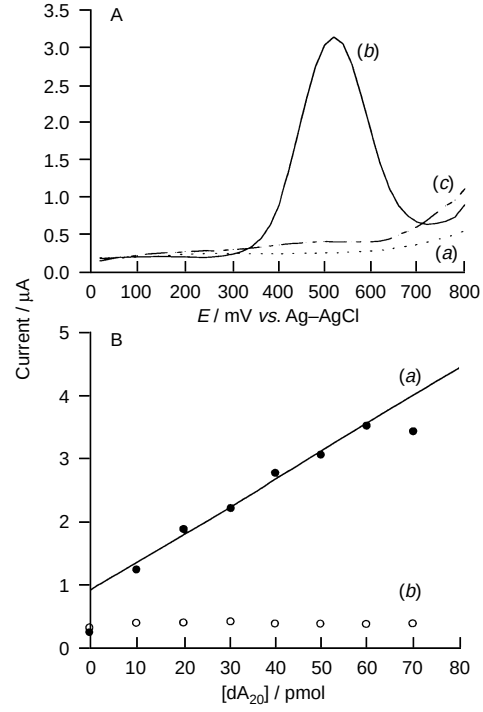


Fig 1 (A) Differential pulse voltammograms (DPVs) of **1** bound to the dT_{20}-immobilized electrode before (*a*) and after hybridization with 60 pmol of dA_{20} (*b*) or dT_{20} (*c*). Differential pulse voltammograms were measured in 50 mM AcOK–AcOH buffer (pH 5.2) with Ag–AgCl and Pt wire as reference and counter electrodes, respectively. Pulse period 200 ms; scan rate 100 mV s^{-1}; pulse amplitude 50 mV; pulse width 50 ms. (B) Correlation of the current response at 521 mV for **1** with the amount of dA_{20} (*a*) and dT_{20} (*b*).

electrode for 5 min. Following washing with 50 mM AcOK–AcOH buffer (pH 5.2) by vortexing for 5 s at 20 °C, cyclic voltammograms (CVs) and differential pulse voltammograms (DPVs) of the complex were measured in the same buffer. Fig. 1(A) shows examples of DPVs for this electrode treated with dA_{20} (target DNA) or dT_{20} (non-target DNA). It is clear that the electrochemical signal is generated only in the presence of complementary oligonucleotide dA_{20} [trace (*b*)] and the current response obtained for dT_{20}, non-complementary to the sequence of dT_{20}, was barely above background [trace (*c*)]. A current response due to the ferrocenyl moieties of **1** increased linearly up to 60 pmol with an increase in the amount of dA_{20} (correlation coefficient 0.990) and then levelled off as shown in Fig. 1(B) [trace (*a*)]. The amount of dA_{20} at the break point (60 pmol) was in agreement with the amount of the probe dT_{20} immobilized on the electrode (64 pmol). The estimated detection limit was 1.0 fmol of target oligonucleotide. This procedure could be repeated several times and the current response per immobilized oligonucleotide was reproducible even with electrodes of different lot samples.

We estimated the amount of the ligand **1** bound on this electrode to be 13 pmol from the area under the CV peak after hybridizing with 60 pmol of dA_{20}. This value is about 30 times smaller than that expected from Scatchard analysis, which revealed that three base pairs of double stranded DNA are required to accommodate a single molecule of **1**. Therefore, *ca*. 400 pmol of **1** ought to be bound to 60 pmol of $dA_{20}dT_{20}$. This discrepancy can arise from several reasons. First, intercalation and redox reaction of **1** on the electrode surface could be less efficient than those in solution. Alternatively, part of **1** could undergo dissociation from DNA during washing of the complexed and intercalated electrode. Despite this low efficiency, the electrochemical responses of the active electrode were stable during the experiment (*ca*. 2 min).

In conclusion, the electrochemically active threading intercalator **1**, coupled with a DNA-carrying electrode, enabled the sensitive detection of target DNA fragments. The whole manipulation was carried out over a short period of time as long as the sensor is prepared and yet the sensitivity of detection is ultra-high, making this sensing system most feasible for practical use in DNA analysis and gene diagnosis.

Quantitative formation of the intermediate of alkene insertion in the copolymerization of *p*-methylstyrene and carbon monoxide catalyzed by [(Pr^{i}DAB)Pd(Me)(NCMe)]$^+$BAr$_4^-$

Carla Carfagna,*† Mauro Formica, Giuseppe Gatti, Alfredo Musco and Annarita Pierleoni

Università degli Studi di Urbino, Istituto di Scienze Chimiche, Piazza Rinascimento, 6-61029 Urbino (PS), Italy

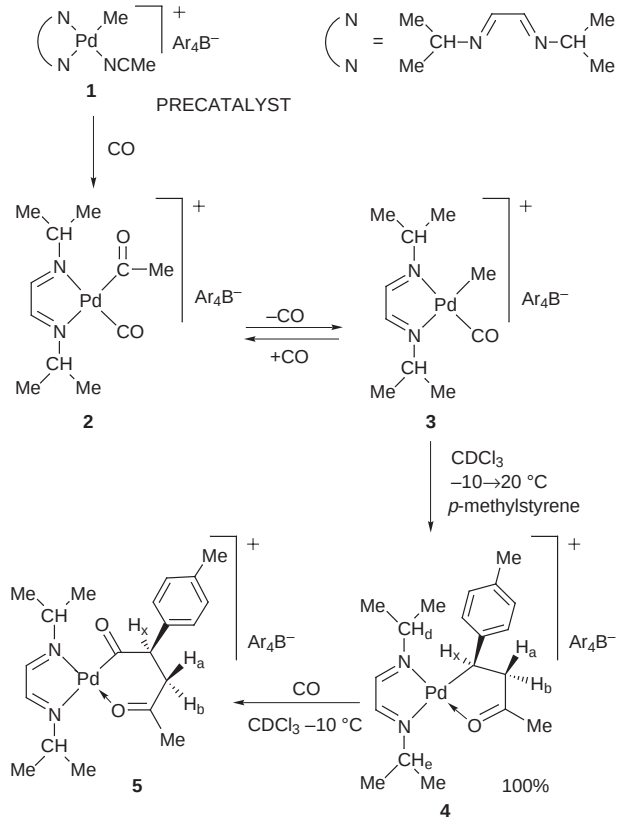
The intermediate after the first CO and *p*-methylstyrene insertion in the chain growth process of the copolymerization of these monomers has been quantitatively obtained from [(Pr^{i}DAB)Pd(Me)(NCMe)]$^+$[{3,5-(CF$_3$)$_2$C$_6$H$_3$}$_4$B]$^-$ in CHCl$_3$ at 20 °C.

In recent years there has been increasing interest in carbon monoxide olefin copolymerization.[1] We and others have found that ionic Pd complexes with non-coordinating anions and chiral nitrogen ligands, such as bioxazolines, are active precatalysts for the copolymerization of styrene and carbon monoxide, to yield isotactic optically active polymers.[2,3] The use of achiral nitrogen ligands, however, leads to syndiotactic copolymers.[4]

From our recent study, the objective of which was to test the catalytic properties of various nitrogen ligands with different π-acceptor capacity,[5] the complex [Pr^{i}DABPd(Me)(NCMe)]$^+$[{3,5-(CF$_3$)$_2$C$_6$H$_3$}$_4$B]$^-$ **1** (Pr^{i}DAB = 1,4-di-isopropyl-1,4-diaza-buta-1,3-diene) proved to be a very active precatalyst in the copolymerization of styrene and 4-methylstyrene with carbon monoxide, giving alternating syndiotactic polyketones under very mild conditions (1 bar CO and 0 °C). In addition, the complex **1** is a convenient starting point for modelling the first steps of the polymer chain growth, as described here.

By exposure of the precatalyst solution **1** to a CO atmosphere, under conditions used for the copolymerization reaction, the corresponding acetyl carbonyl complex **2**‡ was obtained, which reversibly releases one CO group; bubbling nitrogen through a CH_2Cl_2 solution at −15 °C resulted in the formation of **3**, and exposure of the solution of **3** to CO atmosphere led to the regeneration of **2**[1j] (Scheme 1). The structure of **3**§ was confirmed by the presence, in the ^{13}C NMR spectrum, of the Pd–CO resonance at δ 174.8 and by the absence of the acetyl signals.

We then focused our attention on the next step, the olefin insertion, to see whether our catalytic system would allow quantitative insertion and isolation of the reaction product. We performed the reaction using directly the more reactive compound **3** which was isolated as a white powder from **2**. By adding an equimolecular amount of *p*-methylstyrene at −10 °C to a slightly yellow $CHCl_3$ solution of **3** and heating gently to 20 °C, a colour change to dark orange occurred. The new compound formed in 100% yield corresponds to the 5-membered palladacycle **4**, in agreement with the NMR evidence.¶ In particular, in the carbonyl region of the ^{13}C NMR spectrum, the resonance of a typical acetyl group at δ 224.9 is present, while the Pd–CO signal has disappeared. This result is confirmed by the IR spectrum, which shows an absorption at 1721 cm^{-1} for the acetyl CO coordinated to Pd.[1j,6f] Moreover, the CH_2 and CH signals are detected in the DEPT ^{13}C NMR spectrum. The CH–CH_2 fragment is confirmed by the corresponding three-spin pattern observed in the ^{1}H NMR spectrum, where the relatively high value of the geminal coupling J_{ab} = −19.7 Hz is typical of a CH_2 linked to a CO group, while the values of the two vicinal couplings, J = 8.3 and 3.5 Hz, are representative of two



Scheme 1

substantially different dihedral angles. Evidence for two non-equivalent isopropyl groups is given by the two different CH chemical shifts observed in both the ^{1}H and ^{13}C NMR spectra. Moreover, the two methyl groups, within each isopropyl group, are non-equivalent due to the dissymmetry introduced by the styrene monomeric unity. The signals of the two *meta* aromatic hydrogens are assigned on the basis of NOEs with the adjacent methyl, while the remaining *ortho* aromatic hydrogens show NOEs with CH_x. The *ortho* hydrogens also show NOEs with CH_d, thus allowing the assignment of the latter. Moreover the NOE observed between the *ortho* hydrogens and CH_a but not CH_b is in agreement with an orientation of the phenyl group closer to CH_a. Therefore the conformation across the CH–CH_2 bond is as depicted in the Newmann projection in Fig. 1, in agreement also with the values of J_{ax} = 8.3 and J_{bx} = 3.5 Hz,

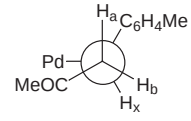


Fig. 1

due to nearly *anti* and *gauche* relationships, respectively. This suggests that the conformation of the pentatomic ring is slightly folded.

Insertions of different alkenes into metal–acyl bonds have already been reported[6,1*j*] but to the best of our knowledge there are in the literature only two examples of reaction of styrene with a palladium–acyl complex. After insertion, the reaction products have been described either as a mixture of allylic and chelate structures in very rapid equilibrium[1*c*] or as an allylic intermediate.[7] Therefore it appears that the quantitative formation of 5-membered palladacyle **4** as the only observable species is unprecedented. Compound **4** can be isolated as a relatively stable dark red oil by removing the solvent under reduced pressure; in $CHCl_3$ solution it proved to be stable up to 50 °C.

In the next step, CO was bubbled through a solution of **4** in $CHCl_3$ at −10 °C for 15 min, yielding the six-membered chelate complex **5** in solution.‖ Evidence for the insertion of CO comes from the doubling of the CO signals in the ^{13}C NMR spectrum and in the IR spectrum. The deshielding observed for both the proton and carbon resonances of the CH group of the CH–CH_2 fragment shows that the CO has inserted into the Pd–CH bond, as expected.[1*j*]

In conclusion, the results of this work show that by using the proper ligand it has been possible for the first time to quantitatively obtain and determine the conformation of the first intermediate in the syndiotactic copolymerization of CO and styrene derivatives, *i.e.* the 5-membered palladacyle **4**; it results from the insertion of *p*-methylstyrene into the Pd–acyl bond formed in **3** as a result of α-methyl migration. Furthermore, it has been possible to obtain the new complex **5** which represents the second step of the copolymerization reaction.

We are currently exploring the use of the isolable complex **4**, as a preformed catalyst, for the synthesis of syndiotactic copolymers.

Triplet state photophysics in an aryleneethynylene π-conjugated polymer

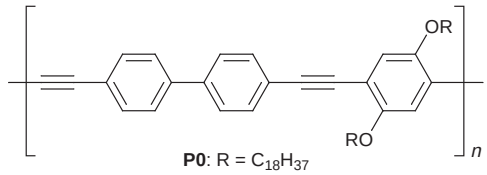
Keith A. Walters, Kevin D. Ley and Kirk S. Schanze*†

Department of Chemistry, University of Florida, Gainesville, FL 32611-7200, USA

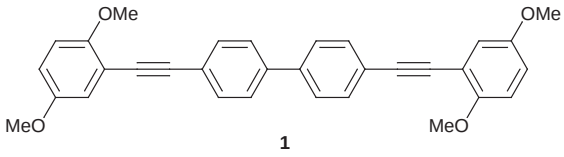
The triplet state photophysics of a polyaryleneethynylene π-conjugated polymer and a related model compound are investigated with various techniques, including laser flash photolysis and time-resolved thermal lensing (TRTL).

The photophysical and photochemical properties of π-conjugated polymers have been of significant recent interest.[1] Although most work on the photophysics of π-conjugated polymers has focused on the $^1\pi,\pi^*$ manifold, considerable evidence suggests that $^3\pi,\pi^*$ excitons are also involved in their rich photochemistry.[2–5] Unfortunately, owing to the absence of phosphorescence in most π-conjugated polymers[2] little is known about the absolute energies and yields of the triplets produced by direct excitation.

We recently initiated a photophysical study of aryleneethynylene-based π-conjugated polymers that contain a photoactive transition metal chromophore in the π-conjugated backbone.[6,7] A primary objective of this work is to understand the interaction between backbone-based $^1\pi,\pi^*$ and $^3\pi,\pi^*$ excited states and metal complex-based $d \rightarrow \pi^*$ charge transfer excitations. However, in order to pursue this line of investigation in the metal–organic polymers, it is necessary to have a firm understanding of the properties of the $^1\pi,\pi^*$ and $^3\pi,\pi^*$ excited states of the all-organic polymers. Here, we report the results of a detailed photophysical study which compares the photophysical properties of the singlet and triplet manifolds of aryleneethynylene polymer **P0** and model compound **1** in dilute THF solution (Scheme 1).‡



P0: R = $C_{18}H_{37}$



1

Scheme 1

Pulsed laser excitation (355 nm, 10 ns FWHM, 4 mJ pulse^{-1}) of **1** and **P0** affords a long lived transient [τ(**1**) = 142 μs, τ(**P0**) = 169 μs§], which is assigned to a $^3\pi,\pi^*$ state. The triplet state difference absorption spectra of **1** and **P0** (Fig. 1) are characterized by bleaching of the ground state π,π^* absorption band [λ_{max}(**1**) = 360 nm, λ_{max}(**P0**) = 410 nm] and a broad (triplet–triplet) absorption band that extends to longer wavelengths. Interestingly, the difference spectra of **1** and **P0** are remarkably similar, except that the bleach and absorption bands are red-shifted in the polymer. The qualitative similarity in the triplet–triplet absorption spectra implies that the electronic structure of the triplet state is similar in the model and polymer.

In order to determine the triplet energies of **1** and **P0** (E_T), Stern–Volmer quenching studies were carried out with a series

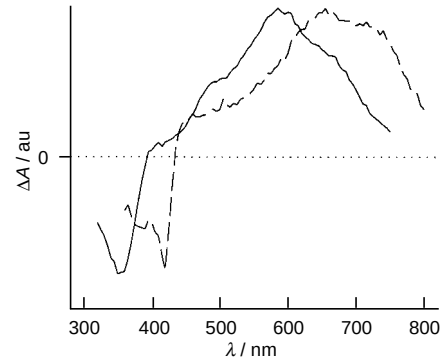


Fig. 1 Triplet state difference absorption spectra of (solid line) **1** and (dashed line) **P0** in degassed THF solution

of triplet acceptors of varying energy.[8,9]¶ Triplet quenching rate constants (k_q) were obtained from Stern–Volmer analysis of the observed triplet decay lifetimes in vacuum degassed THF solutions as a function of quencher concentration. The triplet energies were then estimated by fitting the experimental Sandros plots (Fig. 2)[10] with a Marcus equation that is appropriate for bimolecular reactions which occur at or near diffusion control,[11,12]

$$k_q = \frac{k_d}{1 + \exp(\Delta G/RT) + (k_{-d}/k_{en}^0)\exp(\Delta G^{\ddagger})} \quad (1a)$$

$$\Delta G^{\ddagger} = \Delta G + \frac{\lambda}{\ln 2}\ln\left\{1 + \exp[-(\Delta G \ln 2)/\lambda]\right\} \quad (1b)$$

where k_d and k_{-d} are the rate constants for forward and reverse diffusion in solution, k_{en}^0 is a pre-exponential factor, λ is the reorganizational energy and $\Delta G = (E^{00}_{Acceptor} - E_T)$. By using parameters derived from a previous study[13] ($k_d = 1.0 \times 10^{10}$

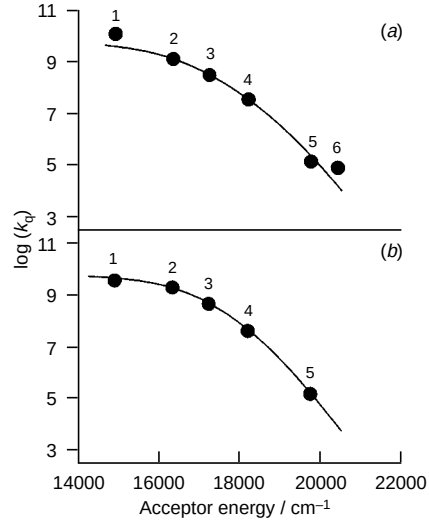

Fig. 2 Sandros plots for (*a*) **P0** and (*b*) **1**. Points are experimentally determined rate constants with various triplet energy acceptors,¶ and fitted lines are calculated as explained in the text.

Table 1 Photophysical properties of model compound **1** and polymer **P0**[a]

[a] THF solutions at 298 K. [b] Fluorescence quantum yields determined using 9,10-dicyanoanthracene (DCA) and perylene as actinometers (Φ_{DCA}^{EtOH} = 0.89, $\Phi_{Perylene}^{EtOH}$ = 0.89). [c] Values based on a Marcus fit to quenching data as described in text. [d] Upper limit. [e] See footnote §. [f] See foonote **.

M^{-1} s^{-1}, k'_{-d} = 2.0 × 10^{10} M^{-1} s^{-1}, k_{en}^0 = 5 × 10^{10} s^{-1}), best fits of the Sandros plots for **1** and **P0** were attained by varying λ and E_T in eqn. (1). These values are listed in Table 1, and plots of the fitted quenching data are shown in Fig. 2. Surprisingly, E_T for the model compound and the polymer is the same within experimental error (±5%).

A second objective of the present study was to determine the triplet yields (Φ_T) for **1** and **P0**. However, in order to determine this parameter it is necessary to know the fluorescence quantum yields (Φ_{fl}). Therefore, fluorescence spectra of **1** and **P0** were obtained [λ_{max}(**1**) = 413 nm, λ_{max}(**P0**) = 433 nm], and Φ_{fl} values were determined from the integrated fluorescence spectra (Table 1).[14]‖ Fluorescence lifetimes (τ_{fl}) for **1** and **P0** are also listed in Table 1. Next, the triplet yield (Φ_T) for **P0** was determined by time-resolved thermal lensing (TRTL).[15,16] In this method, Φ_T is derived from the ratio of the 'slow' and 'total' heat deposition signals (U_{slow} and U_{total}, respectively) after correcting for the energy of the pump laser ($E_{h\nu}$) and the fluorescence quantum yield,

$$U_{slow}/U_{total} = E_T\Phi_T/(E_{h\nu} - E_S\Phi_{fl}) \quad (2)$$

where E_S is the energy of the singlet state (Table 1). The U_{slow}/U_{total} ratio of a vacuum degassed THF solution of **P0** was determined to be 0.15, and the triplet yield calculated with eqn. (2) is listed in Table 1.** Unfortunately, Φ_T for **1** could not be measured with TRTL owing to strong triplet–triplet absorption at the thermal lensing probe wavelength (633 nm). However, the experimentally derived Φ_{fl} for **1** (0.90) provides an upper limit for Φ_T ($\leqslant$0.1).**

The photophysical characterization of the singlet and triplet states of **1** and **P0** allows us to assess the effect that the extended π-conjugation in the polymer has on its triplet state properties. It is surprising that E_T is the same for the polymer and model compound. However, the more important parameter is the singlet–triplet splitting energy (E_{ST}), which is defined as $E_S - E_T$. Interestingly, E_{ST} is lower by almost 1000 cm^{-1} in **P0** compared to **1** (5600 *vs.* 6500 cm^{-1}). The lower E_{ST} indicates that the electron exchange energy is smaller in the polymer,[17] which presumably is due to the fact that the delocalization of the LUMO (and/or the HOMO) for the $\pi \rightarrow \pi^*$ transition is greater in **P0** than in **1**. Moreover, it is of interest that the experimentally determined E_{ST} for **P0** is comparable to values calculated using semi-empirical MO theory.[18,19]

The rates of radiative decay, non-radiative decay and intersystem crossing (k_r, k_{nr} and k_{isc}, respectively) for the $^1\pi,\pi^*$ state of **1** and **P0** have been determined by using the experimental Φ_{fl}, τ_{fl} and Φ_T values (Table 1). First, note that k_r is comparable in **1** and **P0**. This is not surprising given that the orbital basis and transition dipole for radiative transitions are similar in the model and the polymer. By contrast, k_{nr} and k_{isc} are significantly larger in **P0** than in **1**. The larger non-radiative decay rate in the polymer may arise from 'defect sites' (*e.g.* unreacted end groups and/or defects in the polymer backbone) that quench the $^1\pi,\pi^*$ exciton. The larger (effective) intersystem crossing rate in **P0** may arise from the smaller E_{ST} value.

We gratefully acknowledge the National Science Foundation (Grant No. CHE-9401620) for support of this work.

† E-mail: kschanze@chem.ufl.edu

‡ **P0** was synthesized *via* a Pd-mediated cross-coupling reaction of the polymer subunits (see ref. 7 for complete synthetic details). *Selected characterization*: **P0**: GPC ($CHCl_3$, polystyrene standards) M_n = 65.2 kD, M_w = 209.2 kD (PDI = 3.2). ^{1}H NMR ($CDCl_3$) δ 0.87 (bt, t), 1.24 (br, s), 1.56 (br, m), 1.84 (br, m), 4.04 (br, t), 6.92 (br, s), 7.0 (br, s), 7.62 (br, s). ^{13}C NMR ($CDCl_3$) δ 14.1, 22.7, 26.1, 29.4, 29.7, 32.0, 69.7, 87.0, 94.8, 114.0, 116.9, 122.8, 126.8, 132.1, 140.0, 153.7. **1**: ^{1}H NMR ($CDCl_3$) δ 3.79 (s, 6 H, OCH_3), 3.89 (s, 6 H, OCH_3), 6.86 (m, 4 H, phenyl), 7.08 (d, 2 H, phenyl), 7.63 (d, 8 H, biphenyl). ^{13}C NMR ($CDCl_3$) δ 55.8, 56.5, 86.7, 93.2, 112.2, 112.9, 115.8, 118.0, 122.7, 126.7, 132.1, 139.9, 153.2, 154.5.

§ In ref. 6 we reported the triplet lifetime for a sample of **P0** in Ar-purged THF (τ_T = 4 μs). In that study the lifetime was suppressed due to quenching by residual oxygen. The triplet lifetimes reported herein are for samples that were freeze–pump–thaw degassed five times and sealed at 10^{-5} Torr. It is conceivable that even under these conditions the triplet lifetime is suppressed by oxygen quenching.

¶ Triplet acceptors (see Fig. 2): 1, anthracene; 2, [4,4′-bis(carboethoxy)-2,2′-bipyridyl]Re(CO)$_3$Cl; 3, *trans*-stilbene: 4, (2,2′-bipyridyl)Re(CO)$_3$Cl; 5, biacetyl; 6, *p*-terphenyl.

‖ In ref. 6 we reported the fluorescence quantum yield for **P0** in Ar-purged THF (Φ_{fl} = 0.28). The sample of **P0** used in that study was structurally equivalent to that used in the present study, but it had a substantially lower molecular weight (M_n = 13.5 kD, M_w = 37.4 kD). The higher molecular weight of the sample of **P0** used in the present study accounts for the larger fluorescence yield reported herein.

** The Φ_T values for **P0** and **1** were confirmed using photoacoustic calorimetry [Φ_T (**P0**) = 0.12, Φ_T (**1**) = 0.05].

Stereoselective conversion of 2′,3′-dideoxydidehydro carbocyclic nucleosides into 2′-deoxy carbocyclic nucleosides

James V. Barkley,[a] Anupma Dhanda,[a] Lars J. S. Knutsen,[b]†‡ May-Britt Nielsen,[a] Stanley M. Roberts*[a]§ and David R. Varley[c]

[a] *Department of Chemistry, Liverpool University, Liverpool, UK L69 7ZD*
[b] *Novo-Nordisk A/S, Novo Nordisk Park, DK-2760, Malov, Denmark*
[c] *Department of Chemistry, Exeter University, Exeter, Devon, UK EX4 4QD*

Treatment of 2′,3′-dideoxydidehydro carbocyclic nucleosides 5–9 with *N*-bromoacetamide in AcOH gives bromoesters 10–14 with good stereocontrol: debromination and hydrolysis furnishes 2′-deoxy carbocyclic nucleosides, *e.g.* 22.

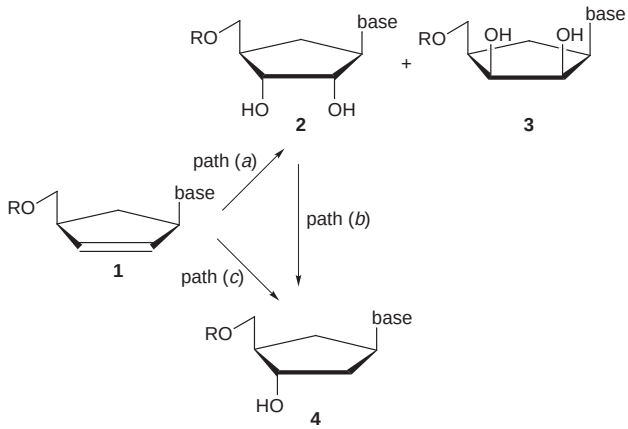
The preparation of 2′,3′-dideoxydidehydro carbocyclic nucleosides **1** (Scheme 1) has been the subject of a great deal of attention, owing to the biological activity of carbovir and related compounds.[1] The conversion of the readily-available alkenes of general stucture **1** into structurally more complex carbocyclic nucleosides **2** and 2′-deoxy carbocyclic nucleosides **4** has been fraught with difficulty. For example, bis-hydroxylation of compounds **1** tends to give an equimolar mixture of isomers corresponding to *ribo*- and *lyxo*-sugars **2** and **3**.[2] The preference for the formation of the carbocyclic *ribo*nucleoside on steric grounds is countered by a stabilizing Cieplak effect which favours formation of the *lyxo* analogues.[3]

Conversion of *ribo*-carbocyclic nucleosides **2** into 2′-deoxy *ribo*-carbocyclic nucleosides **4** [path (*b*)] through reaction of the diol with AcBr in MeCN and subsequent hydrodehalogenation is marred by the formation of the desired bromohyrins corresponding to the *ara*- and isomeric *xylo*-bromohydrins in an unfavourable 1 : 5 ratio.[4]

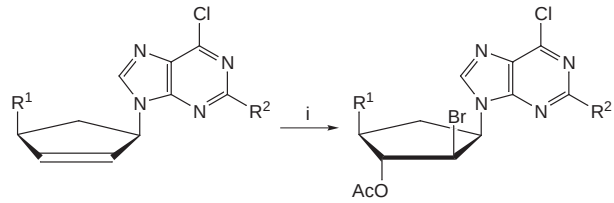
Direct conversion of carbocyclic nucleosides of type **1** into deoxy *ribo* systems of type **4** [path (*c*)] by hydroboration was investigated by Deardorff *et al.*;[5] unfortunately the 3′-hydroxy and the 2′-hydroxy compounds were both obtained, in a 2 : 1 ratio.

Herein we report a novel stereoselective method for the transformation of alkenes **1** into the corresponding alcohols **4**.

Most of the starting materials for this study (**5**, **6**, **8** and **9**) were prepared from (±)-*cis*-1-acetoxy-2-(acetoxymethyl)-cyclopent-4-ene; a typical procedure is described below. Compound **7** was prepared from compound **5**.¶



Scheme 1



5	$R^1 = CH_2OAc$, $R^2 = NH_2$	**10**
6	$R^1 = CH_2OAc$, $R^2 = H$	**11**
7	$R^1 = CH_2OAc$, $R^2 = Cl$	**12**
8	$R^1 = CH_2OCPh_3$, $R^2 = NH_2$	**13**
9	$R^1 = CH(OAc)CH_2OAc$, $R^2 = NH_2$	**14**

Scheme 2 *Reagents and conditions*: i, NBS or *N*-bromoacetamide, AgOAc, AcOH, 18 h, room temp.

Treatment of the cyclopentene derivative **5** with NBS or *N*-bromoacetamide and AgOAc in AcOH afforded bromoacetate **10** as the sole product in 68% yield (Scheme 2). This bromoester was recrystallized and the stereochemistry confirmed by X-ray crystallography (Fig. 1).‖

Similarly, compounds **6**–**8** produced the corresponding haloesters **11**–**13** in 47–69% yield.** In the latter case the NMR spectrum of the crude product, besides the major product **13**, gave evidence of a few percent of an isomeric product, in too small an amount to isolate. Treatment of the diester **9** under the standard reaction conditions afforded the expected product **14** (49%) [with spectroscopic properties in accord with the assignments for compounds **10**–**13** and an isomeric substance (13%)]. We tentatively assign a 2′-acetoxy-3′-bromo structure to the minor product on the basis of NMR spectroscopy.

The conversion of the alkenes **5**–**9** into the bromoesters **10**–**14** is reminiscent of the conversion of the cyclopentene

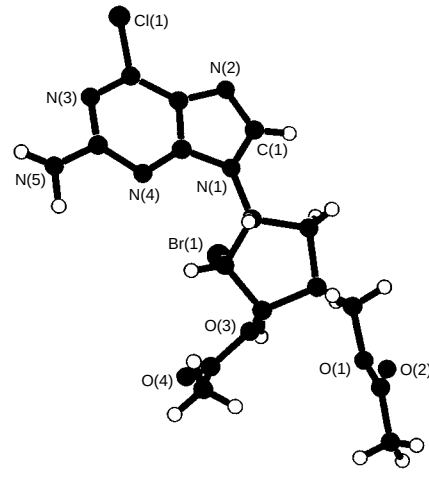


Fig. 1 X-Ray structure of compound **10**

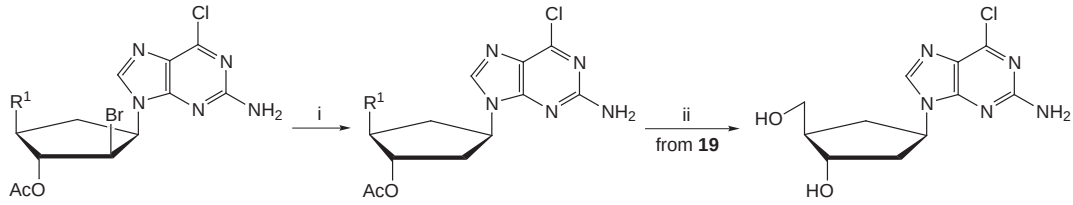
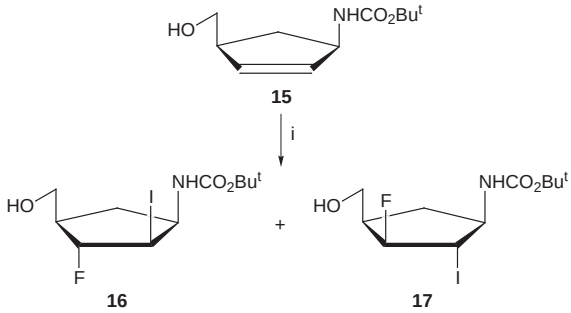


10 $R^1 = CH_2OAc$ **19**
14 $R^1 = CH(OAc)CH_2OAc$ **20**
18 $R^1 = CH_2OH$ **21**

22

Scheme 4 *Reagents and conditions*: i, Bu^n_3SnH, AIBN, THF, heat, 3–7 h (68–92%); ii, K_2CO_3, MeOH, 2 h (96%)

derivative **15** into the dihalides **16** and **17** (ratio 8 : 1) (Scheme 3), in that in both cases the major product is formed *via* the intermediacy of a *syn*-halonium ion.[6] However, the preferential formation of compound **16** was explained by a proposed stabilisation of the *syn*-iodonium ion by the adjacent hydroxy group, a phenomenon which is clearly impossible in our cases. Instead we believe that the formation of the *syn*- and *anti*-bromonium ions are reversible processes and only on formation of the *syn*-bromonium ion is attack by the nucleophile possible, from the more exposed face and distant from the heteroatom bonded to C-1′.



Scheme 3 *Reagents and conditions*: i, *N*-iodosuccinimide, tetrabutylammonium dihydrogen trifluoride, CH_2Cl_2

Detritylation of bromoester **13** was accomplished using aq. AcOH to furnish the alcohol **18** in 66% yield. Treatment of compounds **10**, **14** and **18** with tri-*n*-butyltin hydride in hot THF furnished the nucleoside analogues **19**–**21** (Scheme 4).‡‡ Methanolysis of the diester **19** provided the 2′-deoxycarbocyclic nucleoside in almost quantitative yield.

In summary, the stereocontrolled addition of Br/OAc to dideoxydidehydro carbocyclic nucleosides give facile access to 2′-bromo-2′-deoxyribo carbocyclic nucleosides.[7]

Novo-Nordisk A/S provided studentships for A. D., M.-B. N. and D. V. R. and this financial support is gratefully acknowledged.

¶ *Synthesis* of **5**. 2-Amino-6-chloro-9*H*-purine (264 mg, 1.56 mmol) and NaH (60% dispersed in mineral oil, 68 mg, 1.71 mmol) were dissolved in anhydrous DMF (7.0 ml) and stirred for 10 min at room temperature and at 50 °C for 10 min. The reaction mixture was added to a suspension of (±)-(1*R*,2*R*)-1-acetoxy-2-(acetoxymethyl)cyclopent-4-ene (339 mg, 1.71 mmol) and tetrakis(triphenylphosphine)palladium (180 mg, 0.156 mmol) in DMF (7.0 ml) using a cannula, rinsing with anhydrous THF (3 × 2.0 ml). The reaction was excluded from light and stirred for 3 h at 50 °C. The reaction mixture was then cooled to room temperature. Water (25 ml) was added and the mixture was extracted wtih CH_2Cl_2 (4 × 50 ml). The combined organic layers were dried with $MgSO_4$ and the solvent was evaporated *in vacuo* to give a crude yellow oil. The oil was purified by column chromatography on silica gel eluting with CH_2Cl_2–EtOH (19 : 1) giving **5** (50% yield) as a clear oil.

Synthesis of **7**. Compound **5** (224 mg, 0.728 mmol) was dissolved in CH_2Cl_2 (8 ml) and the solution was cooled to 0 °C. Me_3SiCl (276 μl, 2.184 mmol) was added followed by isopentyl nitrite (292 μl, 2.184 mmol) which was added slowly to maintain the temperature at 0 °C. The reaction mixture was stirred for 2 h at 0 °C and for 5 h at room temperature. Water (5 ml) was added and the mixture was extracted with CH_2Cl_2 (3 × 10 ml). The combined organic layers were concentrated *in vacuo* to give a crude yellow oil. The oil was purified by column chromatography on silica gel eluting with EtOAc–light petroleum (2 : 1) giving **7** (60% yield) as a clear oil.

‖ *Crystal data* for **10**: $C_{15}H_{17}BrClN_5O_4$, M = 446.69, colourless prism, monoclinic, $P2_1/n$, 0.15 × 0.20 × 0.25 mm, a = 15.597(5), b = 7.077(2), c = 17.178(2) Å, β = 96.13(2)°, V = 1885.4 Å^3, T = −120 °C, Z = 4, μ(Mo-Kα) = 23.29 cm^{-1}; 3769 reflections measured, 3630 unique, R = 0.055, R_w = 0.080. CCDC 182/834.

Phosphorus complex of corrole

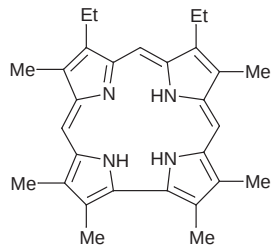
Roberto Paolesse,*[a] Tristano Boschi,[a] Silvia Licoccia,[a] Richard G. Khoury[b] and Kevin M. Smith[b]†

[a] *Dipartimento di Scienze e Tecnologie Chimiche, Università di Roma Tor Vergata, Roma, 00133, Italy*
[b] *Department of Chemistry, University of California, Davis, CA 95616, USA*

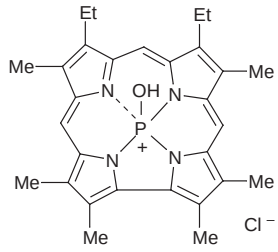
Reaction of 8,12-diethyl-2,3,7,13,17,18-hexamethylcorrole (1) with $POCl_3$ in pyridine affords the first non-metal derivative of corrole; in this compound, 2, the phosphorus is in a pentavalent state and is different from analogous complexes of porphyrins.

Non-porphyrin polypyrrolic macrocycles represent a novel field of research which has experienced impressive expansion in the last few years.[1] These compounds are particularly intriguing for both theoretical and experimental reasons. For example, they can enable studies of the way in which skeletal variations influence the aromaticity and the chemical properties of the macrocycles, thereby opening potential applications of these molecules in different fields, ranging from catalysis to biomedical sciences.

Among porphyrin analogues, corrole (*e.g.* **1**) was one of the first examples to be reported in the literature; it was synthesized



1



2

more than 30 years ago by Johnson and Kay during their attempts to approach the corrin nucleus of vitamin B_{12}.[2] But recent investigations using the corrole macrocycle have revealed interesting differences in its coordination behavior compared with the analogous porphyrin complexes. Corrole, for example, is able to stabilize high oxidation states for coordinated metals, and to retain a planar conformation even when the peripheral positions are fully substituted.[1a,b] Despite these interesting properties, the coordination chemistry of corrole is substantially limited to the first row transition metals; expansion of the so-called 'periodic table' of metallocorrolates should allow researchers to study, in more detail, the coordination behavior of this macrocycle. In particular, coordination of phosphorus can be intriguing due to the non-metal character of this element and because it is, in its pentavalent state, the smallest ion so far coordinated to a porphyrin.[3] Herein we report the synthesis and characterization of the first example of a phosphorus corrole derivative.

Reaction of 8,12-diethyl-2,3,7,13,17,18-hexamethylcorrole (**1**; H_3EMC)[2] with $POCl_3$ in pyridine at room temperature showed an immediate spectrophotometric change, with the formation of the spectrum of the characteristic corrole monocation.[4] When the mixture was heated at reflux the optical spectrum quickly changed (indicating the formation of a complex), with the complete disappearance of the absorbance characteristic of the corrole; Fig. 1 shows the optical spectra of the corrole monocation and the phosphorus complex. Evaporation of the solvent and recrystallization from CH_2Cl_2–hexane afforded a purple powder. In complexes with porphyrins, phosphorus has been reported to be hexacoordinated in a +V oxidation state;[3] in the case of octaethylporphyrin a transient +III state has been reported to be an intermediate during the metallation reaction.[3] In the present case of corrole, the electronic absorption spectrum is similar to those of other main group metallocorrolates.[5] By analogy with porphyrins it can be classified as 'normal',[6] thereby indicating the presence of the +V oxidation state for the coordinated phosphorus.

The ^1H NMR spectrum of the phosphorus corrole was also typical of a metallocorrolate, with the absence of internal NH resonances and the expected pattern for peripheral substituents. ^{31}P NMR spectroscopy showed a resonance for coordinated phosphorus at −102.5 ppm (relative to external H_3PO_4), which is significantly different from phosphorus complexes of porphyrins in which the phosphorus signal is at *ca.* −200 ppm.[7] This feature indicated that the diamagnetic ring current effect is less influential in determining the phosphorus resonance in the corrole derivative compared with porphyrin complexes. This difference can be attributed to two major factors: (i) the diminished aromatic character of corrole relative to porphyrin, and/or (ii) a different coordination geometry of phosphorus in the corrole complex. Both ^1H and ^{13}C NMR spectra ruled out the first hypothesis because resonances of the corrole derivative have almost the same chemical shifts as do the analogous porphyrinates.[8] A different coordination geometry seems more likely because the EI mass spectrum of the corrole complex showed a molecular peak at *m/z* 483, indicating the presence of only one ligand at an axial position. Analogous phosphorus porphyrinates are hexacoordinated.[3]

X-Ray characterization‡ performed on a single crystal of the phosphorus corrolate **2** allowed its unambiguous structural identification. The molecular structure is shown in Fig. 2. The phosphorus atom exhibits pentacoordinated geometry, lying more than 0.4 Å out of the mean corrole plane toward the oxygen atom of the axial hydroxy group. The P–O bond distance of 1.531 Å can be attributed to a single bond and is similar to the observed P–O distance in an analogous porphyrin complex.[3] The P–N bond lengths average 1.80 Å. These lengths

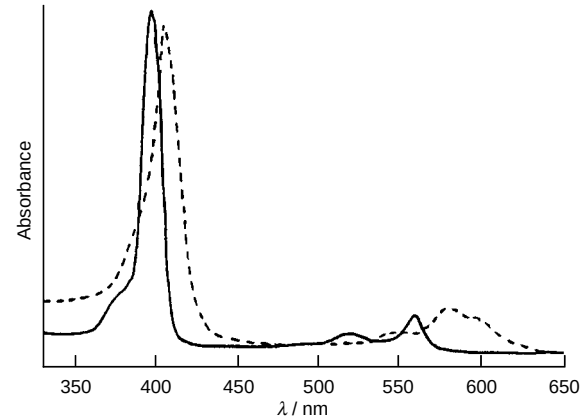


Fig. 1 Optical spectra, in CH_2Cl_2, of $[H_4EMC]^+$ (– – –), and [(EMC)-P(OH)]Cl (**2**), (——)

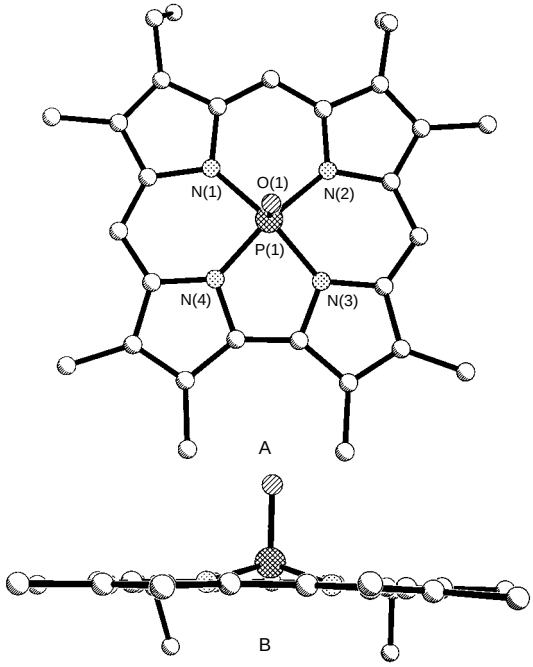

Fig. 2 Molecular structure‡ of [(EMC)P(OH)]Cl (**2**). A, top view; B, edge on view. The chloride counterion is omitted.

are shorter than those measured in any other metal complexes of this macrocycle[1a,b] and are not equivalent, as usual for metallocorrolates. Contrary to the situation in porphyrin derivatives the phosphorus corrolate macrocycle is almost planar, the mean plane deviation of the 23 core atoms being 0.0245 Å. The cationic nature of the macrocycle is confirmed by the presence of a chloride counterion.

The phosphorus complex reported herein is the first non-metal derivative of corrole; moreover, it represents a further example of different coordinative behavior of this macrocycle compared with the analogous and more ubiquitous porphyrin macrocycle. We are presently investigating the axial chemistry of this complex, and these studies will be the subject of a full paper.

Rotational oscillation of two interlocked porphyrins in cerium bis(5,15-diarylporphyrinate) double-deckers

Kentaro Tashiro, Takashi Fujiwara, Katsuaki Konishi and Takuzo Aida*†

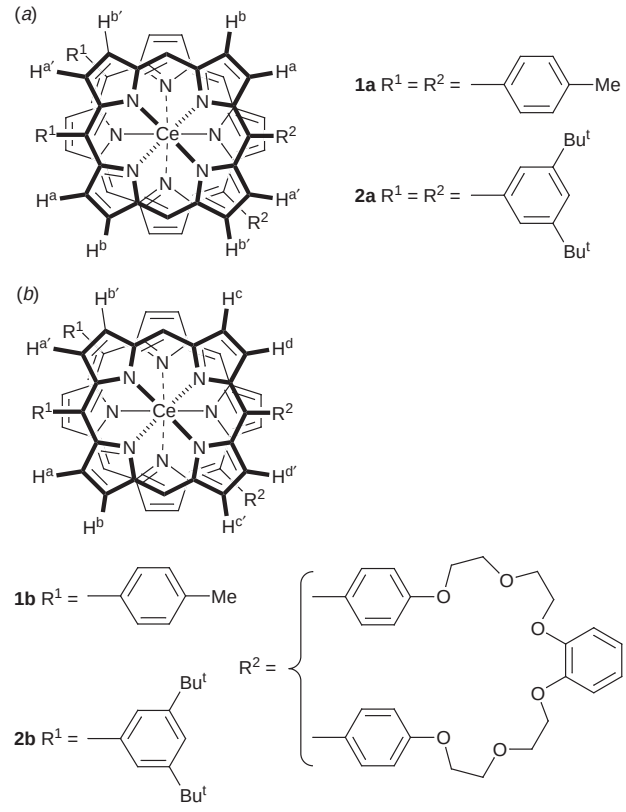
Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan

Dynamic NMR coupled with racemization studies on chiral cerium bis(5,15-diarylporphyrinate) double-deckers demonstrate that the two interlocked porphyrin ligands oscillate rotationally around the metal center.

Oscillating molecules are interesting in their potential utilities for sensors, information transfer/storage devices and molecular machines, and several examples of molecular and supramolecular oscillating systems have been reported to date.[1,2] Particularly interesting are oscillators consisting of chromophoric units because of a possible switching of their oscillation characteristics by light and/or redox. Metal bis(porphyrinate)s are double-decker complexes, in which a metal atom is sandwiched by two chromophoric porphyrin ligands.[3] Recently, we have found that the porphyrin ligands in cerium bis(porphyrinate)s rotate thermally around the metal center, through studies on optical resolution and racemization behavior of a chiral cerium bis(tetraarylporphyrinate) with a symmetry group D_2.[4] The chirality of the complex originates from the staggered geometry of the two facing porphyrin ligands, where the relative rotation of the ligands leads to racemization. Herein we report that cerium bis(5,15-diarylporphyrinate)s are potential molecular oscillators, in which the two interlocked porphyrin ligands rotationally oscillate back and forth around the metal center.

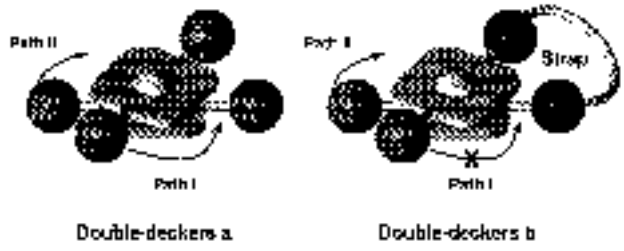
We have already reported that the D_2-symmetric, chiral cerium complex **1a**, in contrast to a zirconium analogue of the same porphyrin ligands, shows no sign of optical resolution in chiral HPLC, as a result of racemization *via* a fast rotation of the porphyrin ligands.[4] Our motivation to the present study arose from a preliminary observation that enantiomeric separation of **2a**‡ by chiral HPLC was also unsuccessful in spite of the presence of interferant bulky *meta*-substituents (Bu^t) on the *meso*-phenyl groups perpendicular to the porphyrin plane. In order to compare the rotatability of the porphyrin ligands in **2a** with that of **1a**, temperature-dependent NMR signal coalescence profile was investigated for exchangeable proton signals *via* ligand rotation. At a low temperature such as −20 °C in $CDCl_3$, **2a** showed four doublet signals at δ 8.48 (*a*), 8.58 (*a*′), 8.76 (*b*) and 8.84 (*b*′) [Scheme 1(*a*)] owing to nonequivalent pyrrole-β protons,§ where the exchangeable pairs are signals *a*/*a*′ and *b*/*b*′. Upon elevating the temperature, the paired signals *a* and *a*′, for example, coalesced completely at 0 °C. From this coalescence profile, the rate constant for the rotation of the porphyrin ligands in **2a** was evaluated at 0 °C to be 0.52×10^2 s^{-1},¶ which is almost comparable to that of **1a** (0.63×10^2 s^{-1}) at 1 °C.[4]

Here one should note two possible rotating paths, I and II, for the complex to racemize (Scheme 2), where path II is sterically more demanding than path I, since the former path must transiently involve an energetically disfavored 'eclipsed conformation' with respect to the two facing porphyrin ligands. In order to evaluate the rotating rate *via* path II, we synthesized two new chiral double-decker complexes **1b** and **2b**, which bear a flexible oligoether strap between the two porphyrin ligands.‡ Their CPK models suggested that path I is unlikely to occur even when the oligoether strap adopts the most extended



Scheme 1

conformation, thereby allowing selective evaluation of the rotating rate *via* path II. Prior to dynamic NMR studies, we investigated the possibility of optical resolution of these two strapped complexes by chiral HPLC,‖ where **2b** was successfully separated into enantiomers. The enantiomers exhibited clear mirror-image circular dichroism (CD) spectra to each other (Fig. 1), but the spectral intensity at 10 °C gradually decreased with time, where the rotating rate constant *via* path II was evaluated to be 0.39×10^{-3} s^{-1}.¶ In sharp contrast,



Scheme 2

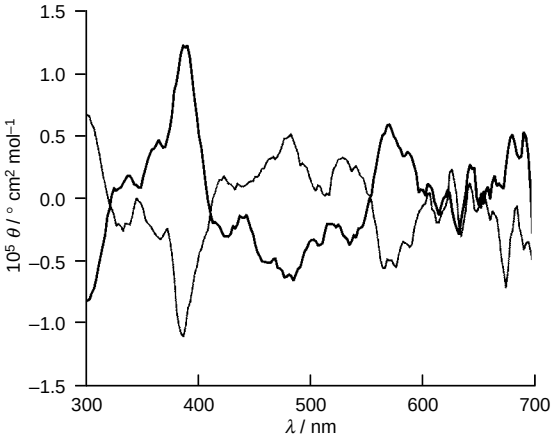


Fig. 1 Circular dichroism (CD) spectra of the enantiomers of **2b** in hexane–EtOH (1/1) at 10 °C

complex **1b** showed no sign of optical resolution, indicating that **1b** is more subject than **2b** to the ligand rotation *via* path II.

In order to evaluate the rotation rate of **1b**, we conducted ^{1}H NMR spectroscopy in $CDCl_3$ at varying temperatures. If the relative rotation of the porphyrin ligands is slower than the NMR chemical shift timescale, **1b** should display eight non-equivalent pyrrole-β signals because of the low symmetry of the molecular structure. In fact, we observed at 0 °C eight doublets at δ 8.30 (*a*), 8.38 (*d*), 8.54 (*d*′), 8.60 (*a*′), 8.68 (*b*), 8.72 (*c*), 8.81 (*b*′) and 8.82 (*c*′) [Scheme 1(*b*)]§, where exchangeable pairs *via* ligand rotation are *a*/*a*′, *b*/*b*′, *c*/*c*′ and *d*/*d*′, as determined from the cross-peaks in the EXSY spectra. However, even upon elevating the temperature to 55 °C, none of the paired signals coalesced, indicating that the site exchange in **1b** is much slower than that in the non-strapped analogue **1a**. Thus, the saturation transfer method[5,6] was applied, which is informative of exchange phenomena much slower than the NMR chemical shift timescale: When the pyrrole-β signal *d*′ was irradiated at, *e.g.*, 25 °C (δ 8.50), the paired signal *d* (δ 8.35) decreased to one-third in intensity. As the temperature was lowered, the saturation transfer was less pronounced, and virtually disappeared at 0 °C. From the degree of saturation transfer from the signals *d*′ to *d* at 10 °C, the rate constant for the rotation of the porphyrin ligands (path II) in **1b** was evaluated to be 0.37 s^{-1},** which is almost three orders of magnitude larger than that of **2b**.

The observed rotation rates for the strapped complexes (**1b** and **2b**), compared with those for non-strapped **1a** and **2a**, allow us to estimate that the rotation *via* sterically more demanding path II takes place much less frequently at every 10^2 to 10^5 times the rotation *via* path I occurs. Therefore, cerium bis(5,15-diarylporphyrinate) double-deckers may be regarded as molecular oscillators, where the two facing porphyrin ligands rotationally oscillate around the metal center, because of the interlocking by the *meso*-aryl groups. Studies on stimuli-responsive oscillations of metal bis(porphyrinate) double-deckers are the subject worthy of further investigation.

Metal silicates by a molecular route as catalysts for epoxidation of alkenes with *tert*-butyl hydroperoxide

David Juwiler,[a] Jochanan Blum[b] and Ronny Neumann*[a]†

[a] *Casali Institute of Applied Chemistry, Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem, Israel 91904*

[b] *Department of Organic Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel 91904*

Macroporous, site isolated metal silicates are synthesized by a molecular route; the molybdenum silicate is especially active for the selective epoxidation of alkenes with *tert*-butyl hydroperoxide.

The epoxidation of alkenes with 'redox molecular sieves' has been studied intensively during the last decade.[1] The titanium-substituted silicalite of the MFI structure, TS-1, has been the flagship of this effort. The small pored TS-1 is remarkably effective for epoxidation of small linear olefins due to the isomorphous distribution of titanium in the silicalite framework leading to isolated Ti–$(OSi)_4$ active centers held responsible for its unique activity. In the quest to develop similar catalysts viable for larger substrates, most attention has been directed towards mesoporous catalysts such as Ti–MCM-41.[2] A much less studied approach has been to use amorphous metallosilicate aerogels[3] and xerogels[4] prepared by sol–gel synthesis. The use of the sol–gel technique has limited the possibility of obtaining only M–O–Si connectivities (M = Ti, V, Mo and W) because the rate of reaction of the metal alkoxides in the sol–gel method is much faster than that of the silicon alkoxide.[5] Reduced metal site isolation considerably reduces the catalytic effectiveness of amorphous metallosilicates. Recently, a non-aqueous molecular route has been described for the preparation of metal silicates[6] [eqn. (1)] (M = Ti, Zr, Hf, Cu) which by design leads to metal site isolation within the silicate.

$$MCl_4 + HOSi(OBu^t)_3 \longrightarrow M[OSi(OBu^t)_3]_4 \xrightarrow{\Delta} M[O(SiO)_3]_4 + CH_2CMe_2 + H_2O \quad (1)$$

The molecular route procedure is based on the synthesis of an alkoxy intermediate which forms a metal silicate polymer by thermal elimination of isobutene and water rather than by hydrolysis and condensation as in the sol–gel technique. We have now utilized this technique to prepare macroporous titanium, vanadium, molybdenum and tungsten silicate. The molybdenum analog was especially active towards the selective epoxidation of bulky alkenes with *tert*-butyl hydroperoxide (TBHP).

The metal silicates described in this paper were prepared by adapting the method reported for the titanium silicate.[7] Thus, 40 mmol tri-*tert*-butoxysilanol[7,8] in 100 ml toluene was reacted with 10 mmol of metal chloride, $TiCl_4$, $V(O)Cl_3$, $Mo(O)Cl_4$ and $W(O)Cl_4$, respectively, in the presence of 40 mmol Et_3N at room temperature for 2 h. The precipitates were filtered and then calcinated for 12 h at ~250 °C to yield TiO_2–$4SiO_2$, $VO_{2.5}$–$3SiO_2$, MoO_3–$4SiO_2$ and WO_3–$4SiO_2$, respectively. The calcination temperature was chosen after thermogravimetric measurements showed clean peaks for isobutene and water elimination at this temperature.‡ N_2—physisorption measurements using the BET method showed that the metal silicates were macroporous with large pore sizes of 130 ± 20 Å and relatively low surface areas of 25 ± 5 $m^2\ g^{-1}$. The IR spectra showed the expected peak[9] at 950–960 cm^{-1} attributable to the Si–O stretching vibration polarized by the metal atom.§

The catalytic activity of the four metallosilicates was first compared using the reactive but bulky cyclooctene as the model substrate (Table 1). Using 30% hydrogen peroxide as oxidant, reactivity was very low and the metal silicate was dissolved into the homogeneous phase, presumably by aqueous hydrolysis. On the other hand, using 6 M *tert*-butyl hydroperoxide in *n*-decane as oxidant, a high yield of cyclooctene oxide was observed for the molybdenum silicate, MoO_3–$4SiO_2$. The vanadium silicate showed intermediate activity, whereas TiO_2–$4SiO_2$ and WO_3–$4SiO_2$ were only slightly active. With both oxidants there was no cyclooctene conversion without metal silicate. The stability of MoO_3–$4SiO_2$ was tested by filtering the reaction mixture at reaction temperature. There was no discernible loss in activity when the heterogeneous silicate was recycled in three consecutive runs. No metal leaching into the organic phase was measurable.¶

Table 1 Epoxidation of cyclooctene catalysed by metal silicates[a]

Metal silicate	Conversion (mol%) (Oxidant 30% H_2O_2)	Conversion (mol%) (Oxidant 6 M TBHP)
TiO_2–$4SiO_2$	0	5
$VO_{2.5}$–$3SiO_2$	0	40
MoO_3–$4SiO_2$	5	90
WO_3–$4SiO_2$	15	7

[a] Reaction conditions: 1.5 mmol cyclooctene, 1.5 μmol metal silicate (according to formula in table above), 0.1 ml 30% H_2O_2 + 1 ml acetone or 0.25 ml 6 M TBHP in *n*-decane, 60 °C, 12 h. Analysis was carried out by GLC (HP-5890) using a dimethyl polysiloxane column (RTX-1, 30 m, 0.32 mm id, 0.25 μm coating).

A more complete examination of the activity of MoO_3–$4SiO_2$ was carried out using different alkene substrates. First, the effect of the TBHP:alkene ratio was studied in the epoxidation of linear alkenes (Fig. 1). In general, doubling the amount of

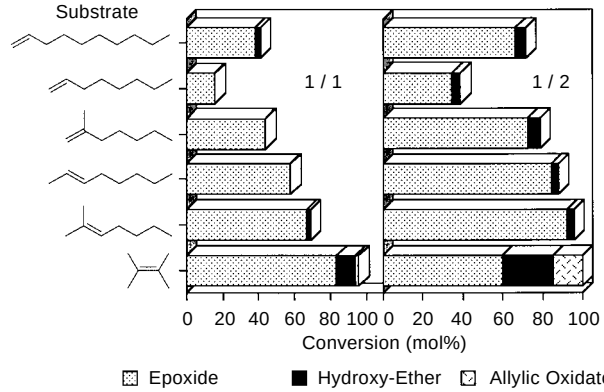

Fig. 1 Epoxidation of linear alkenes catalysed by MoO_3–$4SiO_2$ as a function of the oxidant : substrate ratio. Reaction conditions: 1.5 mmol substrate, 7.5 μmol (0.5 mol%) metal silicate, 1.5 mmol 6 M TBHP in *n*-decane (left panel), 3.0 mmol 6 M TBHP in *n*-decane (right panel), 50 °C, for dec-1-ene 80 °C, 12 h. Analysis was carried out by GLC (HP-5890) using a dimethyl polysiloxane column (RTX-1, 30 m, 0.32 mm id, 0.25 μm coating). Unknown products were identified by GC–MSD (HP-GCD) under similar conditions.

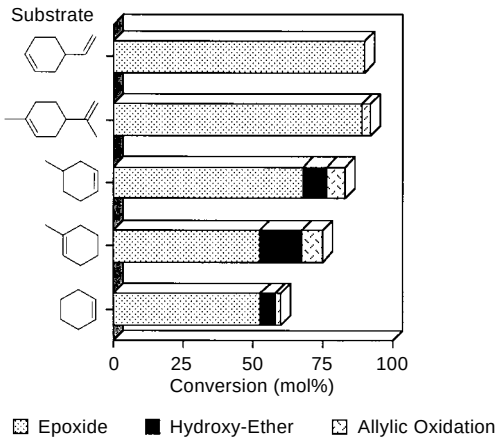

Fig. 2 Epoxidation of cyclic alkenes catalysed by MoO_3–$4SiO_2$. Reaction conditions: 1.5 mmol substrate 7.5 μmol (0.5 mol%) metal silicate, 1.5 mmol 6 M TBHP in *n*-decane, 50 °C, 12 h. For limonene and 4-vinylcyclohexene 0.15 μmol (0.1 mol%) metal silicate was used. Analysis was as described for Fig. 1.

TBHP increases the conversion and yield to epoxide, but the selectivity is somewhat lowered due to formation of α,β-hydroxy *tert*-butyl ethers by ring opening of the epoxide formed. In very reactive (nucleophilic) compounds such as 2,3-dimethylbut-2-ene excess oxidant also brought on formation of allylic oxidation products. An increase in the reaction temperature was also beneficial for the epoxidation reaction. For example, in the opoxidation of dec-1-ene, the conversions under conditions given in Fig. 2 (TBHP:1-decene = 2 : 1) were 37, 72 and 96 mol% for 50, 80 and 110 °C, respectively, with some decrease in selectivity to epoxide from 93% (50 and 80 °C) to 85% at 110 °C. The reactivity of bulkier cyclic alkenes has also been investigated (Fig. 2). In contrast to the microporous TS-1, there was no sieving effect and all substrates tested were reactive. For the monofunctional cyclic alkenes moderate selectivity was observed with some epoxide ring opening to the α,β-hydroxy *tert*-butyl ethers and the formation of a mixture of allylic oxidation products. 4-Vinylcyclohexene reacted quite selectively to form epoxide at the ring double bond (10 : 1 ratio). In addition, a small amount of diepoxide was formed (ratio monoepoxides : diepoxide = 13.3). The reaction of limonene was considerably less selective. Both epoxides were formed in similar amounts. There was a considerable amount of diepoxide formed as well (ratio monoepoxides : diepoxide = 5.5) as well as a small amount of allylic oxidation products. It is notable that the decrease in the amount of catalyst has a positive effect on reaction selectivity coupled with only a small decrease in conversion. The MoO_3–$4SiO_2$ prepared by the molecular route is a new heterogeneous catalyst for effective epoxidation of alkenes with anhydrous TBHP and compares well with 'redox molecular sieves'[1] and amorphous aerogels.[3]

Photocurrent responses associated with heterogeneous electron transfer at liquid/liquid interfaces

David J. Fermín, Zhifeng Ding, H. Dung Duong, Pierre F. Brevet and Hubert H. Girault*†

Laboratoire d'Electrochimie, Departement de Chimie, Ecole Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland

Photocurrent measurements originating from the electron transfer between photoexcited water soluble porphyrins and hydrophobic redox species are studied at the polarised water/1,2-dichloroethane (DCE) interface.

Artifical photosynthesis still remains a formidable technological challenge and a focal point for scientists well into the next century. Apart from solar cells based on dye sensitised colloidal semiconducting films,[1,2] no major breakthrough has been achieved in the field of solar energy conversion since the solid state photovoltaic cell.[3] A novel approach may rely on interfaces between two immiscible electrolyte solutions (ITIES), in which electron exchange involves redox centres separated by a defect-free junction. Despite recent advances in photochemistry[4] and electrochemistry at ITIES,[5,6] very few works have dealt with photocurrent measurements associated with heterogeneous electron transfer processes.[7–9] The present report describes photocurrent responses corresponding to the oxidation/reduction of a photoexcited water soluble porphyrin by hydrophobic redox centres such as TCNQ and 1,2-diferrocenylethane (DFCET) at the water/DCE interface.

One of the major obstacles for studying electron transfer at ITIES are the interferences introduced by ion transfer reactions.[5] Therefore, it is critical that charged species remain in their respective phases over a certain potential range. This condition was achieved by cell 1, where $Zn(TPPC)^{4-}$ denotes zinc tetrakis(carboxyphenyl)porphyrin and BTPPATPBCl is the organic electrolyte bis(triphenylphosphoranylidene)ammonium tetrakis(4-chlorophenyl)borate. Under the cell 1 arrangement, a potential window of *ca.* 0.8 V can be obtained without any significant faradaic response in the dark. The polarisation of the liquid/liquid interfaces (1.54 cm^2 surface area) was performed by a custom built four-electrode potentiostat.

Photocurrent measurements were also obtained with low frequency chopped light and lock-in detection (Stanford Research SR830).

Photocurrent transient responses associated with the heterogeneous quenching of $Zn(TPPC)^{4-}$ by TCNQ and DFCET are displayed in Fig. 1. The Galvani potential difference was determined from the formal transfer potential of tetramethylammonium ion (TMA), $\Delta^{w_o}\phi^{0'}_{TMA} = 0.160$ V.[10] Wavelengths < 450 nm were cut off by a Schott filter in order to avoid the absorption region of the ferrocene derivative. By convention, a positive current corresponds to a negative charge crossing from the organic to the aqueous phase. It is observed that the current is positive in the presence of the electron donor, and negative for the case of the electron acceptor. In the absence of either quencher or sensitiser, no photocurrent responses are obtained within the potential window.

The fact that neither reactants nor products transfer across the interface indicate that photocurrent responses are associated with heterogeneous electron transfer phenomena. Kotov and Kuzmin[11–13] have studied the case where a homogeneous photoreaction is followed by transfer of the charge products across the water/DCE interface. The shapes of the transient responses reported by these authors are essentially different to those observed in Fig. 1, and an order of magnitude slower. The heterogeneous nature of the electron transfer process is further confirmed by the dependence of the photocurrent sign on whether the excited state of the porphyrin is reduced or oxidised.

The transient photocurrent in Fig. 1 depends on the applied Galvani potential difference across the interface. For TCNQ, the photocurrent is rather small at positive potentials and increases toward negative potentials. The photocurrent exhibits an in-phase response followed by a slow decay upon illumination. When the illumination is interrupted, a positive overshoot is observed before the photocurrent relaxes to zero. These

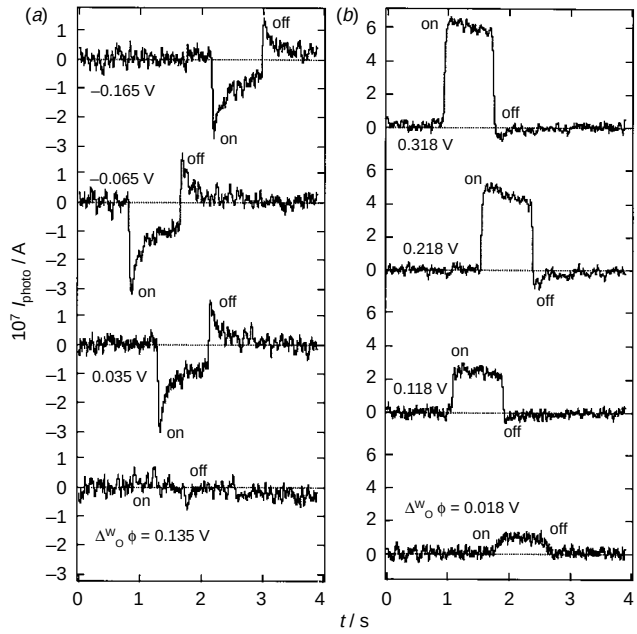

Fig. 1 Photocurrent transient measurements at various Galvani potential differences obtained from cell 1 and employing as quenchers TCNQ (*a*) and DFCET (*b*). Illumination was provided by a 450 W Arc-Xe lamp. λ < 450 nm were cut by a Schott filter. It is observed that the photocurrent is negative (electron transfer from water to DCE) in the presence of TCNQ and positive for DFCET.

transients resemble the behaviour observed for interfacial electron–hole recombination at p-type semiconductor/electrolyte junctions.[14] For DFCET, the recombination features are not so evident, but the photocurrent increases progressively as the potential is increased.

Photocurrent action spectra obtained at various Galvani potential differences are contrasted with the transmission absorption spectrum of the system in Fig. 2. The similar features in both spectra confirm the relation between electron transfer and the excited state of the porphyrin. It is observed the onset of the Soret band, which corresponds to the second singlet excited state S_2 located at *ca.* 430 nm. The photocurrent spectra also show three Q band transitions in the region 500–630 nm, which are associated with the first singlet excited state S_1 (560 nm) and its vibrational overtones. Although the wavelength of the photocurrent responses coincides with the absorption bands, the relative intensities are somehow different. The origin of this effect is still unclear, but it could indicate that the porphyrin involved in the electron exchange process have a different environment in comparison to the bulk porphyrin, probably due to adsorption.

Some of the features observed in the photocurrent transients in Fig. 1 can be explained in terms of a competition between product separation following the electron transfer step and the return electron transfer (recombination). In analogy with homogeneous photochemistry, the complex formed during the electron transfer phenomena can be denominated ion pair.[4,15] In the present case, this intermediate has an essentially heterogeneous stucture, therefore the forward electron transfer as well as the recombination reaction involve faradaic responses. In general, the photoelectrochemical reduction of a sensitiser S by an electron donor Q can be represented by Scheme 1 where $[S^{-}\cdots Q^{+}]$ represents the intermediate ion pair, and the subindexes w, o and int stand for aqueous, organic and interfacial region respectively. According to this mechanism, the initial photocurrent will be determined by the competition between electron transfer [eqn. (3)] and the decay of the excited state [eqn. (2)]. The subsequent decay of the photocurrent will be an effect of the recombination reaction [eqn. (5)], and the steady state photocurrent will be a function of the rate constants k_1–k_4. A quantitative analysis of the transient responses is currently in preparation.

$$S_w \xrightarrow{h\nu} S_w^* \qquad \text{Photoexcitation} \qquad (1)$$

$$S_w^* \xrightarrow{k_1} S_w \qquad \text{Decay of the excited state} \qquad (2)$$

$$S_w^* + Q_o \xrightarrow{k_2} [S^{-}\cdots Q^{+}]_{int} \qquad \text{Electron transfer} \qquad (3)$$

$$[S^{-}\cdots Q^{+}]_{int} \xrightarrow{k_3} S_w^{-} + Q_o^{+} \qquad \text{Product separation} \qquad (4)$$

$$[S^{-}\cdots Q^{+}]_{int} \xrightarrow{k_4} S_w + Q_o \qquad \text{Recombination} \qquad (5)$$

Recent results reveal that the photocurrent density is independent of the angle of illumination and linearly dependent on the light intensity.[16] This behaviour further suggests that the porphyrin molecules involved in the photocurrent responses are effectively confined to the liquid/liquid contact surface. It has also been found that diffusion effects become significant at high photocurrent levels ($> 10^{-5}$ A cm^{-}).[16]

Several other quenchers have been studied, showing different kinetics of electron transfer and recombination. In general, recombination features are dependent on the applied potential, indicating that the competition between recombination and product separation is affected by the Galvani potential difference. Moreover, the initial photocurrent is also dependent on the applied potential, reflecting a change in the electron transfer rate constant. The fact that the photocurrent increases as the potential becomes more negative in the case of TCNQ, and with increasing potentials for DFCET, suggests that these effects are not related to changes in the interfacial concentration of the porphyrin.[5,17,18] In contrast to the behaviour at semiconductor/electrolyte interfaces, the experimental evidence indicates that the activation energy for the electron transfer is affected by the applied potential.

The results presented in this report indicate that $Zn(TPPC)^{4-}$ is an ideal sensitiser for the study of heterogeneous electron transfer across the water/DCE interface. Both positive and negative photocurrents can be obtained upon replacing an electron donor for an electron acceptor in the organic phase. The photocurrent responses exhibit the same feature of the absorption spectra of the porphyrin. Evidence of back electron transfer appears in a similar fashion to electron–hole interfacial recombination at the semiconductor/electrolyte junctions.

Dinuclear cyclometallated platinum(II) complex as a sensitive luminescent probe for SDS micelles

Li-Zhu Wu,[a] Tsz-Chun Cheung,[a,b] Chi-Ming Che,[a]*† Kung-Kai Cheung[a] and Michael H. W. Lam[b]

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China*
[b] *Department of Biology and Chemistry, City University of Hong Kong, Tat Chee Ave., Hong Kong, PR China*

The photoluminescent properties of two dinuclear cyclometallated Pt^{II} complexes, $[Pt_2L^1{}_2(\mu\text{-dppm})]^{2+}$ 1 and $[Pt_2L^2{}_2(\mu\text{-dppm})]^{2+}$ 2, in SDS micellar solution are studied and 1 is found to undergo enhancement of luminescence as well as switching of emissive states upon incorporation into SDS micelle.

Metal–metal to ligand charge transfer (MMLCT) emission has been receiving growing interest in the photophysics and photochemistry of dinuclear Pt^{II} diimine complexes.[1] Such emission depends on the extent of Pt^{II}–Pt^{II} and/or ligand–ligand interactions. These interactions are weak under normal circumstances, but are sensitive to the surrounding environment. Thus, with suitable molecular design, such MMLCT emission of dinuclear Pt^{II} systems may serve as a means to probe the chemical environment in which the Pt^{II} complex is presented. One potentially important application is the probing of transformations in micellar microheterogenerous environments.[2] Here, we highlight a conformational non-rigid dinuclear cyclometallated Pt complex $[Pt_2L^1{}_2(\mu\text{-dppm})]^{2+}$ **1** (dppm = $Ph_2PCH_2PPH_2$) (Fig. 1) as a new spectroscopic probe for SDS micelles.[3] The flexible conformation of the Pt^{II} complex prompts the intramolecular metal–metal and/or ligand–ligand interactions, and hence its MMLCT emission, to be sensitive to the microheterogenerous environments of the SDS micelles (Scheme 1).

The ligand L^1 [4-(*p*-diethylphosphonophenyl)-6-phenyl-2,2′-bipyridine] was obtained from the reaction between 4-(*p*-bromophenyl)-6-phenyl-2,2′-bipyridine and diethyl phosphite in the presence of a Pd^0 catalyst.[4] The dinuclear Pt^{II} complex **1** was prepared by stirring $[PtL^1Cl]$ and 1,2-bis(diphenylphosphino)methane in MeCN–EtOH. It was isolated as a PF_6^- salt. For comparison, an analogous complex, $[Pt_2L^2{}_2(\mu\text{-dppm})]^{2+}$ **2** [L^2 = 4-(4-chlorophenyl)-6-phenyl-2,2′-bipyridine] (Fig. 1), without $PO(OC_2H_5)_2$ groups was also prepared.‡ The structure of **2**$[PF_6]_2$ has been characterized by X-ray crystallography (Fig. 2).§ The two planar $[PtL^2]$ units are nearly parallel to each other with a dihedral angle of 4.6°, and staggered with a torsion angle of 27.2°. The configurations of the two $[PtL^2]$ units are identical and are related by a C_2 axis passing through the $–CH_2–$ unit of the dppm ligand. The intramolecular Pt–Pt distance is 3.150(1) Å. This is shorter than the intramolecular Pt–Pt distance of $[Pt_2L^3{}_2(\mu\text{-dppm})]^{2+}$ (L^3 = 6-phenyl-2,2′-bipyridine) (3.301 Å)[5] but is comparable to that in $[Pt_2(NH_3)_4(\mu\text{-}C_4H_5N_2O_2)_2]^{2+}$ (3.131 Å).[6] The structure of **1** is expected to resemble that of **2** as the spectroscopic properties of **1**$[PF_6]_2$ and **2**$[PF_6]_2$ are similar,¶ we envisage that there is also weak metal–metal and/or ligand–ligand interactions in the former complex.

Emission spectra of **1**$[PF_6]_2$ in CH_2Cl_2 and **2**$[PF_6]_2$ in MeCN show low energy bands at 648 nm and 661 nm, respectively, which are both attributable to the MMLCT $\{^3[(d\sigma^*)\sigma(\pi^*)]\}$ transitions.[1] However, in MeOH, no emission from **1** can be observed. This is most probably due to quenching by solvent molecules at the open coordination sites. As shown in Fig. 3(*a*), addition of SDS micelles to an aqueous solution of **1** leads to an emission with λ_{max} at 530 nm (τ = 1.4 μs), which is similar to the MLCT emissions of related mononuclear cyclometallated Pt^{II} complexes.[7] Interestingly, no MMLCT emission can be observed. We attribute that the SDS micelle creates a protecting environment for the Pt^{II} complex so that enhancement of emission is recorded upon incorporation of the dinuclear Pt^{II} complex. The fact that the emission of **1**–SDS micelle is very different from those observed in CH_2Cl_2 solution and solid state suggests no intramolecular and/or intermolecular Pt^{II}–Pt^{II} interaction between the two cyclometallated Pt^{II} units upon incorporation of the complex in the SDS micelle.

It is well established that with increasing ionic strength, micelles will undergo substantial transformations in size and shape to create cylindrical micelles with large aggregation number and SDS head groups will be brought closer in proximity.[8] We found that the emission properties of **1** in the SDS micelle are dramatically altered by the addition of counter cations. Fig. 3 shows the emission spectra of **1** in the SDS micellar solution recorded at different NaCl concentrations. Initial addition of NaCl slightly enhances the intensity and

lifetime of the 530 nm emission. An additional emission maximum at 650 nm gradually develops as [NaCl] increases. The 650 nm emission corresponds well to the ^{3}MMLCT emission of **1** recorded in CH_2Cl_2 solution and in solid state. Time resolved emission spectra of **1** in SDS micellar solution recorded at [NaCl] = 0.5 M show different decay rates for the 530 and 650 nm emission maxima. This indicated that the two emissions are coming from two different excited states. Presumably they are the MLCT excited states of the two non-interacting cyclometallated Pt^{II} units and the MMLCT excited states of two interacting ones (Scheme 1), respectively. The sensitive responses of the luminescent properties of **1** to [NaCl] can be rationalized as follows. The cyclometallated Pt^{II} molecules may not reside too deep in the SDS micellar cores and are still subjected to quenching by the solvent molecules. Addition of Na^+ brings the SDS head groups closer in proximity through a reduction in electrostatic repulsion. This would reduce water penetration at the micellar surface and enhance the hydrophobicity of the medium so that solvent induced non-radiative decay at the open coordination sites is prohibited. Thus, the intensity and lifetime of the 530 nm emission are both enhanced upon initial addition of NaCl. Importantly, the alignment of the SDS head group with Na^+ cations would also force two cyclometallated Pt^{II} units close enough for intramolecular metal–metal and/or ligand–ligand interaction (Scheme 1). This ultimately leads to an accessible MMLCT excited state and accounts for the 650 nm emission at high NaCl concentration. The alignment of the SDS head groups in the micellar solution would be expected to depend on the size of the counter cations. We found that addition of K^+ or NH_4^+ gave a similar effect on the photoluminescence of the micellar solution of **1**. However, the bulky NMe_4^+ cation did not give rise to any low energy emission with $\lambda_{max} \geqslant 600$ nm.

The above data show that the emission properties of a cyclometallated dinuclear Pt^{II} complex are sensitive to the micelle environment. Switching from MLCT to MMLCT emission is observed upon micellar transformation. This reveals the potential application of weak metal–metal interaction present in a conformational non-rigid molecule as a sensitive probe for micellar microheterogeneous environments.

A novel, internally-solvated phosphinomethanide; crystal structure of $Li[C(SiMe_3)_2\{P(C_6H_4CH_2NMe_2\text{-}2)_2\}]$

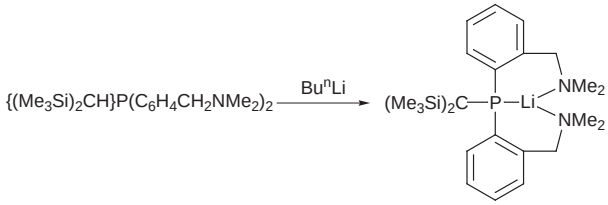
William Clegg, Simon Doherty,*† Keith Izod*† and Paul O'Shaughnessy

Department of Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU

Metallation of $P\{CH(SiMe_3)_2\}(C_6H_4CH_2NMe_2\text{-}2)_2$ with Bu^nLi yields a novel lithium phosphinomethanide in which the ligand exhibits an unprecedented tridentate PN_2 coordination mode and in which there are no short contacts between lithium and the planar carbanion centre.

Over the last decade an extensive chemistry has emerged for phosphorus-stabilised carbanionic ligands such as the phosphinomethanides, R_2PCR_2, and diphosphinomethanides, $(R_2P)_2CR$. Interest in these ligands arises from their ability to bind to metal centres in a variety of coordination modes, providing varying degrees of steric hindrance and electron donation. Mono-, di- and tri-phosphinomethanides are known to coordinate as monodentate C-donors,[1] η^2-CP-donors,[2] bidentate PP-donors,[3] heteroallyl ligands,[4] and bridging ligands.[5] We now describe a unique coordination mode for such a ligand in a lithium derivative of an amino-functionalised phosphinomethanide.

Treatment of the tertiary phosphine $P\{CH(SiMe_3)_2\}(C_6H_4CH_2NMe_2\text{-}2)_2$ **1** with 1 equiv. of Bu^nLi in diethyl ether yields the novel phosphinomethanide $Li[C(SiMe_3)_2\{P(C_6H_4CH_2NMe_2\text{-}2)_2\}]$ **2**, isolated in high yield as yellow, air-sensitive plates (Scheme 1).‡ Whilst metallation of the related ligand $HC(PMe_2)(SiMe_3)_2$ requires heating under reflux with Bu^nLi for three weeks in hexane,[1] metallation of **1** was complete within 12 h at room temperature. It is reasonable to attribute the enhanced susceptibility of **1** towards deprotonation to chelation assistance, *i.e.* the coordination of an amino-group to lithium prior to the deprotonation step.



Scheme 1

The room temperature ^1H NMR spectrum of **2** exhibits two $SiMe_3$ signals, together with extremely broad resonances due to the benzylic and NMe_2 protons. These latter signals sharpen considerably at 60 °C, which suggests a dynamic process, possibly involving changes in chelate ring conformation or dissociation of the NMe_2-groups, in solution. In contrast, the ^{31}P and ^7Li NMR spectra of **2** consist of a sharp quartet and doublet respectively [$^1J(^{31}P–^7Li)$ 88.9 Hz], suggesting that a Li–P interaction is maintained in solution.

Since the addition of polydentate amines to lithium phosphinomethanides favours the formation of C-bonded species,[1] we were interested to observe the influence of intramolecular coordination of the dimethylamino groups on the structure of **2**. Unexpectedly, an X-ray diffraction study of **2** revealed an unprecedented tridentate PN_2 coordination mode for the phosphinomethanide ligand (Fig. 1).§ The lithium lies in a trigonal pyramidal environment (sum of angles at Li = 326.1°), coordinated solely by the phosphorus and nitrogen atoms of the ligand, forming two puckered, six-membered chelate rings, each with a bite angle of *ca.* 98°. The carbanion centre C(1) is perfectly planar [sum of angles at C(1) = 359.4°] and has no significant intra- or inter-molecular contacts to Li. Few examples of planar, isolated carbanions have been reported and the majority of these contain highly delocalised polyarylmethanide derivatives.[6]

As is common in phosphinomethanide species, the P–C(1) distance in **2** [1.735(3) Å] is substantially shorter than that expected for a P–C single bond, suggesting significant P–C multiple bond character. Indeed the P–C(1) distance in the tertiary phosphine $\{(Me_3Si)_2CH\}P(CH_2C_6H_4\text{-}2\text{-}NMe_2)_2$ **3**, which is isomeric with **1**, is 1.865(2) Å.[7] The P–C(1) distance in **2** is considerably longer than both the P–CH_2 distance of 1.702(2) Å in $[(PhCH_2)_2NLi\cdot CH_2PPh_3]_n$, a Li complex of a neutral P^V ylide,[8] and the P–C bond length range of 1.64(1) to 1.690(5) Å in a series of lithiated phosphine oxide compounds.[9] Such a difference is to be expected since these latter compounds are P^V derivatives with substantial ylidic character. The Si–C(1) distances of 1.818(3) and 1.826(3) Å are similar to previously reported Si–C distances in other silicon-stabilised carbanions.[10]

The Li–P distance of 2.427(6) Å is short in comparison to analogous distances in lithium phosphinomethanides where the ligand binds in its more usual coordination modes. For example, the Li–P distances in $[Li\{C(PMe_2)(SiMe_3)_2\}]_2$[1] and (tmen)-$Li\{C(PPh_2)_2(SiMe_3)\}$[3] are 2.519(4) and 2.530(7) Å, respectively. This may reflect the increased ionic contribution to the Li–P interaction associated with the delocalisation of charge from the carbanion centre to phosphorus.

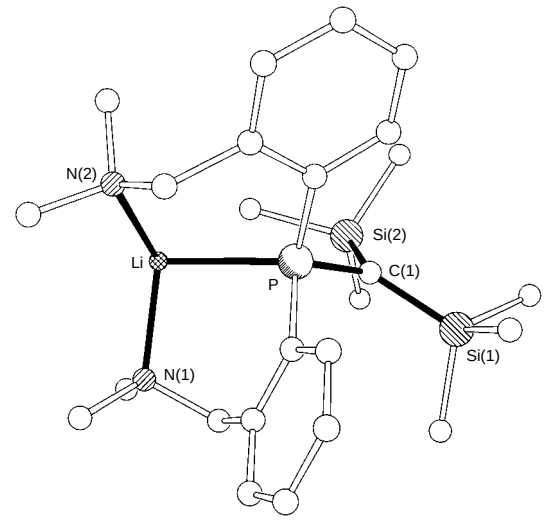


Fig. 1 Molecular structure of **2** (H atoms omitted for clarity). Selected bond lengths (Å) and angles (°): Li–P 2.427(6), Li–N(1) 2.096(6), Li–N(2) 2.083(6), C(1)–P 1.735(3), C(1)–Si(1) 1.818(3), C(1)–Si(2) 1.826(3), P–Li–N(1) 98.4(2), P–Li–N(2) 97.4(2), N(1)–Li–N(2) 130.3(3), Li–P–C(1) 126.31(16), P–C(1)–Si(1) 126.26(18), P–C(1)–Si(2) 113.61(17), Si(1)–C(1)–Si(2) 119.49(16).

Investigations into the coordination behaviour of this and related amino-functionalised phosphinomethanides are currently in progress.

Synthesis of polystyrene and silica gel polymer hybrids *via* π–π interactions

Ryo Tamaki, Ken Samura and Yoshiki Chujo*

Department of Polymer Chemistry, Graduate School of Engineering, Kyoto University, Yoshida, Sakyo-ku,Kyoto, 606-8501, Japan

Homogeneous polystyrene and silica gel polymer hybrids have been prepared utilizing the sol–gel reaction of phenyltrimethoxysilane; π–π interactions between phenyl groups of the organic polymer and those of silica gel were found to play a critical role for the homogeneity.

In recent years a large variety of organic and inorganic polymer hybrids have been synthesized by the sol–gel technique utilizing alkoxysilanes.[1–4] A most noticeable characteristic of these hybrid materials is the molecular-level integration of organic and inorganic elements. The interactions that have been utilized to integrate organic and inorganic phases are generally classified into two groups; covalent bonding and hydrogen bonding interactions.[2] The former interaction is attained by the incorporation of silane coupling groups into organic segments.[5] The latter interaction is effective when organic segments have polar functional groups such as amide and urethane groups. The interaction acts between these functional groups and residual silanol groups of silica gel.[1] On the other hand, π–π interactions are known as one of the types of attractive non-covalent bonding interactions which play a critical role in, for example, the stabilization of the double helical structure of DNA and complexation in host–guest systems.[6] Here we introduce a new approach to synthesize homogeneous polymer hybrids utilizing π–π interactions. Homogeneous polymer hybrids of polystyrene and silica gel were successfully prepared by this method.

Polystyrene and silica gel polymer hybrids were prepared by utilizing a sol–gel reaction of phenyltrimethoxysilane (PhTMOS). The sol–gel reaction proceeds *via* hydrolysis and subsequent condensation of alkoxysilanes. When an alkyl-substituted alkoxysilane is used as a starting material, the alkyl group is introduced into silica gel since the Si–C bond does not undergo hydrolysis reaction. Thus, phenyl groups would be introduced into the silica gel by the sol–gel reaction of PhTMOS.

As shown in Scheme 1, the alkoxysilane was added to a THF solution of polystyrene (M_w = 24 500, M_n = 17 700, M_w/M_n = 1.39) followed by an addition of 0.1 M HCl as catalyst. The mixture was then heated at 30 °C and the temperature was gradually raised to 80 °C and the sample kept at this temperature for a week. For comparison, other alkoxysilanes such as tetramethoxysilane (TMOS) methyltrimethoxysilane (MTMOS) and isobutyltrimethoxysilane (Bu^{i}TMOS) were also used as starting materials. The mass ratio of alkoxysilane to polystyrene was 0.1 or 1.0. Homogeneity of the obtained polymer hybrids was evaluated optically. Transparency of the polymer hybrids is attained only when silica gel particles embedded within polystyrene are smaller than the wavelength of light.[2] As shown in Table 1, transparent polymer hybrids were obtained for both mass contents when PhTMOS was used as a starting material for the sol–gel reaction. In contrast, polymer hybrids became translucent or turbid when TMOS, MTMOS or Bu^{i}TMOS were used. Other alkoxysilanes containing a phenyl ring were also employed for the synthesis of the polymer hybrids. Mesityltrimethoxysilane (MesTMOS) gave homogeneous polymer hybrids when the mass ratio was 0.1. However, the homogeneity deteriorated as the mass ratio was increased to 1.0. The result might be attributed to methyl groups on the phenyl ring of MesTMOS, which are suspected to interrupt the π–π interaction. When phenethyltrimethoxysilane (PhenethylTMOS) was used as the starting material homogeneous polymer hybrids were obtained for both mass contents. These results demonstrate that a phenyl ring is necessary for the homogeneous dispersion of polystyrene and silica gel. In addition, as was observed for MesTMOS, spatial bulkiness on

[a] 0.5 g of PS was dissolved in 5 ml of THF with $RSi(OR)_3$ and acid catalyst. The mixture was heated at 30–80 °C in an oven.

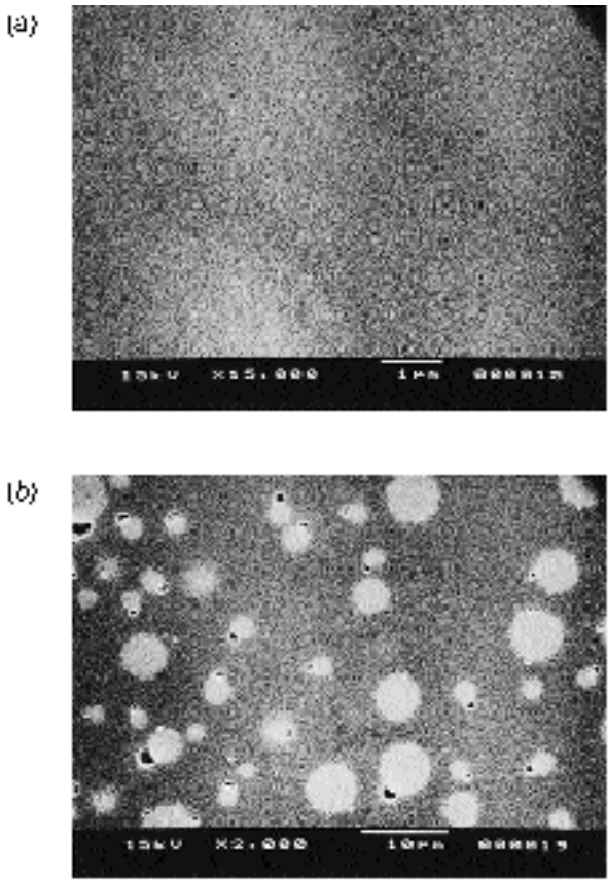

Fig. 1 Scanning electron micrographs of (*a*) a polymer hybrid prepared from PhTMOS and PS (*b*) a polymer hybrid prepared from MTMOS and PS

the phenyl rings was found to lead to deterioration of the homogeneity. Considering these results, it is expected that the stacking between phenyl rings of polystyrene and silica gel, rather than hydrophobic interactions, is critical for the homogeneous dispersion of the polymer and silica gel. Clear differences were observed in SEM measurements. As shown in Fig. 1, phase separation appeared in the polymer hybrid prepared from MTMOS with a mass ratio of 0.1 and silica gel domains of $\geqslant 5$ μm were observed. On the other hand, a polymer hybrid prepared from PhTMOS showed no recognizable segregation at this level. As the mass ratio of alkoxysilanes was increased to 1.0, the size of silica gel domains increased to 50 μm in the polymer hybrid prepared from MTMOS, while the polymer hybrid prepared from PhTMOS still showed a uniform image.

We also carried out the synthesis of polymer hybrids starting from poly(diallylphthalate) and polycarbonate as organic components which also have phenyl rings as repeating units. As observed in the case of polystyrene, transparent polymer hybrids were obtained when PhTMOS or PhenethylTMOS was used as a starting reagent for the inorganic part, while other alkoxysilanes such as TMOS, MTMOS or Bu^{i}TMOS gave only inhomogeneous polymer hybrids.[7] These results indicate that π–π interactions are quite effective for the synthesis of homogeneous polymer hybrids of aromatic polymers and silica gel.

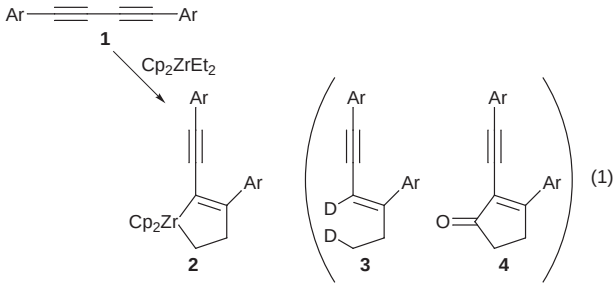
Reductive elimination of α-alkynyl substituted zirconacyclopentenes: formation of cyclobutene derivatives

Yuanhong Liu,[a] Wen-Hua Sun,[a] Kiyohiko Nakajima[b] and Tamotsu Takahashi*[a]†

[a] *Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060, Japan*
[b] *Department of Chemistry, Aichi University of Education, Igaya, Kariya 448, Japan*

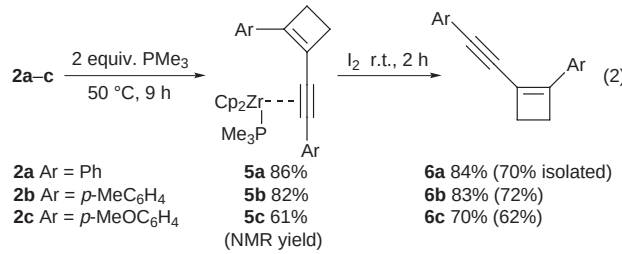
Reductive elimination of α-alkynyl substituted zirconacyclopentenes, prepared from diaryldiynes and Cp_2ZrEt_2, proceeded upon heating or in the presence of dimethyl acetylenedicarboxylate to give alkynylcyclobutene derivatives.

Reductive elimination of two organic groups on metals is a basic reaction step for making new C–C bonds.[1] Although this step has been intensively investigated for late transition metal compounds, it has not been well studied for early transition metal compounds such as zirconium. To the best of our knowledge, only a few reductive couplings of two organic groups of organozirconium compounds have been reported, such as photolysis or oxidation of diphenylzirconocene producing biphenyl,[2] CO insertion into organozirconocenes or zirconacycles followed by migration giving ketone derivatives,[3] or an alkynyl–phenyl coupling *via* ate-complexation.[4] Here we report that the reductive coupling of α-alkynyl substituted zirconacyclopentenes, prepared by the reaction of diaryldiynes with Cp_2ZrEt_2, proceeded upon heating or in the presence of additives such as dimethyl acetylenedicarboxylate to give alkynylcyclobutene derivatives.

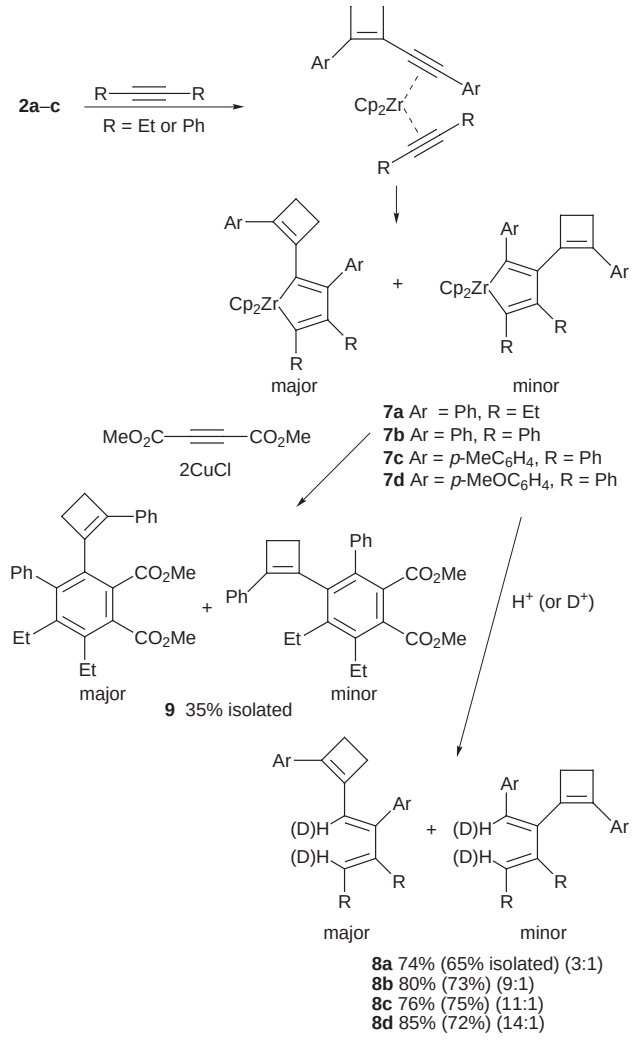


We have already reported that a reaction of diynes with $Cp_2Zr(CH_2{=}CH_2)$ *in situ* prepared from Cp_2ZrEt_2 afforded α-alkynylzirconacyclopentenes (**2**) which gave a dideuterated enyne **3** after deuterolysis [5] and α-alkynylcyclopentenones **4** by treatment with CO/I_2 [reaction (1)].[6] Here we find that, upon heating **2a**–**c** in THF at 50 °C for 9 h in the presence of 2 equiv. of PMe_3, a reductive elimination reaction of **2a**–**c** proceeds to afford the complexes **5a**–**c** in 61–86% NMR yields. Treatment of **5a**–**c** with an excess of I_2 produced alkynylcyclobutenes **6a**–**c** in 70–84% NMR yields based on diynes [reaction (2)]. This indicates that reductive elimination of **2a**–**c** took place to give cyclobutene derivatives. The Cp_2Zr^{II} species formed by the reductive elimination were trapped as alkyne complexes stabilized by PMe_3 and **6a**–**c** to give **5a**–**c**.[7]‡ This is the first example of the direct formation of cyclobutene derivatives from zirconacyclopentenes, to the best of our knowledge.[8]

In the presence of 1 equiv. of hex-3-yne instead of PMe_3, zirconacyclopentadienes **7a**–**d** were formed.[9] After hydrolysis of **7a**–**d**, cyclobutenyldienes **8a**–**d** were obtained in 74–85% yields as mixtures of two regioisomers in a ratio of 3 : 1 as expected (Scheme 1). Deuterolysis of **7a** instead of hydrolysis



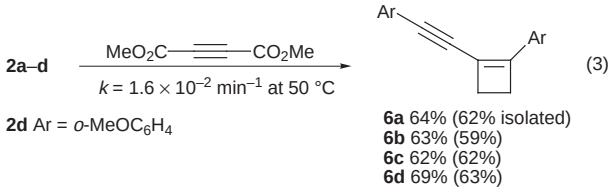
afforded a dideuterated product with > 98% deuterium incorporation. The zirconacyclopentadiene **7a** was further converted into benzene derivatives **9** as a mixture of two



Scheme 1

regioisomers by the reaction with dimethyl acetylenedicarboxylate by our method.[10] The structure of minor isomer **9** was determined by X-ray analysis.§

Addition of dimethyl acetylenedicarboxylate to **2a**–**d** induced the direct formation of free **6a**–**d** in 64, 63, 62 and 69% NMR yields, respectively [reaction (3)]. Although the zirconium species trapped by dimethyl acetylenedicarboxylate was not clearly detected in this reaction, NMR study of this reaction revealed that the cyclobutene formation from **2a** at 50 °C obeys the first order rule and the reaction rate was 1.6×10^{-2} min^{-1}. This indicates that the presence of dimethyl acetylenedicarboxylate does not cause the reductive elimination. Dimethyl acetylenecarboxylate liberates **6** from zirconium.



(3)

Note that the cyclobutene formation was also induced by the reaction of **2a** with allyl chloride,[11] vinyl butyl ether,[12] and a homoallyl bromide[13] as shown in Scheme 2. Hydrolysis of these reaction mixtures gave the corresponding products **10**–**12** in 70, 53 and 60% yields, respectively.

An efficient chemical method for removing N-terminal extra methionine from recombinant methionylated human growth hormone

Osamu Nishimura,*[a]† Masato Suenaga,[a] Hiroaki Ohmae,[a] Shinji Tsuji[a] and Masahiko Fujino[b]

[a] *Biotechnology Laboratories, Pharmaceutical Research Division, Takeda Chemical Industries, Ltd., Yodogawa-ku, Osaka 532, Japan*

[b] *Takeda Chemical Industries, Ltd., Chuou-ku, Osaka 541, Japan*

Conversion of recombinant methionylated human growth hormone (Met-hGH) into its non-methionylated form (hGH) has been successfully achieved by a chemical process, which consists of a transamination reaction and phenylene-1,2-diamine treatment.

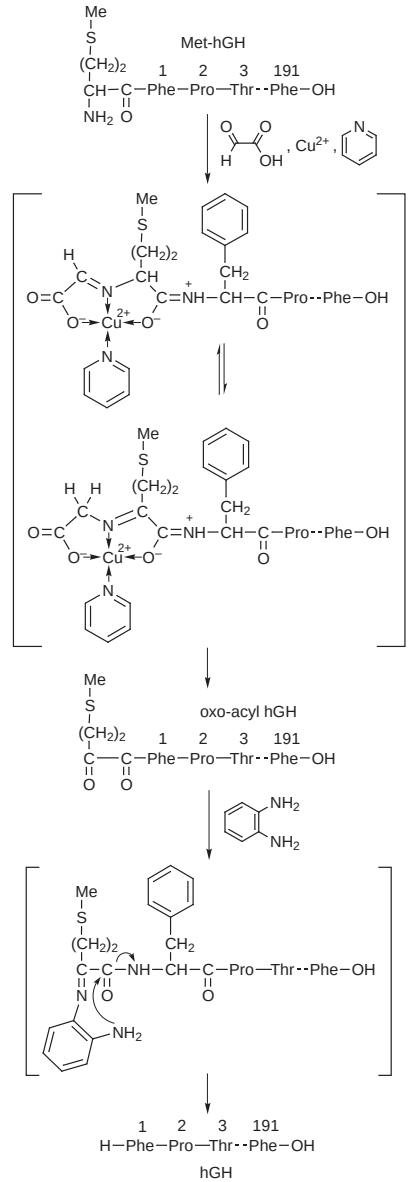
Production of recombinant proteins for clinical use has been increasing with the advent of genetic engineering technology. However, there are still numerous problems in the production of recombinant proteins. Typically, difficulties remain in the addition of methionine at the N-terminus corresponding to the initiation cordon (ATG),[1] refolding from inactive inclusion bodies,[2–4] post-translational modification[5–7] and heterogeneity[8,9] caused by endogenous proteases. We have encountered and given some answers to these problems during the production of various kinds of recombinant proteins in our laboratories, such as interferon-α,[5] interferon-γ,[6,8] interleukin-2[10] and the basic fibroblast growth factor mutein.[7]

Recombinant proteins are often produced with an additional methionine at the N-terminus because methionine aminopeptidase is strongly influenced by the kind of amino acid residue.[11] Thus, the N-terminal methionine is hard to cleave when the side chain of the adjacent amino acid is bulky or charged. Recombinant human growth hormone(hGH) produced in *Escherichia coli* is fully methionylated[1] because the N-terminal amino acid is phenylalanine. The removal of the additional N-terminal methionine is a great concern in the production of recombinant hGH for therapeutic applications since physiological features, such as biological activity, stability *in vivo* and antigenicity of methionylated derivatives, may be different from those of the natural species. In this regard, we have previously reported a procedure for cleavage by aminopeptidase M.[12]

Dixon and co-workers removed the N-terminal residue of *Pseudomonas* cytochrome c-551 after transamination[13,14] in order to study whether the N-terminal residue is essential for the function of the protein or not. However, this method has never been used to remove an additional methionine at the N-terminus of recombinant proteins. We took advantage of this method for the production of hGH from Met-hGH[12] produced in *E. coli*, and found it to be of great value as a versatile procedure for the preparation of non-methionylated hGH, as well as other non-methionylated recombinant proteins.

Here we describe our chemical procedure for removing extra-methionine at the N-terminus and show the first example of removing an additional methionine at the N-terminus of a recombinant protein using a chemical method.

To obtain hGH, we optimized both the transamination and the scission reaction and found that the best conditions were: 8 mM $CuSO_4$, 0.5 M glyoxylic acid and 10% pyridine for the former and 40 mM phenylene-1,2-diamine, 2 M NaOAc and 2 M AcOH for the latter. As shown in Scheme 1, Met-hGH[12] was converted into the oxo-acyl form‡ and then passed through a column of Sephadex G-25.§ The resulting product was cleaved with phenylene-1,2-diamine¶ to give crude hGH, in *ca.* 70% conversion yield, which was then purified by chromatography on Sephadex G-25, followed by DEAE-5PW.‖ Thus, about 60 mg of the purified hGH was obtained from 100 mg of Met-hGH. To confirm the structural identity of the purified hGH, protein chemical analysis was performed. The N-terminal amino acid sequence, the C-terminal amino acid and the amino acid analysis were all in good agreement with those predicted from the corresponding cDNA sequence. The purified hGH was migrated as a single band on SDS-PAGE and showed the electrophoretic mobility of a *ca.* 22 kDa species under reducing conditions (Fig. 1). Copper ions were not detected in the



Scheme 1

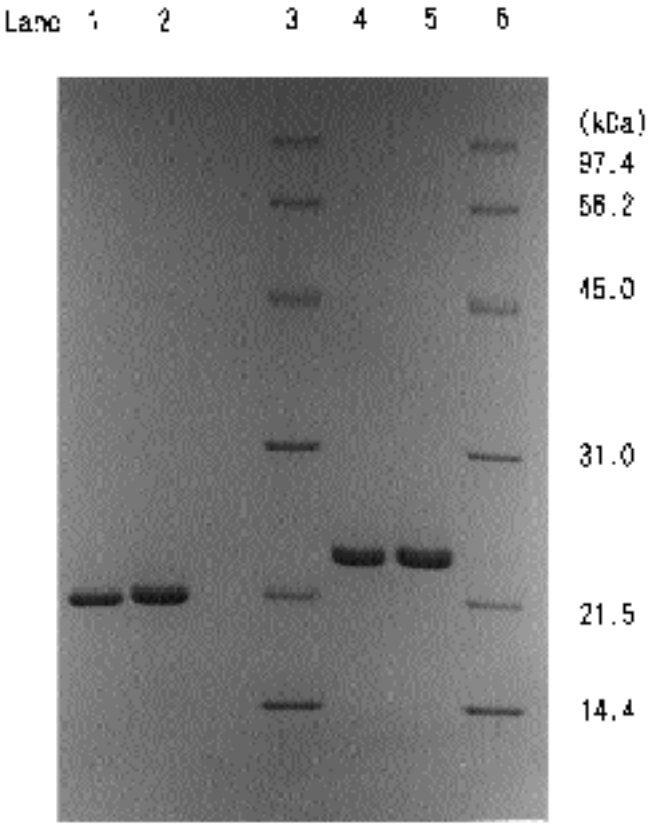


Fig. 1 SDS-PAGE of Met-hGH and hGH obtained from Met-hGH after transamination. Lanes 1 and 2: nonreducing conditions. Lanes 4 and 5: reducing conditions. Lanes 1 and 4: hGH. Lanes 2 and 5: Met-hGH. Lanes 3 and 6, marker proteins.

purified hGH when checked by AAS. To obtain further structural information, the purified hGH was subjected to mapping analysis.** As shown in Fig. 2, the peptide map obtained was identical to that of authentic hGH.†† The purified hGH also had the same order of activity as that of authentic hGH,†† when assayed using Nb2 Node lymphoma cells,[15] indicating that hGH obtained from Met-hGH has essentially the same chemical and biological identity as that of authentic hGH.††

In conclusion, we could obtain hGH from Met-hGH by a chemical method, and we could also apply the same procedure to other methionylated recombinant proteins including neurotrophin-3,[4] interleukin-2[10] and betacellulin,[16] to give the corresponding desired proteins having no methionine at the N-terminus. These results suggest that the present method might be widely applicable to the preparation of non-methionylated recombinant proteins for clinical use and show a new way for the production of recombinant proteins.

‡ To 3.75 g of glyoxylic acid monohydrate were added 1.2 ml of 0.5 M $CuSO_4$ and 7.5 ml of pyridine and the total volume was adjusted to 15 ml. Then 60 ml of Met-hGH (protein content 1.67 mg ml^{-1}) solution containing 3 M urea was added and incubated for 1 h at 25 °C.

§ The reaction mixture was applied at a flow rate of 0.5 l h^{-1} to a Sephadex G-25 (Pharmacia Biotech, Sweden) column (4.6 × 60 cm) equilibrated with 20 mM Tris-HCl buffer (pH 8.0) containing 2.5 M urea, and the sample was eluted with the same buffer. The main fraction (200 ml) was pooled.

¶ 200 ml of the protein solution, 200 ml of 4 M NaOAc, 4 M AcOH, 3 M urea and 1.73 g of phenylene-1,2-diamine were mixed and incubated for 3 days at 4 °C. In order to minimize oxidation, nitrogen was bubbled through the solutions to remove as much oxygen as possible and the incubations were carried out under nitrogen.

‖ The reaction mixture was applied at a flow rate of 2 l h^{-1} to a Sephadex G-25 (Pharmacia Biotech, Sweden) column (11.3 × 80 cm) equilibrated with 20 mM Tris-HCl buffer (pH 8.0) containing 2.5 M urea and the sample was eluted with the same buffer. The pooled fraction (1000 ml) was applied at a flow rate of 1 l h^{-1} to a DEAE-5PW (Tosoh Corporation, Japan) column (5.53 × 20 cm) equilibrated with 50 mM Tris-HCl buffer (pH 8.0) containing 2.5 M urea. After adsorption, the protein was eluted with a linear gradient of pH (8–4) between 50 mM Tris-HCl buffer (pH 8.0) containing 2.5 M urea and 50 mM MES buffer (pH 4.0) containing 2.5 M urea. The main fraction (150 ml) (protein content 0.4 mg ml^{-1}) was pooled.

** hGH was dissolved in 0.2 M Tris-HCl buffer (pH 8.0). The solution was incubated with TPCK-treated-trypsin (Worthington Biochemical Corp.) at a substrate-enzyme ratio of 25 : 1 (w/w) at 37 °C for 18 h, followed by a second enzyme addition to give a final concentration of 12.5 : 1 (w/w). At the end of the digest (6 h), the pH was lowered to 3 with 1 M HCl. The tryptic peptides were analyzed by reversed-phase HPLC (RP-HPLC) using a C8P-50 (Showa Denko, Japan) column (4.6 × 300 mm) and eluted at a flow rate of 0.8 ml min^{-1} with a linear gradient of 8–56% MeCN in the presence of 0.1% TFA.

†† The hGH standard was obtained from the National Institute of Health Sciences (Japan).

The X-ray crystal structure of 3-ethynylcyclopropene shows that the carbon–carbon double bond of the molecule is unusually short [1.255(2) Å], whereas theoretical calculations suggest a relative insensitivity of the bond length to adjacent orbital interactions.

Recent crystallographic studies of lightly-substituted cyclopropenes have illustrated the uncommon bonding modes in these small-ring hydrocarbons, such as formation of bent, banana-like bonds.[1,2] One of our groups recently reported the preparation of highly unsaturated analogs, such as 3-ethynylcyclopropene **1**,[3]

1

and sought to investigate the solid-state structures of these compounds. In keeping with the extraordinary geometrical results, we report herein the X-ray crystal structure of **1** as well as model calculations to explain the experimental atomic distances for **1**.

Molecule **1** was prepared according to the literature method.[3] A single crystal (mp −94 °C) was grown using the low-temperature techniques described previously.[4,5] The structure analysis was performed at 120 K.¶ With intermolecular H···H separations of 2.73 Å or greater, the crystal packing of **1** is assumed not to cause significant distortions. The molecular structure and bond distances and angles are presented in Fig. 1 and Table 1, respectively. As expected, the sp^3 bond angle about C(1)–C(3)–C(2) is highly constrained, being only 49.4°. The most striking feature of the bond lengths found for **1** is the amazingly short C=C bond. At 1.255 Å, this value is midway between the accepted values of a typical double and triple bond.[6] The analogous bond length in structurally related 3-ethenylcyclopropene **2** is somewhat longer at 1.279 Å.[2b] All of the other bond lengths and bond angles of **1** are typical of their respective structural subunits. A systematic error in the measurement of the C(1)–C(2) bond distance is rather unlikely since the ellipsoids of the anisotropic displacement parameters

Table 1 Interatomic distances and angles for **1**

Atoms	Distance/Å	Atoms	Angle (°)
C(1)–C(2)	1.255(2)	C(1)–C(2)–C(3)	65.2(1)
C(1)–C(3)	1.500(2)	C(2)–C(1)–C(3)	65.4(1)
C(2)–C(3)	1.502(2)	C(1)–C(3)–C(2)	49.4(1)
C(3)–C(4)	1.448(2)	C(1)–C(3)–C(4)	121.4(1)
C(4)–C(5)	1.184(2)	C(2)–C(3)–C(4)	121.4(1)
		C(3)–C(4)–C(5)	179.0(1)

are not elongated in the direction of the double bond.[7] In any case, the C(1)–C(2) bond length in **1** is the shortest crystallographically observed carbon–carbon double bond known in any hydrocarbon.[8]

2 R = $CH{=}CH_2$ **6** R = Me
3 R = NO_2 **7** R = H
4 R = CHO **8** R = F
5 R = C≡N **9** R = NH_2

In order to gain some insight into the nature of the cyclopropene structural fragment, a series of 3-monosubstituted cyclopropenes **2**–**9** was calculated in addition to **1**.[9] We first surveyed the variation in length of the C=C bond with regard to computational method (Table 2). Convergence in RHF methods is around a value of 1.27 Å; the effects of increasing basis set size was minimal. The effects of dynamic correlation were tested using a variety of techniques, including density functional techniques, Moller–Plesset theory of order 2 and the coupled cluster doubles method. The effect of each technique can be identified by focusing on the different dynamic correlation methods using the same basis set [DZ(2df,2p)]. Dynamic correlation of any type tends to increase the predicted bond length from the restricted Hartree–Fock method. Centering on the hybrid method of including dynamical correlation, and further increasing basis set size, one arrives at a convergent value for the double bond length around 1.28 Å, 0.03 Å longer than experiment. We feel it is unlikely that higher level calculations will decrease the bond length any nearer to the experimental value; thus, our best estimate of equilibrium bond length is 1.28 Å.

Given the result of the basis set analysis on **1**, we opted for a highly polarized basis set available in CADPAC, and performed computations on **1**–**9** using RHF/8s6p3d and B3PW91/8s6p3d methods (Table 3). The range of computed double bond lengths is only 0.02 Å, indicating a weak sensitivity of C(1)–C(2) length with regard to the C(3) substituent. The addition of dynamic electron correlation increases the predicted bond lengths uniformly by *ca*. 0.015 Å across the series, and makes no change in the trend. The experimentally measured value for **2** (1.279 Å) is well-bracketed by the computational predictions, but the values predicted for **1** are 0.01–0.02 Å longer than that

7 With high bond orders, *e.g.* triple bonds, X-ray methods tend to determine bond distances too short because in the refinement procedure the atom positions are shifted towards the bonding electrons. In such cases the ellipsoids are streched in the bonding direction; however, this is not the case with **1** (Fig. 1). This effect can be reduced by high angle refinements or applying a weighted scheme which increases the weights for high angle data. In our case this had only a very small effect.
8 A search of the Cambridge crystallographic data base revealed the previous record holder of shortest C=C bond in a hydrocarbon to be 3-ethenylcyclopropene **2** [ref. 2(*b*)].
9 Reported here are Restricted Hartree–Fock (RHF), density functional (DFT), hybrid density functional (HDFT), Moller–Plesset perturbation theory (MP2) (ref. 10) and coupled cluster doubles (CCD) (ref. 11) theories. These calculations were performed using CADPAC (ref. 12) and GAUSSIAN94 (ref. 13) programs. Basis sets are reported including 6-31G(ndqf,mp) (ref. 14), 6-31GE, DZ(nd,mp), (ref. 15) and the 8s6p3d basis set, where the number of f functions (q = 0–1), d functions (n = 0–3) and p functions (m = 0–3). The 6-31GE and 8s6p3d basis sets are special to CADPAC. The former basis is obtained from the 6-31G basis by (i) adding diffuse s and p functions with exponents 1/3 that of the lowest exponent in the parent basis, and (ii) using two sets of polarization functions, which are slightly on the diffuse side. The result is a basis set between DZP and TZ + 2P type basis sets in quality which is biased towards property calculations. The latter basis is one of the largest polarized double-z sets used in this study. The DFT method employed was Beck's 1988 functional (ref. 16) along with Perdew and Wang's 1991 gradient-corrected correlation functional (ref. 17), denoted BPW91. The HDFT method includes a mixture of Hartree–Fock exchange with DFT exchange-correlation, denoted B3PW91. This is Becke's 3 parameter functional (ref. 18) where the nonlocal correction is provided by the Perdew 91 expression (ref. 17). A B3LYP [correlation functional including both local and nonlocal terms provided by Lee, Yang and Parr (refs. 18, 19)] calculation is done for comparison purposes. The nature of each stationary point was uniquely characterized by analytically calculating and diagonalizing the matrix of energy second derivatives (Hessian) to determine the number of imaginary frequencies.

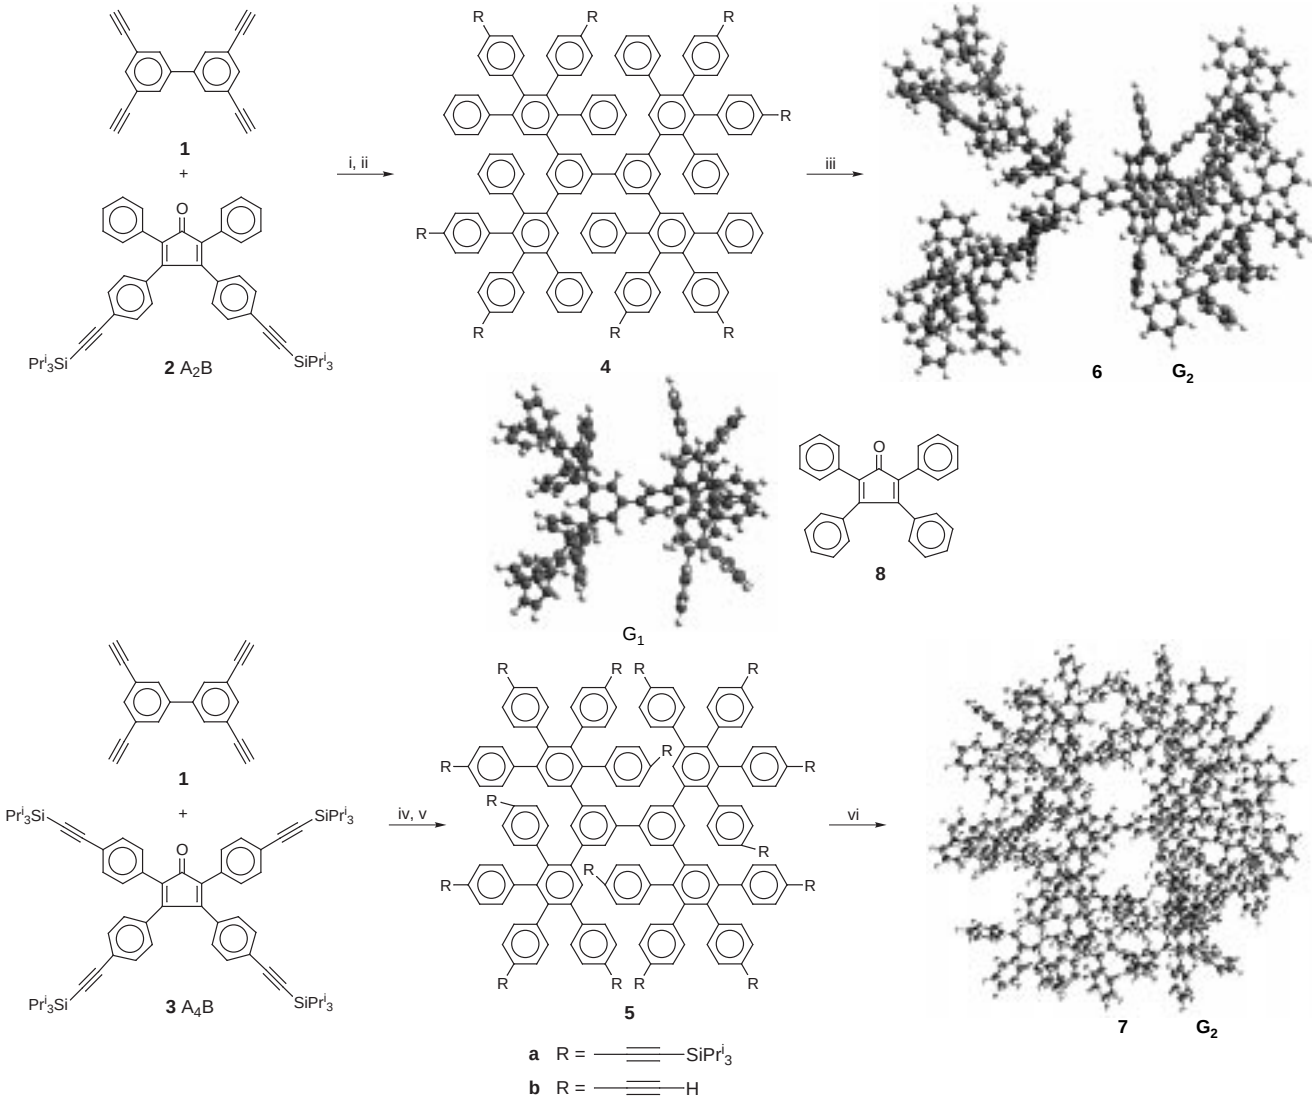
Spherical polyphenylene dendrimers *via* Diels–Alder reactions: the first example of an A_4B building block in dendrimer chemistry

Frank Morgenroth, Alexander J. Berresheim, Manfred Wagner and Klaus Müllen*†

Max-Planck-Institut für Polymerforschung, Ackermannweg 10, 55128 Mainz, Germany

The [2+4]cycloaddition of the novel A_4B building block 2,3,4,5-tetrakis(4-triisopropylsilylethynylphenyl)cyclopenta-2,4-dienone 3 with 3,3',5,5'-tetraethynylbiphenyl 1 allows the rapid synthesis of a spherical polyphenylene nanoparticle with 102 benzene rings.

Dendrimers form highly symmetric layered molecules that adopt a spherical shape at higher generations.[1,2] The three-dimensional form of dendrimers is determined by the core, the interior building blocks and the surface groups. Our synthetic approach towards polyphenylene dendrimers is based on the selective Diels–Alder cycloaddition of 3,4-bis(4-triisopropylsilylethynylphenyl)-2,5-diphenylcyclopenta-2,4-dienone **2** with the four dienophile functions of 3,3',5,5'-tetraethynylbiphenyl **1**.[3,4] Compound **2** reacts only as diene since the triisopropylsilyl (TIPS) groups make the ethynyl functions inaccessible for dienophiles (see Scheme 1). The TIPS groups of the first dendrimer generation **4a** can be removed quantitatively using Bu_4NF and the resulting **4b** can undergo another [2+4]cycloaddition with **2**. This cycloaddition-deprotection sequence allows the synthesis of a third generation dendrimer, consisting of pentaphenylbenzene units, which has a diameter of about 5 nm according to computer generated ball-and-stick models.[4] As revealed by molecular dynamics simulations on the second



Scheme 1 *Reagents and conditions:* i, Ph_2O–α-methylnaphthalene (1 : 1), 180–200 °C, 14 h, 89%; ii, Bu_4NF, THF, 25 °C, 5 h, > 98%; iii, **8**, Ph_2O–α-methylnaphthalene (1 : 1), 180–200 °C, 15 h, 86%; iv, Ph_2O–α-methylnaphthalene (1 : 1), 180–200 °C, 14 h, 77%; v, Bu_4NF, THF, 25 °C, 5 h, 87%; vi, Ph_2O–Bu^tOMe (8 : 11), 190 °C, 44 h, 62%

generation dendrimer **6**, the higher dendrimer generations represent shape-persistent nanoparticles.

Here we investigate the influence of the branching unit on the shape of the dendrimer employing **1** as core and a four-directional A_4B building block **3** rather than the A_2B building block **2**. Thereby, we introduce 2,3,4,5-tetrakis[4-triisopropylsilylethynylphenyl)cyclopenta-2,4-dienone **3** as a powerful multifunctional reagent that allows the rapid construction of a spherical polyphenylene architecture.

Cyclopentadienone **3** contains four dienophile units and one diene function and can thus be regarded as an A_4B building block which represents, to the best of our knowledge, the first example of a dendrimer branching element possessing a multiplicity higher than 3.[5] Compound **3** was prepared by the base-catalyzed condensation of 4,4'-bis(triisopropylsilyl)benzil and 1,3-bis(4-triisopropylsilylethynyl)acetone (83%, red crystals).[6] The acetone was obtained *via* the Sonogashira coupling[7] of triisopropylsilylacetylene and 1,3-di(4-bromophenyl)acetone (82%). The latter was synthesized by converting 4-bromobenzyl bromide with $Fe(CO)_5$ in the presence of NaOH under phase transfer conditions (CH_2Cl_2–H_2O; 43%).

The four-fold Diels–Alder reaction of the A_4B building block **3** with the tetraethynylbiphenyl **1** led to the first dendrimer generation **5a** (77%, white solid). After cleaving the TIPS groups (**5b**), further reaction with **3** provided a mixture of products, determined by mass spectrometry, consisting of the desired sixteen-fold Diels–Alder product, and mainly of the fourteen-fold [2+4]cycloaddition product.† In contrast, addition of tetraphenylcyclopentadienone **8** to **5b** led smoothly to the desired sixteen-fold Diels–Alder product **7** exclusively, which was isolated as a white solid in 62% yield (see Scheme 1).

The different results obtained by the reaction of **5b** with **2** or **3** can be easily rationalized by looking at ball-and-stick models, which were generated using the MM2 (85) force field with the CERIUS 2 program package and applying the Conjugate Gradient 200 algorithm (compare Scheme 1):[8] As expected, the appearances of the corresponding first generations **4** and **5** are very similar, as both dendrimers contain 22 benzene rings and differ only in the number of substituents, while having the same spatial extension. The corresponding second generations already exhibit clearly dissimilar shapes. The dendrimer **6**, with 62 benzene rings, synthesized using the A_2B building block **2**, possesses a dumb-bell like structure, whereas the use of the A_4B building block **3** leads to 'nanoball' architecture **7**, which possesses 102 benzene rings. As the second generations of both dendrimers have a maximum extension of about 4 nm, the density of benzene rings is dramatically increased in **7**. In the case of the more strongly branched dendrimer **7** the space available for a new dendrimer shell is sufficient to accommodate the incoming eighty unsubstituted benzene rings spherically around the dendrimer core. The fact that the 64 sterically demanding TIPS groups of the A_4B building blocks cannot be accommodated, proves the concept of densest packing.[9,10] The preferred formation of the fourteen-fold cycloaddition product can be understood according to Tomalia as a sterically induced stoichiometry.[11]

The obtained dendrimers exhibit unexpectedly good solubility in common organic solvents such as toluene and CH_2Cl_2. Therefore, they can be fully characterized by matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF-MS) as well as ^1H and ^{13}C NMR spectroscopy. The perfect agreement between calculated and experimentally determined *m*/*z* ratios for the dendrimers as well as GPC analysis confirm their monodispersity.§ With respect to the physical properties of the dendrimers their thermal stability is noteworthy. The thermogravimetric analysis yielded decomposition temperatures well above 450 °C for the TIPS substituted and 580 °C for the unsubstituted dendrimers under air.

The special features of the results presented above can be summarized as follows: (i) in contrast to the established concept based on metallo-organic coupling reactions for the construction of polyphenylene dendrimers[12] (as well as the closely related hyperbranched polyphenylenes),[13] the growth of the dendrimers presented here is achieved *via* [2+4]cycloaddition followed by a desilylation; (ii) using the A_4B building block **3** and the core **1** the second dendrimer generation exhibits properties such as spherical shape in spite of the core's D_{2h} symmetry and the densest packing of benzene rings which one would generally expect only for higher generation numbers; (iii) using a defined dendrimer core, the shape of the dendrimer formed depends on the cyclopentadienone used.

Our current investigations involve light scattering experiments on higher dendrimer generations as well as microscopic visualization after adsorption on substrate surfaces.

Self-assembly of (*P*)-heterohelicenediol into a four-leaf clover motif

Kazuhiko Tanaka*† and Yoshinori Kitahara

Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto 606-8224, Japan

(*P*)-2,13-Bis(hydroxymethyl)heterohelicenediol [(*P*)-1] self-assembles through a right-handed helical network of hydrogen bonds to form a four-leaf clover motif; a full turn of the helix comprises four chiral subunits which associate in a *left-handed* helical manner with a 4_3 screw axis.

The construction of highly ordered supramolecular structures has important implications not only for the developement of new materials such as nanoscale molecular devices,[1–4] but also for the synthesis of artificial systems that can mimic biological functions.[5] Among the self-assembled supramolecular architectures, such as tapes,[6] capsules,[7] spheres,[8] squares,[9] cylinders[5] and helices,[10,11] helical arrangements[12,13] are characterized by chirality based on the screw sense [right-handed (*P*) or left-handed (*M*) helicity], and hence the helicoselective (or enantioselective) synthesis of helical motifs is an active field of research in supramolecular chemistry.[14] Here we report the first example of construction of a four-leaf clover motif from optically active (*P*)-2,13-bis(hydroxymethyl)dithieno[3,2-*e*:3′,2′-*e*′]benzo[1,2-*b*:4,3-*b*′]bis[1]benzothiophene [(*P*)-**1**] (Fig. 1).[15]

Crystals suitable for X-ray crystallographic analysis were grown from a solution of (*P*)-**1** in CH_2Cl_2–acetone.‡ The stereoview of the crystal structure (Fig. 2) clearly shows that (*P*)-**1** self-assembles through a right-handed helical network of hydrogen bonds. A full turn of the helix comprises four chiral helicenediols and the pitch of the helix is 15.49 Å. The most remarkable feature of (*P*)-**1** is that the right-handed helicenediols arrange in a *left-handed* helical manner and the cloverleaf motif repeats by the 4_3 screw axis. In the supramolecular structure, one of the hydroxy functionalities of (*P*)-**1** forms an intramolecular bridge to the other hydroxy group of the same molecule and also forms an intermolecular hydrogen bond to one of the hydroxy groups of an adjacent molecule (Fig. 3). The

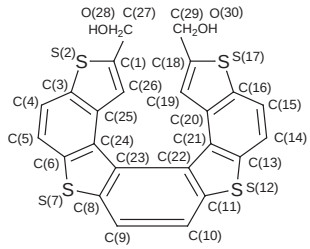

Fig. 1 Numbering scheme of heterohelicenediol

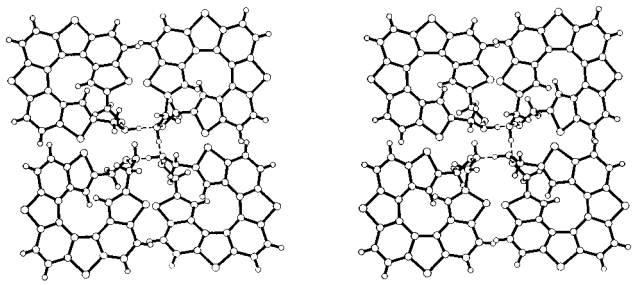

Fig. 2 A stereoview of the four-leaf clover motif of (*P*)-heterohelicenediol assembled along the *c* axis

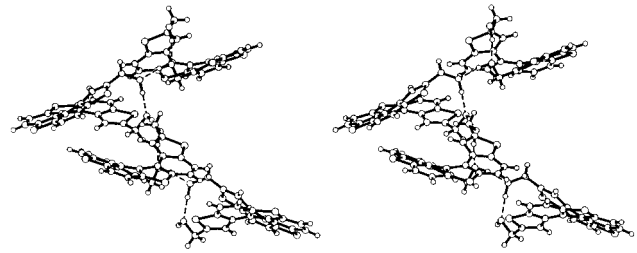

Fig. 3 Stereoview of (*P*)-heterohelicenediol from the crystallographic *b* axis

interplanar angle between the terminal thiophene rings of (*P*)-**1** is 33.83° (Table 1). This is in contrast with the guest-free racemic heterohelicenediol (*PM*)-**1** which self-assembles to form an alternate-leaf motif (Fig. 4).§ In the crystal of (*PM*)-**1**, the two stacking columns, consisting of helicenediols of the same helicity, are aligned along the *c* axis. Since each hydroxy group of (*PM*)-**1** interacts with one of the hydroxy functions of an adjacent molecule *via* an intermolecular hydrogen bond, the interplanar angle between the terminal thiophene rings increases to 44.70° (Table 1). This represents an increase of

Table 1 Interplanar angles between the adjacent rings and the terminal thiophene rings (°)

	(*P*)-**1**	(*PM*)-**1**	(*PM*)-**1**·EtOH[a]
ring(1)–ring(2)	8.40	5.82	8.29
ring(2)–ring(3)	6.92	7.70	8.29
ring(3)–ring(4)	9.73	10.46	11.63
ring(4)–ring(5)	9.35	12.72	9.33
ring(5)–ring(6)	8.73	9.84	7.10
ring(6)–ring(7)	6.33	6.61	7.30
ring(1)–ring(7)	33.83	44.70	37.96

[a] Ref. 16.

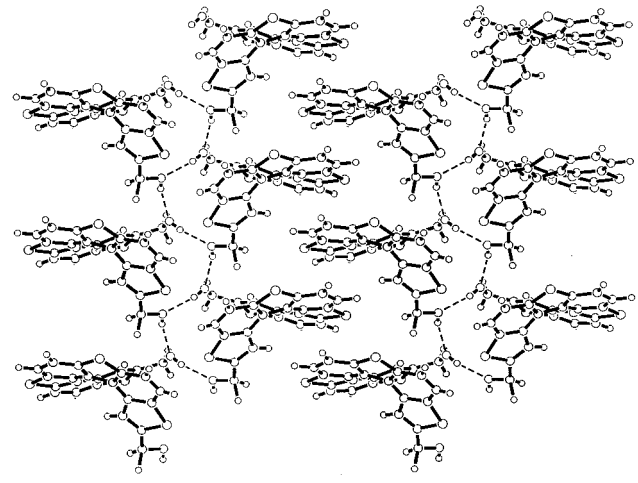

Fig. 4 Side view of the hydrogen-bonding network showing an alternate-leaf motif of racemic heterohelicenediol

10.87° or 32.1%. When the racemic heterohelicenediol (*PM*)-**1** forms an inclusion complex with EtOH through helical hydrogen-bonding, the interplanar angle decreases to 37.96°.[16] These results clearly indicate that the helicene framework exhibits significant elasticity by changing its dihedral angle. The distortion from planarity locates on the central aromatic rings of the helical framework, and therefore the dihedral angles between two adjacent rings range from 8.73 to 9.73 for (*P*)-**1** and from 9.84 to 12.72° for (*PM*)-**1**. However, the double bond character of two helicenediols are unchanged. Thus, the carbon–carbon bond distances of the outer rings range from 1.33 to 1.36 Å in the case of (*P*)-**1** and from 1.33 to 1.37 Å in (*PM*)-**1**, and the inner carbon–carbon bond distances [C(20)–C(21), C(22)–C(23) and C(24)–C(25)] are 1.42 Å for (*P*)-**1**, and in a range of 1.41 to 1.43 Å for (*PM*)-**1**. The inner carbon–carbon bond lengths in the thiophene rings [C(19)–C(20), C(21)–C(22) and C(25)–C(26)] range from 1.43 to 1.47 Å for both (*P*)-**1** and (*PM*)-**1**. The common feature of these helical geometry is that the carbon–sulfur bond distances in the thiophene rings of (*P*)-**1**, (*PM*)-**1** and (*PM*)- **1**·EtOH are uniformly lengthened from 1.71 to 1.73 Å.

The present results reveal for the first time that the helical conjugated π-electron framework of helicenediol **1** acts as a helical spring due to the pattern of hydrogen bonds.

This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas 'Organic Nonlinear Optics' (No. 09222212) from the Japanese Ministry of Education, Science, Culture and Sports.

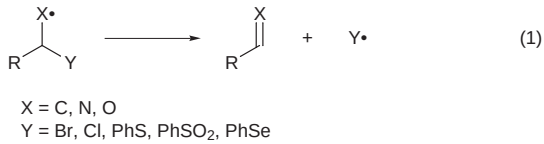
Relative β-elimination rates of heteroatoms from alkyl and aminyl radicals

Sunggak Kim*† and Jae Ho Cheong

Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon, 305-701, Korea

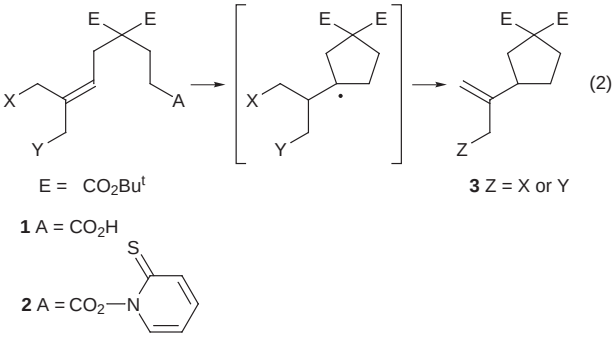
The relative β-elimination rates of heteroatoms from alkyl radicals are in the order of Br≥PhSe > PhS > $PhSO_2$ > Cl, whereas the order of PhSe > $PhSO_2$ > PhS ~ Br is observed for β-eliminations from aminyl radicals, indicating a dependence on the nature of radicals.

The β-elimination reaction of heteroatoms is one of characteristic properties of radical reactions [eqn. (1)][1] and its driving



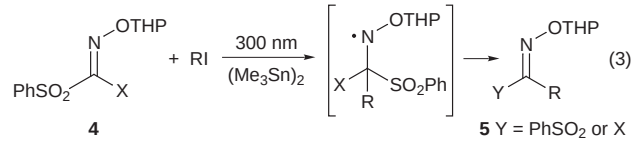
force is known to be relief of ring strain,[2] the evolution of CO_2 and SO_2,[3] or the generation of a π-bond along with the cleavage of a weaker σ-bond. The ease of β-fragmentation depends on (i) the strength of the σ-bond broken (C–Y) and also (ii) the nature of π-bonds formed (C=X).[4] In the former case, it is expected that the weaker the breaking bond is, the faster the β-fragmentation would be. As far as we are aware, there are no reports of the β-elimination of heteroatoms from aminyl radicals. We conceived that it could be possible that the relative β-elimination rates of heteroatoms from alkyl and aminyl radicals would depend on the nature of π-bonds formed and we investigated this intriguing possibility.

Although relative β-elimination rates of heteroatoms from alkyl radicals were reported previously,[6] we briefly examined the β-elimination rates using *N*-hydroxypyridine-2-thione ester **2** [eqn. (2)][7] and experimental results are shown in Table 1.

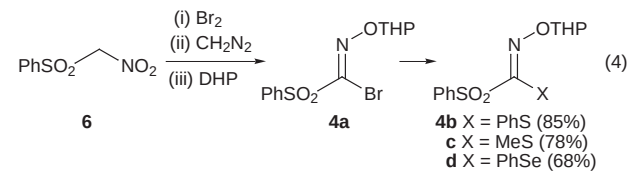


Treatment of acid **1** with *N*-hydroxypyridine-2-thione (1.2 equiv.), DCC (1.2 equiv.) and DMAP (0.1 equiv.) in CH_2Cl_2 at room temperature for 2 h afforded the thiohydroxamate **2**, which decomposed to some extent during isolation. Thus, the reaction was carried out in CH_2Cl_2 at 50 °C without isolation of **2**. To examine the relative β-elimination rates of the bromo and the phenylthio groups, when **2a** was heated at 50 °C for 5 h, the bromide was preferentially eliminated (entry 1). A same result was obtained with **2b** for the competition between the bromide and the phenylsulfonyl groups (entry 2). However, the elimination of the bromide competed more equally with that of the phenylseleno group, although the former was favored over the latter to some extent (entry 5). Furthermore, the phenylsulfonyl group underwent preferential elimination in the presence of the chloride (entry 4) and the elimination of the phenylthio group was much faster than that of the phenylsulfonyl group, although the phenylsulfonyl group underwent elimination to a small extent (3%) (entry 3).[8] When the present reactions were monitored in $CDCl_3$ by ^1H NMR spectroscopy, the allyl species **3** turned out not to be susceptible to radical addition-elimination by the radical species ejected in the elimination step. Thus, the relative rates of β-eliminations of heteroatoms from alkyl radicals are in the order of Br≥PhSe > PhS > $PhSO_2$ > Cl.

To study the effect of aminyl radicals on the β-eliminations of heteroatoms, we utilized the radical reaction of phenylsulfonyl substituted oxime ethers [eqn. (3)]. Recently, we reported free



radical acylation approaches involving alkyl radical additions to sulfonyl substituted oxime ethers as acylating agents.[9] Phenylsulfonyl bromo oxime ether **4a** was prepared by the known procedure using (phenylsulfonyl)nitromethane **6** by three-step sequence involving bromination, *O*-methylation with CH_2N_2 and the subsequent protection as a THP ether.[10] The bromide group in **4a** was further displaced by sodium thiophenoxide, sodium thiomethoxide and sodium benzeneselenoate in THF to afford **4b** (85%), **4c** (78%) and **4d** (68%) [eqn. (4)]. As shown



in Table 2, when a solution of 4-phenoxybutyl iodide, **4a** and hexamethylditin in benzene was irradiated at 300 nm for 16 h, somewhat surprisingly the bromo oxime ether was obtained in 78% yield (entry 1), indicating that the phenylsulfonyl group

was preferentially eliminated over the bromide group. This result is in sharp contrast with the above results obtained for alkyl radicals (Table 1). Similar results were also obtained with **4b** and **4c** (entries 2 and 3), showing the preferential elimination of the phenylsulfonyl group over the phenylthio and methylthio groups. However, competition between the phenylsulfonyl and the phenylseleno groups showed that the phenylseleno group was eliminated preferentially (entry 4). Attempts to study the relative β-elimination rate between the phenylthio group and bromide[10,11] were unsuccessful because the intermolecular addition of an alkyl radical onto the phenylsulfenyl bromo oxime ether (entry 5) turned out to be inefficient.

The results obtained in this study are rather interesting and indicate that phenylsulfonyl groups on aminyl radicals undergo facile elimination relative to the bromide, methylthio, and phenylthio groups. We have no clear answer why the relative rates of β-elimination of heteroatoms, particularly the phenylsulfonyl group, from alkyl and aminyl radicals are so different. When the contributing resonance structures of **7** and **4** were compared (Fig. 1), we suggest that resonance in **4** is much more important than resonance in **7**, thereby giving unusually strong carbon–bromine and carbon–sulfur bonds in **4** due to the contribution of significant double bond character. Apparently, resonance contribution from the phenylsulfonyl group is not possible.

We thank the Korea Research Foundation and OCRC for financial support, and Dr C. Schiesser, University of Melbourne, for helpful suggestions.

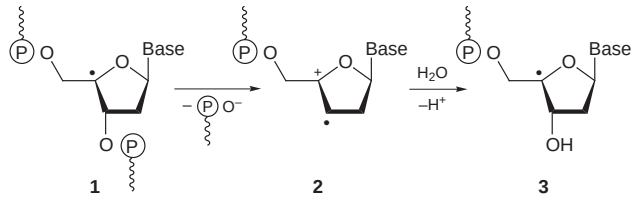
Radical-chain racemisation of tetrahydrofurfuryl acetate under conditions of polarity-reversal catalysis: possible implications for the radical-induced strand cleavage of DNA

Yudong Cai and Brian P Roberts*†

Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ

Alkanethiols with electron-withdrawing *S*-alkyl groups and silanethiols act as polarity-reversal catalysts to promote the radical-chain racemisation of (*R*)-tetrahydrofurfuryl acetate at 60 °C, while simple alkanethiols are ineffective.

There is now good evidence that, at least under anaerobic conditions, strand cleavage of DNA which involves the 4′-radical **1** proceeds as shown in Scheme 1, *via* an intermediate radical cation **2** which can subsequently trap a nucleophile to give an α- alkoxyalkyl radical of the type **3**.[1] In principle, if the radical **3** (or a similar oligonucleotide-derived α-oxyalkyl radical) were to abstract hydrogen from an undamaged strand to regenerate the 4′-radical **1**, a homolytic *chain* process for the cleavage of DNA could be established. If such a radical-chain mechanism for the destruction of DNA could be promoted when desirable in a therapeutic context (*e.g.* to amplify the effects of radiation damage to a tumour or to increase the effectiveness of the various antineoplastic agents that operate *via* radical pathways[2]), the biological implications would be of considerable importance.

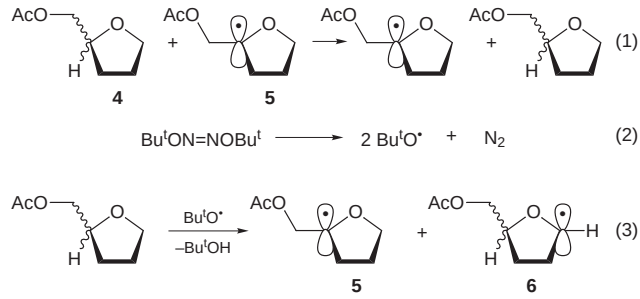


1 **2** **3**

Scheme 1

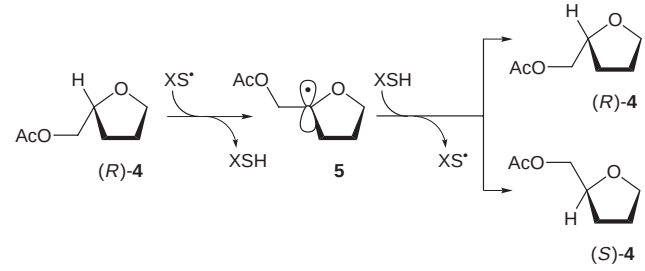
However, hydrogen-atom abstraction by **3** from the 4′-position in DNA is an (essentially) thermoneutral process that involves two radicals of almost identical electronegativity, and such reactions would be expected to be very slow at moderate temperatures.[3] The radicals **1** and **3** should be nucleophilic species, with relatively low ionisation energies, and it occurred to us that the overall transfer of hydrogen from DNA to **3** (or to another α-oxyalkyl radical) might be promoted by a suitable polarity-reversal catalyst[4,5] of the type El–H, where El• is an electrophilic radical. Here we report the results of experiments designed to investigate this general possibility, by examining the effects of polarity-reversal catalysts on the identity reaction [eqn. (1)] of tetrahydrofurfuryl acetate **4**.

The extent to which the overall reaction [eqn. (1)] takes place was judged by starting with (*R*)-tetrahydrofurfuryl acetate[6] and monitoring the enantiomeric excess (ee) of the remaining ester as a function of time, using chiral-stationary-phase GLC (Supelco β-DEX 120, 30 m × 0.25 mm bore capillary column; 0.25 μm coating containing permethylated β-cyclodextrin). When a benzene solution containing (*R*)-**4** (99.4% ee, 0.50 mol dm^{-3}), *tert*-butylbenzene or methyl benzoate (0.30 mol dm^{-3}, as an internal concentration standard for GLC analysis) and di-*tert*-butyl hyponitrite[7] (TBHN, 0.025 mol dm^{-3}) was heated at 60 °C under argon for 3 h, *ca.* 10% of **4** was consumed and the ee of the remaining (*R*)-ester was undiminished. The TBHN acts



4 **5** **6**

as a thermal source of *tert*-butoxyl radicals [eqn. (2)]‡ which, in the absence of other reagents, will abstract hydrogen from **4** to give mainly the α-alkoxyalkyl radicals **5** and **6** [eqn. (3)].§ We conclude that neither **5** nor **6** abstracts hydrogen directly from **4** to give **5** at a significant rate under the reaction conditions. The experiment was then repeated in the presence of small amounts (usually 5 mol% based on **4**) of various thiols as potential polarity-reversal catalysts, and the results are presented graphically in Fig. 1. Under these conditions, only a trace of tetrahydrofurfuryl acetate was consumed during the first 90 min, although a small amount (⩽5%) of the ester was consumed subsequently when the thiol concentration had become very low. It can be seen that while 5 mol% of a simple alkanethiol such as *tert*-dodecanethiol (mixture of isomers) or dodecane-1-thiol causes only a very small amount of racemisation of (*R*)-**4**, thiols with electron-withdrawing groups attached to sulfur bring about a significant increase in the rate of racemisation and evidently act as polarity-reversal catalysts for the overall reaction [eqn. (1)], according to the chain propagation cycle shown in Scheme 2. Thus, 1-thio-β-D-glucopyranose tetraacetate, 2,2,2-trifluoroethanethiol¶ and, in particular, triphenylsilanethiol are efficient catalysts. The more sterically-demanding triisopropylsilanethiol and the less acidic methyl thioglycolate (MeO_2CCH_2SH) were less effective while, as expected, L-cysteine ethyl ester (a model for glutathione) was totally ineffective. Of course, hydrogen-atom abstraction by XS• to form **6** followed by 'repair' to regenerate **4** is an unobservable process in the present system.‖ Abstraction of hydrogen from **4** by XS• is evidently more efficient when the substituent X is an electron-withdrawing group, probably



Scheme 2

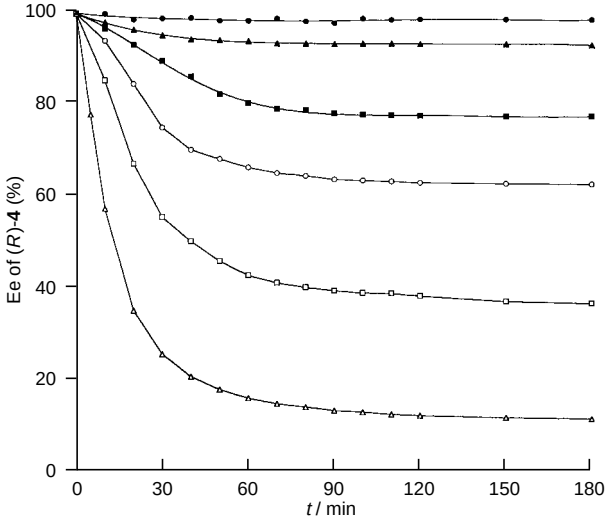


Fig. 1 The racemisation of (*R*)-tetrahydrofurfuryl acetate in benzene at 60 °C in the presence of various thiols (5 mol% based on the acetate): (●) *tert*-dodecanethiol, (▲) dodecane-1-thiol, (■) methyl thioglycolate, (○) 2,2,2-trifluoroethanethiol, (□) 1-thio-β-D-glucopyranose tetraacetate and (△) triphenylsilanethiol (in order of increasing efficiency as catalysts)

because the S–H bond is stronger and the thiyl radical is more electrophilic when the sulfur atom is relatively electron deficient.[3b,5c] The silyl group acts as a π-electron-pair acceptor.

Triisopropylsilanethiol is a less effective catalyst than triphenylsilanethiol, which may be a consequence of relatively slow transfer of a hydrogen atom from and to a tertiary site when the XS group is bulky. With 5 mol% TBHN and 5 mol% thiol catalyst, racemisation does not go to completion (see Fig. 1). Apart from depletion of the initiator, this is presumably a result of removal of thiyl radicals by self-coupling to give disulfide and, especially in the later stages of the reaction when the thiol concentration is reduced, by combination of XS$^{\bullet}$ with the radicals **5** or **6**. When the initial amount of Ph_3SiSH was increased to 10 mol%, under otherwise identical conditions, the rate of racemisation of (*R*)-**4** *decreased*, while with 2.5 mol% Ph_3SiSH the initial rate of racemisation was slightly greater than that achieved with 5 mol% catalyst, although the final ee after 3 h (33%) was appreciably larger. We interpret these results as indicating that at high thiol concentrations rotational exchange between the enantiomeric conformations of **5** becomes competitive with trapping of this radical by thiol to regenerate **4**, so that **5** begins to retain a memory of the absolute configuration of the molecule of **4** from which it was derived. It follows that the rate of racemisation provides a lower limit for the rate of the overall reaction [eqn. (1)] under conditions of polarity-reversal catalysis.

We conclude that the thermoneutral reaction shown in eqn. (1) is subject to polarity-reversal catalysis by appropriately substituted thiols. Provided that the possible protective effect of glutathione can be overcome (perhaps by reversible binding of the polarity-reversal catalyst to DNA), it may be possible to apply this principle to amplify radical-induced damage to DNA *in vivo*, especially in the oxygen-deficient environment present in many types of tumour cell.[9] Encouragingly, racemisation of (*R*)-**4** still takes place in the presence of *both* Ph_3SiSH (5 mol%) and *tert*-dodecanethiol (5 mol%), albeit at an initial rate about six times slower than that observed in the presence of the silanethiol alone.

These results will also have implications for the design of enantioselective radical-chain reactions based on the use of homochiral thiols as polarity-reversal catalysts,[5e] when it is obviously important to *suppress* racemisation of the product.

We are very grateful to Drs D. J. Madge and A. B. Tabor for useful discussions and to Dr P. Anastasis (Kiralchem Ltd.) for all his help in supplying the enantiopure tetrahydrofurfuryl alcohol from which (*R*)-**4** was prepared.

‡ The half-life of TBHN at 60 °C is *ca*. 55 min [ref. 7(*a*)].

§ When a cyclopropane solution containing **4** and di-*tert*-butyl peroxide was irradiated with UV light while the sample was in the microwave cavity of an EPR spectrometer (ref. 8), overlapping EPR spectra of **5** and **6** were observed between 180 and 280 K; at 270 K the value of [**5**]/[**6**] was *ca*. 0.7. At 270 K, the radical **5** showed $a(2\ H_{\beta}^{exocyclic})$ 8.60, $a(2\ H_{\beta})$ 26.14, $a(2\ H_{\gamma})$ 0.75 and $a(2\ H_{\delta})$ 2.08 G, and g 2.0030; the radical **6** showed $a(1\ H_{\alpha})$ 13.50, $a(1\ H_{\beta})$ 30.89, $a(1\ H_{\beta}')$ 25.26, $a(2\ H_{\gamma})$ 0.75 and $a(1\ H_{\delta})$ 2.25 G, and g 2.0032. The hyperfine splitting constants confirm that the radical **5** preferentially adopts the conformation shown, in which the exocyclic C_{β}-O bond eclipses the formal C_{α}–$2p_{\pi}$ SOMO, although two-fold rotation about the C_{α}–C_{β} bond is evidently sufficiently fast at 270 K to render the two faces of the ring magnetically-equivalent. However, below *ca.* 260 K, selective line-broadening was observed in the spectrum of **5**, indicating that rotational exchange between the two enantiomeric conformations is no longer fast on the EPR timescale.

¶ This thiol is volatile (bp 36 °C) and some could have been lost by evaporation during the reaction.

‖ While the *tert*-butoxyl radical abstracts hydrogen at comparable rates from the two carbon atoms adjacent to the ring-oxygen in **4**, it is likely that thiyl radicals (especially the less bulky ones) will be more selective and give mainly **5** by attack at the tertiary CH group.

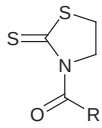
X-Ray crystal structure of 1,6-diacetyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril, a highly twisted acetamide

Christopher N. Cow, James F. Britten and Paul H. M. Harrison*†

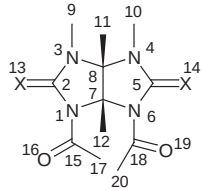
Department of Chemistry, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada L8S 4M1

In the structure of 1,6-diacetyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril, as determined by X-ray crystallography, one acetyl group lies essentially coplanar with the attached thioureido ring (τ = 2.6°), while the plane through the other acetyl group is highly twisted (τ = 55.0°) relative to the corresponding thiourea moiety to which it is appended.

Twisted amides, in which interaction between the nitrogen lone pair and the carbonyl π system is diminished or prevented, have attracted considerable interest, since they display unusually high reactivity towards nucleophiles, and have thus been proposed to act as models for the enzymic activation of peptide units.[1,2] In many cases, the amide bond is forced into a twisted conformation as a result of the covalent chemical bonding within the molecule,[2,3] while in others, the twist results either from enforced pyramidalization of nitrogen,[4] or else from steric effects.[1,5,6] In the latter regard, for example, Yamada[6] reported that 3-pivaloyl-1,3-thiazolidine-2-thione **1** has a twist angle τ =



1 R = Bu^t
2 R = Me



3 X = S
4 X = O

74.3°, where τ is defined as 1/2 (ω_1 + ω_2), and ω_1 and ω_2 are the O=C–N–C and C–C(O)–N–C′ dihedral angles, as defined by Winkler and Dunitz,[7] with the alteration suggested by Yamada.[6] The N–C(O) bond in **1** is long (1.448 Å) when compared to 3-acetyl-1,3-thiazolidine-2-thione **2**, (1.413 Å), which also possesses a much smaller twist angle (τ = 20.1°). Compound **1** is highly reactive towards nucleophiles, even at neutral pH.[1,6,8] In contrast, 3-pivaloyl-1,3-oxazolidine-2-one is unreactive;[1] the presence of the thione moiety thus contributes to the twisting of the amide bond in **1**.

We have shown that glycoluril derivatives can act as templates to facilitate a rapid, intramolecular Claisen-like condensation reaction between acyl groups attached to N(1) and N(6).[9] We have proposed that this process is facilitated in part by the comparatively high electrophilicity of the acyl groups attached to the glycoluril moiety, as has been observed for tetraacetylglycoluril by Hase and Kuhling as well as by Tice and Ganem.[10] In view of the steric strain between the two *N*-acyl groups attached to the same side of a glycoluril system, and the close structural relationship between glycolurils and oxazolidinones,[9] we reasoned that this electrophilic character might result from twisting around the bond between the glycoluril and the attached acyl groups. To test this hypothesis, we examined the X-ray crystal structures of several acylglycolurils. Herein, the X-ray crystal structure of 1,6-diacetyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril‡ **3** is described. The results show that steric crowding in this derivative enforces a highly twisted conformation in *one* of the two acetyl groups in **3**.

The preparation of diacetyl dithioglycoluril **3** has been reported previously.[11] Crystals of **3** were obtained by slow evaporation of a solution in CH_2Cl_2.§ ORTEP drawings of two orthogonal views of the molecule are given in Fig. 1, along with selected bond lengths. In this structure, one acetyl group is held close to coplanar with the thioureido ring of the glycoluril (τ = 2.6°), while the other is twisted significantly out of the ureido ring plane, with τ = 55.0°. This out of plane twist is accompanied by a significant lengthening of the N–C(O) bond, from 1.397(3) Å for the coplanar acetyl group [N(1)–C(15)] to 1.447(3) Å for the twisted amide [N(6)–C(18)]. Careful examination of the crystal packing in **3** showed no close non-bonded interactions around the twisted acetyl group.¶ Although the protons of both acetyl groups appeared at the same chemical shift by NMR analysis, at least down to −60 °C, IR spectroscopy of **3** confirmed the presence of one twisted amide bond in solution. Thus, the spectrum‖ exhibits two distinct C=O stretching absorptions, at 1738 and 1680 cm^{-1}. In contrast, monoacetyl dithioglycoluril[11] exhibits a single stretch at 1681

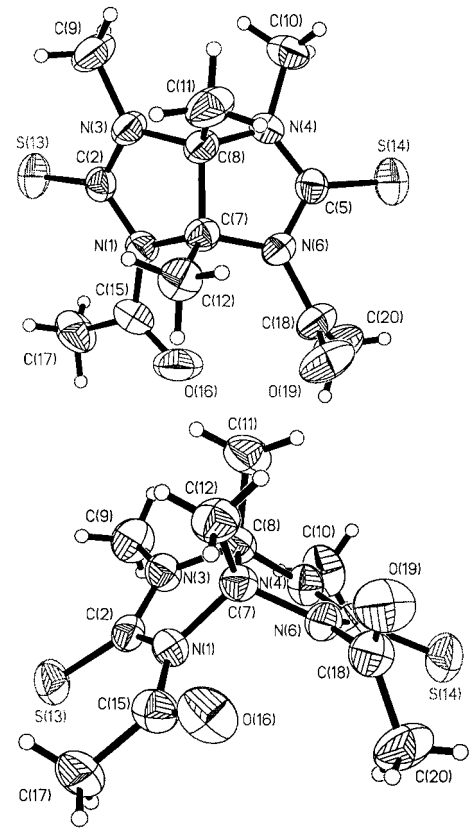


Fig. 1 Two approximately orthogonal ORTEP diagrams of the X-ray crystallographic structure of glycoluril **3**. Selected bond lengths (Å) and angles (°): N(1)–C(2): 1.394(3), N(1)–C(15) 1.397(3), N(1)–C(7) 1.505(3), C(2)–S(13) 1.650(2), C(5)–N(6) 1.367(3), C(5)–S(14) 1.660(2), N(6)–C(18) 1.447(3), N(6)–C(7) 1.461(3), C(15)–O(16) 1.211(3), C(18)–O(19) 1.190(3), C(5)–N(6)–C(18) 122.6(2), C(2)–N(1)–C(15) 129.9(2).

cm^{-1}. This shift to higher frequency with increasing τ is analogous to that reported by Yamada.[6] Thus, the twisted and untwisted acetyl groups apparently interconvert on a time scale between that of NMR and IR analysis.

The observed twist angle is unique to the best of our knowledge for any acetamide: **3** is much more twisted than **2**, and approaches the value for the far more hindered pivaloyl derivative **1**, without requiring the presence of the *tert*-butyl group for steric interaction. The presence of sulfur plays an important role in this effect, since the oxygen analog **4** has τ = 1.5 and 21.6° for the untwisted and twisted acetyl groups respectively, but otherwise resembles **3** in geometry.[12] The twist in glycolurils **3** and **4** is probably the result of unfavourable electrostatic interactions between the two acyl oxygen atoms, which would be forced into close proximity if both acetyl groups were to remain coplanar with their respective attached ureido rings. The larger twist in **3** could result from further steric interactions between the acyl methyl group and the thione (*cf.* **2**); however, the lack of twisting of one acetyl group in **3** suggests that this effect is not major. Rather, we prefer to explain the twist as being due to electron density on nitrogen being pushed into the thione in **3** to a greater extent than into the corresponding carbonyl group in **4**.[14] This effect results in less overlap of the nitrogen lone pairs with the carbonyl groups of the twisted acetyl moieties. The unfavourable interaction of the two acyl oxygen atoms can thus more readily be mitigated in **3** by twisting one acetyl group into the observed twisted conformation. The distances between the two acyl oxygen atoms are 3.03 Å in **3** and 2.84 Å in **4**. One amide resonance interaction in **3** is thus almost fully maintained, while that in the twisted acetyl group is severely compromised. This explanation is consistent with greater electron density on N(6) than on N(1) which results in an increased bond length for N(1)–C(2) compared to N(6)–C(5). Also, shortening of the N(6)–C(7) and concomitant lengthening of the C(7)–N(1) bonds, as well as the tilt of the C(12) methyl group towards the N(1) side of the molecule, and other distances and angles on the acyl-substituted side of **3** are fully in agreement with our interpretation.

Whether activation of the acyl carbon of **3** as a result of this twist enhances the intramolecular Claisen-like condensation of diacylglycolurils is under investigation. It is interesting to speculate that similar unfavourable interactions between a substrate amide carbonyl oxygen atom and another negatively polarized oxygen functionality in a protease could provide a mechanism for twisting of the substrate amide bond prior to nucleophilic attack by water.

§ *Crystal data* for **3**: $C_{12}H_{18}N_4O_2S_2$, M = 314.42, T = 300 K, monoclinic, space group $P2_1/n$ (no. 14), a = 10.1648(1), b = 14.4512(3), c = 10.2116(2) Å, β = 99.881(1)°, V = 1477.77(4) Å^3, Z = 4, D_x = 1.413 Mg m^{-3}, graphite monochromated Mo-Kα rotating anode radiation, λ = 0.71073 Å, μ = 3.67 cm^{-1}, crystal size 0.3 × 0.2 × 0.1 mm, 12 100 reflections (3035 unique) with θ > 26.5° measured using a Siemens SMART CCD area detector; R_{int} = 0.040 after SADABS absorption correction ($T_{min,max}$ = 0.684, 0.940); full-matrix least-squares refinement on F^2 using SHELXTL software, $wR2$ = 0.123 for all data, $R1$ = 0.047 for 2150 reflections with $I > 2\sigma$, 254 parameters, S = 1.071, non-hydrogen atoms anisotropic, hydrogens isotropic; residual $\Delta\rho_{min,max}$ = −0.195, 0.226 e Å^{-3}. CCDC 182/840.

¶ There appears to be only one other reported crystal structure for an acylglycoluril, that of 1,4-dinitro-3,6-diacetylglycoluril (ref. 13), which is described as having only a small twist angle. In this case, similar arguments were made in relation to the crystal packing not influencing the twist of the acyl groups.

‖ The FT-IR spectrum of **3** was recorded in $CHCl_3$, on a Bio-Rad SPC 3200 spectrophotometer.

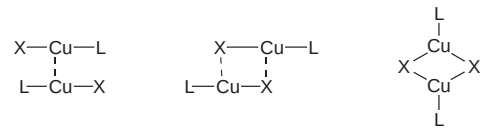
Association of two-coordinate copper(I) complexes: switching on and off Cu···Cu, ligand···ligand and Cu–ligand interactions

Xiang-Yang Liu, Fernando Mota, Pere Alemany, Juan J. Novoa* and Santiago Alvarez*†

Departament de Química Inorgànica and Departament de Química Física Universitat de Barcelona, Diagonal 647, 08028 Barcelona, Spain

A combined theoretical *ab initio* and structural database study is presented of the different interactions that allow two-coordinate copper(I) molecules to associate, from weak interactions to chemical bonds, giving rise to different structures.

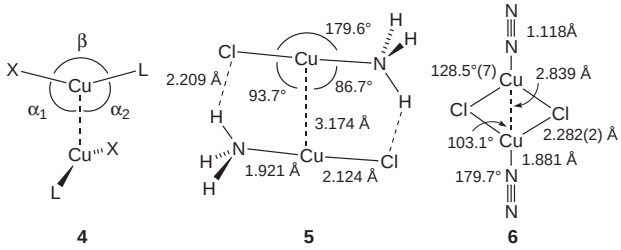
Copper(I) complexes[1,2] with stoichiometry CuXL appear as bimolecular aggregates with Cu···Cu (**1**, with the two monomers in an eclipsed or a rotated conformation) or Cu···X (**2**) contacts, or forming dimers with a cyclic Cu_2X_2 core as in **3**, or



1 **2** **3**

intermediate geometries. Also binuclear complexes with bidentate ligands bridging two copper atoms present molecular structures topologically equivalent to **1**. The Cu···Cu distances in these compounds span a large range (from 2.6 to 3.5 Å), suggesting the existence of weakly bonding interactions between the d^{10} ions, similar to those extensively studied for the related silver(I) compounds.[3–6]

The first semiempirical studies of bimolecular copper(I) aggregates,[7] based on extended Hückel calculations, proposed that mixing of the occupied d_{z^2} with the empty p_z atomic orbitals would convert the repulsion between the closed d shells into a weak bonding interaction. *Ab initio* studies have been reported for copper(I) complexes with monoatomic bridges,[8,9] and for the association between rigid monomers in $[Cu(PH_3)Cl]_2$ or in the interpenetrated networks of Cu_2O.[10,11] However, the rich structural chemistry of the [CuLX] groups outlined above has not been analyzed in detail and an explanation for the factors that determine the choice between structures **1**–**3** is still needed. For this reason, we present here the results of a theoretical *ab initio* MP2 (triple-ζ + polarisation basis set) study of the intermolecular interactions between two-coordinate copper(I) complexes in the model compounds $[Cu(NH_3)Cl]_2$, $[Cu(N_2)Cl]_2$ and $[Cu(PH_3)Cl]_2$, combined with a structural database analysis.‡ The structural parameters that describe the geometry of a bimolecular aggregate **4** are the bond angle β, the



4 **5** **6**

intermolecular angles Cu–Cu–Cl (α_1) and Cu–Cu–E (α_2, E = N, P), and the torsion angle Cl–Cu–Cu–Cl (τ).

The most remarkable features of the optimized structure of $[Cu(NH_3)Cl]_2$ **5** are its eclipsed conformation, a relatively long Cu···Cu distance and the existence of short intermolecular N–H···Cl contacts. A dimer of type **3** with bridging chloro ligands was explored for $[Cu(NH_3)Cl]_2$, but no minimum was found for such a structure or for the alternative **2**, and the hydrogen-bonded structure **5** was always obtained in the optimization procedure. Nevertheless, a strong bonding interaction exists between the two bent monomers in a rhombic structure **3** of $[Cu(NH_3)Cl]_2$ [−40 kcal mol^{-1}] although the energy required to bend the monomers (17 kcal mol^{-1} per monomer) makes the bonding energy relatively small (−7 kcal mol^{-1}). Hence, the intermolecular aggregate of type **5** with two hydrogen bonds is more stable (bonding energy −22 kcal mol^{-1}) than the rhombic form at the present level of computation. The choice of a ligand with weaker or no hydrogen bonding capabilities, such as PH_3 or N_2 in $[Cu_2L_2Cl_2]$ (L = PH_3 or N_2), makes a structure of type **1** less favorable, with only a weak Cu···Cu interaction left. Therefore, structure **3** becomes the most stable one in these cases, with dissociation energies of 17 and 18 kcal mol^{-1} for L = PH_3 and N_2, respectively (optimized structural parameters for the latter shown in **6**). Notice that the halophosphine complexes of stoichiometry $Cu(PR_3)X$ crystallize with structure **3** (13 structures) predicted to be more stable by our calculations, except for those with the bulkiest phosphines which give isolated monomers (four structures).

