Fig. 2 Molecular structure of the cation of complex **IV**. Selected bond distances (Å) and angles (°): Ni1–O3 2.061(2), Ni2–O3 2.087(2), Ni1–O5 2.121(2), Ni2–O5 2.096(2) Ni1–O4 2.065(2), Ni2–O6 2.062(2), Ni1–Ni2 3.032(1), O4–Ni1–O3 80.27(6), O4–Ni1–O5 97.90(6), O5–Ni1–O3 84.62(6), O5–Ni2–O3 84.62(6).

In contrast to the above reaction of $gluH_2A_2$ with the hydrolase model **B**, reaction with the urease model **A** gives the tetrameric nickel hydroxamate complex **IV**§ $[Ni_4(OAc)_2(gluA_2)_2(tmen)_4][OTf]_2$ (Fig. 2) with accompanying loss of urea. The tetramer contains two sets of nickels atoms Ni1 and Ni2 and their symmetry equivalents, each set bridged by one hydroxamate group of one ligand and one hydroxamate group of the other ligand. As in the corresponding dibridged monohydroxamate (**II** in ref. 5), the deprotonated OH groups O3 and O5 bridge the two nickel centres Ni1 and Ni2, while the carbonyl oxygens O4 and O6 each coordinate to their respective nickel centres Ni1 and Ni2. The bond angles and distances in the dinickel hydroxamate bridges in **IV** and in **II** (ref. 5) are very similar. The structure is duplicated in the other part of the tetramer through the centre of inversion (Fig. 2) with opposite nickel centres, Ni1 and Ni2 being 9.742(1) Å apart. In **I** the Ni–O(bridging) distances Ni2–O6 and Ni1–O6 of 2.040(3) and 2.059(2) Å, respectively, are slightly shorter than the hydroxamate bridging Ni–O distances Ni1–O3 and Ni2–O3 of 2.061(2) and 2.087(2) Å respectively, in the tetramer **IV** (Fig. 2) which may be a factor promoting cyclisation in **I**.

Replacement of bridging water and carboxylates by the deprotonated OH group of the hydroxamic acid is probably part of the driving force of these facile reactions since the resulting bridging oxygen is a feature of all of the complexes which we have studied so far as well as in the dinickel complex containing two salicylhydroxamate bridges.[9] This structural feature also occurs in biological systems such as the acetohydroxamate complex with the C319A variant of urease[6] and the *p*-iodo-D-phenylalanine hydroxamate complex with *Aeromonas proteolytica* aminopeptidase(AAP).[10]

Finally, the displacement of coordinated urea from **A** by $gluH_2A_2$ but not by AHA suggests that inhibition of urease by dihydroxamic acids may also involve displacement of the urea substrate as well as the water molecules (which act as a base source) which is probably the mode of their inhibition by acetohydroxamic acid.

We thank Professor K. Nolan, Royal College of Surgeons in Ireland, for helpful discussions and the EUCOST D8 programme, Project D8/0010/97 for support.

‡ Satisfactory microanalyses were obtained for compounds **I**–**IV**. *Preparations* of **I**–**III**: to a solution of **B** (1 mM) in CH_2Cl_2 under nitrogen was added 1 mM of triflate (OTf) (or tetrafluoroborate BF_4^-) and stirred for 1 h followed by 1 mM of $gluH_2A_2$ in methanol. The reaction was monitored by the appearance of IR peaks at 1710, 1750 and 1590 cm^{-1} due to acetic acid and co-ordinated hydroxamate respectively. After work-up, a solution in CH_2Cl_2 was layered with diethyl ether, pentane and 2,2-dimethoxypropane to give blue–green crystals of **I** suitable for X-ray crystallography, **II** and **III** were prepared similarly.

Preparation of **IV**: as for **I**–**III** above but replacing **B** by the urea complex **A** and omitting the addition of triflate ion. Suitable crystals were obtained in this case by vapour diffusion of diethyl ether into a solution of **IV** in methanol/CH_2Cl_2 (1 : 2).

Crystallography: Crystal data: for **I**: $C_{22}H_{44}F_3N_5Ni_2O_{10}S$, M = 745.10, triclinic, space group $P\bar{1}$, a = 10.7655(9), b = 15.7266(13), c = 20.8115(18) Å, α = 73.612(3)°, β = 84.827(3) °, γ = 81.397(3) ° U = 3338.0(5) Å^3 , Z = 4 , λ = 0.71073 Å, μ = 1.262 mm^{-1}. 11303 independent reflections were measured. Final $R1$ = 0.0435 and $wR2$ = 0.1158.

For **IV**: $C_{20}H_{45}F_3N_6Ni_2O_{10}S$, M = 736.10, monoclinic, space group $P2_1/c$, a = 12.4205(7), b = 12.6790(7), c = 20.8914(12) Å, β = 107.1940(10)°, U = 3142.9(3) Å^3 Z = 4 , λ = 0.71073 Å, μ = 1.340 mm^{-1}, 7412 independent reflections were measured. Final $R1$ = 0.0355 and $wR2$ = 0.0867.

Data were collected using a Siemens SMART CCD area-detector diffractometer. Refinement was by full-matrix least squares on F^2 for all data using SHELXL-97.[11] Hydrogen atoms were added at calculated positions and refined using a riding model.

§ Abbreviations: OTf = $CF_3SO_3^-$, OAc = $CH_3CO_2^-$, AHA = acetohydroxamic acid, AA = deprotonated acetohydroxamic acid, $gluH_2A_2$ = glutarodihydroxamic acid, $gluA_2$ = deprotonated glutarodihydroxamic acid.

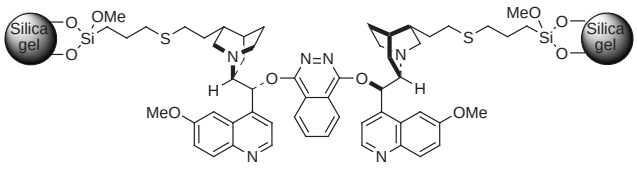
Received (in Cambridge, UK) 7th September 1998, Accepted 5th October 1998

Excellent enantioselectivities of up to > 99% ee have been achieved in the heterogeneous asymmetric aminohydroxylation of *trans*-cinnamate derivatives using silica gel-supported $(QN)_2PHAL$ [SGS-$(QN)_2PHAL$ **1]; the dark brown **1**·Os complex, recovered by simple filtration after reaction, could be reused without any loss of enantioselectivity.**

Highly efficient methods for osmium-catalyzed asymmetric aminohydroxylation (AA) of alkenes in the presence of $(DHQ)_2PHAL$ or $(DHQD)_2PHAL$ ligands have been discovered recently by Sharpless and co-workers.[1] Initially, the catalytic AA reaction exploited TsNClNa (Chloramine-T) as the oxidant/nitrogen source.[1a,b] Subsequently, with the development of new procedures which utilize carbamates-[1d] and amide-derived oxidants,[1e] the substrate scope and selectivity has been greatly improved. The resulting chiral β-amino alcohol group is an important structural element in many biologically active molecules as well as the starting point in the design of many chiral ligands.

Recently, we prepared silica gel-supported $(QN)_2PHAL$ [SGS-$(QN)_2PHAL$ **1**],[2] which with OsO_4 yielded excellent



enantioselectivities in asymmetric dihydroxylation of alkenes (> 99% ee for *trans*-stilbene). Moreover the catalytic system, the SGS-$(QN)_2PHAL$ **1**–osmium complex, could be reused after simple filtration without any significant loss of enantioselectivity. UV analysis of the filtrate of the simple mixture of ligand **1** and OsO_4 in $Bu^tOH–H_2O$ (1:1) in several molar ratios (1:1, 2:1, 4:1 *etc*.) showed that the binding affinity of **1** to OsO_4 is much greater than that of the homogeneous analogue $(DHQ)_2PHAL$. No trace amounts of osmium could be found in all filtrates examined. These results encouraged us to examine the efficiency of **1** in the heterogeneous AA reactions. We report here our preliminary findings.

The heterogeneous AA reactions of *trans*-cinnamate derivatives using **1** were carried out either with $EtOCONH_2/Bu^tOCl/NaOH$[1d] or AcNHBr/LiOH[1e] as the oxidant/nitrogen source under the same reaction conditions adopted for the analogous homogeneous process (Scheme 1). The results are summarized in Table 1. The data show that all reactions examined using **1** exhibited excellent enantioselectivities. Generally, the amide-based AA reactions (Table 1, entries 4 and 6) gave higher yields and ees (> 99% ee) than those employing the carbamate-based chemistry (entries 1–3). In particular, the AA reactions at 4 °C with amide as oxidant gave similar chemical yields (71–76%) and ees (> 99% ee) to those obtained in homogeneous AA reactions.[1e] It is noteworthy that when these reactions were carried out at room temperature, the chemical yields were significantly decreased (*ca*. 30–40% yield), whereas the ees were maintained. The reactions always stopped after *ca*. 50% conversion, and the pH of the mixture at the end of the reactions was about 5–6. It is probable that Hoffmann rearrangement[3] of the *N*-bromoacetamide is a significant concurrent reaction at this temperature.

4	**2d**	AcNBrLi	$Bu^tOH–H_2O$	7	71	> 99	2*R*,3*S*
5[d]	**2d**	AcNBrLi	$Bu^tOH–H_2O$	7	30	> 99	2*R*,3*S*
6	**2e**	AcNBrLi	$Bu^tOH–H_2O$	9	76	> 99	2*R*,3*S*
7[d]	**2e**	AcNBrLi	$Bu^tOH–H_2O$	9	32	> 99	2*R*,3*S*
8[e]	**2e**	AcNBrLi	$Bu^tOH–H_2O$	7	81	> 99	2*R*,3*S*

[a] In all cases 4 mol% $K_2OsO_2(OH)_4$ and 5 mol% ligand were used. The reactions in entries 1–3 were carried out at 10 °C under the same reaction conditions as those reported in ref. 1(*d*). The reactions in entries 4–7 were carried out at 4 °C under the same reaction conditions as those reported in ref. 1(*e*). [b] Isolated yields by column chromatography. [c] The ees and absolute configuration were determined by chiral HPLC analysis.† [d] Reaction was carried out with **1**·Os complex recovered from the reaction in entries 4 and 6 respectively without further addition of $K_2OsO_2(OH)_4$. [e] Reaction was carried out with **1**·Os complex recovered from the reaction in entry 6 with the addition of small amounts of $K_2OsO_2(OH)_4$ (2 mol%).

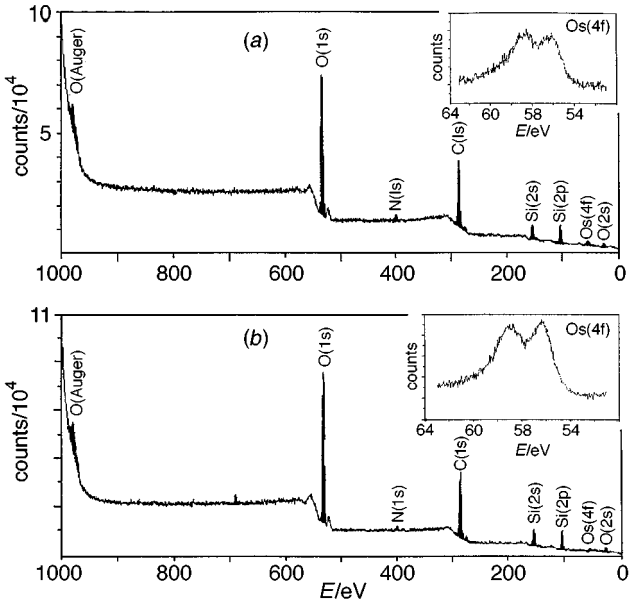

Fig. 1 XPS-spectra of the **1**-Os complex recovered after reaction, entry 4 (a) and entry 6 (b).

The efficiency with which the catalyst can be recycled has also been examined. The dark brown-coloured **1**·Os complex was recovered by simple filtration after each reaction (entries 4 and 6), which is not possible in a homogeneous process. XPS (X-Ray Photoelectron Spectroscopy)-analysis (Fig. 1) of the samples shows clearly that these recovered complexes contain osmium. However, the recovery yields were not high enough ($< 50\%$). The rest of the osmium was obviously lost to the mother liquor. The AA reactions were repeated with these samples without further addition of osmate salt. As shown in entries 5 and 7, the required amino alcohols **3d**,**e** were obtained in 30 and 32% yield with $> 99\%$ ee, respectively. Moreover, the addition of small amounts of osmium to the recovered catalyst regenerated completely the reaction conditions (entry 8). These results indicate the viability of the repetitive use of osmium and the chiral ligand, which is a current intrinsic limitation of catalytic AA and AD reactions.

In conclusion, we have achieved excellent ees for the heterogeneous catalytic AA of alkenes using a silica gel-supported bis-cinchona alkaloid **1**. Moreover, the recovered dark brown-coloured **1**·Os complex can be reused without any loss of enantioselectivity. We have also determined the Os content of this complex by XPS analysis. Further studies are currently in progress to increase the product yield, and the recovery of both the chiral ligand and the osmium.

This research was supported by a grant (MOST 2N17410) from the Ministry of Science and Technology in Korea.

Alkenyl *O*- and *C*-glycopyranoside homodimerization by olefin metathesis reaction

Romyr Dominique, Sanjoy K. Das and René Roy*

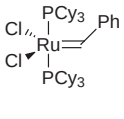
Department of Chemistry, University of Ottawa, Ottawa, K1N 6N5, Canada, Ontario.
E-mail: rroy@science.uottawa.ca

Received (in Cambridge, UK) 28th July 1998, Accepted 5th October 1998

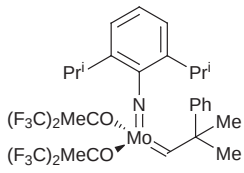
Using ruthenium-catalyzed olefin metathesis, several *O*- and *C*-allyl and *O*-pentenyl D-galactopyranoside and lactoside homodimers were prepared in high yields.

Multivalent neoglycoconjugates have been exhaustively utilized to probe and enhance carbohydrate–protein interactions at the molecular level.[1] Moreover, glycoclusters[2] and dendrimers[3] are also emerging as potential carbohydrate-based therapeutic agents.[4] Several examples exist in which ligand-induced receptor and protein dimerization occurred as a general mechanism for signal transduction.[5] It is conceivable that signal transduction and receptor shedding could also be triggered by carbohydrate oligomers.[6]

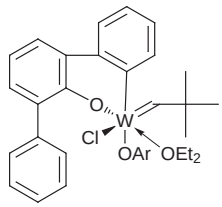
Transition metal catalyzed olefin metathesis has gained an important position in organic syntheses in recent years.[7–10]



1



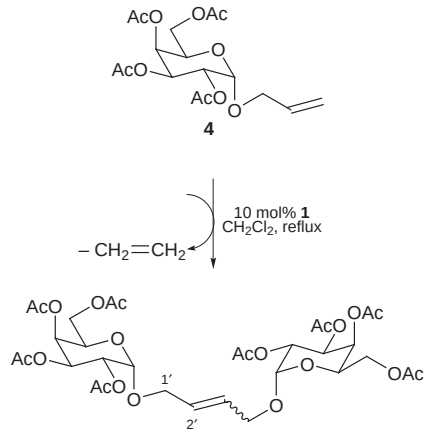
2



3

Ruthenium carbene complex **1** developed by Grubbs and coworkers[7] and Schrock's molybdenum catalyst **2**[8] are very useful in this respect. Because of its unique properties, high reactivity, stability to air, and remarkable functional group tolerance, benzylidenebis(tricyclohexylphosphine)dichlororuthenium **1** has been chosen as the catalyst of the year. Ruthenium and molybdenum carbenoids have been scarcely used in carbohydrate chemistry.[9] It seemed appealing to apply the olefin metathesis reaction toward the synthesis of carbohydrate homodimers. The only example of carbohydrate homodimerization was reported by Descotes *et al.*[10] in his sugar bolaform syntheses using a tungsten aryloxo complex such as **3**. However, the tungsten-catalyzed alkenyl glycoside homodimerizations were unsuccessful with *O*-allyl glycosides as well as benzyl-protected sugar derivatives. Herein, we report the efficient and high yielding synthesis of some biologically important carbohydrate homodimers starting from either peracetylated or perbenzylated *O*- and *C*-allyl as well as *O*-pentenyl galactopyranosides using ruthenium benzylidene complex **1** (Scheme 1).

Treatment of allyl 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside **4** with 10 mol% of Grubbs' catalyst **1** in refluxing CH_2Cl_2 under a nitrogen atmosphere resulted in the clean formation of homodimer **5** in 92% yield as a mixture of *E* and *Z* stereoisomers in 5:1 molar ratio (Scheme 1).† The only other by-products isolated from these sequential [2+2] cycloaddition and cycloreversion equilibria were the recovered starting material (3%) along with trace amount of cross-metathesis product obtained from the initially released styrene. In order to compare the catalytic activity of Grubbs' catalyst **1** to that of Schrock's catalyst **2**, we repeated the reaction between **4** and 10



Scheme 1

mol% of **2** in CH_2Cl_2. The reaction, performed under Schlenk conditions, provided the same dimer **5** in 80% yield. Since in both cases the yields were more or less the same, catalyst **1** was preferred because of its operational simplicity.

The ratio of the inseparable *E* and *Z* isomers was determined from analysis of the ^{1}H NMR spectrum of the crude mixture. It is generally accepted that the carbon α to a double bond is more shielded in the *Z* isomer than in the *E* isomer due to the γ effect.[11] So, the empirical relationship $\delta_{\alpha(Z)} < \delta_{\alpha(E)}$ allowed us to determine the relative configuration of the *E* and *Z* stereoisomers. For instance, the ^{13}C NMR spectrum of **5** showed the α carbon of the *Z* isomer at δ 63.5, whereas that of the *E* isomer appeared at δ 67.4 ($\Delta\delta$ 3.9 ppm).

Similarly, olefin metathesis of the corresponding peracetylated β-anomer **6** with 10 mol% of catalyst **1** under the same reaction conditions provided homodimer **7** in 95% yield as a mixture of *E* and *Z* isomers in a 4:1 ratio (Table 1).‡ To further explore the scope of this reaction, *O*-pentenyl β-D-galactopyranoside **8**, allyl β-lactoside **9**, α-*C*-allyl galactopyranoside **10**[12] and β-*C*-allyl galactopyranoside **11**[13] were prepared and reacted with Grubbs' catalyst under the same reaction conditions to give compounds **12–15** respectively. The reactions proceeded successfully with high yields and the results are summarized in Table 1. Then we turned our attention to the synthetically more useful benzyl protected sugars, using allyl 2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranoside **16**. Treatment of **16** with **1** also proceeded smoothly to provide **17** in 76% yield.

In conclusion, Grubbs's ruthenium benzylidene catalyzed olefin metathesis reaction was applied toward the synthesis of polyfunctionalized carbohydrate homodimers for the preparation of potential cross-linkers of biological interest in signal transduction. The reaction is general, high yielding, and compatible with the usual carbohydrate protecting groups. Further work is now in progress to explore the scope of the reaction.

We are thankful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support.

Rhodium-catalysed direct *ortho* arylation of 2-arylpyridines with arylstannanes *via* C–H activation

Shuichi Oi,* Susumu Fukita and Yoshio Inoue

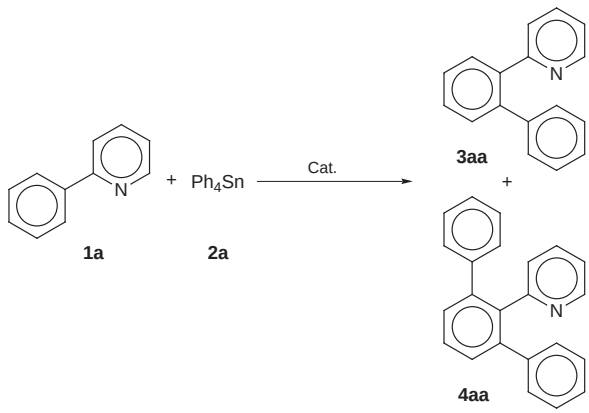
Department of Materials Chemistry, Graduate School of Engineering, Tohoku University, Sendai 980-8579, Japan. E-mail: oishu@aporg.che.tohoku.ac.jp

Received (in Cambridge, UK) 1st September 1998, Accepted 2nd October 1998

The *ortho* position of the aromatic ring of pyridyl group-substituted aromatic compounds was directly arylated with tetraarylstannanes in the presence of a catalytic amount of a rhodium(I)–phosphine complex.

Transition metal-catalysed cross-coupling reactions of aromatic compounds with arylated typical metal compounds such as Mg, Zn, B, Si and Sn are useful synthetic routes to biaryl compounds.[1] A variety of aromatic compounds such as ArI (Cl, Br), ArOTf, ArOMs, $ArOP(O)(OR)_2$, ArOR, ArSR and ArN_2BF_4 have been used for the cross-coupling reactions with typical arylated metal compounds. These reactions involve C–X bond cleavage [X = halide, OTf, OMs, $OP(O)(OR)_2$, OR, SR and N_2BF_4] *via* the oxidative addition of a low valent transition metal (M) complexes and subsequent transmetalation between the resultant C–M–X species and arylated metal compounds. There has, however, been no report of the cross-coupling reaction between the aromatic C–H bond and organometal compounds. In 1993, Murai *et al*. reported ruthenium-catalysed *ortho* alkylation of acetophenones with terminal alkenes, which represented the first effective catalytic C–C bond formation involving the cleavage of an aryl C–H bond.[2] It is thought that chelation of the acetyl group of acetophenone directs the ruthenium complex to cleave the *ortho* C–H bond. The pyridyl group has also been known to direct transition metal-catalysed C–H bond cleavage of an aromatic ring as in the rhodium-catalysed *ortho* alkylation of pyridylbenzenes with terminal alkenes[3] and ruthenium-catalysed carbonylation with CO and terminal alkenes.[4] We report herein our finding that the *ortho* position of pyridylbenzenes is directly arylated with tetra-arylstannanes in the presence of a catalytic amount of a rhodium(I)–phosphine complex.

Initial work was centered on the reaction of 2-phenylpyridine **1a** with tetraphenylstannane **2a** in the presence of a catalytic amount of various transition metal complexes (Scheme 1). The results are summarized in Table 1. The $[RhCl(C_8H_{14})_2]_2$–PPh_3 catalytic system produced singly phenylated product **3aa** in 24% yield (entry 1). Other phosphine ligands such as PCy_3, $P(OPh)_3$ and dppe were less effective, giving **3aa** in lower yields (entries 2–4). The highest yield was obtained using



Scheme 1

Table 1 Reaction of **1a** with **2a** in the presence of a catalytic amount of various transition metal complexes[a]

Entry	Catalyst	Yield (%)[b]
1	$[RhCl(C_8H_{14})_2]_2 + 4PPh_3$	24
2	$[RhCl(C_8H_{14})_2]_2 + 4PCy_3$	10
3	$[RhCl(C_8H_{14})_2]_2 + 4P(OPh)_3$	6
4	$[RhCl(C_8H_{14})_2]_2$ + 2dppe	7
5	$RhCl(PPh_3)_3$	29
6	$RhCl(CO)(PPh_3)_2$	5
7	$Pd_2(dba)_3{\cdot}CHCl_3 + 4PPh_3$	0
8	$Pt_2(dba)_3{\cdot}CHCl_3 + 4PPh_3$	0
9	$[IrCl(cod)]_2 + 4PPh_3$	0
10	$Ru_3(CO)_{12} + 6PPh_3$	0

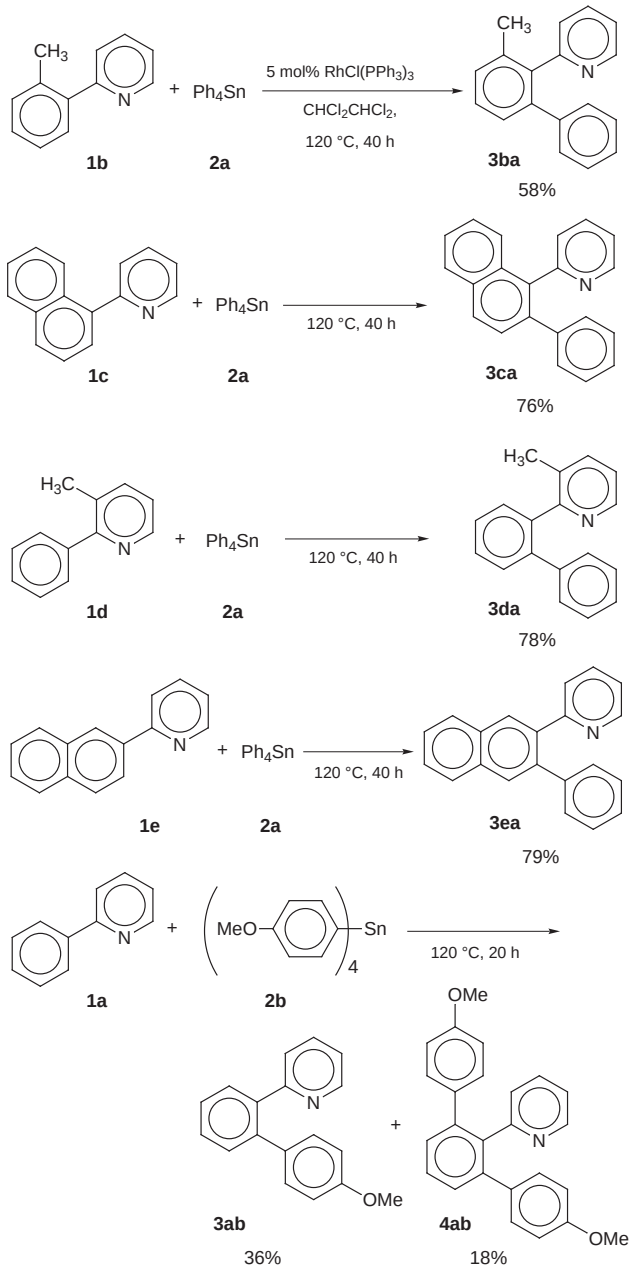
[a] A mixture of **1a** (0.5 mmol), **2a** (0.75 mmol) and metal complexes (10 mol% of **1a**, based on metal) in THF (1.5 ml) was stirred in a sealed vial under N_2 at 120 °C for 20 h. Product was **3aa**. [b] Determined by GLC.

$RhCl(PPh_3)_3$, affording **3aa** in 29% yield (entry 5), while the use of $RhCl(CO)(PPh_3)_2$ gave **3aa** in only 5% yield (entry 6). In these cases, only a trace amount of doubly phenylated product **4aa** was observed. Other low valent transition metal complexes of Pd, Pt, Ir and Ru did not show any catalytic activity (entries 7–10). The reaction of **1a** with **2a** was then carried out in various solvents in the presence of 5 mol% of $RhCl(PPh_3)_3$. The results are summarized in Table 2. The reactions in toluene, THF and MeCN afforded the product **3aa** in low yields of 14, 16 and 12%, respectively, together with a trace amount of **4aa** (entries 1–3). The yield of the products slightly increased using chlorinated alkanes such as $CHCl_3$, 1,2-dichloroethane and 1,1,1-trichloroethane as solvent, affording **3aa** in 32, 37 and 27%, respectively. Surprisingly, 1,1,2,2-tetrachloroethane exhibited a dramatic effect, giving **3aa** and **4aa** in good yields of 65 and 20%, respectively. In this case, trichloroethylene originating from the solvent *via* dehydrochlorination was detected by GLC after the reaction. In order to study the effects of this olefin on the reaction, a small amount (0.25 mmol) of trichloroethylene was added to the reaction of **1a** and **2a** using THF as solvent. This experiment afforded **3aa** and **4aa** in improved yields of 42 and 3%, respectively, compared to the

Table 2 Reaction of **1a** with **2a** in the presence of a catalytic amount of $RhCl(PPh_3)_3$ in various solvents[a]

		Yield (%)[b]	
Entry	Solvent	**3aa**	**4aa**
1	Toluene	14	0
2	THF	16	1
3	MeCN	12	0
4	$CHCl_3$	32	2
5	$ClCH_2CH_2Cl$	37	1
6	$MeCCl_3$	27	1
7	$Cl_2CHCHCl_2$	65 (56)	20 (20)

[a] A mixture of **1a** (0.5 mmol), **2a** (0.5 mmol) and $RhCl(PPh_3)_3$ (5 mol%) in solvent (1.5 ml) was stirred in a sealed vial under N_2 at 120 °C for 20 h. [b] Determined by GLC. Yields in parentheses are for isolated compounds.



Scheme 2

original yields of 16 and 1% (see Table2, entry 2). Thus the trichloroethylene generated *in situ* during the reaction may partly be responsible for the remarkable effect of 1,1,2,2-tetrachloroethane.

Results for the reactions of other pyridyl-substituted aromatic compounds **1** with arylstannanes **2** in the presence of 5 mol% of $RhCl(PPh_3)_3$ in 1,1,2,2-tetrachloroethane are shown in Scheme 2.†‡ The reactions of **2a** with 2-(2-methylphenyl)pyridine **1b** and 2-(1-naphthyl)pyridine **1c** having only one *ortho* C–H bond on the aromatic ring gave singly phenylated products **3ba** and **3ca**. in good yields. 3-Methyl-2-phenylpyridine **1d** containing two possible reactive *ortho* C–H bonds gave singly phenylated product **3da** in 78% yield selectively. As was described in ref. 3 and 4, the steric interaction between the phenyl group and the methyl group in **3da** prevented the second phenylation. 2-(2-Naphthyl)pyridine **1e** was also phenylated only at the 3-position of the naphthalene ring, affording singly phenylated product **3ea** in 79% yield selectively. In this case, the steric hindrance of the 8-position of the naphthalene ring would prevent phenylation at the 1-position. Tetra(*p*-methoxyphenyl)-stannane **2b** reacted with **1a** affording **3ab** and **4ab** in 36 and 18% yield, respectively.

Although the mechanism of the present reaction is not yet clear, a reaction pathway involving the N atom-directed oxidative addition of the low valent rhodium complex to the *ortho* C–H bond of the phenyl ring followed by phenylation with tetraphenylstannane may be possible.

The reaction reported herein represents the first example of the cross-coupling reaction between aromatic C–H bonds and organometal compounds, and provides a new method for direct arylation of the *ortho* position of pyridyl-substituted aromatic compounds. Further work is now in progress to determine the full scope of this reaction.

Notes and references

† The structures of the compounds **3aa**, **3ba**, **3ca**, **3da**, **3ea**, **3ab**, **4aa** and **4ab** were in a complete accord with the obtained IR, MS, ^1H and ^{13}C NMR and elemental analysis data. The assignment of signals in ^1H and ^{13}C NMR spectra was confirmed by ^1H–^1H COSY and ^1H–^{13}C HMQC spectra.

‡ Typical experimental procedure: A mixture of **1a** (74.2 mg, 0.478 mmol), **2a** (213.5 mg, 0.500 mmol) and $RhCl(PPh_3)_3$ (23.1 mg, 0.025 mmol) in 1,1,2,2-tetrachloroethane (1.5 ml) was stirred in a sealed vial under N_2 at 120 °C for 20 h. The reaction mixture was taken up in $CHCl_3$ and washed with diluted aqueous ammonia and water. After the $CHCl_3$ layer was dried over K_2CO_3, the solvent was evaporated, and then the residue was purified by medium-pressure preparative liquid chromatography (Yamazen Corp., Ultra Pack column, silica gel, 40 μm, 60 Å, 26 × 300 mm) eluting with 3% acetone in $CHCl_3$ to give **3aa** (62.5 mg, 56%) and **4aa** (28.8 mg, 20%). Yields shown in Scheme 2 are for isolated compounds.

Enantioselective Claisen rearrangement of difluorovinyl allyl ethers

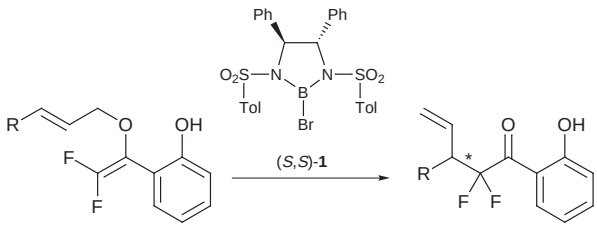
Hisanaka Ito, Azusa Sato, Tetsuo Kobayashi and Takeo Taguchi*

Tokyo University of Pharmacy and Life Science, Horinouchi, Hachioji, Tokyo 192-0392, Japan.
E-mail: taguchi@ps.toyaku.ac.jp

Received (in Cambridge, UK) 29th May 1998, Revised manuscript received 5th October 1998, Accepted 5th October 1998

The enantioselective Claisen rearrangement of difluorovinyl allyl ethers was achieved, for the first time, in moderate to good enantioselectivity using a chiral boron reagent as the Lewis acid.

The development of a preparative method for chiral organofluorine compounds is very important in the field of medicinal chemistry.[1] The Claisen rearrangement of difluorovinyl allyl ethers is a powerful tool for the synthesis of β-substituted α,α-difluorocarbonyl compounds.[2] Although enantioselective versions of the Claisen rearrangement have been studied for the construction of chiral molecules,[3] there has been no report dealing with the reaction of difluorovinyl allyl ethers. We recently reported the highly enantioselective aromatic Claisen rearrangement of *o*-allyloxyphenol derivatives mediated by the chiral boron reagent **1**.[4] The efficiency of this system is based on the σ-bond formation of the chiral boron reagent **1**[5] with the phenolic hydroxy group in the substrate and the subsequent coordination of the ethereal oxygen to the boron atom to form a rigid chiral environment in the substrate and to promote the reaction at low temperature. We report herein the application of this system to the enantioselective Claisen rearrangement of difluorovinyl allyl ethers (Scheme 1).

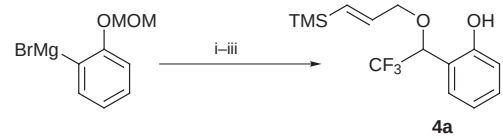


Scheme 1

The substrate **2** having a phenolic hydroxy group was selected, because of the importance of a binding site to the chiral boron reagent **1** in forming a coordinated cyclic intermediate and promoting the reaction. Compound **4a** was prepared from the reaction of 2-methoxymethoxyphenylmagnesium bromide with gaseous trifluoroacetaldehyde generated easily by the reaction of 2 equiv. of trifluoroacetaldehyde ethyl hemiacetal with P_2O_5 at 100 °C, followed by the allylation of the hydroxy group by using 1.2 equiv. of NaH and 1.5 equiv. of (*E*)-1-bromo-3-trimethylsilylprop-2-ene and deprotection under acidic conditions (Scheme 2). Other compounds **4b–d** were also synthesized by the same procedure (32–57% yield). Compound **4** was converted to **2** *via* elimination of fluoride by treatment with 2.5 equiv. of Bu^nLi at −78 to 0 °C in Et_2O. After neutral workup, the vinyl ether **2** was treated with 1.5 equiv. of (*S*,*S*)-**1** in the presence of 1.5 equiv. of Et_3N in CH_2Cl_2 at −78 °C and then the mixture was stirred at ambient temperature to give the rearranged product **3**. The results are summarized in Table 1.

In the chiral boron-mediated Claisen rearrangement, the reaction temperature and enantioselectivity were found to be affected by the configuration of the olefin (*E* or *Z*) and the steric bulkiness of the substituent R at the γ-position. Thus, in the case of **4a** having a TMS substituent, the reaction proceeded at −78 °C to give **3a** with high asymmetric induction (entry 1), while in the reaction of the substrate derived from **4b** having an *E* primary alkyl substituent, a slightly higher temperature was required, giving rise to the product **3b** with moderate selectivity (entry 2).[7] With the *Z* substrate derived from **4c**, the direction of asymmetric induction was opposite to that with *E* substrate **4b** (entry 3).

The absolute stereochemistry of **3d** was determined as shown in Scheme 3. The diastereoselective Claisen rearrangement of **5**



Scheme 2 *Reagents and conditions*: i, trifluoroacetaldehyde generated from its hemiacetal with P_2O_5, THF, 0 °C, 92%; ii, NaH (1.2 equiv.), (*E*)-1-bromo-3-trimethylsilylprop-2-ene, THF–DMF, room temp.; iii, 10% HCl, MeOH, reflux, 31% over 2 steps.

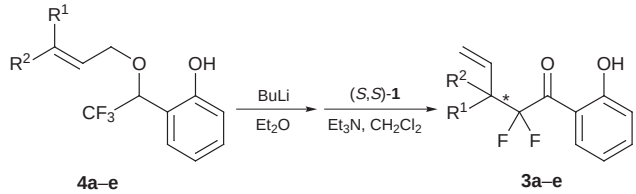


Table 1 The enantioselective Claisen rearrangement of difluorovinyl allyl ethers

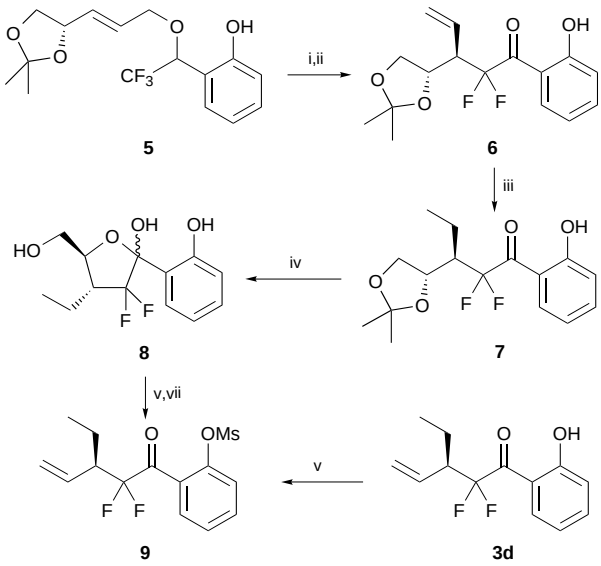
[a] Ref. 6. [b] Isolated yield based on **4**. [c] Optical purity determined by HPLC using a Chiralcel OD column. [d] Optical purity was determined by HPLC using a Chiralcel AD column.



Scheme 3 *Reagents and conditions*: i, Bu^{n}Li, Et_2O; ii, toluene, 70 °C, 47% over 2 steps (5:1); iii, H_2, Pd/C, MeOH, 79%; iv, 10% HCl, THF, 60 °C; v, MsCl, Et_3N, CH_2Cl_2, vi, NaI, butanone, reflux; vii, Zn, AcOH, H_2O–THF, 65% from **7**.

smoothly proceeded to give **6** as a major isomer (47%, 5:1), which has an *R* configuration at the newly formed chiral center.[8] Hydrogenation of the olefin of **6** (79%) and the subsequent deprotection of the acetonide group by acid treatment gave compound **8** as an anomeric mixture. After mesylation of the primary and phenolic hydroxy groups of **8**, the product was converted to the olefin **9** in 65% yield (four steps). The enantioselective Claisen rearrangement product **3d** was also converted to **9** by mesylation. Determination of the absolute stereochemistry of **3d** as *R* configuration could be achieved by comparison of the specific rotation of each compound.

The observed enantioselectivity is possibly explained as shown in Fig. 1. The six-membered intermediate is formed by the attachment of the chiral boron reagent **1** to the phenolic hydroxy group, and the subsequent coordination of the ethereal oxygen to the boron atom. In the case of (*S*,*S*)-**1** and the *Z* isomer of **2**, the *Si* face of the difluorovinyl ether moiety is shielded by

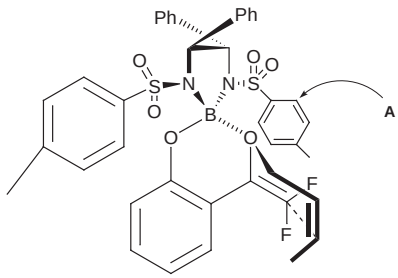


Fig. 1

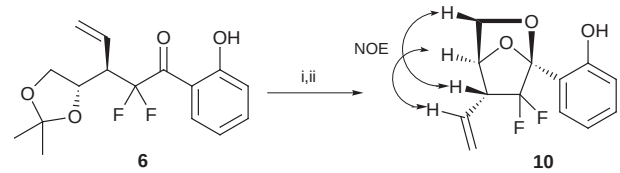

Scheme 4 *Reagents and conditions*: i, 10% HCl, THF, 60 °C; ii, toluene, 100°C, 63% over 2 steps.

the tolylsulfonyl group (**A**), thus the allylic moiety approaches preferably from the *Re* face to avoid steric interaction with **A** in the chair like transition state.

In conclusion, we have demonstrated for the first time enantioselective Claisen rearrangement of difluorovinyl allyl ethers using the chiral boron reagent **1** and the substrate **2** having a phenolic hydroxy group to form an efficient chiral environment.[9]

This work was partially supported by a Grant-in-Aid (No. 09672163) from the Ministry of Education, Science, Sports and Culture, Japan.

Intramolecular hydrogen bond-promoted C–C bond formation: reaction rate enhancement and regioselective allylation of carbonyl compounds

Hajime Ito, Yasuaki Ujita, Jun-ichi Tateiwa, Motohiro Sonoda and Akira Hosomi*

Received (in Cambridge, UK) 15th September 1998, Accepted 6th October 1998

An intramolecular hydrogen bond promotes rate enhancement in both the allylation and the reduction of carbonyl compounds and also regioselective allylation.

For the design of synthetic reactions, external catalysts or mediators are usually utilized for improving selectivity and mildness of reaction conditions.[1] In the allylation reaction of carbonyl compounds with an allylmetal reagent such as an allylsilane or allyltin, Lewis and Brønsted acid catalysts are often employed for this purpose.[2–4] Usually, the strong acidity of the Lewis or Brønsted acid is needed to complete the reaction. However, the strong acid sometimes causes decomposition of both the allylmetal reagent and the substrate. In order to overcome this drawback, we have introduced an intramolecular hydrogen bond into the substrate to activate the substrate and to stabilize the transition state of the reaction. Although active arguments for the contribution of hydrogen bonds in the transition state of an enzymatic system have been presented, there are fewer reports on the utilization of the stabilization effect of the hydrogen bond in the transition state in C–C bond formation between carbonyl compounds and organometallic reagents.[5,6] To explore the synthetic utility of the hydrogen bond, we focused our attention on the features of the intramolecular hydrogen bond. Its moderate acidity and localization in a specific position in the substrate serve synthetic utility. Here we describe rate enhancement in the allylation and the reduction of a carbonyl group and the regioselective allylation promoted by an intramolecular hydrogen bond.

There are numerous reports on the condensation reaction of an aldehyde with trialkylallyltin promoted by a Lewis or Brønsted acid catalyst.[3–5] The thermal reactions of trialkylallyltin with carbonyl compounds at high temperature or high pressure have also been reported. In our first series of experiments, the activation effect of an intramolecular hydrogen bond in the nucleophilic reaction of organotin compounds was measured at low temperature without the addition of an acid catalyst (Table 1).