We analyzed in some detail the potential energy surface of $[Cu(NH_3)Cl]$ in its staggered conformation (τ = 90°), in which both ligand···ligand and ligand···metal interactions are minimized. The interaction between two linear $[Cu(NH_3)Cl]$ monomers (with $\alpha_1 = \alpha_2$ = 90°) is found to be attractive by 1–3 kcal mol^{-1} for all the range of distances between 2.5 and 5.0 Å. The bonding energy presents a maximum (−3.2 kcal mol^{-1}) at Cu···Cu 3.004 Å, similar to the values reported by Pyykkö *et al*. for $[Cu(PH_3)Cl]_2$ with a similar geometry,[10] and to that found for the interaction between rigid networks in Cu_2O.[11] They probably indicate the existence of a weakly bonding Cu···Cu interaction in the staggered form, which should coexist with the stronger ligand···ligand hydrogen bonding in the most stable eclipsed structure **5**. Bending the monomers does not improve the intermolecular interaction, although aggregates in which β is as small as 165° are still stable toward dissociation into linear monomers. Interestingly, the Cu···Cu distance is predicted to shorten for smaller bond angles (Fig. 1, triangles), a behavior that can be also found for the experimental data (Fig. 1, squares and circles for inter- and intra-molecular contacts, respectively).The aggregate in the eclipsed conformation is stabilized by slipping the two monomers (*i.e.* α_1 = 87°, α_2 = 93° and β = 177°), while the Cu···Cu distance (2.694 Å) is significantly shortened.

Further support for the bonding nature of the Cu···Cu contact in both its eclipsed and staggered forms has been obtained from a topological analysis[12] of the calculated electron density of $[Cu(NH_3)Cl]_2$. A bond critical point was found between the two Cu atoms in $[Cu(NH_3)Cl]_2$, with electron densities of 0.017 and 0.028 for the eclipsed and staggered structures, respectively, consistent with a weak bonding interaction. The values found for all characteristic parameters of the critical points are similar to those for closed shell interactions such as the O–H···O

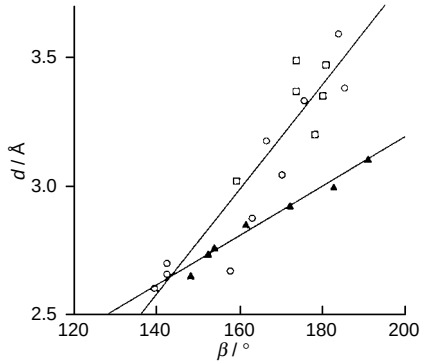


Fig. 1 Optimized Cu···Cu distance as a function of the bond angle β for the dimer $[Cu(NH_3)Cl]_2$ (triangles). Structural data for intermolecular (squares) and intramolecular (circles) contacts with flexible bridging ligands in an eclipsed conformation also plotted for comparison.

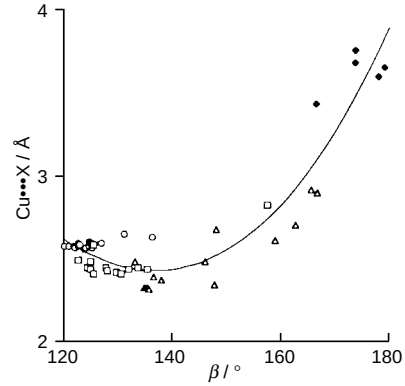

Fig. 2 Longest Cu···X distance as a function of the bond angle β for bimolecular aggregates $[CuLX]_2$ of types **1** and **2**, and for dimers **3**, where X = Cl (triangles, 13 structures), Br (squares, 14 structures), I (circles, 21 structures) or N (diamonds, 5 structures)

hydrogen bonds (see ref. 12, p. 292). In addition, bond critical points between the hydrogen and chlorine atoms in the eclipsed conformer confirm the existence of inter-ligand hydrogen bonds. A previous study of the electron density in a bridged silver(I) binuclear complex also showed the bonding nature of the Ag···Ag interaction.[13] It is interesting to stress that in $[Cu(NH_3)Cl]_2$ there is Cu···Cu bonding even if the copper atoms are 3.174 Å apart. In contrast, a similar analysis of the electron density of the rhombic structure of $[Cu(N_2)Cl]_2$, with a shorter Cu···Cu distance (2.839 Å), shows no bond critical point between the copper atoms. These results clearly show that it is the molecular topology, not the distance, that determines the existence of a Cu···Cu bonding interaction. Such results are consistent with the importance of the d_{z^2}–p_z hybridization[4,7] for the Cu···Cu interaction (possibly a part of the important correlation effects in post Hartree–Fock calculations[5]): in the intermolecular aggregate $[Cu(NH_3)Cl]_2$ the empty p_z orbital of Cu can participate in the Cu···Cu interaction, and a bond critical point is found between the copper atoms. In contrast, in the optimized structure of $[Cu(N_2)Cl]_2$, the p_z orbital is involved in metal–ligand bonding (corresponding to a formal sp^2 hybridization at Cu), the d_{z^2}–p_z donor–acceptor interaction should be quenched, and no Cu···Cu bond critical point is found.

The variety of structures found for the bimolecular aggregates of the [CuLX] compounds can be explained taking into account the reluctance of the monomers to bend, together with the variety of intermolecular interactions available to them: (*i*) weak Cu···Cu bonding interaction, (*ii*) intermolecular hydrogen bonds between ligands, (*iii*) new Cu–X bonds (when the X ligands have unshared electron pairs), and (*iv*) steric hindrance imposed by highly bulky ligands L that may prevent two monomers from approaching close enough to allow bonding interactions. For instance, a Cu···Cu contact at 2.810 Å is found in a staggered conformation with no supporting metal–ligand or hydrogen-bonding interactions in $[Cu(pyFc)_2][CuCl_2]$ [pyFc = 1,1′-bis(2-pyridyl)octamethylferrocene].[14] On the other hand, the hydrogen-bonded structure **5** found for our model compound has an experimental counterpart in $[Cu(Me_4pip)Br]$[15] (Me_4pip = 2,2,6,6-tetramethylpiperidine), which presents a N–H···Br distance of 2.653Å and a Cu···Cu distance of 3.362 Å.

The attractive Cu···X interaction predicted in our calculations for $[Cu(L_2)Cl]_2$ (L = PH_3, N_2) that may result in the formation of a rhombic dimer of type **3** is in keeping with the coordinative unsaturation of Cu^I in two-coordinate complexes, manifested in their well known tendency to form three- or four-coordinate compounds.[1,2] In fact, one can view the different structures experimentally found as snapshots along the pathway that takes one from bimolecular aggregates of type **1** to dimers of type **3**, along which the Cu···X distance and the bond angle β are expected to decrease in a concerted way. This is precisely what is found (Fig. 2) for the structurally characterized dimers of type **3** and those weakly bound aggregates of type **1** or **2** (with X = Cl, Br, I or N). Alternatively, the [CuLX] monomers associate through Cu···X contacts forming chains of trigonally coordinated Cu atoms, that have been structurally characterized for X = L = Br.[15] When the two ligands have an unshared electron pair as in the $[CuX_2]^-$ monomers, two Cu···X contacts per molecule can be formed, thus giving chains of tetrahedrally coordinated Cu atoms, as frequently found in the salts of the $[CuX_2]^-$ anions (X = Cl, Br, or I).

Parallel synthesis of alkyl methacrylate latexes for use as catalytic media

Paul D. Miller and Warren T. Ford*†

Department of Chemistry, Oklahoma State University, Stillwater, OK 74078, USA

Among thirty-two anion exchange latexes prepared by parallel synthesis, those containing 2-ethylhexyl methacrylate units are the most active as catalytic media for alkaline hydrolysis of *p*-nitrophenyl alkanecarboxylates.

Cationic polymers and colloids, such as soluble polyelectrolytes,[1] macroscopic anion exchange resins,[2] surfactant micelles,[1,3] and 0.2 μm diameter latex particles[4] in aqueous media catalyze reactions of anions with uncharged organic compounds. The catalytic activities are due primarily to high local concentrations of the anionic and uncharged reactants in the small volume fraction of the polymer or colloid phase or pseudophase in the aqueous mixture, although enhanced intrinsic rate constants sometimes contribute. Amounts of less than 1 mg ml^{-1} of polystyrene latexes containing quaternary ammonium anion exchange sites increase the rate of *o*-iodosobenzoate-catalyzed hydrolysis of *p*-nitrophenyl diphenyl phosphate up to 6300 times faster than in water alone.[4] These rate enhancements in anion exchange latexes are as high or higher than those in cationic micelles,[5] and the activity persists at very low particle concentrations, whereas surfactants have high catalytic activity only above the critical micelle concentration.

An important potential application of colloidal catalysts is hydrolytic decontamination of toxic organophosphates, phosphonates and fluorophosphonates which are widely used as insecticides and are stockpiled as chemical warfare agents.[6] However, these polystyrene latex particles failed to promote the hydolysis of diisopropyl fluorophosphate (DFP) in pH 11 aqueous media,[7] probably due to an unfavorable partition coefficient of the aliphatic DFP into the aromatic polystyrene latex particles. Reasoning that aliphatic polymers would absorb larger amounts of aliphatic reactants, we synthesized a family of cationic latexes from copolymers of alkyl methacrylates and vinylbenzyl chloride and tested their activities for basic hydrolysis of active esters.

Diversity strategies for the synthesis of biologically active compounds are employed at all major pharmaceutical companies, have been used in search of superconductive, magnetic, and phosphorescent materials,[8] and have been used to prepare polymer catalysts.[9] One widespread method is the combinatorial synthesis of different compounds in polymer beads that can be separated and tested individually. Since latex particles are too small to be separated as single beads, we employed a parallel method to prepare a diverse series of alkyl methacrylate-based catalysts.

Twenty-nine latex copolymers of 25 mass% vinylbenzyl chloride (VBC, 70 : 30 *m* : *p*) and 73 mass% aliphatic methacrylates were prepared on a 500 mg scale using 1% divinylbenzene to cross-link the particles, 1% (*m*,*p*-vinylbenzyl)-trimethylammonium chloride to stabilize the particles during growth, and 2,2′-azobis(*N*,*N*′-dimethyleneisobutyramidine) dihydrochloride as a water-soluble radical initiator. The latexes differed in the number and combination of aliphatic monomers present. Polymerizations were carried out using sets of 12 test tubes, each containing a different mixture of monomers and a 7 mm stirring bar. The test tubes were supported in a 60 °C water bath on a multiplate magnetic stirrer. Anion exchange sites in the form of quaternary ammonium groups were introduced to six latexes at one time in separate vials in a sealed pressure reactor by reaction of the vinylbenzyl chloride component with either trimethylamine (TMA) at 60 °C or tributylamine (TBA) at 95 °C. Methanol was added to the vials and to the reactor to promote permeation of the polymers by the amines and to equalize pressure inside and outside the vials. Each quaternized latex was purified by repeated washing and ultrafiltration through a 0.1 μm membrane filter on a syringe. The resulting anion exchange particles contained 19–20 mol% of quaternary ammonium units (Fig. 1). Representative samples were 130–140 nm in diameter by TEM measurements.

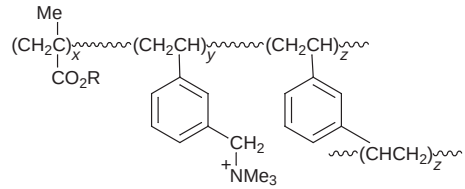

Fig. 1 Structure of TMA-quaternized latexes

Table 1 presents the results of screening the catalytic activities of 0.6 mg ml^{-1} alkyl methacrylate latexes for hydrolysis of *p*-nitrophenyl (PNP) hexanoate (Scheme 1) in pH 9.4 borate buffer solution.

Rate enhancements relative to rates in the absence of latex ranged from 2.3 for the polystyrene–TMA latex (15 in Table 1)

Table 1 Observed rate constants for hydrolysis of PNP–hexanoate in latex dispersions

Latex	Methacrylate[a,b]	$10^3\ k_{obs}/s^{-1}$
1	Butyl	2.0
2	Isobutyl	2.1
3	2-Chloroethyl	1.8
4	Tetrahydrofurfuryl	2.3
5	2-Ethylhexyl	4.1
6	Butoxyethoxyethyl	1.9
7	Ethoxyethoxyethyl	1.8
8	2-Ethylbutyl	2.0
9	*n*-Hexyl	2.1
10	*n*-Octyl	3.1
11	*n*-Decyl	3.3
12	*n*-Dodecyl	3.5
13	Tetrahydropyranyl	1.8
14	Furfuryl	1.9
15	Polystyrene	0.8
16	Butyl (TBA)	5.1
17	Polystyrene (TBA)	3.9
18	2-Ethylhexyl (TBA)	5.4

[a] All latexes were quaternized with trimethylamine except 16, 17 and 18 which were quaternized with tributylamine. [b] Latex concentration was 0.6 mg ml^{-1}, quaternary ammonium ion concentration $[N^+]$ = 62 μM, and substrate concentration 2.5 μM in 0.02 M borate buffer (pH 9.4) at 30.0 °C. Psuedo-first-order rate constants were calculated for formation of *p*-nitrophenoxide measured by increase of absorbance at 410 nm over the first 20% conversion. The k_{obs} values were reproducible to within 5% from triplicate measurements with each latex, and from triplicate preparations of latexes 1, 5 and 15–18. k_w for the reaction in the absence of latex was $3.26 \times 10^{-4}\ s^{-1}$.

Table 2 Intraparticle rate constants and equilibrium constants

	Styrene		Butyl MA		2-Ethylhexyl MA	
PNP ester	$10^3\ k_L/s^{-1}$	$10^{-3}\ K$/ dm^3 mol^{-1}	$10^3\ k_L/s^{-1}$	$10^{-3}\ K$/ dm^3 mol^{-1}	$10^3\ k_L/s^{-1}$	$10^{-3}\ K$/ dm^3 mol^{-1}

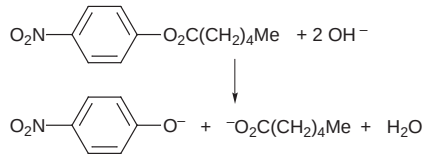
Octanoate	5.7	69	5.3	74	5.1	88



Scheme 1

to 16.5 for the 2-ethylhexyl methacrylate–TBA latex (18), and all alkyl methacrylate–TMA latexes were more active than the polystyrene–TMA latex. There was a sizable increase of activity on increase of the alkyl chain length from hexyl (9) to octyl (10) but only smaller increases between other pairs of C_{2n}-alkyl methacrylate latexes (1, 9–12). The branched 2-ethylhexyl methacrylate latex (5) was more active than the linear octyl methacrylate latex (10) having the same number of carbon atoms. Fourteen more TMA-quaternized latexes (not shown) containing mixtures of two methacrylate monomers and VBC gave rate constants between those of the latexes in Table 1 containing the same individual monomers. Finally Table 1 indicates that particles containing TBA sites (16–18) are more active than those containing TMA sites (1,5,15).

Activities of the styrene, butyl methacrylate and 2-ethylhexyl methacrylate-based latexes were measured at 5–6 different particle concentrations. Pseudo-first order intraparticle rate constants (k_L) for the hydrolysis of PNP-acetate, hexanoate, and octanoate and equilibrium binding constants (K) of the PNP ester to quaternary ammonium ion sites in the latex were calculated from double reciprocal plots of duplicate measurements of each rate constant using eqn. (1), where k_w is the rate

$$1/(k_{obs}-k_w)=1/(k_L-k_w)K[N^+] + 1/(k_L-k_w) \quad (1)$$

constant in the absence of latex.[10] (A 'binding constant' of the nonionic PNP ester to the ion exchange sites is a misnomer. 'Partition coefficient' would be better, but the binding constant formalism[10] is easy to apply.) The results are reported in Table 2.

The major differences in the activities are due to the binding constants: the longer the aliphatic chain of the PNP ester, and the more lipophilic the quaternary ammonium ion, the greater the binding constant. The much larger increases in the binding constants from polystyrene–TMA to polystyrene–TBA than with the corresponding methacrylate latexes is due to the TBA increasing the aliphatic character of aromatic latexes more than of aliphatic latexes.

Parallel synthesis has enabled rapid evaluation of 32 latex catalysts and selection of the most informative ones for analysis of intraparticle rate constants and binding constants. This diversity approach can be used to identify active polymer catalysts for many other important chemical reactions.

This research was supported by the U.S. Army Research Office.

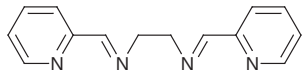
From helicate to infinite coordination polymer: crystal and molecular structures of silver(I) complexes of readily prepared di-Schiff bases

Paul K. Bowyer, Keith A. Porter, A. David Rae, Anthony C. Willis and S. Bruce Wild*†

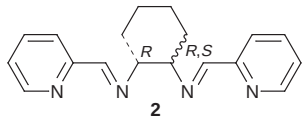
Research School of Chemistry, Institute of Advanced Studies, Australian National University, Canberra, ACT 0200, Australia

The readily prepared di-Schiff base of pyridine-2-aldehyde and ethane-1,2-diamine 1 reacts with silver(I) tetrafluoroborate to form by self-assembly the double-stranded D_2-helicate (±)-$[Ag_2\mathbf{1}_2](BF_4)_2$; the corresponding Schiff base of (1*R*,2*R*)-cyclohexane-1,2-diamine [(*R*,*R*)-2] reacts with silver(I) nitrate to produce the homochiral single-stranded C_2-coordination polymer *M*-$\{[Ag\{(R,R)\text{-}\mathbf{2}\}]NO_3{\cdot}2H_2O\}_\infty$.

Double- and triple-stranded helicates are generated when metals combine with ligands containing appropriate metallophilic and helicating elements. Thus, the bis(methylene)oxy group inserted between a pair of semi-rigid 2,2′-bipyridines destabilises single-stranded mononuclear metal chelates of univalent Group 11 ions, but facilitates the self-assembly of double-stranded dinuclear metal helicates.[1,2] Moreover, a homochiral helicating element in the ligand can induce considerable stereoselectivity in the product.[3] There is now available a wide variety of structural motifs for the self-assembly of double- and triple-stranded helicates, many of which are derived from ligands having as their metallophilic elements familiar chelating entities, including 2,2′-bi- and oligo-pyridines and related compounds,[4] and a tetra(tertiary phosphine).[5] Herein we report the syntheses and crystal and molecular structures of silver(I) complexes of the readily prepared di-Schiff bases **1**[6] and (*R*,*R*)-**2**,[7] *viz*. the double-stranded helicate (±)-$[Ag_2\mathbf{1}_2](BF_4)_2$ and the



1



2

infinite single-stranded coordination polymer *M*-$\{[Ag\{(R,R)\text{-}\mathbf{2}\}]NO_3{\cdot}2H_2O\}_\infty$. The crystal and molecular structures of the related double-stranded helicate (±)-$[Ag_2\{(R,S)\text{-}\mathbf{2}\}_2](CF_3SO_3)_2$ have been determined previously[8] and detailed NMR spectroscopic investigations of this compound and the parent (±)-$[Ag_2\mathbf{1}_2](CF_3SO_3)_2$ have indicated that both helicates have two-fold symmetry in solution.[8,9] In other work, it has been shown that silver(I) combines with a single enantiomer of a bis(pyridyl) ligand derived from L- or D-tartaric acid to give an extended single- stranded helicate, whereas the corresponding racemic form of the ligand produces a disilver(I) complex incorporating both enantiomers in a *meso* arrangement.[10]

The complex (±)-$[Ag_2\mathbf{1}_2](BF_4)_2$ was isolated as pale-yellow prisms from acetonitrile–diethyl ether, mp 221–221.5 °C (decomp.).‡ The ^{1}H NMR spectrum of the complex in [$^2H_3$]acetonitrile is consistent with the presence of a pair of homotopic ligands[2] and the electrospray MS of the complex at a cone potential of 25 V displays a pattern of peaks in the range *m*/*z* 776–783 due to $[Ag_2\mathbf{1}_2{\cdot}BF_4]^+$. The salt crystallises as a racemic compound in the orthorhombic space group $C222_1$ (no. 20) with four pseudo inversion related pairs of cations and associated anions in the unit cell [Fig. 1(*a*)].§ Each disilver(I) cation has D_2 symmetry with the two homotopic ligands spanning both silver(I) ions. The Ag···Ag distance in the cation is 3.024 Å (av.). The overall structure can be described as a modulation of an idealised *Fddd* parent structure in which true inversion relates two substructures of *F*222 symmetry with *C*-centred layers of the different substructures interleaved perpendicular to ***c***. Within a layer, the dimeric cation occupies a site of 222 symmetry with the anions located on two-fold rotation axes parallel to ***b*** at 1/2, ± 0.15, 0 from the cation. The modulation lowers the symmetry of the structure from *Fddd* to $C222_1$ (a subgroup of *Fddd*) and destroys the crystallographic symmetry relationships between the substructures, which now also have $C222_1$ symmetry. The modulation displaces layers of one substructure along ***a*** and displaces layers of the other substructure along ***b***, while retaining a pseudo inversion between adjacent layers. Layers of the first substructure contain two-fold rotation axes parallel to ***a*** that relate adjacent layers of the second substructure and layers of the second substructure contain two-fold rotations parallel to ***b*** that relate adjacent layers of the first substructure. The asymmetric unit for the space group $C222_1$ contains two quarters of a dimeric cation and one anion from the first substructure and two quarters of a dimeric cation and two half anions from the second sub-

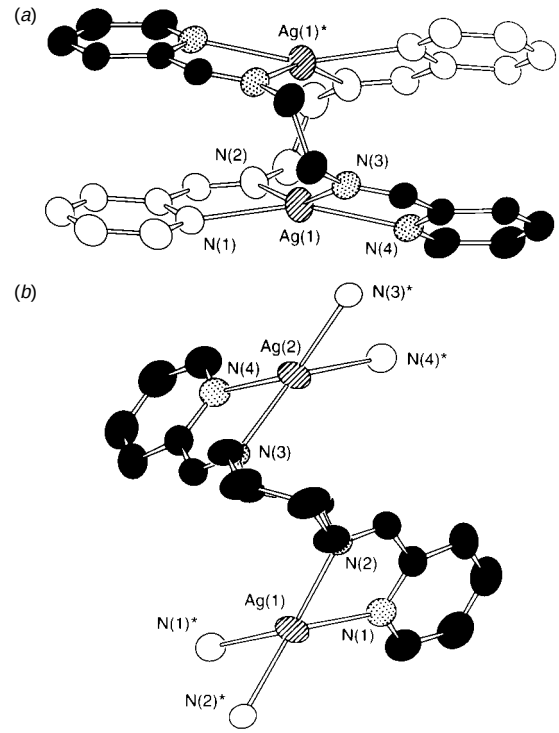


Fig. 1 Molecular structures of double-stranded helical cation of (±)-$[Ag_2\mathbf{1}_2](BF_4)_2$ (*a*) and of repeating unit of cation of single-stranded *M*-$\{[Ag\{(R,R)\text{-}\mathbf{2}\}]NO_3{\cdot}2H_2O\}_\infty$ (*b*)

structure. It was not necessary to invoke disorder in the structure.

The complex *M*-{[Ag{(*R*,*R*)-**2**}]NO_3·$2H_2O$}$_\infty$ crystallises as amber plates from acetonitrile–diethyl ether in the hexagonal space group $P6_522$. The polynuclear metal cation of the complex is an infinite helical polymer of C_2 symmetry with each interlocking Ag_2N_4 unit completing 0.73 turns of a left-handed (*M*) helix [Fig. 1(*b*)]. The pitch of the single-stranded palindromic helix is 6.5 Å and the Ag···Ag distances are 5.42 Å (av.). Each tetrahedral silver ion in the helix has the *S* configuration. Parallel helical chains form layers perpendicular to ***c*** with the 6_5 screw axis of $P6_522$ relating adjacent layers to give an overall structure of *M* helicity. The reference layer at z = 1/4 propogates parallel to ***a***, inducing pseudorotation axes midway between the real rotation axes (Fig. 2). The pseudosymmetry of the structure allows the possibility of homometric solutions, a translation of 1/2 ***b*** relating alternative positions for the polymer chain that produces the same intensities should the 1/2 ***a*** translation hold exactly. The ligands enclose N(terminal)–Ag–Ag–N(terminal) angles of 190.5° (av.), implying an average pitch of 7.3 Å for the Ag_2N_4 helical core. Comparative refinement allowed the absolute structure to be determined. The ^{1}H NMR spectrum in [$^2H_3$]acetonitrile and the electrospray MS of the complex are consistent with disproportionation of the polymer into dinuclear metal helicates in solution. The helical displacements in the helicate and the helicalpolymer are evident in the space-filling diagram given in Fig. 3. Fig. 1 shows the *ob* and *lel* arrangements of the central carbon–carbon bonds in the two structures. The crystal molecular structures of two other single-stranded helicate polymers derived from achiral ligands have been described previously.[11,12] To our knowledge, however, the only other homochiral coordination polymer to be structurally characterised is the complex *P*-{Ag[(*R*,*R*)-DIOP]NO_3}$_n$ {DIOP = (4*R*,5*R*)-*trans*-4,5-bis[(diphenylphosphino)methyl]-2,3-dimethyl-1,3-dioxalane} in which each silver ion in the polymer is coordinated by two phosphorus atoms of adjacent (*R*,*R*)-DIOP ligands and a nitrate-*O* atom.[13]

‡ Satisfactory elemental analyses were obtained.

§ *Crystal data* for (±)-[Ag_2**1**$_2$](BF_4)$_2$: $C_{28}H_{28}Ag_2B_2F_8N_8$, M_r 865.93, pale yellow block, space group $C222_1$ (no. 20), a = 10.420(2), b = 25.036(7), c = 25.202(7) Å, U = 6573(3) Å^3, Z = 8; D_c = 1.749 g cm^{-3}, μ(Mo-Kα) = 12.67 cm^{-1}. Philips PW1100/ 20 diffractometer; T = 293 K, ω–2θ scan method. A total of 4176 unique data were collected in the range 5 ⩽ 2θ ⩽ 55° of which 1650 [$I > 3\sigma(I)$] were used for the refinement. Initial unconstrained refinement of the data gave an R value of 0.060, but spreads in equivalent bond lengths were as high as 0.2 Å, which indicated refinement difficulties associated with the pseudo-inversion centre relating adjacent layers of the structure. Subsequent constrained refinement using the program RAELS96 (A. D. Rae, Australian National University, Canberra, Australia) with use of 176 independent parameters to describe the 53 anisotropic non-hydrogen atoms in the structure gave R and R_w values of 0.048 and 0.059, respectively, with a uniform distribution of error over all data classes. *M*-{[Ag{(*R*,*R*)-**2**}]NO_3·$2H_2O$}$_\infty$: $C_{18}H_{28}AgN_5O_7$, M_r 498.29, pale yellow hexagonal plate, space group $P6_522$ (no. 179), $a = b$ = 10.876(4), c = 63.522(8) Å, U = 6507(4) Å^3, Z = 12; D_c = 1.526 g cm^{-3}, μ(Cu-Kα) = 77.78 cm^{-1}. Rigaku AFC6R diffractometer; T = 296 K, ω scan method. A total of 2067 independent reflections having 2θ ⩽ 120° were measured. Constrained refinement (RAELS96) with use of 109 variables to describe the 31 non-hydrogen atoms in the asymmetric unit and their anisotropic thermal motion gave R and R_w values of 0.072 and 0.101, respectively, for 1026 reflections with [$I > 3\sigma(I)$] for a poorly diffracting thin plate. The homometrically related structure refined to an R value of 0.15. Refinement in $P6_122$ gives the incorrect helicity for the ligand and produces worse refinement statistics. CCDC 182/843.

Michael addition to α,β-unsaturated arene ruthenium(II) cyclopentadiene complexes: *endo* nucleophilic addition

Robert M. Moriarty,*[a]† Livia A. Enache,[a] Richard Gilardi,[b] George L. Gould[a] and Donald J. Wink[a]

[a] *Department of Chemistry, University of Illinois at Chicago, Chicago, IL 60607-7061, USA*
[b] *Laboratory for the Structure of Matter, Naval Research Laboratory, Washington, DC 20375-5341, USA*

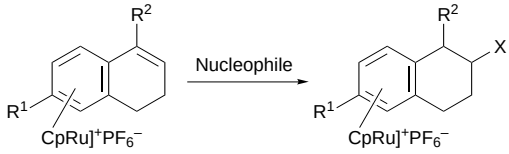
Certain carbon and sulfur nucleophiles add to the β-terminus of the styrene system in α,β-unsaturated arene ruthenium(II) cyclopentadiene complexes, and unexpected *endo* addition occurs preferentially in some cases.

Metals in either their neutral (Cr^0, Fe^0, Mo^0) or charged state (Fe^{II}, Ru^{II}, Pd^{II}, Os^{II}, Co^{II}) activate complexed unsaturated ligands towards nucleophilic addition.[1] This behaviour is due to net inductive withdrawal of electron density from the ligand and stabilization of the anionic charge resulting from addition of the nucleophile. The addition of the nucleophile occurs on the *exo* face of the ligand, distal to the metal.[2] Within the context of this direct nucleophilic addition to the complexed ligand, one might anticipate that conjugate addition could likewise occur in α,β-unsaturated ligated systems such as styryl or 1,2-dihydronaphthalene, and indeed this has been observed; in both cases η^6-chromium(0) complexes of the aromatic ring were used. In the simplest case, tricarbonyl(η^6-styrene)chromium,[3] this type of reaction occurred in 7–30% yield, but with a discouraging mixture of side-products. Better synthetic results were obtained by Semmelhack and in the case of addition of $LiCMe_2CN$ upon tricarbonyl(η^6-1,2-dihydronaphthalene)chromium.[3b,4] The stereochemistry of the product was proposed to correspond to *exo* addition, on the basis of a ^1H NMR spectrum of the decomplexed ligand.[4a] Two other examples of conjugate addition to arene-$Cr(CO)_3$ complexes were reported.[5]

Because of our interest in nucleophilic displacement reactions upon (η^6-arene)(η^5-cyclopentadienyl)ruthenium(II) complexes,[6] we studied the Michael addition in this series with α,β-unsaturated arene ligands. The objectives were to make the reaction more synthetically useful, partly as the rate of the nucleophilic displacement, *via* addition-elimination, on aryl halides increases in the order $Cr^0(CO)_3 < Mo^0(CO)_3 \ll CpFe^+ < Mn^+(CO)_3$,[7] and also to establish the stereochemistry of the addition relative to the result observed with the $Cr(CO)_3$ group. The substrates and transformations are shown in Scheme 1.[8]

Pure *endo* forms of products **2b** and **2c**, and the *exo* form of **4** could be separated *via* fractional recrystallization from acetone–water and the X-ray structures of the major isomers could be determined.‡

The X-ray structure of the major product from reaction of **1c** with KCN is in Fig. 1. The Cl Me and C2 CN are *syn* and on the same face as the metal. This highly strained array corresponds



1a $R^1 = R^2 = H$
b R^1 = OMe, $R^2 = H$
c R^1 = OMe, R^2 = Me

2a $R^1 = R^2 = H$, X = CN — *endo*:*exo* 1:1
b R^1 = OMe, $R^2 = H$, X = CN — *endo*:*exo* 2:1
c R^1 = OMe, R^2 = Me, X = CN — *endo*:*exo* 3:1
3a $R^1 = R^2 = H$, X = SPh — *endo*:*exo* 3:1
b R^1 = OMe, $R^2 = H$, X = SPh — *endo*:*exo* 5:4
c R^1 = OMe, R^2 = Me, X = SPh — *endo* only

Scheme 1

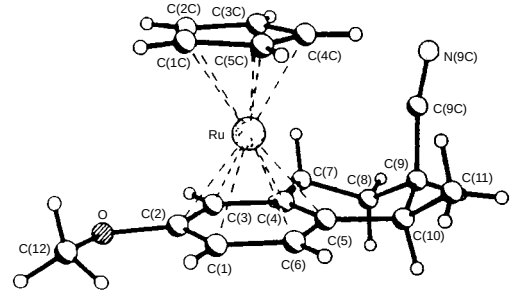


Fig. 1 X-Ray structure of compound **2c**

to *endo* addition and *exo* protonation and differs from the result observed for conjugate addition in two cases in which the stereochemistry was determined.[3b,5b] A similar preference for the *endo* addition was determined from combined NMR and X-ray studies of other products in our study (Scheme 1). An X-ray of the major component of product **2b** also shows *endo* selectivity. The major component of product **4** was the 'expected' *exo*.

How is one to explain *endo* nucleophilic addition? In a direct displacement upon a metal-complexed aromatic ring, basically an S_N2 type mechanism, the nucleophile attacks at the carbon atom undergoing displacement forming a new bond to that center (with inversion) with concomitant cleavage of a bond to the metal, *i.e.* the ligated metal is the 'leaving group'.[10] This description requires *exo* attack. Conjugate addition of the type studied here is controlled by the stereoelectronic effects of the S_N2' reaction.[11] This process occurs with *syn* stereochemistry, although it has not been recognized that the carbon–metal bond could constitute the leaving group [Fig. 2(*a*)]. Fig. 2(*b*) shows the orbital representation which reveals the LUMO of the complex and the preference for *syn* addition.

The reactions were generally slower for **1b** as compared to **1a** (rate retarding effect of OMe) and slower still for **1c** (steric effect of Cl methyl group). With KCN (5 equiv.) in DMF–H_2O in the presence of NH_4Cl (3 equiv.), the conditions required for the complete disappearance of the starting material for 70 °C overnight for **1a** → **2a** and 90 °C overnight for **1b** → **2b** and **1c** → **2c**. The yields of *endo*/*exo* mixtures of isomers after chromatographic separation on silica gel (acetone–CH_2Cl_2 1:4) were 86 (*endo*:*exo* 1:1), 85 (*endo*:*exo* 2:1) and 82% (*endo*:*exo* 3:1) respectively. The reactions with thiophenol

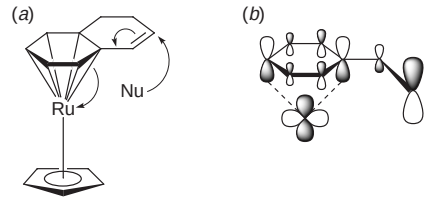

Fig. 2 (*a*) The S_N2' type mechanism illustrating *endo* conjugate nucleophilic addition to styrene-type substrates complexed to Ru^{II}. (*b*) Simple orbital diagram which represents LUMO calculated from ZINDO for the $CpRu(C_{10}H_{10})^+$ model.

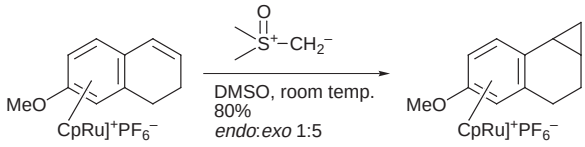

1b **4**

Scheme 2

(1.5 equiv.) were carried out in NMR tubes in CD_3CN in the presence of Hunig's base (Pr^i_2NEt). Judging by the disappearance of the signals of the starting material in the NMR spectrum, substrate **1a** reacted completely in 30–45 min when 2 equiv. of base was used at 45 °C, and overnight with only 0.5 equiv. of Hunig's base at 25 °C. Substrate **1b** reacted completely at 45 °C overnight in the presence of Hunig's base (0.5 equiv.), and substrate **1c** reacted in only *ca.* 80% when treated with Hunig's base (0.5 equiv.) at 60 °C for 36 h. The observed *endo : exo* ratios were: **3a** (3 : 1), **3b** (5 : 4) and **3c** (*endo* only).

A more advanced example is the Corey–Chaykovsky cyclopropanation in which dimethyloxosulfonium methylide[9] is used in a reaction which occurs at room temp. within minutes (**1b** → **4**) (complete disappearance of the starting material, 80% isolated yield after chromatography, *endo : exo* 1 : 5, Scheme 2).

How does one reconcile *endo* addition with the observed *exo* addition of Semmelhack and others?[3b,5a] These workers used Li carbon anions and the conjugate addition in these cases is reversible.[12] Accordingly, the least hindered *exo* (*cis*-1,2) product perdominates. In contrast, our cyanide addition method involving *in situ* NH_4Cl/H_2O insures formation of the kinetic product, by immediate protonation at the benzylic position. Kinetic control is also possible in the addition of PhSH in the presence of less than 1 equiv. of base. In agreement with the interpretation, cyclopropanation (**1b** → **4**) yields the *exo* product in 5 : 1 ratio because of the reversibility associated with carbanion addition in the absence of a protic acid.[9,13] Semi-empirical quantum calculations (ZINDO, INDO1 level basis set)[14] on a (η^5-cyclopentadienyl)(η^6-1,2-dihydronaphthalene)-Ru cation model complex, as well as its Fe substituted analog, indicate that a nucleophilic attack at the *endo* face of the conjugated π-system is slightly preferred over the *exo* face. Furthermore, the model calculations indicate that an *anti* stereochemistry of protonation to the resulting η^5-pentadienyl form of the intermediate [Fig. 2(*a*)] as the α-styryl C would be expected, consistent with the major selectivity observed in the Ru system reported here. Interpreting these predictive models in the context of the stereochemistries reported for S_N2' addition[11] indicate that a general model in which attack of the nucleophile *syn* to the leaving group (Ru–C bond) in π-complexed styryl or dihydronaphthyl complexes is reasonable. Further theoretical and experimental studies are in progress to test this hypothesis.

This work was supported through NSF grant CHE-9520157.

8 Various nitrogen nucleophiles (hydrazine, methylhydrazine, *gem*-dimethylhydrazine, 1,2-dimethylhydrazine, 1,2-ethylenediamine, ethylamine, ethanolamine) were also studied. Oxygen nucleophiles did not undergo addition to **1a**–**c** under our conditions. Since no stereochemical *endo : exo* assignments could be reliably made from the available data, the nitrogen nucleophiles (NMR tube experiments, [$^2H_6$]DMSO) were not extensively included in the present study. Still, they displayed extremely interesting reactivity patterns worth noting (data from ^{1}H NMR, ^{13}C NMR, HRMS + FAB analysis). With H_2NNH_2, H_2NEt and $H_2NCH_2CH_2NH_2$, **1**–**c** reacted completely in 30 min at rt (*ca.* 80% conversion of **1a** in the first 5 min). H_2NNHMe adds slower than hydrazine itself, and H_2NNMe_2, adds even slower. $H_2NCH_2CH_2OH$ reacted very slowly, with < 30% conversion, when heated up to 100 °C. Pr^iNH_2 and MeNHNHMe did not react even after 48 h at rt or 60 °C overnight.

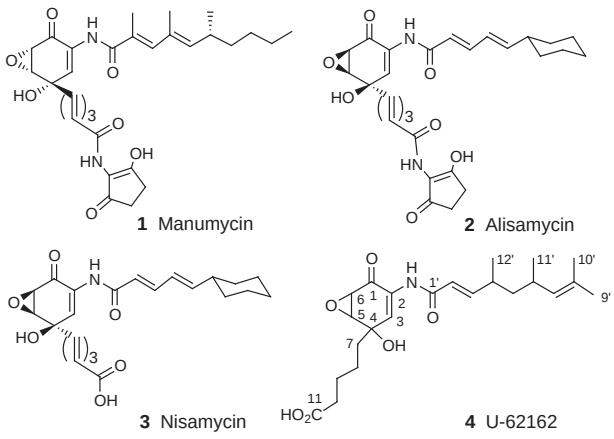
The first synthesis of the *Streptomyces* derived antibiotic U-62162

Lilian Alcaraz and Richard J. K. Taylor†

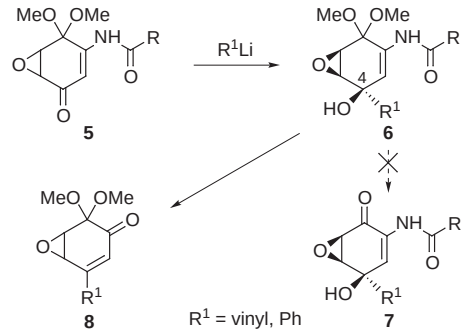
Department of Chemistry, University of York, Heslington, York, UK YO1 5DD

U-62162, a member of the manumycin family of antibiotics, has been prepared as a mixture of diastereoisomers and shown to contain a *syn*-hydroxy epoxide nucleus and a 1,3-*syn*-disposed dimethyl unit in the upper side chain; the cornerstone of the synthetic route utilises organometallic addition to a monoprotected quinone epoxide—the first time this approach has been successfully employed to prepare a manumycin antibiotic.

The manumycin group of natural products, which includes manumycin A **1**[1] and alisamycin **2**,[2] have attracted a great deal of attention due to their antibiotic, antitumour and enzyme inhibitory properties.[1–4] With two exceptions, all members of this family have a 2-amino-3-hydroxycyclopentenone polyenamide lower side chain. The exceptions are nisamycin **3**,[3] which is the carboxylic acid corresponding to alisamycin, and U-62162 **4**.[4] U-62162, an antibiotic isolated from *Streptomyces verdensis* (UC-8157), was reported by researchers from the Upjohn Company in 1982, and has a unique five-carbon saturated lower side chain terminating in a carboxylic acid. Extensive NMR experiments were carried out to assign structure **4**, but the only stereochemical information revealed was the *E*-orientation of the alkene in the top side chain.



We recently reported[5] the first total synthesis of alisamycin **2** and nisamycin **3**. The initial synthetic approach investigated for these compounds involved organometallic elaboration of the monoprotected quinone epoxide **5**, as summarised in Scheme 1.



Scheme 1

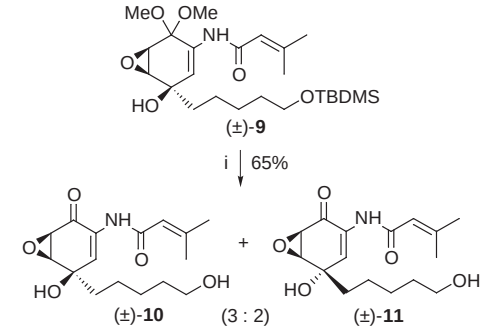
This approach was ultimately unsuccessful because of the lability of the C-4 hydroxy group, which is tertiary and doubly allylic in adduct **6** when R^1 is an unsaturated lower side chain; attempted hydrolysis of the acetal moiety to give **7** resulted, under a wide range of conditions, in the formation of degradation products, one of which was tentatively identified as enone **8**. A successful alternative approach to alisamycin and nisamycin was eventually designed,[5] but we were intrigued by the possibility that the original methodology, shown in Scheme 1, might be applicable to the synthesis of related compounds in which the hydroxy group is less labile, *i.e.* where R^1 is not alkenyl. Here we describe the successful implementation of this approach for the synthesis of U-62162.‡

Model studies (Scheme 2) were carried out to assess the viability of this approach. Compound **9**, prepared using similar procedures to those described later, was treated with TsOH in aqueous acetone, giving a reasonable yield of the required alcohols **10** and **11**. The fact that the two epimers were formed during the reaction indicates that some carbocation formation is still occurring, but as the enamide unit remained intact, and hydrolysis products of type **8** were not observed, this route was thus adopted for the synthesis of U-62162.

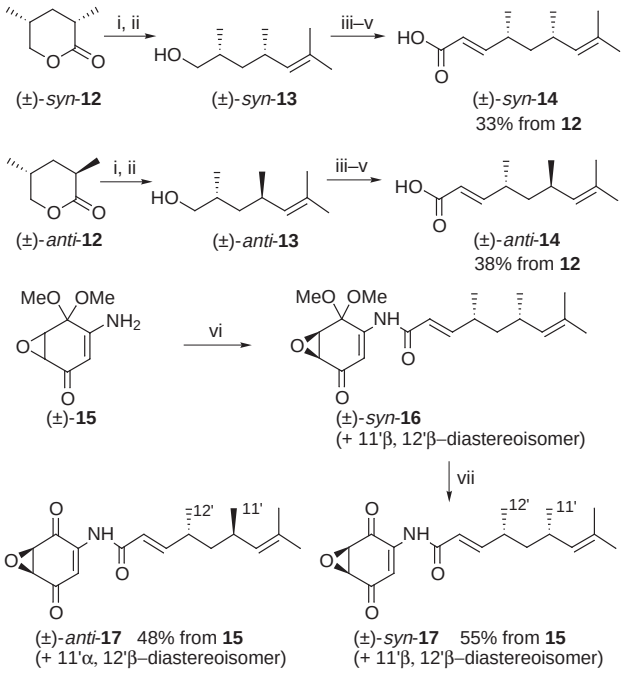
The first objective in the natural product synthesis was to elucidate the relative stereochemistry of the side chain methyl substituents in the upper side chain (Scheme 3). The readily available[7] *syn*- and *anti*-dimethylvalerolactones **12** were therefore converted into the isomeric alcohols **13** and on to the acids **14** using the straightforward sequence illustrated. Treatment of acids **14** with oxalyl chloride in CH_2Cl_2 gave the corresponding acid chlorides which were used to acylate amine **15**.[5] The resulting adducts **16**, as diastereomeric mixtures, were then converted into quinone epoxides **17** *via* the three-step sequence shown.

The high-field NMR spectra of the *syn*- and *anti*-diastereomers of **16**, **17** and the other acylated intermediates, were compared to the data published for U-62162.[4] Significant differences were observed, which indicated that the natural product contained the *syn*-dimethyl arrangement [*e.g. syn*-**17**: δ_H 0.91 (3 H, d, *J* 6.5, H-11′); *anti*-**17**: δ_H 0.89 (3 H, d, *J* 6.5, H-11′); U-62162:[4] δ_H 0.91 (3 H, d, *J* 6.6, H-11′). We therefore set out to convert *syn*-**16** into U-62162 (Scheme 4).

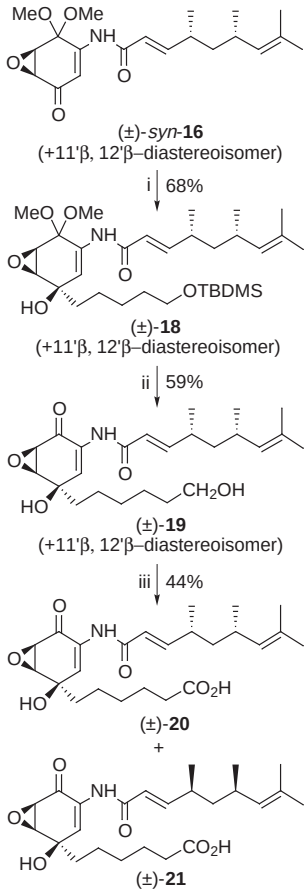
5-*tert*-Butyldimethylsilyloxy-1-iodopentane[8] was transmetallated (Bu^tLi, Et_2O) and then treated with *syn*-**16**; as



Scheme 2 *Reagents and conditions*: i, TsOH, aq. acetone



Scheme 3 *Reagents and conditions*: i, DIBAL-H, THF, −78 °C (ref. 7); ii, $Ph_3P{=}CMe_2$, THF, 0 °C; iii, DMSO, $(COCl)_2$, −60 °C, then Et_3N, CH_2Cl_2, room temp.; iv, $Ph_3P{=}CHCO_2Et$, CH_2Cl_2, room temp.; v, LiOH, aq. MeOH–THF; vi, acid chloride from **14**, LiOBu^t, THF, 0 °C; vii, $LiHBEt_3$, THF, −78 °C, then K10, CH_2Cl_2, room temp., then PDC, CH_2Cl_2, room temp.



Scheme 4 *Reagents and conditions*: i, $Li(CH_2)_5OTBDMS$, Et_2O, −78 °C; ii, TBAF, THF, room temp., then TsOH, aq. acetone; iii, PCC, NaOAc, CH_2Cl_2, room temp., then $NaClO_2$, KH_2PO_4, 2-methylbutene, aq. Bu^{t}OH, room temp.

expected,[5] addition occurred with total stereoselectivity from the face opposite the epoxide. The deprotection of adduct **18** could be carried out directly using TsOH in aqueous acetone but the process was rather slow and inefficient. The preferred method involved fluoride-induced desilylation followed by acetal hydrolysis using TsOH. This sequence gave diol **19** (accompanied by a small amount of the *anti*-hydroxy epoxide§ which was easily removed by chromatography). Oxidation of **19** to an inseparable mixture of the corresponding acids **20**/**21** was achieved by a two-step procedure (PCC, then sodium chlorite). Compounds **20**/**21,** although a diastereomeric mixture, showed data consistent with that published for U-62162 [*e.g.* δ_H (synthetic) 7.42 (d, *J* 2.5, H-3) 3.68 (dd, *J* 4.0, 2.5, H-5), 3.55 (d, *J* 4.0, H-6); δ_H (published[4]) 7.43 (d, *J* 2.7, H-3) 3.69 (dd, *J* 4.0, 2.7, H-5), 3.56 (d, *J* 4.0, H-6); δ_C (synthetic) 190.2 (C-1), 130.6 (C-2), 130.3 (C-3), 71.2 (C-4), 58.6 (C-5), 53.7, C-6); δ_C (published[4]) 189.6 (C-1), 130.0 (C-2), 129.8 (C-3), 70.6 (C-4), 57.9 (C-5), 53.0, C-6)].§ The *syn*-hydroxy epoxide arrangement, now confirmed for U-62162, is in accord with the biosynthetic rationale recently proposed by Gould and Floss.[9]

This research establishes an efficient route to the antibiotic U-62162 and also provides further stereochemical information. We are now working to assign U-62162 as **20** or **21** and to complete an enantioselective synthesis.

We thank the European Community for a Marie-Curie Fellowship (L. A.), and Professor P. Kocienski for helpful advice concerning the preparation of compounds **12.**

Notes and References

‡All new compounds were fully characterised by high field ^1H and ^{13}C NMR spectroscopy and by high resolution mass spectrometry, with the exception of those in Scheme 2 (NMR characterisation only). All compounds are racemic and **16**–**19** are mixtures of diastereoisomers.

§ The *anti*-hydroxy epoxide isomer of **19** was also converted into the corresponding diastereomeric U-62162 analogues. The NMR spectrum of this mixture showed significant differences to **20**/**21** [*e.g.* δ_H 7.55 (d, *J* 3.0, H-3); δ_C 128.9 (C-3), 60.2 (C-5)], providing further evidence that the natural product possesses the *syn*-hydroxy epoxide stereochemistry.

New procedures for the Juliá–Colonna asymmetric epoxidation: synthesis of (+)-clausenamide

Michael W. Cappi,[a] Wei-Ping Chen,[b]† Robert W. Flood,[a] Yong-Wei Liao,[b] Stanley M. Roberts,*[a]‡ John Skidmore,[a] John A. Smith[c] and Natalie M. Williamson[a]

[a] *Department of Chemistry, Liverpool University, Liverpool, UK L69 7ZD*
[b] *College of Pharmacy, Second Military Medical University, Shanghai 200433, PR China*
[c] *School of Biological Sciences, Liverpool University, Liverpool, UK L69 7ZB*

The oxidation of chalcone 1 to optically active epoxide 2 [a precursor of (+)-clausenamide (+)-3] may be effected using a 15-mer or 20-mer of L-leucine bound to a PEG based support; poly-L-leucines of this type may be used as immobilised catalysts in a fixed-bed reactor.

The polyamino acid catalysed asymmetric epoxidation of α,β-unsaturated ketones was discovered by Juliá and Colonna.[1] The reaction entailed taking a polyamino acid, such as poly-L-leucine, and allowing it to swell to form a gel in the presence of an organic solvent, 4 M aq. NaOH and H_2O_2. After several hours, the substrate was added to the three-phase system (insoluble polyamino acid, organic solvent–substrate, and water–H_2O_2–NaOH). This system was used by Lantos[2] and Ferreira[3] in the synthesis of selected target molecules.

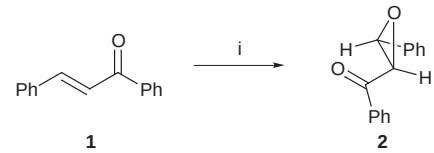
Recently, it has been shown that the original three-phase system used by Juliá and Colonna can be replaced by a non-aqueous two-phase system[4] and this modified procedure has been used to prepare diltiazem, Taxol™ side-chain[5] and other interesting structures.[6]

These recent advances in the utilisation of the Juliá–Colonna oxidation focused our attention on three issues: (i) understanding the mechanism of the reaction; (ii) finding a suitable methodology for conducting the reaction on a large scale; and (iii) broadening the range of target molecules that can be made by using the Juliá–Colonna technique as the key step. Some progress has been made in each of these areas, as detailed below.

Understanding the mechanism of the Juliá–Colonna oxidation is the key to the application of the methodology to a broader range of substrates. Typically the polyamino acid catalyst is prepared by synthesis of the appropriate amino acid *N*-carboxy anhydride (NCA) and then initiating polymerisation using a nucleophile (water, an alcohol or an amine). Using L-leucine and 1,3-diaminopropane this procedure gives a polymer with a molecular weight range of 1500–3000;[7] it was of interest to determine whether the heterogeneous nature of the polymer and/or the method of preparation[8] were important with regard to the intriguing catalytic properties of the system.

Thus, L-leucine NCA was polymerised using a polyethylene glycol polystyrene based[9] amino nucleophile as the initiator to give CAT 1. At the same time a PEG-polystyrene supported 15-mer of L-leucine (CAT 2) and a PEG-polystyrene supported 20-mer of L-leucine (CAT 3) were prepared using a peptide synthesiser. The effectiveness of these catalysts for the conversion of chalcone **1** into the corresponding epoxide **2** (Scheme 1) is detailed in Table 1.

It is clear that the homogeneous polymers of leucine behave in a very similar manner to the material prepared in the usual way from the *N*-carboxy anhydride. This is the first time that a simple polyamino acid, prepared using a peptide synthesiser, has been shown to catalyse the Juliá–Colonna asymmetric epoxidation reaction. Variation in the amino acid content of the homogeneous peptide chain (*i.e.* 'point mutation' of the 'synthetic enzyme'[10]) is currently under way to help to elucidate the mechanism of this fascinating reaction.



1 **2**

Scheme 1 *Reagents and conditions:* i, biphasic conditions: base, oxidant, *e.g.* urea–H_2O_2, solvent, *e.g.* THF, room temp.

Under the biphasic reaction conditions the polypeptide does not swell to any appreciable extent. This suggested that the substrate in a suitable solvent might be passed through a column of the catalyst mixed with the oxidant to furnish a fixed-bed reactor convenient for a large scale continuous flow synthesis of optically active epoxides. A miniature system was studied.

Poly-L-leucine, immobilised on cross-linked aminomethyl-polystyrene[11] (CLAMPS), was slurry packed into a Pasteur pipette together with oxidant. A solution of chalcone **1** dissolved in a solvent containing DBU (0.5% v/v) was passed through the column. Gratifyingly, good conversions of **1** to epoxide **2** of good to excellent optical purity was observed. A comparison of two oxidants and five solvents (Table 2) suggested that DABCO–H_2O_2[12] and *tert*-butyl methyl ether are the components of choice for further study.

The epoxide **2** was utilised to prepare (+)-clausenamide **3**, an antiamnaesic agent with potent hepatoprotective activity[13] (Scheme 2). Oxidation of ketone **2** under the conditions recommended by Flisak[14] afforded the ester **4**, which was converted into the amide **5** using (±)-2-methylamino-1-phenylethanol. Oxidation of the hydroxy amide **5** and subsequent base-catalysed cyclisation under prescribed conditions[15] furnished a 1 : 1 mixture of diastereomeric lactams (+)-**7** and (−)-**8** [epimerisation of (−)-**8** to provide further quantities of (+)-**7** may be effected by base[16]]. Diastereoselective reduction of (+)-**7** with $NaBH_4$ generated (+)-clausenamide (+)-**3** in 89% yield; the synthetic material had physical properties in accord with those documented previously.[17] This naturally occurring compound is now available from chalcone **1** in six steps and 40% overall yield.

Table 1 Oxidation of chalcone **1** using polyleucine catalysts[a]

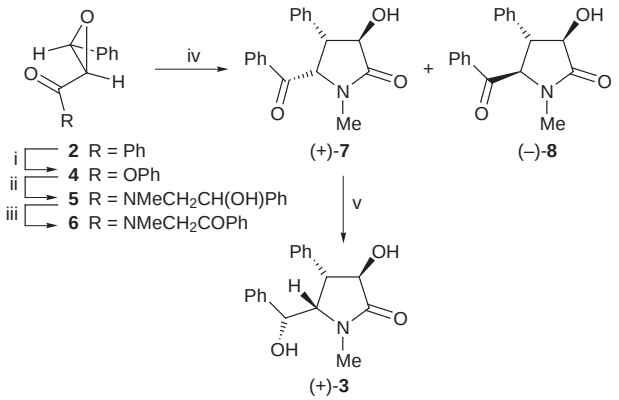
Catalyst	*t*/h	Conversion (%)	Ee[b] (%)
CAT 1	1.5	78	83
CAT 2	1.5	89	87
CAT 3	1.5	66	89

[a] Typical reaction conditions: chalcone (25 mg) in THF (0.75 cm^3) with catalyst (50 mg), DBU (6 equiv.) and urea–H_2O_2 (4.8 equiv.). [b] Ees determined by chiral HPLC.

Table 2 Oxidation of chalcone **1** using a fixed-bed of poly-L-leucine[a]

Oxidant	Solvent	Residence time/min	Conversion (%)	Ee[b](%)
Urea–H_2O_2	THF	15	63	94
Urea–H_2O_2	EtOAc	20	87	96
Urea–H_2O_2	Bu^{t}OMe	20	93	96
DABCO–H_2O_2	THF	15	80	98
DABCO–H_2O_2	CH_2Cl_2	15	74	84
DABCO–H_2O_2	EtOAc	15	57	92
DABCO–H_2O_2	Bu^{t}OMe	20	> 97	> 98
DABCO–H_2O_2	MeCN	25	87	86

[a] *Reagents and conditions*: immobilised poly-L-leucine (300 mg) was packed in a column with oxidant (30 mg). Chalcone **1** (50 mg) in solvent (0.5 cm^3) was added and the column was eluted with the same solvent. [b] Ees determined by chiral HPLC.



Scheme 2 *Reagents and conditions*: i, MCPBA, CH_2Cl_2, reflux, 78%; ii, (±)-2-methylamino-1-phenylethanol, CH_2Cl_2, 0 °C to room temp., 93%; iii, $KMnO_4$–$CuSO_4$, CH_2Cl_2, room temp., 76%; iv, aq. LiOH, Et_2O–THF, room temp., 93%; v, $NaBH_4$, MeOH, 0 °C to room temp., 83%

Mechanism-based inhibition of carbohydrate-mediated biological recognitions

Pamela Sears† and Chi-Huey Wong

Department of Chemistry and the Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, CA 92037, USA

Carbohydrates are often associated with specific biological recognition, targeting and signalling processes that play important roles in both normal and disease states. The efforts of many groups have been directed toward the synthesis of complex saccharides and saccharide mimics in the hope of understanding these recognition processes and developing effective agents for their intervention. As compared to research with other classes of biomolecules, however, the pace of major advances in glycobiology and development of carbohydrate-based therapeutics has been relatively slow, due to a combination of factors including the complexity of glycans in natural systems and a lack of facile synthetic techniques and analytical methods available for carbohydrate-related research. This review discusses some of the most recent developments in the field, with particular emphasis on the use of combined chemical and enzymatic approaches for the synthesis of saccharides and mimetics. Some of the highlights include the studies of selectin–carbohydrate and aminoglycoside–RNA interactions, and the synthesis and evaluation of inhibitors of glycoprocessing enzymes.

Although ubiquitous in nature, carbohydrates represent one of the least exploited classes of biomolecules. It is now known that carbohydrates are key elements in various molecular recognition processes. Carbohydrates play a role in infection by a variety of pathogens; they are important for cellular trafficking in acute and chronic inflammation and metastasis; and they play key roles in differentiation, development, regulation and many other intercellular communication and signal transduction events.[1] At the molecular level, carbohydrate-mediated recognition processes are not well understood, however. Although several potential targets for therapeutic intervention have been recognized, the rate of development of saccharide-based pharmaceuticals has been slower than that of the other classes of biomolecules. This is due to a number of factors. First, there are still some extremely difficult technical problems faced by glycobiologists and glycochemists. There is no replication system available for the amplification of minute amounts of carbohydrates to facilitate structure analysis and synthesis, nor is there a machine available for the solid-phase synthesis of oligosaccharides to facilitate the study of their functions. Because cells glycosylate lipids and proteins in a very heterogeneous fashion, it is not feasible to simply grow cells and purify the glycoproteins and glycolipids to homogeneity in large quantity. The heterogeneity of natural glycoconjugates also makes characterization difficult, although recent advances in mass spectral analysis have facilitated structural identification of oligosaccharides with picomoles of material. In addition, the synthesis of free oligosaccharides—not to mention glycoconjugates—in large quantities for research and therapeutic purposes is very difficult and expensive. Secondly, carbohydrates generally possess poor properties for drug development. The affinity of carbohydrates for their protein receptors is almost inevitably weak,[2–6] with dissociation constants in the millimolar range, and carbohydrates are generally orally inactive and sensitive to glycosidases *in vivo*. As a result, carbohydrates may only be used in injectable form for the treatment of acute symptoms.

It is clear, however, that these recognition processes are of fundamental importance in organism development, cell–cell communication, and cell and protein targeting. They are involved in the progression of a variety of diseases, such as invasion and metastasis of tumors. Likewise, many disease states are associated with changes in glycosylation at the cellular level. Pharmaceutical control of such recognition processes may therefore be beneficial. Furthermore, understanding the mechanism of carbohydrate recognition may lead to the development of new concepts and new strategies to tackle the problems of carbohydrate-based drug development. This

review focuses on some of the most recent efforts toward the synthesis of complex carbohydrates, carbohydrate mimetics and inhibitors of glycoprocessing enzymes. It concentrates on the development of molecules that inhibit the natural functions of selectins, RNA, glycosidases and glycosyltransferases.

Cellular trafficking *via* selectin–carbohydrate interactions

A new class of carbohydrate-binding glycoproteins called selectins have recently been identified on the surface of specific cell types. These glycoproteins have been named E-,[7] P-[8] and L-selectins[9,10] according to the cell type on which each was initially found (*i.e.* endothelium, platelets and lymphocytes, respectively). The selectins are all homologous and have similar tertiary structures. The *N*-terminal region is made up of a calcium-dependent lectin-like domain and an epidermal growth factor-like (EGF) domain, which are necessary for carbohydrate binding. Following these are a number of modules (~ 60 amino acids) similar to those found in certain complement binding proteins. The exact number of modules depends on the selectin, though their function is, as yet, unknown. The X-ray crystal structure of the lectin and EGF domains of human E-selectin was determined[11] and its amino acid sequence is homologous to another mammalian lectin, the mannose binding protein,[12] for which the structure has also been solved. Carbohydrate ligands that are recognized by the selectins have been identified. E-Selectin recognizes sialyl Lewis X (SLe^x) on the surface of neutrophils.[13–15] P-Selectin also binds sialyl Lewis X on neutrophils or leukocytes with a lower affinity.[16,17] L-Selectin weakly recognizes sialyl Lewis X on endothelial cells but the affinity is higher with a sulfate group on the 6-position of Gal[18,19] or perhaps more likely on the 6-position of the GlcNAc residue.[17,20] Some sulfated Le^x also bind to E- and P-selectin[21] and questions regarding the true physiological ligands for these selectins still exist, particularly since the specificity of the selectins towards these ligands is by no means absolute.

The selectin–carbohydrate interaction is initiated at an early stage of the inflammatory reaction[22,23] or metastasis.[24–26] As illustrated in Fig. 1, when tissue injury occurs, cytokines are released to signal endothelial cells to display P- and then E-selectins to recruit neutrophils to the site of injury. Recruitment is mediated by the adhesion of neutrophils to endothelial cells through the multivalent interaction of SLe^x and P- or E-selectin on the respective cell surfaces, followed by a more tight interaction between integrins on neutrophils and the intercellular adhesion molecule (ICAM-1) on endothelial cells, resulting in the extravasation of neutrophils at the site of injury. Over recruitment of neutrophils can be deleterious, causing damage to normal cells and leading to inflammation. Intervention of this process by partially inhibiting the adhesion step has thus been considered to be a new strategy for creating anti-inflammatory agents, and it is expected that many acute symptoms such as reperfusion injury, stroke, asthma and arthritis may be treated with this approach. In support of this idea, the carbohydrate ligands of these selectins, especially those of E- and P-selectin, have been shown to be potentially useful for the treatment of these acute symptoms.[27,28]

Chemoenzymatic synthesis of oligosaccharides and glycoproteins

The syntheses of SLe^x and related structures[29–34] have played a very important role in defining the structure–function relationship. Studies with these molecules have not only provided confirmation of the function of the ligand but have also unravelled the essential groups involved in ligand recognition (Fig. 2). For SLe^x interaction with E- and L-selectins, it has

been shown that the three hydroxy groups of fucose,[35,36] the 2- and 6-hydroxy groups of galactose[37] and the carboxylate of neuraminic acid[35] are essential for binding and that the GlcNAc residue is not critical.[38] For P-selectin, the essential functional groups are generally the same, but the 2- or 4-hydroxy group of fucose seems not to be critical.[35] These discoveries together with the conformations of SLe^x determined by NMR spectroscopy[39–43] provide a basis for the design of new structures to mimic the active conformation of SLe^x, which may lead to the discovery of new and better anti-inflammatory agents.

The conformation of SLe^x in solution[39] is different from that bound to E- and P-selectin,[42] especially in the orientation of the neuraminic acid residue, though similar to that bound to L-selectin.[43] The conformational and structure–function relationship studies suggest it should be possible to design small molecules that are constrained to resemble the active form of SLe^x and thus improve the inhibition potency (Fig. 2).

Regarding the preparation of SLe^x, enzymatic techniques have been developed for its large-scale synthesis,[39] and the use of glycosyltransferases coupled with regeneration of sugar nucleotide substrates, first illustrated in the synthesis of *N*-acetyl lactosamine,[44] has proven to be useful for the large-scale process. SLe^x has been prepared on kilogram scales based on this strategy. This multienzyme system not only eliminates the problem of product inhibition caused by the released nucleoside (di)phosphates, but also reduces the cost of the expensive sugar nucleotide. This method has been extended to the synthesis of hyaluronic acid,[45] and we believe that, once the appropriate glycosyltransferases are available, it should be possible to produce any biologically known oligosaccharide in large quantities based on this methodology, since methods for the regeneration of all sugar nucleotides have been developed.[46] To date, a wide variety of glycosyltransferases have been cloned. An up-to-date listing can be found in our recent review.[47] Many of the enzymes are inactive when produced in bacterial expression systems, but the development of new high-level eukaryotic expression systems (especially using yeast,[48] baculovirus,[39] and *Aspergillus*[49]) for the preparation of glycosyltransferases has made possible the large-scale enzymatic synthesis of oligosaccharides.

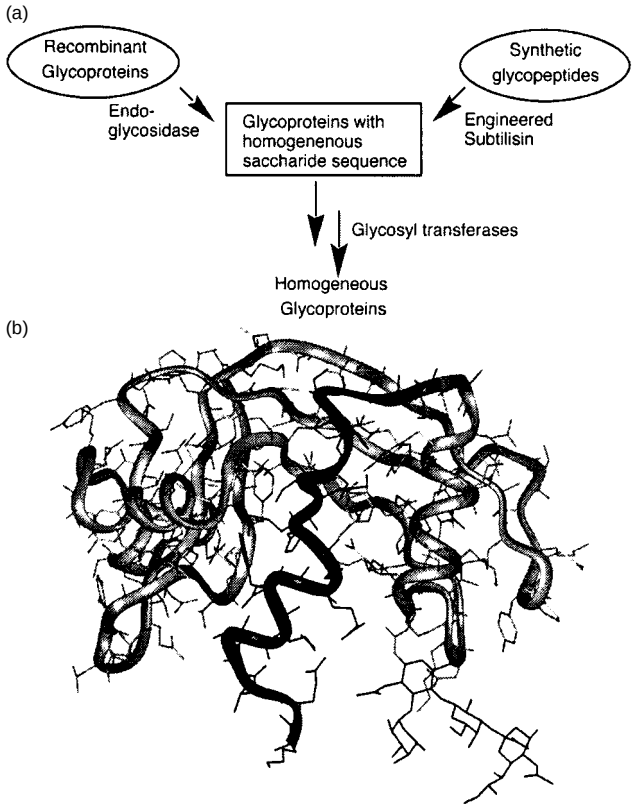

Fig. 3 (a) Strategies for enzymatic synthesis of glycoproteins containing well-defined oligosaccharides; (b) sialyl Lewis X-Ribonuclease A glycoform

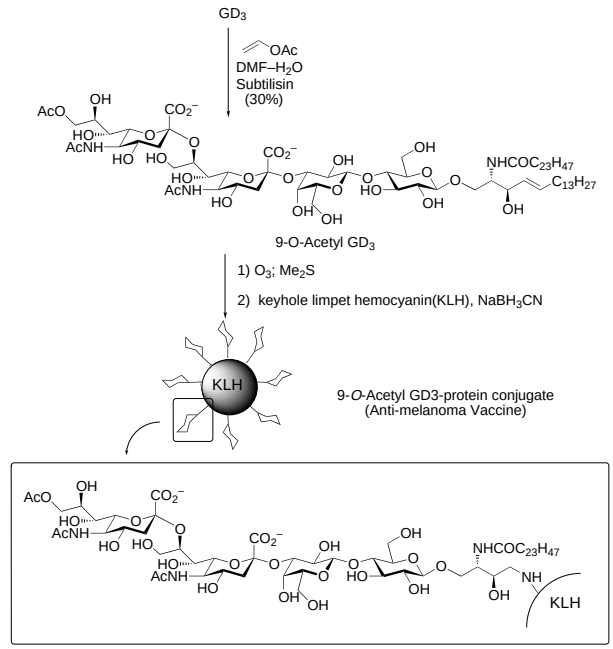

Fig. 4 Enzymatic synthesis of the melanoma antigen 9-*O*-acetyl-GD_3 for the preparation of vaccines

Sulfation of saccharides, too, can be accomplished enzymatically, and can be coupled with regeneration of PAPS for the large-scale synthesis of oligosaccharide sulfates.[50] *N*-Acetyllactosamine-6-sulfate, for example, has been prepared from *N*-acetyllactosamine, and this disaccharide can be easily converted to SLe^x-6-sulfate with commercially available α-1,3-fucosyltransferase and α-2,3-sialyltransferase.

Glycosyltransferases can be applied to solid-phase synthesis[51,52] and coupled with other enzymatic reactions to expand the scope of their synthetic application. As an alternative approach, the normally hydrolytic glycosidases can be forced into the synthetic direction by addition of large amounts of acceptor, or by sequestering the product. A glycosidase-catalyzed synthesis of disaccharides, for example, can be coupled *in situ* with a glycosyltransferase reaction to improve the overall yield.[53] Complex glycopeptides and glycoproteins, while not easily accessible by normal solid-phase synthesis, can be synthesized chemoenzymatically as well. A (short) monoglycosylated peptide ester may be ligated to another peptide in aqueous solution *via* subtilisin-catalyzed aminolysis, and the resulting glycopeptide may then be further elaborated with glycosyltransferases.[54–56] Several engineered thermostable thiosubtilisins have proven to be quite useful for glycopeptide synthesis, and the mechanisms of increased aminolysis to hydrolysis and stabilization have been elucidated.[54,57,58] Recently, subtilisin has been applied to the synthesis of new ribonuclease glycoforms, as illustrated in Fig. 3.[55] Other engineered subtilisins useful for peptide ligation have been developed by Wells and co-workers for the total synthesis of ribonuclease A and its analogs.[59] The enzymatic synthesis of glycoproteins is useful as currently there is no method available for the preparation of homogenous glycoproteins. The strategy illustrated in Fig. 3 may be useful in this regard. Glycoproteins produced by fermentation, which are inevitably heterogeneous in their carbohydrate composition, may be remodelled to a homogeneous species *via* enzymatic (endoglycosidase) removal of the heterogeneous saccharide units, followed by addition of new sugars with glycosyltransferases. The enzymatic method for glycopeptide synthesis is complementary to the solution- and solid-phase chemical approaches,[60–62] but may be more suitable for the synthesis of large glycopeptides.

Enzymatic elaboration can be extended to lipids, as well. The ganglioside GM_3 may be converted to GD_3 with α-2,8-sialyltransferase (GD_3 synthase), and the melanoma antigen 9-*O*-acetyl-GD_3 can be prepared from GD_3 *via* subtilisin-catalyzed acetylation in DMF using vinyl acetate[63] (Fig. 4).

Rational design and synthesis of sialyl Lewis X mimetics

As mentioned previously, complex carbohydrates may not be ideal candidates for drug development, and so the development of carbohydrate mimetics which contain additional recognition groups (hydrophobic or charged) and are simpler, more stable, more active than the parent structure, and perhaps orally active has become an interesting subject for research [see Fig. 5(a) for an overall strategy]. In the case of the SLe^x–selectin interaction, the structure–function relationship study and conformational analysis have led to the rational development of SLe^x mimetics which may be comparable to or even better than the natural ligand as inhibitors of selectins. Several groups have been actively engaged in this effort, and several SLe^x mimetics developed [see Fig. 5(b) and relative activity][64–72] have been shown to have IC_{50} values for the selectins decreased from the millimolar range for SLe^x to the low micromolar range for the mimetics.

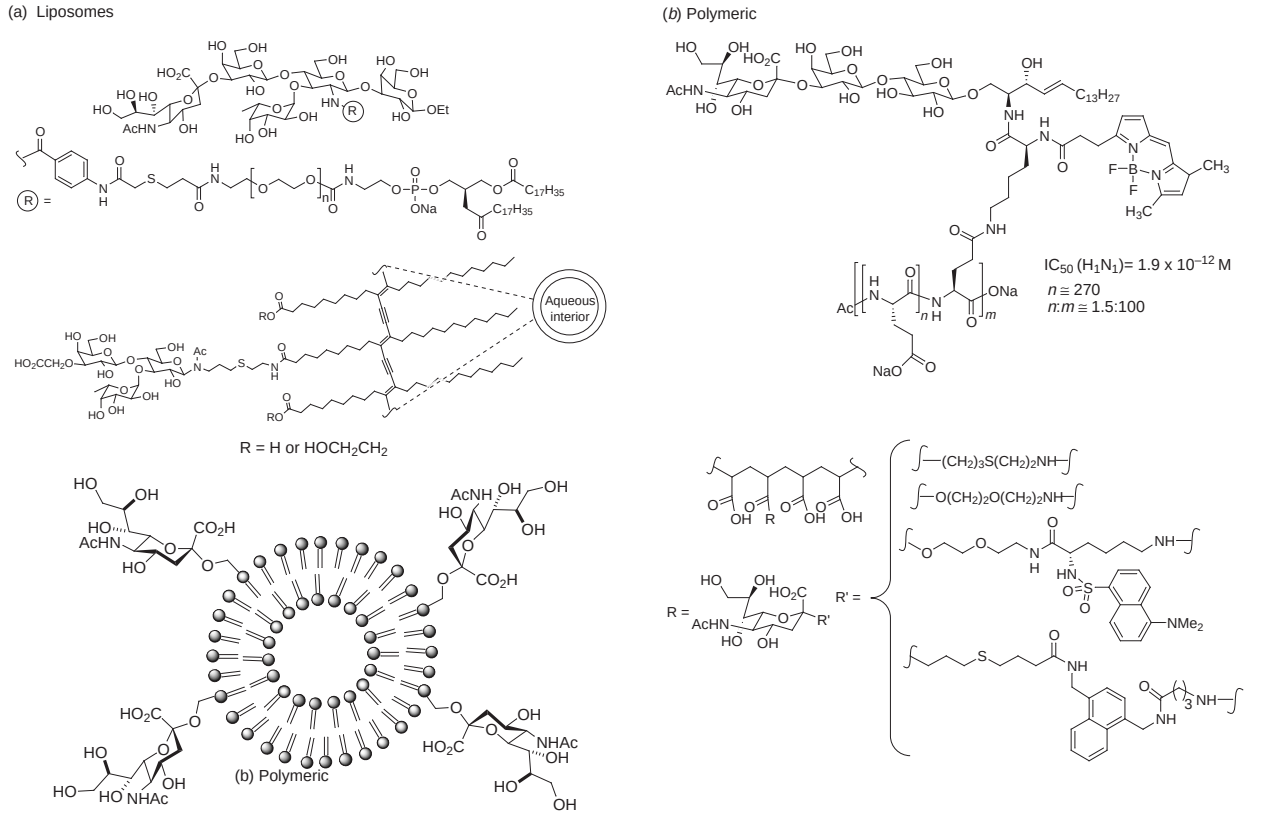

Fig. 6 Representative carbohydrate-based multivalent inhibitors of selectins and influenza haemagglutinin, both (a) liposome-based and (b) polymer-based

Polyvalent inhibitors of receptor–ligand interaction

Cell-surface receptor–ligand interactions, such as selectin–ligand interaction, are often multivalent, and so the inhibitor prepared in a multivalent form is expected to increase the inhibition potency. Indeed, both polymeric and liposome-like SLe^x derivatives have been shown to be much more active (by a factor of ~70–5000 depending on the structure and formulation) than the monomeric species as inhibitors of E- and P-selectin.[73,74] One should be careful, however, in extrapolating *in vitro* binding constants to *in vivo* activities. Polyvalent structures composed of ligands that are expected to show moderate non-specific binding in their monomeric form may show not only an increase in the strength of specific binding, but an increase in the strength of non-specific binding as well. For example, a polymer composed of repeating units of a ligand with a single cationic group will bind strongly to a polyanionic species, even though the monomer binds the polyanionic species only weakly. This is the principle of ion exchange

resins, after all. One should therefore begin with a molecule that has good specificity for the target of interest. In the future, perhaps the SLe^x mimetics described above, which already have better affinities for the selectins than SLe^x itself, can be converted to a multivalent form to increase the activity and specificity.

Previous work on the inhibition of the influenza virus haemagglutinin interactions with the host cell-surface sialoglycoproteins has also demonstrated the effectiveness of polyvalent inhibitors, and highly effective inhibitors with IC_{50} values ranging from 10^{-11}–10^{-12} M have been developed.[75,76] Some representative carbohydrate-based polyvalent systems are shown in Fig. 6.

Combinatorial approaches for discovering carbohydrate mimetics

The combinatorial approach has also been used in finding peptides that bind to E-selectin.[77] In many cases, the carbohydrate–receptor interaction is not well understood, so the aforementioned rational design of carbohydrate mimetics becomes difficult. In such cases, the combinatorial synthesis approach is perhaps the most effective way of finding lead inhibitors. Alternatively, the combinatorial approach can be useful for lead optimization. For example, the aminoglycoside antibiotic Neomycin B has recently been found as inhibitor of the Rev response element (RRE),[78] but the inhibition has not been well studied with regard to the origin of the selectivity. This is true with respect to the interaction of many other aminoglycoside antibiotics with certain sequences of RNA, including ribozymes.[79] However, one interesting common feature of these antibiotics is that most of them contain a *trans*-1,3-hydroxylamine or *trans*-1,3-diamine motif. Our recent model study also indicates that phosphodiesters complex the gluco-type 1,3-hydroxylamine more strongly than a bicyclic guanidine, and may also interact with the Hoogsten face of guanine[80] (see Fig. 7). This finding has led us to use a combinatorial approach to rapidly synthesize a library of

aminoglycoside mimetics containing either the neamine core or the 2,6-dideoxy-2,6-diaminoglucose (Fig. 8) and screen the library for new compounds that bind to RRE[81] or other RNA sequences, especially the bacterial 16S rRNA A site, a useful target for preventing bacterial infection.[82] As a result, several Neomycin B mimetics have been found to be more active than Neomycin B itself.[81] The combinatorial synthesis is facilitated by the use of the polyethylene glycol ether as the carrier. The product can be easily isolated by precipitation with ether, so that chromatography is not necessary.[83] Both rational and library approaches have also been used to develop new aminoglycoside antibiotic mimetics to target the bacterial 16S rRNA A site and some potent new antibiotics have been discovered.[82]

Inhibition of glycosidases and glycosyltransferases

Another strategy for the intervention of carbohydrate recognition processes is to inhibit the enzymes associated with oligosaccharide biosynthesis. Both glycosidases and glycosyltransferases are important enzymes involved in the processing and synthesis of oligosaccharides and are therefore obvious targets for intervention. The mechanisms of glycosidases have been well studied[84–86] and means for inhibition of these enzymes have been developed.[87–92] Glycosyltransferase reactions are thought to proceed through transition states similar to those of the glycosidase reactions, which are believed to proceed through a half-chair transition state with a substantial sp^2 character developed at the anomeric center [Fig. 9(A)].[49,93,94] Based on this mechanistic rationale, many transition-state analog inhibitors of glycosidases, especially iminocyclitols, have been developed [Fig. 9(B),(C)]. The five-, six- and seven-membered iminocyclitols have been synthesized based on the sequence of aldolase reaction and Pd-mediated reductive amination.[89,95] These nitrogen-containing heterocycles have also been used as key components in the synthesis of glycosyltransferase inhibitors.[89] In addition, both bisubstrate and trisubstrate analogs and fluorinated sugar nucleotides have been developed as glycosyltransferase inhibitors.[94,96–99]

Conclusions and future prospects

Molecular recognition of carbohydrates and related structures in biological systems represents a new frontier of research. Many of these recognition events occur at the very early stage of disease development and other signalling processes and new strategies and techniques are needed to study the recognition events in detail. Chemistry will continue to play a key role in uncovering the molecular mechanism of carbohydrate recognition and in development of novel structures to control the recognition process and combat disease. As the principles of carbohydrate recognition become well understood, carbohydrate mimetics will be developed to overcome some of the undesirable properties of parent structures, and additional groups (such as hydrophobic groups) complementary to the receptor can be further incorporated to the mimetics to enhance binding and to improve the activity. Finally, the multivalency strategy can then be utilized to further increase the activity and to control *in vivo* the function of carbohydrates.

Binding of D-serine-terminating cell-wall analogues to glycopeptide antibiotics

André M. A. van Wageningen, Thomas Staroske and Dudley H. Williams*†

Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW

Binding studies of –L-Lys-D-Ala-D-Ser-terminating ligands, used as model systems for cell-wall precursors found in VanC resistant bacteria, with vancomycin, chloroeremomycin and teicoplanin show that they bind to these glycopeptides in a similar manner as –L-Lys-D-Ala-D-Ala-terminating ligands, but that the binding constants are one to two orders of magnitude lower.

The glycopeptide antibiotics vancomycin and teicoplanin are well-known for their theurapeutic use as antibiotics of last resort against methicillin-resistant *Staphylococcus aureus* (MRSA).[1] The antibacterial activity of the glycopeptides results from interference of the synthesis of the growing bacterial cell wall by binding to the precursor peptide sequence terminating in –L-Lys-D-Ala-D-Ala.[2,3] The molecular features responsible for the antibacterial activity of these antibiotics are well understood. Important features promoting activity include dimerisation of the antibiotics, in the cases of vancomycin and chloroeremomycin (also known as A82846B and LY264826), and the presence of a membrane anchor (a C_{11} alkyl chain) in the case of teicoplanin.[2,3]

Recently there has been a rise in the number of cases of vancomycin-resistant enterococcal infections in hospitals.[4] In most cases this resistance is caused by the presence of peptidoglycan precursors terminating in –D-Ala-D-Lac rather than –D-Ala-D-Ala; so-called VanA and VanB resistance.[5] It has been demonstrated that the glycopeptides bind –D-Ala-D-Lac-terminating cell-wall analogues in a similar way[6] to the corresponding –D-Ala-D-Ala-terminating ones but considerably weaker.[6,7] A different form of vancomycin resistance seems to be specifically found in *E. gallinarum* and *E. casseliflavus*.[8–10] In these bacteria cell-wall precursors terminating in –D-Ala-D-Ser have been found.[11] Vancomycin shows reduced activity against these VanC resistant bacteria (MIC 2–32 μg ml^{-1}), whereas teicoplanin remains more or less active (MIC ⩽ 0.5 μg ml^{-1}).[12,13]

Although binding constants for *N*-acetyl-D-Ala-D-Ser towards vancomycin and teicoplanin have been determined,[14] no evidence is provided that these ligands bind in a similar way to the –D-Ala- and –D-Lac-terminating peptides. Therefore, we decided to investigate the molecular details of the binding of –D-Ser-terminating cell-wall analogues using di-*N*-acetyl-L-Lys-D-Ala-D-Ser (synthesised in our laboratory by solid phase peptide synthesis). The tripeptide was used as we believe that this tripeptide is a better model system for the cell-wall precursors than the dipeptide. Her we report our initial results on the binding of –D-Ser-terminating peptides to vancomycin, chloroeremomycin and teicoplanin.

UV difference spectrophotometry was used to determine the binding constants of the different antibiotics to di-*N*-acetyl-L-Lys-D-Ala-D-Ser.‡ The results are summarised in Table 1.

It is clear that vancomycin and chloroeremomycin show reduced binding to the –D-Ser-terminating tripeptide compared to binding the –D-Ala-terminating cell-wall analogue. Significantly, vancomycin binds more weakly to the tripeptide terminating in –D-Ser relative to that terminating in –D-Ala by a factor of 20; this difference is larger than that between the corresponding dipeptides (a factor of 7 difference).[14] The decrease is, however, not as dramatic as that observed for the –D-Lac-terminating cell-wall analogue. This may explain the increased activity of vancomycin against bacteria showing VanC resistance compared to bacteria with VanA or VanB resistance. Furthermore, the results indicate that the difference in activity of vancomycin and teicoplanin against VanC resistant bacteria may be caused by the difference in binding strength to the –D-Ser-terminating peptide, which is about one order of magnitude greater for teicoplanin. In general, the results indicate that the introduction of a hydroxymethyl group, present on the serine residue, compared to the methyl group on the alanine residue does not result in as large a change in binding energy as to the change of the amide group to an ester group (as found in lactate-terminating peptides).

In complexes with ligands terminating in –D-Ala[15] and –D-Lac[6] a large downfield shift occurs in NMR spectra of the signal corresponding to the amide proton of residue 2 (w_2), due to the formation of a hydrogen bond between the ligand carboxylate and the amide proton. In case of the –D-Ser-terminating ligand the chemical shift of w_2 of chloroeremomycin moves from δ 8.48 (free antibiotic) to *ca.* 11.2 in the fully bound complex.§ This clearly indicates the formation of hydrogen bond from the amide hydrogen to the carboxylate of the D-Ser residue.

To gain evidence that not only was the carboxylate anion of the –D-Ser tripeptide bound in the manner typical of a cell-wall analogue to a glycopeptide antibiotic, but also that the whole peptide was anchored in the usual way, two-dimensional NOESY and TOCSY spectra were obtained.¶ The experiments establish that the serine sidechain is buried against ring 4, that the alanine methyl group points towards proton 7d (see Fig. 1), that the lysine sidechain is situated over ring 7 of the antibiotic, and that the lysine backbone Ac group is adjacent to the *epi*-vancosamine sugar attached to residue 6 (Table 2). A schematic representation of the inferred binding of the serine tripeptide to the glycopeptide antibiotics is represented in Fig. 1.

In conclusion, we have demonstrated that glycopeptides bind –D-Ala-D-Ser-terminating cell-wall analogues, found in bacteria with VanC resistance, in a similar way as –D-Ala-D-Ala- and –D-Ala-D-Lac-terminating cell-wall analogues. The binding strength of the –D-serine-terminating tripeptides is lower than the corresponding alanine ones, but not as low as the –D-lactate-terminating peptides, which can account for the less severe nature of the resistance observed in bacteria exhibiting VanC resistance.

Table 1 Summary of binding constants (K_{ass}) to glycopeptide antibiotics with tripeptide cell-wall analogues, di-*N*-acetyl-L-Lys-D-Ala-X, determined by UV difference spectrophotometry

	K_{ass}/dm^3 mol^{-1}		
Antibiotic	X = D-Ala	X = D-Lac	X = D-Ser
Vancomycin	1.5×10^6 [a]	410[b]	$(7 \pm 2) \times 10^4$
Chloroeremomycin	1.3×10^6 [c]	245,[d] 1.6×10^3 [b]	$(8 \pm 1) \times 10^4$
Teicoplanin	1.6×10^6 [e]	n.d.[f]	$(5 \pm 1) \times 10^5$

[a] Ref. 17. [b] Ref. 7. [c] Ref. 16. [d] Ref. 6. [e] Ref. 18. [f] n.d. = not determined.

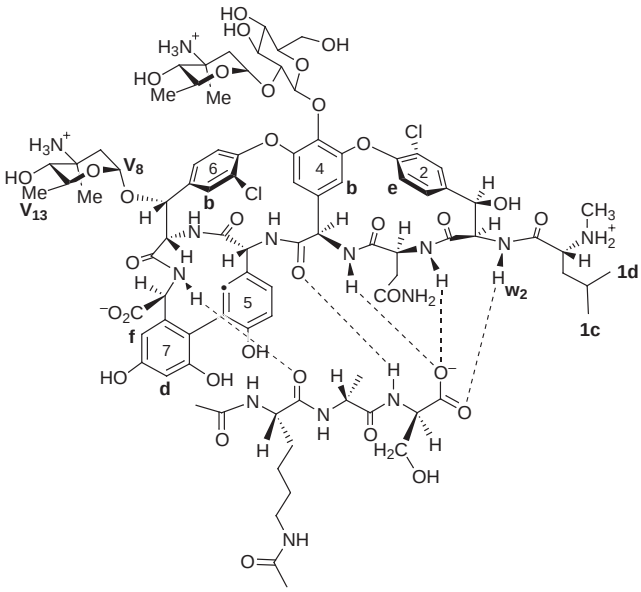

Fig. 1 Exploded view of the binding of di-*N*-acetyl-L-Lys-D-Ala-D-Ser to chloroeremomycin. Dashed lines indicate hydrogen bonds.

Table 2 Observed NOEs between di-*N*-acetyl-L-Lys-D-Ala-D-Ser and chloroeremomycin

Assignment	δ (ppm)	Observed NOEs
D-Ser-α	4.33, 4.45[a]	1c, d
D-Ser-β	2.53, 2.54[a]	2e, 4b
	3.38, 3.65[a]	2e
D-Ala-α	4.84	6b
D-Ala-β	1.15	7d
Lys-α-Ac	2.06	6b, V_8, V_{13}
Lys-β	1.66	7f
Lys-γ	1.48	7f

[a] Two chemical shifts observed due to the different environments in each half of the asymmetric antibiotic dimer.

We thank the Dutch Technology Foundation STW (A. M. A. v. W.) and the EPSRC (T. S.) for financial support, Eli Lilly for the gift of chloroeremomycin, and Lepetit for the gift of teicoplanin.

Notes and References

† E-mail: dhw1@cam.ac.uk

‡ UV spectrophotometry was carried out on a UVIKON 940 dual beam spectrophotometer. Both the reference and sample cells contained 50 μM antibiotic in 0.1 mol dm^{-3} phosphate buffer (pH 4.5, 298 K). Aliquots of a ligand solution containing 50 μM antibiotic were added to the sample cell. The solution was stirred after each addition, and the absorbance at both *ca.* 240 and *ca.* 280 nm was measured repeatedly until stable. The data at *ca.* 240 nm were subtracted from those at *ca.* 280 nm and analysed as previously described (ref. 16).

§ The limiting chemical shift of w_2 for the vancomycin complex could not be determined due to low solubility of the complex.

¶ The spectra were obtained from samples containing chloroeremomycin (15 mmol dm^{-3}) and di-*N*-acetyl-L-Lys-D-Ala-D-Ser (15 mmol dm^{-3}) in D_2O and 10% D_2O–H_2O at 290 K (pH 4.5). The NOESY and TOCSY spectra were recorded on a Bruker DRX 500 spectrometer in phase-sensitive mode using Time Proportional Phase Increment (TPPI) to give quadrature detection in f_1. 2048 complex data points were recorded in f_2 and 512 real points in f_1 using mixing times of 100–150 ms. Zero filling was used to give a final transformed matrix of 2048 × 2048 real points.

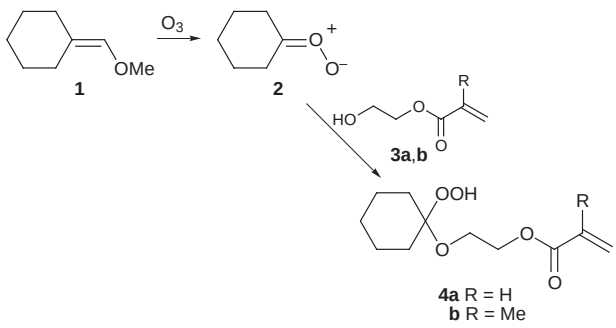
Treatment of (1-hydroperoxy)cyclohexyloxyethyl acrylate with either iron(II) sulfate or iron(II) sulfate/copper(II) chloride affords novel 13-membered macrolides *via* tandem radical scission-cyclisation reactions.

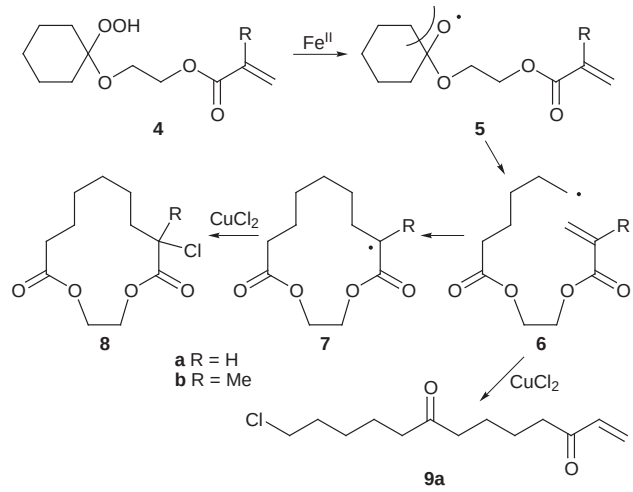
The development of synthetic strategies to macrocyclic compounds has attracted considerable attention because many of them are naturally occurring and several possess important biological properties.[1,2] In this respect, intramolecular radical addition to α,β-unsaturated ketones has been found to provide convenient access to a variety of macrocycles.[3] This method is generally based on the intramolecular cyclisation of the long-chain unsaturated radicals generated by the reaction of the corresponding iodo enones and their homologues with tributyltin hydride.[4] We report herein that the iron(II)-mediated fragmentation of the readily prepared 1-(hydroperoxy)-cycloalkyloxyethyl acrylates provides an alternative approach to the synthesis of novel macrolides.[5,6]

The key to our approach is the ease of preparation of the desired intermediate unsaturated hydroperoxy acetals **4**. Thus, treatment of a solution of vinyl ether **1** and unsaturated alcohol **3** (3 equiv.) in CH_2Cl_2 with ozone (1 equiv.) at −70 °C resulted in the selective ozonolysis of the electron rich vinyl ether **1** to give carbonyl oxide **2** which was subsequently captured by **3** affording the corresponding hydroperoxide **4** in moderate yield (**3a**, 27%; **3b**, 40%) (Scheme 1).[7] Subsequent treatment of a solution of the hydroperoxide **4a** in MeCN with a solution of iron(II) sulfate (1 equiv.) and copper(II) chloride (3 equiv.) in water at room temperature gave the macrolide **8a** (49%) and the acyclic diketone **9a** (17%) (Scheme 2).‡ Compound **8a** was shown to be the structurally novel 13-membered bislactone by X-ray crystallographic analysis (Fig. 1).§ From hydroperoxide **3b**, the corresponding chloro-substituted macrolide **8b** was obtained in 35% yield, along with the unidentified acyclic products.¶

These results indicate that the acyclic radical **6**, generated by sequential fragmentation of the O–O bond to give oxy radical **5** followed by β-scission of the cyclohexylidene ring, had undergone a very efficient intramolecular cyclisation to give **7**, which in turn reacted with copper(II) chloride to provide the chlorinated macrolide **8**.[8]



Scheme 1



Scheme 2

In the absence of copper(II) chloride, the reaction of the hydroperoxide **4a** with iron(II) sulfate (2 equiv.) yielded three new crystalline products: the monomeric bislactone **10a** (18%) and two dimeric isomers **11a** (Scheme 3). X-Ray crystallographic analysis of the higher melting dimer (mp 168 °C; 25%) demonstrated unambiguously that this was the *meso*-isomer (Fig. 2).‖ Thus, the other dimeric isomer **11a** (mp 140.5–141.5 °C; 25%) was assigned as the *dl* form. From the hydroperoxide **4b**, the monocyclic macrolide **10b** was obtained in 25% yield along with unidentified acyclic products. Since the corresponding dimeric compounds were not observed in significant quantities, it appears that the sterically more hindered radical **7b** does not undergo dimerisation as readily as **7a**.

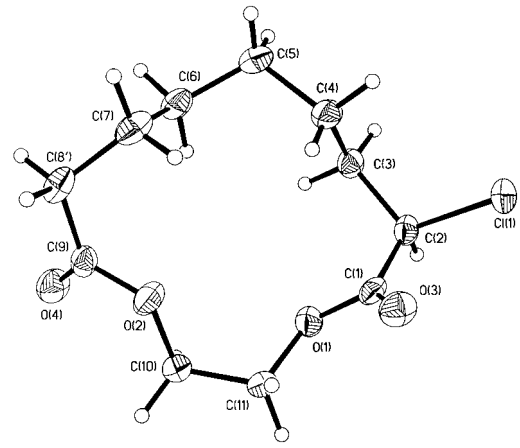


Fig. 1 The molecular structure of macrolide **8a** as determined by X-ray crystallography (ORTEP, 50% probability ellipsoids for non-hydrogen atoms) (ref. 10)

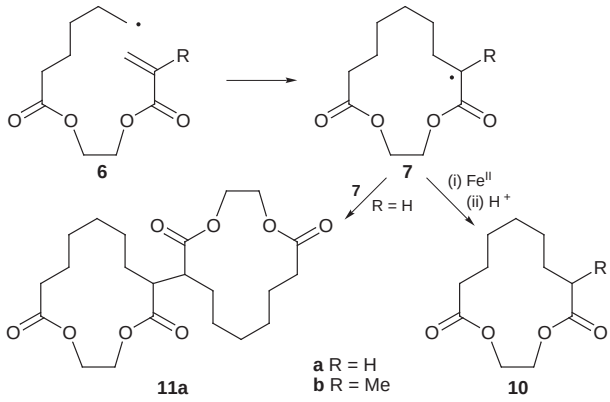

Scheme 3

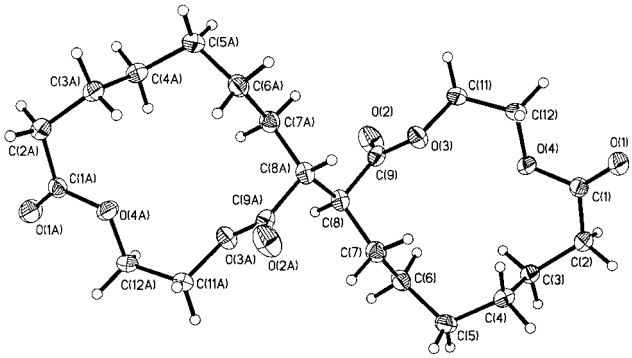

Fig. 2 The molecular structure of the dimeric macrolide **11a** as determined by X-ray crystallography (ORTEP, 50% probability ellipsoids for non-hydrogen atoms) (ref. 10)

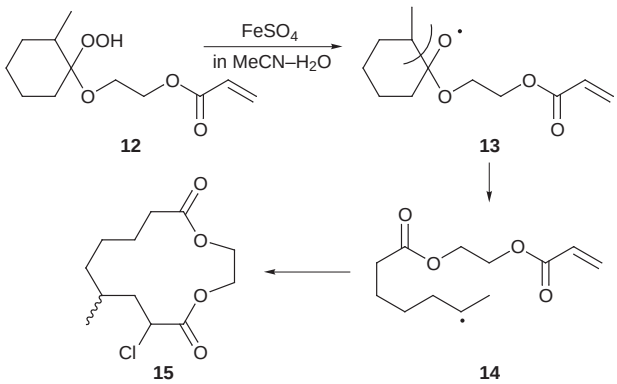
The iron(II) catalysed decomposition of the methyl-substituted hydroperoxide **12** results in the formation of the monomeric chloromacrolide **15** as the sole isolable product (54%, a mixture of two isomers in the ratio *ca*. 2 : 1). Thus, intermediate **13** had undergone a selective β-scission of the cyclohexylidene ring *via* the more highly substituted radical **14** as outlined in Scheme 4. Similar selectivity has been observed previously in the thermal rearrangements of α-substituted 1,2,4-trioxanes.[9]

In summary, the readily available unsaturated hydroperoxy acetals such as **4** offer considerable potential as precursors of novel macrolides. The fragmentation-cyclisation reactions take place under relatively mild conditions and do not require high



Scheme 4

dilution techniques (0.01–0.05 M). Moreover, the mode of termination can be controlled by the judicious choice of reaction conditions.

‡ All new compounds gave satisfactory microanalytical and spectroscopic data.

§ *Crystal data* for **8a**: $C_{11}H_{17}ClO_4$, M = 248.70, colourless needles, monoclinic, space group $P2_1/c$ (No. 14), a = 15.1404 (12), b = 5.0426 (4), c = 16.1490 (11) Å, β = 100.550 (5)°, U = 1212.12 (2) Å^3, Z = 4, D_c = 1.363 g cm^{-3}, $F(000)$ = 528, μ(Mo-Kα) = 0.312 cm^{-1}. The intensity data were collected on a Siemens P4 diffractometer at 160 (2) K using graphite monochromated Mo-Kα radiation (λ = 0.710693 Å). The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 using anisotropic temperature factors for the non-hydrogen atoms (SHELXTL[10]). At convergence, the discrepancy indices R_1 and wR_2 were 0.032 [for 1942 data with $F_o > 4\sigma(F_o)$] and 0.0878 (all 2111 unique data) respectively. The final difference Fourier map contained no feature greater than ±0.31 e Å^{-3}.

¶ Since the separation of **8b** from other acyclic products was difficult, the reaction mixture was ozonised further to break down the latter. Thus, **8b** could be cleanly isolated by column chromatography on silica gel.

‖ *Crystal data* for **11a** (higher mp dimer): $C_{22}H_{34}O_8$, M = 426.49, colourless prisms, triclinic, space group $P\bar{1}$ (No. 2), a = 5.0600 (10), b = 8.512 (2), c = 13.090 (2) Å, α = 88.800 (10), β = 83.78 (2), γ = 77.010 (10)°, U = 546.1 (2) Å^3, Z = 1 (molecule on an inversion centre), T = 160(2) K, D_c = 1.297 g cm^{-3}, $F(000)$ = 230, μ(Mo-Kα) = 0.098 cm^{-1}. The final discrepancy indices R_1 and wR_2 were 0.0341 [for 1595 data with $F_o > 4\sigma(F_o)$] and 0.0883 (all 1907 unique data) respectively. The final difference Fourier map contained no feature greater than ±0.20 e Å^{-3}. CCDC 182/842.

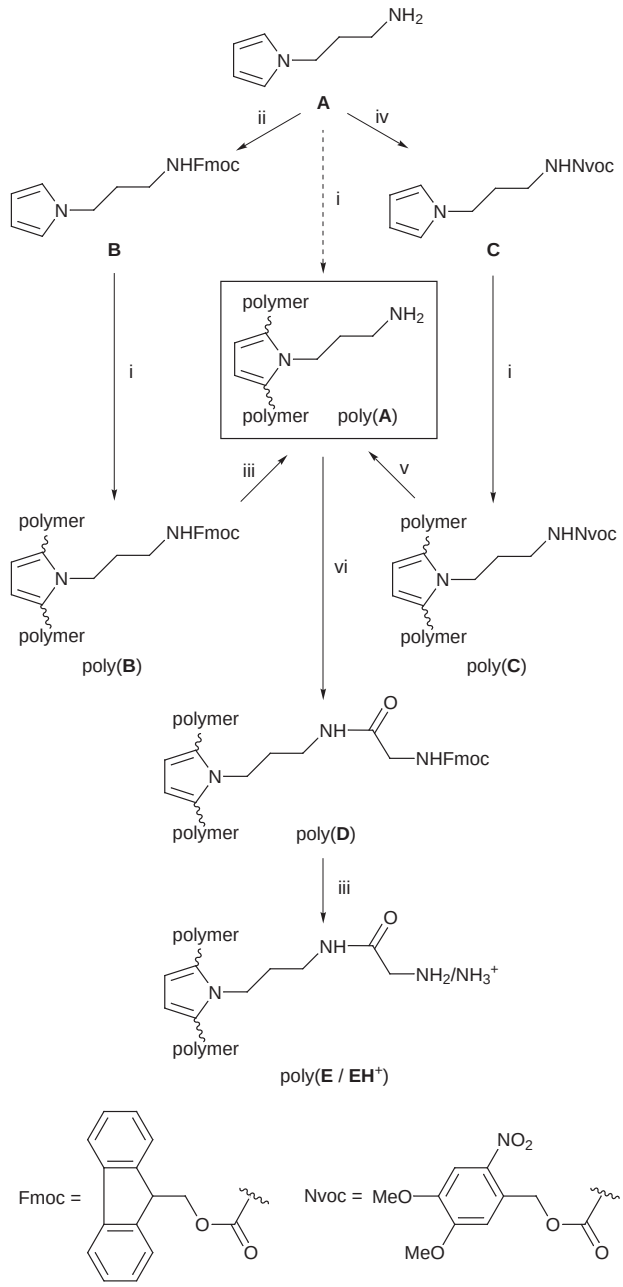
Amine protection/(photo)deprotection strategies allow functionalisation of electrode bound poly(pyrrole) films *via* reactions with active esters.

Polymers with substituent groups covalently anchored along the conjugated backbone of poly(pyrrole) or poly(thiophene) constitute a class of hybrid materials possessing potentially interactive electrical and molecular domains. They are consequently receiving considerable attention for sensing, electrocatalysis and other applications.[1–3] For example, a change in the redox response of an oligonucleotide functionalised pyrrole occurs upon recognition (binding) of a strand of complementary DNA.[3] The range of materials that can be made, and also aspects of their microfabrication, have been somewhat circumscribed by the need to synthesise and electropolymerise the appropriately substituted pyrrole or thiophene *monomer*.[4] This is problematic in cases where the desired substituent group is sensitive to the oxidative conditions of electropolymerisation or where the substituent is an inhibitor of this process. We have shown that one way in which such problems can be overcome is by *post-polymerisational modification* of pre-formed electropolymers which possess active ester groups.[4] The desired substituent groups are covalently attached to the polymer by amide or ester bond formation, and this general approach has been successfully adapted by others.[5] The converse derivatisation, reaction of *amine functionalised electropolymers* with active esters, could provide a complementary strategy for electropolymer functionalisation. This has the attraction that well-established protocols for solid-phase amine chemistry that have been developed on Merrifield resins might be adapted to electropolymers.[6] Herein we describe some first steps in this direction (Scheme 1).

Anodic oxidation of 3-pyrrol-1-ylpropylammonium cation **AH**$^+$ (Pt or vitreous carbon, 0.2 M $[NBu_4][BF_4]$–MeCN) gives the electroactive polymeric film poly(**AH**$^+$). The electropolymer can be (reversibly) deprotonated to give the free amine form, poly(**A**) but is otherwise quite unreactive: pentafluorophenolate active esters fail to modify bulk films of poly(**A**). Penetration of the film by the reagent is presumably prevented by close-packing of the polymer chains.

The problem is overcome by generating amine groups within the polymer from *N*-protected precursors. Fluoren-9-ylmethoxycarbonyl (Fmoc) and 6-nitroveratryloxycarbonyl (Nvoc) derivatised monomers **B** and **C** were synthesised from **A** (Scheme 1). Both of the *N*-protected monomers undergo facile electropolymerisation, as typified by the potentiodynamic growth of poly(**C**) (Fig. 1). Base deprotection of poly(**B**) or photodeprotection of poly(**C**) gives poly(**A**) (Scheme 1), as illustrated by the FTIR spectra shown in Fig. 2.

In contrast with the inertness of poly(**A**) produced directly by electrooxidation of **A**, the amino polymer generated by *either* deprotection route readily forms amide derivatives upon reaction with pentafluorophenolate active esters. For example, diffuse reflectance FTIR spectroscopy shows that poly(**A**) formed by photolysis reacts with Fmoc-glycine pentafluoro-



Scheme 1 *Reagents and conditions*: i, MeCN, 0.2 M $[NBu_4][BF_4]$, 5 mM **AH**$^+$; ii, FmocCl, Na_2CO_3, dioxane–water (1 : 1), 12 h, 22 °C; iii, 30% piperidine–MeCN, 1 h, room temp.; iv, NvocCl, Na_2CO_3, dioxane–water (1 : 1), 12 h, 22 °C; v, irradiation of 1 μm film for 4 h in 1% $HBF_4 \cdot 2Et_2O$–MeCN using 30 W mercury UV/pyrex filter transmitting through 1 cm of solvent under nitrogen; vi, 25 mM Fmoc-glycine pentafluorophenolate ester in 12% Et_3N–MeCN, room temp., 4 h

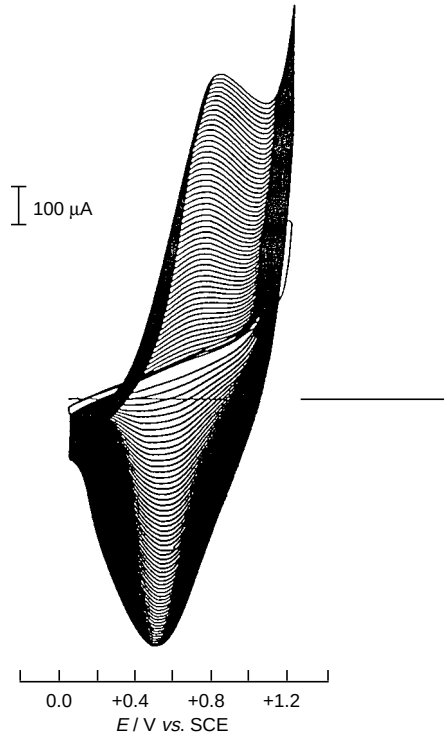


Fig. 1 Potentiodynamic growth of the Nvoc protected polymer, poly (**C**). The polymer was grown on a polished Pt disc electrode of radius 0.32 cm by cycling the potential between 0.0 and 1.20 V *vs.* SCE at 50 m V s^{-1} in 0.2 M $[NBu_4][BF_4]$–MeCN–5 mM **C**.

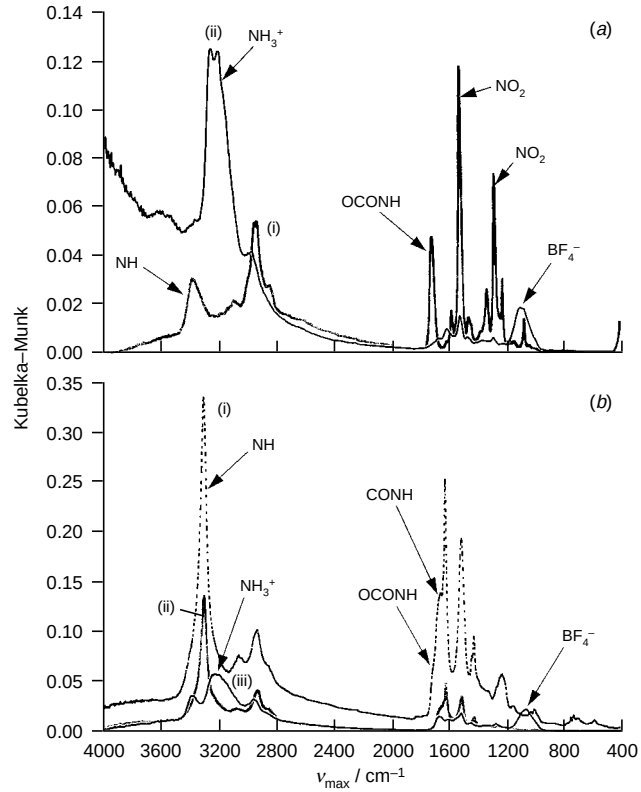

Fig. 2 (*a*) Diffuse reflectance FTIR spectra of (i) the Nvoc protected poly(**C**) and (ii) deprotected alkylammonium poly(**AH**$^+$) produced by photolysis of poly(**C**). (*b*) Diffuse reflectance FTIR spectra of (i) the Fmoc-glycine derivative, poly(**D**), formed by treating the poly(**A**) modified electrode with Fmoc-glycine pentafluorophenolate ester, (ii) the deprotected poly(**D**), which gives the amine film poly(**E**) by removal of Fmoc with piperidine, and (iii) the alkylammonium film poly(**EH**$^+$) formed by protonation of poly(**E**) (1% v/v $HBF_4 \cdot 2Et_2O$ in MeCN). Modifying the groups within the polymer changes the diffuse reflectivity characteristics of the film and thus relative band intensity *between* spectra.

phenolate (Fig. 2). Moreover, this Fmoc-glycine-derivatised film, poly(**D**), can in turn be chemically deprotected with piperidine to unmask the fresh terminal amine groups of poly(**E**).

The difference in polymer reactivity clearly lies with access to the amine groups and is explained by deprotection affording molecular cavities around these groups and/or the relatively bulky Fmoc and Nvoc groups producing a more open polymer network.

Although the deprotection pathways lead to a decrease in conductivity, as judged from the redox response of the polymer backbone, optimisation of the deprotection conditions and/or the use of protected 3-substituted pyrroles may be expected to lead to enhanced conductivity.

In conclusion, we have shown that an amine-functionalised electropolymer based on an N-substituted poly(pyrrole) can be made either directly or by chemical or photochemical deprotection routes. The deprotection routes afford polymers which react with active esters to form amides, whereas the directly synthesised amino polymer is unreactive under the same conditions. Finally, we note that (i) the chemical and photolytic deprotection strategies offer a means of *patterning* electropolymers with arrays possessing differing molecular functions,[7] (ii) 'cavity formation' by amine deprotection/photodeprotection might provide a means for molecular *imprinting* of an electropolymer,[8] and (iii) successive protection/deprotection/peptide bond formation cycles (Merrifield chemistry) can be performed on electropolymers.

One pot synthesis of mono- or bi-cyclic phosphiranes and phosphirenes

Maria Zablocka,[b] Yannick Miquel,[a] Alain Igau,[a] Jean-Pierre Majoral*[a]† and Aleksandra Skowronska*[b]

Treatment of phospholene oxide 1, vinylphosphine oxide 11 or alkynylphosphine oxide 14 with [Cp_2Zr] 2 followed by addition of a chlorophosphine leads to various phosphiranes and phosphirenes.

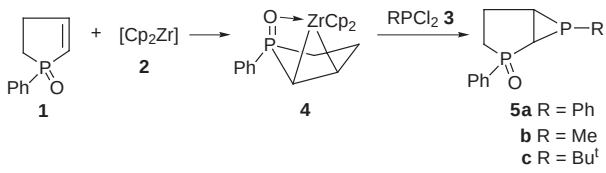
The heterocyclic chemistry of phosphorus is underdeveloped in comparison with its oxygen, nitrogen and sulfur counterparts in spite of the fact that a number of phosphorus rings appear to be useful reagents and ligands. Indeed, a recent review covers the rich and versatile chemistry of three-membered carbon–phosphorus heterocycles.[1] Several routes for the preparation of these derivatives, namely phosphiranes, phosphirenes, diphosphiranes, diphosphirenes and related species, have been reported. In contrast only a few syntheses of fused ring systems incorporating at least one phosphirane ring and another phosphorus containing heterocycle are known.

In the course of our studies devoted to the use of zirconium derivatives as tools in organic, organometallic and main group element chemistry,[2] we developed a new method for the preparation of fused ring systems involving phospholene oxide **1**, zirconocene [Cp_2Zr] **2** and dichlorophosphines $RPCl_2$ **3**. Such a methodology can be extended to the synthesis of various substituted phosphiranes and phosphirenes. We report here the general one pot preparation of some of these new compounds.

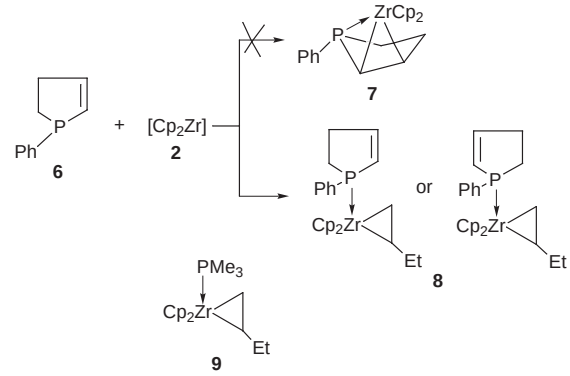
Treatment of phospholene oxide **1** with [Cp_2Zr] **2**[3]—prepared *via* the reaction of Cp_2ZrCl_2 with 2 equiv. of Bu^nLi at −78 °C in THF—leads to the formation of the zirconacyclopropaphospholane oxide **4** (Scheme 1). The ^{31}P NMR spectrum of **4** exhibits a resonance at δ 81.5 (compared with **1**, δ = 62.0). Such a significant deshielding effect suggests the participation of the phosphoryl group to the stabilization of the resulting zirconium complex **4**.[4] This assumption is corroborated by IR spectroscopy: the ν(PO) band is shifted from 1193 (**1**) to 1162 cm^{-1} (**4**).[5] Compound **4** is further characterized by ^1H NMR as well as by ^{13}C NMR spectroscopy, which shows, for example, the expected deshielded signals for the carbon atoms directly linked to zirconium.[6] Addition of phenyl(dichloro)phosphine to **4** in THF at −78 °C proceeds with removal of Cp_2ZrCl_2 and formation of the phosphiranophospholane oxide **5a** [δ_P 60.6 and −177.4 (d, J_{PP} 8.3 Hz)]. The shielded signal at δ −177.4 is typical for a phosphirane structure,[1,7] while the resonance at δ 60.6 fits well with the phospholane part of **5a**. Such a bicyclic structure is corroborated by ^{13}C NMR analysis.[6]

A similar exchange reaction involving **4** and either methyl- or *tert*-butyl-(dichloro)phosphine affords the fused bicyclic systems **5b** or **5c**, respectively [**5b**: δ_P 63.6 and −191.1 (d, J_{PP} 7.1 Hz); **5c**: δ_P 55.0 and −174.8 (d, J_{PP} 30.1 Hz)] (Scheme 1).

It should be emphasized that, in marked contrast to the behaviour of **1** towards **2**, the phospholene **6** does not give the



Scheme 1



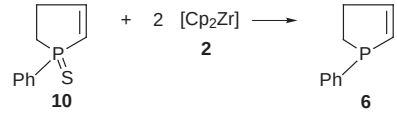
Scheme 2

expected zirconacyclopropaphospholane derivative **7**, but instead the zirconocene complex **8** (Scheme 2) is characterized. The structure of **8** can be unambiguously established by NMR analysis.[6] Investigation of the [Cp_2ZrCl_2 + 2Bu^nLi] reaction has been found to give $Cp_2Zr(nBu)_2$ at −78 °C, which then decomposes to give $Cp_2Zr(CH_2{=}CHEt)$ (the effective source of **2**) identified as its PMe_3 complex **9**.[8] Therefore compound **6** plays the role of PMe_3 and the olefinic part of **6** is not involved in the reaction. Addition of phenyl(dichloro)phosphine to **8** gives **6** and the products of the reaction of zirconocene **2** with phenyl(dichloro)phosphine, *i.e.* $(PhP)_4$ and $(PhP)_5$.

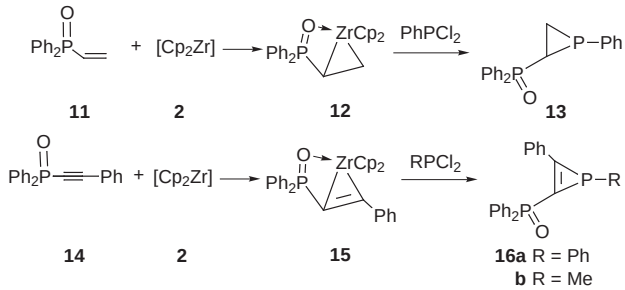
It should also be noted that the reaction of the phospholene sulfide **10** with **2** proceeds quite differently: only desulfurization occurs with the formation of **6**[9] (Scheme 3).

This demonstrates clearly, for the first time, the key role played by a phosphoryl group for the stabilization of intermediates and for the orientation of reactions involving phosphorus derivatives and zirconium species. Up to now only the dramatic influence of the phosphorus lone pair of phosphines has been pointed out.[10]

The same remarkable behaviour is found when the linear vinylphosphine oxide **11** is treated with **2** and then with phenyl(dichloro)phosphine. The reaction proceeds *via* the formation of the zirconium complex **12** (δ_P 47)[4] to give the phosphirane **13** [δ_P 31.3 and −178.3 (d, J_{PP} 30 Hz)][6] (Scheme 4). Such a reaction is not limited to olefinic systems. Indeed addition of the acetylenic phosphine oxide **14** to a THF solution of **2** at −78 °C leads to the fully characterized zirconacyclopropene species **15**.[4,6] Further addition of phenyl- or methyl-(dichloro)phosphine to **15** gives new phosphirene derivatives **16a** or **16b**, respectively (Scheme 4). No traces of phosphirane or phosphirene is detected when the same reactions are conducted with the corresponding linear vinyl or acetylenic phosphines instead of the phosphine oxides **11** or **14**.



Scheme 3



Scheme 4

Mechanistic studies and extension of these reactions to other substrates are underway.

Cuprophilicity, a still elusive concept: a theoretical analysis of the ligand-unsupported Cu^{I}–Cu^{I} interaction in two recently reported complexes

Density functional theory (DFT) calculations explain the short ligand-unsupported Cu^{I}–Cu^{I} contact recently reported for the $[CuL]^{+}[CuCl_2]^{-}$ complex [L = 1,1′-bis(2-pyridyl)octamethylferrocene] by a strong electrostatic attraction (−64 kcal mol^{-1}) between the two moieties and rule out the initially suggested metallophilic interaction, but cuprophilicity might account for the dimerization occurring in a family of trimetallic complexes.

Weak attraction between transition metal atoms with closed-shell electronic configuration was first evidenced by Schmidbaur *et al*. in the cases of intra- and intermolecular Au^{I}–Au^{I} contacts.[1] The term aurophilicity was coined to describe these interactions, but it soon became clear that similar aggregation processes could also involve metal atoms other than gold, such as Tl^{I} or Hg^{II}.[2] These closed-shell interactions in inorganic chemistry have been reviewed by Pyykkö.[2] The occurrence of analogous metallophilic[3] effects involving lighter metal atoms and more specifically Cu^{I} has been the subject of a long debate due to the intramolecular character of the reported interactions.[2,4] Recently, two examples of unsupported Cu^{I}–Cu^{I} contacts with metal–metal distances of 2.905 Å[5] and 2.810 Å[6] have been tentatively assigned to cuprophilic interactions. On the theoretical side, recent studies by Pyykkö *et al*. suggest that the stabilization of the $ClCuPH_3$ model dimer due to the metallophilic interaction between the Cu^{I} atoms does not exceed −1.5 kcal mol^{-1} when extrapolated to the best level of theory, and is associated with a rather long metal–metal distance of 3.143 Å.[7] The goal of this study was to investigate by means of DFT and extended Hückel calculations other possible origins for the unsupported Cu^{I}–Cu^{I} interactions in the two complexes for which cuprophilicity has been addressed.

Metallophilic interactions are not easy to characterize from quantum chemical calculations. Pyykkö *et al.*[2,3] have demonstrated that metallophilicity is due to attractive dispersion forces that should overcome the Pauli repulsion between the d^{10} or the d^{10} s^2 closed shells. For metals of the third transition row, the attractive forces are greatly enhanced by relativistic effects.[2,7] Since neither *ab initio* Hartree–Fock nor DFT calculations account for dispersion-type R^{-6} terms these levels of theory unavoidably predict repulsive behaviour between unsupported metallophilic fragments.[2,3] Conversely, if these methods are able to account for an attractive interaction, it should be clear that it is not of the metallophilic type.

This is the principle of the investigations performed on $[CuL]^{+}[CuCl_2]^{-}$ [L = 1,1′-bis(2-pyridyl)octamethylferrocene] **1** for which a cuprophilic interaction had been tentatively suggested to explain the short Cu^{I}–Cu^{I} contact (2.810 Å) observed between the two copper subsystems.[6] Complex **1** has been slightly modeled by replacing octamethylferrocene with ferrocene (**1′**) and by assuming perfect C_{2v} symmetry, which implies that the coordination axes of the anion and the cation are perpendicular (Fig. 1). We then carried out a full geometry optimization of **1′** by means of gradient-corrected DFT calculations.‡ Selected geometrical parameters obtained from the calculation are reported in the caption of Fig. 1 and compared to experiment. The observed environment of the copper atoms is reproduced by the calculation with great accuracy, including the Cu–Cu bond length (calc. 2.822 Å, exptl. 2.810 Å). The interaction energy between the two fragments is calculated to be −64.1 kcal mol^{-1}, after BSSE correction. The presence of a bonding interaction at this level of theory and its order of magnitude clearly show that the attraction between the $[CuL]^{+}$ and the $[CuCl_2]^{-}$ subunits should not be assigned to cuprophilicity. Since the interaction involves charged moieties, the bonding may instead be due to Coulombic forces. Mulliken population analyses, carried out either from the extended Hückel (EHT) or from the DFT orbitals, indicate that the charge transfer between the two moieties is negligible (Table 1). The negative charge in the $(CuCl_2)^{-}$ fragment is distributed between the chlorine atoms while the Cu atom remains either neutral (+0.04e, DFT), or significantly positive (+0,24e, EHT). Even though the point charge distributions in the cationic fragment is noticeably different for EHT and DFT (Table 1), the $(CuCl_2)^{-}/(CuL)^{+}$ electrostatic attraction computed from the point charge model are similar (62.0 kcal mol^{-1} with EHT, −67.9 kcal mol^{-1} with DFT) and practically reproduce the fragment interaction energy obtained from DFT calculations. Other models of space partitioning[8,9] applied to the DFT wave function, however, predict some charge transfer toward the $(CuL)^{+}$ moiety and the fragment electrostatic energies computed from those models are scaled accordingly (Table 1).

In order to obtain an estimate of the fragment/fragment Coulombic interaction independent of space partitioning, we relied on standard energy decomposition analysis[10,11] and computed the total energy starting from the wave functions computed for the $(CuCl_2)^{-}$ and $(CuL)^{+}$ fragments assumed isolated, but occupying their geometrical positions in the complex. The interaction energy is now −69.4 kcal mol^{-1}. The difference with respect to the value of −64.1 kcal mol^{-1} reported above corresponds to the fragment relaxation energy. The fragment interaction energy is made up of: (i) the Pauli

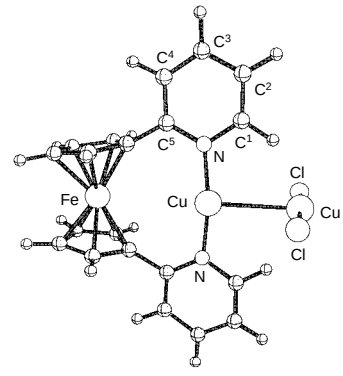

Fig. 1 Molecular structure of **1′** optimized from gradient corrected DFT calculations (C_{2v} symmetry assumed). Selected bond lengths (Å) and angles (°): Cu–Cu 2.822 (2.810); Cu–Cl 2.119 (2.095); Cu–N 1.895 (1.925); Cu···Fe 3.74; Fe-Ω 1.668 (Ω centroid of a Cp ring); N–Cu–Cu 95.0 (94.3); Cl–Cu–Cu 88.8 (89.1). Numbers in parentheses are the averaged experimental values.

Table 1 Point charge distributions (electrons) computed for **1′** using (i) the Mulliken space partitioning applied to the EHT and to the DFT wave functions, and (ii) the Hirshfeld[8] and the Voronoi[9] space partitionings, both applied to the DFT wave function. The electrostatic interaction energy between the two fragments is calculated from those point charges

repulsion, +38.8 kcal mol^{-1}; (ii) the Coulombic attraction, −86.4 kcal mol^{-1}, and (iii) the energy associated with electron reorganization in the complex, which is also attractive and reaches −21.8 kcal mol^{-1}. This latter term includes the stabilization due to the mutual polarization of the two fragments which is a purely electrostatic effect that can be distinguished from charge transfer and orbital interaction.[11] This energy decomposition analysis stresses the importance of the Pauli repulsion which should not be exclusively assigned to the Cu^I–Cu^I contact, but also to the two short Cu···H1 distances (2.28 Å). It also proves, without assuming any space partitioning, the prominent influence of the Coulombic interaction.

Siemeling and colleagues[6] noted that a complex closely related to **1**, $[Cu(C_5H_3NMe_3\text{-}2,4,6)_2][CuCl_2]$ **2**,[12] does not display a similar Cu–Cu interaction. The structure of **2** is characterized by the stacking of planar $[Cu(C_5H_3NMe_3\text{-}2,4,6)_2]^+$ fragments separated by $(CuCl_2)^-$ moieties perpendicular to the N–Cu–N axis, but the Cu···Cu distance is now 3.61 Å.[12] This increase of the interfragment separation may be tentatively assigned to steric crowding induced by the presence of four Me substituents. However, providing a final answer to this problem will require the geometry optimization of models of **2**, with and without the Me substituents.

The case of $[Cu_3L'_3]_2$ {L′ = 2-[3(5)-pyrazolyl]pyridine} **3**[5] and related dimers of Cu^I_3 and Ag^I_3 complexes[13] seems more relevant to metallophilic interactions. Preliminary calculations of the extended Hückel type carried out on these molecules indicate that the Mulliken charge of the copper atoms is close to zero and confirm that no significant orbital interaction is at work between the two monomers. However, a conclusive argument proving the existence of metallophilic interactions on such large systems is at present impossible to obtain from quantum chemical calculations. It is however of interest to extrapolate from Pyykkö's calculations on $[ClMPH_3]_2$[7] the order of magnitude of the metallophilic stabilization in **3** and in its silver counterpart.

Pyykkö's potential energy curves were obtained at the *ab initio* MP2 level of calculation with very large basis sets.[7] They display energy minima at 3.208 Å for Au, 3.113 Å for Ag and 3.137 Å for Cu. The curves are however extremely shallow, especially for copper. The stabilization energy computed at the minimum is −3.07 kcal mol^{-1} but a separation of 4.5 Å still provides a favourable interaction which amounts to −1.2 kcal mol^{-1}. The crystal structure of **3** displays two short-range Cu–Cu interactions (2.905 Å) between the two monomers, but also six Cu···Cu distances between 4.44 Å and 4.75 Å.[5] Most of the metallophilic stabilization (*ca*. 60%) might then originate in these long distance interactions. However, providing a quantitative estimate for the overall stabilization energy requires caution. A comparison between MP2 calculations and more elaborate methods carried out for $[XAuPH_3]_2$ (X = H, Cl) indicates that MP2 overestimates the real stabilization energy by a factor of 2.[2,7] Scaling down accordingly the value deduced from Pyykkö's potential energy curves provides an overall stabilization of *ca*. −6 kcal mol^{-1} due to the cuprophilic effect between the two monomers, 60% of which is assigned to the intermediate range Cu···Cu interactions. A similar reasoning applied to the silver equivalent of **3** yields an estimate of *ca*. −7.5 kcal mol^{-1} for the metallophilic interaction, but in this case the intermediate range interactions account for no more than one third of the global stabilization.

All calculations were carried out on workstations purchased with funds provided by the DGICYT of the Government of Spain and by the CIRIT of Generalitat of Catalunya (Grants no. PB95-0639-C02-02 and SGR95-426). We are pleased to thank Dr Pierre Braunstein for stimulating discussions.

‡ *Computation*: gradient-corrected DFT calculations on complex **1** have been carried out by means of the ADF program.[14] We used the local spin density approximation characterized by the electron gas exchange ($X\alpha$ with α = 2/3) together with Vosko–Wilk–Nusair[15] parametrization for correlation. Becke's nonlocal corrections to the exchange energy[16] and Perdew's nonlocal corrections to the correlation energy[17] were added. Slater basis sets of triple-ζ+ polarization quality were used to describe the valence electrons of C, N, O and H. For first-row atoms, a 1s frozen core was described by means of a single Slater function. For copper, the frozen core composed of the 1s to 2sp shells was also modelled by a minimal Slater basis; 3sp electrons were described by double-ζ Slater functions, 3d and 4s by triple-ζ functions and 4p by a single orbital.[18]

Crystal engineering through charge transfer interactions; assisted formation of a layered coordination polymer (4-cyanopyridine)cadmium(II) iodide·diiodine

Rosa D. Bailey, Laura L. Hook and William T. Pennington*†

Department of Chemistry, Clemson University, Clemson, South Carolina 29634-1905, USA

Formation of a layered coordination polymer (4-cyanopyridine)cadmium(II) iodide is assisted by n–σ* donor–acceptor interactions between coordinated iodine atoms of the layers and iodine molecules which bridge adjacent layers.

We are very interested in the role that (n–σ*) charge transfer interactions might play in the design of functional solids. We have utilized this interaction to prepare a variety of diazine·I_2 complexes in which N···I charge-transfer interactions at either end of both the donor and acceptor molecules result in the formation of extended chains.[1] More recently we have reported on the utility of N···I based charge transfer complexes for the interconversion of polymorphic forms of a donor molecule, tetrapyridylpyrazine,[2,3] and have begun a systematic investigation of complexes of iodine with a variety of nitrogen-based donors.[4]

We are also interested in the role that coordination polymers might play in structure design. Group 12 (IIB) metal halides are particularly promising, owing to the variety of coordination numbers and geometries provided by the d^{10} configuration of the metal center. This structural diversity is closely dependent on factors such as the dimensions of the metal ions and halides, nature of other ligands, and the availability of other structure controlling interactions, such as hydrogen-bonding and charge transfer.[5–7] If this diversity can be controlled, group 12 metal halides offer an ideal system for structural engineering and design.

We have found that pyrazine forms 1 : 1 complexes with cadmium(II) halides, CdX_2·pyrazine (X = Cl **1**, Br **2**, I **3**).[8] All of the complexes crystallize as infinite CdX_2 chains in which cadmium atoms are doubly bridged by pairs of halide atoms; pyrazine ligands complete the pseudo-octahedral coordination of the cadmium atoms and link the CdX_2 chains to form extended two-dimensional layers. Numerous attempts to form a similar architecture with the bridging ligand, 4-cyanopyridine, were unsuccessful; however, an interesting bis-pyridyl complex, bis(4-cyanopyridine)cadmium(II) iodide **4**, was formed.[9] This complex crystallizes as infinite CdI_2 chains, in which cadmium atoms are doubly bridged by pairs of iodine atoms; 4-cyanopyridine ligands coordinated through the pyridyl nitrogen atom occupy *trans* positions to complete an octahedral coordination about the cadmium. The chains are associated into layers through self-association of the cyano groups. When co-crystallized with mercury(II) iodide (1 : 2 ratio) bis(4-cyanopyridine)cadmium(II) iodide·$2HgI_2$ **5** is formed. The layer structure of **4** is essentially unchanged in **5**, as the mercury(II) iodide molecules are intercalated between the layers.

Based on the donor–acceptor interactions between coordinated iodine atoms and the mercury center observed in **5**, it was anticipated that a similar interaction might occur with molecular iodine serving as the acceptor. Here, we report the construction‡ of a layered structure, (4-cyanopyridine)cadmium(II) iodide which was the unattainable target of our previous efforts. It is particularly significant that the formation of this structure is made possible by the assistance of n → σ* charge transfer interactions between the coordinated iodides and a complexed neutral iodine molecule.

Similar to the (pyrazine)CdX_2 complexes, 4-(cyanopyridine)cadmium(II) iodide I_2 **6** (Fig. 1) crystallizes as infinite CdI_2 chains in which cadmium atoms are doubly bridged by pairs of iodide atoms; adjacent cadmium atoms in the chain are related by mirror symmetry perpendicular to the ***a***-axis at (0 *y z*).§ The 4-cyanopyridine ligand is bonded through both the pyridyl and nitrile groups to complete a pseudo-octahedral coordination of the cadmium atoms and acts as a bridging ligand to link the CdI_2 chains related by a 2_1 operation parallel to ***b*** at (1/4 *y* 1/4), to form extended two-dimensional layers (Fig. 2). The layers are bisected by a mirror plane perpendicular to the ***c***-axis at (*x y* 1/4). The layers are joined in the stacking direction (the ***c***-axis) through an n → σ* charge transfer interaction from the

(Atoms labelled with a lower-case character were generated by the following symmetry operation: a *x*, *y*, 1/2 − *z*; b 1/2 − *x*, −1/2 + *y*, 1/2 − *z*; c 1 − *x*, *y*, *z*; d − *x*, *y*, *z*; e 1/2 − *x*, 1/2 − *y*, 1 − *z*; f 1/2 − *x*, 1/2 − *y*, −*z*.)

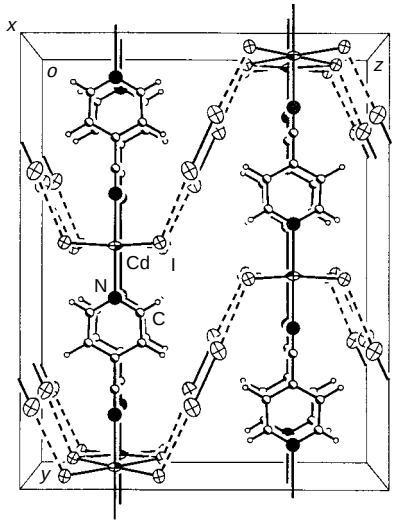

Fig. 2 Crystal packing of **6**, viewed down the ***a***-axis, parallel to the CdI_2 chains

coordinated iodine atoms as donors to either end of a bridging I_2 molecule.

The Cd–I···I donor–acceptor (n → σ* charge transfer) interactions are present at either end of the I_2 molecule and involve both of the coordinated iodine atoms. The interactions occur at approximately tetrahedral angles at the coordinated iodide and are oriented in a linear fashion to the I–I σ-bond. The I···I distances are well within the sum of van der Waals radii for iodine (1.98 Å),[10] and are similar to those seen in the related compounds, $Cd(NH_3)_4I_2{\cdot}I_2$ [3.386(2) Å] and $Cd(NH_3)_4(I{\cdot}I_2)_2$ [3.3780(9) Å].[11]

That these interactions occur only to the cyano-coordinated side of the CdI_2 plane is a result of the smaller size of the cyano-group; unfavorable steric interactions involving the pyridine rings prevent interaction on the other side of the CdI_2 plane.¶ When 4-cyanopyridine and cadmium(II) iodide are combined in a variety of stoichiometric ratios (1 : 1, 1 : 2, 2 : 1) in the absence of I_2, compound **4** is the only product formed. The considerably weaker donor strength of the nitrile group relative to the pyridyl group is presumably the reason for preferred formation of **4**. When I_2 is present, however, combination of cadmium(II) iodide and 4-cyanopyridine in the same stoichiometric ratios yields **6** as the only product. Formation of **6** and the fact that 4-cyanopyridine does serve as a bridge in this compound appears to be a result of the structural support provided by the charge transfer complexed iodine molecules which link adjacent groups in a zigzag fashion to form a reinforced three-dimensional network.

Thermal analysis of **6** by TGA‖ showed an initial mass loss of *ca.* 42% with an onset temperature of 83 °C. A second mass loss of 11% occurred at 163 °C, and the remainder of the mass was lost at 408 °C. These data suggest that **6** thermally decomposes by initial loss of the bridging I_2 molecule (35% by mass) coupled with a small amount of the ligand, the remainder of the ligand is lost in the second event, followed by sublimation of cadmium iodide at high temperature. The initial process is probably more complicated than simple diffusion of I_2 out of the solid. Powder diffraction on a sample of **6** heated to 120 °C for approximately 20 h revealed CdI_2 as the only crystalline product. This result coupled with our observation that recrystallization of **6** from ethanol gives **4** and CdI_2, and that leaching of **6** with boiling hexane leaves behind only solid CdI_2 suggests that the layered structure of **6** is tenuous. Removal of the supporting I_2 molecules leads to total collapse of the two-dimensional architecture and of the compound itself.

Continuing efforts to find gentler methods to remove or perhaps to exchange the I_2 supports through a diffusion process are underway. The stabilization of **6** by charge transfer interactions suggests the utility of these highly directional and attractive forces for isolating other metastable structures, and we are actively pursuing additional examples of this interesting phenomenon.

We thank the National Science Foundation for funds to purchase the Rigaku and Scintag diffractometers used in this work. We also thank Dr T. W. Hanks of Furman University for assistance with thermal analysis and for helpful discussion.

Data were collected on a reddish-brown platelet (0.02 × 0.15 × 0.15 mm) at −110 ± 1 °C by using a Rigaku AFC7R (18 kW) diffractometer with graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å) to $2\theta_{max}$ of 50.0°. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined isotropically. CCDC 182/863.

¶ All attempts to prepare similar compounds with ligands possessing only larger pyridyl donors (such as pyrazine and 4,4′-bipyridine) have been unsuccessful, presumably due to steric protection of the metal halide donor sites.

‖ Thermal gravimetric analysis of **6** was performed on a Perkin-Elmer Series 7 analyzer with the TGA7 software package (version 2.20). For onset calculations, the samples were heated at a constant rate of 5 °C min^{-1} from 25 °C until all of the material had evaporated.

Asymmetric Diels–Alder reaction *via* enzymatic kinetic resolution using ethoxyvinyl methyl fumarate

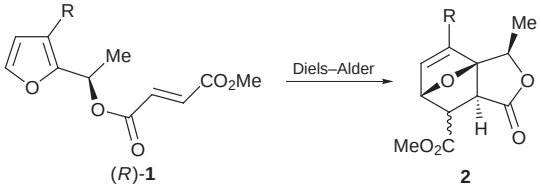
Yasuyuki Kita,*† Tadaatsu Naka, Masashi Imanishi, Shuji Akai, Yasushi Takebe and Masato Matsugi

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6, Yamada-oka, Suita, Osaka 565 Japan

A domino-type asymmetric [4 + 2] cycloaddition reaction following enzymatic kinetic resolution using ethoxyvinyl methyl fumarate is described.

We have already reported that ethoxyvinyl esters are better acylating reagents for enzymatic kinetic resolution of alcohols than the generally used vinyl esters.[1] One of the remarkable features of these acylating reagents is the facile preparation of esters bearing various acyl moieties.[2] Therefore, we planned a novel reaction system based on the idea that the acyl moiety inserted by enzymatic kinetic resolution is used in the subsequent reaction stage. Here we report a convenient asymmetric one-pot [4 + 2] cycloaddition reaction following an enzymatic kinetic resolution using readily-prepared ethoxyvinyl methyl fumarate.

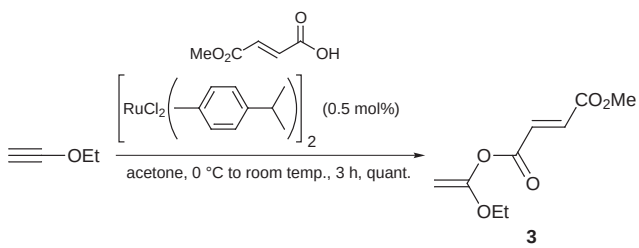
The enatiomerically pure 7-oxabicyclo[2.2.1]heptene derivative **2** is a useful compound in the syntheses of many natural products.[3] Many synthetic approaches to **2** have been reported to date,[4] and the intramolecular Diels–Alder reaction of the enantiomerically pure furfuryl fumarate derivative **1** is one of the most effective methods (Scheme 1).[5]



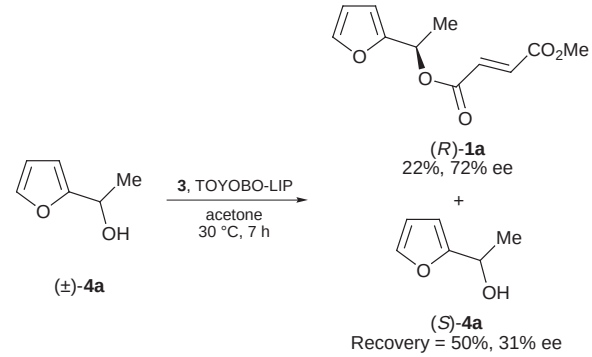
Scheme 1

We anticipated an easy and highly stereoselective synthesis of optically active **2** *via* the enzymatic acylation of (±)-furfuryl alcohol **4** using ethoxyvinyl methyl fumarate **3**, followed by rapid intramolecular Diels–Alder reaction between the inserted fumarate moiety and the diene moiety on the furan ring. In the reactions related to the kinetic resolution by enzymatic acylation, use of the acylating reagent not only as an acyl donor but also as a component of the next reaction stage has rarely been reported.‡ The unknown ethoxyvinyl methyl fumarate **3** was prepared by the reported[6] method shown in Scheme 2 and used as an acetone solution without further purification.§

First, we examined which enzyme was suitable for kinetic resolution of (±)-**4a** using **3** as the acylating reagent. We checked the optical purity of the acylated product **1a** prior to the



Scheme 2

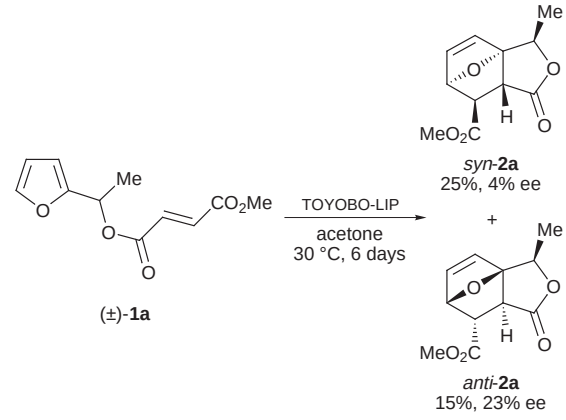


Scheme 3

formation of cycloadduct **2**. After screening a number of enzymes (amano AK, AY, PS, PPL, PLE, A-6, meito-MY, OF, chirazyme L3, TOYOBO-LIP)¶ we found that only TOYOBO-LIP gave an optically active furfuryl methyl fumarate (*R*)-**1a** (22% yield, 72% ee) (Scheme 3). The absolute configuration of the product **1a** was determined by converting the unreacted **4a** to the known nitrobenzoate derivative.[7]

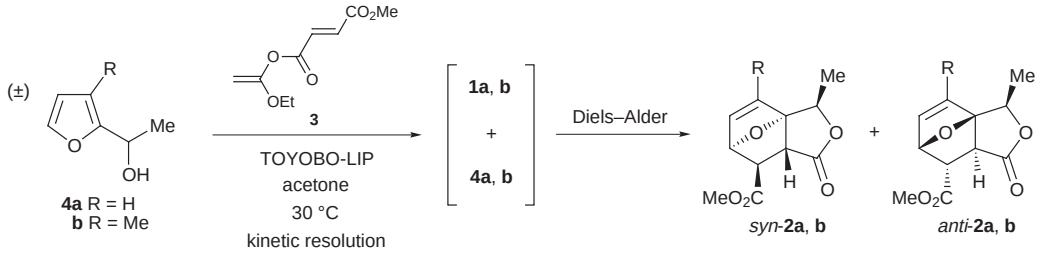
Next, we studied the influence of enzyme TOYOBO-LIP on the intramolecular Diels–Alder reaction of (±)-**1a**.[8] Consequently, we found that the cycloadduct product, *syn*-**2a** (4% ee), was obtained with 24% de in preference to *anti*-**2a** (23% ee).‖ Thus it is apparent that enzyme TOYOBO-LIP played an important role in the diastereo- and enantio-facial selectivity of this intramolecular cycloaddition process (Scheme 4).[9]

Although it can be assumed that the enzymatic hydrolysis, which utilizes the small amount of water in the solvent, depends on the asymmetric environment produced by TOYOBO-LIP,[10] how the enzyme participates in the face-selectivity of the cycloaddition remains to be elucidated at the present time. This result suggests that the possibility exists of increasing the enantioselectivity observed at the enzymatic kinetic resolution stage (72% ee) by carrying out the cycloaddition reaction in the same pot. In practice, we succeeded in the highly stereoselective



Scheme 4

Table 1 Asymmetric Diels–Alder reaction following kinetic resolution using enzyme



Entry	Substrate	Solvent	*t*/days	Total yield of **2** (%) (% de)[a]	Ee (%)[b] *syn*-**2**	Ee (%)[b] *anti*-**2**	Recovery of **1** (%)	Recovery of **4** (%) (absolute config. of major **4**)
1	**4a**	Acetone	6	18 (26)	86	93	21	56 (*S*)
2	**4a**	Acetone	8	32 (24)	79	81	20	18 (*S*)
3	**4a**	THF	8	28 (24)	81	48	5	38 (*S*)
4	**4b**	Acetone	1	43 (100)	84	N.D.[c]	N.D.[d]	39 (*S*)
5	**4b**	THF	1	37 (100)	84	N.D.[c]	N.D.[d]	33 (*S*)

[a] Diastereomeric excess was determined *via* ^{1}H NMR analysis of the crude product. [b] Enantiomeric excess was determined by HPLC (Chiralcel OJ). [c] *anti*-**2b** was not detected *via* ^{1}H NMR analysis. [d] **1b** was not detected by thin layer chromatography.

synthesis of **2** (*syn*-**2**: 84–86% ee, *anti*-**2a**: 93% ee) as a result of carrying out the enzymatic kinetic resolution and cycloaddition in one pot in acetone (Table 1, entry 1). The success of this one-pot reaction is mainly due to the acylating reagent **3**, which could be used without a work-up procedure, since compound **3** is not stable and cannot usually be isolated.

In conclusion, we developed a novel methodology such that the acyl moiety inserted during an enzymatic kinetic resolution was used as part of the constituent structure during the next reaction stage.** In this one-pot reaction, an interesting phenomenon was observed, *i.e.* the optical purity of the enzymatic acylated product was increased during the cycloaddition stage. Consequently, we achieved the convenient synthesis of optically active **2**. This one-pot asymmetric synthesis might be applied to the syntheses of other useful biologically-active compounds, and other applications are now being developed.

‡ Only one example of an enzymatically acrylated product being utilized in the synthesis of chiral polymers has been reported; A. Ghogana and S. Kumar, *J. Chem. Soc., Chem. Commun.*, 1990, 134.

§ Ethoxyvinyl methyl fumarate was used as an acetone solution, since it could not be purified due to its instability. Although the solution contained a catalytic amount of the ruthenium complex, it has already been confirmed that enzymatic kinetic resolution of various alcohols is not affected by the ruthenium complex. Details of these results will be reported in the near future.

¶ LIP is *Pseudomonas aeruginosa* on Hyflo Super-Cel and is commercially available from TOYOBO.

‖ In the absence of an enzyme, the diastereomeric excess was 10% de in this cycloaddition reaction using (*R*)-**1**; B. Thomas and S. Jürgen, *Tetrahedron: Asymmetry*, 1997, **8**, 703.

** *Typical procedure*: a mixture of (±)-furfuryl alcohol **4a** (0.5 mmol), LIP (100 mg) and ethoxyvinyl methyl fumarate (0.5 mmol) (see footnote §) was stirred at 30 °C. After 6 days, the reaction mixture was filtered through a Celite pad and the filtrate was concentrated *in vacuo*. The residue was purified by column chromatography over silica (hexane–EtOAc) to give cycloadduct **2a** (40 mg, 18%), furfuryl methyl fumarate (*R*)-**1a** (46 mg, 21%) and furfuryl alcohol (*S*)-**4a** (73 mg, 56%).

Rare earth stabilization of mesoporous alumina molecular sieves assembled through an N°I° pathway

Wenzhong Zhang and Thomas J. Pinnavaia*†

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, MI 48824-1322, USA

The incorporation of 1.0–5.0 mol% Ce^{3+} or La^{3+} ions in MSU-X alumina molecular sieves, prepared through an N°I° assembly pathway, dramatically improves their thermal stability without altering the mesopore size or the wormhole channel motif.

Following the supramolecular assembly of M41S mesoporous molecular sieves in 1992,[1] there have been relatively few reports of mesostructured aluminas. Davis and coworkers[2] have prepared porous aluminas (*ca*. 20 Å pore diameters) by the hydrolysis of aluminium alkoxides in the presence of a carboxylate surfactant as the structure director. The assembly pathway involved S–I complexation reaction between the surfactant (S) and the inorganic reagent (I), as judged by the presence of IR bands characteristic of chelating carboxylate groups. Yada *et al*.[3] reported the preparation of hexagonal alumina mesostructures by electrostatic S^-I^+ assembly of dodecyl sulfate surfactants and aluminium nitrate. However, the mesostructures were not stable to surfactant removal. In contrast, we have obtained mesoporous alumina molecular sieves, denoted MSU-X, by N°I° assembly of electrically neutral polyethylene oxide surfactants (N°) and an aluminium alkoxide as the inorganic precursor (I°).[4,5] These materials exhibited wormhole channel motifs and BJH pore diameters that can be extended beyond 100 Å, depending on the surfactant size.

One limitation of MSU-X alumina molecular sieves is the loss of surface area and porosity when they are heated above 500 °C. The potential applications of these materials in catalysis and other materials areas could be greatly extended by improving their thermal stability. One possible approach to improving the thermal stability of a metastable alumina is to dope the oxide framework with rare earth cations. For instance, the incorporation of rare earths into γ-alumina (pseudoboehmite) and other transition aluminas is known to stabilize these metastable phases against sintering and conversion to α-alumina (corundum). Two stabilization mechanisms have been proposed, namely, the formation of a surface rare earth aluminate phase[6] and the simple replacement of Al^{3+} by rare earth ions in the pseudoboemite structure, which reduces the lability of the oxide matrix.[7] Analogous mechanisms might also be effective in stabilizing the non-crystalline (amorphous) framework walls of MSU-X alumina molecular sieves against collapse at elevated temperatures. In the present work, we demonstrate that MSU-X aluminas indeed are stabilized by doping with rare earth metal ions.

The incorporation of Ce^{3+} or La^{3+} into MSU-X aluminas was accomplished by first dissolving the corresponding rare earth nitrate in a solution of the non-ionic surfactant in warm butanol. The solution was cooled to room temperature and then aluminium *sec*-butoxide was added with stirring. After an additional 1 h of stirring at ambient temperature, a dilute solution of water in *sec*-butanol was added dropwise. The reaction vessel was then placed in a reciprocating shaker bath at 45 °C for a period of 40 h. Recovery of the as-synthesized reaction products was achieved by filtration and air drying.

The molar compositions of the above reaction mixtures were as follows:

$$0.05\ Ce^{3+}\ (\text{or } 0.01\ La^{3+}) : 1.0\ Al(Bu^sO)_3 : 0.40\ \text{Tergitol}\ (\text{or } 0.20\ \text{Pluronic}) : 3.0\ H_2O : 15.5\ Bu^sOH$$

where the non-ionic surfactants are Tergitol® 15-S-12 (Union Carbide) with the formula $C_{15}H_{33}E_{12}OH$ (E is a polyethylene oxide segment) and Pluronic® P65 or P123 (BASF) block copolymers with the respective compositions $E_{19}P_{30}E_{19}$ and $E_{20}P_{69}E_{20}$ (P is a isopropylene oxide segment).

Essentially all of the N° surfactant could be removed from the alumina mesostructures by extraction with hot ethanol. For convenience, however, the as-synthesized products were freed of surfactant and prepared directly for N_2 adsorption studies in one step by calcining at 500 °C for 6.0 h. Under the calcination conditions the pure alumina mesostructures assembled from the three N° surfactants begin to collapse, as evidenced by a broadening of the one-line diffraction pattern and a decrease in the surface area and pore volume. Upon the introduction of 1–5 mol% rare earth ions, however, the thermal stability of the framework is greatly improved, as judged by substantial increases in surface areas and liquid pore volume (see below).

N_2 adsorption–desorption isotherms for alumina molecular sieves doped with 5.0% Ce^{3+} and 1.0% La^{3+} are shown in Fig. 1. The positions of the pore filling steps in the adsorption curves shift to higher P/P_0 values with increasing surfactant size, as expected for pore structures formed by a supramolecular assembly process. The desorption hystereses signify some

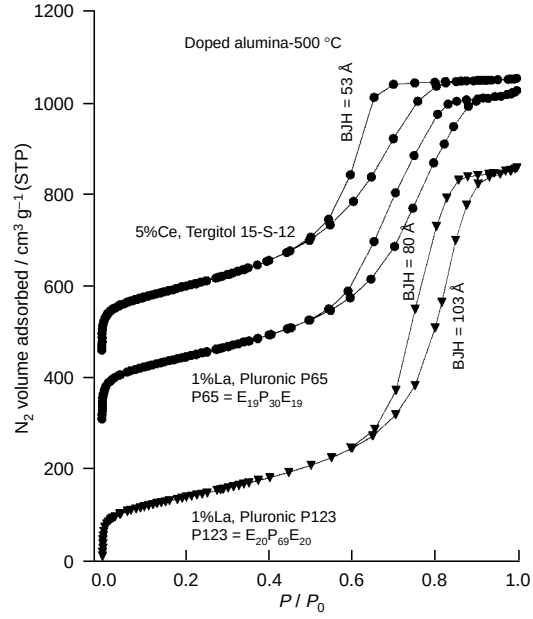

Fig. 1 N_2 adsorption–desorption isotherms of rare earth-stabilized MSU-X alumina molecular sieves assembled in the presence of the non-ionic surfactants Tergitol 15-S-12, Pluronic P65, and Pluronic P123 as structure directors and calcined at 500 °C. The BJH pore sizes obtained from the desorption isotherms are included for comparison.

Table 1 Physical properties of mesoporous MSU-X alumina molecular sieves prepared by N°I° assembly

Surfactant	Rare earth (mol%)	Calcination temp.[a]/ °C	S_{BET}/ $m^2\ g^{-1}$	BJH pore size/Å	Liquid pore volume/$cm^3\ g^{-1}$	XRD, *d*/nm
15-S-12	0	500	391	50	0.48	7.8
15-S-12	0	600	267	55	0.31	8.0
15-S-12	5 (Ce)	500	530	53	0.92	8.0
15-S-12	5 (Ce)	600	357	54	0.65	8.0
P65	1 (La)	500	517	80	1.11	> 8.3
P123	1 (La)	500	487	108	1.31	> 10.0

[a] All the samples were calcined in air for 6 h.

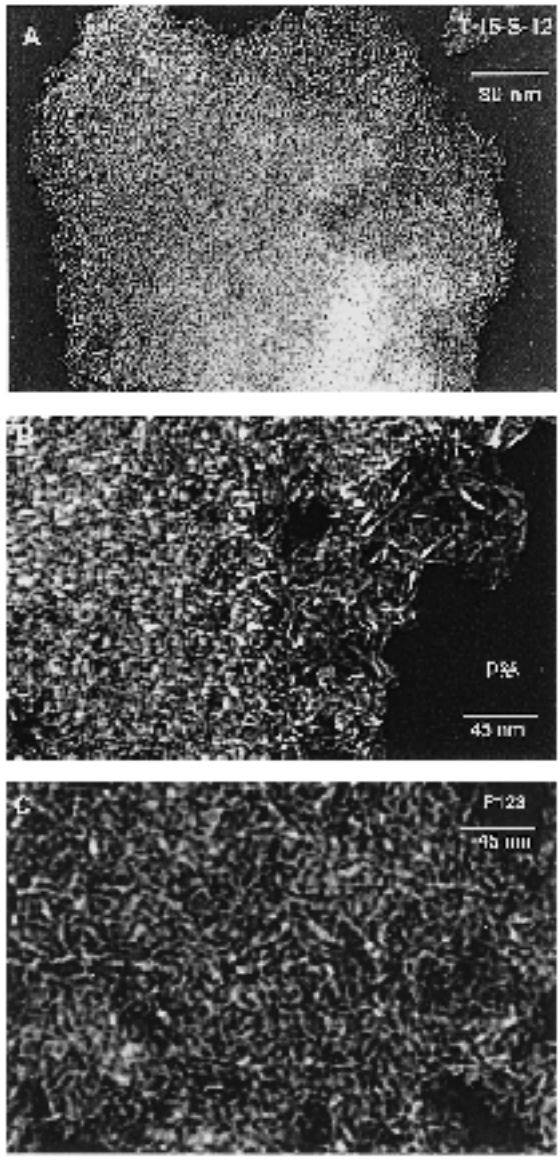

Fig. 2 TEM images of rare earth-stabilized MSU-X alumina molecular sieves assembled from non-ionic surfactants and calcined at 500 °C: (A) 5.0% Ce^{3+}, Tergitol 15-S-12; (B) 1.0% La^{3+}, Pluronic P65; (C) 1.0% La^{3+}, Pluronic P123

degree of pore blocking. These qualitative features of the isotherms also are observed for the pure alumina mesostructures. Furthermore, the doped mesostructures exhibit XRD basal spacings and wormhole TEM images (*cf*., Fig. 2) equivalent to those observed for the pure alumina phases. Therefore, the introduction of the rare earth cations at the 1.0–5.0 mol% level does not alter the N°I° assembly of MSU-X aluminas.

As can be seen from the results provided in Table 1, the incorporation of 5.0 mol% Ce^{3+} in the alumina framework assembled from Tergitol® 15-S-12 results in a 35% increase in the surface area after calcination at 500 or 600 °C. Moreover, the presence of the rare earth nearly doubles the pore volume without changing the average BJH pore size. Thus, the thermal stability of the amorphous framework walls clearly is enhanced without sacrificing the channel size or packing motif. Improved thermal stability also is realized for the La^{3+}-doped mesostructures assembled from Pluronic surfactants, even at the 1 mol% doping levels.

We conclude from the above results that the framework walls of mesoporous MSU-X molecular sieve aluminas are stabilized by the incorporation of rare earth cations. This stabilization effect is general in scope and can be applied over a range of rare earth metal ion loadings to structures assembled from different families of non-ionic polyethylene oxide surfactants. Although the framework walls in MSU-X alumina molecular sieves are amorphous and lack the quasi-crystalline order of transition aluminas, the stabilization mechanisms most likely are related. Thus, rare earth doping also should be effective in stabilizing the amorphous walls of alumina mesostructures assembled through S–I and S^-I^+ pathways.[2,3]

Based in part on the absence of XRD evidence for the formation of rare earth aluminates upon calcination, we favor a stabilization mechanism in which the lability of the oxide framework is reduced through site substitution of aluminium by rare earth cations. The incorporation of the rare earth cations into the oxide framework occurs during the mesostructure assembly process. We may rule out a doping process in which the rare earth is first incorporated into the mesostructure by complexation to the polar ethylene oxide head groups of the surfactant phase and then subsequently transferred into the framework upon calcination. Rare earth incorporation into the framework occurs even when the surfactant is removed from the mesostructure by solvent extraction under ambient conditions. Thus, the direct incorporation of the rare earth cations into the framework structure is a general feature of the assembly pathway.

The partial support of this research by the National Science Foundation through CRG grant CHE-9633798 is gratefully acknowledged.

Synthesis of novel monoazo benzotriazole dyes specifically for surface enhanced resonance Raman scattering‡

Duncan Graham,*† Clare McLaughlin, Gerard McAnally, Joanna C. Jones, Peter C. White and W. Ewen Smith

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL

Surface enhanced resonance Raman scattering (SERRS) has considerable potential as an ultra-sensitive analytical technique; for the first time the synthesis of specific dye ligands designed to overcome major problems in obtaining reliable SERRS is described.

Surface enhanced resonance Raman scattering (SERRS) has recently proven to be an extremely sensitive and selective technique for the detection and identification of suitable molecules.[1–4] It has significant advantages, being applicable to a wide range of chromophores and provides molecularly informative analysis with minimal separation procedures at attomolar concentrations or below. The main problem for analysis by SERRS is that the technique lacks reliability and reproducibility. We report for the first time the synthesis of four dyes specifically designed to provide effective and reliable SERRS. They are based on simple azo structures and utilise a surface complexing group to release the advantages of SERRS for accurate and reliable analysis.

The technique requires the adsorption of a suitable analyte onto an appropriate metal surface, excitation of the surface with light and collection of the scattered radiation. The Raman component of scattering, enhanced by contributions from molecular resonance and surface enhancement can rival fluorescence in efficiency and provide molecularly specific signals. In this study silver colloid is used to provide the metal surface[5] and 457.9 nm excitation was provided by an argon ion laser. The main problem is to produce a chromophore for both resonance and surface attachment which will withstand changes in conditions of the analyte solution and will not desorb from the silver.

The dyes synthesised use benzotriazole as a surface attachment group. Benzotriazole dyes have been synthesised before but only as dyes and not metal complexing agents for improved spectroscopy.[6] Benzotriazole is commonly used as an anti-tarnish agent on silver and is believed to adhere by complexing to more than one silver ion to form a polymeric species coated on the surface.[7–9] Thus covalent attachment to the surface is possible and the orientation of the dye will be fixed. This eliminates changes in peak wavenumber owing to orientational changes or desorption from the surface commonly observed below monolayer coverage.[10] The colloid used is stable for three to six months due to the high negative charge on the surface and has been routinely used for analysis previously.[3,5] The main advantage of covalent attachment through benzotriazole is that the process is essentially irreversible and can displace surface charged species. Thus, once attached the dye remains in position over a wide range of experimental conditions and concentrations to provide reproducible analysis.

Four monoazo dyes containing benzotriazole were synthesised by diazotising 5-aminobenzotriazole§ and coupling¶ to phenylamine analogues (Fig. 1). The analogues used were aniline, anisidine, dimethoxyaniline and naphthalamine to produce the dyes 4-(5′-azobenzotriazolyl)phenylamine **1**, 3-methoxy-4-(5′-azobenzotriazolyl)phenylamine **2**, 3,5-dimethoxy-4-(5′-azobenzotriazolyl)phenylamine **3** and 4-(5′-azobenzotriazolyl)naphthalen-1-ylamine **4**.‖ The amino derivatised aromatics were chosen for two reasons. Firstly the amine group provides a suitable point for derivatisation once the dye has been synthesised and secondly the aromatic ring is highly activated towards electrophilic attack of the diazonium. The diazotised aminobenzotriazole is not a strong electrophile and requires an activated aromatic ring, *i.e.* aniline and the presence of a buffer. In this case sodium acetate buffered to a pH of 6.0 by the addition of glacial acetic acid was used. The buffer ensured the aromatic amine was not protonated thus maintaining the reactivity. Acetone was added to aid solubility and allow the reaction to proceed smoothly. The products precipitated and were purified by trituration using methanol and diethyl ether.

Each of the dyes produced distinct, strong SERRS at 1×10^{-7} M except 4-(5′-azobenzotriazolyl)phenylamine **1** which was used at a concentration of 1×10^{-5} M (Fig. 2). The enhancement obtained depends on the separation between the electronic maximum and the laser frequency. In the case of dye **1**, the spectrum is weak because the absorbance maximum is well away from the excitation frequency and hence from resonance. Major peaks which appear in all four are the quadrant stretch of the phenyl ring just above 1600 cm^{-1}, the azo stretch above 1400 cm^{-1}, and bands at around 1150 and 950 cm^{-1} which correspond to more complex phenyl and bridge stretching modes.

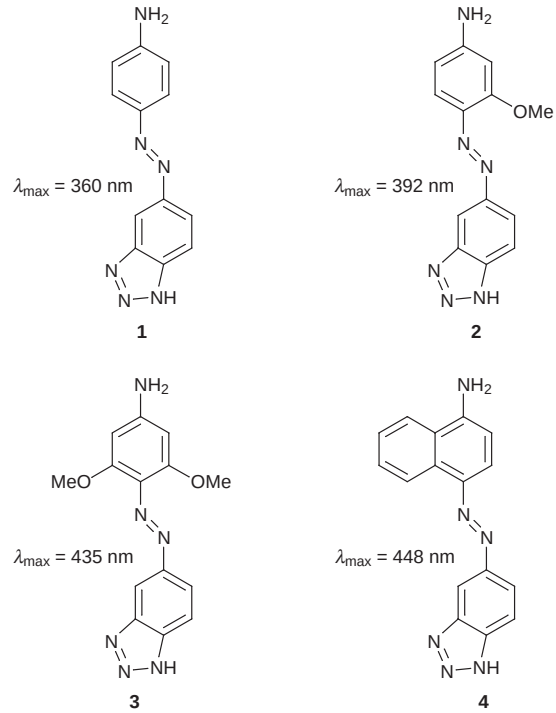

Fig. 1 The four benzotriazole dyes synthesised and their corresponding λ_{max} in methanol

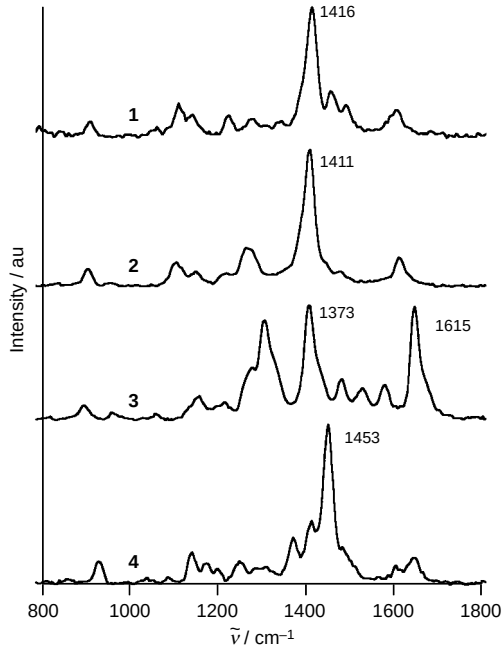

Fig. 2 SERRS spectra of the dyes at 457.9 nm at 1×10^{-7} M except for **1** which was at 1×10^{-5} M

Three dyes produce similar spectra and exact peak positions can be used to discriminate between them. However, when a second methoxy group is added to anisidine analogue, the resulting dye produces a spectrum which is quite different. The extra electron donation of the methoxy group has probably twisted the ring and also created sufficient electron donation to produce partial bonding to the C–N and N=N bonds.

Surface enhancement of vibrations is dependent upon the orientation of the molecule on the surface.[10] Hence different vibrations are enhanced as the molecular orientation changes producing a variation in spectra. Changes in surface orientation are related to the concentration of the analyte on the surface. However by making use of the strong complexing nature of benzotriazole on the silver a structure locked in one conformation can be obtained. The vibrations enhanced will always be the same at any concentration therefore increasing reliability. Dye **3** was studied in more detail between 5×10^{-9} and 1×10^{-6} M and unlike previous studies the relative intensities and position of the signals remained constant. The signal intensity obtained was proportional to concentration which will allow development of quantitative analysis by SERRS.