Under THF reflux conditions without the addition of a Lewis acid, no adducts were observed for a mixture of tributylallyltin and benzaldehyde, which has no intramolecular hydrogen bond. Although salicylaldehyde **1a** reveals a relatively strong intramolecular hydrogen bond between the hydroxy group and the oxygen atom in the carbonyl group, attempts to afford an allylation product were unsuccessful under the same conditions (entry 1). Introduction of an electron-withdrawing substituent *para* to the hydroxy group provided allylation product **3b** in moderate yield (entry 2). A nitro group *para* to the hydroxy group was most efficient and gave products **3c**,**d** in good yields even at room temperature (entries 3–5). In entry 4, unreacted allyltin was recovered almost quantitatively. Next, in order to clarify the role of the hydroxy group in this reaction, we carried out experiments using carbonyl compounds **1d**,**e** which have no hydrogen bond, and found that such substrates gave no adduct under the same conditions described above (entries 6 and 7). Addition of *p*-nitrophenol was not effective for the allylation

c 12%

Scheme 2

(entry 8). These results clearly show that the hydroxy group of the substrate enhanced the reaction rate of the allylation. In view of the reaction mechanism, two paths are proposed for this rate enhancement (Scheme 1). The first one is that the intramolecular hydrogen bond directly promotes the allylation involving the stabilization of the transition state. In the second path, metalation of the hydroxy group first occurrs to give intermediate **A**. Another nucleophile attacks the carbonyl group of **A** activated by coordination to the internal stannyl group to give the product. The second path is not acceptable on the basis of the experimental result, namely, that 1 equiv. of tributylallyltin is sufficient to complete the reaction. The low reactivity of intermediate **A**, generated *in situ* by the reaction of **1c** with tributyltin methoxide, also suggests the second path can be ruled out.[7,8] These results indicate that the intramolecular hydrogen bond directly promoted the allylation reaction.

The intramolecular hydrogen bond also mediates reduction of carbonyl compounds with tributyltin hydride (Scheme 2). Similar reactivity tendency was also observed in this case. The substrate having an intramolecular hydrogen bond gave reduced product **4a** in good yield.

The immobility of the proton in the hydrogen bond made possible regioselective reaction of a multi-functional compound.[9] An aldehyde which has two carbonyl groups was prepared to examine the selectivity of the allylation.[10] The carbonyl group which is activated by the hydrogen bond was selectively allylated with tributylallyltin (Table 2). The selectivity was very high and minor product **7** was scarcely observed in these cases (entries 1 and 2). Substrates that have no hydrogen bond gave allylated products in poor yield (entries 3 and 4). These results show that an intramolecular hydrogen bond activates a particular functional group in the substrate selectively and stabilizes the transition state to enhance the reaction rate.

In conclusion, a low-acidic intramolecular hydrogen bonding promotes nucleophilic reaction to a carbonyl group. Although the precise mechanism of these reactions involving a low-barrier hydrogen bond (LBHB) is still unclear, this method offers a new tool in organic synthesis.[6]

First principles location of the transition state for formation of dimethyl ether in a zeolite

Eric Sandré,[a] Michael C. Payne[a] and Julian D. Gale*[b]

[a] *Cavendish Laboratory (TCM), University of Cambridge, Madingley Road, Cambridge, UK CB3 0HE*
[b] *Department of Chemistry, Imperial College, South Kensington, UK SW7 2AY. E-mail: j.gale@ic.ac.uk*

Received (in Exeter, UK) 12th August 1998, Accepted 6th October 1998

A new transition state searching algorithm has been used to determine the mechanism for methanol condensation to form dimethyl ether within the microporous environment of the zeolite, chabazite, using periodic boundary conditions and density functional theory.

Zeolites are powerful catalytic materials, combining acidity resulting from framework impurities with shape selectivity due to the spatial confines of the microporous environment.[1] Consequently they have found application in many commercial processes and as the variety of framework topologies and dopant ions increases so the possibilities multiply.

Amongst the existing applications of aluminosilicates, the methanol to gasoline reaction[2] is one of the most studied both from an experimental and theoretical perspective. Despite this, there still remain many unanswered questions concerning the precise nature of the role of the zeolite in the reaction mechanism. What is known for certain is that initially methanol condenses to produce dimethyl ether and subsequently hydrocarbons are generated, though it is unclear whether the ether actually lies on the pathway for C–C bond formation or whether it is a competing side reaction.[3]

There are two widely considered mechanisms for the formation of dimethyl ether from methanol in zeolites. In the first mechanism methanol is adsorbed at an acid site and dissociates to produce a framework coordinated methoxy group and water. Although the activation energy for this to occur directly has been shown to be too high, several studies have indicated that the participation of a second methanol lowers the barrier.[4] The second possible mechanism involves the direct S_N2 reaction of one methanol with another. In this scheme, the coordination of one methanol to the acidic hydrogen of a Brønsted acid site leads to weakening of the C–O bond making the methanol more susceptible to nucleophilic attack. The essential difference between the mechanisms is that in the first one the zeolite plays an active chemical role in the pathway, whereas in the second it acts primarily as an acidic solvent. Previous theoretical studies[5,6] have demonstrated that the direct condensation of methanol leads to a sequence of intermediates which are lower in energy and is therefore likely to be the preferred mechanism.

While periodic boundary condition methods have been previously used to study the structure of zeolites and adsorption of molecules within them,[6,7] these studies have not included the location of transition states for *in situ* chemical reactions. Although methods for locating transition states, with or without analytical second derivatives, are well establish for conventional molecular quantum chemistry, particularly when working in internal coordinates, the same is not true for the solid state.

In this work we use for the first time a new refined version of the synchronous transit method in Cartesian space to locate a transition state within a periodic zeolite structure. Here a reaction coordinate is defined—in this case a C–O bond length that is being broken or formed—and a minimisation is performed subject to this distance being constrained through the use of a Lagrange multiplier. Minimisations are performed at two points, one on the reactant and one on the product side. The lower energy point is then moved along the reaction coordinate towards the other point until it is higher in energy, at which stage the process is reversed. At each stage an unconstrained minimisation is performed to ensure that the point is on the correct side of the barrier.

We have used the above approach to locate the transition states for methanol condensation both in the gas phase and within the confines of a microporous environment. As in our previous work[8] we have chosen the zeolite chabazite for the aluminosilicate since the small unit cell of formula $HAlSi_{11}O_{24}$ is computationally tractable and the high symmetry of the purely siliceous material greatly reduces the number of configurational possibilities for the acid site. Furthermore, this system is known to be an active catalyst for the conversion of methanol to dimethyl ether. [9]

All calculations have been performed using planewaves to expand the valence electronic wavefunctions up to a cut-off of 620 eV with the nuclei and core electrons being represented by norm-conserving non-local pseudopotentials.[10] The gradient-corrected density functional of Perdew and Wang (GGA)[11] has been used throughout. Calculations were performed using only the gamma point in the Brillouin zone as this had previously been found to be sufficient. All atoms were allowed to relax freely, except for the distance constraint between the atoms defining the reaction coordinate and the unit cell was held fixed.

When two methanol molecules per acid site are adsorbed in the zeolite the minimum energy configuration has been shown to consist of a methoxonium cation which is hydrogen bonded to an oxygen of the framework, adjacent to aluminium, on one side and to the second methanol on the other.[6] This second methanol is then able to form a hydrogen bond to a more remote oxygen of an Si–O–Si bridge, though dynamical simulations show this interaction to be much weaker.[12] In order for condensation to occur, the second methanol has to first migrate to a configuration which is 61 kJ mol^{-1} higher in energy in which its dipole aligns with that of the methoxonium cation so that the geometry is suitable for nucleophilic attack (Fig. 1).

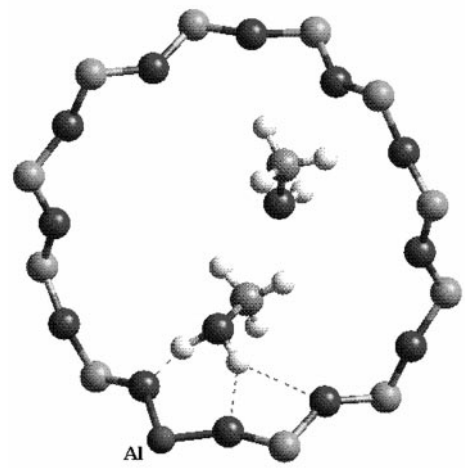

Fig. 1 Reactant configuration for two methanols adsorbed with in chabazite.

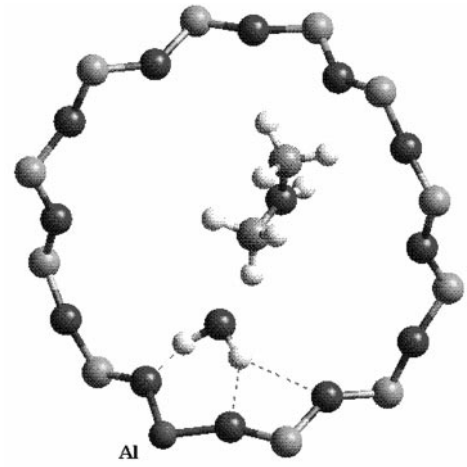

Fig. 2 Initially formed local minimum for the products of methanol condensation, dimethyl ether and water, within the cage of chabazite.

This we take as the reactant configuration for the transition state search.

The arrangement of the products, dimethyl ether and water, as initially formed is shown in Fig. 2. The water molecule remains coordinated to the aluminium defect site in the framework while the dimethyl ether is formed in the protonated state but with no hydrogen bonding possible. Subsequent to this reaction the dimethyl ether can rotate to form a strong hydrogen bond to the water molecule and proton transfer can occur.

For the transition state search, the length of the C–O bond of dimethyl ether which is being formed during the nucleophilic attack is used as the reaction coordinate. The resulting energy profile along the reaction coordinate is illustrated in Fig. 3, the

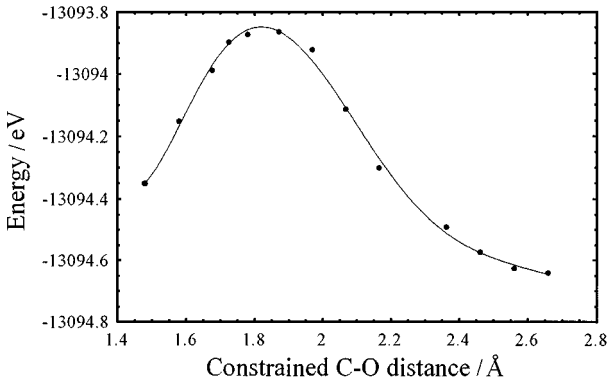

Fig. 3 Plot of energy *versus* constrained C–O distance for the bond being formed in dimethyl ether during methanol condensation within chabazite. Filled circles represent the actual energies, while the solid line is a sixth order polynomial fit to these values.

solid line shows a sixth order polynomial fit and is included as a guide, though it is clear that the shape of the local energy surface is more complex. The transition state occurs quite late when the length of the C–O bond being created has reached a value of 1.8 Å, as compared to the final bond length of 1.45 Å. The local geometry around the carbon at the saddle point is trigonal bipyramidal as would be expected for a true S_N2 mechanism, with the oxygens being approximately equidistant and axial while the CH_3 group has carbenium ion character (Fig. 4).

The predicted activation energy for this process is 71 kJ mol^{-1} when starting from the appropriate minimum energy configuration for two methanol molecules. If the energy required to reach this state is included in the activation energy then the overall value is 132 kJ mol^{-1}. The comparable values for these energetics obtained from previous calculations on gas phase cluster models for zeolites are 89 and 145 kJ mol^{-1}.[5] If we assume that any shift in the values due to differences in basis sets and functionals are small, then we can conclude that the

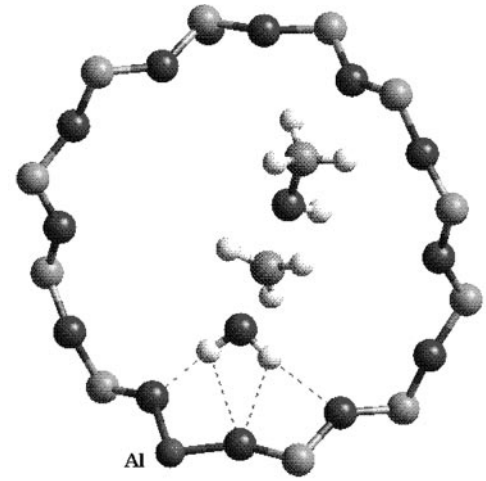

Fig. 4 Transition state structure for conversion of methanol to dimethyl ether.

effect of the full zeolite structure is to lower the activation energy as would be expected. However, given that the reaction occurs with the transition state away from the framework itself this suggests that the primary effect of the zeolite is to act as a polarisable medium which stabilises any charge separation that occurs in the transition state. Significantly, there are no strong directional interactions formed between the activated complex and the zeolite.

In this work we have studied the condensation of methanol to form dimethyl ether and shown that the zeolite catalyses the reaction by acting as a polarisable medium which lowers the energy of charge separation in the transition state. However, the real challenge that lies ahead is to explain the full mechanism of gasoline formation. An advantage of the present method of locating transition states is that no assumption about the reaction pathway is necessary, just a knowledge of the reactants and products. The possibility that there may be multiple minima and transition states between the two chosen configurations can be handled straightforwardly in this way and therefore complex mechanisms may now be determined in combination with a realistic periodic model of a zeolite catalyst.

These calculations were performed on the Hitachi SR2201 located at the University of Cambridge High Performance Computing Facility. J. D. G. acknowledges the support of the Royal Society through a University Research Fellowship.

Received (in Corvallis, OR, USA) 17th June 1998, Accepted 7th October 1998

Incorporation of 2-phenyl-1,3-dithiane 1 into ZSM-5 generated 1,2-dithiolane radical cation $2^{\cdot+}$, the EPR spectrum of which shows an orthorhombic powder pattern (g_1 = 2.0293, g_2 = 2.0193, g_3 = 2.0030); each *g* component showed a 1:4:6:4:1 pattern (a_1 = 10.5, a_2 = 9.3 and a_3 = 9.2 G) due to coupling to four equivalent ^{1}H nuclei, suggesting that the pseudo-axial and −equatorial α-protons undergo conformational equilibration whereas the sulfur centers are held stationary on the EPR time scale.

In the past three decades the structures and properties of zeolites have been extensively studied as prototypes of acidic industrial catalysts.[1–3] In addition, a wide range of organic radical cations have been generated, either spontaneously or upon inclusion of appropriate precursors into zeolites.[4–8] Radical cations generated by this method typically have extended lifetimes and can be studied by conventional spectroscopic techniques. We are interested in zeolite-induced radical cation reactions; our contributions to intra-zeolite chemistry include oxidative deprotonation,[9] dehydrogenation[10] and cyclization.[11]

In a recent study of diphenyl disulfide **3** we observed the EPR spectrum of the 'extended' radical cation $\mathbf{3}^{\cdot+}$,[11] even though this species undergoes rapid conversion to thianthrenium ion $\mathbf{4}^{\cdot+}$ in solution. In an attempt to observe the EPR spectrum of a similarly elusive species, 2-phenyl-1,3-dithiane radical cation $\mathbf{1}^{\cdot+}$, we incorporated **1** into ZSM-5 (Scheme 1). The resulting EPR spectrum supports the conversion of $\mathbf{1}^{\cdot+}$ to $\mathbf{2}^{\cdot+}$ and offers unique insights into the mobility of this radical cation in the zeolite channels.

Incorporation of 2-phenyl-1,3-dithiane **1** into Na-ZSM-5 at room temperature produced an EPR spectrum that can be interpreted as an orthorhombic powder pattern with g_1 = 2.0293, g_2 = 2.0193 and g_3 = 2.0030; each *g* component showed hyperfine coupling (hfc) due to four equivalent protons (1:4:6:4:1 pattern, a_1 = 10.5, a_2 = 9.3 and a_3 = 9.2 G; Fig. 1). The average *g* value, g_{avg} = 2.0172, is in reasonable agreement with the isotropic *g* value, g_{iso} = 2.0183, reported for the radical cation of 1,2-dithiolane, $\mathbf{2}^{\cdot+}$, in solution.[12,13] Likewise, the average hfc observed in the zeolite, a_{avg} = 9.7 G, agrees well with the isotropic coupling constant of 9.75 G reported for $\mathbf{2}^{\cdot+}$ in solution.[12,13] The identity of the species was confirmed by an essentially identical EPR spectrum obtained upon incorporation of an independently synthesized[14] sample of **2** into ZSM-5.

The generation of $\mathbf{2}^{\cdot+}$ by oxidative ring contraction of **1** has precedent in solution; either chemical or electrochemical oxidation of **1** led to the debenzylated, ring-contracted species, $\mathbf{2}^{\cdot+}$.[15–17] In fact, anodic oxidation of dithioacetals has been used to remove the dithiane protecting group of carbonyl compounds. The mechanism for the ring-contraction of dithiane radical cations appears to be understood in general terms.[15–17] This conversion has two principal elements, the formation of an S–S bond and the detachment of the benzyl group. This conversion is formulated typically *via* a disulfide dication.

1,2-Disulfide dications have been observed by fast time-resolved spectroscopy in solution[18] and have been invoked recently in zeolite media.[11] The formation of the S–S bond in the 1,3-dithiane radical cation may favor the second oxidation step. The benzyl function may be removed by two consecutive nucleophilic displacements at the dication.[15–17] In view of the limited diameter of the ZSM-5 channels and the dimensions of **1** and its radical cation and dication, these species should not be accessible to external nucleophiles. Instead, Lewis base sites within the zeolite framework are the likely reagents.

The dynamic behaviour of $\mathbf{2}^{\cdot+}$ in the internal voids of the zeolite is also unusual. The *g* factor anisotropy of $\mathbf{2}^{\cdot+}$ at room temperature indicates that this species is not tumbling or rotating rapidly on the EPR time-scale. On the other hand, the conformational re-orientations ('flickering') of the methylene group (C_4) is still fast, based on the equivalence of the pseudo-axial and −equatorial α-protons at C_3 and C_5. This implies that one or both sulfur centers bearing spin and charge are held rigidly in a potential well or are 'attached' covalently to the zeolite network, whereas the mobility of the trimethylene segment is unaffected by the 'anchoring' of the sulfur centers (Scheme 2). This observation establishes an interesting differ-

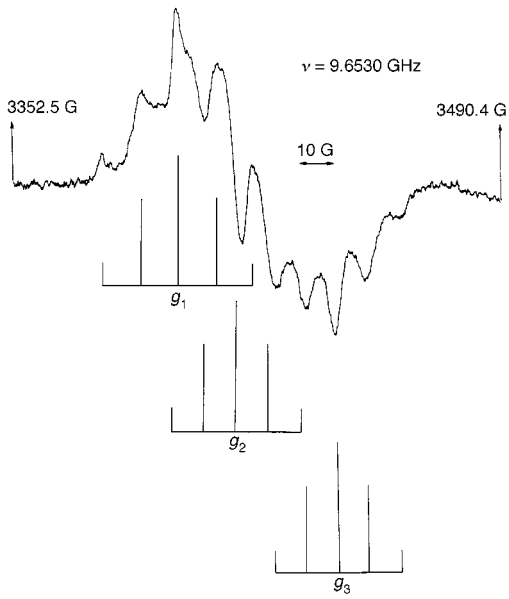

Fig. 1 Room temperature EPR spectrum obtained upon sequestering **1** into ZSM-5. The spectrum is interpreted as an orthorhombic powder pattern with *g* factors g_1 = 2.0293, g_2 = 2.0193 and g_3 = 2.0030, split into 1:4:6:4:1 patterns (a_1 = 10.5, a_2 = 9.3 and a_3 = 9.2 G) due to coupling with four equivalent ^{1}H nuclei. The spectrum is assigned to radical cation $\mathbf{2}^{\cdot+}$.

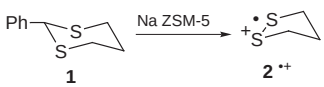

Scheme 1

Scheme 2

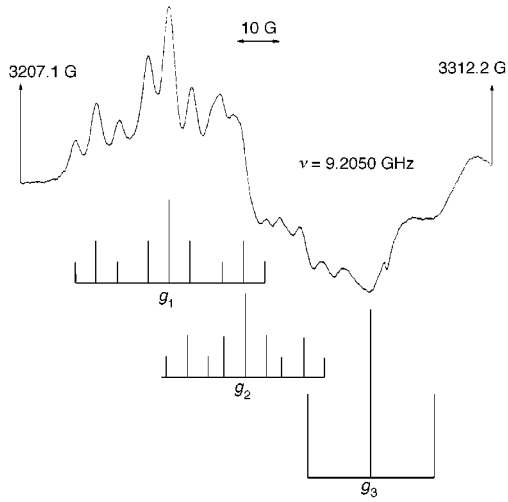

Fig. **2** Low-temperature (77 K) EPR spectrum of $\mathbf{2}^{\cdot+}$, an orthorhombic powder pattern with g_1 = 2.0298, g_2 = 2.0190 and g_3 = 2.0023. Each g component is split into triplet of triplets (interaction with two non-equivalent groups of two ^{1}H nuclei), a_1 = 16.2 and 4.9, a_2 = 13.3 and 4.6 and a_3 = 14.7 G, unresolved.

ence between the dynamicas of $\mathbf{2}^{\cdot+}$ in the zeolite and in solution. In solution, the flickering can be arrested without causing g factor anisotropy;[12,13] in contrast, the zeolite spectrum shows significant g factor anisotropy even when flickering rapidly.

The dynamics of **2** and its radical cation are well-documented in fluid solutions as a function of temperature. The five-membered ring of **2** is slightly twisted around the S–S bond; the sulfur lone pairs are aligned at a dihedral angle of *ca.* 30°.[19] Oxidation of **2** results in a subtle structure change; the sulfur lone pairs (and the S–CH_2 bonds) in $\mathbf{2}^{\cdot+}$ become eclipsed, facilitating the delocalization of spin and charge between the sulfur centers. The planar arrangement of the CH_2–S–S–CH_2 segment forces the bridging methylene group out of plane; a planar structure is a low-lying transition state between two equivalent 'envelope' conformers. At room temperature, the conformers equilibrate rapidly causing the four α-protons to be equivalent (a = 9.75 G, 4H). The inversion slows down with decreasing temperature; the pseudo-axial and −equatorial ^{1}Hs become non-equivalent at 180 K (a = 16.25 G, 2H; a = 3.9 G, 2H).

The low temperature dynamic behavior of $\mathbf{2}^{\cdot+}$ in the zeolite is similar. At 77 K, the flickering of the methylene group is sufficiently slowed to render the α-protons non-equivalent; each g component shows a triplet of triplets (Fig. 2). As in the room temperature spectrum, the splitting is well resolved in the downfield component. However, the g tensor of $\mathbf{2}^{\cdot+}$ remains orthorhombic, similar to that at room temperature.

The severely restricted mobility of $\mathbf{2}^{\cdot+}$ in the zeolite channels was unexpected. Because of its relatively small size (Fig. 3), we had expected $\mathbf{2}^{\cdot+}$ to tumble freely in the zeolite channels. Several radical cations of comparable size showed essentially isotropic spectra; for example, the sharp lines observed for 2,3-dimethylbut-2-ene radical cation in silicalite (a = 11.8 G; 11 of 13 lines are detected) are compatible with essentially free rotation of this radical cation.[20,21] In pentasil zeolites, the corresponding spectra have considerably greater linewidths, apparently due to interaction with the zeolite host and the resulting reduced mobility. Of course, the rotation of bulkier molecules is expected to be hindered; this is confirmed, for example, by the broad(ened) lines observed for anethol radical cation[10] or by the anisotropic (powder type) spectra of iminoxyls in ZSM-5.[9]

Concerning the question of whether the radical cation, $\mathbf{2}^{\cdot+}$, is 'held' in a potential well or covalently linked to the zeolite network, we can exclude the second possibility. The covalent

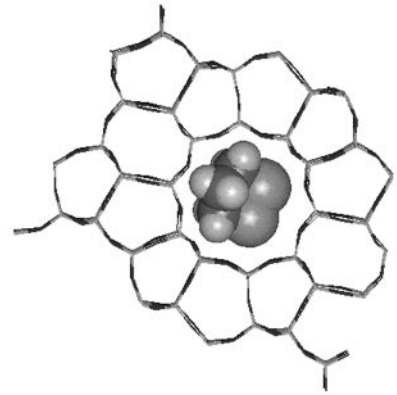

Fig. **3** Molecular modeling visualizing the docking of 1,2-dithiolane radical cation, $\mathbf{2}^{\cdot+}$, optimized at the UHF/6-31G* level of theory, inside the straight channels of ZSM-5.

link would most likely involve bonding of one sulfur atom to the zeolite. The resulting aggregate would be unsymmetrical; its spin density would be localized at the unattached sulfur center, creating a species in which only one CH_2 group is coupled. This is clearly incompatible with the EPR spectrum.

In summary, the formation of 1,2-dithiolane radical cation, $\mathbf{2}^{\cdot+}$, upon inclusion of 2-phenyl-1,3-dithiane, **1**, into Na-ZSM-5 shows several interesting features. The removal of the benzyl function requires nucleophilic displacement; since the intermediate is not accessible to an external nucleophile, Lewis base sites within the zeolite framework are the likely reagent. The orthorhombic g tensor of $\mathbf{2}^{\cdot+}$ in the zeolite indicates that the radical cation is held in a coulombic well within the network of oxygen centers; however, intramolecular processes, such as the ring inversion of the β-methylene group, are unaffected.

Support of this work through grant NSF CHE–9714850 and two NSF equipment grants is gratefully acknowledged.

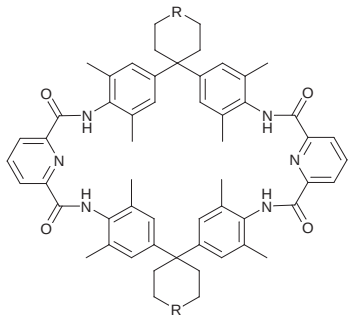
Received (in Cambridge, UK) 24th April 1998, revised manuscript received 9th September 1998, Accepted 11th September 1998

An amide macrocycle with a highly preorganised cavity containing both polar and non-polar recognition sites forms stable complexes with cyclic dipeptides in water *via* amide–amide hydrogen-bonds, NH–π hydrogen-bonds and hydrophobic contacts.

Host–guest systems have been extensively studied in organic solvents and the requirements for designing efficient selective receptors are well-understood.[1] In contrast, the development of comparable systems which function in water has proved much more challenging, because the compounds are not only more difficult to handle, but also more difficult to understand due to the complex behaviour of the solvent. Hydrophobic cavities have been the focus of synthetic recognition systems in water,[2] but there are a limited number of examples where hydrogen-bonding sites have been used in conjunction with hydrophobic binding to provide selective binding in water.[3] It is this arrangement that is the characteristic feature of protein binding pockets which usually have complicated arrays of polar and non-polar sites, and the interplay of their recognition and desolvation properties is one of the factors that makes it difficult to disentangle the complexities of biological recognition.[4] Here we describe a simple synthetic host–guest system which allows us to study this interplay of polar and non-polar binding interactions in water.

The synthesis and recognition properties of **1** have been reported.[5] The water soluble analogue **2** was prepared in the



1 R = CH_2
2 R = N^+Me_2 Cl^-

same way. The two quaternary ammonium centres on the receptor periphery were sufficient to confer good water solubility on the macrocyle, and ^{1}H NMR dilution experiments showed no evidence of any aggregation or micelle formation at millimolar concentrations.

Single crystals of **2** suitable for X-ray crystallography of were grown from a water–MeCN mixture.‡ The macrocycle cavity is filled by a cluster of water molecules in the crystal [Fig. 1(*a*)]. Although the waters are within H-bonding distance of each other and sites on the macrocycle (2.8–3.1 Å), partial occupancy and the poor quality of the X-ray data preclude a detailed assignment of the H-bond network. We have previously obtained an X-ray crystal structure of the organic soluble

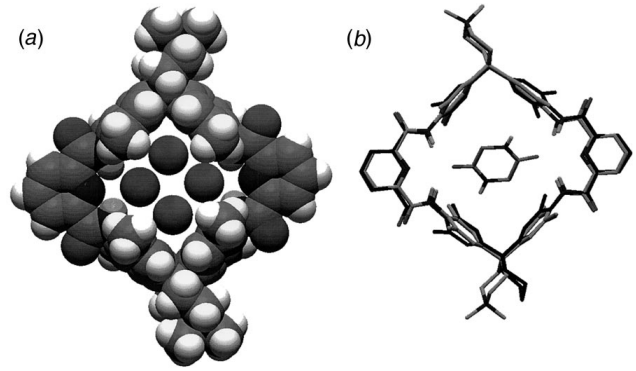


Fig. 1 (*a*) The X-ray crystal structure of **2** showing the positions of the water molecules which solvate the cavity. (*b*) The X-ray crystal structure of **2** superimposed on the X-ray crystal structure of the **1**·**8** complex.

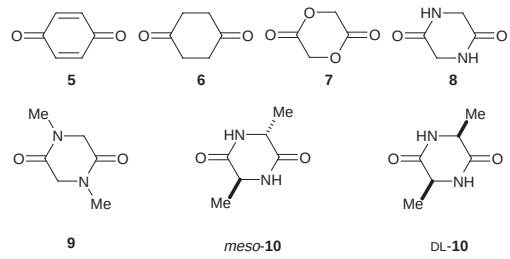
analogue **1** complexed with glycine anhydride **8**,[5] and Fig. 1(*b*) shows this structure superimposed on the structure of **2**. The only difference between the chemical structures of the two macrocycles is the replacement of cyclohexane by quaternised piperidine on the periphery of the macrocycle. The only difference between the conformations of the macrocycles in the two X-ray structures is the orientation of one of these peripheral groups: the geometry of the cavity and arrangement of functional groups is identical, which reflects the high degree of preorganisation conferred on this system by the intramoelcular pyridine–amide hydrogen-bonds.

The recognition properties of the new receptor **2** were investigated by ^{1}H NMR titration experiments in H_2O–D_2O (9 : 1). No detectable changes were observed upon addition of benzoquinone **5** or the diester **7**. The binding constants for the



5 **6** **7** **8**

9 *meso*-**10** DL-**10**

other guests investigated are listed in Table 1. The structures of the complexes were determined from the limiting complexation-induced changes in chemical shift and a ROESY experiment for the most stable complex, which is formed with alanine anhydride **10**. The downfield shift for the signal due to the **2** amide protons shows that they form H-bonds with the carbonyl groups of the guests (Table 1). Characteristic upfield shifts are observed for the signals due to CH protons (δ −0.9 to −1.1), the amide protons (δ −0.5) and the methyl protons (δ −0.6 to −0.8) of all the guests which shows these protons are shielded by the aromatic side-walls of the macrocycle on complexation.

Table 1 ^{1}H NMR titration data: association constants and limiting changes in chemical shift for formation of 1 : 1 complexes with macrocycle **2** in water. Data for complexation with macrocycle **1** in $CHCl_3$ are shown for comparison

Guest	K_a/M^{-1} host **2** in water	$\Delta\delta$ (ppm) of **2** amide NH	K_a/M^{-1} host **1** in $CDCl_3$
5	< 5	—	230
6	94 ± 9	+0.1	850
7	< 5	—	340
8	71 ± 8	+0.3	1.0×10^6
9	100 ± 10	+0.1	—
meso-**10**[a]	100 ± 10	+0.7	—
DL-**10**	760 ± 80	+0.5	—

[a] The values for *meso*-**10** were determined by titrating a mixture of DL-**10** and *meso*-**10** into **2**. Using the data obtained previously for DL-**10**, the mixed titration could be analysed in a straightforward manner, because complexation with **2** caused the signals due to DL-**10** and *meso*-**10**, which were initially coincident, to split (these compounds are clearly bound in slightly different geometries inside the macrocycle).

These changes in chemical shift are very similar to those observed for complexation with **1** in $CHCl_3$ and suggest that the structures of all of the complexes are similar to that shown in Fig. 1(*b*).

Cyclohexane-1,4-dione **6**, glycine anhydride **8** and the bis(*N*-methyl) derivative **9** all bind with comparable affinity. We have previously measured the association constants for **1** with guests **5–8** in $CHCl_3$, and the stabilities are all substantially reduced in water, which reflects the increase in solvent competition for the hydrogen-bonding sites (Table 1). However, the selectivity in $CHCl_3$ is quite different from that in water: the association constant for **6** is reduced by an order of magnitude in water; for **5** and **7**, it is at least two orders of magnitude lower, and for **8**, it is four orders of magnitude lower. This trend reflects the relative polarity of the guests and the strength of their interaction with water: more polar guests are more difficult to desolvate in water and are therefore bound weakly. Clearly, decreasing the polarity of the guest should increase binding in water, and we therefore examined three dimethyl derivatives of glycine anhydride. For **9** and *meso*-**10**, there is no increase in affinity, and CPK models suggest that these guests do not fit properly into the cavity. However, the association constant for the other isomer DL-**10** is significantly larger, indicating good shape complementarity which allows additional hydrophobic interactions with the methyl groups to be realised. Intermolecular NOEs observed in a ROESY experiment on the **2**·**10** complex confirm that the **10** methyl groups are close to the aromatic side-walls of the receptor in the complex.

Evidence that NH–π hydrogen-bonds are involved in recognition in this system comes from the rates of exchange of the amide protons with water. H_2O–D_2O (9:1) was used as the solvent, so that we could monitor the amide signals during the NMR titrations. However, this necessitated the use of a solvent suppression sequence which removed the signals due to the amides of **8** and **10**. These protons are in fast exchange with the solvent, but the signals due to the amides of receptor **2** were unaffected by solvent suppression, because they are intramolecularly hydrogen-bonded and exchange slowly with solvent. However during the course of the titration, signals due to the **8** and **10** amide protons appeared and increased in intensity until they reached a similar intensity to the signals due to the host. This implies that complexation of these guests protects the amides from exchange with solvent in the same way as conventional hydrogen-bonds and provides direct evidence for NH–π hydrogen-bonding in these complexes.[5,6]

Thus the functional group interactions responsible for recognition are amide–amide hydrogen-bonds, NH–π hydrogen-bonds and hydrophobic CH–π interactions. Although it is difficult to interpret simplistic binding experiments of this type in terms of individual interaction energies,[6,7] there are some interesting observations to be made in these systems. The association constants for **6** and **8** are very similar: desolvation of **8** is much more difficult than desolvation of **6**, which suggests that either the magnitude of the NH–π interaction in water is comparable to a hydrophobic CH_2–π interaction or that the amide–amide hydrogen-bonds are stronger than the ketone–amide hydrogen-bonds despite the competition with water. Compound **8** is a very polar substrate with very few useful recognition sites for binding in water, and yet **2** is able to complex it with reasonable affinity. The water cluster which solvates **2** presents a polar recognition surface which has a lot of similarities with that of glycine anhydride [Fig. 1(*b*)]. However, the release of these water molecules to bulk solvent on guest complexation is entropically favourable and may be enthalpically favourable for the water which solvates the non-polar part of the receptor.[2a] The most stable complex is formed with DL-alanine anhydride DL-**10**, where hydrophobic interactions with the two methyl groups are responsible for the ten-fold increase the association constant relative to glycine anhydride **8**.

Novel photoinduced aromatization of Hantzsch 1,4-dihydropyridines

Mei-Zhong Jin, Li Yang, Long-Min Wu, You-Cheng Liu and Zhong-Li Liu*

National Laboratory of Applied Organic Chemistry, Lanzhou University, Lanzhou, Gansu 730000, China. E-mail: liuzl@lzu.edu.cn

Received (in Cambridge, UK) 11th September 1998, Accepted 6th October 1998

4-Alkyl- and/or aryl-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylates (Hantzsch 1,4-dihydropyridines) are quantitatively oxidized to the corresponding pyridine derivatives by irradiation in CCl_4 *via* a photoinduced electron transfer mechanism.

A plethora of reagents has been used for oxidation of 1,4-dihydropyridine (DHP) derivatives,[1] a class of model compounds of NADH and drugs for treatment of cardiovascular diseases.[2] Generally, strong inorganic oxidants, such as nitric acid,[3] ceric ammonium nitrate[4] or ferric or cupric nitrates,[5] must be used to accomplish the oxidation. Recent developments include using nitric oxide,[6] pyridinium chlorochromate[7] and clay-supported cupric nitrate accompanied by ultrasound-promotion[8] to improve the efficiency of the aromatization. However, yields are generally moderate and/or tedious work-up procedures are required. We report herein a very convenient, clean and efficient approach for the oxidation of Hantzsch 1,4-dihydropyridines by direct photolysis of the substrate in CCl_4. To the best of our knowledge, this is the first report on photochemical aromatization of Hantzsch 1,4-dihydropyridines (DHPs).

DHP **1** (1 mmol) was dissolved in 25 ml of CCl_4 or CCl_4–MeCN (9:1 v/v) and irradiated with a 250 W high pressure mercury lamp in a Pyrex bottle under argon atmosphere at ambient temperature. After irradiation the solvent was removed under reduced pressure and the corresponding pyridine derivative **2** was obtained in pure form and almost quantitative yield (Scheme 1). One exception is 4-(2-furyl)-DHP **1g** which gave 85% of **2g** together with 13% of de-furyl product **2a**. The results are summarized in Table 1.

It was found that $CHCl_3$ was generated during the reaction, as evidenced by GC, and the solution became acidic after irradiation. Hence there is no doubt that C–Cl bond cleavage takes place during the photolysis. Similar CCl_4- and/or $HCCl_3$-promoted photo-fragmentation reactions have recently been reported from this laboratory[9,10] and by Whitten and co-workers.[11] Therefore, a photoinduced electron transfer mechanism is proposed, as outlined in Scheme 2.

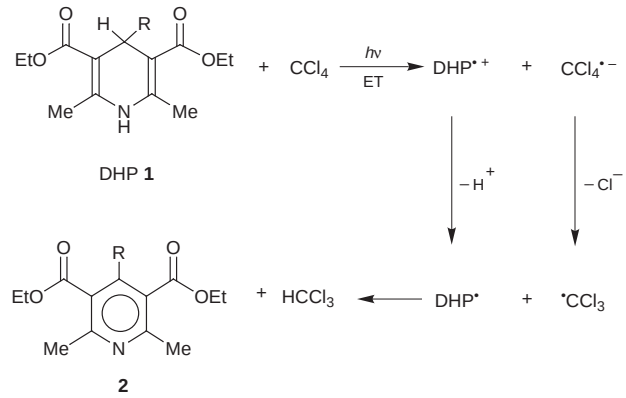

Scheme 2

The critical step in this mechanism is the extremely fast dechlorination of the radical anion of CCl_4. It is well known that alkyl and aryl halides are subject to reductive dissociation upon accepting an electron either electrochemically or photochemically.[12] The lifetime of the radical anion of CCl_4 was reported to be extremely short (less than 10 ps).[13] Therefore, C–Cl bond breaking and electron transfer may even take place concertedly which, in turn, effectively circumvents the back electron transfer and makes the reaction very efficient. Maslak and co-workers[14] have termed unimolecular fragmentation of radical ions as mesolytic cleavage and demonstrated the tremendous facilitation of bond cleavages obtainable from the mesolytic processes. The present reaction involves mesolytic cleavages of both radical anions (aniomesolysis) and radical cations (catiomesolysis), hence, it can be considered as a double mesolytic fragmentation reaction. The aniomesolysis helps to prevent back electron transfer, which enhances the quantum yield of the photolysis, and the catiomesolysis facilitates the deprotonation from DHP. These two effects make the reaction very efficient. This strategy may be applicable to the enhancement of the efficiency of other photoinduced electron transfer reactions. In addition, since no additional oxidant is required other than the solvent CCl_4, and no any waste is produced, this reaction can also be considered as a facile green chemical reaction for the synthesis of pyridine derivatives and may be extended to other synthetic reactions

The authors thank the National Natural Science Foundation of China for financial support.

Polymer backbone disassembly: polymerisable templates and vanishing supports in high loading parallel synthesis

Christopher P. Ball, Anthony G. M. Barrett,* Lydie F. Poitout, Marie L. Smith* and Zoë E. Thorn

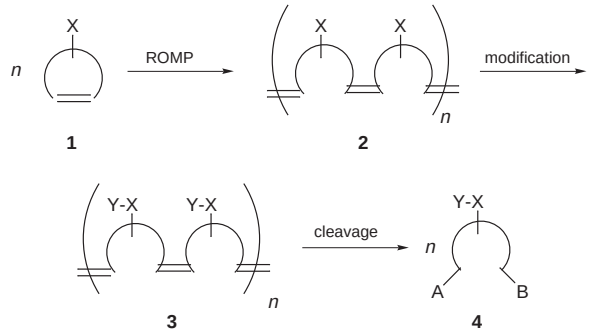
Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: m.stow@ic.ac.uk

Received (in Liverpool, UK) 7th August 1998, Accepted 6th October 1998

In the synthesis of a library of *N*-alkyl-3-aza-8-oxabicyclo[3.2.1]octane-6,7-dimethanol derivatives, prepared from an 7-oxabicyclo[2.2.1]hept-2-ene-5,6-dimethanol derivative *via* ring opening metathesis polymerisation using $Cl_2(Cy_3P)_2Ru{=}CHPh$, selective alkylation, ozonolytic scission of the polymer backbone and reductive alkylation, purification was facilitated by the differential solubility of the polymer intermediates.

The emergence of combinatorial methodologies and parallel syntheses have dramatically accelerated synthetic chemistry and the quest for novel pharmaceuticals and other specialty chemicals.[1] Many state-of-the-art parallel syntheses rely upon polymer-supported procedures in which the substrate is attached to a support throughout a synthetic sequence. Assay is either carried out on the support or following late release. Such supported syntheses are aided by the 'polymer advantage' which allows (i) solid phase reactions to be driven to completion by the addition of excess solution phase reagents which are simply removed by filtration techniques and (ii) the separation of reaction products from the polymer post-cleavage. There is clear merit in maximising substrate loading so that for any given synthesis, sufficient substrate is produced at a minimum resin weight such that compound authentication, bioassay and compound archiving are facilitated. As such there is need to maximise the loadings yet to also facilitate on-support analysis. The use of PEG supports clearly addresses the need for easy solution-based analyses but these supports are not ideal in terms of loadings. On the other hand, the preparation of polymer supported dendritic materials[2] leads to improved loadings yet does not greatly facilitate analysis. The use of insoluble polymers often necessitates the utilisation of time-consuming, non-standard analytical techniques, *e.g.* solid state NMR spectroscopy, in order to determine the character of the polymer-bound substrates.

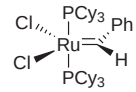
Herein, we report the concept of polymer backbone disassembly for the preparation of synthetic libraries. In this approach the substrate is also the monomer building block for the polymer. As such the polymer loading should ideally approach quantitative. The polymerisation of an appropriate monomer (starting material) to form an insoluble (or differentially soluble) polymeric material is followed by substrate modification for the introduction of chemical diversity. Finally oxidative disassembly generates the modified monomers which are in fact the small molecules of interest. Polymers derived from ring opening metathesis polymerisation (ROMP)[3] fulfil these criteria and were chosen for initial evaluation in the strategy outlined in Scheme 1. ROMP polymers are, unlike cross-linked polystyrene resins, generally soluble in a range of organic solvents yet insoluble in others. Thus, chemical modifications may be carried out in a homogenous environment thereby avoiding poor solvation which often inhibits reactions carried out with insoluble solid supports. Moreover, reactions may be probed using standard solution phase spectroscopic techniques and the ability to rapidly determine the nature of the attached substrate offers a significant advantage over standard solid-phase organic synthesis. Following synthesis, the ROMP



Scheme 1

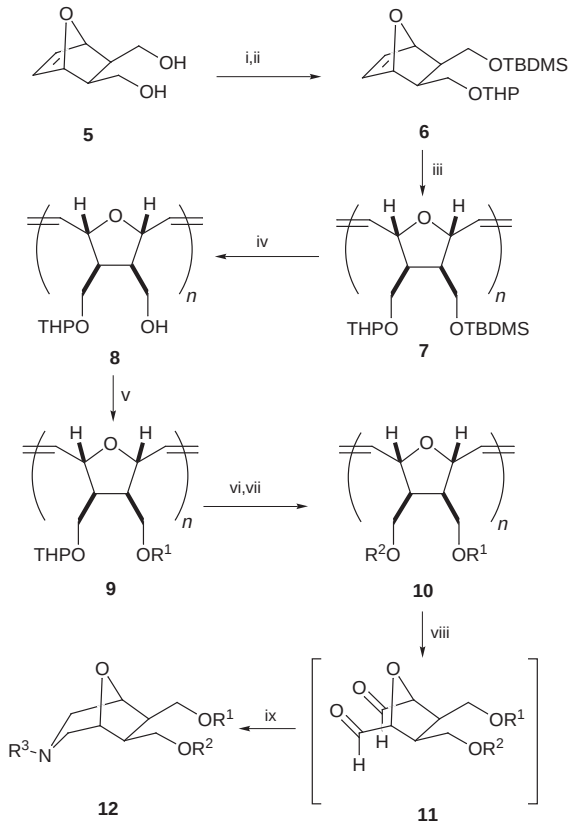
polymers may be precipitated by the correct choice of solvent to afford solids which can be washed to remove excess reagents. In this respect ROMP polymers show similar behaviour to the PEG polymers recently further developed by Janda *et al*.,[4] after the pioneering work by Bayer, Mutter and Shemyakin.[5]

Norbornene, 7-oxanorbornene and cyclobutene ROMP monomers containing functional groups which are either hydrophilic or hydrophobic in nature are readily available and many offer the opportunity for post-polymerisation chemical modification required for library generation. 7-Oxanorbornene **6** was chosen for initial study as depicted in Scheme 2. The monomer **6** is readily prepared from diol **5** *via* mono-silylation followed by tetrahydropyranyl protection. The use of orthogonal protecting groups[6] allows for a stepwise hydroxy group modification strategy to be utilised in library synthesis. Polymerisation of **6** using the Grubbs catalyst **13**[7] and chain



13

termination with ethyl vinyl ether[8] gave polymer **7** as an off-white foam which was most conveniently isolated (90%) following repeated precipitation from 1,2-dichloroethane solution with MeOH. Both ^{1}H and ^{13}C NMR spectra were consistent with polymer **7** having a 1:1 *trans*:*cis* stereochemistry.[8] Selective desilylation of polymer **7** gave the corresponding polyol **8** as a THF-insoluble precipitate which was washed with THF and Et_2O and dried *in vacuo*, whereupon ^{1}H and ^{13}C NMR spectra (acetone-d_6) indicated complete removal of the *tert*-butyldimethylsilyl residues. Alkylation of polymer **8** using MeI or 4-bromobenzyl bromide (R^1X) in the presence of NaH in THF gave the corresponding THF-soluble polymeric ethers **9** which were precipitated from MeOH. In turn, cleavage of the tetrahydropyranyl ether of **9** using TsOH in a MeOH–THF–CH_2Cl_2 (1:2:1) mixture and precipitation from THF followed by further alkylation with MeI or 4-bromobenzyl bromide (R^2X) afforded the polyethers **10** which were isolated in the same way as **9**. All polymers were isolated cleanly and with high recovery.



Scheme 2 *Reagents and conditions*: i, NaH, THF, TBDMSCl, 78%; ii, dihydropyran, cat. PPTS, CH_2Cl_2, 92%; iii, **13**, $ClCH_2CH_2Cl$, then $EtOCH{=}CH_2$ quench, 90%; iv, Bu_4NF, THF; v, NaH, THF, R^1X; vi, TsOH, MeOH–THF–CH_2Cl_2 (1:2:1); vii, NaH, THF, R^2X; viii, O_3, CH_2Cl_2, −78 °C, then EtOH, Me_2S; ix, $NaBH(OAc)_3$, R^3NH_2.

The three functionalised polymers **10** were disassembled by ozonolysis with a Me_2S work-up to reveal the corresponding dialdehydes **11** which were not isolated. Direct *in situ* reductive amination[9] with $BnNH_2$, $BuNH_2$ and (cyclohexylmethyl)amine gave the corresponding 3-aza-8-oxabicyclo[3.2.1]octanes **12** in overall yields of around 30% from the starting polymer **7**. The same nine 3-aza-8-oxabicyclo[3.2.1]octane derivatives **12** were prepared from monomer **6** by sequential double deprotection and monoalkylation, ozonolysis and reductive amination. Overall yields in these reactions were comparable (30–40%).

We have demonstrated the utility and advantage of polymer backbone disassembly for the rapid generation of small molecule targets using polymer **7**. Advantages include ease of intermediate purification and facile reaction monitoring. The modification of polymer **7** for library construction with different chemistry is ongoing and will be reported in due course.

We thank Rhône-Poulenc Rorer for the most generous support of our programs on parallel and combinatorial syntheses under the auspices of the TeknoMed project. In addition we thank GlaxoWellcome Research Ltd. for their endowment (to A. G. M. B.), the Royal Society for a Dorothy Hodgkin fellowship (to M. L. S.), the EPSRC for a studentship (to Z. E. T.), Professor Vernon Gibson (for the kind donation of Grubbs catalyst **13**) and the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

Received (in Cambridge, UK) 3rd August 1998, Accepted 2nd October 1998

Density functional theory (DFT) calculations for the crystal structures of polymorphs of the glycine zwitterion are reported; with unit cell parameters constrained at experimentally determined values, energy minimized configurations for three known glycine polymorphs are in good agreement with crystallographically determined structures, and the calculated energies are in qualitative agreement with observed lattice stabilities.

Molecular orbital calculations, employing Hartree–Fock,[1] density functional theory (DFT),[2] or even an appropriate combination of both methods[3] are standard techniques for the structural and energetic description of molecular systems. Significant developments have also recently taken place in the use of first principles methods to represent ionic and covalently bound periodic systems, such as silicon and zeolites, typically employing plane-wave and plane-wave/pseudo-potential approaches.[4–7] However, the simulation of molecular solids using first-principles methods has received considerably less attention[8] and the use of such methods to address the relative energies of crystal polymorphs less still. The lack of suitably refined protocols underlies this comparatively low level of application. Nevertheless, the results presented here show that such calculations are now within the compass of contemporary quantum mechanical methods and computational resources.

To explore the ability of periodic DFT method calculations to describe molecular crystals, calculations were conducted targeting the known polymorphic structures of the glycine zwitterion and using DMol[3].[9–11] The level of theory employed has been shown to be effective in the description of isolated molecules.[12]†

Initial investigations addressed the selection of a suitable quantum mechanical Hamiltonian and basis set. These calculations employed the β-glycine polymorph, which possesses a unit cell containing two symmetry related molecules and a total of 20 atoms.[13] Here results for the BLYP[14–17] functional are summarized. A minimal basis resulted in a 0.34 Å RMS deviation between minimized and observed structures, a double numeric basis (0.33 Å), a double numeric basis with polarization functions on heavy atoms (0.22 Å) and double numeric basis with polarization functions on all atoms (0.21 Å). Of the basis sets sampled then, optimal structural agreement is achieved on full geometry optimization with a so-called double numeric basis set with polarization functions on all atoms (DNP). The DNP basis set has been demonstrated to provide an efficient route to molecular polarizabilities and charge distributions as a result of its reasonable representation of the tail of the wavefunction.[10] However, the ability of this computational approach to describe the relative energetics of polymorphic crystal structures is perhaps of more interest.

To address the calculation of such relative polymorph energies, crystallographically determined structural starting models for α- and γ-glycine were employed.[18,19] As an additional test of the simulation protocol two incorrectly packed arrangements of glycine molecules were used as starting points; S1, containing four molecules in the unit cell dimensions of the α-polymorph, and S2, containing two molecules with cell dimensions of the β-polymorph.

Table 1 The relative BLYP energies, per glycine molecule, of the α-, β- and γ-glycine polymorphs. Also tabulated are the relative energies of hypothetical packing arrangements S1 and S2 and the root mean squared (RMS) displacements between the experimental structure and energy minimized structure

	Polymorph				
	α	β	γ	S1	S2
Energy/kcal mol^{-1}	0.0	2.3	2.0	5.8	15.9
RMS/Å	0.19	0.21	0.30	0.33[a]	1.20[a]

[a] RMS between starting and energy minimized structure.

Energetic results for the systems considered are collected in Table 1. The similarity of the relative energies obtained in the DFT calculations for the α-, β- and γ-polymorphs is mirrored in the experimental observation that all polymorphs are formed at temperatures close to room temperature, with the α-polymorph having the greatest observed stability.[18] The energy differences obtained in the simulations are small and entropic contributions to the lattice stability have not been considered in the present calculations. The inclusion of vibrational entropy would, of course, be possible with increased computation times through calculation of the system's dynamical matrix and appropriate integration of the resulting phonon spectrum. However, the fact that the relative energies of incorrectly packed molecular arrangements S1 and S2 are higher than the observed polymorph energies is of significant interest. For the polar β- and γ-polymorph crystals such a procedure assumes that the macroscopic dipolar energy of the structures is not significant.[20,21] This appears to be a reasonable approximation.[22]

Fig. 1 shows starting structures and optimized structures for each of the polymorphs investigated. Good agreement is

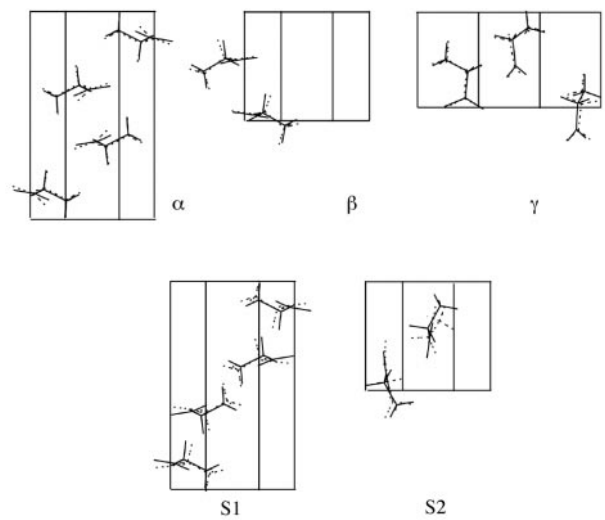

Fig. 1 Structural agreement between energy minimized (dashed line) and experimental structures (solid line) for α-, β- and γ-glycine polymorphs. Hypothetical packing arrangements S1 and S2 (dashed line) show comparison with starting points (solid line).

Table 2 Mulliken (ref. 23) derived partial electronic charges obtained with the BLYP Hamiltonian and DNP basis sets for α-, β- and γ-glycine polymorphs and hypothetical packing arrangements S1 and S2 (molecules 1 and 2). Also tabulated are partial electronic charges for an isolated molecule in the configuration of the unique molecule of the α-glycine polymorph

		Isolated molecule	Polymorph

	H4	0.137	0.200	0.174	0.147	0.198	0.196	0.184

obtained between simulation and experiment for the known crystal models. The lowest RMS displacement between optimized and experimental structure (0.19 Å) is obtained for the α-polymorph, a structure determined using neutron diffraction data with the lowest crystallographic *R* value of the polymorphs (R = 0.032).[19] The starting geometries of incorrectly packed arrangements, S1 and S2, are altered by the optimization procedure to a greater extent than the observed polymorphs. In neither case do the resulting structures resemble the experimental polymorph structures.

For S1 the structural deviation has an RMS value of 0.33 Å implying that, in this case, energy minimization is able to locate a stationary point in the vicinity of the starting structure. S1 was generated using the unit cell and asymmetric unit of the α-polymorph and applying the symmetry operations of the $P2_1/c$ spacegroup. This procedure yields a packing configuration similar for half the molecules to that of the α-polymorph (spacegroup $P2_1/n$). For S2 larger structural changes are evident in both the RMS displacement (1.2 Å) and in Fig. 1. This polymorph was generated by randomly placing two molecules within the cell of the β-polymorph.

The present calculations employ the experimental unit cell dimensions as a constraint. This reduces computation times through a reduction in the number of variables used to describe the system. However it is important to note that cell parameter data, through indexed powder diffraction patterns, are among the most readily obtained structural information for solid state materials. The current calculations, which focus on the optimization of the geometry within the unit cell, provide valuable information that augments experimental observation and leads to the full description of the crystal.

The magnitudes of partial charges are key to the accuracy of models employing classical mechanics. Table 2 collects the Mulliken[23] charges for each of the atoms of the glycine molecule in the calculations conducted. The calculations are performed within a $P1$ triclinic simulation cell. However, for the α-, β- and γ-polymorphs symmetry is maintained during the optimization, hence charges are reported for a single molecule only. S1 was produced with the $P2_1/c$ spacegroup and also has four equivalent molecules, one of which is listed. For S2, symmetry is not present and charges for both molecules are listed. Interestingly for the experimental polymorphs there is little difference between the atomic partial charges obtained, despite the differences in local environment that each crystal form necessarily imposes on its constituent molecules. For the hypothetical packing arrangements S1 and S2, differing charge distributions are exhibited on several atoms, most notably O1, O2 and N. Also tabulated in Table 2 are gas phase derived atomic charges using the same basis set and Hamiltonian for the structure of the unique molecule of the α-polymorph. The magnitude of charges on oxygen and nitrogen atoms of the isolated molecule are lower than in the crystal structure calculations. The unambiguous definition of atomic partial charges from supplied molecular orbitals is not straightforward.[24,25] In particular Mulliken analysis is sensitive to the choice of basis set. However, these findings, using a particular charge definition method[23] and uniform basis set and calculation type, indicate that the practice of transferring partial charges from gas phase calculations to the condensed phase may lead to an inaccurate description of the charge distribution exhibited by molecules in the crystalline state. Of course, no such ambiguity affects the first-principles calculations where charge density and its variation with environment are both consequences of the molecular orbitals obtained in the solution of the Schrödinger equation.

The calculations demonstrate that energy minimization leading to a determination of the relative energetics of molecular crystals is practical using first principles methods.‡

Notes and references

† The Brillouin zones of the polymorphs were sampled at the Γ point only. A detailed report on the effect of the choice of Hamiltonian and basis set on the structures and energies for molecular solids is in preparation. Geometry optimization (varying all atomic coordinates within the fixed cell) required calculation times of a few days on a single processor of an Origin 200 SGI (180 MHz) workstation.

Received (in Cambridge, UK) 4th August 1998, Accepted 6th October 1998

A flavin–oligonucleotide conjugate forms a stable triple helix with a double-stranded DNA sequence of HIV-1, and selectively photocleaves it at the 3′-G of a GG doublet located 7 bases away from the flavin position.

Oligonucleotides can be used as selective inhibitors of gene expression.[1] Binding to double-stranded DNA results in short triple helix formation which can block transcription.[2] Moreover, attachment to the oligonucleotide of a reactive group that can irreversibly damage the target DNA in a site-specific fashion should potentiate the inhibitory properties of the oligonucleotide.[2,3]

As a substituent of triple helix forming oligonucleotides (TFOs), flavins such as riboflavin **1** (vitamin B2, Fig. 1) have the advantage of displaying low toxicity and might be activated *in vivo* by diaphorases to produce oxygen species to damage a DNA target.[4] Flavin–TFOs might also be useful tools for *in vitro* studies: riboflavin is one of the most efficient natural photosensitizers, and has previously been shown to induce DNA oxidation[5] and selective RNA cleavage.[6] Upon irradiation, netropsin–flavin conjugates are sequence-specific DNA-cleaving molecules,[7] and flavin–peptide conjugates are able to repair a cyclobutane uracil dimer incorporated into an oligonucleotide.[8] Here, we show that flavin–oligonucleotide conjugates selectively photocleave a double stranded DNA target present in the HIV-1 genome and display original DNA photosensitisation properties.

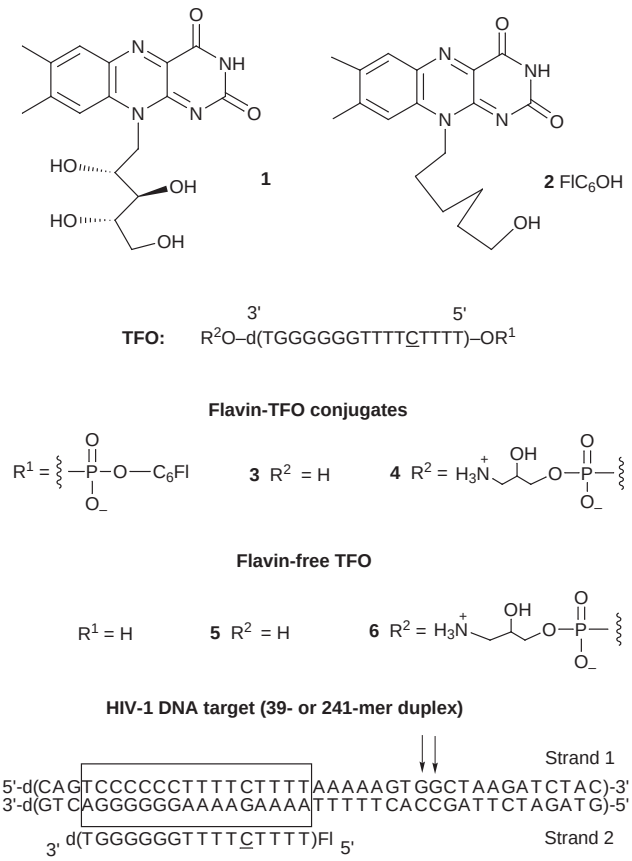

Fig. 1 Structures and sequences (phosphodiester linkages). d(C): 5-methyl-2′-deoxycytidine; DNA target: PPT sequence in a 39 or 241 base pair duplex present in the HIV-1 genome. The arrows indicate the sensitive GG doublet.

The flavin–TFO conjugates **3** and **4** (Fig. 1) were prepared as previously described.[9] The selected 16-mer TFO sequence has been previously shown to allow triple helix formation with duplexes containing the sixteen consecutive bases of the polypurine tract (PPT, Fig. 1) of the HIV-1 genome.[10] The target duplex was obtained from a 241-mer PCR fragment cloned into a pGEM-3Z plasmid. That the triple helix, formed upon hybridisation of the flavin–oligonucleotide conjugate **4** or the corresponding oligonucleotide **6** to the target duplex, was located as predicted was shown from footprinting experiments (data not shown). The protection of the whole PPT sequence of the 241 base pair fragment from hydrolysis by DNase I increased with increased amounts of both oligonucleotides. It should be noted that only the flavin–TFO conjugate **4** gave rise in the absence of irradiation to a large cleavage enhancement selectively at the guanine residue located 7 bases downstream of the triplex-duplex junction. This could be due to a local deformation of the duplex specifically induced by the flavin–TFO.

Triplexes were irradiated for 60 min with UV light and both strands of the target were analyzed by electrophoresis. The observed photocleavage was highly selective as it occurred exclusively on strand 1 and at the closest DNAse I-sensitive GG sequence, located 7 bases downstream of the triplex–duplex junction (Fig. 2, lane 13). No cleavage on strand 2 could be detected in spite of the presence of a GG sextuplet. With the free flavin **2**, alone (lane 7) or in the presence of the flavin-free TFO **6** (lane 11), the photocleavage occured at all G multiplets. No cleavage was observed with the flavin-free TFO (lane 9).

In all cases, irradiation was absolutely required as no reaction occured in the dark (lanes 6, 8, 10, 12). It is interesting to note that the flavin system is very photoreactive; a low intensity light source is able to induce the cleavage (365 nm, 5 mW cm^{-2}, 100 W UV or desk lamp). DNA cleavage was monitored by gel electrophoresis after removal of the major part of spermine by precipitation. Reaction yields were found to depend on the heating time before electrophoresis in the presence of urea (pH 8), suggesting that base damage was heat-labile. Whereas only 25% of the target was cleaved after 3 min heating at 90 °C, the yield was greater than 50% after 30 min heating. Further treatment with 1 M piperidine at 90 °C for 30 min did not increase this yield significantly.

To further characterize the reaction, we used 39-mer oligonucleotides as the target duplex containing the PPT sequence (Fig. 1). Again, a remarkably time- and light-dependent selective cleavage was obtained, with the labile site almost exclusively located at the 3′-guanine of the 5′-GG-3′

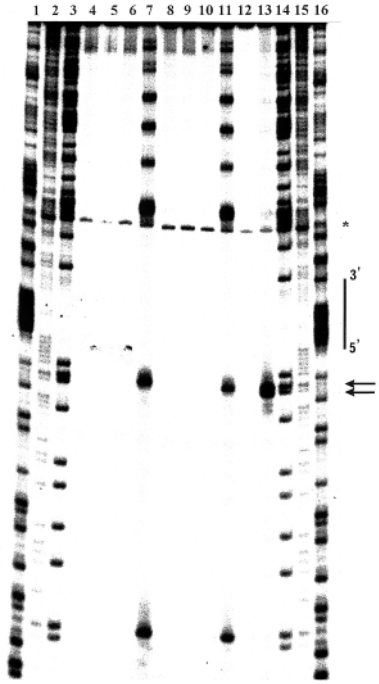

Fig. 2 Phosphoimager picture of a 12% denaturing polyacrylamide gel showing the cleavage products of a 241 base pair duplex DNA target (10 nM, Fig. 1), labeled on strand 1 at the 3′-end, alone (lanes 4,5) or incubated with 10 μM of the flavin **2** (lanes 6,7), the flavin-free TFO **6** (lanes 8,9), both **2** and **6** (lanes 10,11) or the flavin–TFO conjugate **4** (lanes 12, 13). Irradiated samples (lanes 5, 7, 9, 11, 13) are compared to dark samples (lanes 4, 6, 8, 10, 12). Sequencing reactions: T (lanes 1, 16), [G+A] (lanes 2, 15), G (lanes 3, 14). Hybridisation: overnight at room temperature, 20 mM Tris, pH 6.8, 5 mM $MgCl_2$, 0.25 mM spermine, 0.5 μg ml^{-1} of calf thymus DNA; irradiation (365 nm): 1 h at 4 °C, precipitation in EtOH and then heating in urea (7 M, pH 8, 10 mM Tris, 1 mM EDTA) at 90 °C for 5 min. The vertical line shows the presumed position of the flavin–TFO with the flavin moiety at the 5′-end. The arrows show the unique site of damage in the case of **4**. The starting DNA material contained one contaminant (asterisk).

sequence of the target (data not shown). Longer irradiation times also generated a minor amount of cleavage at the 5′-guanine. While alkaline treatment did not significantly affect gel profiles, treatment of the irradiated samples with the enzyme formamidopyrimidine-DNA glycosylase (Fpg) before electrophoresis revealed a second type of damage. The latter, most likely due to the formation of 8-oxo-7,8-dihydro-2′-deoxyguanosine (8-oxodGuo),[11] was detected exclusively at the 5′-guanine of the same sensitive 5′-GG-3′ sequence (data not shown).

Similar results were obtained with the flavin–oligonucleotide conjugate **3**. These results provide the first indication of the potential of flavin–oligonucleotide conjugates as selective DNA photocleaving agents. Cleavage of a viral target occured at only one GG site among 26 G multiplets present in the duplex target (with a total of 111 G). It is likely that the observed DNA damage is the result of electron transfer from guanine to the photoexcited flavin acceptor,[12] in agreement with GG doublets being the most efficient donors.[13] In addition to this high selectivity, this system displays several original features which have yet to be understood: (i) both the 3′- and 5′-G of the GG doublet are damaged while previous studies indicated a higher sensitivity for the 5′-G,[13] and (ii) the reactive doublet is several bases away from the presumed flavin site. Whether the reaction is made possible by a local bending of the HIV DNA in the proximity of the PPT boundary, thus allowing a direct interaction between the flavin and the GG doublet (direct H-abstraction from the sugar or electron transfer), or by a long-range electron transfer[14] is a fascinating question which remains to be elucidated.

We thank Jacques Laval for the gift of Fpg, and financial support from Agence Nationale de la Recherche sur le SIDA (ANRS) is gratefully acknowledged.

A novel metalorganic route for the direct and rapid synthesis of monodispersed quantum dots of indium phosphide

Mark Green and Paul O'Brien*

Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: p.obrien@ic.ac.uk: Fax No., 0171-594-5825

Received (in Cambridge, U.K.) 14th August 1998, Accepted 2nd October 1998

Nanometric particles of InP are readily prepared by the decomposition of the complex $In(PBu^t_2)_3$ at 167 °C in 4-ethylpyridine; the resulting materials show marked quantum confinement effects, and was investigated using optical absorption and photoluminescence spectroscopies, and transmission electron microscopy.

There is considerable current interest in the synthesis of compound semiconductors as isolated particles with dimensions of the order of nanometers.[1] Such materials are small enough to show quantum confinement effect and the electronic properties of the material depend on the size of the particles. The majority of work to date has concerned on II–VI materials[2] which are for many reasons easier to prepare than III–V or II–V semiconductors.[3] Initial attempts to prepare III–V materials focused on the reaction of separate sources in a high boiling point solvents[4] or an electrospray method.[5] However, the properties of the materials were somewhat disappointing. Recently better quality materials have been prepared by thermolysis reactions in TOPO (tri-*n*-octylphosphine oxide), an adaptation of the highly efficient route first described by Murray *et al.* for the preparation of CdSe from dimethylcadmium and tri-*n*-octylphosphine selenide.[2] These methods for III–V TOPO capped quantum dots were initially developed by Micic *et al.*[6,7] and have been further exploited by Alivisatos and co-workers[8,9] and materials with near band edge luminescence have been prepared. However, the methods used fairly ill-defined precursor systems such as an aged solution of $InCl_3$–TOPO in reaction with neat $E(SiMe_3)_3$ (E = As, P). Growth and annealing to form the final crystalline material can take up to a week (at 250 °C) and the resulting product is polydispersed and contaminated with In_2O_3 waste material

We have recently succeeded in using the phosphide compound $[MeCdPBu^t_2]_3$[10] for the preparation of high quality samples of nanocrystalline Cd_3P_2,[11] and have now developed the use of related compounds for the synthesis of III–V materials. We report here, the use of a single molecule precursor in the 'one pot' preparation of nanometric InP quantum dots.

The problems encountered in the synthesis of III–V dots can in part be attributed to covalent nature[3] of the semiconductor and the related effect of strong precursor–solvent interactions. In these systems, nucleation and growth tend to be high temperature processes and temporal separation of the two is difficult, the resulting products are hence often polydispersed and amorphous. The use of a reactive single-source precursor overcomes this problem.

The single source precursor $In(PBu^t_2)_3$ was prepared as described by Jones and coworkers, by reacting $InCl_3$ with 3 equiv. of $LiPBu^t_2$ in hexane.[12] Decomposition to InP was effected by reflux in 4-ethylpyridine (20 ml) for 0.5 h (167 °C, 0.4 g, 0.7 mmol).

$$In(PBu^t_2)_3 \xrightarrow{\text{heat}} \text{Q-InP}$$

Addition of a non-solvent (light petroleum) resulted in flocculation of the InP quantum dots. The powder was then redispersed in either pyridine or 4-ethylpyridine and centrifuged to remove waste material, an optically clear solution of nanoparticles resulted. At this point, addition of excess non-solvent produces a nanodispersed powder of the semiconductor. Electronic spectroscopy of this material showed a band edge of 1.92 eV, as determined by the direct band gap method[13] with an excitonic shoulder at *ca.* 2.72 eV (455 nm), a significant blue shift from the bulk band gap of 1.27 eV.[14] Luminescence spectroscopy shows strong broad near band edge luminescence with λ_{max}. at 2.32 eV (534 nm) (Fig. 1) slightly red shifted from the absorption. Size fractionation has little effect on band edge, indicating the system is highly monodispersed. The sample consists of a large number of relatively monodispersed dots, with an average diameter of 7.24 ± 1.24 nm which is easily observed in TEM experiments (Fig. 2).

This work clearly shows that the use of defined precursors has potential in the preparation of high quality quantum dots. Indeed, the presently reported procedure is both simpler and

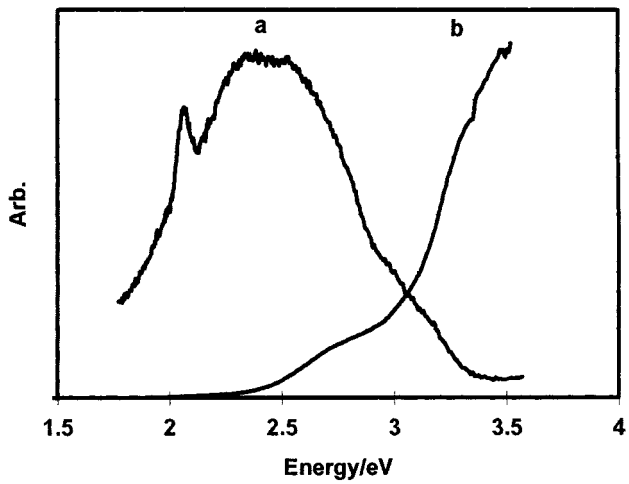

Fig. 1 Luminescence (a) and UV (b) spectra of Q-InP synthesised at 167 °C. Feature at *ca.* 2 eV is a second order excitation (λ_{exc} = 300 nm).

more rapid than those known to date. Work on other III–V materials is continuing in our laboratory and preliminary results have been obtained which show that organically passivated GaP and InAs can be prepared by related methods.

We thank Keith Pell (Basic Medical Science, QMW, University of London) for TEM and SEM work. Paul O'Brien is the Royal Society Amersham International Research Fellow and the Sumitomo/STS Professor of Materials Chemistry. We thank the EPSRC for grants supporting work on single molecule precursors for quantum dots. M.G. thanks the EPSRC for a studentship and BT for CASE support.

Morphological control of ordered mesoporous silica: formation of fine and rod-like mesoporous powders from completely dissolved aqueous solutions of sodium metasilicate and cationic surfactants

Shoichiro Shio,*[a] Asa Kimura,[a] Michihiro Yamaguchi,[a] Koichi Yoshida[a] and Kazuyuki Kuroda[b]

[a] *Shiseido Basic Research Laboratories, 1050 Nippa-cho, Kohoku-ku, Yokohama-shi, 223-8553, Japan. E-mail: shio_shoichiro@po.shiseido.co.jp*

Received (in Columbia, MO, USA) 1st May 1998, revised manuscript received 18th September 1998, Accepted 23rd September 1998

Fine and rod-like silica-based mesoporous powders with very short diameter and length have been obtained through (1) the complete dissolution of both sodium metasilicate and cationic surfactants and (2) subsequent rapid pH-adjustment for the formation of silica-surfactant mesophase products.

There has been much interest on ordered mesoporous silica molecular sieves because of their large pore sizes with narrow pore size distributions, thermal stability, *etc.*[1–4] It is now apparent that the morphological control as well as handling and texture of mesoporous silica is extremely important in industrial applications. Silica-based mesoporous molecular sieves can be applied to the adsorption and release of moisture and/or lipid components and can be utilized as an adsorbent of perfume, if they are available as minutely sized powders, which is important in the cosmetic industry.

There have been several reports[5–15] which describe methods to control the shape of powders. Rod-like powders were prepared by controlling the surfactant-water content, the concentration of aluminium species, and the condensation rate of silica in the reaction system[7–9] or by bacterial templating.[10] Schacht *et al.* controlled the shape of powders by changing the condensation rate of silica in the phase boundary of O/W emulsion particles and furthermore they obtained individual hexagonal mesoporous silica fibers.[11,12] Precise morphological control of ordered mesoporous powders, in particular, controlling the length of mesopores has not yet been achieved by the procedures described above. The present method is a simple combination of (1) the use of a completely clear solution of both sodium metasilicate and surfactants at low concentrations and (2) rapid pH adjustment (from 13 to 8.5) for the formation of silicate–surfactant mesophase products. Lin *et al.* reported the formation of rod-like mesoporous powders by using a clear surfactant solution and by adjusting the pH value of the final mixture to *ca.* 10 followed by heat treatment at 100 °C for 48 h.[7–9] However, the uniqueness of the present method is the utilization of a clear solution containing both silica species and surfactants and subsequent pH adjustment to 8.5, resulting in instant gel formation, without further heat treatment.

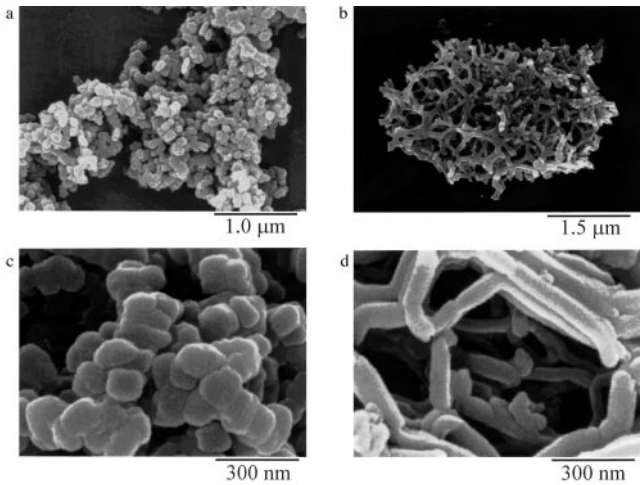

Fig. 1 Field emission scanning electron microscopic (FE-SEM) images of calcined mesoporous powders (Hitachi S-4500, acceleration voltage 15 kV). (a) Fine mesoporous powder (C_{18}-product) (magnification; ×20 000), (b) fine mesoporous powder (C_{18}-product) (magnification; ×100 000), (c) rod-like mesoporous powder (C_{22}-product) (magnification; ×30 000), (d) rod-like mesoporous powder (magnification; ×100 000).

Fine ordered mesoporous powders (C_{18}-product), which have a pore length of *ca.* 100 nm and a particle diameter of *ca.* 100 nm, were synthesized by using stearyltrimethylammonium chloride. Rod-shape ordered mesoporous powders (C_{22}-product), which have a pore length of *ca.* 300 nm and a diameter of *ca.* 50 nm, were also synthesized using behenyltrimethylammonium chloride.

Stearyltrimethylammonium chloride [$C_{18}H_{37}NMe_3Cl$] (STC) (Wako Chemical) and behenyltrimethylammonium chloride [$C_{22}H_{45}NMe_3Cl$] (BTC) (Toho Kagaku) were used in this study. Sodium metasilicate (0.5 mol, Nakarai Tesuku) and STC or BTC (0.1 mol) were dissolved in 1.0 dm^3 deionized water at 70 °C. White precipitates appeared when the pH value of the clear aqueous solution was adjusted to 8.5 by 2 M HCl within 3–5 min at 70 °C. The precipitates after the pH-adjustment were filtered at once, washed five times with water and once with acetone, and dried at room temperature for 12 h. To remove organic materials, the complexes were calcined at 700 °C in air for 5 h.

Powder XRD (JDX 3500 diffractometer) peaks of the C_{18} and the C_{22}-product show four peaks corresponding to (100), (110), (200) and (210) of a hexagonal array, being much broader than those reported for MCM-41 and FSM-16. The *d*-spacings (d_{100}) in the powder XRD patterns of the C_{18}-product before and after calcination were 4.1 and 3.8 nm, respectively. The d_{100} values of the C_{22}-product before and after calcination were 4.8 and 4.3 nm, respectively.

Typical morphologies of the calcined products are shown in Fig. 1. The FE-SEM image at high magnification of the calcined C_{18}-product [Fig. 1(b)] shows fine particles with rounded corners and *ca.* 100 nm diameter.

The morphology of the C_{22}-product is rod-like (*ca.* 50 nm in diameter and 300–500 nm in length) [Fig. 1(d)]. The powders have much shorter diameters and lengths than those of rod-like mesoporous powders reported previously,[7,12] and the rod-like powders formed a 3D-network structure. These results clearly show that the shape of powders can be controlled by a change in alkyl chain lengths of the surfactants.

TEM images (Fig. 2) of the calcined C_{18} and C_{22}-product also clarify the uniqueness of the powders. All the images of the C_{18}-product show ordered mesophases of *ca.* 100 nm in length [Fig. 2(a) and 2(b)]. Because such very short channels reduce the flow time of guest molecules in the mesoporous channels, the C_{18}-product should be an excellent reaction medium for organic substances. The TEM image of the C_{22}-product shows a rod-like shape which has a limited number of channels [Fig. 2(c)].

The N_2-adsorption isotherms (Micromeritics ASAP 2400) of the C_{18} and C_{22}-product showed typical behavior of ordered mesoporous silica. The C_{18} and C_{22}-product have BET specific surface areas of 1050 and 900 $m^2\ g^{-1}$, and pore diameters of 3.0 and 3.5 nm (BJH method), respectively. In addition to the mesopores, the calcined C_{22}-product had a broader range of pore size distribution of 30–100 nm, arising from the 3D network structure of the rods. This finding affords us an additional larger range of pores indicating a short-range hierarchical mesoporous structure. The total pore volumes including mesopores and macropores of the calcined C_{18} and C_{22}-product were 1.3 and 2.8 ml g^{-1}, respectively. Although the specific surface area of the C_{22}-product was a little lower than that of the C_{18}-product, the total pore volume of the C_{22}-product was approximately twice that of the C_{18}-product, which is due to the network formation of rod-like mesoporous powders.

The a_0 values of hexagonal structure [$a_0 = 2d_{100}/\sqrt{3}$] of the calcined C_{18}- and C_{22}-product were 4.4 and 5.0 nm, respectively. The wall thicknesses of these mesoporous materials are estimated from the a_0 values and the pore diameters. Although the calcined C_{22}-product has a different shape from the calcined C_{18}-product, the wall thicknesses for each showed very similar values (*ca.* 1.5 nm). This result suggests that the C_{18} and C_{22}-product were obtained *via* the same formation mechanism.

Because both sodium metasilicate and the surfactants are dissolved completely in water at 70 °C, the surfactants form micelles and silicate ions adhere on them. The shape of surfactant micelles is controlled by several complex factors including (1) the concentration of surfactants, (2) the alkyl chain lengths of surfactants, (3) the concentration of formed salts by adding HCl, and (4) the concentration of silicate species for which the ionic charge varies with pH. Since an increase of the aggregation number of micelles in salt–surfactant solution has been reported,[16] the possible increase of aggregation number (which induces the formation of rod-like micelles) is speculated to be due to silicate ions which can play the role of a salts and the shape of micelles will change from spherical to rod-like. Silicate ions show two condensation steps which depend on the pH of the solution. The first step is the condensation of silicate ions on micelles and the second is the condensation between polymerized silicate species adsorbed on each micelle.[17] The second step gives self-assembled materials with hexagonal structure. Rapid pH adjustment (< 3–5 min) prevents further aggregation of the mesophase, since condensation of silicate ions occurs instantly and uniformly in the solution.

The shape of mesoporous powders is thought to be controlled by the competition between the rate of change in the shape of the surfactant assemblage (from rod-like to spherical by pH adjustment) and the condensation rate of silicate ions during the pH adjustment. If the condensation rate of silicate ions is faster than that of the change in the shape of the surfactant assemblage, the shape of the surfactant does not change markedly, therefore, the shape of the product should conform to the long rod-like shape of the micelles.

Because BTC, with longer alkyl chains, can lead to a longer assembled state relative to STC, the formation of a rod shape of the C_{22}-product is speculated to be due to the faster condensation rate of silicate ions than that of the structural change of the micelles. The same reaction pathways are expected for the system with STC, and the appearance of the C_{18}-product strongly suggests shorter assembled states of STC in aqueous solution.

The authors express their gratitude to Dr N. Ueno (Shiseido Laboratories) for fruitful discussion and his critical reading of this manuscript.

An organotemplated vanadium(IV) borate polymer from boric acid 'flux' synthesis, $[H_2en]_4[Hen]_2[V_6B_{22}O_{53}H_8]\cdot 5H_2O$

Ian D. Williams,* Mingmei Wu, Herman H-Y. Sung, X. X. Zhang and Jihong Yu

Departments of Chemistry and Physics, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong, China. E-mail: chwill@ust.hk

Received (in Cambridge, UK) 28th July 1998, Accepted 25th August 1998

A new 1-D inorganic chain polymer $[H_2en]_4[Hen]_2[V_6B_{22}O_{53}H_8]\cdot 5H_2O$, consisting of $[V_6B_{20}O_{50}H_6]$ cluster subunits linked together through diborate bridges, has been synthesised with high yield and purity by a molten boric acid 'flux' method in which V_2O_5, en and H_3BO_3 (1 : 6 : 25) were heated together at 180 °C for 3 days; the clusters have a central band of six square-pyramidal V^{IV}=O vanadyl groups, which are capped top and bottom by two raft-like polyborate ligands of formula $[B_{10}O_{16}H_3]$.

There has been much recent interest in mixed organic–inorganic materials, especially for the formation of new microporous materials such as metal phosphates.[1,2] For these phosphoric acid is used commonly as a precursor with a variety of basic metal sources and organic templates. Since the discovery of various microporous aluminoborates by Xu and coworkers[3,4] we have been interested in the use of boric acid as a possible reagent in place of phosphoric acid to assist formation of microporous transition-metal borates. Whilst use of H_3PO_4 and H_3BO_3 in tandem can result in the formation of hybrid borate–phosphate phases,[5,6] recently Haushalter *et al.* have shown that hydrothermal reaction of vanadium oxides with boric acid can give rise to novel mixed-valence vanadium borate clusters.[7,8a] Yamase *et al*. have also reported a similar vanadoborate.[8b]

Herein we report that use of molten boric acid as flux can lead to other boron-rich cluster phases and even allow the direct connectivity of such clusters to novel inorganic polymers by additional borate bridges. Furthermore the reaction products are not only different from analogous hydrothermal syntheses, but they are typically of higher purity and yield. This becomes important for strategies in which the formed clusters are to be used as synthetic intermediates.