The technique has now been shown to be reliable and since it is sensitive to changes in the environment and structure of the chromophore, there is considerable scope for the synthesis of designed dyes to permit specific analytical procedures to be developed for ultra-sensitive analysis. For example the ligands require chemical functionalisation to allow addition of groups such as metal complexing functions or attachment to target analyte molecules such as DNA. This is a significant breakthrough which demonstrates that with the correct attention to surface chemistry SERRS can be used as a reliable analytical method.

Notes and References

‡ This work arose from initial studies with a different focus by Heather Wilson, PhD, University of Strathclyde, 1994.

§ *Diazotisation*: 5-aminobenzotriazole (1.0 g, 1.1 equiv., 7.63 mmol) was dissolved in HCl (5 ml, 50% v/v) and diazotised by dropwise addition of sodium nitrite (0.578 g, 1.2 equiv., in 5 ml H_2O) at 0 °C. An excess of sodium nitrite was detected using starch iodide paper. A dark blue colour indicated excess nitrous acid which inferred the formation of the diazonium salt.

¶ *Coupling*: the amine (1 equiv.) was dissolved in sodium acetate buffer (1.0 M, 5 ml, pH 6.0) and acetone (5 ml). Diazotised aminobenzotriazole (1.1 equiv.) was added to this solution dropwise at 0 °C with stirring over 1 h after which the solution was neutralised by addition of sodium hydroxide (2 M). The solid produced was isolated by filtration and washed with saturated KCl (3×50 ml) prior to purification by trituration using metahnol and diethyl ether.

‖ All novel compounds were characterized by UV spectrometry, proton NMR and FAB mass spectrometry. The purity of the compounds was confirmed by HPLC [retention time for **2** = 4.9 min at 430 nm from methanol–water (60 : 40)] owing to the difficulty in crystallisation. **2**: 40%, R_f [CH_2Cl_2–CH_3OH (9/1)] 0.34; δ_H[400 MHz, $(CD_3)_2SO$] 3.96 (3 H, s, OCH_3), 6.46 (1 H, s, H-2), 6.61 (1 H, d, *J* 8.8, H-5), 7.10 (2 H, br s, NH_2), 7.85 (1 H, dd, *J* 6.0 H-6), 7.98 (2 H, d, *J* 10.2, H-6′,7′), 8.18 (1 H, s, H-4′); λ_{max}(MeOH) 392 nm; FAB MS: *m*/*z* 269.1144 [$C_{13}H_{12}ON_6$ (*M* + 1) < 0.1 ppm].

First total synthesis of (+)-3-deoxy-D-*glycero*-D-*galacto*-2-nonulosonic acid (KDN) from a non-carbohydrate source

Martin Banwell,*[a]† Chris De Savi[a] and Keith Watson[b]

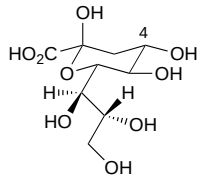
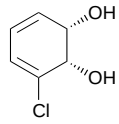
[b] *Biota Chemistry Laboratory, Chemistry Department, Monash University, Clayton, Victoria 3168, Australia*

Enantiopure *cis*-1,2-dihydrocatechol 2, a product obtained by microbial oxidation of chlorobenzene, has been converted into KDN 1 *via* a ten step reaction sequence.

In 1986 Inoue isolated the deaminated sialic acid (+)-3-deoxy-D-*glycero*-D-*galacto*-2-nonulosonic acid (KDN, **1**) from the



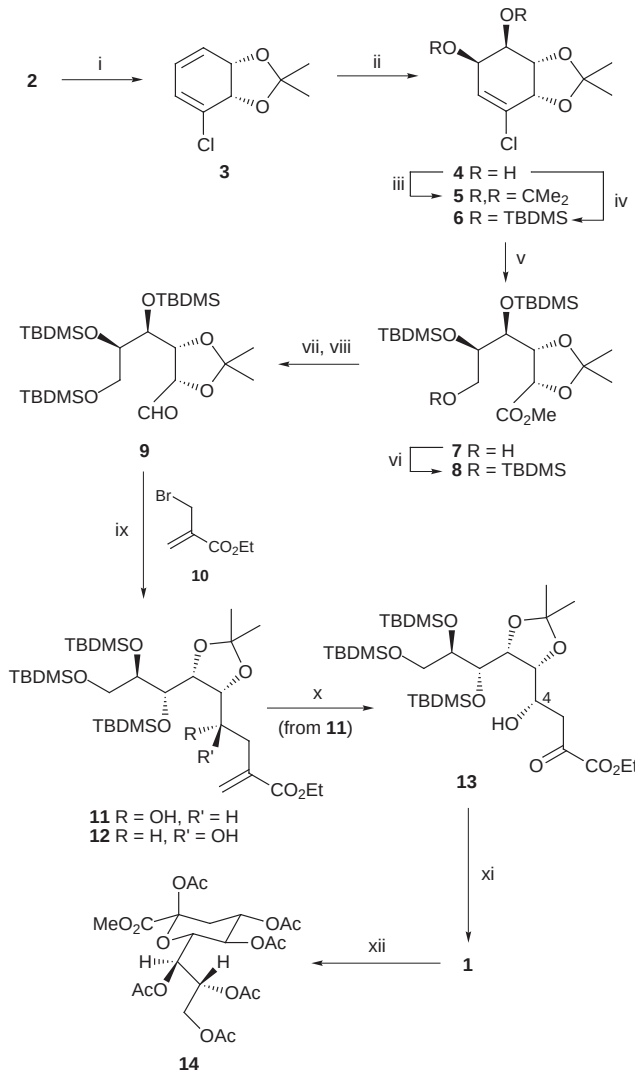
1



2

membrane polysialoglycoproteins of rainbow trout eggs.[1] Since KDN is likely responsible for protection of the egg membrane from attack by bacterial sialidases,[2] this compound is of interest as a sialic acid analogue that could be incorporated into other biologically relevant glycoproteins in order to protect them against sialidase activation by certain bacteria.[3] Such possibilities have sparked considerable interest in KDN glycoscience with the result that several syntheses of the title compound have now been reported.[1,4] All of these involve elaboration of carbohydrate-based starting materials. We now describe the first total synthesis of KDN from a non-carbohydrate source. The reaction sequence used will enable the preparation of novel analogues including those which incorporate ^{17}O-, ^{13}C- and/or ^{2}H-labels in various combinations. Such analogues[5] should be useful for probing the biological role(s) of KDN and related carbohydrate natural products.

The reaction sequence leading to compound **1** was inspired by the seminal work of Hudlicky and co-workers who have demonstrated the value of *cis*-1,2-dihydrocatechols as starting materials for the synthesis of various pentoses and hexoses.[6,7] In the present work (Scheme 1) the *cis*-1,2-dihydrocatechol **2**, which is obtained in >99% ee *via* microbial oxidation of chlorobenzene, was used. Thus, the acetonide derivative, **3**,[8] of compound **2** underwent regioselective and diastereofacially-selective *cis*-dihydroxylation on reaction with osmium tetraoxide and the resulting diol **4**[8] was reacted with 2,2-dimethoxypropane in the presence of toluene-*p*-sulfonic acid (TsOH) to give the *bis*-acetonide **5**‡ {99%, $[\alpha]_D$ + 68 (*c* 3.4)§}. Surprisingly, this last compound failed to react with ozone, perhaps because both faces of the π-bond are hindered by the *endo*-methyl groups associated with the adjacent 1,3-dioxolane rings. To circumvent such difficulties, diol **4** was converted into the corresponding bis(*tert*-butyldimethylsilyl ether) **6**[9] {83%, mp <25 °C, $[\alpha]_D$ − 56 (*c* 6.4)} which underwent smooth ozonolytic cleavage to give, after a reductive work-up with $NaBH_4$, the ester alcohol **7** {99%, $[\alpha]_D$ + 12 (*c* 6.8)}. The *tert*-butyldimethylsilyl ether derivative, **8** {100%, $[\alpha]_D$ + 2 (*c* 1.5)}, of the latter compound was then prepared in quantitative yield by standard methods. This compound was converted, over two conventional steps, into the unstable D-mannose derivative **9** {87% from **8**, $[\alpha]_D$ + 14 (*c* 5.8)}. Reaction of compound **9** with Vasella's pyruvate anion equivalent **10**,[10,11] under conditions we have used previously,[12] gave a *ca.* 2 : 3 mixture of the *syn*- and *anti*-addition products, **11** {37%, $[\alpha]_D$ + 10 (*c* 1.9)} and **12**



Scheme 1 *Reagents and conditions*: i, see ref. 8; ii, see ref. 8; iii, $Me_2C(OMe)_2$, TsOH (cat.), 18 °C, 1.0 h; iv, TBDMSCl (4 equiv.), imidazole (5 equiv.), DMF, 18 °C, 16 h; v, O_3, MeOH, −78 to 0 °C, 0.1 h, then $NaBH_4$ (4 equiv.), 18 °C, 2 h; vi, TBDMSOTf (1.5 equiv.), 2,6-lutidine (3 equiv.), CH_2Cl_2, 0 to 18 °C, 16 h; vii, LAH (1.5 equiv.), THF, −10 °C, 2 h; viii, $(COCl)_2$ (1.2 equiv.), DMSO, CH_2Cl_2, −78 to 0 °C, 1 h, then Et_3N (2.6 equiv.); ix, Zn dust (4.0 equiv.), sat. aq. NH_4Cl, THF, 0 to 18 °C, 1.5 h; x, O_3, MeOH, −78 °C, 0.033 h, then Me_2S (5 equiv.), −78 to 18 °C, 2 h; xi, 4 : 1 TFA–H_2O, 18 °C, 18 h; xii, Dowex 50W resin (H^+ form), MeOH, 6 h, 18 °C, then Ac_2O (10 equiv.), DMAP (trace), pyridine, 18 °C, 20 h

{52%, $[\alpha]_D$ + 16 (*c* 1.6)}, respectively. The components of this mixture were readily separated from one another by semi-preparative HPLC and compound **11** was then subjected to reaction with ozone. In this way the α-keto ester **13** {98%, $[\alpha]_D$ + 5 (*c* 2.2)} was obtained. Treatment of compound **13** with 4 : 1 TFA–water at 18 °C for 16 h resulted in deprotection of all the hydroxy groups as well as cyclisation to give KDN which was identical, as judged by ^{1}H NMR analysis, with an authentic sample prepared by enzymatic methods.[4g] For the purposes of further spectroscopic characterisation, KDN was esterified using MeOH and the intermediate methyl ester subjected to exhaustive acetylation. In this way the KDN derivative **14**[13] {68% from **13**, mp 100–104 °C; lit.,[13] 104–105 °C; $[\alpha]_D$ − 17 (*c* 1.9); lit.,[13] − 20 (*c* 0.7)} was obtained and the structure of this compound follows from spectroscopic data.¶ In addition, this material proved identical with a sample {$[\alpha]_D$ − 17 (*c* 1.2)} prepared from authentic KDN. Interestingly, while ozonylitic cleavage of compound **12** gave 4-*epi*-**13** {98%, $[\alpha]_D$ + 17 (*c* 5.0)}, sequential treatment of the latter compound with TFA–water, acidic MeOH then Ac_2O–pyridine only gave a complex mixture of uncharacterisable products.

We thank the Institute of Advanced Studies for financial support and the ARC for the provision of an APA (Industry) Scholarship to C. D. S. Dr Gregg Whited (Genencor International Inc.) is thanked for providing generous quantities of diol **2**.

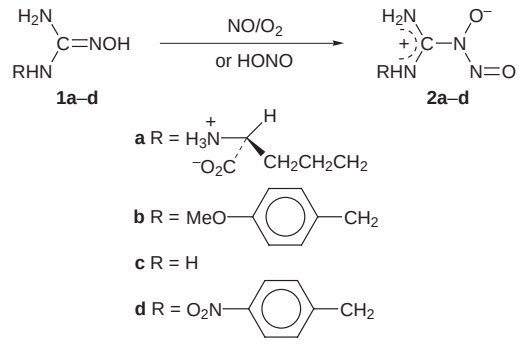
***N*-Hydroxyguanidines can be nitrosatively converted to zwitterionic diazeniumdiolates of crystallographically-confirmed structure H_2N^+=C[NHR][N(O)NO]$^-$, whose hydrolytic dissociation at physiological pH leads to both NO and N_2O; the results appear to account for the formation of the 'potential intercellular nitric oxide carrier' produced on exposing N^G- hydroxy-L-arginine (a metabolic intermediate in mammalian NO biosynthesis) to aerobic NO.**

Nitric oxide (NO) is a recently discovered bioeffector molecule that is critically involved in regulation of blood pressure, neurotransmission, sexual function, immunity and an array of other physiological phenomena.[1] It is rapidly destroyed by biochemical oxidants such as oxyhemoglobin, superoxide and oxygen,[2] leading to speculation that its regulatory properties might depend, in part, on conversion to a biochemical storage form[3] that protects it from oxidation while in transit from the site of biosynthesis in one cell to the target of its required signalling action in another.

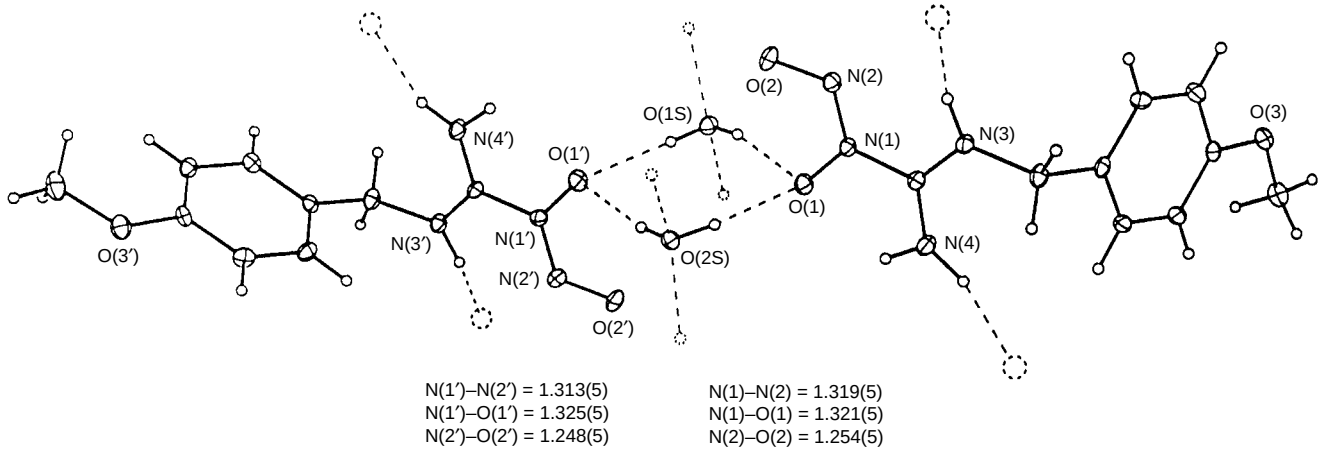
Recently, the formation of such a 'potential intercellular nitric oxide carrier' was reported to occur on exposing N^G-hydroxy-L-arginine **1a**, an intermediate in NO biosynthesis, to aerobic nitric oxide solutions.[4] The product was ultraviolet-active and longer lived as a vasodilator than molecular NO,[5] but its structure has yet to be elucidated.

We present evidence here based on work with model *N*′-substituted *N*-hydroxyguanidines that this bioactive compound may be a naturally occurring diazeniumdiolate (Scheme 1, structure **2a**). While there was no observable reaction when NO was bubbled into degassed solutions of *N*′-(*p*-methoxybenzyl)-*N*-hydroxyguanidine **1b** in water, subsequent introduction of air led to appearance of an ultraviolet maximum at 322 nm, a result reminiscent of that seen with both *N*-hydroxyguanidine **1c**[5] and **1a** itself.[6] A similar outcome was observed when NO_2 was introduced instead of air into anaerobic solutions of **1b** and NO, suggesting that N_2O_3, formed either on autoxidation of NO or on radical coupling of NO with NO_2, had reacted nitrosatively[7] with **1b**. When alternate nitrosation conditions were effected by dissolving 0.1 g of **1b**·HCl in 2 ml of 0.1 M aqueous AcOH and adding 1 equiv. of sodium nitrite as a saturated aqueous solution at 0 °C, a crystalline precipitate began to form that, when collected after 20 min of total reaction time (yield of **2b** 95%, mp 136–147 °C with gradual decomposition), was suitable for X-ray diffractometric investigation without further purification. (Indeed, attempts to recrystallize this relatively unstable substance have thus far led to partial decomposition.) The molecular structure,§ refined to an *R* value of 0.034, is shown in Fig. 1.

The crystallographic data show that nitrosation of **1b** occurred at the nitrogen bound to the oxygen atom to give a diazeniumdiolate product **2b**, as shown in Scheme 1. Noteworthy structural features include the cisoid oxygens in the



Scheme 1



N(1′)–N(2′) = 1.313(5)
N(1′)–O(1′) = 1.325(5)
N(2′)–O(2′) = 1.248(5)

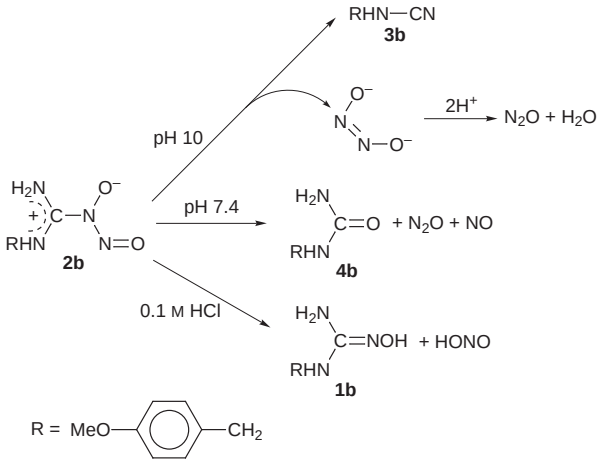
N(1)–N(2) = 1.319(5)
N(1)–O(1) = 1.321(5)
N(2)–O(2) = 1.254(5)

Fig 1 Molecular structure of the asymmetric unit of **2b** summarizing bond lengths within the diazeniumdiolate (ONNO) groups. Dotted atoms are symmetry related. Dotted bonds are hydrogen bonds.

$N_2O_2^-$ group and the presence of two different conformers of **2b** along with two water molecules in the asymmetric unit that forms a hydrogen bonded helix (Fig. 1). Similar results were obtained on nitrosation of the *p*-nitrophenyl analogue **1d**; although the structure of the diazeniumdiolate product **2d** did not refine well (R = 0.125), this was due to disorder in the crystal which could not be modelled in the refinement. The atomic connectivity and atom assignments are, however, well defined.¶

Rapid measurement of the ultraviolet spectrum on dissolution of **2b** in water permitted quantitative determination of the characteristic chromophore's extinction coefficient (2.5 mM^{-1} cm^{-1} at λ_{max} = 322 nm). The NMR spectrum, run at −50 °C in CD_3OD–tetramethylsilane to minimize the rapid decomposition observed at room temperature, consisted of singlets for the CH_3O and CH_2 protons at δ 3.77 and 4.57, respectively, and an aryl AA′BB′ pattern with shifts of δ 6.93 and 7.30 (*ortho* and *meta* to OCH_3, respectively) and J = 8.6, 2.7, and 0.4 Hz for the *ortho*, *meta* and *para* couplings, respectively. The mass spectra of **2b** and **2d** were unusual (but not unprecedented) in their failure to produce an observable MH^+ ion in either the electrospray or fast atom bombardment modes; strong peaks due to the respective benzyl cations were seen in both cases, but ^{15}N-labelling indicated that the terminal NO was rapidly lost even under the mildest possible electrospray conditions.

Compound **2b** was found to decompose with gas evolution on dissolution in aqueous media. At pH 10, *N*-(*p*-methoxybenzyl)cyanamide **3b** and N_2O were each produced in ⩾95% yield in a relatively slow reaction (half-life at 37 °C variable but estimated as 15–25 min) that is presumably initiated by deprotonation of the NH_2 group followed by loss of *cis*-hyponitrite (⁻O–N=N–O⁻), a known progenitor of N_2O.[8] Compound **2b** tended to disappear more rapidly as pH was lowered, with a half-life at pH 3 of about 5 min; some denitrosation was observed at very low pH, **1b** being the most abundant of the organic products seen in 0.1 M HCl. The major gaseous product at low pH proved to be NO, reaching yields of 0.9 moles per mole of **2b** at pH 3 compared with 0.25 moles of N_2O. While the mechanism of NO formation is not clear at this time, there can be little doubt about its production; its identity was confirmed both by the presence of its aqueous autoxidation product, nitrite ion,[9] in the reaction mixture and by a well-established, highly selective chemiluminescence method.[10] In physiological buffer (10 mM phosphate, pH 7.4), *N*-(*p*-methoxybenzyl)urea **4b** was produced in 90% yield, with 8% conversion to **3b** and a small amount of an unidentified product also detected by HPLC. At pH 7.4, 0.5 moles of N_2O were produced along with 0.3 moles of NO per mole of **2b** dissociated. These reactions are summarized in Scheme 2. Comparable results were observed on hydrolysis of **2c** and **2d**.



Scheme 2

Since nitrosation of all four *N*-hydroxyguanidines **1a**–**d** yields hydrolytically unstable products with ultraviolet maxima near 320 nm that generate significant quantities of NO in neutral buffer, the crystallographic data for products **2b** and **2d** strongly suggest that the 'nitric oxide carrier' seen by Hecker *et al.*[4] on exposing **1a** to aerobic NO was diazeniumdiolate **2a**.

We postulate that our data may be of two-fold biological significance. First, if free **1a** can be shown to encounter suitably nitrosating conditions *in vivo*, the product **2a** would constitute a naturally occurring diazeniumdiolate that spontaneously releases NO at physiological pH; two other natural products containing the diazeniumdiolate functional group, dopastin and alanosine, have been reported to release NO only on one-electron oxidation.[11] Second, the NO-generating properties of compounds **2** may render them useful as prodrugs for treating clinical disorders arising from deficiencies of biosynthetic NO.[1] The possible medicinal value of **2** and analogous structures will be investigated.

Synthesis and application in asymmetric synthesis of azacrown ethers derived from D-glucose

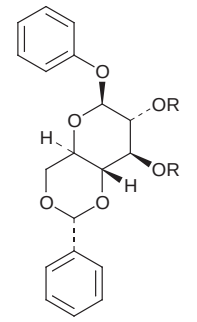
Péter Bakó,[a]† Kristóf Vizvárdi,[a] Zoltán Bajor[a] and László Tõke*[b]

[a] *Department of Organic Chemical Technology, Technical University of Budapest, H-1521 Budapest, Hungary*
[b] *Organic Chemical Technology Research Group of the Hungarian Acadamy of Sciences at the Technical University of Budapest, H-1521 Budapest, Hungary*

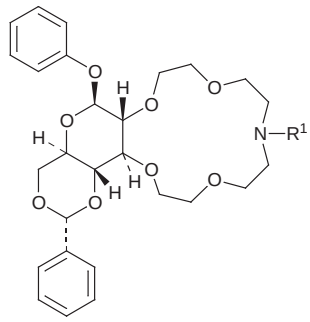
New chiral monoaza-15-crown-5 derivatives and lariat ethers anellated to phenyl β-D-glucoside have been synthesized which show significant asymmetric induction as phase transfer catalysts in the Michael addition of 2-nitropropane to chalcone (84% ee) and in the Darzens condensation of phenacyl chloride with benzaldehyde (74% ee).

One of the most attractive types of asymmetric synthesis is that in which chiral products are generated under the influence of chiral crown ether catalysts. Although many optically active crown ethers have been prepared, only a few have been used successfully as catalysts in asymmetric reactions.[1] Previously, we reported the asymmetric Michael addition of phenyl acetate to acrylate catalyzed by chiral crown ethers composed of two glucose units (85% ee).[1,2] The substituents on the sugar unit of the macrocycle[1,2] and the side arms at the nitrogen atom in the crown ring[3] play an important role in the catalytic activity of the crown ethers. The latter compounds with heteroatoms in the side arm, named lariat ethers or armed crown ethers, are known to display special complexation, high lipophilic character and unique guest specificity *via* macroring–side arm cooperativity.[4] It is therefore reasonable to study the effect of using different pendant arms on the chiral crown ether catalyst in asymmetric reactions.

We now report on the synthesis and application of new monoaza-15-crown-5 compounds **4**–**12**.



1 R = H
2 R = $(CH_2)_2O(CH_2)_2Cl$
3 R = $(CH_2)_2O(CH_2)_2I$



4 R^1 = Bu
5 R^1 = $Pr^i{}_2CH$
6 R^1 = C_6H_{11}
7 R^1 = $C_6H_{11}CH_2$
8 R^1 = Bn
9 R^1 = $Ph(CH_2)_2$
10 R^1 = $HO(CH_2)_2$
11 R^1 = $MeO(CH_2)_2$
12 R^1 = $HO(CH_2)_3$

Their synthesis starts from phenyl 4,6-*O*-benzylidene-β-D-glucopyranoside **1**. The vicinal free hydroxy groups in compound **1** were alkylated using the method of Di Cesare and Gross,[5] with bis(2-chloroethyl) ether acting as solvent and reagent, under liquid–liquid (LL) two-phase reaction conditions, in the presence of tetrabutylammonium hydrogen sulfate (as a phase transfer catalyst) and 50% aq. NaOH to give compound **2** (room temperature, 8 h, column chromatography). The exchange of chlorine for iodine in **2** was carried out using NaI in acetone (reflux, 24 h), resulting in the bis(iodide) derivative **3**. Compound **3** was cyclized with various primary amines: *n*-butylamine, 2,4-dimethylpentan-3-ylamine, cyclohexylamine, cyclohexylmethylamine, benzylamine, 2-phenylethylamine, ethanolamine, 2-methoxyethylamine and propanolamine, respectively, according to the method described previously,[6] which requires dry Na_2CO_3 in MeCN as solvent (reflux, 32–40 h, column chromatography). We thus obtained the corresponding 15-membered macrocycles **4**–**12**, the yields of the ring closure steps after chromatography being in the range 32–54% (Table 1). All structures were ascertained by ^{1}H NMR, ^{13}C NMR, COSY, mass and elemental analysis.‡

Table 1 Yield and characterisation data of compounds **2**–**12**

Compound	Yield (%)[a]	$[\alpha]^{20}$ (c 1, $CHCl_3$)	Mp/°C

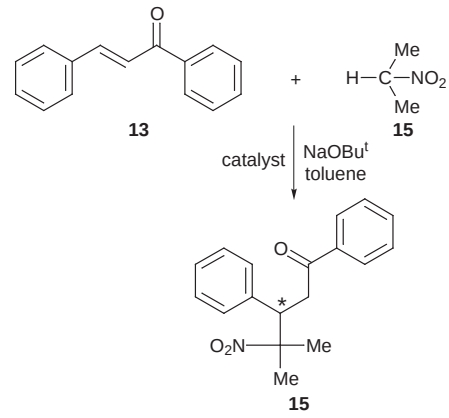
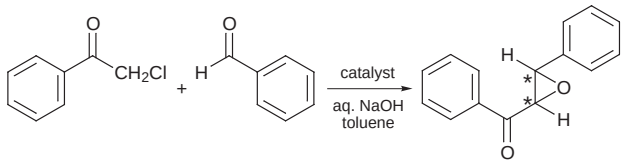
12	45	−44.9	oil

[a] After column chromatography.

Compounds **4**–**12** were then used as phase transfer catalysts in different reactions in which enantiomeric mixtures can be formed. These catalysts proved to be effective in two reactions: the Michael addition of 2-nitropropane to chalcone (Scheme 1),



Scheme 1



16 17 18

Scheme 2

and the Darzens condensation of phenacyl chloride with benzaldehyde (Scheme 2).

The Michael addition was carried out in a solid–liquid (SL) system; in toluene, employing solid NaOBu^t as base (35 mol%) and chiral catalyst (7 mol%) at room temperature.§ After the usual work-up procedure the adduct was isolated by preparative TLC, and the asymmetric induction, expressed in terms of the enantiomeric excess (ee), was monitored by measuring the optical rotation of the product **15** and comparing it with literature values[3] and by ^{1}H NMR analysis using (+)-Eu(hfc)$_3$ as a chiral shift reagent. The results are shown in Table 2.

As can be seen, the substituents at the N-atom of the catalyst have a significant influence on both the chemical yield and the enentioselectivity. In all cases the (*S*)-(+)-adducts **15** were found to be in excess. The catalyst having the bulky 2,4-dimethylpentan-3-yl group at the N-atom gave the lowest chemical yield and chiral induction (entry 2), and the crown ether having a phenylethyl group (**9**) proved to be the best (entry 6). The methyl ether **11** showed a higher ee value than its free hydroxy analogue **10** (entry 8 and 7). The length of the side arm is decisive: catalyst **8** having a benzyl group shows poor chiral induction (6% ee), while compound **9** containing a phenylethyl group gives high enantioselectivity (84% ee).

The Darzens condensation (Scheme 2) was performed in a binary LL system, using a toluene–30% aq. NaOH (5 : 1) mixture.¶ The work-up procedure and determination of ee was carried out in a similar manner to that mentioned for the Michael addition. In all cases the epoxy ketone product **18** with a negative optical rotation was found to be in excess, which on the basis of the optical rotation of the pure enantiomer, corresponds to an absolute configuration of (2*R*,3*S*).[7] Low enantioselectivities were obtained using catalysts **4**–**8** (entries 1–5). The macrocycle **10** [R = $(CH_2)_2$OH] having the hydrophilic hydroxyethyl group at the N-atom gave 52% ee (entry 7) but this value was dramatically reduced (13% ee) for its methyl ether **11** (entry 8). It is interesting to note that the effect of the compound containing a free hydroxy group on the magnitude of the enantioselectivity for the Darzens condensation is the reverse of that for the Michael reactions (entries 7 and 8). The importance of the chain-length at the N-atom in the catalytic activity is reflected particularly in the experiment shown in entry 9: catalyst **12** [R = $(CH_2)_3$OH] proved to be the most effective, resulting in 74% ee at room temperature. With regard to the effectiveness of the crown ether structure for enantiomeric induction, we suppose that the substituent at the nitrogen atom of the catalyst takes part in the complexation of the salt of the anion by complexation of the cation in the third dimension, working as a pseudo-lariat ether, and as a consequence increases the effectiveness of the phase transfer process. Reactions running in the absence of chiral catalyst give only racemic products.

Table 2 Effect of chiral crown catalysts **4**–**12** on the asymmetric Michael addition and Darzens condensation

		Michael addition		Darzens condensation	
Entry	Catalyst	Yield (%)[a]	Ee (%)[b]	Yield (%)	Ee (%)[b]
1	**4**	61	27	92	4
2	**5**	15	4	33	3
3	**6**	50	23	94	4
4	**7**	53	24	70	8
5	**8**	56	6	88	4
6	**9**	78	82 (84)[c]	72	30
7	**10**	71	45	86	52 (53)[c]

§ The Michael addition was performed as follows: 1.44 mmol of chalcone and 3.36 mmol of 2-nitropropane were dissolved in 3 ml of anhydrous toluene, and then 0.1 mmol of crown ether and 0.5 mmol of base were added. The mixture was stirred under an Ar atmosphere. After completing the reaction (8–40 h) a mixture of 7 ml of toluene and 10 ml of water was added. The organic phase was processed in the usual manner. The product was purified on silica gel by preparative TLC with hexane–ethyl acetate (10 : 1) as eluent; mp 146–148 °C, $[\alpha]_D^{20}$ + 68 (*c* 1, CH_2Cl_2) (84% ee) (lit.,[3] +80.8, for pure enantiomer), δ_H 7.85 (m, 2 H, Ph), 7.52 (m, 3 H, Ph), 7.25 (m, 5 H, Ph), 4.18–3.25 (m, 3 H, CH_2, CH), 1.62 (s, 3 H, CH_3), 1.54 (s, 3 H, CH_3).

¶ Typical experimental procedure for the asymmetric Darzens condensation: a toluene solution of 1.3 mmol of phenacyl chloride (3 ml) was treated with 1.9 mmol of benzaldehyde and 0.1 mmol of catalyst in 0.6 ml of 30% NaOH solution. The mixture was stirred under Ar atmosphere. After completing the reaction 7 ml of toluene were added, the organic phase washed with water, dried over $MgSO_4$ and the solvent evaporated. The residue was chromatographed on preparative silica gel of 2 mm thickness (Kieselgel 60 GF_{254}), using CH_2Cl_2 as eluent; $(\alpha)_{578}^{20}$ −111 (*c* 1, CH_2Cl_2) (52% ee) (lit.,[7] −214, for pure enantiomer); δ_H 8.01 (m, 2 H, Ph), 7.60 (t, 1 H, Ph), 7.48 (t, 2 H, Ph), 7.40–7.30 (m, 5 H, Ph), 4.29 (d, *J* 2, 1 H), 4.08 (d, *J*, 1 H).

Photochemical reduction of nitrite to ammonia at a solid phase photoredox system

J. Rajan Premkumar and Ramasamy Ramaraj*

School of Chemistry, Madurai Kamaraj University, Madurai-625 021, India

The photoassisted reduction of the nitrite anion to ammonia in alkaline aqueous solution was achieved by illumination with visible light in the presence of $[Ni(teta)]^{2+}$ and $[Ru(bpy)_3]^{2+}$ adsorbed Nafion membrane.

The reduction of nitrogen oxyanions has been one of the most interesting aspects in recent chemistry concerned with the development of new methods for artificial nitrogen fixation and the conversion of pollutants such as NO_x into useful chemicals, and also in bioinorganic chemistry in comparing enzymatic reactions with their model ones.[1–7] In artificial photosynthesis, the aim is to mimic the ability of green plants and other photosynthetic organisms in their use of sunlight to make high energy chemicals.[8] In homogeneous solution, the photoredox products recombine in the dark to regenerate the starting materials or undergo side reactions to deplete the concentration of the high energy products.[8] Attempts to construct artificial solar energy conversion systems have been made in terms of the use of micro- and macro-heterogeneous reaction environments such as micelles, bilayers, *etc.*[8–10] However, the utilization of the solid–solution interface has not been studied extensively except in the context of photogalavanic cells. Tris(2,2′-bipyridine)ruthenium(II), ($[Ru(bpy)_3]^{2+}$) has been established as the best photosensitizer for photoredox reactions both in homogeneous and in microheterogeneous media.[8,11,12] Here we describe the utilization of $[Ru(bpy)_3]^{2+}$ and the macrocyclic nickel(II) complex $[Ni(teta)]^{2+}$, (teta = 5,5,7,12,12,14-hexamethyl-1,4,8,11,-tetraazacyclotetradecane) in the solid phase which can be used efficiently to realize a multistep photoreduction of nitrite to ammonia.

The $[Ru(bpy)_3]^{2+}$ and the macrocyclic $[Ni(teta)]^{2+}$ complex ions were prepared according to literature procedures.[13,14] $[Ni(teta)]^{2+}$ was adsorbed into Nafion membrane (1 cm^2 area, Aldrich) by dipping the membrane into an aqueous solution containing a known concentration of $[Ni(teta)]^{2+}$. The membrane Nf/$[Ni(teta)]^{2+}$ was then washed and dipped in distilled water. The $[Ni(teta)]^{2+}$ complex was adsorbed irreversibly and the amount of $[Ni(teta)]^{2+}$ adsorbed into the Nafion membrane was determined by measuring the decrease in the absorbance of $[Ni(teta)]^{2+}$ (λ_{max} = 460 nm, ε_{460} = 40 $dm^3\ mol^{-1}\ cm^{-1}$) in solution after dipping. The $[Ni(teta)]^{2+}$ adsorbed Nafion membrane was then dipped in an aqueous solution containing a known concentration of $[Ru(bpy)_3]^{2+}$ and then washed with distilled water to give the membrane Nf/$[Ni(teta)]^{2+}$/$[Ru(bpy)_3]^{2+}$. $[Ru(bpy)_3]^{2+}$ was also adsorbed irreversibly and the amount of $[Ru(bpy)_3]^{2+}$ adsorbed in the Nf/$[Ni(teta)]^{2+}$/$Ru(bpy)_3]^{2+}$ membrane was determined by measuring the decrease in the absorbance of $[Ru(bpy)_3]^{2+}$ (λ_{max} = 452 nm, ε_{452} = 14 600 $dm^3\ mol^{-1}\ cm^{-1}$) in solution after dipping. The Nf/$[Ni(teta)]^{2+}$ and Nf/$[Ni(teta)]^{2+}$/$[Ru(bpy)_3]^{2+}$ membranes were characterized by absorption and emission spectra. Fig. 1 shows the absorption spectra of $[Ni(teta)]^{2+}$ in Nafion membrane recorded using JASCO 7800 spectrophotometer. [Ni-(teta)]$^{2+}$ adsorbed into Nafion membrane is evident [Fig. 1(*b*)] when compared to $[Ni(teta)]^{2+}$ in water [Fig. 1(*a*)]. A similar result was also obtained for the Nf/$[Ni(teta)]^{2+}$/$[Ru(bpy)_3]^{2+}$ membrane.

The Nf/$[Ni(teta)]^{2+}$/$[Ru(bpy)_3]^{2+}$ membrane was dipped into a photolysis cell containing deaerated aqueous 1 mol dm^{-3} sodium nitrite–1 mol dm^{-3} sodium hydroxide and then irradiated with visible light. A 500 W tungsten–halogen lamp was used as the light source with a water filter cell (6 cm pathlength with Pyrex glass windows) and a Pyrex-glass filter to cut off IR and UV radiations. The distance between the light source and the Nafion membrane was 40 cm. After 30 min irradiation, the cell solution was tested for ammonia, hydroxylamine and hydrazine.[15] Only ammonia was identified as the sole nitrite reduction product. The ammonia concentration was determined using Nessler's reagent and careful spectroscopic analysis in the 400–430 nm wavelength range.[16] The samples for analysis were obtained by interrupting the photochemical process at intervals for several seconds and transferring 1 ml of the solution to a 5 ml standard measuring flask (smf). Then 0.5 ml of freshly prepared Nessler's reagent[17] was added to the smf and the solution was made up to a volume of 5 ml with water. A calibration curve was obtained by dissolving a standard amount of ammonium chloride in water and using Nessler's reagent as described above.[16]

The yield of NH_3(aq) formed after 30 min irradiation using samples containing different amounts of $[Ru(bpy)_3]^{2+}$ in Nf/$[Ni(teta)]^{2+}$ matrix was determined [Fig. 2(*b*)] and the corresponding turnover numbers (TON) of the adsorbed $[Ru(bpy)_3]^{2+}$ complex based on yields of NH_3(aq) are shown in Fig. 2(*a*). The TON for $[Ru(bpy)_3{}^{2+}$ was obtained from the relation: 6 × mol of NH_3(aq) produced/mol of $[Ru(bpy)_3]^{2+}$ adsorbed.

The results were reproducible and the Nafion membrane was stable over months and could be reused in repeated experiments. The absence of any one reaction component (visible light, $[Ni(teta)]^{2+}$, $[Ru(bpy)_3]^{2+}$ or $NaNO_2$) in the solid–solution photoredox system led to no formation of NH_3(aq). When the homogeneous solution containing the photoredox system [Ni-(teta)]$^{2+}$–$[Ru(bpy)_3]^{2+}$ was irradiated (*i.e.* in the absence of

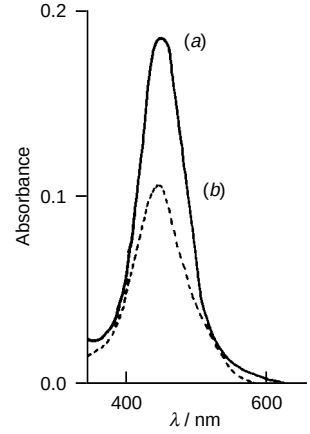

Fig. 1 Absorption spectra of (*a*) $[Ni(teta)]^{2+}$ in water and (*b*) $[Ni(teta)]^{2+}$ adsorbed in Nafion membrane

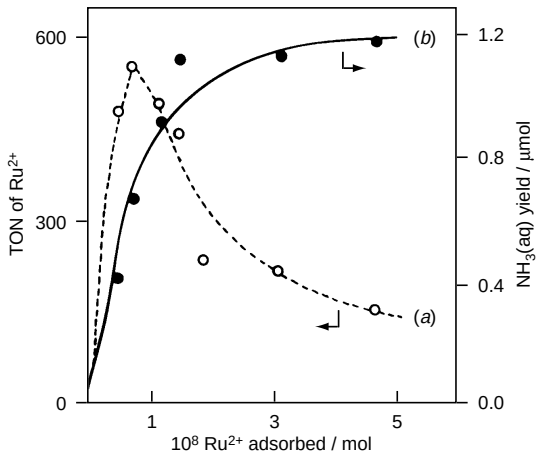

Fig. 2 (*a*) Turnover numbers (TONs) of $[Ru(bpy)_3]^{2+}$ and (*b*) yields of NH_3(aq) observed for the Nf/$[Ni(teta)]^{2+}$/$[Ru(bpy)_3]^{2+}$ matrix (1 cm²) dipped in deaerated aqueous 1 mol dm^{-3} $NaNO_2$–1 mol dm^{-3} NaOH. Irradiation time 30 min; 3.75×10^{-6} mol of $[Ni(teta)]^{2+}$ was adsorbed.

Nafion) negligible amounts of NH_3(aq) were produced compared with Nf/$[Ni(teta)]^{2+}$/$[Ru)bpy)_3]^{2+}$.

The amount of $[Ru(bpy)_3]^{2+}$ adsorbed into the Nafion matrix was found to influence the yield of NH_3(aq) produced [Fig. 2(*b*)]. An increase of concentration of $[Ru(bpy)_3]^{2+}$ in the Nafion increased the yield of NH_3(aq) and the TON of $[Ru(bpy)_3]^{2+}$ up to a limiting value, above which a decrease in the TON was observed [Fig. 2(*a*)], at higher local concentrations, the self quenching of the excited state $[Ru(bpy)_3]^{2+}$ complex and a light filtering effect were predominent.

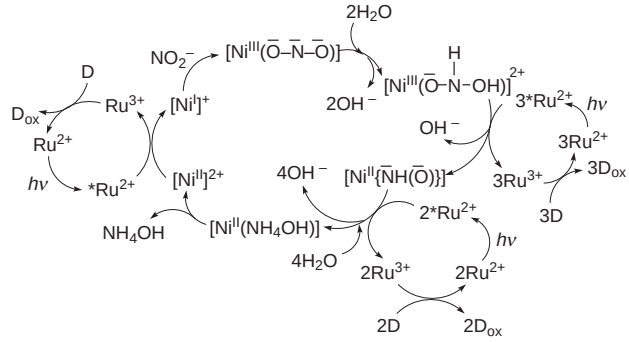
In the solid-phase photoredox system, the excited-state electron-transfer quenching between $*[Ru(bpy)_3]^{2+}$ and $[Ni(teta)]^{2+}$ (Ni^{II}) complex produces $[Ru(bpy)_3]^{3+}$ and $[Ni(teta)]^{+}$ (Ni^{I}) complex. The latter (Ni^{I}) reacts[18] with NO_2^- to produce $[Ni(O^-–N^-–O^-)]$ (Ni^{III}). This species undergoes successive reductions and finally produces $[Ni(teta)]^{2+}$ and NH_3(aq) (Scheme 1). The overall reaction is given by eqn. (1). The role

$$NO_2^- + 6e^- + 5H_2O \rightarrow NH_3(aq) + 7OH^- \qquad (1)$$

of Nafion matrix in the photo-induced electron transfer reaction between $[Ru(bpy)_3]^{2+}$ and the $[Ni(teta)]^{2+}$ complexes is (*i*) immobilization of positively charged metal complexes in a dispersed state and (*ii*) provision of a microheterogeneous environment for the reacting molecules.

The present work demonstrates the importance of the immobilization of photoredox molecules in a solid matrix to realize the multistep one-electron transfer process by a series of one-electron transfer reaction (Scheme 1). Investigations into the role of the $[Ru(bpy)_3]^{2+}$ and $[Ni(teta)]^{2+}$ catalyst in Nafion membrane in the production of ammonia by nitrite reduction are under way.

We acknowledge the Department of Science and Technology for providing financial assistance. J. P. acknowledges the Council of Scientific and Industrial Research for the Research Associateship. We also thank Professor S. Rajagopal for his valuable suggestions.



Scheme 1 Schematic illustration of photocatalytic reduction of nitrite at a Nafion matrix containing $[Ni(teta)]^{2+}$ and $[Ru(bpy)_3]^{2+}$. $[Ni^{II}]^{2+}$ = $[Ni(teta)]^{2+}$, Ru^{2+} = $[Ru(bpy)_3]^{2+}$. D = electron donor (H_2O), and D_{ox} = oxidized species of electron donor.

Novel approaches towards the generation of excited triplets of organic guest molecules with zeolites

Kasi Pitchumani,[a] Manoj Warrier,[a] John R. Scheffer*[b] and V. Ramamurthy*[a]†

[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*
[b] *Department of Chemistry, University of British Columbia, Vancouver, Canada V6T 1Z1*

Alkali metal cation-exchanged zeolites (M^+X or M^+Y) can be used as 'microreactors' in which to carry out photochemical rearrangement reactions of organic guests.

Considering that a number of reactions originate from excited states that are not efficiently reached by direct excitation, it is important to establish strategies that generate molecules in their excited triplet states within zeolites.[1] We show below that three approaches can be used to generate triplets of organic molecules within zeolites. The 'heavy and light atom effects' employ the cations present within zeolites to perturb the excited state dynamics of the guest molecules; the sensitization technique utilizes a second guest molecule (a sensitizer) to turn on triplet reactivity.

Dibenzobarrelene **1a** and benzobarrelene **1b** and enones **1c** and **1d** were chosen as probe molecules for the present study because their photochemical behavior is known to be multiplicity-dependent and relatively simple (Scheme 1).[2] As shown in Fig. 1, molecules such as **1a** can easily be accommodated within the supercages of a zeolite.

To conduct cation-dependent photochemistry, **1a**–**d** were introduced into the cavities of zeolites M^+X by adsorption from hexane solution and irradiated either as powders or as hexane slurries. Experiments were also carried out with M^+Y zeolites. The approach involving the use of a triplet sensitizer employed acetophenone, *p*-methoxyacetophenone, α-aminoacetophenone hydrochloride and xanthone as the second component. These were introduced into zeolite K^+Y by adsorption from hexane solution. The resulting vacuum-dried, sensitizer-containing zeolite complexes were then transferred to hexane solutions of **1a**–**d** to produce a series of 'double-loaded' complexes. The mole ratio of sensitizer to reactant was maintained at 1 : 1 in every case, but the amount of material loaded onto the zeolite, the loading level, was varied from 13 to 85, a loading level of 13 referring to an average of one molecule of sensitizer and one reactant molecule for every 13 zeolite supercages. The double loaded zeolite complexes were photolyzed as hexane slurries or as powders at $\lambda > 290$ nm (Pyrex), where reactants do not absorb significantly. Following photolysis, the organic materials were extracted from the zeolites with diethyl ether or tetrahydrofuran and analyzed by capillary gas chromatography. Mass balances were excellent (> 85%), indicating that the photoproduct ratios were not skewed by selective inclusion of one of the products. The results for cation dependent chemistry are summarized in Table 1. Results from sensitization studies (only a few sensitizers) are compiled in Table 2. Since the behavior of enones **1c** and **1d** was identical to that of **1a** and **1b** upon sensitization results are not shown.

Table 1 Photoproduct distribution from irradiation of compounds **1a** and **1b** in M^+X and M^+Y zeolites[a]

			Slurry[b]	
Medium	Compound	Conv. (%)	% COT **2**	% SBV **3**
MeCN	**1a**		77	23
Acetone	**1a**		0	100
LiX	**1a**	4 (23)[c]	33 [80][d]	67 [20]
NaX	**1a**	6 (20)	38 [72]	62 [28]
KX	**1a**	17 (30)	53 [57]	47 [43]
RbX	**1a**	16 (26)	25 [31]	75 [69]
CsX	**1a**	24 (41)	13 [17]	87 [83]
TlX	**1a**	98 (88)	< 1 [+]	> 99 [> 99]
Hexane	**1b**		96	4
Sens.[e]	**1b**		0	100
NaX	**1b**	77	95	5
KX	**1b**	59	92	8
RbX	**1b**	63	86	14
CaX	**1b**	84	88	12
TlX	**1b**	90	8	92

[a] The product ratios were independent of % conversion within the estimated error limits of ±2% and represent an average of at least 5 independent runs. [b] Slurry irradiations were conducted in hexane for 2 h. Solid state irradiations were carried out for 20 h. Conversions are comparable, since all irradiations were conducted under identical conditions. [c] Numbers in parentheses are for solid state irradiations. [d] Numbers in brackets are for zeolites saturated with water. [e] Acetophenone sensitization in hexane solution.

Table 2 Photoproduct distribution from irradiation of compounds **1a** and **1b** in K^+Y zeolite containing various triplet energy sensitizers[a]

Compound (Sensitizer)	Loading level[b]	Slurry[c] % COT **2**	Slurry[c] % SBV **3**	Solid[c] % COT **2**	Solid[c] % SBV **3**
(4-Methoxyacetophenone)					
1a	25	< 1	> 99	< 1	> 99
1a	40	4	96	< 1	> 99
1a	85	13	87	< 1	> 99
(α-Aminoacetophenone HCl)					
1a	25	8	92	5	95
1a	40	16	84	10	90
(4-Methoxyacetophenone)					
1b	13	10	90	1	99
1b	25	34	66	2	98
1b	40	51	49	20	80
(α-Aminoacetophenone HCl[d])					
1b	13	39	61	18	82
1b	25	54	46	63	37

[a] The product ratios were independent of % conversion within the estimated error limits of ±2% and represent an average of at least 5 independent runs. [b] Loading level refers to the average number of supercages per guest molecule. For example, a value of 25 indicates one probe molecule and one sensitizer molecule per 25 supercages. [c] Slurry irradiations were conducted in hexane for 2 h. Solid state irradiations were carried out for 20 h. Conversions are comparable since all irradiations were conducted under identical conditions. [d] In this case, the sensitizer is anchored to the zeolite *via* an ionic bond, which allows the photoproducts to be removed selectively and the complex reused. No decrease in zeolite efficiency was seen after as many as 6 runs.

Of the three techniques, the sensitization method was found to be general. Triplet–triplet energy transfer occurred in every case (**1a**–**d**) in the doubly loaded K^+Y zeolites. In the presence of an equimolar amount of sensitizer, triplet yields of well over 90% are readily attainable. *p*-Methoxyacetophenone is the sensitizer of choice among those tested. Sensitization works well even when there is only one sensitizer and one acceptor molecule present in 40 or more zeolite cages.

The heavy atom response of compounds **1a** and **1b** is stronger than that observed in the oxadi-π-methane rearrangement of **1c** and **1d**. Essentially 100% triplet state behavior is observed with **1a** and **1b**. The triplet state product observed with **1c** and **1d** never exceeded more than 30% even with Tl^+ as the cation.[3,4] Based on the observations made with the above four systems we conclude that 'El Sayed's rule' holds good within zeolites as well: the degree of heavy atom effect on mixing the states of different multiplicity depends on the electronic configuration ($n\pi^*$ and $\pi\pi^*$).[5]

An unusual observation was made with light cations in the case of **1a**. For **1a**, the Li^+ and Na^+ exchanged zeolites lead to surprisingly large amounts of triplet photoproduct **3a** (67 and 62%, respectively), but the reaction is relatively slow. This 'light atom' effect disappears, however, when the complexes are equilibrated with water before use. The exact mechanism by which Li^+ and Na^+ bring about triplet chemistry in the case of **1a** is not clear. We speculate that by binding strongly to the guest molecule, the light atoms perturb its symmetry characteristics and thus influence the intersystem crossing rates relative to an unperturbed molecule. Consistent with this suggestion, the effect falls off with N^+ (62%) and K^+ (47%), which are expected to bind less strongly. Further where solvation of the cations by water disrupts their strong binding to dibenzobarrelene, the 'light atom' effect of Li^+ is completely eliminated (20% triplet), and there is a normal progressive increase in perturbing power for the others (Na^+, 28%; K^+, 43%; Rb^+, 69%; Cs^+, 83%; Tl^+, > 99%); the classical heavy atom effect becomes increasingly important as the atomic number of the perturbing ion increases.

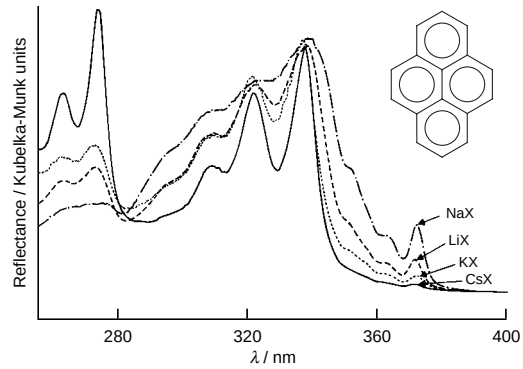

Fig. 2 Diffuse reflectance spectra of pyrene within 'dry' M^+Y zeolites. The intensity of the S_0 to S_1 band is dependent on the cation.

Interactions between light cations and included guest molecules such as benzene and anthracene adsorbed on zeolites were noted as early as 1963.[6] The perturbations of electronic states as well as the modifications of the vibrational modes are explained by a lowering of the symmetry of aromatic molecules in the adsorbed state. Our own observations with pyrene are consistent with the above suggestions.[7] Diffuse reflectance spectra recorded for pyrene, at a low loading level (Fig. 2), within a number of cation exchanged X and Y zeolites suggest that the interaction between the cation and pyrene is strong and that the strength of interaction depends on the polarizability of the cation. In Fig. 2, the intensity of the 0–0 transition of the S_0 to S_1 band is dependent on the charge density of the cation present within supercages. Our working model is that the symmetry reduction of the aromatic molecule occurs due to strong interaction between the cation and the aromatic along the π face resulting in slight bending of the aromatic plane. The example provided here indicates that such symmetry reductions also may influence the S_1 to T_n intersystem crossing process as well.

The authors thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research (V. R. and J. R. S.). Financial support by the Natural Sciences and Engineering Research Council of Canada (J. R. S.) and Chemical Sciences Program, The US Department of Energy (V. R.) is also gratefully acknowledged. J. R. S. thanks M. D. Fryzuk for helpful discussions.

Synthesis of an oxorhenium(v) corrolate from porphyrin with detrifluoromethylation and ring contraction

Man Kin Tse, Zeying Zhang, Thomas C. W. Mak and Kin Shing Chan*†

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

Metallation of highly electron deficient 5,10,15,20-tetrakis(trifluoromethyl)porphyrin 1 with [$Re_2(CO)_{10}$] in refluxing PhCN resulted in a novel synthesis of oxorhenium(v) 5,10,15-tris(trifluoromethyl)corrolate 2 characterized by single crystal X-ray crystallography.

A new family of porphyrins having highly electron deficient perfluoroalkyl groups in the *meso*-positions has been efficiently synthesized recently by the acid-catalyzed condensation of perfluoro-1-(2′-pyrrolyl)alkan-1-ols.[1] Metallo-perfluoroalkylporphyrins have attracted considerable interest owing to their special non-planar conformation,[1] unusual electronic features,[2] and catalytic properties.[3] In order to explore the chemistry of these electron deficient metalloporphyrins, we have prepared the metal complexes of the porphyrin 5,10,15,20-tetrakis(trifluoromethyl)porphyrin (H_2TCF_3P, **1**). In the course of metallation of **1** with [$Re_2(CO)_{10}$], we have discovered a novel oxorhenium(v) corrolate **2**, [Re(TCF_3C)(O)], with concomitant detrifluoromethylation and ring contraction of the porphyrin **1** (Scheme 1).

When **1** was refluxed with [$Re_2(CO)_{10}$] in benzonitrile in N_2 for 1 h, the brown solution changed to pink. After cooling in air for 1 h, the solution turned to a muddy green suspension. A diamagnetic red product **2** was obtained in *ca.* 9% yield after chromatographic separation in air, together with other uncharacterized side products. The diamagnetic ^{1}H NMR spectrum of **2** showed a doublet at δ 9.88 (J 4.8 Hz) and a multiplet at δ 10.09 with integration ratio of 1 to 3, respectively. The β-pyrrolic protons were therefore non-equivalent. Moreover, the molecular ion appeared at 702 in the mass spectrum and was too low for any expected carbonyl or oxorhenium porphyrin.‡

The structure of **2** was obtained from a single crystal X-ray study.§ The structure was shown to be an oxorhenium corrolate **2** [Fig. 1(*a*)] with detrifluoromethylation and ring contraction having taken place at one of the *meso*-carbons of **1**. C(1) and C(19) of **1** were bonded together with a distance of 1.417(4) Å to form a corrole skeleton. The distances between the opposite nitrogens N(1)···N(3) and N(2)···N(4) were 3.751 and 3.754 Å, respectively, and were shorter than that of the free base porphyrin **1** by *ca.* 30%.¶ The central rhenium lay in a square pyramidal environment in which the corrolate trianion constructed the basal square and the oxygen acted as the axial ligand with Re=O bond length of 1.662(2) Å.[4] The characteristic Re=O stretching frequency appeared at about 994 cm^{-1} in the IR spectrum.[5] Owing to the contraction of the porphyrin to corrole, the large central rhenium deviated from the mean plane of the nitrogens by 0.701 Å [Fig. 1(*b*)] toward the oxygen to accommodate the typical Re–N bond distance of 2 Å.[5] To the best of our knowledge, it is the first oxorhenium porphyrin like macrocycle to be characterized by X-ray crystallography.

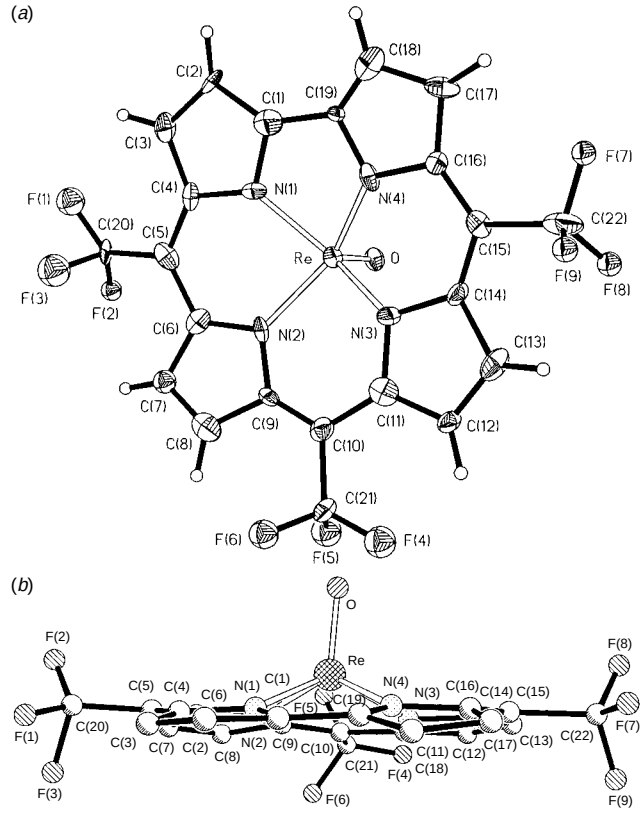

Fig. 1 (*a*) ORTEP view of [Re(TCF_3C)(O)] showing the atom labelling. The thermal ellipsoids are drawn at a 35% probability level and hydrogen atoms have been omitted for clarity. (*b*) Simplified diagram of the side view of [Re(TCF_3C)(O)].

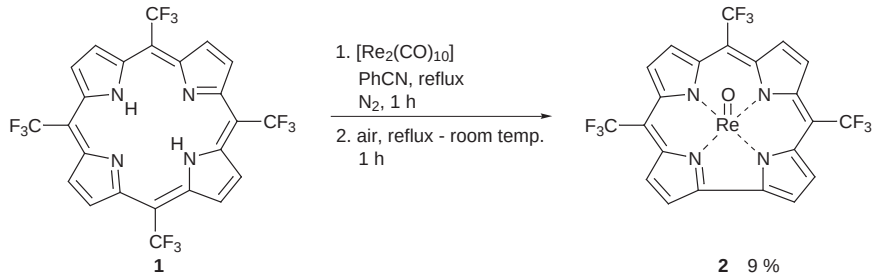

1 **2** 9 %

Scheme 1

The novel oxorhenium corrolate likely arose from the reduction of **1** by $[Re_2(CO)_{10}]$ *via* a cyclopropane intermediate. The formation of cyclopropane product has been reported in the reaction of octaethylporphyrinogen with transition metals.[6] The driving force for corrole formation is probably due to the release of steric hindrance in this and other non-planar porphyrin-like macrocycles.[7] However, the mechanism of novel detrifluoromethylation and ring contraction to form a corrole from a porphyrin remains unclear. Further studies of the electron deficient corrole are in progress.

We thank Direct Grant of the Chinese University of Hong Kong and Shell Chemical Company of Hong Kong for financial support.

Regio- and stereo-specific addition of chlorodibutyltin hydride to prop-2-ynylic ethers

Terence N. Mitchell*† and Said-Nadjib Moschref

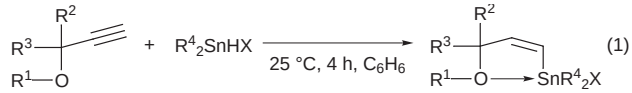
Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany

A number of prop-2-ynylic ethers smoothly undergo regio- and stereo-specific hydrostannation with chlorodibutyltin hydride in good to nearly quantitative yield at room temperature in benzene.

The importance of vinyltins in cross-couplings of the Stille–Migita type[1] has recently led to efforts to find new approaches to their preparation. A very useful approach has recently been designed by Yamamoto and co-workers,[2] who used zirconium and hafnium tetrachlorides as Lewis acid catalysts in the hydrostannation of alkynes; a refinement of this procedure[3] involves the *in situ* preparation of the tin hydride from the corresponding chloride and triethylsilane. In all cases reported, the procedure gave single isomers derived from *trans* attack of the tin hydride.

The disadvantage of this methodology is that the Lewis acid centre is blocked when the alkyne contains substituents bearing a lone pair; thus we have found that prop-2-ynylic ethers or amines, which are synthetically much more important than simple alkynes, do not react satisfactorily.

In an attempt to circumvent this problem we had recourse to the long-known but relatively little used chlorodibutyltin hydride,[4] which is readily prepared by mixing the dihydride[5] and dichloride. A hint of the potential of this reagent had been provided relatively recently by Davies,[6] who observed a rapid hydrostannation of a prop-2-ynylic alcohol (2-methylprop-3-yn-2-ol, 2 h at room temperature in toluene), though with the formation of a *Z*/*E* isomer mixture. An exothermic reaction occurs when the hydride chloride is mixed with prop-2-ynylic ethers [reaction (1)], but when the two reagents are mixed slowly at room temperature and stirred for 4 h in benzene the hydrostannation occurs in yields which are good to virtually quantitative (63–99%), only one single isomer being detected.



(1)

This is in clear contrast to the behaviour of tributyltin hydride, which gives product mixtures containing predominantly either the *E*- or the *Z*-isomer (depending on the amount of tin hydride used) when allowed to react under free radical conditions with unsubstituted prop-2-ynylic alcohols and ethers;[7] in contrast, a clean reaction does occur (*via* regiospecific *trans* addition) with substituted prop-2-ynylic residues attached to either oxygen[8] or nitrogen,[9] though yields are variable. Table 1 gives details of the ethers used in this work and the respective yields. The reactions are carried out as follows: the dialkyltin dihydride[5] (2.5 mmol) is added at 0 °C during 10 min to the dichloride (2.5 mmol) with constant stirring. The mixture is stirred for 0.5 h at room temperature and a solution of the prop-2-ynyl ether[10] (5 mmol) in benzene (5 ml) is added during 10 min with stirring. The reaction mixture is stirred for 4 h at room temperature, the volatiles removed at the oil pump, and the colourless oil (which solidifies on storing at 5 °C) obtained is characterised by multinuclear NMR spectroscopy.

Table 1 Addition of halodialkyltin hydrides to prop-2-ynyl ethers

Prop-2-ynyl ether				Halodialkyltin hydride		
	R^1	R^2	R^3	R^4	X	Yield (%)[a]
1a	Allyl	Pr	H	Bu	Cl	93
1b	2-Methylallyl	H	H	Bu	Cl	71
1c	Cyclohex-2-enyl	H	H	Bu	Cl	> 91
1d	But-2-enyl	H	H	Bu	Cl	63
1e	Et	Me	Me	Bu	Cl	> 98
1f	2-Furyl	H	H	Bu	Br	97
1g	2-Methylallyl	H	H	Bu	Br	> 98
1h	2-Furyl	H	H	Et	Cl	> 98
1i	2-Furyl	H	H	Me	Cl	> 98
1j	Et	Me	Me	Me	Cl	97

[a] From integration of ^{1}H NMR spectra.

The ^{1}H NMR spectra confirm that the reaction has occurred in a *trans* manner with attack of the tin at the terminal carbon [^3J(H,H) = 12–13 Hz]. In a control experiment with hex-1-yne a mixture of *E* (^3J = 18 Hz) and *Z* (^3J = 12.5 Hz) isomers is observed, clearly demonstrating that the ether oxygen determines the reaction course. The tin resonance occurs at relatively high field [1 to 13 ppm compared with 56 (*E*) and 67 ppm (*Z*) in the isomers derived from hex-1-yne], suggesting intramolecular coordination between oxygen and tin in the product. This is confirmed by the carbon-13 data: one-bond tin–carbon coupling constants are of a magnitude expected for pentacoordination at tin (540–664 Hz). Analogous results are obtained using other compounds R_2SnHX (R = Me, Et; X = Cl, Br). Treatment of the vinyltins (**1**) with Grignard reagents lead to the corresponding trialkyltin species: thus, for example, treatment of (**1f**) with EtMgBr leads to a product showing the expected NMR spectroscopic data [δ(^{119}Sn) −40.5 ppm, vinyl ^{1}H–^{1}H coupling constant 10.4 Hz].

An unusual reaction of hexafluoroacetone with methylenediphosphines. Facile synthesis of carbodiphosphoranes

Igor Shevchenko†

Institute of Bioorganic Chemistry, Murmanskaya Street 1, 252660 Kiev, Ukraine

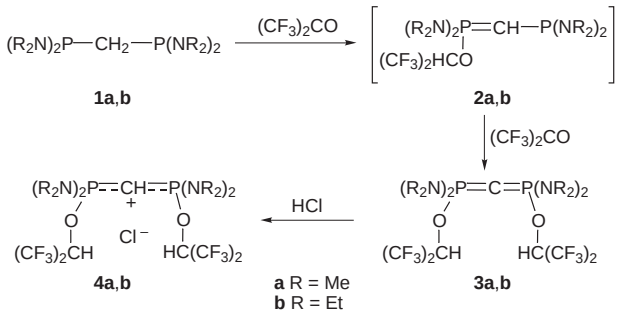
The oxidation of bis[bis(dialkylamino)phosphinyl]methanes with hexafluoroacetone does not lead to the expected dioxaphospholane heterocycles, but yields quantitatively carbodiphosphoranes.

It is well known that phosphines react with 2 equiv. of hexafluoroacetone (HFA) to give phosphoranes in which the phosphorus atom is part of a dioxaphospholane heterocycle.[1–4] It turns out that this is not the only possible pathway for this reaction. Here we report on an unusual reaction of HFA with bis[bis(dialkylamino)phosphinyl]methanes **1a,b** which gives quantitatively carbodiphosphoranes **3a,b** (Scheme 1). Formally this reaction can be considered to be an addition of the tautomeric P–H ylide form of **1** to the carbonyl function of HFA. The presence of a methylene group between the two phosphorus atoms is thus a necessary condition for this reaction.

After slow bubbling of gaseous HFA through a solution of **1a** or **1b** in hexane at 20 °C, NMR spectra of the reaction mixtures show the presence of only compound **3a** or **3b**, respectively; the ^{31}P NMR spectra of the reaction mixtures display one singlet at δ 33–37. Carbodiphosphorane **3a** is stable in hexane solution at room temperature for several hours, whereas **3b** containing the more bulky diethylamino substituents is respectively more stable and its hexane solution can be stored without decomposition for two days. Evaporation of the solvent causes decomposition of the molecule.

The choice of hexane as a solvent is very important for this reaction. In other solvents carbodiphosphoranes **3a,b** are less stable and their synthesis may be accompanied by the formation of byproducts. The ^{1}H NMR spectra of **3a** and **3b** were recorded immediately after HFA had been added to a solution of **1a** or **1b** in [$^2H_8$]toluene.‡ They show a characteristic low field septet at δ 6.2, confirming the location of the two equivalent protons α to the CF_3 groups. It is interesting that the dimethylamino groups of **3a** appear in the ^{1}H NMR spectrum, not as a doublet, but as a pseudo-triplet at δ 2.59 with a broadened central line, which is consistent with the NMR data of known compounds. The analogous carbodiphosphorane having chlorine atoms instead of HFA units at the two phosphorus atoms shows the same pattern for the Me_2N groups in its ^{1}H NMR spectrum.[5]

The mechanism of this reaction probably includes the intermediate formation of monoylides **2a** or **2b**. However, we could not detect these compounds *via* NMR spectroscopy. Even if only 1 equiv. of HFA was added to the methylenediphosphines **1a,b** the ^{31}P NMR spectrum of the reaction mixture displayed only two equal signals, for the starting compound **1** and the reaction product **3**.



Scheme 1

The ylidic structure of carbodiphosphoranes **3a,b** is confirmed by their reaction with HCl, which gives the stable salts **4a,b**. As a strong base, **3a,b** reacts with ammonium hydrochlorides. That is why **4a,b** can also be formed in small quantities together with **3a,b**, if starting methylenediphosphines **1a,b** are contaminated with dialkylammonium chlorides. However, **4a,b** are not soluble in hexane and can be easily separated. The structures of **4a,b** are entirely consistent with the NMR data obtained.§ In contrast to most carbodiphosphoranes described previously,[6–10] compounds **3a,b** are easily obtainable and can be used in further reactions without isolation from the reaction mixture. The possible application of **3a,b** in Wittig reactions and the presence of hydrogen atoms α to the CF_3 groups make these compounds interesting synthons for organic and elementoorganic synthesis. We are currently investigating their chemical properties.

Dedicated to Doctor Hans-Martin Schiebel on the occasion of his 65th birthday.

Synthesis of $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ *via* ion exchange in liquid ammonia—a new, versatile access to ionic fullerides

Klaus Himmel and Martin Jansen*†

Institut für Anorganische Chemie der Rheinischen Friedrich-Wilhelms-Universität Bonn, Gerhard-Domagk-Str. 1, 53121 Bonn, Germany

The ammoniate $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ is prepared from K_2C_{60} *via* cation exchange in liquid ammonia; the structure of the compound is determined by X-ray crystal structure analysis.

Since the discovery of superconductivity in K_3C_{60},[1] ionic fullerides have been in the focus of scientific interest. However, up to now research has been restricted to fullerides of alkali (including the analogous Tl^+), alkaline earth and some rare earth metals,[2] which form directly from the respective metal and fullerene during solid state reactions. Several attempts have been made to introduce other metals.[3] In most cases, however, the composition and constitution of the products could not be determined conclusively. To our knowledge, only the compounds $Na_{2+x}Hg_yC_{60}$[4] and $[Ni(C_5Me_5)_2]C_{60}\cdot CS_2$[5] have been fully characterized.

As the alkali fullerides readily dissolve in liquid ammonia,[6,7] ion exchange in this solvent using a thoroughly dried macroreticular exchange resin could offer a general approach to the synthesis of fullerides with any counterion that can be loaded onto the resin and is soluble in liquid ammonia, at the same time. Recently, we have shown this route to be suitable for the synthesis of fullerides with organic cations.[8] The preparation of the novel fulleride $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ reported here, and of isostructural $[Mn(NH_3)_6]C_{60}\cdot 6NH_3$ and $[Cd(NH_3)_6]C_{60}\cdot 6NH_3$,[9] extends the applicability of the exchange route to transition metals, and thus broadens its scope significantly.

Reacting a solution of K_2C_{60} in ammonia with an ion exchange resin loaded with Ni^{2+} yielded $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ in black shiny crystals.‡ Suitable crystals were selected in an inert oil matrix under a microscope and were used for an X-ray single crystal structure analysis.§

$[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ crystallises in a distorted rock salt type of structure (Fig. 1). Nickel hexaammine complexes occupy the octahedral sites in a fcc fulleride sublattice. Each molecule of ammonia of solvation is coordinated *via* a hydrogen bond to one ammonia in the ligand sphere of the ammine complex. This extended coordination sphere of Ni^{2+} can fit its shape flexibly to the needs of the octahedral site of the C_{60}^{2-} sublattice, at the same time fixing the fulleride anion orientationally. The thermal parameters of the fulleride (Fig. 2) are reasonable and do not indicate any disorder. The shortest intermolecular carbon to carbon distance is 3.36 Å (3.11 Å in neutral C_{60}). By comparing the shortest Ni–C distance (4.62 Å) with the distance between the centre of the octahedral site and the nearest carbon atom in fcc C_{60} (3.65 Å) it becomes evident that the accommodation of the hexaammine complex and the extra six solvent molecules per formula unit leads to a considerable expansion of the C_{60} sublattice. The quite strong deviation of the crystal structure from the ideal cubic symmetry of rock salt indicates that packing requirements more strongly determine the structure than do electrostatic interactions. Hydrogen atoms of the solvent ammonia show the shortest intermolecular distances to the fulleride. This fact suggests an interaction of N–H dipoles with electron density on the fulleride surface that could be responsible for the localisation of the anion in a fixed orientation. Similar interactions of C–H dipoles have been discussed previously.[10]

Dianions C_{60}^{2-} should be subject to Jahn–Teller distortion due to the asymmetric occupation of the degenerate t_{1u} orbital of neutral C_{60}. The nature and the degree of this distortion, however, have been discussed controversially.[11] In particular, it can be very difficult to separate distortions caused by an intrinsic Jahn–Teller effect from those due to a low site symmetry of the unit under discussion. The fulleride dianion in the present structure is somewhat distorted from the ideal I_h symmetry. The mean distance of the carbon atoms from the centre of the fulleride is 3.541(2) Å with a spread from 3.555(2) Å (C13) to 3.520(3) Å (C16). Though the range is larger than in neutral C_{60} (0.012 Å),[12] it could well be a result of the interactions with the low symmetrical environment established by the hydrogen atoms. Actually, we have shown that in an environment of higher symmetry the point symmetry I_h of a divalent fulleride can be retained.[13]

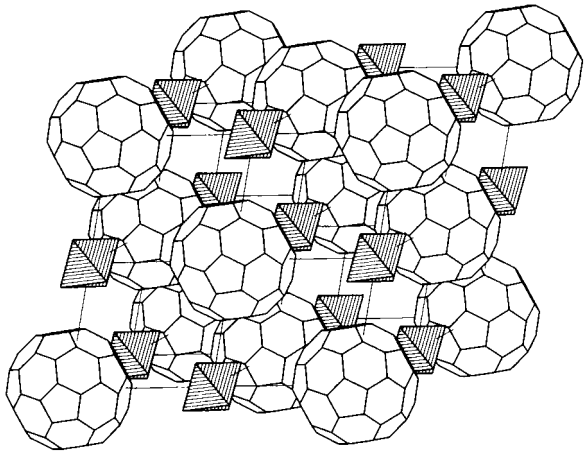

Fig. 1 Distorted rock salt type arrangement of fulleride dianions and nickel hexaammine cations (octahedra)

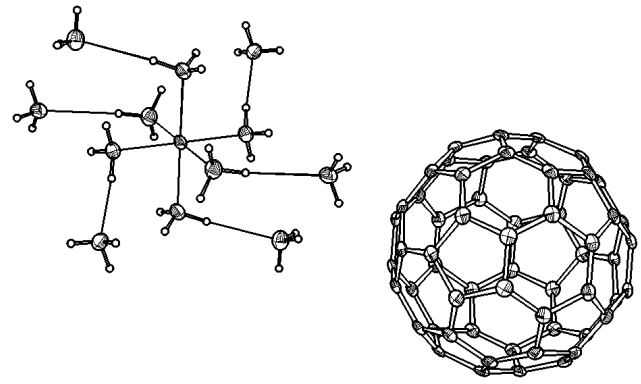

Fig. 2 ORTEP plot[15] (50% probability ellipsoids) of the cationic and anionic units in $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$

Apart from the Ni compound presented in this paper we have been able to synthesise $(BnNMe_3)_2C_{60}\cdot 3NH_3$;[8] $(PhNMe_3)_2C_{60}\cdot 4NH_3$, $[Mn(NH_3)_6]C_{60}\cdot 6NH_3$ and $[Cd(NH_3)_6]C_{60}\cdot 6NH_3$[9] *via* ion exchange in liquid ammonia, which demonstrates the wide, general applicability of the procedure developed. As an attractive option, these ammoniates offer access to fullerides of transition metals by removing ammonia *in vacuo* and/or at elevated temperatures.

We wish to thank Hoechst AG, Frankfurt, for providing C_{60}.

‡ Preparation of nickel hexaammine fulleride ammoniate: 1 g of exchange resin (Amberlyst 15, Fluka) loaded with Ni^{2+} was thoroughly dried and placed on one side of a H-type glass vessel equipped with a glass sieve (porosity 3). 80 mg (1.0×10^{-4} mol) K_2C_{60} were placed on the other side of the sieve. After cooling (ethanol–dry ice slush) ammonia was condensed into the vessel until the glass sieve was completely covered. The reaction mixture was stored at 230 K for about 3 weeks. In this time K_2C_{60} slowly diffused onto the ion exchange resin where $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$ precipitated as shiny black platelets that are sensitive to air, moisture and elevated temperature. The crystals were removed from liquid ammonia, transferred into an inert oil mixture (1 : 1 Perfluorpolyether 216, Riedel-de Haën/ Perfluorpolyether Fomblin Y HVAC 40/11, Aldrich) which was cooled with a nitrogen stream to 230 K, and picked up on the tip of a glass capillary mounted on a goniometer head.

§ *Crystal data* for $[Ni(NH_3)_6]C_{60}\cdot 6NH_3$: $C_{60}H_{36}N_{12}Ni$, M = 938.72, black platelets, triclinic, space group $P\bar{1}$ (no. 2), a = 988.3(2), b = 1021.1(2), c = 1050.2(2) pm, α = 77.79(2), β = 80.04(2), γ = 79.64(2)°, V = 1.0089(3) nm^3, Z = 1, D_c = 1.619 g cm^{-3}, μ(Mo-Kα) = 0.55 mm^{-1}. 4611 reflections measured, 3959 independent, 3653 reflections observed with $I > 2\sigma(I)$, 361 parameters, no restraints. Diffraction data were collected with an Enraf-Nonius CAD4 diffractometer (Mo-Kα, λ = 71.069 pm) at 113(2) K to θ_{max} = 26°. The structure was solved by the Patterson method and refined on F^2 using all independent reflections.[14] Hydrogen atoms of the ammonia molecules were located by difference Fourier synthesis. The final wR_2 value was 0.099 [corresponding to a conventional R value of 0.037 by using only reflections with $I > 2\sigma(I)$]. CCDC 182/844.

Simultaneous 1,2-, 1,3- and 1,4-addition of trithiazyl trichloride to a conjugated diene

Charles W. Rees* and Tai-Yuen Yue

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY

1,4-Diphenylbuta-1,3-diene and trithiazyl trichloride 1 react to give a bi(thiadiazole) 2, an isothiazoloisothiazole 3, a dithiazolothiazine 4 and the thiazinodithiatriazepines 5 and 6, all of which could arise from initial addition of the trimer 1, or its monomer, to the conjugated diene by 1,2-,1,4- and, for the first time to an all-carbon diene, 1,3-('criss-cross') cycloaddition reactions.

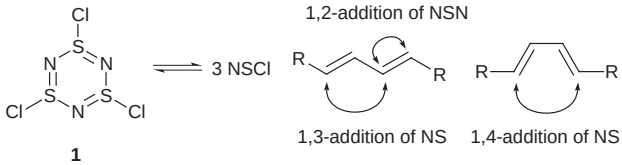
We have shown that trithiazyl trichloride $(NSCl)_3$ **1**, in thermal equilibrium with its monomer N≡SCl,[1] converts monoenes and monoynes directly into 1,2,5-thiadiazoles.[2] Furthermore, 1-alkyl-2,5-diphenylpyrroles are similarly converted into the bi(1,2,5-thiadiazole) **2**, thus reacting as masked 1,3-dienes.[3] It would be interesting therefore to explore the reaction of the reagent **1** with acyclic conjugated dienes where 1,3- and 1,4-cycloaddition, as well as 1,2-cycloaddition, can be envisaged, as shown in Scheme 1.

When (*E,E*)-1,4-diphenylbuta-1,3-diene was treated with a deficiency of **1** (1 mol) in refluxing CCl_4 for 30 min a rapid and complex reaction ensued, from which five crystalline organic compounds **2**–**6** were isolated in low yields† by careful chromatography and shown to be derivatives of five different, rare or new heterocyclic ring systems (Scheme 2). The same five products were obtained in higher yields,† shown in brackets in Scheme 2, when the diene was treated with **1** (1 mol) in refluxing toluene for 1 h. With more trimer (3 mol) in refluxing toluene for 16 h, the reaction was less complex and **2** was the major product (60%). In spite of their very different structures, the carbon connectivity of the starting diene is retained in all of these products.

The bi(1,2,5-thiadiazole) **2** was identical with that formed from *N*-alkyl-2,5-diphenylpyrroles.[3]

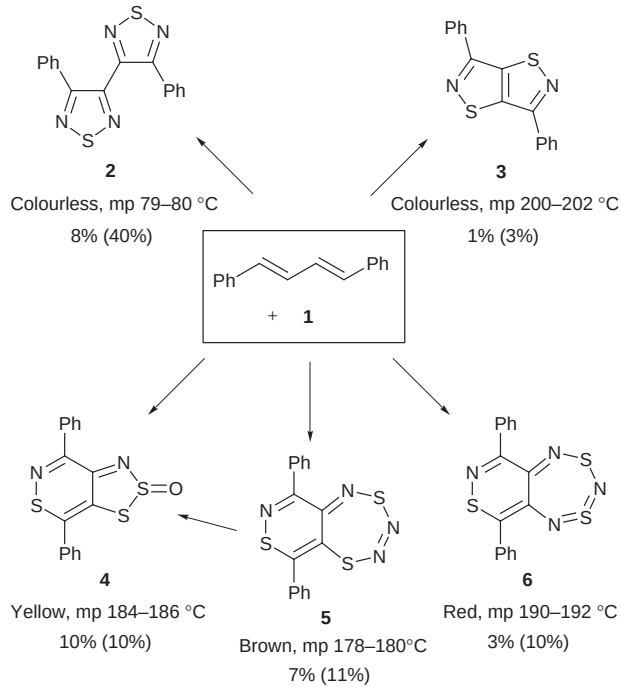
The isothiazolo[5,4-*d*]isothiazole structure **3** was suggested by its high stability and symmetry (^{1}H and ^{13}C NMR) and its mass spectrum, which gave fragments for PhCN and C_2S_2. This product was synthesised independently from the oxime of 5-benzoyl-3-phenylisothiazole[4] and disulfur dichloride in DMF at 100 °C, providing another approach to this rare ring system.

The new dithiazolo[4,5-*d*]thiazine *S*-oxide structure **4** was based on its spectroscopic properties and confirmed by X-ray crystallography.[5] The sulfoxide group suggested that formation of **4** had involved oxidation, possibly during isolation; an examination of the five products **2**–**6** showed that all were stable to air except for the brown compound **5** which was oxidised to **4** when adsorbed on silica. Compound **5** was rapidly and cleanly converted into **4** by MCPBA in CH_2Cl_2 at room temperature. Link scan mass spectrometry showed that **4** and **5** gave the same pattern of daughter ions, the same species ($C_{16}H_{10}N_2S_3$) being



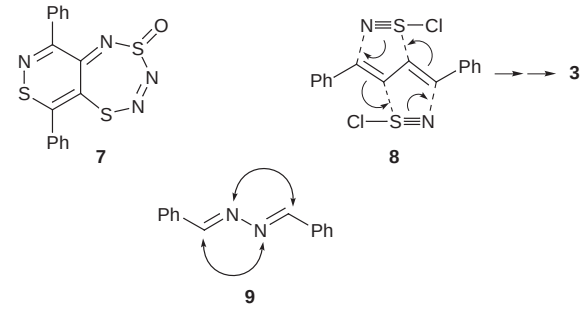
1

Scheme 1



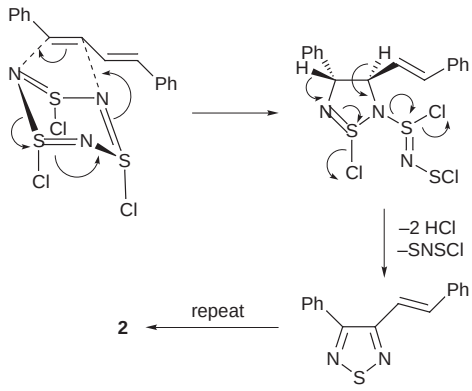
Scheme 2

formed from **4** by loss of O and from **5** by loss of N_2. This suggested the new thiazinodithiatriazepine structure **5** for the brown product, which agreed with all its spectroscopic properties, including the dominant loss of N_2 in the mass spectrum. Conversion of **5** into **4** could result from oxidation at the least hindered sulfur atom, to give **7**, followed by extrusion of N_2.



The structure of the final product **6**, which is isomeric with **5**, was assigned on the basis of spectroscopic properties and a chemical degradation. Its molecular ion was much stronger than that of **5** and showed no loss of N_2.

The formation of all five products can be explained by initial 1,2-, 1,3- and 1,4-cycloaddition processes (Scheme 1). The bi(thiadiazole) **2** is probably formed by addition of the trimer, as



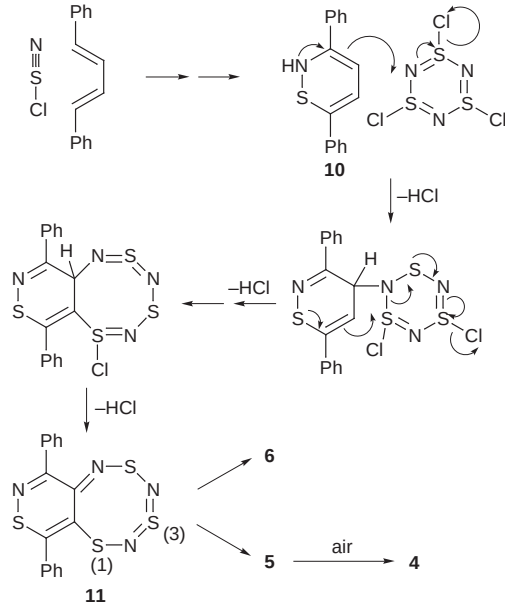
Scheme 3

an N–S–N unit, across C_1–C_2 and C_3–C_4, exactly as for monoenes[2] and pyrroles,[3] as shown in Scheme 3.

The structure of the isothiazoloisothiazole **3** suggests the addition of S–N units, possibly the monomeric species N≡SCl, across C_1–C_3 and C_2–C_4, as shown in **8**. Subsequent elimination of HCl and oxidation, possibly *via* chlorination, would give the stable aromatic system **3**. Such 'criss-cross' cycloadditions[6] have been reported for azabutadienes, particularly for azines such as 1,4-diphenyl-2,3-diazabuta-1,3-diene **9**,[7] but the present reaction is, we believe, the first example of a criss-cross cycloaddition to an all-carbon diene.

The 1,2-thiazine ring common to the remaining products suggests the 1,4-addition of an N–S unit, probably the monomer, to the diene. Since at least four molecules of monomer are required to form compounds **5** and **6**, it is possible that the Diels–Alder process is followed by reaction with a molecule of trimer, with overall elimination of 4 HCl units to give the intermediate **11** (Scheme 4). Initial Diels–Alder reaction, elimination of HCl and a hydrogen shift would give 3,6-diphenyl-1,2-thiazine **10**, which is nucleophilic at C_4. Attack on the trimer **1** at nitrogen, followed by a second nucleophilic attack by C_5 at sulfur and elimination of the remaining HCl, could give the key intermediate **11**. This is formally a 16π antiaromatic system which could become 14π by extrusion of any one of the sulfur atoms. Extrusion of S_3 or S_1 would then lead to the observed products **5** and **6**, respectively, and **4** has been shown to arise by oxidation and N_2 extrusion from **5**.

Thus the initially puzzling array of products from this one diene can be explained by invoking all three cycloaddition modes of the diene with the reactive trimer **1** and its more reactive monomer. At present the only product produced in high yield is the bi(1,2,5-thiadiazole) **2**, under more vigorous conditions; the analogous di-*p*-tolyl compound was also the main product from the same reaction of the corresponding butadiene.



Scheme 4

It is hoped that similar reactions of unsymmetrical and functionalised conjugated dienes will prove to be more selective and hence of synthetic as well as mechanistic value.

We gratefully acknowledge financial support from the Commonwealth Scholarship Commission and the British Council (T-Y. Y.) and from MDL Information Systems (UK) Ltd, Professor D. J. Williams for the X-ray structure determination, the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, and a referee for valuable comments.

Notes and References

† Yields are based on the minimum amount of trimer **1**, which is in deficiency, required to give each product.

Highly selective coupling of organoboron compounds *via* oxovanadium(v)-induced oxidation

Takuji Ishikawa, Suguru Nonaka, Akiya Ogawa and Toshikazu Hirao*†

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565-0871, Japan

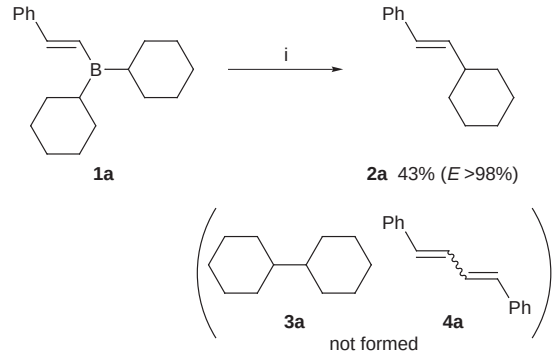
Reaction of organoboranes or organoborane ate complexes (obtained by treatment with Bu^{n}Li or CsF) with oxovanadium(v) compounds results in the intramolecular oxidative coupling of organic groups on the boranes or borates.

One-electron oxidation of organometallics with metallic oxidants is expected to offer synthetically useful transformations *via* intermediates with a higher oxidation state involving organometallic radical cation species.[1] An oxovanadium(v) compound, $VO(OR)X_2$, has been revealed to be an efficient one-electron oxidant,[1a,2] as exemplified by oxidative desilylation of organosilicon compounds.[3] The reaction path is explained by the intermediacy of radical cations and radicals *via* desilylation, which provides a versatile route to electrophilic synthetic equivalents. Carbon–carbon bond forming reactions *via* oxidation of organoboranes using metallic oxidants have not been investigated except for a few transformations of functional groups.[4] We herein report a novel ligand coupling of organoboron compounds induced by an oxovanadium(v) compound.

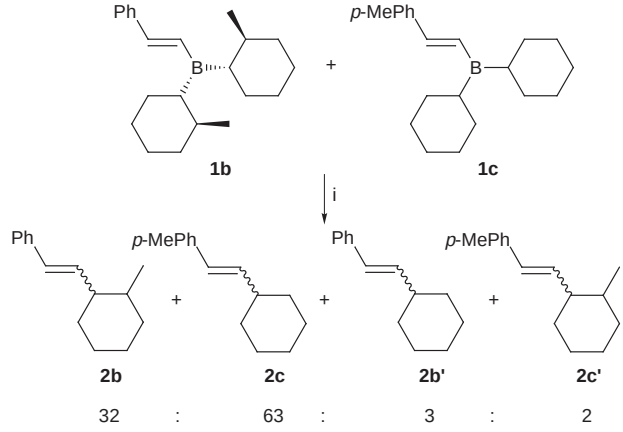
When organoborane compound **1a**, derived from phenylacetylene and dicyclohexylborane,[5] was treated with 3 equiv.[6] of $VO(OEt)Cl_2$ at room temperature in CH_2Cl_2, [(*E*)-2-phenylethenyl]cyclohexane **2a** was selectively produced without the formation of bi(cyclohexyl) **3a** and 1,4-diphenylbutadiene **4a**, as shown in Scheme 1. It should be noted that the coupling reaction occurs selectively.

To gain insight into the reaction pathway, the following crossover reaction was examined (Scheme 2). When an equimolar mixture of bis(2-methylcyclohexyl)[(*E*)-2-phenylethenyl]borane **1b** and dicyclohexyl[(*E*)-2-(4-methylphenyl)ethenyl]borane **1c** was treated with $VO(OEt)Cl_2$, 1-methyl-2-(2-phenylethenyl)cyclohexane **2b** and [2-(4-methylphenyl)ethenyl]cyclohexane **2c** were produced, with only trace amounts of crossover products **2b′** and **2c′**. Although trace amounts of crossover products were obtained, the result may imply that the coupling reaction proceeds intramolecularly.

The corresponding ate complexes of the organoboranes are expected to undergo more facile oxidation. A higher yield was attained in the reaction of the borate **5a** generated from **1a** and Bu^{n}Li (Scheme 3).[7] No butylated product was detected in the reaction mixture, indicating that the organic groups are effectively differentiated in the coupling reaction. The stereoisomer was, however, obtained in a small amount. Use of $VO(OPr^i)_2Cl$, which has a lower oxidation capability, decreased the yield. CH_2Cl_2 was found to be superior to Et_2O as a solvent.



Scheme 1 *Reagents and conditions*: i, $VO(OEt)Cl_2$ (3 equiv.), CH_2Cl_2, room temp., 2 h



Scheme 2 *Reagents and conditions*: i, $VO(OEt)Cl_2$ (3 equiv.), CH_2Cl_2, −78 °C, 4 h

Representative results for the borate **5** are summarized in Table 1. A distinct substituent effect was observed with R^1. Starting from the 2-(4-methylphenyl)ethenyl- and 2-(ethoxycarbonyl)ethenyl-substituted boranes **1c** and **1e**, highly stereoselective coupling reactions were performed, but the organoborate derived from **1f** did not couple under the reaction conditions. These findings suggest that the coupling reaction is controlled by the electronic nature of the substituents in **5**. The reaction of the ate complex **5d** with $VO(OEt)Cl_2$ afforded 1-phenylhex-1-ene **2g** as the main product, in sharp contrast to the above-mentioned observation. The cyclopentyl group was found to scarcely participate in the coupling reaction under the conditions described, but oxidation with $VO(OPr^i)_2Cl$ led to the incorporation of the cyclopentyl group together with **2g**.

Use of CsF or TBAF to form organoborate **6a**[7] improved the stereoselectivity, giving the *E* isomer exclusively (Scheme 4).

Although the reaction path is ambiguous, the intramolecular ligand coupling is achieved *via* oxidation with the oxovanadium(v) compound. The oxidation of alkenylborates with iodine is known to give the corresponding coupling products as a single stereoisomer, in which an ionic mechanism is proposed generally.[5a,8] On the other hand, the present oxovanadium-

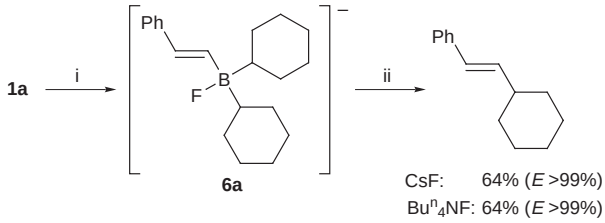
[a] All reactions were performed at room temperature for 2 h unless otherwise stated. [b] Determined by ^1H NMR spectroscopy based on the alkyne. Isolated yield is shown in a parentheses. [c] The olefinic geometry. [d] Reaction temperature is −78 °C, *syn* : *anti* = 50 : 50. PhCH=CHBu **2g** was isolated in 10% yield ($E:Z$ = 93 : 7). [e] **2g** was isolated in 40% yield ($E:Z$ = 85 : 15). [f] **2g** was isolated in 20% yield ($E:Z$ = 95 : 5).



Scheme 4 *Reagents and conditions:* i, CsF or TBAF (1 equiv.), CH_2Cl_2, room temp., 1 h; ii, $VO(OEt)Cl_2$ (3 equiv.), CH_2Cl_2, room temp., 2 h

induced reaction of **5** provides the coupling products with *E* configuration preferentially. Taking this stereochemical observation into account in the oxidation of **5**, a radical-like species is assumed to be involved as an intermediate in the intramolecular coupling step, since a radical species is generated by aerobic oxidation of triethylborane[9] and electrochemical oxidation of borates.[10] Further investigations are now in progress.

The use of the facilities of the Analytical Center, Faculty of Engineering, Osaka University, is acknowledged. This work was partly supported by a Grant-in-Aid for Scientific Research on Priority Areas from the Ministry of Education, Science, and Culture, Japan.

Palladium-mediated intramolecular acylation reaction in the attempted phosphinylation of a sterically hindered trifluoromethylsulfonyloxybiaryl carboxylic ester†

Gerhard Bringmann,*[a]‡ Andreas Wuzik,[a] Christoph Vedder,[a] Matthias Pfeiffer[b] and Dietmar Stalke[b]

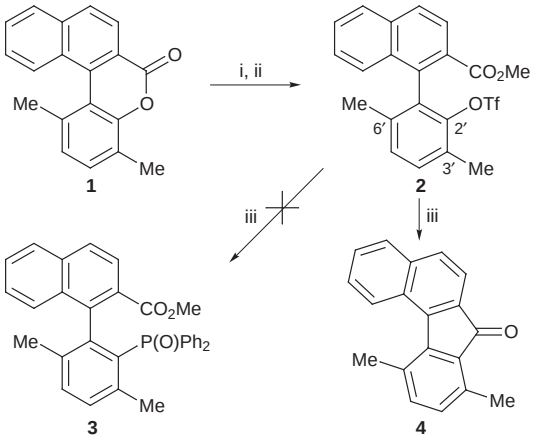
[a] *Institut für Organische Chemie der Universität Würzburg, Am Hubland, 97074 Würzburg, Germany*
[b] *Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, 97074 Würzburg, Germany*

The unexpected palladium-assisted cyclization reaction of a sterically hindered *o*-methoxycarbonyl-*o′*-trifluoromethylsulfonyloxybiaryl gives fluorenone 4, *via* intramolecular acylation instead of the attempted phosphinylation.

Chiral phosphine ligands, mostly bisphosphines, constitute versatile tools for efficient transition metal catalyzed asymmetric reactions.[1] For some types of reactions, however, the use of bisphosphine transition metal complexes is hampered by their lack of reactivity and selectivity towards the desired reaction pathway. These problems can be overcome by the use of monodentate phosphine ligands ('MOP' ligands) introduced by Hayashi *et al*., who have demonstrated the efficiency of such ligands in enantioselective hydrosilylation and allylic alkylations.[2,3]

A promising novel MOP ligand with a biaryl backbone would be **3**, which, in contrast to related axially chiral binaphthyl derivatives previously prepared,[2,3] should exhibit a distinctly higher steric hindrance—and thus stereo-differentiation—in the proximity of the phosphorous part. Its *O*-trifluromethylsulfonyl activated synthetic precursor **2** should easily be synthesized in an enantiomerically pure form, with either configuration at the biaryl axis, by atropisomer-selective ring cleavage[4] of the configuratively unstable[5] lactone-bridged biaryl **1**. Here we report on the preparation and attempted phosphinylation of **2** (here still in racemic form), leading to a novel palladium-mediated ring closure to give fluorenone **4**.

Triflate **2**§ was synthesized from lactone **1**¶ by ring cleavage with $MeOH–K_2CO_3$ and esterification of the resulting free phenolic oxygen function with Tf_2O (Scheme 1). Reaction of **2** with $HP(O)Ph_2$ in the presence of $Pd(OAc)_2$ (10 mol%) and Hünig's base ($EtNPr^i_2$) according to Hayashi's method[6] gave no detectable amount of the anticipated phosphine oxide **3**, the most conspicuous product being a yellow nonpolar compound (28% isolated yield‖), which turned out to be the unexpected fluorenone **4**.**



Scheme 1 *Reagents and conditions*: i, MeOH, K_2CO_3, THF, room temp., 1 h; ii, Tf_2O, DABCO, CH_2Cl_2, 0 °C, 12 h; iii, $Pd(OAc)_2$, dppp, $HP(O)Ph_2$, $EtNPr^i_2$, Me_2SO, 100 °C, 6 d

Its structure was elucidated mainly *via* NMR, mass and combustion analytical data and confirmed by an X-ray structure analysis of single crystals obtained from light petroleum–Et_2O (2 : 1) (see Fig. 1), which unambiguously proves the unexpected tetracyclic constitution.†† Due to the steric hindrance in the C(5)–C(4c)– C(4b)–C(4a))–C(4) 'bay' with the adjacent methyl group at C(4), the molecule is not flat, but helically twisted, giving rise to two enantiomers. These are both found in the crystal, Fig. 1 arbitrarily showing the *M*-helical enantiomer. The overall molecular distortion of the 'inner spiral loop',[7] *i.e.* the sum of the dihedral angles α [C(13)– C(4)–C(4a)–C(4b), 5.6(9)°], β [C(4)–C(4a)–C(4b)–C(4c), 23.7(9)°] and γ [C(4a)–C(4b)–C(4c)–C(5), 10.4(8)°], is distinctly smaller (39.7°) than for comparably substituted lactones related to **1** (> 60°).[7]

The reason why no phosphine oxide **3** was formed must be seen in the unusually high steric hindrance at the substitution site, C-2′, which is bounded (as in other cases) by the bulky

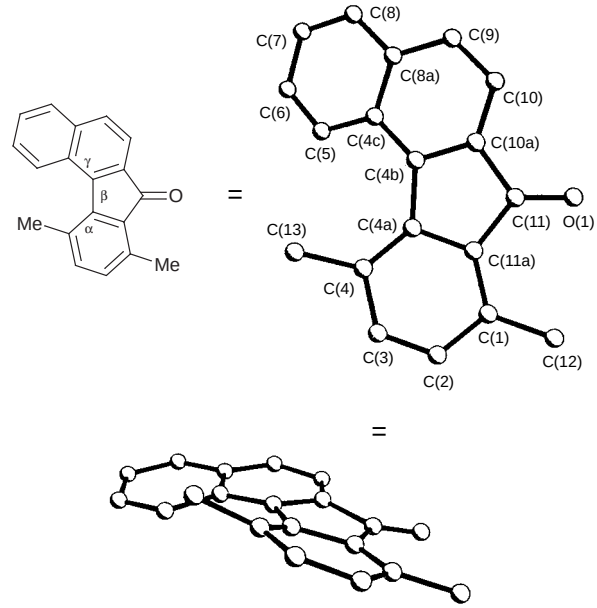


Fig. 1 Molecular structure of fluorenone **4** in the crystal. All hydrogen atoms are omitted for clarity. 5 **6**

Scheme 2 *Reagents and conditions*: i, $Pd(OAc)_2$, dppp, $HP(O)Ph_2$, $EtNPr^i_2$, Me_2SO, 100 °C, 6 d

substituted naphthyl residue at C-1′ *and* by the unprecedented additional methyl group at C-3′ (Scheme 1). That this extra steric hindrance is responsible for the failure of the introduction of the sterically demanding phosphorus substituent was demonstrated by successfully performing the desired substitution on the regioisomeric compound **5**,‡‡ in which the methyl group is located at C-4′ (Scheme 2). Under the same reaction conditions as applied above, this triflate smoothly gave the desired phosphine oxide **6**,§ in high yields (74% of isolated pure material) and within the 'normal'[6] reaction time of about 12 h. The much slower fluorenone formation from the 3′-methyl isomer **2**, apparently by C–C bond formation of the presumed 2′-palladated intermediate§§ with the methoxycarbonyl substituent on the naphthalene part, took about a week.

To the best of our knowledge, the ring closure reaction of **2** to give **4** is the first intramolecular acylation mediated by $Pd(OAc)_2$ to give substituted fluorenone systems. Initial attempts to enhance the yield of **4** and decrease the reaction times, *e.g.* by using larger amounts of the palladium catalyst, gave improved yields of up to 42%, while in the absence of either $Pd(OAc)_2$, $EtNPr^i_2$ or $HP(O)Ph_2$, no reaction took place. Investigations to further optimize this new reaction, also with respect to the suppression of the likewise observed deoxygenation, and to investigate its possible application to natural product synthesis, are in progress.

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347 'Selektive Reaktionen Metall-aktivierter Moleküle') and by the Fonds der Chemischen Industrie.

†† *Crystal data* for **4**: $C_{19}H_{14}O$, orange needles, crystal dimensions 0.3 × 0.3 × 0.3, M = 258.30, monoclinic, space group $P2_1/c$, a = 11.602(3), b = 14.641(2), c = 7.7016(14) Å, β = 102.914(8)°, V = 1275.1(4) Å^3, Z = 4, D_c = 1.345 g cm^{-3}, μ = 0.081 mm^{-1}, F(000) = 544, 2810 reflections collected ($3 \leqslant \theta \leqslant 23°$) at 173(2) K, 1664 independent (R_{int} = 0.1079), 1663 used in the structure refinement, $R1$ = 0.0652 [$I \geqslant 2\sigma(I)$], $wR2$ = 0.1665 [all data], gof = 0.974 for 184 parameters, largest difference peak/hole = 0.233/−0.307 e Å^{-3}. Data were collected from a shock-cooled crystal on an Enraf-Nonius CAD4 four circle diffractometer (graphite-monochromated Mo-Kα radiation, λ = 0.71073 Å) equipped with low temperature devices (ref. 8). The structure was solved by direct methods (SHELXS-96 (ref. 9) and refined by full-matrix least-squares methods against F^2 (SHELXL-96) (ref. 10). Anisotropic refinement of all non-H atoms. R values: $wR2 = [[w(F_o^2 - F_c^2)^2]/[w(F_o^2)^2]]^{1/2}$, $R1 = ||F_o| - |F_c||/|F_o|$. CCDC 182/859.

‡‡ The triflate **5** was synthesized analogously to compound **2**, starting from the corresponding *o*-methoxycarbonyl-*o*′-hydroxybiaryl, which had been prepared earlier (ref. 11).

§§ We suspect that the oxidative addition of the aryl triflate to the Pd reagent, comparable to the first reaction step of a Heck reaction, is the initiating step, leading to an Ar–Pd–OTf species, for which the deoxygenation product (see note ‖) constitutes a significant hint. This Pd intermediate should then further react with the ester functionality.

Rearrangement of *o*-(chloromethyldimethylsilyl)phenylmethoxide: evidence for an apical position of the migrating group in a trigonal bipyramid intermediate

Yousef M. Hijji,† Paul F. Hudrlik*‡ and Anne M. Hudrlik

Department of Chemistry, Howard University, Washington, DC 20059, USA

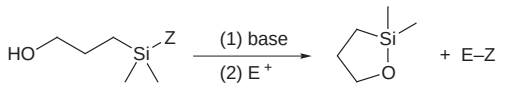
Chloromethylsilane 5a undergoes a rearrangement reaction to give oxasilacyclopentane 9 rather than oxasilacyclohexane 10, indicating that the methyl group migrates in preference to the aryl group.

Rearrangements of α-substituted organosilanes, with migration of an organic group from silicon to carbon, have been found to take place under acidic,[1] basic[1–4] or thermal[1] conditions. Little is known about the stereochemistry of the migration reaction, although migration from the apical position of a trigonal bipyramid has been suggested.[4] In contrast, the stereochemistry of nucleophilic substitutions at silicon has been extensively studied, and is generally interpreted as proceeding through pentacoordinate trigonal bipyramid intermediates, usually with entering and leaving groups in the apical positions.[5] With the increasing use of carbon-functional organosilicon compounds in organic synthesis, it is important to establish the stereochemistry of the fundamental reactions in organosilicon chemistry.[6] We report the first evidence for the stereochemistry of the base-induced rearrangement.

We have previously found the γ-oxidopropyl group on silicon to be effective as an internal nucleophile, and reported the cleavage reactions of γ-hydroxysilanes **1** (for generation of benzyl and allyl anion equivalents) (Scheme 1),[7] and the rearrangement reactions of γ-hydroxysilanes **2** (forming carbon–carbon bonds *via* a silicon template) (Scheme 2).[2]

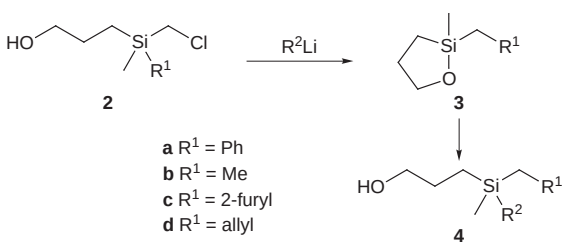
More rigid γ-hydroxysilanes would be expected to be more efficient for this purpose, and we have therefore been studying the use of *o*-silylbenzyl alcohols **6** in the cleavage and rearrangement reactions. In the course of this work, we have found that *o*-silyl benzyl alcohols **6** can be easily prepared by rearrangement of silyl ethers **5** of *o*-bromobenzyl alcohol with Li or Bu^{t}Li in Et_2O (Scheme 3).[8]

Silyl ether **5a** provides an opportunity to study the relative importance of migratory aptitude (aryl *vs.* methyl) compared to stereochemical preference of the migrating group (apical *vs.* equatorial). Compound **5a**§ was prepared in 78% yield by treatment of *o*-bromobenzyl alcohol with 1.3 equiv. of $ClSiMe_2CH_2Cl$ in Et_2O–NEt_3 for 1 h at room temperature. [An impurity (*ca.* 6% by GC), believed to be $(ClCH_2Si)_2O$ was present: GC–MS *m/z* 181 (40%, $M^+ - CH_2Cl$), 153 (100); additional peaks at δ 2.76 (s) and 0.24 (s) in the ^{1}H NMR spectrum.] Treatment of **5a** with Bu^{t}Li in THF (30 min at −78 °C, then removal of the cold bath for 5 min, and workup by addition of saturated $NaHCO_3$) led to disappearance of **5a** with appearance of one product, assigned as oxasilacyclopentane **9**. [Some $(ClCH_2Si)_2O$ (*ca.* 7% by GC) was also observed in the GC and GC–MS.] Compound **9** is believed to arise *via* rearrangement (see Scheme 3) to γ-oxidosilane **7**, followed by methyl migration (presumably *via* trigonal bipyramid intermediate **8**, see Scheme 4). Aryl migration would have given oxasilacyclohexane **10**.

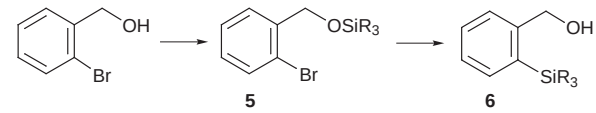


1 Z = Bn, allyl

Scheme 1

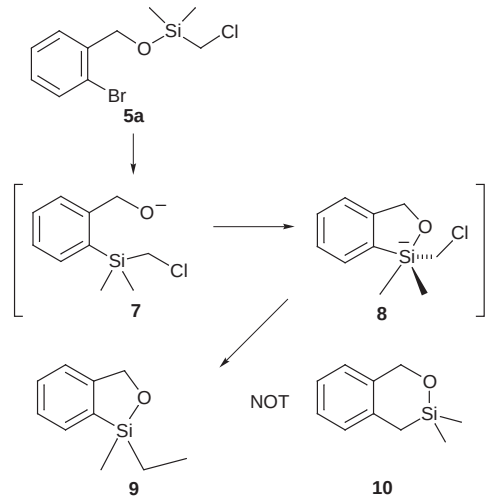


Scheme 2



Scheme 3

The structure of **9** was supported by the spectra, in particular the mass spectrum, which showed the base peak at 149 ($M^+ -$ Et), and the ^{1}H NMR spectrum, which was different from that reported for oxasilacyclohexane **10**.[9] The ^{1}H NMR spectrum of the crude product included δ 7.2–7.6 (m, ArH) 5.16 (s, CH_2O) and 0.39 (s, MeSi), as well as peaks due to $(ClCH_2Si)_2O$ (singlets at δ 2.76 and 0.24) and a small amount of THF. [Comparison with the reported ^{1}H NMR spectrum of compound **10**[9] suggested that **10**, if present, was less than 10%.] The ^{13}C NMR spectrum showed δ 6.30 ($SiCH_2CH_3$), 8.83 ($SiCH_2CH_3$), 71.72 (CH_2O), 121.55, 126.73, 129.49, 131.21, 134.14 (small), 150.07 (small), as well as 30.72 (small, $SiCH_2Cl$), peaks for THF, and three peaks in the SiMe region. The GC–MS showed *m/z* 178 (15%, M^+), 163 (8, $M^+ -$ Me), 149 (100, $M^+ -$ Et), 135 (8) and 105 (11). The structure of **9** was further confirmed by



Scheme 4

treatment (in THF) with excess MeLi (−78 °C, 1 h) which gave a mixture of *o*-(ethyldimethylsilyl)benzyl alcohol[8] (major) and *o*-(trimethylsilyl)benzyl alcohol[8] (minor).[10]

Migratory aptitudes in rearrangements of halomethylsilanes under basic conditions have been correlated with the ability of the migrating group to stabilize a negative charge.[3,4] In our studies of the rearrangement reactions of γ-hydroxysilanes **2**, we found that the phenyl group had a greater migratory aptitude than the methyl group, as expected.[2] Treatment of γ-hydroxysilane **2a** with several bases resulted in oxasilacyclopentane **3a**, the product of phenyl migration; in some cases, a small amount (< 5%) of 2-phenyl- 2-ethyl-1-oxa-2-silacyclopentane, the product of methyl migration, was also observed. (Treatment of γ-hydroxysilane **2a** with 2 equiv. of MeLi in Et_2O gave product **4a**, presumably by trapping of **3a** with MeLi.)[2]

The comparison of the migratory aptitudes in the acyclic system **2a** (phenyl migration) with those in the cyclic system **5a** (methyl migration) is very interesting. Perhaps the cyclic system **8a** has geometrical constraints which disfavor aryl migration. To the extent oxygen would prefer the apical position in a trigonal bipyramid intermediate (apical entry, electronegativity, see **8**),[11] the Si–Ar bond in the *o*-benzyl alcohol system would have to be equatorial. The preference for methyl migration in **5a** suggests that *migration is favored by an apical position of the migrating group in a trigonal bipyramid intermediate.* This work also suggests that *o*-silylbenzyl alcohol substrates should be useful for carbon–carbon bond forming reactions *via* rearrangements without interference from the aryl group.

A new probe of superconductivity: quantitative measurements on defined electron transfer with solute at the interface between liquid electrolyte and oxocuprate electrode in the superconducting state

Stephen J. Green,[a] David R. Rosseinsky,*[a]† Andrei L. Kharlanov[b] and J. Paul Attfield[b]

[a] *Department of Chemistry, The University, Exeter, UK EX4 4QD*
[b] *IRC in Superconductivity, University of Cambridge, Cambridge, UK CB3 0HE*

The rate of electron transfer, between dissolved decamethylferrocene molecules and an oxocuprate high temperature superconductor [Tl 1223] electrode, represented in impedance spectroscopy by an electrical resistance term R_{CT}, is shown to be measurable (R_{CT} tending to dip around the superconducting transition temperature), so opening up the prospect of a new, controllably variable, probe of superconductivity.

There are now oxocuprate high-temperature superconductors (HTSCs) having superconducting transition temperatures T_c of 135 K.[1] Superconductivity at even higher temperatures would significantly enhance technological applicability. The resistanceless current in a superconductor is carried by paired charge carriers which form below T_c, usually together with an energy gap around the Fermi level in the density of states. Despite protracted efforts, the mechanism of oxocuprate HTSC superconductivity is not well understood.[2] Linking an understanding of the pairing mechanism to the oxocuprate structure clearly presents the most promising route to maximizing T_c by design; here we suggest a novel probe towards that goal, monitoring the rates of electron transfer directly to or from the HTSC at and about its T_c.

A liquid electrolyte (chloroethane with tetrahydrofuran and 2-methyltetrahydrofuran, plus a lithium salt electrolyte) is now available[3–6] in which the electron-transfer reactions of freely diffusing electroactive species, here ferrocene or decamethylferrocene, at macrosized Pt electrodes could be followed by cyclic voltammetry at temperatures as low as 99.5 K.[5] Next, at specially designed cryorobust HTSC electrodes[6] (including leads for the *in situ* determination, by a four-point resistivity measurement[6] on the electrode in use, of its superconducting transition temperature), charge transfer between freely diffusing ferrocene and a demonstrably superconducting HTSC microelectrode at 102 K could be clearly detected by cyclic voltammetry.[5] Now we have studied by impedance spectroscopy the temperature dependence of the charge-transfer rate (proportional to the charge-transfer conductance R_{CT}^{-1}), and report here our observations on electron transfer between decamethylferrocene and the HTSC Tl 1223 electrode comprising the recently synthesized[7] $(Tl_{0.5}Pb_{0.5})(Sr_{1.6}Ca_{0.4})Ca_2Cu_3O_9$.‡

The equipment has been described in detail.[6] The precise value of T_c for the Tl 1223 was determined by magnetic susceptibility (Fig. 1). The behaviour of an electrode/electrolyte interface can be represented§ by R_{CT} (inversely proportional to charge-transfer rate), and (in parallel) the parameter C_{eff} which approximates to the double layer capacitance; it can thus be examined by electrochemical impedance studies together with standard procedures§ for fitting the equivalent circuit elements. The variation of R_{CT} and C_{eff} with temperature, through T_c, is shown in Fig. 2 (together with a notional time-constant $R_{CT} \times C_{eff}$, and the parameter§ Φ) where increases or decreases from otherwise smooth curvature occur when the sample traverses T_c. Excursions from smooth curves in the temperature range about T_c have been repeatedly observed[8] for these parameters in solid-state electrochemical reductions of Ag^+ with an electrolyte of solid Rb_4AgI_5, and also for an oxocuprate electrode immersed in liquid electrolyte when the solvent itself has been reduced,[9] though a decrease rather than an increase in their capacitance parameters has been observed in these related systems. The limited amount of experimental data available has left interpretation of the HTSC transitions speculative apart from Kuznetzov's theory[2,10] and a recent primitive elaboration[11] of the Ginsburg–Landau SC model which effects a decrease in double-layer capacitance on temperature increase up to T_c. Gluzman and Kuznetzov[2] were able to account for the generally observed[8,9] 'hump' in the charge transfer rate around T_c without the participation of paired carriers (disfavoured by increased reorganisation energy of electrolyte[10]),¶ in contradiction of Lorenz *et al.*[8] who assign the increase in the Faradaic current around T_c to paired charge carriers. Lorenz *et al.*[8] do point out that the smaller electrolyte reorganisation energy in solids *cf.* liquids makes pair transfer more likely in their systems than in liquids, with the implication that no excursions from smooth curvature, or 'humps', should occur with liquid electrolytes. Without inflicting excessive violence on our results, excising extreme data points could just accommodate nil excursions from smooth curves (points × in Fig. 2), but such a conclusion can be settled only by further, improved, experiments. However, the major advance represented by our preliminary observations lies in demonstrating the accessibility of choice of

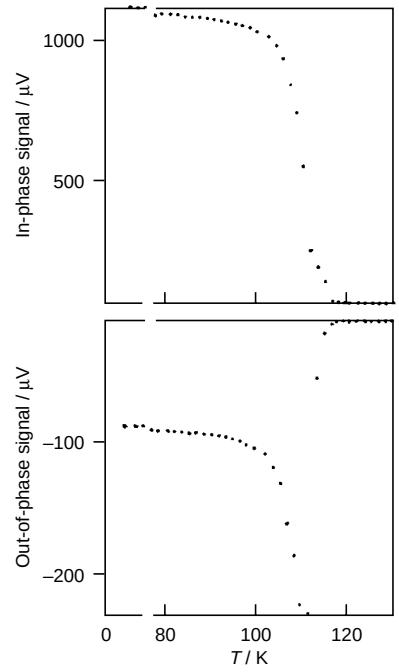

Fig. 1 Magnetic susceptibility measurements on Tl 1223 as in-phase and out-of-phase magnetometer signals showing T_c at 116 K

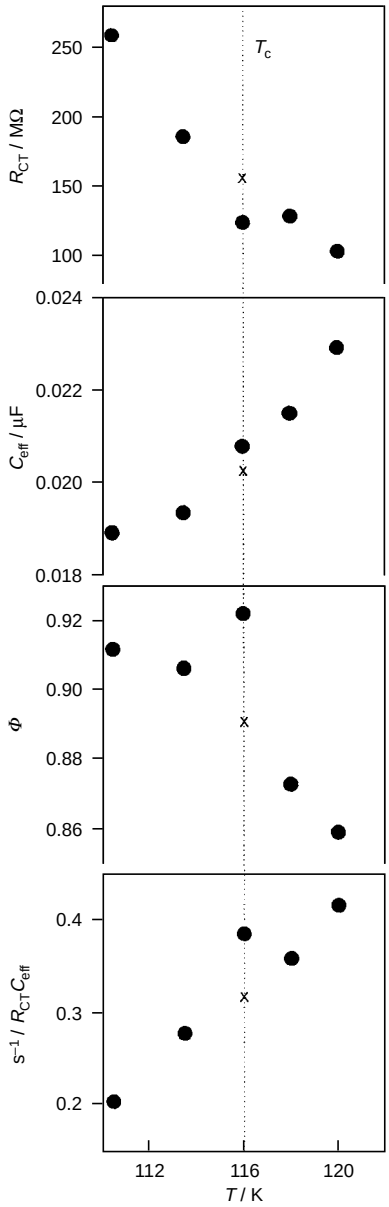

Fig. 2 Top to bottom: charge-transfer resistance R_{CT}, effective double-layer capacitance C_{eff}, phase parameter Φ and (inverse) effective time-constant $1/R_{CT}C_{eff}$ observed for DMFc/Tl 1223 at the electrolyte/electrode interface

solute electroactives, which here is a redox species rather than the electrolyte itself[8] or the actual solvent.[9] Neither of the previous studies[8,9] allows of control of the redox potential of the electroactive species, nor the use of electroactives with two linked redox sites¶ which offer the prospect of probing the transfer of paired charge carriers from within the superconductor. Such innovations should provide new insights into the superconductivity mechanism.[2] This creation of a new probe of superconductivity is clearly notable.

We thank the EPSRC for a grant.

‡ The electroactive species was 5 mM decamethylferrocene (DMFc) with 0.2 M $LiBF_4$ in solvent comprising 16 : 7 : 1 by volume chloroethane–tetrahydrofuran–2-methyltetrahydrofuran. The apparatus[3–6] with the addition of a Solartron 1286 frequency response analyser monitored the electrode response over the frequency range 10–10^5 Hz to a perturbation of ±100 mV superimposed on the HTSC electrode, about the approximate electrode potential for DMFc–$DMFc^+$ of 0 V with respect to the commonly used Ag-wire quasi-reference electrode.

§ Solartron programmes ZPLOT and ZVIEW allow simulation of the observed electrochemical impedance *via* a model circuit consisting of resistance and capacitance-like ($\Phi \neq 1$) circuit elements. The phase-related quantity Φ, unity for a true capacitance, is often fitted as < 1 (*i.e.* $< 90°$ for the current : potential phase difference) for electrochemical processes.

¶ From electrostatic considerations Kuznetzov[10] predicts a disfavouring fourfold increase in the solvent reorganisation barrier for the transfer of paired charge carriers *cf.* transfer of single electrons, to a single acceptor site. However, for transfer to two separate acceptors, the reorganisation energy will increase only twofold, and the transfer should be best favoured if the spacial separation of the acceptors is commensurate with the coherence length of the superconductor. Such a condition will hold for an electroactive species with two appropriately spaced redox centres.

Unique promotion effect of CO and CO_2 on the catalytic stability for benzene and naphthalene production from methane on Mo/HZSM-5 catalysts

Shetian Liu, Qun Dong, Ryuichiro Ohnishi and Masaru Ichikawa*†

Catalysis Research Center, Hokkaido University, Sapporo 060, Japan

The addition of CO and CO_2 to the methane feed results in a remarkable promotion of catalyst stability for direct benzene and naphthalene production from methane on Mo/HZSM-5 and Co modified Mo/HZSM-5 catalysts at 973 K owing to the efficient suppression of coke formation.

The catalytic conversion of methane to petrochemical feedstocks such as ethylene and benzene is of current importance and industrial interest in the effective utilization of carbon resources of natural gas. During the past five years, the non-oxidative conversion of methane to benzene has been studied on zeolite-supported Mo catalysts in terms of the reaction mechanism and catalyst characterization.[1–6] Our recent works demonstrate the methane is effectively dehydrocondensed into various aromatics such as benzene and naphthalene on Mo/HZSM-5 and modified Mo/HZSM-5 at high temperatures of 873–1073 K.[7] Nevertheless, methane conversion decreased drastically after a few hours owing to serious coke deposition on the catalysts. To reduce coke formation, some preliminary efforts have been reported using selected oxidative reagents such as oxygen[2] and carbon dioxide (10% or higher in the methane gas feed),[6] but aromatic product formation was completely inhibited on Mo/HZSM-5 catalysts. Here we describe that the inclusion of CO and/or CO_2 in the methane flow results in the promotion of aromatic product formation and a remarkable improvement of the catalyst stability in the prolonged dehydrocondensation reaction of methane at 973 K on Mo/HZSM-5 and CoMo/HZSM-5 catalysts owing to the substantial suppression of coke formation on the catalysts. Furthermore, ^{13}CO isotopic labeling and temperature programmed oxidation (TPO) experiments demonstrate that the CO added to the methane feed, as a carbon and oxygen donor when it is dissociated on the catalysts, not only is efficiently incorporated into aromatics such as benzene, but also results in removal of the surface coke.

Mo/HZSM-5 and Co modified Mo/HZSM-5 catalysts with 3 wt.% Mo loading were prepared by impregnation (incipient wetness) of NH_4ZSM-5 (SiO_2/Al_2O_3 = 20–1900; surface area, 780–925 $m^2\ g^{-1}$, Toso Co. and CRI Zeolyst, Inc.) with $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ and $Co(NO_3)_2$ aqueous solutions. After the impregnated samples were dried at 393 K and calcined at 773 K in air, catalytic tests were carried out under methane (1 atm), both with and without CO or CO_2, in a continuous microreactor system equipped with a quartz tube (8 mm id) packed with 0.3 g of catalyst pellets of 20–24 mesh, as reported previoulsy.[7] After flushing with He at 973 K, a feed gas mixture of 98% CH_4 with 2% Ar as internal standard for analysis both with and without CO or CO_2 was introduced into the fixed bed reactor at a flow rate of 7.5 ml min^{-1} [space velocity = 1500 ml h^{-1} (g cat)$^{-1}$] through a mass flow controller (Brooks 5850E). Using an internal standard analyzing method, conversion of methane, CO and CO_2, selectivities of hydrocarbon products and coke formed on the catalyst were evaluated to the mass balance for carbon and hydrogen.[7] The reaction between CO and CH_4 on Mo/HZSM-5 was studied by using the isotopic labeling (^{13}CO, 99% enriched) technique in a closed circulating reaction system, and both the gas phase mixture (containing mainly methane, carbon monoxide, ethane and ethylene) and the condensed products (mainly benzene collected using an ethanol–dry ice trap) were analyzed by GC-MS (Perkin-Elmer, Auto System GC, 910 Q-Mass). The coke deposited on the catalyst surface after reaction was evaluated by a TPO technique using 20% O_2 + 80% N_2 as the oxidant, and the tail gas was intermittently analyzed by on-line GC.

The addition of CO to the methane feed gas exerts a significant effect on the catalytic performances of Mo/HZSM-5 and CoMo/HZSM-5 for methane dehydrocondensation to promote the formation of benzene and naphthalene, and on the catalyst stability, as shown in Figs. 1 and 2. Using pure methane as the feed gas the methane conversion and benzene formation rates decreased greatly (less than 1/4–1/5 of the initial activities during 24 h reaction time on stream). By contrast, for methane with 1.8–12% CO in the feed gas, the decrease in methane conversion was much lower, regardless of the partial pressure of CO, as shown in Fig. 1. After attaining a moderate increase of benzene and naphthalene formation rates, compared with those achieved using pure methane in the early stage of the reaction, their formation rates were almost constant during prolonged reaction of more than 50 h. In the steady reaction stage, the amount of CO is almost constant before and after reaction

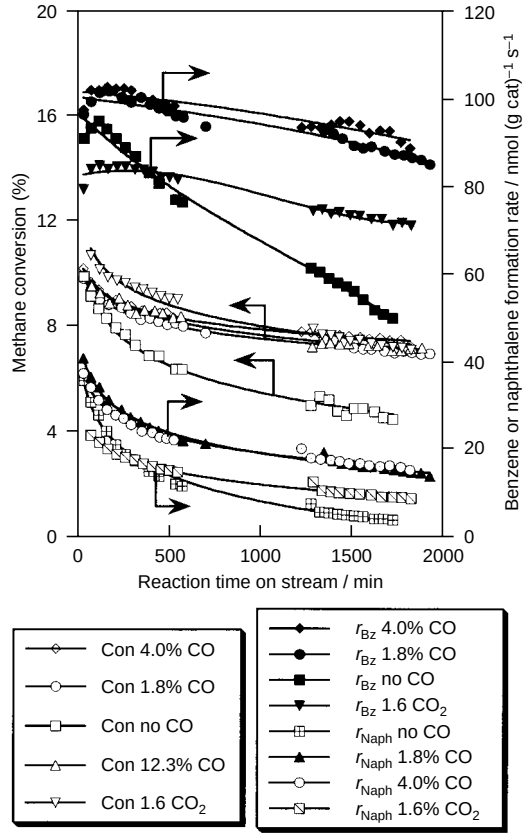

Fig. 1 Catalytic performances of 3% Mo/HZSM-5 for methane aromatization with the addition of CO and CO_2 to the methane feed gas at 973 K [Open symbols represent methane conversion and solid symbols the formation rates of benzene (r_{Bz}) and naphthalene (r_{Naph}), respectively]

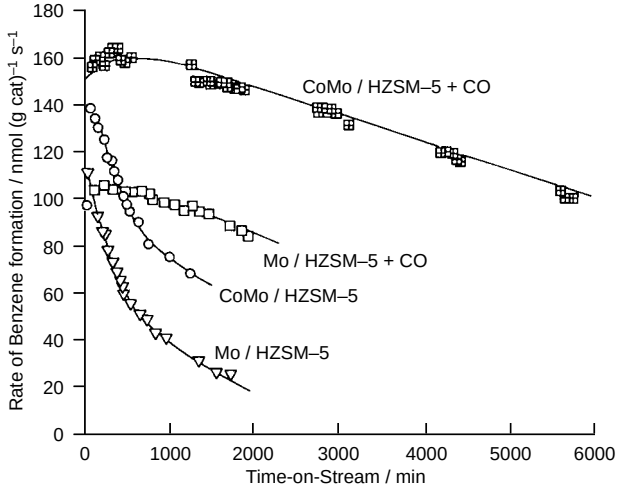

Fig. 2 Rates of benzene formation in methane aromatization reaction on 3% Mo/HZSM-5 (▽) and 1% Co, 3% Mo/HZSM-5 (○) catalysts using pure methane and (□) on 3% Mo/HZSM-5 and (⊞) on 1% Co, 3% Mo/HZSM-5 using methane + 4% CO at 973 K and 1 atm

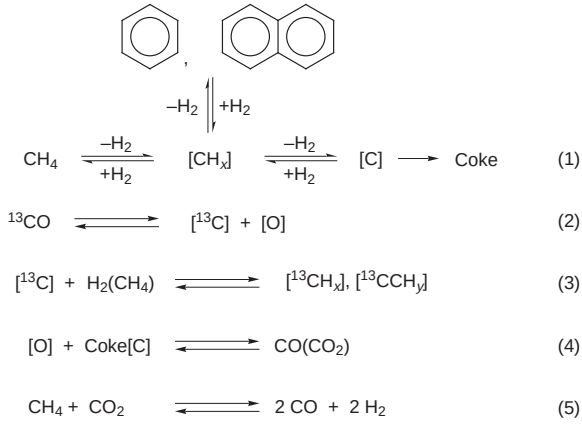
through the catalyst beds in all cases of CO addition. The results imply that CO is regenerated, possibly due to the reaction of the surface carbon with the active oxygen species derived from CO dissociation as shown in Scheme 1.

These remarkable effects (improved catalytic stability, increased promotion of benzene formation) caused by the inclusion of CO have also been observed for modified catalysts such as CoMo/HZSM-5, as is shown in Fig. 2. The benzene formation rates are above 100 nmol (g cat)$^{-1}$ s^{-1} even after 100 h on the CoMo/HZSM-5 in the reaction of CH_4 + 3.5% CO, while the activity decreased greatly [less than 10 nmol (g cat)$^{-1}$ s^{-1}] using pure methane under the same reaction conditions.

Similarly, the stability of the catalyst was also improved by adding a few per cent CO_2 into the feed gas, as shown in Fig. 1. The addition of 1.6% CO_2 yielded higher methane conversion and hydrogen formation rate. Benzene formation was suppressed in comparison with that achieved with CO addition, but it was stable during the prolonged reaction time. Nevertheless, it was found that the addition of larger amounts of CO_2 (> 10%) in the methane feed gas largely inhibited the formation of aromatic products such as benzene. When the partial pressure of CO_2 was low (< 4%) in the feed gas, twice the amount of CO was detected compared with when CO_2 was added to the feed gas on the basis of the carbon content, while no CO_2 was observed in the outlet gas of the reaction. It is suggested that CO_2 is converted with CH_4 to produce twice the amount of CO under these reaction conditions by a reforming process (CO_2 + $CH_4 \rightarrow 2CO + 2H_2$). The formed CO may cause a similar promotion of product formation and improvement of catalytic stability.



Scheme 1

The different effects of CO and CO_2 on methane aromatization may be associated with their different chemical properties: CO is dissociated on the Mo/HZSM-5 catalyst to form the common active CH_x surface species, similar to methane, which is converted to aromatics, and the dissociated [O] may react with surface coke to regenerate CO. However, CO_2 is more active towards reaction with surface CH_x derived from methane dissociation, yielding 2 mol of CO and H_2. Such effective consumption of surface intermediates with CO_2 causes the marked suppression of methane aromatization towards benzene. It is conceivable that benzene formation is a structure sensitive reaction, which requires a large concentration of active CH_x species on the catalysts. No appreciable differences in product selectivities for benzene and naphthalene were found, whether pure methane, or methane plus CO or CO_2 on the Mo/HZSM-5 and Co modified Mo/HZSM-5 catalysts, were used.

It was demonstrated by the TPO experiments that the amount of coke formed on the catalyst surface was greatly reduced by adding various amounts of CO or CO_2 to the methane feed gas. Increasing the CO concentration from 1.7% to 12.0% resulted in suppression of coke formation on the catalyst surface, particularly the irreversible or inert coke which was oxidized to CO_2 at temperatures above 773 K. Increasing the CO_2 partial pressure in the methane feed gas decreased the coke formation to a much lower level; this may be related to its weak oxidizing property (mentioned above).

To understand the role of CO in the methane aromatization reaction, the $^{13}CO + CH_4$ reaction was conducted. The starting composition of the reactant mixture was 8% ^{13}CO + 92% CH_4 with a total pressure around 220 Torr. Even after 5 min at 973 K, the level of ^{13}C incorporation in methane ($^{13}CH_4$) reached 8%. The isotopic abundance of ^{13}C incorporated in the benzene molecules was detected by GC-MS analysis as a random distribution ($^{13}CC_5H_6$ 47.6%, $^{13}C_2C_4H_6$ 36.7%, $^{13}C_3C_3H_6$ 13.0%, $^{13}C_4C_2H_6$ 2.4%, $^{13}C_5CH_6$ 0.3%) regardless of the reaction time of methane on Mo/HZSM-5. These results suggest that the carbon derived from CO dissociation is efficiently incorporated into the benzene formation and the isotopic scrambling reaction between ^{13}CO and $^{12}CH_4$ proceeds rapidly under these reaction conditions at 973 K.

Based on the above results we suggest a unique role of CO in the methane aromatization reaction, resulting in stabilization of catalyst performance and promotion of benzene formation, as shown in Scheme 1. Firstly, CO and CH_4 may dissociate on the catalyst surface, mostly on the Mo sites, to form active species such as [C], [O] and [CH_x] through reactions (1) and (2); the active carbon species [C] from CO is hydrogenated to [CH_x] fragments as illustrated in reaction (3), followed by the oligomerization with [CH_x] derived from CH_4 to form higher hydrocarbons such as benzene and naphthalene in reaction (1) on the catalyst; the dissociated oxygen species [O] from CO may react with the surface inert carbon species (coke) to regenerate CO, resulting in the suppression of coke formation on the catalyst through reaction (4).

Facilitation of the copper(II)-promoted dephosphorylation of adenosine 5′-triphosphate (ATP^{4-}) by the antiviral nucleotide analogue, 9-[2-(phosphonomethoxy)ethyl]adenine (PMEA)‡

Helmut Sigel,*[a]† Claudia A. Blindauer,[a] Antonín Holý[b] and Hana Dvořáková[b]

The antiviral PMEA is able to mimic the structuring adenosine 5′-monophosphate (AMP^{2-}) in the reactive intermediate, $[Cu_3(ATP)(AMP)(OH)]^-$, and to promote the dephosphorylation of ATP; PMEA is about twice as effective as (the ultimate product of this hydrolysis) AMP.

Mechanistic studies on the metal ion-promoted hydrolysis of nucleoside 5′-triphosphates (NTP^{4-}) to nucleoside 5′-diphosphates (NDP^{3-}) and inorganic phosphate (P_i) revealed for this most simple transphosphorylation reaction, which consists of the transfer of a phosphoryl group to water, that the most reactive species contain two metal ions per NTP^{4-}.[1,2] This reflects the known 'general need' for two metal ions in enzymatic phosphoryl transfer reactions.[3] The *in vitro* dephosphorylation of ATP^{4-} in the presence of divalent metal ions (M^{2+}) proceeds *via* dimers of composition $[M_2(ATP)]_2$.[2] Depending on the kind of metal ion involved, hydrolysis occurs either *via* intermolecular H_2O attack or *via* intramolecular hydroxide attack of a phosphate-coordinated $M(OH)^+$ unit,[1b] as is the case with Cu^{2+}. Hence, $[Cu_2(ATP)]_2(OH)^-$ is the most reactive species for Cu^{2+}-promoted dephosphorylation.[1b,2] Such studies with copper are of general interest due to the evidence that there is an ATP-dependent Cu^{II} transporter in the Golgi apparatus[4] and the observation that the Menkes P-type ATPase is a transmembrane copper-translocating pump, which is defective in the human disorder called Menkes disease.[5] There is also a somewhat older suspicion that $Cu(ATP)^{2-}$ is involved in the inhibition of human erythrocyte ($Ca^{2+} + Mg^{2+}$)-ATPase.[6] Mixed Cu(ATP)(L) complexes (L = tryptophanate, *etc*. see also below) protect ATP against hydrolysis.[2]

In the reactive dimeric $[M_2(ATP)]_2$ complexes, which occur in low concentration and involve purine stacking[7] and N^7-M^{2+} coordination, one of the two ATPs takes over a structuring role and thus acts as its own hydrolytic 'enzyme'.§ This role cannot be taken over by adenosine, D-ribose 5-monophosphate or by tubercidin 5′-monophosphate ($TuMP^{2-}$, 7-deaza-AMP^{2-}) because these ligands are unable to form the required bridge in the reactive species, but it can be taken over by adenosine 5′-monophosphate (AMP^{2-}). In the presence of Cu^{2+}, this then leads, by promoting further the reactivity of the Cu^{2+}/ATP system, to the reactive $[Cu_3(ATP)(AMP)(OH)]^-$ species shown in Fig. 1.[8a] How does the related antiviral PMEA behave in this reaction? This adenine-nucleotide analogue (see Fig. 2) is active against various viruses, including hepatitis B (HBV) and human immunodeficiency viruses (HIV-1 and HIV-2).[9,10] After its twofold phosphorylation by cellular nucleotide kinases,[11] the resulting triphosphate analogue can serve as a substrate for the viral DNA polymerase or reverse transcriptase and subsequently terminates the growing nucleic acid chain.[12] Thus it was interesting to see whether $PMEA^{2-}$ would be able to mimic AMP^{2-} in the reactive intermediate (Fig. 1) and to facilitate thus also the Cu^{2+}-promoted dephosphorylation of ATP^{4-}.

The results of our experiments¶ are shown in Fig. 3 in parallel with the data obtained with AMP under identical conditions. These latter data agree (within the error limits) with those obtained previously.[1b] The addition of an approximately sevenfold excess of AMP to the Cu^{2+}/ATP 2:1 system facilitates the dephosphorylation reaction by a factor of about three (Fig. 3).‖ Indeed, $PMEA^{2-}$ can take over the structuring role of AMP^{2-} (or ATP^{4-}) in the reactive species (Fig. 1) and, astonishingly, it is twice as effective!** This is possibly due to the somewhat increased flexibility of $PMEA^{2-}$ compared with AMP^{2-} as a result of the replacement of the ribose residue by the open chain (see Fig. 2).†† To our knowledge, this is the first example demonstrating in a 'simple' reaction a close relationship between PMEA and its parent nucleotide AMP.

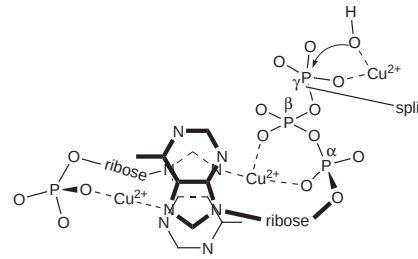

Fig. 1 Probable structure of the reactive $[Cu_3(ATP)(AMP)(OH)]^-$ species. The intramolecular attack of OH^- is indicated on the right-hand side, while the left-hand side shows the metal ion bridging which stabilizes the purine stack by coordination to the phosphate group of AMP^{2-} and to N^7 of ATP^{4-}. In the reactive $[M_2(ATP)]_2(OH)^-$ dimer the structuring ATP^{4-} occupies formally the left side in the above structure.

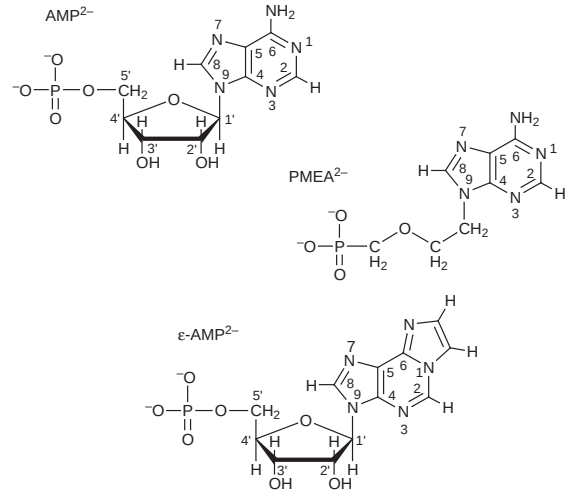

Fig. 2 Structure of the dianion of 9-[2-(phosphonomethoxy)-ethyl]adenine ($PMEA^{2-}$) in comparison with those of adenosine 5′-monophosphate (AMP^{2-}) and 1,N^6-ethenoadenosine 5′-monophosphate (ε-AMP^{2-})

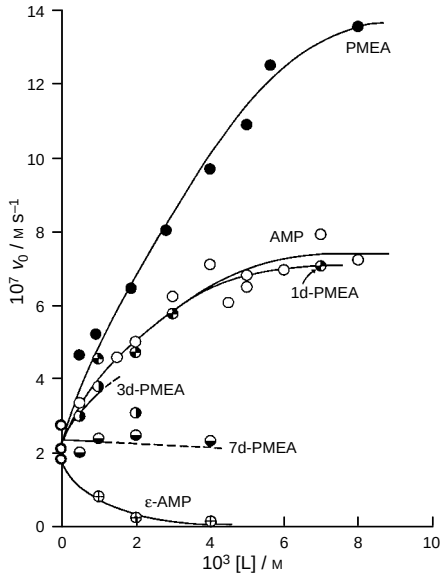

Fig. 3 Influence of PMEA (●) and AMP (○) as well as of some related derivatives (L) on the initial rate v_o (м s^{-1}) of dephosphorylation of the Cu^{2+}/ATP 2 : 1 system ($[Cu^{2+}]_{tot} = 2 \times 10^{-3}$ м and $[ATP]_{tot} = 10^{-3}$ м) in aqueous solution at pH_o 6.70 (I = 0.1 м, $NaClO_4$; 50 °C).¶ The broken lines indicate uncertainty due to precipitation.

These observations initiated further experiments with the deaza derivatives of PMEA, in which the three aromatic nitrogens, N^1, N^3, and N^7 (see Fig. 2), are systematically replaced by a CH unit. Fig. 3 shows that 1-deaza-$PMEA^{2-}$ facilitates the Cu^{2+}-promoted ATP^{4-} dephosphorylation at pH 6.7 about as well as AMP^{2-}.‡‡ Unfortunately, addition of 3-deaza-PMEA and 7-deaza-PMEA to a Cu^{2+}/ATP 2 : 1 system leads, even at relatively low concentrations, to turbidity of the reaction solution and finally to a precipitate. Nevertheless it is evident that 3-deaza-$PMEA^{2-}$ can also facilitate the reaction while some inhibition of the system occurs on addition of 7-deaza-$PMEA^{2-}$. This agrees with previous observations made with $TuMP^{2-}$ (7-deaza-AMP^{2-})[1b] which had confirmed the earlier suggestion[1a] regarding the importance of N^7 for the structure of the reactive intermediate.[2,8a]

To demonstrate how delicate the structure of the reactive intermediate (Fig. 1) is, we repeated a previous Cu^{2+}/ATP 1 : 1 experiment[1b] with 1,N^6-ethenoadenosine 5′-monophosphate (ε-AMP^{2-}; Fig. 2) under the present Cu^{2+}/ATP 2 : 1 conditions. The inhibition of the reaction is dramatic (Fig. 3); a fourfold excess of ε-AMP prevents the dephosphorylation of ATP^{4-} almost completely. The stacking properties of ε-AMP^{2-} are very similar to those of AMP^{2-};[13] however, in Cu(ε-AMP) the metal ion is bound to the phosphate group and the '1,10-phenanthroline'-like N^6, N^7 site[13] which leads to a different orientation of the metal ion in space. Consequently, this AMP derivative cannot take over the structuring role needed in the reactive species (Fig. 1), but it strongly inhibits, as is usual for ternary Cu(ATP)(L) complexes,[1b] the dephosphorylation reaction of the Cu^{2+}/ATP system. This inhibition re-emphasizes how well $PMEA^{2-}$ is suited to mimic AMP^{2-} in certain reactions.

This study was supported by the Swiss National Science Foundation (H.S.) and within the COST D8 programme by the Swiss Federal Office for Education and Science (H. S.) and the Ministry of Education of the Czech Republic (A. H.).

‡ This is part 12 of 'Hydrolysis of Nucleoside Phosphates'; for part 11 see ref. 14.

§ In the presence of metal ions these adenine-nucleotide systems[8a] show thus related properties to ribozymes;[8b] their possible role in early evolution has been discussed.[8a]

¶ The disodium salt of ATP (> 98%; p.a.) was obtained from Serva Feinbiochemica GmbH, Heidelberg, Germany. The other reagents were the same as used previously.[15] The liberated P_i was determined by the molybdate method;[1,14] a critical summary of the methodology is given in ref. 2. No buffers were used to adjust the pH of the solutions because they inhibit metal ion-promoted dephosphorylation reactions.[2] Instead, the pH was adjusted with conc. NaOH or $HClO_4$ using a glass rod ('dotting'; volume changes negligible).[1,2] To obtain the initial pH, *i.e.* pH_o = 6.70, and the corresponding initial rate for the dephosphorylation, $v_o = d[P_i]/dt$ (м s^{-1}), at least two experiments were carried out in this pH range; these results were then interpolated to the desired pH_o as shown, *e.g.* in Figs. 1 and 3 of ref. 1*a* and 2, respectively. Usually v_o is reproducible to ±10%, but for a very rapid reaction and/or an unstable pH the error limit may increase to ±25%. Attempts to carry out the analogous experiments with Zn^{2+} failed due to precipitation; the very low solubility of Zn(PMEA) is known.[16a]

‖ ATP^{4-} hydrolyzes in a 10^{-3} м solution at pH_o 9.5 (I = 0.1 м, $NaClO_4$; 50 °C) with $v_o = 0.015 \times 10^{-8}$ м s^{-1}, whereas in a solution of the same ATP concentration and under the same conditions but in the presence of a twofold excess of Cu^{2+} at pH_o 5.5, where the reaction proceeds *via* $[Cu_2(ATP)]_2(OH)^-$, $v_o = 30 \times 10^{-8}$ м s^{-1};[2] *i.e.* Cu^{2+} promotes the hydrolysis of ATP^{4-} by a moderate factor of 2000. For solutions with [ATP] = 0.1 м the corresponding rates are: ATP alone, $v_o = 1.5 \times 10^{-8}$ м s^{-1}; with Cu^{2+}/ATP = 2 : 1 $v_o = 3 \times 10^{-3}$ м s^{-1}; hence, one obtains a large promotion factor of 2×10^5.[2] At pH_o 6.70 (Fig. 3) the corresponding promotion factors due to Cu^{2+} are only slightly smaller.[2] The pitfalls connected with comparisons of the indicated kind have been discussed in ref. 2 (pp. 515–519). Therefore, conclusions regarding nonenzymatic reactions (*e.g.* ref. 3,17), that divalent metal ions have little effect on the rate of ATP hydrolysis, have to be considered with care; much depends on the metal ion and the conditions (pH, *etc.*) involved.

** This is despite the higher basicity of the phosphonate group in $PMEA^{2-}$ (pK_a = 6.90)[15] compared to that of the phosphate group in AMP^{2-} (pK_a = 6.21)[18] which disfavours Cu^{2+} binding of $PMEA^{2-}$ (due to the competition with H^+) by a factor of about 0.5.

†† For the M^{2+}-binding properties of PMEA see ref. 16.

‡‡ Hence, N^1 has no significant role in the Cu^{2+}-promoted hydrolysis of ATP which contrasts with a recent claim[19] made for the Zn^{2+}/ATP system.

Ion flux and deposition rate measurements made in plasmas of acrylic acid support the view that at low plasma power ions are primarily responsible for deposit growth.

In general, the mechanisms that lead to the deposition of plasma polymers are poorly understood. Yasuda[1] has described plasma polymerisation as proceeding through a rapid step-growth polymerisation (RSGP) mechanism. The RSGP mechanism is very general and was probably not intended to cover the entire range of conditions under which plasma polymer deposits form. However, in the absence of other schemes, it is widely quoted.[2] The nature of the reactive species in the RSGP mechanism is not made clear, but the orthodox view is that they are radicals.

This paper is concerned with the plasma polymerisation of acrylic (propenoic) acid in RF sustained glow-discharges of low input powers, *P*. Previously, functional group retention has been reported in the deposits from plasmas of carboxylic acids[3,4] and unsaturated alcohols.[5] Based on plasma-phase mass spectral measurements of ions and neutrals, we have proposed that functional group retention arises from oligomerisation (ion–molecule) reactions in the plasma.[3–5] At low *P*, dimeric[3–5] and trimeric[3,4] cations have been detected by mass spectrometry and under these same conditions functional group retention was highest.[3–5] The degree of dimer and trimer formation and functional group retention decreased with increased *P*. Deposition of polymer has been attributed to the ion flux arriving at a surface, but this has not been proven.[6]

Ion flux measurements are particularly difficult to make in plasmas used for the deposition of polymers. The problem arises from the build-up of an insulating layer on the active area of the probe used to measure the ion flux. Braithwaite *et al.*[7] have described a novel electrostatic probe that allows ion flux measurements to be made even when the surface of the probe is coated with an insulating material. The principles of operation are described in ref. 7.

To the best of our knowledge, ion flux measurements have not been made before in plasmas of C-, H- and O-containing monomers. The plasma polymerisation of these compounds has received considerable attention, as deposits from these compounds are used to control processes that depend upon surface chemistry. The effect of *P* on ion flux and deposition rate has been investigated. XPS analysis of the solid-phase plasma polymers is undertaken. We correlate changes in ion flux, deposition rate and surface chemistry with those previously reported in the plasma-phase.[4]

The apparatus (described more fully in ref. 8) consisted of a tubular glass reactor which was pumped by means of a rotary pump. The plasma was sustained by an RF generator (13.56 MHz) and amplifier inductively coupled to the plasma reactor. The *P* used was in the range 0.5–15 W and flow rate (ϕ) was fixed at 0.8 cm^3 (STP) min^{-1}. Acrylic acid (Aldrich > 99% purity) was pumped through a needle valve at a pressure of 2.5 $\times$ 10^{-2} mbar. Deposition rate measurements were made using a quartz crystal microbalance (Leybold, Manchester, UK), which was inserted into the plasma region, using a solid support to ensure consistent positioning of the crystal. In a separate series of experiments, the ion flux probe was placed in the plasma, close to where the quartz crystal had been, to determine the relationship between RF power and ion flux to this region. The presence of this probe is no more perturbing than the crystal balance, merely providing a loss surface for ions. The probe is biased negatively by RF pulses and the transient current used to determine ion flux. Changes in the probe voltage are limited to ensure the sheath potential changes at a much slower rate compared to the transit time of the ions crossing the sheath, this having a square-root dependence on ion mass and plasma density. This ensures the measured current is due to the particle fluxes only and not a redistribution of charge in the sheath.[7] This mode of operation makes the probe insensitive to ion mass.

Fig. 1 shows how the deposition rate varies with *P*. It clearly show two regimes: at *P* of < 4 W, the deposition rate increased with *P*; the deposition rate increased three-fold from *P* = 0.5 $\rightarrow$ 3 W. Above *P* = 4 W, the deposition rate remained essentially constant. These regimes are consistent with those previously described in the plasma-phase mass spectrometry of acrylic acid.[4] Over the range *P* = 1–4 W, the ion signal from the dimer of acrylic acid, expressed as the ratio of the intensity of the dimer signal to monomer signal, decreased smoothly by over 90% with *P*. By *P* = 5 W, the dimer signal had effectively fallen to zero.

Fig. 2 shows that the ion flux increased at a constant rate between *P* = 1–3 W (0.1 ± 0.1 $\times$ 10^{18} ions m^{-2} s^{-1}). Just above *P* = 4 W there was a marked jump in ion flux. Ion flux then continued to rise steadily with *P*, up to *P* = 14 W (1 ± 0.1 $\times$ 10^{18} ions m^{-2} s^{-1}).

It is between *P* = 0.5–4 W that the most significant change in the retention of carboxylic acid from the acrylic acid occurred. At *P* = 0.5 W, 80.5% retention of carboxylic acid was achieved, but at *P* = 1 W this was down to 58% retention. Retention continued to decline further with increased *P*, and a wider range of oxygen–carbon functional groups were incorporated into the plasma deposit.

The correlation between ion flux and deposition rate is not a simple one. In the plasma there is both deposition and ablation

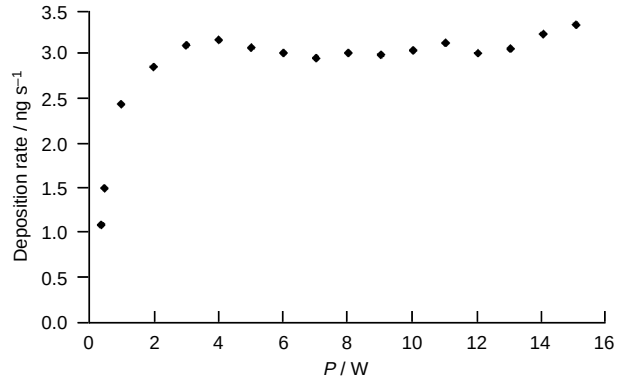

Fig. 1 Measured deposition rates *vs. P*

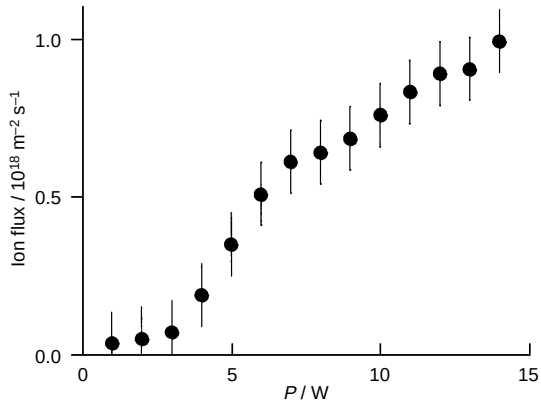

Fig. 2 Measured ion flux *vs. P*

of material. Ablation becomes more important at higher *P*. When this is taken into account, the different trends in ion flux and deposition rate data can be accommodated and fit with our understanding of plasma polymerisation.

In the acrylic acid system, at low *P* (0.5 W) there is extensive oligomerisation in the plasma-gas phase and these oligomers deposit to give a highly functionalised, low molecular weight film. These oligomers make up the bulk of the ion flux, which was too low to measure, with confidence, below $P = 1$ W. The deposition rate was correspondingly low.

The ion flux and deposition rate increased steadily with *P*, but at $P = 4$ W, their behaviour diverges. The deposition rate did not increase further with *P*. The constant deposition rate above $P = 4$ W represents a balance between deposition and ablation, with the increased ion flux being responsible for ablation.

Increased *P* had a dramatic effect on the extent of gas-phase oligomerisation. Above $P = 4$ W, oligomeric species from the plasma do not appreciably contribute to the deposit growth, which may now be explained by the flux of smaller ionic fragments and possibly radical grafting. Incorporation of carboxylic acid functional groups may have occurred by reaction of the surface with 'intact' monomer in the plasma, or other fragments containing carboxylic acid. Oxidation of the surface by the plasma can not be ruled out. At high *P*, the surface chemistry becomes closer to that of a plasma oxidised polymer surface.

This interpretation challenges the more orthodox view that neutral and free radical chemistry are solely responsible for deposit growth. The ability to make ion flux measurements in depositing plasmas is an important advance. The measurements themselves further point to the importance of the ionic component of these plasmas. Ion flux measurements help explain the effect *P* has upon surface chemistry and deposition rates.

The first enantioselective syntheses of vicinal difluoropyrrolidines and the first catalytic asymmetric synthesis mediated by the C_2 symmetry of a –CHFCHF– unit

Charles M. Marson*† and Robert C. Melling

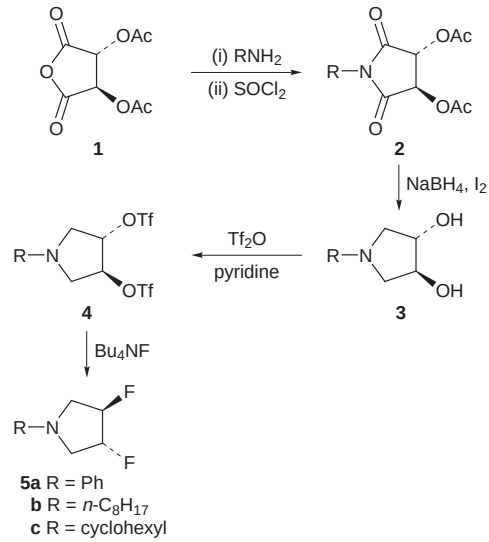
Department of Chemistry, Queen Mary and Westfield College, University of London, London, UK E1 4NS

The first enantiopure vicinal difluorides of C_2 symmetry have been prepared by the introduction of fluorine at both centres in a single operation; the first asymmetric synthesis using a catalyst whose chirality depends on organofluorine asymmetry is described.

The stereoselective synthesis of organofluorine compounds[1,2] is of major importance in many fields, including pharmaceuticals,[1–3] nucleoside and carbohydrate chemistry,[1b] biochemistry,[4,5] liquid crystals[6] and polymers.[7] Many fluorinated α-amino acids are potent antitumour and antiviral agents.[1a,4a] The importance of monofluoro analogues as antimetabolites is illustrated by (2*R*,3*R*)-fluorocitric acid, an aconitase inhibitor that blocks the citric acid cycle.[2,5] Additionally, organofluoro ligands can be more powerful than oxygen ligands in coordinating metals.[8]

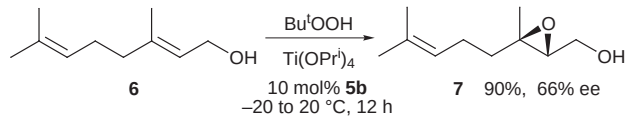
Whereas enantiocontrolled syntheses of monofluoroorganic compounds are well established, synthesis of an enantiopure vicinal difluoro compound, especially of C_2 symmetry, has not to the best of our knowledge been reported prior to this communication.[9,10] Generally, molecular fluorine adds to alkenes with *syn*-stereoselection, thereby precluding the formation of C_2 symmetric difluorides;[11] where *trans*-addition is observed yields are usually low.[12] For example diethylaminosulfur trifluoride (DAST),[13] one of the most commonly used reagents for the conversion of alcohols into fluorides, gives merely a trace of 1,2-difluorocyclohexanes, and with loss of stereointegrity compared with the initial cyclohexane-1,2-diol.[14] SF_4 acts on (+)- or (−)-tartaric acid, exchanging both hydroxy groups for fluorine, but with complete loss of optical activity, by formation of only the *meso*-difluoroacid.[15a] With tartrate esters, XeF_2 was similarly unsuccessful.[10c] Despite those previous accounts, we here report the enantiocontrolled introduction of fluorine at two adjacent carbon stereocentres in a single operation, and describe syntheses of enantiopure vicinal difluorides **5**, and an asymmetric process using some of those difluorides as catalysts.

In view of reports[15] that double vicinal displacements of tartaric acid derivatives by fluoride do not proceed with enantiocontrol, displacements on cyclic systems were investigated. (3*R*,4*R*)-Diacetoxysuccinic anhydride **1**[16] was reacted with a primary amine (1 equiv., 12 h, 20 °C), and the intermediate amido acid treated directly with $SOCl_2$ (2 equiv., 24 h, 20 °C) to give the diacetoxypyrrolidin-2,5-dione **2** (**2a**, R = Ph; **2b**, R = *n*-C_8H_{17}; **2c**, R = cyclohexyl) (Scheme 1). The pyrrolidin-2,5-diones **2** were reduced with $NaBH_4$–I_2 in THF (12 h) and the diols **3** liberated by a two-stage work-up involving stirring with 1:1 AcOH–HCl (10 M) for 10 h, followed by washing with methanolic KOH (2 M). Reaction of the diols **3** with Tf_2O (2 equiv., 4 h, −80 °C) in the presence of pyridine (2 equiv.) afforded the bis(trifluoromethanesulfonates) **4**. These were isolable in the cases of **4a** (R = Ph) and **4b** (R = *n*-octyl) but **4c** (R = cyclohexyl) decomposed rapidly during column chromatography. The bis(trifluoromethanesulfonates) **4** were reacted with Bu_4NF (3 equiv., 16 h, −80 to 20 °C) in THF, resulting in stereoselective introduction of fluorine with clean inversion at both centres to give the difluoropyrrolidines **5a**–**c**, in respective yields of 76, 83 and 40%.‡ To the best of our knowledge, 3,4-difluoropyrrolidines have not been previously prepared, either in racemic or enantiopure form.



Scheme 1

Catalysis of the epoxidation of allylic alcohols by difluorides **5** was investigated; reactions were conducted in CH_2Cl_2 using 15 mol% of $Ti(OPr^i)_4$ and 10 mol% of catalyst (Scheme 2, Table 1, entries 2–7). In the absence of a catalyst, racemic **7** was obtained in 81% yield. Diol **3a** afforded 2,3-epoxygeraniol **7** (97%) in 25% ee in favour of the (2*S*,3*S*)-enantiomer (entry 2).



Scheme 2

Table 1 Asymmetric epoxidation of geraniol (1.6 mmol) with *tert*-butyl hydroperoxide, titanium tetraisopropoxide (15 mol%) and the difluorinated catalyst **5b** (10 mol%)

Entry	Catalyst	*T*/°C	*t*/h	Yield (%)	Ee (%)	Configuration
1	—	−20 to 20	12	81	—	racemic
2	**3a**	−20 to −10	0.67	97	25	(*S*,*S*)
3	**5b**	−20 to 20	1	68	50	(*R*,*R*)
4	**5b**	0	1	74	51	(*R*,*R*)
5	**5b**	**−20 to 20**	**12**	**90**	**66**	(***R*,*R***)
6	**5b**	−80	3	23	27	(*R*,*R*)
7	**5c**	−20 to 20	12	87	10	(*R*,*R*)

The use of **5c** (−20 to 20 °C over 12 h) afforded 2,3-epoxygeraniol (87%) in 10% ee in favour of the (2*R*,3*R*)-enantiomer (entry 7). However, **5b** afforded a 90% yield of 2,3-epoxygeraniol **7** in 66% ee in favour of the (2*R*,3*R*)-enantiomer (entry 5). Entries 3–5 suggest that fluoro groups may provide greater enantioselection than hydroxy groups (entry 2), at least in the case of a C_2 vicinal unit which is part of a heterocyclic ring. The reversal of the major enantiomer of 2,3-epoxygeraniol when using catalyst **3** compared with catalyst **5** would be expected if the modes of binding of the hydroxy and fluoro catalysts had important features in common. Samples of alcohol **7** were converted into the acetate (1 equiv. Ac_2O, 1 equiv. pyridine, 10 mol% DMAP in CH_2Cl_2 at 0 to 20 °C over 2 h), and the ee determined by observation of ^{1}H NMR peak of the acetate methyl group upon treatment with Eu(hfc)$_3$;[17] the acetate (10 mg in 0.5 ml of C_6D_6) was treated with consecutive portions of 10–20 ml of a filtered solution of 35 mg of Eu(hfc)$_3$ in 0.5 ml of C_6D_6.

The presence of fluorine ligands in organic reactions mediated by catalysis is an emerging area of importance.[18] To date, however, the chirality has not been a consequence of the spatial arrangement of the fluorine atoms, but of the asymmetry of an unrelated organic ligand (*e.g.* BINOL).[18] Consequently, the present examples are, to the best of our knowledge, the first examples of asymmetric synthesis catalyzed by a compound whose chirality depends upon organofluorine asymmetry.

In the catalytic asymmetric Sharpless epoxidation,[19] free hydroxy groups on the catalyst (dialkyl tartrate) are a prerequisite for enantioselectivity. In marked contrast to such Sharpless catalysts, the difluorides **5** lack hydroxy groups and are incapable of deprotonation that could lead to ligand exchange, and yet **5a–c** are viable catalysts for asymmetric epoxidation.

Compounds **5a** and **5c** are particularly suitable substructures for liquid crystal applications, and difluoropyrrolidines **5** and their derivatives are currently being evaluated for use as liquid crystals and other new materials; additional catalytic processes are also under investigation.

Support from the EPSRC for a studentship (to R. C. M.) under the ROPA initiative is gratefully acknowledged.

Transfer of alk-1-enyl group from boron to boron: preparation of *B*-[(*E*)-alk-1-enyl]-9-borabicyclo[3.3.1]nonane

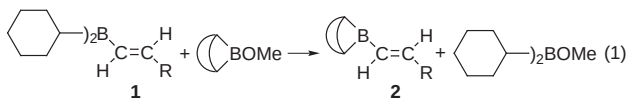
Masayuki Hoshi,*† Kazuya Shirakawa and Akira Arase

Department of Applied and Environmental Chemistry, Kitami Institute of Technology, 165 Koen-cho, Kitami 090-8507, Japan

Treatment of (*E*)-alk-1-enyldicyclohexylborane 1 with *B*-methoxy-9-borabicyclo[3.3.1]nonane (*B*-MeO-9-BBN) at 0 °C results in transfer of alk-1-enyl group from boron to boron to give *B*-[(*E*)-alk-1-enyl]-9-BBN 2 with retention of configuration.

Alkenylboranes have been widely used as one of the most important intermediates in organic synthesis, and generally they are prepared by hydroboration of alkynes with borane derivatives.[1] In some cases, however, hydroboration is not necessarily the most reliable route. For example, a stoichiometric hydroboration of alk-1-yne with 9-BBN is not efficient because it causes dihydroboration to give a significant amount of 1,1-diboryl adduct.[2,3] In order to suppress the dihydroboration, the reaction requires a 100% excess of alk-1-yne and must be carried out at 0 °C for 18 h.[2]

We recently reported that hydroboration of alk-1-ynes with 1,3,2-benzodioxaborole (catecholborane) and hydroboration of 1-haloalk-1-ynes with 9-BBN, both of which are sluggish at room temperature in THF,[4] are accelerated by addition of a catalytic amount (5 mol%) of dicyclohexylborane in THF to afford *B*-[(*E*)-alk-1-enyl]catecholborane and *B*-[(*Z*)-1-haloalk-1-enyl]-9-BBN in high yields, respectively.[5] Dicyclohexylborane probably plays a critical role in a catalytic cycle. In the former reaction, it is presumed that dicyclohexylborane would hydroborate the alk-1-yne and the resulting (*E*)-alk-1-enyldicyclohexylborane would undergo exchange of the alk-1-enyl group for a hydrogen atom of catecholborane to give *B*-[(*E*)-alk-1-enyl]catecholborane with retention of configuration and regeneration dicyclohexylborane. The latter dicyclohexylborane-promoted hydroboration appears to include a similar catalytic cycle. These exchange reactions may belong to the category of not hydroboration but transfer reaction. It seems probable that such transfer reactions provide a method for the preparation of some alkyl- or alkenyl-boranes whose formation is very difficult or inefficient *via* hydroboration. We report here an efficient and stereoselective preparation of *B*-[(*E*)-alk-1-enyl]-9-BBN **2** *via* treatment of (*E*)-alk-1-enyldicyclohexylborane **1** with a slightly excess of *B*-MeO-9-BBN at 0 °C [eqn. (1)].



1 **2** (1)

The reaction of (*E*)-hex-1-enyldicyclohexylborane **1a** in THF with an equimolar amount of *B*-MeO-9-BBN in hexanes was carried out at 0 °C for 1 h, and the reaction mixture, after removal of solvents, was analysed by ^{1}H NMR spectroscopy. In the alkenyl region, the two double triplets at δ 6.20 and 6.73 arising from **1a** decreased considerably while two double triplets appeared at δ 6.23 and 6.83 (*J* 17.3 Hz, *trans* alkenyl protons), indicating that *B*-[(*E*)-hex-1-enyl]-9-BBN **2a**[2,6] had been formed in a stereoselective manner, the ratio of **1a** : **2a** being 20 : 80. In the same spectrum we also observed two singlets, one at δ 3.76 arising from the methyl protons of unreacted *B*-MeO-9-BBN and the other at δ 3.69 arising from those of dicyclohexylmethoxyborane. These results suggest that the (*E*)-hex-1-enyl group transferred from the boron atom of **1a** to the boron atom of *B*-MeO-9-BBN with complete retention of the stereochemistry. The reaction at 0 °C for 2 h improved the ratio of **1a** : **2a** to 8 : 92. The reaction with 1.2 equiv. of *B*-MeO-9-BBN under otherwise identical conditions resulted in a slight increase for **2a**; the **1a** : **2a** ratio was 6 : 94 (entry 1, Table 1). However, no further improvement in the ratio was achieved by increasing the amount of *B*-MeO-9-BBN to 1.5 equiv.