We find that flux reaction of V_2O_5 with 6 mol equiv. of ethylenediamine (en) and 25 H_3BO_3 at 180 °C for 3 days results in the formation of an off-white crude solid. Removal of the residual boric acid through washing with cold water allows isolation of pale-green block-shaped crystals of **1** as a phase-pure material in *ca.* 75% isolated yield based on V. X-Ray powder diffraction shows three strong peaks of approximately 1 : 2 : 1 intensity ratio with *d*-spacings of 11.2 (200), 10.6 (112) and 10.1 (112)/(004) Å respectively. We have found such peaks in the region of 10 Å *d*-spacing to be characteristic of vanadyl polyborate cluster materials and a useful diagnostic tool.[9]

A single crystal X-ray structure analysis† reveals the structure of **1** to be $[H_2en]_4[Hen]_2[V_6B_{22}O_{53}H_8]\cdot 5H_2O$ consisting of an anionic vanadium polyborate chain polymer, together with $(H_2en)^{2+}$ and $(Hen)^{+}$ counterions and five waters of solvation. The polymer has $[V_6B_{20}O_{50}H_6]$ cluster subunits linked together by linear diborate $[B_2O_3H_2]$ bridges. A portion of the polymer chain is shown in Fig. 1.

The clusters have a central band of six square-pyramidal V^{IV}=O vanadyl groups, which are capped top and bottom by two novel raft-like polyborate ligands of formula $[B_{10}O_{16}H_3]$. The charge and oxidation state of the metals and degree of protonation are often difficult to resolve in such structures, however bond valence sum calculations[10] clearly indicate a charge of V^{4+} for each vanadium centre. The six V=O distances of the asymmetric unit range between 1.607 and 1.618(4) Å and the 24 basal V–O distances from 1.945 to 1.973(4) Å. The pale-green colour is also supportive of the purely V^{IV} formulation and is in contrast with the previous findings of Haushalter and Zubieta of orange, red and dark-green mixed V^{IV}–V^{V} clusters.[7,8] All cluster hydrogens were located in difference Fourier maps and were found to be involved in short [B–OH···O] hydrogen bonds with O···O separations≤2.8 Å. In addition, the formulation of the organic counterions was facilitated by the clear observation of four [N–H···N] hydrogen-bond contacts per asymmetric unit of less than 3.0 Å. This means that both fully protonated and partially protonated ethylenediamines must be present, although there is statistical disorder of the protons on each side of the H-bond double wells.

The toroidal arrangement of square-pyramidal vanadyl groups has each neighboring V atom in an edge-sharing arrangement. All V–V internuclear separations are essentially equivalent and between 3.029 and 3.059(2) Å, indicating there is no significant pairing of V centres to form individual V–V bonds, but rather the contacts are consistent with some weak delocalised metal–metal bonding character, through use of d(*xy*) orbitals. In the crystal structure of **1** all polymer chains run parallel to the *b*-axis; studies are being undertaken to investigate the magnetic behaviour of the polymer.

In addition to the discovery of novel magnetic properties, our original goal was to make new classes of microporous materials. The use of cluster subunits is very attractive in this regard since their large size means that even their close packing must allow for significantly large cavity formation. A number of open-framework molybdenum phosphates with cluster subunits have been reported[11,12] and recently an organically templated Fe-PO was recently synthesised by Lii in which large channels are found since Fe_4 cluster subunits are involved.[13]

Formation of the 1-D polymer **1** is also suggestive that useful materials either for magnetic or porous properties might be formed by connecting metal polyborate clusters together *via* suitable cross linking agents. For this purpose however, a synthetic preparation of the structural building block is necessary. Through modification of the flux conditions, we have now isolated a second compound **2**, which contains the cluster building block from **1.** Thus reaction of V_2O_5 : en : H_3BO_3 in the ratio 1 : 2 : 8 at 180 °C for 3 days affords **2** as pale-green bar-shaped crystals in virtually quantitative yield based on V. From these conditions it is essentially phase-pure based on optical examination and powder X-ray diffraction, for which

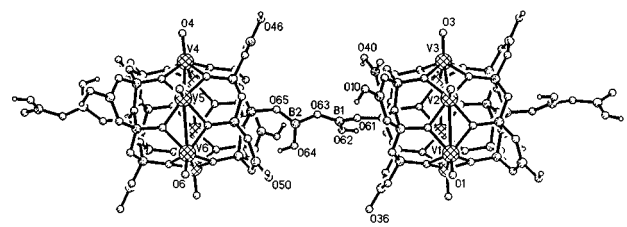

Fig. 1 Structure of **1**, showing a portion of the $[V_6B_{22}O_{53}H_8]_n$ polymer chain.

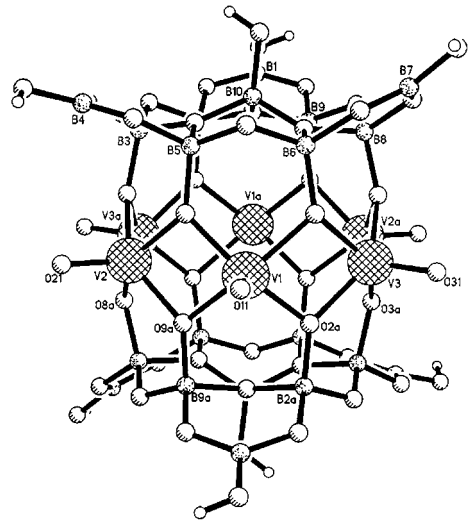

Fig. 2 Side view of the $[V_6B_{20}O_{50}H_8]$ cluster anion of **2**.

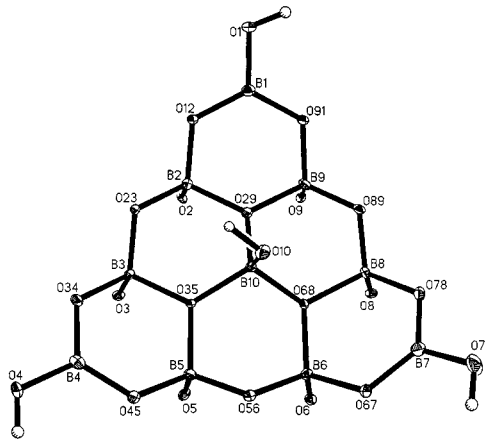

Fig. 3 Raft-like $[B_{10}O_{16}H_4]$ ligand from **2**.

there are 3 different characteristic *d*-spacings of 11.6 (010), 10.6 (001) and 9.8 Å (100)/(101) with an approximate 2 : 1 : 1 intensity ratio.

Single crystal X-ray structure determination† shows **2** to be $[H_2en]_4[V_6B_{20}O_{50}H_8]\cdot 5H_2O$. The structure of the $[V_6B_{20}O_{50}H_8]$ cluster anion of **2** is illustrated in Fig. 2 and its condensed raft-like B_{10} polyborate ligand is shown in Fig. 3. In this case the central boron is terminated by a hydroxy group, rather than being connected to a diborate bridge as in **1**. Boric acid was also used to synthesise the interesting copper polyborate cluster $[Cu_4O\{B_{20}O_{32}(OH)_8\}]^{6-}$ from solution.[14] Although this also has a B_{20} formulation, in this compound the polyborate moiety has an open ring-like structure about a central Cu_4O core.

The crystal structure of **2** is well-ordered and all H-atoms were located in difference Fourier maps. Once more the bond valence sums give V^{4+} for all centres [V=O = 1.605–1.627(2) Å, V–O = 1.932–1.980(2) Å]. The temperature dependent magnetization was measured in a constant applied field of 1 T (MPMS-5S Quantum Design SQUID magnetometer) and indicates that the compound is paramagnetic down to 1.8 K. The calculated moment is 4.03 μ_B per formula unit. This is in contrast to the layer compound $[H_2en][V_2O_5]$ which shows antiferromagnetic coupling between adjacent edge-sharing square pyramidal V^{IV} centres at low temperature.[15] Modelling of the magnetic behaviour is being undertaken, but implies only partial pairing of the six electrons from the d^1 metal centres. We postulate that two electrons are paired in the all-bonding (in-phase) combination of vanadium d(*xy*) orbitals and that the others singly occupy the partially bonding and anti-bonding combinations to give rise to four unpaired electrons and $S = 2$ ground state for the cluster, which may explain the observed magnetic moment. EPR studies will be undertaken to confirm this hypothesis.

Whereas the polymer **1** is practically insoluble in all solvents, (except 1.0 M NaOH which destroys it), the salt **2** is sparingly soluble in hot dmf–water and affords a stable pale-green solution. In this sense it is similar to the large open polyanionic Mo_{154} molybdates and related aggregates.[16] We are now exploring the use of a facile dissolution–precipitation method for synthesis of further hybrid materials from **2**. For example, addition of Ca^{2+} ions to a saturated solution of **2** results in ready precipitation of the calcium salt of the vanadyl cluster as a fine powder.

The advantage of this two-stage synthetic approach is that the complex polyborate cluster can be formed under quite different conditions than are used for its subsequent cross-linking, affording a reasonable degree of design flexibilty. In summary, use of a boric acid flux method can give high yields of phase-pure vanadium borate materials, including both inorganic polymers and discrete cluster compounds. Synthesis of other boron-rich transition-metal phases from the boric acid melt and their potential as synthetic intermediates for formation of microporous materials is under investigation.

The authors wish to thank Mr Alvin Siu for his help with the X-ray work and the Research Grants Council of Hong Kong for financial support. (Grant HKUST 681/96P)

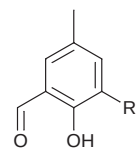
Received 10th September 1998, Accepted 5th October 1998

The EPR-silent species $[Cu(L^2)(Tp^{Ph})]^+$ exhibits a UV–VIS–NIR spectrum that is very similar to that of active galactose oxidase.

Galactose oxidase ('GOase') is a fungal enzyme that catalyses the oxidation of primary alcohols by molecular oxygen.[1] The active site of GOase contains a $[Cu(His)_2(Tyr)_2(OH_2)]$ centre, in which a basal tyrosinate ligand has been chemically modified by an *ortho*-thioether crosslink formed from a cysteine residue, and is involved in a π-stacking interaction with a neighbouring tryptophan side chain.[2] In active enzyme this modified phenoxide ligand is oxidised to a very long-lived radical,[3] whose oxidation potential is +0.40 V *vs.* NHE (compared to +0.9 V for a 'normal' tyrosine side-chain). We describe here a Cu(II) phenoxide complex containing a thioether-substituted phenoxide ligand, designed as a model for the GOase copper complex, and the spectroscopic characterisation of its Cu(II) phenoxyl oxidation product.



R = H, HL^1
R = SMe, HL^2

2-Hydroxy-3-methylsulfanyl-5-methylbenzaldehyde (HL^2) was prepared from 2-hydroxy-5-methylbenzaldehyde (HL^1)[4] by the method of Wang and Stack.†[5] Complexation of hydrated $Cu(BF_4)_2$ by HL (HL = HL^1, HL^2) and $K[Tp^{Ph}]$ ($[Tp^{Ph}]^-$ = tris-3-phenylpyrazolylborate)[6] in CH_2Cl_2 at room temperature affords dark green solutions, from which deep green microcrystals of $[Cu(L)(Tp^{Ph})]$ ($[L]^-$ = $[L^1]^-$, **1**, $[L]^-$ = $[L^2]^-$, **2**)† can be obtained in 40–45% yield after filtration and addition of a large excess of hexanes. Weakly diffracting single crystals of **2** were grown from toluene–hexanes.‡ The structure shows a square pyramidal Cu(II) centre with a N_3O_2 donor set and unexceptional metric parameters (Fig. 1).

The visible spectra of **1** and **2** in CH_2Cl_2 at 293 K each show a d–d absorption at λ_{max} = 685 nm (ε_{max} = 92–93 dm^3 mol^{-1} cm^{-1}). The X- and Q-band EPR spectra of **1** and **2** in 10 : 1 CH_2Cl_2–toluene solution at 110 K exhibit the $g_{\|} > g_{\perp} > g_e$ pattern expected of a $\{d_{x^2-y^2}\}^1$ or $\{d_{xy}\}^1$ Cu(II) ion (for **1**; $g_{\|}$ = 2.284, $g_{\perp}$ = 2.065, $A_{\|}\{^{63,65}Cu\}$ = 160 G: for **2**; $g_{\|}$ = 2.286, $g_{\perp}$ = 2.065, $A_{\|}\{^{63,65}Cu\}$ = 163 G), only one species being detected in solution for both compounds. These spectra are consistent with **1** and **2** possessing essentially identical tetragonal coordination spheres in CH_2Cl_2. Hence, in this solvent the $[L^2]^-$ ligand in **2** is coordinated *via* both O-donors, with no isomerisation to a form containing O,S-coordinated $[L^2]^-$ taking place. While the lack of observable $A\{^{14}N\}$ couplings for **1** and **2** prevents more detailed EPR studies, we have recently proven that related $[Cu^{II}(L)(Tp^{Ph})]$ (L = bidentate ligand) complexes retain their square-pyramidal solid state geometries upon dissolution in CH_2Cl_2.[7] It is therefore probable that the solution structures of **1** and **2** closely resemble those in the crystal.

The cyclic voltammogram (CV) of **2** in CH_2Cl_2/0.5 M $NBu^n_4PF_6$ at 293 K shows a one-electron couple at $E_{½}$ = +0.53 V *vs.* Fc–Fc$^+$, which is chemically reversible for 10 mV s^{-1} ≤ ν ≤ 1 V s^{-1} and which we assign to a $[L^2]^-/L^{2\cdot}$ oxidation. The observation of a chemically reversible oxidation for coordinated $[L^2]^-$ in **2** is very unusual for a phenoxide without encumbering *tert*-butyl substituents.[8] The CV of **2** also exhibits an irreversible secondary oxidation of variable broadness and intensity centered near E_{pa} = + 0.85 V, which is characteristic of partial adsorption of the initial oxidised species onto the Pt electrode;[9] and an irreversible Cu(II/I) reduction at E_{pc} = −1.29 V with associated daughter peaks at E_{pa} = −0.41 and −0.11 V.

Electrooxidation of **2** in CH_2Cl_2–0.5 M $NBu^n_4PF_6$ at 243 K at a potential corresponding to the **2**/$[\mathbf{2}]^+$ couple yields a brown solution exhibiting only a very weak residual EPR signal from

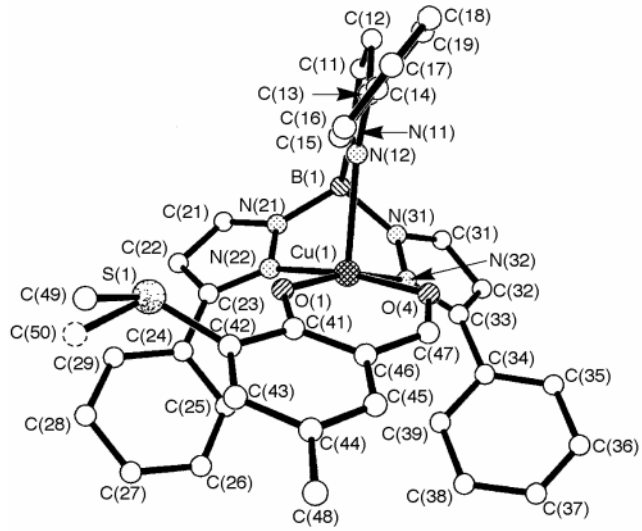


Fig. 1 View of the complex molecule in the crystal of **2**, showing the disordered thioether group. For clarity, all H atoms have been omitted. Selected distances (Å) and angles (°): Cu(1)–N(12) 2.337(6), Cu(1)–N(22) 2.009(6), Cu(1)–N(32) 1.996(7), Cu(1)–O(1) 1.941(7), Cu(1)–O(4) 1.967(5), N(12)–Cu(1)–N(22) 89.7(2), N(12)–Cu(1)–N(32) 90.0(2), N(12)–Cu(1)–O(1) 102.8(2), N(12)–Cu(1)–O(4) 98.7(2), N(22)–Cu(1)–N(32) 87.7(3), N(22)–Cu(1)–O(1) 91.5(3), N(22)–Cu(1)–O(4) 171.3(2), N(32)–Cu(1)–O(1) 167.1(2), N(32)–Cu(1)–O(4) 89.9(2), O(1)–Cu(1)–O(4) 88.9(3).

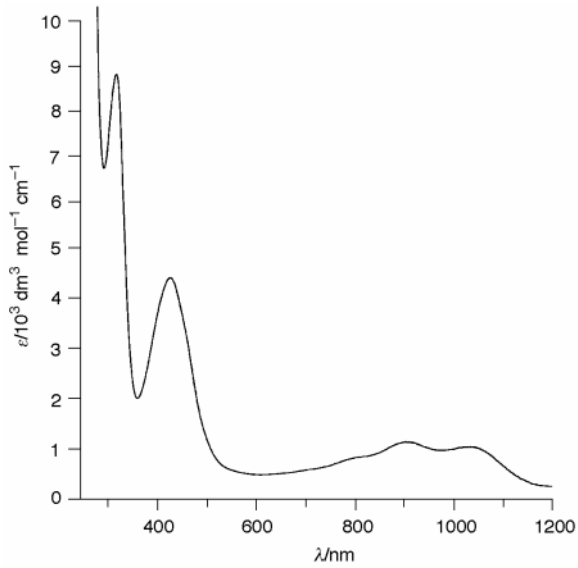

Fig. 2 UV–VIS–NIR spectrum of [**2**]$^+$ in CH_2Cl_2–0.5 M $Bu^n_4NPF_6$ at 243 K.

unreacted **2**. A similar experiment using an optically transparent electrode results in a blue-shift of the $[L^2]^-$-derived absorptions in the UV, and the ingrowth of new peaks in the visible and near-IR regions. The oxidised solution shows λ_{max} = 317 nm ($\varepsilon_{max} \approx 9\,000$ dm^3 mol^{-1} cm^{-1}), 419 (4400), 470 (sh), 725 (sh), 818 (sh), 907 (1200) and 1037 (1100) at 243 K (Fig. 2). Rereduction of this solution at 0 V results in the near-quantitative regeneration of **2**. We ascribe these observations to the generation of an EPR-silent $[Cu^{II}(L^{2\cdot})(Tp^{Ph})]^+$ species [**2**]$^+$. The **2**/[**2**]$^+$ preparative oxidation is not quite reversible, since [**2**]$^+$ decomposes with a half-life of *ca*. 10 h under these conditions; the absorption coefficients quoted above may therefore be slightly underestimated.

Other known Cu(II) phenoxyl complexes, although usually also EPR-silent, give electronic spectra significantly different from [**2**]$^+$, with peaks at λ_{max} = 400–450 nm (ε_{max} = 3000–16 000 dm^3 mol^{-1} cm^{-1}) and 600–680 nm (300–8000).[10] None of these examples contains a thioether side-chain to the phenoxyl ligand, however. Active GOase exhibits two spectroscopic features attributable to the modified tyrosyl radical: a peak at λ_{max} = 444 nm (ε_{max} = 5200 dm^3 mol^{-1} cm^{-1}) and a broad absorption between 600 and 1200 nm, centred at 800 nm (3200) with several low- and high-wavelength shoulders.[11] The similarity of this spectrum to that shown by [**2**]$^+$ (Fig. 2) is striking. The VIS–NIR feature in the spectrum of GOase has been attributed to an inter-ligand charge transfer process between the tyrosyl and tyrosinate ligands.[12] However, the observation of an equivalent broad, structured band for [**2**]$^+$, which lacks a second phenoxide ligand, suggests that $\pi \rightarrow \pi^*$, MLCT and/or LMCT transitions involving the tyrosyl radical should also contribute to this absorption.

Alkanes to nitriles and α-iminoesters. Polyoxotungstate photocatalytic radical chain initiation

Zhanmiao Zheng and Craig L. Hill*

Department of Chemistry, Emory University, Atlanta, Georgia 30322, USA. E-mail: chill@emory.edu

Received (in Bloomington, IN, USA) 30th June 1998, Accepted 22nd September 1998

Irradiation of $W_{10}O_{32}^{4-}$ or $PW_{12}O_{40}^{3-}$, alkanes and methyl cyanoformate in CH_3CN solution produces either the corresponding nitriles or α-iminoesters with high selectivity, depending on the temperature, *via* a mechanism involving two roles for the polyoxotungstate.

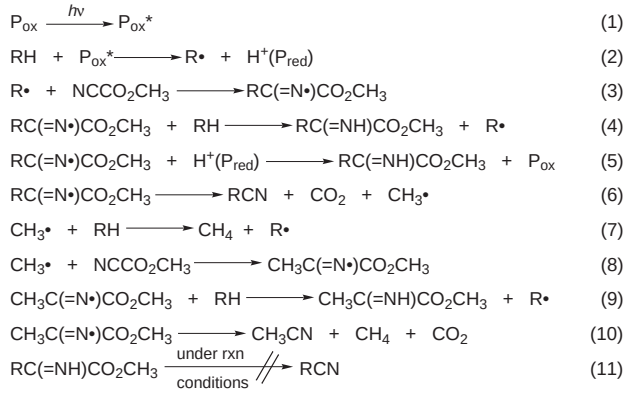
While a host of C–H bond activation or functionalization methods developed in the last few years have provided a wealth of mechanistic information and some unusual or unprecedented transformations, few of the reactions have been of significant synthetic value. Organometallic systems that activate C–H bonds rarely lead to functionalization and are usually not catalytic in the metal complex,[1–5] while more conventional radical and electrophilic systems usually have selectivity or compatibility difficulties.[4,5] We report here the first catalytic conversion of unactivated C–H bonds to two desirable groups in high selectivity: nitriles and α-imino-acetic acid esters (henceforth iminoesters) *via* polyoxotungstate photocatalysis.[6,7] Nitriles are widely used in synthesis,[8] and α-ketoesters (or acids), readily derived from hydrolysis of the iminoesters, have a rich photochemistry and could be used to render hydrocarbon materials, including polyethylene, sunlight degradable and biodegradable.[9] Nitriles have been generated in moderate to good yields *via* organic radicals generated from conventional precursors (not generated catalytically by alkane C–H bond cleavage), by trapping with *tert*-butylisocyanide,[10] or with aryl and alkylsulfonyl cyanides.[11] Alkanes photolyzed in the presence of ClCN[12] or heated with consumption of considerable conventional radical initiator (10–24 mol% benzoyl peroxide) in the presence of methyl cyanoformate also yield nitriles.[13] The latter reaction forms some iminoester but yields were not given. There appear to be no good routes to iminoesters from unactivated C–H bonds.

Irradiation (λ > 280 nm) of CH_3CN solutions of $W_{10}O_{32}^{4-}$ or $PW_{12}O_{40}^{3-}$ containing one of a variety of alkanes and methyl cyanoformate (MCF) produces the corresponding nitriles at T = 90 °C and iminoesters at T = 22 °C. Significantly, the selectivities for these products and turnovers of the polyoxotungstate vary inversely with the concentration of the polyoxometalate and selectivities approach quantitative values at [polyoxotungstate] < 0.05 mM. Table 1 gives the products from many reactions using 1.5 mM polyoxotungstate, a concentration not optimal for selectivity but one permitting by-product quantification needed for mechanism elucidation. At low [polyoxotungstate], the selectivities for nitriles (high T) and iminoesters (low T) exceed those of all literature reactions. Significantly, as both nitriles and iminoesters are of comparable or lower reactivity than the alkanes themselves, these reactions may be of preparative value. For example, the iminoesters derived from 2,3-dimethylbutane and *cis*-1,2-dimethylcyclohexane were isolated in 59 and 67% yields respectively (at 28 and 61% conversions of alkane).

These and other data discussed below rule out many mechanisms and are consistent with eqn. (1)–(10) for this chemistry. Previous studies (product, kinetics, spectroscopic and others) establish that the oxygen-to-tungsten charge-transfer excited states of polyoxotungstates abstract hydrogen atoms, eqn. (1) and (2).[6,7] The chemoselectivities and regioselectivities exhibited by the products in Table 1 indicate the same dominant C–H bond cleaving species is operable in the presence of MCF: (1) the tertiary/primary (3°/1°) C–H cleavage ratios (> 200 for 2,3-dimethylbutane and *cis*-1,2-dimethylcyclohexane), (2) the lack of reactivity of *tert*-butylbenzene (all primary C–H) and (3) the loss of stereochemistry during functionalization of *cis*-1,2-dimethylcyclohexane. The coupling and disproportionation (alkene only detectable) products in Table 1 are more consistent with radicals than other organic intermediates. Three lines of evidence indicate the title processes, unlike most polyoxotungstate photocatalyzed alkane functionalizations, involve radical chains. First, there is significant inhibition by radical inhibitors. This is seen for production of both reduced polyoxotungstate and organic products. For example, the ratio of rates for production of iminoester from 2,3-dimethylbutane using $W_{10}O_{32}^{4-}$, without and with 2.0 mM hydroquinone (HQ) inhibitor, $k_{\text{no HQ}}/k_{\text{with HQ}}$ > 100. This ratio without and with 2.0 mM 2,6-di-*tert*-butylphenol (BHT), $k_{\text{no BHT}}/k_{\text{with BHT}} = 5.7 \pm 0.2$. For HQ and BHT, respectively, *ca*. 10 and < 2% of the light is absorbed by the inhibitor; the rest by $W_{10}O_{32}^{4-}$. Second, the quantum yields for both nitrile and iminoester reactions exceed 1.0 when [polyoxotungstate] < 0.05 mM. Third, $W_{10}O_{32}^{4-}$ inhibits iminoester formation at high [$W_{10}O_{32}^{4-}$]. In contrast, photocatalytic C–H cleavage by $W_{10}O_{32}^{4-}$ generally exhibits conventional kinetics (reaction first order in $W_{10}O_{32}^{4-}$ and in alkane).[6,7]

Inhibition at high [$W_{10}O_{32}^{4-}$] most likely reflects redox capture of radical by polyoxotungstate.[6]

The two propagation steps, eqn. (3) and (4), both of which are precedented in studies involving conventionally generated radicals,[12] sum to the net reaction for production of iminoester. Several additional experiments establish that the mechanism for nitrile formation is eqn. (1)–(3), (6) and (7) [eqn. (8)–(10) are minor processes]: first, quantification of CO_2 (*via* $BaCO_3$) and CH_4 (*via* GC/TCD) products indicates that [nitrile] ~ [CO_2] ~ [CH_4]; second, when the reactions are run in *N*,*N*-dimethylacetamide (DMA), PhCN, or PhCl *versus* CH_3CN, very little CH_3CN [eqn. (10)] and little or no methyl pyruvate derivatives [eqn. (9)] are formed; third, negligible CH_3CH_3 from coupling of $CH_3\cdot$ is observed in CH_3CN (interestingly [CH_3CH_3]/[CH_4] ~ 1 in DMA). Control experiments demonstrated that reduced



(P_{ox} and P_{red} are oxidised and reduced polyoxotungstate, respectively.)

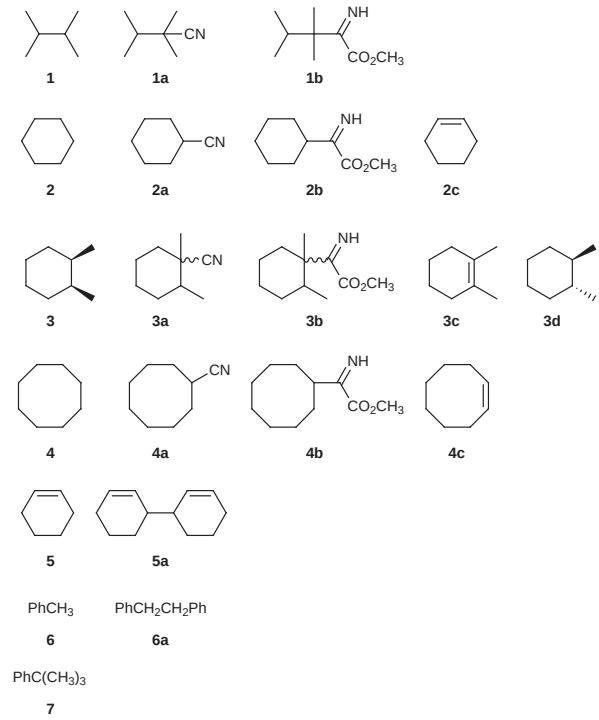
[a] Acetonitrile solutions of polyoxotungstate (1.5 mM) and alkane (0.5 M) and MCF (0.25 M) were irradiated (550 W medium-pressure Hg lamp; Pyrex filter, $\lambda > 280$ nm). The average conversion (based on MCF) was 15% to simplify product distributions for mechanism elucidation. [b] Q = tetra-*n*-butylammonium. [c] *t* = irradiation time. [d] All new compounds were purified and their compositions and purities (> 98%) confirmed by ^{1}H NMR, high resolution MS, and elemental analysis. Moles of indicated product/moles of total organic products as determined by GC. [e] Turnovers = moles of indicated product/moles of polyoxotungstate.



$W_{10}O_{32}^{4-}$ does not react with either MCF (no CN^- is formed) or organic products (iminoester or nitrile). Finally, the yields of iminoester and nitrile correlate strongly (inversely) with each other between 22 and 90 °C, and iminoester does not convert to nitrile under the reaction conditions [eqn. (11) is not operative]. These 2 points suggest that both products derive from a common intermediate, most likely the iminyl radical, $RC(=N\cdot)CO_2CH_3$.

We thank the National Science Foundation (Grant CHE-9412465) for support of this research.

Laboratoire de Chimie Organo-Minérale, UMR 7513 du CNRS, Université Louis Pasteur, Institut Le Bel, 4, rue Blaise Pascal, 67000 Strasbourg, France. E-mail: sauvage@chimie.u-strasbg.fr

Received (in Basel, Switzerland) 22nd July 1998, Accepted 25th September 1998

A new multiporphyrinic [2]rotaxane has been made in which a gold(III) porphyrin is part of the ring; rotation of the string-like fragment within the ring between two diametrically opposed positions is triggered by metallation–demetallation of the central coordination site.

In relation to molecular switches,[1] machines and motors,[2,3] it is of special interest to be able to control at will, amongst other properties, the shape of multicomponent molecular systems. The triggering signal, responsible for the rearrangement of the compound can be photochemical,[4] electrochemical[5] or chemical.[6] Catenanes and rotaxanes are ideally suited for undergoing large amplitude motions under the action of an external stimulus.[7,8]

In the present work, we show that complexing or decomplexing an appropriate metal in a coordination site can bring to close proximity, or spread a long distance apart, given porphyrinic components of the system. The principle is depicted in Fig. 1.

The compound made and studied is a [2]rotaxane in which the string-like fragment bears two zinc(II) porphyrins as blocking groups. The ring through which the string is threaded incorporates a gold(III) porphyrin. It should be noted that these metalloporphyrins are key components of multichromophoric systems undergoing photoinduced electron transfer and proposed as models of given fragments of the photosynthetic reaction centre.[9]

The organic compounds used as intermediates in the synthesis of the [2]rotaxane are represented in Fig. 2. The tetraaryl porphyrin **1** was prepared in 6% yield using pyrrole and a 1 : 1 mixture of the appropriate aldehydes (CF_3CO_2H, in CH_2Cl_2 followed by chloranil treatment[10]). After metallation ($KAuCl_4$) to afford **2** (76%), demethylation (BBr_3) furnished **3** in almost quantitative yield. **5** was obtained by reacting **4**[11] with 2-bromoethanol (K_2CO_3, refluxing DMF) and it was converted to **6** (tosyl chloride, NEt_3, CH_2Cl_2) and subsequently to **7** (NaI, acetone; 30% yield from **4**). Macrocycle **11** was prepared from **3** and **7** (Cs_2CO_3 in DMF, 55 °C; 31% yield). Rotaxane **14** was synthesized following a strategy previously developed in our group for making porphyrin-stoppered rotaxanes.[9] An equimolar mixture of **8**, **11** and $Cu(MeCN)_4^+$ led quantitatively to prerotaxane **12** (not drawn) in which the open chain fragment **8** has been threaded through the ring **11** thanks to the gathering effect of copper(I). The terminal porphyrinic blocking groups of **13** were built from **9**, **10** and **12** (CF_3CO_2H in CH_2Cl_2; chloranil). **14**† was obtained after metallation [$Zn(OAc)_2$] in 13% yield from **8**.

The conformation of **14** is indeed similar to what the drawing of Fig. 3 suggests. In particular, NOE effects measured on $H_{5,6}$ and H_{py} demonstrate unambiguously that a close proximity

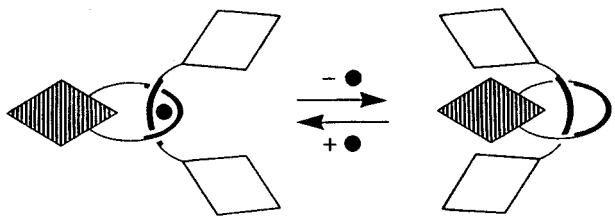

Fig. 1 Control of the mutual arrangement between the gold porphyrin (PAu^+ incorporated in the ring, black diamond) and the zinc porphyrins (PZn end-function of the dumbell, white diamond) by complexation/decomplexation of a metal centre (black circle) within/from the central coordination site. (a) The chemical structure of the two organic constitutive fragments of the rotaxane (ring and thread) is such that, in the complex, the gold porphyrin is remote from the two zinc porphyrins. (b) After removal of the central metal, weak forces may favour an attractive interaction between PAu^+ and the PZn nuclei, leading to a situation in which PAu^+ is pinched between the two PZn units. The interconversion between the situations [(a) and (b)] implies a half-turn rotation of the threaded fragment (axle) within the ring (wheel), the latter being artificially considered as fixed. This motion is reminiscent of the process taking place in the rotary motor of ATP-synthase.[3b]

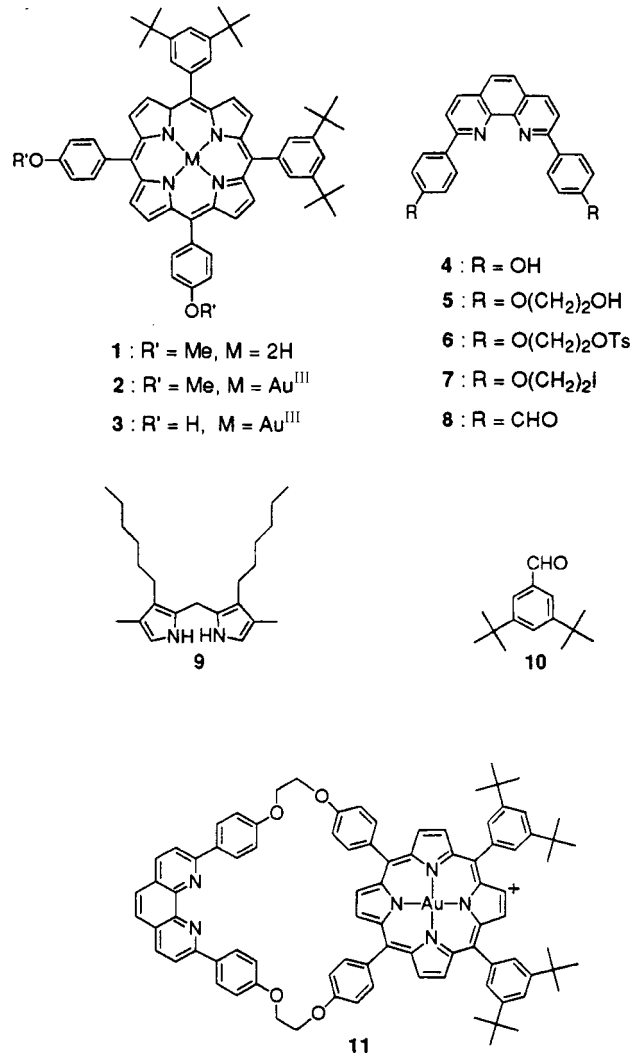

Fig. 2 Intermediates used in the synthesis of the [2]rotaxane.

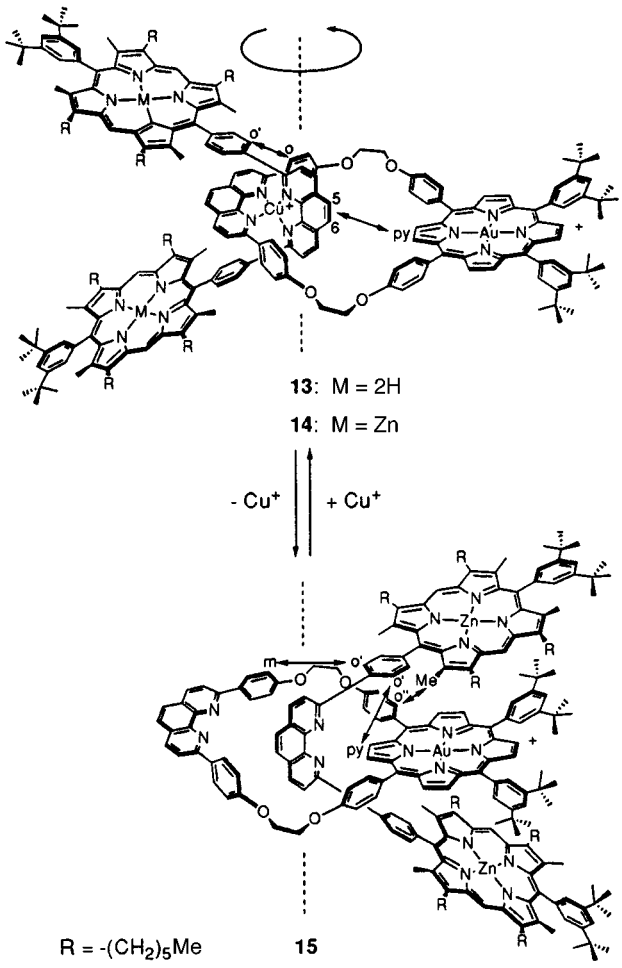

Fig. 3 Metallation–demetallation of the rotaxane induces a complete changeover of the molecule. The most important proton connectivities, as determined by 2D ^{1}H NMR, are indicated by double arrows.

exists between the rear of the 1,10-phenanthroline nucleus belonging to the dumbbell-like fragment and the endocyclic part of the ring-embedded porphyrin. As indicated in Fig. 3, demetallation of **14** affords **15**,† this compound displaying a profoundly modified geometry as compared to **14**. In particular, NOE effects show close proximity between H_m and $H_{o'}$ as well as between H_{py} and $H_{o'}$ and between $H_{o''}$ and H_{Me}, which indicates that the geometry of the molecule is roughly as depicted in Fig. 3.

Space-filling models suggest that within the demetallated rotaxane **15**, free rotation of the 'axle' within the ring can take place. The driving force for bringing PAu^+ between the PZn units, playing the role of two jaws, is certainly related to the extremely different and complementary electronic properties of PAu^+ (electron acceptor) and PZn (electron donor). Very approximate geometrical features can be estimated from the models. Of particular interest are the centre-to-centre (Au···Zn) and the edge-to-edge distances between PAu^+ and PZn. The estimated centre-to-centre separation is *ca.* 19 and *ca.* 7 Å for **14** and **15** respectively. The edge-to-edge distance, which is more relevant to electron transfer, is *ca.* 12 and *ca.* 5 Å for **14** and **15**, although it should be kept in mind that **15** is certainly very flexible, with difficult to estimate interatomic distances. Interestingly, the interconversion between **14** and **15**, although leading to dramatic geometrical changes, is quantitative and reversible. This changeover process can be triggered by other metals such as Ag^+ and Li^+.

We thank the Ministry of Education for a fellowship (to M. L.).

Received (in Cambridge, UK) 31st July 1998, Accepted 5th October 1998

Topological analysis of the experimental and theoretical electron densities in [EtTiCl$_3$(dmpe)] (dmpe = Me$_2$PCH$_2$CH$_2$PMe$_2$) suggests the presence of a (3, −1) bond critical point (CP) between titanium and the β-agostic hydrogen atom; the characteristic curvature in the Ti–C$_\alpha$ bond is proposed as a more general criterion for identifying a β-agostic interaction.

Agostic interactions are of particular interest in organotransition-metal chemistry in view of their potential relevance to important processes like C–H activation. Reliable ways of pinning down these interactions are still at a premium, notwithstanding the numerous examples reported on the basis of structural or spectroscopic measurements or of theoretical studies. Theoretical considerations have lead Popelier and Logothetis (PL) recently to suggest topological analysis of the charge density as a means of identifying agostic interactions.[1] We have tested this hypothesis on a real agostic system by analysing experimental and theoretical electron densities. The ethyltitanium trichloride complex [EtTiCl$_3$(dmpe)] **1** (dmpe = Me$_2$PCH$_2$CH$_2$PMe$_2$) was chosen since its β-agostic interaction has been delineated by a variety of independent techniques.[2]

Long X-ray exposure times hitherto needed for accurate charge density studies have prevented the study of labile organometallic compounds like **1**; with conventional serial data collection techniques using a single scintillation counter, data accumulation may take months. However, Luger and others have demonstrated very recently that charge density studies can be accomplished with exposure times in the order of days using a CCD detector.[3] In our study we have been able to contrive short X-ray exposure times by combining two experiments using a CCD and an imaging plate detector system, both being connected to a rotating anode assembly providing highly intense Mo-Kα radiation. Charge densities were derived from the experimental X-ray data† using the XD program suite[4] based on a standard multipole model as formulated by Hansen and Coppens.[5] Theoretical charge densities were determined by B3LYP DFT calculations[6] using standard basis sets of triple-ζ quality plus polarisation.[7] All such calculations were performed with the Gaussian94 package.[8] The topological analysis of charge densities, based on Bader's 'Atoms In Molecules' (AIM) theory,[9] was effected with the AIMPAC and XD suite.[4,10]

While the geometrical parameters clearly indicate the presence of a β-agostic interaction in **1**: Ti–C 2.1522(9) [2.159], C–C 1.5117(12) [1.518], C$_\beta$–H$_\beta$ 1.13 [1.13], Ti···H$_\beta$ 2.10 [2.12] Å and Ti–C–C 84.5(1) [85.1]° (calculated values in square brackets), no significant charge accumulation between Ti and the C$_\beta$H$_\beta$ unit is evident from the total electron density. More information can be gained from the *gradient vector field* $\nabla\rho(\boldsymbol{r})$ of the calculated and experimental electron density. Hence all bond critical points (CPs)‡ along the bond paths connecting the atoms in **1** can be located [Fig. 1(a,b) and Table 1].