The reaction of various compounds **1** with 1.2 equiv. of *B*-MeO-9-BBN was carried out at 0 °C for 2 h. These results including NMR data for **1** are summarised in Table 1. The reaction of (*E*)-3,3-dimethylbut-1-enyldicyclohexylborane **1b** proceeded smoothly and stereoselectively to give *B*-[(*E*)-3,3-dimethylbut-1-enyl]-9-BBN **2b**; the **1b** : **2b** ratio was 5 : 95 (entry 2). In the reaction of (*E*)-2-phenylethenyldicyclohexylborane **1c** the reaction mixture was analysed by ^{11}B NMR spectroscopy, since the alkenyl protons of *B*-[(*E*)-2-phenylethenyl]-9-BBN **2c** were indistinguishable from those of **1c**. From the ^{11}B NMR spectrum of the reaction mixture in THF–hexanes‡ **1c** was found to be converted to **2c** with a high ratio (**1c** : **2c** = 1 : 99) (entry 3). 3-Substituted *B*-[(*E*)-alk-1-enyl]-9-BBN, having a functionality at a position very close to the alkenyl moiety, may be a potential intermediate because of its poly-functional properties. The present transfer reaction is applicable to such functionalised (*E*)-prop-1-enyldicyclohexylboranes without any difficulties. Thus, (*E*)-3-chloroprop-1-enyldicyclohexylborane **1d** and (*E*)-3-methoxyprop-1-enyldicyclohexylborane **1e** were converted to the corresponding compounds **2** stereoselectively (entries 4 and 5). 3-Substituted (*E*)-prop-1-enyldicyclohexylboranes **1f**–**h** having an oxygen protected with Ac, THP and TMS groups were also converted to *B*-[(*E*)-3-acetoxyprop-1-enyl]-9-BBN **2f**, *B*-[(*E*)-3-(tetrahydro-2*H*-pyran-2-yloxy)prop-1-enyl]-9-BBN **2g** and *B*-[(*E*)-3-(trimethylsiloxy)prop-1-enyl]-9-BBN **2h**, respectively (entries 6–8).

Previously Brown and Gupta reported that boron–carbon bond formation *via* redistribution between trialkylborane and borate required temperatures above 100 °C.[7] It should be noted that the present reaction proceeds smoothly at 0 °C despite the redistribution reaction involving boron–oxygen bond cleavage, and thus appears to be applicable to transfer of alkenyl groups containing a thermally unstable functionality.

One of the characteristic reactions of *B*-alkenyl-9-BBN is the 1,4-addition reaction with but-3-en-2-one.[8] *In situ* addition of **2** to but-3-en-2-one under conditions identical to those described in the literature gave the corresponding 4-(alk-1-enyl)butan-2-one, while the yields were a little lower than those reported. Thus, the present reaction is expected to be synthetically useful, although there may still be room for improvement.

In conclusion, *B*-[(*E*)-alk-1-enyl]-9-BBN **2** can be produced efficiently *via* the reaction of (*E*)-alk-1-enyldicyclohexylborane **1** with *B*-MeO-9-BBN. This transfer of an alk-1-enyl group is performed with complete retention of configuration under very mild conditions. We note that this study provides, to the best of our knowledge, the first example of the transfer of an alk-1-enyl group from boron to boron in stoichiometric amounts. The

First lanthanide complexes and unusual coordination behavior of hexakis(3,5-dimethylpyrazolyl)cyclotriphosphazene

Bo Hwan Koo, Younghun Byun, Eunkee Hong, Youngjo Kim and Youngkyu Do*†

Department of Chemistry and Center for Molecular Science, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea

Reaction of hexakis(3,5-dimethylpyrazolyl)cyclotriphosphazene (L) with $LnCl_3$ (Ln = La, Ce, Nd, Sm) affords new mononuclear lanthanophosphazenes [L·$LnCl_3$] with hendecahedral coordination polyhedron in which the ligand L employs an unprecedented κ⁵N binding core consisting of one cyclotriphosphazene ring nitrogen atom and four pyridinic nitrogen atoms of two sets of geminal pyrazolyl groups.

The use[1–6] of exocyclic donor groups attached to phosphazene skeletal phosphorus appears to be the most versatile method of preparing metallophosphazene complexes, the chemistry of which has been the subject of increasing research interest in conjunction with the potential opportunities for discovering new materials.[7] Successful applications of exocyclic donors such as pyrazolyl[1–4] and cyclopentadienyl[5] groups are cases in point. However, the scope of the coordination chemistry of hexakis(3,5-dimethylpyrazolyl)cyclotriphosphazene (L), a potential multidentate ligand due to its multiple chelate sites,[8] has only been examined with d^{10} metal halides[1] and d^9 Cu^{II} ion,[2] revealing the limited coordination behavior with the binding cores of (κ³N) for mononuclear species and (κ³N–κ²N) and (κ³N–κ³N) for dinuclear complexes. Here, we present the first examples of lanthanophosphazenes [L·$LnCl_3$] (Ln = La, Ce, Nd, Sm) where the ligand L acts as an unprecedented κ⁵N binding core donor for a metal center to form a hendecahedral coordination sphere.

A solid mixture of anhydrous $LnCl_3$ (0.3–0.6 mmol) and L (0.2 mmol) was allowed to react in 20 ml of CH_2Cl_2 under N_2 atmosphere. After being stirred at room temperature for 12 h, the reaction mixture was filtered. The volume of the filtrate was reduced *in vacuo*, and *ca*. 30 ml of Et_2O added. The resulting crystalline solid‡ was collected and recrystallized from CH_2Cl_2–Et_2O, affording the extremely air sensitive analytically pure§ product [L·$LnCl_3$] (Ln = La **1**, Ce **2**, Nd **3**, Sm **4**) in a yield of 50–55%.

In contrast to the single phosphazene ring P–N stretching band at 1226 cm^{-1} for free L, the appearance of two ν_{PN} peaks at *ca*. 1235 and 1210 cm^{-1} for [L·$LnCl_3$] indicates that the phosphazene ring nitrogen atom is involved in coordination to the metal center. In addition, the comparison of the IR spectra suggests that all four lanthanophosphazenes have the same structural core. Single crystal X-ray analysis,¶ performed on **4**, revealed unprecedented κ⁵N pentadentate coordination behavior of L as displayed in Fig. 1. One cyclophosphazene ring nitrogen atom N(1) and four pyridinic nitrogen atoms N(12), N(22), N(32) and N(42) from two sets of geminal pyrazole substituents on P(1) and P(2) constitute the κ⁵N binding core to coordinate $SmCl_3$, forming an eight-coordinate complex. The analysis of the shape parameters[11] indicates that the coordination sphere of **4** can be best described as a distorted hendecahedron illustrated in Fig. 2. The complexation caused P_3N_3 ring puckering the extent of which can be measured from the displacement of the N(1) atom (0.305 Å) from the plane defined by P(1), P(2), P(3), N(2) and N(3) and the dihedral angle of 22.1° between the P(1)N(1)P(2) plane and the P(1)N(3)P(3)N(2)P(2) plane. The overall molecular symmetry approaches *pseudo*-C_s. The Sm atom interacts more strongly with L *via* the phosphazene ring nitrogen atom N(1) than *via* the pyridinic nitrogen atoms: the $Sm–N_{ring}$ bond distance of 2.499 Å is shorter than the average $Sm–N_{pyz}$ distance of 2.832 Å. It is noteworthy that the reversed pattern in interaction between metal centers and the ligand L was observed in previously reported transition metal phosphazene complexes.[1,2]

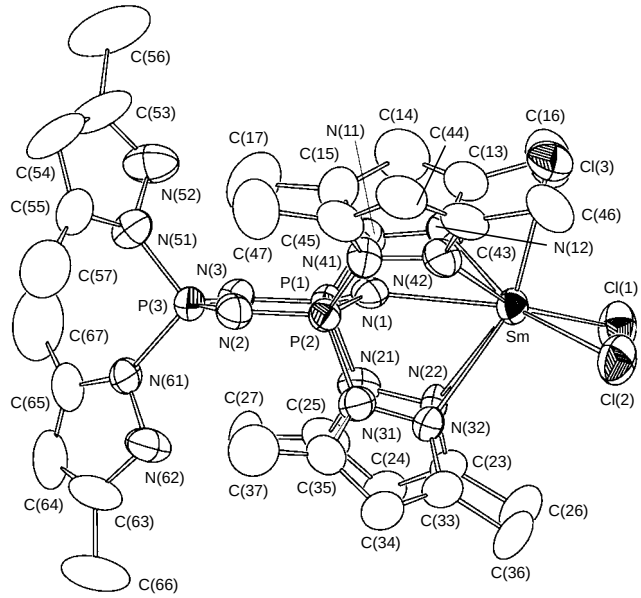

Fig. 1 Molecular structure of **4** showing the atom numbering scheme. Selected bond distances (Å) and angles (°): Sm–Cl(1) 2.659(3), Sm–Cl(2) 2.632(3), Sm–Cl(3) 2.628(2), Sm–N(1) 2.499(8), Sm–N(12) 2.859(10), Sm–N(22) 2.771(8), Sm–N(32) 2.860(8), Sm–N(42) 2.839(10), P(1)–N(1) 1.592(9), P(1)–N(3) 1.564(10), P(2)–N(1) 1.593(9), P(2)–N(2) 1.574(9), P(3)–N(2) 1.577(9); Cl(1)–Sm–N(1) 135.1(2), Cl(1)–Sm–N(12) 78.3(2), Cl(1)–Sm–N(22) 79.8(2), Cl(1)–Sm–N(32) 126.1(2), Cl(1)–Sm–N(42) 160.2(2), Cl(3)–Sm–N(32) 140.2(2).

In solution at room temperature, the compounds [L·$LnCl_3$] lose their solid state symmetry and undergo a new type of fluxional motion (Fig. 3) not seen in d^{10} metal complexes of L.[1]

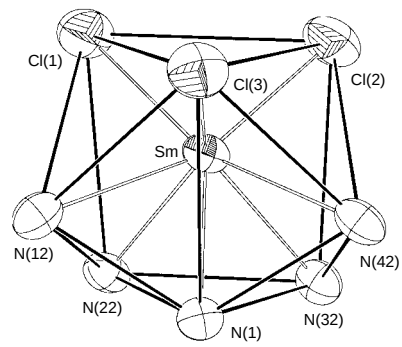

Fig. 2 Hendecahedral coordination geometry of **4**

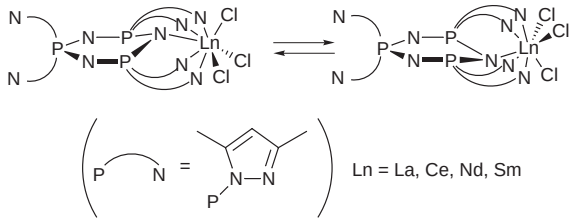

Fig. 3 Solution fluxional motion of $[L{\cdot}LnCl_3]$ in $CDCl_3$

The $^{31}P\{^1H\}$ NMR spectra§ of $[L{\cdot}LnCl_3]$ complexes are of A_2X type, invoking only the rotational motion of geminal pyrazolyl groups at P(3) around P–N bonds. However ^1H-NMR spectra§ in $CDCl_3$ show two pyrazolyl ring proton signals of ratio 2 : 4 and four methyl peaks with 12 : 6 : 6 : 12 ratio and thus indicate the presence of two types of magnetically different pyrazolyl rings in 1 : 2 ratio. Two pyrazolyl rings at P(3) and four pyrazolyl rings involved in coordination are respectively magnetically identical, requiring the presence of a fluxional motion such as the movement of the N(1)–$LnCl_3$ unit as illustrated in Fig. 3. The assignment of the most upfield peak as 3-methyl protons of pyrazolyl groups coordinated to metal was made based on the observation of the upfield shift and simultaneous broadening of the peak upon cooling to 218 K for **4**.

The use of 3,5-dimethyl substituted pyrazole seems critical in preparing compounds of the type $[L{\cdot}LnCl_3]$ since analogous reactions with cyclotriphosphazene ligand containing unsubstituted or mono 3-methyl substituted pyrazoles do not proceed as monitored by *in situ* NMR spectroscopy. Efforts to establish the reactivity scope of $[L{\cdot}LnCl_3]$ toward various reagents including d^{10} metal halides are in progress.

¶ *Crystallographic data* for **4**·$2CH_2Cl_2$: $C_{32}H_{46}Cl_7N_{15}P_3Sm$, M_r = 1132.25, monoclinic, space group $P2_1/c$, a = 16.860(3), b = 17.330(12), c = 18.289(5) Å, β = 113.669(14)°, U = 4894.2(16) Å^3, Z = 4, D_c = 1.537 g cm^{-3}, $F(000)$ = 2276, μ(Mo-Kα) = 1.722 mm^{-1}, R_1 = 0.0552, wR_2 = 0.1412 for 3899 observed reflections [$|F_o| > 4.0\sigma(F_o)$]. Reflection data were collected on an Enraf-Nonius CAD4TSB diffractometer with graphite-monochromated Mo-Kα radiation at 293 K. A total of 4926 data were collected in the range 4° < 2θ < 50°. Two oil-coated crystals were used to collect reflection data due to their rapid decaying nature. All data were collected with the ω–2θ scan mode and corrected for L_p effects. The decay correction of each crystal was applied to the data set. The structure was solved by Patterson's heavy atom methods (SHELXS-86).[9] Non-hydrogen atoms except solvate atoms were refined by full-matrix least-squares techniques (SHELXL-93)[10] with anisotropic displacement parameters. The solvate CH_2Cl_2 molecules exhibited positional disorder and the Cl atoms were each assigned an occupancy factor of 0.4 and 0.6. All hydrogens except disordered CH_2Cl_2 hydrogens were placed at their geometrically calculated positions [$d_{C–H}$ = 0.93(pyrazolyl), $d_{C–H}$ = 0.96(methyl)] and refined riding on the corresponding carbon atoms with isotropic thermal parameters [(1.2U(pyrazolyl), 1.5U(methyl)]. QCM showed that SiO_2/poly(diallyldimethylammonium chloride) (PDDA) film assembly could be achieved in 2 s for 45 nm silica nanoparticle monolayers and 20 s for PDDA monolayers, with film integrity demonstrated by SEM and spectroscopic ellipsometry.

Layer-by-layer assembly of films containing nanoparticles and oppositely charged polyions provides a viable approach to advanced materials or devices with molecularly engineered properties.[1] Building on pioneering work of Iler,[2] who used oppositely charged colloidal particles to make films, linear polyions[3–6] have permitted materials such as dendrimers,[7] proteins,[8] latex[9] and inorganic nanoparticles to be incorporated.[10–14] For most materials used in layer-by-layer electrostatic film assembly, 6–15 min are required for every step of monolayer formation.[2–14] Here we show that time to assemble nanoparticle/linear polyion films can be decreased 100-fold.

Films were assembled with colloidal 45 nm diameter SiO_2 and linear quaternary ammonium polymer poly(diallyldimethyl-ammonium chloride) (PDDA, MW = 70 000) in 0.01 M NaCl at pH 9.5. Silica is negatively charged and PDDA is positively charged at this pH.[14] We monitored assembly with a quartz crystal microbalance (QCM, USI System, Japan)[14,15] in two modes. For stepwise measurement, a Ag- or Au-coated resonator was immersed alternately in polycation or silica solutions for a given period, dried, and the QCM frequency change measured. For *in situ* monitoring, only one side of the resonator was in permanent contact with the surface of the solution and the frequency change was recorded continuously. Films were assembled on electrodes of the QCM resonator by repeating alternate adsorption of PDDA and silica. From the Sauerbrey equation, taking into account characteristics of the quartz resonators (F_o = 9 MHz), the following relation holds between adsorbed dry mass ΔM (ng) on the electrode of area S = 0.16 cm^2 and frequency shift ΔF (Hz):[8,15]

$$-\Delta F = -1.83 \times 10^8 \, \Delta M/S$$

For scanning electron microscopy (SEM, Hitachi S-900), a resonator with an assembled film was cross-sectioned and coated with a 20 Å Pt film. Film thicknesses were measured from cross-sectional images.[14]

Spectroscopic ellipsometry[16] at incidence angles of 70, 72, 76 and 78° and wavelengths of 300–1000 nm was done on films deposited on silicon (100) with native oxide to determine thickness and optical constants using a variable angle spectroscopic ellipsometer (Woollman Co.)

Fig. 1 shows *in situ* QCM of alternate PDDA and SiO_2 adsorption without intermediate sample drying. In the first step, PDDA was adsorbed onto a Ag electrode. QCM frequency decreased during the first 60 s, after which a slower change was observed as adsorption saturation set in. Then, the resonator was immersed in pure water (black dots) for washing. Next, the film was immersed in a SiO_2 dispersion and silica adsorption saturation occurred in several seconds. After subsequent water washing, the film was immersed again in PDDA solution, and so on. Each step was reproducible and the adsorption process reached 90% saturation in 10 s for SiO_2 and 40 s for PDDA.

To find the minimum time for producing good quality films, we tested adsorption times from 15 min to 2 s, drying the films after every other deposition step. Linear growth of film mass and thickness with adsorption cycle number was observed in most cases. The QCM frequency shift was $-\Delta F = 1200 \pm 60$ Hz for SiO_2 and 100 ± 10 Hz for PDDA for 15 min adsorption. A minimal time for the process was found for assembled multilayers by decreasing time and monitoring ΔF corresponding to each layer. For 15 min, 10 min, 5 min, 1 min and 20 s PDDA adsorption gave $-\Delta F = 100$ Hz. For SiO_2 minimal adsorption time was 2 s, with $-\Delta F = 1200$ Hz. SiO_2/PDDA assembly with less than 2 s/20 s adsorption times deteriorated the film growth process. Sample drying after every PDDA deposition was necessary for regular multilayer growth.

We also analyzed the structures of $(SiO_2/PDDA)_{6-24}$ films assembled with 2 s/20 s adsorption times with drying after every deposition step (Table 1). Fig. 2 gives a typical SEM image of such a SiO_2/PDDA film. The image shows densely packed silica spheres and its surface is smooth on the level of one silica sphere (*ca.* ±40 nm). SiO_2/PDDA bilayer thickness was estimated from total film thickness and number of adsorption cycles. For six films assembled with 2 s/20 s times $\langle d \rangle$ = 24.6 ± 0.4 nm, the same as for SiO_2/PDDA assembled with 'traditional' 15 min adsorption steps. This corresponds to mean thickness of closely packed spheres of 45 nm diameter and indicates complete surface filling.

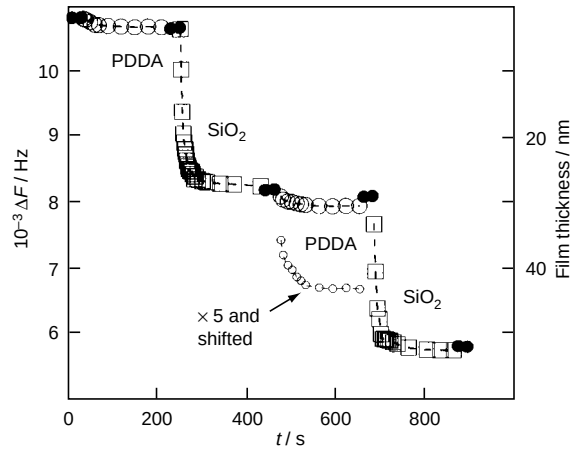

Fig. 1 QCM monitoring of PDDA and SiO_2 sequential adsorption on a silver electrode: PDDA (○), intermediate water-washing (●) and SiO_2 (□). The third step PDDA curve drawn with 5× amplification. 45 nm diameter SiO_2 was used at 10 mg ml^{-1} (Nissan Kagaku, Japan) and 3 mg ml^{-1} linear poly(diallyldimethylammonium chloride) (PDDA, MW = 70 000, Aldrich) were used in 0.01 M NaCl at pH 9.5.

Table 1 Structural parameters of 45 nm SiO_2/PDDA films assembled with 2 s/20 s adsorption

No. of bilayers/ substrate	Total QCM ΔF/Hz	Mass from QCM/ 10^6 g cm^{-2}	Thickness/nm (SEM)	Thickness/nm Ellipsometry	Film density/ g cm^{-3}
4/Si				99	
6/Si				149	
7/Si or Ag	8400	23.0		173	1.38
8/Au	11200	30.6	210		1.45
20/Ag	24500	67.0	480		1.40
24/Ag	33000	90.2	610		1.48

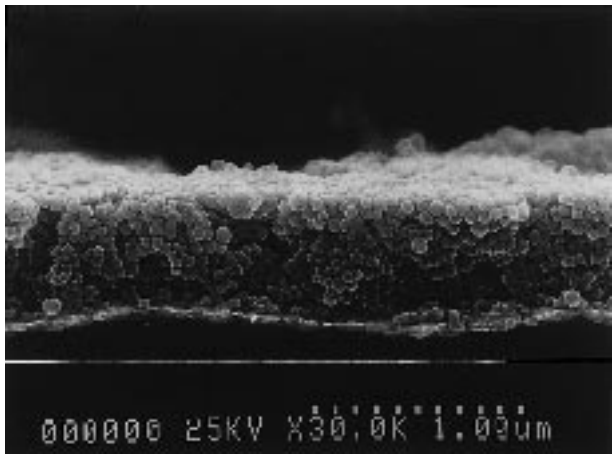

Fig. 2 SEM cross-sectional view of {PDDA+ (45 nm SiO_2/PDDA)$_{24}$} film deposited using the 2 s/20 s monolayer adsorption on silver electrode

Ellipsometric data were modeled with a Lorentz oscillator for an effective medium approximation,[16] to take into account the film's surface inhomogeneities and voids (*cf.* Fig. 2). A graph of ψ and θ values of the seven-bilayer film is given in Fig. 3. The film refractive index at 633 nm was estimated at 1.25, *i.e.* < 1.48 for pure silica.

Bilayer thicknesses from QCM, SEM and ellipsometry for films assembled on different substrates agree very well (Table 1). Average density of SiO_2/PDDA multilayers is $<\rho>$ = 1.43 ± 0.05 g cm^{-3}. To calculate the silica packing coefficient in the

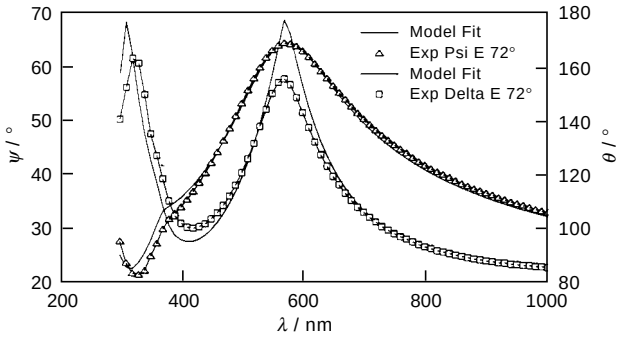

Fig. 3 Ellipsometric measurements of {PDDA + (45 nm SiO_2/PDDA)$_7$} film thickness on silicon wafer: ψ and θ values of the film at 72° incidence and the model fit (see text). Lorentz oscillator constants were determined simultaneously with thicknesses (Table 1) as Am 1.2 = 240 ± 6, Br1.2 = 1.9 ± 0.2, En1.2 = 20.5 ± 0.3.

films, we assumed that the dry film consists of SiO_2, PDDA and air-filled pores. The mass ratio for PDDA to PDDA/SiO_2 is 100 Hz/1300 Hz = 0.077. Taking into account component densities[14] ($<\rho>$ = 1.43, ρ_{SiO_2} = 2.2 and ρ_{PDDA} = 1.1 g cm^{-3}) we obtain the volume ratio $V_{PDDA}/V_{bilayer}$ = 0.1. From the equation $\rho_{PDDA}\,V_{PDDA} + \rho_{SiO_2}\,V_{SiO_2} + \rho_{air}\,V_{air} = <\rho>\,V$, where the air-term is very small, V_{SiO_2}/V = 0.6. This is very close to the theoretical dense-packing coefficient for spheres (0.63), and corresponds to details in the SEM micrographs. SiO_2/PDDA film volume composition is: 60% SiO_2 + 10% polycation + 30% air-filled pores. These pores are formed by closely packed 45 nm SiO_2 and have a typical dimension of 20 nm. The films have controlled pores which could be varied by the choice of nanoparticle diameter.

We estimate the diffusion limitation for surface coverage $A(t)$ by adsorption from solution of particles with diffusion coefficient D[4,17] from $A(t) = 2/\pi C(Dt)^{1/2}$. For t = 2 s, C = 10 mg cm^{-3} and assuming for 45 nm silica $D = 1.1 \times 10^{-7}$ cm^2 s^{-1},[18] $A \approx 3 \times 10^{-6}$ g cm^{-2} and the layer thickness $L = A(t)/<\rho> \approx$ 21 nm. This is reasonably close to the experimental silica layer thickness of 24.6 nm. Thus, 2 s corresponds roughly to the diffusion limited time for SiO_2 monolayer adsorption.

Similar estimates for diffusion limits on PDDA show that in 20 s a hundred monolayers could be delivered to the surface. 20 s does not correspond to diffusion limited adsorption. Hence, conformational changes upon adsorption probably govern the time needed to make uniform monolayers. The mechanism of PDDA relaxation is not clear, but sample drying speeds the process. Relevant ideas about kinetics of polycation adsorption on a charged surface have been discussed.[19]

Molecular Prussian Blue analogues: synthesis and structure of cubic $Cr_4Co_4(CN)_{12}$ and $Co_8(CN)_{12}$ clusters

Julie L. Heinrich, Polly A. Berseth and Jeffrey R. Long*†

Department of Chemistry, University of California, Berkeley, CA 94720 USA

Reactions between $[M(H_2O)_3(tacn)]^{3+}$ (M = Cr, Co) and $[Co(CN)_3(tacn)]$ are demonstrated to produce the molecular box clusters $[Cr_4Co_4(CN)_{12}(tacn)_8]^{12+}$ and $[Co_8(CN)_{12}(tacn)_8]^{12+}$ with core structures consisting of a single cubic unit excised from the Prussian Blue type framework.

The venerable solid pigment Prussian Blue, $Fe^{III}_4[Fe^{II}(CN)_6]_3{\cdot}zH_2O$, is readily prepared by addition of iron(III) ions to an aqueous ferrocyanide solution. This reaction can be generalized to include a variety of octahedral hexaaquo and hexacyano transition metal complexes which combine under similar conditions to form an extensive family of Prussian Blue type compounds:[1,2]

$$x[M(H_2O)_6]^{y+} + y[M'(CN)_6]^{x-} \rightarrow M_x[M'(CN)_6]_y{\cdot}zH_2O \quad (1)$$

The three-dimensional structures adopted by these compounds are based on a simple cubic lattice of alternating metal atoms M and M′ connected *via* linear M′–CN–M linkages. Characteristic of the framework are the cubic cavities demarcated by $M_4M'_4(CN)_{12}$ cages and capable of lodging small neutral molecules or charge-compensating monovalent cations. Such resident species can ordinarily be displaced or exchanged without disrupting the metal–cyanide host framework, giving rise to a range of molecular sieve, ion exchange and catalytic properties.[2–5] In addition, the bridging cyanide ligand is capable of mediating magnetic exchange between neighboring metal centers, and recognition of how the choice of M and M′ can influence the strength of the exchange has enabled the design of bulk magnetic materials with increasingly higher ordering temperatures.[6–9] Recent work has shown how the magnetic properties of these materials can be adjusted electro- and photochemically.[10–11]

In an effort to extend this remarkably diverse chemistry to a molecular level, we have initiated experiments directed toward the preparation of discrete cluster analogues of the cubic cages inherent to the Prussian Blue type structure. Our synthetic approach closely parallels that employed in eqn. (1), relying upon M′–CN–M bridge formation *via* displacement of water by the nitrogen end of cyanide:

$$4[M(H_2O)_3(tacn)]^{y+} + 4[M'(CN)_3(tacn)]^{x-} \rightarrow [M_4M'_4(CN)_{12}(tacn)_8]^{4(y-x)+} \quad (2)$$

Now, however, the tridentate ligand 1,4,7-triazacyclononane (tacn) blocks a single face on each of the transition metal reactants, preventing growth of the three-dimensional framework. Rather, it is proposed that the molecules will assemble into a compact cluster, $[M_4M'_4(CN)_{12}(tacn)_8]^{4(y-x)+}$, consisting of a cube of metal atoms with each edge spanned by a cyanide bridge and each corner capped by a tacn ligand. Herein, we report the initial use of this strategy to construct two such molecular Prussian Blue analogues.

A pink equimolar solution of $[Cr(H_2O)_3(tacn)][CF_3SO_3]_3$[12] and $[Co(CN)_3(tacn)]$[13] in water was boiled to dryness to give an orange residue. The residue was dissolved in a 1 : 1 mixture of acetonitrile and ethyl acetate; careful addition of diethyl ether then permitted separation of a pale orange solid suspension from an orange oil. The solid was collected, washed with ether, and dried to give $[Cr_4Co_4(CN)_{12}(tacn)_8][CF_3SO_3]_{12}{\cdot}8H_2O$ **1** in 46% yield.‡ The IR spectrum of **1** exhibits a single sharp absorption at ν_{CN} = 2177 cm^{-1}, consistent with the symmetry (T_d, ignoring tacn ligand conformations) of the expected cubic cluster. Furthermore, the direction and magnitude of the shift in energy of this absorption relative to that of the $[Co(CN)_3(tacn)]$ precursor (ν_{CN} 2129 cm^{-1}) is characteristic of M′–CN–M bridge formation,[1] and correlates well with the analogous shift from $K_3[Co(CN)_6]$ (ν_{CN} 2126 cm^{-1}) to $Cr[Co(CN)_6]$ (ν_{CN} 2186 cm^{-1}).[14] The positive ion electrospray mass spectrum of **1** confirms the presence of the $[Cr_4Co_4(CN)_{12}(tacn)_8]^{12+}$ cluster, which displays a fragmentation pattern attributable to successive losses of $[Cr(tacn)]^{3+}$ and/or $[Co(CN)_3(tacn)]$ moieties. Crystals of **1** obtained by numerous different methods invariably produced only very broad X-ray diffraction peaks at low θ angles, indicative of poor long-range ordering (presumably due to the many possible similar-energy configurations for packing twelve triflate anions per cluster cation). In the course of these experiments, a solitary crystal of superior quality was encountered and determined by single crystal X-ray analysis to contain a square cluster of formula $[Cr_2Co_2(CN)_6(Me_2SO)_2(tacn)_4]^{6+}$. Apparently, in this particular preparation, a residual amount of dimethyl sulfoxide lingering from the synthesis of $[Cr(H_2O)_3(tacn)][CF_3SO_3]_3$ served to block two of the Cr sites from further reacting to produce a cube.

Cluster preparations involving anions other than triflate were undertaken in hope that an alternative anion shape might promote formation of more rigorously ordered crystals. The compound $[Co_8(CN)_{12}(tacn)_8][OTs]_{12}{\cdot}14H_2O$ **2** was synthesized in 86% yield§ using a procedure similar to that described above. Yellow rectangular plate crystals were grown by allowing a methanol solution of **2** to slowly evaporate. X-Ray analysis¶ revealed the structure of the anticipated cluster with a cubic $Co_8(CN)_{12}$ core (Fig. 1). This cluster, with its novel boxlike geometry,‖ may be regarded as a three-dimensional extension of the above square cluster, as well as previously reported square clusters, such as $[Au_4(CN)_4Pr^n_8]$[18] and the more recent 'supramolecular' squares constructed using a variety of neutral bridging ligands.[19] On average, the clusters measure 4.937(7) Å on a cube edge, slightly smaller than the corresponding cage dimensions of 5.083 and 5.105 Å observed in Prussian Blue[16] and $Co^{II}_3[Co^{III}(CN)_6]_2{\cdot}12H_2O$[17] (to our knowledge, there is no known Prussian Blue analogue containing exclusively Co^{III}), respectively, at ambient temperature. The cyanide ligands spanning each edge deviate slightly (but irregularly) from linearity, as reflected in the Co–C–N and Co–N–C angles, which fall within the range 175(1)–180(1)°. Oxygen atoms from a single tosylate anion are positioned over each of the six cube faces in the crystal. No appreciable build-up of electron density was observed inside the cluster cavity; however, in view of the poor quality of the diffraction data, this does not exclude the possibility that a solvent molecule is present. Square openings (Fig. 2) on the cube faces could potentially permit entry by a guest molecule or ion. Based on the van der Waals radii of carbon and nitrogen, the minimum width of these openings is 1.7 Å, and the minimum diameter of the internal cavity is 3.7 Å. The high positive charge associated with the cubic cage should impart a strong preference for anion

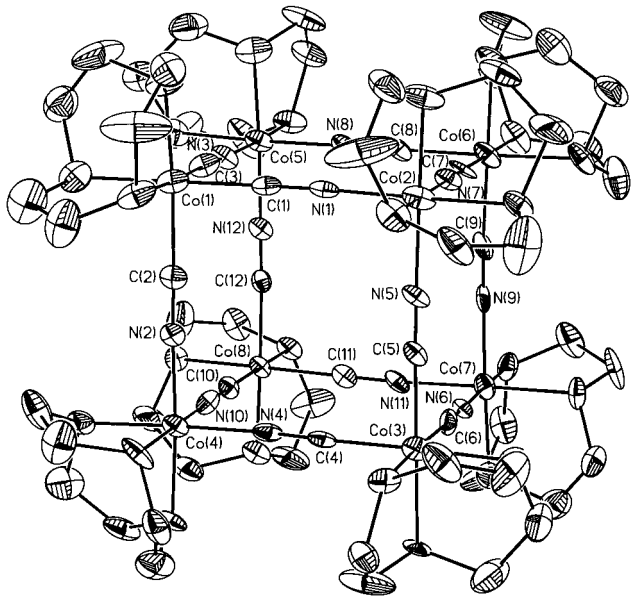

Fig. 1 Structure of the cubic $[Co_8(CN)_{12}(tacn)_8]^{12+}$ cluster in **2** showing 30% probability ellipsoids and the core atom labeling scheme. One orientation of the cyanide ligands is shown;¶ hydrogen atoms are omitted for clarity. Selected mean interatomic distances (Å) and angles (°) (X is a cyanide C or N atom): Co–X 1.89(2), Co–N 1.94(2), X–X 1.15(3), Co···Co 4.937(7); X–Co–X 89.9(7), Co–X–X 178(1), N–Co–X 92.0(9), N–Co–N 86.2(8).

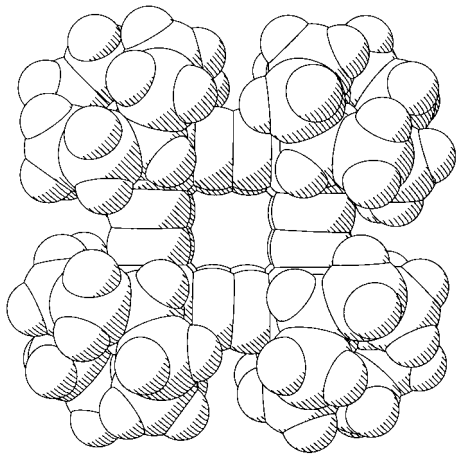

Fig. 2 Space filling model of the $[Co_8(CN)_{12}(tacn)_8]^{12+}$ cluster (including hydrogen atoms) viewed down a cube face

incorporation, as opposed to the cation affinity displayed by Prussian Blue type solids.[2–4]

By varying the metal atoms M and M′ employed in eqn. (2), we hope to produce an array of cubic cluster magnets with a variability in properties comparable to that which has evolved in Prussian Blue type materials.[6–11] The $[Cr_4Co_4(CN)_{12}(tacn)_8]^{12+}$ cluster represents an initial member in this array, possessing four Cr^{III} ions arranged in a tetrahedron over the cube vertices [replacing atoms Co(2), Co(4), Co(5) and Co(7) in Fig. 1] and separated by intervening diamagnetic Co^{III} ions. The temperature dependence of the magnetic susceptibility of **1** was measured using a SQUID magnetometer; a fit of the data to the Curie–Weiss law gives $C = 6.78$ emu K mol^{-1} and $\Theta = 1.21$ K. The effective magnetic moment of 7.5(1) μ_B and associated g value of 1.97 are reasonable for four isolated $S = 3/2$ Cr^{III} ions per cluster molecule.

Investigations further probing the magnetism, electrochemistry, and inclusion properties of these and related molecular Prussian Blue analogues are in progress.

This research was funded by the University of California and NSF Grant No. CHE 97-27410. We thank Dr R. Hage and Unilever for an initial donation of tacn ligand, N. Crawford, M. Shores, Dr J. P. Kirby, Professor J. Leary, Dr U. Andersen and Dr S. Koenig for experimental assistance, Professor J. McCusker for helpful discussions, Professor A. Stacy for use of the SQUID magnetometer and Professor T. D. Tilley for use of the IR spectrometer.

¶ *Crystal data*: $C_{144}H_{224}Co_8N_{36}O_{46}S_{12}$, $M = 4123.82$, monoclinic, space group $P2_1/n$, $Z = 4$, $a = 15.1773(2)$, $b = 36.0654(2)$, $c = 34.5918(4)$ Å, $\beta = 91.337(1)°$, $V = 18929.5(3)$ Å^3, $\mu = 0.900$ mm^{-1}. Data ($2 < 2\theta < 46°$) were collected at 135 K using a Siemens SMART diffractometer with graphite monochromated Mo-Kα radiation. The structure was solved by direct methods with the aid of successive difference Fourier maps, and was refined in three overlapping blocks against all data (26910 unique) using SHELXTL 5.0. The clusters are disordered over two externally indistinguishable orientations (one is shown in Fig. 1), in which only the positions of the cyanide C and N atoms are reversed; an occupancy factor of 0.5C + 0.5N was assigned to each of the cyanide atom sites. (In view of the substitutional inertness of Co^{III} and the sharpness of the ν_{CN} peak in the IR spectrum, it is unlikely that the cyanide bridges have reoriented in the individual cluster molecules.) Ten of the twelve tosylate anions are disordered over at least two positions, and were modeled accordingly. The final agreement factors $R_1 = 0.1476$ and $wR_2 = 0.3882$ are high due to the extensive anion disorder present in the crystal and the accompanying poor data quality. CCDC 182/855.

‖ An abstract reporting the synthesis of related $M_8(CN)_{12}$ (M = Co, Rh) clusters capped by cyclopentadienyl ligands recently appeared.[15]

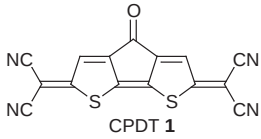
Crystal structures and electrical conducting properties of the first molecular metals based on a novel electron acceptor, 4-oxo-2,6-bis(dicyanomethylene)-2,6-dihydrocyclopentadithiophene (CPDT)

Kazuko Takahashi*† and Shinji Tarutani

Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan

A novel electron acceptor CPDT has been synthesized; the Fermi surfaces of the metallic anion radical salts of CPDT are purely one-dimensional, while the acceptor molecules form rigid and tight two-dimensional networks in the crystal structures of the salts.

Electron-accepting molecules with three terminal electron-withdrawing groups appear to be promising components for organic conductors because they would have high electron accepting abilities as well as highly rigid and coplanar conformations, giving stable anion radicals and dianions owing to the effective conjugation of the three terminal groups.[1] We have now designed and successfully synthesized such a novel acceptor molecule, 4-oxo-2,6-bis(dicyanomethylene)-2,6-dihydrocyclopenta[2,1-*b*;3,4-*b*′]dithiophene (CPDT) **1**. Further-



CPDT **1**

more, we have obtained metallic anion radical salts of **1** and have clarified the conducting properties and crystal structures of the metallic salts. These are the first examples of molecular metals of the heterophene–TCNQ family.[2]

CPDT was synthesized starting from the ketal **2**[3] (Scheme 1). CPDT‡ is reduced reversibly in three successive one-electron transfer reactions to give the stable anion radical, dianion and trianion radical species which demonstrate, by cyclic voltammetry, three pairs of single-electron redox waves with good reversibility at half-wave reduction potentials of +0.04, −0.27 and −1.43 V (*vs.* SCE in CH_2Cl_2 at 25 °C). The first reduction potential is more positive by 0.18 V than that of **4** (−0.14 V). The log K_{sem} value[4] of CPDT (5.26) is larger by 1.36 than that of **4** (3.90), indicating that the anion radical of CPDT is thermodynamically stabilized by delocalization of the unpaired electron over the three terminal electron-accepting groups.

Interestingly, the crystalline anion radical salts $(Me_4N)[CPDT]_2$, $(Et_4N)[CPDT]_2$, $(Me_4P)[CPDT]_2$ and $(Me_4As)[CPDT]_2$, prepared by electrochemical reduction, are metallic at room temperature and their conductivities reach maximum values (σ_{max}) of 170, 290, 55 and 55 S cm^{-1} at the $T_{\sigma max}$ values listed in Table 1. $T_{\sigma max}$ becomes lower as the size of the counter cation in these four salts is increased. Below $T_{\sigma max}$, the metallic states

Table 1 Properties of anion radical salts of CPDT

Cation	Ratio[a]	σ_{rt}[b]/S cm^{-1}	$T_{\sigma max}$/K	T_{MI}/K
Me_4N	1 : 2	160	250	130
Et_4N	1 : 2	260	220	150
Me_4P	1 : 2	47	215	165
Me_4As	1 : 2	42	173	173–185

[a] By elemental analysis. [b] Measured by four probe method on a single crystal.

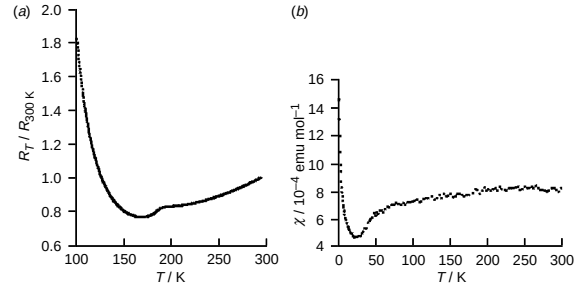

Fig. 1 Temperature dependence of (*a*) the resistivity and (*b*) the magnetic susceptibility of $(Me_4As)[CPDT]_2$

gradually become unstable, and drastic decreases in the conductivities with the transition to the semiconducting phases occurred at *ca.* 130 K for the Me_4N salt, 150 K for the Et_4N salt, 165 K for the Me_4P salt and 173–185 K for the Me_4As salt [Table 1 and Fig. 1(*a*)]. The metallic properties were also confirmed by the temperature dependence of the magnetic susceptibility measurement using a SQUID susceptometer [Fig. 1(*b*)]. The magnetic susceptibilities of the Me_4N and Me_4As salts are invariable from room temperature down to T_{DIA} = 135 and 50 K, respectively, which are regarded as Pauli-like, and decrease drastically at these temperatures with the transition to the diamagnetic phases. The phase transition mechanisms seem to be significantly different from each other, although the crystal structures are isomorphous, as described below. Occurrence of the Peierls type transition is suggested in the Me_4N salt, since T_{MI} is almost identical with T_{DIA}. However, in the Me_4As salt, the magnetic susceptibility does not decrease even after the M–I transition has occurred [Fig. 1(*b*)], and the magnitude of the magnetic susceptibility of the Me_4As salt (8×10^{-4} emu mol^{-1}) is significantly large when compared with those of ordinal molecular metals. These phenomena suggest the existence of a $4k_F$ charge density wave (CDW) growing phase[5] at the temperature region between 150 (T_{MI}) and 50 K (T_{DIA}) in the Me_4As salt.

The crystal structures of the metallic salts $(Me_4N)[CPDT]_2$, $(Me_4P)[CPDT]_2$ and $(Me_4As)[CPDT]_2$, which are isomorphous with each other, were determined by X-ray analysis.§ The unit cell contains four crystallographically equivalent acceptor molecules and two equivalent cations, giving a cation to acceptor ratio of 1 : 2. The formal charge on CPDT is −0.5. The unit cell contains two acceptor columns stacking along the *b*-axis and each column is separated by a cation layer [Fig. 2(*a*)].

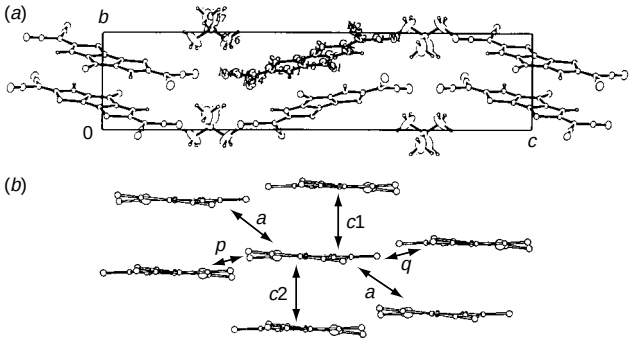

Fig. 2 Crystal structure of $Me_4N[CPDT]_2$: (*a*) projection onto the *bc*-plane and (*b*) overlap mode viewed along the acceptor short axis

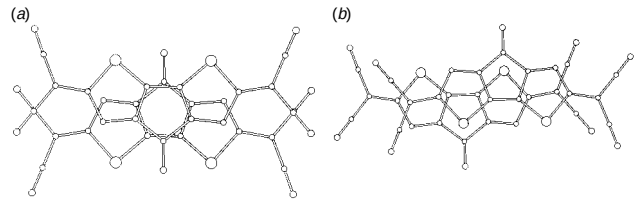

Fig. 3 Overlaping modes of CPDT molecules in $(Me_4N)[CPDT]_2$: (*a*) intra-dimer overlap, (*b*) inter-dimer overlap

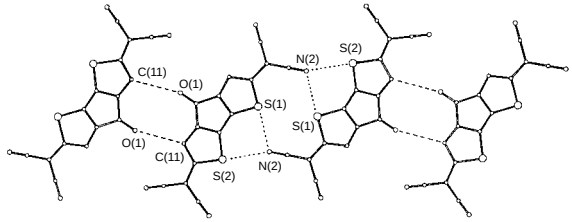

Fig. 4 Side-by-side interaction of CPDT in $(Me_4N)[CPDT]_2$

The acceptor column is constituted by weakly dimerised CPDT molecules with intra-dimer interplanar distances of 3.20–3.21 Å [*c*1 in Fig. 2(*b*)] and inter-dimer interplanar distances of 3.32–3.33 Å [*c*2 in Fig. 2(*b*)]. The overlapping mode is the so-called 'ring-over-ring' type in the intra-dimer overlap and the 'ring-over-bond' type in the inter-dimer overlap (Fig. 3). Interestingly, there are two S1–N2 (3.01–2.97 Å) and two S2–N2 (3.04–2.99 Å) contacts, and there are two short intermolecular hydrogen bonds between O1···H11 (3.25–3.28 Å) along the acceptor short axis in the crystal structures of these salts (Fig. 4). Thus rigid and tight two-dimensional layered intermolecular networks are constructed along the *ab*-plane.

The intermolecular overlap integrals of the metallic salts are summarized in Table 2. There is no significant difference between *c*1 and *c*2, which indicates that the degree of the dimerization is very weak in these salts. On the other hand, the overlap integrals along the acceptor shot axis are less than 1/300 of *c*1 or *c*2 (Table 2), in spite of the existence of the inter-column S–N and O–H contacts. This is ascribed to the extremely small π-atomic orbital coefficients of the O and the S

Table 2 Intermolecular overlap integrals (*S*) of the anion radical salts[a]

	$S/10^{-3}$		
Overlap direction[b]	Me_4N salt	Me_4P salt	Me_4As salt
*c*1 (intra-dimer)	−19.65	−18.83	−18.83
*c*2 (intra-dimer)	16.53	14.37	15.14
a (inter-column)	0.0744	0.0559	0.0713
p (S1–N2 contact)	0.00429	0.0913	0.00393
q (O1–H11 contact)	0.00672	0.0104	0.0260

[a] Calculated with π-atomic orbital coefficients obtained by the extended Hückel MO method using bond angles and bond lengths obtained from the X-ray analysis. [b] The overlap directions are indicated in Fig. 2(*b*).

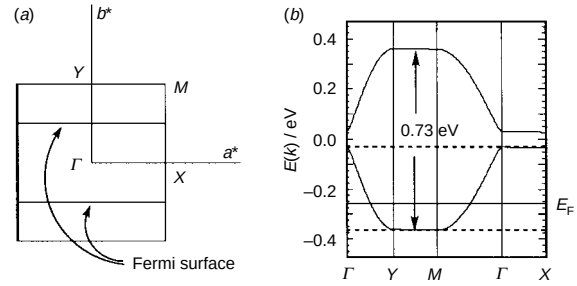

Fig. 5 (*a*) Fermi surface and (*b*) band structure of $(Me_4N)[CPDT]_2$, calculated by the tight binding approximation method

atoms in the LUMO of CPDT. From the tight-binding band calculations[6] using the overlap integrals shown in Table 2, it is demonstrated that these salts have highly one-dimensional Fermi surfaces opened along the *a**-axis [Fig. 5(*a*)]. These salts have a split band structure due to their dimerized crystal structures and the lower energy band is half filled [Fig. 5(*b*)]. The calculated band widths are 0.73, 0.67 and 0.68 eV in the Me_4N, Me_4P and Me_4As salts, respectively. The phase transition of the Me_4N salt at 130 K appears to be caused by a Peierls transition, since salts with a large band width can obtain a large energy benefit by forming the band gap.

Reaction of [Ti(NBu^t)Cl_2(py)$_3$] with $K_2[C_8H_8]$ gave the monomeric, pseudo-two-coordinate complex [Ti(η⁸-C_8H_8)(NBu^t)] 1 which has been crystallographically characterised; the electronic structure of 1 has been investigated using density functional theory calculations and gas phase photoelectron spectroscopy.

As part of an ongoing programme in titanium–imido chemistry we found that the compound [Ti(NBu^t)Cl_2(py)$_3$] provides a useful synthetic entry to a range of sandwich, half-sandwich and other new titanium imido compounds.[1] We noticed that although cyclopentadienyl and, to a lesser extent, arene coligands have been widely used in transition metal imido chemistry,[2] there has been only one report of imido complexes bearing cyclooctatetraenyl coligands, namely the dinuclear μ-arylimido derivatives [M_2(η⁸-C_8H_8)$_2$(μ-$NC_6H_3Pr^i_2$-2,6)$_2$] (M = Zr, Hf).[3] We were therefore interested to see if using the smaller titanium congener would lead to a mononuclear derivative. Here we describe the synthesis and molecular and electronic structure of the cyclooctatetraenyltitanium imido complex [Ti(η⁸-C_8H_8)(NBu^t)] **1**.

Addition of 1 equiv. of $K_2[C_8H_8]$ to [Ti(NBu^t)Cl_2(py)$_3$] in THF at −50 °C gave a dark red solution. Standard workup and crystallisation from pentane gave [Ti(η⁸-C_8H_8)(NBu^t)] **1** as a spectroscopically pure, dark yellow powder in 68% yield. Compound **1** is highly air- and moisture-sensitive, and its ^{1}H and ^{13}C NMR spectra contain signals attributable to a *tert*-butylimido ligand and an octahapto-coordinated C_8H_8 ring. Crystals of **1** suitable for X-ray diffraction analysis could be obtained by careful tube sublimation at 90–100 °C, 5×10^{-6} mbar.‡ The solid state structure of **1** is shown in Fig. 1. The Ti=NBu^t and Ti···C_8H_8 (ring centroid) distances of 1.699(6) and 1.369 Å are normal for terminal titanium-*tert*-butylimido and titanium(IV)-η⁸-cyclooctatetraenyl complexes, respectively.[4] The near-linearity of the Ti=N–Bu^t angle [Ti(1)–N(1)–C(1) 177.1(5)°] is consistent with the imido ligand acting as a four-electron donor to the titanium centre (*vide infra*), giving an overall metal valence-electron count of 16.

The pseudo-two-coordinate, 'one-legged piano stool' geometry for **1** is unique in early transition metal imido and cyclooctatetraenyl ligand chemistry.[2,5] A search of the Cambridge Structural Database[4] for complexes of the type [Ti(η⁸-C_8H_8)(L)$_n$] showed that the formal value of *n* is at least three. As mentioned, there has been only one report of imido complexes bearing cyclooctatetraenyl coligands, these being dinuclear.[3] The molecular structure of [Ti(η⁸-C_8H_8)(NBu^t)] is apparently related to those of the 18 valence electron, later transition metal compounds [Os(η⁶-C_6Me_6)(NBu^t)],[6a] [Ir(η⁵-C_5Me_5)(NBu^t)],[6b] and [Ni(η⁵-C_5H_5)(NO)].[6c] The bonding in these compounds is analagous to that of mixed ring sandwich compounds[7] as we[8,9] and others[10] have previously analysed.

The gas phase He photoelectron (PE) spectrum§ of [Ti(η⁸-C_8H_8)(NBu^t)] **1** is shown in Fig. 2, and numerical data are summarised in Table 1. Its assignment is made relatively straightforward by comparison with related imido and cyclooctatetraenyl compounds.[7b,8] The apparent paucity of low ionisation energy (IE) bands for **1** is explained by the fact that the e_2 ionisation of the Ti–C_8H_8 ring δ bonding orbitals overlaps with the e_1 ionisation of the Ti–N π bonds producing a complex band centred at 8 eV. Band C at 10.91 eV may be assigned to an e_1 ionisation of the C_8H_8 ring π orbitals. An increase in the intensity of bands A and B relative to C in the He II spectrum indicated that the e_2 and $2e_1$ orbitals that give rise to bands A and B have significant metal character.

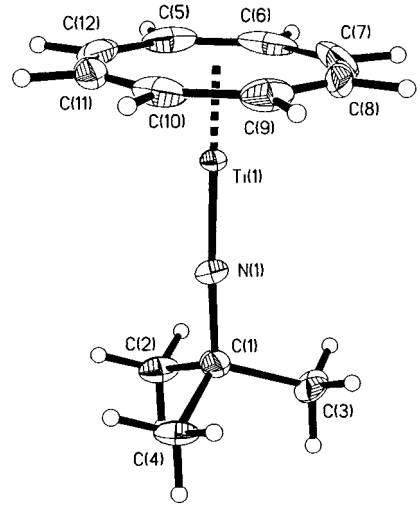

Fig. 1 Displacement ellipsoid plot of [Ti(η⁸-C_8H_8)(NBu^t)] **1**. Hydrogen atoms are drawn as spheres of arbitrary radius. Displacement ellipsoids are drawn at the 40% probability level. Selected bond lengths (Å) and angles (°): Ti(1)–N(1) 1.699(6), Ti(1)–$C_{average}$ 2.280 [range 2.267(8) to 2.290(8)], Ti(1)···C_8(centroid) 1.369; Ti(1)–N(1)–C(1) 177.1(5), C_8(centroid)–Ti(1)–N(1) 179.3.

An interesting comparison may be made with the 17 valence electron, d^1 compound [Ti(η⁸-C_8H_8)(η⁵-C_5Me_5)].[7b] In the PE spectrum of this compound there is an additional low-lying ionisation band of the extra d electron at 5.28 eV, but the e_2 and $2e_1$ bands are also found to be coincident with a maximum at

Table 1 Comparison of calculated ionisation energies (eV) and bond lengths (Å) for **1** and [Ti(η^8-C_8H_8)(NH)], **2**, with experimental values for **1**

	1 (exptl.)	**1** (calc.)	**2** (calc.)
Ionisation energies			
$1e_2$	7.78 (A)	7.70	8.16
$2e_1$	8.05 (B)	7.88	8.91
$1e_1$	10.91 (C)	[a]	10.83
Bond lengths			
Ti–C	2.267(8)–2.290(8)	2.282	2.275
Ti–N	1.699(6)	1.689	1.683
C–C ring	1.37(2)–1.44(2)	1.409	1.408
Bu^t	1.51(1)–1.52(1)	1.519	

[a] SCF convergence not achieved for this ion state.

7.54 eV. Furthermore, the $1e_1$ band lies at 10.5 eV, which is of a very similar energy to that for **1**. Thus we may conclude that the cyclopentadienyl–imido analogy[8] holds for these compounds and that *tert*-butylimido is electronically similar to the pentamethylcyclopentadienyl ligand though it provides one less electron.

Density functional calculations[11] were used to optimise the geometry of **1**.¶ C_s symmetry was assumed but in addition parameters were fixed so that the Ti-ring fragment had C_{8v} symmetry and the N–Bu^t fragment C_{3v} symmetry. Calculated bond lengths and angles are compared with the experimental ones in Table 1 which shows that the agreement is very good. Calculation of IEs‖ for **1** proved difficult because of the low symmetry and the proximity of ion states of identical symmetry. IE calculations were therefore also carried out on [Ti(η^8-C_8H_8)(NH)] **2** as a model for **1**. C_{8v} symmetry was assumed throughout these calculations. The calculated IEs for both **1** and **2** are given in Table 1 along with experimental values for **1**. The *tert*-butyl substituent has a bigger effect on the $2e_1$ IE than the e_2 EI. The closeness of the two ion states means that their exact assignment is uncertain.

Isosurfaces for these two orbitals (e_2 and $2e_1$) together with those for the $1e_1$ and the a_1 N–Ti σ-bonding orbital are shown in Fig. 3. Mulliken population analysis of the ground state structure of **1** gives the Ti contribution to the $2e_1$ and e_2 orbitals as 26% and 21%, while that of $1e_1$ is estimated as 8%. This is consistent with the intensity increase of bands A + B relative to C as the photon energy is increased. The most striking aspect of the metal ligand bonding orbitals is that binding to the imido group is through σ and π orbitals whereas that to the C_8H_8 ring is virtually exclusively through δ symmetry orbitals. This is in contrast to bis-cyclopentadienyl metal complexes where both rings compete for the metal π symmetry orbitals.

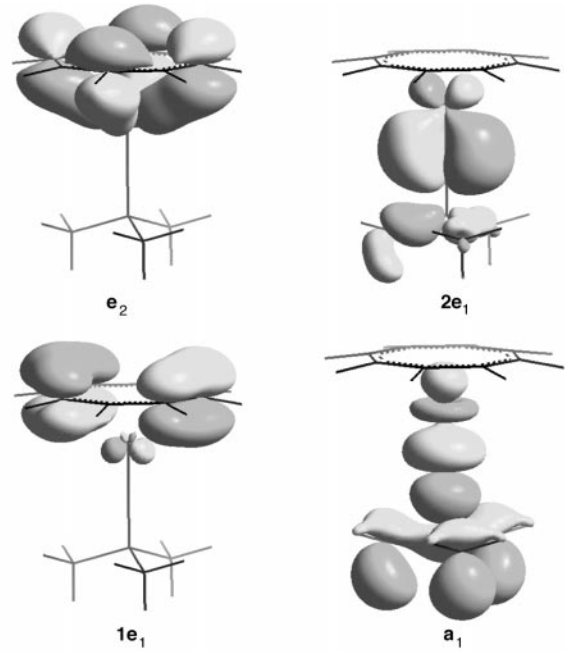

Fig. 3 Isosurfaces for the e_2, $2e_1$, $1e_1$ and M–N a_1 orbitals of **1** (see http://www.rsc.org/suppdata/cc/1998/1235 for a full colour version of this figure)

In conclusion, we have firmly established a new class of early transition metal cyclooctatetraenyl and imido complexes through structural, spectroscopic and theoretical studies. Recent preliminary studies suggest that the Ti=NBu^t linkage in **1** is reactive towards a range of organic substrates. Our work in this area and syntheses of other early transition metal cyclooctatetraenyl–imido complexes are continuing.

§ PE spectra were measured using a PES Laboratories 0078 spectrometer and were calibrated with N_2, Xe and He.

¶ Calculations were performed using the density functional methods of the Amsterdam Density Functional (ADF) code Version 2.3.0.[11] The basis set used triple-ζ accuracy sets of Slater orbitals with a single polarisation function added to main group atoms, 2p on H, 3p on C and N. Cores of the atoms were frozen, (C 1s, N 1s and Ti 3p). Vosko, Wilk and Nusair's local exchange correlation potential[12] was employed with non-local exchange corrections by Becke[13] and non-local correlation corrections by Perdew.[14] Vertical ionisation energies were estimated by calculating the energy of the molecular ion, with identical geometry to the optimised structure for the molecule, in its ground and low lying excited states and subtracting the energy of the molecular ground state.

Linked arene clusters

Brian F. G. Johnson,* Caroline M. Martin and Paul Schooler

University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW

The synthesis, isolation and characterisation of a number of [2$_n$]cyclophane transition metal clusters with nuclearities ranging from four to twelve atoms is described. The primary objective of this work has been to prepare molecules composed of alternating cyclophane and cluster subunits which may be considered as precursors to novel organometallic polymer chains and networks. This aim has been achieved to a certain degree using the [2.2.2]paracyclophane ligand, which has been shown to interact with metal clusters (*e.g.* tetracobalt nonacarbonyl) *via* all three of its aromatic rings. Also, the dimerisation of a hexaruthenium-[2.2.2]paracyclophane complex has yielded a remarkable dodecanuclear bis-arene cluster which may form the basis for a novel linear polymeric chain containing only metal atoms in the backbone. We have also been able to demonstrate that the coordinated [2.2.2]paracyclophane unit is able to embrace metal ions such as Ga^{I} and Ag^{I} giving rise to a concomitant change in the observed IR spectrum of the attached cluster. This perspective highlights these areas of research and also examines the factors controlling coordination mode preferences of the [2$_n$]cyclophane ligand and the central cluster nuclearity and geometry.

The interaction between both transition and main group metal ions with a variety of [2$_n$]cyclophane ligands has been of considerable interest to chemists for several decades.[1] These complexes were initially prepared in order to explore the unusual properties exhibited by the [2$_n$]cyclophane ligands which stem from the overlap of their π molecular orbitals and give rise to highly unique electronic and structural effects.[2] More recently, however, interest has been further stimulated by the potential for the [2$_n$]cyclophane ligands to serve as bridging units between redox-active metal centres in organometallic polymers and networks. Materials of this type are expected to exhibit a wide range of potentially interesting electrical and non-linear optical properties.[3]

The graphitic interaction

Over the past few years we have been actively involved in the study of organometallic cluster complexes, in particular, those containing coordinated arene ring systems.[4] The work described in this article was initially stimulated by the trends that emerged from a detailed examination of the solid-state structures of a number of bis-arene clusters of the type $[Ru_6C(CO)_{11}(arene)_2]$.[5] These investigations revealed an overwhelming tendency for the organic rings to become interlocked thus forming layers of organic substrate interspersed by layers of cluster units. Such layering was invariably found to be a result of the face-to-face (although typically off-centred) arrangement of aromatic ligands in adjacent molecules at distances comparable to that obeserved in graphite. It was also discovered that these packing interactions are propagated throughout the entire solid and result in the formation of supramolecular chains and stacks.[5]

This study revealed that it was primarily the difference in bonding mode adopted by the arene ligands (η^6 or μ_3) combined with their arrangement around the metallic core (*cis* or *trans*) that determined the packing motif within the crystal structure. For example, the two isomeric clusters *trans*-$[Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_6)_2]$ **1** and $[Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_6)(\mu_3\text{-}\eta^2:\eta^2\text{-}C_6H_6)]$ **2** adopt different packing regimes in the solid-state (Fig. 1). In **1**, the molecules are arranged in long columnar structures with an interarene separation of 3.52 Å [Fig. 1(*a*)].[6]

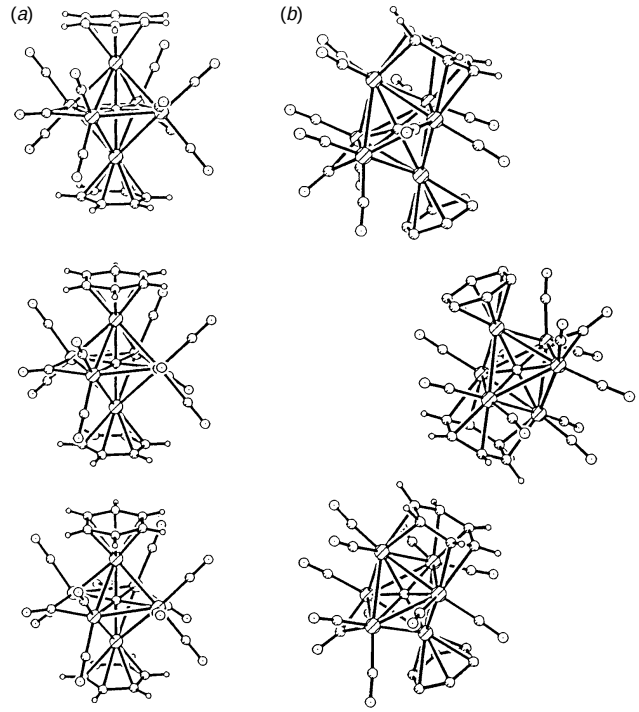

Fig. 1 Solid state packing of (*a*) $[Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_6)_2]$ **1** as rods; and of (*b*) $[Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_6)(\mu_3\text{-}\eta^2:\eta^2\text{-}C_6H_6)]$ **2** as snakes

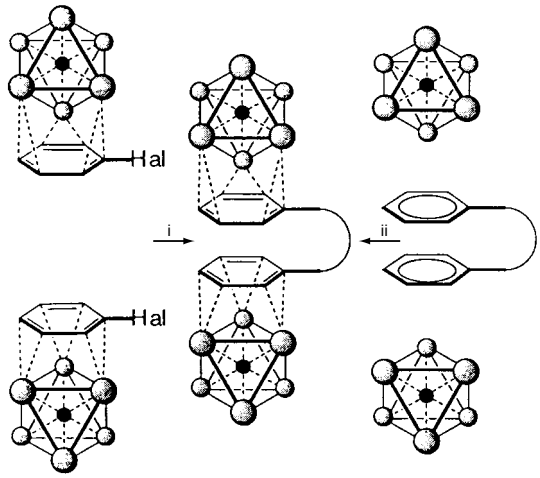
Such a macromolecular structure arises from the arrangement of the arene rings which lie in parallel planes on the central cluster unit and permit the formation of a linear supramolecular rod. In **2**, however, the arene ligands are carried in planes which meet at a dihedral angle of 45°. As would be expected, this results in the introduction of kinks in the columnar structures producing supramolecular snakes instead [Fig. 1(*b*)].[7] In compound **2**, it should also be noted that the only close interactions observed between adjacent molecules in the crystal structure occur between η^6–η^6 bound rings and μ_3–μ_3 bound rings at distances of 3.29 and 3.56 Å, respectively. Although η^6–μ_3 interactions are known for other arene clusters, such as in the crystal structure of $[Os_3(CO)_6(C_6H_6)_2]$,[8] none are observed in that of compound **2**.

The study of these arene–arene interactions is of fundamental importance. This is because it is through such interactions that a mechanism in which charge transfer may occur throughout the crystalline lattice may be envisaged. Furthermore, one could speculate that it may be possible to create strong chemical bridges between adjacent arene clusters thus generating novel two-dimensional polymeric cluster chains and three-dimensional networks. It was with these ideas in mind that the class of ligands known as the cyclophanes, with their unique combina-

tion of strong chemical bridges linking aromatic rings and ability to transfer charge through space from one arene ring to the next within the same molecule, were considered as highly appropriate cluster linking groups.[9]

Linking arene clusters: the cyclophanes

There are two fundamentally different approaches which may be taken in order to produce linked arene clusters. The first involves the generation and subsequent coupling of activated arene clusters, while the second involves the addition of clusters to a pre-linked arene ligand (Scheme 1). The first approach has



Scheme 1 The two principal routes to arene cluster linkage: i, cluster addition before coupling; ii, coupling before cluster addition

proved to be extremely difficult. In this case, the linkage of two arenes involves the initial preparation of halogenated arene cluster derivatives which are then coupled by the use of a reagent such as sodium metal. Such halogenated arene ligands are known to undergo C–halogen bond cleavage upon heating with transition metal carbonyls,[10] while attempting to halogenate the arene whilst coordinated to the cluster is difficult because transition metal carbonyl clusters are usually insufficiently robust to survive the harsh reaction conditions required. It should be noted, however, that the coupling of chromium tricarbonyl arene complexes has been successfully achieved and therefore the possiblity of linking arene clusters in an analogous manner cannot be entirely excluded. In these chromium compounds, the metal may be considered to remove π electron density from the bonded arene and thereby permit the face-to-face coupling of the fragments with enhanced yield.[11] In principle, these effects should be even greater if arene clusters can be coupled in the same way.

The more attractive approach is to use pre-linked arene ligands. Following a review of the literature, it was decided that the [2_n]cyclophanes would be an ideal class of ligand for our purpose.[12] These are a family of molecules whose structures generally consist of stacked aromatic rings held in close proximity by ethano bridges. They are rigid, well defined, and moderately accessible by relatively simple synthetic procedures. Typically, they possess strained molecular structures due to the strength of the electronic repulsions between the arene rings, and they have unusual electronic properties which stem from an 'end-on' overlap of π electron density giving essentially a single π-electron system. As mentioned earlier, this overlap should provide the additional possibility of electronic communication between bridged cluster units. Cyclophane linkages that may act as one, two or three-dimensional connectors such as [2.2]paracyclophane,[13] [2.2.2]paracyclophane,[14] and tetramesitylene[15] respectively, are currently available (Fig. 2). An example of how one can envisage such ligands being used in the construction of supramolecular networks is illustrated in Fig. 3 for the [2.2.2]paracyclophane

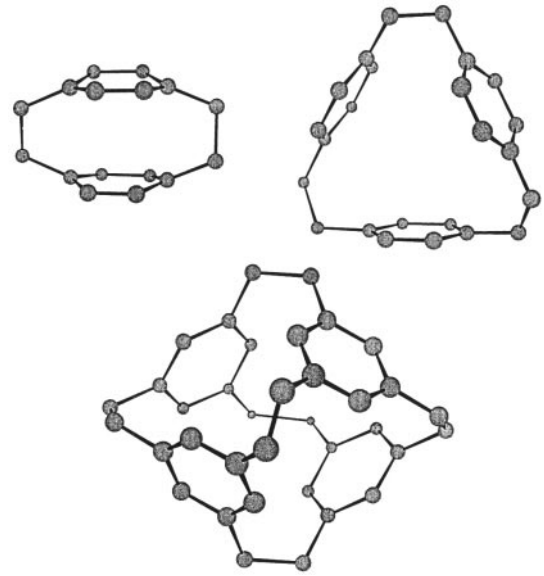


Fig. 2 The molecular structures of [2.2]paracyclophane (top left), [2.2.2]paracyclophane (top right) and tetramesitylene (bottom), respectively

ligand. In this case the triangular ligand can be seen to participate in the formation of hexagonal arrays in analogy to graphite with transition metal clusters forming the edges and cyclophane ligands the nodes.

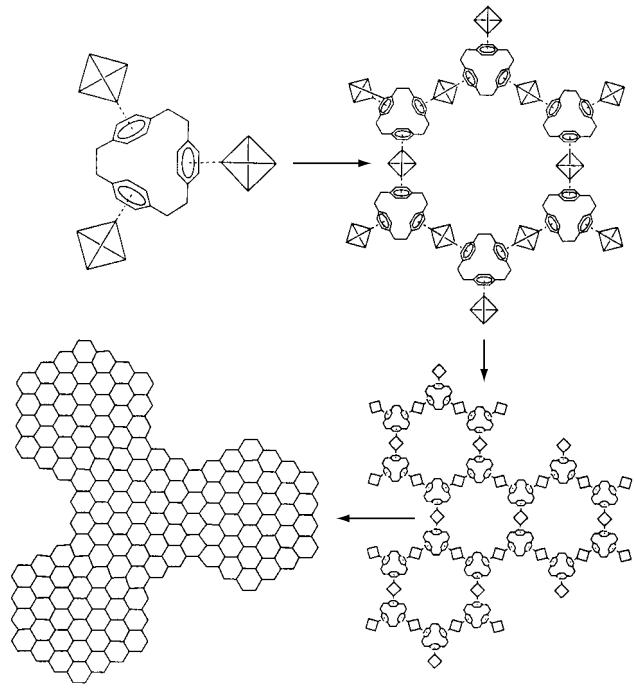

Fig. 3 The construction of a supramolecular hexagonal two-dimensional network using metal centres linked by the [2.2.2]paracyclophane ligand

[2.2]Paracyclophane clusters

Research in this area was initiated using the simplest of the [2_n]cyclophane ligands, [2.2]paracyclophane. The cluster chemistry of [2.2]paracyclophane has recently been reviewed,[16] and therefore only a short account will appear here. [2.2]Paracyclophane carbonyl clusters of ruthenium with nuclearities between two[17] and eight[18] have been structurally characterised and shown to display arene bonding modes ranging from η^6, to μ_2-η^3:η^3 and μ_3-η^2:η^2:η^2.[17–19] There is, however, a marked

tendency for the [2.2]paracyclophane to adopt the facial μ_3 coordination mode, and this is particularly apparent in the hexaruthenium carbido cluster $[Ru_6C(CO)_{14}(arene)]$ where the simpler arenes (benzene, toluene, xylene and mesitylene) tend to adopt the apical η^6 mode.[20] This effect is also apparent from work on the redox coupling reaction of $[Ru_5C(CO)_{14}]^{2-}$ and $[(C_{16}H_{16})Ru(NCMe)_3]^{2+}$ in which the cyclophane ligand, initially bound in an η^6 manner to a single metal atom, migrates during the course of the reaction to produce $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_{16}H_{16})]$ in which the ligand is bound to a triangular metal face.[21]

It is evident, however, that none of the [2.2]paracyclophane compounds observed to date contain separate cluster moieties linked through a cyclophane unit. The reason for this is believed to originate from the through-space resonance effect within the ligand, whereby the electron-withdrawing nature of the cluster attached to one ring deactivates the second uncoordinated ring toward further cluster association. This effect appears to be so large that even single metal fragments such as chromium tricarbonyl will not coordinate to the second ring, and instead, complete displacement of the cluster occurs with the formation of $[Cr(CO)_3(C_{16}H_{16})]$. Therefore, the aims of more recent work have been to achieve cluster linkage using substituted or alternative types of $[2_n]$cyclophane ligand.

Isomerisation and substitution effects

An important aspect of this work is to consider how the nature of the ligand influences the bonding mode adopted upon coordination to a metal cluster. Hence, an investigation into how different bridge substituted [2.2]cyclophanes effect cluster coordination patterns was undertaken. The molecular structures of two isomeric cluster species, $[Ru_6C(CO)_{14}(p\text{-}C_{16}H_{16})]$ **3** and $[Ru_6C(CO)_{14}(m\text{-}C_{16}H_{16})]$ **4**, have been determined by X-ray diffraction and a third, $[Ru_6C(CO)_{14}(o\text{-}C_{16}H_{16})]$ **5**, inferred by spectroscopy (Fig. 4).[20,22] The *para*-substituted ligand is found

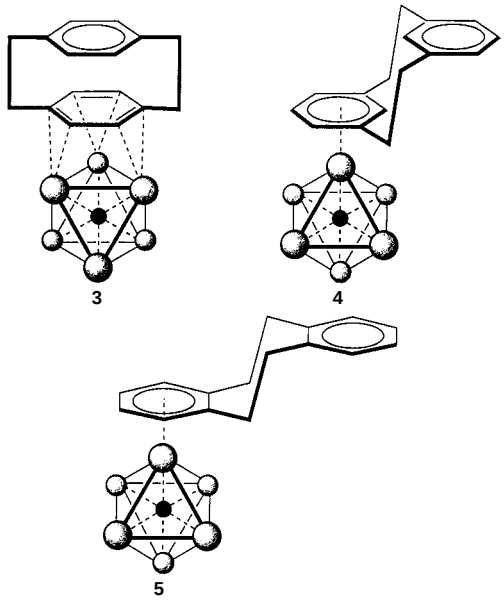

Fig. 4 The structures of three isomeric hexaruthenium [2.2]cyclophane clusters

to adopt a facial μ_3 coordination mode upon the hexaruthenium carbido core, while the *meta*- and *ortho*-isomers prefer to adopt the η^6 bonding mode, interacting with a single metal atom only. There are two possible explanations for this behaviour. Firstly, it may be due to the superior donor capability of [2.2]paracyclophane over [2.2]meta- and [2.2]orthocyclophane, whereby the extensive overlap of π molecular orbitals in the *para*-isomer allows for sufficient supply of electron density for the three metal atoms.[23] There is little, if any, overlap of π molecular orbitals in the *meta*- and *ortho*-isomers and hence, they can be envisaged as only being able to support a single metal atom. This effect has been demonstrated electrochemically for $[Ru_6C(CO)_{14}(C_{16}H_{16})]$, whereby the *para*-isomer is far more difficult to reduce than either the *meta*- or *ortho*-isomers (-0.937, -0.893 and -0.890 V, respectively). Alternatively, the difference in coordination mode may be explained by the inherent distortion of the aromatic rings within the cyclophanes themselves (Fig. 5).[24] In [2.2]paracyclophane, the aromatic

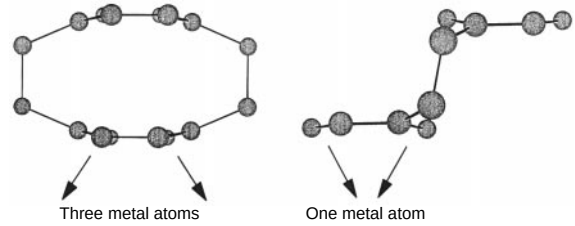

Fig. 5 The molecular structure of (left) [2.2]paracyclophane compared with (right) [2.2]metacyclophane.

rings are convex, bulging outwards from the centre of the molecule due to inter-arene repulsion. Thus, in [2.2]paracyclophane the π orbitals are oriented outwards in such a way that they would be expected to interact more effectively with a trimetallic face than a single metal atom. However, in the *meta*-isomer the aromatic rings are concave, with the π orbitals oriented towards a focal point and thus the ligand is predisposed to interact with only a single metal atom. Furthermore, the distortion of the rings in both [2.2]para- and [2.2]metacyclophanes cause the aromatic C–H bonds to bend out of the plane. In [2.2]paracyclophane this occurs such that the C–H bonds point toward the centre of the molecule and in [2.2]metacyclophane such that they point away. Since the C–H bonds bend away from the underlying metal triangle in, for example $[Os_3(CO)_9(\mu_3\text{-}C_6H_6)]$,[25] it is therefore unsurprising that [2.2]paracyclophane adopts the facial bonding mode on the hexaruthenium cluster. Similarly, since the C–H bonds point toward the metal atom in mononuclear arene complexes it is not surprising either that the [2.2]metacyclophane ligand adopts an apical bonding mode.[26] In [2.2]orthophane the aromatic rings are planar and therefore presumably the preference of this ligand for the apical η^6 mode is not as strong as that of the *meta*-isomer.[27]

Asymmetry

Since [2.2]paracyclophane interacts with metal clusters differently to its monoarene analogue, *para*-xylene,[20] it also seemed important to question whether [2.2]paracyclophane ligands bearing substituents upon their aromatic rings would interact differently from their monomeric analogues; and in cases where this substitution was not symmetrical, it would also be of interest to establish which ring the cluster unit would prefer to coordinate. In this regard, an investigation into the interaction of several ring-substituted [2.2]paracyclophane ligands with ruthenium carbonyl clusters has been carried out; the result of which is illustrated in Fig. 6.[28] It has been shown that the cluster unit always coordinates to the amine substituted ring of the 4-amino[2.2]paracyclophane ligand,[29] whereas it coordinates to the unsubstituted ring of 4-bromo[2.2]paracyclophane.[30] This behaviour may be explained in terms of the relative activating or deactivating effect of the substituents. The amino substituent is thought to push electron density onto the ring, thus making it more activated toward cluster association (as demonstrated by the planar geometry of the nitrogen). In fact, a closer analysis of the metal–ligand interface in $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^1:\eta^2:\eta^2\text{-}C_{16}H_{15}NH_2)]$ **6** suggests that the metal triangle interacts with only five aromatic carbon atoms (Fig. 7); the sixth (that attached to the nitrogen atom) remaining uncoordinated, possibly because it possesses insufficient electron density. The octahedral cluster retains the required electron count of 86 if the

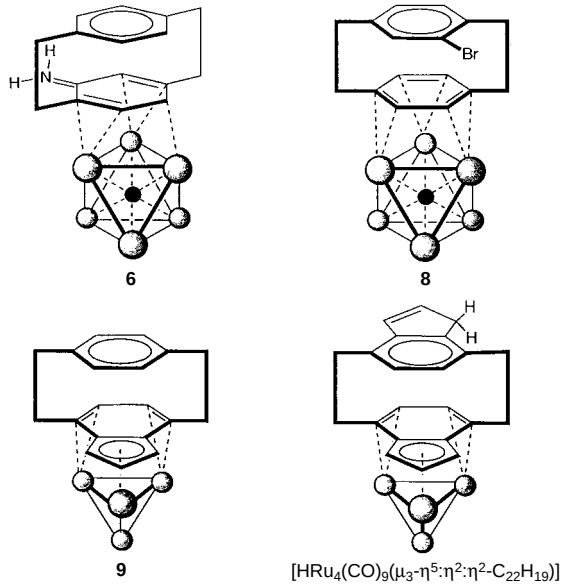

Fig. 6 The structures of some ring-substituted [2.2]paracyclophane ruthenium clusters: the 4-amino[2.2]paracyclophane cluster $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^1:\eta^2:\eta^2\text{-}C_{16}H_{15}NH_2)]$ **6**; the 4-bromo[2.2]paracyclophane cluster $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_{16}H_{15}Br)]$ **8**; the [2.2]parabenzoindenophane cluster $[HRu_4(CO)_9(\mu_3\text{-}\eta^5:\eta^2:\eta^2\text{-}C_{19}H_{17})]$ **9**; and the *anti*-[2,2]paraindenophane cluster $[HRu_4(CO)_9(\mu_3\text{-}\eta^5:\eta^2:\eta^2\text{-}C_{22}H_{19})]$

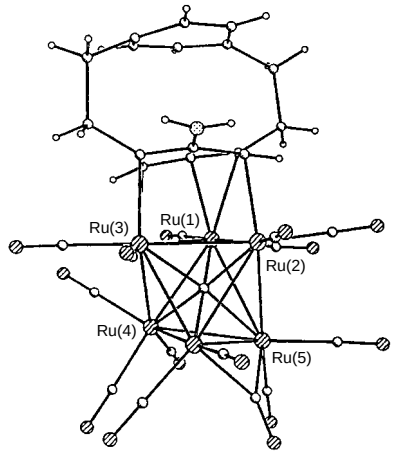

Fig. 7 The molecular structure of $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^1:\eta^2:\eta^2\text{-}C_{16}H_{15}NH_2)]$ **6**

substituted cyclophane is considered as a six electron donating dienyl ligand. It should be noted that this complex, to our knowledge, is the only example of an aniline ring coordinated to a cluster *via* its aromatic ring; other aromatic amine containing compounds such as 2,5-dimethylaniline yield N–H bond activated species only, *e.g.* as with the compound $[HRu_3(CO)_{10}(C_6H_3Me_2NH)]$ **7** (Fig. 8).[31] Presumably 4-amino-[2.2]paracyclophane cannot form such a compound because of the steric constraints imposed by the second aromatic ring.

In contrast, the bromo substituent in $[Ru_6C(CO)_{14}(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_{16}H_{15}Br)]$ **8**, is thought to deactivate the ring toward cluster coordination by pulling electron density away from it, and hence the cluster coordinates to the unsubstituted ring by default. Again this compound is unusual because contrary to the comments made above, the C–Br bond does not undergo oxidative-cleavage. In this example the resistance to C–Br cleavage is probably because the cyclophane unit blocks the path to an aryne or 'cyclophyne' type cluster.[32]

These results suggest that the cluster exerts a significant directing influence upon the substitution chemistry of a coordinated cyclophane ligand. From this, it may be further concluded that the coordinated ring, in for example $[Ru_6C(CO)_{14}(p\text{-}C_{16}H_{16})]$ **3**, should be activated towards nucleophilic attack in aromatic substitution reactions, whereas the uncoordinated ring should be more susceptible to electrophilic attack by default. Hence, in aromatic substitution reactions which employ mild conditions (that is conditions mild enough for the metal clusters to survive such as in the reaction of $[Ru_6C(CO)_{14}(C_6H_6)]$ with phenyllithium[33]), such clusters could be used to prepare unusually substituted [2.2]paracyclophane compounds not easily accessible *via* alternative routes.

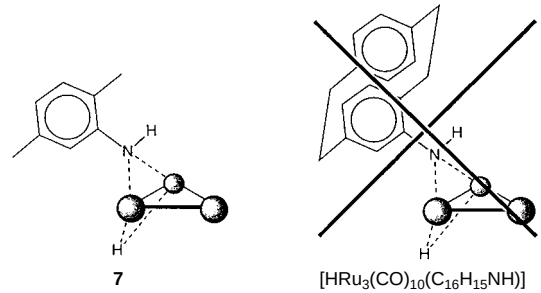

Fig. 8 The structure of the N–H activated cluster $[HRu_3(CO)_{10}(C_6H_3Me_2NH)]$ **7** formed from 2,5-dimethylaniline. 4-Amino-[2.2]paracyclophane does not form an analogous compound, probably due to steric reasons.

Finally, the interaction of the [2.2]parabenzoindenophane[34] and *anti*-[2.2]paraindenophane[35] ligands with transition metal clusters has been investigated in collaboration with Prof. Henning Hopf of Braunschweig, Germany (Fig. 6). Although the former ligand possesses both a benzene and an indene face, it has been found that cluster coordination occurs only *via* the condensed indene face as in, for example, the tetranuclear cluster $[HRu_4(CO)_9(C_{19}H_{17})]$ **9** (Fig. 9). Here the ligand

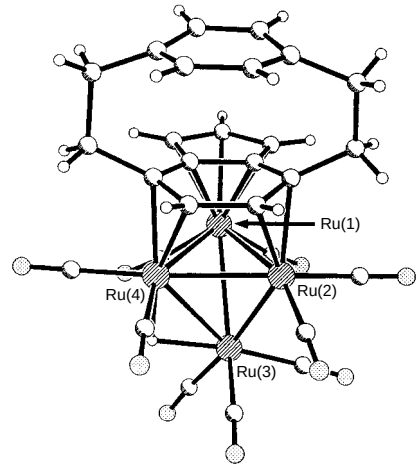

Fig. 9 The molecular structure of $[HRu_4(CO)_9(\mu_3\text{-}\eta^5:\eta^2:\eta^2\text{-}C_{19}H_{17})]$ **9**

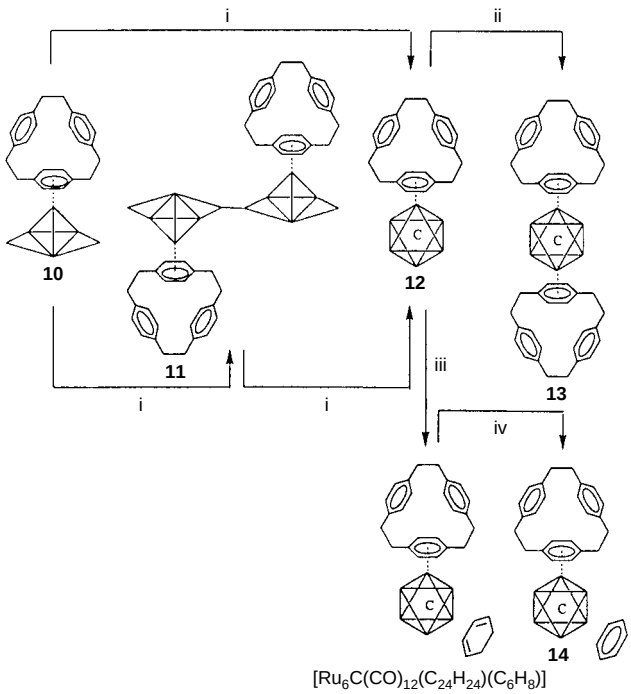
undergoes C–H bond activation which converts the cyclopentadiene ring to a cyclopentadienyl system; as such the cluster coordinates to the ring that is richest in π electron density *via* an η^9-(cyclopentadienyl–diene) interaction. Despite this predisposition of the indene face in [2.2]parabenzoindenophane, *anti*-[2.2]paraindenophane has also been shown to bond to only one cluster unit even though it possesses two indene rings suitable for cluster coordination (Fig. 6). This again is probably due to through space deactivation effects. All attempts to add monometallic fragments such as $[Mo(CO)_4]^+$ and $[FeCp]^+$ to the second cyclopentadiene ring, or to link these *anti*-[2.2]indenophane ruthenium carbonyl clusters by reaction with $FeCl_2{\cdot}2thf$ have so far been unsuccessful.[36]

The interaction of [2.2.2]paracyclophane with ruthenium carbonyl clusters

[2.2.2]Paracyclophane does not yield the diverse range of products observed for [2.2]paracyclophane when reacted with

$[Ru_3(CO)_{12}]$ under similar reaction conditions.[16] Instead, the thermolysis of [2.2.2]paracyclophane with 3 molar equiv. of $[Ru_3(CO)_{12}]$ in octane under reflux over a 6 h period affords just three new complexes: $[Ru_6(CO)_{15}(\eta^6\text{-}C_{24}H_{24})]$ **10** (5%), $[Ru_{12}(CO)_{28}(\eta^6\text{-}C_{24}H_{24})_2]$ **11** ($\approx$0.1%) and $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]$ **12** (30%) (Scheme 2).[37] These may be readily



Scheme 2 Routes to some [2.2.2]paracyclophane ruthenium clusters. *Reagents and conditions*: i, $[Ru_3(CO)_{12}]$, heat in octane; ii, $C_{24}H_{24}$, heat in nonane; iii, cyclohexa-1,3-diene with 2.2 equiv. Me_3NO in CH_2Cl_2; and iv, heat in hexane or 1.1 equiv. Me_3NO in CH_2Cl_2.

separated by thin layer chromatography on silica using dichloromethane–hexane (1 : 2, v/v) as eluent. In each of these compounds the central cluster unit is based on a hexanuclear metal framework but of differing geometries. In compound **10**, the metal atoms are arranged as a doubly edge-bridged tetrahedron (an 88 valence electron cluster). By analogy to the mesitylene complex, $[Ru_6(CO)_{15}(\eta^6\text{-}C_6H_3Me_3)]$,[38] the arene ligand in compound **10** is coordinated in an η^6 manner to the apex of the central tetrahedron that is not involved in edge-bridging, and a dihapto (η^2-μ_4) carbonyl ligand is located in each of the butterfly sites. This compound may be converted by heating in octane to the octahedral hexaruthenium carbido cluster, $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]$ **12**, in which the arene again coordinates to a single metal atom. An intermediate compound, $[Ru_{12}(CO)_{28}(\eta^6\text{-}C_{24}H_{24})_2]$ **11**, is also isolated in trace amounts during this conversion, and the molecular structure of this compound **11** is shown in Fig. 10. It is formally a dodeca-ruthenium bis-arene cluster, which makes it the largest arene cluster prepared by our group to date. This molecule contains a fused bis-(doubly edge-bridged tetrahedron) metallic framework in which ten of the metal atoms are essentially coplanar—all those except the two that carry the cyclophane ligands. It is easy to envisage the process by which compound **11** may be derived from **10** by the simple removal of a single carbonyl ligand from one of the edge-bridging metal atoms and the dimerisation of the resultant unsaturated species to produce the 174 valence electron cluster. The two hexaruthenium units of this cluster are related by an inversion centre and the linking metal–metal bond is located between two edge-bridging metal atoms. Two of the carbonyl ligands which were terminal at the edge-bridging metal atom in compound **10** migrate to a bridging position, possibly in order to stabilise the new linkage in compound **11**. Despite the change of the local arrangement of

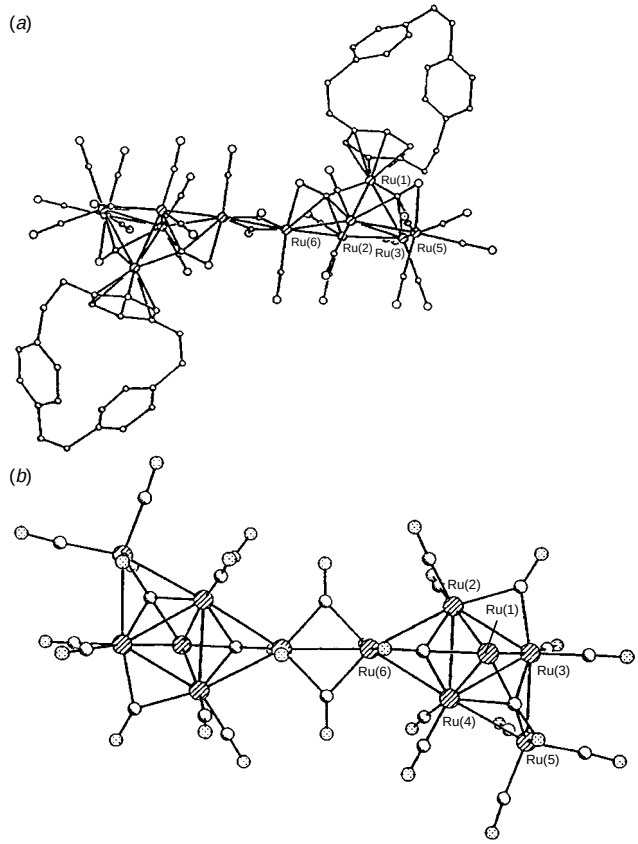


Fig. 10 The molecular structure of $[Ru_{12}(CO)_{28}(\eta^6\text{-}C_{24}H_{24})_2]$ **11**, with (*a*) and without (*b*) the [2.2.2]paracyclophane ligands, respectively

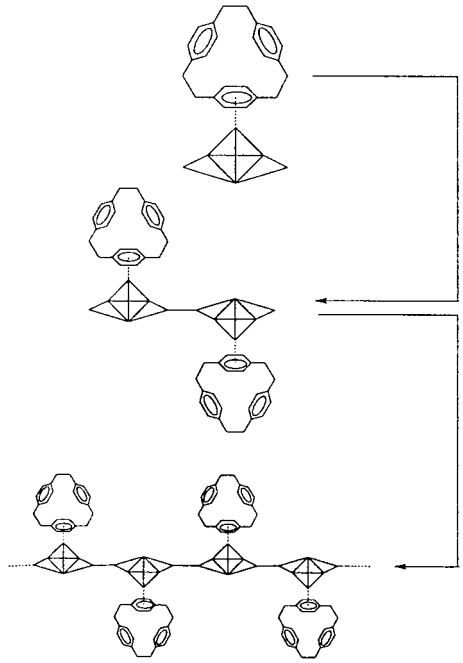
carbonyl ligands at the linkage, the η^2-μ_4-CO ligands are retained in the four butterfly sites of compound **11**.

Since compounds **10** and **11** both possess two edge bridging metal atoms, and compound **10** can dimerise to form compound **11** upon the loss of a carbonyl ligand, it should be possible, at least in principle, for further oligomerisation to occur such that a polymeric material based solely on a metal backbone could be prepared (Scheme 3). However, as yet all attempts to induce further oligomerisation by thermal, chemical or photolytic means have resulted in the now well established closure of the metallic core[39] to form the octahedral hexaruthenium carbido cyclophane cluster $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]$ **12**. It should also be noted that the loss of a carbonyl ligand from the cluster, followed by dimerisation of the resulting unsaturated fragments, as observed in the conversion of **10** to **11**, also provides a mechanism to explain the unexpected and generally observed irreversibility of arene cluster reductions during cyclic voltammetry.

An additional arene ligand may also be introduced onto the monocyclophane hexaruthenium carbido cluster **12**. The reaction of compound **12** with an excess of [2.2.2]paracyclophane in refluxing nonane yields the *trans*-bis-arene derivative $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})_2]$ **13**, while a related mixed arene cluster, $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})(\mu_3\text{-}\eta^2 : \eta^2\text{-}C_6H_6)]$ **14**, in which the cyclophane ligand adopts an apical mode and the benzene ligand a facial bonding mode (Fig. 11 and Scheme 2), is obtained from the reaction of **12** with cyclohexadiene and trimethylamine *N*-oxide.[40] Compounds **13** and **14** are of particular relevance to our objective of preparing organometallic network precursors since the cluster acts as a bridge between two arene ligands here.

The [2.2.2]paracyclophane ligand has also been shown to undergo reaction with $[Ru_5C(CO)_{15}]$, and the cluster $[Ru_5C(CO)_{12}(\eta^6\text{-}C_{24}H_{24})]$ **15** is the sole product formed during thermolysis in heptane.[37] In this compound, the cyclophane replaces all three carbonyl ligands on one basal metal atom of



Scheme 3 The dimerisation of $[Ru_6(CO)_{15}(\eta^6\text{-}C_{24}H_{24})]$ **10** to $[Ru_{12}(CO)_{28}(\eta^6\text{-}C_{24}H_{24})_2]$ **11** and the hypothetical metal based polymer $[Ru_6(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]_n$

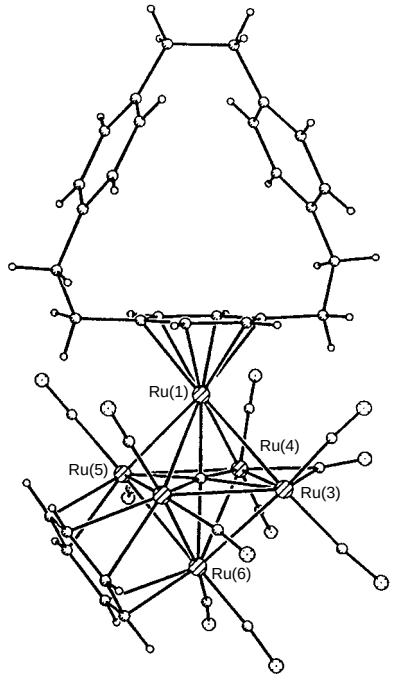


Fig. 11 The molecular structure of $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_6H_6)]$ **14**

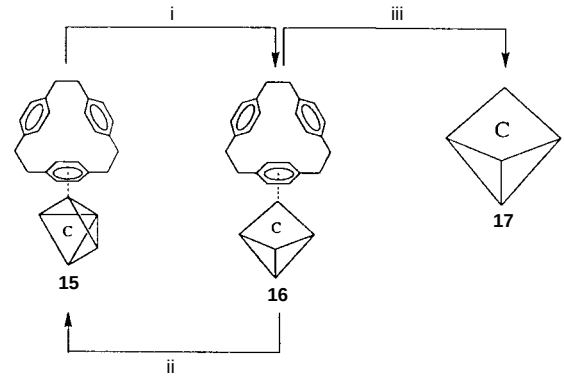
the parent square pyramidal cluster. Under an atmosphere of carbon monoxide, compound **15** undergoes the reversible addition of a carbonyl ligand to form the bridged butterfly complex, $[Ru_5C(CO)_{13}(\eta^6\text{-}C_{24}H_{24})]$ **16** (Scheme 4). This is thought to occur by a mechanism similar to that observed for the analogous benzene cluster, *i.e.* by the coordination of a carbonyl ligand at the metal carrying the arene (formally that richest in electron density) with the concomitant breakage of a base–apex metal–metal bond.[41] However, the unrivalled degree of isomerism displayed by the benzene analogue is not displayed by the [2.2.2]paracyclophane complex (benzene can not only adopt the basal-η^6 bonding mode upon the square pyramidal cluster $[Ru_5C(CO)_{12}]$, but also the apical-η^6 and facial μ_3 modes).[42] Instead, continuous exposure to a carbon monoxide atmosphere



Scheme 4 The reactivity of $[Ru_5C(CO)_{12}(\eta^6\text{-}C_{24}H_{24})]$ **15**. *Reagents and conditions*: i, CO bubble in CH_2Cl_2 over 5 min; ii, N_2 bubble in CH_2Cl_2; iii, 1 atm CO over CH_2Cl_2 for 1 day.

causes compound **16** to release the cyclophane ligand and form the binary cluster, $[Ru_5C(CO)_{16}]$ **17**. Compound **17** possesses the same bridged butterfly metal geometry as the analogous osmium cluster.[43]

A correlation between the chemical shifts of coordinated and uncoordinated aromatic ring protons in ruthenium–[2.2]paracyclophane clusters of differing nuclearities and bonding modes has been discussed in detail elsewhere.[16] This family of ruthenium–[2.2.2]paracyclophane clusters also show marked trends in their ^{1}H NMR spectra as illustrated in Table 1. It

Table 1 ^{1}H NMR characteristics of several ruthenium [2.2.2)paracyclophane clusters

	Compound	M : CO ratio	Mean δ of bound aromatic protons	Mean δ of free aromatic protons
10	$[Ru_6(CO)_{15}(C_{24}H_{24})]$	2.50	5.82	6.82
15	$[Ru_5C(CO)_{12}(C_{24}H_{24})]$	2.40	5.54	6.83
12	$[Ru_6C(CO)_{14}(C_{24}H_{24})]$	2.33	5.25	6.74
14	$[Ru_6C(CO)_{11}(C_{24}H_{24})(C_6H_6)]$	1.83	5.26	6.76
13	$[Ru_6C(CO)_{11}(C_{24}H_{24})_2]$	1.83	5.01	6.69

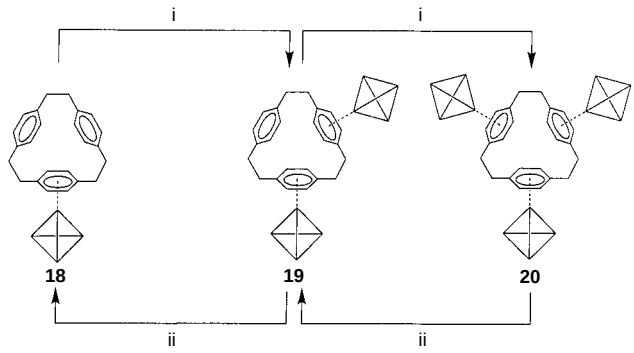
appears that the magnitude of the chemical shift of both the coordinated and free cyclophane rings is somewhat dependent on both the metal to carbonyl ratio of the cluster and, if present, the coordination mode of the second arene ligand. For example, the mean chemical shift of the aromatic protons on the bound ring of the cyclophane moves to higher field as the metal to carbonyl ratio falls and the electron-withdrawing power of the cluster increases. The difference in the chemical shift of the aromatic protons between $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})_2]$ **13** and $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})(\eta_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_6H_6)]$ **14** may be related to the magnitude of interaction between the cyclophane and the cluster. This is weaker for compound **14** because of the influence of the second arene which being in the facial coordination mode is the more tightly bound of the two arene ligands.

The [2.2.2]paracyclophane ligand has been observed only in the apical η^6 bonding mode in ruthenium carbonyl clusters. This is in contrast to [2.2]paracyclophane which tends to adopt the facial μ_3-mode, and again this may possibly be attributed to the observation that the aromatic rings in [2.2.2]paracyclophane adopt a more planar configuration than those in [2.2]paracyclophane.

The interaction of [2.2.2]paracyclophane and cobalt carbonyl clusters

The reaction of [2.2.2]paracyclophane with an excess of $[Co_4(CO)_{12}]$ in hexane, affords three new cluster complexes:

$[Co_4(CO)_9(\eta\text{-}C_{24}H_{24})]$ **18** (20%), $[\{Co_4(CO)_9\}_2(\eta\text{-}C_{24}H_{24})]$ **19** (2%) and $[\{Co_4(CO)_9\}_3(\eta\text{-}C_{24}H_{24})]$ **20** ($\approx$ 0.1%). These may be readily separated by thin layer chromatography on silica using dichloromethane–hexane (1 : 3, v/v) as eluent (Scheme 5).[44]



Scheme 5 The interconversion of compounds $[\{Co_4(CO)_9\}_n(\eta\text{-}C_{24}H_{24})]$ (n = 1, 2 and 3). *Conditions*: i, $[Co_4(CO)_{12}]$, heat in hexane; ii, heat in toluene {clusters removed from cyclophane as $[Co_4(CO)_9(toluene)]$}.

Complex **18** may be conveniently converted to **19** and in turn **19** to **20** by the progressive addition of $[Co_4(CO)_{12}]$ in hexane. Conversely, compound **20** ejects a cluster unit to form **19** and then another to form **18** when heated in toluene. This process occurs *via* arene exchange whereby the metal clusters are transferred from the cyclophane ligand to the toluene forming $[Co_4(CO)_9(\eta^6\text{-}C_6H_5Me)]$. The molecular structures of compounds **18** and **19** have been established by single crystal X-ray diffraction and are shown in Fig. 12(*a*) and (*b*), respectively. In

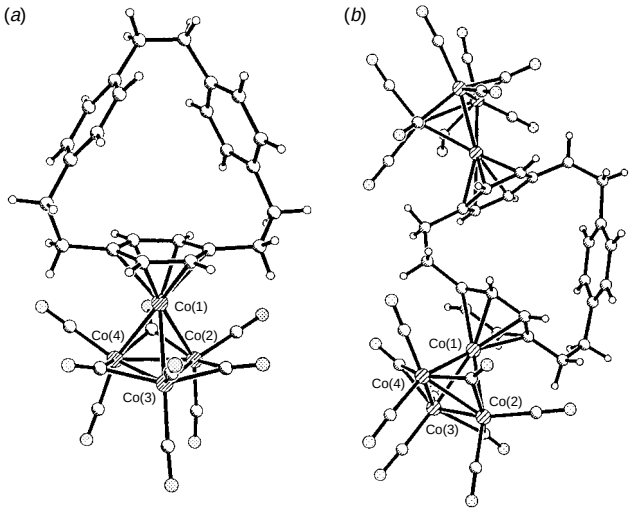


Fig. 12 The crystal structures of (*a*) $[Co_4(CO)_9(\eta\text{-}C_{24}H_{24})]$ **18**; and (*b*) $[\{Co_4(CO)_9\}_2(\eta\text{-}C_{24}H_{24})]$ **19**

both molecules the coordinated rings of the cyclophane ligands are bound to a single metal atom in an η^6-manner and lie parallel to, and staggered with respect to, the more distant underlying metal triangle. Compounds **19** and **20** are the first examples of metal clusters linked by a cyclophane ligand, and are of particular interest as potential precursor sub-units for the construction of one and two-dimensional organometallic networks and polymers discussed above. Furthermore, preliminary electrochemical analyses, although complex, suggest the existence of electronic communication between the metal clusters in compounds **19** and **20**.[44]

The binding of soft metal cations

It has been known for some time that metal atoms and ions may bond to [2.2.2]paracyclophane by *endo*-coordination as well as *exo*-coordination.[45] In *endo*-coordination the metal atom resides in or near the ligand cavity such as in the π cryptates formed with Ga^I and Ag^I salts.[46,47] It has also been possible to demonstrate this effect using the ruthenium [2.2.2]paracyclophane clusters described herein.[37] For example, the addition of either Ga^I or Ag^I salts brings about a considerable change in the IR (carbonyl) spectrum of the parent cluster. This effect may be considered to occur as a consequence of the reduction in the electron density available for carbonyl π back donation which in turn causes a shift of the spectrum to higher wavenumbers. Table 2 illustrates this point for the complexes

Table 2 IR characteristics (carbonyl region) of $[Ru_6C(CO)_{14}(C_{24}H_{24})]$ **12** in the presence and absence of soft metal cations

Compound	Formula	ν_{CO}/cm^{-1} CH_2Cl_2
12	$[Ru_6C(CO)_{14}(C_{24}H_{24})]$	2074, 2023 and 1813
21	$[Ru_6C(CO)_{14}(C_{24}H_{24})Ag][BF_4]$	2084, 2045 and 1878
22	$[Ru_6C(CO)_{14}(C_{24}H_{24})Ga][GaCl_4]$	2089, 2051 and 1894

$[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24}Ag)][BF_4]$ **21** and $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24}Ga)][GaCl_4]$ **22**. A comparison of the IR values of these two compounds with those of the parent cluster $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]$ **12** indicates a clear shift. The magnitude of this shift may be rationalised in terms of the strength of the cation–cyclophane interaction. This is greater for the gallium(I) ion which is thought to be located at the centre of the cyclophane cavity than for silver which only remains at the edge (Fig. 13).[14,46] This behaviour does not extend to the [2.2.2]paracyclophane complexes of cobalt (and even of chromium tricarbonyl) which undergo extensive decomposition on treatment with either Ga^I or Ag^I salts presumably by some redox reaction.

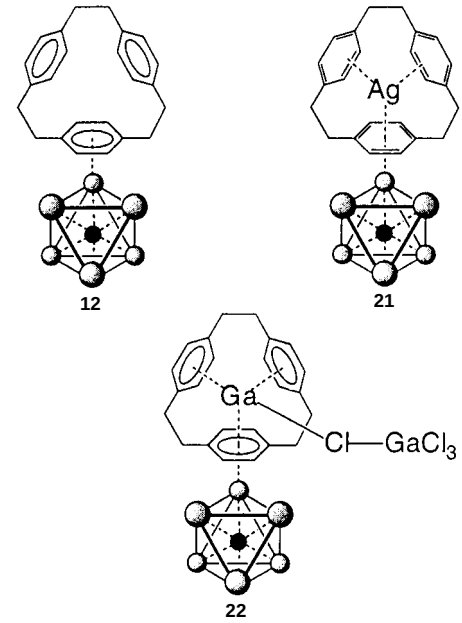

Fig. 13 The binding of Ga^I and Ag^I cations to $[Ru_6C(CO)_{14}(\eta^6\text{-}C_{24}H_{24})]$ **12**

Conclusions

Several novel compounds have been described which will, hopefully, in due course serve as potential building blocks for one- and two-dimensional cluster polymers and networks. These include $[Ru_{12}(CO)_{28}(\eta^6\text{-}C_{24}H_{24})_2]$ **11**, in which there is a metal containing back-bone; $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})_2]$ **13** and $[Ru_6C(CO)_{11}(\eta^6\text{-}C_{24}H_{24})(\mu_3\text{-}\eta^2 : \eta^2 : \eta^2\text{-}C_6H_6)]$ **14**, in which hexaruthenium clusters link two arene ligands together; and

$[\{Co_4(CO)_9\}_2(\eta\text{-}C_{24}H_{24})]$ **19** and $[\{Co_4(CO)_9\}_3(\eta\text{-}C_{24}H_{24})]$ **20**, in which a [2.2.2]paracyclophane bridges two and three tetracobalt clusters, respectively. It should be noted, however, that as yet we have been unable to sustain chain growth in any of these examples. In the case of compound] **11**, the induction of further oligomerisation instead results in conversion to monomeric closed octahedral hexaruthenium carbido clusters. Although it has been possible to prepare ruthenium carbonyl clusters containing two arene ligands it has, so far, proved difficult to introduce a second ruthenium cluster onto the cyclophane ligand. This is thought to be due to the interaction between the cyclophane molecule and the ruthenium cluster being too strong to permit the addition of further metallic units, and the cyclophane being unable to supply sufficient electron density to satisfy two cluster cores. For cobalt, however, each aromatic ring of the [2.2.2]paracyclophane ligand may be utilised in cluster coordination. So far, the introduction of a second cyclophane ligand onto the tetrahedral Co_4 core has been unsuccessful, which is possibly due to the weakness of the metal–arene interaction (as demonstrated by arene exchange reactions with toluene) which permits multiple complexation of clusters by a single ligand, but is too weak to allow the substitution of further carbonyl ligands by a poorer π-accepting cyclophane ligand.

Acknowledgements

We would like to thank the EPSRC, the University of Cambridge and the Newton Trust (P.S.) for financial support. We would also like to thank Prof. Henning Hopf (Technische Universität Braunschweig), Dr Paul J. Dyson (Imperial College, London) and Dr Simon Parsons (University of Edinburgh) for their involvement in this project.

Prof. Brian F. G. Johnson is Professor of Inorganic Chemistry in the Department of Chemistry, the University of Cambridge, Cambridge CB2 1EW. He obtained his PhD from the University of Nottingham (1963). He then spent postdoctoral positions at M.I.T. and the University of Manchester where he became a lecturer (1965). Lectureships were also held at University College London (1967–1970) and the University of Cambridge (1970–1990). He held the Crum Brown Chair of Inorganic Chemistry at the University of Edinburgh (1990–1995) before returning to Cambridge (1995). He was elected as a Fellow of the Royal Society (1991) and Fellow of the Royal Society of Edinburgh (1992).

Dr Caroline M. Martin is an associate lecturer in the Department of Chemistry, the University of Cambridge, Cambridge CB2 1EW. She obtained her PhD from the University of Edinburgh (1994) and she held a postdoctoral fellowship at University College London for one year before moving to her current post (1995).

Paul Schooler is a final year PhD student under the supervision of Prof. Brian F. G. Johnson in the Department of Chemistry, the University of Cambridge, Cambridge, UK CB2 1EW. He will soon take up a postdoctoral position at Texas A.&M. University (October 1998) under the supervision of Prof. F. Albert Cotton.

Universality of LNA-mediated high-affinity nucleic acid recognition

Sanjay K. Singh and Jesper Wengel*†

Department of Chemistry, University of Copenhagen Centre for Synthetic Bioorganic Chemistry, Universitetsparken 5, DK-2100 Copenhagen, Denmark

LNA (locked nucleic acid) is a novel class of nucleic acid mimic structurally closely resembling RNA; incorporation of three LNA monomers together with six ribonucleotide monomers afforded the first ribo-LNA sequence; unprecedented thermal stabilities of duplexes towards complementary DNA and RNA without compromising base-pairing selectivity were obtained for ribo-LNA, thus establishing the universality of LNA-mediated efficient targeting of natural nucleic acids.

LNA (Fig. 1) has been recently introduced as a novel nucleic acid mimic able to induce unprecedented increases in the thermal stability of duplexes towards both DNA and RNA in different 2′-deoxynucleotide sequence contexts.[1,2]‡ Other appealing characteristics of LNA include efficient automated oligomerization, satisfactory aqueous solubility and stability towards 3′-exonucleolytic degradation.[1,2] Further definitions and details are given in Fig. 1 and Table 1.

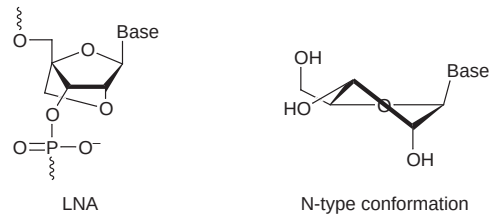

Fig. 1 Structure of the thymine LNA monomer $\mathbf{T^L}$ used in this study. LNA is defined as an oligonucleotide containing one or more LNA monomers. Deoxy-LNA is defined as an LNA consisting of LNA monomers and 2′-deoxynucleotide monomers. Ribo-LNA is defined as an LNA consisting of LNA monomers and ribonucleotide monomers. Also shown is the preferred monomer conformation in A-type duplexes (generally RNA/RNA and DNA/RNA, N-type conformation).

In entries 5–8 (Table 1) the hitherto reported LNA hybridization data (melting temperatures, T_m) for nonamer mixed sequences are summarized[1,2] and compared with the results for the corresponding unmodified reference duplexes. It should be noted that ΔT_m in Table 1 and in the text denotes increases in T_m per LNA monomer incorporated. In this comparative study, the thymine LNA monomer $\mathbf{T^L}$ is used as a representative example, but it is noteworthy that analogous results have been obtained for other pyrimidine and purine LNA monomers.[2] Incorporation of three $\mathbf{T^L}$ monomers together with six deoxynucleotides (to give a nonamer deoxy-LNA) induces remarkable increases in the thermal affinity towards both DNA and RNA (ΔT_m = +5.3 and +7.3 °C, respectively, entries 5 and 6). The fully modified LNA displayed yet higher thermal stabilities (entries 7 and 8). It has been clearly shown that LNA obeys the Watson–Crick base-pairing rules discriminating with excellent selectivity between fully matched and singly mis-matched complementary nucleic acids.[1,2]

Consequently, fully modified LNA as well as deoxy-LNA are able to sequence-selectively recognize complementary DNA/RNA with unprecedented thermal affinities. It is at this point important to note that comparable DNA and RNA recognition has so far only been demonstrated for 2′-fluoro N3′-P5′-phosphoramidates (ΔT_m = +3 to +5 °C).[3] We believe that the explanation offered by these authors, namely a strong pre-organization of the pentofuranose ring of the modified monomers into an N-type conformation[3] (Fig. 1), is viable also for LNA,[1,2] leading eventually to entropically favourable duplex formation.[4]

To explore the universality of LNA-mediated nucleic acid recognition, we decided to examine the properties of the ribo-LNA 5′-r(G$\mathbf{T^L}$GA$\mathbf{T^L}$A$\mathbf{T^L}$GC) (**LNA-1**) consisting of three thymine LNA monomers $\mathbf{T^L}$ and six ribonucleotide monomers. Synthesis of **LNA-1** was efficiently performed by the phosphor-

[a] A = adenosine monomer, C = cytidine monomer, G = guanosine monomer, U = uridine monomer, T = thymidine monomer, ^{Me}C = 5-methylcytidine monomer, $\mathbf{X^L}$ = LNA monomer.[1,2] Oligo-2′-deoxynucleotide sequences are depicted as d(sequence) and oligoribonucleotide sequences as r(sequence). 5′-r(G$\mathbf{T^L}$GA$\mathbf{T^L}$A$\mathbf{T^L}$GC) = **LNA-1**. The melting temperatures (T_m values) were obtained as the maxima of the first derivatives of the melting curves (A_{260} *vs.* temperature) recorded as described earlier.[1,2] ΔT_m values are the increases in the thermal stability per LNA monomer incorporated compared to the corresponding reference duplex. [b] Compared to entry 1. [c] Compared to entry 2. [d] Compared to entry 3. [e] Compared to entry 4.

amidite approach[5] using ribonucleoside 3′-phosphoramidites and thymine LNA monomer 3′-phosphoramidite.[1,2]§

The results of thermal melting studies are shown in Table 1 (entries 9–14). Sharp monophasic transitions were obtained in all experiments. It is convincingly demonstrated that **LNA-1** displays hitherto unseen increases in thermal stability (towards DNA: ΔT_m = +9.3 °C, entry 9, compared to entry 3; towards RNA: ΔT_m = +8.3 °C, entry 13, compared to entry 4). From experiments targeting singly mis-matched complements (entries 10–12 and 14) it is revealed that recognition by **LNA-1** is sequence selective. These results indicate that the chimeric ribo-LNA oligomers (or possibly oligomers consisting of LNA monomers and 2′-*O*-alkylribonucleotide monomers[6]) could prove very useful, *e.g.* for optimizing the properties of antisense oligonucleotides.

Because of the known preference for ribonucleotide monomers in A-type duplexes to adopt an N-type conformation,[7] and the established preorganization of LNA monomers into an N-type conformation,[1,2]‡ we had anticipated an additive effect (though levelling off when increasing the number of LNA monomers) on the thermal stability of duplexes involving ribo-LNA. However, comparison of the T_m values obtained for the fully modified LNA (entries 7 and 8) with the T_m values obtained for **LNA-1** reveals an interesting point. Thus, while introduction of only three LNA monomers leads to increased T_m values of +28 °C (towards DNA, entry 9) and +25 °C (towards RNA, entry 13), the corresponding increases in T_m obtained for the fully modified LNA were comparatively lower, namely +37 and +36 °C, respectively. In other words, the effect of introducing six additional LNA monomers in the nonamer amounts to a total increase in T_m of only +9 and +11 °C, respectively. It seems from these results that an LNA monomer profoundly effects the neighbouring ribonucleotide monomers, probably by inducing an overall preorganization, *e.g.* through increased intra-strand base stacking. A similar trend, albeit less pronounced, can be observed from the data shown in entries 5 and 6 for the deoxy-LNA containing three $\mathbf{T^L}$ monomers. By comparing the T_m values of entries 5 and 9 it is revealed that the thermal affinity towards DNA is larger for **LNA-1** than for the corresponding deoxy-LNA. This fact cannot be explained by the shift from an RNA- to a DNA-like oligomer as the corresponding reference T_m values are similar (28 and 27 °C, entries 1 and 2). Instead, the above suggested effect of the LNA monomers on the surrounding ribonucleotide monomers could be an explanation.

Through the results reported herein and the results reported recently,[1,2] the compatibility of LNA monomers with both ribo- and deoxyribo-nucleotide monomers (as well as the effectiveness of fully modified LNA) for high-affinity recognition of both DNA and RNA targets has been established. The structural variants of LNA evaluated demonstrate the universality of LNA-mediated nucleic acid targeting and indicate superior nucleic acid recognition for ribo-LNA. In addition, the pivotal role of the pentofuranose-phosphate backbone in nucleic acid recognition processes has been stressed. Further studies on thermodynamics and the structure of the duplexes have been initiated in order to fully understand the remarkable properties of LNA.

The Danish Natural Science Research Council and Exiqon A/S, Denmark, are thanked for financial support. Ms Britta Dahl, Ms Jette Poulsen and Dr Carl Erik Olsen are thanked for oligonucleotide synthesis and analysis.

‡ Synthesis of the uracil and cytosine LNA monomers has been independently published by another group (S. Obika, D. Nanbu, Y. Hari, K. Morio, Y. In, T. Ishida and T. Imanishi, *Tetrahedron Lett.*, 1997, **38**, 8735). Oligomerization of these monomers was not reported.

§ **LNA-1** was synthesized on a 0.2 μmol scale on a polystyrene solid support (Pharmacia) derivatized by a cytidine monomer using a Biosearch 8750 DNA Synthesizer. The stepwise coupling yield of the thymine LNA monomer 3′-phosphoramidite {(1*R*,3*R*,4*R*,7*S*)-7-[2-cyanoethoxy(diisopropylamino)phosphinoxy]-1-(4,4′-dimethoxytrityloxymethyl)-3-(thymin-1-yl)-2,5-dioxabicyclo[2.2.1]heptane} was >99% (20 min couplings) which was equivalent to the coupling yields obtained (6 min couplings) for commercial ribonucleoside 3′-phosphoramidites {2′-*O*-*tert*-butyldimethylsilyl-3′-*O*-[2-cyanoethoxy(diisopropylamino)phosphino]-5′-*O*-(4,4′-dimethoxytrityl)-2-*N*-(*tert*-butylphenoxyacetyl)guanosine (Perseptive Biosystems) and -6-*N*-(phenoxyacetyl)adenine (Biogenex)} as determined spectrophotometrically by the release of the DMT cation after each coupling step. After detritylation, the oligomer was cleaved from the solid support and partly deprotected using 40% aqueous methylamine (10 min, 55 °C). After cooling to −18 °C, the solid support was removed (centrifugation) and washed [2 × 0.25 cm^3; EtOH–MeCN–H_2O (3 : 1 : 1, v/v/v)]. The solvents were evaporated, and the residue was desilylated using a method described earlier.[8] Capillary gel electrophoresis[9] was used to document the purity of **LNA-1** (>90%). The composition of **LNA-1** [5′-r(G$\mathbf{T^L}$GA$\mathbf{T^L}$A$\mathbf{T^L}$GC)] was verified by MALDI-MS:[9] $[M - H]^-$ found 2932.9; calculated 2932.9.

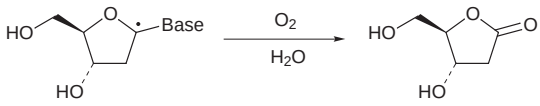
Fate of the C-1′ peroxyl radical in the 2′-deoxyuridine system

Chryssostomos Chatgilialoglu*† and Thanasis Gimisis*‡

I.Co.C.E.A., Consiglio Nazionale delle Ricerche, Via P. Gobetti 101, 1-40129 Bologna, Italy

The mechanism of 2-deoxyribonolactone formation from the reaction of photogenerated 2′-deoxyuridin-1′-yl radical with molecular oxygen in water has been investigated.

A number of agents are able to react with DNA to generate macromolecular radical species.[1] These processes are of considerable importance since they can lead to base modification or strand scissions. As research progresses in the area of the mechanism of attack of oxidative DNA cleavers, it becomes evident that hydrogen abstraction from the C-1′ position is involved in many cases.[2,3] Evidence for the existence of these radical species is mainly based on product studies,[4,5] although spectroscopic and theoretical studies have been reported.[6,7] Furthermore, based on the β-(acyloxy)alkyl radical rearrangement of a C-2′ radical, we have suggested that C-1′ radicals are stabilized substantially by the presence of the base and that the degree of stabilization is similar for purine and pyrimidine moieties.[8] Under aerobic conditions, however, C-1′ radicals **1** afford 2-deoxyribonolactone **2** [eqn. (1)] through a number of

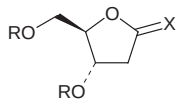


1 **2** (1)

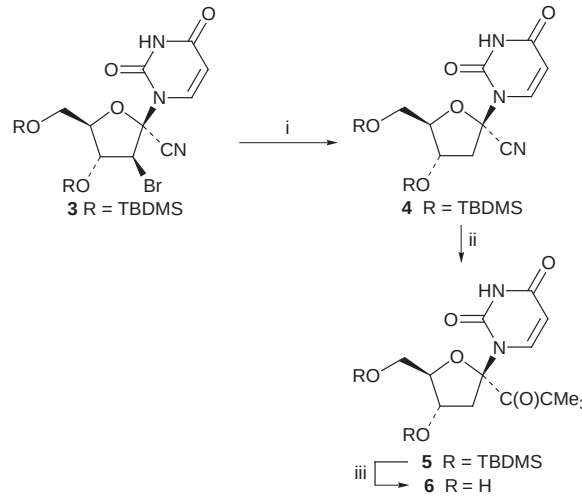
currently disputed pathways.[1,2,5] We report herein an *ex novo* synthesis of *tert*-butyl ketone **6**[9] and the mechanism of the formation of **2** [eqn. (1)].

The recently reported synthesis of **6** has two major drawbacks:[9] (i) a known psiconucleoside triol, prepared by a low yielding, laborious procedure, is used as the precursor,[10] and (ii) a total lack of regioselectivity in the protection step of this triol is observed. For these reasons, we used as our precursor compound **3**, readily available in diastereomerically pure form from the corresponding protected 1′,2′-didehydro-2′-deoxyuridine by a literature procedure.[11] When **3** was treated with $(TMS)_3SiH$[12] under normal free radical conditions, the crystalline cyanide **4** was obtained in excellent yield (94%) (Scheme 1).[13] Short treatment of **4** with excess of Bu^tLi yielded, after silica gel purification, the protected *tert*-butyl ketone **5** as the major product (37% yield, 45% based on recovered starting material).§ Finally, deprotection (NH_4F, MeOH, 60 °C, 24 h, 90%) produced the water soluble adduct **6**.

A quartz tube containing ketone **6** (23 mg; 0.073 mmol) in H_2O (200 μl) was photolyzed with a 500 W high pressure mercury lamp at room temperature. During the photolysis, continuous bubbling of air through the sample ensured the presence of O_2 in the reaction mixture. After 6 h of photolysis, ^1H NMR analysis (CD_3CN) of the lyophilized sample indicated a product ratio of 1 : 0.15 : 0.15 for **6** : **2** : uracil.[14] The products were derivatized with Bu^tMe_2SiCl/imidazole/DMF and isolated by flash chromatography (hexane–ethyl acetate 9:1) to give **7**[14]



7 R = TBDMS, X = ^{16}O
8 R = TBDMS, X = ^{18}O



Scheme 1 *Reagents and conditions:* i, $(TMS)_3SiH$, AIBN, toluene, 80 °C, 2 h, 94%; ii, 3 equiv. Bu^tLi, THF, −78 °C, 5 min, 37%; iii, NH_4F, MeOH, 60 °C, 24 h, 90%

and **5** in 15 and 85% yield, respectively. GC–MS analysis of compound **7** showed an isotopic cluster of $[M - 57]^+$ as reported in Fig. 1(*a*). A control experiment showed that photolysis of the sample under anaerobic conditions gave neither compound **2** nor uracil among the products.

The oxygen source of the carbonyl in the lactone **2** was determined by photolysis of **6** in the presence of ^{16}O–^{16}O and

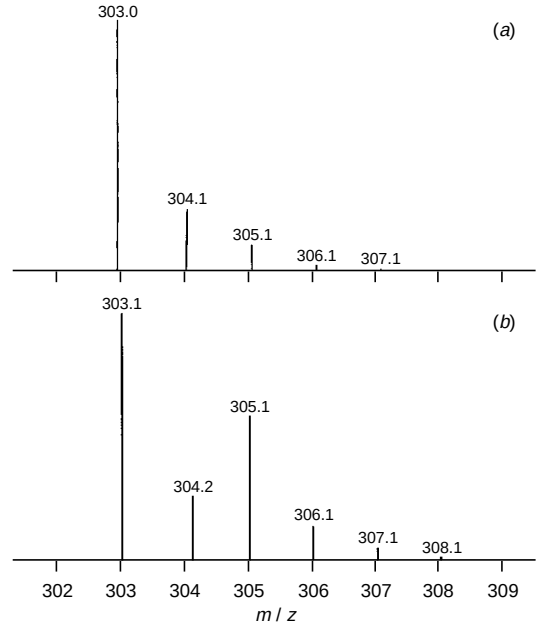


Fig. 1 Isotopic clusters of $[M - 57]^+$ from the electron impact mass spectra of protected 2-deoxyribonolactone obtained by GC–MS analysis. (*a*) Sample isolated from the reaction in $H_2{}^{16}O$ (of natural isotopic distribution). (*b*) Sample isolated from the reaction in $H_2{}^{18}O$ (95 atom% ^{18}O).

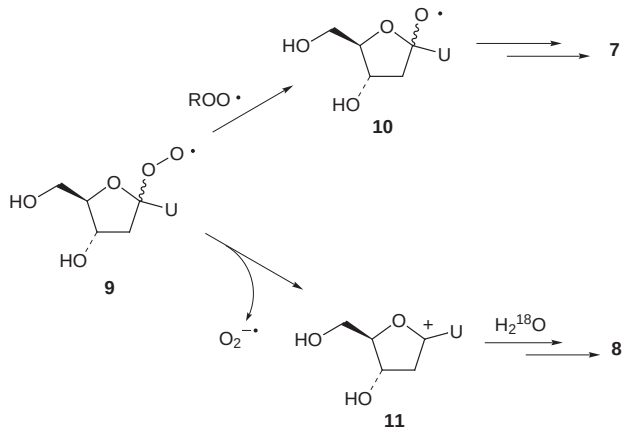

Scheme 2 Proposed mechanism for the formation of 2-deoxyribonolactone

$H_2{}^{18}O$. For this reason, the above experiment was performed in $H_2{}^{18}O$ (95 atom% ^{18}O) as solvent. After work-up, the protected 2-deoxyribonolactone was analyzed by GC–MS. Inspection of the mass spectrum of the isotopic cluster of $[M - 57]^+$, shown in Fig. 1(*b*), indicates the presence of coeluting isotopomers **7** and **8**. Analysis of this isotopic cluster revealed that the product of interest contains 65 and 35% oxygen-16 and oxygen-18, respectively. A control experiment showed that the product lactone **2** does not exchange oxygen with the solvent under the conditions employed.

The mechanism we envisage for the formation of the ^{18}O-labelled 2-deoxyribonolactone is outlined in Scheme 2. Reaction of C-1′ radical **1** with O_2 gives the peroxyl radical **9.** Laser flash photolysis studies showed that rate constant for oxygen trapping of the C-1′ radical is about 1×10^9 M^{-1} s^{-1}.[7] The peroxyl radical **9** decays either *via* a bimolecular reaction with another peroxyl radical to generate the alkoxyl radical **10** or *via* a unimolecular path (heterolytic cleavage) to generate the carbocation **11** and superoxide radical anion.[15a] The heterolytic cleavage of peroxides or alternatively the reaction of electron-rich carbon-centered radicals to give superoxide and carbocations is not without precedent.[15] The cationic intermediate **11** was trapped by $H_2{}^{18}O$, thus demonstrating the partition between the two channels.

An important consequence of the mechanism in Scheme 2 is that the C-1′ peroxyl radical generated on DNA, in the absence of good hydrogen donors, should mainly undergo heterolytic cleavage since the probability that two macromolecular peroxyl radicals meet is low. This finding accentuates the different chemical reactivity exhibited by the C-1′ radical species when compared with the one observed in the more studied C-5′ and C-4′ positions,[1] a reactivity which is mainly due to the presence of the two α-heteroatoms present in the anomeric position. Further work on the reactions of compounds **3** and **4** with a variety of electrophiles and on the kinetics of radical reactions associated with the C-1′ position is in progress.

We are grateful to the European Commission for a ‘Marie Curie’ post-doctoral fellowship to T. G., to NATO for a Collaborative Research Grant, and to Drs C. Ferreri and M. Lucarini for helpful discussions.

Coupling of fluoroform with aldehydes using an electrogenerated base

Rachid Barhdadi, Michel Troupel*† and Jacques Périchon

Laboratoire d'Electrochimie, Catalyse et Synthèse Organique, (UMR7582) CNRS-Université Paris 12 Val-de-Marne. 2, rue H. Dunant, 94 320 Thiais, France

Trifluoromethylated alcohols are easily obtained in a one pot electroreaction in which cathodic reduction of iodobenzene generates a strong base which deprotonates fluoroform, inducing its coupling with aldehydes.

Fluorinated molecules and particularly trifluoromethylated compounds are widely used in the pharmaceutical or agrochemical fields, and much effort has been devoted to establishing improved methods for the introduction into organic substrates of fluoro or trifluoromethyl groups.

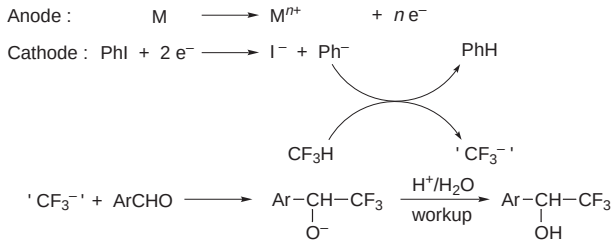
The most common reactants used to achieve trifluromethylation reactions[1] are organometallic compounds, *e.g.* CF_3Cu[2] and CF_3ZnX[3] (X = CF_3, Br, I *etc.*) or the Ruppert reactant CF_3SiMe_3.[4] These compounds are themselves generally prepared from CF_3I or CF_3Br. The electroreduction of CF_3Br is also a convenient method to obtain trifluoromethylated derivatives.[5]

Fluoroform CF_3H is a side product of fluoroorganic chemistry which is not utilised in organic synthesis. Compared to halofluorocarbons, this gas has low toxicity and is not an ozone depleting agent, although it is a powerful greenhouse gas and thus not a useful refrigerant. The use of CF_3H in organic chemistry is a real challenge which could turn an environmental liability into a commercial opportunity. One hindrance is the low reactivity of CF_3H, which is a very weak acid; its pK_a has been estimated to be in the range of 25–28.[6]

Concerning CF_3H as a source of trifluoromethyl anion, the only chemical method reported used strong bases such as Bu^tOK[7] or $MeSOCH_2K$.[8] An electrochemical procedure, which involves an electrogenerated base obtained by electroreduction of pyrrolidone, has also been described.[7] These reactions allow the synthesis of trifluoromethylated alcohols from aldehydes or ketones *via* a low temperature (−50 °C) two step procedure. The solvent DMF seems to play an important role, trapping the CF_3^- anion and giving a tetrahedral intermediate which is the actual trifluoromethylating agent.[8]

We have previously shown that the reduction of aromatic halides such as PhI or PhBr at a cathode covered with an electrolytic deposit of cadmium generates a strong base able to deprotonate weakly acidic molecules, inducing a coupling reaction with electrophilic compounds.[9] The present work is devoted to the extension of this technique to the case of fluoroform, which can then be coupled with aromatic aldehydes under very simple and mild conditions.

The experiments were conducted as a one-step procedure. To DMF was added Bu_4NBF_4 (4×10^{-2} mol l^{-1}) as a supporting electrolyte, an aromatic aldehyde ArCHO (0.5 mol l^{-1}) as the electrophile and iodobenzene (0.5–1.5 mol l^{-1}) as the probase. The solution, maintained at 5–10 °C, was supplied in CF_3H *via* slow bubbling at normal pressure.



Scheme 1

The undivided electrochemical cell has been described elsewhere.[10] The electrolyses were carried out at constant current (1 A dm^{-2}) using a sacrificial magnesium or aluminium anode and a nickel grid cathode freshly coated with a small deposit of cadmium obtained by electroreduction of $CdBr_2$.[9]

We observed that the reaction required an excess of probase and electricity to achieve full conversion of ArCHO. For example, when the electrolysis was conducted in solutions containing PhCHO and PhI (1 : 1), there was 30–40% residual benzaldehyde after the iodobenzene had been consumed. This is probably due to side reactions involving Ph^- and/or CF_3^-, which were not identified. Consequently, all syntheses were performed in the presence of excess iodobenzene (2–3 equiv.) allowing complete transformation of the aromatic aldehyde. Trifluoromethylated alcohols were obtained upon standard workup (solvent evaporation and acidic hydrolysis) and re-

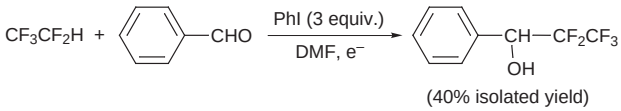
covered in a pure form by suitable extraction and chromatography on silica gel, and characterised by mass, ^{1}H NMR and ^{19}F NMR analysis.

The reaction pathway corresponds to that shown in Scheme 1. Our results, presented in Table 1, show that various aromatic aldehydes yield the corresponding trifluoromethylated alcohols in moderate to good yields. A limitation of this one-pot reaction is that the aldehyde cannot be more easily reduced than the probase PhI. Indeed, when starting from easily reducible compounds, *e.g.* *o*-, *m*- or *p*-(α,α,α-trifluoromethyl)-benzaldehyde, the sole product recovered is the corresponding pinacol. This would also explain the low yield obtained from 2-methoxybenzaldehyde (see Table 1), for which a large amount of pinacol was detected. For aliphatic aldehydes, we achieved success only with pivalaldehyde, as enolizable compounds mainly gave aldolisation products.

Our method is also suitable for the trifluoromethylation of alkyl halides. (Scheme 2). Finally, we have also proved that



Scheme 3

fluorocarbons other than fluoroform can be used. One example is the coupling of pentafluoroethane with benzaldehyde (Scheme 3).

Nickel indenyl complexes as precatalysts for dehydropolymerization of phenylsilane

Frédéric-Georges Fontaine, Talin Kadkhodazadeh and Davit Zargarian*

Département de Chimie, Université de Montréal, Montréal, Québec, Canada H3C 3J7

The complex (1-MeInd)Ni(PPh_3)Cl reacts with $AgBF_4$, $AlCl_3$, methylaluminoxane, or $LiAlH_4$ to produce intermediates which catalyze the dehydropolymerization of $PhSiH_3$.

Polysilanes have attracted a great deal of interest in recent years primarily because of their potential applications in optoelectric devices and as precursors to silicon carbide ceramics.[1] The initial discovery of transition metal-catalyzed dehydropolymerization of silanes[2] and the subsequent development of a class of efficient catalysts for this reaction[3] have shown that this approach holds great promise as a viable method for preparing high molecular mass polysilanes. Some of the best systems reported to date are derivatives of group 4 metallocenes which polymerize primary aromatic silanes to yield linear polysilanes with M_n on the order of 7000 (about 100 monomers), in addition to cyclic oligomers.[4] Most late metal complexes, on the other hand, redistribute silanes or couple them to give oligomers only (dimers, trimers, *etc.*);[5] notable exceptions are some complexes of platinum metals which polymerize aliphatic silanes[6] and cyclic silanes such as silicon-bridged ferrocenophanes[7] and silafluorene.[6] In the course of our studies on the complexes (Ind)Ni(PPh_3)X (Ind = indenyl, 1-methylindenyl; X = Cl, Br, Me)[8] and [(Ind)Ni(PPh_3)L′]$^+$ (L′ = PPh_3, PMe_3, MeCN)[9] we have found the first example of a late metal compound capable of catalysing the polymerization of $PhSiH_3$ to linear chains containing about 30–80 monomeric units, as described below.

Although $PhSiH_3$ does not react with (1-MeInd)Ni(PPh_3)Cl, **1**, addition of $AgBF_4$ to their mixture caused an immediate colour change (wine-red to black) and a vigorous evolution of gas (presumably H_2). The work-up‡ of the reaction mixture after 24 h gave an oily white solid which showed a ^{1}H NMR spectrum typical§ of poly(phenylsilylene); GPC¶ analysis showed that this material contained $(PhHSi)_n$ with M_w = 2017 and M_n = 1469 (Table 1, run 1). Using $AlCl_3$ as initiator gave shorter oligomers‖ (run 2) while methylaluminoxane (MAO) gave comparable results to $AgBF_4$ (run 3). The higher solubility of MAO allows the reactions to be carried out at lower temperatures or in toluene, both of which give improved results (runs 4 and 5).

The formation of Si–Si bonds is rapid at the outset of the reaction but slows down considerably after about 30 min, such that the build-up of higher chains (M_n *ca.* 2000–3000) takes several hours. Extending the reaction time to 7 days results in significantly higher molecular mass polyphenylsilanes for reactions carried out in CH_2Cl_2 (run 3 *vs.* run 6), but is not advantageous for reactions carried out in toluene (run 5 *vs.* run 7). This difference may be related to the higher solubility and/or stability of the catalytically active species (presumably a cation) in CH_2Cl_2 as compared to toluene.** This feature differentiates the present nickel complexes from some of the group 4 metallocene-based catalysts which decompose in chlorinated solvents.[4b]

The amount of solvent is also an important factor in the dehydropolymerization of silanes: the best results are normally obtained with very little or no solvent at all, which favours linear chain growth over the formation of cyclic oligomers.[3b,4a] We found, however, that very concentrated solutions (about 4 M in silane) result in the formation of intractable polymers, implying perhaps a significant degree of cross-linking caused by the coupling of backbone Si–H groups. It appears, therefore, that dilute conditions are better for obtaining polysilanes in this Ni system.

The most likely candidates for the catalytically active species in our system are cationic Ni–H or Ni–SiR_3 species, but we have not succeeded in detecting or isolating any such intermediates. We have found, however, that complex **1** reacts with $LiAlH_4$ to give an intermediate (presumably a neutral Ni–H species)†† which can polymerize $PhSiH_3$ (run 8). These reactions are very sensitive to solvent polarity (run 9), temperature (run 10), and reaction time (run 11), probably reflecting the limited solubility of $LiAlH_4$. Since $LiAlH_4$ can initiate the polymerization of $PhSiH_3$ and is also used in its preparation from $PhSiCl_3$,[10] we decided to explore the possibility of conducting these two steps consecutively in one pot. Thus, reacting $PhSiCl_3$ with an excess of $LiAlH_4$ and adding this mixture to a dilute Et_2O solution of

Table 1 Dehydropolymerization of $PhSiH_3$ with (1-MeInd)Ni(PPh_3)Cl[a]

Run	Initiator	Solvent	[Ni] : init. : Si	*t*/d	10^{-3} M_w	10^{-3} M_n	M_w/M_n
1	$AgBF_4$	CH_2Cl_2	1 : 10 : 90	1	2.0	1.5	1.37
2	$AlCl_3$	CH_2Cl_2	1 : 9 : 90	1	1.3	0.6	2.13
3	MAO	CH_2Cl_2	1 : 9 : 100	1	1.8	1.1	1.69
4	MAO	CH_2Cl_2 (−40 °C)	1 : 9 : 100	1	4.4	2.5	1.80
5	MAO	Toluene	1 : 9 : 100	1	4.8	2.9	1.64
6	MAO	CH_2Cl_2	1 : 9 : 100	7	7.1	5.9	1.20
7	MAO	Toluene	1 : 9 : 100	7	5.0	3.2	1.57
8	$LiAlH_4$	CH_2Cl_2	1 : 4 : 94	1	2.0	1.6	1.21
9	$LiAlH_4$	Toluene	1 : 3 : 100	1	0.6	0.5	1.24
10	$LiAlH_4$	CH_2Cl_2 (−40 °C)	1 : 3 : 100	1	0.7	0.5	1.58
11	$LiAlH_4$	CH_2Cl_2	1 : 4 : 94	7	3.6	1.6	2.27

[a] The initial concentration of $PhSiH_3$ was 0.15 M in all experiments; the yields were > 90% in all cases except run 9 for which the yield *was* 35%.

1 produced the usual colour change accompanied by vigorous evolution of gas.‡‡ The mixture of $(PhHSi)_n$ obtained from this reaction was shown to have M_w = 7565 and M_n = 1541 (M_w/M_n = 4.9).

In conclusion, complex **1** reacts with cationic initiators or $LiAlH_4$ to form species which catalyze the dehydropolymerization of $(PhSiH)_n$ with molecular masses and polydispersities comparable to those obtained from the best early metal systems.[3,4] Some interesting features of this nickel system include no introduction period, good activity at ambient or lower temperatures, tolerance of chlorinated solvents, and relatively narrow polydispersities (*e.g.*, run 6). Studies aimed at elucidating the mechanism of this reaction are in progress.

The authors gratefully acknowledge NSERC (Canada) for financial support of this work, Professors T. D. Tilley and J. F. Harrod for valuable discussions, and Professor Bruce Arndtsen and Ngiap Lim for the use of their GPC.

Notes and References

† E-mail: zargarian.davit@umontreal.ca

‡ The work-up procedure consisted of passing a toluene solution of the reaction mixture, with or without pre-treatment with methanol, through a short column of Celite, followed by evaporation and analysis by ^{1}H NMR and GPC.

§ ^{1}H NMR spectra of $(PhSiH)_n$ ($CDCl_3$, 300 MHz) contain Si–H resonances at δ *ca.* 3.7 for cyclic oligomers and broad signals centred around δ 5 for the linear polysilanes. These resonances appear *ca.* 1 ppm more downfield in C_6D_6.[11]

¶ The molecular masses were determined with a Waters Associates 600E Chromatograph equipped with a refractive index detector (Waters 410 differential refractometer) and Styragel HR 0.5, HR 2, and HR 4 columns in THF calibrated against a polystyrene standard. The manipulation of the peaks was done using the Waters Millennium Chromatography Manager 2010 v2.15 software.

‖ We speculate that the lower molecular masses obtained from the $AlCl_3$-initiated reactions may be caused by secondary reactions promoted by $AlCl_3$ (*e.g.*, silane redistribution or Cl transfer to silane chains).

** A reviewer has suggested that higher molecular mass values in run 6 may arise instead from the conversion of some of the Si–H bonds in the polysilane to Si–Cl as a result of being in contact with CH_2Cl_2 for a few days; the Si–Cl bonds would then be converted to siloxanes during the work-up. Although free radical halogenation of $(PhSiH)_n$ has been observed[12] to occur in CCl_4 and CBr_4, it seems to us that such reactions should be less likely in CH_2Cl_2. Nevertheless, this possibility can not be ruled out, and we caution the reader that the polysilanes obtained in runs 6 may not be pure $(PhSiH)_n$.

†† In our attempts to isolate Ni–H species, we have noted that reacting complex **1** with H^- sources produces a black compound which shows a fleeting signal at δ *ca.* −24 in its ^{1}H NMR spectrum; the isolation of this compound, however, has eluded us so far.

‡‡ The ratio of $PhSiCl_3$: $LiAlH_4$ was *ca.* 1 : 1.3, the reaction was run for four days, and the yield was 80%.

Crystallographic characterization of the helical diketone, $C_{36}H_{14}O_2$, a new product from the flash vacuum pyrolysis of decacyclene in the presence of oxygen

Saeed Attar, David M. Forkey,† Marilyn M. Olmstead and Alan L. Balch*‡

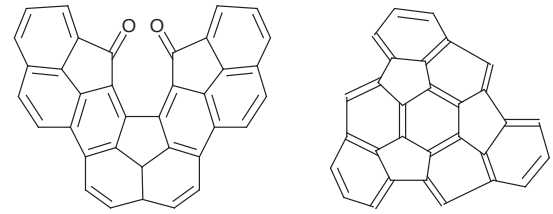
Department of Chemistry, University of California, Davis, California 95616, USA

The helical diketone, $C_{36}H_{14}O_2$, is formed during the flash vacuum pyrolysis of decacyclene in the presence of oxygen and has been characterized by X-ray crystallography.

The synthesis and properties of non-planar, polycyclic hydrocarbons that mimic structural motifs within the fullerenes have recently received considerable attention.[1] While the chemical reactivity of the fullerenes themselves is so far largely confined to reactions on the outer surface of the molecule,[2] the availability of fullerene-shaped hydrocarbons allows the exploration of the chemical behavior of not only the convex exterior but also the concave interior as well as the edges of these curved molecules. The high temperature (1250 °C) flash vacuum pyrolysis (FVP) of deacyclene **1**, as described by Scott and co-workers, produces the fullerene-shaped hydrocarbon $C_{36}H_{12}$ **2**, along with two related products, **3** and **4**, as shown in Scheme 1.[3] Crystallographic characterization of **2** reveals that its structure closely resembles that of C_{60}, with a degree of pyramidalization of the central carbon atoms at the base of the bowl that slightly exceeds that of the fullerene but with some outward splaying at the rim of hydrogenated carbon atoms.[4] Here we describe the identification of another product, the helical diketone **5**, that can form in this pyrolytic process through oxidation.

During several preparations of **2** by flash vacuum pyrolysis of decacyclene with subsequent chromatographic separation of the soluble products,[3] we noted that the contents of the second chromatographic band, the one that usually contained the doubly closed bowl **3**, changed when air leaked into the pyrolysis system. Further examination of this band revealed the presence of a new compound, the diketone **5**, (*Chem. Abstr.*, Index Name, cyclopenta[*pqr*]naphth[2′,1′,8′ : 5,6,7]-*as*-indaceno[1,2,3,4-*tuva*]picene-15,16-dione) which was produced in yields of *ca.* 0.3–0.5%.

The dione **5** has been fully characterized *via* both spectroscopic§ and X-ray crystallographic data. Because of the similarities in molecular symmetry and structure, the dione **5** and the doubly closed bowl **3** show comparable but different features in their ^{1}H NMR spectra. Orange crystals of $C_{36}H_{14}O_2 \cdot 1.125\ CH_2Cl_2 \cdot 0.75\ MeOH \cdot 0.25\ H_2O$ readily form through the diffusion of MeOH into CH_2Cl_2 solution of the compound.¶ Two views of the molecule are shown in Fig. 1. Bond distances within the molecule are given in Table 1.



5 **6**

Although the molecule has no crystallographically imposed symmetry, it is divided into two nearly identical halves with an approximate two-fold axis that passes through the C(13)–C(33) bond. The two C–O distances are consistent with the diketone

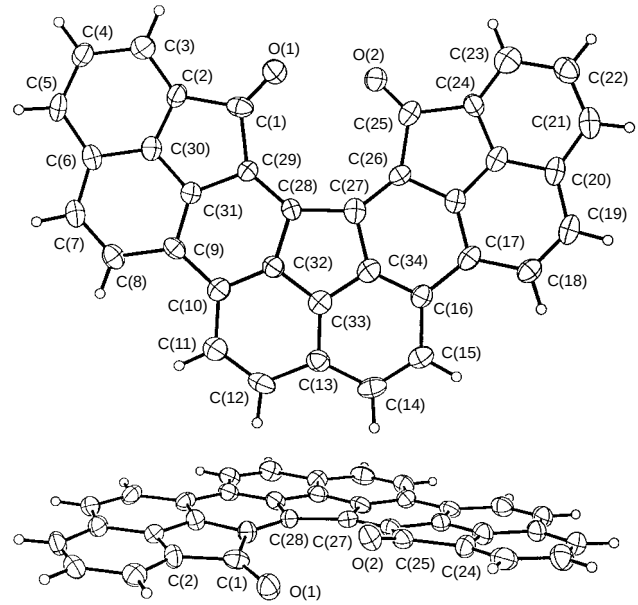


Fig. 1 A perspective view of an isolated molecule of $C_{36}H_{14}O_2$ with 50% thermal contours. The top view looks down on the nearly flat surface of the molecule while the lower view emphasizes the non-planarity and helicity of the region near the two oxygen atoms.

formulation, and the four immediately adjacent C–C bonds are the longest C–C bonds in the molecule. The dione **5** is not planar but has a slight helical twist, as shown in the lower part of Fig. 1. This helicity arises from the juxtaposition of the two oxygen atoms, which bend away from one another to avoid unduly close contact. The non-bonded O···O distance in **5** is 2.708 (6) Å. Fig. 2 shows the distances of the various carbon atoms from the mean plane of the carbon atoms in **5**. Although individual molecules of **5** are chiral, each crystal is a racemate of the two *M* and *P* enantiomers.

In the solid state, the individual molecules of **5** pack in columns along the *b* axis as shown in Fig. 3. Within each column, all molecules have like chirality. However, there are inversion centers between the columns, so that adjacent columns have opposite chiralities. The packing conforms to the β motif, which is one of the four packing arrangements found for polynuclear aromatic hydrocarbons.[5,6] The motif is characterized by a short *b* screw axis and graphitic planes. The β motif is the one utilized by polynuclear aromatic hydrocarbons that are, like the diketone **5**, non-planar.

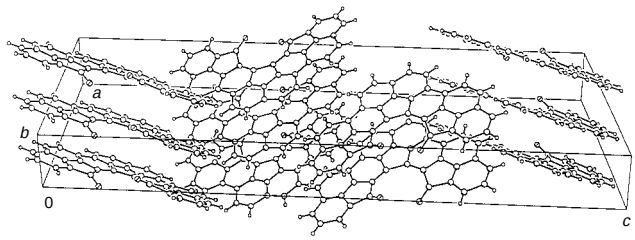

Fig. 3 A view of the solid state packing in $C_{36}H_{14}O_2$

The formation of the diketone **5** during our flash vacuum pyrolysis of decacyclene has been traced to a leak in the gas inlet system that allowed air to enter the gas stream during pyrolysis. It is likely that **5** formed from oxidation of the doubly closed bowl **3**, since **5** and **3** are related by cleavage of one of the C–C bonds on the periphery of the corannulene-like portion of **3**. However, as indicated by mass spectroscopic and NMR data, the doubly closed bowl **3** is not converted into **5** during the general workup of the pyrolysis products, nor does exposure of a solution of **3** to one atmosphere of O_2 in $CHCl_3$ solution for 30 min under room light lead to the formation of the dione **5**. Those pyrolysis reactions that produced **5** yielded little or none of the doubly closed bowl **3**, but did produce **2**. The C–C bonds on the edges of these non-planar hydrocarbons are subject to considerable strain, and as the present case reveals, cleavage of just one such bond in **3** can result in the formation the nearly planar dione **5**, with considerable release of strain. In a related study, cleavage of a carbon–carbon bond on the periphery of the semibuckminsterfullerene, $C_{30}H_{12}$ **6**, has been observed in its reaction with $(Ph_3P)_2Pt(C_2H_4)$.[7] Clearly the chemistry of these non-planar hydrocarbons that are related to fullerenes deserves continued attention,[8] and reactivity at the edges is likely to be a prominent feature.

We thank the National Science Foundation (Grant CHE 9610507) for financial support and Professor G. Stanley for a preprint of ref. 7.

A starburst porphyrin polymer: a first generation dendrimer

Tyler Norsten and Neil Branda*†

Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2E1

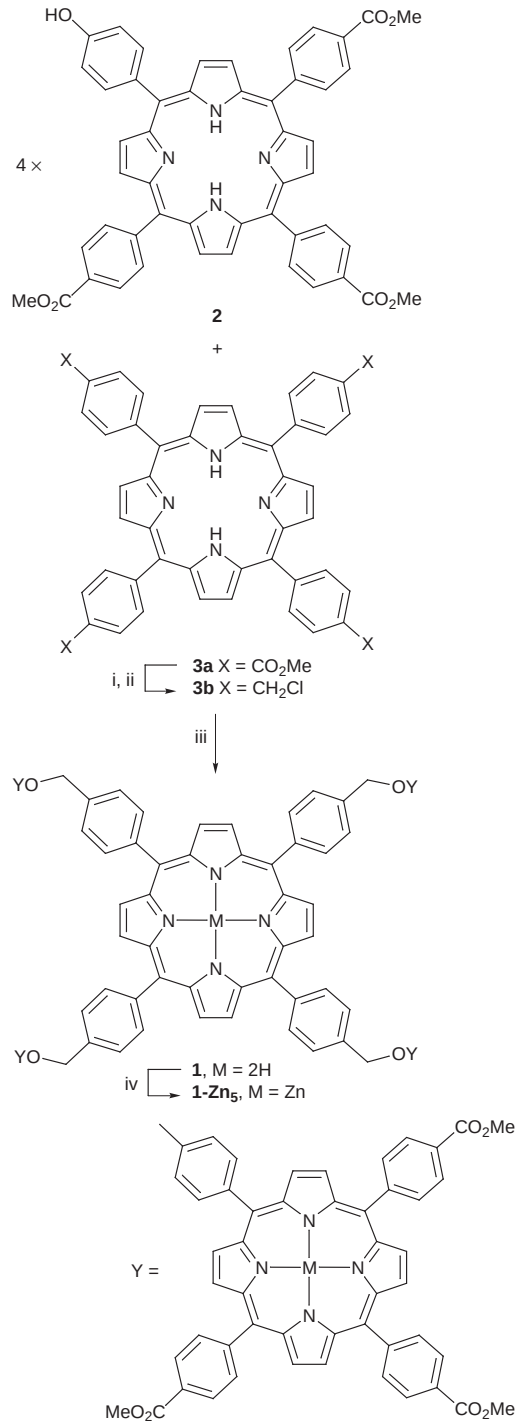
Tetra(chlorobenzyl)porphyrin 3b reacts with 4 equiv. hydroxyphenylporphyrin 2 to give the first example of a pentaporphyrin that can be considered to be a first generation dendrimer.

Porphyrins and metalloporphyrins are fascinating chromophores due predominantly to the fact that their photophysical behaviour is sensitive to the type and position of substitution within or around the ring, as well as the presence of neighbouring porphyrins or other chromophore centres. To better understand the complexity of the electronic or photonic communication between porphyrins,[1] covalently linked conjugated[2] and non-conjugated[3] oligomeric porphyrin assemblies, as well as non-covalently linked supramolecular chromophoric assemblies[4] have been prepared and studied. These short, multiply linked chromophoric polymers are successfully paving the way to a better understanding of the fundamental interactions between neighbouring porphyrin centres.

Dendrimers are a specific class of compounds that comprise one of the fastest growing areas of polymer research.‡[5] These hyperbranched starburst polymers differ from their traditional linear counterparts in that the repeating units cascade outwardly from a central core rather than elongating in a linear fashion. The attraction here is that as successive generations are iterated, dendrimers become increasingly globular and exhibit intriguing structural properties such as internal voids and cavities created by the multiple branches folding back upon themselves. Knowing this, we were surprised when we could not find any examples of a fully porphyrinic dendrimer. There are several examples of the two extreme cases: (1) multiple porphyrins covalently linked onto a non-porphyrin core,[6] and (2) non-porphyrin dendrimer branches fused to a singular porphyrin core.[7] Here we report the first example of a dendrimer where the core and repeating polymeric unit are themselves both porphyrins. It is hoped that this new class of branched chromophores will combine the advantages of the hybrid properties of both porphyrins and dendrimers.

With a divergent§ synthetic approach in mind, the polymeric cycle leading to dendrimer **1** was designed to consist of ester-reduction, activation of the resulting alcohol and coupling to form an ether linkage. The ether linkage was chosen because of its chemical stability towards a wide range of synthetic conditions including those required for future iterations. Another attractive feature of this approach is that both the precursor to the active core **3b** [*meso*-tetrakis(4-methoxycarbonylphenyl)porphyrin **3a**] and the repeating unit [5,10,15-tris(methoxycarbonylphenyl)-20-(4-hydroxyphenyl)-porphyrin **2**] can be prepared in the same one-pot procedure as previously reported.[8] Porphyrins **2** and **3a** are easily separated and purified by trituration with acetone followed by column chromatography (SiO_2). Porphyrin **3a** was reduced[9] with $LiAlH_4$ and the resulting tetraalcohol chlorinated[10] to give the core **3b** following known procedures. The first generation dendrimer **1** was prepared from building blocks **2** and **3b** in one step as outlined in Scheme 1, by coupling 4 equiv. **2** to 1 equiv. **3b** in the presence of NaOH in DMF at 80–100 °C for 24 h. Pentaporphyrin **1** was isolated as a purple solid in 48% yield after purification by column chromatography (SiO_2, $CHCl_3$–2% CH_3CN) and by GPC.

Pentaporphyrin **1** was highly soluble in a wide range of organic solvents such as THF, $CHCl_3$ and CH_2Cl_2. It is



Scheme 1 *Reagents and conditions*: i, $LiAlH_4$, THF, reflux; ii, $SOCl_2$; iii, NaOH, DMF, 80–100 °C; iv, $Zn(OAc)_2{\cdot}2H_2O$, MeOH, $CHCl_3$

interesting to note that it is in fact significantly more soluble than either building blocks **2** or **3**. The pentaporphyrin **1** displays 12 divergent ester groups suitable for submission to future dendrimeric cycles.

The first generation dendrimer **1** was characterized by MALDI-TOF mass spectrometry and ^{1}H NMR and UV–VIS absorption spectroscopies. The ^{1}H NMR and COSY spectra of **1** in $CDCl_3$ are consistent with the assigned structure. A significant difference is observed for the resonances of the two core porphyrin N–H hydrogens (−2.61 ppm) and the eight porphyrin N–H hydrogens located within the peripheral porphyrins (−2.75 ppm) of the starburst. Molecular modeling suggests that the radial porphyrin arms are capable of folding back towards the core of the starburst molecule; however, ROSEY NMR studies show no long-range communication. Minimum energy calculations predict that the four radially linked porphyrins ideally exist in a propeller type arrangement around the core with an edge-to-edge distance of 61 Å. The dendrimer exists in the nanoscale range after only one generation!

The MALDI-TOF mass spectrum of **1** shows a peak at 3883.7 mass units (mu) corresponding to the parent ion [M + H], this is in accordance with the calculated value of 3883.3 mu for $C_{248}H_{174}N_{20}O_{28}$. Also evident are fragmentation peaks separated by 804 mu at 3079, 2275 and 1471 mu corresponding to the consecutive loss of a peripheral porphyrin from the central core (Fig. 1).

The UV–VIS spectrum of the porphyrin dendrimer in $CHCl_3$ shows absorption maxima at 424 (2 140 000),¶ 517 (74 200), 552 (38 200), 591 (23 700) and 647 (17 400) nm. The absorption spectrum of **1** appears to resemble the sum of appropriate model compounds.‖ Studies to quantify any subtle shifts in absorption and changes in molar extinction coefficients are currently under way.

The pentametallo zinc derivative **1**–$\mathbf{Zn_5}$ was cleanly prepared by treating a $CHCl_3$ solution of the free base dendrimer with an excess of a saturated MeOH solution of $Zn(OAc)_2{\cdot}2H_2O$. The MALDI-TOF mass spectrum of **1**–$\mathbf{Zn_5}$ is consistent with the replacement of the 10 porphyrin hydrogen atoms by five zinc atoms, as is the ^{1}H NMR spectrum with the disappearance of the eight peripheral porphyrin hydrogens at −2.75 ppm and the two core hydrogens at −2.61 ppm. As expected, the addition of five metals to the dendrimer greatly decreased its solubility in chlorinated solvents (CH_2Cl_2 and CH_3Cl), however **1**–$\mathbf{Zn_5}$ remained highly soluble in THF.

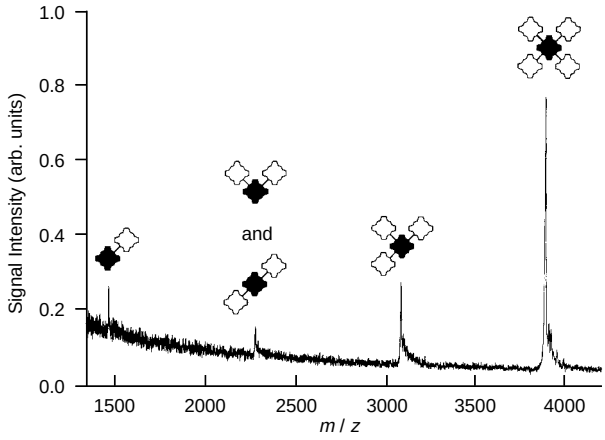


Fig. 1 MALDI-TOF mass spectrum of first generation porphyrin dendrimer **1** showing the parent mass peak [M + H] as well as peaks corresponding to the sequential loss of one peripheral porphyrin (unshaded polygons) from the central core porphyrin (shaded polygon). All-*trans*-retinoic acid was used as the matrix without added cation.[11] Synthetic peptides bracketing the mass of interest (4000 mu) were used as external standards for calibration.

The starbursts **1** and **1**–$\mathbf{Zn_5}$ represent the birth of a new type of dendrimeric framework. It will be interesting to see what electronic or photonic applications the future holds for the next generation.

We are grateful to Dr David Schriemer for his help with the MALDI-TOF mass spectrometry studies and to the Natural Sciences and Engineering Research Council of Canada for financial support.

§ In a divergent approach, dendrimers are constructed from a central core out to the periphery in an iterative fashion of repeating generations. In contrast, a convergent approach builds the dendrimer from the periphery towards the core.

¶ Molar extinction coefficient (ε/M^{-1} cm^{-1}).

‖ Benzyl and phenyl ethers of porphyrins **2** and **3b** respectively were prepared as model compounds for comparative photophysical studies by reacting the hydroxyphenylporphyrin **2** with benzylbromide and by reacting tetrachloroporphyrin **3b** with phenol.

Nucleophilic substitution of optically active 1-alkoxypolyfluoroalkyl sulfonates

Hiroshi Matsutani,[a] Hervé Poras,[a] Tetsuo Kusumoto*[a]† and Tamejiro Hiyama[b]

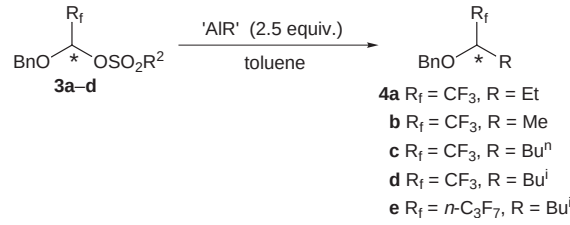
[a] *Sagami Chemical Research Center, Nishiohnuma, Sagamihara, Kanagawa 229-0012, Japan*
[b] *Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Yoshida, Kyoto 606-8501, Japan*

Reaction of 1-alkoxypolyfluoroalkyl sulfonates with lithium tetraalkylaluminates gives stereospecifically alkylated products with a high degree of inversion of configuration; in contrast, the ees of the resulting ethers are slightly reduced in the reaction with trialkylaluminium reagents.

Chiral acetals are versatile building blocks for the synthesis of biologically active agents and functional materials.[1] However, few optically pure compounds are known whose acetal carbon only is chiral.[2] We have recently reported that the Baeyer–Villiger reaction of optically active α-alkoxyalkyl ketones affords optically active 1-alkoxyalkyl carboxylates. The resulting acetals undergo the substitution reaction with lithium dialkylcuprates in the presence of $BF_3{\cdot}OEt_2$ to give optically active alkoxyalkanes with inversion of configuration.[3] We undertook to expand the concept to trifluoroacetaldehyde because fluorinated chiral compounds are receiving increasing attention in view of their remarkable biological and physical properties.[4] Furthermore, the nucleophilic C–C bond-forming substitution reaction at a carbon bearing a trifluoromethyl group with inversion of configuration is unprecedented.[5,6] We report herein a nucleophilic substitution of optically active 1-alkoxypolyfluoroalkyl sulfonates with an organoaluminium reagent[7] to give optically active alkoxypolyfluoroalkanes with a high degree of inversion of configuration.

Optically active 1-alkoxypolyfluoroalkyl sulfonates were prepared according to Scheme 1. Trifluoroacetaldehyde or heptafluorobutanal was liberated *in situ* from hemiacetal **1a** or hydrate **1b**, respectively, and allowed to react with benzyl alcohol to give racemic hemiacetal **2a** or **2b**, which was converted to the corresponding sulfonate with alkane- or arenesulfonyl chloride, triethylamine and DMAP.[5a,8] The resulting hemiacetal derivatives were resolved by HPLC (Daicel CHIRALPAK AD or CHIRALCEL OD) to afford (+)- and (−)-**3a**–**d**. Alternatively, (*S*)-(+)-**3a** (79% ee‡) was prepared by asymmetric addition of benzyl alcohol to trifluoroacetaldehyde using an (*R*)-binaphthol–titanium(IV) complex[9] followed by mesylation at 0 °C.[10]

With sulfonates **3a**–**d** in hand, we then studied C–C bond-forming reactions using various organometallic reagents. In contrast to the corresponding acetaldehyde acetals,[3,11] **3a** did not react with $Bu_2CuLi{\cdot}LiI/BF_3{\cdot}OEt_2$. However, treatment of (*R*)-(−)-**3a** (61% ee) with $AlEt_3$ in toluene at −20 °C gave (−)-2-benzyloxy-1,1,1-trifluorobutane **4a** in 66% yield with 46% ee [eqn. (1) and Table 1, entry 1]. Since the absolute

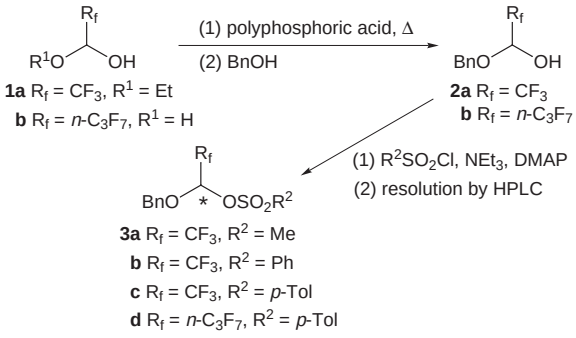


(1)

configuration of ether (−)-**4a** is *S* and that of mesylate (−)-**3a** is *R*,§ we conclude that the reaction has proceeded with inversion of configuration. This is the first observation of a stereospecific nucleophilic substitution reaction giving C–C bond formation at a CF_3-substituted carbon with inversion of configuration, although the enantiomeric excess (ee) of **3a** was slightly lost in **4a**. This observation suggests that Lewis acid $AlEt_3$ induced the formation of an oxocarbenium ion intermediate, which led to racemization to some extent.[3] After some trials, we were delighted to find that the use of $LiAlEt_4$[12] instead of $AlEt_3$ gave (*R*)-(+)-**4a** in 59% yield with 83% ee, starting from (*S*)-(+)-**3a** (83% ee).¶ It is noteworthy that the stereochemical integrity of the substrate was completely maintained (Table 1, entry 2). Thus, the Lewis acidity of the organometallic reagent affects significantly the stereochemical course of the reaction.

To demonstrate the generality of the substitution reaction, optically active sulfonates **3a**–**c** were allowed to react with various organoaluminium reagents. The results are summarized in Table 1. The chirality transfer, *i.e.* the ratio of (% ee of **4**)/(% ee of **3**), is shown also. Using $AlEt_3$, benzenesulfonate (*R*)-(−)-**3b**‖ gave ether (*S*)-(−)-**4a** with 76% chirality transfer (entry 3). On the other hand, the same substrate reacted stereospecifically with $LiAlEt_4$ with 97% chirality transfer (entry 4). Similar results were obtained with optically active tosylate **3c** (entry 5 and 6). Reaction of (*S*)-(+)-**3c**‖ (100% ee) with $LiAlEt_4$ gave (*R*)-(+)-**4a** with 98% ee. Similarly, $AlMe_3$, $AlBu^n_3$, and $AlBu^i_3$ reacted stereospecifically with optically active tosylate **3c**, while the corresponding aluminates ($LiAlMe_4$, $LiAlBu^n_4$ and $LiAlBu^i_4$) reacted with higher stereospecificity (entries 8, 10 and 12 *vs.* entries 7, 9 and 11). The low yield of ether **4b** may be attributed to the poor solubility of $LiAlMe_4$ in toluene (entry 8, Table 1).