At the bond CP of the C–C bond we determine an electron density ($\rho_{b,calc}$ = 1.616 e Å^{-3}), slightly higher than the corresponding value (1.606 e Å^{-3}) for the C–C bond in ethane or EtTiCl$_3$ **2** (1.576 e Å^{-3}), and significantly lower than that (2.326 e Å^{-3}) for the C=C bond in ethene (Table 1). Since the magnitude of the charge density at the bond CP provides a sensitive measure of the bond strength, one might conclude that the C–C bond order in **1** is only slightly enhanced *vs.* **2**. However, the bond ellipticity parameter (ε)§ of the C–C bond in **1** clearly deviates from zero indicating some double bond character. This accords with the experimental observation of shorter C–C bond lengths in **1** *vs.* **2**,[2] and with the topology of the experimental electron densities (Table 1). Like the C–C bond, the agostic C–H$_\beta$ bond in **1** combines the high electron

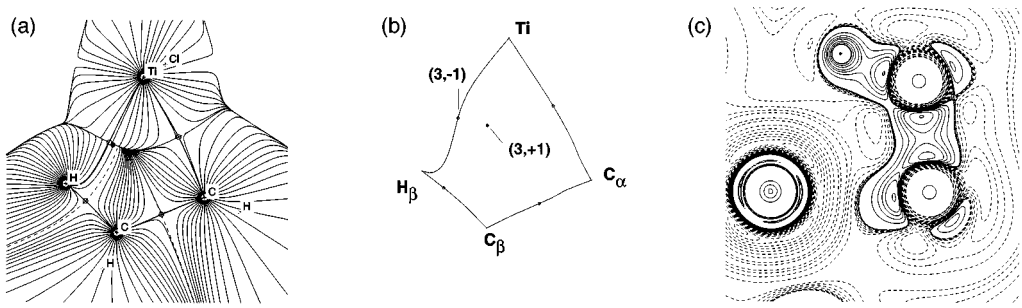

Fig. 1 (a) Calculated gradient vector field $\nabla\rho(\boldsymbol{r})$. Bond CPs are denoted by open circles and the ring CP by a filled circle; nuclei on the molecular plane are denoted by + while the projections of the out-of-plane nuclei are denoted by ÷. Inside the TiC$_\alpha$C$_\beta$H$_\beta$ four-membered ring all gradient paths originate at the (3, +1) ring CP and terminate either at the nuclei or at a (3, −1) bond CP (dashed lines). The gradient vectors linking the (3, −1) bond CP with the atoms constitute the bond paths (thick lines). (b) Bond paths in the TiC$_\alpha$C$_\beta$H$_\beta$ fragment based on experimental charge densities. (c) Experimental-$\nabla^2\rho(\boldsymbol{r})$ function in the TiC$_\alpha$C$_\beta$H$_\beta$ plane (negative values are marked by broken lines).¶

Table 1 Analysis of bond CPs (ρ in e Å^{-3}; ∇^2 in e Å^{-5}; distances in Å, and angles in degrees) in $EtTiCl_3$ and $[EtTiCl_3(dmpe)]$

Unit	Parameter	$EtTiCl_3$ DFT[a]	$EtTiCl_3(dmpe)$ DFT	$EtTiCl_3(dmpe)$ X-Ray

[a] Geometry optimisations in C_s symmetry. [b] Standard (ρ_b, ∇^2_b, ε) values for ethane and ethene at the same level of theory: 1.606, −13.3, 0.0 and 2.326, −24.906 and 0.34, respectively. [c] Corresponding values of the C–C bond in the dmpe backbone: 1.76(2), −15.42(6), 0.06. [d] β-hydrogen atom in the $TiC_\alpha C_\beta$ plane.

density at the bond critical point ($\rho_{b,calc}$ = 1.67 e Å^{-3}) and the large *negative* value of the Laplacian¶ ($\nabla^2\rho_{b,calc}$ = −17.6 e Å^{-5}) characteristic of covalent bonds [Fig. 1(c)]. The topologies of the Ti–C_α and Ti···H_β interactions are, however, different; in each case the electron density at the bond CP ($\rho_{b,calc}$ = 0.63 and 0.21 e Å^{-3}) is rather low, and the Laplacian ($\nabla^2\rho_{b,calc}$ = 1.5 and 3.3 e Å^{-5}) is *positive*.

Similar topologies were found for the corresponding bonds in the agostic model compound $EtTiCl_2^+$ **3** studied by PL, who invoked an ionic, closed shell Ti···H_β interaction.[1] It would seem better to make the distinction between covalent and ionic bonds on the basis of the wavefunction.[11] Compared with **3**, the β-agostic interaction in **1** is significantly weaker,[2] and closer inspection of the gradient vector field indicates that the Ti···H_β bond CP and the ring CP in **1** are proximal and not very pronounced. The electron densities calculated for the Ti···H_β bond CP and the ring CP inside the $TiC_\alpha C_\beta H_\beta$ fragment are nearly identical, differing not significantly by < 0.001 e Å^{-3}. Simultaneously the negative curvature (λ_2) at the bond CP associated with the axis directed at the ring CP almost vanishes. Thus, the bond and ring CPs almost merge into a singularity in ρ, a phenomenon characteristic of bond fission. This conclusion accords with our experimental findings, showing the gradient path between the ring and the Ti···H_β bond CPs to be extremely flat. We expect therefore that Ti···H bond CPs may not always be found in molecules where the agostic interaction is weaker than in **1**.

However, a further characteristic of the agostic interaction manifests itself in the gradient vector map $\nabla\rho(\boldsymbol{r})$ as significant curvature in the Ti–C_α bond path (Fig. 1a,b). This follows the ridge of maximum charge density between a pair of bonded nuclei, the bond CP of the Ti–C bond is displaced outwards by 0.06 Å from the $TiC_\alpha C_\beta H_\beta$ ring. Such behaviour complies with the conclusions of a previous theoretical study,[2] namely that the M–C_α bonding electrons in **1** are delocalised over the entire ethyl group, reduction of the TiCC valence angle permitting Ti to establish a significant covalent interaction with C_β, and perhaps to a lesser extent with H_β. The consequence is a bent Ti–C_α bond path. Inspection of the Ti–C_α bond path of **1** and all the model agostic systems suggested by PL[1] reveals in every case curvature of the Ti–C_α bond. Moreover, the agostic C_β–H_β bonds are bent away from the metal centre. Thus, the bond CP of the C_β–H_β bond is displaced inside the formal $TiC_\alpha C_\beta H_\beta$ ring, a result in keeping with the calculated C_α–C_β–H_β angle which is always several degrees larger than the normal value (*ca.* 109°).

In conclusion, we have shown that experimental electron densities can be obtained for a labile transition-metal complex using now-standard laboratory technology and near-normal data acquisition times. Some agostic interactions may be identified solely on the basis of charge densities, but the non-linearity of the Ti–C_α bond probably offers a more robust criterion of β-agostic interaction.

† *Crystal data* for $[EtTiCl_3(dmpe)]$: $C_8H_{21}P_2Cl_3Ti$, M = 333.4, red rhombic crystals; monoclinic, space group $P2_1/n$, a = 782.95(2), b = 1611.04(2), c = 1182.16(3) pm, β = 91.613(1)°, V = 1490.54(6) × 10^6 pm^3; T = 105(1) K; Z = 4, $F(000)$ = 688, D_c = 1.495 g cm^{-3}, μ = 13.0 cm^{-1}. 35928 (16334) Bragg reflections with $\sin\theta/\lambda_{max}$ = 1.097 (0.66) Å^{-1} were collected on a kappa-CCD system from Nonius [image plate system from Stoe (IPDS)] with a rotating anode generator (Nonius FR591; Mo-Kα, λ = 0.71073 Å) within 48 (32) h. 13425 (CCD data set) and 3205 (IPDS data set) independent reflections; R_{int} = 0.029 (CCD)/0.025 (IPDS). The deformation density was described by a multipole model in terms of spherical harmonics multiplied by Slater-type radial functions with energy-optimised exponents.[12] The multipole expansion was terminated at the hexadecapolar and dipolar level for the heavy and hydrogen atoms, respectively. The C–H bond distances were constrained to the calculated values. The refinement of 434 parameters against 13241 observed reflections [$F > 3\sigma(F)$] converged to R = 0.027, R_w = 0.037, and a featureless residual $\rho(\boldsymbol{r})$. CCDC 182/1048.

‡ (3, −1)/(3, +1) CPs: two curvatures are negative/positive and ρ is a maximum/minimum at the CP in the plane defined by the axes corresponding to the negative/positive curvatures. ρ is a minimum/maximum at the CP along the third axis which is perpendicular to this plane.

§ The ellipticity ε ($\varepsilon = \lambda_2/\lambda_1 - 1$) of a bond is a measure of the asymmetry between the two principal curvatures (λ_1,λ_2) of ρ at the bond CP perpendicular to the bond.

¶ Values of $\nabla^2\rho(\boldsymbol{r}) < 0$ indicate that charge is locally concentrated at $\boldsymbol{r}$, while positive $\nabla^2\rho(\boldsymbol{r})$ values are characteristic of regions suffering local charge depletion.

Received (in Cambridge, UK) 6th October 1998, Accepted 6th October 1998

A new alkali-free synthesis system allows us to prepare aluminosilicate MCM-41 directly in a variety of desirable forms: M-AlMCM-41 (M = H, Cu, Zn, Cd, Ni), the solution ion-exchange and subsequent calcination being avoided; the formation is discussed in terms of a co-assemble process.

Aluminosilicate zeolites with desirable cations compensating the framework charge may find wide applications in areas of adsorption, catalysis[1–3] and nanostructure manufacturing.[4–6] To modify the channels/cages of zeolites with suitable cations, various ion-exchange techniques, such as solid-state interaction,[7,8] impregnation,[9] and chemical vapor deposition[10] have been utilized, besides the conventionally used solution ion-exchange method. However, for the recently developed mesoporous molecular sieve MCM-41,[11,12] which has aroused wide interest, successful ion-exchange has only been performed in solution.[6,13–15] This step, however, will cause some structural collapse owing to the weak hydrothermal stability of MCM-41, especially when the exchange level is high.[14] Further, the ion-exchange occurring in solution will inevitably be incomplete because there is always an equilibrium between the ions within the zeolite channels and those in the liquid. In the present report, we describe a novel co-assemble route for the synthesis of MCM-41, which allows for the direct formation of aluminosilicate MCM-41 in a variety of desirable forms, M-AlMCM-41 (M = H, Cu, Zn, Cd, Ni), the solution ion-exchange step thus being avoided. In addition to this, this method offers us a possibility to obtain a deeper understanding into the formation of MCM type materials. We believe, in the present preparation, a co-assemble process occurs, involving surfactant cations, aluminosilicate species and various ammonia coordinated transition metal complex cations: $M(NH_3)_n^{2+}$ (M = Cu, Zn, Cd, Ni, n = 4, 6).

This novel method owes much to the synthesis medium, which involves the substitution of organic weak bases for the conventionally used NaOH or TMAOH, allowing us to introduce desirable inorganic cations without competition of Na^+ or TMA^+. A typical synthesis of Cu-AlMCM-41 was as follows: an ethylamine ($EtNH_2$) solution (70 wt%) was added to a stirred solution containing distilled water, cetyltrimethylammonium bromide (CTAB) and $AlCl_3{\cdot}6H_2O$. Then to the mixture was added a solution prepared by addition of ammonia solution (NH_3 25 wt%) to a $CuCl_2$ solution. After this, tetraethylammonium orthosilicate (TEOS) was added dropwise, leading to a composition of $1.0SiO_2 : xAl_2O_3 : 2.5xCu^{2+} : 20xNH_4OH : 0.14CTAB : 2.4EtNH_2 : 100H_2O$ ($0.01 < x < 0.03$). The reaction mixture was further stirred for 4 h at room temperature before being heated at 110 °C for 4 days. The blue product was recovered by filtration and washed with distilled water until no Cu^{2+} could be detected in the filtrate. After being dried at ambient temperature, the product was heated in air at 600 °C for 7 h, with a heating rate of 1 °C min^{-1} from room temperature to 600 °C. The as-calcined sample was blue. ICP (inductively coupled plasma emission spectroscopy) analysis shows that the Si/Al ratio can be as low as 16, and the Si/Cu ratio as low as 25. Using same procedures, AlMCM-41 can be prepared with other transition metals, such as Zn, Cd and Ni which can form NH_3-coordinated complex cations in a basic medium required for the synthesis. If no metal ion was introduced, the resultant AlMCM-41 can be obtained in its H-form after calcination, the NH_4^+ exchange and subsequent calcination being avoided.

For both the as-synthesized and calcined M-AlMCM-41 (M = H, Cu, Cd, Ni, Zn), XRD shows clear lines characteristic of well defined hexagonal structures. Especially for H-AlMCM-41, an intense main peak (100) with low FWHH and three weak peaks (110), (200), (210) can be clearly resolved, suggesting a highly ordered structure.

To confirm the successful introduction of desirable cations into the exchanging sites of zeolite MCM-41, we immersed the as-calcined sample (typically Cu-AlMCM-41, Si/Al = 16, Si/Cu = 25), in distilled water or $NaNO_3$ aqueous solution (0.05 M), corresponding to a liquid to solid ratio of 200 ml g^{-1}. After stirring for 1 h, the samples were filtered and the fitrate was collected in both cases. For the slurry with distilled water, no copper content was detected, while for the slurry with $NaNO_3$ copper ions could clearly detected. ICP analysis indicates that up to 65% of copper ions can be exchanged after slurrying twice. The exchangeable nature of the copper ions within the AlMCM-41 strongly confirms that the most of the metal ions are located as charge compensating cations. The as-calcined Cu-AlMCM-41 shows clear sharp lines ($g_{\|}$ = 2.34, g = 2.07) in its EPR spectra at both room temperature and −197 °C and the spectra are similar to dehydrated Cu-AlMCM-41 prepared by solution ion-exchange,[13] but different from pure silica MCM-41 containing Cu^{II} ions.[16] Thus the Cu^{II} cations are likely to be mainly in a six-coordinate environment, as for Cu^{II} exchanged into AlMCM-41 in solution.

To our knowledge, the ion exchanging sites of zeolites are usually produced by substituting trivalent Al^{3+} for silicon atoms and the pure silica MCM-41 shows no or very low ion-exchange capacity.[13] In the present case, the successful incorporation of Al^{3+} into the framework of MCM-41 is established by NMR measurements (Bruker MSL-400 spectrometer), as shown in Fig. 1 for H-AlMCM-41 and Cu-AlMCM-41 samples before and after calcination. The as-synthesized samples show only one signal at 51 ppm, corresponding to four-coordinate Al in the framework sites. Upon calcination, a small fraction of aluminium becomes extraframework in nature, as shown by a small peak at −3.5 ppm. The four-coordinate Al^{3+} within the silica framework will be compensated by various extraframework cations. From the synthesis procedure above, it is apparent that the involvement of $EtNH_2$ as the base source renders the synthesis mixture alkali-free. However, of $EtNH_2$ is basic enough (pK_b = 3.25) not only to form MCM-41 but also to dissolve the Al source material and thus Al^{3+} can be incorporated into the framework readily. Other lyotropic organic amines such as dimethylamine and diethylamine are also suitable for this type of preparation. It is this feature of the synthesis that allows us to introduce various cations into the reaction media, and the cations can be occluded within the bulk product and are subsequently located at the charge-balancing

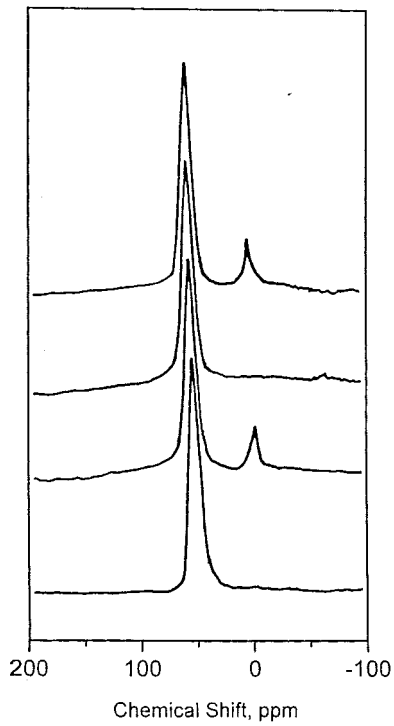

Fig. 1 ^{27}Al MAS NMR spectra of (from bottom to top) as-synthesized H-AlMCM-41, calcined H-AlMCM-41, as-synthesized Cu-AlMCM-41 and calcined Cu-AlMCM-41.

sites upon calcination. On the other hand, ammonia is used to form complex cations with the transition metal ions, preventing them from being precipitated under the basic conditions used.

The occlusion of complex cations within the silicate mesophase may be proposed as a co-assemble process. First, the TEOS molecules are hydrolyzed into oligomeric silicate acids. Then, the surfactant cations (CTA^+) displace the protons of these acids to form inorganic–organic composites, which would further assemble into a periodic mesophase. When the basic conditions are taken into account, the metal cations can also associate with the silicate species by exchanging protons of the silicate acids. As a result, when the cross-linking between the silica leads to solidification of the mesophase the complex cations are occluded within the bulk product. The most likely position of these cations is at the interface between inorganic and organic fractions. Upon calcination to remove the surfactant, the metal complex is decomposed and the remaining metal cations are located at the exchange sites of MCM-41, compensating the negative charge of the aluminosilicate framework. Protonic $EtNH_2$ ($EtNH_3^+$), and NH_3 (NH_4^+) could also be occluded within the as-synthesized MCM-41 at the interface between the surfactant and silicate framework. However, both of these cations can be readily removed by calcination.

Thus, the present co-assemble route offers us not only a convenient route for direct preparation of AlMCM-41 in desirable forms, but is also a potential pathway for encapsulating functional cationic inorganic species within the inorganic–organic interface in a highly dispersed state.

Received (in Basel, Switzerland) 20th August 1998, Accepted 23rd September 1998

A general approach for the rational synthesis of linear trinuclear complexes containing three different metals $M_AM_BM_C$ is described and a member of the series, $Fe^{III}Cu^{II}Ni^{II}$, has been characterized by X-ray crystallography and magnetic susceptibility measurements.

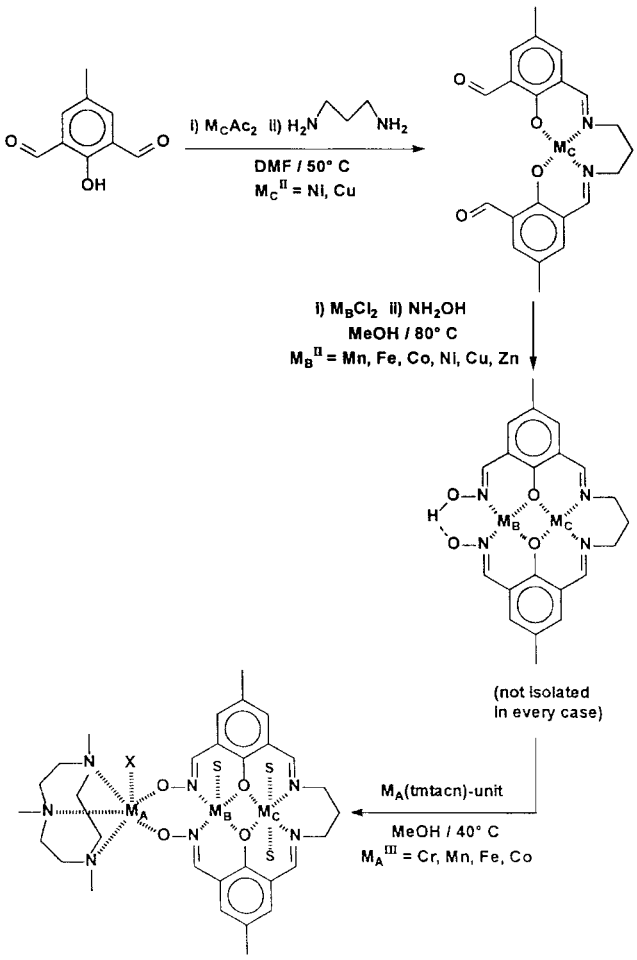
This work stems from our interest in using 'metal oximates' as building blocks for synthesizing hetero- and homopolymetallic complexes containing two,[1] three[2] or four[3] metal centres that constitute a common ground for two areas of current interest, molecular magnetism and metal sites in biology. We have previously demonstrated that using our synthetic strategy it is possible to synthesize a series of complexes of the types $M_AM_BM_A$,[2] $M_AM_BM_BM_A$[4] and $(M_A)_2(\mu_3\text{-}O)_2(M_B)_2$.[3,5] These series are unique and have been proved to be ideal materials for the investigations of exchange mechanism. We describe here a general approach for the rational synthesis of a series of trinuclear complexes containing three different metals $M_AM_BM_C$. To the best of our knowledge these complexes represent the first examples of exchange coupled linear trinuclear complexes containing three different metals. The complexes have been prepared by the general synthetic route shown in Scheme 1. Yields varied between 30% and 50%. Satisfactory analyses (C, H, N, M_A, M_B, M_C) were obtained.

The structure of the complex dication containing the trinuclear core $Fe^{III}Cu^{II}Ni^{II}$, **1**, is shown in Fig. 1.† The coordination geometry of the terminal iron, Fe, is distorted octahedral with three nitrogen atoms, N(1), N(2) and N(3), from the facially coordinated macrocyclic amine, two oxygen atoms, O(1) and O(4), from the oxime ligands and a chloride ion, Cl(1), resulting in the *fac* FeN_3O_2Cl cores. The Fe–O and Fe–N distances are consistent with a d^5 high-spin electron configuration of the Fe centre, as is also evidenced by the Mössbauer spectrum[6] at 80 K, $\delta = 0.45$ mm s^{-1}, $\Delta E_Q = 0.85$ mm s^{-1}. The Fe–Cu–Ni skeleton is almost planar, with an angle Fe–Cu–Ni of 174.0°. The intramolecular separations between the metal centres, Fe···Cu 3.695 Å, Fe···Ni 6.772 Å and Cu···Ni 3.087 Å, are in conformity with the values observed earlier for comparable structures.[2,7] The dihedral angles between the planes FeN(2)N(3)O(1)O(4) and CuN(4)N(7)O(3)O(2), and the latter Cu plane and the Ni plane NiO(3)O(2)N(5)N(6) are 148.5 and 169.4°, respectively.

The geometry of the central Cu(II) centre is square-pyramidal, with the elongated fifth bond (2.43 Å) to axially coordinated oxygen atom O(60) of a methanol molecule. The metrical parameters for the Cu centre are very similar to those of the Cu dimer with the same Schiff-base oxime ligand reported in the literature.[8]

The terminal nickel ion, Ni(II), is coordinated to two azomethine nitrogens, N(5) and N(6), and two bridging phenolate groups, O(2) and O(3), from the Schiff-base oxime ligand. The nickel centre adopts a 6-coordinated environment by interacting with two *trans* axially disposed methanol molecules, O(40) and O(50). The nickel centre is displaced by 0.014 Å from the mean basal plane comprising O(3)O(2)N(5)N(6) atoms toward O(40) or O(50) of a methanol ligand. The equatorial Ni–N and Ni–O (phenoxide) distances are nearly equal, average 2.005(6) Å and 2.025(3) Å, respectively. The Ni–O(methanol) distances are rather long (av. 2.142 Å), as has been observed earlier.[9e] The bridging angles Cu–O(2)–Ni and Cu–O(3)–Ni are equal, 101.6°.

Magnetic data (SQUID) with $H = 2$ T for a polycrystalline sample of FeCuNi, **1**, are displayed in Fig. 2 as μ_{eff} *vs.* *T*. On lowering the temperature μ_{eff} of 6.45 μ_B at 290 K decreases monotonically, approaching a broad minimum around 180 K($\mu_{eff} = 6.40\ \mu_B$) and increases upon further cooling to reach a maximum with a value of 6.91 μ_B at 15 K, which corresponds to the spin-only value for $S = 3$, expected as the ground state for an antiferromagnetically coupled $Fe^{III}Cu^{II}Ni^{II}$ complex. The μ_{eff} *vs.* *T* plot exhibits the expected minimum and indicates an irregular spin-structure[2,9–11] showing a ferromagnetic-like interaction in the temperature range below this minimum. Below 15 K there is a decrease in μ_{eff}, reaching a value of 4.63 μ_B at



Scheme 1

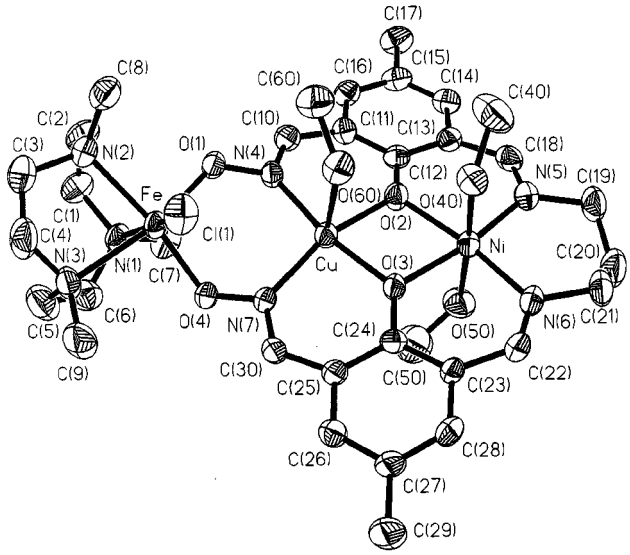


Fig. 1 Structure of the dication $[(tmtacn)Fe(Cl)Cu(CH_3OH)(Schiff\text{-}base\ oxime)Ni(CH_3OH)_2]^{2+}$ with the $Fe^{III}Cu^{II}Ni^{II}$ core. Selected bond lengths (Å): Cu–N(4) 1.951(3), Cu–O(3) 1.956(2), Ni–N(5) 2.000(4), Ni–O(2) 2.025(3), Ni–O(50) 2.137(3), Fe–O(4) 1.916(3), Fe–N(1) 2.211(3), Fe–Cl(1) 2.3383(13).

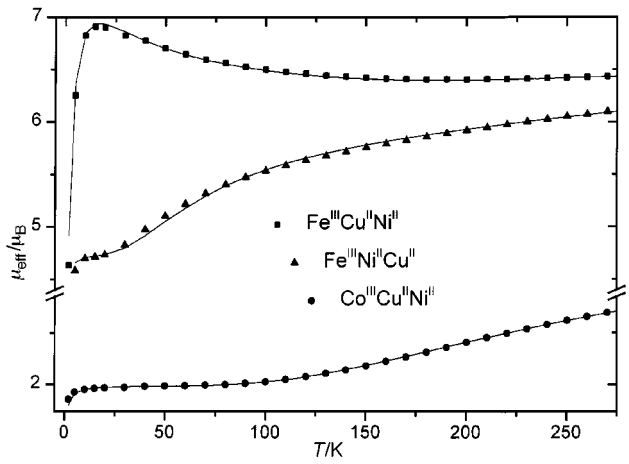

Fig. 2 A plot of μ_{eff} *vs.* T for **1**, **2**, **3**. The solid lines represent the simulations of the experimental data.

2 K; this behaviour might be due to saturation effects or the splitting in the zero-field of the ground state $S_T = 3$. We have confirmed the ground state of $S_T = 3$ by fitting the experimental magnetization curve (7 T) to the Brillouin function for $S = 3$ with $g = 2.075$ in the temperature range 2–290 K. The magnetic interactions operating in this type of linear trinuclear structure result in a ground state of high-spin multiplicity, although the nearest neighbour spin alignments are antiparallel.

A full-matrix diagonalization approach including exchange ($-2JS_1 \cdot S_2$) and Zeeman interactions, together with axial single-ion zero-field interaction (DS_z^2) for the Ni^{II} ion was employed to fit the experimental data. The best fit shown as the solid line in Fig. 2 yields $J_{FeCu} = -19.8\ cm^{-1}$, $J_{CuNi} = -118.6\ cm^{-1}$, $J_{FeNi} = 0$ (fixed), $g_{Ni} = 2.20$ (fixed), $g_{Cu} = 2.10$ (fixed), $g_{Fe} = 2.0$ (fixed), $D = 0$ (fixed).

Our strategy of using 'building blocks' sequentially yields also the isomeric $Fe^{III}Ni^{II}Cu^{II}$, **2**, as is evident by its susceptibility measurements (Fig. 2). The best fit parameters are $J_{FeNi} = -10.6\ cm^{-1}$, $J_{NiCu} = -161.5\ cm^{-1}$, $J_{FeCu} = 0$ (fixed), $g_{Fe} = 2.0$ (fixed), $g_{Ni} = 2.30$ (fixed), $g_{Cu} = 2.10$ (fixed). Thus the exchange interactions in $Fe^{III}Ni^{II}Cu^{II}$, **2**, lead to a different ground state of $S_T = 2$. The exchange interaction between the neighbouring Cu^{II} and Ni^{II} ions in another member of the series, Co^{III}(l.s.)$Cu^{II}Ni^{II}$, **3**, also structurally characterized (data not shown), is of comparable strength, $J_{CuNi} = -125\ cm^{-1}$ (Fig. 2), to that in **1**, $Fe^{III}Cu^{II}Ni^{II}$. The angles Cu–O(phenoxo)–Ni and the distances Cu···Ni are exactly the same in both **1** and **3**, although, in contrast to **1**, the Co–Cu–Ni skeleton is not linear with an angle of 155.6°.

C. N. V. acknowledges thankfully the receipt of a fellowship from DAAD.

Cation flux dependence on carbon chain length in hydraphile channels as assessed by dynamic ^{23}Na NMR methods in phospholipid bilayers

Clare L. Murray and George W. Gokel*

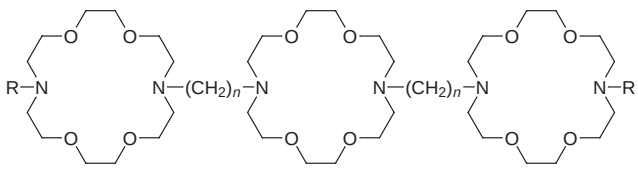
Bioorganic Chemistry Program and Department of Molecular Biology and Pharmacology, Washington University School of Medicine, 660 South Euclid Avenue, Campus Box 8103, St. Louis, MO 63110 USA.
E-mail: ggokel@pharmsun.wustl.edu

Received (in Columbia, MO, USA) 10th August 1998, Accepted 23rd September 1998

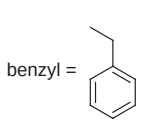
The length dependence for the family of tris(macrocycle) channels has been defined by a combination of synthetic and kinetic studies conducted in phospholipid bilayers.

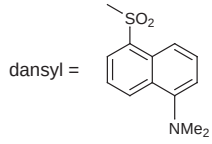
Two modes of cation transport are known to occur *in vivo*: they are designated carrier and channel mechanisms. Both kinds of transport have been studied extensively. The dynamics of carrier transport are generally understood for the limited natural carriers and numerous synthetic ionophores.[1] In the channel mechanism, extensive biophysical and molecular biological studies have defined structural, functional, and selectivity aspects of naturally occurring protein channels.[2] The recent crystal structure of the potassium-selective transmembrane shaker channel has given a view of how the transmembrane helices are positioned within the phospholipid bilayer but mechanistic details in this and other transmembrane proteins remain elusive.[3] The complexity of natural channel compounds has fostered the invention and study of a variety of synthetic model systems that have proved to be more or less successful as ionophores.[4]

We have developed a family of synthetic, transmembrane ionophores based upon crown ethers which have been proved to transport sodium.[5] These compounds consist of three macrocycles connected by hydrocarbon spacers and are terminated by flexible sidechains. We call these compounds 'hydraphiles' in reference to the monster slain by Hercules that had two heads on each neck.[6] The general structure is shown below.



1 *n* = 8, R = benzyl
2 *n* = 10, R = benzyl
3 *n* = 12, R = benzyl
4 *n* = 14, R = benzyl
5 *n* = 16, R = benzyl
6 *n* = 12, R = dansyl





Several of these macrocycle-based channel compounds have been shown by fluorescence methods to transport protons and by dynamic NMR methods to transport alkali metal cations.[5] Considerable evidence has accumulated on the function of these compounds. (1) The central macrocycle is beneficial but not essential for cation transport in the cases where that issue was studied and is probably oriented along the lipid axis in the bilayer. (2) The ionophoretic activity of hydraphiles cannot be explained either by a simple carrier mechanism or by unadorned detergent action.[7] Specifically, neither bis(benzyl)diaza-18-crown-6 nor bis(dodecyl)diaza-18-crown-6 shows any measurable transport in the ^{23}Na NMR experiment. (3) Transport rates generally show a comprehensible structure–activity relationship[5] and follow the Hammett principle.[8] (4) The channel can be blocked by the presence of a hydrogen bond donor attached to the distal macrocycles.[9] In the present work, we wished to gain insight into the structural requirement for spanning the phospholipid membrane's 'hydrocarbon slab.' This insulating portion of the larger bilayer is 30–34 Å across as judged from work reported by Wiener and White[10] and the shaker potassium channel crystal structure.[11] We thus prepared five tris(macrocyclic) hydraphiles that are identical except for the lengths of the spacer chains connecting the central macrocycle to its distal counterpart. It was anticipated that the synthetic channel compounds would show a higher level of cation flux when the length was optimal than when the spacer chains were either too long or too short. In the latter case, a complete shutdown of cation transport was anticipated if the ionophore could not span the insulating regime of the membrane. If the synthetic channel functioned by a carrier mechanism, such a cut-off would not be expected.

Macrocycles **1**–**5** were prepared by a three-step sequence.[12] First, monobenzyldiaza-18-crown-6 ($PhCH_2 < N18N > H$) was prepared either by benzylation of diaza-18-crown-6 or by partial hydrogenolysis of dibenzyldiaza-18-crown-6.[13] Alkylation of $PhCH_2 < N18N > H$ with excess $Br(CH_2)_nBr$ afforded $PhCH_2 < N18N > (CH_2)_nBr$ which was then allowed to react with $H < N18N > H$.[14] Compound **6** was prepared in an analogous fashion except that $H < N18N > H$ was monoalkylated with dansyl chloride rather than benzyl bromide.

Sodium cation flux was measured by using the ^{23}Na NMR-based method of Riddell and co-workers.[15] This technique permits quantitative evaluation of Na^+ transport. The observed rates may be compared with each other and with a standard. Vesicles for the ^{23}Na NMR studies were prepared from phosphatidylcholine (0.14 mmol) and phosphatidylglycerol (0.037 mmol, 4 : 1 w/w). The total Na^+ concentration was adjusted to 100 mM by addition of NaCl. The solutions were buffered using a phosphate buffer held at pH 7.3. The vesicles were prepared by a procedure similar to that described by Papahadjopoulos and Szoka.[16] The preparation used here afforded vesicles having an average diameter of 1750–2000 Å. The total aqueous encapsulation volume in this preparation was 3% as judged by ^{23}Na NMR spectroscopy.

The shift reagent was prepared according to the procedure of Gupta and Gupta[17] from sodium tripolyphosphate and Dy^{3+}. The ^{23}Na NMR chemical shifts were measured as differences between the resonance position in the presence and absence of the Dy^{3+} shift reagent. Compound **6** (standard) or **1**–**5** was incorporated into the vesicles as a CF_3CH_2OH solution ([**1**–**6**] = 5–20 μM). After addition of the subject compound, the samples were agitated and warmed (50–60 °C) for 1 h, cooled to room temperature, and then diluted with D_2O (lock signal) and shift reagent solution. Each solution was allowed to equilibrate for ~1 h before data acquisition. Typically, 240 FID transients were accumulated per data set at 25 °C. The rate results, relative to those determined for **6** (simultaneous with each sample) are recorded in Table 1 and shown graphically in Fig. 1.

The NMR experiment is somewhat complex and we have therefore chosen to normalize the data relative to a simultaneously determined standard (**6**). Transport rates for **6** have

Table 1 Sodium cation transport by tris(macrocycle) ionophores[a]

Cpd.	Structure	Rel. rate[a]
1	$PhCH_2 < N18N > C_8 < N18N > C_8 < N18N > CH_2Ph$	< 2
2	$PhCH_2 < N18N > C_{10} < N18N > C_{10} < N18N > CH_2Ph$	96
3	$PhCH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2Ph$	211[b]
4	$PhCH_2 < N18N > C_{14} < N18N > C_{14} < N18N > CH_2Ph$	201
5	$PhCH_2 < N18N > C_{16} < N18N > C_{16} < N18N > CH_2Ph$	109
6	$Dn < N18N > C_{12} < N18N > C_{12} < N18N > Dn$	100[c]

[a] Rate relative to compound **6**, arbitrarily set at 100. Comparative rates are recorded for 10 μM ionophore concentration. [b] The Na^+ transport rate determined relative to gramicidin (= 100) was 39.[18] [c] The Na^+ transport rate determined relative to gramicidin (= 100) was 23.[19]

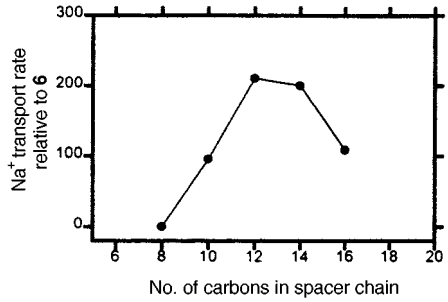


Fig. 1 Na^+ transport *vs.* spacer chain length.

been determined independently more than 10 times and each of the values shown in Table 1 for **1**–**5** represents at least three independent experiments.

Hydraphiles **3** and **6** are both of the form $R < N18N > C_{12} < N18N > C_{12} < N18N > R$ in which R is either benzyl (**3**) or dansyl (**6**). In previous work we noted that the rates for these compounds, relative to gramicidin (= 100), were 39[18] and 23, respectively. The most important observation is that cation flux exhibits clear spacer chain length dependence. Spacer chains having 12 or 14 carbons appear optimal in this system showing relative Na^+ transport rates of 201 and 211, respectively. When the spacer chain length is either increased or decreased by two carbons from the 12–14 range to give **2** or **5**, cation flux is reduced to about half of the previous value. The most striking result, however, is that when the chain length is reduced a further two carbons, $PhCH_2 < N18N > C_8 < N18N > C_8 < N18N > CH_2Ph$ (**1**) proves completely ineffective as an ionophore. Since the hydraphiles are flexible compounds, it seems reasonable that conformational adaptability would still allow function as the chain length increased. If the ionophore must be extended in order to function, the compound must pass a certain size beyond which it simply cannot span enough of the hydrocarbon slab to be functional. This limit appears to have been reached for the octyl spacer chain.

The experimental results presented here resolve two important issues about the hydraphile channel compounds. First, in accord with previous evidence, the carrier mechanism as a possible mode of transport is ruled out. Second, the two-fold changes in transport rates for **2** and **5** compared to **3** or **4** show the sensitivity of this system to dimensional changes of only 4 Å in either direction. This strongly suggests an extended conformation and that the critical membrane span is the insulating hydrocarbon slab rather than the entire phospholipid bilayer.

We thank the NIH for a grant (GM 36262) that supported this work.

6 Hydra is defined in *The American Heritage Dictionary* as 'any of several small freshwater polyps of the genus *Hydra* and related genera, having a naked cylindrical body and an oral opening surrounded by tentacles.' This is structurally appropriate to the present systems. The term hydraphile also connotes to us the concept of hydrophilicity. We favor 'hydraphile' over the more cumbersome 'bolaamphiphile' which evokes a vision of random spheres at the ends of swirling and disorganized tethers.

Diastereoselective cyclopropanation of α,β-unsaturated acetals of a novel camphor-derived chiral auxiliary

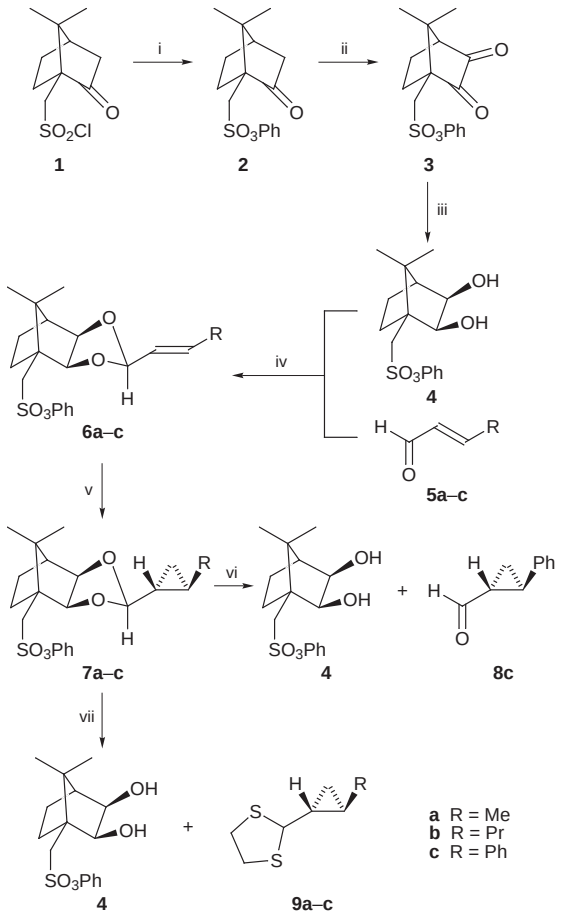
Perry T. Kaye* and Warner E. Molema

Department of Chemistry, Rhodes University, Grahamstown, 6140, South Africa. E-mail: chpk@hippo.ru.ac.za

Received (in Cambridge, UK) 3rd September 1998, Accepted 6th October 1998

Reaction of selected α,β-unsaturated aldehydes with phenyl 2,3-dihydroxybornane-10-sulfonate affords acetals which undergo diastereoselective (>99% de) Simmons-Smith cyclopropanation.

The cyclopropyl group occurs in various natural products[1] and, due to its inherent ring strain, finds use as a structural intermediate in synthesis.[2] Barrett and Kasdorf,[3] for example, have exploited the Charette methodology[4] in tandem asymmetric cyclopropanation reactions in the synthesis of a nucleoside containing five cyclopropane units. The Simmons-Smith reaction[5] is commonly used to construct cyclopropane derivatives, and asymmetric applications involving the use of chiral acetals[6] and ketals[7] have been described. We have recently reported[8] moderate diastereoselectivity (40–70% d.e.) in the Simmons-Smith cyclopropanation of α,β-unsaturated acetals, using bornane-2,3-diol as a chiral auxiliary. Increasing steric demand at C-10 of the bornane skeleton was expected to enhance diastereofacial selectivity, and here we report the synthesis and use of phenyl 2-*exo*,3-*exo*-dihydroxybornane-10-sulfonate **4** as a highly efficient chiral auxiliary for the asymmetric cyclopropanation of α,β-unsaturated acetal derivatives.