Optically active 1-benzyloxy-2,2,3,3,4,4,4-heptafluorobutyl toluene-*p*-sulfonate **3d** derived from heptafluorobutanal also reacted with organoaluminium reagents stereospecifically (entries 12 and 13). Treatment of **3d** with $AlBu^i_3$ afforded optically active ether **4e** with 23% chirality transfer in low yield. In contrast, **3d** reacted with $LiAlBu^i_4$ with 84% chirality transfer. Although the absolute configurations of sulfonate **3d** and ether **4e** remain to be determined, the reaction may be assumed to have proceeded with inversion of configuration as in the cases of **3a**–**c**.



Scheme 1

Table 1 Nucleophilic substitution of optically active 1-alkoxypolyfluoroalkyl sulfonates using organoaluminium reagents

Entry	Substrate	Ee (%)	'AlR'	*T*/°C	*t*/h	Product	Yield (%)	Ee (%)	Chirality transfer (%)[a]

‡ Enantiomeric excess (ee) was analyzed by HPLC with CHIRALCEL or CHIRALPAK (both available from Daicel).

§ The absolute configuration of ethers **4a**–**d** was assigned on the basis of the optical rotation of a corresponding authentic sample prepared from (*S*)-3,3,3-trifluoro-1,2-epoxypropane **5**.

¶ *Typical procedure*. A toluene (2.0 ml) solution of lithium tetraalkylaluminate prepared *in situ* from the corresponding alkyllithium (0.63 mmol) and trialkylaluminum (0.63 mmol) was added dropwise to a stirred solution of **3** (0.25 mmol) in toluene (2.5 ml). The reaction mixture was stirred for the indicated period and quenched with dilute HCl. The resulting mixture was extracted with Et_2O. The organic layer was washed with aq. NaCl, dried and concentrated. The residue was purified by silica gel column chromatography. All new compounds were fully characterized by IR, mass and NMR spectroscopy and elemental analysis.

‖ The absolute configurations of sulfonates **3b**,**c** were estimated on the basis of the configurations of products **4a**–**d** as well as the stereochemical course of the reaction.

Linear fused oligoporphyrins: potential molecular wires with enhanced electronic communication between bridged metal ions

Laurent Jaquinod, Olivier Siri, Richard G. Khoury and Kevin M. Smith*†

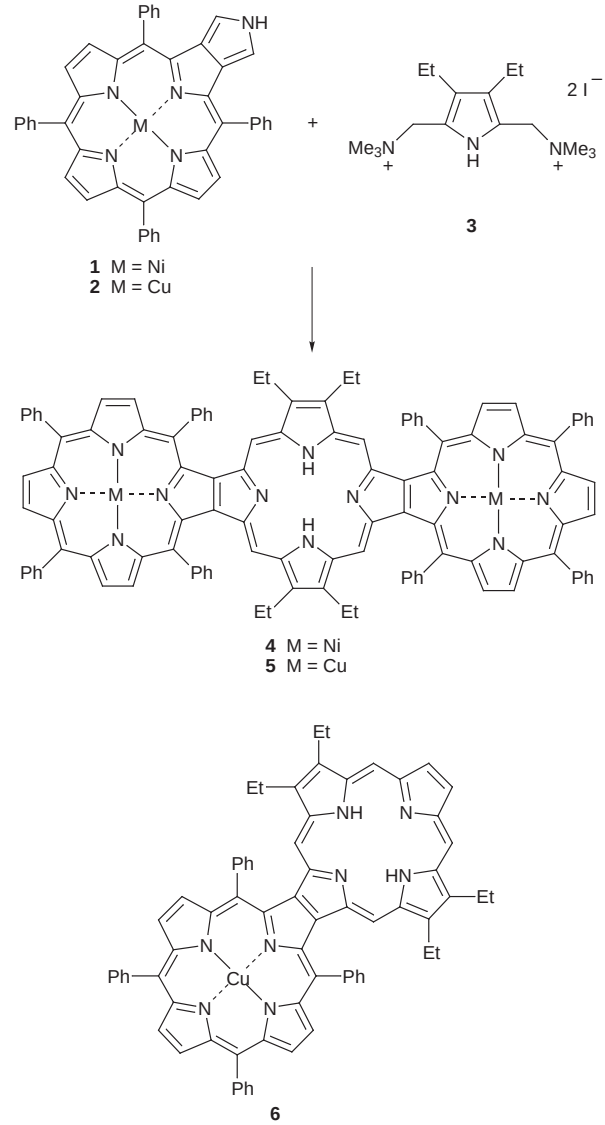
Department of Chemistry, University of California, Davis, CA 95616, USA

Syntheses of nanometer scale, directly beta-fused oligoporphyrins sharing an extended π-system are described.

One-dimensional oligomers containing photoactive and/or redox-active units allow the possibility of long distance delocalization of electron density and metal–metal interactions between multiple metal centres.[1] These appealing architectures may present a range of interesting opportunities based on energy- and electron-transfer processes involving communication along and between these units. Such 'photonic molecular wires' based on side-to-side oligomerization of *meso*-functionalized porphyrins have been studied and have been shown to absorb light at one end of an array of porphyrins and then emit a different photon at the other end.[2] Crossley and Burn outlined criteria which these molecular wires need to meet, and described a synthetic approach to rigid π conjugated porphyrin-based molecular wires.[3] These oligoporphyrins, in which individual porphyrin rings are bridged by coplanar aromatic systems, were synthesized by sequential condensation of porphyrin-2,3-diones and/or porphyrin-2,3,12,13-tetraones with aromatic *ortho*-diamines. The versatility of this methodology was further demonstrated in the recent synthesis of thiophene appended porphyrins[4] and donor bridge-acceptor systems involving porphyrin and phenanthroline.[5] However, the conjugation pathway through bridged oligoporphyrins does not exhibit a large fully-delocalized aromatic network which could possibly give rise to metallic type conduction, and could rather be described as a series of weakly-interacting chromophore conjugation loops.[6] Directly fused oligoporphyrins sharing a common extended π electron system have not been yet synthesized. We now describe their synthesis based on pyrrolo-fused porphyrin building blocks, readily available in three steps from Ni^{II} 5,10,15,20-tetraphenylporphyrin.[7]

Because of the instability of the metal-free fused pyrroloporphyrins,[7b] the oligomerization step was carried out on the more stable nickel or copper complexes, **1** and **2**. Under non-acidic conditions, quaternized 2,5-bis(*N*,*N*-dimethylaminomethyl)-3,4-diethylpyrrole **3**[8] reacted smoothly in refluxing MeOH–THF (1 : 1) with **1** in the presence of 10 equiv. of $K_3Fe(CN)_6$ to afford, after chromatography, an 18% yield of porphyrin trimer **4** [λ_{max} 405, 481 (Soret band), 557, 649, 681, 715 nm] (Scheme 1). Pre-quaternisation of the pyrrole with MeI was found to be necessary in order to enhance its reactivity toward the nucleophilic, but sterically congested, fused pyrroloporphyrin **1**. The formation of a new central free base porphyrin was revealed by the NH resonances (−2.55 ppm) in the ^1H NMR spectrum. The molecular structure of **4**·$(HCl)_2$ was further confirmed by X-ray crystallography. The central porphyrin appears to possess enhanced basicity since $CHCl_3$ readily caused protonation to give the dication (which was crystallized). This protonation phenomenon apparently facilitated the crystal packing by enabling π–π stacking to occur only between terminal porphyrins, thus giving rise to independent linear rods of fused porphyrins (Fig. 1). Attempts to grow suitable crystals of the non-protonated species failed, which was most likely caused by a random π–π stacking. The inner porphyrin dication adopts a saddle conformation with a mean plane deviation of the 24 core atoms of 0.376 Å. Both of the terminal nickel porphyrins adopt a ruffled conformation with a mean plane deviation of the 24 core atoms of 0.411 and 0.428 Å. The porphyrin trimer has an edge-to-edge span of 27.0 Å and the intermolecular distance between metals is 16.16 Å.

Mixed condensation of **2**, **3** and pyrrole [THF–MeOH/$K_3Fe(CN)_6$/reflux] gave the fused dimer **6** [λ_{max} 397, 468 (Soret band), 548, 590, 652 nm], as well as some fused trimer **5** in unoptimized yields of 6 and 5%, respectively (Scheme 1). MALDI-TOF mass spectroscopy confirmed dimer and trimer formation, with ions at *m/z* 1069.5 and 1716.8. Compared with pyrroloporphyrin **1**, the bathochromic shift and hyperchromic effect displayed by the fused porphyrins reflect their extended π-conjugation. The Soret bands of **4**–**6** are significantly red



Scheme 1

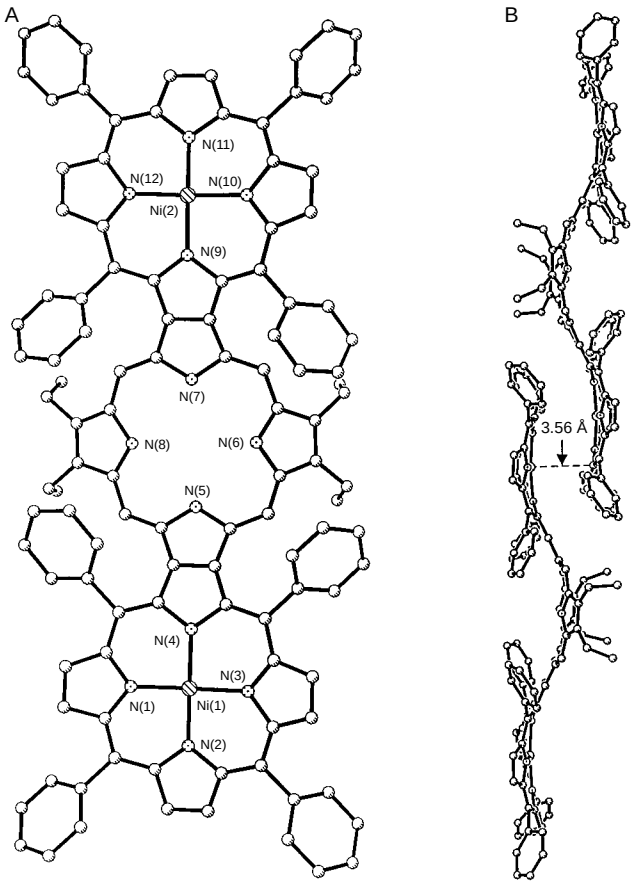


Fig. 1 Molecular structure of **4**. (A) Top view. (B) Side packing view of two trimer molecules. Hydrogen atoms have been omitted for clarity.

shifted from 430 nm (**1**) to 484 and 468 nm in **5** and **6**, respectively. The most notable feature in the absorption spectra is an intense Q band at 652 (dimer **6**) or 722 nm (trimer **5**), reminiscent of a chlorin or bacteriochlorin type visible spectrum. Metallation of **4** using an excess of $Zn(OAc)_2$ in MeOH–$CHCl_3$ gave quantitatively the Ni^{II}–Zn^{II}–Ni^{II} species, **7**. The Q band electronic absorption was found at 742 nm and was shifted to 752 nm upon addition of pyridine. Addition of TFA to a brown solution of free base **4** gave a red–pink dication species displaying three split Soret bands at 414, 455 and 516 nm, and a broad Q band at 838 nm. Surprisingly, these fused linear porphyrins are very soluble in a number of organic solvents, including chlorinated solvents; their protonation even enhances their solubilty.

Further synthetic work is aimed at the functionalization of these systems to generate higher fused oligomers, and at development of the chemistry of the dimer and trimer.

This work was supported by grants from the National Science Foundation (CHE-96-23117) and the National Institutes of Health (HL-22252).

‡ *Crystal Data* for **4**, $C_{112}H_{80}N_{12}Ni_2 \cdot 7.33[CHCl_3] \cdot [CH_3OH] \cdot [2[Cl^-]$: X-ray diffraction data were collected on a Siemens P4 rotating anode diffractometer with a nickel filter monochromator [λ(Cu Kα) = 1.54178 Å] at 130(2) K in $\theta/2\theta$ scan mode to $2\theta_{max}$ = 113°. Crystals were grown from slow diffusion of heptane in a mixture of $CHCl_3$ and MeOH. A single parallelepiped crystal was selected with dimensions 0.16 × 0.08 × 0.04 mm. The crystal lattice was monoclinic with a space group of $P2_1/c$. Cell dimensions were a = 38.335(7), b = 16.994(3), c = 19.110(4) Å, α, γ = 90, β = 100.091(14), V = 12257(4) Å3 and Z = 4 (M = 2689.35, ρ_{calc} = 1.456 g cm^{-3}, μ = 5.628 mm^{-1}). Of 17 517 reflections measured, 16 228 were independent and 8884 had $I > 2\sigma$ (R_{int} = 0.068); number of parameters = 1455. Final R factors were R_1 = 0.1096 (based on observed data) and wR_2 = 0.345 (based on all data). The structure was solved by direct methods and refined (based on F^2 using all independent data) by full matrix least-squares methods (Siemens SHELXTL V. 5.03). Hydrogen atom positions were located by their idealized geometry and refined using a riding model. An absorption correction was applied using XABS2.[9] CCDC 184/848.

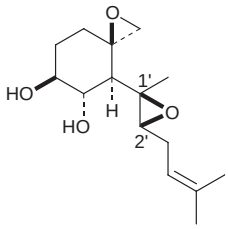
Total synthesis and absolute configuration of FR65814

Seiji Amano, Noriko Ogawa, Masami Ohtsuka, Seiichiro Ogawa and Noritaka Chida*†

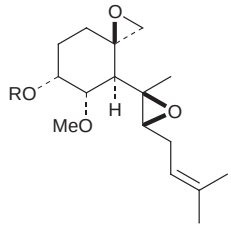
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223-8522, Japan

The chiral and highly stereoselective synthesis of FR65814 1, a novel immunosuppressant, starting from D-glucose is described; this first total synthesis fully confirms the proposed structure of 1.

FR65814 **1** is a sesquiterpene isolated from the culture broth of *Penicillium* and is reported to show potent immunosuppressive



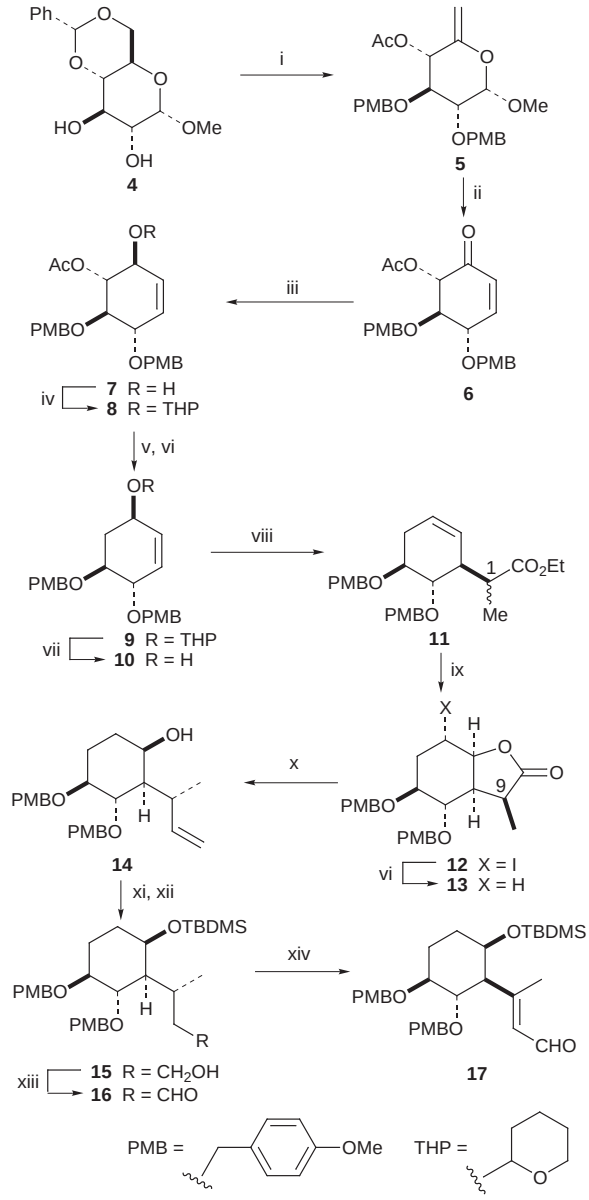
FR65814 **1**



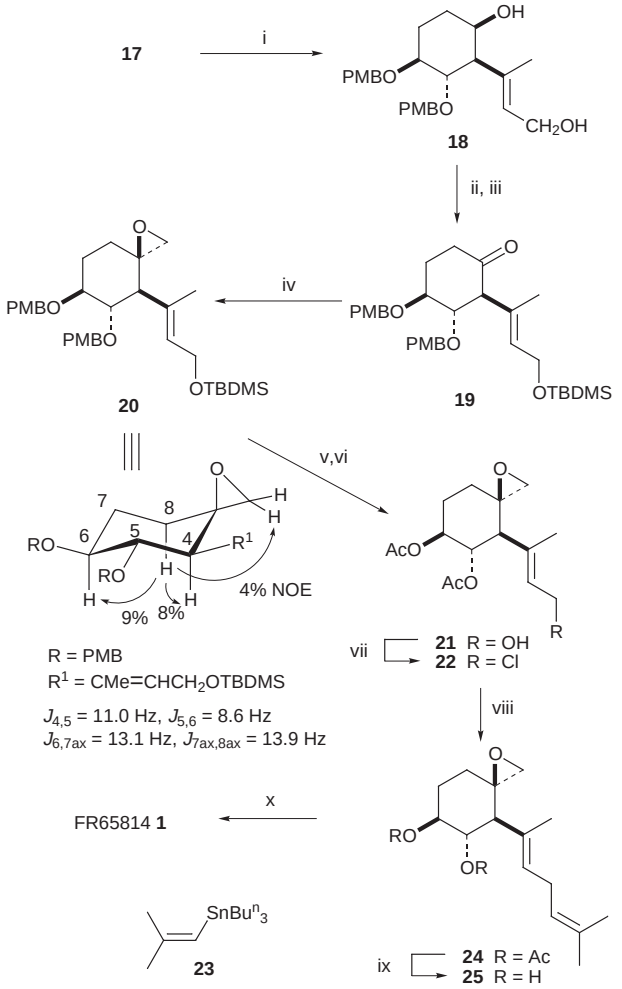
fumagillin **2** R = CO(CH=CH)$_4$CO$_2$H
E
fumagillol **3** R = H

activity.[1] The structure of **1** was tentatively assigned[1] on the basis of the spectral similarity to fumagillol **2**, a hydrolysis product of fumagillin **3**, which showed antiparasitic and carcinolytic activity.[2] The recent discovery of the inhibitory activity of fumagillin against endothelial cell proliferation and tumor-induced angiogenesis has attracted much biological attention,[3] and compounds related to fumagillin are expected to be anti-cancer drug candidates.[3] Such interesting biological activity as well as their challenging structures have stimulated synthetic efforts and the total syntheses of racemic fumagillin[4a] and optically active fumagillol[4b] have been reported. However, no report on the synthesis of **1** has appeared. Here, as a part of our continuous studies on the synthesis of biologically important compounds containing the cyclohexane unit, starting from aldohexoses and utilizing Ferrier's carbocyclization,[5,6] we report the first total synthesis of **1** from D-glucose.

Commercially available methyl 4,6-*O*-benzylidene-α-D-glucopyranoside **4** was transformed into 2,3-di-*O*-(4-methoxybenzyl)-6-deoxyhex-5-enopyranoside derivative **5** (Scheme 1) by essentially the same procedure as that reported for the preparation of the corresponding di-*O*-benzyl derivative[6a] (4-methoxybenzyl chloride was employed instead of benzyl bromide). Catalytic Ferrier's carbocyclization of **5** with Hg(OCOCF$_3$)$_2$ in aqueous acetone,[7] followed by β-elimination afforded cyclohexenone **6** in 84% yield. Reduction of the carbonyl group using Luche's conditions gave allyl alcohol **7** as the sole product in 90% yield. After protection of the alcohol function as a tetrahydropyranyl (THP) ether (99% yield), the acetoxy function in **8** was removed *via* a xanthate to provide **9** in 63% yield. Deprotection of the *O*-THP group afforded **10** in 96% yield. Claisen rearrangement of **10** with triethyl orthopropionate at 140 °C successfully introduced a carbon-side chain with the correct stereochemistry to provide **11** (74% yield).‡ Saponification of the ester group in **11** with Bu^{t}OK in DMSO[8] followed by iodolactonization gave **12** as the sole product,‡ whose iodo function was cleanly removed with Bu$^n_3$SnH to give **13** in 80% yield from **11**. DIBAL-H reduction of **13** afforded the corresponding lactol, whose Wittig reaction with $Ph_3P{=}CH_2$ gave **14** in 90% yield. After protection of the hydroxy group in **14**, the alkene portion was converted into primary alcohol by



Scheme 1 *Reagents and conditions*: i, see ref. 6(*a*); ii, Hg(OCOCF$_3$)$_2$ (5 mol%), acetone–H$_2$O, then MsCl, Et$_3$N, CH$_2$Cl$_2$; iii, NaBH$_4$, CeCl$_3$·7H$_2$O, MeOH, 0 °C; iv, 3,4-dihydro-2*H*-pyran, PPTS, CH$_2$Cl$_2$; v, MeONa, MeOH, then NaH, imidazole, CS$_2$, MeI, THF; vi, AIBN, Bu$^n_3$SnH, toluene, reflux; vii, PPTS, EtOH, 50 °C; viii, EtC(OEt)$_3$, EtCO$_2$H, 140 °C; ix, Bu^{t}OK, DMSO, then I$_2$, KI, aq. NaHCO$_3$–THF; x, DIBAL-H, toluene, −78 °C, then Ph$_3$PMe$_3$Br, BuLi, THF; xi, TBDMSOTf, 2,6-lutidine, CH$_2$Cl$_2$, 0 °C; xii, BH$_3$·THF, THF, 0 °C, then H$_2$O$_2$, NaOH; xiii, Pr$^n_4$NRuO$_4$, NMO, CH$_2$Cl$_2$; xiv, KN(SiMe$_3$)$_2$, TMSCl–Et$_3$N, THF, 0 °C, then Pd(OAc)$_2$, MeCN, 0 °C



Scheme 2 *Reagents and conditions*: i, DIBAL-H, toluene, −78 °C, then Bu^n_4NF, THF; ii, TBDMSCl, imidazole, DMF; iii, DMSO, Ac_2O; iv, $Me_3S(O)I$, NaH, DMSO, room temp.; v, DDQ, CH_2Cl_2–H_2O; vi, Ac_2O, pyridine, then Bu^n_4NF, THF; vii, LiCl, $MeSO_2Cl$, collidine, DMF; viii, **23**, $Pd(PPh_3)_4$ (10 mol%), THF, 50 °C; ix, MeONa, MeOH; x, vanadyl acetylacetonate (5 mol%), Bu^tOOH, CH_2Cl_2, −18 °C

hydroboration-oxidation to provide **15** (85% yield). Perruthenate oxidation[9] of **15** gave aldehyde **16** in 81% yield, which was converted into α,β-unsaturated aldehyde with *E*-geometry§ **17** in 45% yield by silyl enol ether formation followed by treatment with stoichiometric amount of $Pd(OAc)_2$.[10] The *Z*-isomer of **17** was isolated as the minor product (4% yield).

Having finished the preparation of highly oxygenated cyclohexane ring with carbon side-chain, elongation of the carbon chain and introduction of the bis-epoxide functionality were explored. DIBAL-H reduction of **17** and subsequent deprotection of the *O*-silyl group afforded diol **18** (Scheme 2). Protection of the primary alcohol function followed by oxidation of the secondary alcohol with Ac_2O–DMSO generated ketone **19** in 82% yield from **17**. Reaction of **19** with stabilized sulfur ylide[11] proceeded stereoselectively and afforded spiro epoxide **20** as the sole product in 57% yield. The observed coupling constants and NOE of **20** supported the assigned structure. Treatment of **20** with DDQ followed by conventional acetylation afforded diacetate, whose *O*-silyl protecting group was removed to provide **21** in 90% yield. The allyl alcohol **21** was transformed into allylic chloride **22** quantitatively. Stille coupling[12] of **22** with isobutenyltributyltin[13] **23** in the presence of $Pd(PPh_3)_4$ successfully provided the coupling product, *E*-diene§ **24**, in 72% yield. Removal of the *O*-acetyl group gave diol **25** in 95% yield. The final transformation, introduction of the second epoxide functionality, was stereoselectively achieved by vanadium-catalyzed epoxidation[14] to give FR65814 **1** in 70% yield.¶ The spectroscopic (^{1}H and ^{13}C NMR) data for synthetic **1** were identical with those of natural FR65814, and the physical properties of **1** {mp 39–40 °C (from Et_2O–hexanes); $[\alpha]_D^{21}$ − 41 (*c* 0.25, MeOH)} showed good accord with those of the natural product {mp 39–40 °C (from Et_2O–hexanes); mixed mp, 39–40 °C; $[\alpha]_D^{23}$ − 38.4[1] (*c* 2.4, MeOH)}. This successful first total synthesis of **1** confirmed the assigned structure of FR65814, and provided a novel synthetic pathway from carbohydrates to highly oxygenated terpenes possessing a cyclohexane unit.

We thank Fujisawa Pharmaceutical Co., Ltd., (Osaka, Japan) for providing us with natural FR65814. Financial support in the form of a Grant-in-Aid for Scientific Research on Priority Areas from the Ministry of Education, Science, Sports and Culture, of the Japanese Government is gratefully acknowledged.

Notes and References

‡ Compound **11** was obtained as an inseparable diastereomeric mixture at C-1 (1 : 1). Interestingly, epimerization at C-1 occurred during the saponification step and compound **12** was obtained as the single product. The stereochemistry at C-9 in **12** was confirmed by NOE experiments.

§ The NOE experiments clearly showed that the geometry of the double bond in both **17** and **24** should be *E*. No isomerization of the double bond was observed during the coupling reaction between **22** and **23**.

¶ A small amount (less than 5%) of diastereomeric epoxide (1′,2′-diepi-FR65814) was isolated. The chemical shifts and appearance of the hydrogen attached to the carbon bearing epoxide ring (H-2′) of **1** and its diastereomer in the ^{1}H NMR spectra ($CDCl_3$) are found to be characteristic: FR65814, fumagillol, δ 2.61 (dd, *J* 5.9, 7.1); 1′,2′-diepi-FR65814, δ 3.14 (br m); *cf.* δ 2.56 (dd, *J* 5.9, 7.1).

Synthesis of chiral carbohydrate-centered dendrimers

Michael Dubber and Thisbe K. Lindhorst*†

Institut für Organische Chemie der Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany

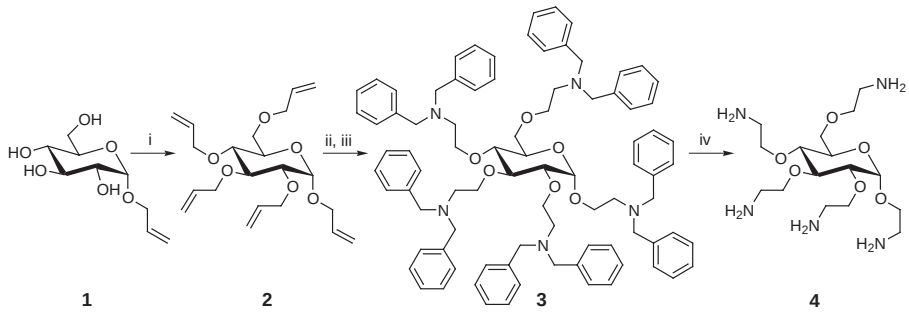
D-Glucose was converted into its per-*O*-(2-aminoethyl)-functionalized derivative 4, which served as initiator core for the construction of the chiral, monodisperse PAMAM-type carbohydrate-centered hybrid dendrimer 7.

Dendrimer chemistry is a rapidly developing field of research.[1] Dendrimers offer the prospect of novel materials with advantagous properties, allowing them to serve as soluble catalysts,[2] dendritic boxes[3] or other supramolecular dendritic arrangements. Furthermore, new applications such as enantioselective synthesis with chiral dendrimers, or favourable bioapplications such as in transfection[4] and glycobiology, are currently being explored. Dendrimer chemistry has been combined with carbohydrate chemistry in order to form multivalent glycomimetics[5] (glycodendrimers) with antiadhesive properties or other carbohydrate containing dendrimers.[6] Other than from the point of view of glycobiology, the combination of carbohydrates and dendrimers is attractive for the manipulation of dendritic structures leading to modified properties of, as yet, unestimated value. Carbohydrate cores are especially appealing for the design of dendrimers due to their easy availibility from the chiral pool and renewable resources, biocompatibility, low toxicity and natural polyfunctionality. In addition, intrinsic chirality may be introduced into dendrimers by using carbohydrate cores.[7] Furthermore, the stereochemical shape of dendrimers may be easily manipulated by choosing differently configurated monosaccharides, and the core multiplicity may be altered by utilizing mono-, di- or even oligosaccharides as carbohydrate cores, such as trehalose or raffinose. This is of special interest as the shape and composition of dendrimers may dramatically affect their host–guest relationships.[8]

Here we report the first synthesis of a carbohydrate-centered Starburst® PAMAM dendrimer based on a reaction sequence which is suited to converting reducing sugars into carbohydrate derivatives which can serve as initiator cores for the development of PAMAM generations. This was exemplified with D-glucose. First, allyl α-D-glucoside **1**, which was obtained by Fischer glycosylation, was perallylated to **2** under phase transfer catalysis (Scheme 1). Partially allylated products were not formed as the allylation rate increases with the extent of allylation of the starting material under these conditions.[9] Ozonolysis of the resulting allyl 2,3,4,6-tetra-*O*-allyl-α-D-glucoside (**2**) was performed in a $NaHCO_3$-buffered CH_2Cl_2–MeOH reaction mixture[10] to yield the desired penta-hemiacetal after reduction with PPh_3. This was characterized as the corresponding pentahydrate by NMR spectroscopy in D_2O. The penta-hemiacetal was submitted to a reductive amination reaction: application of $BnNH_2$ led to nearly inseparable mixtures comprised of cyclic amines, due to intramolecular reactions. However, the use of Bn_2NH and sodium acetoxyborohydride[11] as the reducing agent gave the desired benzyl cluster **3** at −10 °C in high yields without purification problems. Then **3** was converted into the pentaamine **4** by heterogeneous catalytic transfer hydrogenation reaction[12] with ammonium formate and Pd (10% on charcoal) in MeOH in a clean reaction. Thus the target compound **4** could be synthesized starting from allyl glucoside (**1**) in 43% overall yield.

The glucose derivative **4** represents a stereochemically well-defined, oligofunctional molecule with five uniformly functionalized spacers. It may serve as core molecule for the synthesis of carbohydrate-centered glycoclusters[13] or of carbohydrate-centered dendrimers. It was submitted to the reaction sequence leading to PAMAM dendrimer generations, consisting of the exhaustive Michael addition of the polyamine to methyl acrylate, followed by amidation of the resulting methyl esters with ethylenediamine.[14] Indeed reaction of **4** with methyl acrylate led to the decaester **5** in quantitative yield, which was quantitatively converted into the first generation hybrid PAMAM dendrimer **6** with ethylenediamine (Scheme 2). Further branching at the amino functions at the periphery of the molecule led to the eicosaester **7**, also in quantitative yield. The monodisperse structures of **5**–**7** could unequivocally be confirmed by NMR spectroscopy as ^1H–^{13}C HMBC NMR allowed the detection of each individual branch of every molecule.‡ All synthesized compounds are chiral.§ However, the specific rotation values of the carbohydrate-centered dendrimers decrease with increasing generation, according to observations made in the literature,[15] whereas the molar rotation values remain in the same range (*ca.* 400).

In conclusion, a reaction sequence has been elaborated which is generally applicable for the facile and uniform conversion of free saccharides into fully *O*-(2-aminoethyl)-functionalized derivatives such as **4**. These are suited for dendritic expansion, opening the door into a wide array of structurally diverse, but well-defined, carbohydrate-centered PAMAM dendrimers. The new hybrid dendrimers may be custom-designed by choice of the carbohydrate core giving rise to possible advantageous



Scheme 1 *Reagents and conditions*: i, allyl chloride (5 equiv.), 40% aq. NaOH, Bu_4NBr (1 equiv.), 35 °C, 16 h, 76%; ii, O_3, $NaHCO_3$, CH_2Cl_2–MeOH 6 : 1, work-up with PPh_3; iii, $Na(AcO)_3BH$, AcOH, Bn_2NH, THF, work-up with 1 M NaOH, 74% (2 steps); iv, Pd–C (10%), NH_4HCO_2, MeOH, 76%

New optically active hexaaza triphenolic macrocycles: synthesis, molecular structure and crystal packing features

Srinivas R. Korupoju and Panthapally S. Zacharias*†

School of Chemistry, University of Hyderabad, Hyderabad-500 046, India

3 + 3 Condensed optically active hexaaza triphenolic macrocyles 1 and 2 are synthesised and characterised; molecular and close packing structures of macrocycle 2 are discussed.

Synthesis and study of new ligands with phenolic groups is an area of active research interest because of their use as models for biological metal-binding sites, their ability to form metal complexes with interesting magnetic exchange, redox and catalytic properties.[1] 2,6-Diformyl-4-methylphenol[2] **A** is a useful source to synthesise such ligands and oxo-bridged macrocyclic complexes with diamines in the presence of template metal salts.[1] Although 2 + 2 condensed macrocyclic dinuclear complexes are the favoured products, a few 3 + 3 and 4 + 4 multinuclear macrocyclic complexes have been reported,[3] but the free ligands have not been isolated. Preformed ligands are required to investigate host–guest interactions, to synthesise complexes of metals inert to template reactions and complexes of heteronuclear metals. So far only 2 + 2 condensed metal-free macrocycles have been isolated (H^+ as a template ion) from **A**.[4] For the first time we report the synthesis and structural characterisation of a new template-free, 3 + 3 condensed and optically active hexaimine triphenolic Schiff base macrocycle **1** derived from **A** and *trans*-(*R*,*R*)-1,2-cyclohexyldiamine **B**,[5] and its reduced analogue hexaamine triphenolic macrocycle **2**. Macrocycles **1** and **2** have the potential to bind three metal ions through oxo-bridges.

The reaction of **A** and **B** in methanol in equimolar ratio using the high dilution technique affords a 3 + 3 Schiff-base macrocycle **1** as yellow solid in high yield. The molecular ion peak at *m/z* 727 of **1** indicates the condensation of three units of **A** and three units of **B**. The macrocycle **2**, the reduced analogue of macrocycle **1** was obtained by the reduction of **1** with $NaBH_4$ in methanol[6] and was identified by its molecular ion peak at *m/z* 739. Compounds **1** and **2** are also characterised by IR, NMR and CHN analysis.‡ The molecular structure of **2** was confirmed from its crystal structure (crystals of **1** were not suitable for X-ray structure determination).

The X-ray structure of **2**§ was performed on single crystals grown by slow evaporation from benzene. It crystallises in space group *R*3 (no.146) wherein the molecular three-fold symmetry coincides with the crystallographic three-fold axis. The macrocyclic cavity is defined by 27 atoms in which six N-atoms and 21 C-atoms are present. The three phenolic-OH groups projected inside the cavity generate three equivalent N_2O_2 sub-cavities. The geometry of these sub-cavities appears suitable for metal complexation as the two N and two O atoms provide appropriate coordination sites. The macrocycle is stabilised by intra-molecular (O–H···N, N–H···O, N–H···N) hydrogen bonding with H···acceptor distances lying in the range 2.02–2.29 Å. An ORTEP drawing of **2** with intramolecular hydrogen bonding is shown in Fig. 1.

The macrocycle has an internal hydrophilic cavity capable of forming hydrogen bonds and has an external hydrophobic periphery. The molecules are extended in the *ab* plane with the mean plane of the molecule perpendicular to the *c*-axis. It can be seen from the packing diagram (Fig. 2) that each molecule is surrounded by six molecules leading to a trigonal network structure. The organisation of the molecules in the *ab* plane is governed by the hydrophobic interaction between the methyl groups of moiety **A** and methylene groups of moiety **B** and is not assisted by any other observable interactions. The two $CH_3\cdots CH_3$ and cyclohexyl $CH_2\cdots CH_2$ close packing C–C distances are 3.96 and 4.00 Å, respectively. The stacking in the *c*-axis is maintained by inter-molecular N–H···N hydrogen bonding [N(2)–H(2)···N(1): D = 3.22 Å, d = 2.23 Å, θ =

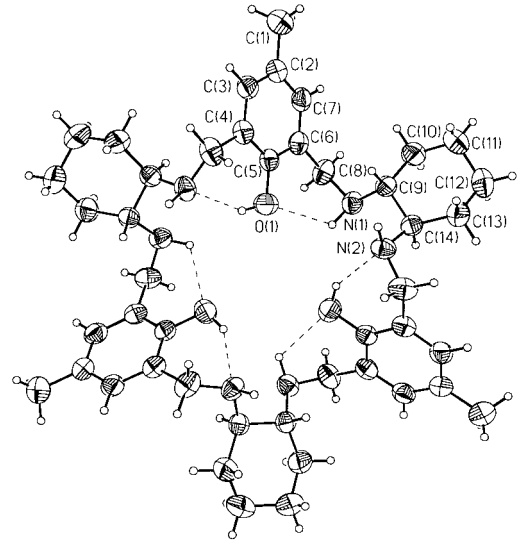

Fig. 1 An ORTEP diagram of macrocycle **2**; thermal ellipsoids are shown at the 50% probability level

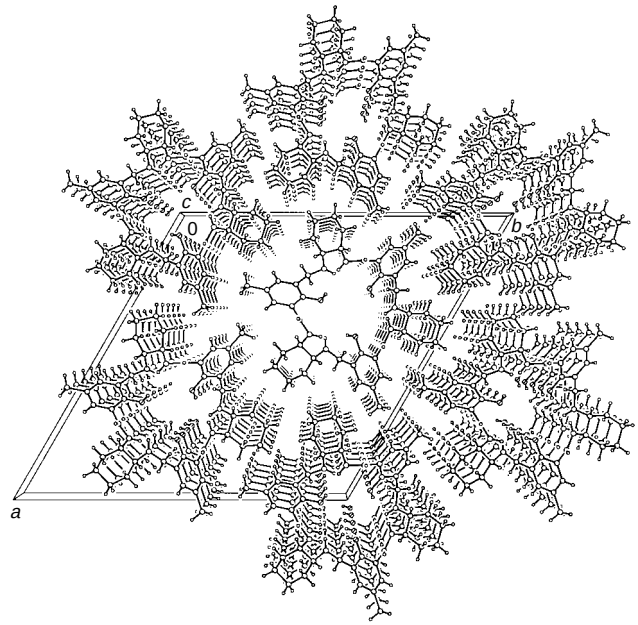

Fig. 2 Stacks viewed down the *c*-axis of macrocycle **2**

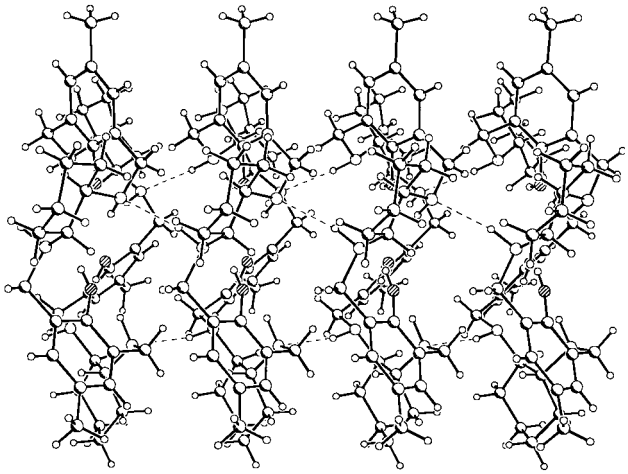

Fig. 3 The intermolecular hydrogen bonds between the molecules viewed down the *Y*-axis of macrocycle **2**

167.32°) and supported by weak C–H···O interactions (H···O, 2.9 Å) leading to a channel like structure. The aromatic rings of the moiety **A** in the stacks are separated by 5.143 Å as shown in Fig. 3. The three-dimensional trigonal assembly of the macrocycle is maintained by hydrophobic interactions in the *ab* plane and hydrogen bonding along the *c*-axis. Although carry-over of the molecular symmetry into the crystal is not very common, the non-centrosymmetric trigonal networking of molecules as shown in Fig. 3 is reported to have important applications in NLO and an example of such arrangements due to intermolecular hydrogen bonding has been reported recently.[7]

The X-ray structure of macrocycle **2** suggests an analogous structure for macrocycle **1**. The successful synthesis of **1** and **2** results from the stability of the 27-membered macrocycle possibly due to its optimum ring size and the intramolecular hydrogen bonding interactions.

Further studies on the host–guest properties of **1** and **2** with metal ions, solvent molecules, organic guest molecules and variations in crystal packing pattern by changing the substituents on the macrocycle in different solvents are in progress.

S. R. K. gratefully acknowledges the UGC, New Delhi for financial support and the National Single Crystal Diffractometer Facility of this department (DST) for crystallography.

Synthesis and characterisation of a microporous zirconium silicate with the structure of petarasite

J. Rocha,*[a]† P. Ferreira,[a] Z. Lin,[a] J. R. Agger[b] and M. W. Anderson[b]

[a] *Department of Chemistry, University of Aveiro, 3810 Aveiro, Portugal*
[b] *Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD*

The synthesis and structural characterisation of AV-3, a microporous sodium zirconium silicate with the structure of the mineral petarasite, are reported.

Recently, the synthesis of inorganic microporous framework solids containing metal atoms in different coordination geometries has raised considerable interest. We have been particularly concerned with the chemistry of microporous titanium silicates containing tetracoordinated Si^{4+} and Ti^{4+} usually in octahedral coordination.[1–3] As a natural extension of this work, we are now engaged in a systematic study aimed at preparing novel microporous zirconium silicates. Although several mineral microporous zirconium silicates are known, so far, little has been done in order to synthesise such solids in the laboratory.[4] Here we wish to report the synthesis and structural characterisation of a synthetic analogue (denoted AV-3, Aveiro microporous solid no. 3) of the rare mineral petarasite (Mont St-Hilaire, Québec, Canada), $Na_5Zr_2Si_6O_{18}(Cl,OH)\cdot 2H_2O$.[5]

AV-3 was prepared in Teflon-lined autoclaves under hydrothermal conditions. An alkaline solution was made by mixing 5.35 g sodium silicate solution (27% m/m SiO_2, 8% m/m Na_2O, Merck), 7.21 g H_2O, 1.43 g NaOH (Merck), 2.00 g NaCl (Aldrich) and 1.00 KCl (Merck). 0.84 $ZrCl_4$ (Aldrich) were added to this solution and stirred thoroughly. The gel, with a composition 1.75 Na_2O : 0.28 K_2O : 1.0 SiO_2 : 0.15 ZrO_2 : 25 H_2O, was autoclaved for 10 days at 230 °C. The crystalline product was filtered, washed with distilled water and dried at ambient temperature, the final product being an off-white microcrystalline powder.

AV-3 samples were characterised by bulk chemical analysis (ICP), powder X-ray diffraction (XRD), scanning electron microscopy (SEM), ^{29}Si and ^{23}Na solid state NMR and FTIR spectroscopies and thermogravimetry (TG).

The crystal structure of petarasite (and AV-3) consists of an open three-dimensional framework built of corner-sharing six-membered silicate rings and [ZrO_6] octahedra (Fig. 1).[5]

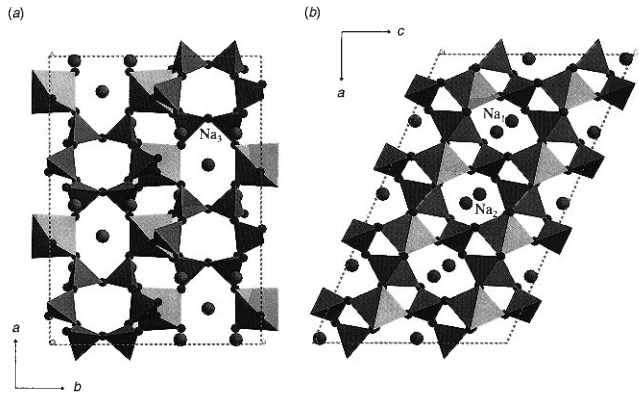

Fig. 1 Polyhedral representations of the petarasite (and AV-3) structure viewed along (*a*) [0 0 1] showing the corner-sharing, six-membered silicate rings and Zr octahedra; Na(3) and Cl ions reside in the elliptical channels; (*b*) [0 1 0] showing the elliptical channels which accommodate the Na(1) and Na(2) ions

Elliptical channels (3.5 × 5.5 Å) defined by mixed six-membered rings, consisting of pairs of [SiO_4] tetrahedra linked by Zr octahedra, run parallel to the *b* and *c* axes. Other channels limited by six-membered silicate rings run parallel to the *c* axis. The sodium, chloride and hydroxyl ions and the water molecules reside within the channels.

Fig. 2 shows the experimental and simulated powder XRD patterns of AV-3. The unit cell parameters have been calculated assuming a monoclinic unit cell, space group $P2_1/m$, and cell dimensions a = 10.771, b = 14.505, c = 6.575 Å, β = 112.664°, and are similar to those reported for petarasite (a = 10.795, b = 14.493, c = 6.623 Å, β = 113.214°).[5]

The AV-3 ^{29}Si solid-state NMR spectrum with magic-angle spinning (MAS) (not shown) displays three peaks at δ −86.6, −91.9 and −94.3 in 1 : 0.9 : 1 intensity ratio. In accord with this observation, the crystal structure of petarasite calls for the presence of three unique Si sites with equal populations.[5]

The sheared ^{23}Na triple-quantum (3Q) MAS NMR spectrum[6] of AV-3 [Fig. 3(*a*)] contains two resolved peaks at δ *ca.* 5.9 and 2.4 (F1) and, due to a distribution of isotropic chemical shifts, a relatively broad signal centred at δ *ca.* 9.6. From the centres of gravity δ_1 and δ_2 (F_1 and F_2 dimensions, respectively) of the two-dimensional spectrum it is possible to estimate the (average) isotropic chemical shift, δ_{iso}, and the second-order quadrupole effect parameters, SOQE, of the lines:[7] S1 (−3.9, 2.1 MHz), S2 (−1.9, 2.5 MHz) and S3 (−1.4, 3.1 MHz). Petarasite contains three crystallographically independent seven-coordinated sodium sites.[5] Na(1) and Na(2) reside in channels parallel to *b* and Na(3) is located in channels parallel to *c*. The [$Na(1)O_5(H_2O)Cl$] and [$Na(2)O_5(H_2O)Cl$] polyhedra are distorted monocapped octahedra, while the [$Na(3)O_6Cl$] polyhedron is a distorted hexagonal pyramid. A second Cl atom may be considered part of the Na(3) coordination and this is, hence, the most distorted sodium site. Accordingly, peak S3, which displays the largest SOQE, is attributed to site Na(3). This assignment is supported by ^1H–^{23}Na cross-polarisation (CP) MAS NMR spectroscopy [Fig. 3(*b*)]. Indeed, the broad low-frequency tail seen in the single-quantum ^{23}Na MAS NMR spectrum, which is due to peak S3 [see F2 projection in Fig. 3(*a*)], is hardly seen in the CP MAS NMR spectrum. Such a behaviour is expected for Na(3) because this site is not coordinated to any water molecules. The Cl and OH ions are disordered over the Na(3) sites and only those environments which contain OH will, in principle, cross-polarise. In contrast,

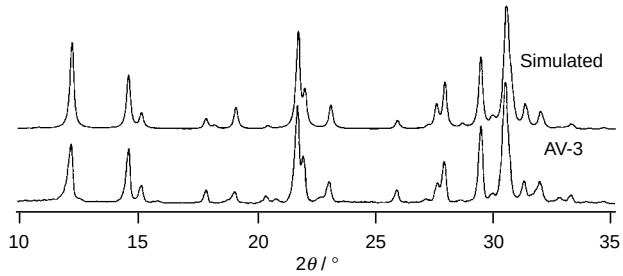

Fig. 2 Experimental and simulated powder XRD patterns of AV-3

sites Na(1) and Na(2), which have water molecules in their coordination spheres, cross-polarise relatively well. The quantification of multiple-quantum MAS NMR spectra is not a trivial problem. Indeed, the intensity of the resonances is not representative of the actual concentration of species because the excitation of the multiple-quantum coherences is strongly dependent on the NMR quadrupole frequency. However, since we have recorded the ^{23}Na 3Q MAS NMR spectrum of AV-3 with a strong (160 kHz) radiofrequency field we believe the measured peak intensities are approximately correct. These have been derived by both volume integration and deconvolution of the isotropic (F1) sum projection. These methods yield for S1, S2 and S3 intensity ratios of 1.0 : 1.0 : 0.8–0.9, respectively, in good agreement with the crystal structure of petarasite.

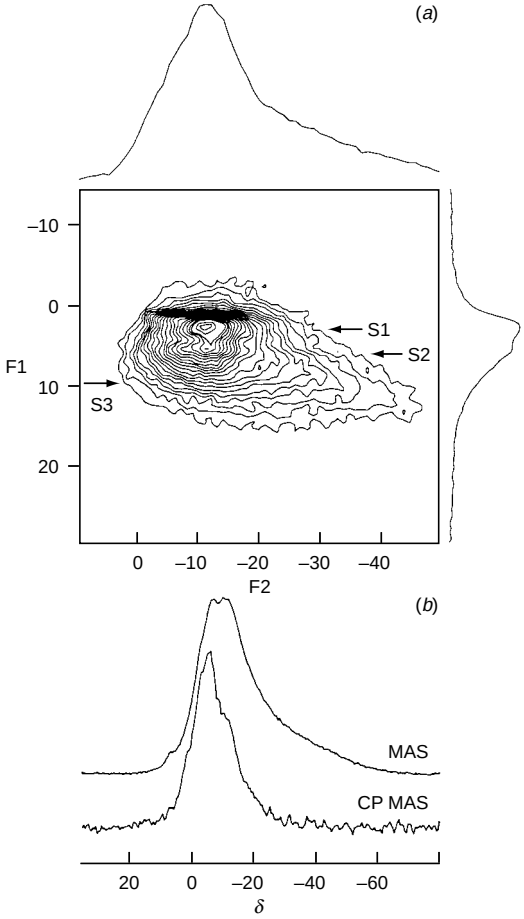

Fig. 3 (*a*) 3Q ^{23}Na MAS NMR spectrum of AV-3 recorded at 105.85 MHz on a Bruker MSL 400P with a rf field amplitude of *ca.* 160 kHz. 210 data points were acquired in the t_1 dimension in increments of 7.0 μs. To produce pure-absorption lineshapes a simple two-pulse sequence was used.[7,9] The ppm scale was referenced to ν_0 frequency in the ν_2 domain and to $3\nu_0$ in the ν_1 domain (reference 1 M aqueous NaCl). (*b*) Single-quantum ('conventional') ^{23}Na MAS and CP MAS NMR (0.5 ms contact time) spectra of AV-3.

TG provides further evidence that the structures of AV-3 and petarasite[8] are very similar. The total AV-3 mass loss between 30 and 830 °C is 5.34% and it is due to the release of molecular water, structural or adsorbed. This value corresponds to 2.4 water molecules and is in excess of the two water molecules revealed by the crystal-structure analysis. Thus, as petarasite,[8] the solid contains a considerable amount of adsorbed water. Between *ca.* 800 and 1100 °C a second stage of dehydration occurs with a mass loss of 3.14% {3.19% in petarasite corresponding to $[Cl_{0.67}(OH)_{0.33}]$}, probably due to the loss of Cl and OH. The parent AV-3 and the material calcined at 750 °C and rehydrated in air overnight at room temperature display similar TGA curves and powder XRD patterns. The fact that the framework does not collapse until the release of Cl indicates that this is an essential constituent of the structure.[8]

The FTIR spectrum of AV-3 (not shown) resembles the spectrum reported for petarasite,[8] and confirms the presence of strucutral and adsorbed water. In addition, the spectrum contains a ring-breathing band at *ca.* 775 cm^{-1} characteristic of ring silicates.

In conclusion, we report the successful synthesis and structural characterisation of a microporous framework zirconium silicate, AV-3, possessing the structure of the rare mineral petarasite.

An enantioselective Baylis–Hillman reaction catalyzed by chiral phosphines under atmospheric pressure

Tadakatsu Hayase,[a] Takanori Shibata,[a] Kenso Soai*[a]† and Yasuo Wakatsuki[b]

[a] *Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo, 162-8601, Japan,*

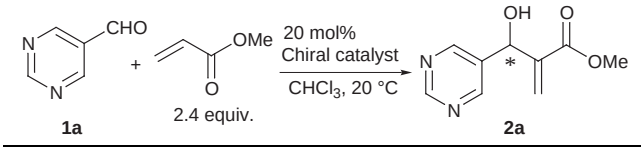
2,2'-Bis(diphenylphosphino)-1,1'-binaphthyl (BINAP) catalyzes the enantioselective Baylis–Hillman reaction between pyrimidine- 5-carbaldehydes and acrylates to provide chiral α-methylene β-hydroxy esters in up to 44% ee under atmospheric pressure.

The condensation of an aldehyde and acrylate is known as the Baylis–Hillman reaction, and increasing interest has been focused on this reaction.[1] It affords α-methylene β-hydroxy esters, which are furnished with functional groups for further transformations.[2] Therefore the development of an enantioselective Baylis–Hillman reaction would provide a useful synthetic tool for the preparation of chiral polyfunctionalized compounds. However, only very limited examples have been reported, such as an enantioselective Baylis–Hillman reaction between nitrobenzaldehyde[3] or aliphatic aldehydes[4] and methyl vinyl ketone catalyzed by chiral tertiary amines. Moreover, very high pressure is required to afford adducts with low to moderate enantiomeric excess (ee). Thus, exploration of enantioselective Baylis–Hillman reactions is a challenging problem.[5]

Here we report the first example, to the best of our knowledge, of a chiral phosphine-catalyzed intermolecular enantioselective Baylis–Hillman reaction under atmospheric pressure.[6,7]

In the presence of a catalytic amount (20 mol%) of various chiral phosphines, the enantioselective Baylis–Hillman reaction of pyrimidine-5-carbaldehyde **1a** with methyl acrylate was examined at 20 °C in $CHCl_3$ (Table 1, entries 1–6). By the use of bidentate chiral phosphines (DIOP, NORPHOS), a chiral phosphine possessing a hydroxy group (BPPFOH) or an axially chiral monodentate phosphine (MOP), Baylis–Hillman adduct **2a** was obtained; however, almost no or only slight asymmetric induction was observed (entries 1–4). On the other hand, we found that (*S*)-BINAP,[8] an axially chiral bidentate phosphine, catalyzes the enantioselective reaction to give chiral (−)-α-methylene β-hydroxy ester **2a** in 44% ee (entry 5). Adduct (+)-**2a** with 43% ee was obtained by the use of (*R*)-BINAP. These enantioselectivities are comparable with those of the reported enantioselective methods using chiral tertiary amines under high pressures.[3,4] (*S*)-Tol-BINAP is also an effective asymmetric catalyst and **2a** was provided in improved yield along with slightly decreased ee (entry 6).

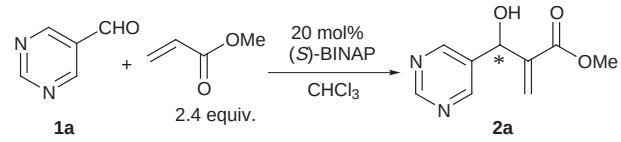
Table 1 Chiral phosphine-catalyzed Baylis–Hillman reaction



Entry	Chiral catalyst	*t*/h	Yield (%)	Ee (%)[a]
1	(2*R*,3*R*)-DIOP[b]	19	28	< 1
2	(2*R*,3*R*)-NORPHOS[c]	21	32	3
3	(*R*,*S*)-BPPFOH[d]	20	46	2
4	(*S*)-MOP[e]	66	53	< 1
5	(*S*)-BINAP	85	24	44
6	(*S*)-Tol-BINAP[f]	89	41	31

[a] Determined by HPLC analyses using a chiral column. [b] DIOP = 2,3-*O*-isopropylidine-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane. [c] NORPHOS = 2,3-bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene. [d] BPPFOH = (*R*)-1-[(*S*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethanol. [e] MOP = 2-(diphenylphosphino)-2′-methoxy-1,1′-binaphthyl. [f] Tol-BINAP = 2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphthyl.

Table 2 Effect of reaction temperature



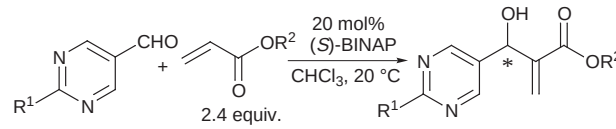
Entry	*T*/°C	*t*/h	Yield (%)	Ee (%)[a]
1	0	127	18	43
2	20	85	24	44
3	50	38	49	42
4	70	19	38	41

[a] Determined by HPLC analyses using a chiral column.

Next, the BINAP-catalyzed Baylis–Hillman reaction was performed at various temperatures (Table 2). In this reaction, the temperature did not significantly affect the enantioselectivities, however, **2a** was obtained in the highest yield (49%) at 50 °C (entry 3).‡

Various acrylates were submitted to this enantioselective Baylis–Hillman reaction (Table 3, entries 1–3). The yield and ee were dependent on the bulk of the acrylate: the less bulky acrylate gave the higher yield and ee. 2-Methylpyrimidine-5-carbaldehyde **1b** also reacts with methyl acrylate in the presence of BINAP. The reaction proceeded slowly but adduct

Table 3 Reaction of aldehydes **1a,b** with various active olefins



Entry	R^1	R^2	*t*/h	Yield (%)	Ee (%)[a]
1	H	Pr^i	95	8	9
2	H	Et	62	12	25
3	H	Me	85	24	44
4	Me	Me	329	18	37
5[b]	Me	Me	62	26	30

[a] Determined by HPLC analyses using a chiral column. [b] Tol-BINAP was used as a chiral catalyst.

2b was obtained in moderate ee (entry 4). Acceleration of the reaction was observed by the use of Tol-BINAP, and **2b** was provided in higher yield but with lower ee (entry 5).

As described, the present chiral phosphine-catalyzed reaction would provide a new method for enantioselective Baylis–Hillman reaction under atmospheric pressure.

‡ *General experimental procedure* (Table 2, entry 3): To a $CHCl_3$ solution (1.0 ml) of (*S*)-BINAP (62.3 mg) and pyrimidine-5-carbaldehyde **1a** (54.4 mg) was added methyl acrylate (0.11 ml) at ambient temperature. The reaction mixture was stirred for 38 h at 50 °C, then it was evaporated to dryness under reduced pressure. Purification of the crude product by TLC gave pure Baylis–Hillman adduct (–)-**2a** (47.8 mg, 49%). The ee was determined to be 42% by HPLC analysis (chiral column: Daicel Chiralcel OD-H, eluent: 3% Pr^iOH in hexane, flow rate: 1.0 ml min^{-1}, wavelength for UV detector: 254 nm, retention time: 36 min for the major isomer and 41 min for the minor isomer).

Phosphorus–carbon bond activation of PMe_3 at a dimolybdenum center: synthesis and structure of $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$

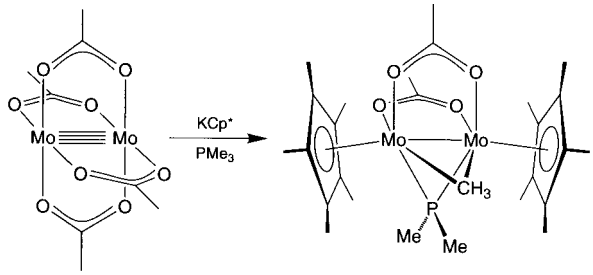
Jun Ho Shin and Gerard Parkin*

Department of Chemistry, Columbia University, New York, New York 10027, USA

The reaction of $Mo_2(\mu\text{-}O_2CMe)_4$ with KCp* in the presence of PMe_3 yields $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ as a result of cleavage of the P–CH_3 bond.

The quadruply bonded dimolybdenum acetato complex $Mo_2(\mu\text{-}O_2CMe)_4$ has been shown to exhibit an extensive chemistry, allowing access to a large variety of mononuclear, dinuclear and polynuclear complexes.[1] In this paper, we report an unusual reaction of $Mo_2(\mu\text{-}O_2CMe)_4$ which results in P–C bond activation of PMe_3 at a dimolybdenum center.

As part of an effort to find new methods of synthesis for permethylcyclopentadienyl molybdenum complexes,[2] we have studied the reaction of $Mo_2(\mu\text{-}O_2CMe)_4$ with KCp* (Cp* = $\eta^5\text{-}C_5Me_5$) in the presence of PMe_3. Interestingly, rather than yielding a 'molybdenocene' derivative,[3] the bridging dimethylphosphido–methyl complex, $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$, is obtained in *ca*. 30% isolated yield over a period of 3 days at room temperature (Scheme 1). The molecular structure of $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ has been determined by X-ray diffraction (Fig. 1 and Table 1),[4] thereby demonstrating that the P–CH_3 bond of PMe_3 has been cleaved. ^1H and ^{13}C NMR spectroscopic data also provide decisive evidence in accord with this formulation. For example, the ^1H NMR spectrum exhibits three doublets at δ 0.97 ($^2J_{PH}$ 10 Hz), 0.91 ($^2J_{PH}$ 9 Hz), and −5.25 ($^3J_{PH}$ 5 Hz) for the $[Mo_2(\mu\text{-}PMe_2)(\mu\text{-}Me)]$ moiety, with the lattermost resonance attributed to the molybdenum methyl group.



Scheme 1

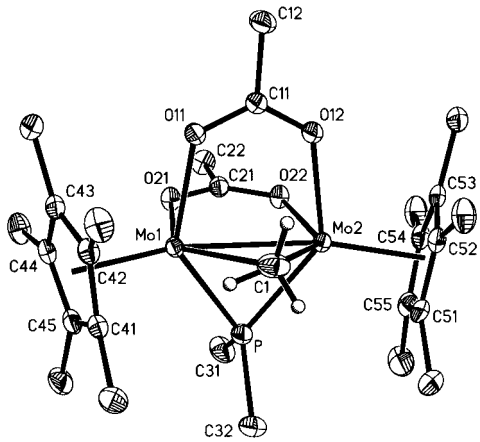


Fig. 1 Molecular structure of $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$

Table 1 Selected bond lengths for $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$

X	*d*[Mo(1)–X][a]/Å	*d*[Mo(2)–X][b]/Å

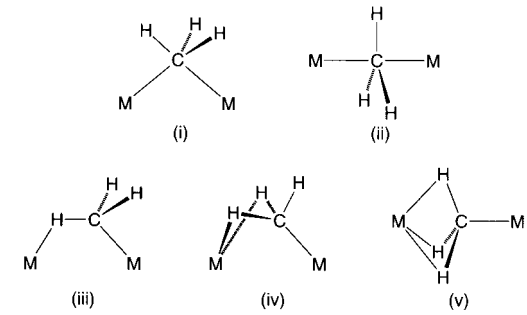
C(*z*4)	2.419(4)	2.421(5)
C(*z*5)	2.352(4)	2.327(5)

[a] $x = 2, y = 1, z = 4$. [b] $x = 1, y = 2, z = 5$.

The facile cleavage of the P–CH_3 bond in the formation of $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is of interest not only because such transformations are rare,[5,6] but also because the P–CH_3 bond cleavage in this system takes precedence over the much more ubiquitous C–H bond cleavage reactions of PMe_3.[7] Furthermore, the structure of $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is noteworthy because both $[PMe_2]$ and [Me] fragments remain coordinated to the metal centers after cleavage has taken place. We are aware of three other examples of P–CH_3 cleavage reactions of PMe_3,[8–10] only one of which yields a product that contains both $[PMe_2]$ and [Me] groups coordinated to a metal, namely the reaction of $CpNi(\mu\text{-}H)(\mu\text{-}CO)WCp_2$ with PMe_3 to give $CpNi(\mu\text{-}PMe_2)(\mu\text{-}CO)WCpMe(PMe_3)$.[8]

In addition to representing a noteworthy example of P–C bond cleavage, $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is also of interest from a structural perspective since there are no examples of dimolybdenum complexes with bridging methyl groups listed in the Cambridge Structural Database.[11,12] Bridging methyl groups have been proposed to adopt five different coordination modes (Scheme 2), which may be classified as (i) symmetric pyramidal,[13] (ii) symmetric planar,[14] (iii) monohapto agostic,[15] (iv) dihapto agostic,[16,17] and (v) trihapto agostic.[17,18] Of these modes, the bridging methyl group in $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is appropriately described as symmetric pyramidal, with chemically equivalent Mo–C bond lengths [2.300(7) and 2.301(7) Å][19] and an acute Mo–C–Mo bond angle [76.4(2)°].[20] The $^1J_{CH}$ coupling constant associated with this methyl group is 113 Hz, less than that for



Scheme 2

typical terminal molybdenum methyl groups (*ca.* 127–136 Hz),[21] and possibly reflects a diminished s-contribution to the C–H bond,[22] rather than an agostic interaction.[20]

The Mo–Mo separation of 2.8447(5) Å in $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is consistent with the presence of a direct Mo–Mo interaction.[23] In this regard, the Mo–Mo separation is longer than the values in complexes with formal double bonds, *e.g.* $[CpMo]_2(\mu\text{-}S)_2(\mu\text{-}SPr^i)(\mu\text{-}PPh_2)$ [2.623(2) Å][24] and $[(C_5Me_4H)Mo(CO)](\mu\text{-}PPh_2)_2[Mo(CO)(C_5Me_4\text{-}P(O)Ph_2)]$ [2.744(1) Å],[25] and notably shorter than the values in other phosphido bridged complexes such as $[CpMo(CO)_2]_2(\mu\text{-}PMe_2)(\mu\text{-}H)$ [3.262(7) Å],[26] $[CpMo(CO)_2]_2(\mu\text{-}PBu^t_2)(\mu\text{-}H)$ [3.247(1) Å],[27] and $[CpMo(CO)_2]_2(\mu\text{-}PPh_2)(\mu\text{-}H)$ [3.244(1) Å].[28,29] Furthermore, the length of the Mo–Mo bond in $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is marginally longer than the W–W separation of 2.78 Å in Chisholm's closely related tungsten complex, $Cp_2W_2(\mu\text{-}\eta^2\text{-}O_2CEt)_2(\mu\text{-}\eta^1\text{-}O_2CEt)(\mu\text{-}NMe_2)$, which has been assigned to a single bond.[30]

In summary, the reaction of $Mo_2(\mu\text{-}O_2CMe)_4$ with KCp* in the presence of PMe_3 yields $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$, the formation of which involves a novel P–CH_3 cleavage reaction of PMe_3.

We thank the US Department of Energy, Office of Basic Energy Sciences (#DE-FG02-93ER14339) for support of this research. G. P. is the recipient of a Presidential Faculty Fellowship Award (1992–1997).

4 $[Cp^*Mo(\mu\text{-}O_2CMe)]_2(\mu\text{-}PMe_2)(\mu\text{-}Me)$ is monoclinic, $P2_1/n$ (no. 14), a = 10.989(1), b = 14.0436(9), c = 18.844(2) Å, β = 90.353(9)°, U = 2908(1) Å^3, Z = 4, T = room temp., R_1 = 0.0404 [$I > 2\sigma(I)$]. The hydrogen atoms of the bridging methyl group were located and refined isotropically, giving the following bond lengths (Å): C1–H1a 0.86, C1–H1b 0.97, C1–H1c 0.84 Å. CCDC 182/868.

6 In contrast to P–C cleavage in alkylphosphines, the cleavage of P–C bonds in arylphosphines is common, with the ease of cleavage typically following the order $P–C_{sp3} < P–C_{sp2} < P–C_{sp}$.[5] The majority of examples of $P–C_{sp3}$ bond cleavage, however, involve degradation of bidentate phosphine ligands.[6a–e] (*a*) V. Riere, M. A. Ruiz, F. Villafañe, C. Bois and Y. Jeannin, *J. Organomet. Chem.*, 1989, **375**, C23; (*b*) I. J. B. Lin, J. S. Lai and C. W. Liu, *Organometallics*, 1990, **9**, 530; (*c*) K.-B. 15 For examples, and for a discussion of the factors responsible for the bridging methyl group in $[\{Cp(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}Me)]^+$ adopting a monohapto agostic interaction, see: B. E. Bursten and R. H. Cayton, *Organometallics*, 1986, **5**, 1051 and references therein.

16 For example, $Cp^*_2Yb(\mu\text{-}Me)_2Pt(dippe)$[16a] and $[CpV(NC_6H_3Pr^i_2)(\mu\text{-}Me)_2]_2(\mu\text{-}Mg)$.[16b] (*a*) D. J. Schwartz, G. E. Ball and R. A. Andersen, *J. Am. Chem. Soc.*, 1995, **117**, 6027; (*b*) M. C. W. Chan, J. M. Cole, V. C. Gibson and J. A. K. Howard, *Chem. Commun.*, 1997, 2345.

17 $[LiBMe_4]$ exhibits both dihapto and trihapto bridging methyl interactions. See: W. E. Rhine, G. Stucky and S. W. Peterson, *J. Am. Chem. Soc.*, 1975, **97**, 6401.

18 For example, $Cp^*_2Yb(\mu\text{-}Me)BeCp^*$. See: C. J. Burns and R. A. Andersen, *J. Am. Chem. Soc.*, 1987, **109**, 5853.

19 For comparison, the mean length for terminal Mo–CH_3 interactions listed in the Cambridge Structural Database is 2.23 Å, with a range of 2.03–2.40 Å.

20 Although a short Mo···H separation of 2.02 Å suggests that some monohapto agostic character to the interaction could be considered, we feel that the equivalence of the Mo–C bond lengths and the acute Mo–C–Mo bond angle is a more important indicator of the type of bridge [see, for example ref. 13(*c*)].

21 For example, $(Cp^{Bu^t})_2MoMe_2$ (128 Hz),[21a] $[(Cp^{Bu^t})_2Mo(CO)Me][I]$ (136 Hz),[21a] $[(Cp^{Bu^t})_2Mo(PMe_3)Me][I]$ (130 Hz),[21a] and $Cp^*Mo(NO)_2Me$ (127 Hz).[21b] (*a*) J. H. Shin and G. Parkin, unpublished work; (*b*) W. L. Elcesser, M. Sörlie and J. L. Hubbard, *Organometallics*, 1996, **15**, 2534.

22 $^1J_{CH}$ coupling constants for hydrocarbons correlate with the hybridization (sp^n) of the bonding orbital according to the relationship $^1J_{CH} = 500(1/1 + n)$. See: (*a*) H. S. Gutowsky and C. S. Juan, *J. Am. Chem. Soc.*, 1962, **84**, 307; (*b*) N. Muller and D. E. Pritchard, *J. Chem. Phys.*, 1959, **31**, 1471.

23 Considering a bridging methyl group as a L–μ-X ligand,[23a] the Mo–Mo interaction may be described as a formal single bond. Alternatively, the interaction may be described as a formal double bond if an electron counting procedure[23b] that does not explicitly consider the 3-center–2-electron nature of the Mo–Me–Mo fragment is used. Direct synthesis of organochlorosilanes by the reaction of metallic silicon with hydrogen chloride and alkene/alkyne

Masaki Okamoto, Satoshi Onodera, Yuji Yamamoto, Eiichi Suzuki and Yoshio Ono*†

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152, Japan

Organosilicon compounds were directly synthesized from metallic silicon, alkene/alkyne and HCl, $EtHSiCl_2$ being obtained with 47% selectivity from Si, C_2H_4 and HCl at 513 K, and CH_2=$CHSiHCl_2$ and $EtHSiCl_2$ with 39 and 23% selectivity, respectively, when C_2H_2 was used in place of C_2H_4.

Methylchlorosilanes, especially dimethyldichlorosilane, are produced industrially by the reaction of metallic silicon with MeCl using a copper catalyst.[1] The direct synthesis of dimethyldichlorosilane is the key step for synthesizing silicone polymers. Various mechanisms have been proposed for this direct synthesis.[2] We carried out the reaction in the presence of butadiene as a silylene trapping agent and found that an appreciable amount of silacyclopent-3-enes was formed together with methylchlorosilanes.[3] This indicates the intermediacy of silylene-type species in this heterogeneous reaction. It was presumed that the silylene species are formed on the surface of a silicon–copper alloy, through which silicon atoms diffuse out to the surface from the phase of metallic silicon. The intermediacy of the silylene species has also been proposed for the selective formation of trialkoxysilanes in the direct reactions of metallic silicon with alcohols.[4]

HCl also reacts with metallic silicon to afford chlorosilanes, mainly trichlorosilane.[5] We presume that the surface silylene is also an intermediate for the selective formation of trichlorosilane.

It is well known that the addition of silylenes to alkenes gives vinylsilanes *via* silacyclopropane intermediates.[6,7] It is very plausible that silylene species at the surface also react with alkenes to form silacyclopropanes. In previous work, we have reported that ethylmethoxysilanes are obtained by the reaction of metallic silicon, MeOH and C_2H_4.[8] When allyl propyl ether was used instead of C_2H_4, allyldimethoxysilane was obtained in 38% selectivity.[9]

In this work, we report that alkylsilanes are directly prepared by the reaction of metallic silicon and HCl in the presence of C_2H_4 or propene. Organosilanes are also obtained by the reaction of metallic silicon, HCl and C_2H_2.

The reactions were carried out in a fixed-bed flow reactor. The mixture of metallic silicon (8.9 mmol) and copper(I) chloride (0.79 mmol) as a catalyst was placed in a quartz tube reactor (id 10 mm) and preheated at 723 K for 10 min. Then, HCl (3 mmol h^{-1}) and C_2H_4 (12 mmol h^{-1}) was fed to the reactor at 513 K. The reactor effluents were analyzed every 10 min by GC.

Fig. 1 shows the time courses of the rates of formation of products and cumulative conversion of silicon. Ethyldichlorosilane and trichlorosilane were obtained as the main products. The rates of formation of these products increased to the maximum with reaction time and then decreased. Small amounts of dichlorosilane and tetrachlorosilane were also formed. The cumulative conversion of silicon reached 36% in 12 h. Though the reaction was stopped at 12 h in the experiment in Fig. 1, further increases in silicon conversion would be attained on further extending reaction time. The overall selectivity for ethyldichlorosilane for 12 h was 47%. The selectivities for dichlorosilane, trichlorosilane and tetrachlorosilane were 6, 45 and 2%, respectively.

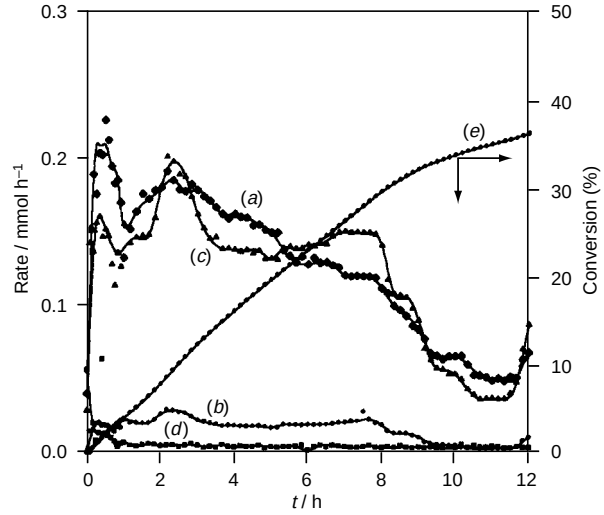

Fig. 1 Time courses of formation rates of the products and cumulative conversion of silicon in the reaction of silicon, HCl and C_2H_4. Preheating: 723 K for 10 min; reaction: 513 K, Si: 8.9 mmol, CuCl: 0.79 mmol. Feed: HCl (3 mmol h^{-1}) and C_2H_4 (12 mmol h^{-1}). Rates of formation of (*a*) ethyldichlorosilane, (*b*) dichlorosilane, (*c*) trichlorosilane, (*d*) tetrachlorosilane and (*e*) conversion of silicon.

Note that ethyldichlorosilane was the sole organosilane produced. To explain this fact, we propose the following reaction scheme involving surface silylene **1** as shown in Scheme 1. In the absence of C_2H_4, the surface silylene reacts with HCl. The subsequent reactions through surface species **2** and **3** lead to the formation of $HSiCl_3$ as the main product. The formation of $HSiCl_3$ by the addition of HCl to dichlorosilylene has been reported.[10] The silylene intermediate **1** reacts with C_2H_4 to form silacyclopropane species **4**. The species **4** is converted into the surface species **5** by attack of HCl. Finally attack of HCl on the species **5** leads to the cleavage of the two Si–Cu bonds to form ethyldichlorosilane.

Use of propene instead of C_2H_4 under similar conditions resulted in the formation of propyldichlorosilane and isopropyldichlorosilane with the selectivities of 10 and 24%, respectively, together with chlorosilanes.

When C_2H_2 was used instead of alkenes, vinyldichlorosilane and ethyldichlorosilane were produced. After preheating the

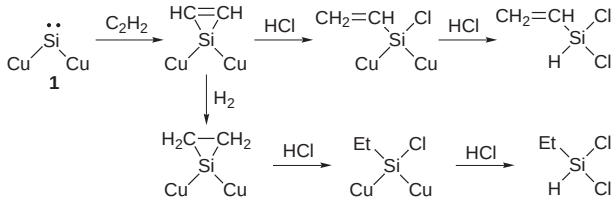

Scheme 2

Table 1 Effect of C_2H_2 : HCl ratio on the Si–HCl–C_2H_2 reaction[a]

C_2H_2 : HCl ratio	Si conversion (%)	(C_2H_3)-$HSiCl_2$ (%)	$EtHSiCl_2$ (%)	H_2SiCl_2 (%)	$HSiCl_3$ (%)	$SiCl_4$ (%)
0.33	15	27	15	4	53	1
0.26	16	34	21	0	45	0
0.2	31	23	11	4	61	1
0.13	37	22	11	5	62	1
0.07	67	10	3	11	76	1
0	85	—	—	6	93	1

[a] Preheating: 723 K for 10 min; reaction: 513 K for 5 h, Si: 8.9 mmol, Cu: 0.20 mmol, HCl: 15 mmol h^{-1}.

silicon–CuCl mixture at 723 K, only HCl (15 mmol h^{-1}) was fed at 513 K for 10 min. During this period, 1% of silicon charged in the reactor was consumed to form chlorosilanes, the main product being $HSiCl_3$. Then, the feed of HCl was changed to a mixture of HCl (15 mmol h^{-1}) and C_2H_2 (4 mmol h^{-1}). Vinyldichlorosilane and ethyldichlorosilane were produced together with chlorosilanes. The overall selectivities in the 5 h reaction for vinyldichlorosilane and ethyldichlorosilane were 39 and 23%, respectively, these two organosilanes accounting for 62% of the products. About 13% of silicon charged in the reactor was consumed in 5 h. A plausible mechanism for the formation of vinyl- and ethyl-dichlorosilane is shown in Scheme 2.

The silylene intermediate **1** reacts with C_2H_2 to form a silacyclopropene surface species, which is attacked by HCl to form a surface species containing a vinyl group. Silacyclopropene intermediates are often postulated in the reaction of silylenes with alkynes, though normally only dimeric products, 1,4-disilacyclohexa-2,5-dienes are obtained.[7,11] The exclusive formation of monomeric products indicates the silylene species do not exist in the vapor phase, but are located on the surface. Formation of ethyldichlorosilane indicates that the hydrogenation of the intermediate(s) occurs on the surface.

Table 1 shows the effect of the C_2H_2 : HCl molar ratio on the product distribution. Without C_2H_2, high conversion of metallic silicon is attained, giving trichlorosilane as a main product. As the C_2H_2 : HCl ratio increases, the reactivity of metallic silicon decreases. The selectivity for organosilanes was highest at a C_2H_2 : HCl ratio of 0.26.

The reactions of silicon, HCl and alkene/alkyne offer a new method for synthesizing organosilanes directly from metallic silicon.

A novel molecular species incorporating a cyclic organolithate anion and a disiloxane-solvated lithium cation

Colin Eaborn,*† Salima M. El-Hamruni, Peter B. Hitchcock and J. David Smith*†

School of Chemistry, Physics and Environmental Sciences, University of Sussex, Brighton, UK BN1 9QJ

The disiloxane $O\{SiMe_2CH(SiMe_3)_2\}_2$ is readily metallated by LiMe in thf (thf = tetrahydrofuran) to give the compound $SiMe_2C(SiMe)_3LiC(SiMe_3)_2SiMe_2OLi(thf)_2$, the crystal structure of which is reported.

In 1983 we reported the first diorganolithate, $[Li(thf)_4][Li\{C(SiMe_3)_3\}_2]$ **1** (thf = tetrahydrofuran)[1] and more recently we described the related cyclic species **2**.[2] We have now obtained and structurally characterized the somewhat more distantly related cyclic lithate **3**, which has unprecedented features.

$[Li(thf)_4][CH_2SiMe_2C(SiMe_3)_2LiC(SiMe_3)_2SiMe_2CH_2]$

2

$[SiMe_2C(SiMe_3)_2LiC(SiMe_3)_2SiMe_2OLi(thf)_2]$

3

We have found that the disiloxane $O\{SiMe_2CH(SiMe_3)_2\}_2$[3] is metallated by LiMe in thf at room temperature, that is much more readily than $(Me_3Si)_3CH$,[4] probably because of initial interaction of the siloxane oxygen atom with the Li of the LiMe.‡ Recrystallization of the product, **3**, from heptane gave crystals suitable for an X-ray diffraction study, which yielded the structure shown in Fig. 1.§

The main novel features of **3** are as follows.

(*a*) In contrast to **1** and **2**, in each of which the lithate anion and the solvated lithium cation are well separated, compound **3** is a molecular dipolar species, the $Li(2)^+$ centre being attached to the lithate ion *via* the oxygen of the siloxane linkage. Both the O(1) and Li(2) atoms have essentially planar geometries [sum of angles 358.6(5) and 360.0(6)°, respectively]. The Si–O–Si angle is 138.5(3)°, a fairly normal value for a siloxane linkage.[5] The angle between the bonds to the thf molecules, O(3)–Li(2)–O(2) 101.2(6)°, is narrow, presumably to minimize steric interactions.

(*b*) As far as we can ascertain compound **3** is the first example of a structurally characterized disiloxane–metal complex in which the ligand is attached to the metal only through its oxygen atom. In all other examples of coordination of disiloxane oxygen to a metal this bonding is supported by bonding through another atom of the ligand; examples include systems of the types Me_3SiO–Pd–Si,[6] Me_3SiO–Zr–CH_2SiMe_2,[7] and Me_3SiO–Li–N–Si.[8] (A polysiloxane analogue of a crown ether complex, $[K(OSiMe_2)_7]^+$,[9] and siloxane-solvation of Na and K centres within complex polysiloxane frameworks[10] were recently reported.) Remarkably, since siloxanes are normally thought to be much weaker donors than organic ethers,[6,7,11] the Li–O bond to the siloxane oxygen in **3**, 1.917(12) Å, is not significantly longer than those to the thf molecules, mean 1.912(12) Å. [See also (*d*) below. In contrast, the O–M bonds in the Pd and Zr compounds mentioned above are rather long, and this was attributed to the poor donor ability of siloxanes.[6,7]] The interaction of the oxygen lone pair with Li leads to a large increase in the Si–O(1) bond length to a mean of 1.704(5) Å from the 1.63–1.64 Å usually found in disiloxanes.[5]

(*c*) The mean Li–C bond length in **3**, 2.12(2) Å, is not significantly different from that in **1**, 2.18(1) Å, or **2**, 2.156(4) Å. To accommodate the demands of the six-membered ring the C–Li–C angle is lowered to 144.2(7)°, compared with 180° in **1** and 171.4(7)° in **2**. The closest contacts between the Li atom and the methyl groups are to C(6) and C(18) [Li–C(6) 3.12, Li–C(18) 3.00 Å], there are corresponding contacts (3.04 Å) in **2**.

(*d*) In contrast to **2**, in which the exocyclic C–$SiMe_3$ bonds and endocyclic C–$SiMe_2CH_2$ bonds are all essentially of equal length, mean 1.829(4)°, in **3** the C–$SiMe_3$ bonds have a mean length of 1.835(4)°, effectively identical with those in **2**, but the endocyclic C–$SiMe_2O$ bonds have a mean length of only 1.806(6)°. This can be attributed to more effective delocalization of carbanionic charge by negative hyperconjugation[12] directed towards oxygen rather than towards carbon.[7] Such enhancement of the negative charge on the oxygen atom could strengthen the O(1)–Li(2) interaction. (Or, from an alternative viewpoint, this interaction could enhance the hyperconjugation.)

(*e*) The mean of the Si–C–Si angles in **3** is 117.3°, compared with 115.9° in **2**, but, the separate values, and those of the Li–C–Si angles, range more widely than in **2**. The Me_3Si–C–$SiMe_3$ angles, mean 114.0(2)°, are markedly smaller than the Me_3Si–C–$SiMe_2O$ angles, mean 119.6°, these latter angles varying

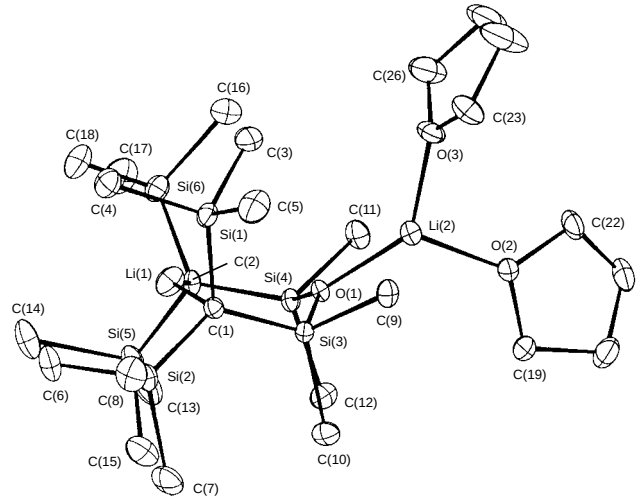

Fig. 1 Selected bond lengths (Å) and angles (°) for **3**: C(1)–Si(1) 1.843(7), C(1)–Si(2) 1.829(7), C(1)–Si(3) 1.809(6), C(2)–Si(4) 1.804(6), C(2)–Si(5) 1.834(7), C(2)–Si(6) 1.836(7), C(1)–Li(1) 2.105(14), C(2)–Li(1) 2.13(2), O(1)–Si(3) 1.706(5), O(1)–Si(4) 1.702(5), O(1)–Li(2) 1.917(12), O(2)–Li(2) 1.909(12), O(3)–Li(2) 1.914(13), Si–Me (mean) 1.886(6); Si(1)–C(1)–Si(2) 113.5(3), Si(1)–C(1)–Si(3) 115.5(3), Si(2)–C(1)–Si(3) 124.4(4), Si(4)–C(2)–Si(5) 117.8(4), Si(4)–C(2)–Si(6) 120.8(4), Si(5)–C(2)–Si(6) 114.6(3), C(1)–Li(1)–C(2) 144.2(7), Li(1)–C(1)–Si(3) 93.2(4), Li(1)–C(2)–Si(4) 94.8(4), Li(1)–C(1)–Si(1) 99.6(5), Li(1)–C(2)–Si(5) 104.5(5), Li(1)–C(2)–Si(6) 97.2(5), Si(3)–O(1)–Li(2) 109.1(5), Si(4)–O(1)–Li(2) 111.0(5) O(1)–Li(2)–O(2) 125.6(7), O(1)–Li(2)–O(3) 133.2(7), O(2)–Li(2)–O(3) 101.2(6), Si(3)–O(1)–Si(4) 138.5(3), O(1)–Si(3)–C(9) 100.3(3), O(1)–Si(3)–C(10) 104.3(3), O(1)–Si(4)–C(1) 99.4(3), O(1)–Si(4)–C(12) 106.1(3), Me–Si–Me (mean) 103.9(4).

from 115.5(3) to 124.4(4)°. As in **2** the two CSi_3 systems on either side of the molecule are distorted and tilted (with respect to the Li–C bonds) differently; presumably this is predominantly to maximize Me···Me distances, but it also accommodates the observed Me···Li interactions. In consequence the molecule as a whole has no symmetry.

Compound **3** can be expected to serve as a source of the dicarbanionic ligand $(Me_3Si)_2\bar{C}SiMe_2OSiMe_2\bar{C}(SiMe_3)_2$. This ligand should give novel cyclic and linear-polymeric derivatives of a range of metals, and may be especially effective in the case of cyclic derivatives of elements for which the dialkylmetals prefer a bent C–M–C framework, *e.g.* Ca,[13] Yb[14,15] and Eu.[15]

We thank the EPSRC for financial support and the Libyan Government for the award of a postgraduate scholarship to S. M. El-H.

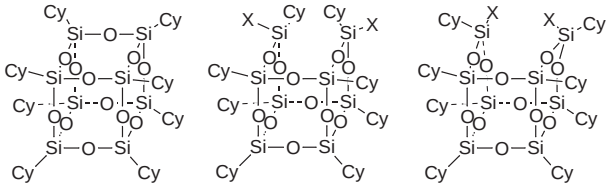
Practical methods for synthesizing four incompletely condensed silsesquioxanes from a single $R_8Si_8O_{12}$ framework

Frank J. Feher,*† Daravong Soulivong and Frank Nguyen

Department of Chemistry, University of California, Irvine, CA 92697-2025, USA

The reaction of (c-C_6H_{11})$_8Si_8O_{12}$ 1 with triflic acid (TfOH) can produce two different ditriflates with the formula (c-C_6H_{11})$_8Si_8O_{11}$(OTf)$_2$, which can be hydrolyzed selectively to four different incompletely condensed silsesquioxane frameworks with the formula (c-C_6H_{11})$_8Si_8O_{11}$(OH)$_2$ (2, 4, 7 and 8).

Incompletely condensed silsesquioxanes have attracted broad interest as models for silica surfaces,[1–3] ligands for main group, transition-metal and lanthanide elements,[4–6] building blocks for network solids,[7,8] and precursors to new families of silsesquioxane-containing polymers.[9,10] Our recent discovery that a single Si–O–Si linkage in a fully-condensed $R_8Si_8O_{12}$ framework (*i.e.* **1**) can be cleaved selectively by strong acids [*e.g.* HBF_4–BF_3 or



1 Cy = c-C_6H_{11} **2** X = OH **3** OTf **4** X = OH **5** NHPh

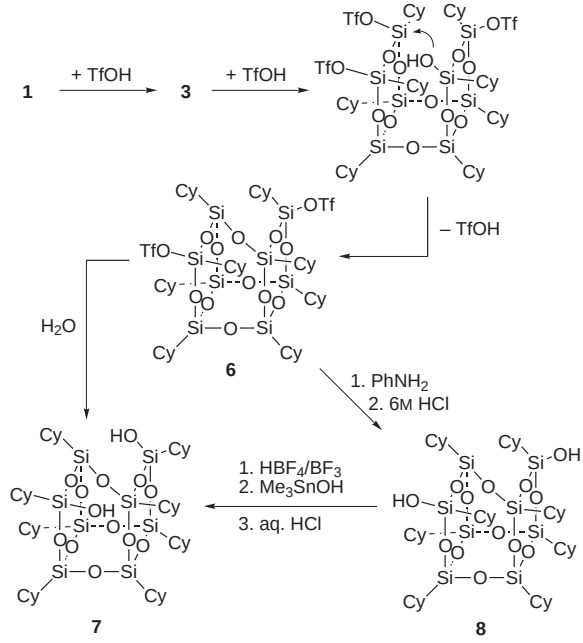
TfOH (triflic acid)] provides an important new method for preparing incompletely condensed frameworks (*e.g.* **2** and **4**),[11] but there are still strong incentives for devising practical routes to silsesquioxanes with reactive SiOH groups. Here, we report an improved method for synthesizing **2**, as well as the discovery of an interesting acid-induced rearrangement reaction of **1** that provides access to two other incompletely condensed frameworks (*i.e.* **7** and **8**).

The reaction of **1** with TfOH (5 equiv., 25 °C, C_6H_6, 30 min) occurs rapidly upon mixing to afford quantitative NMR yields of a C_{2v}-symmetric ditriflate derived from cleavage of a single Si–O–Si linkage (*e.g.* **3**).[11] This ditriflate reacts with a variety of nucleophiles to afford products resulting from substitution of triflate with complete inversion of stereochemistry at Si.[12] When water[11] or aniline[12] are used as nucleophiles in large excess, **4** or **5** can be obtained in high yield. Disilanol **4** is hydrolytically stable, but **5** reacts very slowly with water to afford several products resulting from hydrolysis of Si–N bonds, including disilanol **2**. Both the rate and selectivity of hydrolysis can be greatly increased by performing the reaction with 6 M HCl. Under these conditions, high yields of **2** are obtained within a few minutes of mixing.‡ This route to **2** is far superior to our previously reported method[11] based on Me_3Sn-OH-mediated hydrolysis of fluoride-substituted frameworks, and it allows both **2** and **4** to be prepared from a common intermediate (*i.e.* **3**) which can be obtained in high yield from a readily available $R_8Si_8O_{12}$ framework.

When **1** is reacted with a larger excess of TfOH (10 equiv., 25 °C, C_6H_6, 3 h), cleavage of additional Si–O–Si linkages is observed, but the major product is not a tetratriflate derived from cleavage of the second Si–O–Si linkage. Instead, this reaction produces large amounts (*ca.* 70%) of a new C_2-symmetric framework with two Si–OTf groups. If cleavage of the second Si–O–Si linkage by TfOH and intramolecular displacement of a triflate group both occur with complete inversion of stereochemistry at Si, the mechanism proposed in Scheme 1 predicts that this new ditriflate is **6**.§ This ditriflate reacts with H_2O or aqueous $NaHCO_3$ to afford **7**;¶ hydrolysis of the ditriflate *via* sequential reaction with excess aniline and 6 M HCl affords **8**. The structures of **7** and **8** were established by comparison to authentic samples prepared by alternative methods. Disilanol **8** is available in 15–20% yield *via* the slow (3–36 months) hydrolytic condensation of $CySiCl_3$.[3] Disilanol **7** can be independently synthesized *via* sequential reactions of **8** with HBF_4–BF_3, Me_3SnOH and aqueous HCl. The stereochemical consequences of these reactions are well established and known to invert the stereochemistry of SiOH groups on silsesquioxane frameworks.[11,13,14]

The formation of **6** during the reaction of **1** with TfOH is surprising because it requires formation of an Si_5O_5 ring under conditions where Si_4O_4 rings are cleaved selectively and Si–OH groups are quickly converted into Si–OTf groups by an excess of TfOH. It is difficult to rationalize the high selectivities observed in these reactions. Nevertheless, it is abundantly clear that Si–O–Si cleavage by strong acids can be extremely selective and that the formation of new Si–O–Si linkages can be competitive.

In conclusion, the reaction of **1** with TfOH can produce two different ditriflates (**3** and **6**), which can be hydrolyzed selectively to four different incompletely condensed silsesquioxane frameworks (**2**, **4**, **7** and **8**). These results represent an important advance in the chemistry of discrete silsesquioxanes



Scheme 1

because **1** is available in high yield *via* base-catalyzed hydrolytic condensation of $CySi(OMe)_3$[15] and catalytic hydrogenation of readily available $Ph_8Si_8O_{12}$.[16,17] Our efforts to expand the generality of these reactions, as well as the reaction chemistry of **3** and **6** will be reported in due course.

These studies were supported by the National Science Foundation and Phillips Laboratory (Edwards AFB).

Notes and References

‡ Disilanol **2** was prepared in quantitative yield by adding an excess of 6 M HCl to a solution of **5** in THF. The product obtained after evaporation of the THF and a standard aqueous work-up with Et_2O as an extraction solvent was identical in all respects to an authentic sample of **2** prepared according to ref. 11.

§ The ditriflate tentatively assigned as **6** was prepared by reacting **1** (102 mg, 0.094 mmol) and TfOH (83 μl, 0.943 mmol) at 25 °C for 3 h according to the procedure described for the synthesis of **3**.[11] Repeated attempts to crystallize the crude product were unsuccessful because the ditriflate is extremely water sensitive and highly soluble in all solvents with which it does not react. The crude product obtained after evaporation of the solvent is *ca.* 70% pure (by ^{13}C and ^{29}Si NMR spectroscopy) and should be used immediately to avoid decomposition. Selected characterization data: $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 25 °C), δ 27.35–25.26 (CH_2), 23.24, 23.00, 22.95, 22.66 (s CH, 1 : 1 : 1 : 1). $^{29}Si\{^1H\}$ NMR (99 MHz, $CDCl_3$, 25 °C), δ −62.82, −64.84, −67.25, −68.02 (1 : 1 : 1 : 1). A C_2-symmetric structure with the opposite orientation of Cy and OTf groups is equally consistent with all of our spectroscopic and analytical data. Although this structure it is considered unlikely on the basis of mechanistic considerations, it should not be ruled out until the structure of **6** is confirmed by a single-crystal X-ray diffraction study.

¶ For **7**: ^1H NMR (500 MHz, $CDCl_3$, 25 °C), δ 2.38 (br s, 2 H), 1.73 (br m, 40 H), 1.24 (br m, 40 H), 0.42 (br m, 8 H). $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 25 °C), δ 27.45, 27.40, 27.37, 26.76, 26.70, 26.60, 26.52, 26.45, 26.42 (for CH_2), 23.46, 23.29, 23.27, 22.15 (1 : 1 : 1 : 1 for CH). $^{29}Si\{^1H\}$ NMR (99 MHz, $CDCl_3$, 25 °C): δ −57.47, −66.18, −67.24, −67.76 (1 : 1 : 1 : 1). Synthesis, molecular structure, and reactivity of an Li_2Br_4 octahedrally stabilized organoaluminium bromide dimer

Xiao-Wang Li, Jianrui Su and Gregory H. Robinson*

Department of Chemistry, The University of Georgia, Athens, GA 30602-2556, USA

The synthesis, molecular structure, and reactivity of an unusual Li_2Br_4 octahedrally stabilized organoaluminium bromide dimer, $[(Mes_2C_6H_3)AlBr_3Li]_2$, is described.

Utilization of the sterically demanding 2,6-dimesitylphenyl ligand, ($Mes_2C_6H_3$), with group 13 elements has afforded a number of interesting compounds in recent years. Monomeric compounds of boron, $(Mes_2C_6H_3)BBr_2$,[1] gallium, $(Mes_2C_6H_3)_2GaX$ (X = Cl,[2] Br[3]), and indium ($(Mes_2C_6H_3)_2InBr$,[4] have been reported. Gallium and indium dimers such as $[(Mes_2C_6H_3)GaCl_2]_2$ and $[(Mes_2C_6H_3)InCl_2]_2$[5] have also been prepared. It is particularly significant that this ligand system has been shown to stabilize cyclogallenes, organometallic 2π-electron aromatic moieties, $M_2[(Mes_2C_6H_3)Ga]_3$[6–9] (M = Na, K). In notable contrast, the corresponding organoaluminium chemistry of this ligand has proven considerably less fruitful. Reaction of Me_3SiCl with $[(Mes_2C_6H_3)AlH_3{\cdot}LiOEt_2]_n$ gives $(Mes_2C_6H_3)AlCl_2{\cdot}OEt_2$.[10] Herein we report the synthesis,† molecular structure, and reactivity of the Li_2Br_4 octahedrally stabilized aluminium bromide dimer $[(Mes_2C_6H_3)AlBr_3Li]_2$ **1**. Reaction of **1** with lithium 2,6-diisopropylphenylamide, $Li[N(H)(Pr^i_2C_6H_3)]$, affords $(Mes_2C_6H_3)Al[N(H)(Pr^i_2C_6H_3)]_2$, **2**.

The structure of **1** (Fig. 1)‡ which resides about a center of symmetry, may be described as an Li_2Br_4 octahedrally stabilized aluminium bromide dimer. The Li_2Br_4 octahedron is facilitated by the displacement of the lithium atoms from the *ipso*-carbon atoms of the ligands by $AlBr_3$ moieties. **1** is easily compared with the unsolvated (2,6-dimesitylphenyl)lithium dimer, $[(Mes_2C_6H_3)Li]_2$.[11] Perhaps most interesting is the differences in lithium coordination of **1** compared to that of $[(Mes_2C_6H_3)Li]_2$. In $[Mes_2C_6H_3)Li]_2$ the primary interaction between the lithium and the ligand involves the *ipso*-carbon atoms. The Li–C_{ipso} bond distances are 2.17(1) and 2.16(1) Å while the secondary lithium–carbon interactions (with the *ipso*-carbon atoms of the *o*-mesityl substituents) range from 2.51(1) to 2.56 Å. In striking contrast from $[(Mes_2C_6H_3)Li]_2$, the lithium atoms in **1** only interact with the 2,6-dimesitylphenyl ligand in an η^6-aryl ring fashion with lithium–carbon contacts ranging from 2.38(4) to 2.70(4) Å. In addition to the Li–(η^6-aryl) ring interaction, and quite unlike other reported lithium aryls, the core **1** is further stabilized by weak lithium–bromine contacts: 2.52(2), 2.67(3) and 2.80(3) Å. These distances are considerably longer than the corresponding value reported for gaseous LiBr (2.35 Å).[12] Furthermore, the Li···Li separation in **1** of 3.45(6) Å is considerably longer than the values reported for $[(Mes_2C_6H_3)Li]_2$ (2.31, 2.27 Å). The environment about the aluminium atom may be described as distorted tetrahedral with bond angles ranging from 99.0(5) to 122.5(5)°. The Al–C bond distance in **1** of 1.96(2) Å compares well with other four-coordinate aluminium compounds. The Al–Br bond distances, 2.359(5), 2.285(6) and 2.398(5) Å, for Al–Br(1), Al–Br(2) and Al–Br(3), respectively, are comparable to other reported Al–Br distances.[13–15]

The unusual structure of **1** underscores the often substantial differences in chemical behavior of organoaluminium moieties relative to other group 13 congeners. However, it is interesting that reaction of **1** with $Li[N(H)(Pr^i_2C_6H_3)]$ proceeds in an expected manner affording **2**. The aluminium atom in **2** assumes a trigonal planar geometry [bond angles about Al: 127.3(5), 116.4(2) and 116.4(2)°] (Fig. 2) with generally unremarkable Al–Cl [1.978(11) Å] and Al–N [1.788(6) Å] bond distances. The Al–N bond distance in **2** is quite comparable to values reported for $[CpAl–N(Pr^i_2C_6H_3)]_2$ [1.796(2) and 1.811(3) Å][16] while these are much shorter than the distances reported for $[(Me_3CCH_2)_2Al–N(H)(Pr^i_2C_6H_3)]_2$ [2.013(5) and 2.007(5) Å].[17] **2** contains a mirror plane which bisects the N–Al–N bond

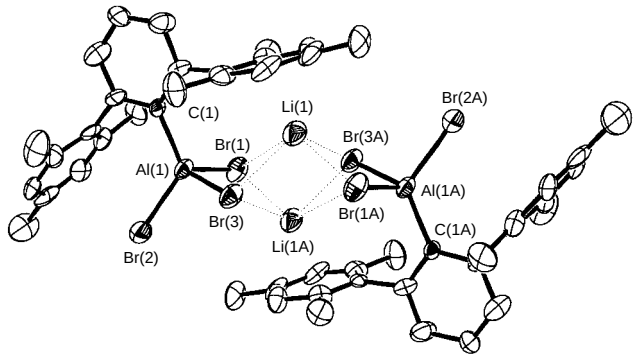

Fig. 1 Molecular structure of $[(Mes_2C_6H_3)AlBr_3Li]_2$ **1**. Selected bond distances (Å) and angles (°): Al(1)–C(1) 1.96(2), Al(1)–Br(1) 2.359(5), Al(1)–Br(2) 2.285(6), Al(1)–Br(3) 2.398(5), Br(1)–Li(1A) 2.67(3), Br(3)–Li(1) 2.52(3), Br(3)–Li(1A) 2.80(3), Li(1)–Li(1A) 3.41(5), Li(1)–C(7) 2.70(3), Li(1)–C(8) 2.70(3), Li(1)–C(9) 2.51(3), Li(1)–C(10) 2.43(3), Li(1)–C(11) 2.38(4), Li(1)–C(12) 2.55(4), C(1)–Al(1)–Br(1) 111.1(5), C(1)–Al(1)–Br(2) 122.2(5), C(1)–Al(1)–Br(3) 115.5(5), Br(2)–Al(1)–Br(1) 106.2(2), Br(2)–Al(1)–Br(3) 99.0(2), Br(1)–Al(1)–Br(3) 100.0(2), Al(1)–Br(1)–Li(1A) 88.5(7), Al(1)–Br(3)–Li(1) 106,1(8), Al(1)–Br(3)–Li(1A) 84.9(7), Li(1)–Br(3)–Li(1A) 79.6(9).

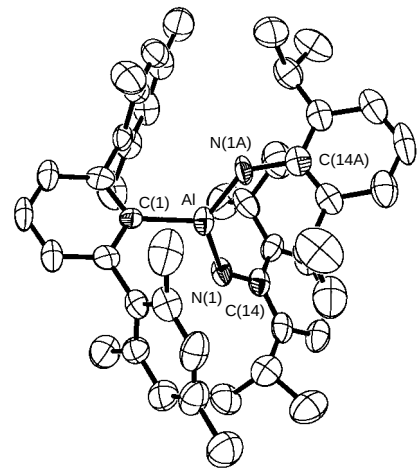

Fig. 2 Molecular structure of $(Mes_2C_6H_3)Al[N(H)(Pr^i_2C_6H_3)_3$ **2**. Selected bond distances (Å) and angles (°): Al(1)–C(1) 1.978(11), Al(1)–N(1) 1.788(6), N(1)–C(14) 1.436(10); N(1)–Al(1)–C(1) 116.4(2), N(1)–Al(1)–N(1A) 127.3(5), C(14)–N–Al(1) 138.1(6).

angle while containing atoms Al, C(1) and C(4). The central phenyl ring of the ligand resides at an angle of 63.2° relative to the aluminium trigonal plane [C–Al(N)–N]. Indeed, significant π-bonding would appear to be precluded in **2** by the fact that both nitrogen trigonals [C–N(H)–Al] are twisted at an angle of 23.1° relative to the aluminium trigonal plane.

The formation of **2** suggests that **1** may be utilized in a variety of reactions as a means to approach other interesting derivatives.

Notes and References

† *Synthesis*: **1** a solution of $(Mes_2C_6H_3)Li$ (0.80 g, 2.5 mmol) in diethyl ether (40 ml) was added over a period of 10 min to an ether (30 ml) solution of $AlBr_3$ (0.67 g, 2.5 mmol) at −78 °C. The reaction mixture was stirred for 3 h and allowed to warm to room temp. over a period of 2 h. The resulting solution became yellow and was stirred for additional 30 h. After filtration, the solution was concentrated. Cooling this solution to −25 °C for several days afforded **1** (0.78 g) as colorless crystals. Yield: 53%, mp 67 °C. ^{1}H NMR (300 MHz, 298 K, [$^2H_8$]THF): δ 1.92 (s, 12 H, *o*′-CH_3), 1.98, (s, 12 H, *o*′-CH_3), 2.13 (s, 6 H, *p*′-CH_3), 2.17, (s, 6 H, *p*′-CH_3), 6.65–6.73 [m, 6 H, CH(aromatic)], 6.76 [s, 8 H, *m*′-CH (aromatic)]. ^{13}C NMR (300 MHz, 298 K, [$^2H_8$]THF): δ 19.91, 20.06, 20.48, 20.62, 20.81 (methyl C); 125.90, 126.32, 126.68, 126.86–134.02, 139.23, 142.12, 145.98 (aromatic C).

2: an ether (50 ml) solution of $Li[N(H)(Pr^i_2C_6H_3)]$ (0.22 g, 1.5 mmol), prepared from $(Pr^i_2C_6H_3)NH_2$ and *n*-C_4H_9Li, at 0 °C in ether, was slowly added to an ether (30 ml) solution of **1** (0.42 g, 0.70 mmol) at −78 °C. The reaction mixture was stirred for 3 h and allowed to warm to room temp. over a period of 2 h, and stirred for additional 30 h. After filtration, the solvent of the yellow solution was evaporated *in vacuo*. The residue was extracted with hexane (50 ml). The volume of the solution was reduced *in vacuo* to *ca*. 15 ml. Cooling the concentrated solution at −25 °C for a week afforded colorless needle crystals of **2**. X-Ray quality crystals were grown from diethyl ether–hexane (1 : 1). Yield: 78%. mp. 154 °C. ^{1}H NMR (300 MHz, 298 K, C_6D_8): δ 1.07 [d, 12 H, $CH(CH_3)_2$], 1.2 [d, 12 H, $CH(CH_3)_2$], 1.90 (s, 6 H, *o*′-CH_3), 1.93 (s, 6 H, *o*′-CH_3), 2.04 (s, 3 H, *p*′-CH_3), 2.08 (s, 3 H, *p*′-CH_3), 3.24–3.29, [m, 4 H, $CH(CH_3)_2$], 4.39 (s, 2 H, NH), 6.63–6.69 [m, 12 H, CH (aromatic)], 6.71–6.73 [m, 4 H, *m*′-CH (aromatic)]. ^{13}C NMR (300 MHz, 298 K, C_6D_8): δ 8.18, 8.26, 16.38, 18.10, 18.38, 18.65, 19.91, 20.17 (alkyl C), 123.20, 123.42, 124.09, 124.75, 124.98–141.2, 142.87, 144.50, 145.96 (aromatic C).

‡ *Crystallographic data* for **1** and **2**: colorless cubic crystals of **1** (0.2 × 0.1 × 0.1 mm) and **2** (0.2 × 0.2 × 0.1 mm) were mounted in glass capillaries under an atmosphere of N_2 in a drybox. Single crystal X-ray intensity data were collected on a Siemens P4 diffractometer (50 kV/40 mA), with graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å) at 21 °C, using the ω scan technique to a maximum 2θ value of 45°. Cell parameters and an orientation matrix for data collection were obtained from a least-squares analysis of the setting of up to 30 carefully centered reflections in the range $15.0° < 2\theta < 30.0°$. Absorption corrections were carried out using the empirical ψ-scan method. The structures were solved by direct methods using the SHELXTL 5.0[18] software package. All non-hydrogen atoms were refined using anisotropic thermal parameters. Hydrogen atoms were placed at ideal positions riding on the attached carbon and nitrogen atoms without further refinement.

Crystal data: **1**: a = 9.982(8), b = 10.179(2), c = 12.948(3) Å, α = 95.30(2), β = 94.90(4), γ = 107.70(2)°, V = 1239.0(11) Å^3, D_c = 1.574 g cm^{-3}, Z = 1 for triclinic space group $P\bar{1}$. Refinement converged at $R1$ = 0.070, $wR2$ = 0.20 using the F^2 refinement for 2150 observed reflections. Data collection and refinement for **2** proceeded in a fashion similar to that described for **1**.

2: a = 24.604(14), b = 10.312(5), c = 18.173(8) Å, β = 115.50(5)°, V = 4161.8(34) Å^3, D_c = 1.106 g cm^{-3}, Z = 4 for monoclinic space group $C2/c$. Refinement converged at $R1$ = 0.097, $wR2$ = 0.23 using the F^2 refinement for 1449 observed reflections. CCDC 182/851.

A two-dimensional network constructed from hexamolybdate, octamolybdate and $[Cu_3(4,7\text{-phen})_3]^{3+}$ clusters: $[\{Cu_3(4,7\text{-phen})_3\}_2\{Mo_{14}O_{45}\}]$

Douglas Hagrman, Pamela J. Zapf and Jon Zubieta*†

Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA

The hydrothermal reaction of $Cu(SO_4)\cdot H_2O$, MoO_3, 4,7-phenanthroline and water yields $[\{Cu_3(4,7\text{-phen})_3\}_2\{Mo_{14}O_{45}\}]$, a material exhibiting a two-dimensional network constructed from $(Mo_6O_{19})^{2-}$ and $(Mo_8O_{26})^{4-}$ clusters linked through planar cyclic $\{Cu_3(4,7\text{-phen})_3{}^3\}^+$ clusters.

Inorganic oxides are ubiquitous in the geosphere and the biosphere[1,2] and are represented not only by the complex aluminosilicates which make up vast proportions of igneous rocks,[3] by ores and gems but also by complex oxides fashioned by biomineralization, such as bones, shells, teeth and spicules.[4,5] The intense contemporary interest in solid state oxides reflects their properties, which endow these materials with applications ranging from heavy construction to microcircuitry.[5] Consequently, there has evolved a significant effort in the manipulation of inorganic oxide microstructures.

One synthetic approach is to mimic Nature's remarkable mixtures of inorganic oxides coexisting with organic molecules. In such materials, the inorganic oxide contributes to the increased complexity and hence functionality through incorporation as one component in a multilevel structured material where there is synergistic interaction between organic and inorganic components.[6] There are now four major classes of materials in which organic components exert a significant structural role in controlling the inorganic oxide microstructure: zeolites,[7,8] mesoporous oxides of the MCM-41 class,[9] biomineralized materials,[10] and microporous octahedral–tetrahedral or square-pyramidal–tetrahedral framework transition metal phosphates (TMPO) with entrained organic cations.[11,12] We have recently identified a fifth class of organic–inorganic oxide hybrid materials: ditopic organonitrogen-templated molybdenum oxides.[13] A common structural motif for this class of materials consists of a molybdate cluster entrained within a scaffolding provided by a coordination cation polymer; for example, $[\{Cu(4,4'\text{-bpy})_4\}Mo_8O_{26}]$ and $[\{Ni(H_2O)_2(4,4'\text{-bpy})_2\}_2Mo_8O_{26}]$ exhibit the δ- and ε- forms of the octamolybate cluster, respectively. As part of our continuing studies of this class of materials, we have sought to exploit rigid linkers other than the linear rod, such as 4,7-phenanthroline which has resulted in the isolation of an unusual two-dimensional array of clusters[14,15] in the material $[\{Cu(4,7\text{-phen})_3\}_2\{Mo_{14}O_{45}]\}\cdot 0.5H_2O$ (**1**).

The hydrothermal reaction of $Cu(SO_4)\cdot H_2O$, MoO_3, 4,7-phenanthroline and water in the mole ratio 1 : 1.8 : 1.7 : 1654 at 200 °C for 99.5 h yielded **1** in 90% yield as brown rhombs. The IR spectrum exhibited a complex pattern of bands in the range 700–950 cm^{-1}, ascribed to ν(Mo=O) and ν(Mo–O–Mo).

As shown in Fig. 1(*a*) and (*c*), the structure of **1**‡ is constructed from the linking of three independent molecular clusters: $\{Cu_3(4,7\text{-phen})_3\}^{3+}$, β-$(Mo_8O_{26})^{4-}$ and $(Mo_6O_{19})^{2-}$. While the hexa- and octa-molybdate clusters are well known aggregates,[16] the trinuclear copper(I) cluster cation provides a novel twenty-one membered cyclic structure. The extended structure is generated through the bonding of terminal and bridging oxo-groups of the clusters to the Cu^I sites of the rings. As shown in Fig. 1(*a*), one motif consists of linear chains of β-$(Mo_8O_{26})^{4-}$ clusters linked through $\{Cu_3(4,7\text{-phen})_3\}^{3+}$ rings into a one-dimensional ribbon. Adjacent parallel ribbons are linked through $\{Mo_6O_{19}\}^{2-}$ clusters into a two-dimensional sheet structure, as shown in Fig. 1(*a*). Each hexamolybdate

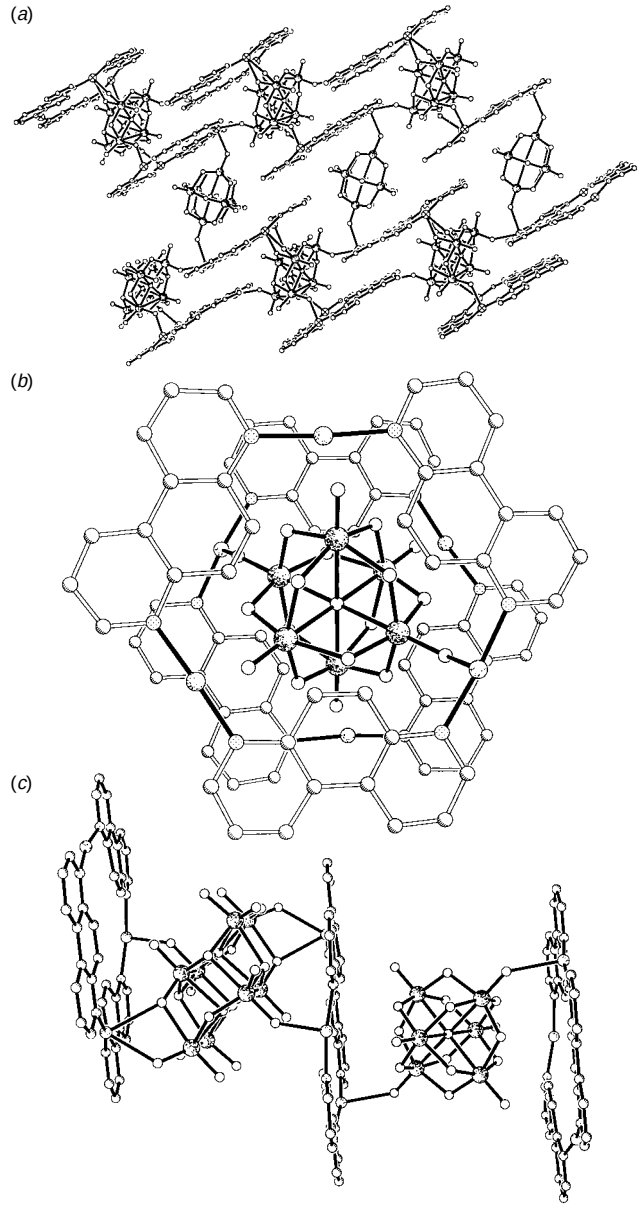

Fig. 1 (*a*) A view of the sheet structure of $[\{Cu_3(4,7\text{-phen})_3\}_2\{Mo_{14}O_{45}\}]\cdot 0.5H_2O$ **1** along the (112) plane, illustrating the linking of $[\{Cu_3(4,7\text{-phen})_3\}_2\{Mo_8O_{26}\}]_n^{2n+}$ chains by $(Mo_6O_{19})^{2-}$ clusters. (*b*) A view of the sandwiching of the $(Mo_6O_{19})^{2-}$ cluster between two nearly coplanar $\{Cu_3(4,7\text{-phen})_3\}^{3+}$ clusters. (*c*) A view of the crosslinking chain of alternating hexanuclear and octanuclear molybdate clusters, contrasting the alignment of the $(Mo_6O_{19})^{2-}$ cluster with the centroids of the $\{Cu_3(4,7\text{-phen})_3\}^{3+}$ rings and the displacement of the $(Mo_8O_{26})^{4-}$ cluster from the centroid causing a parallel shearing of the subsequent Cu_3 ring.

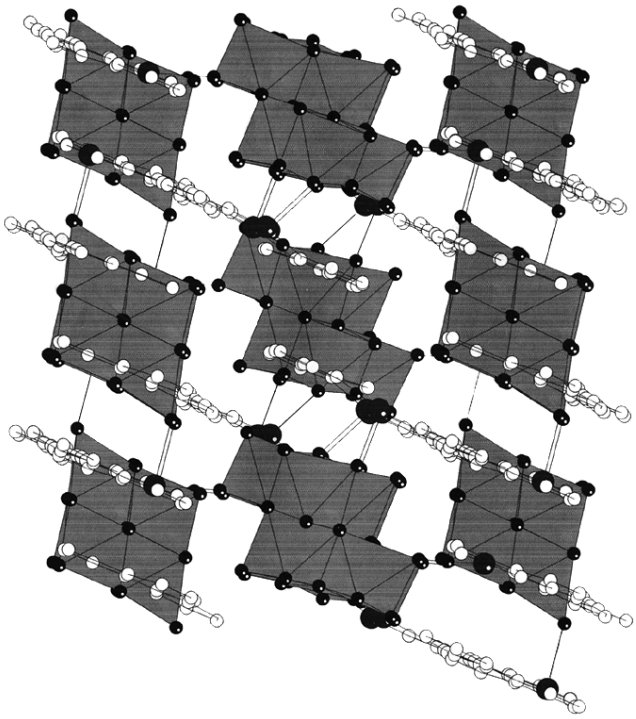

Fig. 2 A polyhedral representation of the cluster stacking parallel to the planes of the $\{Cu_3(4,7\text{-phen})_3\}^{3+}$ rings

cluster is sandwiched between two planar $\{Cu_3(4,7\text{-phen})_3\}^{3+}$ rings as shown in Fig. 1(*b*). The hexanuclear clusters are aligned with opposite Mo_3 triangular faces of the Mo_6 octahedron parallel to the Cu_3 rings. In contrast, the centroid of the β-$(Mo_8O_{26})^{4-}$ cluster does not align with the centroids of the sandwiching Cu_3 rings, which are displaced *ca.* 4.5 Å by parallel shearing with respect to each other. This allows the approach of two additional Cu_3 rings whose interactions with the oxo-groups of the octanuclear cluster propagate the chain. In this fashion, each octamolybdate cluster bonds to four Cu_3 rings, while each hexamolybdate cluster links only two such rings. Each Cu_3 ring bonds to one hexamolybdate and two octamolybdate clusters.

A curious feature of the structure is the presence of both $(Mo_6O_{19})^{2-}$ and β-$(Mo_8O_{26})^{4-}$ clusters as building blocks for the two-dimensional sheet, as shown in Fig. 2. However, this observation reflects the synthetic approach of exploiting hydrothermal conditions which requires a shift from the thermodynamic to the kinetic domain, such that equilibrium phases are replaced by structurally more complex metastable phases.[17] The structure-directing role of the copper coordination complex cluster is manifest in interactions whose geometric correspondence produces the architecture of the network. While it remains premature to classify such syntheses in terms of 'designed' routes, it should be noted that the very complexity of the hybrid material produces a limit on the degree of predictability. Moreover, design may not require total predictability, but rather a reciprocity of structure–function relationships for a class of materials which evolve as sufficient numbers of examples are characterised. Indeed, the chemistry of the Cu–organodiamine–molybdate system appears to be extraordinarily diverse, encompassing a variety of molybdate clusters, chains and sheets as building blocks. In the specific case of 4,7-phenanthroline as ligand, compound **1** was observed in a fairly narrow pH range (*ca.* 6–8), outside of which other as yet unidentified phases were observed.

Upon thermal treatment, **1** exhibits a 0.5 mass% loss at *ca.* 120 °C owing to the loss of the water of crystallization and a further 30 mass% loss between 310 and 350 °C, corresponding to the loss of the organic ligand. When carried out in oxygen, the product of thermolysis is a pale green material of approximate composition $Cu_6Mo_{14}O_{45}$, whose powder diffraction pattern is distinct from that of known copper molybdates. We are investigating the use of hybrid materials such as **1** in the preparation of novel heterometallic molybdate phases.

Synthesis of a highly strained permethylenated cycloocta-1,5-diyne derivative by acid-catalysed thermal rearrangement

Stefan Kammermeier,[a] Rik R. Tykwinski,[b] Peter Siemsen,[a] Paul Seiler[a] and François Diederich*[a]†

Preparation of a dimeric derivative of 1,1,2,2-tetraethynylethane (3,4-diethynylhexa-1,5-diyne) and its unexpected rearrangement to a permethylenated cycloocta-1,5-diyne, the structure of which was confirmed by X-ray crystallography, is reported.

Derivatives of tetraethynylethene (3,4-diethynylhex-3-ene-1,5-diyne) have already been used as building blocks for the preparation of expanded carbon-rich structures.[1] Thus, perethynylated octadehydro[12]annulenes were synthesized by oxidative Hay coupling[2] of *cis*-bis(trialkysilyl)-protected tetraethynylethenes.[3] The same reaction involving their non-planar analogues—derivatives of 1,1,2,2-tetraethynylethane (3,4-diethynylhexa-1,5-diyne)[4,5]—should lead to macrocyclic dimers such as isomeric *syn*-**1** and *anti*-**1**. Here we report the synthesis of these compounds as well as their unexpected, acid-catalysed thermal rearrangement to a permethylenated cycloocta-1,5-diyne, the structure of which was clarified by X-ray crystal structure analysis.

Starting from hexa-1,5-diyne-3,4-dione **2**,[6] the orthoesters **4** and **5** were prepared *via* the diol *meso*-**3** and isolated, in both cases, as an inseparable mixture of diastereoisomers. Subsequent oxidative dimerisation of **5** under Hay conditions gave diastereoisomeric mixtures of *syn*-**1** and *anti*-**1**, which could be separated from each other by column chromatography (Scheme 1). The *syn*-structure with the larger molecular dipole moment was assigned to the product with the longer retention time.

Both *syn*-**1** and *anti*-**1** seemed to be promising precursors to octadehydro[12]annulene **6** (Scheme 2), an interesting, hitherto scarcely available perethynylated antiaromatic annulene.[3] The essential elimination of the orthoester functionality[7] in *syn*-**1** or *anti*-**1**, however, could not be accomplished using the methods developed in our group for the conversion of orthoester derivatives of 1,1,2,2-tetraethynylethanes, such as **4**, into the corresponding tetraethynylethenes. Owing to the instability of *syn*-**1** and *anti*-**1**, both vacuum pyrolysis in the presence of camphorsulfonic acid at 150 °C[5] or heating in 1,2-dichlorobenzene to 170 °C in the presence of catalytic amounts of hydroiodic acid[8] failed to produce **6**. Instead, the latter reaction conditions produced at 120 °C, to our great surprise, exclusively the rearranged product **7**, which was isolated in 41% yield as an inseparable 2 : 1 mixture of diastereoisomers (NMR) featuring unexpectedly high kinetic and thermal stability (Scheme 2).‡

The structure of **7** as a highly strained permethylenated cycloocta-1,5-diyne could only be elucidated by X-ray analysis (Fig. 1).§ The cycloocta-1,5-diyne unit bearing four exocyclic double bonds is nearly planar; the C-atoms *C*H(OR)$_3$ of the two orthoester moieties are approximately 0.7 Å out of the plane. Two diastereoisomers of **7** were isolated from the acid-catalysed thermolysis, owing to the undefined configuration of these two C-atoms. The analysed crystal, however, contained only one diastereoisomer bearing an *anti* arrangement of the ethoxy groups. In the eight-membered ring, the transannular distance between the triple bonds is 2.59 Å, which is in good agreement with similar cycloocta-1,5-diyne derivatives.[9] The internal bond angles at the sp C-atoms (157.4°) differ considerably from the regular geometry. Furthermore, slight bending of the Pr$^i_3$Si groups at the sp centres is observed. This is probably a result of crystal packing effects.

The formation of **7** from **1** can be rationalised by assuming a cascade mechanism consisting of electrocyclic or radical reactions. In the first step, thermal cleavage of the C–C bonds in both dioxolane rings occurs by a conrotatory 12π-electrocyclic ring opening. The presence of HI is clearly important for this process since heating **1** in the absence of the acid catalyst only led to extensive decomposition. The formed intermediate contains two parallel-facing hexa-1,2,3,4,5-pentaene moieties. A formal intramolecular [4π + 4π]-cycloaddition between the central butatriene units finally results in the formation of the strained cycloocta-1,5-diyne system. The parent cycloocta-1,5-diyne system has also been obtained, but in poor yield only

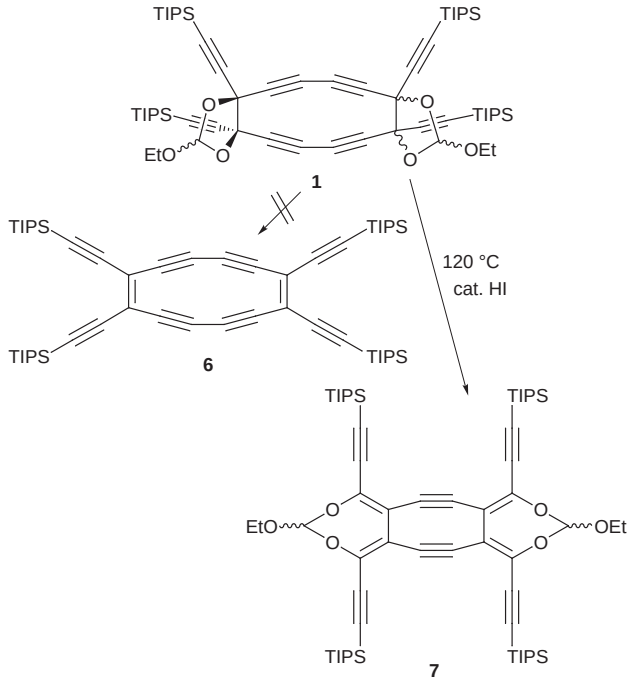

Scheme 2

(2%), by the dimerisation of buta-1,2,3-triene.[9] In both cases, this dimerisation is probably not concerted, but proceeds *via* a biradical mechanism. The higher yield in our system can be explained by the intramolecularity of the reaction in addition to the steric hindrance of the TIPS groups, which precludes intermolecular reactions.

The substitution of the orthoester groups in **1** by other thermally or photochemically removable protecting groups is now under way in order to prepare **6**. Furthermore, experiments with such compounds could clarify the mechanism of the acid required for the formation of **7**.

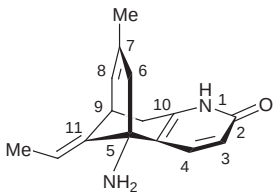
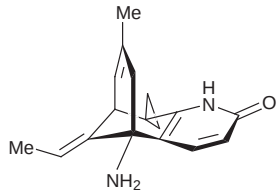
The synthesis of a spirocyclic analog of huperzine A that bears a cyclopropane ring at its 10-position has been carried out in an enantioselective manner using a diastereoselective Michael–aldol reaction; in assays of AChE inhibition, this compound was found to be nearly as active as huperzine A itself, with comparable on and off rates from the enzyme.

Huperzine A (HA), a potent reversible inhibitor of acetylcholinesterase (AChE), is an important psychotherapeutic agent for improving cognitive function in Alzheimer's patients by enhancement of central cholinergic tone.[1] Because of the tremendous promise this alkaloid holds for the palliative treatment of a disease that afflicts millions of individuals worldwide, we and others have been engaged in an intensive effort to explore the structure–activity relationships of this alkaloid.[2] From biological studies with mammalian AChE, Torpedo AChE, mammalian BChEs (butyrylcholinesterases) and mouse AChE mutants, together with molecular modeling studies, mammalian Tyr337(330) and Trp86(84) have been implicated in the binding of HA to AChE.[3] This particular interaction is of the cation (NH_3^+)–π type,[4] while other amino acid residues appear to participate in hydrogen bonding to the pyridone NH and the carbonyl group.[5] The superior inhibition properties of HA have been attributed to the very slow dissociation ($t_{0.5}$ = 35 min) of the AChE–huperzine A complex in solution.[6] To date, we have identified several analogs of HA that have comparable or better activity than the parent structure. In particular, the C-10 axial methyl analog of HA was found to be about 8-fold more potent than HA, whereas the 10,10-dimethyl analog was found to possess comparable activity. In exploring further modifications to this region of the molecule, we felt that it would be of interest to examine a spirocyclic analog bearing a cyclopropyl group at C-10. Such an analog can be viewed as a ring constrained version of the dimethyl derivative. The possibility exists, however, that its activity might be improved due both to the smaller size of the cyclopropyl group and possible electronic effects which may be capable of enhancing interactions with the enzyme.



Huperzine A (HA) **1**



Spirocyclopropyl Analog **2**

The chemical pathway that was followed to assemble the cyclopropyl analog **2** is shown in Schemes 1 and 2. The key intermediate **7b** was obtained in good yield through a sequence of steps starting from the reaction of cyclohexanedione monoethylene ketal **3** with (2-chloroethyl)dimethylsulfonium iodide/Bu^{t}OK in Bu^{t}OH at room temperature to afford the spirocyclohexanone **4** in 60% yield (Scheme 1).[7] The spirocyclohexanone **4** was transformed to the β-keto ester **7a** employing conditions identical to those reported previously.[1,2] Transesterification of **7a** with (−)-8-phenylmenthol gave the desired ester derivative **7b** in 75% overall yield.[8] Next, a diastereoselective Michael–aldol reaction of **7b** with methacrolein was carried out. Under optimal conditions, the reaction was run at −20 °C over a two day period. The alcohol mixture **8a** that formed was converted to a 12.5 : 1 mixture (ratio from ^{1}H NMR analysis) of the olefins **9a** and **9b**, respectively, in 70% yield by NaOAc–HOAc induced elimination of the derived mesylate **8b**. These olefins were readily separable by column chromatography on silica gel using 1 : 9 ethyl acetate–hexanes as eluent. The major isomer **9a** was subjected to a Wittig olefination reaction to afford the *Z*-isomer **10a**. Isomerization of the double bond using thiophenol–AIBN gave a mixture of the *E*- and *Z*-isomers **10b** and **10a** in a 6 : 1 ratio, respectively. The ester group of this mixture was reduced to alcohols **11a** and **11b** by treatment with LAH in THF, and these isomers were separated by column chromatography. The enantiomeric purity of the major isomer **11b** was confirmed at this stage by transforming it to its Mosher ester derivative. ^{1}H and ^{19}F NMR spectroscopy revealed the compound to be of at least 98% optical purity. Jones oxidation of the alcohol **11b** afforded the acid **12**, which was converted to urethane **13** by Curtius rearrangement. Lastly, the required compound **2** was obtained in 75% yield by the removal of the protecting groups from **13** using TMSI in $CHCl_3$ at reflux. The optical rotation of crystalline **2** (mp 235 °C) was found to be −73 (*c* 0.83, $CHCl_3$). For purposes of biological comparison, we also prepared the spirocyclopropyl analog in racemic form, using basically the same approach as above but omitting the transesterification reaction with 8-phenylmenthol.

The biological activity of the analogs of huperzine A was evaluated using AChE purified from fetal bovine serum.[9] AChE

activity was measured in 50 mM sodium phosphate, pH 8.0, at 22 °C as described previously using acetylthiocholine as the substrate.[10] The interaction of HA and its analogs with AChE can be described by eqn. (1):[6]

$$E + HUP\text{-}A \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} E \cdot HUP\text{-}A$$

The ratio k_{off}/k_{on} is the dissociation constant (K_I). The K_I values for the inhibition of FBS AChE with analogs of HA were determined by equilibrating a known amount of enzyme (1–2 units ml^{-1}) with various concentrations of the analog. Plots of percent residual activity *versus* [analog] were used to calculate K_I by the steady state method. The rate constant for the inhibition of AChE was determined by diluting an appropriate volume of stock solutions (1–2 μM) of each analog of huperzine A into the enzyme solution (5–10 units ml^{-1} in 50 mM sodium phosphate, pH 8.0, containing 0.05% BSA) and measuring the residual enzyme activity at various time intervals. Plots of percent residual activity *versus* time at each concentration were used to calculate the rate of inhibition (k_{on}). Direct measurement of the rate constant of regeneration of enzyme activity (k_{off}) was initiated by > 10 000-fold dilution of HA-inhibited AChE (2–4 μM) to ascertain that the rate of inhibition by residual inhibitor was negligible in the reactivation medium.

As is apparent from an examination of k_{on}, k_{off} and the K_Is reported in Table 1, the optically pure 10-spirocyclopropyl analog of HA is comparable in activity to HA itself in both its

Table 1 Kinetic and inhibition parameters for huperzine A, 10,10-dimethylhuperzine A and 10-spirocyclopropylhuperzine A

Inhibitor	$k_{on}/10^{-6}$ M^{-1} min^{-1}	k_{off}/ min^{-1}	K_I[a]/ nM	K_I[b]/ nM

[a] $K_I = K_{off}/K_{on}$. [b] Determined by the steady state method.

inhibition constants and kinetic parameters, and as expected, it is slightly more active than the 10,10-dimethyl analog (comparison of racemic materials). Further studies are now underway to examine whether these 10-substituted analogs show greater elements of neuroprotection from glutamate toxicity than does HA itself. The neuroprotective aspect of HA represents a newly discovered property of this molecule.[11] This pharmacological property together with the AChE inhibitory activity further enhances the value of huperzine A and its analogs as therapeutic agents for the treatment of Alzheimer's disease.[11]

We are indebted to the Department of Defense (DMAD17-93-V-3018) for partial support of these studies.

Preparation, first X-ray structure analysis and reactivity of hexacoordinate silicon compounds with a tetradentate azomethine ligand

F. Mucha, U. Böhme and G. Roewer*†

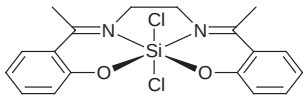
Institut für Anorganische Chemie der Technischen, Universität Bergakademie Freiberg, Leipziger Str. 29, 09596 Freiberg, Germany

Hexacoordinate silicon compounds and polymers with the tetradentate azomethine ligand *N*,*N*′-ethylenebis(2-hydroxyacetophenoneiminate) (H_2salen*) have been prepared and characterized; the X-ray structure analysis of (salen*)SiF_2 clearly demonstrates the octahedral coordination of the silicon atom.

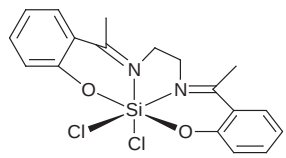
Hypervalent silicon compounds attract interest from both the structural and reactivity point of view.[1] The isolation of such compounds allows detailed insight into mechanistic pathways of nucleophilic substitution at silicon.[1e] On the other hand compounds based on such synthons should exhibit interesting properties as electronic materials. Different types of hypercoordinate silicon compounds have so far been reported: (*a*) the initial compounds were octahedral fluorosilicate $[SiF_6]^{2-}$ and derivatives thereof,[2] (*b*) derivatives of 2,2′-bipyridyl, (*c*) complexes with different bidentate ligands such as 1,3-diketonates, 2-dimethylaminomethylphenyl or 1,2-diolates, (*d*) phthalocyaninato derivatives.[1]

We set out to synthesize hexacoordinate silicon complexes containing the salen* ligand. This ligand is able to chelate to silicon atom through four donor atoms. There are some rare examples of salen silicon compounds known from the literature,[3] but characterization of these compounds seems doubtful.[4] Structural aspects are uncertain owing to the lack of crystal structure data.

Transition metal salen complexes have been investigated extensively.[5] Different types of salen ligands have been applied recently, mainly in transition metal complex catalysts, for the transformation of organic substrates.[6] We used a slightly modified salen ligand [*N*,*N*′-ethylenebis(2-oxyacetophenoneiminate) = salen*] with methyl groups at the azomethine carbon instead of hydrogen. This prevents unwanted side reactions caused by the azomethine protons. The key compound (salen*)$SiCl_2$ **1** can be prepared by two different routes (i and ii, Scheme 1).‡ Elemental analysis indicates the formation of a complex of the composition (salen*)$SiCl_2$. Preparation of **1** *via* reaction of H_2salen* with $SiCl_4$ (route i) yields a product with two ^{29}Si NMR signals and 18 signals in the ^{13}C NMR spectrum. This points to the formation of two different isomers **1a** and **1b** in a ratio of 1 : 1, according to the intensity of the signals. The same type of isomerism has been observed in tin salen compounds and confirmed by Mössbauer spectroscopy.[7]



1a

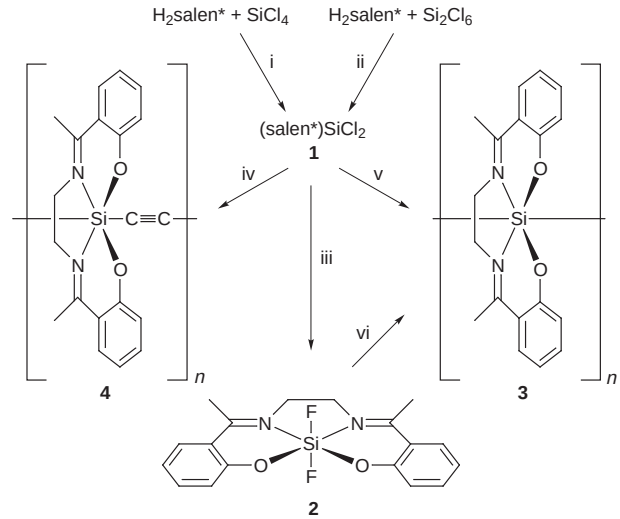


1b

The extremely high field shift of the ^{29}Si NMR signals for the isomers of **1** (δ −186.1, −188.0) indicates the presence of hexacoordinate silicon atoms. Reaction of Si_2Cl_6 with H_2salen* (ii in Scheme 1) gives only one isomer with nine signals in the ^{13}C NMR spectrum and one ^{29}Si NMR signal at δ −188. Hydrogenchloride and hydrogen are evolved in this reaction.

The chlorine atoms in **1** can be substituted for fluorine by treating **1** with ZnF_2 in THF. For the preparation of the fluoro derivative **2** the mixture of isomers **1a** and **1b** was used. The resulting product **2** represents only one isomer as concluded from NMR data. This information hints to a rearrangement of the coordination sites of the salen* ligand during nucleophilic substitution of the chlorine by fluorine. The mechanism of this reaction as well as the energy differences between the isomers **1a** and **1b** seem to be quite interesting and will be subject of further investigation. Complex **2** is more soluble in organic solvents than the chloro derivative and we were able to obtain single crystals of **2** by recrystallization from acetonitrile. The X-ray crystal structure analysis of **2** provides the molecular structure shown in Fig. 1.§ It was solved and refined in space group $P2_1/a$ with four molecules of **2** and four molecules of acetonitrile per unit cell. There is a distorted octahedral coordination geometry around silicon. The fluorine atoms are situated at axial positions (*trans* isomer), whereas the salen* ligand occupies the four equatorial positions.

There are a number of crystal structures of bis(chelate) compounds with hexacoordinate silicon. Most of these have essentially a tetrahedral arrangement around silicon with the coordinated nitrogen donor atoms 'capping' the tetrahedra at relatively large distances (N–Si between 2.5 and 3.0 Å).[8] The Si–F distance in **2** corresponds well with bond length found in other hypervalent silicon compounds (1.60–1.73 Å).[1d,9] The Si–O and Si–N distances are remarkably short compared to other hexacoordinate silicon compounds.[8] The distortion of the octahedral coordination environment around silicon probably originates from the conformation of the chelating salen* ligand.



Scheme 1 *Reagents and conditions*: i and ii, THF, 2 h, reflux, 90%; iii, ZnF_2, THF, 1 h reflux, 20%, extraction with THF; iv, LiCCLi or BrMgCCMgBr, THF–*n*-hexane, 6 h reflux; v, (salen*)$SiCl_2$ and K in ratio 1 : 2, toluene, 6 h reflux; vi, (salen*)SiF_2 and Li, THF, 2 h room temp.

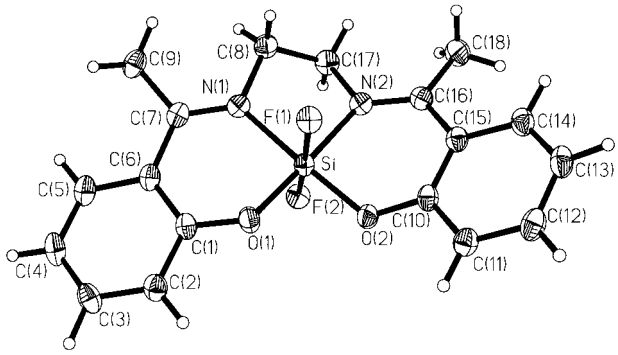


Fig. 1 Crystal structure of **2**. Selected bond distances (Å) and angles (°): Si–F(1) 1.677(1), Si–F(2) 1.670(1), Si–O(1) 1.721(1), Si–O(2) 1.724(1), Si–N(1) 1.931(2), Si–N(2) 1.937(2); F(1)–Si–F(2) 172.40(5), O(1)–Si–N(2) 178.00(6), O(2)–Si–N(1) 1.76.75(6), F(1)–Si–O(1) 91.68(6), F(1)–Si–O(2) 93.85, F(1)–Si–N(1) 86.93(5), F(1)–Si–N(2) 87.36(6), F(2)–Si–O(1) 93.17(6), F(2)–Si–O(2) 92.00(6), F(2)–Si–N(1) 86.96(5), F(2)–Si–N(2) 87.60(6).

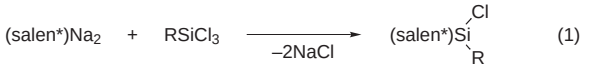
There is a considerable torsion along the atoms N(1)–C(8)–C(17)–N(2) of *ca.* 46°. The result of this is that one azomethine unit is bended under and the other above the plane N(1)SiN(2).

Experiments to obtain stacked polymers **3** by reaction of **1** or **2** with alkaline metals or magnesium are very promising. These polymers are poorly soluble in organic solvents and more stable towards moisture than the monomers. They have been characterized by elemental analysis, IR and NMR spectroscopy. Furthermore it is possible to react **1** with dilithium acetylide or the corresponding Grignard reagent to obtain polymers of type **4** which are linked by Si–C≡C–Si units (Scheme 1). Polymers with similar backbone but different chelating ligands have been described recently.[10]

Complexes of the type (salen*)Si(Cl)R **5** and **6** are available by reaction of Na_2(salen*) with $RSiCl_3$ [R = Me, Ph; eqn. (1)]. Only one isomer is formed in both cases as revealed by NMR data. At present it is not possible to decide whether these are the *cis*- or *trans*-isomers. These organosilicon compounds are more soluble in organic solvents than **1**.



R = Me **5** or Ph **6**

Investigations relating to electric conductivity and optical properties of the new class of silicon polymers **3** and **4** will be carried out in the future. Further studies to explore the chemistry of these truly hexacoordinate silicon compounds are under way.

Hepta-1,6-diene and diallyl ether complexes of palladium(0) and platinum(0): a route to L–M(alkene)$_2$ complexes containing non-activated alkenes

Jochen Krause, Karl-Josef Haack, Günter Cestaric, Richard Goddard and Klaus-Richard Pörschke*†

Max-Planck-Institut für Kohlenforschung, Postfach 10 13 53, D-45466 Mülheim an der Ruhr, Germany

With hepta-1,6-diene and diallyl ether, Pd^0 and Pt^0 form highly reactive homoleptic dinuclear M$_2$(1,6-diene)$_3$ complexes, which are cleaved by donors L (*e.g.* C$_2$H$_4$, phosphanes, phosphites, isonitriles) to afford mononuclear derivatives L–M(1,6-diene); the X-ray structure of (Me$_3$P)Pd{(η^2-CH$_2$=CHCH$_2$)$_2$O} has been determined.

Although d^{10} L–M(alkene)$_2$ complexes with non-activated alkenes are well known for M = Ni, Pt, they are scarce for M = Pd. Indeed, whereas the full series of phosphane derivatives with R = Me, Et, Pr^i, Ph, and Cy is known for the parent ethene complexes (R$_3$P)M(C$_2$H$_4$)$_2$ (M = Ni, Pt), (Cy$_3$P)Pd(C$_2$H$_4$)$_2$[1] is apparently the only reported Pd derivative. In view of their potential importance as a source of the [L–Pd^0] moiety for stoichiometric and catalytic reactions in homogeneous solutions under mild conditions,[2] it is clearly highly desirable to have a convenient route to reactive L–Pd(alkene)$_2$ complexes.

Following on from our synthesis of *rac*/*meso*-(μ-η^2,η^2-C$_7$H$_{12}$){Ni(η^2,η^2-C$_7$H$_{12}$)}$_2$,[3] we have reacted (cod)PdCl$_2$ with Li$_2$cot in hepta-1,6-diene and obtained a colorless precipitate of the Pd derivative **1** (61%). Analogously, reaction in diallyl ether yields complex **2** and in tetramethyldivinyldisiloxane complex **3** (Scheme 1). The latter corresponds to the already known {μ-(η^2-CH$_2$=CHSiMe$_2$)$_2$O}[M{(η^2-CH$_2$=CHSiMe$_2$)$_2$O}]$_2$ (M = Ni, Pt; the Pt *rac*-derivative is structurally characterized).[4] Although complexes **1** and **2** slowly decompose around 0 °C, they are significantly more stable and easier to handle than, *e.g.*, the comparable homoleptic Pd(cod)$_2$ or Pd(C$_2$H$_4$)$_3$.[1,5] In the case of Pt^0, we have prepared complex **4** (65%; mp 110 °C) by the same route as for **1**.

When **1**–**4** are reacted with π- or σ-donor molecules L, such as C$_2$H$_4$, PR$_3$ and P(OR)$_3$ (R = alkyl, aryl), and isonitriles,‡ the bridging 1,6-diene ligand is displaced and complexes of the type L–M(1,6-diene) are obtained in 80–95% yield (Table 1). The products have been characterized by elemental analyses, mass spectra, IR and NMR spectra. In addition, the crystal structure of **15** has been determined (see below). Displacement reactions show that the hepta-1,6-diene ligands are readily replaced by diallyl ether or diallylamine and the latter by the divinyldisiloxane (Scheme 2). The hepta-1,6-diene complexes are the most reactive and hence preferential starting materials. However, for many purposes the diallyl ether complexes are most convenient because of (*i*) good stability and easy isolation and handling, (*ii*) high reactivity, and (*iii*) low price of the ligand. A survey of the literature reveals that **18** has been previously obtained accidentally, but the excellent suitability of this class of complexes as starting materials for further reactions has apparently not been recognized.[6] ¶ L–Pd(1,6-diene) complexes are generally stable

Table 1 Pd^0 and Pt^0 1,6-diene complexes§

Complex	Formula[a]	Selected identifying data[b,c,d]
Pd$_2$(C$_7$H$_{12}$)$_3$ **1**	C$_{21}$H$_{36}$Pd$_2$ (501.4)	Voluminous precipitate, insoluble in thf; slowly decomp. ≈0 °C
Pd$_2$(C$_6$H$_{10}$O)$_3$ **2**	C$_{18}$H$_{30}$O$_3$Pd$_2$ (507.3)	Poorly soluble in thf (−30 °C); slowly decomp. >0 °C
Pd$_2${(CH$_2$=CHSiMe$_2$)$_2$O}$_3$ **3**	C$_{24}$H$_{54}$O$_3$Pd$_2$Si$_6$ (772.0)	Off-white crystals; mp 55 °C
(C$_2$H$_4$)Pd(C$_7$H$_{12}$) **5**	C$_9$H$_{16}$Pd (230.7)	Light yellow; extremely soluble; C$_2$H$_4$: δ(H) 3.39

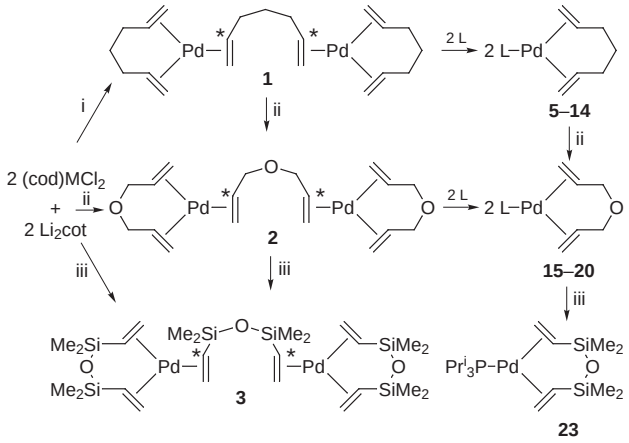
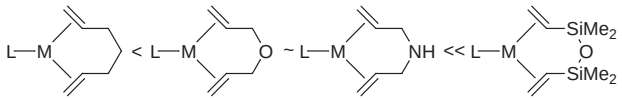
Pt$_2$(C$_7$H$_{12}$)$_3$ **4**	C$_{21}$H$_{36}$Pt$_2$ (678.7)	Voluminous precipitate, poorly soluble in thf; mp 110 °C decomp.
(C$_2$H$_4$)Pt(C$_7$H$_{12}$) **24**	C$_9$H$_{16}$Pt (319.3)	Light yellow; extremely soluble; C$_2$H$_4$: δ(H) 2.91, ^2J(PtH) 59 Hz
(Pr$^i_3$P)Pt(C$_7$H$_{12}$) **25**	C$_{16}$H$_{33}$PPt (451.5)	Orange; mp 75 °C; M$^+$ 451; δ(P) 46.5, ^1J(PtP) 3393 Hz
(Ph$_3$P)Pt(C$_7$H$_{12}$) **26**	C$_{25}$H$_{27}$PPt (553.5)	Yellow; mp 110 °C decomp.; M$^+$ 553; δ(P) 25.8, ^1J(PtP) 3513 Hz

[a] Satisfactory elemental analyses (C, H, P, Pd, Pt) were obtained for all compounds with the exception of non-isolated **5** and **24**. [b] All compounds are colorless, if not indicated otherwise. [c] EI mass spectra at 70 eV; the data refer to ^{106}Pd and ^{195}Pt. [d] ^{31}P NMR shifts (downfield positive) relative to external 85% aqueous H$_3$PO$_4$; solvent is [^{2}H$_8$]thf.



Scheme 1 *Reagents and conditions:* i, hepta-1,6-diene; ii, diallyl ether; iii, tetramethyldivinyldisiloxane



Scheme 2 Sequence of increasing stability (decreasing reactivity) of L–M(1,6-diene) complexes (M = Ni, Pd, Pt)

and we have found that other 1,6-dienes, such as diallylsilanes, are equally applicable. In contrast, L–M(1,6-enyne) complexes (M = Ni, Pd, Pt) are apparently not stable.

The X-ray structure determination of **15** (Fig. 1)‖ reveals a trigonal-planar (*TP*-3) coordination of the Pd atom by the phosphorus atom and the C=C bonds of the diallyl ether ligand. The geometry indicates that the 1,6-diene moiety is able to chelate two coordination sites at a d^{10} *TP*-3 M^0 center with little strain. Thus, the angles D1–Pd–D2, P–Pd–D1, and P–Pd–D2 (D1, D2 are the mid-points of the C=C bonds) are all very close to 120°, and the C=C carbon atoms lie exactly in the coordination plane. Moreover, the Pd^0(1,6-diene) moiety adopts the expected chair-like conformation, and the C=C bonds [mean 1.38(1) Å] are only slightly lengthened as compared with an uncoordinated C=C bond (1.34 Å), indicating that back-bonding is rather weak for Pd^0.

These complexes find application in homogeneous catalysis in those cases where an unsaturated complex fragment [L–Pd^0] (L *e.g.* PPh_3), rather than a coordinatively saturated complex like $Pd(PPh_3)_4$, is expected to catalyze the reaction. For example, we have observed that [L–Pd] complexes (*e.g.* **7** and **16**) catalyze regio- and stereo-selectively the linear trimerization of alk-1-ynes to 1,4,6-trisubstituted *cis*-hexa-1,3-dien-5-ynes between −30 and 20 °C (Scheme 3).[7]

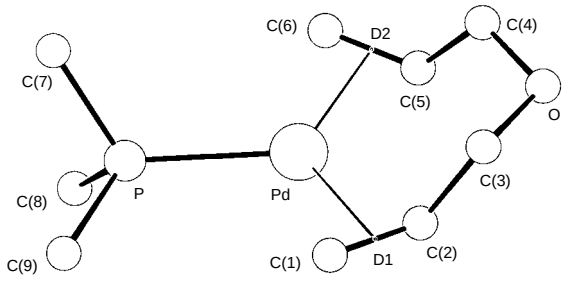


Fig. 1 Molecular structure of **15**. Selected bond lengths (Å): Pd–P 2.303(1), Pd–C(1) 2.151(5), Pd–C(2) 2.155(5), Pd–C(5) 2.157(5), Pd–C(6) 2.160(5), C(1)–C(2) 1.364(8), C(5)–C(6) 1.386(9), D1···D2 3.57(1). Selected bond angles (°): D1–Pd–D2 121.8(6), P–Pd–D1 119.4(3), P–Pd–D2 118.6(3).

Notes and References

† E-mail: poerschke@mpi-muelheim.mpg.de

‡ It is expected that donors such as pyridines, phosphoranes, carbanions and heterocarbenes will coordinate together with 1,6-diene ligands on the Pd and Pt centers, as has already been shown for Ni.[3,8,9]

§ *Representative synthesis protocols:* **1**: a 0.2 M solution of Li_2cot (150 ml, 30 mmol) in diethyl ether was slowly added to a suspension of (cod)$PdCl_2$ (8.57 g, 30 mmol) in 40 ml of hepta-1,6-diene at −78 °C. When the temperature was raised to −40 °C a voluminous precipitate began to form, consisting of **1** and LiCl. At −20 °C the suspension was so dense that it could hardly be stirred. When diethyl ether was evaporated under vacuum at −10 °C, **1** dissolved again. LiCl was removed by filtration, and to the light green solution 50 ml of pentane was added (−30 °C), whereupon pure, colorless **1** precipitated. The product was isolated by filtration, washed with cold pentane, and dried under vacuum (−30 °C). Yield: 4.59 mg (61%).

7: a colorless solution of **1** (501 mg, 1.00 mmol) in 1 ml of hepta-1,6-diene was treated with a solution of PPr^i_3 (320 mg, 2.00 mmol) in 5 ml of pentane. When the mixture was cooled from −30 to −78 °C colorless crystals separated. After disposal of the mother liquor the product was washed with cold pentane and dried under vacuum (20 °C). Yield: 610 mg (84%).

16: a solution of **7** (363 mg, 1.00 mmol) in 5 ml of diethyl ether was treated with diallyl ether (0.13 ml, 1.05 mmol). After 1 h the colorless mixture was cooled to −78 °C, whereupon the crystalline product separated (isolation as described for **7**). Yield: 347 mg (95%). For identifying data see Table 1.

¶ Other Pd complexes with substituted diallyl ether[6] and hepta-1,6-diene-type ligands[10] have been reported previously.

Strong influence of the polyanion structure on the secondary structure of solid heteropolyacids and their catalytic activity; methyl *tert*-butyl ether synthesis in the pseudo-liquid phase of heteropolyacids

Sawami Shikata and Makoto Misono*†

Department of Applied Chemistry, Graduate School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan

It has been shown that the high catalytic activity of a Dawson-type heteropolyacid for gas-phase methyl *tert*-butyl ether synthesis at low temperatures is attributable to its amorphous secondary structure, which brings about a flexible pseudo-liquid phase and facilitates rapid absorption and desorption of molecules.

High catalytic activities of Keggin-type heteropolyacids for gas-phase synthesis of methyl *tert*-butyl ether (MTBE) have already been reported.[1] We recently found that a Dawson-type heteropolyacid ($H_6P_2W_{18}O_{62}$) was more than ten times more active than Keggin-type heteropolyacids ($H_nXW_{12}O_{40}$, X = P, Si, Ge, B, Co) at a low temperature that is favorable for the equilibrium of this reaction.[2,3] In the present study, it has been deduced that the high catalytic activity of $H_6P_2W_{18}O_{62}$ is due to its amorphous and flexible pseudo-liquid phase that is very probably brought about by the elliptical shape of the primary structure (polyanion) of $P_2W_{18}O_{62}^{6-}$. As described below, both heteropolyacids were nearly anhydrous, so that the water content was not regarded to be the main factor controlling the activities.

Pseudo-liquid phase behaviour is a unique phenomenon of heteropolyacids.[4] Polar and basic molecules are rapidly absorbed into the solid lattice and react there, the solid catalyst behaving in a sense like a concentrated solution.[5] This behaviour often brings about high catalytic activities and unique selectivities. MTBE synthesis catalyzed by the heteropolyacids has already been inferred to take place in the pseudo-liquid phase based on the following facts;[3] (*i*) the relative catalytic activities of various heteropolyacids can not be explained by the acidity, but are well correlated with the absorption behavior, (*ii*) the dependence of the rate on methanol pressure was very similar to that for the pseudo-liquid phase observed previously, and (*iii*) the catalytic activity of $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ for which the reaction takes place on the surface was lower than that of $H_6P_2W_{18}O_{62}$, although the acid site concentration on the surface was more than ten times greater for $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ than for $H_6P_2W_{18}O_{62}$.[6]

MTBE synthesis was carried out in a flow reactor at atmospheric pressure at 323 K as reported previously.[3] Prior to the reaction, catalysts were treated in a flow of N_2 at 423 or 523 K. In ordinary experiments, the feed gas was a mixture of methanol, isobutylene and N_2 with a volume ratio of 1 : 1 : 3 and the total flow rate was 90 cm^3 min^{-1}. In *ex situ* XRD measurements, the samples after pretreatment or reaction were quickly transferred onto a sample holder and sealed by polyethylene film to avoid contact with moisture. This was performed in an N_2 flow in the case of thermal pretreatment.

Fig. 1 shows the time courses of MTBE synthesis over $H_3PW_{12}O_{40}$ and $H_6P_2W_{18}O_{62}$, after pretreatments at 423 and 523 K. Just after the start of the reaction, rapid increases in the MTBE yields were observed (0–10 min). These are due to the rapid absorption of reactants and formation of MTBE in the solid bulk as discussed previously.[3] Here the MTBE yields at 10–15 min are regarded to relate to the initial activities. For $H_3PW_{12}O_{40}$, the initial activity was strongly influenced by the pretreatment temperature and the activities at the stationary stage (after 2 h) were very low because of excessive absorption, as reported previously.[3] On the other hand, for $H_6P_2W_{18}O_{62}$, irrespective of the pretreatment temperature, after the absorption progressed in the initial stage and MTBE yield increased rapidly, high stationary catalytic activities were maintained.

Powder XRD patterns for the two kinds of heteropolyacids just after two different pretreatments and after the stationary states of reaction are shown in Fig. 2. The peak intensities in Fig. 2 are normalized on the basis of the peak area of polyethylene film used to cover the samples (marked by solid circles). The Keggin-type heteropolyacid after pretreatment at 423 K [Fig. 2(*a*)(*i*)] showed an ordinary cubic bcc pattern. It was noted that the lattice constant was slightly smaller (d = 11.7 Å) than that of $H_3PW_{12}O_{40}\cdot 6H_2O$ (d = 12.1 Å).[7] After reaction [Fig. 2(*a*)(*ii*)], the cubic pattern was essentially retained, while the lines became broader with a small increase in the lattice constant (d = 12.1 Å) and additional weak lines appeared. After the Keggin-type heteropolyacid was treated at 523 K, the lines were much weaker [Fig. 2(*a*)(*iii*)], indicating that the secondary structure was almost amorphous. It is remarkable that after the reaction, the XRD pattern which was very like that after the reaction of the 423 K-treated sample, appeared again [Fig. 2(*a*)(*iv*)]. According to IR spectra, the primary structures were intact for all of these samples.[6,8]

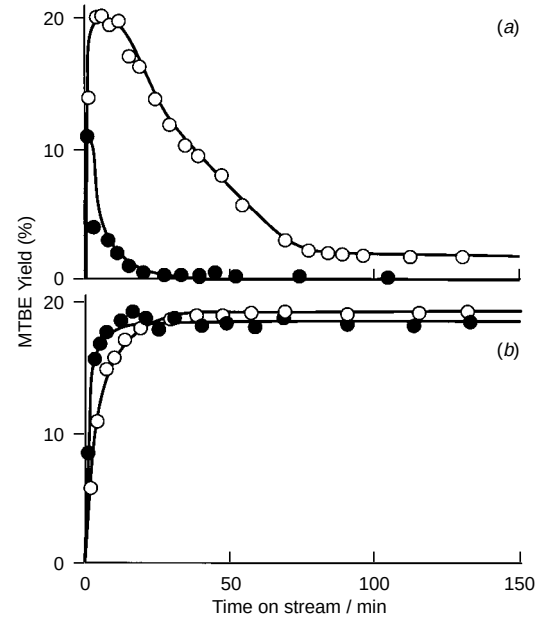

Fig. 1 Effects of pretreatment temperature on MTBE synthesis catalyzed by $H_3PW_{12}O_{40}$ (*a*) and $H_6P_2W_{18}O_{62}$ (*b*) pretreated at 423 K (●), 523 K (○) in an N_2 flow. Catalyst mass: 0.5 g, reaction temperature: 323 K, methanol : iso-C_4H_8 : N_2 = 1 : 1 : 3, flow rate: 90 cm^3 min^{-1}.

Table 1 The secondary structures and the catalytic activities of MTBE synthesis over $H_3PW_{12}O_{40}$ and $H_6P_2W_{18}O_{62}$

Primary structure	Pretreatment temperature/K	Secondary structure: Before reaction	Secondary structure: After reaction	Catalytic activity[a]: Initial	Catalytic activity[a]: Stationary
$H_3PW_{12}O_{40}$	423	Cubic	Cubic	2	> 0
(Keggin type)	523	Amorphous	Cubic	20	< 2
$H_6P_2W_{18}O_{62}$ (Dawson type)	423	Amorphous	Amorphous	17	18
	523	Amorphous	Amorphous	17	18

[a] MTBE yields (%) at the initial (10–15 min) and stationary (after 2 h) stages.

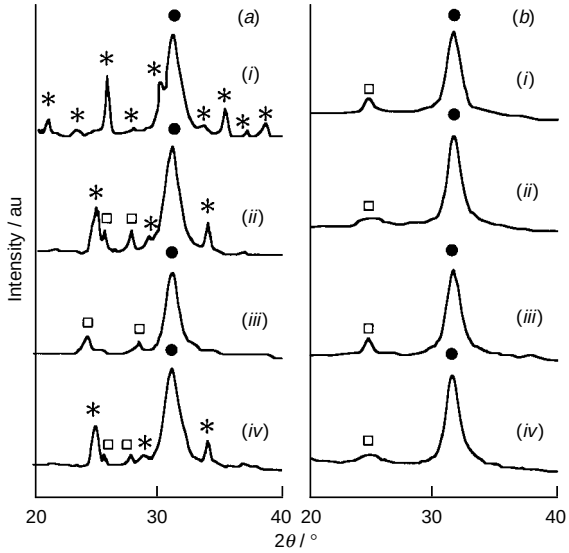

Fig. 2 Powder XRD patterns of $H_3PW_{12}O_{40}$ (*a*) and of $H_6P_2W_{18}O_{62}$ (*b*), before and after MTBE synthesis reaction. (*i*) After pretreatment at 423 K, (*ii*) after reaction at 323 K of the sample (*i*), (*iii*) after pretreatment at 523 K, and (*iv*) after reaction of the sample (*iii*). (●) Peaks of polyethylene film, (*) peaks due to cubic structure and (□) unknown structures.

In contrast, for the Dawson-type heteropolyacid, the XRD lines were weak and broad before and after the reaction for both treatments [Fig. 2(*b*)(*i*)–(*iv*)], indicating that the secondary structure was always mostly amorphous. IR spectra showed that the primary structure (heteropolyanion) was retained. Although there remain unidentified structures, it is evident that the samples of Fig. 2(*a*)(*i*), (*ii*) and (*iv*) are mostly crystalline and those of Fig. 2(*b*)(*i*)–(*iv*) and Fig. 2(*a*)(*iii*) are mostly amorphous.

These structural data are compared with the results of catalytic activity in Table 1. A close correspondence was noted in Table 1 between the secondary structures and the reaction rates observed for the eight cases; two heteropolyacids with two different pretreatments for the initial and stationary states. A high rate was always observed when the secondary structure was amorphous, and a low rate was observed for crystalline cubic structures. For example, $H_3PW_{12}O_{40}$ treated at 523 K showed high activity at first, but the activity declined to a very low level at the steady state, accompanying the change of the secondary structure from amorphous to crystalline (cubic), while $H_6P_2W_{18}O_{62}$ always showed a high activity and amorphous XRD pattern. It was confirmed experimentally that surface areas and pore volumes of the two heteropolyacids little changed with the change of the pretreatment temperature (423 or 523 K). The acid strength also remains constant.[9] According to the DTA–TG analyses, although the water desorbs more easily for the Dawson-type at low temperatures, both heteropolyacids were nearly anhydrous after treatment at 523 K. Moreover, the differences in the water content between the pretreatments at 423 and 523 K were smaller for $H_3PW_{12}O_{40}$ (0.3 H_2O/heteropolyanion) than for $H_6P_2W_{18}O_{62}$ (*ca.* 1 H_2O/heteropolyanion). This is in contrast to the fact that the catalytic behaviour differed more for the Keggin-type [Fig. 1(*a*)] than the Dawson-type [Fig. 1(*b*)] between the 423 and 523 K treatments. Hence, the water content is not the main factor controlling these activities.

We previously indicated[3] that the high catalytic activity of $H_6P_2W_{18}O_{62}$ is brought about by a high-activity state of the pseudo-liquid phase in which moderate amounts of molecules are absorbed and the absorption–desorption is rapid, while the pseudo-liquid phase of $H_3PW_{12}O_{40}$ is in a low-activity state where the absorption is excessive and slow. The transformation between active and less active pseudo-liquid phases with partial pressure was reported previously.[10] If this conclusion is combined with the present results summarized in Table 1, an interesting correlation is deduced between the nature of the pseudo-liquid phase (secondary structure) and the polyanion structure (primary structure). That is, the elliptical shape of the Dawson anion is not suitable for the formation of a stable crystalline structure and leads to an amorphous and flexible structure, the absorption–desorption being easier and catalytic activity high, while the spherical shape of the Keggin anion favors a crystalline cubic structure, where absorption–desorption is slow and catalytic activity is low.

A part of the present study was presented at the Symposium of Catalysis Society of Japan.[11]

Synthesis, structure and Co–C bond homolysis of an intramolecularly bridged (tetrahydrofurfuryl)cobalt(salen) complex: a simple model of enzyme-bound coenzyme B_{12}

Rolf Blaauw,[a] Juul L. van der Baan,*[a]† Sijbe Balt,[a] Martinus W. G. de Bolster,[a] Gerhard W. Klumpp,[a] Huub Kooijman[b] and Anthony L. Spek[b]

[a] *Scheikundig Laboratorium, Vrije Universiteit, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands*
[b] *Kristal-en Structuurchemie, Universiteit Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands*

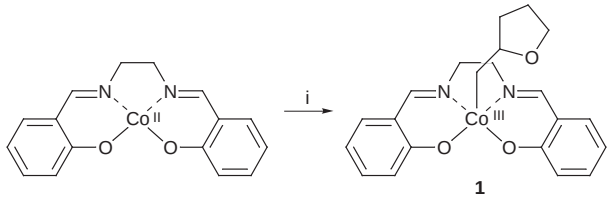
Air oxidation of a Co^{II}(salen) derivative, whose ethanediyl moiety carries a methylene-linked 4-hydroxypent-1-en-3-yl substituent, yields an intramolecularly bridged (tetrahydrofurfuryl)Co^{III}(salen) complex of which the crystal structure has been determined; this B_{12} model is very resistant to Co–C bond homolysis, even in the presence of a large excess of the radical trap TEMPO.

The bond dissociation energy of the Co–C bond of coenzyme B_{12} (5′-deoxyadenosylcobalamin) is estimated to be 31 kcal mol^{-1}. Despite the weakness of the Co–C bond, there is a high efficiency of radical recombination following Co–C bond homolysis,[1] a key step in coenzyme B_{12}-dependent enzymatic rearrangements. It has been suggested that one of the factors responsible for this apparent contradiction is the β-oxygen of the 5′-deoxyadenosyl ligand, which can stabilise the initial pyramidal geometry at the 5′-C of the adenosyl radical and/or impose a rotational barrier to the $C_{4'}$–$C_{5'}$-bond.[2] Radical pair recombination efficiency is expected to be even higher when the cofactor is bound to the active site of the enzyme, where the cobalamin and 5′-deoxyadenosyl moieties are kept close to each other until the substrate enters. Recently, we found that (organo)Co(salen) complexes containing a cobalt-to-salen polymethylene bridge show a much stronger resistance to thermal and photochemical decomposition than the non-bridged complex (*n*-butyl)Co(salen).[3] In order to study whether this resistance would be further enhanced by the introduction of a β-oxygen substituent, we have synthesised a (tetrahydrofurfuryl)Co(salen) complex in which the tetrahydrofurfuryl ligand (as a deoxyadenosyl mimic) is attached to the equatorial salen ligand by a methylene link. Here, we report on the synthesis and structure of this compound and present some preliminary results concerning the photolytic homolysis of its Co–C bond.

Our synthetic approach was based on our finding that (tetrahydrofurfuryl)Co^{III}(salen) **1** is formed in 78% yield when a *ca.* 3×10^{-2} M solution of Co^{II}(salen) in CH_2Cl_2 containing 20 equiv. of pent-4-en-1-ol is exposed to air for 20 h (Scheme 1).§ The formation of **1** may proceed by intramolecular nucleophilic attack by the hydroxy group on an intermediate cobalt(III)–alkene π-complex.[4,5] The reaction is regiospecific: (tetrahydropyran-3-yl)Co(salen) is not formed.

In order to prepare an intramolecularly bridged tetrahydrofurfurylcobalt complex in a way analogous to **1**, we synthesised Co^{II}(salen) derivative **5** according to Scheme 2. Bromide **2** (prepared from but-3-yn-1-ol *via C*-alkylation with $THPOCH_2CH_2Br$, reduction to *trans*-alkenol with LAH, *O*-alkylation with Bu_3SnCH_2I followed by Wittig–Still rearrangement, and bromination with Ph_3PBr_2) was reacted with methyl *N*-benzylideneglycinate to give a monoalkylation product which was then treated with tartaric acid in THF–H_2O at 0 °C to selectively deprotect the amino ester moiety while leaving the THP ether intact. Subsequent conversion of amino ester **3** to 1,2-diamine **4** (isolated as its dihydrochloride) was straightforward and analogous to our previously published procedure.[5] Addition of NaOAc to a solution of **4** and 2 equiv. salicylaldehyde in hot EtOH, followed by reaction of the resulting H_2salen ligand with $Co(OAc)_2$ in THF at 60 °C gave cobalt(II) complex **5** as an orange microcrystalline product. From the ^1H and ^{13}C NMR spectra of compounds **2**–**5** [paramagnetic **5** was characterised after oxidation with iodine to the corresponding iodocobalt(III) complex] it is evident that the alkylation step leading to glycine derivative **3** is diastereoselective, **4** being obtained as a mixture of two diastereomers in a ratio of *ca.* 3 : 1.

Upon exposure to air, a red solution of **5** in CH_2Cl_2 turned green in one day, indicating oxidation to a pentacoordinate organocobalt(III) complex. Concentration *in vacuo* and precipitation with Et_2O furnished a green solid, which was subjected to flash column chromatography (aluminium oxide, 10% MeOH in CH_2Cl_2) to remove traces of cobalt(II) material. The green product (80% yield) was shown by ^1H and ^{13}C NMR spectroscopy to consist of a 3 : 1 mixture of two diastereomers of **6**.¶ Thus, a reaction similar to that of Co^{II}(salen) with pent-4-en-1-ol had occurred, but now in an intramolecular fashion



Scheme 1 *Reagents and conditions*: i, pent-4-en-1-ol (20 equiv.), CH_2Cl_2, O_2

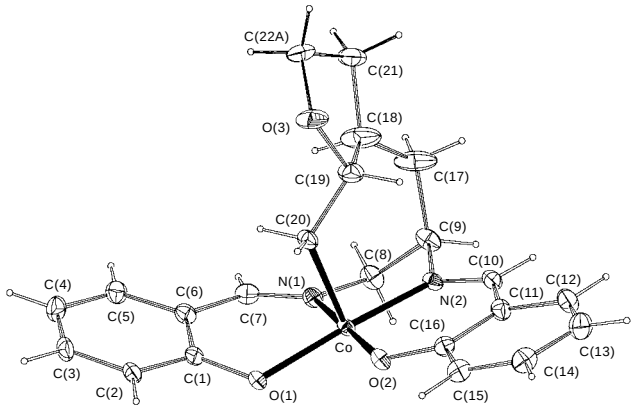

Fig. 1 ORTEP diagram drawn at the 30% probability level and atom numbering scheme of half a dimer of **6a**. The minor disorder component and solvent molecules have been omitted for clarity. Suffix A denotes the major disorder component. Selected distances (Å) and angles (°): Co–C(20) 1.960(6), Co–O(1) 1.932(3), Co–O(2) 1.882(4), Co–N(1) 1.864(5), Co–N(2) 1.886(4), C(19)–C(20) 1.476(9), C(18)–C(19) 1.534(10), C(17)–C(18) 1.422(10), N(1)–C(7) 1.276(8), N(2)–C(10) 1.287(8), C(19)–O(3) 1.456(8); Co–C(20)–C(19) 119.3(4), C(18)–C(19)–C(20) 115.5(6), C(17)–C(18)–C(19) 122.0(8), C(20)–Co–O(1) 91.8(2), C(20)–Co–O(2) 90.0(2), C(20)–Co–N(1) 91.5(2), C(20)–Co–N(2) 92.7(2).

(Scheme 2). The reaction was found to be much faster in MeOH (reaction time *ca*. 1 h), yet gave the two diastereomers of **6** in the same yield and ratio as in CH_2Cl_2.

The major diastereomer of **6** was selectively crystallised from CH_2Cl_2 and gave crystals suitable for X-ray structure analysis, establishing its structure as **6a** (Fig. 1).‖ The solid-state structure of **6a** is a centrosymmetric dimer. Hexacoordination of cobalt is established by the bonding of the cobalt atom of one molecule to a salen oxygen atom of its enantiomeric partner [Co–O = 2.259(3) Å]. Half of the dimeric structure is shown in Fig. 1, together with selected bond lengths and angles.** The Co–C bond length of 1.960(6) Å is comparable with the values found in related organocobalt Schiff base complexes.[6,7] In the crystal structure, the THF moiety is described with a disorder model consisting of two alternative positions for atom C(22). The bond lengths around C(18), the anisotropicity of C(17) and C(18) as well as the distribution of residual electron density around the furan moiety indicate the presence of additional, unresolved disorder, which is most probably conformational in nature. The twist-chair conformation of the carbon bridge and the anti-periplanar orientation of cobalt and oxygen in the *trans*-annulated THF ring are almost identical with those found in the crystal structures of other bridged organocobalt(salen) complexes.[5,6]

Preliminary laser photolysis experiments in toluene show that **6** is very resistant to Co–C bond homolysis. Even in the presence of a large excess of the radical trap TEMPO, the quantum yield Φ is only 0.03 ± 0.005.†† This value is much lower than the quantum yield determined under similar conditions for the (alkyl)Co(salen) complex with a cobalt-to-ligand four-methylene bridge (Φ = 0.25).[3] The quantum yield as a function of trap concentration has also been determined for non-bridged complex **1** and compared to that of (*n*-butyl)Co(salen).[3] The difference in Φ-values at high trap concentration is less pronounced than for the bridged complexes, but nevertheless significant; Φ-values are 0.19 and 0.28 for **1** and (*n*-butyl)Co(salen), respectively. These results support the suggestion that the β-oxygen substituent in (β-alkoxyalkyl)cobalt(III) complexes facilitates radical recombination of cobalt(II) and C· following Co–C bond homolysis.[2] Recombination efficiency is dramatically enhanced in complexes like **6**, whose β-alkoxy substituent is part of an intramolecular bridge which, like B_{12}-dependent enzymes, enforces a close proximity of the alkyl radical to cobalt(II). A detailed study of the homolysis of the Co–C bond of **6** and comparable complexes is in progress.

Quaternary carbons and C-20 not observed.

** *Crystal data* for **6a**: $C_{44}H_{46}Co_2N_4O_6\cdot4CH_2Cl_2$, M_r = 1184.47, red–brown, block-shaped crystal (0.1 × 0.2 × 0.2 mm), monoclinic, space group $P2_1/c$ (no. 14) with a = 11.0406(19), b = 11.0095(19), c = 20.838(4) Å, β = 103.209(14)°, V = 2465.9(8) Å^3, Z = 2, D_c = 1.595 g cm^{-3}, F(000) = 1216, μ(Mo-Kα) = 11.6 cm^{-1}, 15 569 reflections measured, 4341 independent, R_{int} = 0.1097, (1.0 < θ° < 27.5, ω scan, T = 150 K, Mo-Kα radiation, graphite monochromator, λ = 0.71073 Å) on an Enraf–Nonius CAD4 Turbo diffractometer on rotating anode. Data were corrected for Lp effects and for a linear instability of 3% of the reference reflections, but not for absorption. The structure was solved by automated direct methods (SHELXS96). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL96) for 311 parameters; no observance criterion was applied during refinement. A disorder model was introduced to describe the conformational disorder of the tetrahydrofuran moiety. Hydrogen atoms were included in the refinement on calculated positions riding on their carrier atoms. Refinement converged at a final *wR*2 value of 0.1796, *R*1 = 0.0655 [for 2936 reflections with $F_o > 4\sigma(F_o)$], S = 1.047. A final difference Fourier showed no residual density outside −1.00 and 1.28 e Å^{-3} (near CH_2Cl_2, indicating a slight disorder). CCDC 182/849.

†† Samples of **6** (1.0 × 10^{-4} M) and TEMPO (0–1.0 M) in toluene were irradiated with a 337 nm nitrogen laser at 295 ± 0.5 K. Decomposition was followed at the maximum absorbance of the Co^{III}–C band at 668 nm. Detailed experimental set-up and conditions are described in ref. 3.

Neutral isonitrile adducts of alkali and alkaline earth metals‡

Catherine F. Caro, Peter B. Hitchcock, Michael F. Lappert*† and Marcus Layh

The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ

Isonitriles are shown to form stable neutral adducts with some group 1 and 2 metal complexes; the synthesis and structures of $[Li\{N(R)C(Ph)NC(Ph)=CR_2\}(CNPh)]_2$, $[LiNR_2(CNPh)]_2$, $[Mg(CHR_2)_2(CNC_6H_3Me_2\text{-}2,6)_2]$ and $[Mg(CHR_2)(\mu\text{-}Br)(CNBu^t)]_2$ are described (R = $SiMe_3$).

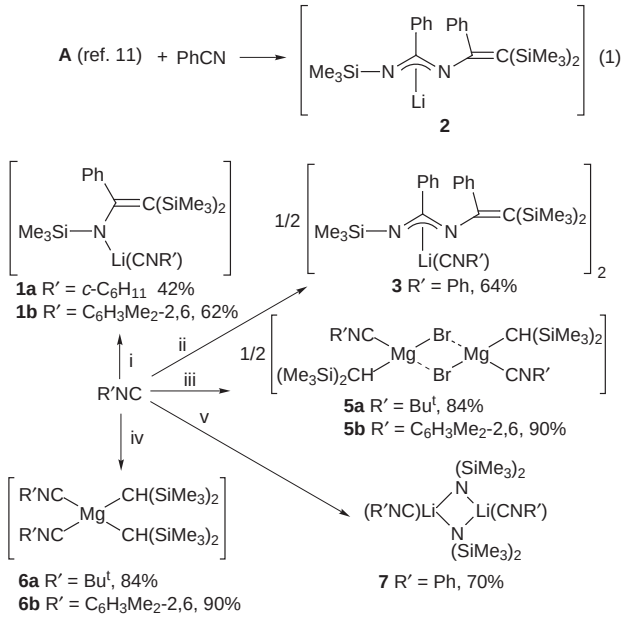
Nitriles and isonitriles are important in transition metal chemistry and nitriles also in the coordination chemistry of main group elements.[1] In contrast, isonitrile adducts of main group elements are rare. They include early reports on labile adducts of trialkyl- or triaryl-boranes,[2] $[AlPh_3\{CN(c\text{-}C_6H_{11})\}]$[3] and polyhedral boranes.[4] Recently, X-ray structures of $[Al(C_5H_5)_3(CNBu^t)]$,[5] the labile $[BPh_3\{CNC_6H_4(OSiMe_3)\text{-}4\}]$[6] and $[B(C_6F_5)(CNAr)\{N(Bu^t)B(C_6F_5)N(Bu^t)C{=}NAr\}]$[7] have been published; and spectroscopic evidence has been provided for the labile $[SiR^1R^2(CNR^3)]$ [R^1 = $C_6H_2\{CH(SiMe_3)_2\}_3$-2,4,6; R^2 = $C_6H_2Me_3$-2,4,6; and R^3 = R^2, Pr^i or $C_6H_2Bu^t_3$-2,4,6][8] and the 1 : 1 adducts of $LiCH(SiMe_3)_2$ and $[Li\{N(Bu^t)C(SiMe_3)C(H)C(SiMe_3)NBu^t\}(CNR')]$ (R′ = Bu^t or $C_6H_3Me_2$-2,6).[9] Boche and coworkers have described the anionic isonitrile complex $[Li(CNPh_2)\{(-)\text{-sparteine}\}(thf)_2]$ (thf = OC_4H_8).[10] We now report the first thermally stable and structurally authenticated complexes of lithium and magnesium in which an isonitrile acts as a neutral ligand.

Addition of an isonitrile R′NC to $Li\{N(R)C(Ph)=CR_2\}(thf)$ **A**[11] yielded (Scheme 1, step i) the enamide **1a** (R′ = *c*-C_6H_{11}) or **1b** (R′ = $C_6H_3Me_2$-2,6), while **A** with PhCN gave [eqn. (1)] the 1,3-diazaallyl **2** which with PhNC gave (Scheme 1, step ii) the dimeric 1 : 1 adduct **3** (R = $SiMe_3$).

Walborsky and Ronman have shown that treatment of an isonitrile R′NC with a lithium alkyl or a Grignard reagent derived from an alkyl halide R″Hal gave the metallo-aldimine, which was a convenient source of various organic compounds (*e.g.* see ref. 12). Surprisingly, we now find that the new Grignard reagent $[Mg(\mu\text{-}Br)(CHR_2)(OEt_2)]_2$ **4** with an isonitrile R′NC simply gave (Scheme 1, step iii) the 1 : 1 adduct $[Mg(\mu\text{-}Br)(CHR_2)(CNR')]_2$ (R′ = Bu^t **5a** or $C_6H_3Me_2$-2,6 **5b**). Even when heated, the latter did not undergo an isomerisation to yield the insertion product, a magnesio-aldimine. Likewise, $Mg(CHR_2)_2$[13] and R′NC gave (Scheme 1, step iv) the thermally stable adduct $[Mg(CHR_2)_2(CNR')_2]$ (R′ = Bu^t **6a** or $C_6H_3Me_2$-2,6 **6b**). These results are all the more unexpected since $LiCHR_2$ readily underwent insertion reactions with the same isonitriles.[9] On the other hand, we now show that the isoelectronic $LiNR_2$ and PhNC gave (Scheme 1, step v) the adduct $[LiNR_2(CNPh)]_2$ **7**, whereas[14] $LiNR_2$ + PhCN readily yielded the benzamidinate insertion product $[Li\{N(R)C(Ph)NR\}]_2$.

The new, pale yellow (**5**) or colourless, highly air-sensitive, readily hydrocarbon-soluble, crystalline solids **1**–**7** gave satisfactory analyses and NMR and IR spectra. Their formulation as isonitrile adducts (rather than insertion products) is consistent with the low frequency shift ($\Delta\delta$) of the $^{13}C\{^1H\}$ NMR spectral signal [δ(R′NC)] and the increase ($\Delta\nu$) in the NC stretching mode ν(R′N≡C) for each of **1**–**7** compared with the value in the free ligand R′NC, Table 1. The trends in $\Delta\delta[^{13}C\{^1H\}]$ and $\Delta\nu$(NC) for (R′NC)ML_n (**1**–**7**) indicate, in valence bond terms, that (*i*) the triply bonded canonical form is more significant in the complex ($R'N^+{\equiv}C^-ML_n \leftrightarrow R'N{=}C{=}ML_n$) than in the free ligand ($R'N^+{\equiv}C^- \leftrightarrow R'N{=}C$:), and (*ii*) the largest values for $\Delta\delta[^{13}C\{^1H\}]$ and $\Delta\nu$(NC) are found for the strongest Lewis acid ML_n in accord with the inequality sequence $Mg(Br)CHR_2$ > $Mg(CHR_2)_2$ > $Li(NR_2)$ > $Li[N(R)C(Ph)=CR_2]$. A cumulene-type canonical form for an isonitrile-transition metal complex is significant when M can participate in $d_\pi \rightarrow \pi^*$ bonding, as in the d^8 $[Ni(CNAr)_4]^{2+}$ [$\Delta\nu$(NC) negative], in contrast to, *e.g.* the d^2 $[Mo[CN)_4(CNMe)_4]$, having $\Delta\nu$(NC) positive.[1]

The X-ray molecular structures of complexes **3** and **6b** are shown in Figs. 1 and 2; those of **5a** and **7** will appear in a full paper.§ In each, the M–C–NR′ and C–N–R′ vectors are close to linear, and the short R′N–C distances are consistent with NC being a triple bond. The trends in the latter (d_{NC}, Table 1) are consistent with the above inequality sequence. The centrosym-



Scheme 1 Synthesis of the isonitrile adducts **1**–**7**. *Reagents and conditions*: i, **A**, Et_2O; ii, **2**, Et_2O; iii, $[Mg(\mu\text{-}Br)\{CH(SiMe_3)_2\}(OEt_2)]_2$ **4**, PhMe; iv, $Mg[CH(SiMe_3)_2]_2$, PhMe; v, $Li[N(SiMe_3)_2]$, C_5H_{12}. Reagents were mixed at −78 °C or −35 °C; the mixture was then brought to *ca.* 25 °C.

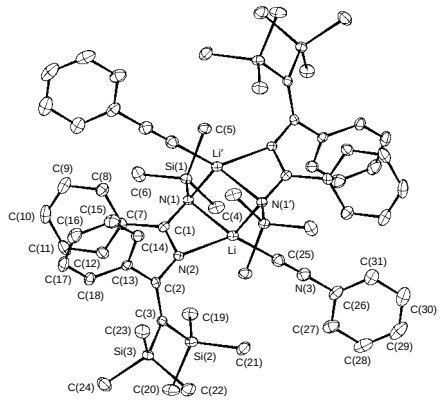

Fig. 1 Molecular structure of **3** with selected bond distances (Å) and angles (°): Li–N(1) 2.174(5), Li–N(2) 2.035(5), Li–N(1′) 2.115(5), Li–C(25) 2.178(6), N(3)–C(25) 1.157(4); N(3)–C(25)–Li 171.4(3), C(25)–N(3)–C(26) 176.0(3)

metric dimer **3** (Fig. 1), having a planar [LiN(1)Li′N(1)′] ring, has a ladder-like structure similar to that of [Li{N(R)C(C_6H_4Me-4)NR}(thf)]$_2$.[14] The shortest metal contact is to N(2) [2.035(5) Å] while the distances Li–N(1) 2.174(5), Li–N(1)′ 2.115(5) and Li–C(25) 2.178(6) Å are significantly longer. Compound **7** is also a dimer, but in contrast to **3**, the Li atoms are only three-coordinate with essentially symmetrical bridging NR_2 groups. The coordination sphere around Li is completed by the neutral isonitrile ligand with a slightly longer Li–C bond than in **3**. The overall geometry is therefore closely related to [{Li(μ-NR_2)L}$_2$] (*e.g.* L = OEt_2[15a] or NBu^t[15b]). Compound **6b** (Fig. 2) is monomeric with a distorted tetrahedral environment at Mg and fairly standard Mg–C σ-bond distances[13] of 2.148(7) and 2.138(9) Å, while the contacts to the neutral isonitrile ligands [2.31(1) Å] are much longer. The Grignard complex **5a** is unusual in that while it is a centrosymmetric dimer in the solid, the two monomeric MgBr(CHR_2) units are only weakly bound, the [Mg(μ-Br)]$_2$ moiety being unsymetrical: Mg–Br 2.561(5), Mg···Br 2.927(5) Å. The former distance is unexceptional, being close to those found (2.56–2.58 Å) in the symmetrical dimers [Mg(μ-Br)(Et)L]$_2$ (L = OEt_2[16a] or NEt_3[16b]) **B** and [Mg(μ-Br)(CHR_2)(OEt_2)]$_2$ **4** (details will be published in the full paper). This contrast between the structures of **4** and **5a** is consistent with the suggestion that the Mg–CNR′ bond is strong. This is further evident by the exceptionally short Mg–CHR_2 distance of 1.89(1) Å; *cf.* 2.114(7) and 2.125(6) Å in **4** or of 2.094(11)–2.18 Å in **B**,[16] which are close to the Mg–CNR′ bond lengths of 2.12(2) Å in **5a**. The angles at N [179(2)°] and C [174(2)°] of **5a** are close to linear.

It is noteworthy that in each of **1**–**7**, the isonitrile ligand is firmly bound to the metal as shown not only by the thermal stability but also that, in at least some of the cases, R′NC displaces Et_2O or thf from a precursor metal substrate (Scheme 1). Such complexes may have opened a new chapter in main group metal coordination chemistry.

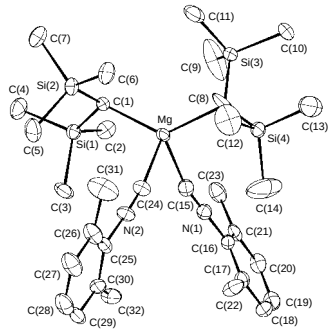

Fig. 2 Molecular structure of **6b** with selected bond distances (Å) and angles (°): Mg–C(1) 2.148(7), Mg–C(8) 2.138(9), Mg–C(15) 2.307(10), Mg–C(24) 2.306(9), N(1)–C(15) 1.140(10), N(1)–C(15)–Mg 168.02(7), C(15)–N(1)–C(16) 177.2(8)

$Ln_2\square Ti_2O_7$ (Ln = La, Nd, Sm, Gd): a novel series of defective Ruddlesden–Popper phases formed by topotactic dehydration of $HLnTiO_4$†‡

V. Thangadurai,[a] G. N. Subbanna[b] and J. Gopalakrishnan*[a]†

[a] *Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore 560 012, India*
[b] *Materials Research Centre, Indian Institute of Science, Bangalore 560 012, India*

Topotactic dehydration of $HLnTiO_4$ (Ln = La, Nd, Sm or Gd) around 480–500 °C yields a new series of metastable layered perovskite oxides, $Ln_2\square Ti_2O_7$, that possess a defective $Sr_3Ti_2O_7$ structure, where the cubooctahedral sites within the double-perovskite layers are most likely vacant.

Several layered oxides consisting of metal–oxygen (MO_6) octahedra are regarded as derivatives of the three-dimensional perovskite ($CaTiO_3 \equiv ABO_3$) structure.[1] Of these, the Ruddlesden–Popper (R–P) phases, $A_2[A_{n-1}B_bO_{3n+1}]$, originally discovered in the Sr–Ti–O system,[2] are the most widely known, because members/derivatives of this family exhibit several important physical properties of current interest. Thus, La_2CuO_4, an $n = 1$ member of this family, is the parent material for the Bednorz–Müller discovery[3] of superconducting layered cuprates, $Sr_{2-x}Ln_{1+x}Mn_2O_7$ (Ln = La or rare earth), $n = 2$ members of this series, exhibit ferromagnetic and magnetoresistive properties[4] and $K_2La_2Ti_3O_{10}$, an $n = 3$ member,[5] exhibits ion-exchange and hydration behaviour appropriate for photocatalytic decomposition of water.[6]

Oxides of the formula $NaLnTiO_4$ (Ln = La, Nd, Sm, Gd), originally synthesized by Blasse,[7] are novel $n = 1$ members of the R–P family exhibiting a unique ordering of Na and La atoms at the alternate interlayer sites between the single perovskite sheets in the sequence $-Ln_2-TiO_{4/2}O_2-Na_2-TiO_{4/2}O_2-Ln_2-$ along the *c*-axis.[8] Clearly, the ordering seems to be dictated by the off-centre distortion of $3d^0$: TiO_6 octahedra[9] giving rise to short and long axial Ti–O bonds, the oxygen to the short Ti–O bonds pointing towards the Na layer. Recently, protonated derivatives, $HLnTiO_4$, have been prepared[10] from $NaLnTiO_4$ by Na^+/H^+ exchange in dilute HNO_3.

Considering the topotactic nature of this ion-exchange which preserves the structural features of the parent $NaLnTiO_4$, $HLnTiO_4$ would consist of the layer sequence $-Ln_2-OTiO_{4/2}(OH)-(OH)TiO_{4/2}O-Ln_2-$ along the *c*-direction (Fig. 1). Accordingly, we visualized that a topotactic dehydration would result in a condensation of the adjacent single-perovskite $TiO_{4/2}O(OH)$ sheets to give double-perovskite $Ti_2O_{10/2}O_2$ ($\equiv Ti_2O_7$) sheets on elimination of a water molecule (Fig. 1). The dehydration product, $Ln_2Ti_2O_7$, would be a novel $n = 2$ member of the R–P series similar to $Sr_3Ti_2O_7$,[2] where the interlayer cubooctahedral Sr-sites in the ($SrTi_2O_7$) perovskite sheets would be vacant. Here we show that indeed dehydration of $HLnTiO_4$ (Ln = La, Nd, Sm, Gd) proceeds by this mechanism yielding a new series of $Ln_2\square Ti_2O_7$ that are related to $Sr_3Ti_2O_7$. It must be mentioned that these layered titanates are truly metastable phases stabilized by the topotactic nature of the dehydration reaction under the mild conditions; the stable titanates of this composition adopt either the <110> terminated layered perovskite structure[11] for $La_2Ti_2O_7$ and $Nd_2Ti_2O_7$ or the pyrochlore structure[12] for the other titanates.

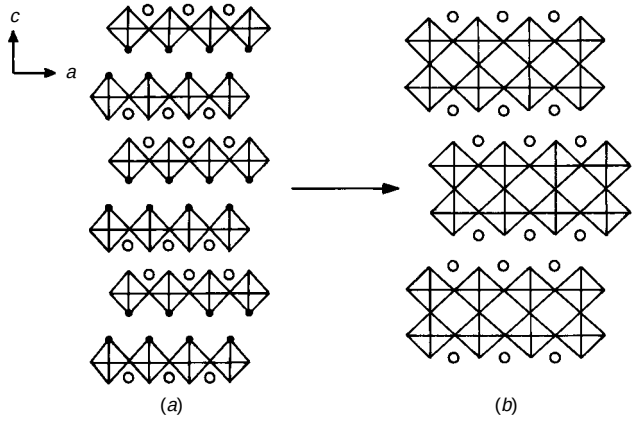

Fig. 1 Schematic representation of dehydration of (*a*) $HLnTiO_4$ to give (*b*) layered $Ln_2\square Ti_2O_7$. The open circles represent Ln atoms and the closed dots in (*a*) denote OH.

$NaLnTiO_4$ (Ln = La, Nd, Sm, Gd) were prepared as reported in the literature[8] by reacting Na_2CO_3, Ln_2O_3 and TiO_2 at 900 °C for 2 days with intermittent grinding. $HLnTiO_4$ were prepared by ion-exchange in 0.1 M HNO_3 as reported in the literature,[10] followed by drying in the air at ambient condition. Powder X-ray diffraction (XRD) patterns (JEOL JDX-8P X-ray powder diffractometer using Cu-Kα radiation) (Fig. 2) and the unit cell parameters (Table 1) obtained by least-squares refinement of the powder XRD data indicated the formation of $HLnTiO_4$.

We investigated the dehydration of $HLnTiO_4$ by thermogravimetry (TG) in air (Cahn TG-131 system, heating rate 1 °C min^{-1}). All the samples showed a single-step mass loss in the region 250–500 °C corresponding to the dehydration reaction

$$2\ HLnTiO_4 \rightarrow Ln_2Ti_2O_7 + H_2O \qquad (1)$$

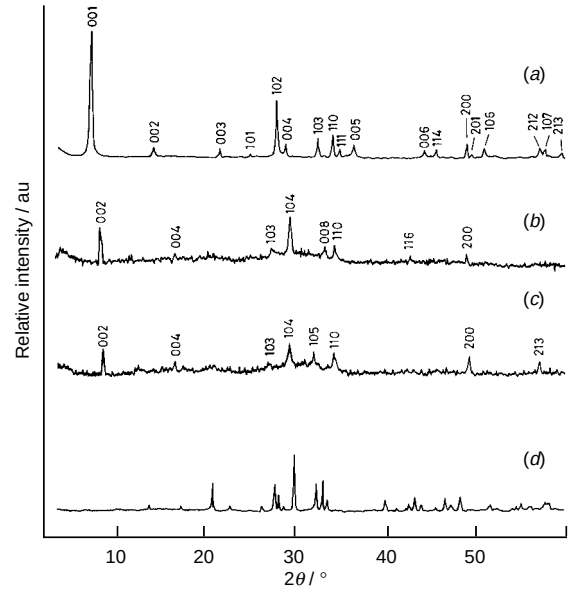

Fig. 2 Powder XRD patterns (Cu-Kα) of (*a*) $HLaTiO_4$, (*b*) $La_2\square Ti_2O_7$, (*c*) $Nd_2\square Ti_2O_7$ and (*d*) sample (*b*) heated at 900 °C; stable $La_2Ti_2O_7$

Table 1 Synthesis conditions and lattice parameters of the parent ($HLnTiO_4$) and product ($Ln_2\square Ti_2O_7$) oxides

Parent	Lattice parameters/Å		Synthesis conditions	Product	Lattice parameters/Å	
	a	*c*			*a*	*c*
$HLaTiO_4$	3.722(2)	12.303(6)	500 °C; 15 min	$La_2\square Ti_2O_7$	3.725(3)	21.68(5)
$HNdTiO_4$	3.694(2)	12.099(6)	500 °C; 15 min	$Nd_2\square Ti_2O_7$	3.705(6)	21.15(8)
$HSmTiO_4$	3.689(1)	11.995(5)	500 °C; 12 min	$Sm_2\square Ti_2O_7$	3.679(2)	21.14(6)
$HGdTiO_4$	3.698(3)	11.769(9)	480 °C; 15 min	$Gd_2\square Ti_2O_7$	3.679(3)	20.81(6)

The mass% losses observed in this temperature range are in agreement with the expected mass losses within ±0.1% error.

In an attempt to characterize the dehydration products, we recorded the powder XRD patterns of the TG residues. The patterns however did not show the characteristic features expected for the formation of a layered $Ln_2\square Ti_2O_7$; instead the patterns showed broad features corresponding to the stable $Ln_2Ti_2O_7$ phases. Heating $HLnTiO_4$ separately in air around 750 °C and above clearly showed the formation of stable $Ln_2Ti_2O_7$ (Fig. 2). We therefore believed that formation of layered $Ln_2\square Ti_2O_7$ would perhaps occur at lower temperatures, immediately after the dehydration. Accordingly, we investigated the dehydration of $HLnTiO_4$ around 450–500 °C for various durations, monitoring the samples by both mass loss and powder XRD. We found that samples (*ca*. 1 g) heated at 480–500 °C for about 15 min in air showed XRD patterns (Fig. 2) characteristic of the desired layered structure. The reflections at *ca*. 10.8, 5.4, 2.6, 1.85 Å (for $La_2\square Ti_2O_7$) clearly indicated the formation of a phase similar to $Sr_3Ti_2O_7$ with a tetragonal unit cell, $a \approx 3.725$ and $c \approx 21.68$ Å. The observation of a strong reflection at *ca.* 3.10 Å which could be indexed as (104) however indicated that the structure would not exactly be the same as $Sr_3Ti_2O_7$ with *I*4/*mmm* space group. Moreover, many of the reflections in the pattern are broad, suggesting poor crystallinity/disorder of the samples. In Fig. 2, we show powder XRD patterns of two of the members (Ln = La, Nd) and in Table 1, we list the lattice parameters of the parent ($HLnTiO_4$) and product ($Ln_2\square Ti_2O_7$) phases together with synthesis conditions.

In order to characterize the layered $Ln_2\square Ti_2O_7$ further, we recorded the electron diffraction (ED) patterns (JEOL JEM 200-CX transmission electron microscope). All the samples are quite crystalline showing typical perovskite like $\sqrt{2}a_c \times \sqrt{2}a_c$ patterns in the [001] direction. When the beam direction is along [010], we see clear evidence for a *ca.* 21 Å repeat in the *c** direction which is consistent with the *c* axis of the tetragonal cell found from XRD patterns (Table 1). We also see lattice fringes with a *ca*. 10 Å repeat (which would correspond to 0.5 *c*) in the lattice image (Fig. 3) recorded with the same [010] beam orientation. The ED patterns however show streaking both in the *a***b**-plane as well as along the *c**-direction, which indicate considerable disorder. Disorder in the *c** periodicity is also seen in the lattice images. The disorder could arise from a turbostratic stacking of the double-perovskite Ti_2O_7 sheets in the dehydrated samples. Despite the disorder, the presence of a tetragonal or pseudotetragonal cell with $\sqrt{2}(\approx 3.7) \times \sqrt{2}(\approx 3.7) \times \approx 21$ Å dimension is clear from the ED patterns for all the $Ln_2\square Ti_2O_7$ members studied, showing that gentle dehydration of $HLnTiO_4$ indeed yields a layered $Ln_2\square Ti_2O_7$ that is related to $Sr_3Ti_2O_7$.

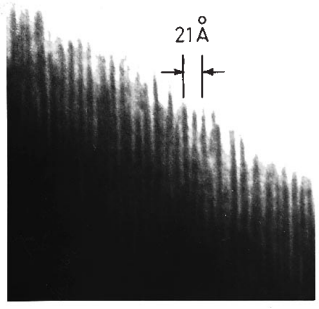

Fig. 3 Lattice image of $La_2\square Ti_2O_7$ corresponding to the electron diffraction pattern recorded with the [010] beam direction, revealing the presence of *ca*. 10 Å fringes in the *c*-direction.

We believe that the present work has shown for the first time the possibility of transforming $n = 1$ R–P members to $n = 2$ members (albeit defective) of the same series by a topotactic dehydration reaction. The key to the success of this $n = 1$ to $n = 2$ transformation lies in the 1 : 1 ordering of the Na and Ln atoms in the precursor $NaLnTiO_4$ oxides, which in turn is dictated by the distortion of d^0 : TiO_6 octahedra giving short and long axial Ti–O bonds.[9] We envisage that the method could be generalized and extended to the synthesis of metastable 2*n* R–P phases from appropriately tailored *n* R–P phases.

We thank the Indo–French Centre for the Promotion of Advanced Research, New Delhi for financial support. One of us (V. T.) thanks the Council of Scientific and Industrial Research, New Delhi for the award of a research fellowship.

1,4,7-Triazacyclononane-1-succinic acid-4,7-diacetic acid (NODASA): a new bifunctional chelator for radio gallium-labelling of biomolecules

João P. André,[a,b] Helmut R. Maecke,*[a] Margareta Zehnder,[c] Ludwig Macko[c] and Kayhan G. Akyel[d]

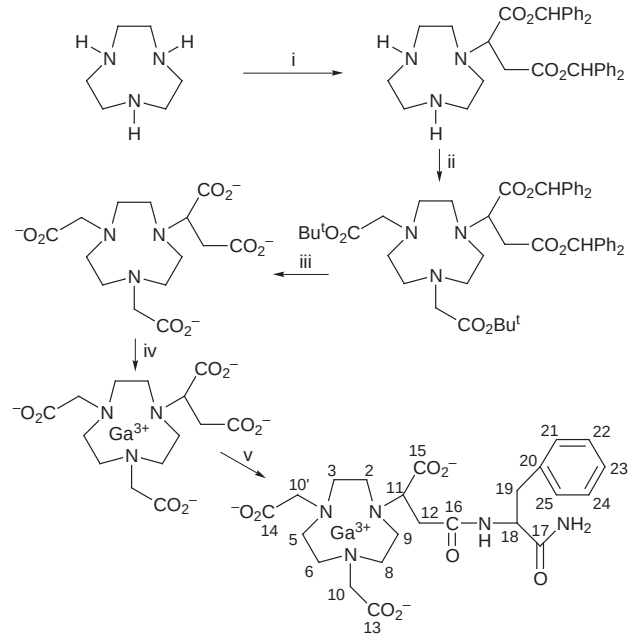
[d] *Novartis Pharma AG, Basel, Switzerland*

A new bifunctional chelator NODASA (1,4,7-triazacyclononane-1-succinic acid-4,7-diacetic acid) has been synthesised, its kinetically inert gallium(III) complex was crystallographically characterized and conjugated to a model aminoacidamide showing the feasibility of a prelabelling approach with ^{68,67}Ga.

Over the past ten years a constant interest in the chemistry of bifunctional chelators useful in biomedical applications has been evident.[1,2] Many were designed for coupling to monoclonal antibodies[3,4] and other biomolecules.[5] Recently bioactive peptides were successfully introduced into the clinic for *in vivo* visualization of tumours.[6,7] As these peptides show very fast blood clearance and diffusion into tissues the use of short lived metallic positron emitters becomes possible. In this context ^{68}Ga ($t_{1/2}$ = 68 min) is of special interest because its half-life is compatible with the rate of localization of small targeting molecules. For our purpose a bifunctional chelator is needed which is comprised of a gallium immobilizing moiety and a short carboxylate arm for coupling to the N-terminal end of bioactive peptides. We aim at using this bifunctional chelator in a preconjugation ^{67,68}Ga-labelling approach of somatostatin analogues. This preconjugation allows the covalent coupling of a well defined radiometal complex of high specific activity; this will be very important with regard to most radiopeptides because of their potential pharmacological effects.

Therefore we synthesised a new N-functionalised 1,4,7-triazamacrocycle in three steps by alkylation of 1,4,7-triazacyclononane (Scheme 1): (i) with 1 equiv. of bis(diphenylmethyl) D,L-bromosuccinate in chloroform; (ii) with 2 equiv. of *tert*-butyl bromoacetate in acetonitrile in the presence of K_2CO_3 followed by deprotection with 6 M HCl (iii). The overall yield of the synthesis of 1,4,7-triazacyclononane-1-succinic acid-4,7-diacetic acid (NODASA) was slightly > 50%.‡

Crystals of Ga(NODASA) were obtained from an aqueous solution of the ligand and $Ga(NO_3)_3$ in equimolar amounts (pH 3, 70 °C, 1 h; Scheme 1 (iv), followed by slow evaporation. Characterization by X-ray diffraction§ showed that the complex is electrically neutral and the Ga^{III} ion is fully chelated in a slightly distorted octahedral environment (Fig. 1). The β-carboxylate remains protonated and does not participate in the complexation. The three nitrogen atoms of the triazacyclononane define a plane in a facial arrangement and three of the pendant carboxylate oxygens constitute another one. These planes are almost coplanar with a dihedral angle of 1.75°. The *trans* N–Ga–O bond angles average 165.4°. This leads to a relative twist of the N_3 and O_3 planes by 14.6° away from a symmetrically staggered conformation, similar to the parent complex Ga(NOTA)[8] and different previously synthesised nickel(II) and chromium(III) NOTA complexes.[9] The variation in the individual Ga–O and Ga–N bond lengths is very small showing overall high similarity to the parent complex Ga(NOTA).[10] Ga(NODASA) was also characterized by its ^{1}H, ^{13}C and ^{69}Ga NMR spectra.¶ A multiplet centered at δ 3.75 (Fig. 2) due to the magnetically non equivalent acetate hydrogens is the most dramatic effect in the ^{1}H NMR spectrum of the chelate in relation to the free ligand, which exhibits a singlet at δ 3.50. The sharp multiplets of the ethylenic protons might show the existence of slow intramolecular processes of interconversion



Scheme 1 Synthesis of the chelate Ga(NODASA) and coupling to D-phenylalanineamide

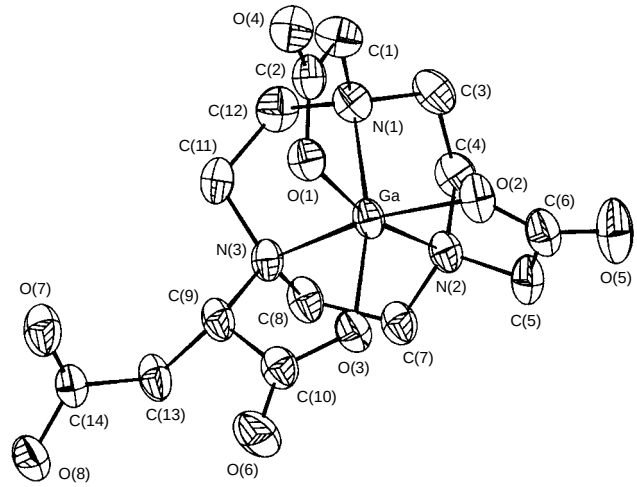


Fig. 1 ORTEP drawing of the Ga(NODASA) complex. Ga–N(1) 2.101(3), Ga–N(2) 2.098(3), Ga–O(1) 1.937(3), Ga–O(3) 1.942(3) Å; O(1)–Ga–O(3) 94.7(1), O(2)–Ga–N(3) 165.6(1), O(2)–Ga–N(2) 82.5(1), N(2)–Ga–N(3) 84.1(1)°.

between the (λλλ) and (δδδ) conformations[11] of the ring backbone arising from the high rigidity of the system.

Although the structural results give some important indications about the binding of Ga^{III} to the macrocycle, the stability of this chelate is very important for successful applications *in vivo*. With a complexation competition method using ^{67}Ga as a radiotracer and NOTA‖ as an auxiliary competing ligand it has been possible to estimate the conditional stability constant for the complex at different pH values. The equilibration has been followed for nine days. The determination of the ligand protonation constants allows the calculation of the thermodynamic stability constant of Ga(NODASA) to $\log K_{Ga(NODASA)}$ = 30.9(0.2) compared to 30.98 of Ga(NOTA).[12]

An even more important indicator for *in vivo* applications is the measurement of the rate of exchange of Ga^{III} in blood serum under the physiological conditions.[14] For this experiment $^{67}Ga^{III}$ is first incubated with about 50 times excess of NODASA at pH 6.2 in 0.5 M ammonium acetate buffer (25 min, 90 °C) in order to incorporate the metal ion. Then the complex is mixed with blood serum and the exchange kinetics with transferrin are measured at 37 °C. This was done by taking aliquots of the serum, separating them by gel filtration, which allows the separation of ^{67}Ga(NODASA) from gallium(III)–transferrin ($\log K$ = 23.7),[13] and measuring the activity in both fractions with use of radiometric detection. The results clearly show that ^{67}Ga–NODASA virtually does not transfer any ^{67}Ga to transferrin over the observed period of 5 days, fulfilling the criterion of high kinetic stability.

The kinetic stability of Ga(NODASA) with respect to the acid-catalysed dissociation has been demonstrated with the aid of the ^{67}Ga complex, kept in 0.1 M glycine–HCl buffer, pH 2, at 37 °C. Aliquots of this solution were analysed by HPLC. After 5 days the complex was still 100% intact.

The fact that the β-carboxylate remains free while the other three carboxylates are involved in five-membered chelate rings, upon coordination to the metal ion, offers a very interesting possibility to couple the chelate to a biomolecule. As a model peptide we coupled D-phenylalanineamide to Ga(NODASA) [Scheme 1 (v), in DMSO–DMF (2 : 1)] using HATU** [15] as the coupling reagent with almost quantitative yield.†† HATU allows coupling of carboxylate functions to primary amines within minutes rendering even the coupling of ^{68}Ga(NODASA) to peptides feasible.

In summary, ^{67,68}Ga(NODASA) can be used in a pre-labelling approach followed by conjugation to a biomolecule. This approach is currently being followed using somatostatin analogues.

Thermally responsive novel anion exchange membranes for electrodialysis

Toshikatsu Sata, Shin-ichiro Emori and Koji Matsusaki

Department of Applied Chemistry and Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai 2557, Ube City, Yamaguchi Prefecture, 755, Japan

Anion exchange membranes containing *N*-isopropylacrylamide as a component showed a decrease in osmotic flux through the membrane, and an increase and decrease respectively in the transport numbers of NO_3^- and SO_4^{2-} relative to Cl^- with increasing temperature.

The concentration of NO_3^- in groundwater has been greatly increasing because of excessive use of artificial fertilizers. The EC proposed that the concentration of NO_3^- in drinking water should be below 25 ppm, however, it exceeds this in many places in Europe and also in Japan. A high NO_3^- concentration in drinking water can endanger human health because this can lead to the formation of nitrosamines and nitriles which cause cell poisoning. Many methods to remove NO_3^- from groundwater have been proposed and tried: reverse osmosis, electrodialysis, ion exchange, *etc.* It is important to preserve the properties of natural water, and electrodialysis is the most suitable method for this purpose. Although it is desirable to perform electrodialysis at high temperature to save energy, using a NO_3^- permselective anion exchange membrane, osmotic flux of water through the ion exchange membranes increases with increasing temperature, and the amount of water processed therefore decreases.

Poly(*N*-isopropylacrylamide) is a well known heat-sensitive polymer.[1] It is soluble in water at room temperature but undergoes a phase separation at temperatures higher than its lower critical solution temperature (LCST, *ca.* 32 °C). At higher temperatures, the intrinsic affinity of *N*-isopropylacrylamide polymer chains for themselves is enhanced due to thermal dissociation of hydrating water molecules from the polymer chains. Hydrophobic interactions between isopropyl groups drastically increase and the polymers condense with each other, precipitating rapidly in the solution. Cross-linked copolymers containing *N*-isopropylacrylamide as a monomer have been also extensively studied as hydrogels used in solute separation,[2] immobilization of enzymes,[3] drug release regulating systems,[4] *etc.* Cross-linked copolymer gels containing ionic monomers such as acrylic acid, 2-methyl-2-acrylamidopropane sulfonic acid, *etc.*, were also reported to show similar swelling and deswelling properties with change in temperature. If ion exchange membranes contain *N*-isopropylacrylamide as a component, it is expected that the membranes will show a thermal response.

Two types of cross-linked anion exchange membranes containing *N*-isopropylacrylamide were prepared: (*i*) 1 part (part by mass) of acrylonitrile–butadiene rubber was dissolved in a mixture of 5 parts of *N*-isopropylacrylamide (supplied by Kojin Co., Ltd.), 10 parts of glycidyl methacrylate, 5 parts of ethylene glycol dimethacrylate and 0.24 parts of benzoyl peroxide (M-1 membrane), (*ii*) 1 part of acrylonitrile–butadiene rubber was dissolved in a mixture of 5 parts of *N*-isopropylacrylamide, 10 parts of dimethylaminoethyl methacrylate, 5 parts of ethylene glycol dimethacrylate and 0.24 parts of benzoyl peroxide (M-2 membrane). The two obtained pasty mixtures were coated on a woven fabric made of poly(vinyl chloride), and polymerized at 85 °C for 24 h under an N_2 atmosphere after covering with a polyester film on both sides. After polymerization, the copolymer membrane from the M-1 composition was immersed in a 1 M aqueous NMe_3 (75 mass%) and acetone (25 mass%) mixed solution for 48 h at room temperautre to introduce quaternary ammonium groups on the glycidyl groups. The M-2 copolymer membrane was immersed in a methyl iodide (60 mass%)–hexane (40 mass%) mixed solution for 24 h to quaternize the tertiary amino groups. A commercial anion exchange membrane, NEOSEPTA AM-1 (Tokuyama Corp.; benzyltrimethylammonium groups; cross-linkage, 10%) was used as a standard anion exchange membrane. Before use, the membranes were equilibrated with 1.0 M HCl and 0.5 M NH_3 alternately several times, and then equilibrated with solutions to be used in the measurements.

Reduced osmotic flux through anion exchange membranes was measured between pure water and 4.0 M NaCl at different temperatures with stirring according to the reported[5] methods. Transport numbers, calculated from a membrane potential, and electrical resistance of the membrane were measured at different temperatures. Water content and ion exchange capacity of the membranes were determined by conventional methods.[5] Electrodialysis was carried out in a four-compartment cell with Ag–AgCl electrodes (solution in each compartment, 100 cm^3; effective membrane area, 2×5 cm).[6] The two middle compartments were separated from the anolyte and catholyte, which consisted of NaCl solution of the same Na^+ concentration as that of the solution to be measured, by a cation exchange membrane (NEOSEPTA CM-2, Tokuyama Corp.; transport number of Na^+ was > 0.99 in the electrodialysis of 0.50 M NaCl solution at a current density of 20 mA cm^{-2}). The anion exchange membrane to be studied was placed at the center of the cell, and a 1 : 1 mixed salt solution, either 0.02 M $NaNO_3$–0.02 M NaCl ($[Na^+] = 0.04$ M) or 0.25 M Na_2SO_4–0.25 M NaCl ($[Na^+] = 0.50$ M) was electrodialyzed at a current density of 1 or 10 mA cm^{-2} for 60 min under vigorous agitation (stirring at 1500 ± 100 rpm). Studied temperatures for electrodialysis were 25.0, 30.0, 32.0, 35.0 and 40.0 °C. All measurements were performed after the membranes, solutions and the cell had been equilibrated at the respective temperature (immersed in a thermostat for > 24 h). After electrodialysis, the change in the concentrations of the anions in the middle compartments was determined by the Mohr method, and chelate back titration or ion chromatography (Hitachi Ion Chromatography L-6000). Then the transport number of anions A relative to chloride ions was calculated by following equation: $P_{Cl}^{A} = (t_A/t_{Cl})/(C_A/C_{Cl})$, where t_A and t_{Cl} are the transport numbers of anions A and Cl^- in the membrane, and C_A and C_{Cl} are the average concentrations of anions A and Cl^- ions in the desalting side solution during electrodialysis, respectively. P_{Cl}^{A} represents the permeated equivalent of anions A through the membrane when 1 equiv. of Cl^- is permeated through. The current efficiency was calculated from the amount of transported anions and electricity measured by coulometry.

Table 1 shows the characteristics of the prepared anion exchange membranes and the commercial membrane. The electrical resistances of the M-1 and M-2 membranes was high and their water content was low compared with those of the commercial membrane because of their low ion exchange capacity. Although transport numbers of the M-1 and M-2 membranes were lower than that of the commercial membrane

Table 1 Characteristics of anion exchange membranes

	NEOSEPTA AM-1	M-1	M-2
Electric resistance[a]	1.1	17.8	12.7
Transport number[b]	0.94	0.84	0.90
Ion exchange capacity[c]	2.25	1.18	0.92
Water content[d]	0.27	0.12	0.07
Thickness/mm	0.13	0.12	0.10
Reinforcing	PVC	PVC	PVC

[a] Ω cm^2; measured with 1000 Hz ac at 25.0 °C after equilibration with 0.5 M NaCl. [b] Calculated from a membrane potential generated from 0.50 M NaCl │Membrane│ 2.50 M NaCl at 25.0 °C. [c] Mequiv. per g (Cl^-) dry membrane at 25.0 °C. [d] g (H_2O) per g (Cl^-) dry membrane, measured at 25.0 °C after equilibration with pure water.

at 25.0 °C, they increased with increasing temperature and reached 0.89 (M-1) and 0.94 (M-2) at 35.0 °C (the transport number of the commercial membrane slightly decreased with increasing temperature: 0.94 at 25 °C, 0.93 at 35 °C). The electrical resistances of both M-1 and M-2 membranes were constant between 32 and 35 °C, while that of the commercial membrane decreased monotonously with increasing temperature.

Fig. 1 shows the change in the reduced osmotic flux through M-1 and commercial membrane. In general, the reduced osmotic flux of water through ion exchange membranes increases with increasing temperature as found for the commercial membrane. However, the M-1 membrane showed completely different behavior: the reduced osmotic flux decreased from 25 °C with increasing temperature and attained a constant value from 32 °C. This is thought to be due to the decrease in hydrophilicity of membrane originated from the aggregation of isopropyl groups in the membranes. In fact, water contents of both M-1 and M-2 membranes decreased with increasing temperature and attained a constant value from 32 °C (water content of the commercial membrane increased: 27% at 25.0 °C; 31% at 40 °C).

Fig. 2 shows the transport number of NO_3^- relative to Cl^-. Although $P_{Cl}^{NO_3}$ of the commercial membrane did not change with temperature, it should be noted that NO_3^- selectively permeate through the anion exchange membranes containing *N*-isopropylacrylamide with increasing temperature. It was reported that hydrophilicity of anion exchange membranes greatly affects the permselectivity between two anions: with decreasing hydrophilicity of the membranes, less hydrated anions such as NO_3^- and Br^- selectively permeate through the membrane, and the permeation of strongly hydrated anions, F^- and SO_4^{2-}, decreases.[6] Because the aggregation of isopropyl groups in the M-1 and M-2 membranes makes the membranes hydrophobic with increasing temperature, the permeation of NO_3^- is thought to be enhanced. Though the ratio of mobilities between NO_3^- and Cl^- in the membrane phase did not change in all membranes with temperature, the ion exchange equilibrium constant between NO_3^- and Cl^- of the M-1 membrane increased with increasing temperature: $K_{Cl}^{NO_3}$ = 1.5 at 25 °C and 2.2 at 35 °C (K_{Cl}^{NO3} of the commercial membrane was 1.95 and independent of temperature.) It is apparent that the decrease in hydrophilicity of the M-1 and M-2 membranes with increasing temperature caused selective uptake of the less hydrated anions NO_3^- (Gibbs hydration energies of NO_3^- and Cl^- are 270 and 317 kJ mol^{-1}, respectively).[7] The decrease in the hydrophilicity of the membranes also decreased permeation of SO_4^{2-} remarkably since SO_4^{2-} is strongly hydrated.[7] This is a desirable property for anion exchange membranes because precipitation of $CaSO_4$ in electrodialyzers and in membranes is a serious problem in electrodialysis. P_{Cl}^{SO4} of the commercial membrane increased slightly with increasing temperature. Finally, the current efficiencies of the M-1 (96%) and M-2 membranes (93%) were slightly lower than that of the commercial membrane (99%). Anion exchange membranes containing *N*-isopropylacrylamide are suitable in electrodialysis to remove NO_3^- from groundwater with low energy without precipitation of $CaSO_4$.

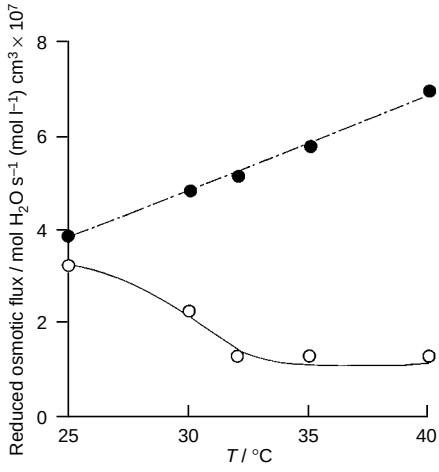

Fig. 1 Change in reduced osmotic flux with temperature. (●) Commercial anion exchange membrane (NEOSEPTA AM-1); ○: M-1 membrane. Measurements in 4.0 M NaCl│Membrane│pure water; effective membrane area = 10 cm^2.

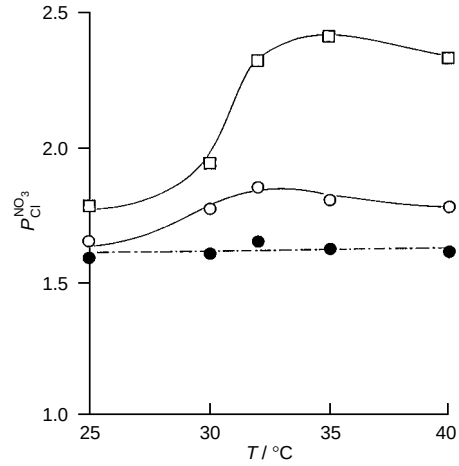

Fig. 2 Change in transport number of NO_3^- relative to Cl^- with temperature. (●) Commercial anion exchange membrane (NEOSEPTA AM-1); ○: M-1 membrane; □: M-2 membrane. A 0.02 M $NaNO_3$–0.02 M NaCl mixed solution was electrodialyzed at different temperatures (current density = 1 mA cm^{-2}).

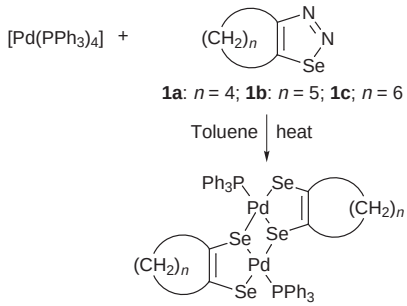
Novel palladium complexes of Se,N,Se tridentate ligands derived from cycloalkeno-1,2,3-selenadiazoles

Susan Ford,[a] Christopher P. Morley*[a] and Massimo Di Vaira[b]

[a] *Department of Chemistry, University of Wales Swansea, Singleton Park, Swansea, UK SA2 8PP*
[b] *Dipartimento di Chimica, Università degli Studi di Firenze, Via Maragliano 75/77, 50144 Firenze, Italy*

The reaction between $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone), a trialkylphosphine, and a cycloalkeno-1,2,3-selenadiazole in toluene under reflux leads in good yield to the complexes $[PdL(PR_3)]$ [L = $SeC(R^1)=C(R^2)N=NC(R^1)=C(R^2)Se$; $R^1–R^2 = (CH_2)_n$; R = Et, Bu^n] containing a novel Se,N,Se tridentate ligand formed by the coupling of two 1,2,3-selenadiazole molecules; the structure of the product with R = Bu^n and *n* = 4 has been determined by X-ray crystallography.

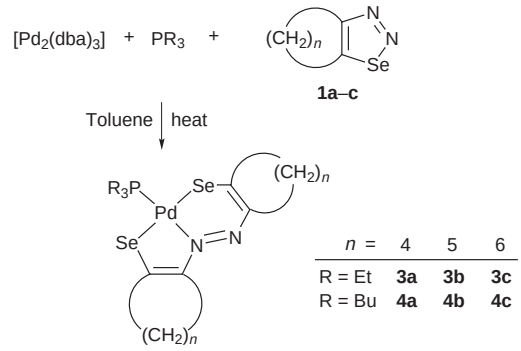
The chemistry of organoselenium ligands has attracted increased attention in the last few years, as a result of both their greater accessibility, and the realisation that they may display significantly different properties from their sulfur analogues.[1] We have previously demonstrated that 1,2,3-selenadiazoles may serve as the precursors to a range of selenium-containing ligands in cyclopentadienylcobalt complexes,[2] and recently reported on their reactions with $[Pt(PPh_3)_4]$.[3] The palladium compound $[Pd(PPh_3)_4]$ behaves quite differently from its platinum analogue, yielding novel dinuclear diselenolenes (Scheme 1).[4] We have now studied the reactivity of a range of cycloalkeno-1,2,3-selenadiazoles (**1a**–**c**) towards other palladium(0) phosphine complexes, generated *in situ* from $[Pd_2(dba)_3]$ **2** (dba = dibenzylideneacetone).



Scheme 1

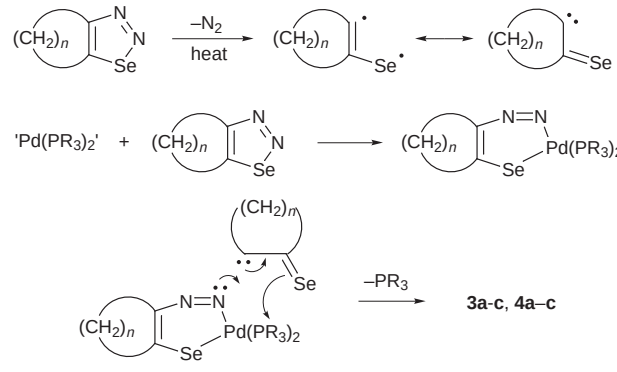
Heating a mixture of 2 equiv. of one of the 1,2,3-selenadiazoles **1a**–**c** with **2**, in the presence of triethylphosphine or tri-*n*-butylphosphine, leads to the formation of a deep purple solution, from which the product **3a**–**c** or **4a**–**c** may be isolated in good yield by column chromatography (Scheme 2).‡ These intensely coloured compounds have the general formula $[PdL(PR_3)]$ and contain the first examples of a new type of ligand L = $SeC(R^1)=C(R^2)N=NC(R^1)=C(R^2)Se$, which may be considered as an alicyclic analogue of an azo-dye.

The detailed mechanism of the reaction remains unclear. In general, 1,2,3-selenadiazoles react *via* elimination of dinitrogen to yield a selenaketocarbene, the fate of which determines the outcome of the reaction.[5] Attack on another molecule of intact 1,2,3-selenadiazole is, to our knowledge, unprecedented. We therefore postulate initial insertion of palladium(0) into the selenium–nitrogen bond of a 1,2,3-selenadiazole molecule, followed by carbon–nitrogen bond formation by addition of a selenaketocarbene to this palladium(II) intermediate (Scheme 3). It is interesting that behaviour analogous to that of $[Pd(PPh_3)_4]$ is not observed. This we ascribe to the greater basicity of the phosphines used in this study, when compared with that of triphenylphosphine.



Scheme 2

The molecular structure of **4a** has been determined by X-ray crystallography§ and is shown in Fig. 1. The palladium atom is square-planar coordinated, with the phosphine *trans* to a nitrogen atom of the novel tridentate Se,N,Se ligand. The twelve atoms associated with the π-system of the ligand [Se–C(C)=C(C)–N=N–C(C)=C(C)–Se] are also coplanar, so that overall this part of the molecule is virtually flat. Only the three *n*-butyl groups on the phosphine protrude significantly from the coordination plane. There are relatively few examples of Pd–Se distances in the literature. The bond lengths in **4a** [2.370(1), 2.371(1) Å] are comparable with the shortest thus far reported. In the related complexes [Pd{PhSeNC(4-MeC_6H_4)NNC(4-MeC_6H_4)NSePh}(PPh_3)][6] **5** and [PdCl{5-MeC_6H_3-2-(N=N-4′-MeC_6H_3-2′-SePh)}][7] **6** the Pd–Se distances are 2.375(1) and 2.4495(4) Å, respectively. The Pd–P distance is typical for PBu^n_3 derivatives, and similar to that in [Pd{2-OC_8H_8N=N(-5′-$NO_2C_6H_3$-2′-O)}(PBu^n_3)] **7**[8] [**4a**, 2.264(2); **7**, 2.289(2) Å]. The Pd–N distance of 2.081(8) is rather long [*cf.* 2.024(2),



Scheme 3

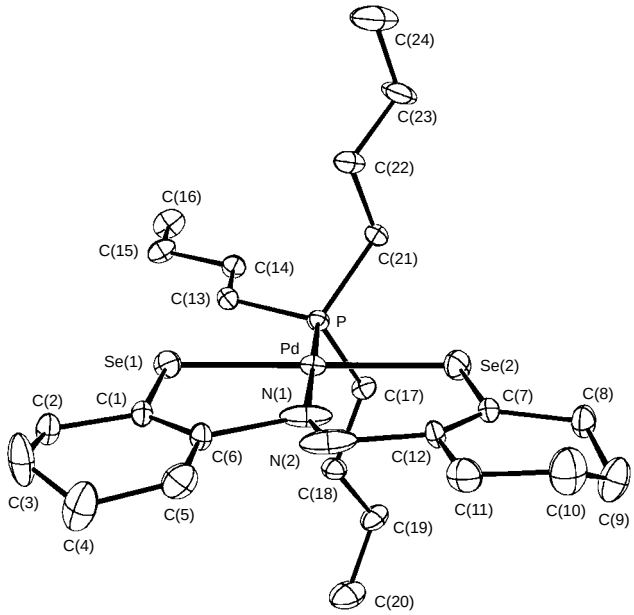


Fig. 1 Structure of **4a** with H atoms omitted for clarity. Selected bond lengths (Å) and angles (°): Pd–N(1) 2.081(8), Pd–P 2.264(2), Pd–Se(1) 2.370(2), Pd–Se(2) 2.371(1); P–Pd–Se(1) 91.72(6), Se(1)–Pd–N(1) 88.0(3), N(1)–Pd–Se(2) 93.1(3), Se(2)–Pd–P 87.23(6).

1.989(2) and 1.997(4) Å in **5**, **6** and **7**, respectively]. There is also considerable thermal motion associated with the nitrogen atoms, implying that the N(1)–Pd interaction is rather weak, and not strongly directional. Detailed discussion of bond angles and bond lengths in the azo-group is therefore not appropriate. The molecular formula is confirmed by the mass spectrum, where there is an intense cluster around m/z = 656 corresponding to the molecular ion, with the expected isotope distribution.

The NMR spectroscopic data show that this structure is maintained in solution for **4a**, and that the structures of **3a**–**c** and **4b**,**c** are similar. The selenium atoms are inequivalent and give rise to two signals in the ^{77}Se NMR spectrum, each of which shows a small splitting (J = 9 Hz) due to coupling to the phosphorus atom in the *cis* position. As expected, each atom in the two alicyclic rings gives a separate ^{13}C resonance.

The complexes **3a**–**c** and **4a**–**c** may be expected to resemble diselenolenes and dithiolenes in having delocalised metal–ligand bonding. We therefore anticipate rich and varied chemical and physical behaviour for these compounds and their derivatives.

We thank EPSRC for the provision of a studentship (to S. F.), Johnson Matthey plc for the loan of palladium salts, and the Ministero dell'Università e della Ricerca Scientifica e Tecnologica for financial support (to M. di V.).

Regiospecific synthesis of 2,3-naphthylenebis(diphenylphosphines) by double insertion of alkynylphosphines into nickel(0)–benzyne complexes

Martin A. Bennett,*† Christopher J. Cobley, Eric Wenger and Anthony C. Willis

Research School of Chemistry, Australian National University, Canberra, ACT 0200, Australia

The double insertion of diphenylprop-1-ynylphosphine into the nickel(0)–benzyne bond of the complexes [Ni(1,2-η-4,5-$X_2C_6H_2$)(PEt_3)$_2$] (X = H, F) forms 2,3-naphthylenebis(diphenylphosphines) regiospecifically.

Small cycloalkynes or arynes, which are short-lived in the free state, are stabilised by coordination to d^{10} transition metal fragments such as ML_2 (M = Ni, L_2 = dcpe,‡ $2PEt_3$; M = Pt, L_2 = dcpe, $2PPh_3$).[1] Unsymmetrical acetylenes (RC≡CR′) undergo double insertion into nickel(0)–benzyne complexes of type **1** to give a mixture of isomeric naphthalenes (**2a**, **2b**), whose ratio is determined by the stereoelectronic properties of the inserted alkyne (Scheme 1).[2,3]

Recently we have been interested in extending this chemistry to alkynylphosphines, which could provide a novel route to functionalised naphthylenebis(tertiary phosphines), potential ligands that are not readily accessible by conventional syntheses.[4] Herein, we report the regiospecific reaction of diphenylprop-1-ynylphosphine[5] with the Ni^0–aryne complexes [Ni(1,2-η-4,5-$X_2C_6H_2$)(PEt_3)$_2$] (X = H **1a**, F **1b**) (Scheme 2).

Reduction of the appropriate (2-bromoaryl)nickel(II) complexes [NiBr(2-Br-4,5-$X_2C_6H_2$)(PEt_3)$_2$] (X = H, F) with lithium in diethyl ether at −40 °C, followed by evaporation of ether and extraction with hexane at −60 °C, yielded yellow solutions of the complexes **1a** and **1b** that were used *in situ* for all subsequent insertion reactions.[2,3] The addition of 2.5 equiv. of diphenylprop-1-ynylphosphine at −78 °C, followed by warming to room temperature, resulted in a dark red solution containing a complex mixture as shown by $^{31}P\{^1H\}$ NMR spectroscopy. However, by addition of bromine, orange nickel(II) complexes of type **3** were isolated and fully characterised.§¶ The high overall yields of **3a** and **3b** (up to 97%), together with the molecular structure determination of the chelate, planar-coordinated dibromonickel(II) complex [$NiBr_2\{C_{12}H_8F_2(PPh_2)\}$] **3b** (Fig. 1), confirmed that the reaction produced regiospecifically 2,3-naphthylenebis(diphenylphosphines) as the only observable insertion products.‖

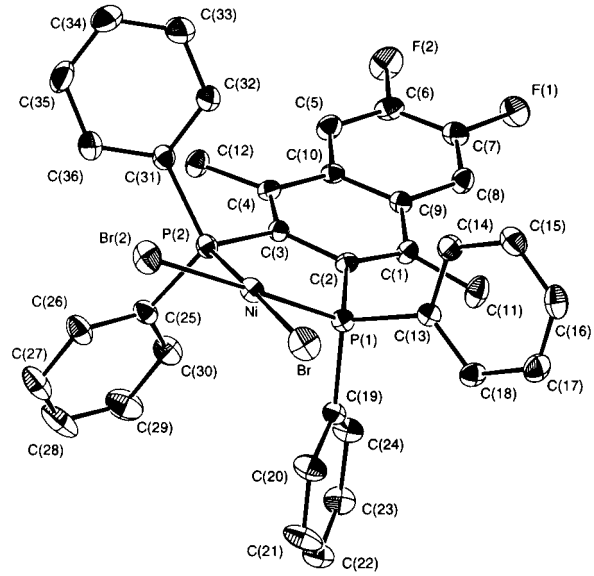

Fig. 1 ORTEP (25% probability) representation of **3b**. Hydrogen atoms have been omitted for clarity.

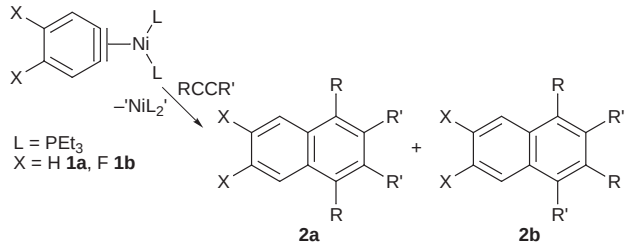
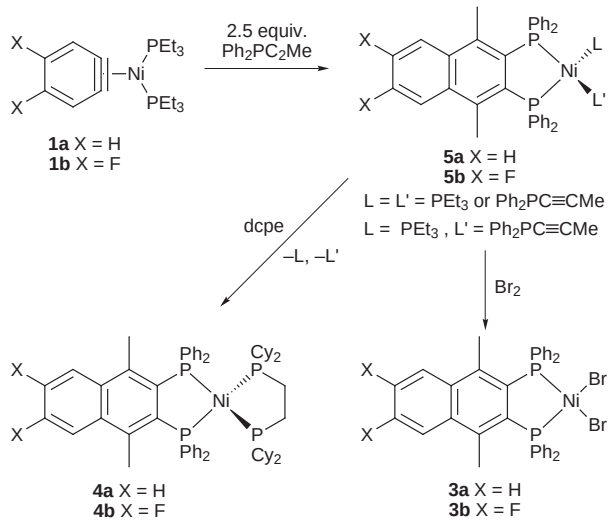


Scheme 1

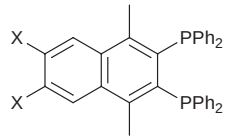


Scheme 2

Treatment of the initial dark red solutions with 1 equiv. of dcpe greatly simplified the $^{31}P\{^1H\}$NMR spectra, which showed in each case the presence of a single Ni^0 complex, [$Ni\{C_{12}H_8X_2(PPh_2)_2\}$dcpe)] (X = H **4a**, F **4b**), together with free PEt_3 and $Ph_2PC{\equiv}CMe$. On the basis of these results, the $^{31}P\{^1H\}$NMR spectrum (202.4 MHz) of the dark red solution could be assigned to a mixture of unsymmetrical nickel(0)–tertiary phosphine complexes of type **5**, all containing the newly formed naphthylenebis(diphenylphosphine) with a combination of PEt_3 or $Ph_2PC{\equiv}CMe$ as ancillary ligands (Scheme 2).

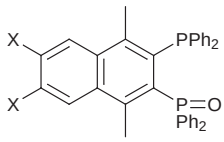
Reaction of **3a** or **3b** over 24 h at 50 °C with a large excess of NaCN in Me_2SO liberated quantitatively the pure 2,3-naphthylenebis(diphenylphosphines) **6a** and **6b** as white solids {overall yields based on [$Ni(cod)_2$] of up to 78%}.§¶

Exposure of **5a** or **5b** to air led to nickel–phosphine bond cleavage and only partial oxidation of the naphthylenebis(diphenyl)phosphines, forming the mono(phosphine oxides) $C_{12}H_8X_2(PPh_2)\{P(O)Ph_2\}$ **7a** and **7b**,[6] the structure of **7b** being

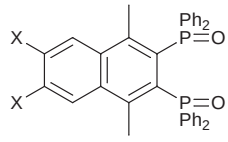


6a X = H
6b X = F

confirmed by X-ray diffraction.‖ The stronger oxidising agent, H_2O_2, was necessary to accomplish complete oxidation to the bis(phosphine oxides), $C_{12}H_8X_2\{P(O)Ph_2\}_2$ **8a** and **8b**.

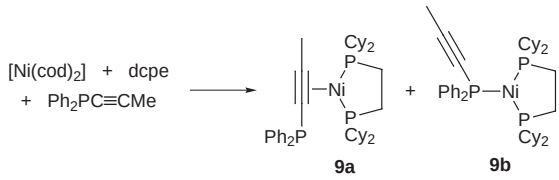


7a X = H
7b X = F



8a X = H
8b X = F

Theoretical calculations[7] suggest that the PPh_2 moiety, like CO_2Me, is electron withdrawing. The regiospecificities described above are indeed similar to those observed in the insertion of methyl 2-butynoate, $MeC{\equiv}CCO_2Me$, into complex **1b**, where the direction of insertion was believed to be electronically controlled and to require π-coordination of the alkyne.[1–3] In agreement, preferential side bonding of the C≡C bond of $Ph_2PC{\equiv}CMe$ to the Ni centre, as opposed to coordination *via* the phosphorus lone pair, has been observed. The reaction between equimolar quantities of $[Ni(cod)_2]$, dcpe and $Ph_2PC{\equiv}CMe$ gave the Ni^0–η^2-alkyne species, $[Ni(\eta^2\text{-}Ph_2PC{\equiv}CMe)(dcpe)]$ **9a**, as the main product; a small amount of the P-bonded isomer **9b**, was also formed (Scheme 3).



9a **9b**

Scheme 3

This chemistry is currently being investigated as a potential method for the synthesis of water-soluble diphosphines. We thank the Royal Society for the award of a Fellowship to C. J. C.

Remarkable effects of side-chain alkyl substituents on thermochromic behavior of peralkyldecasilanes

Kuninori Obata[a] and Mitsuo Kira*[a,b]†

[a] *Photodynamics Research Center, The Institute of Physical and Chemical Research (RIKEN), 19-1399, Koeji, Nagamachi, Aoba-ku, Sendai 980-0868, Japan*

[b] *Department of Chemistry, Graduate School of Science, Tohoku University, Aoba-ku, Sendai 980-8578, Japan*

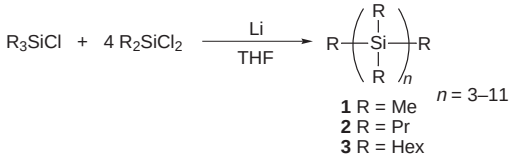
The absorption spectrum of perhexyldecasilane shows marked temperature dependence; a two-site model, similar to the transition from a random coil to an all pseudo-*trans* rod conformation proposed for poly(dihexylsilylene), is proposed to explain this effect.

Much attention has been focused on the remarkable thermochromism and unusual emission spectra of linear peralkylpolysilanes.[1] Typically, while poly(dihexylsilylene) exhibits a broad absorption band at *ca*. 315 nm at room temperature, upon cooling below *ca.* −30 °C, the absorption band becomes much narrower and shifts significantly to higher wavelength; the difference of λ_{max} between the low and high temperature regions ($\Delta\lambda_{max}$) amounts 39 nm.[2a] The origin of the thermochromism is usually ascribed to the transition at low temperatures from a random coil to an all pseudo-*trans* rod conformation of the silicon backbone,[2] while Miller *et al.* have proposed that the red shift at low temperatures is caused by aggregation of polysilane chains.[3] In order to elucidate the origin of the thermochromism of the polysilanes, it is desirable to investigate peralkyloligosilanes with uniform Si chain lengths. However, there has been no study of peralkyloligosilanes other than permethyloligosilanes[4] reported until now, while we have recently reported circular dichroism (CD) spectral features of oligo(dipropylsilylene)s with terminal chiral aralkyl groups.[5] We report here that the absorption spectra of peralkyloligosilanes with ten or more Si atoms in a chain are remarkably temperature dependent, a feature which depends strongly on the side-chain alkyl substituents.

Wurtz coupling of a mixture of a dialkyldichlorosilane and a trialkylchlorosilane with lithium in THF gave a mixture of the corresponding peralkyloligosilanes, as shown in Scheme 1. Oligosilanes having 3–11 Si chains were separated as pure compounds *via* recycle HPLC from a mixture of peralkyloligosilanes. The structures were characterized by means of NMR spectroscopy, elemental analyses and mass spectrometry.‡

The absorption band maxima at 293 K and their dependence on the Si chain lengths of perpropyl- **2** and perhexyloligosilanes **3** were similar to those of permethyloligosilanes,[6] while small alkyl substituent effects were observed. These absorption bands are assigned to the σ→σ* electronic transitions of the Si main chains.[4,6]

Peralkyloligosilanes having more than five Si atoms in a chain showed significant red-shifts of the maxima with lowering temperatures. The most remarkable thermochromism was observed in perhexyloligosilanes with 10 and 11 Si atoms in the chain. Fig. 1 shows the temperature dependence of absorption spectra of peralkyldecasilanes **1a** (**1**, n = 10), **2a** (**2**, n = 10) and **3a** (**3**, n = 10). With lowering temperatures, the absorption maxima of these decasilanes shifted to longer wavelength, but the extent of the red-shift ($\Delta\lambda_{max}$) from 293 to 77 K was markedly dependent on the substituents; $\Delta\lambda_{max}$ values were < 10, 13 and 19 nm for **1a**, **2a** and **3a**, respectively; upon increasing the chain-length of the alkyl substituents, the thermochromic behavior of the decasilanes resembles more closely that of poly(dihexylsilylene). The temperature dependence of the absorption spectrum of **3a** was analyzed using a two-site model similar to the transition from random coil to the all pseudo-*trans* rod conformation model for poly(dihexylsilylene) (Scheme 2). Thus, a linear relationship was observed between $\log(A_1/A_2)$ and $1/T$, where A_1 and A_2 are the areas of the



Scheme 1

Scheme 2

absorptions bands at 290 and 310 nm for **3a**, respectively; the absorption spectra of **3a** were deconvoluted to the two bands by band-shape analysis. From the slope of the linear relationship, the enthalpy difference between the two sites was estimated to be 9 kcal mol^{-1}.

The remarkable effect of the substituents on the temperature dependence of the absorption spectrum of decasilane is ascribed to the importance of the steric energies between the side-chain alkyl substituents. MM2 force field calculations using standard parameters for organosilicon compounds proposed by Allinger[7] showed that the most stable conformation of **1a**–**3a** was as loose helical rods having a dihedral angle of *ca.* 170° for seven Si tetrads, irrespective to the alkyl substituents; the all-*trans* rod structure (the dihedral angle = 180°) showed much higher steric energy due to the severe steric repulsion between alkyl groups in 1,3-positions. The energy differences between the loose helical rod conformation and the other conformations with one *gauche* arrangement in the 7 Si tetrads of a decasilane are 5.3 and 8.9 kcal mol^{-1} for **2a** and **3a**, respectively; this value is much smaller for **1a** (0.5 kcal mol^{-1}). A one-*gauche* conformation in **3a** or **2a** causes severe steric repulsion between alkyl substituents, while the repulsion is less important in **1a**. The steric energy calculated by the MM2 method is in good agreement with the experimental ΔH values for the transition from Site 1 to Site 2, suggesting that the transition occurs between an assembly of conformations with one or more *gauche* Si tetrads to an assembly of all pseudo-*trans* rod conformations including a loose helical conformation.

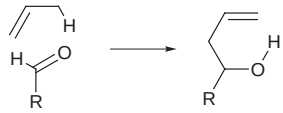
Homogeneous catalysis. Use of a ruthenium(II) complex for catalysing the ene reaction

William W. Ellis, W. Odenkirk and B. Bosnich*†

Department of Chemistry, The University of Chicago, 5735 S. Ellis Avenue, Chicago, IL 60637, USA

The complex *trans*-[Ru(salen)(NO)(H_2O)]$^+$ catalyses the ene reaction between activated enophiles and olefins to give homoallylic alcohols by a stepwise process.

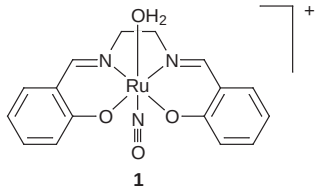
The oxo-ene reaction, which usually involves the addition of alkenes to aldehydes to produce homoallylic alcohols [eqn. (1)],



(1)

is potentially a useful method of carbon–carbon bond construction.[1] Its implementation, however, suffers from a number of difficiencies. Among these is the necessity of employing high temperatures for most reactions. The obvious method for promoting the reaction at lower temperatures by using conventional Lewis acids such as $AlCl_3$,[2] BF_3,[3] $SnCl_4$[4] or $TiCl_4$,[5] can lead to new problems.[1] Whereas these Lewis acids do indeed promote the reaction, they lead to the formation of Lewis acid alcohol intermediates which can release a proton. The released acid can itself act as a catalyst (Prins reaction) and can cause other reactions to occur with the substrates and product. Snider[1,6] has shown that the use of Me_2AlCl can promote the ene reaction without proton interference because the methyl groups are capable of rapidly scavenging the proton to give methane. The resultant formation of alkoxide adducts, however, consumes the Lewis acid promoter and, consequently, the Lewis acid is used in stoichiometric or greater quantities. In addition, alkylaluminium halides have been shown to transfer the alkyl group to the aldehyde[7] and to undergo the Oppenauer oxidation.[8] Milder Lewis acids such as those derived from Zn^{II}[9] and Ti^{IV}[10] have been shown to act as true catalysts for a limited number of intramolecular and intermolecular ene reactions, respectively.

Here we report the use of a new type of Lewis acid catalyst for the ene reaction. It is the d^6 ruthenium(II) complex, *trans*-[Ru(salen)(NO)(H_2O)] SbF_6 **1**, which we have employed for

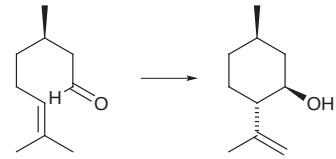


1

catalysing the Diels–Alder[11] and Mukaiyama reactions.[12] The air and moisture stable catalyst **1** is readily prepared in two steps from commercially available [Ru(NO)Cl_3] and the ligand.[11] Although Ru^{II} complexes are generally electron-rich and consequently do not act as Lewis acids, the incorporation of the electron-withdrawing NO^+ ligand, the coordination of hard ligands, namely N and O, and the presence of a positive charge all conspire to produce a Lewis acidic ruthenium centre. Further, because the water ligand *trans* to the NO^+ ligand is very labile,[11] this coordination site is readily available for binding the enophile (usually an aldehyde) to activate it for reaction and, after reaction, the homoallylic alcohol product is expected to be labile for efficient turnover.

Some of these results are collected in Table 1. As is commonly observed for Lewis acid promotion, only electron-difficient carbonyl-containing enophiles engage in the ene reaction at acceptable rates. Generally, ruthenium(II) aquo complexes are weak acids having a pK_a similar to AcOH acid (in water).[13] In order to determine the ability of acid to promote the reactions, 2 mol% TFA was used under the same conditions to promote the reaction shown in entry 1 (Table 1). It was found that < 1% conversion to the ene product occurred after 150 h, indicating that acid is neither responsible for, nor competitive with, the ruthenium catalysed process.

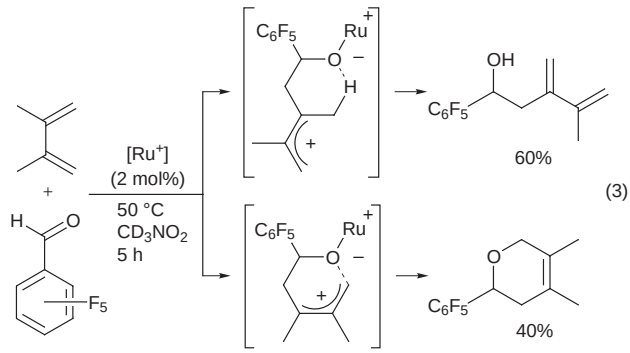
Although, like other promoters, the ruthenium catalyst has its limitations for the ene reaction, it serves to demonstrate that structurally defined transition metal complexes which are not normally oxophilic can be modified to act as genuine catalysts for the generally resistant ene reaction. It is probable, however, that the present catalyst will find practical applications in the intramolecular ene reaction. The conversion of (+)-citronellal to *l*-isopulegol [eqn. (2)] is an important step in the industrial



(2)

production of *l*-menthol[14] where $ZnBr_2$ in stoichiometric amounts at *ca.* 5 °C is used to give *l*-isopulegol in 95% yield over the other isomers. Using 1 mol% of the ruthenium catalyst in $MeNO_2$ at 25 °C, (+)-citronellal is converted to *l*-isopulegol after 6 h. An 80% yield of *l*-isopulegol was obtained, with the remaining product consisting of the other (three) isomers.[9,14,15] Given this efficient conversion, it is possible to entertain the prospect of using chiral analogues of the present catalyst for asymmetric catalytic intramolecular ene reactions.

In order to ascertain if the present catalysed ene reactions are concerted or stepwise processes we have investigated the products from a number of 1,3-dienes. A typical transformation is illustrated in eqn. (3), together with the putative inter-



(3)

mediates. The two products are formed in constant kinetic proportions and are not interconverted in the presence of the

catalyst. The formation of the two products [eqn. (3)] suggests that the ene reaction with the 1,3-diene may occur *via* a non-concerted process where the carbenium ion has sufficient lifetime to promote either the ene reaction or the hetero-Diels–Alder reaction. Although it is recognized that the allylic cation may have a greater stability than a localized carbenium ion formed by monoolefins, the formation of the two products when 1,3-dienes are used indicates that in the present systems the monoolefin ene reactions could proceed by carbenium ion intermediates.[16]

A modular approach to constructing multi-site receptors for isophthalic acid

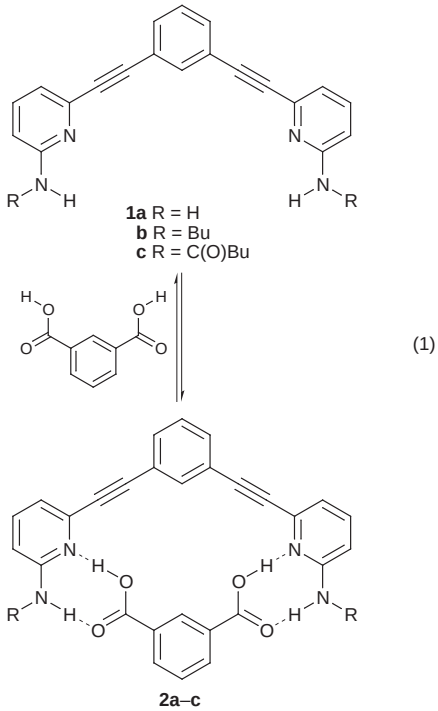
Christopher Bielawski, Yuan-Shek Chen, Peng Zhang, Peggy-Jean Prest and Jeffrey S. Moore*†

Departments of Chemistry, Materials Science & Engineering, and the the Beckman Institute for Advanced Science and Technology, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA

New multi-topic receptors which may serve as building blocks for constructing receptor arrays form highly stable complexes with isophthalic acid.

We are interested in developing simple, modular systems of receptor arrays and multi-topic ligands for the purpose of constructing stable, self-assembled nanostructures through multiple non-covalent interactions. This requires that the associating systems be easily synthesized, show strong supramolecular affinity, and be general for implementation in a variety of molecular designs. While molecular self-assembly is recognized as a method to prepare nanostructures,[1] there exists the need for simple building blocks that can be linked to form arrays of receptors and complementary ligands. Herein we report the design and synthesis of the primary receptor unit **1a**, its heterocomplexation with isophthalic acid, and demonstration of its use in modular construction of multi-site receptors.

The primary receptor unit was designed to be incorporated within oligo(phenyleneethynylene) backbones that have been extensively employed by our group to construct a variety of molecular architectures.[2] 2-Aminopyridines are well-known[3] to associate strongly with carboxylic acids, and a pair of these groups positioned on alternating sites of a 1,3-connected phenyleneethynylene backbone provides excellent shape complementarity to isophthalic acid, as shown in eqn. (1). Molecular



(1)

modeling‡ indicates that both **1a** and isophthalic acid can maintain favorable planar conformations with typical hydrogen bond distances, suggesting that tight binding should be realized. An important feature of this design is the torsional flexibility that exists between adjacent aromatic residues. The rotational barrier[4] about the sp–sp^2 bond is only *ca.* 600 cal mol^{-1}, which permits accessibility to favorable binding geometries. However, the most important aspect of **1a** is its ease of synthesis§ which was accomplished by coupling[5] 2 equiv. of the known[6] 2-amino-6-ethynylpyridine to 1,3-diiodobenzene in 78% yield.

Co-crystallization of **1a** and isophthalic acid from THF by slow evaporation resulted in single crystals suitable for X-ray structure determination.¶ The complex (Fig. 1) packs in 2D sheets with alternating hydrophobic and hydrophilic layers. All hydrogen bond donors and acceptors are fully saturated forming a set of six hydrogen bond interactions for each host and guest in the solid phase. The average dihedral angle between the heterocyclic residues and the phenyl ring is 12.5 ± 1.7°. Job's method[7] confirmed the stoichiometry of **1a** and isophthalic acid to be 1 : 1 in solution.

The binding characteristics of the receptor with 5-*tert*-butylisophthalic acid were determined in solvent systems with varying polarity at 20 °C using ^{1}H NMR titration and dilution methods.[8] As shown in Table 1, the association constant was found to be greater‖ than 10^6 M^{-1} in $CDCl_3$, reflecting a tight fit of the guest with the host. Due to increased solvation, the association constants in 1 : 9 and 1 : 4 [$^2H_6$]DMSO–$CDCl_3$ (v/v) solution were largely reduced to 320 and 80 M^{-1}, respectively.

While probing the potential of **1a** as a principle sub-unit in more complex systems, we anticipated encountering solubility problems. An obvious and synthetically simple solution was to transform the amine groups to more soluble derivatives. Therefore, a pair of analogues **1b** and **1c** were synthesized§ and studied. The association constants of receptors **1b** and **1c** with 5-*tert*-butylisophthalic acid were similar to that of receptor **1a**, all being greater‖ than 10^6 M^{-1} in $CDCl_3$. However, as shown in Table 1, the binding affinity in a 1 : 9 [$^2H_6$]DMSO–$CDCl_3$ (v/v)

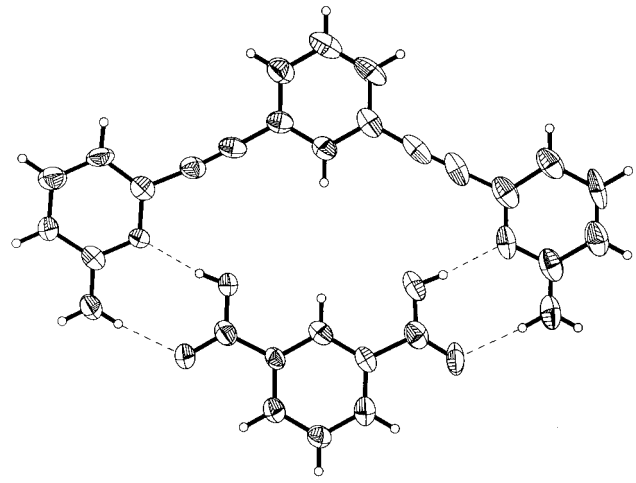


Fig. 1 ORTEP drawing at the 50% probability level of the complex formed between **1a** and isophthalic acid. Hydrogen bonding is indicated by thin dashed lines.

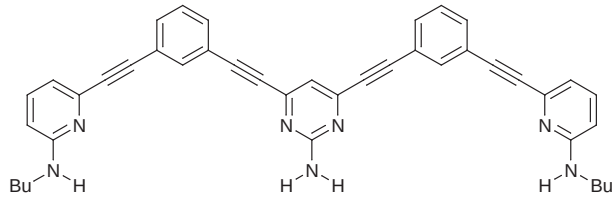
solution showed some noticeable differences. The association constants of **1b** and **1c** with 5-*tert*-butylisophthalic acid were 55 and 50 M^{-1} respectively. The reduction in affinity relative to receptor **1a** is believed to stem both from the increase in the extent of desolvation upon complexation and the greater entropic loss in rotational freedom about the aminopyridine bond. Our results showed that acylation or alkylation are synthetically simple ways to enhance the solubility of **1a** without significantly reducing the binding strength.



3

To demonstrate the modularity of this building block set, receptor **3**, which can potentially bind two units of isophthalic acid, was synthesized§ in a manner similar to that of **1a**. After several attempts at obtaining a crystal structure of receptor **3** and various derivatives of isophthalic acid, only crystals from a dioxane solution of 5-hydroxyisophthalic and **3** were suitable for X-ray diffraction. Although the quality of the crystal¶ was poor, the data set obtained was sufficient to confirm the dual binding of 5-hydroxyisophthalic acid (Fig. 2) and reveal the packing pattern as being similar to complex **2**. In solution, the stoichiometry of the complex was determined to be 2 : 1 by Job's method.[7]

Table 1 Association constants of receptors **1a**–**c** with 5-*tert*-butylisophthalic acid at 20 °C in a variety of solvent systems[a]

	Association constant/M^{-1}		
Receptor	in $CDCl_3$[b]	in 1 : 9 [$^2H_6$]DMSO–$CDCl_3$ (v/v)	in 1 : 4 [$^2H_6$]DMSO–$CDCl_3$ (v/v)
1a	$> 10^6$	320	80
1b	$> 10^6$	55	[c]
1c	$> 10^6$	50	[c]

[a] Association constants were determined by non-linear least-squares fitting of the experimental binding isotherm. The error is ±15%. [b] Estimated lower limit (see footnote ‖). [c] No observable binding affinity.

In conclusion, we have shown that receptor **1a** possesses a high affinity towards isophthalic acid and can easily be modified to alleviate solubility difficulties. The synthesis of **3** demonstrates that **1a** can be implemented as a building block for the construction of arrays of multi-site receptors for isophthalic acid. By combining multi-topic ligands and multi-site receptors, it should be possible to form stable, self-assembled nanostructures. In addition, we are also working on linear (AB) and 2D (AB_2) supramolecular polymers based on host : guest complex **2**. Details of these studies will be reported in due course.

Cationic ruthenium allenylidene complexes as a new class of performing catalysts for ring closing metathesis

A. Fürstner,*[a]† M. Picquet,[b] C. Bruneau,[b] and P. H. Dixneuf*[b]‡

[a] *Max-Planck-Institut für Kohlenforschung, D-45470 Mülheim/ Ruhr, Germany*
[b] *UMR 6509: CNRS - Université de Rennes, Laboratoire de Chimie de Coordination et Catalyse, Campus de Beaulieu, F-35042, Rennes, France*

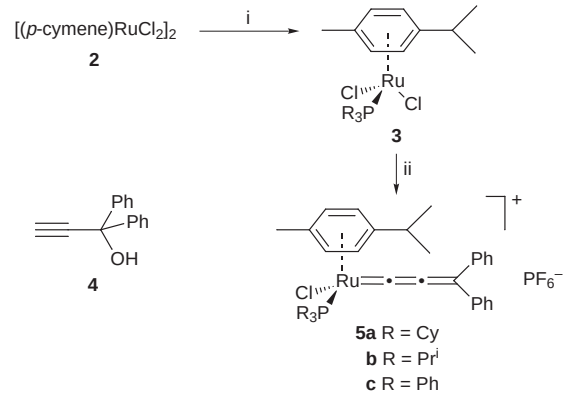
Cationic allenylidene ruthenium complexes [Ru=C=C=CR_2(L)(Cl)(arene)]PF_6 (L = PCy_3, PPr^i_3), easily prepared from $RuCl_2$(L)(*p*-cymene), prop-2-yn-1-ol and $NaPF_6$, are found to be excellent catalyst precursors for ring closing olefin metathesis.

The recent development of a new generation of well-defined catalysts precursors for olefin metathesis has had a tremendous impact on progress in this field.[1,2] Most popular among them are the *neutral 16-electron* ruthenium carbene complexes $Cl_2(PCy_3)_2$Ru=CHR (**1a**: R = Ph, **1b** R = −CH=CPh_2) described by Grubbs[3] which are distinguished by excellent activity as well as good compatibility with various functional groups in the substrates. Since these catalysts are fairly stable against oxygen and moisture, they represent a simple yet efficient tool for advanced organic synthesis and polymer chemistry. A major drawback, however, resides in the use of either diazoalkanes or diphenylcyclopropene for the preparation of these complexes, *i.e.* reagents which are hazardous or rather difficult to make, respectively. However, an improvement of the synthesis of complexes **1** synthesis has just been achieved starting from Ru(H)(H_2)Cl$(PCy_3)_2$.[4]

We now describe a new class of efficient single-component catalyst for ring closing olefin metathesis: the *cationic 18-electron* allenylidene ruthenium complexes [Ru=C=C=$CR_2(PR_3)$-(Cl)(arene)]PF_6 **5**, easily available in three steps from $RuCl_3.xH_2O$, which also provide an unprecedented example of the involvement of metal allenylidene complexes in catalysis.[5]

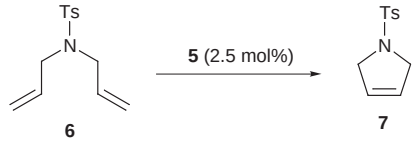
The 18-electron complexes of the general formula (η^6-arene)$RuCl_2(PR_3)$ such as **3**, which are readily obtained from commercially available [(η^6-arene)$RuCl_2]_2$ **2** upon addition of a phosphine,[6] are very active in catalytic transformations of alkynes,[7] but exhibit only very low catalytic activity for ring opening metathesis polymerization (ROMP) of strained cycloalkenes and ring closing metathesis (RCM). However, they can be activated either upon addition of diazoalkanes[8] or by *in situ* irradiation with UV light.[9] A route has been designed in order to straightforwardly introduce around a Ru(+2) site only *one* bulky phosphine, *one* cumulenylidene ligand attached to the metal *via* a Ru=C bond, and *one* easy to displace *p*-cymene group, three likely conditions to produce an active olefin metathesis catalyst precursor. As the activation of prop-2-yn-1-ols with selected ruthenium precursors has been shown to give the Ru=C=C=CR_2 moiety,[10] complexes **3** were reacted with a prop-2-ynyl alcohol such as **4** in the presence of $NaPF_6$ in MeOH at ambient temperature and cleanly led to the formation of the cationic allenylidene complexes **5a-c**, isolated in high yields as violet powders (Scheme 1). It is noteworthy that the corresponding salts with less bulky R_3P groups existed only as transient allenylidene intermediates *in situ* adding methanol to give methoxycarbene [Ru=C(OMe)CH=CR_2] complexes[11] which are inactive as olefin metathesis catalysts.

A preliminary assessment of the performance of these complexes in ring closing metathesis revealed a strong correlation with the nature of the chosen phosphine. In line with



Scheme 1

Table 1 Screening of the catalytic activity of the allenylidene complexes **5**[a]



6 **7**

Entry	Catalyst	Solvent	Additive	*T*/°C	*t*/h	Yield (%)[b]
1	**5c**	toluene	—	80	3	2
2	**5b**	toluene	—	80	3	66
3	**5b**	CH_2Cl_2	—	40	26	95 (76)
4	**5a**	toluene	—	80	3	79
5	**5a**	toluene	—	80	4	100 (83)
6	**5a**	toluene	PCy_3 (5%)[c]	80	3	31

[a] General conditions: diene (1 mmol), catalyst (0.025 mmol), solvent (5 ml). [b] GC yield (isolated yield). [c] Based on the diene.

Table 2 Ring closing metathesis employing Ru-allenylidene catalyst **5a**[a]

Substrate	Product	Yield (%)
 **8**	 **9**	75
 **10**	 **11**	40
 **12**	 **13**	90
 **14**	 **15**	73
 **16**	 **17**	85

[a] All reactions using **5a** were carried out in toluene at 80 °C using a catalyst loading of 5 mol%.

previous observations with ruthenium-based initiators,[3,8,9] their catalytic activity decreases in the order PCy_3 > PPr^i_3 ≫ PPh_3 (Table 1). With **5a** (2.5 mol%) as the catalyst, diene **6** is quantitatively cyclized to dihydropyrrole **7** after 4 h in toluene at 80 °C (entry 5). Dichloromethane can also be used, although the turnover frequency of **5** is slightly lower in this particular reaction medium at 40 °C (*cf.* entries 2 and 3).

Having established the optimum reaction conditions, we applied catalyst **5a** to RCM of a set of representative diene substrates. As can be seen from the results compiled in Table 2, this catalyst nicely applies to the formation of essentially all ring sizes ≥ 5, including macrocyclic and medium sized products. The isolated yields obtained were found to be good to excellent and are comparable to those previously obtained using the Grubbs carbenes **1** [**9**: 75% *vs.* (68%);[12] **13**: 90% *vs.* (79%);[2c] **15**: 73% *vs.* 83%;[2a] **17**: 85% *vs.* 77%[2d]]. Only in the case of the 10-membered ring of jasmine ketolactone **11**, did the allenylidene complex **5a** turn out to be somewhat less efficient [**11**: 40% *vs.* (86%)[13]].

Particularly noteworthy are the smooth cyclizations of the conformationally flexible dienes **12** and **14** to 16- and 18-membered cycloalkenes **13** and **15**, respectively. The hydrogenation of compound **13** under standard conditions leads to the macrocyclic musk exaltolide,[14] which is used as a valuable perfume ingredient. Disaccharide **17** is an advanced intermediate *en route* to tricolorin A, a carcinostatic resin glycoside isolated from *Ipomoea tricolor*.[2d] The examples summarized in Table 2 clearly highlight the excellent compatibility of the allenylidene catalyst **5a** with various functional groups, including even unprotected secondary hydroxy groups.

Although the mode of action of these new metathesis catalysts and the nature of the actual intermediates involved in the catalytic cycle require further indepth studies, we have shown that the addition of an excess of PCy_3 strongly retards the metathetic conversion.

Current work in our laboratories is aiming at investigating the mechanism as well as to further explore the preparative scope of these readily accessible and highly promising metathesis catalysts, since they allow substantial possible variations of their basic structural motive.

The authors are grateful to Deutscher Akademischer Austauschdienst (DAAD) for a stipend to M. P., covering his stay in Mülheim for a three month period. We also thank K. Langemann and T. Müller, Mülheim, for providing various starting materials.

Palladium-catalyzed cross-coupling of organolead compounds with organostannanes

Suk-Ku Kang,*† Hyung-Chul Ryu and Sang-Chul Choi

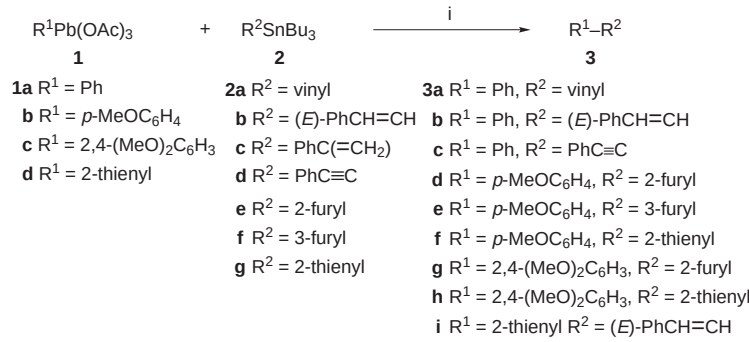
Department of Chemistry, Sung Kyun Kwan University, Natural Science Campus, Suwon 400-746, Korea

The palladium-catalyzed cross-coupling of organolead triacetates with organostannanes has been accomplished in the presence of $Pd_2(dba)_3{\cdot}CHCl_3$ (5 mol%) and NaOMe (5 equiv.) in MeOH–MeCN (1 : 1) under mild conditions.

The palladium-catalyzed cross-coupling of organostannanes with aryl of vinyl halides and triflates, known as the Stille reaction,[1] has become a versatile tool in organic synthesis. Main group metals such as lead(IV),[2] bismuth[3] and thallium[4] have been of limited use in cross-coupling reactions. Recently, Pinhey[2] reported the arylation, alkenylation and alkynylation of organolead(IV) tricarboxylates with soft carbon nucleophiles. As an alternative to organic electrophiles, hypervalent iodonium compounds were employed in the cross-coupling with organostannanes.[5] However, the coupling reaction of organolead compounds as electrophiles with organostannanes is not known. Here we report the cross-coupling of organostannanes with organolead(IV) compounds.

Initially, we examined the cross-coupling of phenyllead triacetate **1a**[6] with vinyl tributylstannane **2a** to determine the optimum reaction conditions. After series of fruitless experiments, we found that the use of NaOMe as a base was crucial in this coupling. Of the catalysts $Pd_2(dba)_3{\cdot}CHCl_3$, $Pd(OAc)_2$ and $PdCl_2$ tested, $Pd_2(dba)_3{\cdot}CHCl_3$ was the best. Even though $CHCl_3$ was also effective, the solvent system MeOH–MeCN (1 : 1) was most suitable. To avoid homocoupling, CuI (10 mol%) was added as a cocatalyst (Scheme 1).[7]

Phenyllead triacetate **1a** was reacted with vinyl tributylstannane **2a** in the presence of NaOMe (5 equiv.) using $Pd_2(dba)_3{\cdot}CHCl_3$ (5 mol%) and CuI (10 mol%) as catalysts in MeOH–MeCN (1 : 1) at room temperature for 2 h to afford styrene **3a** as the sole product in 80% yield (entry 1, Table 1). Under the same conditions the reaction of **1a** with the β-styrylstannane **2b** gave the coupled product (*E*)-β-stilbene **3b** in 72% yield (entry 2). When phenyllead triacetate **1a** was treated with α-styrylstannane **2c**, (*E*)-β-stilbene **3b** was also obtained as the sole product *via* the mechanism of *cine* substitution[8] in 40% yield (entry 3). For the alkynylstannane **2d**, the reaction with **1a** gave the coupled product **3c** in 79% yield (entry 4). When the same reaction was conducted in $CHCl_3$ as the only solvent, the coupled product **3c** was obtained in 45% yield along with the homocoupled product (30%).[9] Treatment of 2-furyl(tributyl)stannane **2e**, 3-furyl(tributyl)stannane **2f**, and 3-thienyl-substituted stannane **2g** with *p*-methoxyphenyllead triacetate **1b**[10] afforded the substituted furans **3d**,[11] **3e**[12] and thiophene **3f**[13] in 73, 70 and 85% yields, respectively (entries 5–7).‡ For the coupling of **1b** with 2-furyl stannane **2e** under the same conditions without addition of CuI as catalyst, the coupled product **3e** was obtained in 60% yield after 7 h along with the homocoupled product (25%). However, the addition of CuI (10



Scheme 1 *Reagents and conditions*: i, $Pd(dba)_3{\cdot}CHCl_3$ (5 mol%), CuI (10 mol%), NaOMe (5 equiv.), MeOH–MeCN (1 : 1)

Table 1 Palladium-catalyzed cross-coupling of organostannanes with organolead triacetates

Entry	Organolead compounds	Organostannanes	*T*/°C	*t*/h	Product	Isolated yield (%)[a]
1	**1a**	**2a**	room temp.	2	**3a**	80 (trace)
2	**1a**	**2b**	room temp.	2	**3b**	72 (trace)
3	**1a**	**2c**	60	3	**3b**	40
4	**1a**	**2d**	room temp.	2	**3c**	79 (10)
5	**1b**	**2e**	room temp.	2	**3d**	73 (10)
6	**1b**	**2f**	60	2	**3e**	70 (trace)
7	**1b**	**2g**	60	2	**3f**	85 (10)
8	**1c**	**2e**	room temp.	3	**3g**	72 (trace)
9	**1c**	**2g**	room temp.	3	**3h**	73 (trace)
10	**1d**	**2b**	60	2	**3i**	62 (10)

[a] The yields in parentheses are the yields of the homocoupling products, which are easily separated by column chromatography.

mol%) improved the yield to 73% yield with reduced reaction time (2 h) and reduced homocoupling (10%). The 2,4-dimethoxyphenyllead triacetate **1c**[14] was also coupled with 2-furyl and 2-thienyl substituted stannanes **2e** and **2g** at room temperature for 3 h to afford the coupled products **3g**§ and **3h**[15] in 72 and 73% yields, respectively (entries 8 and 9). Finally, 2-thienyllead triacetate **1d**[16] was reacted with (*E*)-β-styrylstannane **2b** to give the coupled product **3i**[17] in 62% yield (entry 10). The results are summarized in Scheme 1 and Table 1.

Although the detailed mechanism for the role of NaOMe remains to be elucidated, it is presumed that organolead trimethoxide $RPb(OMe)_3$ is formed[18] and drives facile oxidative addition[19] with Pd^0 to give polar reactive intermediate $RPdPb(OMe)_3$, which allows the transmetallation and coupling to proceed under mild conditions

A typical procedure is as follows: To a stirred solution of *p*-methoxylphenyllead triacetate **1b** (140 mg, 0.28 mmol) and NaOMe (77 mg, 1.42 mmol) in MeOH–MeCN (1 : 1, 3 ml) was added $Pd_2(dba)_3{\cdot}CHCl_3$ (14 mg, 5 mol%) and CuI (5 mg, 10 mol%), followed by 2-thienyl(tributyl)stannane **2g** (100 mg, 0.27 mmol) *via* syringe at room temperature under N_2, and the reaction mixture was stirred at 60 °C for 2 h and cooled to room temperature. The reaction mixture was extracted with Et_2O (20 ml), washed three times with water, dried over anhydrous $MgSO_4$ and evaporated *in vacuo*. The crude product was separated by SiO_2 column chromatography (hexanes, R_f = 0.28) to afford the coupled product **3f** (44 mg, 85%).

In conclusion, the palladium-catalyzed cross-coupling reaction of organolead triacetates with organostannanes was achieved under mild conditions.

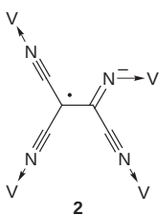
Several classes of organic magnets based upon the tetracyanoethenide radical anion, [TCNE]$^{\cdot-}$, either unbound, μ, and μ_4 bonded to zero, two and four metal sites have been reported. The putative μ_4 bonded V(TCNE)$_x$ room temperature magnet has been extended to include M(TCNE)$_x$ (M = Mn, Fe, Co, Ni) magnets. M for this class of magnets is assigned to be in the divalent oxidation state. A σ-[TCNE]$_2^{2-}$ dimer intermediate has been isolated. The intrachain magnetic coupling for the 1-D coordination polymers having [TCNE]$^{\cdot-}$ μ-bridge bonded to [Mn^{III}porphyrins]$^+$ is discussed in the context of a structure–function correlation arising from the dihedral angle between the [Mn^{III}TPP]$^+$'s MnN$_4$ and [TCNE]$^{\cdot-}$ mean planes and the magnitude of magnetic coupling. This correlation is ascribed to the increasing importance of the σ-Mn^{III} d_{z^2}/[TCNE]$^{\cdot-}$ p_z overlap with decreasing dihedral angle.

From time immemorial magnets comprised a few metals or their oxides with the key component of all magnets, the unpaired electron spins, solely residing in d- or f-orbitals. Extension to organic radicals was first discussed in 1963 from a conceptional point of view,[1] but their experimental realization was not achieved until 1985. At that time [Fe(C$_5$Me$_5$)$_2$]$^{\cdot+}$[TCNE]$^{\cdot-}$ (TCNE = tetracyanoethylene) with a magnetic ordering temperature, T_c, of 4.8 K was reported to be the first magnet with spin residing in a p-orbital[2] that (i) required spins in p-orbitals, (ii) exhibited magnetic hysteresis, (iii) did not have extended network bonding in 1, 2 or 3 dimensions, (iv) was soluble in conventional organic solvents, and (v) did not require metallurgical preparative methods. Today, molecule-based magnets include many diverse examples of materials exhibiting magnetic ordering including ferromagnets, ferrimagnets, canted/weak ferromagnets, metamagnets and spin glasses. Materials range from p-orbital-based organic nitroxides,[3,4] p/d-orbital-based mixed organic radicals/organometallic or inorganic coordination systems,[4–6] to the more classical d-orbital-based inorganic coordination compounds (*e.g.* mixed metal oxalates and cyanides),[4,5] with several classes of the organic/metal-ion-containing-ones possessing TCNE studied in our laboratory. As is the intent of feature articles in this journal, we provide a personal account of the results on two classes of TCNE-based magnets, namely, M[TCNE]$_x$ and [Mn(porphyrin)][TCNE] magnets. Broad reviews on molecule-based magnets, however, are available.[3–6]

M(TCNE)$_x$ Magnets

In 1991 V(TCNE)$_x$·y(CH$_2$Cl$_2$) ($x \sim 2$; $y \sim 1/2$) **1a**, prepared from the room temperature reaction of V^0(C$_6$H$_6$)$_2$ and TCNE, was reported to be a magnet below a critical temperature estimated to be ~400 K.[4,7] Owing to the structural disorder, variable composition and extreme oxygen/water sensitivity the structure and oxidation state assignment of this valence-ambiguous material has yet to be elucidated. Although the structure is as yet unknown, based upon the magnetic, IR, and elemental analyses data, **1a** is formulated as V^{II}(TCNE)$_2$·1/2(CH$_2$Cl$_2$) with S = 3/2 V^{II} and two S = 1/2 [TCNE]$^{\cdot-}$ systems. A 3-D network structure **2**, with each vanadium



2

surrounded by up to six ligands which are primarily nitrogens from different [TCNE]$^{\cdot-}$ species, and the [TCNE]$^{\cdot-}$ species binding up to four different vanadiums *via* σ-N bonds, is proposed.

Compound **1a** exhibits a field-dependent magnetization, $M(H)$, between 1.4 and 350 K (Fig. 1), and saturates to *ca.* 6 × 10^3 emu Oe mol^{-1} at 2 K and 19.5 kG. Assuming a Landé g value of 2, the expected maximum or saturation magnetization, M_s, for ferromagnetic coupling between S = 3/2 V^{II} and the two S = 1/2 [TCNE]$^{\cdot-}$ species (*ie.* S_{total} = 5/2) is 28 × 10^3 emu Oe mol^{-1}. In contrast, antiferromagnetic coupling, leading to ferrimagnetic behavior as observed for magnetite (Fe$_3$O$_4$), leads to an S_{total} of 1/2 with M_s expected to be 5.6 × 10^3 emu Oe mol^{-1}. The latter is in good agreement with the observed value. Hysteresis, characteristic of magnets' composition and shape, with a coercive field of 60 G is observed at room temperature (Fig. 2). The strong magnetic behavior is readily observed by its being attracted to a permanent magnet at room temperature (Fig. 3). Thus, **1a** is the first example of organic-based material with a critical temperature exceeding room temperature. The critical temperature exceeds 350 K, the thermal decomposition temperature of the sample, and a linear extrapolation to the

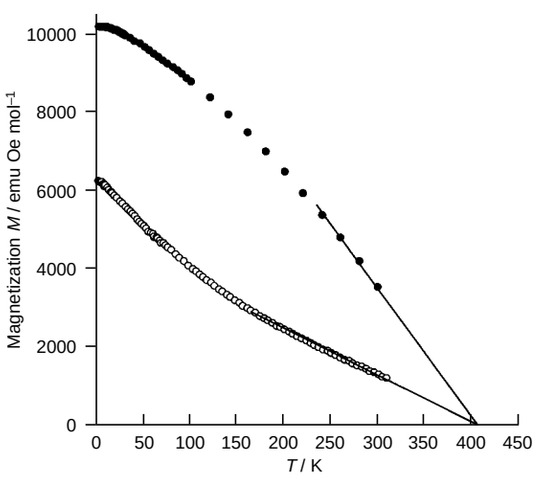


Fig. 1 Magnetization as a function of temperature [$M(T)$] at 1 kG for V(TCNE)$_x$·y(CH$_2$Cl$_2$) prepared from (○) V(C$_6$H$_6$)$_2$ **1a**[7] and (●) V(CO)$_6$ **1b**[8]

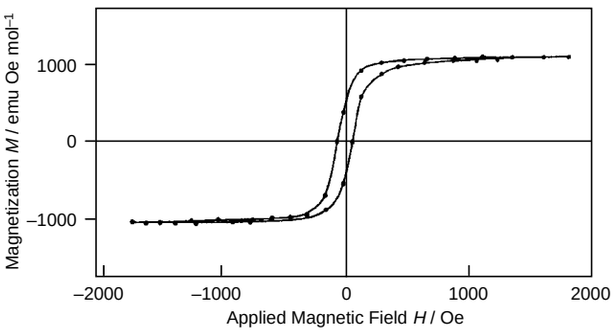

Fig. 2 Hysteresis $M(H)$, of $V(TCNE)_x{\cdot}y(CH_2Cl_2)$ **1a**, at room temperature

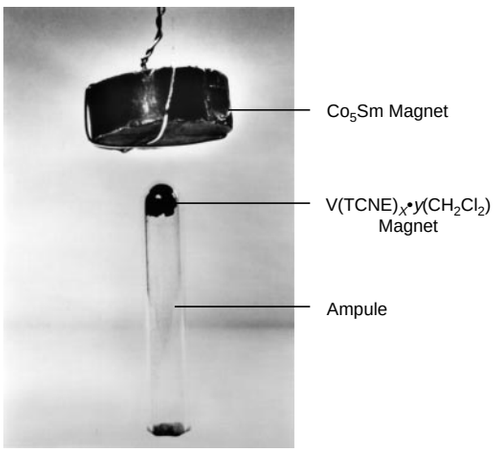

Fig. 3 Photograph of a powdered sample of **1a** being attracted to a Co_5Sm magnet at room temperature

temperature at which the magnetization should vanish leads to an estimate of $T_c \sim 400$ K (Fig. 1). Compound **1a** is also a semiconductor with a room temperature conductivity of $\sim 10^{-3}$ S cm^{-1} which decreases with decreasing temperature. At low temperatures the conductivity becomes frequency dependent, suggesting a hopping conduction mechanism.[7d]

Thermal treatment of **1a** reduces the magnetization. At room temperature **1a** has a *ca.* 50 day half-life. Sealed samples heated for 10 h at 100 °C are significantly less magnetic, while heating to 160 °C for 48 h destroys magnetic ordering; however, the number of spins remains essentially unchanged. Concomitantly, the infrared spectra in the ν_{CN} region are altered slightly with the absorption at 2195 cm^{-1} moving to higher energy at 2206 cm^{-1}. Air exposure further alters the infrared spectra, with the major absorption in the $\nu_{C\equiv N}$ region shifting to 2220 cm^{-1}. Likewise, **1a** rapidly decomposes in air and looses magnetic ordering. Infrared analysis of the decomposed product has much weaker absorptions at 2225 cm^{-1} which is in the region reported for TCNE[0 9] as well as TCNE π-bonds to metals atoms or ions.[10]

The reaction of $V(C_6H_6)_2$ and other strong acceptors such as TCNQ, perfluoro-TCNQ ($TCNQF_4$), $C_4(CN)_6$, 2,3,5,6-tetrachlorobenzoquinone (chloranil), 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) and 2,3,5,6-tetracyanobenzoquinone (cyanil)[11] led to insoluble precipitates of unknown composition. These materials do not exhibit field-dependent magnetic susceptibilities and their high temperature susceptibilities can be fitted to the Curie–Weiss expression with $\theta < 0$ characteristic of antiferromagnetic, not ferromagnetic, behavior. Hence, magnets of nominal $V(acceptor)_x{\cdot}y(solvent)$ composition based on strong acceptors other than TCNE have yet to be prepared.

Compound **1a** is a structurally disordered material; hence, improved preparative routes leading to less disorder as well as avoiding the difficult-to-obtain $V(C_6H_6)_2$ were sought. Unlike $V^0(C_6H_6)_2$, the reaction of isoelectronic $V^0(C_5H_5)(C_7H_7)$ with TCNE did not afford a room-temperature magnet.[8] This is due to the greater oxidation potential of $V^0(C_5H_5)(C_7H_7)$ (0.34 V *vs.* SCE) with respect to $V^0(C_6H_6)_2$ (−0.28 V). Similarly, the reactions of $[TCNE]^{\cdot-}$ and $[V^I(C_6H_6)_2]^+$ or TCNE and $V^{II}(C_5H_5)_2$ did not afford a room-temperature magnet. Since the reaction of $V^0(C_6H_6)_2$ and TCNE leads to a strongly magnetic material, but the reaction of $[V^I(C_6H_6)_2]^+$ and $[TCNE]^{\cdot-}$ does not, the mechanism of the reaction is crucial in the formation of the room-temperature magnet and it is presently being investigated. In contrast, the room-temperature reactions of $V^0(CO)_6$, $[V^I(C_6H_6)_2][V^{-I}(CO)_6]$, $[V^{II}(NCMe)_6][V^{-I}(CO)_6]_2$, $[V^{II}(NCMe)_6]^{2+}$ and $[V^{II}(THF)_6][V^{-I}(CO)_6]_2$ with TCNE led to room-temperature magnets; while the reactions of $[Et_4N][V^{-I}(CO)_6]$ and $Na[V^{-I}(CO)_6]{\cdot}2$diglyme did not.[8] The reaction of $V^0(CO)_6$ with TCNE was studied in detail.[8]

The elemental composition suggests that the magnets prepared from $V(C_6H_6)_2$ or $V(CO)_6$ have similar compositions. The similarity of the IR spectra for the magnets prepared from $V(C_6H_6)_2$ (*i.e.* **1a**) and $V(CO)_6$ (*i.e.* **1b**) and the absence of $\nu_{C\equiv O}$ stretches in the 1800 to 2000 cm^{-1} region for the latter magnet strongly suggest that all the carbonyls are expelled from the vanadium coordination sphere upon the reaction of $V(CO)_6$ with TCNE.[8] This was confirmed from the quantification of CO-loss *via* Toepler pump measurements for [eqn. (1)],

$$V(CO)_6 + y\ TCNE \rightarrow V(TCNE)_y(CO)_{6-x}\ (\mathbf{1b}) + x\ CO \quad (1)$$

with $x = 5.9 \pm 0.1$. Thus, all the six carbonyls are lost. Based on the lack of CO and the similarity between the IR spectra for the magnets prepared from $V(CO)_6$ (**1b**) and $V(C_6H_6)_2$ (**1a**), both are assigned the same structural building block **2**. Nonetheless, differences between the ν_{CN} absorptions for **1a** and **1b** indicate that the two magnets are structurally inequivalent and different magnetic behavior is observed, although both have a T_c 400 K (Fig. 1).

The M for **1b** (Fig. 1), is 10 300 emu Oe mol^{-1} at 4.2 K and 3600 emu Oe mol^{-1} at room temperature and an applied magnetic field of 1 kG; an increase of 67 and 133% at these temperatures, respectively, as compared to **1a**. Whereas M decreases monotonically with increasing T for **1a**, this is less evident at low temperatures for **1b**. The unusual linear decrease of M with increasing T is consistent with extensive disorder in the sample, and suggests that the **1b** is less disordered. Hysteresis with a coercive field of 15 Oe is observed at room temperature and at 4.2 K for the **1b**. This is significantly lower than the 60 Oe value observed for **1a** (Fig. 2).[7] The extrapolated T_c for **1b** is ~400 K, comparable to **1a** (Fig. 1).[7] The results of the magnetic behavior for **1** give hope that more molecular/organic/polymeric magnets with higher T_cs will be available in the future. Already a room temperature a Prussian blue-structured magnet, also based on vanadium, has been reported.[12]

In addition to forming **1** *via* the solution reaction of TCNE and $V(C_6H_6)_2$ or $V(CO)_6$, these reactions were also carried out without solvent. No reaction occurred upon the reaction of TCNE and $V(C_6H_6)_2$, while an immediate blue precipitate occurred with TCNE and $V(CO)_6$ at the surface of the TCNE crystals or on the walls of the reaction vessel if both TCNE to $V(CO)_6$ were co-sublimed. For the latter product, the IR spectrum and magnetic properties were very similar to materials prepared from solution. However, this material has reduced oxygen sensitivity. This difference is attributed to its much lower surface area when compared to the fine (~100 m^2 g^{-1}) powders that are formed from solution.[13]

Due to T_c exceeding room temperature, applications for this magnet can be envisioned.[14] One application is for magnetic shielding, the attenuation of magnetic fields found in many electronic applications, *e.g.* high voltage lines. The feasibility of using **1** for this applications has been demonstrated (Fig. 4).[15]

Synthesis of the $V(TCNE)_x{\cdot}y$(solvent) magnet using solvents other than CH_2Cl_2 results in similar materials with varying

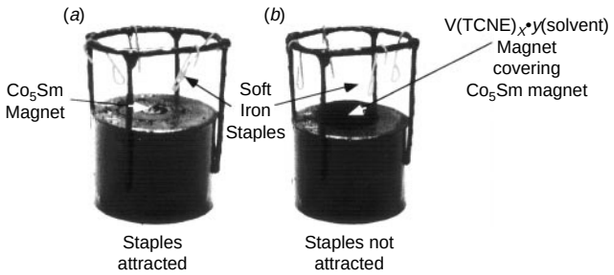

Fig. 4 Illustration of the $V(TCNE)_x{\cdot}y(CH_2Cl_2)$ magnet being an effective magnetic shield at room temperature; rods (paper clips) of soft-iron are attracted to a Co_5Sm permanent magnet (*a*); however, when a 1.7 mm pellet of $V(TCNE)_x{\cdot}y(CH_2Cl_2)$ is placed between the Co_5Sm magnet and the rods they hang freely (*b*) demonstrating magnetic shielding

degrees of structural order. For example, there is increasing disorder in the structure as the CH_2Cl_2 is replaced by THF[7b] (T_c ~ 210 K) and MeCN[7c] (T_c ~ 100 K). The exact magnetic ordering temperature varies with preparation conditions and resulting structural order. With increasing order these materials show features of correlated spin glass behavior. Additional examples of this class of magnets are needed to understand the chemistry and physics.[7,8] To date the reaction of $V(C_6H_6)_2$ or $V(CO)_6$ with other strong acceptors does not form magnetically ordered materials. Attempts to replace V with Cr, *i.e.* the reaction of TCNE with $Cr(C_6H_6)_2$ or $Cr(CO)_6$, lead to nonmagnetically ordered, but ferromagnetically coupled, $[Cr(C_6H_6)_2][TCNE]$[16] and a substitution reaction with $Cr(CO)_6$ forming $Cr(CO)_5(TCNE)$.[17] However, magnets of $M(TCNE)_2{\cdot}y$(solvent) stoichiometry have recently been reported.

$M(TCNE)_2{\cdot}y(CH_2Cl_2)$ (M = Mn, Fe, Co, Ni) have been prepared *via* the reaction of $MI_2{\cdot}x$MeCN in CH_2Cl_2.[18] The ν_{CN} absorption bands for $M(TCNE)_2{\cdot}xCH_2Cl_2$ are consistent with coordinated $[TCNE]^{\cdot-}$ and are similar, albeit sharper and occur at higher in energy, to that observed for $V(TCNE)_x{\cdot}y(CH_2Cl_2)$. In contrast to disordered $V(TCNE)_x{\cdot}y(CH_2Cl_2)$, $M(TCNE)_2{\cdot}xCH_2Cl_2$ (M = Mn, Fe) give X-ray powder patterns, which have yet to be indexed.

The spin and oxidation states of $Fe(TCNE)_2{\cdot}xCH_2Cl_2$ **3** were determined from ^{57}Fe Mössbauer spectroscopy.[18] Above 95 K, **3** has absorptions with large chemical shift [δ = 1.23 mm s^{-1}] and quadrupole coupling [ΔE_q = 3.26 mm s^{-1}] characteristic of hexacoordinate, high-spin Fe^{II} compounds[19] (Fig. 5). Below 95 K, the spectra become more complex due to magnetic

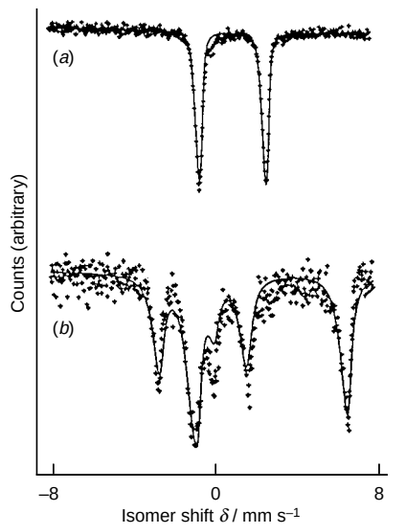

Fig. 5 ^{57}Fe Mössbauer spectra of $Fe(TCNE)_2{\cdot}xCH_2Cl_2$ at (*a*) 50 and (*b*) 100 K[18]

splitting [δ = 1.24 mm s^{-1}; ΔE_q = 3.31 mm s^{-1}, H_{int} = 229 KOe] (Fig. 5) in agreement with the critical temperature determined *via* magnetic studies (*vide infra*).

Complex **3** has a complex magnetic behavior which is essentially independent of preparation and amount of solvent.[18] The susceptibility cannot be fitted to the Curie–Weiss law, $\chi \propto (T - \theta)^{-1}$, as expected for high-spin d^6 Fe^{II} in an octahedral environment with spin-orbit coupling. A spontaneous magnetization occurs below a T_c of 121 K, taken here as the intercept with the temperature axis of the initial slope of the magnetization as a function of temperature (Fig. 6). At 2 K the

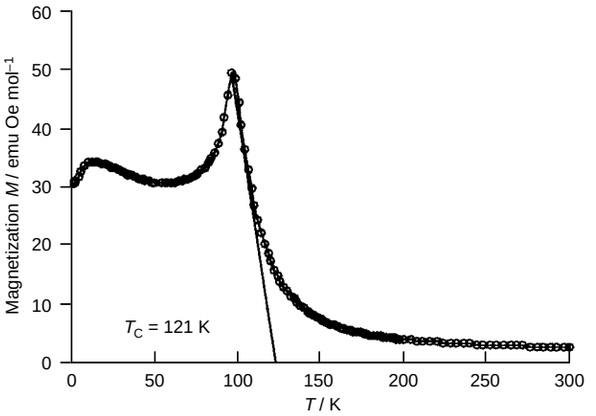

Fig. 6 Zero-field cooled magnetization as function of temperature for $Fe(TCNE)_2{\cdot}0.75CH_2Cl_2$

magnetization shows a complex, poorly understood response to the field, reminiscent of metamagnetic behavior. At 5 T and 2 K the observed magnetization is *ca.* 16 900 emu Oe mol^{-1}; however, higher fields are necessary to achieve saturation. This value of saturation magnetization corresponds to three S = 1/2 spins and exceeds the comparable value of 10 300 emu Oe mol^{-1} for $V(TCNE)_x{\cdot}y(CH_2Cl_2)$ prepared from $V(CO)_6$[8] by 63%, as well as exceeding the expectation of that from antiferromagnetically coupling between an S = 2 Fe^{II} site and two S = 1/2 $[TCNE]^{\cdot-}$, *i.e.* 11 200 emu Oe mol^{-1}, but is substantially less than the expectation from ferromagnetic coupling, *i.e.* 33,500 emu Oe mol^{-1}. Although the T_c shows little dependence on the synthetic route, hysteresis loops taken at 2 K show a strong variation in the coercive field ranging from 300 to 3000 G. Likewise, the detailed field and zero field cooled curves also have a strong dependency on reaction conditions and aging.

$Fe(TCNE)_2{\cdot}xCH_2Cl_2$ shows remarkable thermal stability. The IR spectrum and X-ray powder pattern, as well as magnetic data of a sample heated at 130 °C for 38 h, suggest that the chemical and structural features of the materials are preserved after the heat treatment, except for the apparent solvent loss. Some thermal degradation is observed from magnetic measurements on a sample treated at 180 °C, and massive decomposition is evident from IR studies when the material is heated to 200 °C. TGA data show that although desolvation starts at temperatures as low as 40 °C, it does not approach completion until the sample decomposes. Since CH_2Cl_2 is a poorly coordinating solvent, the high desolvation temperature may be attributed to CH_2Cl_2 being trapped into a three-dimensional network, and is only completely released when the structure collapses. $Fe(TCNE)_2{\cdot}xCH_2Cl_2$ is not pyrophoric as is $V(TCNE)_x{\cdot}y$(solvent), but it does decompose in air.

Reactions of TCNE and MeCN solvates of MI_2 (M = Mn, Co, Ni) led to $M(TCNE)_2{\cdot}xCH_2Cl_2$ species which magnetically order with T_c values of 44 (M = Ni, Co) and 107 K (M = Mn)[8] (Table 1). The nearest neighbor spin coupling energy, J, can be estimated from the mean-field expression of $T_c = JzS(S + 1)/3k_B$, where k_B = Boltzmann's constant, z = number of nearest neighbors, *i.e.* 6, and assuming $H = -2JS_a{\cdot}S_b$. The

Table 1 Summary of the infrared ν_{CN} absorption bands, saturation magnetization M_s, ordering temperature T_c and exchange energy J for $M(TCNE)_2{\cdot}xCH_2Cl_2$ (M = V, Mn, Fe, Co, Ni)[18]

Metal	Saturation magnetization[a] M_s/ emu Oe mol^{-1}	T_c/K	J/K[b]
V[c]	10 300	~400	53
Mn[d]	19 000	107	6.1
Fe[d]	16 900	121	10
Co[d]	8 000	44	5.9
Ni[d]	15 800	44	11

[a] 2 K and 5 T. [b] See text. [c] Ref. 7. [d] Ref. 18.

resulting estimates of J ranges as V ≫ Ni ~ Fe > Mn ~ Co (Table 1). $Mn(TCNE)_2{\cdot}xCH_2Cl_2$ is isostructural to $Fe(TCNE)_2{\cdot}xCH_2Cl_2$ based upon powder diffraction data; however, for M = Ni, Co the solids diffract poorly and do not appear to be isomorphous to $M(TCNE)_2{\cdot}xCH_2Cl_2$ (M = Fe, Mn). Hence, based upon the composition and the similarity of the ν_{CN} absorptions for M = Mn, Co and Ni, we assign all the metals as being divalent. Likewise, the elusive oxidation state of V in the room temperature $V(TCNE)_x{\cdot}yCH_2Cl_2$ magnet is again assigned the divalent oxidation state.[7,8]

Hysteresis is observed for all the magnets below T_c, however, as observed for $V(TCNE)_x{\cdot}y(CH_2Cl_2)$,[7,8] the coercive field varies from preparation to preparation. Nonetheless, the observed coercive fields range from 50 (M = Ni) to 6500 Oe (M = Co). The shape of the hysteresis curves is characteristic of metamagnetic behavior in some cases, *e.g.* for $Fe(TCNE)_2{\cdot}0.75CH_2Cl_2$ at 2 K (Fig. 7) and, along with more detailed magnetic studies, including ac measurements, is the focus of future research.

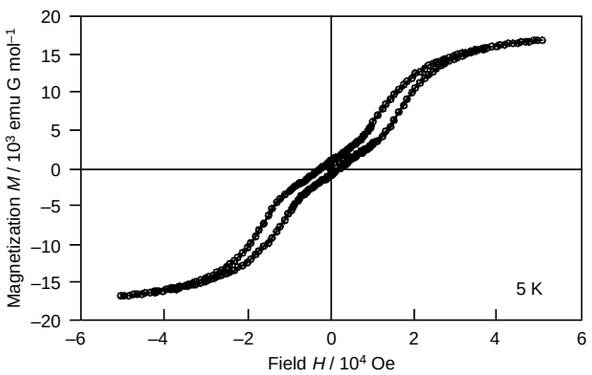

Fig. 7 An example of the observed hysteretic $M(H)$ for $Fe(TCNE)_2{\cdot}0.75CH_2Cl_2$ at 2 K. The observed coercive field for this sample is 2300 Oe and the sample saturates to 16 900 emu Oe mol^{-1}.

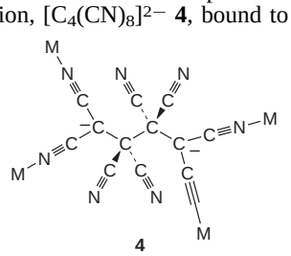
Hence, a new synthetic route enabling the preparation of several new examples of molecule-based magnets of $M^{II}(TCNE)_2{\cdot}xCH_2Cl_2$ composition has been identified. These new magnets have T_c values that exceed 100 K and coercive fields as great as 6500 Oe.

While preparing the $M^{II}(TCNE)_2{\cdot}xCH_2Cl_2$ magnets, crystals (light yellow for M = Mn; dark brown for M = Fe) which did not magnetically order were isolated. Single crystal X-ray diffraction studies revealed the unprecedented octacyanobutanediide dianion, $[C_4(CN)_8]^{2-}$ **4**, bound to four octahedral



4

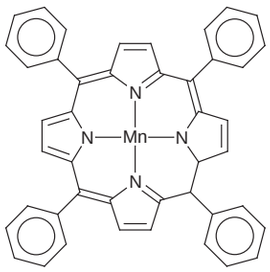
M^{II}s in a plane with the MeCN molecules filling the axial coordination sites, *i.e.* $Mn[C_4(CN)_8](NCMe)_2{\cdot}CH_2Cl_2$ **5** and $Fe[C_4(CN)_8](NCMe)_2{\cdot}MeCN$ **6**.[20] Compound **4** is disordered about the midpoint of the central C–C bond for M = Mn, but is ordered for M = Fe, and has long 1.59 (2) (M = Mn) and 1.627 (14) Å (M = Fe) central C–C bonds suggesting that it is a weak bond. This is the first example of a σ-dimer of $[TCNE]^{\cdot-}$, however, several examples of a structurally related σ-dimer of $[TCNQ]^{\cdot-}$ (TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane) have been reported.[21]

Compounds **5** and **6** are paramagnets obeying the Curie–Weiss law above 5 K. This is consistent with diamagnetic $[C_4(CN)_8]^{2-}$ weakly coupling the metal spin sites (S = 5/2 Mn^{II}). Upon desolvation of **5** and **6** at 100 °C the ν_{CN} IR absorptions disappear and new ν_{CN} bands characteristic of the $M(TCNE)_2{\cdot}xS$ magnets[20] (M = Mn, Fe) appear. Desolvated **5** magnetically orders at a T_c of 95 K,[20] in reasonable agreement with samples prepared from CH_2Cl_2.[18] Compound **6** behaves in a similar fashion upon desolvation. These observations suggest that upon desolvation the S = 0 μ_4-$[C_4(CN)_8]^{2-}$ reforms two S = 1/2 $[TCNE]^{\cdot-}$ units which can bind to additional metal centers, providing stronger spin coupling leading to the observed magnetic ordering. Evidence for this type of bond breaking has been reported for σ-dimers of $[TCNQ]^{\cdot-}$.[21a]

Hence, additional members of the $M(TCNE)_x$ class of magnets have been characterized, and in the case of Fe the metal is assigned to be divalent as previously proposed for $V(TCNE)_x{\cdot}y$solvent.[7] Furthermore, an intermediate in the formation of the $M(TCNE)_x$ class of magnets, namely $[C_4(CN)_8]^{2-}$ **6**, has been identified and structurally characterized.

[Mn(porphyrin)][TCNE]-based magnets

Another class of TCNE-based magnets is exemplified by $[Mn^{III}TPP]^{+}[TCNE]^{\cdot-}$ (TPP = *meso*-tetraphenylporphinato), which forms a coordination polymer (1-D) that was characterized to be a ferrimagnet with T_c 14 K.[22] With the goal of identifying the importance of 1-D with respect to 3-D interactions and developing a structure–function relationship for this class of magnetic materials, as well as preparing new molecule-based magnets with enhanced T_cs, we have pursued the study of this class of compounds.



MnTPP

$[Mn^{III}TPP]^{+}[TCNE]^{\cdot-}$ forms uniform parallel 1-D chains in the solid state with each S = 2 Mn^{III} bonded to four porphyrin nitrogens (*ca.* 2.00 Å) and axially to two $[TCNE]^{\cdot-}$ nitrogens (*ca.* 2.30 Å), and each S = 1/2 $[TCNE]^{\cdot-}$ is *trans*-μ-bonded to two Mn^{III} species, [Fig. 8 (*a*)]. The magnetic susceptibility of $[MnTPP]^{+}[TCNE]^{\cdot-}{\cdot}2PhMe$ can be fitted to the Curie–Weiss expression above 280 K with θ ~ −15 K, and between 115 and 250 K with an effective θ, θ', of +61 K. A minimum in the value of χT, characteristic of 1-D ferrimagnetic behavior, is observed at ~310 K and field-dependent susceptibility is observed below 50 K. Magnetic ordering occurs below 13 K (as determined by scaling analysis[22c]) and hysteresis with a coercive field of 375 G was obtained at 5 K.[22] Thus, [MnTPP][TCNE] is a representative example of a new structure type of organic-based magnetic materials, and is an excellent model system for

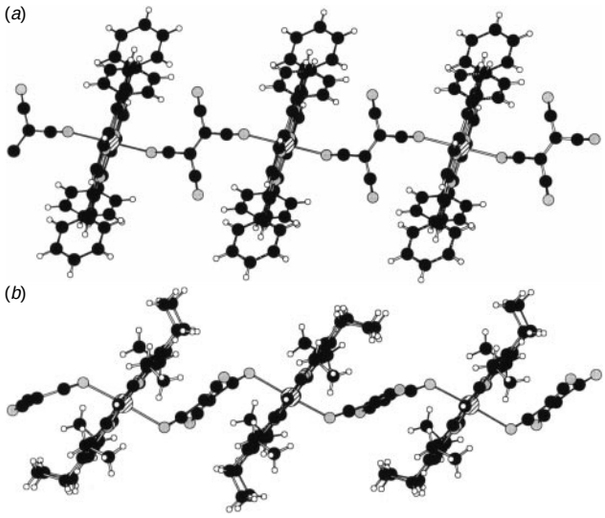


Fig. 8 (*a*) Segment of a uniform chain of the ferrimagnetic [Mn^{III}TPP]-[TCNE]·2PhMe coordination polymer (the solvent is omitted for clarity). (*b*) Alternating chain segment of the paramagnetic [Mn^{III}OEP][TCNE] coordination polymer.

studying a number of unusual magnetic phenomena, for example, the magnetic behavior of mixed quantum/classical spin systems.

In addition to modification of the porphyrin ring, the clathrate nature of this class of metalloporphryins[23] enables the introduction of different solvents into the structure to alter the inter- and intra-chain couplings and the magnetic properties. In this review we focus on modification of the [MnTPP][TCNE] structure type and discuss the consequent magnetic properties.

[MnTPP][TCNE]·2PhMe **6**[22*a*] has been crystallographically characterized. Likewise, the [TCNE]$^{\cdot-}$ salts of 4-methoxyphenyl (**7**),[24] 4-chlorophenyl (**8**)[25] and 2-fluorophenyl substituted [MnTPP]$^{+}$ (**9**)[24] and *meso*-tetrakis(3,5-di-*tert*-butyl-4-hydroxyphenyl)porphinatomanganese(III), MnTP′P[26] (**10**), have been studied by single crystal X-ray diffraction. Furthermore, to extend this system the analogous TCNE electron-transfer salt was prepared with the easier-to-oxidize MnOEP (OEP = octaethylporphyrinato).[27]

[MnOEP][TCNE] has weak ferromagnetic coupling as evidenced by the fitting of the susceptibility to the Curie–Weiss expression with a θ' of +7 K.[27] However, unlike [MnOEP][TCNE], magnetic ordering is not observed above 2 K. The differences in the magnetic properties are ascribed to structural differences. Although both [MnTPP][TCNE]·2PhMe and [MnOEP][TCNE] form parallel 1-D chains (Fig. 8), due to the differing orientations of [TCNE]$^{\cdot-}$ within a chain they are alternating chains for [MnOEP][TCNE] instead of being uniform chains as for [MnTPP][TCNE]·2PhMe. Thus, uniform chains appear to be important to achieve long range magnetic order.[27]

A correlation of the dihedral angle, ϕ, between the [Mn^{III}TPP]$^{+}$ MnN_4 and [TCNE]$^{\cdot-}$ mean planes and the magnitude of magnetic coupling has been observed for ditoluene solvates of five [TCNE]$^{\cdot-}$ salts, **6**–**10**.[28] The magnitude of magnetic coupling is determined from T_{min}, the temperature at which a minimum in $\chi T(T)$ or $\mu(T)$ plots occurs, as expected for antiferromagnetically coupling linear chain systems,[29] and the effective θ, θ', obtained from a fit of the data to the Curie–Weiss expression. A correlation to T_{min} is preferred as it is model independent; however, for strongly coupled systems T_{min} is not observed as it occurs at temperatures exceeding the measurement range. T_{min}, however, can be estimated from a fit of the data to the Seiden expression for isolated 1-D chains comprised of alternating quantum (S = 1/2) and classical (S > 1/2) spins.[30]

The smaller ϕ the stronger the magnetic coupling, *i.e.* the greater T_{min} and θ' (Fig. 9). Hence to attain strong intrachain coupling systems with more acute dihedral angles are sought and, based on **10**, 3,5-disubstituted [MnTPP]$^{+}$s are preferred over 2- or 4-substituted [MnTPP]$^{+}$s which from the data acquired to date have higher ϕ values. To test this postulate several 3,5-disubstituted systems are being studied. Likewise, pressure also may force such systems to have reduced angles and also lead to higher T_c values.

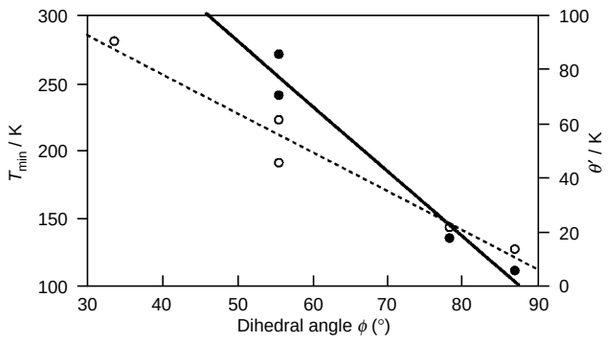

Fig. 9 Correlation of the dihedral angle ϕ between the MnN_4 and [TCNE]$^{\cdot-}$ mean planes with the temperature at which $\chi T(T)$ data has a minimum, (T_{min}, ● and solid line) and the effective θ value (θ'; ○ and dashed line)[28]

The aforementioned correlation between ϕ and T_{min} and θ' is attributed to the overlap between the [TCNE]$^{\cdot-}$ *N*-bound to Mn^{III} π* SOMO and the four Mn^{III} SOMO d orbitals. [The energy of the latter increase as $d_{xy}{}^1$ (b_1) < $d_{xz}{}^1$, $d_{yz}{}^1$ (e) < $d_{z^2}{}^1$ (a_1) < $d_{x^2-y^2}$ (b_1).[31]] From MO considerations (determined from semi-empirical INDO/SCF calculations) the expected d_π–p_z (d_π = d_{xz}, d_{yz}) overlap is not as important as the σ–d_{z^2}/p_z overlap between Mn^{III} and the [TCNE]$^{\cdot-}$ (Fig. 10).[28] Furthermore, the smaller ϕ increases the σ–d_{z^2}/p_z overlap between Mn^{III} and the [TCNE]$^{\cdot-}$ leading to an increased intrachain coupling, as reflected in T_{min} and θ' (Fig. 10).

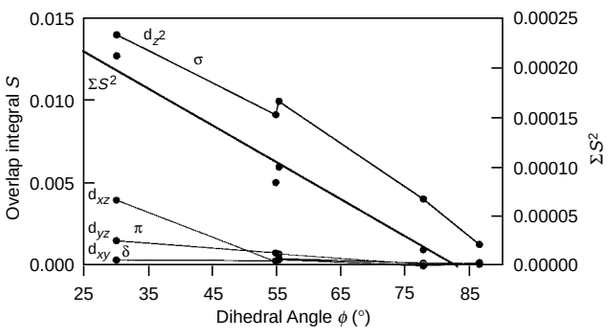

Fig. 10 Correlation of the dihedral angle ϕ between the MnN_4 and [TCNE]$^{\cdot-}$ mean planes with the semi-empirical INDO/SCF calculated d_{yz}-, d_{xz}-, d_{xy}- and d_{z^2}-like overlap integrals S with the [TCNE]$^{\cdot-}$ π* SOMO and the sum of the squares of these overlap integrals ΣS^2

While the σ overlap between the [TCNE]$^{\cdot-}$ p_z orbital and the Mn d_{z^2} orbital controls the intrachain magnetic exchange, the three-dimensional magnetic ordering temperature, T_c, depends upon this term *and* the interchain exchange. The later term is governed by the competition between antiferromagnetic exchange due to orbital overlap between porphyrin moieties of adjacent chains and an effective exchange due to dipolar interactions between chains. The dipolar term can be ferromagnetic or antiferromagnetic depending upon the structural order in the compound and the role of single ion anisotropy.[32]

Joel S. Miller was born in Detroit, MI and received his Bachelor of Science in Chemistry from Wayne State University (1967) and PhD from UCLA (1971). After a postdoctoral fellowship at Stanford University he joined the Xerox Webster Research Center in 1972 and later joined the now-defunct Occidental Research Corporation. He was Visiting Professor of Chemistry at the University of California, Irvine, CA. He joined the Central Research & Development Department at the Du Pont Company in 1983 where he was a Research Supervisor for solid state science. He has been a Visiting Scientist at the Weizmann Institute (1985) and a Visiting Professor of Chemistry at the University of Pennsylvania (1988). He joined the faculty of Department of Chemistry at the University of Utah in 1993. He is on the advisory board of *Advanced Materials* and *Journal of Materials Chemistry*, and a member of the Inorganic Synthesis Corporation. His research interests focus on the solid state magnetic, electrical and optical properties of molecular (organic, organometallic and inorganic coordination) compounds and electron transfer complexes as well as the surface modification of solids. Currently he is actively involved in synthesis and characterization of molecular/organic based ferromagnets. In addition to patents he has edited eleven monographs and published over 300 papers in these and other areas.

Arthur J. Epstein was born in Brooklyn, NY and received his BS in Physics from the Polytechnic Institute of Brooklyn in 1966 and his PhD in Physics from the University of Pennsylvania in 1971. After a year as Member of the Technical Staff of The MITRE Corporation and thirteen years at the Xerox Webster Research Center where he was Principal Scientist, he joined The Ohio State University in 1985 as Professor of Physics and Professor of Chemistry. In 1997 he was appointed as Distinguished University Professor. He has been the Director of The Ohio State University Center for Materials Research since 1989. He also has been adjunct Professor of Physics at the University of Florida and has been a visiting Professor at the Université Paris-Sud and the Technion—Israel Institute of Technology—and is presently Adjunct Professor of Chemistry at University of Utah. He is a Regional Editor for *Synthetic Metals*. His current research interests include experimental and theoretical study of magnetic, electronic/optical and transport phenomena of synthetic magnets (molecular, organic and polymeric magnets) and synthetic metals (conducting polymers, organic and molecular materials), including the study of excitations and their dynamics. He is also active in the exploration of potential applications of unconventional magnetic, electronic and optical materials for which he consults with several companies. In addition to having originated twenty patents and editing five conference proceedings, he has published over 500 papers in these and other areas.

Synthesis of fully sulfonated polyaniline: a novel approach using oxidative polymerisation under high pressure in the liquid phase

Hardy S. O. Chan,[a,b] Annette J. Neuendorf,[c] Siu-Choon Ng,*[a] Pauline M. L. Wong[a] and David J. Young*[c]†

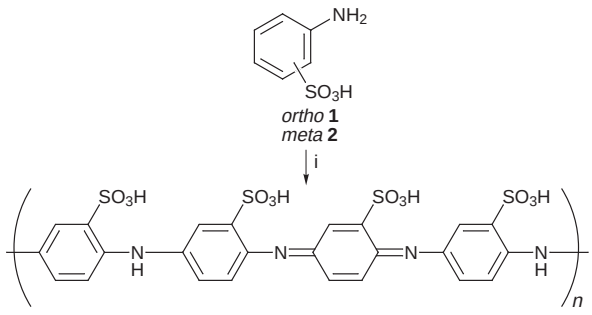
The oxidative polymerisation of *o*- and *m*-aminobenzenesulfonic acid has been achieved for the first time at high pressures to yield fully sulfonated polyaniline (SPANI) which is self-doping, water soluble and electrically conducting.

Polyaniline (PANI) has received considerable attention over the past few decades on account of its high electrical conductivity, environmental stability and capacity for reversible doping to an electrically conductive state by external Brønsted acids.[1] More recently, the development of 'self-doped' PANI derivatives incorporating *N*-alkylsulfonic acid,[2] methylphosphonic acid[3] or sulfonic acid[4] moieties have been reported, of which the latter displayed the highest conductivity. This sulfonated polyaniline (SPANI) was synthesised by post-polymerisation treatment of PANI emeraldine base or pernigraniline base with fuming sulfuric acid[4a–d] to achieve 50% sulfonation, or by treatment of PANI leucoemeraldine base with fuming sulfuric acid[4e] to afford a 75% sulfonated polyaniline with electrical conductivity of *ca.* 0.1 and 1 S cm^{-1} respectively. The production of 100% sulfonated SPANI has hitherto not been reported but would be predicted to have even greater water solubility and possibly higher conductivity.[4e] The oxidative polymerisation of *o*-aminobenzenesulfonic acid **1** or *m*-aminobenzenesulfonic acid **2** would obviously provide fully sulfonated SPANI but attempts so far by both chemical or electrochemical methods[4b,5] have been unsuccessful, presumably due to steric hindrance and the strongly deactivating influence of the electron withdrawing sulfonic acid moiety. Incorporation of an electron donating methoxy group onto the monomer does, however, allow oxidative polymerisation and poly(3-amino-4-methoxybenzenesulfonic acid) has been prepared in this way[5,6] and has found applications for electron device fabrication[5] and in a novel polymer complex.[7] The room temperature conductivity of this methoxy-SPANI is, however, significantly less than that for 50 or 75% sulfonated SPANI[5,6] which has been attributed to the larger twist of the phenyl rings and increased interchain separation.[6] We now present the first report of a facile preparation of fully sulfonated SPANI by oxidative polymerisation of **1** and **2** under the influence of high pressures in the liquid phase (Scheme 1).



Scheme 1 *Reagents and conditions*: i, $Na_2S_2O_8$, high pressure, catalyst

Monomers **1** and **2** were polymerised at 19 kbar with $Na_2S_2O_8$ (1.25 equiv.) in aqueous LiCl (1.0 or 5.0 M) and with 5% $FeSO_4$ for 18 h at 20 °C. The usual requirement for added HCl to solubilise the monomer was not necessary and so the conductivity of the resulting polymers was exclusively due to self doping. After this period, the dark-green solution was freeze-dried, dissolved in a minimum amount of water and dialysed through cellulose acetate dialysis tubing with a molecular weight cut-off of 1000 g mol^{-1}. The yield of the polymers after dialysis and evaporation of the water was 10%. The addition of a small amount of aniline has been shown to facilitate the polymerisation of anilines bearing electron withdrawing nitro[8] or cyano[9] substituents. In combination with high pressure, the addition of 10% aniline had a dramatic effect on yield with essentially quantitative recovery of SPANI (Table 1) and no noticeable effect on the water solubility of the resulting polymer.

While the conductivity of polymers **3**–**8** was less than that reported for SPANI prepared by post-polymerisation sulfonation, these conductivity values are for 'as-synthesized' polymer (*i.e.* without addition of external dopant) and are comparable to externally doped *N*-alkylsulfonated polyaniline[2] and methoxy-SPANI.[5,6] The UV–VIS spectra of **3**–**8** gave three absorption bands. The band with λ_{max} at 306–324 nm is attributed to $\pi_B \rightarrow \pi^*$ and low lying $\pi_B \rightarrow \pi_Q$ transitions; the second with λ_{max} at 448–450 nm is consistent with low-lying π_B–π_S excitation to the polaron band whilst the third with λ_{max} at 565–624 nm is attributable to π_B–π_Q transition.[3b] Upon dedoping by addition of base, the absorption band at 448–450 nm was greatly diminished, showing the decreased contribution of the low-lying $\pi_B \rightarrow \pi_S$ transitions. The FTIR spectra gave the characteristic absorption bands for quinoidal and benzenoid stretchings at 1590 and 1500 cm^{-1} respectively, as well as absorption bands of the sulfonic acid group at 1200 and 1020–1072 cm^{-1}.

The bulk *S*/*N* ratios (Table 1) indicate 100% sulfonation for polymers **3**, **4**, **6** and **7** and a lower degree of sulfonation for polymers **5** and **8** for which 10 mol% aniline was used to assist initiation. We ascribe the higher than expected bulk hydrogen and surface oxygen content to the extremely hygroscopic nature of these zwitterionic polymers. The C1s XPS signals of the polymers can be deconvoluted into three components, each with a FWHM (full width at half maximum) of 1.6 eV; C–C or C–H at 285 eV, C–N or C=N at 286 eV and C–O at 287 eV. The N1s signals can be deconvoluted into four environments each with a FWHM of 1.6 eV; –NH– at 399.7 eV, –$^+$NH– at 401.2 eV, –$^+NH_2$– at 402.5 eV and an unidentified component at 400.7 eV. This last environment was also reported by Yue and Epstein.[4c]

In conclusion, we have demonstrated for the first time that high pressure in the liquid phase facilitates the direct oxidative polymerisation of **1** and **2** which is otherwise not possible at ambient pressure. The polymer yield is substantially increased by the addition of a small amount of aniline. The resulting SPANI is highly water soluble. Despite a higher degree of sulfonation than is possible by post-polymerisation sulfonation

Table 1 Summary of reaction conditions and polymer characterisation data

Monomer	SPANI	Reaction conditions	Yield (%)	Bulk atomic ratio (surface at. ratio)	σ^a/S cm^{-1}
1	**3**	1.0 M LiCl 0.05 equiv. $FeSO_4$	10	$C_{6.9}H_{8.9}N_{1.0}S_{1.0}$	10^{-4}
1	**4**	5.0 M LiCl 0.05 equiv. $FeSO_4$	10	$C_{7.1}H_{10.0}N_{1.0}S_{1.1}$ $(C_{18.1}N_{1.0}S_{0.8}O_{6.9})$	10^{-3}
1	**5**	5.0 M LiCl 0.05 equiv. $FeSO_4$ 0.1 equiv. aniline	98	$C_{6.3}H_{8.1}N_{1.0}S_{0.8}$ $(C_{8.1}N_{1.0}S_{1.0}O_{17.0})$	10^{-3}
2	**6**	1.0 M LiCl 0.05 equiv. $FeSO_4$	10	$C_{6.8}H_{9.6}N_{1.0}S_{1.0}$	10^{-5}
2	**7**	5.0 M LiCl 0.05 equiv. $FeSO_4$	10	$C_{6.2}H_{8.6}N_{1.0}S_{1.0}$ $(C_{16.0}N_{1.0}S_{0.9}O_{6.7})$	10^{-4}
2	**8**	5.0 M LiCl 0.05 equiv. $FeSO_4$ 0.1 equiv. aniline	100	$C_{6.4}H_{8.4}N_{1.0}S_{0.7}$	10^{-3}

[a] As determined using the four-point probe method.

of PANI,[4] the conductivity of the 'as-synthesised', high pressure SPANI is less than that of the latter and suggests the possibility of pressure induced defects. While these reactions were conducted at 19 kbar, we have observed that polymerisation of **1** will occur at pressures down to *ca.* 15 kbar, while **2** polymerises down to *ca.* 10 kbar. These reactions were catalysed with 5 mol% Co^{2+}. This difference in the reactivity of *ortho* and *meta* isomers has been reported for the oxidative polymerisation of cyanoanilines and ascribed to the relative effect of the electron withdrawing substituent on the spin densities at N and C4 in the oxidised monomers.[9] We are currently attempting to quantify the effect of pressure on reaction rate for the polymerisation of anilines. Preliminary rate measurements at different pressures for the ammonium persulfate oxidation of 2-methoxyaniline[10] conducted in a high pressure spectrophotometric cell[11] indicate a large, negative activation volume (ΔV^* of the order of -60 cm^3 mol^{-1}). Such a value would be consistent with charge development (and associated electrostriction of solvent) in the transition state[12] for the rate determining oxidation of aniline[13] and equates to a substantial rate enhancement (by a factor of *ca.* 12 at 1 kbar and a factor of *ca.* 10^{13} at 10 kbar, assuming a linear dependence of ln k on pressure[14]). This large effect suggests that the polymerisation of other unreactive aniline monomers may be viable at elevated pressures.

Calix[4]arenes with hard donor groups as efficient soft cation extractants. Remarkable extraction selectivity of calix[4]arene *N*-(X)sulfonylcarboxamides for Hg^{II}

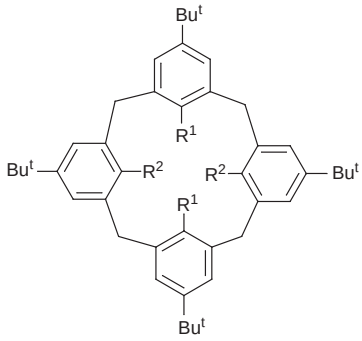
Galina G. Talanova, Hong-Sik Hwang, Valdimir S. Talanov and Richard A. Bartsch*†

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1601, USA

Calix[4]arene *N*-(X)sulfonylcarboxamides efficiently extract Hg^{II} from acidic aqueous nitrate solutions with excellent selectivity over alkali, alkaline earth and many transition metal ions, including Pb^{II}, Ag^{I} and Pd^{II}.

Metal complexes of calixarene-based macrocyclic ligands are attracting ever-increasing attention,[1–3] especially for applications in metal ion separation processes. During the last decade, remarkable progress in the transition metal chemistry of calixarenes has been achieved.[3] Recently, several papers have appeared which report utilization of calixarene derivatives in separations of soft heavy metal ions, *e.g.* Ag^{I}, Au^{III}, Pd^{II}, Pt^{II} and Cd^{II}.[4,5] However, only very limited information on Hg^{II} extraction with calixarene-based ligands is available in the literature.[5]

Recently we synthesized new calix[4]arenes **1**–**4** with two



1 R^1 = OMe, R^2 = $OCH_2C(O)NHSO_2CF_3$
2 R^1 = OMe, R^2 = $OCH_2C(O)NHSO_2Me$
3 R^1 = OMe, R^2 = $OCH_2C(O)NHSO_2Ph$
4 R^1 = OMe, R^2 = $OCH_2C(O)NHSO_2C_6H_4NO_2$-4
5 R^1 = OBu, R^2 = $OCH_2C(O)NHSO_2Ph$
6 R^1 = OBu, R^2 = OCH_2CO_2H
7 R^1 = OBu, R^2 = OCH_2CO_2Et
8 R^1 = OMe, R^2 = OCH_2CO_2H
9 $R^1 = R^2$ = OMe
10 $R^1 = R^2$ = OH
11 R^1 = OBu, R^2 = OH

N-(X)sulfonylcarboxamide groups of 'tunable' acidity that exhibit good extraction selectivity for Pb^{II} over alkali and alkaline earth metal cations, as well as Cd^{II}, Co^{II}, Cu^{II}, Ni^{II} and Zn^{II}.[6] However, these ligands failed to extract Pb^{II} in the presence of Hg^{II}.[6] This unexpected favoring of a soft metal cation over a harder metal cation by ligands containing hard donor groups encouraged us to investigate the solvent extraction of Hg^{II}, Ag^{I} and Pd^{II} by **1**–**4** and related calix[4]arene derivatives **5**–**10** which have different pendant functional groups [*N*-(X)sulfonylcarboxamide, carboxylic acid, ester, ether, phenol]. To the best of our knowledge, this is the first report in which calixarene-type compounds without soft donor functions have been employed as Hg^{II} extractants.

The complexing abilities of calixarene-based ligands are known to vary significantly with alterations in their structures and conformations.[2] To study Hg^{II} extraction, we used the previously reported, conformationally mobile calix[4]arene *N*-(X)sulfonylcarboxamides **1**–**4**, as well as the related new compounds **5**–**7** which are restricted to the cone conformation. Calix[4]arene *N*-(X)sulfonylcarboxamide **5**‡ was prepared from the corresponding calixarene dicarboxylic acid **6**§ by the procedure described for the synthesis of **1**–**4**.[6] We also utilized proton-ionizable calixarenes **8**[8] and commercially available **10** which exist in cone conformations in $CHCl_3$ solution due to intramolecular hydrogen bonding, but may change into other conformations when converted into metal salts, and the conformationally flexible, non-ionizable derivative **9**[9] which is predominantly the partial cone conformer in $CHCl_3$.[10]

Although all of the calixarenes **1**–**10** were found to extract Hg^{II} from acidic (pH 2.5) aqueous nitrate solutions into $CHCl_3$¶ to some degree, the metal loadings of the ligands are noted to vary markedly with their structures and functional group types (Fig. 1). The calix[4]arene *N*-(X)sulfonylcarboxamides **1**–**4** extract Hg^{II} most efficiently. Even though the 'tunable' acidity of the calixarene *N*-(X)sulfonylcarboxamides alters their extraction properties for harder metal cations,[6] no significant difference in Hg^{II} loading was observed for **1**–**4** under the experimental conditions. For the conformationally flexible ligand **3**, the Hg^{II} loading was found to be considerably higher than that for analogue **5** which has a cone conformation. The calix[4]arene dicarboxylic acids **6** and **8** are weaker Hg^{II} extractants than the corresponding *N*-(X)sulfonylcarboxamides. The somewhat higher Hg^{II} loading for dicarboxylic acid **8** compared to **6** is ascribed to a greater conformational flexibility of the former. Conversion of calix[4]arene dicarboxylic acid **6** into the corresponding diester **7**, which also is restricted to the cone conformation, slightly reduces the level of Hg^{II} extraction. A conformational change from cone to partial cone is thought to be primarily responsible for the significant increase in Hg^{II} loading when the phenolic group in **10** was replaced with anisole units in **9**.

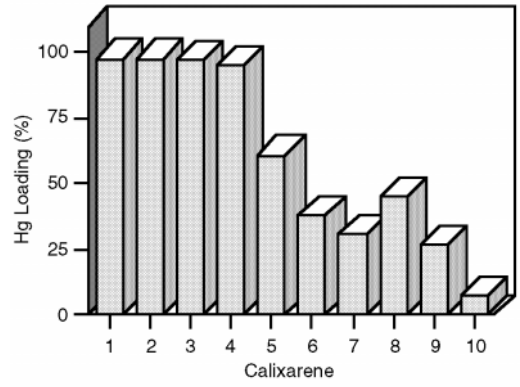


Fig. 1 Hg^{II} loading in extractions of 0.25 mM Hg^{II} from aqueous nitrate solutions at pH 2.5 into $CHCl_3$ with 0.25 mM calixarenes **1**–**10**

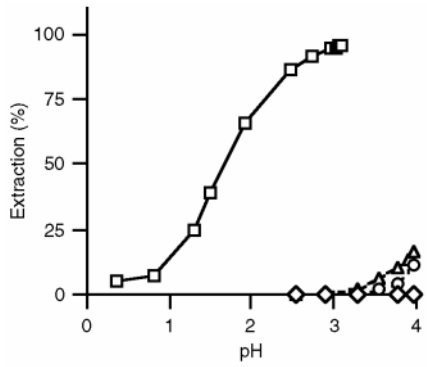

Fig. 2 pH profiles for Ag^{I} extraction from 1.00 mM aqueous $AgNO_3$ into $CHCl_3$ with 1.00 mM calix[4]arene *N*-(X)sulfonylcarboxamides **1**–**4**: (□) **1**, (◇) **2**, (○) **3** and (△) **4**

Coordination of Hg^{II} alters the UV spectra of calixarenes **1**–**10** in $CHCl_3$. The absorption bands at 270–279 nm (for the substituted benzene rings) undergo hypsochromic shifts that are greatest for **1**–**4** (17–23 nm). Analogous spectral changes were not observed when $CHCl_3$ solutions of the ligands were contacted with 1.0 M NaOH. With Cl^- as the counterion instead of NO_3^- under otherwise identical conditions, Hg^{II} extraction was found to decrease dramatically for all of the calixarenes **1**–**10**.

Further investigation of the conformationally flexible calixarene *N*-(X)sulfonylcarboxamides **1**–**4** reveals extraction complex stoichiometries of two metal ions per ligand molecule. The extraction constants determined for ligands **1**–**4** vary as X is changed in the order: CF_3 > Me > Ph > 4-$O_2NC_6H_4$. This ordering differs from that found for Pb^{II},[6] as well as alkali and alkaline earth metal cations, and indicates that the size rather than the electron-withdrawing ability of X is important in Hg^{II} extraction.

The results presented above suggest a significant contribution to the complex stability by π-interactions between Hg^{II} and the electron-rich aromatic rings in the calixarene framework. Previously, π-complexes of calixarenes with other soft heavy metal ions, Ag^{I} and platinides(II), have been reported.[2,3,11]

The calix[4]arene *N*-(X)sulfonylcarboxamides **1**–**4** are also efficient Ag^{I} extractants from acidic and neutral solutions.‖ Unlike Hg^{II} binding, the propensities of these ligands for Ag^{I} extraction are controlled by their acidities. Only ligand **1** extracts Ag^{I} at pH < 3, while a higher pH is required for weaker NH-acids **2**–**4** (Fig. 2). A similar trend is noted for extraction of Pd^{II} by **1**–**4**. Therefore, calixarene *N*-(X)sulfonylcarboxamides **2**–**4** are remarkably selective in Hg^{II} extraction from acidic (pH 2.0–2.5) nitrate solutions, since they efficiently extract Hg^{II} with negligible loadings of alkali, alkaline earth, and many transition metal cations, including Pb^{II}, Ag^{I} and Pd^{II}. Further investigation of soft metal ion separations with calix[4]arene *N*-(X)sulfonylcarboxamides is in progress.