Scheme 1 *Reagents and conditions*: i, PhOH, pyridine; ii, H_2SeO_3, dioxane; iii, $NaBH_4$, MeOH; iv, TsOH, $MgSO_4$, benzene; v, Et_2Zn, CH_2I_2, CH_2Cl_2, −10 °C; vi, (for R = Ph) TsOH, THF–H_2O, reflux, 72 h; vii, $HSCH_2CH_2SH$, TsOH, CH_2Cl_2.

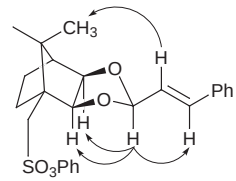


Fig. 1 NOE interactions observed in the NOESY spectrum of the acetal **6c**.

Treatment of (+)-camphor-10-sulfonyl chloride **1** with phenol in pyridine at 0 °C afforded the phenyl ester **2** in 81% yield (Scheme 1), the corresponding camphorquinone **3**† being obtained by subsequent selenous acid (H_2SeO_3) oxidation. Reduction of the diketone **3** with $NaBH_4$ gave the required diol **4**, which was unambiguously characterised by elemental (HRMS) and spectroscopic analysis.‡

Following the procedure developed for the synthesis of bornane-2,3-diol acetals,[8] the diol **4** was condensed with the α,β-unsaturated aldehydes **5a–c** to give the corresponding acetals **6a–c** in 64–74% yield. ^1H and ^{13}C NMR analyses indicated the formation of a single diastereomeric acetal in each case. The presence of heteroatoms and bulky substituents is known to inhibit pseudorotation in 1,3-dioxolane rings[9] and, in the systems studied here, fusion to the rigid bicyclic bornane skeleton is likely to lock the 1,3-dioxolane ring into an envelope conformation. Steric factors are expected to favour formation of the *exo*-acetals—an expectation supported by the NOE interactions observed for the cinnamaldehyde acetal **6c** (Fig. 1) and confirmed by single crystal X-ray analysis of this compound (Fig. 2).§

The Simmons-Smith organozinc reagent exhibits high affinity for ethereal oxygen, and transition state steric demands are considered to be significant.[10] Computer modelling¶ (Fig. 3) clearly indicates the capacity of the phenyl sulfonate moiety to hinder access to the 'front' face of the unsaturated acetals **6a–c**, and initial coordination of the organozinc reagent to the less

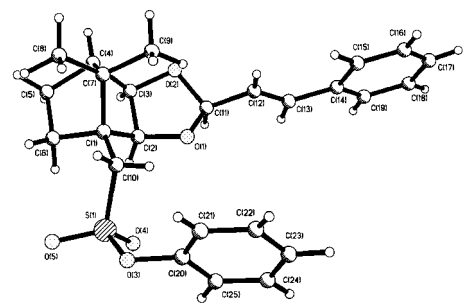

Fig. 2 X-Ray crystal structure of the acetal **6c** at 173 K, showing the crystallographic numbering.

hindered acetal oxygen O(7) is predicted to precede methylene delivery from the 'back'.

Cyclopropanation of the acetals **6a–c** was effected by their dropwise addition (as solutions in dry CH_2Cl_2) to a cold, vigorously stirred mixture of Et_2Zn and CH_2I_2 in CH_2Cl_2.[8] Work-up and preparative layer chromatography afforded the cyclopropyl derivatives **7a–c** in good material yield (76–95%) and with complete diastereoselectivity (> 99% de).‖ Confirmation of the predicted stereochemical bias was achieved by hydrolysis of acetal **7c** to afford the known[11] laevorotatory (1*R*, 2*R*)-aldehyde **8c**;** the remarkable resistance of the acetal **7c** to acidic hydrolysis under various conditions is attributed to steric crowding. Release of the chiral auxiliary **4** (in 83–87% yield) from the cyclopropyl derivatives **7a–c** was finally achieved by transthioacetalisation,[12] the corresponding dithiolanes **9a–c** being isolated in 87–92% yield.††

We thank the Foundation for Research and Development (FRD) and Rhodes University for generous financial support, and Dr Leanne Cook (University of the Witwatersrand) for the X-ray crystallographic analysis.

The effect of strain on reactivity: poor leaving groups increase strain-induced inhibition of alkene-forming elimination

Luca Volta and Charles J. M. Stirling*

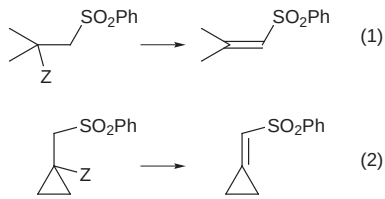
Department of Chemistry, The University, Sheffield, UK S3 7HF. E-mail: c.stirling@sheffield.ac.uk

Received (in Liverpool, UK) 28th September 1998, Accepted 6th October 1998

Elimination to form a carbon–carbon double bond exocyclic to a cyclopropane ring is inhibited by factors which increase from 1.4 to $10^{4.5}$ as the leaving group becomes poorer; strain induced in the transition structure can amount to some 50% of the enthalpy difference between strained and unstrained products.

The effect of strain on reactivity is a very familiar phenomenon, but one which has only rarely been quantified.[1] In order to quantify the effects of strain on reactivity properly, systems of known and defined strain energy are required (not always a simple matter) and reactions of unambiguous mechanism are also needed (not always a simple matter either). In this connection, earlier work from these laboratories has examined acceleration of 1,2-elimination by incorporation of the leaving group in a strained ring.[2–4] In such cases acceleration results from the release of strain, effectively lowering the energy of the transition structure relative to the starting material. We have also examined the effect of strain in the inhibition of higher order eliminations leading to strained ring products in which the effects of strain are remarkably variable.[5,6] Both situations have been examined theoretically[7,8] and the correlation between theory and practice is good.

We now report on the kinetics of formation of methylenecyclopropanes in activated 1,2-eliminations which reveal the impact of strain as the transition structure changes. The systems we have examined, involving five different leaving groups (Z) are in Table 1, giving rate constants for the unstrained [eqn. (1)] and strained reactions [eqn. (2)] respectively. Making the



assumption that strain energies are unaffected by substituents, the strain energy difference between substrate and product for the methylenecyclopropane systems of eqn. (2) amounts to 50 kJ mol^{-1}. This is the strain energy difference between cyclopropane and methylenecyclopropane[9] although its origin is under discussion.[10]

The open-chain halides **1** were obtained by homolytic addition of sulfonyl halides to 2-methylpropene.[11] Addition of thiophenol to the alkenyl sulfone **2** gave sulfide **3** which on oxidation gave the bis-sulfone **4** The cyclopropanes were obtained by the routes of Scheme 1. Reactions were run in ethanolic sodium ethoxide to allow direct comparisons with earlier results; the product from the open-chain substrates was the conjugated alkene **2** and non-conjugated alkene **2a**,[12] while the cyclopropanes gave the ethoxy adduct **10** from slow elimination followed by rapid addition to the electrophilic methylenecyclopropane **7**. The unlikely alternative course of direct substitution was ruled out by the piperidine test in which, for example, the bis-sulfone **9** failed to react with piperidine in ethanol (too weakly basic) but reacted rapidly with piperidine in ethanolic sodium ethoxide to give the piperidino derivative **11** (piperidine more nucleophilic than ethoxide).

Reactions were followed by UV spectroscopy for reactions in which the product alkene was detectable and otherwise by GC. Reactions were first order in substrate and first order in base.

Before comment on the impact of strain differentials can be made, it is crucial to be certain of the mechanism of the reactions in each case. Two methods to throw light on the mechanisms have been adopted; the observed rate constants have been compared with the rates of ionisation obtained by interpolation on a Taft plot[13] of $k_{ionisation}$ in ethanolic sodium ethoxide *versus* the inductive constant σ^*. It can be seen that for the leaving groups SO_2Ph, SPh and OMe, the rate constant for ionisation is greater than the elimination rate constant. This points for each case to the $(E1cB)_R$ mechanism, in which a pre-equilibrium with the carbanion is established with the base–solvent system. The rate-determining step in each case, therefore, is the expulsion of the leaving group from the intermediate carbanion. The second procedure was to carry out reactions in EtOD and to examine by ^2H NMR spectroscopy recovered starting material for deuterium incorporation. In all of these cases, starting material had exchanged considerably with the solvent, confirming the conclusions from interpolation. By contrast, with the halogen leaving groups, the observed rate constants in all cases are close to or greater than the interpolated ionisation rate constants and no incorporation of deuterium occurred in exchange experiments. These observations point

Table 1 Elimination to form unstrained and strained alkenes

	Rate constants/mol^{-1} dm^3 s^{-1}				
	Open chain		Cyclopropane		
Z	k_{EtO^-} [a]	$k_{ion.}$ [a,b]	k_{EtO^-} [a]	$k_{ion.}$ [a,b]	k_{rel} unstrained:strained
Br	2.3×10^2	2.3×10^1	3.2×10^2	3.2×10^1	0.7
Cl	7.8×10^1	4.1×10^1	5.5×10^1	5.7×10^1	1.4

either to the E2 mechanism, in which departure of the leaving group is concerted with β-proton removal, or to the $(E1cB)_I$ mechanism, in which it is not. For the latter mechanism, a close similarity between k_{EtO^-} and $k_{ionisation}$ is to be expected. This is true for the chlorides, but the comparison for the bromides suggests concerted mechanisms.

For 1,2-eliminations, it can reasonably be concluded that the more difficult the leaving group is to expel, the greater is the degree of double-bond character in the transition structure required to expel it. In earlier work[14] we were able to compare accurately the leaving abilities of a series of groups placed β to a sulfonyl-stabilised carbanion. These groups included SO_2Ph, SPh and OMe in descending order of nucleofugality. Nucleofugalities of halide leaving groups could not be assigned because, as in the present work, the reactions did not follow the $(E1cB)_R$ mechanism. Our observation of probable E2 and/or $(E1cB)_I$ mechanisms for the halides mentioned above, suggests higher nucleofugalities for the halogens, as would be expected.

The results of Table 1 show that as the nucleofugality of the leaving group decreases, so the ratio of the reactivities of the unstrained to the strained substrates increases. This reveals a consistent picture in which as the nucleofugality of the leaving group decreases, so the degree of double bond character in the transition structure increases and the additional strain of the double bond exocyclic to the cyclopropane ring is increasingly felt.

This leaves the important question of the extent of strain inhibition in these reactions. In the system with the largest unstrained to strained reactivity ratio, *i.e.* with Z = OMe, the inhibition amounts to a factor of some 29,000 or about 26 kJ mol^{-1} in $\Delta G^{\ddagger}$. This amounts to about 50% of the strain energy difference between strained and unstrained products. When the leaving group is halogen, the unstrained and strained substrates have almost identical reactivities and there appears to be so little double bond character in the transition structure that reactions are little inhibited by formation of a strained alkene product.

We thank the University of Sheffield for the support of this work and Elaine Frary for preliminary experiments.

Synthesis of axially chiral *N,N*-diethyl 2,6-disubstituted benzamides utilizing planar chiral (arene)chromium complexes

Hiroshige Koide[a] and Motokazu Uemura*[a,b]

[a] *Department of Chemistry, Faculty of Integrated Arts and Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan. E-mail: uemura@ms.cias.osakafu-u.ac.jp*

[b] *Research Institute for Advanced Science and Technology, Osaka Prefecture University, Sakai, Osaka 599-8570, Japan*

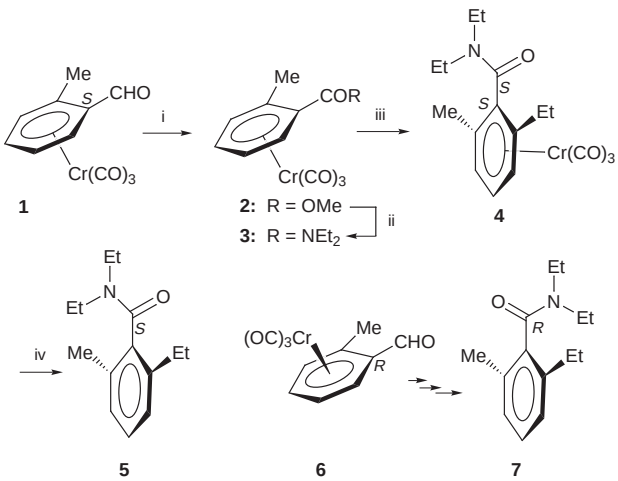
Received (in Cambridge, UK) 3rd August 1998, Accepted 28th September 1998

Axially chiral *N,N*-diethyl 2,6-disubstituted benzamides are prepared stereoselectively in an optically active form from a planar chiral (arene)chromium complex.

The tertiary arylamides with 2,6-disubstituents are a class of atropisomeric compounds[1] and the chromatographic separation of some racemates to optically active axial aromatic carboxamides has been achieved by using HPLC on a chiral stationary phase.[2] Clayden and co-workers have reported[3] the synthesis of *diastereomeric* atropisomers by reaction of *N,N*-dialkyl 2-lithio-1-naphthamides with the aldehydes, or reduction of *N,N*-dialkyl-2-acyl-1-naphthamides, or laterally lithiation of *N,N*-dialkyl 2-alkyl-1-naphthamides followed by eletrophilic quenching. The asymmetric deprotonation of *N,N*-dialkyl-1-naphthamides with a combination of butyllithium/(−)-sparteine followed by quenching with alkylhalides giving the axially chiral *N,N*-dialkyl 2-alkyl-1-naphthamides in an optically active form has been recently reported by Beak.[4] However, the optical purity of the axial aromatic carboxamides obtained by this asymmetric deprotonation with the chiral base is moderate. To the best of our knowledge, there is no previous report of asymmetric synthesis of *N,N*-dialkyl 2,6-disubstituted aromatic carboxamides in an *enantiomerically pure form*.

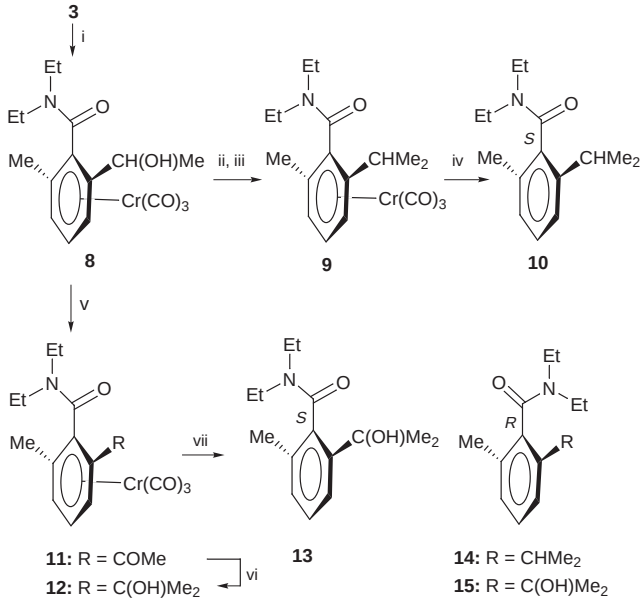
We wish to report the asymmetric synthesis of axially chiral *N,N*-dialkyl 2,6-disubstituted benzamides in an *enantiomerically pure form* by using a planar chiral arene chromium complex.

Both enantiomers of the axially chiral 2-ethyl-6-methylbenzamide were synthesized as shown in Scheme 1. Enantiomerically pure (−)-tricarbonyl(*o*-methylbenzaldehyde)chromium (**1**)[5] was oxidized to the corresponding (−)-methyl benzoate chromium complex **2** ($[\alpha]_D^{26}$ −100.0)† with active manganese dioxide and sodium cyanide in acetic acid and methanol in 85% yield. Conversion of the methyl ester to the corresponding (+)-*N,N*-diethylamide complex **3** ($[\alpha]_D^{26}$ +8.4) was achieved by treatment with lithium diethylamide in THF at −78 °C in 80% yield. Directed *ortho* lithiation[6] of *N,N*-diethyl *o*-methylbenzamide complex **3** with Bu^{t}Li in the presence of TMEDA followed by quenching with ethyl iodide gave the axially chiral (−)-(S_{Ar},S_{ax})[7]-tricarbonyl(*N,N*-diethyl 2-ethyl-6-methylbenzamide)chromium (**4**) ($[\alpha]_D^{25}$ −31.0) in 36% yield, along with 15% yield of tricarbonyl(*N,N*-diethyl 2-propylbenzamide)chromium *via* benzyl methyl lithiation. In this *ortho* lithiation, the *N,N*-diethyl benzamide complex **4** was obtained as a single axially chiral compound without formation of the corresponding (*R*)-axial isomer. The stereochemistry of the axially chiral benzamide complex **4** was determined by X-ray crystallography,‡ and the axial chirality was found to be the (*S*)-configuration in which the diethylamino part was oriented in an *anti*-conformation to the tricarbonylchromium moiety, and the amide carbonyl oxygen is in a *syn*-orientation. The X-ray crystal structure shows that the dihedral angle between the plane of the amide and the aryl ring is approximately perpendicular. The formation of **4** as the single axial isomer by electrophilic quenching of the *ortho*-lithiated intermediate may be attributed to the stereoelectronic repulsion between the tricarbonylchromium and diethylamino fragments. After producing the axially chiral *N,N*-diethyl 2-ethyl-6-methylbenzamide chromium complex **4**, we next investigated an oxidative demetalation giving a chromium free axially chiral *N,N*-diethyl 2-ethyl-6-methylbenzamide. Thus, a solution of (−)-**4** in ether was exposed to sunlight at 0 °C until the yellow color of the solution disappeared. The demetalation product, *N,N*-diethyl 2-ethyl-6-methylbenzamide (**5**) has a positive optical rotation value ($[\alpha]_D^{26}$ +14.0). Similarly, the corresponding axially chiral antipode (−)-*N,N*-diethyl 6-ethyl-2-methylbenzamide (**7**) ($[\alpha]_D^{26}$ −13.0) was obtained from the antipode (+)-tricarbonyl(2-methylbenzaldehyde)chromium (**6**)[5] by following the same reaction sequence. The optical purities of the axial *N,N*-diethyl 2-ethyl-6-methylbenzamides, **5** and **7**, were found to be ~94% ee.[8] However, the optical rotation values of these chromium free axial benzamides slowly decreased on standing at room temperature.

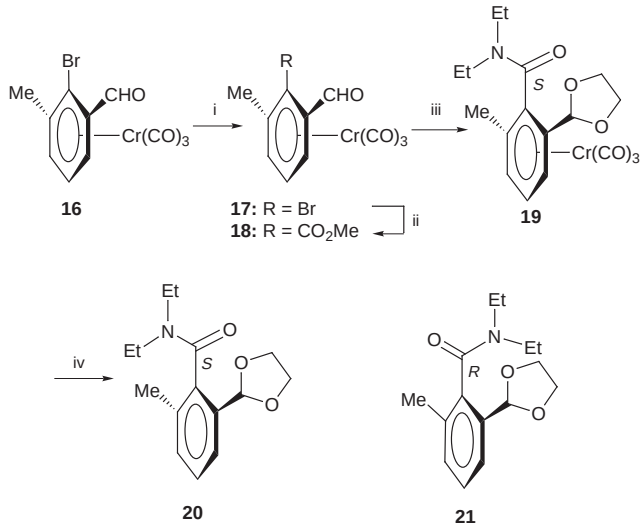


Scheme 1 i, MnO_2, NaCN, AcOH, MeOH, 85%; ii, $LiNEt_2$, THF, −78 °C, 80%; iii, Bu^{t}Li, TMEDA, THF, −78 °C, then EtI, 36%; iv, *hv*, O_2, diethyl ether, 0 °C, 90%.

Since the *N,N*-diethyl 2-ethyl-6-methylbenzamide underwent slow racemization at room temperature,[9] the sterically bulky substituent was next introduced at the *ortho*-position to inhibit the axial isomerization (Scheme 2). The *o*-lithiated intermediate derived from **3** was trapped with acetaldehyde to produce a diastereomeric mixture of **8** at the newly created benzylic center in a ratio of 54 : 46 in 44% yield. The diastereomeric mixture **8** was acetylated, and then treated with triethylaluminium to give tricarbonyl(*N,N*-diethyl 2-methyl-6-isopropylbenzamide)chromium (**9**) ($[\alpha]_D^{24}$ −54.0) *via* a tricarbonylchromium-stabilized benzylic carbocation intermediate[10] in 60% yield. Alternatively, the hydroxide of diastereoisomeric complex **8** was oxidized with acetic anhydride and DMSO to afford acetophenone complex **11** which was further converted to tertiary-alcohol complex **12** ($[\alpha]_D^{25}$ +37.0) by treatment with $MeCeCl_2$



Scheme 2 i, Bu^{s}Li, TMEDA, THF, −78 °C, then MeCHO, 44%; ii, Ac_2O, pyridine, DMAP; iii, Me_3Al, CH_2Cl_2, −78 °C, 60% from **8**; iv, *hν*, O_2, diethyl ether, 0 °C, 98%; v, DMSO, Ac_2O, 88%; vi, $MeCeCl_2$, THF, −78 °C, 94%; vii, *hν*, O_2, diethyl ether, 0 °C, 90%.



Scheme 3 i, $HO(CH_2)_2OH$, *p*-TsOH, MeCN, $MgSO_4$, 84%; ii, Bu^{n}Li, TMEDA, diethyl ether, then ClCOOMe, 83%; iii, $LiNEt_2$, THF, −78 °C, 60%; iv, *hν*, O_2, diethyl ether, 0 °C, 90%.

in 74% overall yield. These tricarbonylchromium-complexed axially chiral benzamides **9** and **12** gave the (*S*)-axially chiral benzamides **10** ($[\alpha]_D^{23}$ +9.8) and **13** ($[\alpha]_D^{27}$ +63.2) in >99% ee[8] by oxidative demetalation, in which the optical purities of these compounds did not change after prolong standing (36 h) at room temperature. On the other hand, the corresponding (*R*)-axially chiral 2-methyl-6-substituted benzamides **14** ($[\alpha]_D^{23}$ −9.8) and **15** ($[\alpha]_D^{27}$ −63.2) with its optical antipode were prepared from **6** by the same reaction sequence. Thus, axially chiral *N*,*N*-diethyl 2,6-disubstituted benzamides were stereoselectively prepared in enantiomerically pure form by *ortho* lithiation of the planar chiral (benzamide)chromium complex.

Furthermore, the enantiomerically pure axially chiral *N*,*N*-diethyl 2,6-disubstituted benzamide was also stereoselectively prepared by conversion of the methyl ester of planar chiral tricarbonyl(methyl 2,6-disubstituted benzoate)chromium to the diethylamide group as follows (Scheme 3). Thus, the enantiomerically pure (−)-tricarbonyl(2-bromo-3-methylbenzaldehyde)tricarbonylchromium (**16**) ($[\alpha]_D^{27}$ −752.6) was converted to the corresponding tricarbonylchromium complex of methyl 2,6-disubstituted benzoate **18** ($[\alpha]_D^{27}$ −10.4) by usual method. Complex **18** was treated with lithium diethylamide at −78 °C in THF to produce stereoselectively (−)-*N*,*N*-diethyl benzamide **19** ($[\alpha]_D^{25}$ −75.2) with (*S*)-axial configuration as a single isomer in which the stereochemistry was determined by X-ray crystallography.‡ No diastereoisomeric (*R*)-axial benzamide chromium complex was obtained in this reaction. It is reasonable to assume that the sterically bulky diethylamino group approached from the *exo*-side to the tricarbonylchromium moiety. Complex **19** was exposed to sunlight to produce the enantiomerically pure[8] axially chiral benzamide **20** ($[\alpha]_D^{27}$ +33.7). The corresponding (−)-(*R*)-axial benzamide **21** ($[\alpha]_D^{27}$ −33.2) was also prepared from the antipode (+)-(3-methyl-2-bromobenzaldehyde)tricarbonylchromium by the same reaction sequence. This axially chiral compound **20** is stable against axial isomerization at room temperature.

In conclusion, we have demonstrated that axially chiral *N*,*N*-diethyl 2,6-disubstituted benzamides can be prepared with high optical purities by using planar chiral tricarbonyl(arene)chromium complexes.

Partial financial support for this work was provided by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan. We acknowledge the financial support by The Asahi Glass Foundation and Ciba-Geigy Foundation (for Japan).

Received (in Cambridge, UK) 23rd September 1998, Accepted 5th October 1998

The low-temperature reactions of $[Sb(NMe_2)_3]$ with $[CyPH_2]$ and [CyPHNa] (1 : 1 : 1 equiv.) and of $[As(NMe_2)_3]$ with [^{t}BuPHLi] (1 : 3 equiv.) in TMEDA–thf [TMEDA = $Me_2NCH_2)_2$] produce [{*cyclo*-$(CyP)_4Sb$}Na·Me_2NH·TMEDA]$_2$ 1 and [{*cyclo*-(^{t}BuP)$_3$As}Li·TMEDA·thf] 2, respectively; at higher temperatures these reactions generate Zintl compounds containing Sb_7^{3-} and As_7^{3-} anions.

In earlier work we showed that a variety of dimethylamido Sb(III) reagents can be employed in the syntheses of a range of stable heterometallic imido cages containing Sb(III) anions (such as $[Sb(NR)_3]^{3-}$ and $[Sb_2(NR)_4]^{2-}$).[1] The reaction of $[Sb(NMe_2)_3]$ with [CyPHLi] (1 : 3 equiv. respectively) gives the Sb(III)/Li complex [{Sb{PCy)$_3$}$_2$Li$_6$·6Me_2NH] (Cy = C_6H_{11}) in which all the Me_2NH produced as a byproduct solvates the six Li^+ cations of the core.[2] Unlike the imido analogue, thermal decomposition of this complex occurs (*ca.* 30–40 °C) to produce the Zintl compound $[Sb_7Li_3·6Me_2NH]$, the product resulting from elimination of the phosphinidene groups (as is illustrated by the isolation of *cyclo*-$[CyP]_4$).[3] This unique phosphinidene coupling reaction (by which molecular cages are converted into molecular alloys) provides the means for the solution deposition of thin photoemissive alkali metal antimonate films[4] from molecular single-source precursors at low temperatures (*i.e.*, an 'alloy paint' approach) rather than using metal vapours.

In order to assess the generality of this approach we decided to investigate a range of reactions of $[E(NMe_2)_3]$ (E = As, Sb) with primary phosphines $[RPH_2]$ and primary phosphido alkali metal complexes (RPHM) (M = Li–Cs) (analogous to those we had used previously for the imido systems[1]). The low-temperature reaction (< 0 °C) of $[Sb(NMe_2)_3]$ with $[CyPH_2]$ (Cy = cyclohexyl) (1 : 1 equiv.) followed by addition of [CyPHNa] (1 equiv.) in the presence of excess TMEDA [= $(Me_2NCH_2)_2$] was performed in order to obtain the heterobimetallic cage [{Sb_2(PCy)$_4$}$_2$$Na_4$], the imido analogue of which ([{Sb_2(NCy)$_4$}$_2$$Na_4$]) was produced under similar conditions using [CyNHNa] and [$CyNH_2$].[5] However, the initial product of this reaction is [{*cyclo*-CyP}$_4$SbNa·TMEDA·Me_2NH]$_2$ **1**,† containing a heterocyclic [{CyP}$_4$Sb]$^-$ anion. Similarly, the low-temperature reaction (*ca.* 25 °C) of [^{t}BuPHLi] with $[As(NMe_2)_3]$ (3 : 1 equiv.) in the presence of TMEDA–thf leads to the direct formation of [{*cyclo*-(^{t}BuP)$_3$As}Li·TMEDA·thf] **2**,† containing a related [{^{t}BuP}$_3$As]$^-$ anion, rather than giving [{As(^{t}Bu)$_3$}$_2$$Li_6$] (*cf.* [{Sb(^{t}Bu)$_3$}$_2$$Li_6$] which is obtained by a similar reaction from $[Sb(NMe_2)_3]$ and [^{t}BuNHLi][6]). At higher temperatures [*ca.* 60 and 110 °C (in toluene), respectively] Zintl compounds containing As_7^{3-} are isolated.† The almost quantitative yields of the latter and the earlier isolation of $[CyP]_4$ from the thermolysis reaction of [{Sb{PCy)$_3$}$_2$Li$_6$·6Me_2NH] to the Zintl compound $[Sb_7Li_3·6Me_2NH]$[3] suggests that elimination of $[RP]_n$ rings from the [{CyP}$_4$Sb]$^-$ and [{^{t}BuP}$_3$As]$^-$ anions of **1** and **2** is a fundamental step in the formation of these Zintl ions. The precise mechanism of this process is still under investigation.

X-Ray crystallographic studies of **1** and **2** were undertaken at low temperature.‡ Complex **1** (Fig. 1) consists of centrosymmetric dimers [{*cyclo*-CyP}$_4$SbNa·TMEDA·Me_2NH]$_2$, in which two heterocyclic [{CyP}$_4$Sb]$^-$ anions are associated by two Na^+ cations. The central Sb_2Na_2 ring has a planar, rhombic shape [Sb(1)–Na(1)–Sb(1a) 87.0(1), Na(1)–Sb(1)–Na(1a) 93.0(1)°], with the pattern of alternating Sb–Na bond lengths [Sb(1)–Na(1) 3.617(4), Sb(1)–Na(1a) 3.229(4) Å] indicating that the two monomer units are only loosely associated (*cf.* estimated 2.98 Å for the Sb–Na bond). Although a similar metallacyclic [(^{t}BuP)$_4$Ni] fragment has been observed in the structure of [{(*cyclo*-^{t}BuP)$_4$Ni}(η^2-^{t}BuP)$_2$],[7] the closest p block relatives to **1** are the neutral heterocycle [SbP(2,4,6-^{t}Bu$_3$C$_6$H$_2$)]$_2$ (composed of a four-membered P_2Sb_2 ring with an endocyclic Sb–Sb bond)[8] and complexes containing the cyclic $[P_5]^-$ anion.[9] Alkali metal Li–Sb bonded complexes have been reported previously;[10] however, **1** is the first containing a Na–Sb bond.

Complex **2** consists of discrete monomers [{*cyclo*-(^{t}BuP)$_3$As}Li·TMEDA·thf], in which a heterocylclic [{*cyclo*-(^{t}BuP)$_3$As}]$^-$ anion is bonded by its anionic centre to a Lewis base solvated Li^+ cation (Fig. 2). The As–Li bond length in **2** [2.62(2) Å] is within the range observed in other complexes of this type (2.46–2.76 Å).[11] The formation of a four-membered P_3As anion in **2**, as opposed to a five-membered unit similar to that found in the related Sb(III) system **1**, may simply result from the smaller covalent radius of As (the shorter As–P bonds being accommodated into a four membered ring unit without inducing excessive strain). The closest relative of **2** is [(^{t}BuP)$_3$As]$_2$, a principal product of the Wurtz coupling reaction

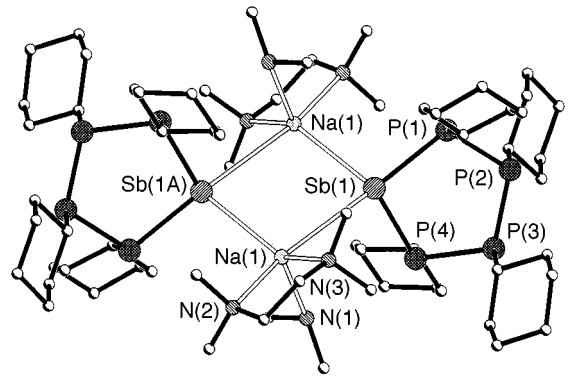

Fig. 1 Molecular structure of **1** with H atoms omitted for clarity. Key bond lengths (Å) and angles (°): Sb(1)–P(4) 2.489(3), Sb(1)–P(1) 2.541(3), P(1)–P(2) 2.192(4), P(2)–P(3) 2.192(4), P(3)–P(4) 2.184(4), Sb(1)–Na(1) 3.617(4), Sb(1)–Na(1a) 3.229(4), Na(1)–N(3) 2.46(1), Na(1)–N(1) 2.49(1), Na(1)–N(2) 2.49(1); P(1)–Sb(1)–P(4) 99.7(1), Sb(1)–P(1)–P(2) 105.7(1), P(3)–P(2)–P(1) 110.9(2), P(4)–P(3)–P(2) 109.4(2), Sb(1)–P(4)–P(3) 105.6(2), Na(1)–Sb(1)–Na(1a) 93.0(1), Sb(1)–Na(1)–Sb(1a) 87.0(1). Symmetry transformations used to generate equivalent atoms $-x + 2$, $-y + 1$, $-z$.

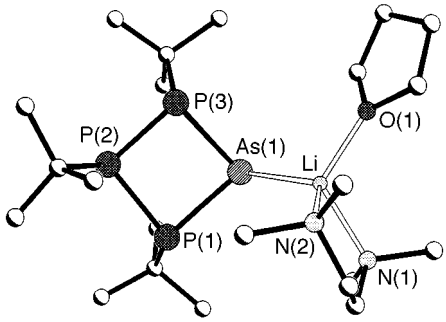

Fig. 2 Molecular structure of **2** with H atoms and the disorder on the thf and TMEDA ligands omitted for clarity. Key bond lengths (Å) and angles (°): As(1)–P(1) 2.333(4), As(1)–P(3) 2.324(3), As(1)–Li 2.62(2), P(1)–P(2) 2.203(4), P(2)–P(3) 2.198(4), Li–N(1,2) av. 2.10, Li–O(1) 1.92(2); P(1)–As(1)–P(3) 85.1(1), P–As–Li av. 107.5, As(1)–P(1)–P(2) 88.2(1), As(1)–P(3)–P(3) 88.5(1), P(1)–P(2)–P(3) 91.4(2).

of $AsCl_3$, $^tBuPCl_2$ and Mg, which consists of two [($^tBuP)_3As$] rings linked by their As centres.[12]

In conclusion, the aforementioned reactions provide direct access to a unique family of group 15 heterocyclic anions (**1** and **2** being the first examples of this type to be characterised). The application of these species as sources of [{RP}$_n$E]$^-$ (E = Sb, As) ligands to other main group and transition metals and the thermolysis of the resulting complexes is an interesting prospect.

M.), the Gottlieb Daimler- und Karl Benz-Stiftung (A. R.) and Electron Tubes, Ruislip, UK (Case award for A. D. H.) for financial support.

Notes and references

† *Synthesis* of **1**: [Sb(NMe$_2$)$_3$] (5.1 ml, 1.74 mol dm^{-3} in toluene, 8.8 mmol) was added dropwise to a chilled solution of $CyPH_2$ (1.17 ml, 8.8 mmol) in hexane (20 ml). The solution was allowed to warm to room temperature and stirred (10 min). The orange solution produced was transferred by syringe into a chilled (*ca.* −20 °C) solution of [CyPHNa] [prepared *in situ* by the reaction of $PhCH_2Na$ (1.0 g, 8.8 mmol) with $CyPH_2$ (1.17 ml, 8.8 mmol) in hexane (10 ml)–thf (5 ml)]. The reaction mixture was allowed to warm to *ca.* 0 °C. An excess of TMEDA (*ca.* 3.0 ml, 20 mmol) was added and the solution was filtered while cold. Crystallisation at −35 °C (24 h) gave red plates of **1**. Yield 1.1 g (16% on the basis of Sb supplied). Decomp. 75 °C to black solid. ^{1}H NMR (+25 °C, 250 MHz, [$^2H_8$]toluene), δ 1.0–2.0 (overlapping m, 40H, {CyP}$_4$), 2.22 (d, 4H ($^2J_{31_{P-H}}$ *ca.* 6.4 Hz), C(α)-H of {CyP}$_4$), 2.10 (br s, 16H, TMEDA), 2.46 (s, 6H, Me_2NH). Elemental analysis. Calc. C, 50.4; H, 8.8; N, 5.5; P, 16.3. Found: C, 49.0; H, 8.6; N, 5.2; P 15.1%.

Synthesis of **2**: to a stirred, chilled suspension of [LiPH^{t}Bu]$_n$ (6.0 mmol of monomer) in toluene (20 ml) and TMEDA (1.0 ml) was added a solution of [As(NMe$_2$)$_3$] (2.0 mmol, 0.92 cm^3, 2.17 mol dm^{-3} in toluene). The suspension was stirred and gradually allowed to warm to 0 °C, at which stage an orange precipitate was observed. Then thf (20 ml) was added and the mixture stirred for 48 h after which an orange solution (with a fine precipitate) remained. This was filtered off and the solvent reduced to *ca.* 8 ml, the solid produced was redissolved by the addition of thf (*ca.* 1 ml) and storage at −18 °C (12 h) gave orange crystals of **2** suitable for X-ray diffraction studies. Isolated samples of **2** (placed *in vacuo* for *ca.* 15 min, 10^{-1} atm) contain no thf solvate. The following data refer to this material; yield 0.27 g (2% on the basis of As supplied to the reaction); mp. 115 °C to clean orange oil; IR (Nujol), major bands at 1260 m, 1032 s cm^{-1}; ^{1}H NMR (250 MHz, +25 °C, [$^2H_8$]thf), δ 2.39 (s, 4H, CH_2, TMEDA), 2.13 (s, 12H, Me_2N, TMEDA), 1.07 (d, 18H, $^3J_{P-H}$ 11.5 Hz), 1.01 (d, 9H, $J_{31_{P-H}}$ 10.5 Hz); ^{31}P NMR (101.256 MHz, +25 °C, [$^2H_8$]thf; rel. to 80% H_3PO_4–D_2O), δ 7.87 (t), −74.50 (d) (ratio 1 : 2, $^2J_{31_{P-31_P}}$ 179.4 ± 0.8 Hz); Elemental analysis. Calc. C, 46.8; H, 9.3; N, 6.1; P, 20.1. Found: C, 46.0; H, 9.3; N, 7.2; P, 17.6%.

The syntheses and structures of [Sb_7Na_3·3TMEDA·3thf] **3** and [As_7Li_3·3TMEDA]·PhMe **4** (see last ref. 11) obtained in the high temperature reactions will be discussed in a later paper.

‡ *Crystal data*: for **1**: $C_{64}H_{134}N_6Na_2P_8Sb_2$, M = 1525.02, monoclinic, space group $P2_1/n$, a = 11.168(3), b = 22.420(4), c = 16.468(3) Å, β = 92.71(2)°, U = 4118.6(14) Å^3, Z = 2, D_c = 1.230 Mg m^{-3}, λ = 0.71073 Å, T = 223(2) K, μ(Mo-Kα) = 0.859 mm^{-1}. Data were collected on a Siemens P4 diffractometer. The crystal diffracted very weakly at high angle; of a total of 5646 data collected (1.82° ⩽ θ ⩽ 21.00°) 4439 were independent (R_{int} = 0.0532). Relatively high thermal displacement parameters indicated some disorder of the cyclohexyl rings but it was not possible to resolve this. Empirical absorption corrections were applied after initial refinement with isotropic displacement parameters.[13] The structure was solved by direct methods and refined by full-matrix least-squares on F^2 to final values of $R1[F > 4\sigma(F)]$ = 0.069 and $wR2$ = 0.214 (all data);[14] largest peak and hole in the final difference map 0.772 and −0.843 e Å^{-3}.

For **2**: $C_{22}H_{51}AsLiN_2OP_3$, M = 534.42, monoclinic, space group $P2_1/n$, a = 12.238(7), b = 15.574(12), c = 16.27(1), β = 105.23(5)°, U = 2993(4) Å^3, Z = 4, D_c = 1.186 Mg m^{-3}, T = 180(2) K, μ(Mo-Kα) = 1.311 mm^{-1}, F(000) = 1144. Data were collected on a Siemens-Stoe diffractometer using ω–θ scans (3.56 ⩽ θ ⩽ 22.50). Of a total of 7645 reflections, 3900 were independent (R_{int} = 0.1036). The structure was solved using direct methods and refined by full matrix least squares on F^2 to final R indices of $R1$ = 0.086 [$F > 4\sigma(F)$] and $wR2$ = 0.200 (all data);[14] largest peak and hole in the final difference map 1.269 and −0.622 e Å^{-3}. The C atoms of the thf ligand and one of the C atoms of each of the Me_2N groups of the TMEDA were disordered over two sites and were refined with half occupancy. CCDC 182/1045.

Molecular structures of 1,12-$B_{12}H_{10}(CO)_2$ and its dihydrate 1,12-$B_{12}H_{10}[C(OH)_2]_2$—a novel bis-carbene complex

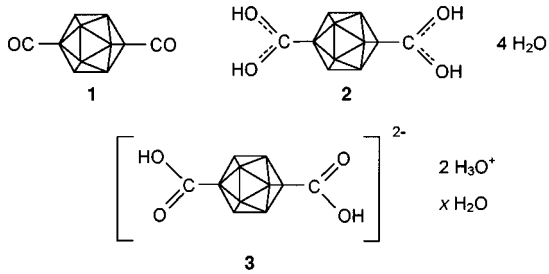
Mark A. Fox,* Judith A. K. Howard, Janet M. Moloney and Kenneth Wade*

Chemistry Department, Durham University Science Laboratories, South Road, Durham, UK DH1 3LE. E-mail: m.a.fox@durham.ac.uk

Received (in Cambridge, UK) 4th September 1998, Accepted 5th October 1998

Crystal structures of the dicarbonyl 1,12-$B_{12}H_{10}(CO)_2$ and its hydrated form 1,12-$B_{12}H_{10}(CO_2H_2)_2{\cdot}4H_2O$ show little π-bond character in their B–C bonds but contain significant distortions from the regular B_{12} icosahedron geometry; the hydrate, until now thought to be a hydroxonium salt, contains dihydroxycarbene ('protonated carboxylic acid') ligands $C(OH)_2$.

The three-dimensional aromaticity and π-acidity of polyhedral boranes[1] lends interest to their derivative chemistry when potentially π-bonding ligands are present.[2,3] The dianion $[B_{12}H_{12}]^{2-}$ has particular interest in this connection as it contains the electronically highly delocalized robust B_{12} icosahedron[4] present in tough ceramic materials like elemental boron, boron carbide and metal borides. The I_h symmetry of the dianion is expected to be lowered on attachment of ligands with π bonding potential. We here report structural studies on two neutral complexes 1,12-$B_{12}H_{10}L_2$ in which two opposed hydride ligands of $[B_{12}H_{12}]^{2-}$ are replaced by neutral potentially π-acidic ligands L of a type normally associated with transition metals, namely the carbonyl ligand L = CO or a Fischer carbene ligand L = $C(OH)_2$. The known dicarbonyl $B_{12}H_{10}(CO)_2$ **1**, synthesized from $[B_{12}H_{12}{}^{2-}]$ and CO under high pressure and temperature in low yield,[5,6] had been subjected to a recent photoelectron and theoretical study[7] which suggested it contained single B–C and triple C≡O bonds though this had not been structurally confirmed. The bis(dihydroxycarbene) complex $B_{12}H_{10}[C(OH)_2]_2$ **2**, prepared by us in a neutral hydrated form by hydration of **1**, had hitherto been regarded[5,6,8] as a hydroxonium salt $[H_3O^+]_2[B_{12}H_{10}(CO_2H)_2]^{2-}$ **3** with two carboxylic acid residues CO_2H replacing two hydrogen ligands of $B_{12}H_{12}{}^{2-}$. The hydrate **2** appears to be the first structurally characterized compound with two carbene diol groups. A preliminary potentiometric titration of **2** in water gave pK_a values of 4.2 and 9.0 for loss of the first and second protons respectively.