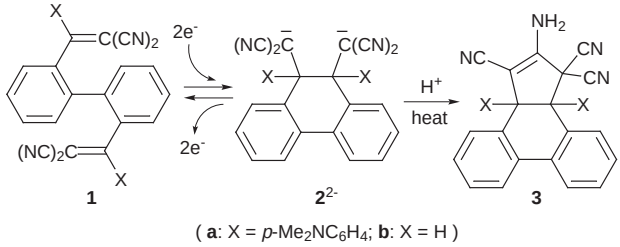
Biphenyl-type electron acceptors exhibiting dynamic redox properties: a novel electrochromic system with 'write protect' option

Takanori Suzuki,*† Hyou Takahashi, Jun-ichi Nishida and Takashi Tsuji

Division of Chemistry, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan

A novel redox pair undergoing reversible C–C bond making/breaking has been constructed based on a bis(dicyanovinyl)biphenyl derivative and a dianion with the dihydrophenanthrene skeleton; further cyclization of the latter to an enaminonitrile endows the 'write protect' option to its electrochromic response.

Recently much attention has been focused on molecules whose geometry and properties can be controlled by the external stimuli.[1] From this point of view redox systems undergoing reversible C–C bond making/breaking upon electron transfer (ET) are interesting[2] and might be applicable to the construction of electrochemical switches or molecular devices[3] based on their optical response and bistability. We have designed the novel redox pair shown in Scheme 1 which has the following interesting features: (*i*) 2,2′-bis(dicyanovinyl)biphenyls **1** are expected to undergo facile ring closure to dihydrophenanthrene-type dianions $\mathbf{2}^{2-}$ upon two-electron reduction; (*ii*) the resulting dianions are sterically congested molecules and will regenerate the starting material **1** by C–C bond cleavage upon oxidation; (*iii*) in the case of *p*-dimethylaminophenyl derivatives **1a** and $\mathbf{2a}^{2-}$, a sharp change in color is expected during ET because only the former shows strong absorption in the visible region due to the *p*-(dicyanovinyl)aniline skeleton; (*iv*) besides the reversible interconversion between **1** and $\mathbf{2}^{2-}$, further cyclization to **3** induced by protonation of $\mathbf{2}^{2-}$ endows the system with the 'write protect' option in its response (Scheme 2). Here, we report the preparation and unique redox properties of the title acceptors and their reduction products.

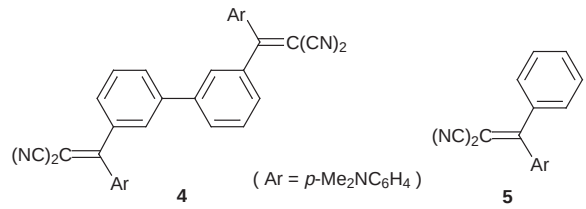


Scheme 1

Scheme 2

Condensation reaction of 2,2′-diformylbiphenyl with malononitrile in the presence of $TiCl_4$ and pyridine[4] gave **1b**‡ (mp 224–226 °C) as colorless crystals in 54% yield. Dye **1a**‡ (mp 333–334 °C) was prepared from 2,2′-diiodobiphenyl *via* its 2,2′-dilithio derivative[5] by successive reactions with *p*-dimethylaminobenzonitrile and malononitrile,[6] and obtained as orange plates [λ_{max} (MeCN): 455 nm (log ε 4.24), 279 (4.02)] in 7% yield.

Voltammetric analyses have revealed quite different behavior of **1a** compared with the *m,m*-isomer **4**.§ The redox behaviour of **4** is nearly identical to that of reference compound



5,[6] which undergoes reversible one-electron reduction to $\mathbf{5}^{\cdot-}$ (E^{red} = −1.28 V) and oxidation to $\mathbf{5}^{\cdot+}$ (E^{ox} = +1.08 V). By contrast the reduction process of **1a** (E^{red} = −1.29 V) is irreversible in the sense that the corresponding anodic peak is absent in its cyclic voltammogram (Fig. 1). Instead, a new peak appeared in the anodic region (+0.04 V). This was assigned to the oxidation peak of $\mathbf{2a}^{2-}$ by independent measurement, and a new cathodic peak corresponding to the reduction of **1a** was observed after the oxidation of $\mathbf{2a}^{2-}$. Such hysteresis in redox waves is characteristic of 'dynamic' redox systems that undergo reversible and drastic structural change upon ET.[1b,2] Electrochromic behaviour was shown by spectrophotometric monitoring of the electrochemical reduction of **1a**, and the isosbestic point at 380 nm is indicative of the quantitative conversion to $\mathbf{2a}^{2-}$ (Fig. 2).

The stereospecific nature of the ring closure was evidenced by product analysis on the mixture obtained by the reaction of **1a** with SmI_2 then with acid.¶ Thus, *trans*-H_2**2a**‡ (mp 221–223 °C) was formed free from the *cis*-isomer and isolated in 64% yield as the sole product. Only by heating in EtOH, does this material isomerize quantitatively to *trans*-**3a**‡ (mp 198–200 °C) by Thorpe condensation[8] which no longer regenerates **1a** upon oxidation, suggesting that 'write protection' can be performed very easily.

Thorpe condensation occurred more rapidly in the absence of dimethylaminophenyl groups. Thus, the enaminonitrile *trans*-**3b**‡ (mp 276–278 °C; $^3J_{HH}$ 13.2 Hz) was obtained as the major

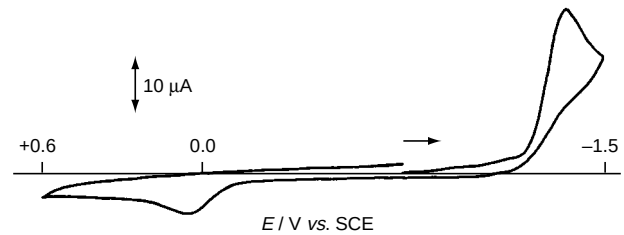


Fig. 1 Cyclic voltammogram of dye **1a** in MeCN (*E*/V *vs.* standard calomel electrode, 0.1 mol dm^{-3} NEt_4ClO_4, Pt electrode, scan rate 500 mV s^{-1}). The oxidation peak at +0.04 V is absent when the voltammogram was first scanned anodically. Another oxidation peak at +1.07 V was also observed but not shown, which corresponds to the oxidation of dimethylaniline moieties as in **4** and **5**.

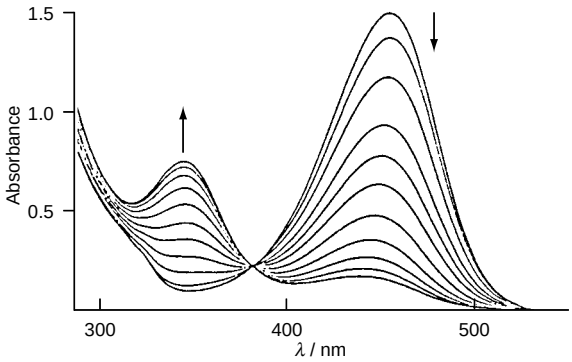

Fig. 2 Changes in UV–VIS spectrum of **1a** (3 ml soln., 7.34×10^{-5} mol dm^{-3} in MeCN containing 0.05 mol dm^{-3} NEt_4ClO_4) upon electrochemical reduction (480 μA) at 1 min intervals

product when **1b** [$E^{red} = -0.87$ V (irrev.)] was reduced with SmI_2. Although *trans*-H_2**2b**‡ (decomp. 250–270 °C) could be isolated as a primary product, the ratio of *trans*-H_2**2b** to *trans*-**3b** varied run-by-run depending on the work-up conditions, and in one case *trans*-**3b** free from *trans*-H_2**2b** was obtained in 83% yield. Careful examination of the mixture showed that *cis*-**3b**‡ (mp 281–282 °C; $^3J_{HH}$ 8.3 Hz) was also formed as a minor component [(*trans*-H_2**2b** + *trans*-**3b**): *cis*-**3b** = 10 : 1], which was separated and purified by reverse phase HPLC. These results indicate that the bulkiness of aryl groups in **1a** plays an important role in confining the stereochemical course of the reductive cyclization of **1**. At the same time, the aryl groups retard isomerization to **3**, thus preventing unintended 'write protection'.

This work was supported by the Ministry of Education, Science, and Culture, Japan (No. 08640664). NMR spectra were measured by Ms. Kazuyo Nakaoka at the Center for Instrumental Analysis (Hokkaido University).

‡ All new compounds gave satisfactory analytical values.

§ Compound **4**‡ (mp 202–204 °C) was also formed in 0.5% yield when the dilithiobiphenyl was generated from biphenyl and Bu^nLi–TMEDA[7] and used for the preparation of **1a**. This result suggests tht the direct lithiation of biphenyl affords a small amount of 3,3′-dilithio derivative.

¶ Similar reduction of *m*,*m*-isomer **4** with SmI_2 did not induce cyclization but instead hydrogenation of two vinyl groups thus giving the tetrahydro derivative H_4**4**‡ (mp 110–112 °C).

Nanomolar determination of copper(II) and zinc(II) using supramolecular complexes of *meso*-tetrakis(4-*N*-methylpyridyl)porphine on polyglutamate

Emanuele Bellacchio,[a] Sergio Gurrieri,[b] Rosaria Lauceri,[a] Antonio Magrì,[a] Luigi Monsù Scolaro,[c] Roberto Purrello*[a]† and Andrea Romeo[c]

The remarkable acceleration of Cu^{II} and Zn^{II} insertion in cationic porphyrins monodispersed on a polyglutamate anionic surface allows determination of the two metal ions down to nanomolar concentrations.

In the last few years a large number of fluorescent sensors for pH or metal ions have been designed and synthesized by means of a supramolecular 'covalent' approach.[1] Most of them are two-component systems in which a 'receptor' unit is covalently linked to a 'sensing' one.

Owing to their high absorption coefficients and tunable fluorescence emission, porphyrins are excellent sensing units.[2] The introduction of polar groups at the periphery of the porphine ring makes them water-soluble and allows the formation of 'non-covalent' supramolecular species on oppositely charged templates.[3] Using this alternative supramolecular approach, it has been recently shown that the complexes of the tetraanionic *meso*-tetrakis(4-sulfonatophenyl)porphine on polylysine can be effective as pH-sensors.[3a] This 'non-covalent' strategy therefore allows one to achieve specific photochemical sensors‡ by mixing commercially available chemicals. On the other hand, the formation of these supramolecular complexes depends upon several factors (such as pH, ionic strength, *etc*.) and consequently they are less 'robust' than those obtained by the classical 'covalent' approach.

This report deals with supramolecular complexes formed by the tetracationic *meso*-tetrakis(4-*N*-methylpyridyl)porphine (H_2T4) and polyglutamate. As a result of a remarkable increase of the metallation reaction rate, this complex behaves as sensitive and specific fluorescent sensor for the determination of nanomolar concentrations of biologically relevant metal ions such as Zn^{II} and Cu^{II}.

Indeed, porphyrin metallation could be used, in principle, as a simple tool for analytical determination of trace amount of metal ions because, in most cases, the absorption and/or the emission properties of the metallo- and the free-porphyrins are quite different from each other, so that the two species can be clearly distinguished.§ Despite this, these reactions have been rarely used for analytical applications,[5] a major limitation being the slow rate of metal insertion.

Under the experimental conditions used in this work (succinate buffer 2 mM, pH = 5.6, [H_2T4] = 1 μM, [poly-L-glutamate] = 200 μM in residue) H_2T4 is mainly monodispersed on the anionic polypeptide.¶ In fact, only a small red shift ($\Delta\lambda$ = 4 nm) and hypochromicity (15%) of the Soret band was observed, while any characteristic feature of porphyrin assembly formation (such as resonance light scattering[6] or induced circular dichroism signals in the Soret region) was absent. Absorption experiments show that the addition of Zn^{II} to such H_2T4–polyglutamate supramolecular complexes leads to a shift of the Soret band at 440 nm (Fig. 1). Also, the main Q-band of H_2T4 (518 nm) is progressively replaced with that of ZnT4 (562 nm) (Fig. 1). These spectroscopic features are diagnostic

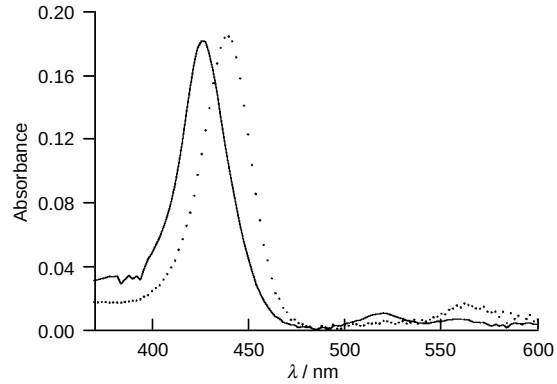

Fig. 1 Absorption spectra (pathlength = 1 cm) of H_2T4 (1 μM) in the presence of polyglutamate (200 μM) at pH 5.6 (succinate buffer 2 mM), before (—) and after (···) the addition of $ZnSO_4$ (0.05 μM)

of the formation of ZnT4. Note that the addition of successive aliquots, each containing a few pmol of Zn^{II}, leads to a linear increase of the fluorescence intensity at 622 nm‖ (ZnT4 emission maximum), as shown in Fig. 2.

The presence of polyglutamate turns out to be essential to observe a reasonable time response of the method. In the presence of the anionic polypeptide, Zn^{II} insertion was completed in about 10 min whereas in its absence, even after 24 h no evidence of metallation was observed *i.e.* the formation of the polyglutamate–H_2T4 supramolecular complex 'catalyzes' the insertion of Zn^{II}. Preliminary kinetic data show that the metallation rate under such conditions is about 1000 times higher compared to the 'uncatalyzed' reaction.**

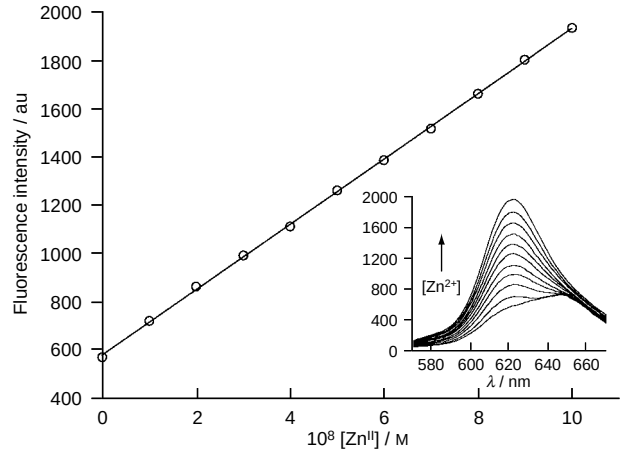

Fig. 2 Plot of fluorescence intensity at 622 nm (λ_{ex} = 445 nm) *vs.* Zn^{II} concentration, for a solution of H_2T4 (1 μM) in the presence of polyglutamate (200 μM) at pH 5.6 (succinate buffer 2 mM)

A similar behaviour was observed for the same system when Cu^{II} was employed in place of Zn^{II}. Here, the formation of the metalloporphyrin was confirmed by the gradual replacement of the H_2T4 Q-band (518 nm) with that of CuT4 (550 nm), as the Cu^{II} concentration was increased. However, since the CuT4 formed is non-fluorescent, we monitored the disappearance of H_2T4 monodispersed on polyglutamate. Here, as well, a plot of H_2T4 emission fluorescence intensity (λ_{ex} = 422 nm, λ_{em} = 655 nm) *vs*. Cu^{II} concentration (Fig. 3) shows a linear behavior.

Interestingly, the pH dependence of the metallation rate is also influenced by the presence of polyglutamate. For example, it has been reported that, in the presence of nitrate, the metallation rate is almost unaffected in the pH range 4.4–5.5 and accelerated at higher pH.[7] On the contrary, in the presence of polyglutamate the metallation rate increases with pH (*i.e.* with the number of negative charges on the polypeptide) in the range *ca*. 4.5–5.5 and then does not increase further at higher pHs. Also, at pHs lower than *ca*. 4.5 the insertion reaction is not catalyzed by polyglutamate. This observation suggests that, unlike other ligands,** the 'catalytic' role of the anionic template must be related to its electrostatic field by (i) increasing the 'local' concentration of metal ions,[8] and (ii) partially shielding the positive charges of the H_2T4 monodispersed on it (thus facilitating the approach of the cationic metal ions to the cationic porphyrins). As expected according to this hypothesis, no appreciable increase of metallation rate was observed when Zn^{II} or Cu^{II} were added to the solution containing the tetraanionic *meso*-tetrakis(4-sulfonatophenyl)-porphine monodispersed on the protonated polylysine. Most likely, the state of the porphyrins also plays a role in the reaction rate trend observed at pH lower than *ca*. 4.5. Decreasing the pH, H_2T4 tends to aggregate on polyglutamic acid.¶ In this case, the porphyrins face-to-face arrangement[9] should reduce the accessibility of the metal ions to the porphine 'core'. This hypothesis is in good agreement with previous experiments by Pasternack *et al.*[10] which show that aggregation and/or intercalation of porphyrins onto or into synthetic DNA have a negative influence on porphyrin metallation rate. Therefore, the nature of the matrix and of the supramolecular complex (*i.e.* of the molecular recognition processes) is crucial to allow the catalysis of the metal insertion by an anionic template.

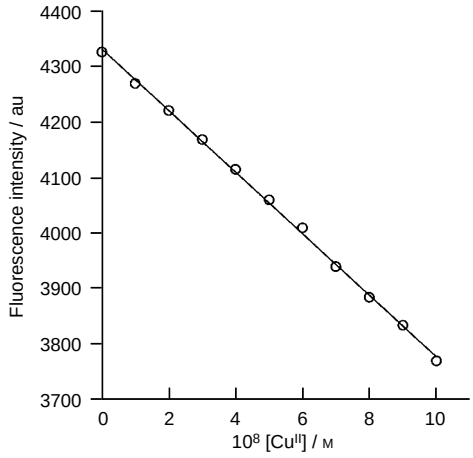

Fig. 3 Plot of fluorescence intensity at 655 nm (λ_{ex} = 422 nm) *vs.* Cu^{II} concentration, for a solution of H_2T4 (1 μM) in the presence of polyglutamate (200 μM) at pH 5.6 (succinate buffer 2 mM)

Finally, the addition of other metal ions, such as Co^{II}, Fe^{II}, Mg^{II}, Mn^{II} and Ni^{II} does not cause any of the spectroscopic variations described above in a time interval comparable to that observed for Zn^{II} and Cu^{II}. A reasonable explanation for this behavior is that the 'uncatalyzed' rate of insertion for Co^{II}, Fe^{II}, Mg^{II}, Mn^{II} and Ni^{II} in H_2T4 is much lower than that of Zn^{II} and Cu^{II}.

In conclusion, a selective and very sensitive supramolecular sensor for metal ions has been obtained by means of extremely simple routes. To date, the non-covalent nature of these species, and therefore their relatively low robustness, has hindered their application for the development of chemical devices. Further studies are currently in progress in our laboratory to investigate possible technological applications.

‡ The term sensor in the following context is not used to indicate a device, but rather a chemical system able to recognize a species and to report its recognition (*e.g.* by spectroscopic variations).

§ For example, absorption and emission maxima for ZnT4 and H_2T4 are λ_{ex} = 436 nm, λ_{em} = 622 nm, and λ_{ex} = 422 nm, λ_{em} = 655 nm, respectively. On the other hand, the insertion of Cu^{II} causes a complete quenching of the fluorescence of H_2T4 (a weak emission, centered at *ca.* 770 nm, has been found in water, but only when CuT4 is intercalated into natural or synthetic DNAs).[4]

¶ H_2T4 is aggregated on polyglutamate in the pH range 3.4–4.5, and is monodispersed on the polypeptide both at higher and lower pHs (E. Bellacchio, S. Gurrieri, L. Monsù Scolaro and R. Purrello, in progress).

‖ In order to minimize the contribution of H_2T4 fluorescence, the excitation wavelength used in these experiments is 445 nm.

** Acceleration of porphyrins metallation has been also observed in the presence of simple ligands such as acetate, pyridine, ammonia, nitrate and ascribed to labilization of the water molecules bound to the metal ion.[7]

Synthesis of highly branched block copolymers of enantiomerically pure amino acids

Andrew C. Birchall and Michael North*†

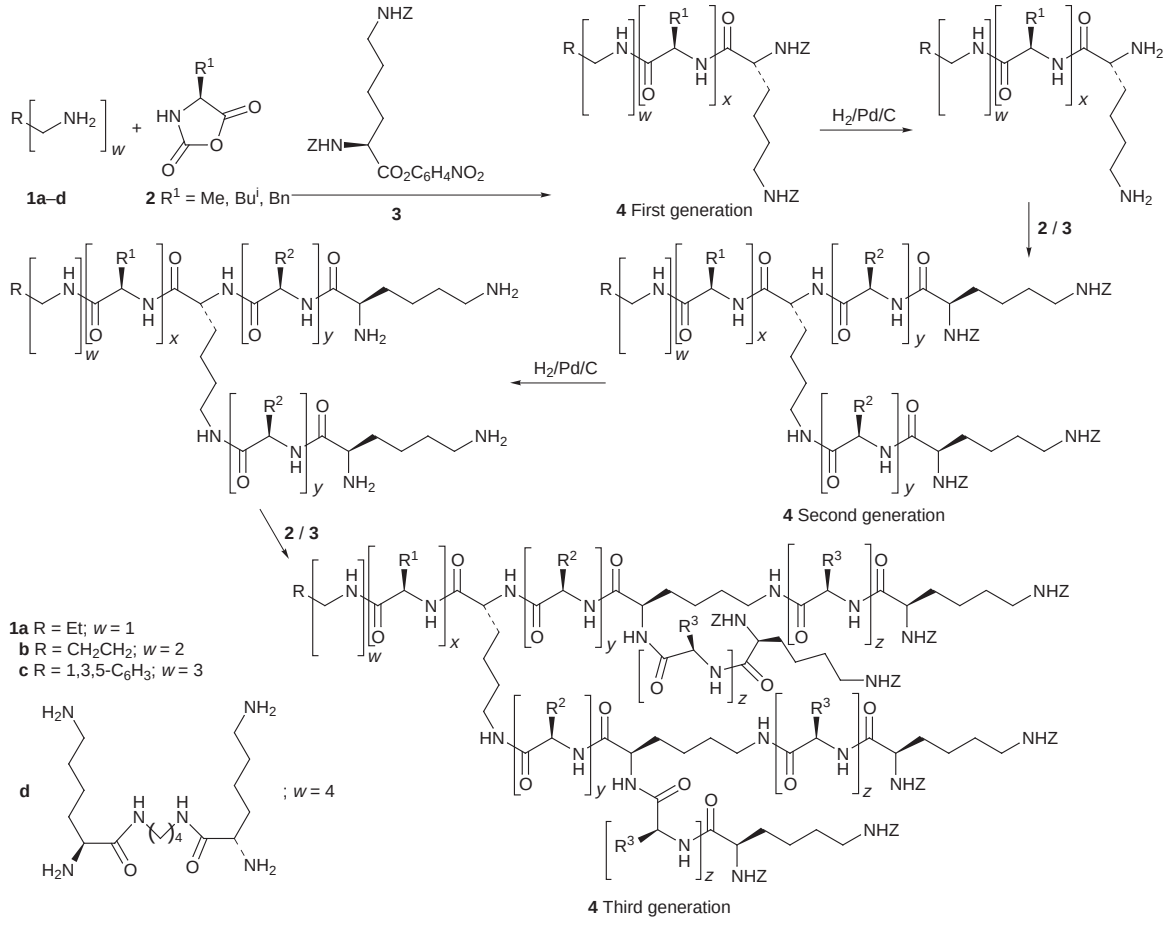
Department of Chemistry, University of Wales, Bangor, Gwynedd, UK LL57 2UW

The combination of multifunctional initiators and the use of lysine residues to introduce branch points into poly(amino acids) allow the synthesis of highly branched poly(amino acids).

In recent years, there has been considerable interest in the synthesis of synthetic polymers with non-linear molecular architectures.[1] Much work in this area has concentrated on the synthesis and investigation of dendrimers,[2] polymers which have precisely controlled molecular weights and geometry. However, for many applications, the variety of molecular weights found in conventional synthetic polymers leads to desirable physical properties. Thus there is a need for methodology which will allow the synthesis of polydisperse, highly branched polymers. We have an ongoing interest in the preparation of synthetic polymers derived from biomonomers,[3] and here the synthesis of highly branched, polydisperse poly(amino acid)s is reported.

The synthesis of the desired polymers is outlined in Scheme 1. An initiator **1a**–**d** containing one to four primary amino groups was used to polymerize the *N*-carboxy anhydride **2** of an amino acid.‡ This is a well known process for the preparation of poly(amino acid)s,[4] however it was anticipated that, provided termination reactions could be avoided, the addition of *N*,*N*′-di(benzyloxycarbonyl)lysine *p*-nitrophenyl ester **3** to the polymerization mixture would produce capped polymers **4**. Subsequent hydrogenation of polymers **4** would reveal two primary amino groups on each chain of the initial polymer which could be used to initiate the polymerization of a second *N*-carboxy anhydride of an amino acid. Capping of this polymerization by lysine derivative **3** would give the next generation of the polymer, and the process could be repeated indefinitely to give highly branched poly(amino acids).

In practice, unfunctionalized amino acid *N*-carboxy anhydrides **2** were employed in order to avoid the undesired termination reactions which are known to occur with functionalized amino acids such as γ-esters of glutamic acid.[5] It was also found to be advantageous to keep each polymer chain relatively short (5–10 amino acids) in order to avoid solubility problems, although even polymers prepared in this way were soluble only



Scheme 1

[a] The numbers in brackets correspond to the average number of amino acids incorporated into each branch of the polymer as determined by ^{1}H NMR spectroscopy. [b] M_n and M_w values were obtained from GPC data calibrated with polystyrene standards. [c] Calculated from the integration trace of the ^{1}H NMR spectrum.

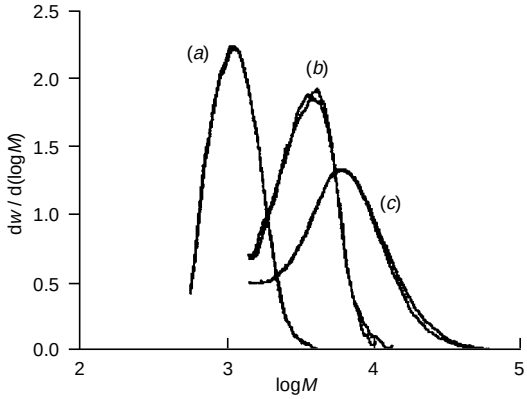

Fig. 1 The GPC chromatograms for the polymers corresponding to entries (*a*) 1, (*b*) 2 and (*c*) 3 in Table 1. Each chromatogram was run in duplicate.

in polar aprotic solvents, which restricted the methods which could be used for their characterization. Initial studies were carried out using propylamine **1a** as a monofunctional initiator, and the polymerizations were repeated to the third generation. The structures and molecular weights of the polymers are given in Table 1. In each case, the polymers were characterized by solution state ^{1}H NMR spectroscopy, solution or solid state ^{13}C NMR spectroscopy and GPC. Typical GPC chromatograms are shown in Fig. 1. It is apparent from Fig. 1 that the molecular weight of the polymer increases as each amino acid is added to the polymer, and that the peak corresponding to the precursor polymer disappears at each stage. In some cases (*e.g.* entries 4–6 in Table 1), however, the low molecular weights of alanine and leucine combined with the small number of residues being introduced meant that GPC was unable to detect the change in the size of the polymer.

Having shown that branched polymers could be prepared by this methodology, the use of initiators **1b**–**d**[6]§ bearing two to four primary amino groups was investigated. As Table 1 shows, in each case it was possible to obtain the desired branched poly(amino acid)s exactly as in the case of initiator **1a**. However, an increasing discrepancy between the calculated and experimental M_n values is apparent in these polymers (*e.g.* entries 7–9 in Table 1). This is probably due to the fact that GPC separation is based on molecular size rather than molecular weight, and for branched polymers, the relationshp between molecular size and molecular weight is non-linear.

In conclusion, we have shown that it is possible to prepare highly branched polymers derived from amino acids. The polymers are expected to have a number of applications including asymmetric catalysts, biomimetic polymers, biodegradable polymers and biocompatible polymers. Our work in this area is continuing.

The authors thank the EPSRC for a studentship (to A. C. B.), and the EPSRC GPC (RAPRA UK Ltd.), solid state NMR (Durham) and mass spectrometry (Swansea) services for their invaluable assistance with this work.

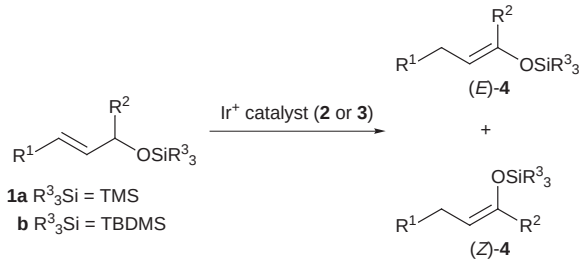
A stereoselective isomerization of allyl silyl ethers to (*E*)- or (*Z*)-silyl enol ethers using cationic iridium complexes

Toshimichi Ohmura, Yasuo Shirai, Yasunori Yamamoto and Norio Miyaura*†

Division of Molecular Chemistry, Graduate School of Engineering, Hokkaido University, Sapporo 060-8628, Japan

A cationic iridium complex, prepared *via* the hydrogenation of $[Ir(cod)_2]PF_6$–$2PPr_3$ is found to be an excellent catalyst for the stereoselective isomerization of primary allyl silyl ethers to (*E*)-enol ethers and secondary allyl ethers to (*Z*)-enol ethers.

The transition metal-catalyzed positional isomerization of double bonds is an excellent method which has been used in a variety of organic transformations,[1] such as the synthesis of ketones or aldehydes from allylic alcohols, the conversion of allylic ethers to enol ethers, and the transfer of double bonds to the carbon adjacent to carbonyl groups. Among them, the catalytic isomerization of allyl ethers to enol ethers has been studied quite extensively because the procedure is convenient and straightforward and uses readily available substrates, although their stereoselective transformation has not received much attention. The enol ethers thus obtained are either (*Z*)- or (*E*)-isomers, or a mixture of two in most cases. For example, a ruthenium complex gives an equilibrium mixture with the (*Z*)-enol ether predominating (*Z* > 55–68%),[2] while a cationic iridium(III) complex, in contrast, stereoselectively produces (*E*)-enol ethers (*E* > 97%).[3]



Scheme 1

We have recently demonstrated the efficiency of a cationic iridium catalyst for the stereoselective preparation of (*E*)-γ-alkoxyallylboronates from (3-alkoxy-1-alkenyl)boronates.[4] However, the difficulty in reproducing high stereoselectivities on various substrates prompted us to re-investigate the reactioin detail. One of the early, and still one of the most frequently used, routes to (*E*)- or (*Z*)-silyl enol ethers is the trapping of ketone or aldehyde enolates generated under conditions of either kinetic or equilibrium control conditions.[5] However, the catalytic isomerization may offer a reliable and economical route from readily available allylic alcohols (Scheme 1).

The cationic iridium(III) complex **2** generated *in situ* by hydrogenation of $[Ir(cod)(PMePh_2)_2]PF_6$ in THF, produced a very active catalyst, reported by Felkin, which isomerizes primary allyl ethers to (*E*)-enol ethers, but it was unfortunately

Table 1 Effect of catalysts on the isomerization of **1b** (R^1 = H, R^2 = Ph)[a]

Entry	Catalyst	Yield (%)	*E* : *Z*
1	$[Ir(cod)(PPh_2Me)_2]PF_6/H_2$	trace	
2	$[Ir(cod)(PPh_2Me)_2]PF_6$/catecholborane	12	36 : 64
3	$[Ir(cod)(PPh_3)_2]PF_6$/catecholborane	10	42 : 58
4	$[Ir(cod)_2]PF_6$–$2PMe_3/H_2$	0	
5	$[Ir(cod)_2]PF_6$–$2PEt_3/H_2$	76	8 : 92
6	$[Ir(cod)_2]PF_6$–$2PPr_3/H_2$	92	12 : 88
7	$[Ir(cod)_2]PF_6$–$2PBu_3/H_2$	96	10 : 90
8	$[Ir(cod)_2]PF_6$–$2PCy_3/H_2$	0	
9	$[Ir(cod)_2]PF_6$–dppe/H_2	0	

[a] To a solution of catalyst (3 mol%) in CH_2Cl_2 (3 ml)–acetone (0.5 mmol) was added **1b** (R^1 = H, R^2 = Ph) (0.5 mmol), and the resulting solution was then stirred for 30 min at room temperature. The catalysts were prepared *in situ* by bubbling hydrogen into a solution of $[Ir(cod)(PR_3)_2]PF_6$ or into a mixture of $[Ir(cod)_2]PF_6$ (0.015 mmol) and R_3P (0.03 mmol) (entries 1 and 4–9). To a solution of $[Ir(cod)(PR_3)_2]PF_6$ (3 mol%) and **1b** (0.5 mmol) was added catecholborane (3 mol%) at room temperature (entries 2 and 3).

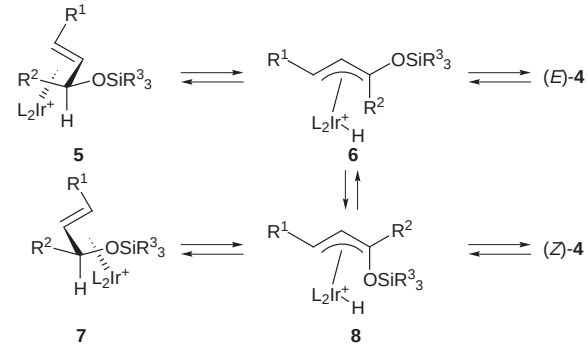
[a] Hydrogen was bubbled into a mixture of $[Ir(cod)_2]PF_6$ (0.015 mmol) and PPr_3 (0.03 mmol) in acetone (3 ml) or CH_2Cl_2 (3 ml)–acetone (0.5 mmol) to give a pale yellow solution of the catalyst **3**. The excess hydrogen was then removed by bubbling argon into the solution. An allyl silyl ether (0.5 mmol) was added and the resulting mixture was then stirred for 30 min at room temperature. [b] The reaction was carried out for 10 min in the presence of 1 mol% of the catalyst because the conditions using 3 mol% catalyst for 30 min resulted in lower selectivity (*E* = 87–93%). [c] Catecholborane (0.015 mmol) was added to a mixture of $[Ir(cod)(PPh_2Me)_2]PF_6$ (0.015 mmol) and allyl silyl ether (0.5 mmol) in acetone. [d] The reaction accompanied by 5–6% of CH_2=CEtOSiR$^3{}_3$.

not effective for secondary allyl ethers such as **1b** (R^1 = H, R^2 = Ph) (entry 1 in Table 1). Similarly to the treatment with hydrogen, various metal hydrides were found to activate the Ir-cod complexes, presumably by removing the cod ligand *via* hydrometalation. The addition of catecholborane or DIBAL-H (1 equiv.) generated the more active catalyst solution than treatment with hydrogen, but the arylphosphine derivatives did not give good results due to their large steric hindrance (entries 2 and 3). Finally, Ir–trialkylphosphine complexes **3** obtained by hydrogenation of a mixture of $[Ir(cod)_2]PF_6$[6] and R_3P (R = Et, Pr, Bu) (2 equiv.) gave an excellent catalyst for the isomerization of secondary allyl ethers with (*Z*)-**4** predominating (*Z* = 88–92%) (entries 5–7). Trimethylphosphine, tricyclohexylphosphine (PCy_3) and bidentate phosphine ligands such as dppe are not effective (entries 4, 8 and 9).

The isomerization of the representative allyl silyl ethers with **3** (R = Pr) is summarized in Table 2. In an acetone solution, the isomerization of primary allyl ethers was completed within 30 min, provided (*E*)-**4** in high yields and with high selectivity, results which were comparable to those obtained for reactions catalyzed by **2** (entries 1–5). The reaction was further accelerated in a mixed solvent of acetone and CH_2Cl_2 giving (*Z*)-**4** predominantly (*E* : *Z* = 24 : 76) (entry 1), although all attempts for the stereoselective preparation of (*Z*)-**4** were unsuccessful. The *Z*-selectivity further improved for secondary allyl trimethylsilyl ethers (entries 6–10), especially when R^2 was a secondary alkyl unit (entries 8 and 9). Both catalysts reported by Felkin (**2**) and **3** worked well for primary allyl ethers (entry 4), but **3** demonstrated a higher catalytic efficiency for secondary allyl ethers.

The iridium-catalyzed isomerization of allyl ethers proceeds through the oxidative addition of an allylic C–H bond to the iridium(I) metal center giving a *syn*-π-allyliridium complex **6** which selectively led to (*E*)-**4** (Scheme 2).[1–3]

The ^1H NMR study reveled that the isomerization involves two process: the first and selective formation of (*E*)-**4** (kinetically controlled process) is followed by equilibration to a mixture of (*E*)- and (*Z*)-**4** through the *anti*-π-allyl intermediate (thermodynamically controlled process) which is slow in a solvent coordinating to the iridium metal center such as acetone.[7] Thus, the stereochemistry of **4** is highly dependent on the solvents and the substrates. When primary allyl ethers were



Scheme 2

reacted in acetone, the kinetic products [(*E*)-**4**] were obtained through the *syn*-π-allyl intermediate [**5** → **6** → (*E*)-**4**]. On the other hand, high *Z*-selectivity was achieved for secondary allyl ethers under conditions leading to equilibration, where the steric difference between the R^2 and R_3Si groups controls the stereochemistry of the products [**5** → **6** → **8** or **7** → **8** → (*Z*)-**4**].

Mukaiyama aldol reactions of π-allyltricarbonyliron lactone and lactam complexes bearing trimethylsilyl enol ether side-chains. Not just formal, but genuine 1,7 induction of chirality

Steven V. Ley,*† Liam R. Cox, Ben Middleton and Julia M. Worrall

Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW

A comparison of diastereoselectivities in the Mukaiyama aldol reactions of three types of trimethylsilyl enol ether substituted iron carbonyl complexes has provided evidence for the stereodirecting effect of remote substituents in π-allyltricarbonyliron lactone and lactam complexes.

The complexation of an organic ligand to a metal can influence the stereoselectivity of its reactions in a variety of ways. We have previously demonstrated the use of the π-allyltricarbonyliron lactone framework[1] as a chiral template to provide diastereocontrol in the manipulation of a ketone functionality appended to the allyl unit.[2,3] The reactions of such ketones with nucleophiles proceed with predictable stereochemistry, the ketone adopting an s-*cis* conformation and the nucleophile approaching *anti* to the bulky $Fe(CO)_3$ moiety. This parallels the reactivity pattern of the related η⁴ dienone tricarbonyliron complexes (Fig. 1).[4]

More recently, we have shown that trimethylsilyl enol ethers derived from *endo* substituted π-allyltricarbonyliron lactone complexes can undergo highly diastereoselective Mukaiyama aldol reactions with a variety of aldehydes under $BF_3{\cdot}OEt_2$ activation.[5] The selectivity in these reactions is more difficult to explain, as it is dependent only on the ability of the enol ether side-chain to distinguish between the prochiral faces of the Lewis acid–aldehyde complex. Interestingly, the trimethylsilyl enol ethers of η⁴ dienone tricarbonyliron complexes have been reported to show poor diastereoselectivity in their reactions with aldehydes under $BF_3{\cdot}OEt_2$ activation.[6] This apparent difference in the influence of the structurally similar enol ether substrates implies that the lactone portion of the π-allyl complexes might be involved in controlling the delivery of the aldehyde. More specifically, the *endo* substituent at the lactone tether, *seven* carbon atoms distant from the developing stereocentre, could interact directly with the incoming Lewis acid–aldehyde complex (Fig. 2).

This communication reports an investigation of diastereocontrol in the Mukaiyama aldol reactions of π-allyltricarbonyliron lactone and lactam complexes by variation of the substitution pattern at the tether and a direct comparison with a representative η⁴ diene tricarbonyliron complex.

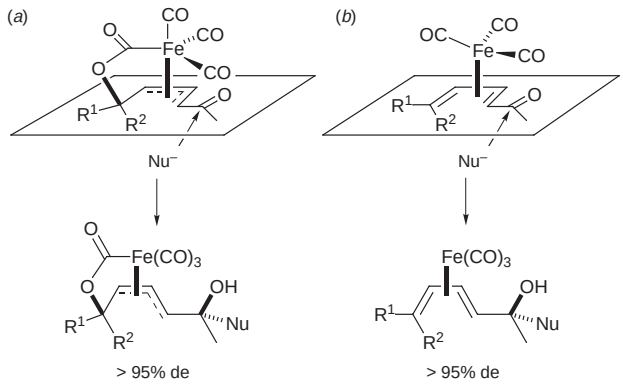

Fig. 1 Tricarbonyliron-mediated diastereocontrol: reaction of (*a*) ketone functionalised π-allyltricarbonyliron lactones and (*b*) η⁴-dienone complexes with nucleophiles

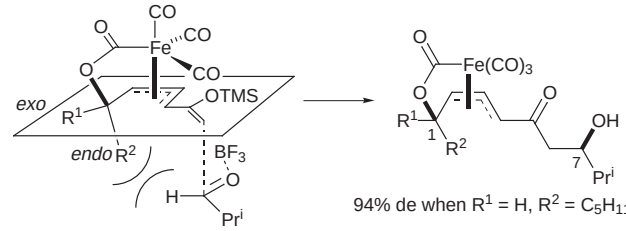

Fig. 2 Possible involvement of the *endo* substituent in directing Mukaiyama aldol reactions of π-allyltricarbonyliron lactone complexes

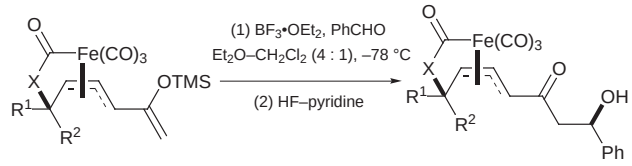
Trimethylsilyl enol ethers were prepared in excellent yields from the corresponding methyl ketone complexes by reaction with TMSOTf and Et_3N in CH_2Cl_2 at 0 °C. Treatment with premixed benzaldehyde and $BF_3{\cdot}OEt_2$ in Et_2O–CH_2Cl_2 at −78 °C afforded mixtures of TMS protected and unprotected aldol products which were desilylated using HF–pyridine during the work-up. A comparison of the yields and diastereoselectivities obtained using π-allyltricarbonyliron lactone and lactam complexes is shown in Table 1.

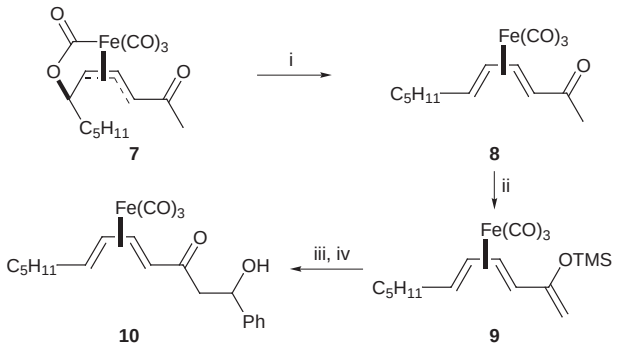
The *endo* substituted complexes **1**, **2**, **3** and **5** showed good to excellent levels of asymmetric induction in their reactions with benzaldehyde. The slightly lower diastereomeric excess obtained with the *endo* phenyl complex **3** may reflect the contribution of a favourable interaction between the aromatic rings of the complex and aldehyde. The diastereomeric excesses obtained when the complex was *exo* substituted (complexes **4** and **6**) were significantly reduced, showing that an important

Table 1 Mukaiyama aldol reaction of silyl enol ethers derived from π-allyltricarbonyliron lactone and lactam complexes with benzaldehyde



Complex	R^1	R^2	X	Yield (%)	De (%)[a]
1	H	C_5H_{11}	O	81	86
2	H	Me	O	81[b]	87
3	H	Ph	O	72	67
4	C_5H_{11}	H	O	53	55
5	H	Me	NBn	66[b]	90
6	Me	H	NBn	62[b]	57

[a] Diastereomeric excess determined by comparison of integrals in the ^1H NMR spectrum of the crude reaction mixture. [b] Reaction carried out in neat CH_2Cl_2 due to low Et_2O solubility of the substrate; this led to improved yields but did not affect the de.



Scheme 1 *Reagents and conditions*: i, $Ba(OH)_2$ MeOH, room temp., 15 min, 92%; ii, Et_3N, TMSOTf, CH_2Cl_2, 0 °C, 90 min, 92%; iii, $BF_3{\cdot}OEt_2$, PhCHO, Et_2O–CH_2Cl_2 (4 : 1), − 78 °C, 1 h; iv, HF–Py, THF, 30 min, 64% yield over 2 steps, 25% de

element of the stereocontrol is indeed lost when the *endo* substituent R^2 is replaced by hydrogen. No significant difference in selectivity was observed between π-allyltricarbonyliron lactone and lactam complexes.

The (*E*,*E*) η^4-diene complex **8** was easily prepared from lactone complex **7** by treatment with barium hydroxide solution.[2b,7] Formation of the trimethylsilyl enol ether **9** in the usual way and reaction with benzaldehyde under standard conditions resulted in the formation of aldol product **10** with only 25% diastereomeric excess (Scheme 1). The selectivity is therefore significantly lower than even that achieved with *exo* substituted lactone and lactam complexes. The relative stereochemistry of the major diastereoisomer was determined for the reactions of complexes **1**, **6** and **9** by stereospecific reduction of the β-hydroxy ketone products to 1,3-diols followed by acetonide formation[5] and was found to be the same in each case as shown.

In summary, the Mukaiyama aldol reactions of a range of *endo* substituted π-allyltricarbonyliron lactone and lactam complexes proceed with high yields and diastereoselectivities. The lack of an *endo* substituent results in a significant decrease in the observed selectivity. A further decrease in selectivity occurs when the mode of attachment of the iron tricarbonyl unit is altered by conversion of the π-allyl complex into an η^4 diene complex. It therefore appears that the tricarbonyliron lactone or lactam unit provides control on a number of different levels during the reaction. The silyl enol ether functionality is maintained in a specific orientation and shielded from one face by the tricarbonyliron group, while on the opposite face a remote substituent is projected to create a chiral environment, restricting the possible orientations of the incoming boron trifluoride–aldehyde complex.

Synthesis and structure of the heterobimetallic oxo complex $[(thf)(Me_2NH)_2Cl_2Cr^{III}]_2\{ClSn^{II}(\mu\text{-}O)\}_2$

Michael A. Beswick,[a] Nick Choi,[b] Mary McPartlin,[b] Marta E. G. Mosquera,[a] Julie S. Palmer[a] and Dominic S. Wright*[a]†

[a] *Chemistry Department, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *School of Chemistry, University of North London, Holloway Road, London, UK N7 8DB*

The reaction of $[Sn(NMe_2)_2]$ with a suspension of $CrCl_3$ and H_2O in thf gives the molecular $Cr^{III}Sn^{II}$ oxo complex $[(thf)(Me_2NH)_2Cl_2Cr]_2\{ClSn(\mu\text{-}O)\}_2$ 1, in which the O atoms of a central Sn_2O_2 ring coordinate two Cr^{III} cations.

Oxo complexes of Sn are an extensive and highly structurally varied class of compounds. Organotin(IV) oxo complexes are commonly prepared by hydrolysis of organotin(IV) halides or carboxylates or by the oxidation of organotin(II) complexes.[1] The functionality and steric bulk of the organic groups is crucial in dictating the geometries of the metal cores in these species and the nuclearity of the resulting cage arrangements. In contrast, structurally characterised tin(II) oxo complexes are rare and there are no general methods for their preparation.[2] The trapping of SnO fragments into molecular arrangements has been achieved by their incorporation into the frameworks of tin(II)/(IV) host complexes,[2a,c,e] by the formation of Lewis acid/base adducts with tin(II) complexes,[2b,d] or by coordination of transition metal carbonyls to the Sn lone pairs.[2f,g] In previous studies we showed that the low-temperature reactions of primary amines with dimethylamido p block metal reagents $\{[E(NMe_2)_x]$; E = Sn (x = 2), Sb (x = 3)$\}$ furnishes a simple route to imido and phosphinidene cage compounds [Scheme 1(*a*)].[3] We describe here the discovery that the analogous reactions of metal aqua complexes with dimethylamido p block reagents provide a new route to heterometallic oxo-complexes [Scheme 1(*b*)].

(*a*) $R{-}NH_2 + [E(NMe_2)_x] \longrightarrow [R{-}N\{E(NMe_2)_{x-2}\}] + 2Me_2N$

(*b*) $M{-}OH_2 + [E(NMe_2)_x] \longrightarrow [M{-}O\{E(NMe_2)_{x-2}\}] + 2Me_2N$

Scheme 1

The reaction of $[Sn(NMe_2)_2]$ with Bu^tNH_2–NH_3–1,4-dioxane in thf followed by addition of $CrCl_3$ was initially undertaken with a view to preparing a heterometallic Sn^{II}/Cr^{III} imido/nitrido complex. However, the product is a mixture of Sn^{II}/Cr^{III} oxo complexes $[(Me_2NH)_2(thf)CrCl_2]_2\{ClSn(\mu\text{-}O)\}_2\cdot L$ (L = 1,4-dioxane or Bu^tNH_2), the oxo ligand arising as a result of partial hydrolysis of the precursor $CrCl_3$. Further studies revealed that basic conditions catalyse this reaction and the stoichiometric reaction of a mixture of $CrCl_3$ and H_2O (1 : 1 equiv.) in thf–Bu^tNH_2 (1 equiv.) with $[Sn(NMe_2)_2]$ (1 equiv.) affords $[(Me_2NH)_2(thf)CrCl_2]_2\{ClSn(\mu\text{-}O)\}_2\cdot Bu^tNH_2$ (**1**·Bu^tNH_2) as the sole product (Scheme 2).‡

$$2CrCl_3 + 2H_2O \xrightarrow[\text{base}]{2[Sn(NMe_2)_2]} [\{(thf)(Me_2NH)_2CrCl_2\}_2\{ClSn(\mu\text{-}O)\}_2]$$
1

Scheme 2

An X-ray crystallographic study of **1**§ as the 1,4-dioxane solvate reveals that the complex is composed of bimetallic molecules $[(Me_2NH)_2(thf)CrCl_2]_2\{ClSn(\mu\text{-}O)\}_2$ (Fig. 1) which are loosely associated by lattice-bound 1,4-dioxane molecules into a hydrogen-bonded network *via* C–H···O hydrogen bonds to the terminal thf ligands. Although a few examples of mixed transition metal–p block metal oxo complexes have been structurally characterised, all of these have relied on alkoxide functionalities to support the association of the metals, *e.g.* in $[Pb_2Ti_2(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_4(OPr^i)_4]$.[4] The molecular arrangement of **1**, effectively resulting from the trapping of a central $[ClSn(\mu\text{-}O)]_2$ fragment by the coordination of the O centres to two Cr^{III} cations, is unique among main group oxo compounds. The closest analogy is found in the tin(II) complex $[\{Me_3Si(NBu^t)_2Sn_2O\}SnCl_2]$ in which a $SnCl_2$ molecule is coordinated by the O atom of a $[Me_3Si(NBu^t)_2\{Sn_2(\mu\text{-}O)\}]$ ligand.[2b]

Despite the planarity of the O centres of **1** and the possibility of a degree of multiple bond character in the Cr–O bonds, the pattern of bond lengths and angles found in the $[Sn(\mu\text{-}O)]_2Cr_2$ portion of **1** is consistent with its formulation as a coordination complex between a $[ClSn(\mu\text{-}O)]_2^{2-}$ dianion and two Lewis base solvated $CrCl_2^+$ cations {rather than the alternative resonance extreme involving $[Cl_2Cr{=}O]^-$}. The central, planar $[Sn(\mu\text{-}O)]_2$ ring of **1** is rhombic shaped, with the internal angles at Sn and O [Sn–O–Sn 104.2(2), O–Sn–O 75.8(2)°] being similar to those present in the dimeric units of more elaborate tin(II) oxo compounds.[2e] In addition, the Sn–O bonds fall in the expected range (Sn–O av. 2.11 Å in **1**; *cf. ca.* 2.05–2.10 Å[2]). Significantly, the Cr–O bonds [1.893(4) Å] are only marginally below the value expected for single Cr–O bonds (*ca.* 1.93 Å)[5] and noticeably longer than those found for Sn–O–Cr linkages in organotin(IV) chromates.[6] In addition to their coordination by the O centres of the $[Sn(\mu\text{-}O)]_2$ ring, each of the Cr^{III} ions is also coordinated by two *trans*-Me_2NH ligands, by two *trans*-Cl^- ions and by one thf ligand, giving an octahedral geometry which is typical of Cr^{III}. The orientation of the Me_2NH groups, whose

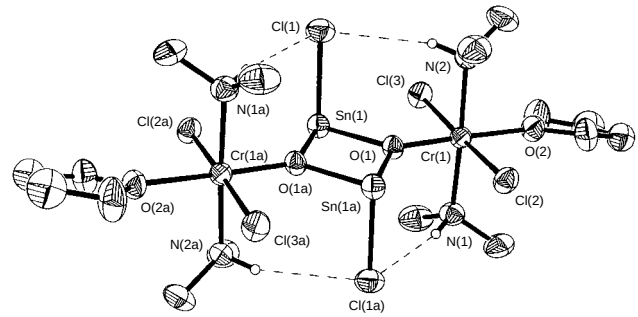

Fig. 1 ORTEP drawing of centrosymmetric molecular structure of **1**·1,4-dioxane. Thermal ellipsoids are at the 40% probability level. Selected bond lengths (Å) and angles (°); Sn(1)–Cl(1) 2.541(2), Sn(1)–O(1) 2.108(4), Sn(1)–O(1a) 2.103(4), Cr(1)–O(1) 1.893(4), Cr(1)–N(1) 2.140(5), Cr(1)–N(2) 2.135(5), Cr(1)–Cl(2) 2.327(2), Cr(1)–Cl(3) 2.334(2), Cr(1)–O(2) 2.108(4), H(2)···Cl(1) 2.59, H(1)···Cl(1a) 2.77, O(1)–Sn(1)–O(1a) 75.8(2), Sn(1)–O(1)–Sn(1a) 104.2(2), Cr(1)–O(1)–Sn(1, 1a) mean 127.9, O(1)–Cr–O(2) 178.4(2), N(1)–Cr(1)–N(2) 176.9(2), Cl(2)–Cr(1)–Cl(3) 177.94(8). Symmetry transformations used to generate equivalent atoms, a $-x + 1, -y - 1, -z + 1$.

H atoms are directed toward the Sn-bonded Cl^- ligands, and the presence of relatively short H···Cl contacts [H(2)···Cl(1) 2.59, H(1)···Cl(1a) 2.77 Å] indicates that the molecular arrangement of **1** is partially supported by hydrogen bonding. Further evidence for hydrogen bonding is the slight axial distortion of the Me_2NH groups towards the Cl atoms [N(2)–Cr(1)–N(3) 176.9(2)°]. These interactions give a reason for the *trans* coordination of the Cr^{III} cations by the Me_2NH and Cl^- ligands (as opposed to the alternative *cis* isomer).

Further studies are in hand to determine the generality of similar deprotonation reactions in the synthesis of hetero-metallic oxo and nitrido complexes containing a variety of mixed-metal compositions.

‡ *Synthesis of* **1**·Bu^tNH_2: to a suspension of anhydrous $CrCl_3$ [0.31 g, 2.5 mmol, (Aldrich 99.9%)] in thf (20 ml) was added degassed H_2O (0.05 ml, 2.5 mmol). The mixture was stirred for 24 h at 25 °C. Bu^tNH_2 (0.26 ml, 2.5 mmol) was added and after stirring at 25 °C (20 min) the temperature was lowered to −78 °C and $[Sn(NMe_2)_2]$ (0.52 g, 2.5 mmol) in thf (10 ml) was added slowly. The mixture was allowed to warm to room temperature and the green solution produced was filtered to remove a white precipitate. The filtrate was reduced to *ca*. 20 ml under vacuum and storage at 5 °C (48 h) gave light brown crystals of **1**·Bu^tNH_2. Yield 0.38 g, 31%. decomp. > 255 °C to black solid. IR (Nujol), ν_{max}/cm^{-1} 3352w, 3166w (N–H str), other bands at 1288w, 1256m, 1118s, 1080m, 1018s, 922m, 871m, 800m, 721w. ^1H NMR [$(CD_3)_2SO$, +25 °C, 250 MHz], 5.80 (br s, Me_2NH), 3.59 (s), 1.76 (s, thf), 2.32 (s, Me_2NH), 1.21 (s, Bu^tNH_2), overlapping of the resonances due to paramagnetic broadening made accurate integration impossible. Anal. calc. for **1**·Bu^tNH_2, C, 24.5; H, 5.2; N, 7.2; Cl, 21.8. Found; C, 23.8; H, 5.3; N, 7.2; Cl, 20.4%.

The reaction of $[Sn(NMe_2)_2]$ (0.53 g, 2.5 mmol) in thf (20 ml) with NH_3 (1.27 ml solution of 0.5 mol dm^{-3} in dioxane, 0.64 mmol) and Bu^tNH_2 (0.20 ml, 1.91 mmol) was aimed at the formation of the cubane $[Sn_4(NBu^t)_3NH]$. A red–brown solid formed after a few minutes. To this was added $CrCl_3$ (0.10 g, 0.81 mmol, 'anhydrous'). The mixture was stirred (1 h) giving a dark green solution. The insoluble material was filtered off and the filtrate concentrated to *ca.* 10 ml. Et_2O (3 ml) was added and storage at 5 °C (48 h) gave **1**·1,4-dioxane and **1**·Bu^tNH_2 as a mixture in low yield. The ^1H NMR spectrum is identical to that obtained separately for **1**·Bu^tNH_2 (δ 1.19, Bu^t) but with a dioxane resonance at δ 3.60. Only **1**·1,4-dioxane could be obtained as crystals from the mixture and repeated attempts to obtain single crystals of **1**·Bu^tNH_2 have so far failed.

§ *Crystal data* for **1**: $C_{10}H_{26}Cl_3CrN_2O_3Sn$, M = 998.74, monoclinic, space group $P2_1/n$, a = 8.002(1), b = 14.956(2), c = 15.855(2) Å, β = 99.81(1)°, U = 1869.9(5) $Å^3$, Z = 2, D_c = 1.77 Mg m^{-3}, λ = 0.710 73 Å, T = 223(2) K, μ(Mo-Kα) = 2.351 mm^{-1}, F(000) = 996. Data were collected on a Siemens P4 diffractometer using an oil-coated rapidly-cooled crystal of dimensions 0.30 × 0.30 × 0.30 mm by the ω–2θ method (1.88 ⩽ θ ⩽ 25.00°). Empirical absorption corrections were applied after initial refinement with isotropic displacement parameters.[7] Of a total of 4391 collected reflections, 3295 were independent (R_{int} = 0.027). The structure was solved by direct methods and refined by full-matrix least squares on F^2 to final values of $R1[F > 4\sigma(F)]$ = 0.040 and $wR2$ = 0.114 (all data) [$R1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ and $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = 1/[\sigma^2(F_o^2) + (0.0535P)^2 + 2.9000P]$, $P = F_o^2 + (2F_c^2/3)$];[8] largest peak and hole in the final difference map 0.60 and −0.58 e $Å^{-3}$. Two of the C atoms of the Cr-bonded thf ligands are disordered. These were modelled with 1 : 1 occupancy. CCDC 182/869.

The synthesis of *meso*-5,15-bis(*m*-aminophenyl)porphyrin bearing two acridine derivatives and of its manganese(III) complex was achieved; in the presence of oxygen atom donors, the metalloporphyrin was shown to cleave double-stranded DNA.

Although the development of abiotic or biomimetic systems capable of probing[1] and/or cleaving[2] DNA has been a topic of active research over the last two decades, the design and synthesis of topo- and regio-selective artificial nucleases is still a current challenge.

The cleavage of DNA may either occur under hydrolytic or oxidative conditions. Dealing with the latter case, transition metal complexes,[3] in particular metalloporphyrins[4] have been shown to act, in the presence of oxygen donor reagents, by oxidation of the sugar units. The interactions between the tetracationic manganese porphyrins complexes such as *meso*-tetrakis(4-*N*-methylpyridiniumyl)porphyrinatomanganese(III) pentaacetate Mn–TMPyP[4] and DNA is believed to occur within the minor groove rich in A–T sequences by electrostatic charge/charge interactions with the negatively charged phosphodiester groups. Since the initial observation of interactions between acridine derivatives and double-stranded DNA (mainly by intercalation) by Lerman in 1961,[5] this mode of interaction between a large variety of intercalators such as acridine[6] and methidium[7] derivatives with nucleic acid oligomers has been well studied.

Our approach to the design of artificial nucleases was based on the positioning, by double intercalation using two acridine moieties, of oxidative cleaving centres such as metalloporphyrin complexes. In this vein, a class of abiotic DNA cleaving agent combining a metalloporphyrin core, two spacers and two 9-aminoacridine moieties was designed and prepared (Fig. 1). The spacer connecting the reactive centre to the intercalators may be amino acids of variable length such as aminobutyric, aminovaleric or aminocaproic acids allowing to control the distance between the porphyrin and the acridine centres. Dealing with geometrical features, *i.e.* the positioning of the acridines with respect to the porphyrin core, based on molecular models, the *meso*-5,15-diarylporphyrin bearing an amino function at the *meta* position of each phenyl group appeared to be the most appropriate choice. Analogues of bleomycin based on a porphyrin core functionalised at β-pyrrolic positions by two acridine derivatives have been reported.[8]

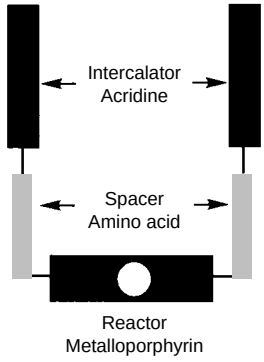

Fig. 1 Schematic representation of an abiotic nuclease based on a metalloporphyrin core functionalised by two acridine intercalators using amino acids as spacers

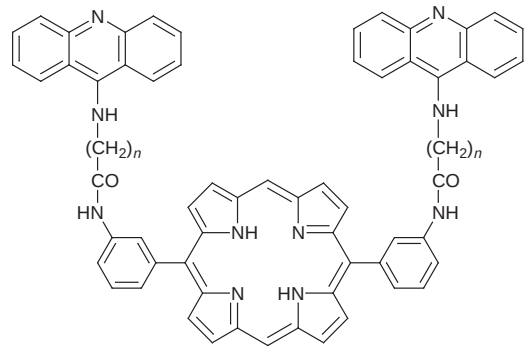
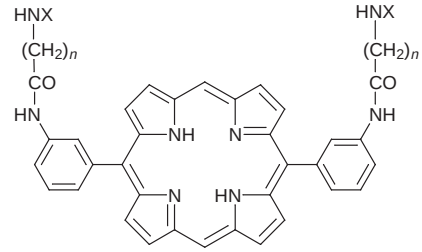
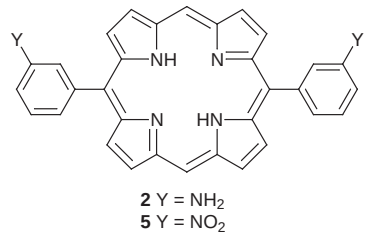
Here, we report the synthesis of compound **1** (Scheme 1) and the DNase activity of its manganese complex.

The synthetic strategy employed to prepare the compound **1** was based on the synthesis of bis(*m*-aminophenyl)porphyrin **2** followed by introduction of the spacer groups affording compound **3** and finally the introduction of acridine moieties. Whereas the synthesis of *meso*-arylporphyrins bearing amino groups at the *ortho* or *para* positions of the phenyl groups is well documented,[9] only few reports dealing with the preparation of the *meso*-*meta*-aminophenylporphyrins have been reported.[10,11] Compound **2** was prepared in two steps by modification of the described procedure for the bis(*o*-aminophenyl)porphyrin.[12] The condensation of 2,2-dipyrrylmethane,







Scheme 1

prepared following reported procedures,[13] with 3-nitrobenzaldehyde (*ca.* 5 mM) in CH_2Cl_2 in the presence of catalytic amounts of CF_3CO_2H (TFA) afforded the nitroporphyrinogen which was oxidised by *p*-chloranil affording the nitroporphyrin **5**. The latter, owing to its rather poor solubility, was not isolated but directly reduced at 70 °C to the amino compound **2** by treatment with $SnCl_2$/HCl.[14] Since the overall yield was rather low (2%), in order to optimise it, both the nature of the acid and the ratio of reactants were varied. The use of a Lewis acid such as $BF_3{\cdot}OEt_2$ instead of the protonic acid TFA increased the yield to 7%. However the highest yield of 12% was reached by increasing the concentration of reactants to the 20 mM range. The rather poor yield may be related to the low reactivity of the aldehyde used.

On the other hand, starting with aminobutyric acid [$H_2N(CH_2)_3CO_2H$] the NH_2 group was protected using the Boc group [$HNBoc(CH_2)_3CO_2H$][15] and then the carboxylic acid moiety was activated by treatment with ethyl chloroformate [$BocHN(CH_2)_3CO_2COEt$].[16] The condensation of the latter in the presence of Et_3N with compound **2** in a mixture of THF and toluene afforded the protected compound **4** in 60% yield. The deprotection of the Boc group was achieved in quantitative yield by treatment with AcOH–HCl[16] affording **4**·2HCl. The condensation of the latter with 9-phenoxyacridine[17] in phenol at 120 °C gave, after recrystallisation from Et_2O–MeOH, the final compound **1** in 56% yield.

The **1**–Mn^{III} complex was prepared at 120 °C by reacting ligand **1** with $Mn(OAc)_2{\cdot}4H_2O$ in DMF in the presence of 2,4,6-trimethylpyridine for 2 h. The metallation was followed in DMF by UV-VIS spectroscopy which revealed a bathochromic shift of the Soret band from 408 to 458 nm and a reduction of the number of Q bands from four to two. After precipitation by adding diethyl ether and washing the solid with water, the complex was purified by column chromatography [basic alumina, CH_2Cl_2–MeOH (9/1)] and characterised by MS (FAB positive mode: $M^+ = 1070$).

The nuclease activity of the **1**–Mn complex was tested at room temperature on the supercoiled double-stranded ΦX174 DNA (form I) at various concentrations and pH values using phosphate buffer in the presence of either $KHSO_5$[18] or magnesium monoperphthalate (MMPP),[19] two oxidants able to generate high-valent manganese–oxo species.[20] The addition of the oxidant initiated the DNA cleavage reaction. The cleavage products were analysed on agarose gel by electrophoresis as previously reported.[18,19]

As expected, no degradation of DNA was observed under the same conditions in the absence of **1**–Mn or in the presence of free ligand **1**. The cleaving activity of **1**–Mn was observed at 1 μM and 500 nM concentrations in the presence of 1 or 10 mM $KHSO_5$, respectively. Although the cleavage of supercoiled DNA in the presence of 10 mM $KHSO_5$ appeared to be more spectacular since 90% of form I was transformed into forms II and III, the efficiency of the **1**–Mn complex was found to be below that observed with Mn–TMPyP for which DNA cleavage was detected at 5 nM in the presence of 10 μM $KHSO_5$.[18] However, in marked contrast with the tetracationic Mn–TMPyP complex for which a strong salt effect due to electrostatic interactions with DNA was observed,[18] the DNA cleavage activity of **1**–Mn was not affected by modification of the ionic strength of the reaction mixture by addition of NaCl. This absence of a salt effect is in agreement with the possible intercalation of the acridine moieties of the complex between DNA base pairs.

The nuclease activity of **1**–Mn with MMPP was one order of magnitude higher than with $KHSO_5$ (the same cleavage efficiency was observed at 0.1 mM with MMPP and at 1 mM with $KHSO_5$). A similar difference has been previously found with Mn–TMPyP as cleaver.[19]

Finally, the appearance of the linear DNA form III before the complete conversion of form I indicated that **1**–Mn is probably able to perform some direct double-strand breaks (see ref. 18 for a discussion of double-strand breaks resulting from the accumulation of single-strand breaks in opposition to direct double-strand breaks). This observation is in favour of a strong interaction, probably by intercalation of the acridine moieties, between the metalloporphyrin and DNA.

In conclusion, a new porphyrin bearing two acridine intercalators was designed and prepared. Its manganese complex was shown to cleave double-stranded DNA in the presence of different oxygen atom donors involving mainly single-strand breaks with a participation of direct double-strand breaks. Work is in progress to demonstrate the role of the spacer amino acid moieties and to investigate the physico-chemical aspects of the cleaving process and the possible bis-intercalation behaviour of this DNA cleaver.

Sulfone-calixarenes: a new class of molecular building block

Gilles Mislin,[a] Ernest Graf,[a] Mir Wais Hosseini,*[a]† André De Cian[b] and Jean Fischer[b]

[a] *Laboratoire de Chimie de Coordination Organique, Université Louis Pasteur, (UMR 7513 CNRS), F-67000 Strasbourg, France*
[b] *Laboratoire de Cristallochimie et Chimie Structurale, Université Louis Pasteur, (UMR 7513 CNRS), F-67000 Strasbourg, France*

The synthesis of a new calix[4]arene derivative based on the linkage of the phenolic rings by four sulfone groups was achieved and its 1,3-alternate conformation in the crystalline phase, resulting from both inter- and intra-molecular H-bonding, was established by crystallography.

Over the past two decades, the calixarene framework has been the most used macrocyclic structure.[1,2] The increasing interest in these compounds seems to be due to their versatility. Indeed, a variety of calixarene based molecules displaying a wide range of properties ranging from molecular receptors and enzyme mimics as well as extractants to liquid crystals and conducting polymers have been reported. In our own hands, calix[4]arene derivatives have been used either for the design of hollow molecular modules[3,4] and their assembly into inclusion molecular networks in the crystalline phase,[5] or as backbones for the design of exo-ligands.[6–8]

In dealing with calix[4]arene **1**, its structural and functional tunings at various positions have been extensively studied. Whereas partial or complete substitution of the *p-tert*-butyl moieties by a variety of groups leads to the modification of the upper rim, the functionalisation of the hydroxyl moieties affords modified calixarenes at the lower rim. On the other hand, examples of partial[7] or complete[8,9] replacement of the OH by SH groups have been also reported. However, dealing with the linkage of the aromatic rings, only recently few examples of substitution of CH_2 groups by Me_2Si[10] or S[11,12] have been reported. An example of tetrathiacalix[4]arene based on four thiophene moieties has been also published.[13]

Here we report the first synthesis as well the solid state structural analysis of a new class of calix[4]arene analogues based on the linking of four phenolic rings by sulfone groups. These compounds may be of interest for the design of new receptors and backbones.

The synthetic strategy for the preparation of the tetrasulfone **6** was based on the complete oxidation of the thiacalix **3** (Scheme 1). The latter was obtained following the reported procedure.[11a] In a first attempt, all four OH moieties of **3** were protected as methoxy groups prior to the oxidation of the sulfide linkages to sulfones. The treatment of **3** under reflux with MeI in the presence of NaH in dry THF–DMF (1 : 9) for two days afforded, after recrystallisation from $CHCl_3$–MeOH, the desired compound **4** in 73% yield. The complete oxidation of **4** to the tetrasulfone **5** was first attempted by refluxing the compound **4** in a 30% H_2O_2–glacial AcOH mixture for eight days. Probably owing to the low solubility of **4**, the reaction isolated yield was only *ca.* 10%. The latter was increased to 88% when performing the oxidation with *m*-chloroperbenzoic acid in $CHCl_3$ at room temp. for 4 days. The pure compound **5** was isolated by recrystallisation from CH_2Cl_2–MeOH. Since the removal of the protecting groups by treatment with a large excess of BBr_3 in CH_2Cl_2 afforded the final compound **6** in only *ca.* 30% yield, the direct oxidation of the tetrasulfide **3** was carried out in 59% yield using 30% H_2O_2–glacial AcOH. The pure compound **6** was obtained after crystallisation from THF–hexane.

5 X = SO_2, R^1 = Bu^t, R^2 = Me
6 X = SO_2, R^1 = Bu^t, R^2 = H

Scheme 1

In solution, for all compounds **4**–**6**, both the ^1H and ^{13}C NMR spectra were extremely simple and in agreement with the proposed structure. In marked contrast with calix **1** derivatives for which both the ^1H and ^{13}C NMR signals corresponding to the methylene groups are usually used for conformational assignment in solution, due to the absence of such NMR probes for the thia- and sulfone-calix[4]arenes **2**–**6** their conformation could not be established unambiguously. For both compounds **4** and **5**, no changes in the proton spectra could be detected between −85 and 125 °C. However, bidimensional (^1H,^1H) ROESY experiments at room temp. showed correlations between the methoxy groups and both the CH_3 and CH aromatic proton indicating thus a rapid conformational interconversion. For the final compound **6** the dramatic changes observed upon cooling from 25 to −100 °C indicated temperature dependent conformational dynamics.

In the solid state, all compounds **4**–**6** were studied by X-ray diffraction methods on monocrystals. Suitable monocrystals‡ were obtained by slow diffusion of MeOH into a CH_2Cl_2 solution of either compound **4** or **5**, or by slow evaporation of a chlorobenzene solution of the compound **6**. In marked contrast with the tetramethoxy derivative of **1** which was shown to adopt a partial cone conformation,[14] and with the tetrathiacalix[4]-

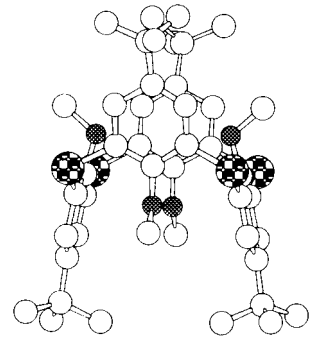

Fig. 1 X-Ray structure of the tetrasulfide **4** demonstrating the adopted 1,3-alternate conformation in the crystalline phase; for clarity H atoms are not presented

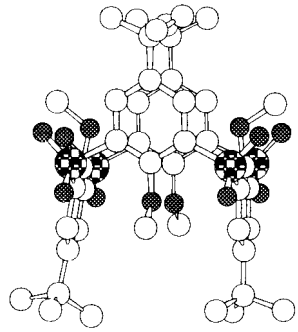

Fig. 2 X-Ray structure of the tetrasulfone **5** demonstrating the adopted 1,3-alternate conformation in the crystalline phase; for clarity H atoms are not presented

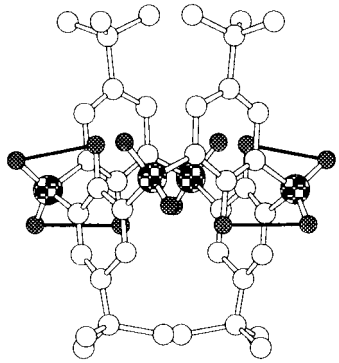

Fig. 3 X-Ray structure of the tetrasulfone **6** demonstrating the adopted 1,3-alternate conformation in the crystalline phase. The bold lines represent the intramolecular H-bonding pattern; for clarity H atoms are not presented.

arene **2** and the parent compound **3** which were present in cone conformation,[12] the thia analogue **4** was found to be in the 1,3-alternate conformation (Fig. 1).

For the two sulfone derivatives **5** (Fig. 2) and **6** (Fig. 3), again the conformation was found to be 1,3-alternate with oxygen atoms of the sulfones pointing outward. The average SO bond distance was *ca.* 1.43 and 1.44 Å for **5** and **6**, respectively. The average CS bond distance was *ca.* 1.77 Å for both cases. The average distance between two adjacent sulfur atoms was *ca.* 5.52 Å.

Based on the observed average O···O distance between two adjacent oxygen atoms of *ca.* 2.70, 2.85 and 2.64 Å for **1**, **2** and **3** respectively, as previously proposed in the case of **1**,[1] for both compounds **2**[12] and **3**[12] the cone conformation was, at least partially stabilised, by an array of intramolecular H-bonds. Interestingly, the 1,3-alternate conformation for compound **6** may be also rationalised in terms of H-bonding between the OH and SO_2 groups (Fig. 3). Indeed, O···OS distances varying from 2.81 to 3.02 Å were observed. Furthermore, compound **6** was found to form a 3-D network through intermolecular H-bonding between the OH and SO_2 groups belonging to adjacent units with an average O···OS distance of *ca.* 2.87 Å (Fig. 4).

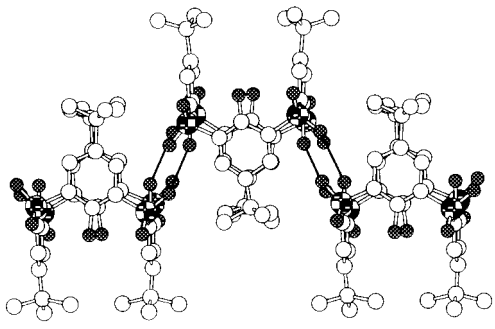

Fig. 4 A portion of the X-ray structure of the 3-D network formed between consecutive compounds **6**. The 3-D network is obtained by intermolecular H-bonding between OH and SO groups; for clarity H atoms are not presented.

In conclusion, the synthesis of new calix[4]arene derivatives based on sulfone linkages between the phenolic rings was achieved. All compounds were shown to adopt the 1,3-alternate conformation in the solid state. In the case of *p-tert*-butyltetrasulfonecalix[4]arene **6**, due to inter- and intra-molecular H-bonds, a 3-D network was observed in the solid state. The use of sulfonecalix derivatives for the design of receptors and building blocks is under current investigation.

We thank H. Akdas and L. Bringle for their help with the preparation of some of the reported compounds and the CNRS and the Institut Universitaire de France (IUF) for financial support.

Comments on the elusive crystal structure of 4-iodo-4′-nitrobiphenyl

Norberto Masciocchi,*[a] Mirka Bergamo[b] and Angelo Sironi*[a]

[a] *Dipartimento di Chimica Strutturale e Stereochimica Inorganica, Università di Milano, via Venezian 21, 20133, Milano, Italy*
[b] *Dipartimento di Chimica Inorganica, Metallorganica ed Analitica, Università di Milano, via Venezian 21, 20133 Milano, Italy*

The recently proposed crystal structure of 4-iodo-4′-nitrobiphenyl is here confirmed on the basis of experimental diffraction data on single crystals and powders of high crystallinity; a reinterpretation of the nature of the (faulted) material studied in the original paper is also presented.

In a recent issue of Chemical Communications, Sarma *et al.* (hereafter, Sarma) reported[1] the design, based on the strength of Ar–NO_2···I–Ar interactions, of a new crystal phase, possessing second harmonic generation (SHG) properties. It was reported therein that single-crystal X-ray diffraction (XRD) on two crystals of 4-iodo-4′-nitrobiphenyl (INB) with different morphology (obtained by recrystallization from benzene or nitromethane) afforded, in both cases, an F-centered orthorhombic lattice, but no reliable structural model; accordingly, it was suggested that all samples chosen for single-crystal analysis were flawed, since the ordered structural model, obtained by the combination of XRD (cell/space group), semiempirical quantum chemistry calculations (molecular conformation), crystallochemical considerations (approximate location) and constrained lattice energy minimisation (final coordinates), did not match the observed intensity data.[1]

Sarma found that INB molecules form polar ribbons running along [001] through robust Ar–NO_2···I–Ar interactions (a well defined[2] supramolecular synthon[3]); however, in contrast with such robustness, the features observed in the XRPD pattern were modelled by a significant small-particle-size broadening effect along [001] (with an average coherent domain of 50 Å, accounting for three INB molecules only!). Suspecting a two-dimensional polytypic behaviour like that found in (C_5Me_5)ReO_3,[4] we decided to reconsider the INB problem by coupling XRPD, computer simulation of faulted crystals and conventional 'single-crystal' X-ray diffraction.

We have synthesized INB as described in refs. 1 and 5, and found that the reaction product is, according to GC–MS, a mixture of INB and of the symmetrically substituted dinitro- (DNB) and diiodo-biphenyls (DIB), in an approximate 90 : 9 : 1 ratio, while in the XRPD pattern only the two major phases (INB and DNB) could be recognized. Recrystallization from benzene, nitromethane or hexane eventually afforded only one crystal phase (INB, although, according to GC–MS, traces of DNB were still present), whose XRPD pattern revealed a well crystallized system with no anisotropic broadening (FWHM $< 0.2°$ 2θ). It was of note that our XRPD data (Fig. 1) can be indexed with the published INB cell parameters but show an intensity distribution different from that reported in Fig. 2 of ref. 1; in particular, two, previously unobserved, intense low angle peaks are now present.

Recrystallization from nitromethane spontaneously afforded light yellow INB crystals of very good quality, whose structure was easily solved and successfully refined in space group *Fdd*2 on data from two different crystals (which were found to differ only in the amount of racemic twinning present: none for crystal 1 and [73 : 27] for crystal 2).‡ The derived structural model is very similar to that proposed in ref. 1 and, allowing a rather good match (R_p = 0.10) between observed and calculated XRPD data (see Fig. 1), it correctly describes also the bulk. Accordingly, INB can afford highly crystalline samples.

In spite of our efforts, we were unable to prepare the poorly crystalline phase originally reported as INB. Nevertheless, we would like to tentatively propose, in the absence of direct experimental data, two possible explanations for Sarma's observations.

The substitution of one INB molecule by DNB generates an unstrained faulted ribbon, as schematically shown in Fig. 2, which, despite the inversion of the NO_2···I link, possesses fully ordered C and H atoms (note that DIB could act in the same manner while the copresence of DIB and DNB allows for any number of faults). The insertion of a single DNB molecule per

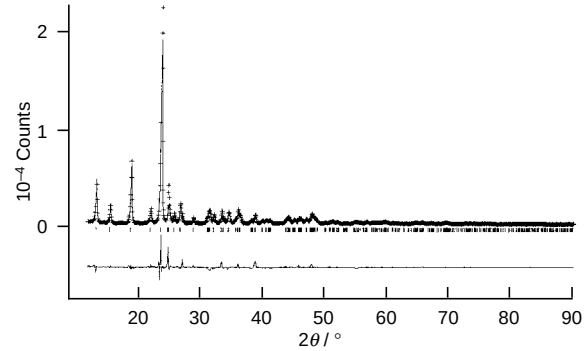

Fig. 1 Rietveld refinement plot of the INB phase with peak markers and difference plot at the bottom. Note that the first two log-angle peaks are consistent with the structural model and do not require any anisotropic broadening correction in order to spread their intensity into the background.

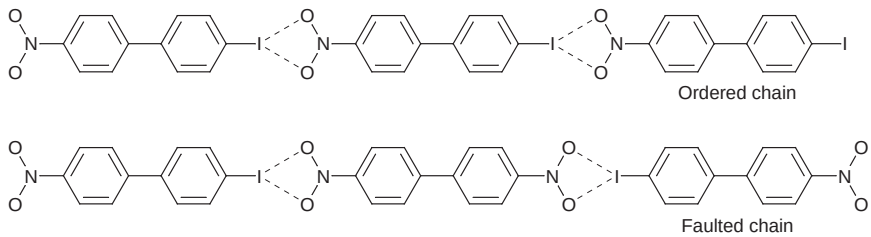

Fig. 2 Schematic drawing of the polarity inversion of one INB chain in the presence of a single DNB molecule per chain (conditioned disorder). Note that at most one DNB molecule can fit in an INB chain; DIB would act in the same manner, while the simultaneous presence of DIB and DNB allows for any number of faults (up to a random disorder).

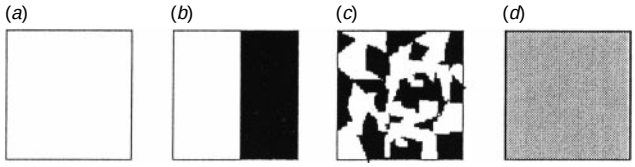

Fig. 3 Schematic drawing of the tiling of the *ab* plane of INB crystals with black and white dots (for up and down polar INB chains, respectively), showing a polar single crystal (*a*), a racemic (macro)twin (*b*), a faulted paracrystal with many twin boundaries (*c*) and a fully disordered *Fddd* (microtwinned) phase (*d*)

chain behaves similarly to a single error in the stacking sequence of pure INB which, however, would induce some strain. This kind of fault, as shown by Hulliger *et al*. for the 1,4-nitrophenylpiperazine–perhydrotriphenylene inclusion compound,[6] may evolve into a 180° [001] twinned macrostate with a fuzzy interface whose size depends on their intrinsic probability. However, since high error frequencies imply small interfaces, sharp XRPD peaks and possible SHG effects (while, low, non-zero probabilities lead to large 'interfaces', broad XRPD peaks§ and no SHG), the presence of DNB (or of less likely INB inversion faults) can be taken as responsible for all experimental evidences only if crystals of intermediate nature occur.

Alternatively, since inversion of the polarity of a whole (ordered) chain marginally affects the overall packing (more or less like an inversion fault, which inverts only 'half' a chain), Sarma's specimen may consist of a two-dimensional polytypic phase with (randomly distributed) microdomains of inverse polarity, large enough to guarantee SHG properties, but 'flawing' the original X-ray analysis, much like what is found for solid $(C_5Me_5)ReO_3$.[4] Indeed, juxtaposition of antiparallel domains in the *ab* plane can afford, on lowering the size of the homopolar regions, (*a*) untwinned *Fdd*2 single crystals (our crystal 1); (*b*) racemic (macro)twins (crystal 2); (*c*) two dimensional polytypes (Sarma's specimen); (*d*) disordered (*i.e.* microtwinned) *Fddd* 'single' crystals (Fig. 3). Since cases (*a*) and (*b*) would lead to sharp XRPD features and case (*d*) cannot be SHG active, only case (*c*) fits Sarma's experimental observations. That 2D polytypic crystals from different preparations may have different 'structures' should not surprise, particularly after it has been shown that crystals from the same batch and even different portions of the same good looking 'single' crystal may possess different peak intensities, reflecting the different ratio of ordered *vs*. disordered (*i.e.* boundary) regions.[4]

Summarizing, single-crystal and powder diffraction analyses of INB afforded an unambiguous crystal structure with long polar ribbons of INB molecules packed, in *Fdd*2, in a head-to-tail fashion, as originally inferred in ref. 1. This agrees well with the proposed robustness of the $NO_2\cdots I$ synthon, which has been extensively used in devising supramolecular assemblies of organic molecules.[7] Unfortunately, even if the outcome of the work reported by Sarma *et al*. happens to match the true INB crystal structure, the nature of their material (single crystals and bulk) remains obscure.

We acknowledge the Italian MURST and CNR (CSSMTBO) for funding. The courtesy of Dr G. A. Ardizzoia, who run the GC–MS measurements, is also acknowledged. We also thank Professor A. Gavezzotti for helpful discussions.

5-Acceptor-substituted 4-amino-2-arylazothiazoles. A unique black monoazo chromophoric system

John Griffiths*† and Conrad J. Riepl

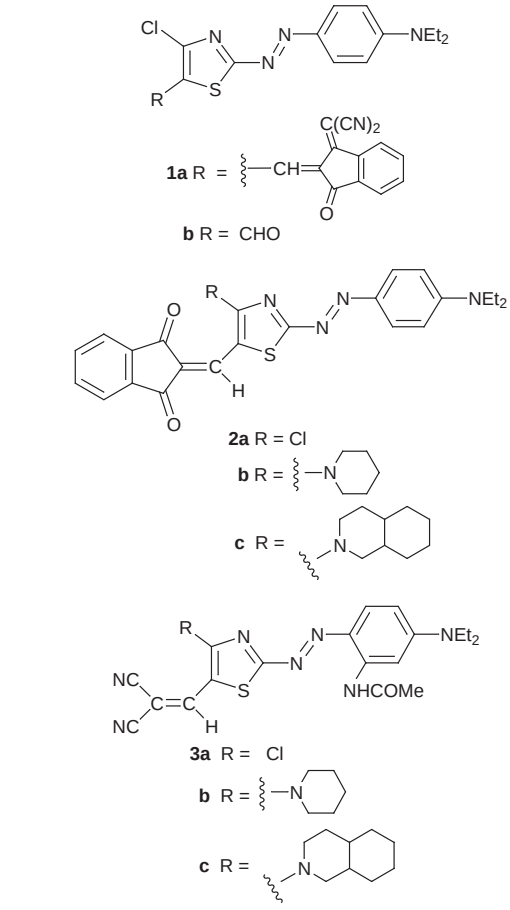
Department of Colour Chemistry, The University of Leeds, Leeds, UK LS2 9JT

Replacement of the chlorine substituent in blue dyes of the 5-acceptor-4-chloro-2-(4-*N*,*N*-dialkylaminophenylazo)thiazole type by a tertiary amino group produces a black monoazo chromophoric system with three π → π* bands spanning the whole of the visible spectrum.

Black dyes, *i.e.* those with two or more absorption bands extending across the whole of the visible spectrum, are rare, and known examples invariably have a large molecular size in order to provide the requisite conjugation and number of chromophoric sub-units for multiple π → π* transitions in the visible range. The most commonly encountered examples are bis-azo or higher poly-azo dyes; their large size can lead to problems associated with aggregation or low solubility and this can limit their technical application. The traditional alternative is to use mixtures of dyes, even though these may introduce dye compatibility and shade reproducibility problems. Given the currently increasing importance of soluble black colorants in areas such as ink-jet and other digital printing systems, liquid crystal displays and optical filters, there is a growing need for the development of new, relatively low molecular weight black chromophores which can overcome these difficulties. We now describe the synthesis of a unique 2-arylazothiazole chromophoric system, whereby simple replacement of a chlorine substituent by an amino group causes a dramatic change in the light absorption properties of the molecule, and the single visible π → π* absorption band is replaced by three intense π → π* bands more or less equally spaced across the visible spectrum.

The 5-acceptor-4-chloro-2-(4-*N*,*N*-dialkylaminophenylazo)-thiazole dyes, as exemplified by **1** and **2a**,[1] are highly polarised molecules that show a single intense π → π* absorption band in the range *ca.* 550–800 nm,[2] which can be considered to involve electron density migration from the amino group into the azo group, thiazole ring and the 5-acceptor substituents on the latter ring. Whilst normally violet to blue–green in colour, the use of multiple donor groups in the donor ring and powerful acceptor groups R in **1** (*e.g.* **3a**) can displace the band into the near IR region, leading to useful near-IR dyes.[2] The 4-chloro substituent in molecules such as **1**, **2a** and **3a** should be capable of nucleophilic replacement, particularly if the 5-substituent is strongly electron withdrawing, and this was investigated in the case of the indane-1,3-dione derivative **2a**.

A solution of the blue dye **2a** and piperidine (2 equiv.) in THF was heated under reflux, when the colour of the solution became black, and after 6 h the reaction was judged to be complete by TLC analysis. After filtration to remove piperidine hydrochloride, the solution was evaporated and the product recrystallised from a mixture of CH_2Cl_2 and EtOH to afford **2b** as black crystals in 65% yield. The structure was confirmed by microanalysis, mass spectrometry and NMR spectroscopy. The dye was readily soluble in solvents such as toluene and CH_2Cl_2, giving black solutions which showed three absorption bands in the visible region. The absorption spectra of **2a** and **2b** in cyclohexane are compared in Fig. 1(*a*) and (*b*). The second band of **2b** shows vibrational structure, which is most evident in non-polar solvents such as cyclohexane [Fig. 1(*b*)]. In CH_2Cl_2 the absorption maxima occurred at 437, 528 (shoulder at 500 nm) and 665 nm (ε_{max} 19 900, 26 500 and 29 400 l mol^{-1} cm^{-1}, respectively). Thus, introduction of the piperidino group into the thiazole ring generates three visible π → π* absorption



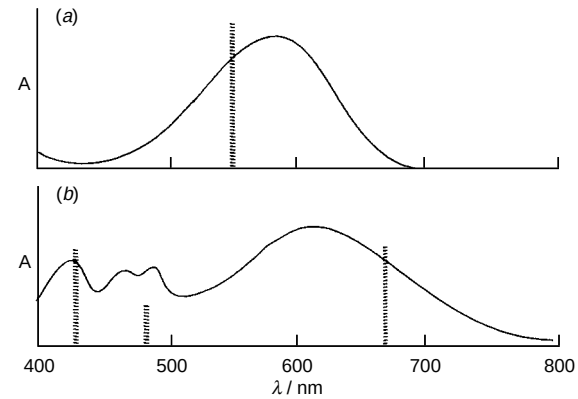


Fig. 1 Absorption spectra of (*a*) **2a**, and (*b*) **2b** in cyclohexane. Vertical broken lines represent the PPP-MO predicted absorption band λ_{max} values and relative intensities.

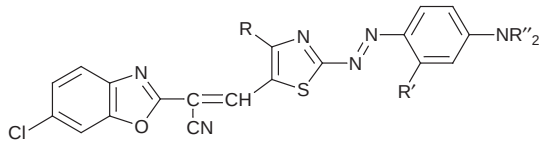
bands in place of the original single band. Such a dramatic change in the characteristics of a dye chromophore induced by a single substituent appears to be without precedent.

The electronic origin of the three bands was examined by application of PPP-MO theory to the π-chromophores of **2a** and **2b**.[3] Using standard parameters[3,4] the method predicted correctly that replacing the chlorine atom in **2a** by an amino group produces three visible absorption bands (Fig. 1).

The absorption bands, in order of increasing transition energy, approximate to the one electron excitation processes: HOMO → LUMO, HOMO → (LUMO + 1) and (HOMO-1) → (LUMO), although there is extensive configuration interaction between the three excited states. From the wavefunctions for these various orbitals one can deduce that the longest wavelength band involves the whole of the conjugated π system, the second band is associated predominantly with the 4-amino-5-acceptor-thiazole residue, and the shortest wavelength band is confined predominantly to the arylazo residue and the thiazole ring. All three bands show positive solvatochromism, shifting respectively from 608, 493 and 424 nm in cyclohexane to 677, 532 and 433 nm in DMF.

Replacement of the chlorine atom in the thiazole ring could also be effected with a variety of secondary amines, and with other 5-acceptor substituted analogues of **2a**. Thus the deeply coloured dyes **2c**, **3b**,**c** and **4**‡ were prepared in 50–95% yields by heating the appropriate chlorine-substituted dye and amine in solvents such as THF, EtOH and CH_2Cl_2. All showed the characteristic three visible absorption bands of this type of chromophore, their solutions ranging from dark blue, through greenish black to neutral black in colour. In general the rate of the replacement reaction and product yields were enhanced when the arylamine group had an acylamino substituent capable of hydrogen bonding to the azo group (*e.g.* **3**, **4b**,**c**,**e**).



4a R =  R′ = H, R″ = Et

b R =  R′ = NHAc, R″ = Pr

c R = NMe_2, R′ = NHAc, R″ = Pr

d R =  R′ = H, R″ = Et

e R =  R′ = NHAc, R″ = Pr

The success of the chlorine replacement reaction is critically dependent on the nature of both the reacting amine and the thiazole 5-acceptor group. Weakly nucleophilic amines, *e.g.* primary and secondary arylamines, do not react, whereas primary alkylamines cause extensive decomposition of the chromophore, leading to (among other products) the parent aldehyde dye (*e.g.* formation of **1b** from **2a**). If the 5-acceptor group is particularly electron withdrawing then it undergoes preferential attack by the amine, leading to degradation of the chromophore and formation of red products. For example **1a** gave only decomposition products on reacting with a range of secondary amines. In the case of the aldehyde derivative **1b** reversible addition of the amine to the formyl group occurred, giving the unstable magenta aminohydroxy derivative.

The dyes **2b**,**c**, **3b**,**c** and **4** represent a new class of black chromophore that is capable of considerable structural diversity. Preliminary investigations have shown that hydrolytic, thermal and photochemical stability properties are typical for azo dyes of this general type and thus these systems offer considerable potential for the development of novel black colorants for many technical applications.

We thank the EPSRC National Mass Spectrometry Service Centre for provision of mass spectrometry services.

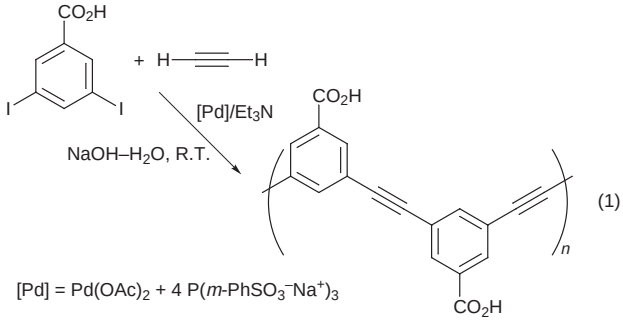
In aqua synthesis of a high molecular weight arylethynylene polymer with reversible hydrogel properties

Chao-Jun Li,*[a]† William T. Slaven IV,[a] Yi-Ping Chen,[b] Vijay T. John[c] and Suguna H. Rachakonda[c]

[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*
[b] *Department of Cell and Molecular Biology, Tulane University, New Orleans, LA 70118, USA*
[c] *Department of Chemical Engineering, Tulane University, New Orleans, LA 70118, USA*

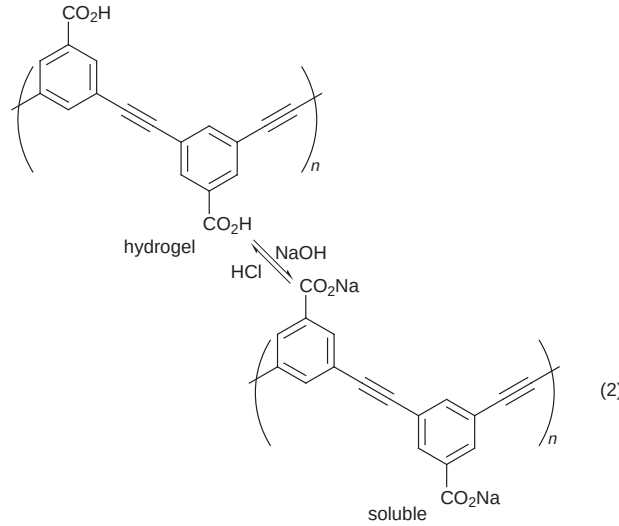
Palladium catalyzed copolymerization of 3,5-diiodobenzoic acid with acetylene gas in a basic aqueous medium provides a high molecular weight (~60 000), zig-zag phenylethynylene polymer; the polymer has been characterized by a variety of methods and has a high thermostability, is soluble in basic solutions and is reversibly switchable from soluble to hydrogel states in water by changing the pH of the solvent.

Poly(arylethynylene)[1] is an important class of conjugated polymer exhibiting properties such as photoluminescence,[2] electronic conductivity[3] and non-linear optical properties.[4] These polymers also exhibit exceptionally high quantum yields of fluorescence in comparison to other conjugated polymers.[5] Such properties render the polymer useful for applications in constructing polymer light emitting diodes (polymer LEDs),[6] organic magnetic materials,[7] molecular wires and antennas[8] and fluorescence sensors.[9] Recently, Nelson *et al.* have also shown that an arylethynylene-based oligomer mimics protein folding, which has exciting potential for biological applications.[10] However, the potential applications of these materials for electronic and optical purposes are often limited by their low solubility and low degree of the polymerization. The increased interest in the properties of polyarylethynylene-type materials has led to the attachment of various bulky substituents by various groups to increase their solubility in organic solvent.[1] Alternatively, Kondo *et al.* introduced irregularity in the polymer chain to increase their solubility and degree of polymerization.[11] However, the structural irregularity may also change its electronic and optical properties. During our studies of aqueous organic reactions,[12] and as part of our continuing interests in synthesizing arylethynylene-type polymers and oligomers,[13] we recently reported an efficient synthesis of arylethynylene polymer and oligomers through polymerization of aryl halides with acetylene gas in an aqueous medium.[14] However, the polymers that we generated had the same limitation of insolubility and low molecular weight. In an attempt to overcome these difficulties, we decided to explore the synthesis of water-soluble polyarylethynylenes. Here we report that the palladium catalyzed copolymerization of 3,5-diiodobenzoic acid with acetylene gas in a basic aqueous medium provides a high molecular weight, zig-zag arylethynylene polymer [eqn. (1)] which can be processed readily.



(1)

Previously, there has been a very limited study of the synthesis of water-soluble rigid-chain polyelectrolytes in the literature. The more noticeable advance in this area was the synthesis of a water-soluble poly(*p*-phenylene) reported by Wallow and Novak through the Suzuki reaction,[15] and a water-soluble poly(thiophene) sensor material reported by McCullough *et al.*[16] In the present investigation, the polymerization was carried out by reacting 3,5-diiodobenzoic acid with acetylene gas in the presence of a water-soluble palladium catalyst, cuprous iodide as a co-catalyst, 1 equiv. NaOH and 3 equiv. Et_3N in water. The water-soluble palladium catalyst was generated *in situ* from palladium acetate and tris(*m*-sulfophenyl)phosphine trisodium salt, as used by Casalnuovo and others.[17] The monomer used in the present study was prepared according to literature procedure.[18] After stirring the reaction mixture for three days at room temperature, the polymer was readily isolated by addition of dilute HCl, giving a dark brown solid in its free acid form. The polymer thus generated has no substantial solubility in all other solvents tested except in dilute aqueous NaOH solution. On the other hand, the polymer is readily soluble in dilute NaOH. Under neutral or slightly acidic conditions, the polymer becomes a hydrogel which holds water about eight times of its original weight after centrifuging. It can be reversibly transformed into the water-soluble and hydrogel states by changing the pH of the medium [eqn. (2)], which has



(2)

potential biomedical and environmental applications.[19] It should be noted that throughout the polymerization process, the polymer remained soluble in the reaction medium, which is essential for the formation of high molecular weight polymers.

The polymer thus generated has been characterized by a number of methods. The two potential types of aromatic hydrogens exhibited a broad resonance around 8.2–8.4 ppm in the ^1H NMR spectrum (D_2O–NaOD). The IR (KBr pellet)

spectrum displays typical absorption peaks corresponding to free carboxylic acid (3700–3100 and 1772 cm^{-1}) and aromatic functionality.[20] Absorption due to the acetylene stretch vibration (2100–2210 cm^{-1}) is insignificant. Raman spectroscopy of the aqueous solution of the corresponding sodium carboxylate salt showed several absorption peaks in the acetylene region, indicating the presence of polymers with different lengths.[21] The UV–VIS spectrum shows two major bands with absorption maxima at 210 and 288 nm respectively. The molecular weight (M_w = 66 000 g mol^{-1}) of the polymer was determined by agarose gel electrophoreses relative to double-stranded DNA markers.[22] Trace amounts of even higher molecular weight polymers were also observed. Thermogravimetric analysis (TGA) of the polymer showed the expected high thermal stability of common poly(arylethylene)s.[1] The polymer is stable up to 300 °C. It exhibited a one stage degradation with an onset decomposition at *ca.* 400 °C. Differential scanning calorimetry (DSC) measurements show an endotherm at 100 °C which may be due to removal of adsorbed water.

In conclusion, we have developed a simple process for obtaining high molecular mass poly(arylethylene)s. The polymer shows hydrogel properties in its carboxylic form and is reversibly switchable from water-soluble to hydrogel states. Presently, we are evaluating the potential applications of such water-soluble arylethynylene polymers.

Support of this research was provided in part by the Center of Bioenvironmental Research (DOD) and the Center for Photoinduced Processes (NSF-LEQSF). We thank the reviewers for their valuable comments. C. J. L. is an NSF CAREER Awardee (98-02).

Total syntheses of (+)-castanospermine and (+)-6-epicastanospermine

Sung Ho Kang*† and Joon Seop Kim

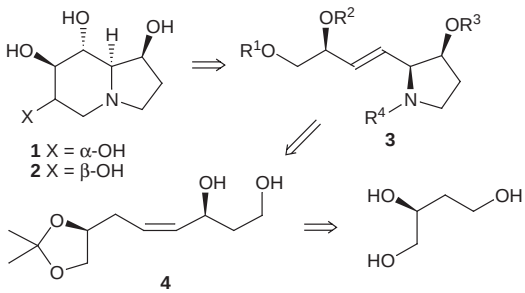
Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea

A divergent synthetic route to (+)-castanospermine 1 and (+)-6-epicastanospermine 2 has been developed *via* phenylselenoamidation of trichloroacetimidate derived from allylic alcohol 7, and dihydroxylations of *trans*-olefins 14 and 18 to dispose the three contiguous asymmetric centers, one amino group and two hydroxy groups.

The naturally occurring hydroxylated indolizidine alkaloids such as (−)-swainsonine, (+)-castanospermine **1** and (+)-6-epicastanospermine **2** continue to enjoy considerable attention from synthetic and medicinal chemists due to their pronounced biological activities. Their inhibition of enzymatic glycosidic hydrolysis is closely related with the potential chemotherapeutic utility for the treatment of diabetes,[1] cancer,[2] viral diseases[3] and AIDS.[4] Their intriguing molecular structures and promising medicinal value led us to explore their efficient synthetic routes. Here we describe total syntheses[5] of (+)-castanospermine **1** and (+)-6-epicastanospermine **2**, which have been isolated from *Castanospermum australe*[6] and *Alexa leiopetala*.[7]

Based on our retrosynthetic analysis toward **1** and **2**, a crucial synthetic step was a stereoselective dihydroxylation of *trans*-olefin **3** (Scheme 1). While the effect of the allylic amino group in **3** on the stereochemical outcome was in question,[8] its allylic alkoxy group was properly disposed for the desired α-dihydroxylation according to Kishi's empirical rule.[9] Another key step was to produce a *syn*-amino alcohol as a prospective precursor to **3** *via* intramolecular phenylselenoamidation of trichloroacetimidate derived from *cis*-olefinic allylic alcohol **4**.[10]

(*S*)-Butane-1,2,4-triol reacted with *p*-anisaldehyde in the presence of PPTS in benzene using a Dean–Stark trap to give a 7.5–8 : 1 mixture of 6- and 5-membered benzylidenes (Scheme 2). After Swern oxidation[11] of the inseparable mixture, the resulting aldehydes were olefinated with phosphonium salt **5** prepared from (*S*)-butane-1,2,4-triol[12] to afford a 19 : 1 mixture of *cis*-olefin **6**, $[\alpha]_D^{28}$ +110.8 (*c* 1.5, $CHCl_3$), and the corresponding *trans*-olefin in 69% combined overall yield, along with 7% of the isomeric olefins generated from the 5-membered benzylidenes. Hydrolysis of **6** with PPTS in MeOH at 0 °C removed its *p*-methoxybenzylidene group chemoselectively to provide diol **4**, $[\alpha]_D^{27}$ +9.9 (*c* 1.3, $CHCl_3$), in 86% yield. The primary hydroxy group of **4** was regioselectively silylated with TBDPSCl in the presence of imidazole at −60 °C to furnish silyl ether **7**, $[\alpha]_D^{22}$ −2.6 (*c* 2.2, $CHCl_3$), in 92% yield. For the unprecedent phenylselenoamidation, **7** was treated with

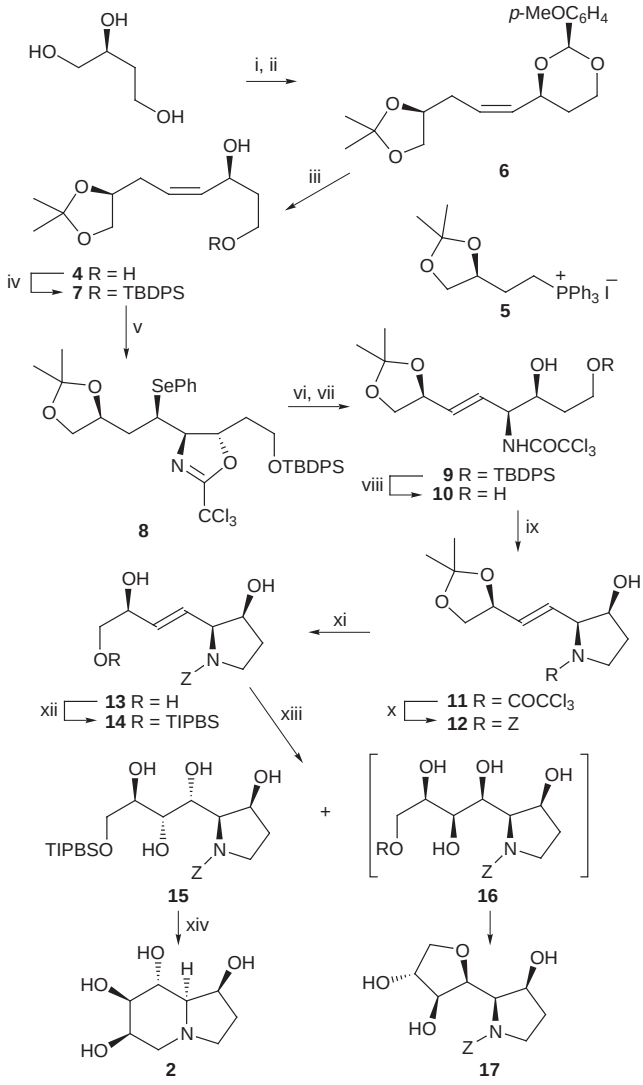


Scheme 1

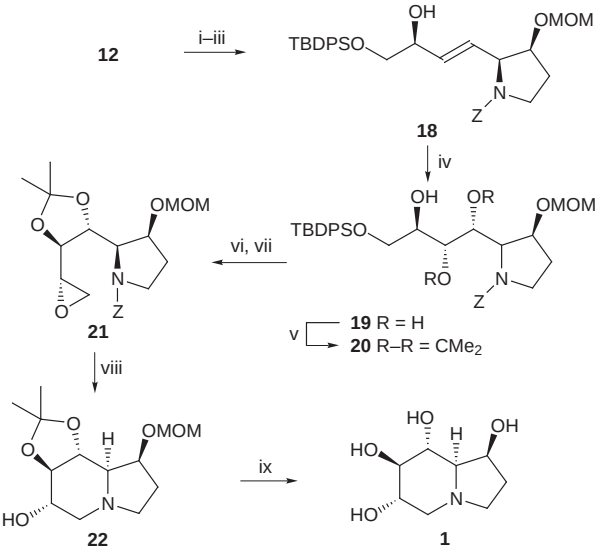
Cl_3CCN in the presence of DBU in MeCN at 0 °C, and subsequently cyclized using phenylselenyl chloride in the presence of methyl 2,2,2-trichloroacetimidate and Et_3N in MeCN at −20 °C to produce an inseparable 15 : 1 mixture of *trans*-oxazoline **8** and the isomeric *cis*-oxazoline in 63% combined yield. In this cyclization, the addition of methyl 2,2,2-trichloroacetimidate was essential to suppress the formation of the corresponding trichloroacetate from trichloroacetimidate. Subjection of the mixture to PPTS in aqueous MeOH induced partial hydrolysis of the oxazoline groups to give hydroxy trichloroacetamides, of which the desired *syn*-stereoisomer, $[\alpha]_D^{22}$ −6.8 (*c* 2.0, $CHCl_3$), was readily separated in 87% yield from the *anti*-stereoisomer. Oxidative elimination of the *syn*-stereoisomer with H_2O_2 in THF afforded *trans*-olefin **9**, $[\alpha]_D^{24}$ +15.8 (*c* 3.7, $CHCl_3$), in 84% yield contaminated with less than 3% of *cis*-isomer.

The next event was a stereoselective dihydroxylation of the introduced *trans*-olefinic double bond. In order to attain better stereoselectivity, **9** was variously functionalized by changing the protecting groups and the molecular structural shapes. It was found that the most promising outcomes could be obtained with benzyloxycarbonyl (Z)-protected pyrrolidine derivatives. Accordingly, **9** was desilylated in 92% yield and then the resultant alcohol **10**, $[\alpha]_D^{21}$ +34.9 (*c* 0.7, $CHCl_3$), was cyclized under Mitsunobu conditions[13] using diisopropyl azodicarboxylate (DIAD) and PPh_3 in THF at 0 °C to provide pyrrolidine **11**, $[\alpha]_D^{24}$ +58.6 (*c* 1.0, $CHCl_3$), in 88% yield. Treatment of **11** with BnONa in THF resulted in the formation of Z-protected pyrrolidine **12**, $[\alpha]_D^{26}$ +54.9 (*c* 1.1, $CHCl_3$), in 90% yield. After removal of the acetonide group under acidic conditions, the obtained triol **13**, $[\alpha]_D^{25}$ +17.0 (*c* 3.0, MeOH), was regioselectively sulfonated with 2,4,6-triisopropylbenzenesulfonyl chloride (TIPBSCl) in pyridine to furnish monosulfonate **14**, $[\alpha]_D^{25}$ +18.9 (*c* 1.2, $CHCl_3$), in 83% overall yield based on 15% of the recovered **13**. Dihydroxylation of **14** with a catalytic amount of OsO_4 in the presence of NMO in aqueous acetone[14] at 0 °C produced the requisite tetraol **15**, $[\alpha]_D^{23}$ +9.2 (*c* 1.1, $CHCl_3$), in 88% yield along with less than 8% of **17**, which was undoubtedly formed by the spontaneous intramolecular etherification of the isomeric tetraol **16**. Subjection of **15** to hydrogenolysis followed by *in situ* cyclization in the presence of Et_3N gave (+)-6-epicastanospermine **2**, $[\alpha]_D^{23}$ +2.8 (*c* 0.6, MeOH), in 66% yield.[15]

For the synthesis of (+)-castanospermine, **12** was converted into silyl ether **18**, $[\alpha]_D^{25}$ −12.6 (*c* 1.7, $CHCl_3$), in 88% overall yield by protection of the secondary hydroxy group with $MeOCH_2Cl$ (MOMCl), hydrolysis of the acetonide group and monosilylation of the primary hydroxy group with TBDPSCl in sequence (Scheme 3). Osmylation of **18** gave triol **19**, $[\alpha]_D^{24}$ −4.9 (*c* 0.7, $CHCl_3$), in 91% yield along with 6% of the isomeric β-dihydroxylated triol. When **19** was exposed to acetone in the presence of TsOH, the desired dioxolane **20**, $[\alpha]_D^{23}$ −7.1 (*c* 1.5, $CHCl_3$), was prepared in 92% yield by ketalization of the two *syn*-hydroxy groups, accompanied by 2% of the regioisomeric dioxolane. In order to secure the correct stereochemistry at 6-position of (+)-castanospermine, the remaining hydroxy group of **20** was inverted by mesylation followed by desilylation to afford epoxide **21**, $[\alpha]_D^{21}$ −19.7 (*c* 1.2, $CHCl_3$), in 87% overall yield. Removal of the Z group in **21**



Scheme 2 *Reagents and conditions*: i, *p*-anisaldehyde, PPTS, PhH, Dean–Stark trap; ii, $(COCl)_2$, DMSO, Et_3N, then **5**, Bu^nLi, HMPA, THF, −78 to 0 °C; iii, PPTS, MeOH, 0 °C; iv, TBDPSCl, imidazole, DMF, CH_2Cl_2, −60 °C; v, Cl_3CCN, DBU, MeCN, 0 °C, then PhSeCl, $MeOC(=NH)CCl_3$, Et_3N, MeCN, −20 to −15 °C; vi, PPTS, H_2O, MeOH, 20 °C; vii, 30% H_2O_2, THF, 0 to 20 °C; viii, Bu_4NF, THF, −5 to 0 °C, then aq. NaH_2PO_4; ix, DIAD, Ph_3P, THF, 0 °C; x, NaOBn, THF, 20 °C; xi, TsOH, MeOH, 20 °C; xii, TIPBSCl, pyridine, 20 °C; xiii, OsO_4, NMO, acetone, 0 °C; xiv, H_2, 10% Pd/C, MeOH, 20 °C, then Et_3N, reflux



Scheme 3 *Reagents and conditions*: i, MOMCl, Et_3N, CH_2Cl_2, reflux; ii, TsOH, MeOH, 20 °C; iii, TBDPSCl, imidazole, DMF, CH_2Cl_2, −60 °C; iv, OsO_4, NMO, H_2O, acetone, 0 °C; v, TsOH, acetone, 20 °C; vi, MsCl, DMAP, Et_3N, CH_2Cl_2, 20 °C; vii, Bu_4NF, THF, 20 °C, then 5 M NaOH; viii, 5% Pd/C, cyclohexene, EtOH, reflux; ix, conc. HCl, MeOH, reflux, then Dowex 50WX8-100 ion-exchange resin

was anticipated to induce 6-*endo* cyclization rather than 5-*exo* cyclization due to the *anti* arrangement of the dioxolane ring. Indeed heating **21** under catalytic transfer hydrogenation conditions[16] provided only indolizidine **22**, $[\alpha]_D^{22}$ +39.5 (*c* 0.8, $CHCl_3$), in 76% yield. Finally methanolysis of **22** with methanolic HCl furnished (+)-castanospermine **1**, mp 205–207 °C (decomp.), $[\alpha]_D^{22}$ +79.7 (*c* 1.0, MeOH), in 96% yield.[15]

In summary, we have accomplished total syntheses of (+)-castanospermine **1** and (+)-6-epicastanospermine **2**, which culminated in the stereoselective phenylselenoamidation of trichloroacetimidate (from **7**) and the asymmetric dihydroxylation of **14** and **18** to establish the four contiguous chiral centers.

This work was supported by the Korea Advanced Institute of Science and Technology and the Organic Chemistry Research Center sponsored by the Korea Science and Engineering Foundation. Dedicated to Professor Yoshito Kishi on the occasion of his 60th birthday.

The $^{18}O/^{16}O$ induced proton isotope shift in water

Natalia D. Sergeyeva,[a] J. P. Jacobsen*[b]† and N. M. Sergeyev[c]

[a] *Russian Peoples' Friendship University, 117198, Moscow, Russia*

[c] *Department of Chemistry, Moscow State University, Moscow, 119899, Russia*

Measurements of proton NMR spectra at 750 MHz of dilute solutions of water in nitromethane reveals a small proton isotope shift due to $^{16}O/^{18}O$ substitution equal to about 1 ppb.

There has been much recent interest in the isotope shifts induced by the substitution of ^{18}O for ^{16}O. In the extensive review of Risley and van Etten[1] proton isotope shifts in water induced by $^{18}O/^{16}O$ substitution are reported as covering the very wide range from −70 to +300 ppb. In early work Pinchas and co-workers[2–4] used separate samples of the pure isotopomers in order to prevent proton exchange. The strong dependence of the water shielding upon concentration, temperature and certain uncontrolled impurities makes these results questionable.

Recently, we performed measurements of the $^{18}O/^{16}O$ induced proton isotope shift using dilute solutions of an $H_2{}^{16}O$ and $H_2{}^{18}O$ mixture in nitromethane.[5] At a proton NMR frequency of 300 MHz we found no splitting of the H_2O singlet. This suggested that the $H_2{}^{18}O/H_2{}^{16}O$ isotope shift is less than 0.5 Hz (about 2–3 ppb). The availability of NMR spectrometers with higher magnetic fields makes it possible to measure an isotope effect of this size. Here we describe a successful attempt to measure this isotope shift on a 750 MHz NMR spectrometer.

The crucial requirement in obtaining the NMR parameters of individual water molecules is to stop the proton (or proton–deuteron) exchange in order to prevent the collapse of spin multiplets and to exclude any effect on the NMR line shape. To obtain reliable results it is necessary to use dilute solutions of water in organic solvents.[6] The solvent has to be carefully dried to eliminate the residual water.

We used [$^2H_3$]nitromethane purchased from Merck with the deuteration levels of 99.44% (±0.01%) according to our estimates. The proton signal of the residual CHD_2NO_2 was used to determine the water content in the solvent. [$^2H_3$]Nitromethane was dried by several freezing–thaw–pumping cycles using P_2O_5 as a drying agent *in vacuo* and passed through a series of traps to eliminate traces of the drying agent. The final water content never exceeded 0.01 mol%. We used double distilled $H_2{}^{16}O$, 99.1% $H_2{}^{18}O$ and 30% $H_2{}^{17}O$ enriched water purchased from Isotech and 99.96% D_2O purchased from Merck. Small amounts of D_2O were added to the solutions of water to control the rate of exchange by monitoring of the HDO lines. A small amount of dried TMS was added to control the resolution and the water line shape. We used a Young sample tube for mixing the components to control *via* ^1H NMR spectra the water content at all stages of the sample preparation. The dosages of TMS and water mixtures were done by vaporization into the precalibrated volumes. The final solution was distilled in a 5 mm sample tube and sealed under vacuum. All bulbs and sample tubes used were treated according to the procedure described earlier[7] and kept under vacuum.

A 750 MHz Varian INOVA NMR spectrometer was used to obtain the ^1H NMR spectra. Typical proton NMR spectra of a 0.25 mol% solution of a 20 : 10 : 1 $H_2{}^{16}O$–$H_2{}^{18}O$–D_2O mixture in [$^2H_3$]nitromethane taken in the temperature range from 30 to 80 °C are shown in Fig. 1. Fig. 1(*a*) contains lines from $H_2{}^{16}O$–$H_2{}^{18}O$, while Fig. 1(*b*) contains lines from $H^{16}OD$–$H^{18}OD$. Values of the $^{18}O/^{16}O$ induced proton isotope shifts were measured to be the following: 30 °C: 0.79 ± 0.05; 45 °C: 0.93 ± 0.05; 60 °C: 1.04 ± 0.05; 80 °C: 1.08 ± 0.05 (all values are in ppb).

It is worth noting that the water linewidth is about 0.3 Hz, revealing a decrease with temperature. In all cases the $H_2{}^{18}O$ signal appears at higher field in accord with a very well known trend[8] that heavier isotopic substitution produces high fields displacements.

In Fig. 1(*b*) the multiplet for HDO is shifted to high field by about 23 Hz (*ca.* 30.6 ppb), in exact agreement with the previously found H/D induced proton isotope shift for water.[5,9] The HDO signal shows a superimposition of the triplet of $HD^{16}O$ and that of $HD^{18}O$, with the two low field components of the $HD^{18}O$ triplet almost overlapping the two high field components of the $HD^{16}O$ signal. It is of interest that the $^{18}O/^{16}O$ induced proton isotope shift for HDO estimated from spectra at 80 °C is equal to 1.1 Hz (1.4 ± 0.1 ppb). Comparing this value with the $^{16}O/^{18}O$ induced proton isotope shift for H_2O equal to 0.86 Hz (1.08 ± 0.05 ppb at 80 °C) we can suggest an anomalously strong (0.32 ± 0.15 ppb) nonadditivity effect.[10]

We also performed measurements of the proton NMR of water 30% enriched by ^{17}O. According to mass spectral analysis it contains ^{16}O, ^{17}O and ^{18}O in percentages of 25.5, 30.7 and 43.7%, respectively. The ^1H NMR spectrum of a 0.5% solution of this water in [$^2H_3$]nitromethane is shown in Fig. 2. Fig. 2(*b*)

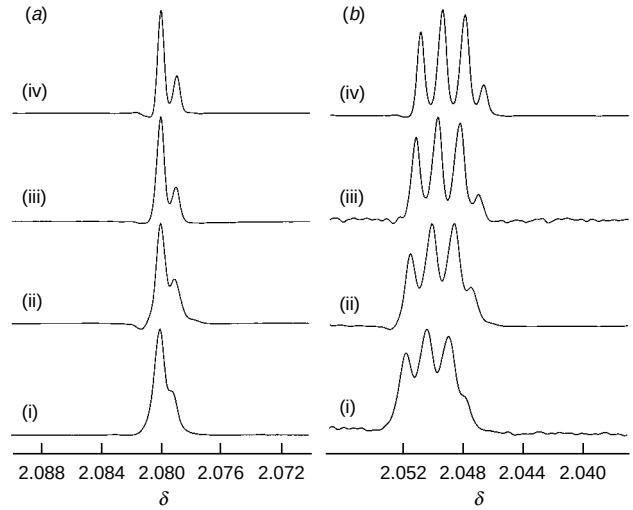

Fig. 1 Two different regions of the ^1H NMR spectrum of a 0.25 mol% solution of a $H_2{}^{16}O$–$H_2{}^{18}O$–D_2O mixture in [$^2H_3$]nitromethane at (i) 30, (ii) 45, (iii) 60 and (iv) 80 °C. The intensity of the signals in (*b*) has been multiplied by 25 compared to (*a*). In all four spectra the signal for $H_2{}^{16}O$ is referenced to δ 1.959 to reset the temperature effect on this signal. The spectrum was recorded at 750 MHz with a sweep width of 5000 Hz, an aquisition time of 8.0 s and 1 transient. The FID was processed using slight resolution enhancement and Fourier transformed in 128 K. (*a*) The signal from $H_2{}^{16}O$–$H_2{}^{18}O$ showing the increasing values of the isotope effect. (*b*) The signal from $HD^{16}O$–$HD^{18}O$ confirming the $^{16}O/^{18}O$ isotope effect.

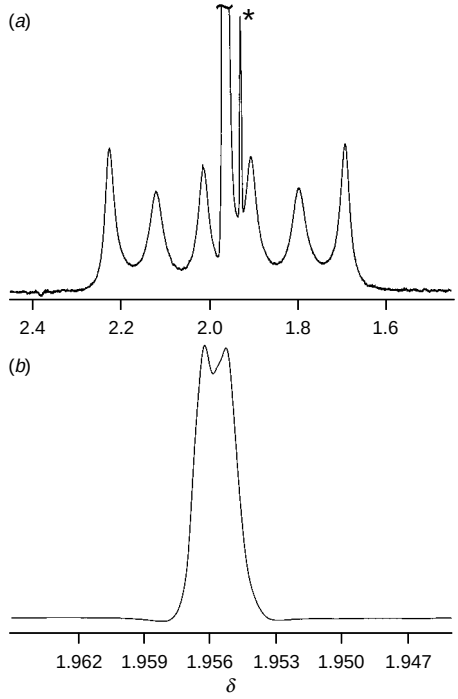

Fig. 2 The 750 MHz ^{1}H NMR spectrum of a 0.5 mol% solution of $H_2{}^{16}O$–$H_2{}^{17}O$–$H_2{}^{18}O$ in [$^2H_3$]nitromethane. The spectrum was recorded at 750 MHz with a sweep width of 5000 Hz, an aquisition time of 8.0 s and 1 transient. (*a*) The sextet of $H_2{}^{17}O$; the intensity of the signals has been multiplied by 100 compared to the upper trace. The signal due to HDO is marked by an asterisk (*). The FID was processed using exponential apodization and Fourier transformed in 128 K. (*b*) The signals corresponding to $H_2{}^{16}O$ and $H_2{}^{18}O$ are separated by an isotope shift equal to 1.1 ppb. The FID was processed using slight resolution enhancement and Fourier transformed in 128 K.

shows the central strong signal due to $H_2{}^{16}O$ and $H_2{}^{18}O$ with the $^{16}O/^{18}O$ induced proton isotope shift equal to (1.1 ± 0.1 ppb), in accord with the spectrum of pure ^{18}O water (Fig. 1).

The sextet of $H_2{}^{17}O$ caused by the coupling of protons in H_2O with ^{17}O (spin 5/2) is shown in Fig. 2(*a*). The small signal of HDO seen to the right of the $H_2{}^{16}O/H_2{}^{18}O$ signal is due to traces of heavy water in the solvent. All components of the sextet contain additional selective broadening due to the relatively slow ^{17}O relaxation.[11,12] The three low field components of the ^{17}O multiplet (less distorted by the central signal) have linewidths equal to *ca.* 20, 33 and 26 Hz, respectively, in full accord with theory.[11] It is interesting to note that, for a similar solution, we found in the ^{17}O NMR spectra at a similar temperature (*ca.* 60 °C) line widths of *ca.* 10 Hz.[5] This indicates that the measurement of ^{17}O–H coupling constants is best performed using ^{17}O rather than ^{1}H NMR spectroscopy. We intend to obtain accurate data on ^{17}O–^{1}H coupling constants and T_1 data for ^{17}O relaxation using iterative calculations with the QUADR program.[13] Also of interest is the possibility of checking the additivity of isotope shifts, as the $H_2{}^{16}O/H_2{}^{17}O$ isotope effect should be close to half of the $^{16}O/^{18}O$ induced proton isotope shift.

We can now state that disagreements with the old data are due to the inconsistent methods of measuring small isotope effects used in the early work.[2–4] The data now obtained are in good agreement with other data on proton isotope shifts due to heavier isotope substitution, *e.g.* of $^{12}C/^{13}C$ substitution.[8]

In parallel with this experimental study, the $^{18}O/^{17}O/^{16}O$ induced proton isotope shifts were studied theoretically[14] and the calculated values are in good agreement with the experimental ones.

The Danish Instrument Center for NMR Spectroscopy of Biological Macromolecules is acknowledged for the use of the 750 MHz NMR spectrometer. The authors thank the INTAS for a research grant (No. 94-448). The work was supported in part by the Danish Natural Science Research Foundation (Grant No. 9600856). The authors thank Professor J. Oddershede, Department of Chemistry, Odense University, for suggesting the experiments and Drs W. T. Raynes and R. Wigglesworth for fruitful discussions and for information about the results of the calculations.

Synthesis and optical resolution of a fluorescent chiral calix[4]arene with two pyrene moieties forming an intramolecular excimer

Takashi Jin*[a]† and Kenji Monde[b]

An inherently fluorescent chiral calix[4]arene 2 with two pyrene moieties forming an intramolecular pyrene excimer has been synthesized and optically resolved by an HPLC method using a chiral-packed column.

Calixarenes are unique host molecules which have complexing abilities toward ions and/or organic molecules.[1] Recent interest in the synthesis of calixarenes has focused on chiral species, since such a chiral host has potential as an enantioselective artificial receptor of chiral or racemic ligands.[2] Chiral calix[4]arenes have been produced by the addition of chiral residues to calix[4]arene skeletons,[3] or by the introduction of asymmetric substituent patterns into the lower rim[4] or the phenolic rings.[5] Although more than twenty studies of the synthesis of chiral calix[4]arenes have been reported, there are only a few examples of fluorescent chiral calix[4]arenes.[4b,5g] Fluorescent-detectable chiral calixarenes have a great advantage in their high sensitivity as enantioselective sensors of biologically important organic molecules. Herein we describe a simple method for the synthesis of a tri-*O*-alkyated fluorescent chiral calix[4]arene (ABBH-type) that has two pyrene moieties *via* a two-step alkylation of the parent calix[4]arene.

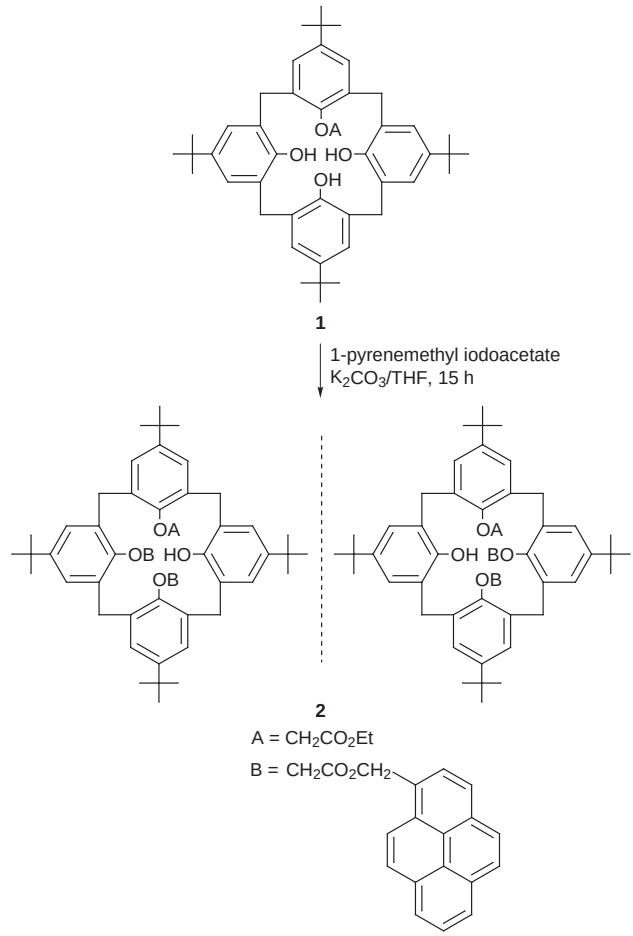
The fluorescent calix[4]arene **2** was synthesised by the reaction of **1**‡ (92 mg) with 2 equiv. (100 mg) of pyren-1-ylmethyl iodoacetate (Molecular Prob. Inc.) in the presence of K_2CO_3 (103 mg) in anhydrous THF (Scheme 1). Racemic compound **2** was obtained as a white powder (55% yield) after a simple chromatographic purification. The structure of **2** was identified by ^{1}H NMR and FD mass spectroscopy.§

The ^{1}H NMR spectrum of **2** showed four singlets for the *tert*-butyl groups and four pairs of doublets from the bridging CH_2 groups, suggesting that the pyrene moieties were introduced to the proximal positions of the lower rim and that **2** adopted a cone conformation. Considering the intensity of the pyrene protons in the NMR spectrum and the results of the FD mass spectrum, calix[4]arene **2** should have an ABBH configuration with two pyrene moieties. To clarify the substituted pattern, a ^{1}H NMR spectrum of **2** in the presence of a chiral shift reagent was measured. The addition of Pirkle's reagent [(S)-(+)-1-(9-anthryl)-2,2,2-trifluoroethanol] to a $CDCl_3$-solution of **2** caused doubling of the methylene signals of the OCH_2CO groups (δ 4.56 and 4.69). This result confirmed that the substituted pattern of calix[4]arene **2** was of the ABBH type, not the ABHB type.

Optical resolution of **2** was performed *via* an HPLC method using a chiral-packed column (Chiracel OD, Daicel, 0.46 × 25 cm). Fig. 1(*a*) shows an HPLC chromatogram for the optical resolution of **2**. Up to 1 mg of **2** per injection could be separated completely in two fractions. To check the enantiomeric resolution, the first and second fractions were subjected to circular dichroism (CD) measurements. The CD spectra [Fig 1(*b*)] were mirror images of each other, indicating that the compounds from the first and second fractions were optical isomers.

The fluorescence spectrum of the first fraction was identical with that of the second fraction. Fig. 2(*a*) shows the fluorescence spectrum of the isomer from the first HPLC fraction. It shows a dual emission resulting from a pyrene monomer (*ca.* 390 nm) and excimer (480 nm),[6] while the fluorescence spectrum of pyrene at the same concentration as **2** afforded only monomer emissions [Fig. 2(*b*)]. The intensity ratio of the monomer/excimer emission **2** was less affected by the concentration in the range from 10^{-4} to 10^{-7} mol dm^{-3}. This indicates that the excimer emission results from an intramolecular excimer, not from an intermolecular excimer.

We examined the fluorescence properties of two enantiomers (the first and second fractions of **2**) toward three chiral guests in the $CHCl_3$–EtOH (30 : 1) at 25 °C. We found that the intensity of the excimer emission of **2** (3.9 μmol dm^{-3}) increased up to 2-fold by addition of L-phenylalanine methyl ester, L-alanine methyl ester or L-phenylglycinol in the presence of Na^+ (76 μmol dm^{-3}). However, differences in the fluorescence intensities between the two isomers of **2** in the presence of the



Scheme 1 *Reagents and conditions:* i, pyren-1-ylmethyl iodoacetate, K_2CO_3, THF, 15 h

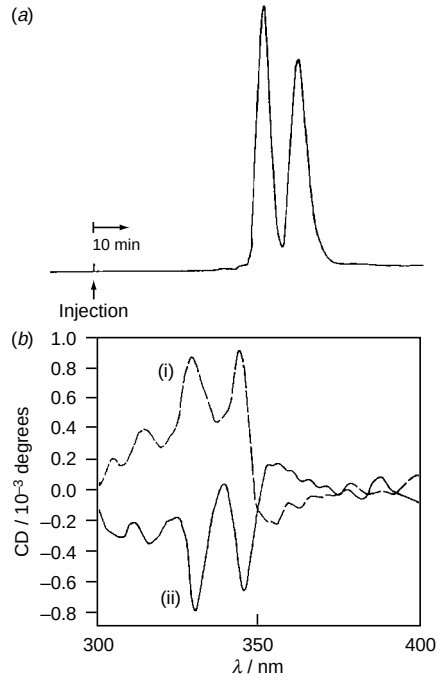


Fig. 1 (*a*) An HPLC chromatogram for optical resolution of racemic **2**. Column: Chiracel OD (0.46 × 25 cm); eluent: hexane–Pr^{i}OH (95 : 5); flow rate: 0.2 ml min^{-1}; T = 40 °C. (*b*) CD spectra of the enatiometric pair of **2** ($CHCl_3$, 25 °C): (i) first fraction, (ii) second fraction.

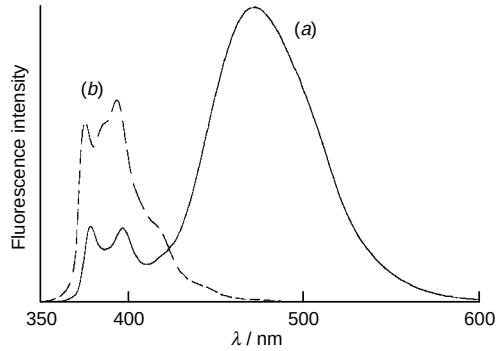

Fig. 2 Fluorescence spectra of the isomer (first fraction) of **2** and pyrene in $CHCl_3$ at 25 °C: (*a*) [**2**] = 3.9 μmol dm^{-3}, (*b*) [pyrene] = 3.9 μmol dm^{-3}

chiral guests were too small to evaluate the chiral discriminating ability of **2**.

To the best of our knowledge, compound **2** is the first example of a tri-*O*-alkylated fluorescent chiral calix[4]arene (ABBH type). So far, $Ba(OH)_2$ and BaO have been the only bases that stop the *O*-alkylation reaction at the tri-*O*-substituted stage.[7] Shinkai and co-workers have reported an inherently chiral calix[4]arene of the ABBH type *via* tri-*O*-alkylation of calix[4]arenes using $Ba(OH)_2$, where an excess amount of alkyl halide (*ca*. 10 equiv.) was used to accomplish alkylation.[4a,c] We found that a tri-*O*-alkylated chiral calix[4]arene **2** with a cone conformation could be easily prepared by a stoichiometric reaction with **1** and pyren-1-ylmethyl iodoacetate in the presence of K_2CO_3. Since chiral calix[4]arene **2** has a phenolic OH group, further modifications of **2** can be easily carried out. Applications for chiral calix[4]arene **2** are the subject of ongoing investigation in our laboratory.

This work was supported in part by a Grant-in-Aid from the Ministry of Education, Culture, and Science, Japan. We thank Professor M. Takasugi for his kind offer of the chiral-packed column.

Reaction of triphenylbismuthonium 2-oxoalkylides with benzils. A novel one-pot conversion of symmetrical 1,2-diketones into *O*-aroyl enolates of unsymmetrical 1,3-diketones

M. Mizanur Rahman, Yoshihiro Matano and Hitomi Suzuki*†

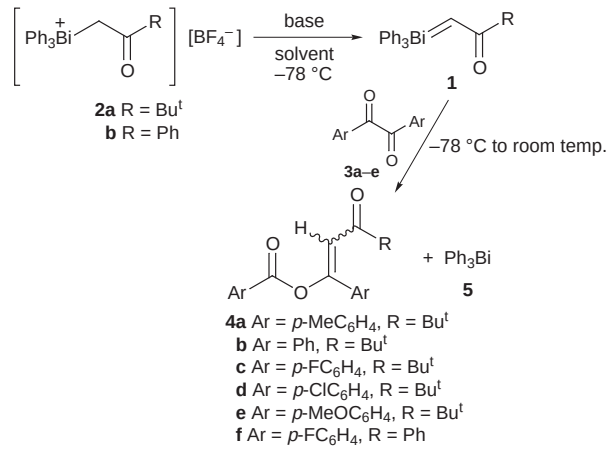
Department of Chemistry, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto 606-8224, Japan

Triphenylbismuthonium 2-oxoalkylide 1, generated *in situ* from the corresponding onium salt 2 and base in THF at low temperatures, reacts with benzils 3 to give *O*-aroyl enolates of unsymmetrical 1,3-diketones 4 in moderate to good yields.

Ylide chemistry in carbon–carbon bond forming reactions has long been an active area of organic synthesis. However, in contrast to the extensive studies and general utility of phosphonium, arsonium and stibonium ylides,[1] little attention has been paid to the bismuthonium ylides.[2,3] Recently, we have found that triphenylbismuthonium 2-oxoalkylides **1** easily couple with aldehydes and *N*-sulfonylaldimines to give α,β-epoxy ketones and α,β-aziridino ketones, respectively.[4,5] This reaction mode is only observed for bismuth among all the group 15 elements; phosphonium, arsonium and stibonium 2-oxoalkylides are known to undergo Wittig-type reactions with these substrates.[1] Although ylides **1** do not react with simple ketones or esters, they readily couple with α-dicarbonyl compounds such as ethyl pyruvate and *ortho*-quinones, giving the epoxides or tropones depending on the structure of the substrates employed.[6] Here we report an unexpected result from the reaction of triphenylbismuthonium 2-oxoalkylides **1** with benzils **3**, where *O*-aroyl enolates of unsymmetrical 1,3-diketones **4** are formed *via* the carbon-to-oxygen migration of the aroyl moiety.

Treatment of benzil **3** with 1 equiv. of triphenylbismuthonium 2-oxoalkylide **1**, generated *in situ* from the corresponding onium salt **2** and a base in THF at low temperatures, readily gave an intimate *E*/*Z*-mixture of *O*-aroyl enolates **4** and triphenylbismuthane **5** (Scheme 1).‡ The reaction conditions were optimized using onium salt **2a** and 4,4′-dimethylbenzil **3a** (Table 1). Regardless of the order of adding the base and the substrate, enolates **4a** were obtained in similar yield (entries 1 and 2). Among several bases examined, KOBu^t gave the best results (entries 1–6). As for the solvent, a mixed solvent system THF–CH_2Cl_2 (1 : 1) gave better yields than THF alone, probably because of the improved solubility of **2a** in the former solvent (entries 1, 3, 8 *versus* 5, 6, 9). The stereoselectivity of the reaction was low, the *E*/*Z* isomeric ratio being around 4 : 6. Benzil **3b**, 4,4′-difluorobenzil **3c** and 4,4′-dichlorobenzil **3d** all underwent similar coupling reactions to yield the corresponding enolates **4b**–**d** and bismuthane **5**, respectively (entries 7–10). In contrast, 4,4′-dimethoxybenzil **3e** reacted with **2a** in the presence of KOBu^t to give enolate **4e** and triketone **6** in 12 and 10% yields, respectively (entry 11). The reaction between **3c** and ylide **1b**, generated *in situ* from **2b** and KOBu^t, afforded the corresponding enolate **4f** (entry 12).

O-Aroyl enolates **4** obtained were characterized by NMR, IR and mass spectroscopy as well as by elemental analysis.§ The ^{1}H NMR spectra of **4a**–**d** showed the olefinic protons of the *E*- and *Z*-isomers at around δ 6.7–6.9 (in $CDCl_3$) as two singlet peaks. In the IR spectra of **4a**–**d**, two strong carbonyl

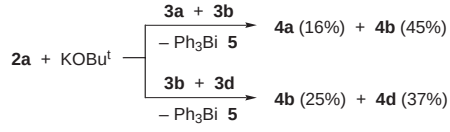


Scheme 1

Table 1 Reaction of bismuthonium salts **1** with benzils **3** in the presence of a base[a]

Entry	Salt	Benzil	Base	Solvent	Enolate	Yield (%)[b]	*E* : *Z* ratio
1	**2a**	**3a**	KOBu^t	THF	**4a**	53 (86)	42 : 58
2[c]	**2a**	**3a**	KOBu^t	THF	**4a**	55 (85)	42 : 58
3	**2a**	**3a**	$NaN(SiMe_3)_2$	THF	**4a**	43 (67)	41 : 59
4	**2a**	**3a**	$KN(SiMe_3)_2$	THF	**4a**	44 (69)	40 : 60
5	**2a**	**3a**	KOBu^t	THF–CH_2Cl_2	**4a**	65 (90)	42 : 58
6	**2a**	**3a**	$NaN(SiMe_3)_2$	THF–CH_2Cl_2	**4a**	47 (72)	41 : 59
7	**2a**	**3b**	KOBu^t	THF	**4b**	58 (88)	39 : 61
8	**2a**	**3c**	KOBu^t	THF	**4c**	55 (78)	50 : 50
9	**2a**	**3c**	KOBu^t	THF–CH_2Cl_2	**4c**	67 (91)	51 : 49
10	**2a**	**3d**	KOBu^t	THF	**4d**	63 (88)	45 : 55
11	**2a**	**3e**	KOBu^t	THF	**4e**	12 (42)[d]	40 : 60
12	**2b**	**3c**	KOBu^t	THF	**4f**	20 (80)	N.d.[e]

[a] All reactions were carried out using an equimolar amount of reagents. A 1 : 1 mixture of THF–CH_2Cl_2 was used in entries 5, 6 and 9. In every case, bismuthane **5** was recovered in good yield. [b] Isolated compounds. Numerals in parentheses refer to the conversion yields based on unrecovered benzil. [c] KOBu^t was added to a solution of **2a** and **3a** in THF at −78 °C. [d] Triketone **6** was obtained in 10% isolated yield. [e] Not determined.



Scheme 2 *Reagents and conditions*: **2a** (1.0 mmol), **3a,b,d** (1.0 mmol), KOBu^t (1.0 mmol), THF (15 cm^3), −78 °C to room temp.

absorptions were observed at 1746–1760 and 1672–1684 cm^{-1}; the former was assigned to the ester carbonyl and the latter to the keto carbonyl stretching bands, respectively. These structural assignments were further confirmed by an X-ray diffraction analysis of the *Z* isomer of **4a**.¶

In order to shed light on the reaction pathway, competitive reactions were carried out for the pairs **3a**/**3b** and **3b**/**3d** (Scheme 2). As expected, the more electron-deficient benzil was more reactive toward ylide **1a**, suggesting that the nucleophilic attack of the ylide carbanion on the carbonyl function in **3** is the rate-determining stage of the present coupling reaction.

The 1,2-diketone structure seems to be indispensable for the present new type of 1,2-carbonyl transposition; ethyl benzoylformate **7**, which is an α-keto ester, reacted with ylide **1a** to give an epoxide **8** (Scheme 3). A plausible reaction mechanism is depicted in Scheme 4, where the negatively charged oxygen atom of the initial adduct **9** attacks the neighboring carbonyl carbon atom to form intermediate **10**, in which the carbon-to-oxygen migration of the aroyl group takes place under simultaneous elimination of the triphenylbismuthonio group as bismuthane **5**.‖ This interpretation is supported by the following findings. The Darzen reaction between α-bromopinacolone and benzil resulted in the formation of a mixture of *cis/trans*-2-aroyl-2-aryl-3-pivaloyl oxiranes **11**, which did not isomerize to enolate **4** under the present conditions. Moreover, on treatment with KOBu^t, triketone **6** derived from the reaction of **1a** and **3e** could not be converted to **4e**. Therefore, the reactivity inherent in **1** stands in marked contrast to that of its phosphorus counterpart, which is shown to undergo the Wittig reaction with benzil to afford α,β-unsaturated ketones.[7]

Homologation of 1,2-diketones to 1,3-diketones usually requires a multistep sequence. However, 1,2-diketones **3** can be directly transformed into unsymmetrical 1,3-diketones in the form of enolates **4** using triphenylbismuthonium 2-oxoalkylides **1** as the *in situ* reagent. This type of carbon–carbon bond construction based on 1,2-carbonyl migration is unprecedented in ylide chemistry[8] and is a potential new method in organic synthesis. Further investigation of this aspect of the chemistry of bismuthonium ylides is now in progress.

‡ *Typical procedure*: To a stirred suspension of onium salt **1a** (313 mg, 0.50 mmol) in THF (8 cm^3) was added KOBu^t (56 mg, 0.50 mmol) at −78 °C. After 10 min, 4,4′-dimethylbenzil **3a** (119 mg, 0.50 mmol) was added and the resulting mixture was allowed gradually to warm to room temperature. Evaporation of the solvent under reduced pressure gave an oily residue, which was chromatographed on silica gel (hexane–EtOAc) triphenylbismuthane **5** (185 mg, 84%), recovered **3a** (47 mg, 40%) and an intimate mixture of (*E*/*Z*)-enolates **4a** (90 mg, 53%; *E* : Z = 42 : 58) in this order. The *E*/*Z* isomer ratio was estimated by ^{1}H NMR integration of the olefinic protons. The equation proposed by Pascual *et al*.[10] was used for stereochemical assignment of compounds **4**, where the olefinic proton peak appearing at high field was always assigned to the *E*- isomer.

§ *Selected data* for **4a**: $\delta_H(CDCl_3)$ (*E*-isomer) 1.29 (9 H, s), 2.36 (3 H, s), 2.42 (3 H, s), 6.74 (1 H, s), 7.19 (d, 2 H, *J* 8), 7.29 (d, 2H, *J* 7), 7.78 (d, 2 H, *J* 8), 8.0 (d, 2 H, *J* 8); (*Z*-isomer) 1.20 (9 H, s), 2.36 (3 H, s), 2.42 (3 H, s), 6.90 (1 H, s), 7.19 (d, 2 H, *J* 8), 7.29 (d, 2 H, *J* 7), 7.55 (d, 2 H, *J* 8), 8.09 (d, 2 H, *J* 8); ν_{max} (KBr)/cm^{-1} 1746 (C=O), 1684 (C=O); *m*/*z* (EI) 279 (M$^+$ − 57). Highly active, stable, catalysts for the Heck reaction; further suggestions on the mechanism

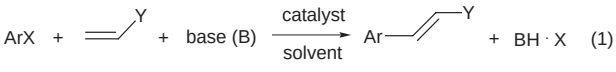
Bernard L. Shaw,*† Sarath D. Perera and Elaine A. Staley

School of Chemistry, University of Leeds, Leeds, UK LS2 9JT

Tri(1-naphthyl)phosphine gives palladacycles which are very active catalysts for Heck reactions; mechanisms based on a Pd^{II}–Pd^{IV} cycle are proposed and a new, very efficient method of separating the product from the catalyst has been devised, which involves treatment with cyanide ion.

The Heck alkenation reaction [eqn. (1)] is very important in

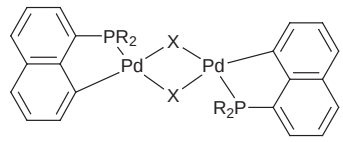


organic synthesis with many applications. Frequently, a Heck catalyst has been generated *in situ* from $Pd(OAc)_2$ and a tertiary phosphine, L = PPh_3 or $P(C_6H_4Me\text{-}o)_3$. This is assumed to give some PdL_2, which forms part of a catalytic cycle involving Pd^0–Pd^{II}. Recently, highly efficient catalysts using cyclopalladated $P(C_6H_4Me\text{-}o)_3$ have been reported.[1a,b] One of us has suggested a quite new mechanism for such catalyses with reversible nucleophilic attack on Pd^{II}-coordinated alkene being a key step in the promotion of oxidative addition of ArX, in a Pd^{II}–Pd^{IV} catalytic cycle.[2] Previously, as part of an extensive study on the effects of steric compression, we found that 1-naphthylphosphines could give particularly stable metallacycles,[3] with metallation in the 8- or *peri*-position. We have now found tri(1-naphthyl)phosphine (PNp_3) cyclopalladates to give very stable palladacycles, which are excellent catalysts for Heck reactions.

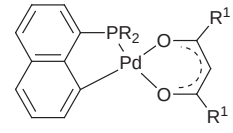
On heating PNp_3 with $Pd(OAc)_2$ in toluene the metallacycle **1a** was obtained. **1a** showed broad NMR spectra at 25 °C, probably due to exchange at the bridging acetates; the spectra sharpened at −60 °C. Broad NMR spectra were similarly found for the palladacycles prepared from $Pd(OAc)_2$ and $P(C_6H_4Me\text{-}o)_3$.[1a] We treated **1a** with acetylacetone and converted it into the mononuclear acetylacetonate **2a** which showed sharp NMR spectra at 25 °C. **2a** can be more conveniently made by treating $[Pd(acac)_2]$ with PNp_3 in hot benzene. **2b** was similarly prepared from PNp_3 and $[Pd(hfacac)_2]$. We have similarly cyclopalladated $P(C_6H_4Me\text{-}o)_3$ to give **3a** and **3b**. All these new palladacycles have been fully characterised.

The palladacycles **1a**, **2a** and **2b** are excellent catalysts for Heck reactions. Some of our catalytic results are summarised in Table 1. Thus treatment of iodobenzene with styrene at 120 °C for 5 days using 10^{-4} mol% catalyst **2b** gave stilbene in 65% isolated yield, *i.e.* a turn over number (TON) of 650 000. No palladium metal was formed and the final reaction solution was extremely pale yellow. Treatment of iodobenzene with methyl acrylate at 95 °C for 13 days using 5×10^{-5} mol% of catalyst **2b** gave methyl cinnamate with a TON of 1 120 000, the highest turnover number yet reported for a Heck reaction; with 10^{-3} mol% catalyst reacting at 95 °C for 5 d we isolated methyl cinnamate in 88% yield with a TON of 88 000. Herrmann and Beller's catalysts gave TONs of up to 100 000, or in the presence of much NBu_4Br as promoter, 1 000 000; NBu_4Br is expensive and we tried to achieve high TONs without it. 4-Bromoacetophenone reacted with styrene at 125 °C over 7 h to give 4-acetylstilbene in 94% isolated yield using catalyst **1a** (entry 5); similarly with 4-bromocyanobenzene (entry 6). Bromobenzene, a relatively inactive bromide, gave a 77% yield of stilbene after reacting with styrene at 115 °C for 30 h using catalyst **2b** (entry 7). In entry 8 we used sodium acetate as the base and the acetylacetonate catalyst **2a**. Examples of catalyses using **3a** and **3b** are also given. The entries given in Table 1 all refer to isolated yields of crystalline products. Apart from entry 3, where column chromatography was used, and entry 1, the products were separated from the palladium catalyst using an extraction process that we have devised. This depends on the enormous affinity of palladium for cyanide ion: the formation constant for $[Pd(CN)_4]^{2-}$ is *ca.* 10^{52}.[4] The extraction process works very well for the examples given in Table 1.‡

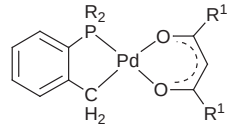
We suggest a mechanism for the Heck reactions catalysed by **1a**, **2a** or **2b** which is analogous to that proposed by one of us[2] for Heck reactions. The mechanism involves Pd^{II}–Pd^{IV}, with the alkene coordinating to the Pd^{II} being reversibly attacked by a nucleophile, such as OAc^-, $acac^-$, OH^-, Br^- or I^-, to give a negatively charged alkyl species **5** in which the Pd^{II} is electron rich and oxidatively adds ArX. Loss of nucleophile regenerates the coordinated alkene and migration of Ar from Pd^{IV} to coordinated alkene followed by β-hydrogen migration, gives the product ArCH=CHY and removal of HBr by the base regenerates the Pd^{II} catalyst of type **1**, (see Scheme 1).



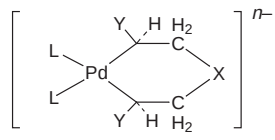
1a R = naphthyl, X = OAc
1b R = naphthyl, X = I
1c R = naphthyl, X = Br



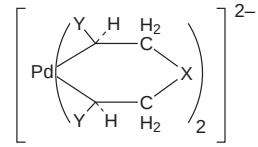
2a R = naphthyl, R^1 = Me
2b R = naphthyl, R^1 = CF_3



3a R = *o*-tolyl, R^1 = Me
3b R = *o*-tolyl, R^1 = CF_3



10a X = OC(=O)O
10b X = O



11a X = OC(=O)O
11b X = O

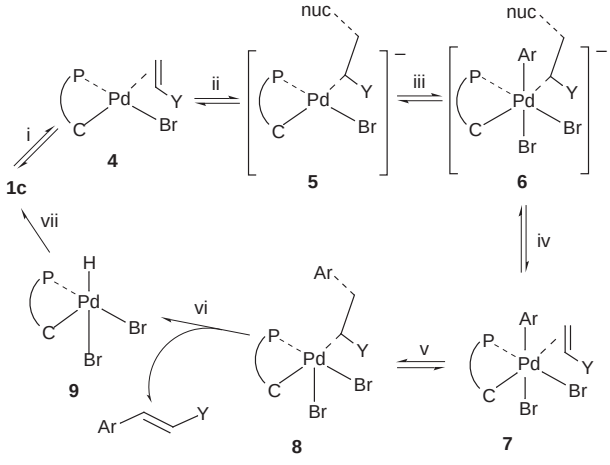
5	bab	sty	2/2.6	**1a** (5.2×10^{-3})	7 h (125)	94 (180)
6	bcb	sty	2/3	**1a** (5.2×10^{-3})	7 h (125)	85 (165)
7	PhBr	sty	10/12.5	**2b** (10^{-2})	30 h (115)	77 (770)
8	PhI	sty	2/2.2	**2a** (10^{-2})	24 h (95)	56 (115)
9	PhI	sty	2/3	**3a** (7×10^{-3})	8 h (95)	83 (240)
10	PhI	sty	10/12.5	**3b** (10^{-2})	4 h (95)	90 (900)
11	PhI	mac	2/2.2	**2a** (1.9×10^{-3})	24 h (95)	72 (760)

[a] Except for entry 8, an equivalent amount of tri-(*n*-butyl)amine to the aryl halide was used as base; in entry 8, 4 mmol of sodium acetate was used. The catalyst was dissolved in dmf, *e.g.* 1 cm³ in entry 1. Experimental details available upon request from the authors. [b] bab = 4-bromoacetylbenzene, bcb = 4-bromocyanobenzene, sty = styrene, mac = methyl acrylate.

In the so-called exceptionally mild 'Jeffrey' conditions for effecting a Heck reaction, *viz* [$Pd(OAc)_2$], an aryl iodide and an alkene such as CH_2=CHY reacting in dmf at *ca.* 30 °C in the presence of sodium hydrogen carbonate or potassium carbonate, with much added NBu_4Cl as phase-transfer catalyst, very good yields are obtained. One of us suggested that the remarkable ability of aryl iodide to oxidatively add to Pd^{II} at such as low temperature arises because HCO_3^- or CO_3^{2-} attacks two coordinated alkenes to give chelated dialkyl species **10a** and **11a**, X = CO_3.[2] **11a** is an 'ate' complex with an extremely electron-rich palladium. We now suggest that under these conditions the bridging group X could be an oxygen atom, formed from water + base attacking two coordinated alkenes, *i.e.* **10b** and **11b**. Water is known to promote Heck reactions including under Jeffrey conditions.[5] We suggest that one function of the large cations such as NBu_4^+ is to help stabilise in solution large anions such as of type **10** or **11** and analogous species from palladacycles. Because of the beneficial effect of water we deliberately did not dry our reagents nor the dmf solvent (≥0.1% water). Electron rich 'ate' complexes of iron(II) or cobalt(II) *e.g.* $[FeMe_4]^{2-}$ or $[CoMe_4]^{2-}$, react with a series of vinyl bromides, such as β-bromostyrene, even at −78 °C, undergoing oxidative addition/reductive elimination:[6] 'ate' complexes of Pd^{II}, Ni^{II} and Pt^{IV} are known. We also suggest that attack on two-coordinated alkenes by H_2O + base could give **12**, as an electron rich Pd^{II} complex which oxidatively adds ArX and which could participate in a catalytic cycle similar to that shown in Scheme 1. Recently, the very stable and sterically hindered chelates of type **13** have been shown to be very stable catalysts for Heck reactions giving very high TON but requiring high reaction temperatures (140 °C) even with iodides.[7] We suggest a mechanism similar to that shown in Scheme 1 for catalyses by **13**.



Scheme 1 Proposed mechanism for the Alkenation reaction using a palladacycle of type **1** or **2** and an aryl bromide. After several cycles the bromide **1c** will be formed and is used in the Scheme. i, CH_2=CHY; ii, reversible attack by nucleophile (OAc^-, Br^-, $acac^-$ or OH^-); attack is shown on the terminal carbon atom but it could be on the internal carbon; iii, oxidative addition of ArBr; iv, loss of nucleophile; v, migration of Ar to terminal carbon; vi, β-hydrogen elimination; vii, removal of HBr by base.

Notes and References

† E-mail: b.l.shaw@chem.leeds.ac.uk

‡ For entry 5 the reaction mixture was dissolved in CH_2Cl_2 (10 cm³) and the organic layer washed successively with water, with a solution of NaCN (2 mg) in water (5 cm³), with 2 M HCl, and finally with water; evaporation and crystallisation from MeOH gave the product;. similarly for the other entries. For syntheses involving methyl acrylate, diethyl ether was used in the work up. Preliminary work suggests that the treatment with NaCN gives a little PNp_3 but the main product seems to be a rapidly interconverting mixture of sodium salts of type $[Na^+]_n[Np_2PC_{10}H_6Pd(CN)_{n+1}]^{n-}$ which is not soluble in CH_2Cl_2 or Et_2O, is very soluble in MeOH and presumbably sufficiently soluble in dilute aqueous NaCN; very small quantities are involved, typically μg of Pd.

Synthesis and solid-state structure of $[K_3(thf)_2\{PH(Mes)\}_3]_\infty$ (Mes = 2,4,6-$Me_3C_6H_2$): the first potassium phosphanide with a polyhedral arrangement of K and P atoms

Christoph Frenzel, Peter Jörchel and Evamarie Hey-Hawkins*†

Institut für Anorganische Chemie der Universität Leipzig, Talstrasse 35, D-04103, Leipzig, Germany

KPH(Mes) (Mes = 2,4,6-$Me_3C_6H_2$), prepared from potassium and PH_2(Mes) in refluxing toluene, crystallises from thf–pentane as $[K_3(thf)_2\{PH(Mes)\}_3]_\infty$ 1, in which the basic structural feature is a chain of tetragonal pyramids of KP_5 units, which share common edges, and two additional K atoms located over two adjacent edges of one trigonal face of the pyramid.

While lithium phosphanides have been widely employed as phosphanide-transfer reagents,[1] their heavier congeners have remained largely unexplored. Furthermore, most structural studies have focused on the solid-state structures of lithium phosphanides,[2,3] and little is known about the structures of the heavier alkali metal analogues. A few examples of sodium,[3,4] potassium,[3a,5] and caesium phosphanides[4] have been reported, most of which, like the majority of lithium derivatives, exhibit dimeric M_2P_2 arrangements or polymeric one-dimensional ladders[5] consisting of alternating M–P and P–M steps. Lithium phosphanides also form one-dimensional polymeric zigzag or helical –M–P–M–P– chains.

In our studies on potential phosphinidene (PR) precursors, we are interested in the synthesis and solid-state structures of P–H functionalised alkali metal phosphanides, MPHR. We now report the synthesis and solid-state structure of $[K_3(thf)_2\{PH(Mes)\}_3]_\infty$ **1**.

When KPH(Mes)‡ is extracted with thf and the solution (10 ml) layered with pentane (10 ml), yellow crystals of $[K_3(thf)_2\{PH(Mes)\}_3]_\infty$ **1** are obtained on standing for two weeks at room temperature (yield of isolated product: 80%). **1** is insoluble in toluene or pentane and sparingly soluble in ether, but dissolves rapidly in thf. The proton-coupled ^{31}P NMR spectrum§ in thf exhibits a doublet at δ −141.6, which is shifted to low field relative to PH_2(Mes) (δ −153.9)[6] and Li(thf)$_2${PH(Mes)} (δ −163.4).[7]¶ The $^1J_{PH}$ coupling constant of 156 Hz is lower than those of PH_2(Mes) (207.3 Hz)[6] and Li(thf)$_2${PH(Mes)} (187 Hz).[7]

1 crystallises in the centrosymmetric monoclinic space group $P2_1/n$.‖ The asymmetric unit contains three types of potassium and phosphorus atoms. Potassium atom K(1) is surrounded in a tetragonal-pyramidal fashion by five P atoms, two of which [P(1A) and P(2A)] are generated by the 2_1 axis. Furthermore, the 2_1 axis generates a polymeric chain of edge-sharing tetragonal pyramids in which the apical P atoms alternately point upwards and downwards (Fig. 1). Potassium atom K(1) is almost coplanar with P(1), P(2), P(1A), P(2A) (deviation 0.08 Å), and the pyramidal structure is only slightly distorted, the P–K–P angles ranging from 88.28(4) to 92.32(4)°. The K–P distances range from 3.306(2) to 3.451(1) Å and are comparable to those in KPH(Mes*) [Mes* = 2,4,6-$Bu^t_3C_6H_2$, K–P 3.271(2), 3.181(2), 3.357(2) Å],[5] which, however, has an infinitely extended, centrosymmetric ladder structure, and the related compound [K(thf)$_2${P(Mes)(SiFBu$^t_2$)}]$_2$ [K–P 3.230(1) Å].[3a] Similar K–P distances are also found in [Cp*$_2$ZrP$_3$K(thf)$_{1.5}$] [Cp* = C_5Me_5, K–P 3.37(1)–3.61(1) Å],[8,9] [Cp$_2$ZrH{P(Mes*)}K(thf)$_2$]$_2$ [K–P 3.497(9), 3.67(1) Å],[9] a potassium phospholide [K–P 3.264(1), 3.256(1) Å],[10] and a phospholylsamarium complex [$(PC_4Me_4)_6Sm_2(KCl)_2$-$(C_6H_5Me)_3]_\infty$ [K–P 3.263(5), 3.383(5) Å].[11] In the solid-state compound KP, a polymeric helical chain of P atoms [$^1_\infty$ (P^-)] is surrounded by K atoms with short distances of 3.08–3.39 Å, and longer distances of 3.62–3.86 Å.[12]

The two remaining potassium atoms of **1**, K(2) and K(3), are located above the adjacent edges, P(3)–P(2A) and P(3)–P(1A), respectively, of a P_3 face of the tetragonal pyramid, with K–P distances in the expected range of 3.29–3.35 Å (Fig. 1). Both K atoms interact weakly with a third P atom [K(2)–P(1) 3.669(1), K(3)–P(2) 3.936(2) Å]. The coordination environment around the K(2) and K(3) atoms (Figs. 2 and 3) is completed by a disordered thf molecule and K–aryl interaction [η^3 and η^1

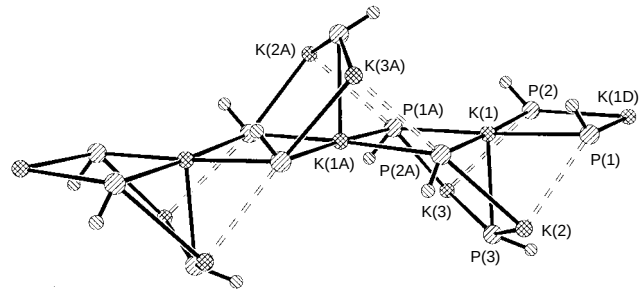

Fig. 1 Arrangement of the KP_5 fragment of **1** (SHELXTL PLUS; XP).[15] Only the K, P and H atoms (of P–H) are shown. Selected bond lengths (Å) and angles (°): K(1)–P(1) 3.368(1), K(1)–P(2) 3.397(1), K(1)–P(1A) 3.364(1), K(1)–P(2A) 3.451(1), K(1)–P(3) 3.306(2); P(1)–K(1)–P(2) 90.88(3), P(2)–K(1)–P(1A) 89.25(4), P(1A)–K(1)–P(2A) 91.46(3), P(2A)–K(1)–P(1) 88.28(4), P(1)–K(1)–P(1A) 177.25(3), P(2)–K(1)–P(2A) 177.23(3), P(1)–K(1)–P(3) 91.52(4), P(2)–K(1)–P(3) 90.34(4), P(1A)–K(1)–P(3) 91.23(4), P(2A)–K(1)–P(3) 92.32(4).

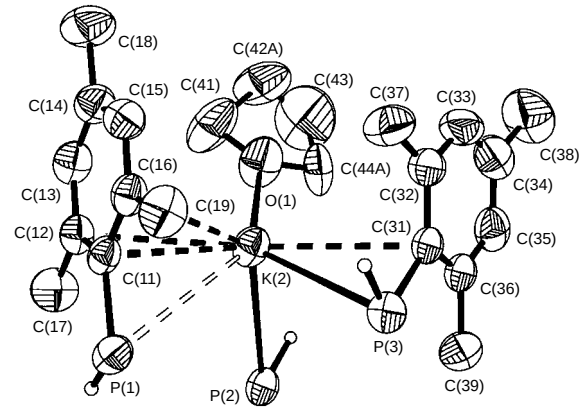

Fig. 2 Environment around K(2) (ORTEP, 50% probability, SHELXTL PLUS; XP).[15] Only one position of the disordered thf and the P–H hydrogen atoms are shown. Selected bond lengths (Å): K(2)–O(1) 2.654(3), K(2)–P(1) 3.669(1), K(2)–P(2A) 3.354(2), K(2)–P(3) 3.323(2), K(2)–C(31) 3.329(4), K(2)–C(12) 3.199(4), K(2)–C(11) 2.991(3), K(2)–C(16) 3.238(4).

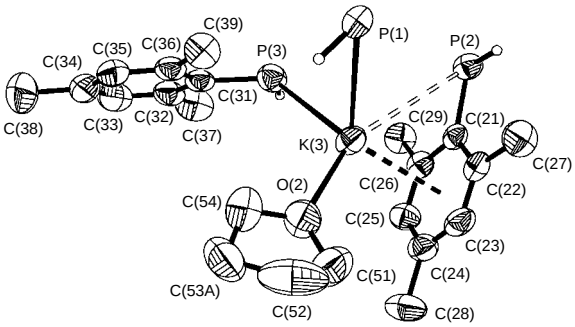

Fig. 3 Environment around K(3) (ORTEP, 50% probability, SHELXTL PLUS; XP).[15] Only one position of the disordered thf and the P–H hydrogen atoms are shown. Selected bond lengths (Å): K(3)–O(2) 2.666(3), K(3)–P(1A) 3.324(2), K(3)–P(2) 3.936(2), K(3)–P(3) 3.291(2), K(3)–C(21) 3.013(3), K(3)–C(22) 3.076(4), K(3)–C(23) 3.226(4), K(3)–C(24) 3.344(4), K(3)–C(25) 3.269(4), K(3)–C(26) 3.125(4).

coordination of the mesityl rings of P(1) and P(3) to K(2), and η^6 coordination of the mesityl ring of P(2) to K(3)] with K–C distances of 2.991(3)–3.344(4) Å. Similarly, K–aryl interaction was observed in KPH(Mes*) [η^3 coordination of Mes*, K–C 2.884(4)–3.197(4)], which is obtained solvent-free even on crystallisation from thf–toluene.[5]

In **1**, which was crystallised from thf–pentane, π interaction with the aryl rings is apparently preferred to coordination of additional thf molecules. Similarly, π coordination of arene ligands to potassium[11,13] and the heavier alkali metals[14] has often been reported in the literature. The caesium phosphanide $[Cs(thf)_{0.5}P(SiPr^i_3)\{Si(F)(Is)_2\}]_\infty$ (Is = 2,4,6-$Pr^i_3C_6H_2$) also exhibits η^3 and η^6 coordination of the aryl rings of the Is substituents to Cs.[4]

The alkali metal phosphanide presented here is the first example of a potassium phosphanide with a polyhedral arrangement of K and P atoms, in contrast to the corresponding lithium phosphanide, $[Li(thf)_2\{PH(Mes)\}]_\infty$,[7] which has a helical one-dimensional Li–P–Li–P arrangement. More information on the structural diversity of alkali metal phosphanides will be needed before the factors that determine the structural arrangement in the solid state are fully understood.

We gratefully acknowledge support from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie; the company Chemetall provided a generous donation of potassium metal.

Selective fluorescence detection of fluoride using boronic acids

Christopher R. Cooper, Neil Spencer and Tony D. James*†

School of Chemistry, The University of Birmingham, Edgbaston, Birmingham, UK B15 2TT

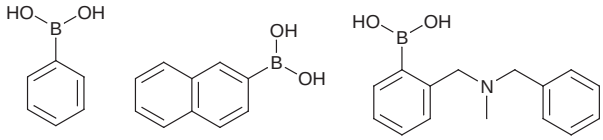
Fluorescent PET (photoinduced electron transfer) sensors 1,2 and 3 with boronic acid receptor units show F^- selective fluorescent quenching in aqueous solution at pH 5.5.

Neutral and ionic synthetic molecular receptors for anions are the focus of many research groups. Anion receptors can consist of protonated nitrogens, metal ions, hydrogen bonding sites and Lewis acid receptors.[1–6] The conversion of binding information between ions and synthetic molecular receptors into readable fluorescent outputs has attracted the attention of many research groups.[7–12] There is interest in following the uptake and metabolism of F^- in both plants and animals and in the analysis of drinking water. Fluoride concentrations are currently determined using electrodes prepared from LaF_3.[13] Electrodes for determining F^- concentrations are sensitive and selective, but, under certain circumstances a method for the direct visualisation of intracellular F^- would be of great advantage, especially to analytical biochemists.

The system presented here is based on the Lewis acid–base interaction between boron and anions. When boron binds with certain anions the hybridisation changes from sp^2 to sp^3.[14,15] Boron centred fluoride receptors were first studied by Katz, who trapped fluoride ions between two electron accepting boron atoms in 1,8-naphthalendiylbis(dimethylborane).[16,17] More recently Reetz combined a Lewis acid boron and crown ether to create a ditopic host for F^- and metal ions.[18] Paugam and Smith have used the tetrahedral fluoride adduct of phenyl boronic acid with fluoride to accelerate saccharide transport at neutral pH.[19] Shinkai and coworkers have recently developed a F^- receptor based on ferrocene boronic acids, the binding is measured electrochemically[20] or by the colour change of a redox coupled dye molecule.[21]

Work by the groups of Czarnik and Shinkai on saccharide sensors has shown that boronic acids exist as tetrahedral boronate anions at pH values above their pK_a, and that the tetrahedral boronate anion can quench the fluorescence of directly attached fluorophores by the mechanism of photoinduced electron transfer (PET).[22,23] With this work we decided to investigate whether F^- can also quench fluorescence on formation of a tetrahedral fluoride adduct.

When phenylboronic acid **1**‡ and 2-naphthylboronic acid **2**‡



1 **2** **3**

are titrated with KF in a 50% (w/w) methanol–water buffer at pH 5.5[24] the fluorescence of the phenyl and naphthyl fluorophores decreases with added KF. (λ_{ex} = 265 nm, λ_{em} = 295 nm and λ_{ex} = 268 nm, λ_{em} = 344 nm, respectively) (Fig. 1). The experimental curves are fitted best using eqn. (1) assuming

$$I = \frac{I_0 + I_\infty K_n[F^-]^n}{1 + K_n[F^-]^n} \quad (1)$$

with:

$$K_n = \frac{[RB(OH)_{3-n}F_n]}{[RB(OH)_2][F^-]^n}$$

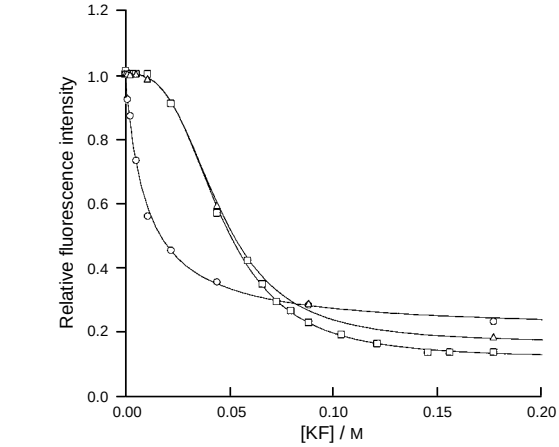


Fig. 1 Fluorescence intensity log [KF] profile of (□) **1**, (△) **2** and (○) **3** at 25 °C; 1.63×10^{-4} M **1** in 50% MeOH–H_2O, pH 5.5, λ_{ex} = 265 nm, λ_{em} = 295 nm; 1.16×10^{-4} M **2** in 50% MeOH–H_2O, pH 5.5, λ_{ex} = 268 nm, λ_{em} = 344 nm; 8.30×10^{-5} M **3** in 50% MeOH–H_2O, pH 5.5, λ_{ex} = 270 nm, λ_{em} = 309 nm

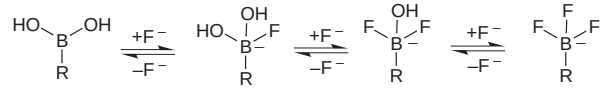
the formation of a trifluoro tetrahedral boronate (n = 3)[25] (Scheme 1). The stability constants K_3 determined from the best fit of these curves are 1.04×10^4 and 1.08×10^4 dm^9 mol^{-3} respectively. Compounds **1** and **2** can effectively detect concentrations of F^- in the range 50–70 mM. Compound **3** was prepared by alkylating 2-bromomethylphenylboronic acid with methyl aminomethylbenzene, an analytically pure sample was obtained by precipitation from $CHCl_3$ by hexane to give a 13% yield. Compound **3** was specifically designed to increase the strength of F^- binding relative to compound **1** by virtue of an additional hydrogen bonding site, which is available when the amine is protonated. The pK_a of the tertiary amine of compound **3** is 5.5, determined from a fluorescence pH titration. At a pH of 5.5 the amine is half protonated and can participate in hydrogen bonding with F^-.[8,10] Also at pH 5.5, **3** has a high fluorescence because PET from the nitrogen is reduced on protonation. When **3** is titrated with KF in a 50% (w/w) methanol–water buffer at pH 5.5[24] the fluorescence of the phenyl fluorophore decreases with added F^-. (λ_{ex} = 270 nm, λ_{em} = 309 nm) (Fig. 1). The experimental curve is fitted best using eqn. (1) and assuming the formation of monofluoro boronic acid derivative (n = 1)[25] (Scheme 1). The F^- stability constant K_1 determined from the best fit of this curve is 101 dm^3 mol^{-1}. Compound **3** can effectively detect concentrations of F^- in the range 5–30 mM. The single fluoride adduct of compound **1** is selectively stabilised by the additional hydrogen bonding from the protonated amine of compound **3** (Fig. 2). Titrations were also carried out using **1**, **2** and **3** with KCl and KBr but no change in fluorescence was observed until very high concentrations of



Scheme 1

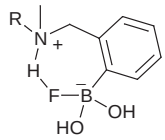


Fig. 2

these salts. A similar exclusive selectivity for F^- was observed by Shinkai and coworkers with ferrocene boronic acid.[20]

Both ^{11}B (128 MHz) and ^{19}F (376 MHz) NMR experiments were perfomed to confirm the presence of the F^- adducts depicted in Scheme 1. The ^{11}B NMR of compound **1** (0.205 M) in 33% (v/v) methanol-D_2O§ at 31 °C shows one boron signal at δ 13.2 relative to an external capillary of BMe_3 as reference. This signal shifted to δ 12.0 on addition of 1 equiv. of KF and to δ 7.4 on addition of 5 equiv. of KF. The ^{11}B NMR of **3** (0.137 M) in 70% (v/v) methanol–D_2O§ at 31 °C shows two boron signals at δ 14.5 and 2.5 corresponding to free boronic acid (sp^2) and nitrogen coordinated boronic acid (sp^3) respectively (At a pH of 5.5 the nitrogen atom of **3** is not fully protonated). On addition of 1 equiv. of KF the signal at high frequency moved to δ 13.5 while the other at low frequency remained at δ 2.5. On addition of 5 equiv. of KF only one signal at δ 2.5 was observed. The observed shifts from high to low frequency in the ^{11}B NMR are consistent with a shift from sp^2 to sp^3 boron on F^- binding.[26]

The ^{19}F NMR of compound **1** (0.205 M) in 33% (v/v) methanol–D_2O§ at 0 °C on the addition of 3 equiv. of KF shows signals at δ −126.9 [KF and $RB(OH)_2F^-$], −137.1 [$RB(OH)F_2^-$] and −147.5 [RBF_3^-] all relative to an external capillary of $CFCl_3$ as reference. The ^{19}F NMR of **3** (15.7 mM) in 50% (v/v) methanol–D_2O§ at 0 °C on addition of 3 equiv. of KF shows a signal at δ 131.6 [KF and $RB(OH)_2F$]. The species detected by ^{19}F NMR[27] are consistent with the F^- adducts depicted in Scheme 1 and the observed fluorescence behaviour. This work represents the first example where fluorescence has been used to detect F^- binding events. The use of these simple molecules has resulted in high F^- selectivity. We believe that with appropriate modifications of the Lewis acid and hydrogen bond donor, F^- selectivity can be fine tuned to any desired F^- concentration range. It is hoped that this work will lead to the development of fluorescent F^- sensors for a variety of industrial and medicinal applications.

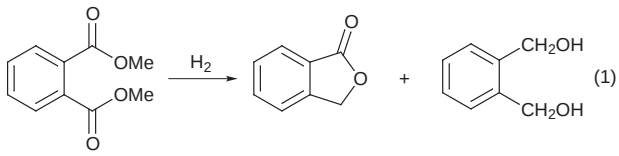
Homogeneous ruthenium catalyzed hydrogenation of esters to alcohols‡

Herman T. Teunissen and Cornelis J. Elsevier*†

Institute of Molecular Chemistry, Universiteit van Amsterdam, Nieuwe Achtergracht 166, NL-1018 WV Amsterdam, The Netherlands

The homogeneous catalytic hydrogenation of aromatic and aliphatic esters to the corresponding alcohols, by a catalyst generated *in situ* from $[Ru(acac)_3]$ and $MeC(CH_2PPh_2)_3$ in an alcoholic solvent under H_2 pressure of 85 bar at 100–120 °C, is described.

The reduction of esters to the corresponding alcohols is an important reaction which is usually achieved by a stoichiometric reaction using lithium aluminium hydride,[1] whereas homogeneous catalytic routes have been scarcely explored.[2–4] For aromatic esters, the only example is concerned with the hydrogenation of dimethyl phthalate (DMP) to phthalide (PHT)

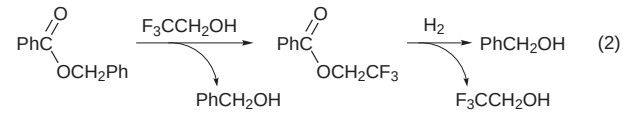


using a ruthenium hydride complex [eqn. (1)];[3a] PHT was obtained in a yield of 11.5% after 144 h at 180 °C under a hydrogen pressure of 130 bar.

Hydrogenation of PHT to 1,2-bis(hydroxymethyl)benzene (BHB) did not occur due to the absence of electron withdrawing substituents which enabled the conversion of DMP to PHT. Therefore, the hydrogenation of unactivated esters to the corresponding alcohols is one of the most intriguing challenges in contemporary hydrogenation catalysis. We have recently reported an important improvement using a catalyst based on $[Ru(acac)_3]$ and $MeC(CH_2PPh_2)_3$ in methanol,[4b] for the homogeneous hydrogenation of dimethyl oxalate. Now, we wish to report a catalytic system which is able to catalyse the hydrogenation of unactivated aromatic and aliphatic esters with very high turnover numbers.§

From Table 1 it is evident that the hydrogenation of DMP to give mainly PHT is feasible under relatively mild conditions (entry 1) employing a system consisting of $[Ru(acac)_3]$ and $MeC(CH_2PPh_2)_3$ in methanol. The catalytic activity (expressed as turnover number, TON) appeared to be strongly influenced by additives. Compared to entry 1, a negative effect is observed with Zn as an additive (entry 2) while positive effects are observed with NEt_3 (entry 3) and HBF_4 (entry 4). A further improvement is observed when the solvent MeOH is replaced by propan-2-ol (IPA). The combination IPA–HBF_4 shows the highest catalytic activity and gives rise to formation of BHB in high yield (entry 5) which was not observed in any previous experiment. Comparing our system with that of Matteoli *et al.*[3a] (entry 6) shows that we have achieved a considerable improvement with respect to turnover numbers and turnover frequencies under relatively mild conditions.

Next, we applied our system to the hydrogenation of benzyl benzoate (BZB, an unactivated ester) which is difficult to hydrogenate to benzyl alcohol (BZOH) (Table 2). In the presence of HBF_4 or NEt_3, we could achieve a TON of 33 (entry 1) and 105 (entry 2), respectively at 120 °C for this conversion. Furthermore, we investigated the influence of fluorinated alcohols on the hydrogenation of benzyl benzoate. These investigations were based on the results of Grey *et al.*,[2] who found that an ester is more easily hydrogenated when electron withdrawing substituents are present. Therefore, we postulated that an integration of transesterification (using *e.g.* 2,2,2-trifluoroethanol) and hydrogenation would lead to a substantial increase in catalytic activity due to substrate activation [eqn. (2)].



The hydrogenation of BZB to BZOH in 2,2,2-trifluoroethanol (TFE) at 120 °C turned out to be very successful (Table 2) and seems to confirm our hypothesis. Compared to the experiments in propan-2-ol (entry 2) the catalytic activity in TFE has drastically increased reaching a turnover number of nearly 900 in the presence of NEt_3 (entry 3). At 100 °C the catalytic activity was significantly lower, as expected (entry 4). Hydrogenation of BZB does not occur in the presence of HBF_4 (entry 5). Instead, three other products are formed: 2,2,2-trifluoroethyl benzoate, benzoic acid and a polymeric material. The formation of benzoic acid (82% isolated yield, TON 1412) was unexpected and is not readily explained. Hydrogenolysis of benzyl esters using heterogeneous palladium catalysts is common[5] but unprecedented for ruthenium complexes. Subsequently, the hydrogenation of BZB was carried out in 1,1,1,3,3,3-hexafluoropropan-2-ol (FIPA) which gave even

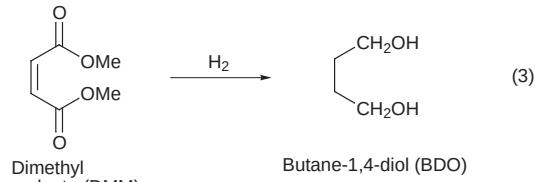
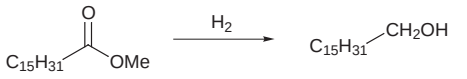
[a] *Conditions*: 120 °C; 85 bar H_2; 16 h; [Ru(acac)$_3$]; 1.15–1.65 equiv. $MeC(CH_2PPh_2)_3$. [b] Apart from the alcohol, significant formation of transesterification product was observed: entry 3 (8%); entry 4 (16%); entry 5 not determined; entry 7 (1%); entry 8 (4%). [c] Yield determined by ^{1}H NMR. [d] T = 100 °C. [e] Isolated yield. [f] $p(H_2)$ = 0 bar. [g] The hydrogenation of the C=C bond is not included in the turnover number.

better results. Hydrogenation of BZB in FIPA occurs with a turnover number of > 2000 (entry 6), which is an enormous step forward in the homogeneous catalytic hydrogenation of unactivated esters. This result was completely unexpected and contradicts the hypothesis of transesterification prior to hydrogenation. In principle, a primary alcohol such as TFE should give rise to transesterification more easily than a secondary alcohol like FIPA.[6] In view of these facts we suggest that the high catalytic activity in FIPA is due to ionic hydrogenation (*vide infra*) rather than to an integration of transesterification and hydrogenation. Compared to the experiment in FIPA, a mixture of TFE and FIPA exhibited a slightly lower activity (entry 8), which also raises objection to our initial hypothesis. Finally, we investigated the possibility of transfer hydrogenation (entry 7). The low catalytic activity in this case emphasizes that a substantial hydrogen pressure is necessary for successful catalysis. Possibly, the ruthenium catalyzed oxidative transformation of BZOH to BZB[7] becomes feasible in the absence of hydrogen pressure thus obstructing a successful transfer hydrogenation.

Using the optimized catalytic system for the conversion of BZB (FIPA, entry 6), we explored the scope of this system using dimethyl maleate (DMM) [eqn. (3)] and methyl palmitate (MP) [eqn. (4)] as substrates. The results show that our system is able

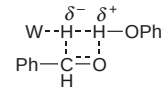


Dimethyl maleate (DMM) — Butane-1,4-diol (BDO) (3)



Methyl palmitate (MP) — Hexadecan-1-ol (HDO) (4)

to catalyze the hydrogenation of these substrates to the corresponding alcohols with, compared to BZB, a high activity for DMM (entry 9) and a slightly smaller activity for MP (entry 10). Altogether we can conclude that efficient hydrogenation of unactivated aromatic and aliphatic esters is possible using [Ru(acac)$_3$] and $MeC(CH_2PPh_2)_3$ in FIPA at 120 °C. Possibly, the remarkable activity in TFE and FIPA compared to IPA is related to the pK_a of the alcohols and not to transesterification. Berke and Burger showed that phenol[8a] and FIPA[8b] drastically influence the rate of insertion of aldehydes into the W–H bond in tungsten nitrosyl complexes. This influence was explained by ionic hydrogenation (*via* **A**).



A

A comparable complex has been reported recently for a ruthenium hydride complex and FIPA.[8c] The unique features of our catalytic system are ascribed to ionic hydrogenation of the ester. Investigations pertaining to the mechanism of the hydrogenation of esters are currently in progress in our laboratory.

We gratefully acknowledge stimulating discussions with Dr J. G. de Vries (DSM, Geleen, NL) and Dr M. J. Doyle (SRTCA, Amsterdam, NL).

§ *General procedure*: first, a solution was prepared of [Ru(acac)$_3$], $MeC(CH_2PPh_2)_3$, the appropriate ester and additive (see Tables 1 and 2) in the appropriate solvent (15 ml) under N_2. Separately, a home-built stainless steel autoclave equipped with a magnetic stirring bar was flushed with dry nitrogen after which the dark red pre-catalyst solution was introduced *via* a needle. The autoclave was flushed with H_2 (at 50 bar), pressurized with hydrogen (85 bar at 20 °C) and heated for 16 h at the indicated temperature. The reaction products were characterized by GC–MS, the yields were determined with GC (internal standard) or ^{1}H NMR.

Scanning tunnelling microscopy investigation of sintering in a model supported catalyst: nanoscale Pd on TiO_2(110)

Peter Stone, Stephen Poulston, Roger A. Bennett and Michael Bowker*†

Catalysis Research Centre, Department of Chemistry, University of Reading, Whiteknights Park, Reading, UK RG6 6AD

Vacuum annealing of metal vapour deposited Pd on TiO_2(110) results in particle formation and sintering with an increase in both the diameter and height of the particles measured using STM.

Metal vapour deposition on oxide single crystals provides a methodology for generating model catalysts which can be studied using conventional surface science techniques.[1,2] Of the wide range of techniques available scanning probe microscopy (SPM) is particularly valuable in that it allows the morphology and size distribution of metal particles on single crystal surfaces to be measured directly. The nucleation and growth of palladium on titania has previously been studied using STM by Goodman and coworkers[3] and Thornton and coworkers.[4] Here, we report the application of scanning tunnelling microscopy (STM) to the investigation of the sintering of Pd particles on TiO_2(110) upon heating in vacuum. STM is particularly advantageous compared to TEM as it measures the height of every particle in the scanned area. The magnitude of the reactivity relates to the area of supported particles which is available for reaction, and in this case particle–particle interactions in which size and shape distributions change will crucially affect the total reactivity. For example, sintering of small particles to form larger particles reduces the total surface area of the supported metal and results in a concomitant loss in catalytic activity. We present STM observations of the variation in particle size and height distributions and relate the observations to sintering. Annealing temperatures of 473 and 973 K correspond to the Hüttig and Tamman temperatures for Pd and roughly correspond to the expected onset of metal adatom and metal nanoparticle mobility respectively.[5] These observations represent the first analysis of the sintering process in this system by STM and the results are expected to be general for a wide variety of other systems.

Pd overlayers were prepared by Pd vapour deposition onto the TiO_2 surface at *ca.* 300 K. The Pd source consisted of a Pd wire wound tightly around a W filament. The TiO_2(110) surface was prepared by repeated sputter-anneal (>973 K) cycles to produce a slightly streaky (in the $<110>$ direction) (1×1) LEED pattern indicating the surface was slightly reduced. Pd deposition was monitored using Auger electron spectroscopy with the amount of Pd estimated from a calibration experiment of Pd deposition on Cu(110). The rate was estimated to be 2×10^{-3} ML s^{-1} where 1 ML is 1.1×10^{15} atoms cm^{-2}. The growth mode of Pd on TiO_2(110) at 300 K has been established to be of the classical nucleation type where Pd monomers are mobile while dimers form stable nuclei for subsequent growth in the Volmer–Weber mode (3D-islanding).[3]

Deposition of >1.5 ML Pd produced continuous, though rough Pd films which could be imaged in the STM. Annealing to 473 K produced particulate films, which is consistent with surface Pd mobility (Hüttig temperature) as small particles have been formed from a thin film. Deposition of <1.5 ML produces particles in the as-deposited overlayer. Fig. 1 shows STM images of 1.7 ML Pd on TiO_2 which has been vacuum annealed to (*a*) 473 K for 15 min and then (*b*) 973 K for a further 15 min. The Pd particles in Fig. 1(*a*) form a fairly homogeneous overlayer with some variation in particle size and height. This can be seen more quantitatively in Fig. 2 which shows (*a*) the particle size and (*b*) height distributions for this overlayer at this and two higher annealing temperatures (773 and 973 K). The same surface annealed to 973 K, Fig. 1(*b*), displays a significantly changed particulate array. The Pd particles show a reduction in particle number density from 7.5×10^{-2} to 6×10^{-3} nm^{-2} and display a much greater variety in size and height (Fig. 2). This change is characteristic of particle sintering as a result of mass transport of Pd particles on the surface (Tamman temperature). We believe that the mechanism of sintering in this system is by coalescence, that is, two or more particles join together to form the larger particles. Fig. 1(*b*) shows evidence of coalescence of the particles, in this image it is clear to see that some of the particles have merged together (see regions 1 and 2 on the image). In addition, if Ostwald ripening was the mechanism, we would expect to see smaller particles at some stage during the sintering process, which is not observed. The mean (s.d.) particle diameter varies between 42 (10 Å) after annealing at 473 K to 56 (11 Å) at 773 K and 87 (15 Å) at 973

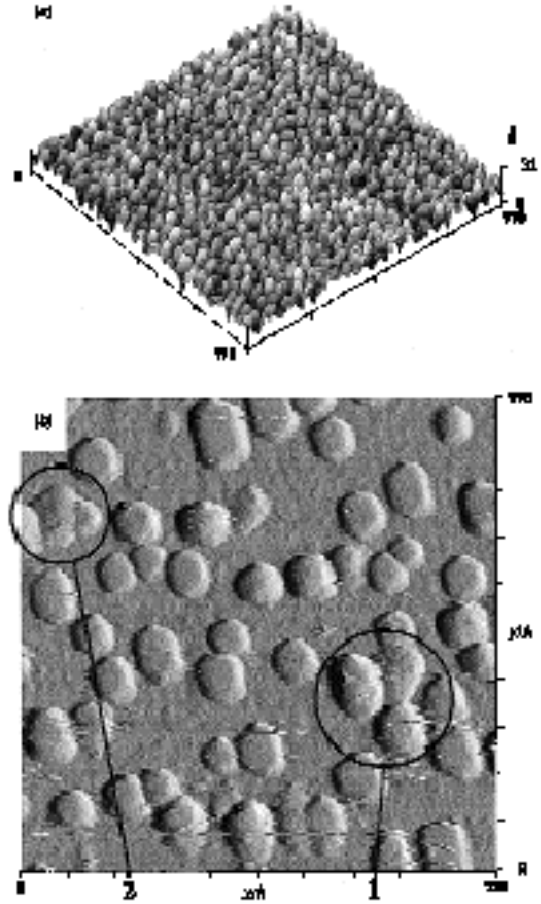

Fig. 1 STM images of 1.7 ML Pd on TiO_2(110) after annealing for 15 min at (*a*) 473 K (sample bias 0.5 V, tunnelling current 1 nA) and (*b*) 973 K (sample bias 2 V, tunnelling current 1 nA). The scan area of each image is 998×998 Å.

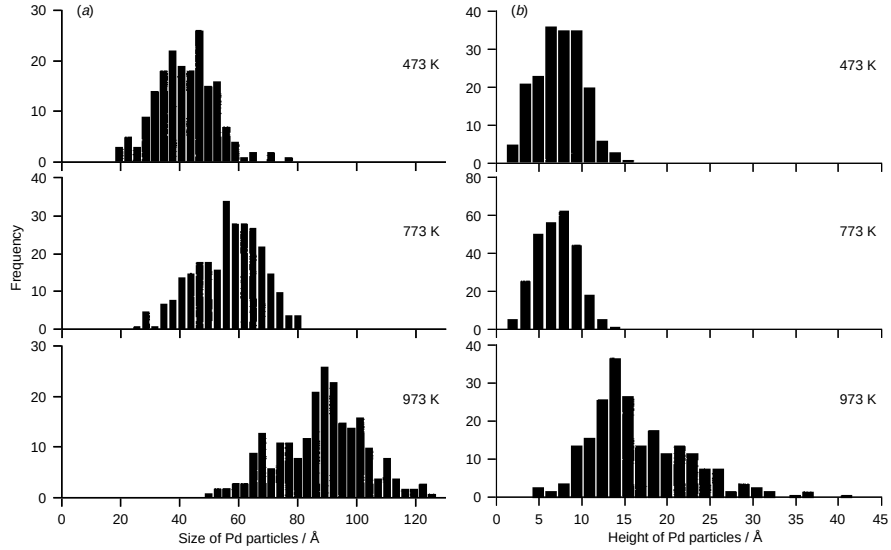

Fig. 2 Particle size distributions for 1.7 ML Pd on TiO_2(110) annealed to three different temperatures; 473, 773 and 973 K. (*a*) Size (diameter) and (*b*) height of particles.

K. The corresponding mean particle heights are 7.3 (2.7 Å), 6.8 (2.4 Å) and 16.6 (6.2 Å). The standard error for the mean particle diameter and height is (±1 Å) and (±0.5 Å) respectively.

At Pd coverages of 5 ML the same analysis of particle size with annealing temperature was not possible as well defined particulate arrays were not formed until the surface was annealed to 973 K. Other Pd coverages between 0.6 and 3 ML display the same trend on annealing as that shown above for the case of 1.7 ML though the measured particle densities after annealing to 973 K decrease with decreasing Pd coverage. After annealing at 973 K for lower Pd coverages it is possible to image the clean (1 × 1) surface between the particles.

In summary, we have investigated the sintering of particles in a model catalyst system, Pd on TiO_2. The as-deposited film displays little structure but annealing to 473 K produces distinct clusters, while further annealing at 973 K results in the sintering of these particles which we believe to be by the mechanism of coalescence.

Cationic amphitropic gemini surfactants with hydrophilic oligo(oxyethylene) spacer chains

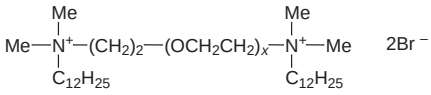
Michael Dreja,† Susanne Gramberg and Bernd Tieke*‡

Institut für Physikalische Chemie der Universität zu Köln, Luxemburger Straße 116, D-50939 Köln, Germany

New gemini diammonium surfactants have been synthesized in which the spacer chain consists of oligo(oxyethylene) units and which exhibit thermotropic liquid crystalline lamellar α and β as well as lyotropic mesophases.

Surfactant molecules usually consist of a hydrophilic headgroup attached to a hydrophobic alkyl chain. They self-assemble into micellar and lyotropic liquid crystalline mesophases when mixed with water. If the self-organization process occurs on heating, thermotropic liquid crystalline phases are often observed. Many amphiphilic compounds can form thermotropic as well as lyotropic mesophases, and therefore they are labelled as amphitropic.[1] Recently, bis(quaternary ammonium) surfactants ('gemini surfactants') have been prepared, in which two hydrophilic headgroups are linked *via* a hydrophobic alkylene or heteroatom-modified spacer chain.[2,3] Here we report on a new series of amphitropic gemini surfactants (12-EO$_x$-12) in which hydrophilic headgroups as well as hydrophilic spacer chains are simultaneously present for the first time. A study of the effect of the hydrophilic oligo(oxyethylene) spacer length on the amphitropic aggregation is presented.

Gemini surfactants 12-EO$_x$-12 with x = 2–5 were obtained in



two steps *via* bromination of the corresponding oligo(oxyethylene)glycols HO–(CH$_2$)$_2$–(EO)$_x$–OH (0.1 mol) with PBr$_3$ (0.15 mol) in dry dioxane.[4] The resulting dibromides (0.06 mol) were quaternized with *N*,*N*-dimethyldodecylamine (0.13 mol) under reflux in anhydrous EtOH for two days. Evaporation yielded white solids which were recrystallized at least three times from ethyl acetate to give the desired products in good yields (50–70%). For comparison, 12-EO$_x$-12 with x = 0 or 1 were also prepared.[2,3a] The purity of all compounds was confirmed by elemental analysis and ^{1}H NMR spectroscopy.§

The thermotropic behaviour of the surfactants was characterized using polarized optical microscopy (POM), differential scanning calorimetry (DSC) and X-ray diffraction (XRD). The surfactants with $x \leqslant 4$ form one or two mesophases on heating, either an L$_\beta$ (viscous neat) or an L$_\alpha$ (smectic A) phase. The transition temperatures as well as the transition enthalpies are compiled in Table 1. The results were taken from the first DSC heating runs because the compounds are thermally unstable at high temperatures and partially decompose. Subsequent DSC scans are therefore significantly changed, as similarly observed by Fuller *et al.* for a series of conventional gemini surfactants.[5a] The first heating scans were always reproducible. For 12-EO$_0$-12, two mesophases were observed, while 12-EO$_1$-12 shows only one mesophase. For 12-EO$_2$-12, again two mesophases occur. 12-EO$_3$-12 and 12-EO$_4$-12 show a single mesophase each and clearing temperatures much lower than those of the compounds with shorter spacer chains. For 12-EO$_5$-12, no thermotropic mesophase was observed. This may be due to the higher flexibility of the spacer chains introduced by the additional oxygen atoms.

In Fig. 1, the first DSC heating run for 12-EO$_2$-12 is shown as a typical example. The four phase transitions are clearly recognizable. The occurrence of the mesophases was further identifed by the characteristic textures to be seen in the POM. In the case of 12-EO$_0$-12 and 12-EO$_1$-12, the optical textures are not easily discernable, since the materials exhibit a very high viscosity. Only after long thermal or mechanical treatment, birefringent cloudy textures occurred resembling that of a viscous neat phase. This effect was also reported for gemini surfactants with hydrophobic spacer chains.[5a] In contrast, the textures formed immediately for the compounds with x being 2–4. In Fig. 2(*a*) and (*b*), the fan-like textures of the viscous neat phase of 12-EO$_2$-12 at 120 °C and the mosaic texture of its smectic A phase at 180 °C are shown. Upon shearing, the mosaic texture at 180 °C is converted into oily streak textures.

The assignment of the mesophases was confirmed using XRD. The XRD spectrum of Fig. 3 indicates that the crystalline phase of 12-EO$_2$-12 has a layered structure with a period of 24.8

[a] K = crystal; L$_\beta$, L$_\alpha$ = lamellar mesophases; I = isotropic liquid; nd = not determined.

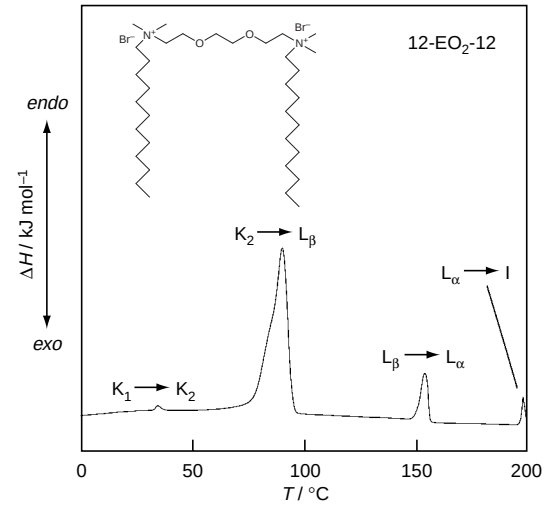

Fig. 1 First DSC heating scan of 12-EO$_2$-12 at 10 °C min^{-1}

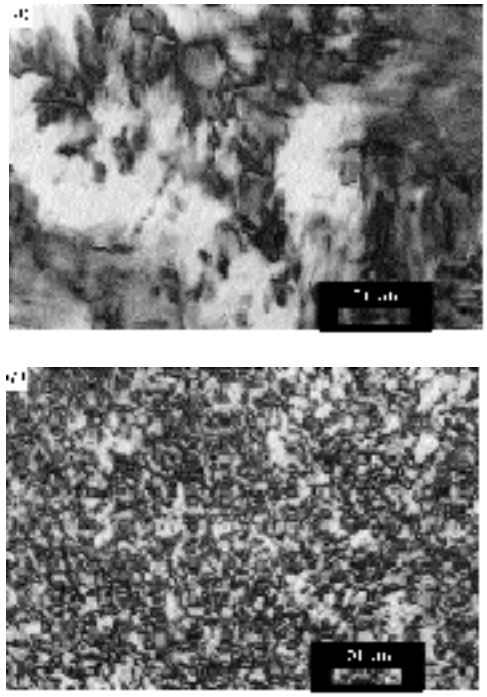

Fig. 2 Polarizing micrographs of the fan-like texture of 12-EO_2-12 at 120 °C (*a*) and of the mosaic textures at 180 °C (*b*)

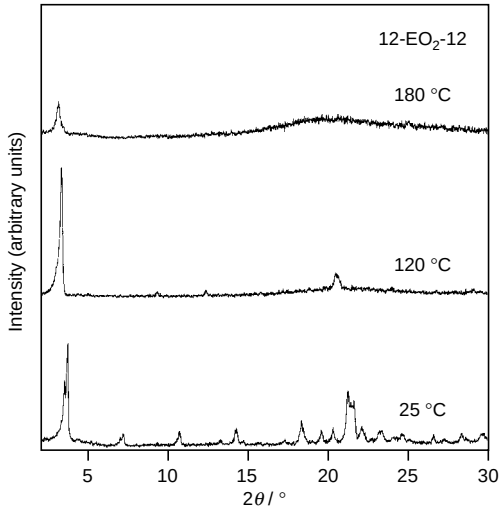

Fig. 3 XRD spectra of 12-EO_2-12 at 25, 120 and 180 °C

phase of 12-EO_2-12 has a layered structure with a period of 24.8 Å. The splitting of the low angle peak may indicate the presence of two coexisting crystalline modifications. At 120 °C, the typical diffraction pattern of an L_β phase is apparent,[6] indicating that the alkyl chains attain a hexagonal packing with fully extended chain conformation. The layer period is increased to 26.7 Å. At 180 °C, 12-EO_2-12 adopts a smectic A structure[6] indicating a disordered, liquid-like conformation of the alkyl chains and a layer period of 28.6 Å. Compared with a fully extended molecule (45.4 Å) or two extended C_{12} chains (33.4 Å), the repeat distance is much smaller. Therefore, we assume an interpenetrating bilayer structure, as similarly proposed for conventional gemini surfactants[5] and U-shaped benzimidazolium salts reported recently.[7] For the L_α-phase of 12-EO_3-12, a period of 29 Å was found, while 12-EO_4-12 has a layer spacing of 25.2 Å in the viscous neat phase. Both values are very similar to that of 12-EO_2-12 and indicate the same structural arrangements in the mesophases.

For all compounds, hexagonal (H_1), cubic (V_1) and lamellar (L_α) lyotropic mesophases were observed in water at certain concentration intervals in the temperature range from 25 to 100 °C using the contact preparation technique. Lyotropic phase behaviour sets in at concentrations above 36 ($x = 0$) to 66 wt% ($x = 5$). The hexagonal phase is stable in the whole temperature range for all surfactants except for $x = 0$, where it disappears above 50 °C. The bicontinuous cubic phase is formed for 12-EO_x-12 with $x = 2$–4 between 25 and 100 °C, for $x = 0$ only above 35 °C, and for $x = 1$, 4 above 50 °C. For $x = 0$, the lamellar phase occurs above 65 °C, for $x = 1$ above 50 °C and for $x = 2$ above 40 °C. For $x = 4$ it is stable during the whole temperature range and for $x = 3$, 5, only until the transition to the isotropic melt occurs (see Table 1).

In summary, the mesophase behaviour of the 12-EO_x-12 compounds is rather complex. Compared to geminis with short and hydrophobic spacer units, the 12-EO_x-12 compounds with $x \geqslant 2$ form thermotropic liquid crystalline phases quite readily, which can be easily identified. Therefore, such compounds may be useful as solvents for chemical reactions or as templating agents in the synthesis of inorganic materials. The lyotropic mesophase behaviour of the surfactants is also of considerable interest, since gemini surfactants with a hydrophobic spacer chain have been found to form ternary polymerizable microemulsions with styrene in water.[8] Gemini surfactants with hydrophilic oligo(oxyethylene) spacer are expected to exhibit similar or even improved properties due to a higher flexibility.

Financial support by the Deutsche Forschungsgemeinschaft (project Ti219/5-1) is gratefully acknowledged.

The uranium(IV) triflates $[U(Cp^*)_2(OTf)_2]$, $[U(Cp)_2(OTf)_2(py)]$, $[U(Cp)_3(OTf)]$, $[U(cot)(OTf)_2(py)]$ and $[U(OTf)_4(py)]$ have been synthesized by protonation of amide or alkyl precursors with pyridinium triflate; the crystal structures of $[U(Cp^*)_2(OTf)_2(OH_2)]$ and $[U(Cp)_3(OTf)(CNBu^t)]$ have been determined.

Transition metal triflates (trifluoromethanesulfonates) are much considered as Lewis acid catalysts in a variety of organic reactions, as well as precursors in inorganic and organometallic synthesis.[1] While the utility of lanthanide triflates has been clearly recognized in recent years,[2] scant attention has been paid to the actinide counterparts; a few thorium(IV) triflates have been reported[3,4] and the only uranium triflates are uranyl derivatives.[5] Here, we present the first uranium(IV) triflates, $[U(OTf)_4(py)]$, and a series of cyclopentadienyl and cyclooctatetraene derivatives; these were conveniently synthesized by using the pyridinium triflate as a novel reagent for the protonolysis of U–C and U–N bonds. We also describe the crystal structures of $[U(Cp^*)_2(OTf)_2(OH_2)]$ and $[U(Cp)_3(OTf)(CNBu^t)]$.

We first tried to prepare the cyclopentadienyl complexes $[U(Cp^*)_2(OTf)_2]$ **1** and $[U(Cp)_3(OTf)]$ **2** since $[U(Cp^*)_2X_2]$ and $[U(Cp)_3X]$ compounds are regarded, for most X groups, as models in organouranium chemistry. In an NMR test experiment, $[U(Cp^*)_2Me_2]$ was treated at 20 °C in toluene with 2 equiv. of HOTf; immediate evolution of gas was observed and the spectrum showed a new single signal at δ 20.1, corresponding to the Cp* groups. The solution was evaporated and crystallization of the red–brown powder from thf–pentane gave a few crystals of $[U(Cp^*)_2(OTf)_2(OH_2)]$; these were characterized by X-ray crystallography (*vide infra*). Difficulties were encountered when the above reaction was performed in a preparative scale; products resulting from protonation of Cp* ligands were also formed in variable yields. Other attempts to prepare **1** by treating the complexes $[U(Cp^*)_2X_2]$ (X = Me, NMe_2, Cl) with AgOTf in thf or benzene were unsuccessful; complicated mixtures were obtained and thf was quickly polymerized. We found that the best way to obtain complex **1** was the reaction of $[U(Cp^*)_2Me_2]$ with PyHOTf, which could be easily reproduced, and gave **1** in satisfactory yield. A solution of the pyridinium salt (219 mg) in thf (25 cm^3) was slowly added to the bis(alkyl) complex (215 mg) in thf (20 cm^3) at −70 °C; the mixture was stirred for 1 h at 20 °C and after evaporation to dryness, the red–brown powder was extracted in toluene and washed with pentane (78% yield). Similar treatment of $[U(Cp^*)_2(NMe_2)_2]$ also gave **1** in good yield. By following the same procedure, the organouranium compounds $[U(Cp)_3X]$ (X = NEt_2, Bu^n), $[U(Cp)_2(NEt_2)_2]$ and $[U(cot)\{N(SiMe_3)_2\}_2]$ were transformed into $[U(Cp)_3(OTf)]$ **2** (brown, 93%), $[U(Cp)_2(OTf)_2(py)]$ **3** (orange, 60%) and $[U(cot)(OTf)_2(py)]$ **4** (brown, 92%), respectively. It is noteworthy that **3** was stable towards ligand exchange reactions, whereas $[U(Cp)_2Cl_2]$ and its Lewis base adducts could not be isolated.[6] In the presence of an excess of Bu^tNC in thf–pentane, **2** was converted into $[U(Cp)_3(OTf)(CNBu^t)]$, the crystal structure of which was determined (*vide infra*); interestingly, the triflate group of **2** was not displaced by the isocyanide molecule.

The pyridinium triflate proved thus to be very efficient in the protonolysis reactions of U–C and U–N bonds. In contrast to triflic acid, this commercial powder is not hygroscopic, does not polymerize thf, can be stored for a long time and is easy to handle. This reagent was also useful to prepare a pyridine adduct of the homoleptic uranium(IV) triflate $[U(OTf)_4]$ while more classical routes, by reacting UCl_4 with HOTf or AgOTf, were not straightforward. The complex $[U(OTf)_4(py)]$ **5** was synthesized in 76% yield by treating the metallacycle $[U\{N(SiMe_3)(SiMe_2CH_2)\}\{N(SiMe_3)_2\}_2]$ (250 mg) with PyHOTf (319 mg) in pyridine (20 cm^3). The solution was heated at 110 °C for 20 h and after partial evaporation and addition of diethyl ether, deposited a green microcrystalline powder. Complex **5** would be a useful precursor for the synthesis of organometallic derivatives. For example, its reactions with K_2cot or $[U(cot)_2]$ in thf afforded **4** in almost quantitative yield (NMR experiments), providing a new access to monocyclooctatetraene uranium compounds; it is noteworthy that the chloride analogue $[U(cot)Cl_2(thf)_2]$ could not be obtained by similar treatment of UCl_4.[7]

Complexes **1**–**5** were characterized by elemental analyses (C, H, N or S) and ^1H NMR spectroscopy.‡ Besides a dimeric triflate bridged thorium compound,[3] $[U(Cp^*)_2(OTf)_2(OH_2)]$ and $[U(Cp)_3(OTf)(CNBu^t)]$ are the only actinide(IV) triflates to have been crystallographically characterized; the bis(triflate) derivative is also, from the data of the CCDC, the first structurally characterized organouranium compound with a coordinated H_2O molecule. The structures are shown in Fig. 1 and 2 together with selected data.§ The monomeric complexes adopt, respectively, a bent-sandwich configuration with an unsymmetrical arrangement of OTf and H_2O ligands in the

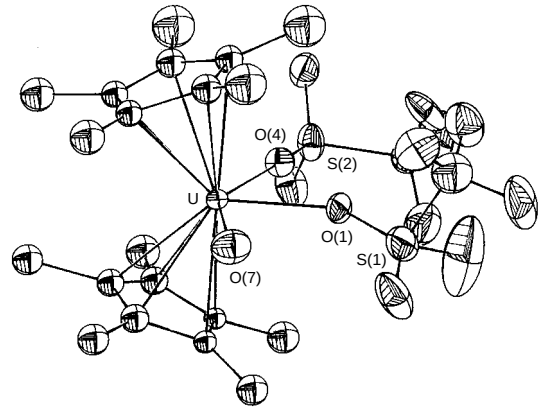

Fig. 1 X-Ray crystal structure of $[U(Cp^*)_2(OTf)_2(OH_2)]$. Displacement ellipsoids are shown at the 33% probability level. Selected bond distances (Å) and angles (°): U–O(1) 2.36(1), U–O(4) 2.40(1), U–O(7) 2.57(2), O(1)–S(1) 1.48(1), O(4)–S(2) 1.45(1); O(1)–U–O(4) 74.8(6), O(1)–U–O(7) 70.2(6), O(4)–U–O(7) 145.0(6), U–O(1)–S(1) 154.3(9), U–O(4)–S(2) 173.7(9).

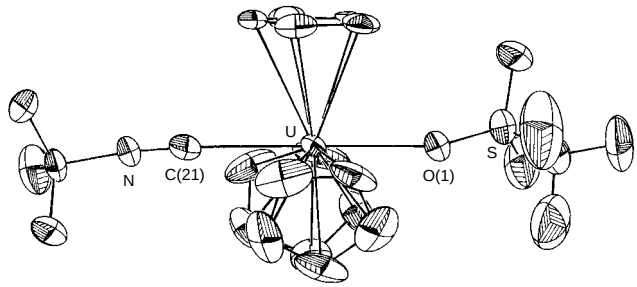

Fig. 2 X-Ray crystal structure of $[U(Cp)_3(OTf)(CNBu^t)]$. Displacement ellipsoids are shown at the 40% probability level. Selected bond distances (Å) and angles (°): U–O(1) 2.485(9), U–C(21) 2.59(2), O(1)–S 1.456(9), C(21)–N 1.13(2); O(1)–U–C(21) 179.3(4), U–O(1)–S 157.7(6), U–C(21)–N 175(1).

equatorial girdle,[8] and a nearly ideal trigonal bipyramidal structure with the Cp groups occupying the equatorial vertices.[9] Coordination of H_2O and Bu^tNC to the U^{IV} centre is unexceptional, with U–O(7) and U–C(21) bond distances of 2.57(2) and 2.59(2) Å. In both compounds, the triflate ligands are monodentate and, as expected for this weakly nucleophilic group, the U–O bond lengths which average 2.42(6) Å are longer than usual U–O σ bond distances (2.0–2.2 Å). In the bis(triflate) compound, the U–O–S angles are inequivalent and rather obtuse, with U–O(1)–S(1) and U–O(4)–S(2) equal to 154.3(9) and 173.7(9)°, respectively; similar structural features were previously noted in the yttrium complex $[Y\{C_6H_{12}N_3(CH_2CONH_2)_3\}(OTf)_2(H_2O)][OTf]$.[10]

In conclusion, the first uranium(IV) triflates were prepared by protonolysis of alkyl and amide precursors with pyridinium triflate; this convenient and efficient reaction should be of general interest for the synthesis of metal triflates. By comparison with their chloride analogues, uranium triflates should exhibit distinct structure and reactivity patterns, and open new perspectives in actinide chemistry.

[a] *Centre for Chemical Synthesis, Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*

[b] *Department of Chemistry, The University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

The reaction of $[Pd(cod)Cl_2]$ (cod = cycloocta-1,5-diene) with *rac*-diphenyl[2.2]paracyclophanylphosphine $PPh_2(C_{16}H_{15})$ affords *trans*-$[Pd\{PPh_2(C_{16}H_{15})\}_2Cl_2]$ and $[Pd\{PPh_2(C_{16}H_{15})\}Cl_2]_2$ in approximately equal yield which co-crystallise to form an unusual solid-state material.

Crystallisation of organic compounds is a common phenomenon and often of commercial value.[1] In inorganic/organometallic chemistry many anion–cation pairs[2] and to a lesser extent conformational isomers and polymorphs[3] have been recognised. However, co-crystals composed of two different neutral molecules are very rare and most can be classified as those which have two or more very similar molecules, often differing in a substituent on a ligand[4] or by the presence of slightly different ligand such as replacement of one halide for another.[5] Some co-crystals contain an inorganic/organometallic species in which a small or cylindrical 'solvent-like' molecule has been co-crystallised, for example, HgX_2 (X = I, Cl, F) and metallocenes.[6] We have also found one example of a co-crystal containing a neutral mononuclear and dinuclear complex[7] and one example involving clusters[8] in the literature.

We have been investigating the synthesis of [2.2]paracyclophanyl–phosphine ligands and studying their coordination chemistry.[9] This substituent was chosen as [2.2]paracyclophane has unusual nucleophilic behaviour with respect to its coordination chemistry.[10] Another group have also recently reported the synthesis of a chiral diphosphine with a [2.2]paracyclophane backbone which has some very impressive applications in catalysis.[11] We report here the synthesis of a new [2.2]paracyclophane containing phosphine and the discovery that it reacts with $[Pd(cod)Cl_2]$ to afford two $Pd^{II}Cl_2$ complexes which form a co-crystalline material in the solid-state.

The reaction of $C_{16}H_{15}Li$,[12] with PPh_2Cl, added dropwise in diethyl ether, affords diphenyl[2.2]paracyclophanylphosphine $PPh_2(C_{16}H_{15})$ in 62% yield after recrystallisation from ethanol. Reaction of this phosphine with $[Pd(cod)Cl_2]$ in dichloromethane at room temperature for 1 h affords an orange solution which exhibits two singlets of approximately equal intensity at δ 33.93 and 33.53 in its ^{31}P NMR spectrum. From later observations we assume these to be due to the two complexes *trans*-$[Pd\{PPh_2(C_{16}H_{15})\}_2Cl_2]$ **1** and $[Pd\{PPh_2(C_{16}H_{15})\}Cl_2]_2$ **2** and not from diastereomers of the same complex. The *cis*- and *trans*-platinum(II) chloride complexes of *rac*-$PPh_2(C_{16}H_{15})$ also show only one main resonance in their ^{31}P NMR spectra excluding the ^{195}Pt satellites.[13] Crystals were grown by removing the solvent and redissolving the solid in dichloromethane–diethyl ether. After allowing the solution to evaporate at room temperature for several days orange crystals formed which were suitable for single crystal X-ray diffraction analysis.‡ This reveals the remarkable co-crystalline structure described below.

The structures of **1** and **2** are shown in Figs. 1 and 2,

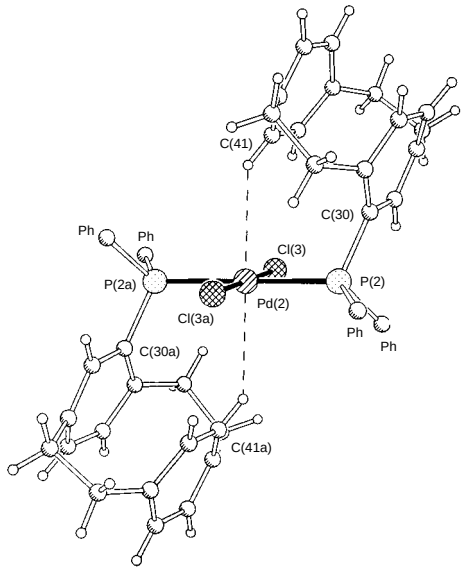

Fig. 1 Molecular geometry of **1**; selected bond lengths (Å) and angles (°): Pd(2)–P(2) 2.355(2), Pd(2)–Cl(3) 2.301(2), P(2)–C(30) 1.826(7), Pd(2)···H(41) 2.853, Cl(3)–Pd(2)–P(2) 88.07(7)

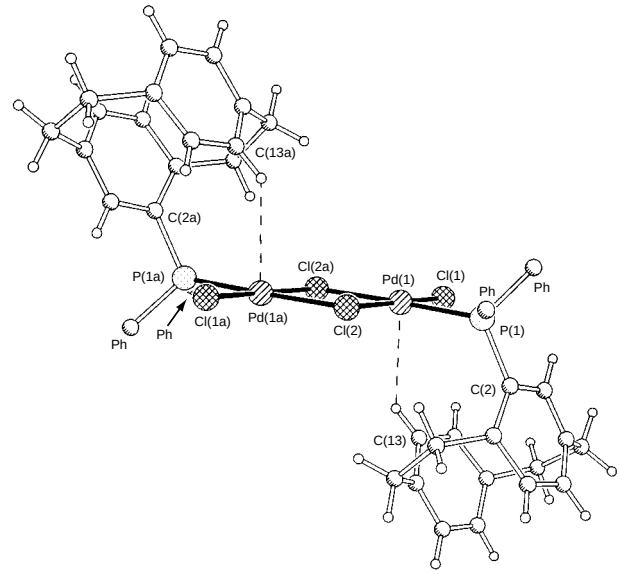

Fig. 2 Molecular geometry of **2**; selected bond lengths (Å) and angles (°): Pd(1)–P(1) 2.229(2), Pd(1)–Cl(1) 2.280(2), Pd(1)–Cl(2) 2.332(2), Pd(1)–Cl(2a) 2.429(2), P(1)–C(2) 1.816(7), Pd(1)···H(13) 2.933, P(1)–Pd(1)–Cl(2a) 177.29(8), Cl(1)–Pd(1)–Cl(2) 177.29(8)

respectively, together with principal bond parameters. In both **1** and **2** one of each enantiomer of $PPh_2(C_{16}H_{15})$ is present. The phosphines adopt a *trans*-conformation in **1** presumably due to the steric bulk of the [2.2]paracyclophanyl-substituent. The axial sites above and below the square plane are occupied by intramolecular interactions involving a proton on the [2.2]paracyclophane rings of each phosphine ligand (Pd···H 2.85 Å). The structure of **2** comprises a chloro-bridged dimer in which each palladium centre is approximately square planar. As in **1** and other similar square planar complexes[14] the axial sites form weak intra- or inter-molecular interactions in the solid state. In **2** the [2.2]paracyclophanyl group of each phosphine occupies one site on each of the palladium(II) centres (Pd···H 2.93 Å). The other site is occupied *via* an intermolecular interaction and it is this that possibly gives rise to the formation of the co-crystal (see below).

The crystal is composed of alternating layers of **1** and **2** intercalated with dichloromethane solvent molecules. There is one direct, albeit weak, hydrogen bond between **1** and **2** involving the Cl atoms on **1** with a phenyl ring proton on **2** (Cl···H 2.83 Å), shown in Fig. 3. Perhaps more importantly, compounds **1** and **2** are linked indirectly *via* one of the two CH_2Cl_2 solvent molecules as shown in Fig. 4. There is a bifurcated hydrogen bonding interaction between the H atom on the solvent with one terminal Cl (H···Cl 2.83 Å) and one bridging Cl (H···Cl 2.80 Å) of**2**. A Cl atom of this same solvent molecule also interacts with the H atom of a cyclophane attached to the phosphine in **1** (Cl···H 2.86 Å) thereby forming a **1**···Cl–C–H·**2** linkage (see Fig. 4). The second CH_2Cl_2 connects molecules of **1** *via* two interactions involving the H and Cl atoms of both the solvent and the complex. At this stage we can only speculate as to the precise role of the solvent but since it links **1** and **2** it may play a part in the co-crystallisation process. In this material partial desolvation has taken place but the co-crystal still retains its structure. We intend to examine the influence of solvents with various hydrogen bonding capabilities as well as the influence of the halide coordinated to the Pd^{II} centre.

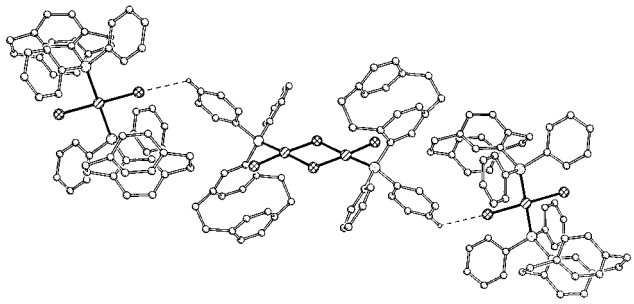

Fig. 3 The direct interaction, **1**··**2**

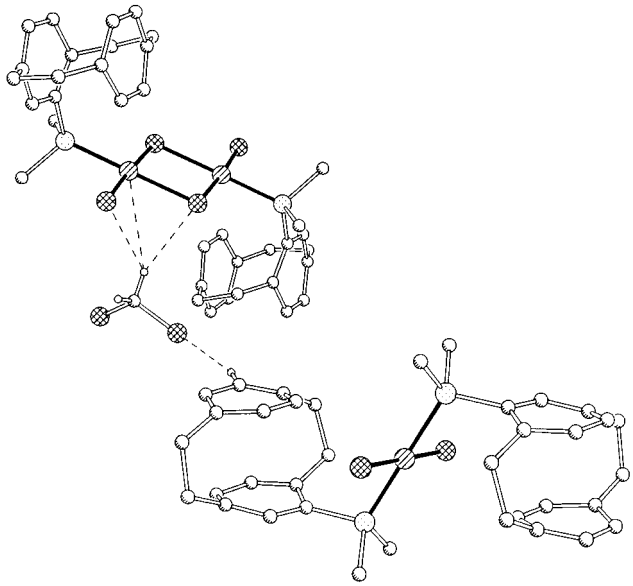

Fig. 4 The indirect solvent bridging interaction, **1**···Cl–C–H·**2**

Enantioselective hydrogenation of a cyclic imidoketone over chirally modified Pt/Al_2O_3

Niklaus Künzle, Andras Szabo, Markus Schürch, Guozhi Wang, Tamas Mallat and Alfons Baiker*†

Laboratory of Technical Chemistry, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zürich, Switzerland

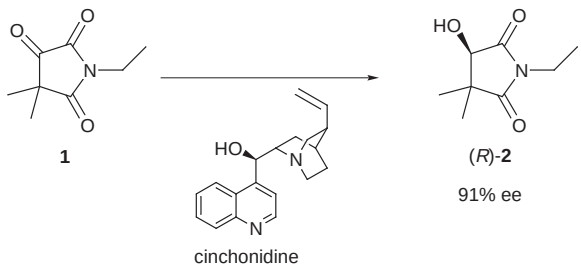
1-Ethyl-4,4-dimethylpyrrolidine-2,3,5-trione 1 has been synthesized, and hydrogenated with 91% ee to (*R*)-1-ethyl-3-hydroxy-4,4-dimethylpyrrolidine-2,5-dione (2) using a 5 mass% Pt/Al_2O_3 catalyst modified by cinchonidine

In the past decade the enantioselective hydrogenation of carbonyl compounds has been one of the most intensively studied areas in asymmetric catalysis.[1] An efficient strategy for achieving reasonable enantioselectivity over solid catalysts is the modification of an active metal by adsorbed auxiliaries from the chiral pool.[2] Since the first application of cinchona-modified Pt,[3] considerable effort has been made to broaden the application range of this catalyst system. Good to high ee values were obtained in the hydrogenation of α-ketoesters[4] and acids,[5] and ketopantolactone.[6] The hydrogenation of other types of activated carbonyl compounds, such as α-diketones,[7] trifluoracetophenone[8] and pyruvamides,[9] was less successful affording only 60% ee or less. It seems that the Pt-cinchona system possesses unusually high substrate specificity.

In a systematic study, intended to reveal the nature of enantioselective hydrogenation of ketoimides over chirally modified Pt metals, a remarkable ee was obtained in the reduction of 1-ethyl-4,4-dimethylpyrrolidine-2,3,5-trione **1**. The starting material **1** was synthesized from racemic pantolactone [(*R*,*S*)-2-hydroxy-3,3-dimethyl-γ-butyrolactone] in two steps. The lactone ring was cleaved by ethylamine and oxidation of the resulting amide with pyridinium dichromate gave **1**.‡

The hydrogenation of the cyclic imidoketone **1** (Scheme 1) was carried out in a magnetically stirred (frequency: 1000 min^{-1}) 100 ml stainless steel Baskerville autoclave equipped with a glass liner and PTFE cover. 60 mg of a 5 mass% Pt/Al_2O_3 (Engelhard 4759) catalyst was pretreated for 90 min in a hydrogen stream at 400 °C, as described earlier.[6] Under standard conditions the reaction was carried out using 3.2 mmol **1** and 10 μmol cinchonidine in 5 ml toluene, at 15 °C and 70 bar hydrogen pressure. The reaction was stopped when hydrogen consumption ceased. No other product besides **2** could be detected by gas chromatography.

For the determination of the absolute configuration of the product, the pure (*R*)-enantiomer of **2** has been synthesized starting from (*R*)-pantolactone. The hydroxyl function of (*R*)-pantolactone was protected by a tetrahydropyranyl group. After treatment with ethylamine, the resulting hydroxyamide was oxidized by pyridinium dichromate in DMF. Deprotection in the presence of TsOH gave (*R*)-**2** in optically pure form. Gas chromatographic analysis using a chiral column (WCOT Cyclodextrin-β-2,3,6-M-19, Chrompack) proved that (*R*)-**2** was identical with the major enantiomer obtained in the hydrogenation.



Scheme 1 Hydrogenation of **1**. *Conditions:* 5 mass% Pt/Al_2O_3, 9 μmol l^{-1} cinchonidine, 70 bar H_2, toluene, 15 °C.

Preliminary studies revealed that the enantiodifferentiation in the hydrogenation of **1** over the Pt–cinchonidine catalyst system was rather sensitive to the reaction medium. Good ee could be obtained only in weakly polar solvents, such as toluene. In polar and protic polar solvents (*e.g.* DMF, EtOH) the ee dropped to 20% or below. The only exception was acetic acid. The polarity of this solvent characterized by the empirical solvent parameter,[10] E^T_N, is about the same as that of EtOH, but the ee was remarkably higher (*ca.* 70 % instead of 20%, respectively, under standard conditions). Previously, the outstanding ee in acetic acid in the enantioselective hydrogenation of ethyl pyruvate was attributed to the protonation of the quinuclidine N atom of cinchonidine in acetic acid.[11] We assume that, similarly to the hydrogenation of ethyl pyruvate and ketopantolactone,[6] in the transition complex the quinuclidine N atom of cinchonidine interacts with the O atom of the activated carbonyl group *via* hydrogen bonding. Catalytic studies and molecular modeling are presently being carried out to confirm this assumption and uncover the role of acid in the enantiodifferentiation.

High hydrogen concentration on the Pt surface favoured the enantiodifferentiation, as illustrated in Fig. 1. This condition can be achieved by applying at least 30 bar hydrogen pressure and efficient stirring.

A reliable kinetic analysis based on the rate of hydrogen consumption could not be carried out owing to the small amount of substrate. In order to check the possible influence of mass transport limitation on the enantioselectivity, the stirring frequency was varied between 250 and 1000 min^{-1}. No significant change in ee was observed in this range of stirring frequency.

The influence of modifier concentration is illustrated in Fig. 2. A maximum of 91% ee was achieved at 9 μmol l^{-1} cinchonidine concentration in toluene; this value corresponds to a substrate : modifier molar ratio of 70 000. It should be

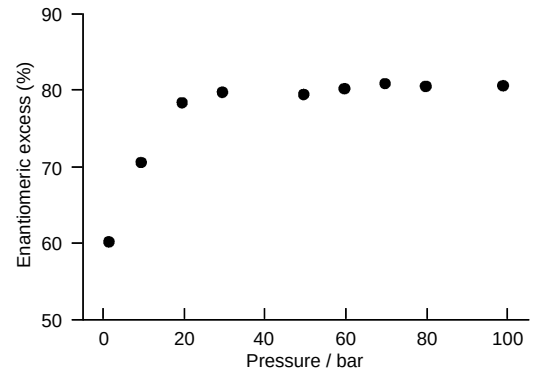


Fig. 1 Influence of hydrogen pressure on the enantiomeric excess (standard conditions except the pressure)

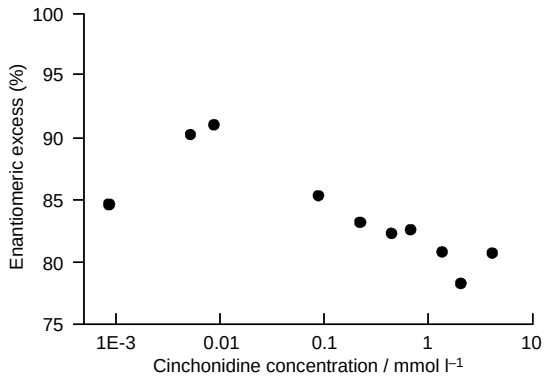

Fig. 2 Influence of modifier concentration on the enantiomeric excess (under otherwise standard conditions)

emphasized that no special pretreatment is required for establishing the 'chiral environment' on the Pt surface; the surface cinchonidine concentration is controlled by its bulk concentration and by the competitive adsorption of hydrogen, substrate and solvent.

The ee decreased with increasing temperature but the change (only 5% under standard conditions) was minor between +15 and −20 °C.

The influence of the above discussed reaction parameters is rather similar to those reported for the enantioselective hydrogenation of α-ketoesters[4] and ketopantolactone[6] over the same catalyst system, but distinctly different from that observed in the hydrogenation of trifluoracetophenone.[8]

Finally it should be mentioned that so far, there was no other substrate besides ethyl pyruvate[3] which could be hydrogenated with an ee exceeding 90% using the Pt–cinchona system. The chiral tertiary alcohol **2** can be used as an auxiliary in enantioselective Diels–Alder reactions. Promising results have already been reported for a similar application of (*R*)-pantolactone and an (*S*)-*N*-methyl-2-hydroxysuccinimide.[12]

Financial support by the Swiss National Science Foundation (Chiral 2) is kindly acknowledged.

Enantioselective photoelectrocyclization within zeolites: tropolone methyl ether in chirally modified NaY

Abraham Joy,[a] John R. Scheffer,[b] David R. Corbin[c] and V. Ramamurthy*[a]†

[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*

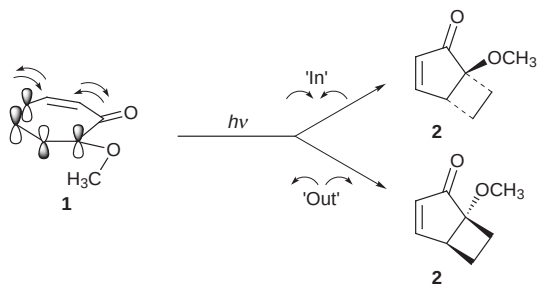
Tropolone methyl ether, included within chirally modified Y zeolite, upon irradiation yields a product of 4e electrocyclization in *ca.* 40% ee.

During the past decade, many elegant and efficient chiral induction strategies have been developed for a variety of thermal reactions.[1] There are, however, considerably fewer examples of asymmetric induction in photochemical transformations.[2] A recent successful approach in this latter context has been to make use of confined media such as inclusion complexes and crystals.[3–5] Zeolites offer advantages over other confined media in that they can be used for catalysis,[6] and our long range objective is to prepare reusable zeolite-based materials for asymmetric catalysis of photochemical processes. First, however, we must establish the feasibility of employing zeolite matrices for non-catalytic asymmetric induction, and here we illustrate our strategy with the well known photocyclization of α-tropolone methyl ether **1** as an example.[7,8]

Upon exposure to UV light, α-tropolone methyl ether undergoes 4π-electron disrotatory electrocyclic ring closure to yield the bicyclic photoisomer **2** (Scheme 1).[7] Irradiation in solution results in a racemic mixture as the result of an equal probability of 'in' and 'out' rotation as illustrated in Scheme 1. An obvious approach to control the mode of cyclization is to adsorb compound **1** on a surface, since under these conditions, it is possible that the surface could interfere with one of the two modes of disrotation. Even then racemic products would be expected because compound **1** should not show any preference for adsorption from either enantiotopic face. On the other hand, when the surface is chiral, preferential adsorption from one of the two enantiotopic faces is likely, and under such conditions, one might anticipate enantioselectivity in the formation of photoproduct **2**. This is illustrated in Fig. 1. Enantioselectivity has indeed been achieved in this system by this strategy and the results are presented below. The medium we have used to achieve the desired goal is a zeolite. In the absence of readily available chiral zeolites, we have created an asymmetric environment within a zeolite by the adsorption of chiral organic molecules.[9]

A typical experimental procedure consisted of stirring tropolone methyl ether (0.01 M) and a chiral inductor (0.1 M) with activated NaY (300 mg) in dichloromethane–hexane (1 : 4) for 12 h at room temperature. The zeolite containing both the reactant and a chiral inductor was collected by filtration, washed with an excess of hexane and irradiated (450 W medium pressure mercury lamp, Pyrex filter) as a hexane slurry for 2 h. Sample handling was carried out under laboratory conditions (temperature = 20 °C, humidity 55%). The product was extracted with dichloromethane and analyzed by chiral GC (Supelco β-DEX column). The results are presented in Table 1.



Scheme 1

Independent control experiments established that the numbers reported here are not skewed due to preferential adsorption of one enantiomer of the product within the chirally modified zeolite. The system is well behaved in the sense that, as expected, the optical antipode of the chiral inductor always gave the opposite enantiomer of the product (compare entries 2 and 7; 8 and 9; and 10 and 11 in Table 1). The need for a chiral inductor was clear, since irradiation of compound **1** in unmodified NaY gave racemic **2**. The zeolite is also essential as shown by the fact that none of the chiral inductors listed in Table 1 led to any enantioselectivity when photolyzed with compound **1** in solution (dichloromethane–hexane).

Examination of Table 1 reveals that not all chiral inductors are equally effective. Those that contain only one functional group (entries 15–18, Table 1) gave low or negligible chiral induction; more effective were those that contain both an amine and an alcohol functionality, and of these, norephedrine consistently gave good results. As a result, several additional experiments were carried out with norephedrine as the chiral inductor. In one set of experiments (entries 1, 2, 5–7, Table 1), the effect of changing the nature the alkali metal cation present within the zeolite was explored. While no clear trend was evident, this did indicate that NaY and RbY give the best results. In a second set of experiments (entries 2–4), the effect of temperature was briefly examined, which showed that −20 °C is optimum; above room temperature the enantiomeric excess (ee) also decreases and becomes zero at 60 °C.

At low conversions (< 10%, NaY, room temp.), the ee was relatively low (*ca.* 20%), which may be the result of reaction occurring faster at unencumbered sites with no chiral inductor

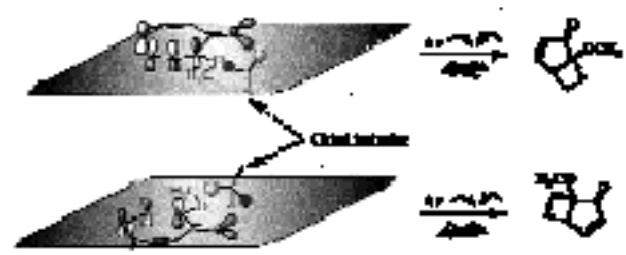


Fig. 1 Influence of a chiral agent on the mode of adsorption of tropolone methyl ether on a surface. On the top surface interactions are between methoxy and dark grey substituent, and carbonyl and light grey substituent. On the bottom surface they are reversed. Assuming one pair of interactions is preferred over the other, tropolone methyl ether will prefer to adsorb in this mode over the other.

Table 1 Dependence of enantiomeric excess on chiral inductor, zeolite and temperature[a–c]

18	(−)-Borneol/NaY	< 1	—

[a] All irradiations were done on samples that contained 1 mg of tropolone methyl ether and 25 mg of the chiral inductor in 200 mg of dry NaY. [b] Samples were irradiated for 2 h and conversions were within 50%. [c] Tropolone methyl ether and the chiral inductor were co-induced within NaY by three methods. In the first tropolone methyl ether and the chiral inductor were added simultaneously to a suspension of NaY and stirred, in the second the tropolone methyl ether was included into NaY and to the dried sample of tropolone methyl ether-NaY, the chiral inductor was added and stirred. In the third method the sequence in the second approach was reversed. [d] Unless indicated otherwise, the temperature of the reaction was 22 °C. [e] The peak with shorter retention time is arbitrarily assigned to be isomer A.

nearby. Beyond this point, the ee increased and reached a plateau of *ca.* 35% ee at 30% conversion; conversions beyond 50% were not attempted owing to secondary photoreactions of product **2**.[7] Values reported in Table 1 correspond to conversions in the range 35–50%.

From the results presented in Table 1, we tentatively conclude that a three point interaction between the reactant molecule, the chiral inductor and the zeolite interior is necessary to induce preferential adsorption of **1** from a single prochiral face. The fact that monofunctional chiral inductors fail to yield significant enantioselectivity supports this idea. The recognition points in the case of norephedrine are most likely the hydroxyl, amino and aryl groups of the inductor, the cations of the zeolite and the carbonyl and methoxy groups of tropolone methyl ether. The cations present in the zeolite help to anchor the chiral inductor to the interior surface. The overall arrangement as we visualize it is illustrated in Fig. 2,[10] which shows the hydrogen bonding between norephedrine and tropolone methyl ether as well as the electrostatic interaction between the cation on the zeolite and the phenyl group of norephedrine. This view reveals that one of the faces of tropolone methyl ether is fairly open while the other is encumbered by the zeolite surface. Such an arrangement is expected to favor one of the two modes of disrotatory cyclization. The fact that 100% enantioselectivity is not observed suggests that not all molecules are present in this idealized arrangement.

The results presented here provide encouragement for further exploration of chiral induction within modified zeolites.[11] For the first time, the phenomenon of asymmetric induction within a zeolite appears to be amenable to a simple model, a model that can be used to plan future experiments exploring the utility of zeolites as media for enantioselective photoreactions. Such research is under way in our laboratories.

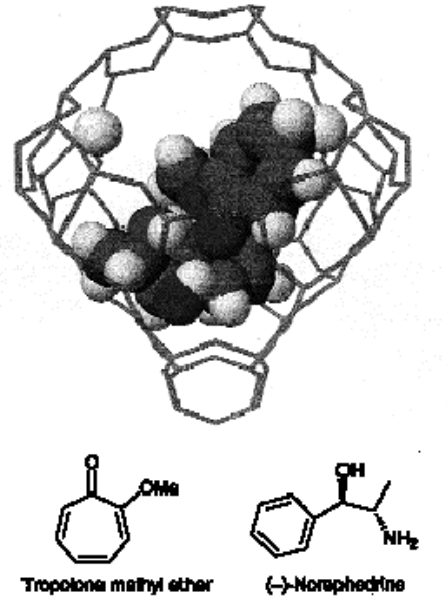

Fig. 2 Tropolone methyl ether and norephedrine included within a supercage of a NaY zeolite. The model shows hydrogen bonding interactions between the reactant and the chiral inductor and electrostatic interaction between the zeolitic cation and the chiral inductor. The cations help to anchor the chiral inductor and the chiral inductor helps to adsorb tropolone methyl ether preferentially from one enantiotopic face.

Structure and dynamics of all of the stereoisomers of europium complexes of tetra(carboxyethyl) derivatives of dota: ring inversion is decoupled from cooperative arm rotation in the *RRRR* and *RRRS* isomers

Judith A. K. Howard,[a] Alan M. Kenwright,[a] Janet M. Moloney,[a] David Parker,*[a]† Marc Port,[b] Michel Navet,[b] Olivier Rousseau[b] and Mark Woods[a]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*
[b] *Guerbet s.a., Aulnay-sous-Bois, 95943 Roissy-Charles de Gaulle, France*

The absolute configuration of the four stereoisomeric α-substituted derivatives of dota has been defined; in their Eu complexes, 2D-NMR methods have revealed that in solution ring inversion is independent of pendant arm rotation and the (*RRRR*)-[EuL^{1a}] complex which in the solid state crystallises as a square antiprismatic structure.

The octadentate ligands derived from 1,4,7,10-tetraazacyclododecane (cyclen) by tetra-*N*-substitution define an important subgroup of modern lanthanide complexation chemistry.[1] Eight-coordinate tetraacetate ('dota'), phosphinate and carboxamide derivatives form kinetically robust complexes in aqueous solution, permitting their use in targeted radiotherapy,[2] as contrast agents in magnetic resonance imaging (MRI)[3] and as single-component luminescent probes in biochemical analyses.[4] In the lanthanide complexes of dota, or its achiral carboxamide derivatives, there are two independent elements of chirality, associated with the ring N–C–C–N and side-arm N–C–C–O torsion angles (*i.e.* each five-ring chelate is δ or λ). Accordingly there are four stereoisomers, related as two pairs of enantiomers, which may interconvert in solution *via* ring inversion (δδδδ → λλλλ) or concerted arm rotation (Δ → Λ). Either motion, in isolation, will exchange the coordination geometry between a square-antiprismatic arrangement, [Δ(λλλλ)/Λ(δδδδ)], with an N_4/O_4 twist angle of *ca.* 40°, and a more open twisted square antiprism [Δ(δδδδ)/Λ(λλλλ)] with a twist angle of *ca.* 29°. Introduction of a stereogenic centre β or γ to the ring nitrogen has been shown to impart considerable rigidity into the complex, inhibiting arm rotation in particular, as shown with the tetraphosphinoxymethyl complexes, and leading to preferential formation of one major stereoisomer in solution.[1,5,6] The effect of introducing a substituent α to each ring nitrogen on the structure and solution dynamics of the derived europium complexes is now described.[5b] Such a substitution gives rise to 6 ligand stereoisomers L^1 defined by the absolute configuration at carbon: *RRRR* (*SSSS*), *RSSS* (*SRRR*), *RSRS* and *RRSS*. In the corresponding lanthanide complexes, for a given ligand configuration, there are theoretically four stereoisomeric complexes (Fig. 1), which in principle may exchange by sequential arm rotation and/or ring inversion.

Alkylation of cyclen with racemic dimethyl-2-bromoglutarate (K_2CO_3–MeCN) led to formation of a mixture‡ of the expected diastereoisomeric esters. Base hydrolysis (6 M NaOH, 80 °C) afforded a mixture of ligands L^{1a}–L^{1d} which was separated by factional crystallisation and analysed by reverse-phase HPLC. The absolute configuration of each ligand was established by an X-ray structural analysis. Europium complexes of each ligand were formed by heating with $Eu(NO_3)_3$ at pH 5.5 (18 h, 90 °C). The complexes were purified by crystallisation from water. Proton NMR spectra for each complex were recorded (Fig. 2), highlighting the symmetry of the complex in solution. Thus in the high frequency region of the shifted spectrum, the C_4-symmetric complex [EuL^{1a}] gave rise to only two signals (δ_H 24.2 and 44.0) in ratio 4 : 1. ^{1}H–^{1}H COSY NMR showed that these resonances correspond to an axial ring proton in each of the isomeric species, consistent with earlier NMR analyses of such systems.[7,8] With the 'C_2-symmetric' complex [EuL^{1c}], two pairs of axial ring protons were observed also in a ratio of 4 : 1; with both [EuL^{1b}] and [EuL^{1d}] which lack any rotational symmetry, each of the four 'axial' ring hydrogens gave rise to a separate resonance and the observed ratio of stereoisomers was *ca.* 2 : 1 and ⩾ 12 : 1 respectively.

A concerted arm rotation will interconvert the axial protons of the major isomer with the axial protons of the minor isomer. However, a ring inversion interconverts the axial protons of the major isomer with equatorial protons of the minor (Fig. 1). Such processes have been observed with [Eu(dota)]$^-$ at room temperature.[8,9] Two-dimensional exchange spectroscopy (^{1}H

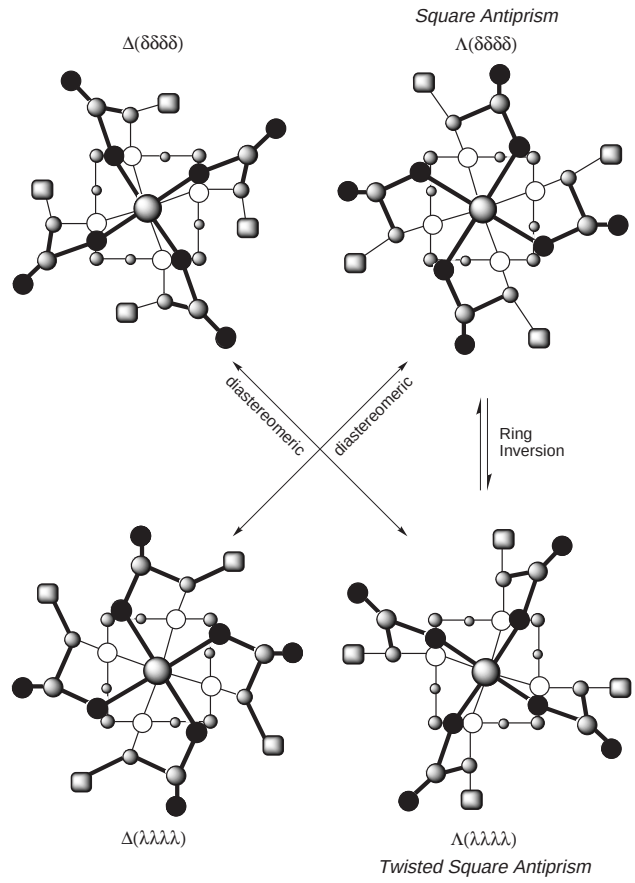

Fig. 1 Stereoisomerism in chiral eight- or nine-coordinate lanthanide complexes of α-alkylated derivatives of dota: ring inversion interconverts (δδδδ) and (λλλλ) isomers, and concerted arm rotation allows Δ and Λ isomers to exchange. The shaded square represents an alkyl group.

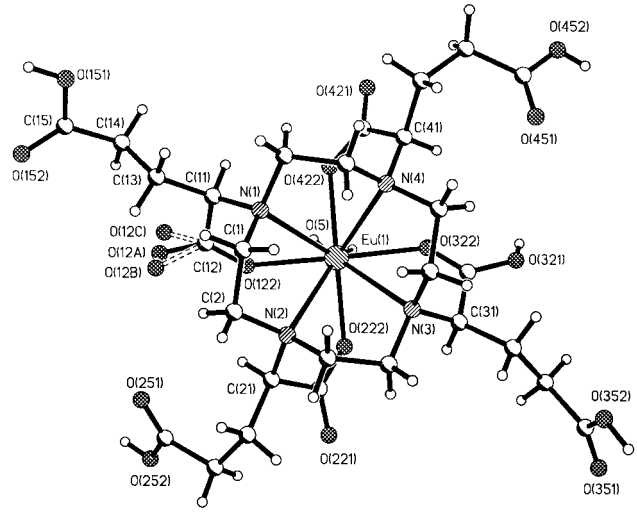

Fig. 3 Structure of (*RRRR*)-[Eu(H_5L^{1a})(H_2O)] in the crystal showing the mono-capped square antiprismatic geometry about the Eu ion, and the left-handed lay-out of the pendant arms

EXSY) was used to probe these processes in the complexes [EuL^{1a}], [EuL^{1b}] and [EuL^{1c}] (293 K, pD 6). The 2-D EXSY spectra of [EuL^{1a}] and [EuL^{1b}] showed cross-correlations between related axial and equatorial protons, indicating that ring inversion is occurring at room temperature. No cross-peaks were observed arising from the interconversion of axial protons in the major and minor isomers. This is consistent with fast ring inversion but slow arm rotation, on the NMR timescale. Thus, major/minor isomer interconversion occurs primarily through ring inversion, rendering two of the four possible diastereoisomeric structures less accessible. This accounts for the observation of just two species in solution in the ^{1}H NMR spectrum (Fig. 2). On warming the sample, the two high frequency axial protons began to broaden and the minor resonance moved towards the major, with coalescence not observed but likely to be not much above 60 °C. The rate of exchange between the two isomers through ring inversion (λλλλ to δδδδ), was measured by selective pulse inversion methods, examining the axial proton (H_{ax}, δ 44) to equatorial (H_{eq}, δ −8) exchange process. The measured rate was 45 ± 15 s^{-1}, very similar to that found for [Eu(dota)]$^-$,[8] indicating clearly that the process of ring inversion is independent of arm rotation. The situation with [EuL^{1c}] was quite different: at room temperature, cross-peaks associated with both arm rotation and ring inversion were observed indicating that both processes were occurring at comparable rates. Indeed the EXSY spectra were very similar to those defined for [Eu(dota)]$^-$.[8]

The structure of the neutral complex [Eu(H_5L^{1a})] was determined by X-ray crystallography§ and both the (*RRRR*) and (*SSSS*) complexes crystallised together (in $P\bar{1}$) (Fig. 3). The Eu ion is nine-coordinate with Eu–O and Eu–N distances averaging 2.38 and 2.68 Å and the Eu–water oxygen bond distance was 2.445(7) Å. For the (*RRRR*)-enantiomer, the ring adopted a square [3333] conformation with each five-ring (N–C–C–N) chelate in a δ configuration (N–C–C–N torsion angle averaging +59.4°) and the N–C–C–O torsion angles were all negative (averaging −34.1°) consistent with a Λ configuration. For the (*SSSS*)-enantiomer, both sets of torsion angles were of opposite sign. Thus the configuration of the stereogenic centre at carbon in the ligand determines both the overall helicity of the complex and its 'macrocyclic' ring configuration, in the solid-state structures. In solution (Fig. 2), comparison of the ^{1}H NMR spectrum of [EuL^{1a}] with those of its three diastereoisomers and [Eu(dota)]$^-$,[9] suggests that the minor isomer also possesses the Λ(δδδδ) configuration (specifying *R* configuration). The major isomer in solution must then adopt the Λ(λλλλ) configuration. In the complexes of [EuL^{1b}], [EuL^{1c}] and [EuL^{1d}], it follows that the major isomer must adopt a square antiprismatic geometry. Thus it is the minor isomer of [EuL^{1a}] that has crystallised preferentially.

$[(DippNH)_2Al(\mu\text{-}NHDipp)_2Li\cdot thf]$ 1 and $[thf\cdot Li(\mu\text{-}NHCy)_3Sn(\mu\text{-}NHCy)_3Li\cdot thf]\cdot C_6H_5Me$ 2 are produced from the reactions of $AlCl_3$ and $SnCl_4$ or $MeAlCl_2$ and $MeSn(NMe_2)_3$ with the apporopriate primary amido lithium precursors [RNHLi; R = 2,6-$Pr^i_2C_6H_3$ (Dipp), C_6H_{11} (Cy)]; both complexes have ion-paired structures in the solid state with the retention of potentially reactive N–H functionality providing precursors for heterometallic species containing $[M(NR)_x(NHR)_{n-x}]^{(1+x)-}$ anions (M = Al, n = 4; M = Sn, n = 6).

One area of current interest to us is the investigation of the metallation reactions of primary amido and phosphido p block and transition metal complexes [of the type $M(NHR)_n^{x-}$] with a series of main group metal reagents (such as dimethylamido complexes).[1] Some indication of the scope of this approach to the synthesis of heterometallic arrangements is provided by the reaction of the $[Sb(NHCy)_4]^-$ (Cy = C_6H_{11}) with $Sb(NMe_2)_3$ which gives the *spiro* anion $[(Me_2N)Sb(\mu\text{-}NCy)_2Sb]^-$.[2] However, further in-roads in this area have been hampered by the surprising lack of well defined homoleptic primary amido and phosphido metal complexes which we sought as precursors for metallation. In some cases this situation reflects the ease of formation of imido complexes in the reactions of REHLi with metal halides.[3] We report here the syntheses and X-ray crystal structures of $[(DippNH)_2Al(\mu\text{-}NHDipp)_2Li\cdot thf]$ **1** (Dipp = 2,6-$Pr^i_2C_6H_3$) and $[thf\cdot Li(\mu\text{-}NHCy)_3Sn(\mu\text{-}NHCy)_3Li\cdot thf]\cdot C_6H_5Me$ **2**.

Compounds **1** and **2** can be prepared directly by the reactions of $AlCl_3$ with DippNHLi (1 : 4 equiv., respectively) and $SnCl_4$ with CyNHLi (1 : 6 equiv., respectively) (Scheme 1). The same complexes are also formed in the reactions of $MeAlCl_2$ with DippNHLi (1 : 3 equiv., respectively) and $MeSn(NMe_2)_3$ with CyNHLi (1 : 3 equiv., respectively). These reactions presumably involve intra- or inter-molecular deprotonation of RNH– groups by the Me groups of $MeAlCl_2$ and $MeSn(NMe_2)_3$.‡

The X-ray study of **1**§ reveals that it exists as an ion-paired complex in the solid state in which an $[Al(NHDipp)_4]^-$ anion is attached through two μ-NDipp groups of a thf solvated Li^+ cation (Fig. 1). The effect of the bridging of two of the DippNH groups to the Li^+ cation is to elongate the associated Al–N bonds (av. 1.95 Å) compared to those made with the terminal DippNH ligands (av. 1.85 Å). The coordination to the Li^+ cation also has a large affect on the geometry of the $[Al(NHDipp)_4]^-$ anion, with the N–Al–N angle within the $Al(\mu\text{-}N)_2Li$ rings being compressed (av. 93.6°) and the N–Al–N angle between the terminal ligands being expanded (av. 117.7°) as a result. Similar structural variations are found in the related amido complexes $[(pyrN)_2Al(\mu\text{-}Npyr)_2Li\cdot L_2]$ (pyr = pyrrolidinido; L = pyrNH, thf),[4] although the mono- rather than bis-solvation of the Li^+ cation in **1** leads to slightly longer Al–(μ-N) bonds and slightly shorter Li–N bonds. In addition, the resulting planar, three-coordinate geometry of the Li^+ cation of **1** gives rise to further α-C–H···Li interactions (range Li···H av. 2.30 Å) with a Pr^i group of each of the bridging DippNH ligands. These

interactions appear to be relatively weak and have no apparent effect on the geometry of the Al(μ-N)$_2$Li rings. Similar interactions are now commonplace in organolithium chemistry[5] and are also found in other lithium aluminate complexes in which the alkali metal cation has a low coordination number.[6]

Although an extensive range of primary amido Al complexes have been reported previously, the vast majority of these have been neutral oligomers of the type [R′$_2$Al(μ-NHR′)]$_n$ prepared by metallation of RNH$_2$ with AlR′$_3$.[7] Complexes containing primary amido Al anions are far rarer and, to our knowledge, the only compounds of this type to be structurally elucidated are the heteroleptic organo-primary amido complexes [(Ph$_3$CNH)$_2$AlBu$^t_2$]Li,[8] [(Mes)$_2$Al(NHBu^t)$_2$Li·*n*(thf)] (Mes = 2,4,6-Me$_3$C$_6$H$_2$; *n* = 1, 2),[9] [Li(thf)$_4$] [(DippNH)AlBu$^i_2$Bu^t],[9] and [(DippNH)AlBu^{t}Me$_2$]Li·3thf.[9,10] Although several tetrakis(amido) complexes adopt similar structures to **1**,[4,11] this complex is the first example containing a primary amido anion of the type [Al(NHR)$_4$]$^-$. The formation of this unit in the reaction of MeAlCl$_2$ with DippNHLi is of particular interest bearing in mind the apparently low basicity of the Me groups in [(DippNH)AlBu^{t}Me$_2$]Li·3thf,[9,10] which even when subjected to prolonged reflux fails to eliminate methane.

The X-ray structure of **2**§ shows that the complex is the ion-paired species [thf·Li(μ-NHCy)$_3$Sn(μ-NHCy)$_3$Li·thf]·C$_6$H$_5$Me, composed of a central [Sn(NHCy)$_6$]$^{2-}$ dianion which uses all six of its NHCy groups to bond to two thf solvated Li$^+$ cations (Fig. 2). There is one lattice-bound molecule of toluene per formula unit. The coordination of the two Li$^+$ cations gives rise to a contraction in the skeletal N–Sn–N angles of the resulting Sn(μ-N)$_3$Li units (av. 82.3°) and introduces considerable distortion in the geometry of the Sn^{IV} centre away from pure octahedral. Despite the apparent similarity of the geometries of two Li$^+$ cations of **2**, they are crystallographically different. The large variation in the Sn–N bond lengths within the [Sn(NHCy)$_6$]$^{2-}$ dianion [range 2.06(2)–2.27(2) Å] roughly mirrors the different degrees of interaction of the bridging NHCy groups with each Li$^+$ cation, the longest Sn–N bonds being associated with the shortest Li–N interactions and the shortest Sn–N bonds with longer Li–N contacts. The distortions within the framework of **2** suggest that this arrangement is highly strained. Although the structure of **2** is comparatively simple, few related Sn–N bonded compounds appear to have been structurally characterised. The closest relatives to **2** are ion-separated species containing inorganic EX$_6^{2-}$ anions (E = Si–Pb; X = N$_3^-$, SCN$^-$, SeCN$^-$, CN$^-$).[12] Complex **2** contains the first example of a hexa(amido) group 14 dianion to be characterised in the solid state.

Our studies of the reactions of homoleptic complexes of groups 13 and 14 with a range of metallating reagents [such as E(NMe$_2$)$_x$ (E = Sb, *x* = 3; E = Sn, *x* = 2)] are still at an early stage. However, there are good reasons for thinking that complexes like **1** and **2** (containing reactive N–H functionalities) will be of value as precursors in the synthesis of heterometallic species containing [M(NR)$_x$(NHR)$_{n-x}$]$^{(1+x)-}$ anions (M = Al, *n* = 4; M = Sn, *n* = 6). Recent work by Rutherford and Atwood has shown that deprotonation of species of the type [R$_2$AlNHR′] can be easily accomplished with organolithium reagents[9,10] and our own studies have revealed that various p block metal bases readily deprotonate primary amido metal complexes.[1,2] Further studies will be aimed at the synthesis of such 'multianion' species and the applications of these as new ligands to a range of main group and transition metals.

We gratefully acknowledge the EPSRC (C. N. H., M. McP.), The Leverhulme Trust (M. A. B.), The Turkish Government (M. T.) and The Spanish Government (M. E. G. M.) for financial support.

Note added at proof. During the proof stage another example of a primary amido Al^{III} complex was reported (J. S. Silverman, C. J. Carmalt, D. A. Neumayer, A. H. Cowley, B. G. Burnett and A. Decken, *Polyhedron*, 1998, **17**, 977).

Isolation and structural determination of octacyanobutanediide, $[C_4(CN)_8]^{2-}$; precursors to $M(TCNE)_x$ magnets‡

Jie Zhang,[a] Louise M. Liable-Sands,[b] Arnold L. Rheingold,*[b] Rico E. Del Sesto,[a] Douglas C. Gordon,[a] Brian M. Burkhart[c] and Joel S. Miller*[a]†

[a] *Department of Chemistry, University of Utah, Salt Lake City, UT 84112-0850, USA*

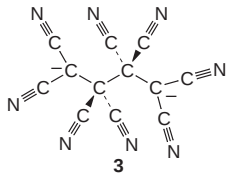
The reaction of $MI_2{\cdot}x$Me$_3$CN (M = Mn, Fe) and TCNE (tetracyanoethylene) leads to unprecedented $[C_4(CN)_8]^{2-}$ μ_4-metal complexes which have been crystallographically characterized and are precursors to $M(TCNE)_x{\cdot}y$S magnets.

The study of cyanocarbons has led to the discovery of both molecule-based conductors[1] and magnets[2] as well as several new classes of compounds based upon reduction of the nitrile triple bond.[3,4] While generalizing the room-temperature molecule-based magnet $V(TCNE)_x{\cdot}yCH_2Cl_2$[5] to magnetic systems based upon other metals, we discovered several new magnets in this class: $M(TCNE)_2{\cdot}x$S (M = Mn, Fe, Co, Ni; S = MeCN, CH_2Cl_2).[6] In contrast to the V magnet, the Fe and Mn magnets exhibit X-ray powder diffraction. Therefore, we attempted to grow single crystals of these magnets *via* slow diffusion of $MI_2{\cdot}x$MeCN (M = Mn, Fe) and TCNE in a H-tube using either MeCN–CH_2Cl_2 (M = Mn) or pure MeCN (M = Fe). Crystals of new compounds (light yellow for M = Mn; dark brown for M = Fe) were isolated with ν_{CN} IR absorptions at 2304m, 2275m, 2212s, 2205s, 2153s, and 2096m (sh) cm^{-1} for M = Mn and 2307m, 2280m, 2213s, 2154s, and 2108w cm^{-1} for M = Fe. These ν_{CN} absorptions are similar to, but distinguishable from, those observed for the $M(TCNE)_2{\cdot}xCH_2Cl_2$.[6] magnets. The absorptions above 2230 cm^{-1} are assigned to coordinated MeCN, while the latter are assigned to reduced nitriles and were initially thought to be associated with a metal-bound reduced form of TCNE.

Single crystal X-ray diffraction studies‡ of $Mn[C_4(CN)_8](NCMe)_2{\cdot}CH_2Cl_2$ **1** and $Fe[C_4(CN)_8](NCMe)_2{\cdot}$MeCN **2** each revealed the unprecedented octacyanobutanediide dianion, $[C_4(CN)_8]^{2-}$ **3**. This dianion is bound to four



3

octahedral M^{II} centres (M = Mn, Fe) in a plane with the MeCN molecules filling the axial coordination sites, and the non-coordinated CH_2Cl_2 (**1**) and MeCN (**2**) lying in diamond-shaped holes in the structure, Figs. 1 and 2. Adjacent planes are eclipsed. The interlayer M···M separaions are 7.626(2) and 9.356(4) Å, respectively, for **1**, and **2**, while the intralayer M···M separations are 7.581(2) and 9.344(2) Å for **1**, 7.562(4) and 9.368(4) for **2**.

Compound **3** is disordered about the midpoint of the C(5)–C(5′) bond for M = Mn and ordered for M = Fe. The chemically equivalent M–N, C≡N, NC–C and $(MNC)_2$C–C distances average 2.218(4), 1.151(6), 1.389(7) and 1.615(10) Å, respectively, for Me = Mn, and average 2.221(7), 1.151(10), 1.398(11) and 1.508(9) Å, respectively, for M = Fe. The central C–C bond is 1.59(2) (M = Mn) and 1.627(14) Å (M = Fe). The terminal C_4-backbone carbon atoms are sp^2 hybridized as indicated by the average angle of 119.0° (M = Mn) and 119.8° (M = Fe) while the central carbon atoms are sp^3 hybridized [average angles are 109.5° (M = Mn) and 109.4° (M = Fe)].

This is the first example of a σ-dimer of $[TCNE]^{\cdot-}$, however, several examples of a structurally related σ-dimer of $[TCNQ]^{\cdot-}$ (TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane) have been reported.[7] The backbone C–C bonds are significantly longer[8] than the conventionally accepted value of 1.54 Å for an sp^3–sp^3 C–C bond length and are comparable to the central C–C bond for the σ-dimers of $[TCNQ]^{\cdot-}$ (1.630–1.659 Å).

For **1** thermogravimetric analysis–mass spectrometry (TGA–MS) reveals a one-step mass loss between 100 and 120 °C, during which both MeCN and CH_2Cl_2 are simultaneously observed in the effluent gas. The 34.3% mass loss is in good agreement with the formula $Mn[C_4(CN)_8](NCME)_2{\cdot}CH_2Cl_2$ (34.9%). At *ca*. 250 °C a second mass loss occurs which is accompanied by the generation of C_2N_2 and HCN. An exothermic event is also observed in the DSC data at this temperature. This mass loss is only 4%, corresponding to *ca.* 0.7 CN per Mn. The observation of C_2N_2 and HCN is consistent with the formation of CN˙ radicals which either combine or

abstract hydrogen. Despite the lower volatility of MeCN as compared to CH_2Cl_2, **2** loses solvent very rapidly when removed from the mother-liquor and cannot be isolated with all three MeCN molecules present. A sample with 1.7 MeCN per Fe was obtained after drying *in vacuo* at room temperature. TGA–MS on this material shows that it loses the remaining solvent at 100 °C and formation of C_2N_2 begins at *ca.* 150 °C and peaks at 320 °C. We have observed similar thermal decomposition processes in other compounds containing $[TCNE]^{\cdot-}$ such as $[NBu_4][TCNE]$ and K[TCNE]. Thus, we believed that desolvation leads to cleavage of the long central C–C bond of $[C_4(CN)_8]^{2-}$ to reform $[TCNE]^{\cdot-}$ which subsequently decomposes to form the observed byproducts, HCN and C_2N_2.

Compound **1** is a paramagnet with a room temperature effective moment of 6.7 μ_B and obeys the Curie–Weiss law above 5 K. This is consistent with a diamagnetic $[C_4(CN)_8]^{2-}$ which weakly couples the metal spin sites ($S = 5/2$ Mn^{II}), albeit with a larger than expected room temperature moment. The magnetic properties of **2** are as yet undetermined since it cannot be isolated without loss of solvent.

Upon desolvation of **1** at 100 °C the ν_{CN} absorptions disappear and new ν_{CN} bands characteristic of the $Mn(TCNE)_2 \cdot xCH_2Cl_2$ magnet (2225, 2182, and 2170 cm^{-1})[6] appear. In addition the room temperature moment increases. The desolvated sample magnetically orders at a T_c of 95 K, in reasonable agreement with the value previously reported (107 K) for $Mn(TCNE)_2 \cdot xCH_2Cl_2$ prepared directly in CH_2Cl_2.[6] **2** behaves in a similar fashion upon desolvation. The desolvated material has ν_{CN} IR absorptions characteristic of the $Fe(TCNE)_2 \cdot x$MeCN ($x = 1.7$) magnet (2280, 2220, 2164 and 2117 cm^{-1}) and orders magnetically at *ca.* 6 K $[Fe(TCNE)_2 \cdot x$MeCN orders at *ca.* 8 K].[6] These observations are consistent with the TGA–MS data and indicate that desolvation leads to formation of $S = 1/2$ $[TCNE]^{\cdot-}$ which can bind to additional metal centers and provide strong spin coupling leading to the observed magnetic ordering. Evidence for this bond breaking has been reported for σ-dimers of $[TCNQ]^{\cdot-}$.[7a]

Silica condensation reaction: an *ab initio* study

J. C. G. Pereira,[a,b] C. R. A. Catlow*[a]† and G. D. Price[b]

[a] *Davy Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albermarle Street, London, UK W1X 4BS*

***Ab initio* techniques are used to investigate the mechanisms and energetics of condensation of two $Si(OH)_4$ monomers in a simulated hydrated environment; the calculated activation energies accord well with those measured for silica condensation in sol–gel systems.**

The kinetics of the silica-based condensation reaction have been widely investigated, using a variety of spectroscopies and scattering techniques.[1] Silicate clusters in solution have also been identified[2,3] using NMR and gas chromatographic techniques. However, because of the multitude of simultaneous reactions in solution, it is difficult to extract information about individual events using only experimental data.

The chemistry of silica has also been studied extensively using theoretical techniques.[4] A simple mechanism for the silica hydrolysis reaction was suggested,[5] with an activation energy of 21.9 kcal mol^{-1}, close to the experimental energy barrier for silicate and quartz dissolution. All these calculations were carried out in the gas phase, ignoring hydration effects. Moreover, no systematic *ab initio* studies of the silica condensation reaction have been reported to date, even for gas phase systems.

We have therefore studied the simplest condensation reaction, $2Si(OH)_4 \rightarrow Si_2O(OH)_6 + H_2O$, using DF theory coupled with a continuum dielectric model, COSMO,[6,7] to describe the electrostatic conditions found in real silica solutions. This conductor-like screening model is a continuum dielectric model, where a solute molecule is embedded in a dielectric continuum of permittivity ε. The interface between the cavity formed by the solute and the dielectric, the solvent accessible surface, has thus a surface charge distribution, arising from the polarisation of the dielectric medium in response to the charge distribution of the solute. The COSMO model calculates the screening charges in a conductor ($\varepsilon = \infty$), for arbitrarily shaped cavities, using a non-iterative procedure, and then the dielectric screening energy and its gradient are scaled by $(\varepsilon - 1)/(\varepsilon + \frac{1}{2})$, to take into account the effect of the dielectric.

All calculations used the DMOL code[8] with the local BLYP functional[9,10] and a DNP double numerical basis set.[11] All atomic arrangements were first optimised *in vacuo* and subsequently recalculated including hydration effects, as a single energy point, without reoptimisation. We considered mechanisms effected by acid catalysis (corresponding to pH < 3) as in most experimental work.[12,13] A methanol environment was chosen for the COSMO calculations, to fit better the electrostatic conditions found in real sol–gel solutions, where the alcohol is usually the main component. Typical compositions are water/alkoxide = 2–4 and alcohol/alkoxide = 4–10.

Acid catalysed condensation reactions are effected by the attack of a neutral monomer on a protonated monomer resulting in a protonated dimer and a water molecule; $Si(OH)_4H^+$ and $Si_2OH(OH)_6^+$ are therefore key species in the condensation reaction. The protonation energy for both clusters, presented in Table 1, shows that this process is exothermic in the gas phase and endothermic in the methanol environment. In addition, we find that it is more energetically favourable to protonate the cluster rather than the monomer. In gas phase calculations, the key factor is always the additional charge, which may generally be delocalised more effectively in larger systems; consequently, the side of the equilibrium where the charge is hosted by a larger species tends to have a lower energy. In the solvated medium, simulated by the COSMO methodology, this charge stabilisation effect is drastically reduced: it now requires more energy to protonate the $Si_2O(OH)_2$ dimer than the $Si(OH)_4$ monomer. As the electron-withdrawing effect of OSi groups is greater than that of OH groups,[1] the bridging O in $Si_2O(OH)_6$ is less basic than the four terminal O in $Si(OH)_4$. The general implication of this effect is that in acid conditions, larger neutral species attack the smaller, protonated monomers, as observed.[12]

Protonated species formation

$Si(OH)_4 + H_3O^+ + \Delta E \rightarrow Si(OH)_3(H_2O)^+ + H_2O$	
without hydration	$\Delta E = -18.8$
with hydration	$\Delta E = +7.4$
$Si_2O(OH)_6 + H_3O^+ + \Delta E \rightarrow Si_2OH(OH)_6^+ + H_2O$	
without hydration	$\Delta E = -22.3$
with hydration	$\Delta E = +12.9$

Table 1 Formation energies, *in vacuo* and methanol environments

The energy for the condensation reaction, from the protonated reactants to the protonated products, is presented in Table 2. The results for the reaction in the gas phase are again dominated by the effects of charge distribution. The energy of the condensation reaction is negative, because the dimer is larger than the monomer. In the solvated environment, where these charge effects are relatively unimportant, the reaction is endothermic, essentially because the products have groups that are more electron withdrawing than those of the reactants. The results for the calculations with a solvated environment agree with the trends predicted experimentally for these clusters in solution.[12]

Protonated species reactions

$Si(OH)_4 + Si(OH)_3(H_2O)^+ + \Delta E \rightarrow Si_2OH(OH)_6^+ + H_2O$	
without hydration	$\Delta E = -6.3$
with hydration	$\Delta E = +5.1$

Table 2 Condensation energy, *in vacuo* and methanol environments

We now study two detailed mechanisms of condensation: the S_N2 attack (illustrated in Fig. 1) in which the attack occurs from the opposite side to the leaving group and the lateral attack (Fig. 2) in which the attack occurs sideways. To ensure that the energy surface for the reaction was adequately searched we performed, in each case, two sets of calculations. In the first, we started from the reactants, with the protonated monomer having its equilibrium $Si–O^+$ distance of 1.88 Å. During the course of the reaction, the distance, *d*, between the oxygen of the attacking monomer and the Si of the protonated monomer was reduced in a succession of steps from *ca.* 8 Å to the equilibrium value (for the protonated dimer) of 1.83 Å; at each step along the path, *d* was held fixed and all other parameters were optimised. In the second set of calculations, we started from the products, with the protonated dimer having its equilibrium O^+–Si distance of 1.83 Å. We successively decreased the distance, *d′*, between the oxygen of the leaving water molecule and the Si of the

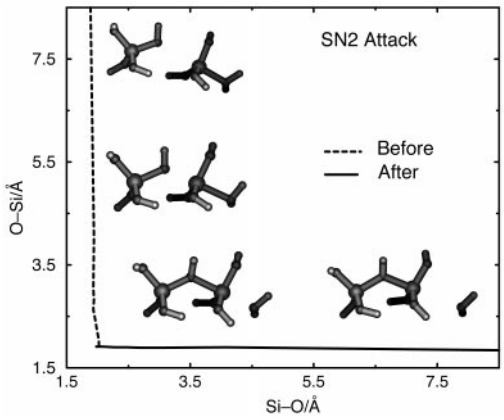

Fig. 1 S_N2 mechanism for the condensation reaction $Si(OH)_4 + Si(OH)_4H^+ \rightarrow Si_2OH(OH)_6^+ + H_2O$. The *y* axis represents the oxygen–silicon distance, (O–Si), between the attacking monomer and the protonated monomer; the *x* axis represents the silicon–oxygen distance, (Si–O), between the protonated dimer and the departing water molecule.

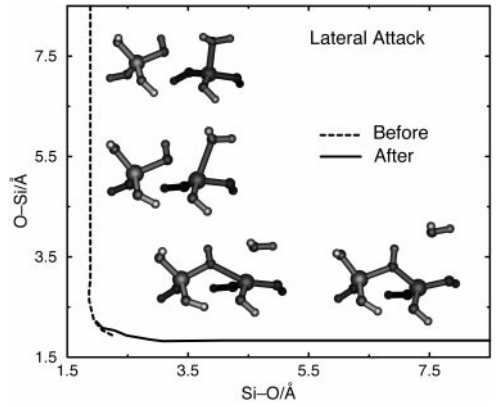

Fig. 2 Lateral attack mechanism for the condensation reaction $Si(OH)_4 + Si(OH)_4H^+ \rightarrow Si_2O(OH)_6H^+ + H_2O$. The *x* and *y* axes are as in Fig. 1.

protonated dimer, from a value of *ca.* 8 Å to the equilibrium value (for the protonated monomer) of 1.88 Å. Again *d′* was fixed in the individual calculations, with all other parameters being optimised. The two sets of calculations, denoted 'before' and 'after', result in similar energy profiles in the intermediate region where they overlap. We note that this step-by-step analysis gives valuable information about the evolution of the charge distribution, which is fundamental in understanding the full transformation from the reactants to the products.

The S_N2 and lateral attack reaction paths, optimised in the gas phase, are very different. While the S_N2 path is composed of two almost straight lines, suggesting a negligible activation energy, the lateral attack path exhibits a small energy barrier.

In the solvated environment, simulated by the COSMO methodology, the energy evolution along the S_N2 reaction path shows first a small energy barrier of 2.5 kcal mol^{-1} before decreasing to a five-silicon intermediate, which is 3.4 kcal mol^{-1} more stable than the reactants, with O–Si 1.91 Å and Si–O 1.98 Å. A second energy barrier of 11.3 kcal mol^{-1}, the largest in the whole reaction process, occurs later, when the Si–O distance is already 4.08 Å.

In the lateral attack mechanism in the solvated environment, after the first 2.5 kcal mol^{-1} energy barrier, a five-coordinate silicon intermediate occurs at O–Si 2.83 Å and Si–O 1.86 (1.9 kcal mol^{-1} less stable than the other reactants). As in the gas phase, a pronounced peak occurs at Si–O 2.48 Å, forming the largest energy barrier in the overall mechanism: 17.3 kcal mol^{-1} (6 kcal mol^{-1} larger than in the S_N2 mechanism). The S_N2 mechanism seems therefore to be an easier route for the conversion of the reactants into the products. However, as the study for the lateral attack shows, several other mechanisms that

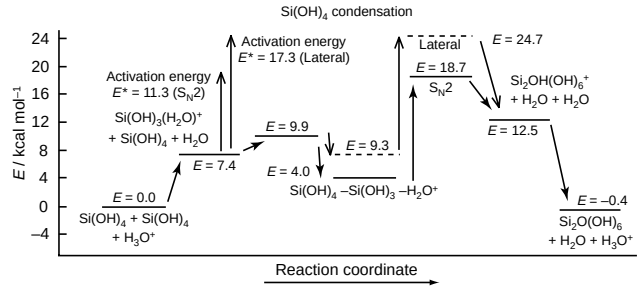

Fig. 3 Energy evolution (kcal mol^{-1}) during the $Si(OH)_4$ condensation reaction, for both S_N2 and lateral attack mechanisms

are energetically and statistically less favourable, should still be possible and may occur simultaneously in the solution.

The global energy evolution from the neutral reactants to the neutral products is depicted in Fig. 3. The difference in energy between reactants and products is small: only −0.4 kcal mol^{-1}. On fully optimising both reactants and products in the COSMO environment, this difference increases to −3.2 kcal mol^{-1}, which is still relatively small. Most significant, however, is the fact that our calculated activation energies are within the range of those measured experimentally for silica condensation reactions in sol–gel systems, in the range 12–15 kcal mol^{-1}.[14,15] We may be confident therefore that we have identified the main mechanisms for this crucially important process. Further calculations will explore stabilities and condensation mechanisms for larger clusters.

We are very grateful to EPSRC for providing both local and national computer resources. One of us (J. C. G. P.) is greatly indebted to Instituto Superior Técnico, Dept. Eng. Materials, Lisboa, and JNICT, Programa Ciência and Programa Praxis XXI, Lisboa, for financial support.

Assembly based on μ_4-bridging thiolate: a new type of polymeric silver(I) complex having a one dimensional chain structure

Weipin Su, Rong Cao, Maochun Hong,*† Jiutong Chen and Jiaxi Lu

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Fuzhou, Fujian 350002, PR China

The polymeric silver(I)–thiolate complex $[\{Ag_8(\mu_4\text{-}SC_2H_4NH_3)_6Cl_6\}Cl_2]_n$ has been prepared from the assembling reaction of silver chloride and 2-mercaptoethylamine hydrochloride in DMF; X-ray diffraction analysis shows the complex has a one dimensional chain structure and all the sulfur atoms of the thiolates exhibit μ_4 bonding bridging four silver(I) centers.

Thiolates are a subject of great interest in the chemistry of transition-metal complexes.[1–4] Dithiolates acting as μ_2 or μ_3 bridging ligands have been used to link metal ions such as Cu^I or Ag^I giving rise to complexes with infinite-chain structures.[5–8] Simple monothiolate ligands acting as μ_2 or μ_3 bridges are very common in transition metal chemistry,[8,9] however, those acting as μ_4 bridges and linking metal atoms to form polymeric complexes in one infinite chain or in network structures are unknown.[10] Recently, we have explored ways to design syntheses of polymeric complexes with chain structures by using coinage metal ions and dithiolate ligands.[11] By changing from dithiolate to monothiolate bridging ligands, we obtained a new type of polymeric silver(I) complex having a one dimensional chain structure and metal–metal interactions in which the thiolates show μ_4 bridging linking four Ag^I centers.

We have found that it is possible to use this simple monothiolate ligand to generate an unusual one dimensional molecular component of ligand bridged Ag^I ions.

By very slowly mixing a DMF solution of AgCl and NEt_4Cl and a DMF solution of 2-mercaptoethylamine hydrogen chloride in an H-tube at room temperature, a large quantity of colorless prismatic crystals deposited.‡ Clearly, the synthesis of the polymeric silver(I) 2-mercaptoethylamine complex can be approached from the controlled assembling reaction of $[AgCl_2]^-$ and $HSC_2H_4NH_2{\cdot}HCl$ in DMF [eqn. (1)]. In this

$$8n[NEt_4][AgCl_2] + 8nHSC_2H_4NH_2{\bullet}HCl \rightarrow \underset{\mathbf{1}}{[\{Ag_8(\mu_4\text{–}SC_2H_4NH_3)_6Cl_6\}Cl_2]_n} + 8n[NEt_4]Cl + 2nHSC_2H_4NH_2{\bullet}HCl \quad (1)$$

reaction, one mole of HCl is liberated for each Ag^+ added and shows the zwitterion $^-SC_2H_4NH_3^+$ acts as a ligand to form the complex. A crystallographic analysis reveals that the complex is a polymer and the octanuclear cation $[Ag_8(SC_2H_4NH_3)_6Cl_6]^{2+}$ constitutes the building-block unit. The octanuclear units, possessing a crystallographic mirror plane through Ag(1), Ag(3) and S(2) (Fig. 1), are bound by Ag–S and Ag–Ag interactions to form a one dimensional chain structure along the *b* axis and the chains are linked by hydrogen bonds in the crystal (Fig. 2). Two types of coordination environments for Ag^I ions are present: six Ag^I ions have a distorted tetrahedral S_3Cl coordination environment, generated by the sulfur atoms of the zwitterions and terminal chloride; the other two are trigonal planar with an S_3 coordination environment from the sulfur atoms of the zwitterion. All six zwitterions $^-SC_2H_4NH_3^+$ exhibit μ_4 bridge linking four metal centers. The occurrence of μ_4 bridging coordination of thiolate ligands in transition metal chemistry is very limited.[10] This is the first example of an $Ag_4(\mu_4\text{-}S)$ bridge coordination mode for thiolate found in silver(I) chemistry and the third example of a $M_4(\mu_4\text{-}S)$ bridge coordination mode of the zwitterion found in transition metal thiolate chemistry (the other examples being $[Cu_{13}Cl_{13}(SC_2H_4NH_3)_6]$[10a] and $[\{Cu_8Cl_6(SC_2H_4NH_3)_6\}Cl_2]_n$[10b]). The coordination geometry of all the sulfur atoms is a highly distorted square pyramidal $CSAg_4$ unit with one carbon atom at the apex and four silver atoms in the equatorial plane. The four Ag–S bonds in the μ_4-S(1)Ag_4 unit are all similar in length [2.577(5), 2.583(5), 2.611(5), 2.690(5) Å], while those in the μ_4-S(2)Ag_4 unit are non-equivalent, one shorter at 2.440(7) Å, two at 2.626(4) Å and one longer at 2.917(7) Å. The average Ag–S bond distance [2.634(7) Å] is much longer than that [2.248 Å] in $[Cu_{13}Cl_{13}(SC_2H_4NH_3)_6]$[10a] and slightly longer than those for Ag^I–SR involving three- or four-coordinate silver (2.40–2.55 Å).[3,4] The Ag–Ag separations range from 2.976(2) to 3.046(3) Å with an average value of 3.003 Å. All are best considered as non-bonding,[3] although the values are very similar to those present in metallic silver (2.88 Å).[12] The average Ag–Cl bond distance [2.489(5) Å] is slightly longer than that (2.448 Å) in $[Cu_{13}Cl_{13}(SC_2H_4NH_3)_6]$[10a] and lies in the normal range for Ag^I–Cl bonds.[4] Two Cl^- are not coordinated to silver atoms, but are bonded to NH_3^+ *via* a strong hydrogen bond N–H···Cl (N···Cl= 3.20 Å) in the crystal.

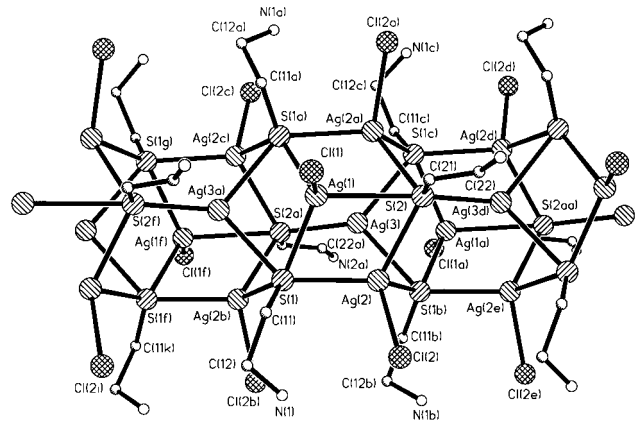

Fig. 1 Perspective view of an octanuclear unit in the polymeric chain in $[\{Ag_8(\mu_4\text{-}SC_2H_4NH_3)_6Cl_6\}Cl_2]_n$. Photopromoted oxidative cyclization of an *o*-phenylene-bridged Schiff base *via* a manganese(III) complex, leading to a fluorescent compound, 2-(2-hydroxyphenyl)benzimidazole

Takashi Fukuda,[a] Fuminori Sakamoto,[a] Minoru Sato,[b] Yoshiharu Nakano,[a] Xiang Shi Tan[a] and Yuki Fujii*[a]†

Visible light photolysis of [*N*,*N*′-*o*-phenylenebis(salicylideneaminato)]diaquamanganese(III) resulted in the fluorescent compound 2-(2-hydroxyphenyl)benzimidazole by a one electron redox reaction between Mn^{III} and the Schiff base ligand, followed by the base-hydrolysis of the oxidized Schiff base, and then the cyclization of the base-hydrolyzed product.

The photoactivation of manganese complexes is an attractive theme both in the modeling of PSII and in the development of a new photoreaction.[1–4] It has been known that, upon visible light irradiation, in the presence of *p*-quinone, manganese(III) complexes with tetradentate Schiff base ligands having the salen-type skeleton generate molecular oxygen;[5–7] in the absence of *p*-quinone, rearrangement of the coordinated Schiff base ligand occurs.[8] Recently, we examined the photolysis of [*N*,*N*′-*o*-phenylenebis(salicylideneaminato]diaquamanganese-(III) **1** and observed a photopromoted oxidative cyclization of the coordinated Schiff base ligand, and the effective formation of the fluorescent compound 2-(2-hydroxyphenyl)benzimidazole **2**, which is useful as a laser dye, high-energy radiation detector, molecular energy storage system, and fluorescent probe.[9–11] **2** is usually prepared from salicylic acid and *o*-phenylenediamine in polyphospholic acid at 190 °C in 14% yield.[12] This photoreaction thus provides a new and effective synthetic method for the fluorescent compound **2** and its derivatives.‡

Cation **1** was prepared by a literature method,[13] and isolated as its perchlorate salt.§ Absence of Mn^{II} was confirmed by EPR spectroscopy. Slow evaporation of methanol solution of the complex produced crystals suitable for single crystal X-ray structure analysis.¶ An ORTEP drawing of **1** is shown in Fig. 1. The structure of the complex cation comprises a planar tetradentate Schiff base ligand tightly bound to the Mn^{III} center *via* two Mn–N bonds [1.981(2), 1.978(2) Å] and two Mn–O bonds [1.859(1), 1.875(1) Å], and by axial methanol and water molecules which complete an octahedron around the Mn^{III} ion. Longer Mn–O distances to the apical ligands [2.272(2) Å for Mn–H_2O and 2.291(2) Å for MeOH] may be partly attributed to the Jahn–Tellar effect for the d^4 ion, although it is common for solvated Mn–O distances to be longer than chelated ones.[14] No hydrogen bond between the phenolic oxygen atoms of the Schiff base ligand and apical water or methanol was observed.[6]

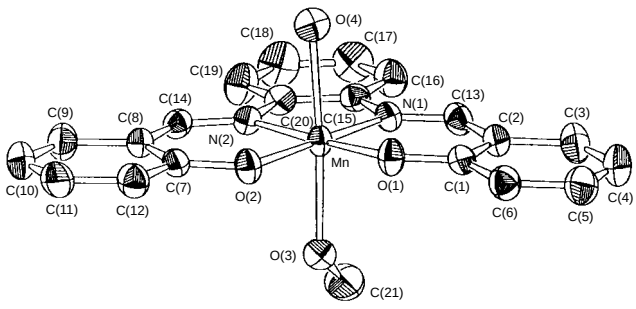

Fig. 1 An ORTEP drawing of cation **1** with thermal ellipsoids at 50% probability. Hydrogen atoms are omitted for clarify.

Fig. 2 shows the time courses of UV–VIS (320 nm), fluorescence (432 nm), and EPR spectra of **1** in water at initial pH = 6.4 under irradiation with visible light (150 W tungsten halogen lamp with UV cut filter L-39). The UV–VIS spectral change exhibited an isosbestic point at 223 nm, and the half life ($t_{1/2}$) of **1** was 11–15 h at pH 6.4.‖ A similar spectral change also occurred in the dark but was very slow ($t_{1/2}$ ≈55 h). Our preliminary experiments revealed that the photopromotion occurs by the irradiation into the CT band (400 ± 20 nm), but hardly for the π → π* (335 ± 20 nm) and d → d (540 ± 20 nm) bands. Further, the reaction becomes faster with increase of solution pH ($t_{1/2}$ ≈ 9 h at pH 7.5, ≈ 5 h at pH 8.6).

On the other hand, the fluorescence and EPR intensities of the photoreaction solution increased with the decay of **1**, indicating that the fluorescent compound, assigned as 2-(2-hydroxyphenyl)benzimidazole **2**, was formed at early stages of the reaction. The EPR spectra show typical six-line Mn^{II} signals (g = 2.013), which proves that the Mn^{III} was reduced to Mn^{II} during this reaction. Since neither molecular oxygen nor hydrogen peroxide were detected in the photoreaction solution, it is strongly suggested that intramolecular one electron redox occurred between Mn^{III} and the coordinated Schiff base ligand. A similar photoreaction also occurred under vacuum, however, no EPR signal corresponding to an organic radical was observed.

From the photoreaction solution, **2** and salicylaldehyde **3** could be separated both in about 40% yield by extraction with ethyl acetate, followed by silica-gel column separation using ethyl acetate–*n*-hexane (1 : 2) as eluent (R_f = 0.6 for **2**, R_f = 0.8 for **3**).** In addition to **2** and **3**, under argon, *N*,*N*′-

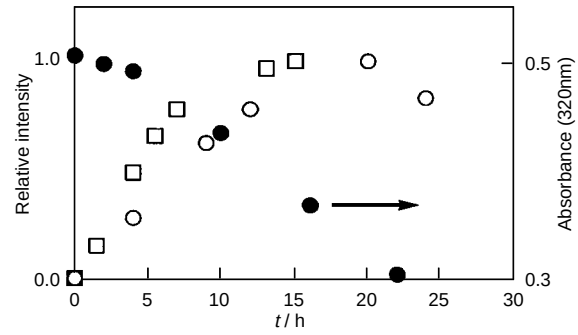

Fig. 2 Time courses of UV–VIS, fluorescence and X-band EPR spectra of the photolysis solution of **1** at pH = 6.4 and 25 °C. The complex concentration is 2.0 × 10^{-5} mol dm^{-3} for UV–VIS (●) and fluorescence (○) and 1.0 × 10^{-3} mol dm^{-3} for EPR (□). Fluorescence: λ_{ex} = 325 nm, λ_{em} = 432 nm, EPR: microwave power = 5 mW, microwave frequency = 9.238 GHz, 0.5 mT modulation amplitude, 25 °C.

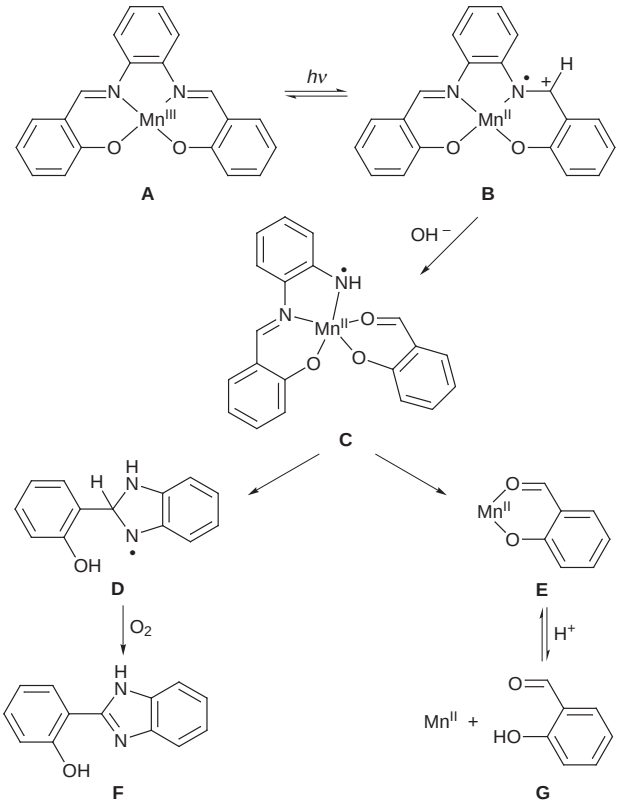

Scheme 1

o-phenylenebis(salicylideneamine) **4** was isolated in *ca*. 10% yield as a photoreaction product of **1**.

On the basis of these facts, the reaction mechanism (Scheme 1) is suggested as follows: (*i*) Mn^{III}–Schiff base complex **A** is reduced to Mn^{II} complex **B** with partially oxidized Schiff base ligand, for which visible light promotes the reaction (the reaction has been shown to be enhanced by excitation at the CT band of **1**, probably by LMCT). **B** is thought to be a transient radical and a similar radical has been proposed by Floriani and coworkers.[15] (*ii*) **B** is base-hydrolyzed to form radical **C**, followed by cyclization of the partially oxidized Schiff base ligand to produce radical **D** and Mn^{II} complex **E**, **D** is oxidized by O_2 to produce **F**. These processes are very fast, since final products **F** and Mn^{II} appear from the start of the reaction with no organic radical being detected in the timescale of EPR measurement. No detection of radical **D** under vacuum may be due to a redox reaction between **A** and **D**, which results in the formation of the corresponding Mn^{II}–Schiff base complex and **F**. This is partly supported by the fact that the Schiff base ligand **4** is detected under argon but not under air. Evidence for base-hydrolysis of **B** is the formation of salicylaldehyde **G** and rate enhancement with increase of solution pH. A study of the detailed reaction mechanism is under way.

This work was partly supported by a Grant-in-Aid for Science Research (No. 09440224 and No. 97370) from the Ministry of Education, Science and Culture of Japan.

Three-dimensional redox-active layered composites of Au–Au, Ag–Ag and Au–Ag colloids

Ron Blonder, Laila Sheeney and Itamar Willner*†

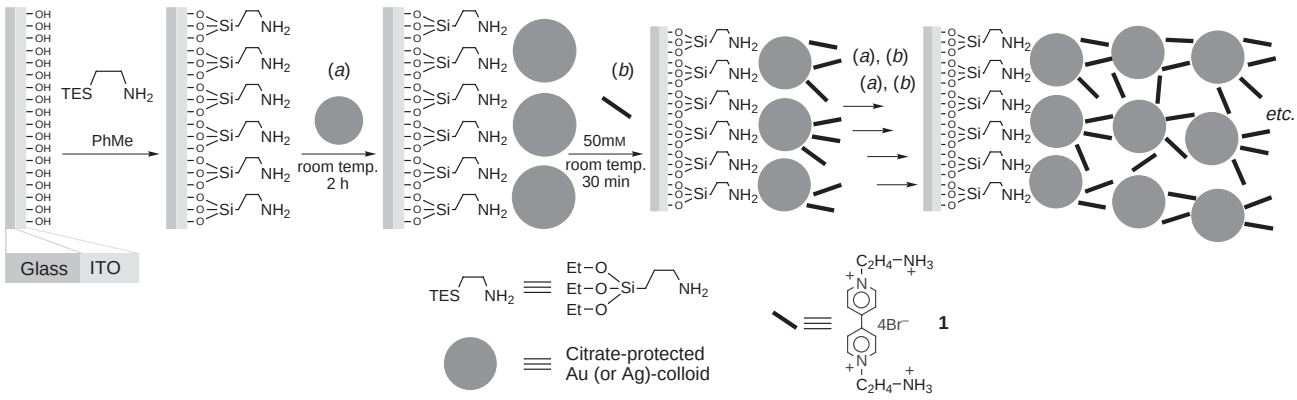
Institute of Chemistry and The Farkas Center for Light-Induced Processes, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

Ordered layered three-dimensional networks of Au, Ag and Au/Ag colloids are assembled in a stepwise synthesis using *N*,*N*′-bis(2-aminoethyl)-4,4′-bipyridinium as a redox-active crosslinker.

The ordered assembly of metal particles on solid supports, *i.e*. glass or conductive ITO-glass attracts substantial research effort due to the unique electronic and optical properties of nanoscale metal colloid particles.[1,2] Surface-enhanced Raman spectroscopy (SERS) of adsorbate monolayers on Au-colloids,[3,4] electrochemistry of redox-active monolayers associated with rough Au-colloid monolayers,[5] conductivity of three-dimensional Au-colloid assemblies,[6] and second-harmonic generation at layered Au-colloids,[7] were examined. Nanometer-size organization of the metal colloids is of importance to tailor microelectronic nano-devices. Indeed, it was shown that two Au_{55} clusters could act as a tunnel resonance resistor.[8] The assembly of metal colloid monolayers was accomplished by the functionalization of glass or conductive glass supports with surface thiolate or surface amino groups, acting as a ligation monolayer for the association of the colloids.[3,4] Alternatively, functionalized capped-metal colloids were reacted with modified surfaces to yield the respective monolayers. Colloid arrays were deposited on solid supports using dithiolate crosslinkers[10] or thiol-tagged oligonucleotides.[11] The bridging units separating the dithiol or the double-stranded oligonucleotide units control the inter-particle distances and the resulting conductivity features of the colloid arrays. The optical and electronic properties of metal colloids can be tuned by the preparation of bimetallic particles. Specifically, gold/silver composites or alloys have received interest with respect to their optical and electronic features.[4–6] Layered and ordered colloidal Au/Ag composites have been studied to date only to the extent that Ag-clad Au layers are generated by the electrochemical deposition of Ag on Au nanoparticles.[12]

In the present study, we describe the novel assembly of ordered three-dimensional metal colloids composed of Au colloids, Ag colloids and composite Au and Ag colloids. The colloids are crosslinked by a redox-active molecular bridging unit. We find that the molecular redox-active unit is electroactive in the three-dimensional colloid array, implying that electron transport through the colloid particles is feasible. To our knowledge, we present for the first time a synthetic method to assemble mixed composites of Au and Ag in an ordered way.

Au colloids were prepared by citrate reduction of an $HAuCl_4$ solution to yield Au particles of 12 ± 2 nm size.[13] Ag colloids were similarly prepared by citrate reduction of $AgNO_3$ solution [in the presence of iron(II) sulfate] to generate particles exhibiting a diameter corresponding to 31 ± 2 nm.[14] Glass slides or indium tin oxide (ITO) conductive glass were functionalized with triethoxy aminopropylsilane to yield an amino-functionalized surface. Interaction of the functionalized surface with the Au or the Ag colloid for 1.5 h yields the primary metal colloid monolayer, Scheme 1. These monolayers were subsequently reacted with *N*,*N*′-bis(2-aminoethyl)-4,4′-bipyridinium **1**, as the crosslinking reagent of the colloid monolayers. Further interaction of the surfaces with the Au colloid or the Ag colloid yield the respective two-layer Au/Au, Ag/Ag or Au/Ag assemblies, Scheme 1. By the additional interaction of the layered colloid assemblies with the crosslinking unit **1** and the respective metal colloid, a controlled number of metal particles with the respective ordering of the metal colloid layers, could be deposited onto the glass supports. Fig. 1(A) shows the absorption spectra changes upon assembly of a four-layer assembly of Au colloids. The absorption band, λ_{max} = 522 nm, increases almost linearly upon increasing the number of colloid layers associated with the surface. At high surface coverages, an additional absorbance at *ca*. 640 nm is observed. This band was attributed to a collective interparticle clustered plasmon.[3] Similarly, Fig. 1(B) shows the absorbance changes upon the assembly of a four-layer structure of Ag colloids. The absorbance of the Ag colloid, λ_{max} = 430 nm, increases as the number of layers is increased. Fig. 1(C) shows the absorbance spectra of a composite monolayer composed of one Au and one Ag layer. The composite assembly consists of two absorbance



Scheme 1 Stepwise assembly of metal particle multilayer arrays

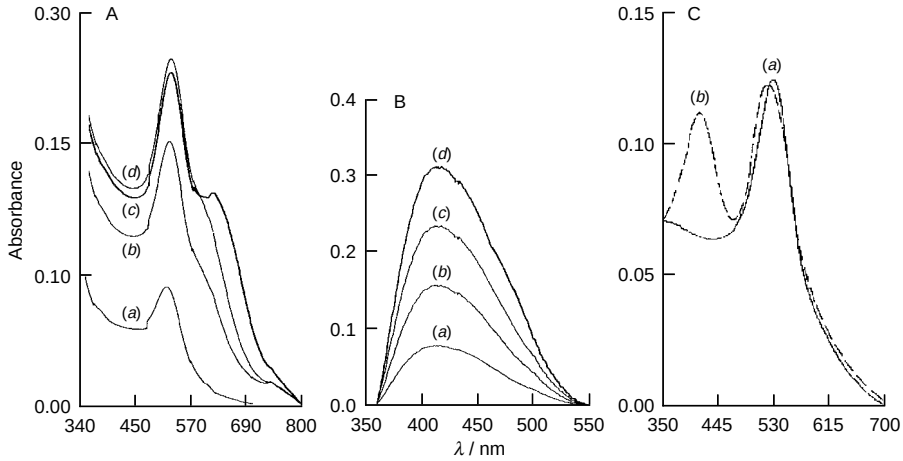


Fig. 1 (A) Absorbance spectra of an ITO glass upon the stepwise assembly of Au colloid (12 ± 2 nm, diameter layers); (*a*) 1, (*b*) 2, (*c*) 3, (*d*) 4 layers. (B) Absorbance spectra of an ITO glass upon the stepwise assembly of Ag colloid (31 ± 2 nm, diameter); (*a*) 1, (*b*) 2, (*c*) 3, (*d*) 4 layers. (C) Absorbance spectra of a composite Au/Ag metal colloid array; (*a*) one Au colloid layer assembled on an aminopropyl siloxane functionalized monolayer, (*b*) Ag colloid deposited onto the Au monolayer using **1** as crosslinker. All multilayers were assembled by functionalization of the respective colloid layer with the crosslinker **1** by the interaction of the colloid with a 50 mM solution of **1** for 0.5 h.

maxima at 520 and 430 nm, characteristic of the Au and Ag colloids, respectively.

Fig. 2 shows the cyclic voltammograms of the *N*,*N*′-bis(2-aminoethyl)-4,4′-bipyridinium redox-active crosslinking units upon the assembly of the four-layered Au colloid. The electrochemical response of the bipyridinium units is enhanced as the number of layers is increased. Coulometric analysis of the bipyridinium relay units associated with the first Au colloid layer, reveals a surface coverage of 7.3×10^{-11} mol cm^{-2} (geometrical area). As the surface coverage of Au colloids on glass was estimated by electromicroscopy measurements[4,5] to be *ca*. 1×10^{11} particles cm^{-2}, it suggests that *ca*. 450 bipyridinium bridging units are associated with each Au particle. Coulometric analysis indicates that the surface coverage of the bipyridinium units associated with the four-layer Au colloid assembly increases almost linearly upon the formation of the three-dimensional network (Fig. 2, inset).

In conclusion, we have demonstrated a novel method to assemble three-dimensional metal colloid networks consisting of Au, Ag or composite Au/Ag colloids and an amino-bifunctional redox-active briding unit as crosslinker. Electrostatic attraction between the crosslinker and the citrate-protected metal particles presumably leads to the assembly of the systems. The results demonstrate the formation of ordered composite layered assemblies of Au and Ag particles and reveal a means for the pre-planned structuring of composite multilayer assemblies. The electrochemical characterization of the bridged colloid assembly reveals that the redox-active molecular components are electrically contacted in the colloid lattice. This supports the suggestion that the Au particles act as nanoparticle conductive layers for electron transport through the network.

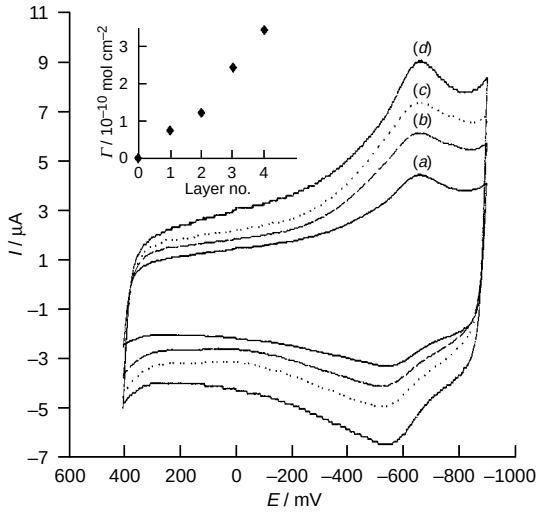

Fig. 2 Cyclic voltammograms of the Au-colloid layers functionalized by *N*,*N*′-bis(2-aminoethyl)-4,4′-bipyridinium **1**; (*a*) 1, (*b*) 2, (*c*) 3, (*d*) 4 layers. All measurements were recorded in phosphate buffer, pH = 7.0, scan rate 100 mV s^{-1}. Inset: Surface coverage of **1** *vs*. number of Au colloid layers.

Palladium-catalysed carbon–carbon bond formation in supercritical carbon dioxide

Michael A. Carroll and Andrew B. Holmes*†

Melville Laboratory for Polymer Synthesis, Department of Chemistry, University of Cambridge, Pembroke Street, Cambridge, CB2 3RA UK

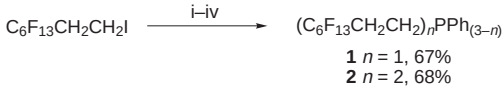
Novel fluorinated phosphine palladium complexes are prepared and employed in the first examples of palladium-catalysed carbon–carbon bond formation in supercritical carbon dioxide.

Supercritical carbon dioxide ($scCO_2$) has recently emerged as an environmentally benign substitute for volatile organic solvents.[1] Above the critical temperature (31.1 °C) and pressure (73.8 bar) carbon dioxide possesses hybrid properties of both a liquid and a gas. Control of the solvent density by variation of the temperature and pressure enables the solvent properties to be 'tuned' to substrates and reactants. These aspects have been used to advantage in polymer synthesis[2–4] and more recently in the preparation of 'small molecules'.[4,5] The particular attraction of $scCO_2$ must reside in the 'added value' as has been recognised in its application to heterogeneous catalytic processes and in asymmetric catalytic hydrogenation/hydroformylation.[6,7] In this respect synthetic transformations on small molecules could be coupled with the advantages of processing (separation/purification) technologies[8] to provide significant benefits over the use of conventional solvents.

We have chosen to study metal-catalysed bond forming reactions, but the majority of the commercially available metal-based catalysts, typically those bearing phosphine or amine ligands, are unsuitable for use in CO_2 owing to their low solubility.[9] Here we describe the synthesis of a range of fluorinated phosphines which enable various palladium-mediated reactions to be conducted in $scCO_2$.

Highly fluorinated compounds have been shown to have unusually high solubility in $scCO_2$, and their incorporation into phosphine-based ligands was expected to improve the solubility of the corresponding metal complexes. Such compounds can be prepared by adding the Grignard reagent $C_6F_{13}CH_2CH_2MgI$ to chlorophosphines to give a range of potential ligands for the solubilisation of palladium complexes in carbon dioxide (Scheme 1). Similar work has recently been reported regarding the preparation of these and other, similar ligands for applications in the 'fluorous' phase.[10] A simple but indirect means of purification of the required phosphines was achieved by temporary conversion to the corresponding oxide. Regeneration of the phosphine was achieved in excellent yield by treatment with Cl_3SiH and Et_3N.

The effect of the fluorinated phosphines **1** and **2** on the solubility of palladium complexes in $scCO_2$ was then examined, and the results are summarised in Table 1. It is evident that the solubility of the palladium complexes was dramatically improved. However, the degree of 'fluorination' required to confer solubility is dependent on the particular complex, those species having a higher degree of ionic character requiring an increased level of fluorination (Table 1, entries 4 and 7).‡



Scheme 1 *Reagents and conditions*: i, Mg, Et_2O, room temp., 12 h; ii, $Cl_nPPh_{(3-n)}$, Et_2O, room temp., 3 h; iii, $NaIO_4$, acetone, room temp., 12 h; iv, Et_3N, Cl_3SiH, toluene, 100 °C, 12 h

The soluble palladium complexes§ (Table 1, entries 5 and 8) were then used to catalyse three important carbon–carbon bond forming reactions, namely the Heck, Suzuki and Sonogashira couplings. The Heck reaction has emerged as one of the most versatile members of this group.[11] Table 2 (entry 1) illustrates that the reaction in $scCO_2$ with electron deficient alkenes occurs in a superior yield to that reported for conventional solvents; intramolecular processes are also possible (entry 2). The palladium-catalysed coupling of boronic acids with aryl or vinyl halides, the Suzuki reaction, has certain advantages for the coupling of two sp^2 centres.[12] This too can be conducted in $scCO_2$ (entries 3 and 4) in yields that are comparable to those achieved in conventional solvents. Finally, the Sonogashira coupling reaction[13] affords functionalised acetylenic compounds also in satisfactory yield.¶ The use of a more basic (secondary rather than tertiary) amine in palladium-mediated transformations typically leads to an improvement in yield. However, in $scCO_2$ very little difference is observed between the two. It is not yet clear whether this is due to carbamic acid formation.[14] Electron deficient amines, such as perfluorotrihexylamine, despite having improved solubility, exhibit a detrimental effect.

It is of note that the work-up procedures are significantly easier than those associated with standard reaction conditions. Typically the use of a polar solvent such as DMF and a water soluble base (carbonate or alkoxide) requires extraction of the product with an organic solvent according to conventional isolation techniques. By contrast, a simple pressure change in the $scCO_2$ reactor allows the gaseous/liquid reaction medium to be vented (possibly through a conventional solvent) thus eliminating liquid/liquid partition.

In summary, new fluorinated phosphine palladium complexes have been prepared and used as homogeneous catalysts in supercritical carbon dioxide. Important palladium-mediated carbon–carbon bond forming processes are now accessible and are expected to lead to considerable advances in synthetic methodology in due course.[15]

Table 1 Solubility of phosphine palladium complexes in $scCO_2$

Entry	Complex	L	Solubility
1	PdL_2Cl_2	PPh_3	Insoluble

‡ *Typical procedure* for determining solubility in supercritical carbon dioxide: $Pd(PPh_3)_2Cl_2$ (7 mg, 0.01 mmol) was placed in a 10 ml stainless steel cell. The cell was sealed and completely filled with liquid carbon dioxide (*ca.* 1000 psi). The cell was then heated to 70 °C and the state of the solid was monitored by viewing through a sapphire observation window. After 10 min at the final temperature the cell was allowed to cool. When the pressure had dropped below 2000 psi the cell was vented into CH_2Cl_2 (100 ml), the cell was opened once atmospheric pressure was reached and was washed out with a further quantity of CH_2Cl_2 (20 ml).

§The determination of the crystal structure of PdL_2Cl_2 (L = **2**) is currently under investigation.

¶ *Typical procedure* for the Sonogashira reaction using the catalyst PdL_2Cl_2 (L = **2**) in $scCO_2$: Bis[bis(1*H*, 1*H*, 2*H*, 2*H*-perfluorooctyl)-phenylphosphino]palladium dichloride‖ (89 mg, 0.05 mmol), copper(I) iodide (9 mg, 0.05 mmol), iodobenzene (0.11 ml, 1 mmol), phenylacetylene (0.11 ml, 1 mmol) and triethylamine (0.15 ml, 1.1 mmol) were placed in a 10 ml stainless steel cell. The cell was sealed and pressurised to approximately 1000 psi (full of carbon dioxide). The suspended reagents were magnetically stirred and afforded a dark red-coloured medium as the cell was heated to 60 °C. The reagents were stirred at this temperature for 64 h when a crystalline deposit formed on the sapphire window. The cell was then cooled, and when the pressure had dropped below 2000 psi the cell was vented into Et_2O (100 ml). The cell was opened once atmospheric pressure was reached and washed out with a quantity of CH_2Cl_2 (10 ml). The organic fractions were combined and concentrated *in vacuo* to give the crude product. The product was purified by flash column chromatography on silica gel, eluting with hexane to give diphenylacetylene as a white crystalline solid (110 mg, 0.62 mmol, 62%), mp 58–60 °C; δ_H(250 MHz; $CDCl_3$) 7.56–7.61 (4 H, m, *o*-Ph), 7.33–7.43 (6 H, m, *m/p*-Ph); δ_C 131.7 (*o*-C), 128.5 (*m*-Ph), 128.4 (*p*-Ph), 123.4 (quaternary Ph), 89.5 (alkyne). A similar procedure (excluding CuI) was used for the Suzuki reaction. The Heck procedure employed the *in situ* generated palladium acetate complex. All reactions showed similar colour and physical behaviour.

‖ All new compounds gave spectroscopic (NMR, IR, HRMS) data in accordance with their proposed structure.

Palladium-catalyzed carbon–carbon bond coupling reactions, the Heck and Stille reactions, proceed in supercritical carbon dioxide with a number of phosphine ligands including tris[3,5-bis(trifluoromethyl)phenyl]phosphine, which affords high conversions and selectivities.

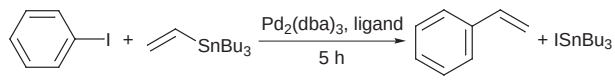
Elevated pressures[1] have been reported to offer benefits for homogeneous catalyst lifetime[2] and selectivity.[3] Such pressure-related advantages, in combination with the properties of supercritical carbon dioxide ($scCO_2$), led us to explore homogeneous catalytic reactions in this medium. A number of recent reports describe examples of homogeneous catalytic reactions in $scCO_2$ including hydrogenations,[4] hydroformylations,[5] epoxidations[6] and polymerizations.[7] We report the first demonstration that palladium-catalyzed carbon–carbon coupling reactions can be carried out in supercritical CO_2. We have examined catalyst activity, selectivity and ligand effects in $scCO_2$ in a first step toward capitalizing on the benefits of high pressures for homogeneous palladium-catalyzed reactions. The reactivity and selectivity of Heck[8] and Stille[9] reactions using several different phosphine ligands in $scCO_2$[10] were compared to those in organic solvents (THF and toluene).

All reactions in $scCO_2$ were carried out batchwise in magnetically stirred, custom built 316 stainless steel reactors with sapphire windows to allow viewing of the contents at high pressure.[11] Stille cross-coupling reactions of PhI and vinyl(tributyl)tin in CO_2 (345 bar) were run at 90 °C for 5 h using a number of different ligands (Table 1). The highest conversion in $scCO_2$ was achieved with the tris[3,5-bis(trifluoromethyl)phenyl]phosphine ligand **4** (> 99%) which was comparable to the results using tri-2-furylphosphine **3** (86%), a ligand noted for high palladium-coupling activity.[9c] PPh_3 **2** and tri-*o*-tolylphosphine **1** were characterized by significantly lower turnover numbers, with PPh_3 **2** resulting in conversions only slightly higher than the reaction in the absence of added ligand. We also ran the Stille coupling reaction of PhI with vinyl(tributyl)tin with the same ligands in CO_2 and THF at 50 °C and found that the conversions were considerably higher in THF. For example, in THF at 50 °C the tri-2-furylphosphine and tris[3,5-bis(trifluoromethyl)phenyl]phosphine ligands both resulted in conversions above 95% while slightly lower conversions (81%) were measured with PPh_3. The conversion in $scCO_2$ at 50 °C for the Stille reaction was only 28% after 5 h using the tri-2-furylphosphine ligand.

The much higher conversions in $scCO_2$ for tris[3,5-bis(trifluoromethyl)phenyl] phosphine appear to arise from the enhanced solubilization of the catalytically active palladium–phosphine complexes. A number of reports have demonstrated the ability of fluorine substitution on organic polymers and ligands to enhance solubility in $scCO_2$.[7a,7b,12,13] In particular, Leitner has recently reported catalytic activity in $scCO_2$ for rhodium catalysts containing perfluoroalkyl-substituted arylphosphines.[12] Although we have not carried out any quantitative solubility studies, we observed no visible precipitation for the Stille coupling reactions in CO_2 using the tris[3,5-bis(trifluoromethyl)phenyl]phosphine ligand. We did, however, observe significant precipitation in CO_2 (presumably palladium–phosphine complexes) under identical conditions with PPh_3. The perfluorinated ligand, tris(pentafluorophenyl)-phosphine, also conferred solubility indicated by no observed precipitation, although lower conversions (≤ 75%) were obtained.

In order to further probe these ligand effects, and to benchmark the chemical reactivity in CO_2 with organic solvents, we carried out preliminary kinetic studies of the Stille coupling of PhI and vinyl(tributyl)tin at 75 °C in $scCO_2$ and toluene. Reaction rates were determined as initial rates[14] using a high pressure reactor with a six-port sampling valve for CO_2, which has been described previously,[11] and standard Schlenk-ware for toluene. As shown in Table 2, the initial rate of reaction using tris[3,5-bis(trifluoromethyl)phenyl]phosphine **4** was twice that of PPh_3 **2** in both CO_2 and toluene. Moreover, the

Table 1 Stille cross-coupling of PhI with vinyl(tributyl)tin using $Pd_2(dba)_3$ in supercritical CO_2[a]



Ligand	Conversion (%)	Selectivity[c] (%)	TON[d]/h^{-1}
Tri-*o*-tolylphosphine **1**	9	99	0.5
No ligand	38	96	1.9
PPh_3 **2**	49	96	2.5
Tri-2-furylphosphine **3**	86	97	4.3
$P[3,5\text{-}(CF_3)_2C_6H_3]_3$ **4**	> 99	99	> 5

[a] 90 °C, 5 h, 345 bar CO_2, 2 equiv. of phosphine ligand for each equiv. of palladium(0) in all coupling reactions, [2.7 mmol (0.790 ml) vinyl(tributyl)tin, 2.7 mmol (0.3 ml) PhI, 0.054 mmol (0.048 g) $Pd_2(dba)_3$, 0.216 mmol phosphine ligand], reactions were quenched in acetone and analyzed by GC using known standards and confirmed by GC–MS and/or ^{1}H NMR spectroscopy. [b] Conversion = iodobenzene reacted (%). [c] Selectivity = styrene (%) with respect to all products formed. [d] TON/h^{-1} = [(moles of iodobenzene) × (% conversion)]/[(moles of catalyst added) × (hours of reaction)].

Table 2 Rates of Stille coupling reactions in supercritical CO_2 and toluene[a]

	k/min^{-1}	
Ligand	CO_2	Toluene
PPh_3 **2**	0.016	0.034
$P[3,5\text{-}(CF_3)_2C_6H_3]_3$ **4**	0.036	0.057

[a] 75 °C, 0.024 mmol (0.022 g) $Pd_2(dba)_3$, 2.4 mmol vinyl(tributyl)tin, 2.4 mmol PhI, 33 ml toluene or 33 ml CO_2 at 310 bar used. Initial rates measured by GC with internal standard (octafluoronaphthalene). Initial rates (30 min) were obtained from a ln [c/c_o] *vs.* time plot and are accurate to within 10%.

Table 3 Heck cross-coupling reaction in supercritical CO_2[a]

	R = CO_2Me			R = Ph		
L	Conversion (%)	Selectivity (%)	TON/h^{-1}	Conversion (%)	Selectivity (%)	TON/h^{-1}
Tri-*o*-tolylphosphine **1**	35	80	1	—	—	—
No ligand	17	82	0.5	37	99	1
PPh_3 **2**	—	—	—	20	99	0.6
Tri-2-furylphosphine **3**	96	78	2.7	—	—	—
$P[3,5\text{-}(CF_3)_2C_6H_3]_3$ **4**	94	91	2.6	99	99	2.8
$P(C_6F_5)_3$ **5**	—	—	—	99	99	2.8

[a] 90 °C, 24 h (R = CO_2Me), 12 h, 0.3 mmol ligand, 0.15 mmol (0.034 g) $Pd(OAc)_2$, 15 mmol (2.25 ml) Et_3N, 5 mmol (0.560 ml) PhI, 25 mmol (2.25 ml) methyl acrylate, octafluoronaphthalene internal standard. Reactions were analyzed as in Table 1.

observed rates in $scCO_2$ were within a factor of two of those observed in toluene for both phosphine ligands (Table 2). The initial rates of the PPh_3 **2** and tris[3,5-bis(trifluoromethyl)phenyl]phosphine **4** ligands are similar but the conversions are so different, suggesting that the enhanced solubility of the trifluoromethyl substituted system is probably more important than any increased activity through electronic effects. We found that the much less basic fluorinated ligand, tris(pentafluorophenyl)phosphine **5**, also enhanced solubility relative to PPh_3 **2** but the initial rate was two orders of magnitude less than the other ligands, presumably due to electronic effects.

We have also examined the palladium-catalyzed Heck coupling of PhI with simple olefins using several phosphines in $scCO_2$ at 90 °C. As Table 3 illustrates, we observe that the fluorinated phosphines result in high conversions for both styrene and methyl acrylate (> 94%), similar to the proven tri-2-furylphosphine ligand. The non-fluorinated triarylphosphines led to lower conversions (20–35%), which were comparable to reactions run in the absence of added ligand. Unlike the Stille couplings, the reaction solution for all the Heck couplings was dark and opaque and prevented even qualitative observation of precipitation; however, we believe the higher turnovers for the fluorinated phosphines probably arise from enhanced solubilization of the palladium complexes.

In summary, we have observed that both Heck and Stille couplings can proceed in supercritical CO_2 with rates and selectivites comparable to those in toluene. Of particular note, we find that fluorinated phosphines, particularly tris[3,5-bis(trifluoromethyl)phenyl]phosphine, result in high conversions due to the ability of these ligands to enhance the solubility of the metal complexes in $scCO_2$. 'CO_2-philic' ligands such as fluorinated phosphines should expand the utility of $scCO_2$ for homogeneous catalysis. Another logical extension of our work would be to explore supercritical fluids at pressures reported[2] to be high enough (> 1 kbar) to enhance some catalytic reactions.

This work was supported as part of the Los Alamos Catalysis Initiative by The Department of Energy through Laboratory Directed Research and Development (LDRD) funding, and a grant from the US EPA, Office of Pollution Prevention and Toxics (Grant Number 1877-97-1). We would like to acknowledge many helpful discussions with Dr Tom Baker and Dr Steve Buelow.

ortho-Vinylation reaction of anilines

Masahiko Yamaguchi,*[a]† Mieko Arisawa[a] and Masahiro Hirama[b]

[a] *Faculty of Pharmaceutical Sciences, Tohoku University, Aoba, Sendai 980-8578, Japan*
[b] *Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-8578, Japan*

_N_-Alkylanilines and anilines are vinylated at the *ortho*-position with ethyne in the presence of $SnCl_4$–Bu_3N.

Vinylanilines are versatile intermediates for the synthesis of heterocyclic compounds and functionalized polymers, and the elimination reaction of (aminophenyl)ethanol derivatives is the most common method used to prepare these compounds.[1] The Wittig reaction has also been used for the formation of aryl olefins.[2] The vinyl group can be introduced to haloanilines employing either the Heck reaction or the Stille coupling reaction.[3] Cleavage of heterocyclic compounds has also been examined.[4] In some cases, such sequences of reactions were conducted *via* vinylated nitroarenes.[5] All these methods, however, required stepwise transformations, and direct introduction of the vinyl group to the aniline nucleus was desired. In this context, the vinylation of cyclopalladated acetanilide reported by Horino is interesting, although the use of a stoichiometric amount of the palladium compound is inconvenient from a synthetic point of view.[6] Previously, we reported the direct *ortho*-vinylation of phenols with ethyne,[7] and the methodology is extended here to the direct *ortho*-vinylation of anilines (Scheme 1).

Scheme 1

Ethyne was bubbled into a chlorobenzene solution of *N*-methylaniline and $SnCl_4$–Bu_3N (4 equiv.) at −50 °C for 30 min. Then, the mixture was heated at 80 °C for 40 min, during which time ethyne was continuously introduced. The reaction was quenched by treating with 2 M KOH and THF at reflux for 1 h. After aqueous workup, the crude products were trifluoroacetylated with TFAA and Et_3N giving *N*-methyl-2′-vinyl trifluoroacetanilide in 77% yield. In contrast to the vinylation of phenol, the aniline reaction required the continuous introduction of ethyne during heating to obtain satisfactory results.

Several *para*- and *meta*-substituted *N*-methylanilines were treated with ethyne under the above conditions, and the results are summarized in Scheme 2. The vinylation was applicable to various substituted *N*-alkylanilines including halogen and methoxy derivatives. *N*-Benzyl- and *N*-butyl-aniline could also be vinylated. In the case of *meta*-substituted derivatives, the reaction took place at the less hindered site predominantly. It may be interesting to note that 3-fluoroaniline showed higher selectivity than the chloro derivative, and electronic effect also appeared to affect the selectivity. *ortho*-Substituted anilines such as 2-methyl-*N*-methylaniline did not give the expected product. This may be due to steric reasons, since *ortho*-substituted anilines lacking the nitrogen substituent gave the vinylated products (*vide infra*). Absence of the divinylated product in the reaction of *N*-methylanilines could be ascribed to the same reason.[8] The trifluoroacetyl group could readily be removed by treatment with KOH and MeOH at reflux for 10 min. The present methodology was also used to alkenylate *N*-methylanilines with aromatic and aliphatic alk-1-ynes.

The vinylation of anilines lacking the nitrogen substituent required modification of the workup procedures. *para*-Methylaniline was treated with ethyne at 80 °C for 2 h, and worked up in 2 M KOH and THF in the presence of excess ethylenediamine at reflux for 5–8 h to give a mixture of 2-vinylaniline,

2,6-divinylaniline and the starting material in yields of 46, 5 and 23%, respectively. The chelating reagent was required in the workup for the effective protonation of vinylstannane, which is an intermediate of the present vinylation reaction.[7,8] The protonation of the organotin compound appeared to be slower for vinylanilines than for *N*-methylvinylanilines and vinylphenols. The considerable amount of starting material recovered is not due to nitrogen protonation, since aniline hydrochloride could be converted to the vinylaniline. *N*-Vinylation was also excluded since reactions of alk-1-ynes with *para*-methylaniline gave no trace of the corresponding methyl ketones. When 4-methylaniline was treated with the $SnCl_4$–Bu_3N in C_6D_5Cl, at least two species were detected by ^1H NMR spectroscopy. Probably only a part of the stannylated aniline could participate in the vinylation. The secondary trifluoroacetamide moiety of these products hydrolyzed more slowly than the *N*-methyl derivatives, and harsh conditions were required: heating with KOH in MeOH–H_2O (96 : 4) for 35–48 h. Based on these experiments a method to convert anilines to *ortho*-vinylanilines was established which involved vinylation, trifluoroacetylation and deprotection (Scheme 3). The synthesis gave the vinylated products in moderate overall yields.

Vinylaniline derivatives are one of the most attractive precursors for the synthesis of indoles. While sulfonylated anilines are known to cyclize effectively,[9] the reaction of unprotected aniline is rare. Although Hegedus reported the palladium-catalyzed reaction of *ortho*-vinylaniline,[9] their applicability remained unexplored. When 2-vinyl-*N*-methylanilines prepared in the present study were treated with $PdCl_2(MeCN)_2$ at THF reflux for 18 h in the presence of quinone and LiCl, *N*-methylindoles were obtained in high yields (Scheme 4). A shorter reaction time of 10 h was employed for 2-vinylanilines to avoid decomposition. Thus, the applicability of the Hegedus method turned out to be broad.

Typical procedures are as follows. Ethyne was bubbled into a solution of Bu_3N (24.0 mmol, 5.76 ml), $SnCl_4$ (24.0 mmol, 2.76 ml) and *N*-methylaniline (6.0 mmol, 642.6 mg) in chlorobenzene (60 ml) at −50 °C for 1 h. The reaction mixture was heated at 80 °C for 1.5 h, during which bubbling was continued. 2 M KOH (240 ml) and THF (40 ml) were added, and the mixture was heated at reflux for another 1 h. On cooling the organic materials were extracted with Et_2O, washed with brine, dried over $MgSO_4$ and filtered. After removal of Et_2O under reduced pressure, Et_3N (8.4 ml) and TFAA (8.5 ml) were added to the resultant chlorobenzene solution, and the mixture was stirred at −10 °C for 12 h. An aqueous workup followed by flash chromatography (hexane–EtOAc, 30 : 1) over silica gel gave *N*-methyl-2′-vinyl trifluoroacetanilide (72%, 990 mg).

Pyrrole-embedded [60]fullerenes

Uwe Reuther and Andreas Hirsch†

Institut für Organische Chemie, Henkestraße 42, D-91054 Erlangen, Germany

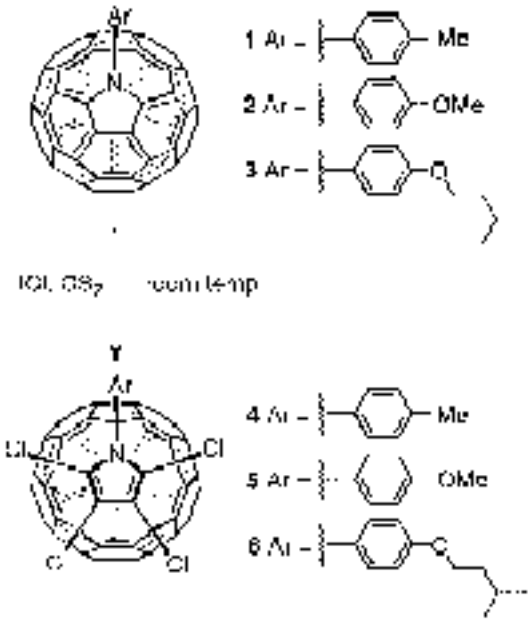
The treatment of the monoarylated azafullerenes $ArC_{59}N$ with iodine monochloride in carbon disulfide leads to the exclusive formation of the tetrachlorinated heterofullerenes $Cl_4ArC_{59}N$ which contain a pyrrole moiety in the fullerene cage.

Recently, we reported on the synthesis of arylated heterofullerenes $ArC_{59}N$.[1] These systems are suitable compounds for the investigation of the chemistry of azafullerenes, because they are stable and more soluble than the parent dimer $(C_{59}N)_2$.

Here, we report on the facile chlorination of azafullerenes $ArC_{59}N$ with ICl. The reaction of C_{60} with ICl was previously described by Birkett *et al.*[2] and leads to the quantitative formation of $C_{60}Cl_6$. This C_s symmetrical compound exhibits an addition pattern with five Cl atoms attached in 1,4 positions at the outer and one at the inner perimeter of a corannulene substructure, leaving a cyclopentadiene moiety within the fullerene framework. Consequently, the reaction with azafullerene derivatives $ArC_{59}N$ should yield the related tetrachlorinated species $Cl_4ArC_{59}N$ containing an integral pyrrole moiety decoupled from the conjugated π-system of the fullerene cage.

For the synthesis of the pyrrole-embedded fullerenes **4**–**6** a freshly prepared solution of 25 equiv. of ICl in CS_2 was added to a solution of 1 equiv. of the azafullerene derivatives **1**–**3** in CS_2 at room temperature (Scheme 1). This mixture was stirred for 10 min and then allowed to stand in the dark for three days for the decomposition of the excess ICl. Subsequently, the solvent and most of the iodine were removed *in vacuo*. After chromatography on silical gel (toluene) the chlorinated compounds **4**–**6** were isolated in 50–60% yield as orange powders (**6** had to be further purified by HPLC on a semipreparative Cosmosil column). The reaction can easily be monitored by HPLC using a Cosmosil column and toluene as eluent, since compounds **4**–**6** show a significantly longer retention time than the corresponding educts. Compounds **4** and **5** are only sparingly soluble in CS_2. This turned out to be a serious problem, as no ^{13}C NMR spectra of sufficient intensity could be obtained. Compound **6** however is soluble enough (about 3 mg ml^{-1} in CS_2) to obtain a well-resolved ^{13}C NMR spectrum corroborating the depicted structure.‡ The spectrum shows 26 resolved of the 28 expected signals for the sp^2 C-atoms of the fullerene cage between δ 160 and 128. The eight different carbon atoms of the isopentoxyphenyl moiety resonate at δ 22.54, 25.15, 37.93, 66.25, 115.19, 126.35, 128.78 and 159.95. Because of the long relaxation times of the sp^3 C-atoms of the fullerene cage their signals do not show up using a delay time of 6 s. To detect these signals longer pulse delay times, *e.g.* 16 s, are required.[3] In order to avoid very long measurements, we decided to use undeuterated 1,2-dichlorobenzene as solvent making use of the solvent heteronuclear NOE.[4] The two expected sp^3 signals appear at δ 57.31 and 58.42‡ In $C_{60}Cl_6$, the corresponding C-atoms resonate at δ 54.93 and 55.42.[2] The signal for Cl (Fig. 1) appears at δ 70.19. The ^1H NMR spectra of **4**–**6** resemble those of the educts **1**–**3**.‡ All signals show an upfield shift which is stronger for those hydrogens closer to the fullerene cage. The resonances are centred at δ 2.52, 7.42 and 8.06 for **4**, 3.91, 7.16 and 8.11 for **5** and 1.01, 1.73, 1.87, 4.05, 7.05 and 8.06 for **6**. The UV–VIS spectrum of **6** is very similar to that of $C_{60}Cl_6$,[2] with the λ_{max} values‡ located at 237, 283, 345, 394, 434, 475 and 518 nm. The FTIR spectrum of **6** displays intense bands‡ for the C–Cl vibrations at 846 and 817 cm^{-1}. The FTIR and UV–VIS spectra of **4** and **5** are basically identical to those of **6**.‡ In the mass spectra (FAB, MALDI-TOF, EI) of **4**–**6** no M^+ peak could be detected due to facile loss of the Cl addends.[5]

An AM1 calculation (SPARTAN 4.0) on **4** (Fig. 1) reveals a geometry of the integral pyrrole moiety which is very similar to



Scheme 1

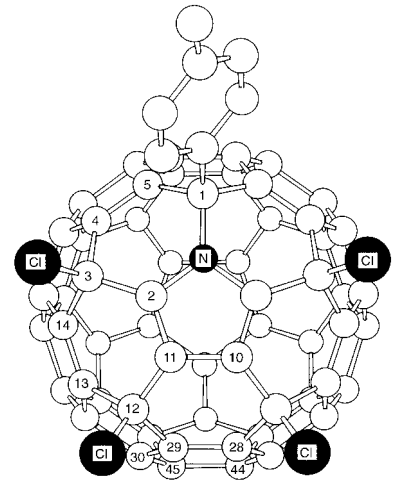


Fig. 1 AMl calculated structure of **4**. Selected bond lengths (pm): N–C2 140.8, C2–C11 140.7, C10–C11 143.4, C1–N 148.0, C2–C3 149.8, C11–C12 148.4, C1–C5 155.1, C4–C5 136.7, C3–C4 152.9, C3–C14 153.9, C13–C14 136.9, C12–C13 153.5, C12–C29 153.7, C28–C29 137.0, C29–C30 145.0, C30–C45 138.8, C44–C45 145.4.

the parent pyrrole. For example, the bond distances between C2–N, C2–C11 and C10–C11 are 140.8, 140.7 and 143.4 pm. Those of the parent compound are 139.2, 140.2 and 142.5 pm (AM1) or 137.0, 138.2 and 141.7 pm (exp.).[6] The pyrrole moiety is not completely planar; the dihedral angle between N–C2–C11–C10 is about 4°. The cage-centred HOMO of **4** has its coefficients exclusively on the [6,6]-bonds forming the equatorial belt of **4**, *e.g.* between C30 and C45. The shortest remaining double bonds are those located at the outer perimeter of the corannulene subunit. For example, the bond length between C4 and C5 is 136.7 pm. The highest Mulliken charges are also found at these C-atoms, whereas the charges at the C-atoms of the southern hemisphere are zero. These factors could be relevant for the regioselectivity of further addition reactions to systems like **4**–**6**.

The chlorine addends can be easily removed from the cage by treatment of **4**–**6** in 1,2-dichlorobenzene with an excess of PPh_3 at room temperature. The parent compounds **1**–**3** were obtained in good yield.[5,7]

Investigations on the chemistry of fulleropyrroles like **4**–**6**, and especially on their use as potential precursors for $C_{58}N_2$ derivatives formed by an azide addition/dechlorination sequence, are currently underway.

We thank the Deutsche Forschungsgemeinschaft (DFG) for financial support.