Suitable crystals of $B_{12}H_{10}(CO)_2$ **1** for X-ray crystallography were formed by slow sublimation at 40–50 °C (0.005 mmHg) for 2–3 days. A crystal of the dicarbonyl **1**† was flash-cooled to 100 K and an X-ray diffraction study reveals a well ordered structure in the space group *Cmca*.‡ The molecule has 2/*m* site symmetry, which results in only nine atoms being crystallographically unique. The bond lengths of B–C and C–O and the nearly linear BCO angle in **1** are typical of BCO groups in neutral borane carbonyls.[9] The molecular structure with significant bond lengths and angles is shown in Fig. 1. A crystal of the hydrate $B_{12}H_{10}(CO_2H_2)_2{\cdot}4H_2O$ **2**,§ formed by recrystallization with water, was also flash-cooled to 90 K and shows a well ordered structure in space group *C*2/*c* with two independent water molecules in the asymmetric unit.¶ The hydrate **2** has two carbene diol $C(OH)_2$ groups with identical C–O and O–H bond lengths within experimental error. Fig. 2 shows the molecular structure with significant bond lengths and angles. The supramolecular structure of **2** consists of sheets of cages mediated by water molecules on the (101) plane with hydrogen bond distances (O···H/Å) of 1.73(2) and 1.80(2) between the diol groups and the water molecules, and 1.92(2) and 1.97(2) between the water molecules.

Bond order calculations carried out on the molecular geometries of **1** and **2** using the AM1 program[2] show little π bonding between the borane cluster and the carbonyl groups in **1** and negligible between the cluster and the carbene diol groups

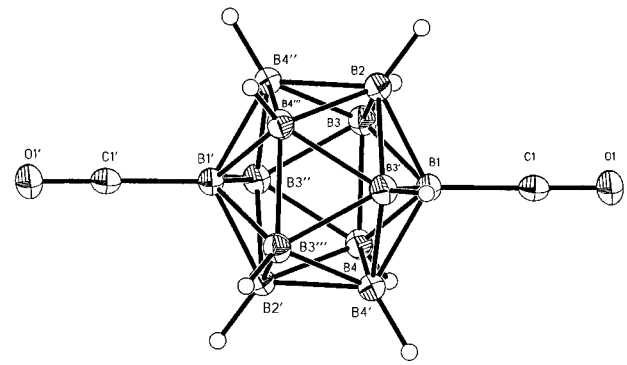


Fig. 1 Molecular structure of **1** (50% ellipsoids). Important interatomic distances (Å) are: O(1)–C(1) 1.119(2), C(1)–B(1) 1.543(2), average B–B distances; polar–tropical 1.768, tropical–tropical 1.824, tropical–tropical′ 1.779. Selected angles (°) O(1)–C(1)–B(1) 179.18(12), C(1)–B(1)–B(2) 117.28(9), C(1)–B(1)–B(3) 118.26(5), C(1)–B(1)–B(4) 119.66(8).

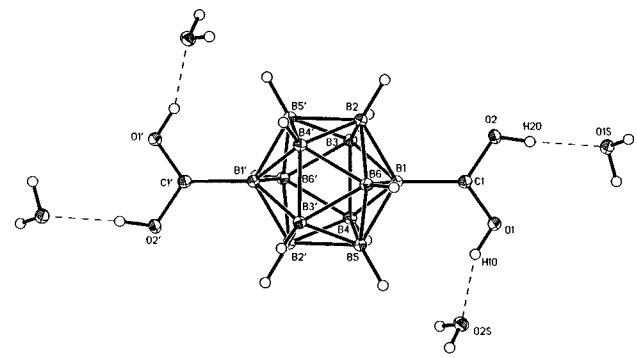

Fig. 2 Crystal structure of **2** (50% ellipsoids). Important interatomic distances (Å) are: O(1)–C(1) 1.289(1), O(2)–C(1) 1.287(1), O(1)–H(10) 0.86(2), O(2)–H(20) 0.84(2), C(1)–B(1) 1.589(1), average B–B distances; polar–tropical 1.779, tropical–tropical 1.801, tropical–tropical′ 1.783. Selected angles (°) C(1)–O(1)–H(10) 116.3(12), C(1)–O(2)–H(20) 110.3(12), O(1)–C(1)–O(2) 114.66(9), O(1)–C(1)–B(1) 125.26(9), O(2)–C(1)–B(1) 120.08(8), C (1)–B(1)–B(2) 119.75(8).

Table 1 Bond lengths and bond orders for B–C and C–O bonds in **1** and **2**

	Bond length (Å)		Total bond order		π-Bond order	
	B–C	C–O	B–C	C–O	B–C	C–O
1	1.543(2)	1.119(2)	0.843	2.422	0.114	1.464
2	1.589(1)	1.287(1)	0.828	1.328	0.064	0.407
		1.289(1)		1.274		0.369

in **2** (Table 1). There is π electron delocalization in all C–O bonds, the carbonyl group bond order is roughly 2.5 in **1** whereas the carbenediol group in **2** has two C–O bond orders of around 1.5 (like those found in symmetrical chelating carboxylates). AM1 calculated Mulliken charges give an overall charge of +0.4 for the carbonyl group in **1** and +0.5 for the diol group in **2**. The molecular structures of **1** and **2** remain largely unchanged in solution as experimental ^{11}B NMR data are in accord with calculated GIAO/NMR data‖ (using the GAUSSIAN94 program) generated from their X-ray geometries.

The distortion of the B_{12} cage geometry in **1** from regular I_h is interesting. If one regards the B_{12} icosahedron as globular, with the substituted boron atoms occupying polar sites, the remainder occupying tropical sites, the dicarbonyl **1** show lengthening of the boron–boron bonds within the tropics, shortening of the bonds linking tropical to polar boron atoms, but little change in the distances linking northern to southern tropical boron atoms (average bond distances shown in the figure captions) compared to $B_{12}H_{12}^{2-}$ (average B–B distance 1.784 Å). The icosahedron is thus squashed from pseudospherical to oblate spheroidal along the polar axis (distances: polar–polar 3.19 Å and tropical–tropical′ 3.45 in **1**, *cf*. 3.39 in $B_{12}H_{12}^{2-}$). Compound **2** and the only other known 1,12-$B_{12}H_{10}L_2$ derivative structurally characterized[10] (L = SMe_2) show similar distortions but these are not as extreme as in **1**.

The remarkably close structural relationship of the substituents in boranes **1** and **2** and in carbocations[11] $MeCO^+$ (C–O 1.110 Å) and $MeC(OH)_2^+$ (C–O 1.273 Å) respectively implies that compounds **1** and **2** can be viewed as neutral main group analogues of bis-carbocations. Further evidence of the close relationship is shown in the ^{13}C NMR peak seen at 200.2 ppm in **2** like those carbene carbons in the carbocations $RC(OH)_2^+$ whose peaks are observed in the 215–190 ppm region.[12] There are parallels of the boranes **1** and **2** with transition metal carbonyl and dioxycarbene $C(OR)_2$ complexes,[13] in which the metal–carbon bonds are always shorter to the carbonyl group than to the dioxycarbene group.

Our findings have implications for other supposed carboxylic acid derivatives of other borane anions. Hydration of the borane dicarbonyls, 1,10-$B_{10}H_8(CO)_2$ and 1,7-$B_{12}H_{10}(CO)_2$, have been reported[5,6] to give carboxylic acids, $[H_3O^+]_2$[1,10-$B_{10}H_8(CO_2H)_2^{2-}$] and $[H_3O^+]_2$[1,7-$B_{12}H_{10}(CO_2H)_2^{2-}$], respectively whereas the related mono-anions, 2-$B_{10}H_9(CO)^-$ and $B_{12}H_{11}(CO)^-$, were reported[14] to produce $[H_3O^+]_2$[2-$B_{10}H_9(CO_2H)^{2-}$] and $[H_3O^+]_2[B_{12}H_{11}(CO_2H)^{2-}]$. Carbenediol groups are probably present in these hydrates. The dicarboxylic acid dianion in **3** is likely to exist in metal salts[6] generated from **2**.

We thank Professor T. R. Spalding (Cork) for discussions and a sample of **1**, Dr R. Kataky for help with the pK_a measurements. We are grateful to EPSRC (M. A. F.) and the Durham University Christopherson fellowship (J. A. K. H.) for financial support.

Direct observation of highly distorted hexa-coordinated aluminium in andalusite by very fast ^{27}Al MAS NMR

João Rocha*

Department of Chemistry, University of Aveiro, 3810 Aveiro, Portugal. E-mail: rocha@dq.ua.pt

Received (in Cambridge, UK) 7th September 1998, Accepted 12th October 1998

Highly distorted hexa-coordinated Al in andalusite can be detected by very fast (> 30 kHz) ^{27}Al magic-angle spinning (MAS) and triple-quantum MAS NMR spectroscopy.

Andalusite is a naturally occurring aluminium silicate named after Andalusia (Spain) where it has been found, and it is one of the three known Al_2SiO_5 polymorphs, the other being sillimanite and kyanite. The crystal structure of andalusite consists of [AlO_6] octahedra forming chains parallel to *c* which are cross-linked by [SiO_4] tetrahedra and [AlO_5] trigonal bipyramids.[1,2] Several studies reporting ^{27}Al magic angle (and variable angle) spinning NMR spectra of andalusite are available.[3,4] ^{27}Al is a half-integer quadrupole (I = 5/2) nucleus and obtaining a good MAS NMR spectrum of andalusite presents a great challenge because all the aluminium nuclei are in highly distorted environments (characterised by large quadrupole coupling constants) and, hence, give very broad peaks.[4] In particular, the [AlO_6] octahedron is so distorted that its ^{27}Al MAS NMR resonance has not previously been observed, even when the sample was spun at 15 kHz.[4] Recently, NMR probes capable of achieving spinning rates of 30–35 kHz became commercially available. Here, we wish to report that the use of such a probe and very fast (> 30 kHz) MAS allows the detection of the broad hexa-coordinated ^{27}Al NMR andalusite resonance. In addition, we also show that by combining very fast MAS and very powerful (> 250 kHz) radiofrequency (rf) fields a ^{27}Al triple-quantum (3Q) MAS NMR spectrum[5] of andalusite can be recorded.

Andalusite from Minas Gerais, Brazil, was characterised by powder X-ray diffraction and ^{29}Si MAS NMR (single peak at δ −79.6). 'Conventional' (single-quantum) ^{27}Al MAS NMR spectra of andalusite recorded at different spinning rates are shown in Fig. 1. In order to obtain meaningful relative signal intensities we have used short (0.6 μs, equivalent to 10^0) and strong rf pulses. The 32.5 kHz MAS spectrum clearly contains two broad resonances centred at δ *ca.* 13 and −110 (with peak singularities at δ −46 and −184), displaying characteristic second-order quadrupole lineshapes. The former has been previously assigned to penta-coordinated aluminium.[3,4] In our 9.4 T magnetic field, the presence of the very broad peak centred at δ *ca.* −110 becomes apparent at MAS rates in excess of 20 kHz, but its lineshape is only well defined at *ca.* 30 kHz. The second-order quadrupole patterns can be simulated to yield the isotropic chemical shifts, δ_{iso}, the quadrupole coupling constants, C_Q, and the asymmetry parameters, η (Fig. 2). The following values are obtained for the penta- and hexa-coordinated Al species, respectively: δ_{iso} 35.5 and 13.0; C_Q = 5.8 and 15.3 MHz; η = 0.69 and 0.08. These quadrupole parameters are in good agreement with previously reported data (C_Q = 5.9 and 15.6 MHz; η = 0.70 and 0.08 for penta- and hexa-coordinated Al, respectively).[3,4,6] The relative intensities of these two Al peaks (the spinning sidebands arising from the m = +1/2 ↔ m = −1/2, central transition hexa-coordinated Al line are included) measured directly from the spectrum are in a 1 : 0.85 ratio, respectively. According to the published crystal structure, this ratio should be 1 : 1 and, thus, NMR slightly underestimates the hexa-coordinated Al population. A more precise estimation of the two Al populations requires the simulation not only of the central transition ^{27}Al MAS NMR spectrum but also of the (±3/2 ↔ ±1/2 and ±5/2 ↔ ±3/2) satellite-transitions spectra. This work is in progress in our laboratory.

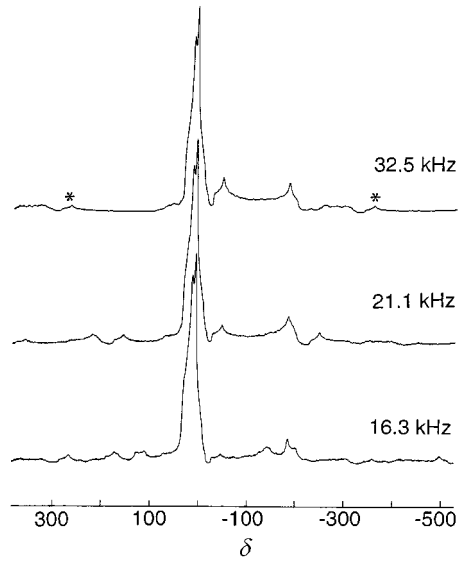

Fig. 1 ^{27}Al MAS NMR spectra of andalusite recorded at 104.3 MHz on a Bruker MSL 400P spectrometer using a Bruker 2.5 mm double-bearing probe, 0.3 s recycle delays, and the spinning rates indicated. Chemical shift reference $[Al(H_2O)_6]^{3+}$. The asterisks denote spinning sidebands arising from the central transition hexa-coordinated Al line.

The large C_Q values of the andalusite Al species make the excitation of ^{27}Al NMR multiple-quantum coherences a very difficult task. We were particularly interested in finding out whether the hexa-coordinated ^{27}Al NMR resonance (with C_Q = 15.3 MHz) could be observed in a triple-quantum experiment. Fig. 3 shows the ^{27}Al 3Q MAS NMR spectrum of andalusite recorded with a very fast sample spinning. The penta-coordinated Al peak is clearly seen and it exhibits an almost undistorted lineshape (inset in Fig. 3). Although very weak, the hexa-coordinated Al resonance is observable. Both peaks (in

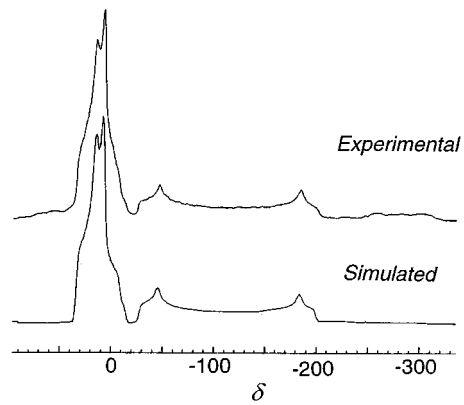

Fig. 2 Experimental and simulated ^{27}Al MAS NMR spectra of andalusite (spinning rate 32.5 kHz).

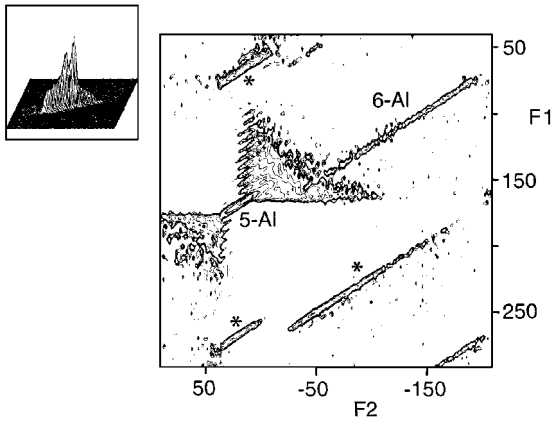

Fig. 3 Unsheared ^{27}Al triple-quantum MAS NMR spectra of andalusite recorded with a rf field amplitude of *ca*. 265 kHz and a spinning rate of 30.2 kHz. 512 data points (864 transients per point) were acquired in the t_1 dimension in increments of 1 μs (or 4.1 μs for the inset spectrum). To produce pure-absorption lineshapes a simple two-pulse sequence was used.[7] The ppm scale was referenced to ν_0 frequency in the ν_2 domain and to $3\nu_0$ in the ν_1 domain (reference $[Al(H_2O)_6]^{3+}$). The inset depicts the penta-coordinated Al resonance. Asterisks denote spinning sidebands along F1.

particular the latter) display strong spinning sidebands along F1.

In the recent past, the use of relatively slow (< 15 kHz) MAS did not allow the detection of Al in highly distorted environments and, thus, the correct quantification of aluminium by NMR was sometimes impossible. ^{27}Al NMR resonances with quadrupole coupling constants in excess of 15 MHz can now be studied with commercially available MAS probes at sample spinning rates of *ca*. 30 kHz. In addition, combining fast MAS and very strong rf fields (> 250 kHz) allows the excitation of ^{27}Al 3Q NMR coherences of highly distorted (C_Q up to *ca*. 15 MHz) Al species.

We acknowledge FEDER and PRAXIS XXI for financial support.

A blue electroluminescent molecular device from a tetranucluear zinc(II) compound $[Zn_4O(AID)_6]$ (AID = 7-azaindolate)

Yuguang Ma, Hsiu-Yi Chao, Ying Wu,† S. T. Lee,‡ Wing-Yiu Yu and Chi-Ming Che*

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong. E-mail: cmche@hkucc.hku.hk

Received (in Cambridge, UK) 7th July 1998, Accepted 23rd September 1998

A tetranuclear zinc(II) compound with 7-azaindolate (AID) as a bridging ligand exhibits an intense blue emission at 425 nm with a quantum yield of 0.21 in acetonitrile solution at room temperature; a blue-light emitting diode based on the Zn(II) complex as the active emitting layer attains an EL efficiency of 0.25% and brightness of 88 cd m^{-2} at 7.1 V driving voltage with current density of 10 mA cm^{-2}.

The search for new bright blue UV-luminescent metal–ligand compounds is of growing importance in the development of light emitting diode (LED) technology.[1–3] In this regard, polynuclear d^{10} metal complexes are of interest since these compounds are strongly emissive under UV irradiation, and the emission energies can span over a broad spectral range [400–700 nm].[4,5] Previously, we and Peng reported the preparation and crystal structure of a tetranuclear zinc(II) compound $[Zn_4O(AID)_6]$, here denoted as Zn_4, with 7-azaindolate as a bridging ligand.[6] This compound has the following desirable features that enable it to be a good advanced material for blue LED device fabrication: it can be easily prepared and is stable to air and moisture. Our recent studies revealed that it has high thermal stability in air below 400 °C and displays an intense blue photoluminescence with a long lifetime and a high quantum yield at room temperature. The relevant photophysical data are summarised in Table 1. Herein is described a blue LED device with the Zn_4 compound as the active emitting layer.

The Zn_4 compound was prepared by the reaction of zinc(II) acetate with 7-azaindole in methanol, and its crystal structure had already been reported.[6] Schematic representations of the LED devices studied here are shown in Scheme 1. Initially a single-layer LED was fabricated by vacuum deposition of $[Zn_4O(AID)_6]$ (< 200 °C, 2×10^{-6} Torr) onto a glass substrate coated with indium–tin oxide (ITO; sheet resistance 20 Ω □$^{-1}$) to form a thin homogeneous film. The film thickness was found to be 700 Å, and the surface was examined by atomic force microscopy (AFM); the roughness of the surface is 3 nm (RMS amplitude) which is about +4.3% for the film thickness. The surface topology is stable up to 150 °C. The XRD pattern of the Zn_4 thin film revealed a broad peak at 2θ = 15–30°, which contrasts with the sharp peaks at 2θ = 10, 12 and 20° observed for the crystalline powder sample. This indicates that the Zn_4 compound in the vacuum deposited thin film is in an amorphous state. An aluminium cathode (thickness ≈ 2000 Å) was vacuum deposited on top of the Zn_4 film at an evaporation rate of 3–5 Å s^{-1}. The substrate was kept at room temperature during the deposition. The active area of the LED is 2×2 mm^2.

When the single-layer LED was forward biased with the ITO electrode at positive polarity, blue EL was observed. The EL spectrum (Fig. 1) resembles the PL spectrum of the Zn_4 film

Table 1 Photoluminescence data for $[Zn_4O(AID)_6]$ at room temperature

Solvent	λ_{max}/nm	Lifetime/μs	Quantum yield
MeCN	425	0.09	0.21

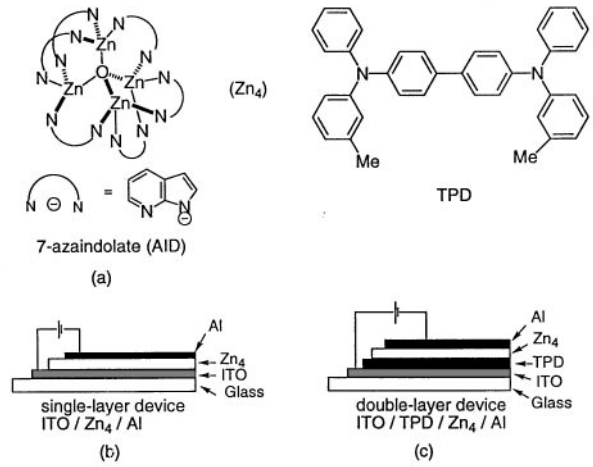
solid state	433	0.05	—



Scheme 1

suggesting that it originates from an excited state of $[Zn_4O(AID)_6]$. However, the brightness of the single-layer device is only 2.5 cd m^{-2} at a driving voltage of 6.5 V and current density of 10 mA cm^{-2}. Because the Zn_4 compound has a high ionisation potential of 5.1 eV [*c.f.* 4.8 eV for tris(8-hydroxyquinolinato)aluminium (Alq_3)], a hole-transport material such as *N*,*N*′-diphenyl-*N*,*N*′-bis(3-methylphenyl)-1,1′-biphenyl-4,4′-diamine (TPD, thickness ≈ 100 Å)[7] was introduced between the emitting Zn_4 and the ITO layers to form a double-layer device as depicted in Scheme 1. The EL brightness and efficiency have thus been greatly enhanced.

Fig. 2 shows the current density–voltage and EL intensity–voltage characteristics of the double-layer LED. When the LED was forward biased with the ITO electrode at positive polarity, blue EL was observed. However, when the device was reverse

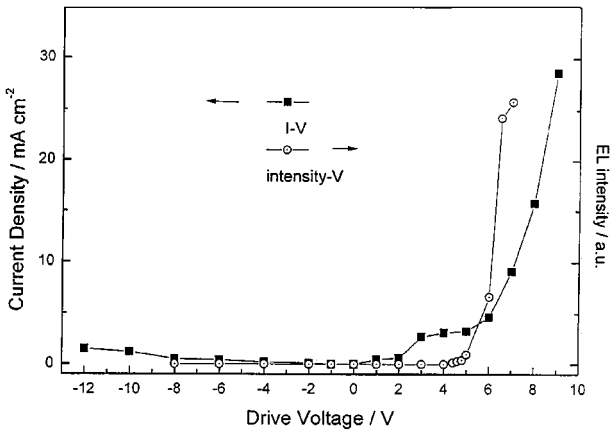

Fig. 2 Current density (*I*)–voltage (*V*) and EL intensity–voltage characteristics.

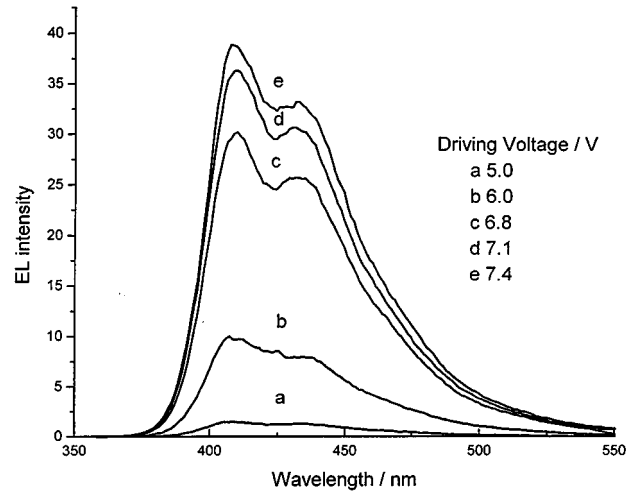

Fig. 3 EL spectra of the double-layer device at various driving voltages.

biased, EL was not observed implying that it is not induced by the dielectric breakthrough of the layer system. The brightness of the device is about 88 cd m^{-2} at a driving voltage of 7.1 V and current density of 10 mA cm^{-2}, and an external EL efficiency of 0.25% (photons per electron) was found, which is 35 times higher than the single-layer device. The double-layer LED shows a rather low turn-on voltage of about 5 V, compared with >12 V usually required for the π-conjugated polymer-based devices.

The EL spectrum of the double-layer LED shows two emission maxima at λ_{em} = 410 and 430 nm (Fig. 3), and this is different from the PL spectrum. We suggest that one of the two emission peaks in the EL spectrum comes from an interface state originating from the TPD and the Zn_4 layers; however, a precise explanation for this emission is not yet known.

Preliminary studies indicated that the present double-layer Zn_4 LED device configuration is stable in open atmosphere. Because of its high thermal stability and high photoluminescence quantum yield, the Zn_4 compound and its related derivatives may provide an alternative to the widely studied Alq_3 compound for future development of LED devices.

The role of singlet oxygen in the photochemical formation of $C_{60}O$

David I. Schuster,* Phil S. Baran, Russell K. Hatch, Ahsan U. Khan and Stephen R. Wilson

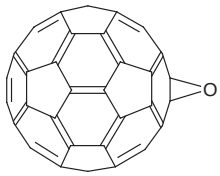
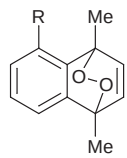
Received (in Liverpool, UK) 20th August 1998, Accepted 6th October 1998

Ground state C_{60} does not give $C_{60}O$ in the presence of singlet oxygen generated thermally from endoperoxides; evidence is presented that the photochemical formation of $C_{60}O$ from C_{60} proceeds *via* reaction of singlet oxygen with the lowest triplet excited state of C_{60}.

Since its synthesis and characterization in 1992 by Smith *et al*.,[1] several studies on $C_{60}O$ **1** have appeared, showing that oxide **1** can be generated through both thermal[2] and photochemical[1] pathways. Dimethyldioxirane,[2a] ozonolysis,[2b–d,f] MCPBA,[2e] P450 cytochrome models,[2g] and a methyltrioxorhenium–H_2O_2 system[2h] all successfully convert C_{60} to **1**. Oxide **1** can also be



Oxide **1**



Endoperoxide **2** R = H

3 R = Me

isolated from the byproducts of fullerene synthesis[3a] and by extended irradiation of C_{60} in an oxygen atmosphere.[1] Although much is known about the photophysical and chemical properties of fullerenes, both the thermal and photochemical mechanisms for the formation of fullerene oxides largely remain a mystery.[3]

Foote and co-workers reported in 1991[4] that C_{60} is a very efficient sensitizer for formation of singlet oxygen ($\Phi = 0.96 \pm 0.02$ at 532 nm), and that C_{60} also quenches $^1O_2$, as shown by the shortening of the decay time of $^1O_2$ luminescence at 1270 nm[5] ($k_q = 5 \pm 2 \times 10^5$ M^{-1} s^{-1}).[4] However, no loss of C_{60} or appearance of new products was observed in the presence of oxygen following hundreds of laser pulses,[3b,4] suggesting that $^1O_2$ does not add to ground state C_{60} in solution. We have confirmed that $C_{60}O$ **1** is not formed upon reaction of C_{60} in toluene with $^1O_2$ when the latter is generated *via* the thermolysis of endoperoxides **2** and **3**.[6] Using an authentic sample of oxide **1**, we verified by HPLC analysis[7] that **1**, if formed, could be present in quantities no more than 0.01% of the total amount of C_{60} present in the solution. The presence of $^1O_2$ in this reaction system was verified by monitoring its emission at 1270 nm, which completely disappeared upon addition of β-carotene.[5,8] When cyclohexa-1,3-diene was added to toluene solutions of C_{60} and endoperoxide **2**, the conversion of the diene to its corresponding 1,4-endoperoxide[9] was detected by HPLC,[7] confirming that $^1O_2$ had indeed been generated under these reaction conditions. We also showed that C_{70} as well as several functionalized derivatives of C_{60} were also uneffected by $^1O_2$ generated thermally from endoperoxide **2**, according to HPLC analysis.[7] Juha *et al*. showed some time ago that C_{60} in fullerene–solvent clathrate microcrystallites was unreactive to a stream of chemically generated $^1O_2$.[10]

The question then remains as to the role played by $^1O_2$ in the photochemical formation of **1**. Could an *electronically excited* state of C_{60} lead to $C_{60}O$ by reaction with $^1O_2$? This question was addressed by photoexciting C_{60} in the presence of endoperoxides **2** and **3** as external sources of $^1O_2$. While endoperoxide **2** releases $^1O_2$ readily at temperatures above 0 °C, endoperoxide **3** does not release $^1O_2$ at room temperature.[6a,b] Thus, no emission at 1270 nm was observed from a toluene solution of **3** at room temperature. Thus, we were able to assess the reactivity of photoexcited C_{60} in the presence of two endoperoxides with very different thermal stabilities. In these reactions, 50 equiv. of endoperoxide were added to a 20 mM solution of C_{60} in benzene-d_6. The solutions were thoroughly degassed on a vacuum line by several freeze-pump-thaw cycles, and were then irradiated for 18 h.[11]

In the case of endoperoxide **2**, HPLC analysis revealed the formation of $C_{60}O$ **1** in 10% yield, higher than that (7%) reported from irradiation of C_{60} in an oxygen atmosphere under analogous conditions.[1] We also observed (HPLC) two additional minor products, presumably isomers of $C_{60}O_2$, as well as a brown precipitate, which were previously observed in the direct photooxygenation reaction.[1] The yield of **1** was far lower (2%) using endoperoxide **3**; furthermore, the higher oxidation products were not observed by HPLC in this case.

Thus, not only does the initial presence of $^1O_2$ in the photochemical reaction system increase the yield of fullerene oxide **1**, the absence of $^1O_2$ significantly decreases the efficiency of formation of **1**. This clearly identifies $^1O_2$ as the key species in the mechanism for fullerene oxide formation under photochemical reaction conditions, and suggests that $C_{60}O$ results from reaction of $^1O_2$ (lifetime 24 μs in benzene, 25 μs in toluene)[12] with an excited state of C_{60}. Such a mechanism was previously suggested[10] but no supporting evidence was presented. Given the very short lifetime of the S_1 state of C_{60} (*ca*. 1.2 ns),[13] and the long lifetime of the corresponding T_1 state (variously reported as 40 to 133 μs),[4,14] the triplet excited state is the obvious choice. If **1** were arising from reaction of C_{60} triplets directly with ground state endoperoxide, the yield of **1** should be similar using **2** and **3**. The large disparity in the yields of **1** suggests that this is at best a minor reaction pathway. We therefore conclude that the dominant photochemical pathway to $C_{60}O$ from C_{60} involves the reaction of C_{60} triplet excited states with singlet oxygen.

We are grateful to the National Science Foundation and the Dean's Undergraduate Research Fund, New York University (grant to P. S. B.), for support of this work. We thank Professor N. E. Geactinov for his assistance in providing access to the singlet oxygen apparatus.

Received (in Cambridge, UK) 17th August 1998, Accepted 6th October 1998

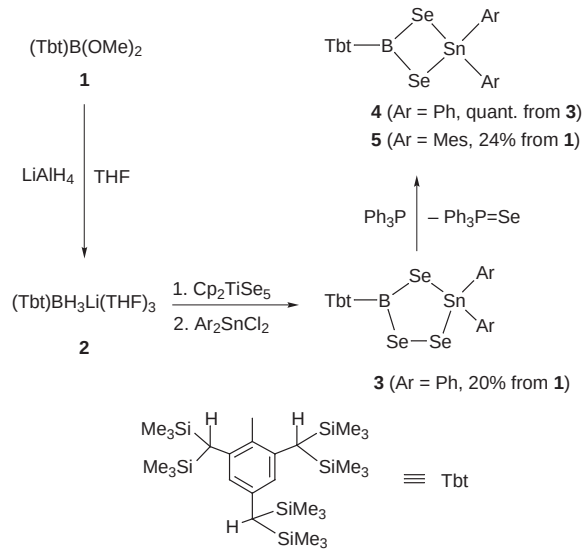
Treatment of an overcrowded aryl trihydroborate bearing 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (Tbt) group with Cp_2TiSe_5 followed by the addition of Ar_2SnCl_2 (Ar = Ph or Mes) and Ph_3P resulted in the isolation of novel selenium-containing four-membered boracycles, 1,3,2,4-diselenastannaboretanes, the thermolysis of which in the presence of 2,3-dimethyl-1,3-butadiene or 2,4,6-tri-*tert*-butylbenzonitrile oxide indicated the formation of a novel class of boron-containing doubly bonded compound, an arylselenoxoborane (Tbt)B=Se.

The chemistry of boracycles containing heavier group 16 elements has been much less investigated than that of the oxygen-containing counterpart such as boroxines [$(RBO)_3$] and other cyclic boronic esters owing to their high sensitivity toward air and moisture.[1] Since a boron atom is known to prefer planar-tricoordinate geometry strongly, small ring compounds containing a boron atom generally have a large ring strain and are quite reactive. Recently, we have reported the synthesis and structures of several stable 1,3,2,4-dithiametallaboretanes, novel sulfur-containing four-membered boracycles, bearing a very bulky and effective steric protecting group, 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (Tbt) group.[2] We have also described that one of those four-membered ring systems, *i.e.* a 1,3,2,4-dithiastannaboretane derivative, provides us with a new and facile route to the boron–oxygen and boron–sulfur double-bond compounds (oxoborane and thioxoborane, respectively), the synthetic methods to which have, so far, not been well established.[3,4] By contrast, until now there have been very few reports on selenium-containing organoboranes.[5]

Here, we report the synthesis and crystal structure of a kinetically stabilized 1,3,2,4-diselenastannaboretane bearing the Tbt group, a novel selenium-containing four-membered boracycle, together with its thermolysis leading to the formation of an arylselenoxoborane (Tbt)B=Se. Oxoboranes and thioxoboranes are known to be important intermediates in the oxidation or sulfurization of elemental boron or other boron compounds and are widely studied from the viewpoints of theoretical and/or gas-phase chemistry.[6,7] On the other hand, selenoxoboranes, selenium analogues of oxoboranes and thioxoboranes, are thought to be much less stable than oxoboranes and thioxoboranes, and there has been only one report on the gas-phase detection of a chloroselenoxoborane in the reaction of elemental boron with Se_2Cl_2 at 1000 °C.[8] Although the synthesis and structure of 1,3,2,4-diselenadiboretane, a dimer of a selenoxoborane, has already been reported by Nöth and coworkers, no description was given for the intermediary selenoxoborane.[9]

The reaction of an overcrowded trihydroborate **2**, synthesized by the reaction of $(Tbt)B(OMe)_2$ **1** with $LiAlH_4$,[2] with titanocene pentaselenide followed by treatment with Ph_2SnCl_2 gave a novel five-membered boracycle, 1,2,4,3,5-triselenastannaborolane **3**, as yellow crystals in 20% yield from **1** (Scheme 1). Although we have attempted the thermolysis of **3** in the hope of cycloreversion into the selenoxoborane (Tbt)B=Se, no change was observed even at 150 °C in the presence of 2,3-dimethylbuta-1,3-diene as a trapping reagent for a selenoxoborane. We next examined ring contraction of **3** to the 1,3,2,4-diselenastannaboretane by deselenation with Ph_3P. The reaction proceeded smoothly and quantitatively at ambient temperature to give the desired 1,3,2,4-diselenastannaboretane **4**, a novel selenium-containing four-membered boracycle (Scheme 1). Compound **4** showed satisfactory spectral and analytical data, but single crystals suitable for X-ray crystallographic analysis were not obtained owing not only to the low crystallinity but also to its high instability in solution. On the other hand, 2,2-dimesityl-1,3,2,4-diselenastannaboretane **5**, which was prepared from **1** and dichlorodimesitylstannane in 24% yield by a synthetic method similar to that of **4**,[10] gave single crystals suitable for X-ray crystallographic analysis upon recrystallization from 1,2-dimethoxyethane. The crystal structure of **5** is shown in Fig. 1.†

The four-membered ring of **5** is not completely planar with the dihedral angle between planes B(1)–Se(1)–Se(2) and Sn(1)–Se(1)–Se(2) being 13.8° due to the steric repulsion between the Tbt group and one of the mesityl group on the tin atom. The geometry around the central boron atom is found to be perfectly trigonal planar ($\Sigma\angle B = 360°$). The angle between the plane



Scheme 1

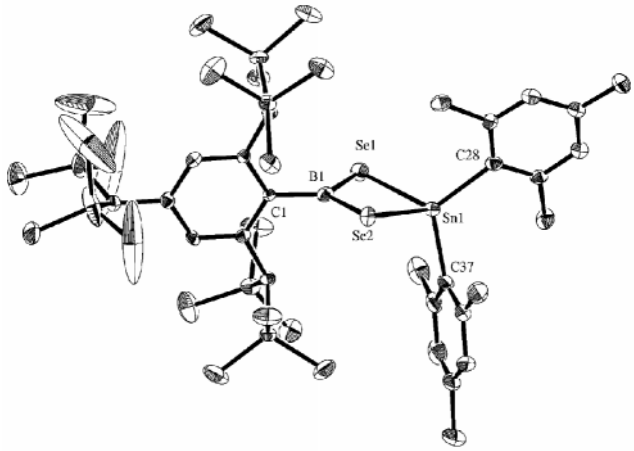


Fig. 1 ORTEP drawing of 2,2-dimesityl-1,3,2,4-diselenastannaboretane **5** with thermal ellipsoid plots (40% probability). Selected bond lengths (Å) and angles (°). B(1)–C(1) 1.557(13), B(1)–Se(1) 1.962(11), B(1)–Se(2) 1.960(10), Se(1)–Sn(1) 2.557(1), Se(2)–Sn(1) 2.566(1), Sn(1)-C(28) 2.149(10), Sn(1)-C(37) 2.127(10), Se(1)–B(1)–Se(2) 114.1(5), Se(1)–B(1)–C(1) 123.2(7), Se(2)–B(1)–C(1) 122.7(8), B(1)–Se(1)–Sn(1) 82.4(3), B(1)–Se(2)–Sn(1) 82.2(4), Se(1)–Sn(1)–Se(2) 79.95(4), C(28)-Sn(1)–C(37) 117.3(3).

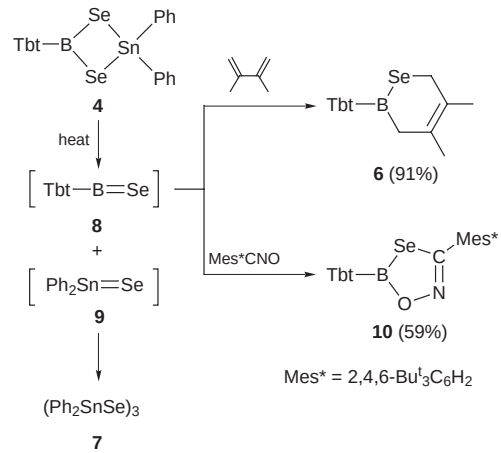
defined by B(1)–Se(1)–Se(2) and the aromatic ring plane of the Tbt group is 86.6°, suggesting no conjugative interaction of π-electrons on the Tbt group with the boron atom. These structural features of **5** are similar to those of the 2,2-dimesityl-1,3,2,4-dithiagermaboretane derivative reported by us.[2b]

Since we have already shown that the 2,2-diphenyl-1,3,2,4-dithiastannaboretane derivative, a sulfur-analogue of **4**, acts as a good precursor of a thioxoborane, (Tbt)B=S, on thermolysis,[4] the thermolysis of **4** was also carried out in the expectation that it would dissociate into a boron–selenium double-bonded species (selenoxoborane) (Tbt)B=Se and diphenylstannaneselone.

When a toluene-d_8 solution of **4** and 2,3-dimethylbuta-1,3-diene in a sealed NMR tube was heated at 100 °C for 12 h, the starting material completely disappeared to afford 4,5-dimethyl-1,2-selenaboracyclohex-4-ene **6** (91%) along with the trimer **7** of diphenylstannaneselone **9** (75%) (Scheme 2). The formation of **6** and **7** clearly indicates the initial retro [2+2]cycloaddition of the diselenastannaboretane ring of **4** into the two units, *i.e.* selenoxoborane **8** and diphenylstannaneselone **9**, followed by the [4 + 2]cycloaddition reaction of **8** with co-existing 2,3-dimethylbuta-1,3-diene and the self-trimerization of **9**. To the best of our knowledge, this is the first example of the trapping reaction of a selenoxoborane. Similarly, thermolysis of **4** at 50 °C in the presence of 2,4,6-tri-*tert*-butylbenzonitrile oxide afforded the [3 + 2]cycloadduct of selenoxoborane **10** (59%)† together with **7** (45%). These results show that the selenoxoborane has a double-bond character like oxoborane and thioxoborane previously reported.[3,4]



Scheme 2

In summary, we have succeeded in the isolation and crystallographic analysis of the first 1,3,2,4-diselenastannaboretane **4**. Compound **4** undergoes thermal cycloreversion into the overcrowded selenoxoborane (Tbt)B=Se, the formation of which was confirmed by the intermolecular [4+2]cycloaddition reaction with a diene.

This work was partly supported by Grants-in-Aid for Scientific Research (No. 09239208 and 09440216) from the Ministry of Education, Science, Sports, and Culture, Japan. M. I. thanks Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists. We also thank Shin-etsu Chemical and Tosoh Akzo Co., Ltds. for the generous gift of chlorosilanes and alkyllithiums, respectively.

Notes and references

† *Crystallographic data* for **5**: $C_{45}H_{81}BSe_2Si_6Sn$, M = 1087.07, monoclinic, space group $P2_1/n$, a = 21.053(5), b = 13.324(4), c = 21.341(5) Å, β = 91.22(2)°, V = 5634(2) Å^3, Z = 4, D_c = 1.271 g cm^{-3}, T = 173 K, $F(000)$ = 2232.00, yellow prism with dimensions 0.65 × 0.40 × 0.10 mm, μ(Mo-Kα) = 19.00 cm^{-1}, $R(R_w)$ = 0.069(0.075). The intensity data (2θ < 55°) for **1** were collected on a Rigaku AFC7R diffractometer with graphite monochromated Mo-Kα radiation (λ = 0.71069 Å), and 13870 reflections (13517 unique) were measured. The structure of **1** was solved by direct methods with SHELXS-86,[11] expanded using Fourier techniques,[12] and refined by the full-matrix least-squares methods using the TEXSAN crystallographic software package.[13] All the non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were located in the calculated positions. The final cycles of the least square refinement were based on 6066 observed reflections [$I > 3\sigma|I|$] and 497 variable parameters. The maximum and minimum peaks on the final difference Fourier map correspond to 3.48 and −1.04 e$^-$/Å^3, respectively. CCDC 182/1052.

C_{60} degrades to $C_{120}O$

Roger Taylor,*[a] Mark P. Barrow[b] and Thomas Drewello[b]

Received (in Cambridge, UK) 27th August 1998, Accepted 6th October 1998

At ambient temperature and in the solid state C_{60} degrades to $C_{120}O$ which is present in up to *ca.* 1% concentration in each of thirteen differently sourced samples examined; traces of $C_{120}O_2$ have also been detected.

When pure [60]fullerene was first obtained,[1] it was observed that films which had been left on the surface of a flask for a few days would not redissolve easily, successive extracts being increasingly dilute and more pink in colour relative to the magenta of the pure fullerene.[2] Oxidation was suspected, but further analysis was not possible at that time.

Recently, we have found that completely insoluble products are formed from fullerenes (especially higher fullerenes) on standing.[3,4] These were provisionally described as graphitic due to this insolubility,[3] but more recent work showed that graphitic planes are absent, and moreover, heating KBr discs of them produces matrix-isolated CO_2.[4] Evidently these derivatives contained oxygen, but no further details of the structures could be deduced.

[60]Fullerene, available now from numerous suppliers, comes with a stated purity. Given this assurance, fullerene researchers have had no need to examine the purity of the material. This has not been problematical because purification is usually affected at the derivative stage. Recently however, we found it necessary to check by HPLC (4.6 mm × 25 cm Cosmosil Buckyclutcher column, toluene eluent at 1 ml min^{-1}) the [70]fullerene level in a new batch of [60]fullerene. While the amount of [70]fullerene was virtually undetectable we were surprised to find a significant peak with a retention time of 14.6 min compared with [60]fullerene at 7.4 min, Fig. 1 ([70]fullerene elutes at 11.8 min under these conditions). The retention time was identical to that for an authentic sample[5] of $C_{120}O$ under our conditions. (NB. The retention times for fullerenes and derivatives vary slightly according to the ambient temperature, column condition, and injection volume, and for the above column/eluent/flow have been described[6] as 7.8 and 15.8 min for C_{60} and $C_{120}O$, respectively.) The eluent solution was straw-coloured, and removal of the toluene produced a brown film, which was much less soluble in toluene than either C_{60} or its oxides, further indicating it to be a dimeric species. Examination of twelve commercial samples from various suppliers, and also one of our own dating from 1990, showed that this component is present in *all* of them, with varying concentrations.

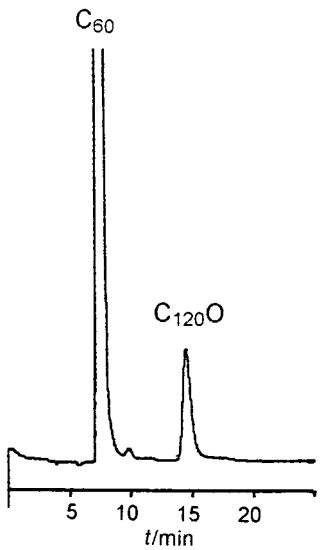

Fig. 1 HPLC of a 1 ml injection of a saturated toluene solution of C_{60}, showing $C_{120}O$ andthe absence of C_{70}.

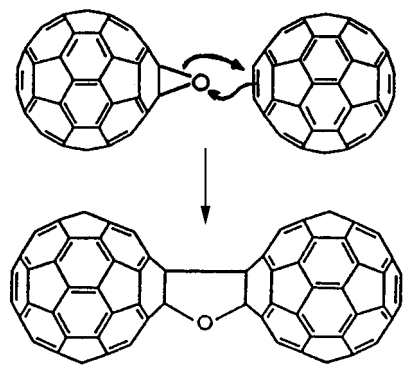
Although an EI mass spectrum of the component showed just C_{60}, a MALDI-TOF mass spectrum proved it to be $C_{120}O$ (*m/z* 1457), and this was confirmed by comparison of the IR spectrum with that of an authentic sample.[5] The common bands are at 1632m, 1463m, 1456sh, 1429, 1384, 1307, 1218, 1183, 1166, 1101m, 1063, 1033m, 1016sh, 960, 849, 831, 807, 780, 765, 746, 711, 606, 589, 574, 551, 527 and 479 nm. The main bands in our spectrum have also been reported very recently.[7]

It is thus ironic that although various groups have gone to some trouble to prepare and isolate $C_{120}O$,[5,8,9] this was actually unnecessary because it is readily available in the first place, and we have been able to extract multimilligram quantities (which crystallise from carbon disulfide as black needles) from commercial C_{60} The literature preparation method consists of converting C_{60} to $C_{60}O$ which was separated and purified, the two reagents being then heated together for many hours, either in the solid state, or under reflux in 1,2-dichlorobenzene, which results in combination to give $C_{120}O$.

$C_{60}O$, which has been produced by oxidation of [60]fullerene under a variety of conditions *viz.* using photosensitizers,[10] chemically generated singlet oxygen,[11] dimethyldioxirane,[12] iodosobenzene/metal catalysts,[13] methyltrioxorhenium–hydrogen peroxide,[14] ozone,[15] 3-chloroperbenzoic acid,[16] and electrochemistry.[17] It is widely assumed that C_{60} undergoes oxidation to $C_{60}O$ on exposure to air, but we believe this has never been demonstrated. We consider that this does indeed happen, but given that the mono-oxide is strained and predicted to be unstable relative to $C_{120}O$,[18] it is quickly captured by a further C_{60} molecule in a [2 + 2] reaction (Scheme 1) to produce $C_{120}O$.



Scheme 1 Conjectured [2 + 2] cycloaddition mechanism for the formation of $C_{120}O$ from C_{60} and $C_{60}O$.

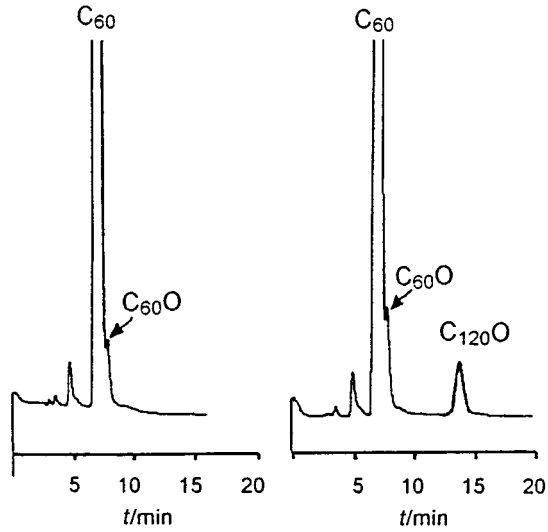


Fig. 2 HPLC traces of saturated toluene solutions (50 μl each) of a C_{60} sample: (a, left) HPLC purified; (b, right) the same material after exposure of the solid to daylight for 40 h.

The possibility that the observed $C_{120}O$ is formed during the arc-discharge process may be discounted since it elutes after [70]fullerene, yet samples in which it is present are entirely free of the latter. Removal of [70]fullerene by chromatographic purification would remove the later-eluting oxide as well. Moreover, given the different separation regimes used by different manufacturers (and none use alumina which was employed to purify our original in-house sample) it would be most surprising that no-one managed to remove any pre-existing $C_{120}O$. In order to provide further information on this point and to confirm our belief that the oxide results from a solid state reaction that occurs at ambient temperature, we exposed a sample of solid HPLC-purified C_{60} to air and daylight for 40 h. Fig. 2(a) and (b) show consecutive HPLC traces for saturated solutions of the solid before and after this exposure. The presence of the $C_{120}O$ peak in the exposed material is apparent, as is the increased intensity of the $C_{60}O$ peak. (The trace of the latter in the purified material arises during the handling and concentration of the HPLC eluent.)

Atmospheric oxidation of [60]fullerene beyond the monoxide stage is likely, giving *e.g.* $C_{60}O_2$ with capture by a further [60]fullerene to give $C_{120}O_2$. Indeed we find evidence of $C_{120}O_2$ in some of the samples, with a peak of retention time under our conditions of 16.9 min, identical to that of an authentic[6] sample. The concentration is however lower than that of $C_{120}O$ despite its formation being energetically more favourable.[18] We believe this is because $C_{60}O$, the $C_{60}O_2$ precursor, is rapidly converted to $C_{120}O$ before further oxidation can occur.

We suggest that $C_{120}O$ may add on further oxygens or $C_{60}O$ molecules (probably remote from the initial addition site, because of steric considerations) to give ultimately a polymer, which is very likely the insoluble oxygen-containing material that we have isolated from various fullerene samples.[3,4] In this connection we find that after a film of HPLC purified C_{60} had stood in daylight during four days, most (*ca.* 70%) would not redissolve readily in toluene (and some not at all). HPLC of the slightly soluble material showed the presence of four components with retention times either similar to, or considerably longer than, the dimeric species described above. This suggests that a mixture of oxygenated dimers and trimers is produced by the more aggressive oxidation, and we hope subsequently to examine these further.

Because the absorption coefficient of $C_{120}O$ is not known (and difficult to measure with any accuracy due to the extremely low solubility in hexane) the percentage present in the examined samples (which varies by a factor of *ca.* 5) is uncertain, but we visually estimate the maximum levels to be around 1%.

These results have consequences. First, they make it difficult to account for the reports[19] that C_{60} has been found to occur naturally. Secondly, the purity levels quoted by suppliers refer to the as-produced material, and are not characteristic of the condition at the time it is used. Thirdly, they make it essential to study the stability of products towards oxidation, if uses are to be found for fullerenes. We know from our own studies that some fullerene derivatives, such as phenylated fullerenes rapidly acquire oxygen on standing,[20] and this may be true for many other derivatives, whilst by contrast, some addends may actually inhibit oxidation. Resolution of this problem must feature amongst the goals of fullerene chemists.

We thank David Box of Dynamic Enterprises Ltd, UK, for providing fullerene samples of different origins.

Synthesis of continuous mesoporous silica thin films with three-dimensional accessible pore structures

Dongyuan Zhao,[a,b] Peidong Yang,[a] David I. Margolese,[a] Bradley. F. Chmelka[b,c] and Galen D. Stucky*[a,b]

[a] *Department of Chemistry,* [b] *Materials Research Laboratory and* [c] *Department of Chemical Engineering, University of California, Santa Barbara, California 93106, USA. E-mail: stucky@chem.ucsb.edu*

Received (in Bloomington, IN, USA) 19th June 1998, Accepted 22nd September 1998

Continuous mesoporous silica thin films with three-dimensional (3-D) accessible pore structures (*Pm*3*n*, *P*6$_3$/*mmc* space groups) have been prepared by a dip-coating technique using cationic surfactants as the structure-directing agents in nonaqueous media under acidic conditions.

The integration of hydrogen bonding interaction at the organic/inorganic interface with organic/inorganic domain assembly and the use of sol–gel and emulsion chemistry in acidic media[1–4] has proven to be a general route for the easy processing of ordered mesoporous materials into desired morphologies.[5–11] Mesoporous silica thin films with highly ordered mesostructures have numerous potential applications in catalysis, sensors, separation, and opto-electric devices.[4–11] We have recently described how surfactant and non-aqueous cosolvents can be used to define mesophase structure,[2–4] and to grow 3-D hexagonal mesostructured silica films at solid–liquid and liquid–vapor interface[7] following the film growth procedures described by Yang *et al.*[5] and Aksay *et al.*[6] for 2-D hexagonal mesostructured silica thin films that have 1-D channel structures with the pore channels oriented parallel to the substrate surface. More recently, the formation of continuous supported cubic and 2-D hexagonal mesoporous silica thin films by sol–gel dip-coating using the above acid synthesis procedure[1–3] with addition of ethanol has been reported by Brinker and coworkers;[11] fine tuning of the conditions for film formation yields high quality, pinhole-free films with the desired thickness.[11]

Here we report the formation by dip-coating[11] of continuous, stable mesoporous silica thin films with 3-D accessible pore structures using cationic surfactants. Large-head-group cationic surfactants such as $C_{16}H_{33}N(C_2H_5)_3Br$ (CTEABr) or gemini surfactants such as $C_{18}H_{37}N(CH_3)_2(CH_2)_3N(CH_3)_3Br_2$ ($C_{18\text{-}3\text{-}1}$) can be used as the structure-directing agent. The thin films exhibit highly ordered mesostructures, which can be 3-D cubic (*Pm*3*n* space group) and 3-D hexagonal (*P*6$_3$/*mmc*) structures with high BET surface areas (up to 1500 m^2 g^{-1}) and varying pore sizes (18–25 Å).

The mesoporous silica films were deposited by dip-coating on polished (100)-silicon wafers or glass sheets. The coating solutions were typically prepared by the addition of 0.78 g CTEABr cationic surfactant dissolved in 10 g ethanol (EtOH) to polymeric silica sols made by an acid-catalyzed process with stirring for 1 h at room temperature. The polymeric silica sols were prepared by heating a mixture of 2.08 g tetraethylorthoxysilicane (TEOS), 5.5 g EtOH, 0.5 g water and 0.4 g (0.1 M) HCl at 70 °C for 1 h. To complete the polymerization of the silicate species and to further improve the thermal stability of the film, the as-deposited film was heated at 80 °C in de-ionized water overnight. After drying, the film supported on the silicon wafer was calcined in air at 500 °C for 4 h to remove the organic template.

Generally, supported silica films prepared using cationic surfactants, such as CTEABr, gemini $C_{18\text{-}3\text{-}1}$, and $C_{16}H_{33}N(CH_3)_3Br$ (CTAB), in nonaqueous solutions under acidic conditions are transparent and continuous (see Fig. 1a). The thickness of the film is uniform, and can be varied from 300 nm to several hundred micrometers by changing the coating solution concentration or the coating time.

Fig. 2 shows XRD patterns of as-deposited and calcined supported silica films prepared using cationic surfactants as the structure-directing agent. As-deposited film with CTEABr shows seven well-resolved diffractions peaks in the 2θ range 1–6° (Fig. 2a), suggesting that the as-deposited film has a highly ordered cubic (*Pm*3*n*) mesostructure with a = 84.4 Å. The XRD pattern remains the same as the film is rotated by 180°, suggesting that the film has an isotropic cubic mesostructure.

After calcination, the XRD pattern (Fig. 2b) of the cubic film shows that the cubic mesostructure is preserved with ≈3% shrinkage (a = 81.7 Å). An additional two peaks indexed as (400), (332) are apparent, possibly due to different shrinkage along the 3-D directions. SEM and photomicroscopy images show that the calcined films with thicknesses < 1 μm are not cracked. TEM images recorded along the [100], [210] and [111] orientations of calcined mesoporous silica films prepared using CTEABr surfactant (Fig. 2b–d) show well-ordered 3-D cubic arrays of mesopores and confirm that the silica film has a highly ordered 3-D cubic (*Pm*3*n*) mesostructure after calcination.

N_2 adsorption–desorption isotherms of calcined silica films show type IV curves without the hysteresis loop, a pore size of 20 Å, a pore volume of 0.54 cm^3 g^{-1}, and a BET surface area of 1200 m^2 g^{-1} (Table 1).

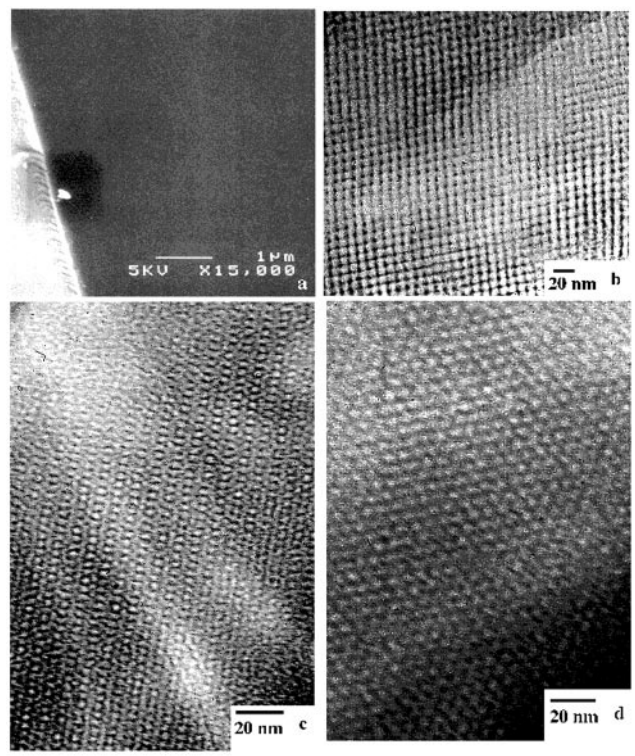

Fig. 1 a, SEM image of as-deposited 3-D cubic mesoporous silica film prepared using CTEABr surfactant. b–d, TEM images of calcined cubic mesoporous silica film with orientations: b, [100] plane; c, [210] plane; and d, [111] plane.

Table 1 Physicochemical properties of mesoporous silica thin films reported in this paper. In each pair with the same surfactant, the second entry was prepared with a high concentration of HCl or a low concentration of surfactant

Surfactant	Phase	Unit cell parameter/Å	Pore size[a]/Å	BET Surface area/m^2 g^{-1}	Pore volume/cm^3 g^{-1}
$C_{16}H_{33}N(C_2H_5)_3Br$	cubic (*Pm*3*n*)	a = 81.7	20	1200	0.54
$C_{16}H_{33}N(C_2H_5)_3Br$	hexagonal (*p*6*mm*)	a = 40.8	18	1080	0.92
$C_{18}H_{37}N(CH_3)_2(CH_2)_3N(CH_3)_3Br_2$	hexagonal ($P6_3/mmc$)	a = 44.7 c = 74.0	24	1500	0.86
$C_{18}H_{37}N(CH_3)_2(CH_2)_3N(CH_3)_3Br_2$	hexagonal (*p*6*mm*)	a = 44.0	25	1160	0.81
$C_{16}H_{33}N(CH_3)_3Br$	hexagonal (*p*6*mm*)	a = 43.9	24	740	0.67
$C_{16}H_{33}N(CH_3)_3Br$	hexagonal (*p*6*mm*)	a = 38.2	19	1490	0.76

[a] After calcination at 500 °C in air, the pore sizes were calculated by using BJH analysis from the adsorption branch of the isotherms.

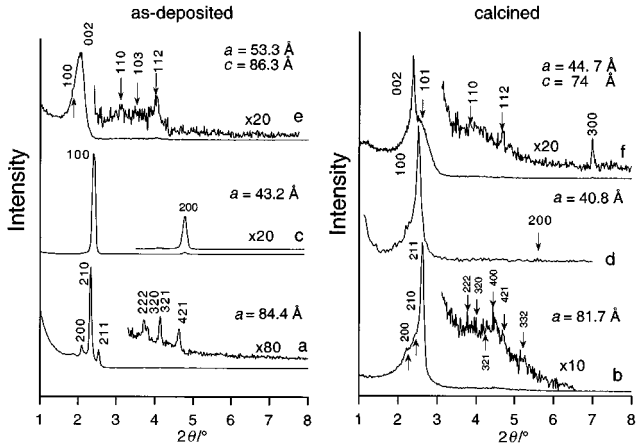

Fig. 2 XRD patterns of a, as-deposited and b, calcined 3-D cubic (*Pm*3*n*) mesoporous silica thin film prepared using CTEABr surfactant; c, as-deposited and d, calcined 2-D hexagonal mesoporous silica thin film prepared using CTEABr surfactant; e, as-deposited and f, calcined 3-D hexagonal mesoporous silica film prepared using gemini $C_{18\text{-}3\text{-}1}$ surfactant.

3-D cubic mesoporous silica thin films can be grown on the substrate over a range of reaction compositions: the ratios can be 1 TEOS : 0.12–0.37 CTEABr : 4.4–8.9 H_2O : 0.0004–0.004 HCl : 10–60 EtOH at room temperature. Unlike aqueous media synthesis [in which CTEABr only favors forming cubic (*Pm*3*n*) silica mesostructures under strongly acidic conditions[1]], in nonaqueous solution, higher concentrations of HCl result in the formation of 2-D hexagonal (*p*6*mm*) silica films confirmed by XRD patterns (Fig. 2c,d) and TEM images. N_2 adsorption measurements show the calcined film to have a pore size of 18 Å, a pore volume of 0.92 cm^3 g^{-1}, and a BET surface area of 1080 m^2 g^{-1} (Table 1).

The 3-D hexagonal mesostructured silica film formed using $C_{18\text{-}3\text{-}1}$ over a range of compositions (1 TEOS : 0.13–0.27 $C_{18\text{-}3\text{-}1}$: 4.4–11 H_2O : 0.0002–0.002 HCl : 10–60 EtOH) at room temperature shows two strong diffraction peaks with *d*-spacings of 46.2 and 43.2 Å, and three weak peaks with *d*-spacings of 30.7, 24.4, 22.5 Å (Fig. 2e). The XRD pattern can be indexed in the 3-D hexagonal space group $P6_3/mmc$ with a = 53.3, c = 86.3 Å. After calcination, the XRD pattern (Fig. 2f) shows four peaks in the 2θ range 1–8°, which can be indexed as (002), (101), (112) and (300). TEM measurements further confirm that the silica film prepared using $C_{18\text{-}3\text{-}1}$ has a highly ordered 3-D hexagonal mesostructure. N_2 adsorption–desorption isotherms show that the calcined films exhibit type IV curves without the hysteresis loop, a narrow pore size distribution at a mean value of 24 Å, and a BET surface area of 1500 m^2 g^{-1} (Table 1).

While in aqueous synthesis, $C_{18\text{-}3\text{-}1}$ surfactant favors formation of only 3-D hexagonal SBA-2,[3] in nonaqueous media lower concentrations of $C_{18\text{-}3\text{-}1}$ surfactant and higher concentrations of HCl yield a hexagonal (*p*6*mm*) oriented silica film with pore channels parallel to the substrate plane. On the other hand, oriented 2-D hexagonal silica films (Table 1) can also be formed through the use of CTAB as the structure-directing agent over a wide range of compositions (1 TEOS : 0.05–0.42 CTAB : 0.8–2 H_2O : 0.0004–0.04 HCl : 10–100 EtOH). The 2-D hexagonal mesostructure is preserved upon changing the concentration of CTAB surfactant and HCl, but the d(100) spacing decreases linearly from 40.8 to 34.5 Å with increase of the concentration of CTAB and HCl. Based on N_2 adsorption measurements, the pore sizes (19–24 Å) of the silica film are also variable with concentration of CTAB and HCl (Table 1). These results suggest that the formation of the silica film occurs with an $S^+X^-I^+$ self-assembly pathway[1] and that CTEABr surfactants have large head group and favor the formation of the 3-D cubic (*Pm*3*n*) mesophase.[3] Higher HCl concentration results in stronger interaction between inorganic and organic species and favors the formation of the 2-D hexagonal mesophase.

Dendritic hydrogen bonding receptors: enantiomerically pure dendroclefts for the selective recognition of monosaccharides

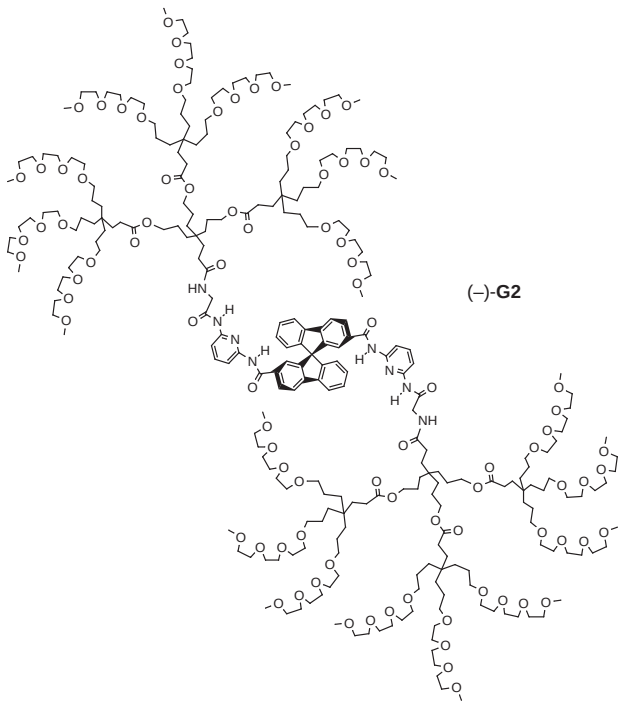
David K. Smith and François Diederich*

Laboratorium für Organische Chemie, ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich, Switzerland. E-mail: diederich@org.chem.ethz.ch

Received (in Cambridge, UK) 21st August 1998, Accepted 2nd October 1998

Enantiomerically pure dendritic cleft receptors (dendroclefts) with a 9,9′-spirobi[9*H*-fluorene] core are prepared for the recognition of glucopyranosides by H-bonding in $CDCl_3$; the enantio- and diastereo-selectivities in the complexation processes are modulated by the presence of the dendritic shell.

The development of functional dendrimers is of great current interest.[1] In particular, the dendritic shell can alter the properties of a functional core.[2] Hydrogen-bonding dendritic hosts have been reported, but the branching does not appear to play an active role in modulating guest recognition.[3] In addition chiral recognition inside a dendrimer is as yet unknown, but possesses great scientific and technological potential.[4] Here we report enantiomerically pure dendritic cleft-type receptors (dendroclefts) of first [(−)-**G1**] and second [(−)-**G2**] generation for the chiral recognition of monosaccharide guests *via* H-bonding.



Dendrocleft (−)-**G2** was targeted by the attachment of flexible branches to a rigid, optically pure 9,9′-spirobi[9*H*-fluorene] initiator core bearing 2,6-di(carboxamido)pyridine moieties in the 2,2′-positions.[5] The resulting dendrimer possesses a buried H-bonding cleft suitable for complexing carbohydrate guests.[5,6] Its periphery is functionalised with neutral polyether groups, which provide excellent solubility in a wide range of solvents, including H_2O.

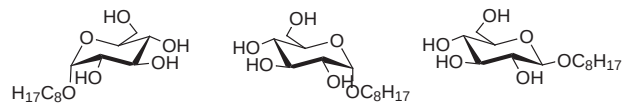
For the synthesis of (−)-**G1** and (−)-**G2** by the convergent approach,[7] the optically active core (−)-**3** was prepared from dicarboxylic acid (−)-(*R*)-**1**[5,8] *via* (−)-**2** and (−)-**G0** (Scheme 1). Attachment of the new dendritic branches **4** or **5**[9] to (−)-**3** provided the optically pure dendroclefts (−)-**G1** and (−)-**G2**, respectively, which were isolated in good yield by preparative gel permeation chromatography {GPC; Biobeads SX-1, CH_2Cl_2 [(−)-**G1**] and THF [(−)-**G2**]}.

Molecular recognition studies were performed by ^{1}H NMR titrations in dry $CDCl_3$ at 298 K using 1-*O*-octyl glucopyranosides (**6–8**) as guests.† Association constants K_a (M^{-1}) and binding free enthalpies $\Delta G°$ (kJ mol^{-1}) for the formed 1:1 complexes are summarized in Table 1. The following conclusions can be drawn.

(i) The complexes formed by the dendroclefts (−)-**G1** and (−)-**G2**, and core (−)-**G0** are of similar strength (K_a between 100 and 600 M^{-1}). Hydrogen bonds between the O-atoms of the sugars and the NH groups of the receptors represent major host–guest interactions in all complexes as evidenced by the large complexation-induced downfield shifts (up to 1.2 ppm at saturation binding) of the NH resonances in the di(carboxamido)pyridine moieties. Apparently, the bulky dendritic shell in (−)-**G1** and (−)-**G2** does not prevent the sugar molecules from penetrating the receptor and interacting with the core H-bonding sites. It is actually quite remarkable that the binding by (−)-**G1** and (−)-**G2** is not weakened by the dendritic shell, which contains a relatively high density of potentially competitive donor oxygen atoms.

(ii) The degree of enantioselectivity in the complexation of the enantiomeric α-glucosides **6** and **7** is reduced upon attachment of the dendritic shells. The difference in stability between diastereoisomeric complexes $\Delta\Delta G°$ decreases from 3.6 kJ mol^{-1} [(−)-**G0**], to 0.8 kJ mol^{-1} [(−)-**G1**], and to 0.5 kJ mol^{-1} [(−)-**G2**].

(iii) On the other hand, the diastereoselectivities of complexation are remarkably enhanced by the presence of the dendritic branches. Thus, the difference in stability between the complexes of the diastereoisomeric guests **7** and **8** increases from 0.7 kJ mol^{-1} [(−)-**G0**], to 1.4 kJ mol^{-1} [(−)-**G1**], and to 2.3 kJ mol^{-1} [(−)-**G2**].



Octyl α-L-glucoside **6** | Octyl α-D-glucoside **7** | Octyl β-D-glucoside **8**

These results indicate that the dendritic shell is controlling the selectivity of complexation at the core, an unprecedented result. There are two plausible reasons for this dendritic modulation of binding selectivity which are currently under investigation. Firstly, the steric demands of the dendritic branching may disfavour certain complexes. Secondly, the oxygen donor atoms in the dendritic shell could participate in the formation of a hydrogen bonding network with the guest, changing the binding selectivity.‡

The use of such dendroclefts as chiroptical sensors[11] is currently under active investigation. Profound changes in the circular dichroism (CD) spectra are observed on addition of the glucopyranoside guests, the response being selective for

Host	Guest	K_a/M^{-1}	$\Delta G°$/kJ mol^{-1}
(−)-**G0**	6	100	−11.4
(−)-**G0**	7	425	−15.0
(−)-**G0**	8	570	−15.7
(−)-**G1**	6	160	−12.6
(−)-**G1**	7	225	−13.4
(−)-**G1**	8	390	−14.8
(−)-**G2**	6	170	−12.7
(−)-**G2**	7	205	−13.2
(−)-**G2**	8	520	−15.5

different sugars and different for (−)-**G0** and (−)-**G2**. In addition, the dendritic receptor is readily recycled owing to the very large size difference between host and guest. Gel permeation filtration through a plug of Sephadex gel LH-20 with MeOH as eluent provides quantitative recovery of pure (−)-**G2** from host–guest solutions.

Efforts are now in progress to synthesise dendritic receptors with even more deeply embedded optically active cores. This general approach to dendritic molecular recognition has great potential, both for modelling the buried active sites of sugar binding proteins[12] and for the development of tunable, recyclable receptors and sensors for various analytes.

Support from the ETH Research Council and the Royal Society (E.S.E.P. fellowship to D. K. S) is gratefully acknowledged.

Notes and references

† ^{1}H NMR titrations (300 MHz) were performed at [dendrocleft] = 0.5 mM and [sugar] = 1.25–12.5 mM in $CDCl_3$ de-acidified with K_2CO_3 and dried over 4 Å molecular sieves. The complexation-induced downfield shifts (up to 1.2 ppm at saturation binding) of the resonances of the NH-protons in the dendroclefts were evaluated by nonlinear least-squares curve fitting. Job plot analyses were in agreement with the exclusive formation of 1:1 host–guest complexes. All titrations were repeated with good reproducibility, and the uncertainty in K_a is estimated as ±10%.

‡ The oxygen atoms in the dendritic shell may control the strength and selectivity of binding, as polar additives are well-known to modify sugar recognition in $CDCl_3$ (ref. 10). The core receptor (−)-**G0** was investigated in $CDCl_3$–THF (99:1) to test the effect of intermolecularly added ether (with oxygen donor atoms) on complexation. The association constants for the complexes with **7** and **8** were K_a = 320 and 390 M^{-1}, respectively. Thus, the binding strength was reduced compared to pure $CDCl_3$, as a result of competitive solvation of host and guest by THF molecules. The diastereoselectivity, however, remained low ($\Delta\Delta G°$ = 0.5 kJ mol^{-1}), and it is evident that addition of THF does not induce the same increase in diastereoselectivity as that caused by the dendritic shell.

Isolation of monomeric s-*trans*-acrylic acid as a hydroxy host inclusion crystal showing anomalous C=O stretching absorptions

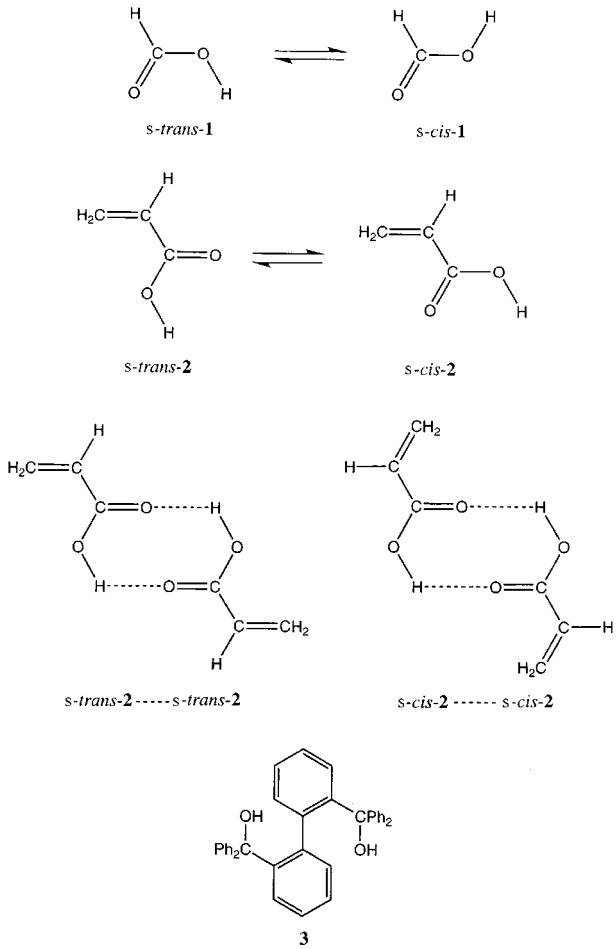
Received (in Cambridge, UK) 27th July 1998, Accepted 13th October 1998

The structure of monomeric s-*trans*-acrylic acid, trapped in an inclusion complex with an hydroxy host, was elucidated by X-ray analysis.

Studies of the molecular conformations and rotational isomerism of organic compounds are of fundamental importance in chemical research. There has been especial interest in the conformations and rotamers of simple organic acids which can be studied readily using spectroscopic methods. For example, studies in the gas phase of the simplest organic acid, formic acid



1, show that the s-*trans*-**1** rotamer is the predominant form. This has been characterized by microwave studies,[1–3] electron diffraction,[4–6] and IR spectroscopy.[7,8] Structural studies of s-*trans*-**1** in low temperature matrices have also been accomplished.[9–11] The other rotamer, s-*cis*-**1**, has also been detected by microwave[12,13] and IR spectroscopy.[14] On the other hand in both the liquid and vapor phases of acrylic acid **2**, the cyclic dimer s-*trans*-**2**···s-*trans*-**2** is a major component existing in equilibrium with monomeric **2**.[15] Microwave spectroscopic studies have established that in the vapor phase at low pressures, comparable amounts of s-*cis*-**2** and s-*trans*-**2** coexist with the dimer.[16,17] In the solid state, however, it was demonstrated that **2** exists as two different cyclic dimers, s-*trans*-**2**···s-*trans*-**2** and s-*cis*-**2**···s-*cis*-**2** by IR spectroscopy.[18] Finally, s-*trans*-**2** and s-*cis*-**2** have been identified by IR spectroscopy in a matrix.[19]

Nevertheless, no rotational isomer of **1** or **2** has never been isolated in the pure state. The challenge to isolate a rotational isomer of **2** might be met by using inclusion crystallization with a hydroxy host compound, since this method has been shown to be useful in trapping an unstable rotamer.[20] For example, a nearly eclipsed rotamer of 1,2-dichloroethane (dihedral angle Cl–C–C–Cl = 36°) has been isolated as a host–guest inclusion compound.[21] Finally, we succeeded in isolating s-*trans*-**2** as an inclusion crystal (**4**) with 2,2′-bis(hydroxydiphenylmethyl)-1,1′-biphenyl **3** and studied its conformation by X-ray analysis.

When a solution of **3** (1 g) in **2** (10 g) was kept at room temperature for 1 h, the 2:1 inclusion compound **4** was obtained as colorless needles [0.84 g, 80% yield, mp 130–150 °C (decomp.); Calc. for $C_{79}H_{64}O_6$: C, 85.53; H, 5.81. Found: C, 85.37; H, 5.82%]. The 2:1 molar ratio was determined by elemental analysis and thermogravimetric measurement. X-ray analysis of **4** showed that six molecules of **3** make a cubic cage in which three molecules of **2** are accommodated by formation of a circle (Fig. 1).† The three acrylic acid molecules comprising the circle were found to be disordered over two sites of equal occupancy. In both sites of disorder, three hydrogen bonds between the OH hydrogen of **2** and the OH oxygen of **3** play an important role in constructing the inclusion lattice of **4**. Since the OH hydrogen of **3** does not participate in any hydrogen bond formation, the *ν*OH of **3** in **4** appeared at higher

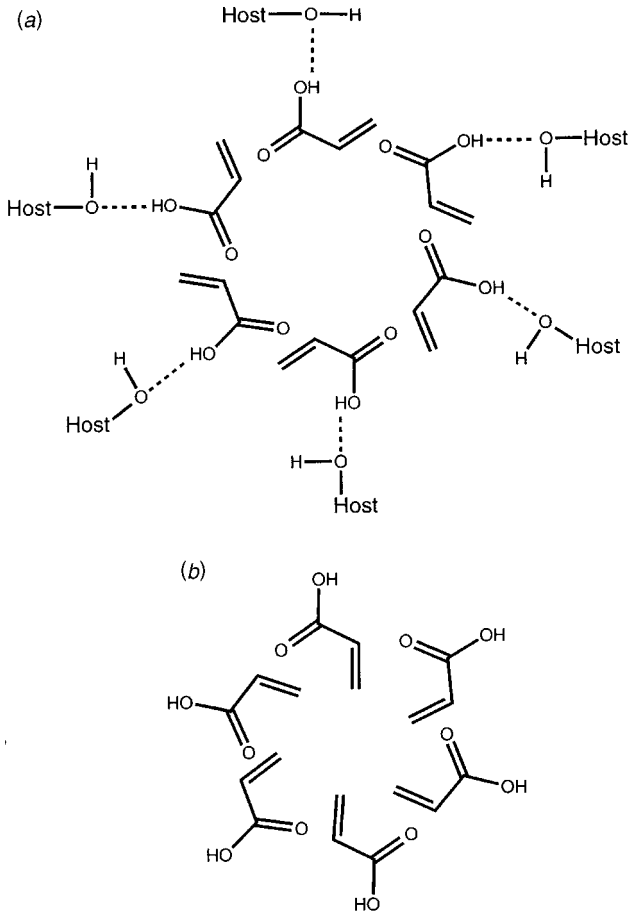

Fig. 2 Schematic drawing: (*a*) a circle of three s-*trans*-**2** molecules in **4** and (*b*) a circle of three s-*cis*-**2** molecules, both involving disorder.

frequency (3290 cm^{-1}) than in pure **3** itself (3230 cm^{-1}). The hydrogen bonds are schematically shown in Fig. 2. It is very clear that **2** exists here as a monomeric form rather than a dimeric one, despite **2** existing as a dimer in the crystalline state at −115 °C.† The formation of the 2:1 inclusion complex in the presence of disorder is analogous to that of **3** combining with acetone molecules in a 2:1 ratio.[22] In the latter case, however, **3** functions as a hydrogen donor and hydrogen bonds between the OH of **3** and C=O of acetone molecule are formed.[22]

This is the first example of the isolation of the monomeric s-*trans* form of **2**, although the dihedral angle between the OH and H_2C=CH groups is a little large (46.5°), as shown in Fig. 1. The C=O and C–OH bonds are also clearly distingishable (Fig. 1). In the small cavity formed by six host molecules of **3**, the dimer of **2** might be too large to be accommodated. The cavity in **4** might also be too small to accommodate **2** in its s-*cis* form. When three s-*cis*-**2** molecules are accommodated to make a similar circle to that of the s-*trans* form, the three vinyl groups are directed inward causing serious steric repulsion, as shown in Fig. 2. Methacrylic acid did not form an inclusion complex with **3** because even if it is included in its s-*trans* form, steric crowding of the methyl groups is significant. These could be the underlying reasons why the monomeric s-*trans*-**2** molecule is isolated.

It is impossible to elucidate the mechanism of the molecular movement of **2** into the cavity, since X-ray analysis can determine only an average situation of molecules, and not their dynamic behavior. However, some speculation on this subject would be worthwhile. For example, the two circles, each consisting of three s-*trans*-**2** molecules (Fig. 1), are interconvertible by either a shift down or up accompanied by a 60° rotation in the plane of the circle. Since an X-ray analysis of **4** at −100 °C gave almost the same result as that obtained at room temperature, such molecular movement would occur quite easily. DSC trace of **4** showed two endotherm peaks at 126 and 255 °C, which correspond to release of the guest and the melting point of the host, respectively. Solid-state ^{13}C CP MAS NMR spectroscopy of **4** showed a broad C=O signal for **2** at δ 169.[23] On the other hand, the ^{13}C NMR spectrum of **4** in $CDCl_3$ showed a sharp C=O signal at δ 170.

It was also found that **2** shows anomalous νOH absorptions in the IR spectrum of **4**. The C=O stretching absorptions are split into three weak bands at 1726, 1699 and 1687 cm^{-1}. Each of these peaks is comparable in strength to those of the νCH=CH_2 absorptions of **2** at 1632 cm^{-1} and of the benzene ring of **3** at 1597 cm^{-1}. This is an unusual phenomenon since acetone in its inclusion complex with **3** showed a normal strong νC=O absorption at 1710 cm^{-1}. In order to know whether this anomalous νC=O absorption appears only in this case or not, some other inclusion compounds with **3** were prepared and their IR spectra studied.

The host **3** formed inclusion compounds with propanoic acid and ethyl acetate in 2:1 ratios. In these inclusion compounds, propanoic acid (1740, 1735, 1818, 1707, 1700 and 1685 cm^{-1}) and ethyl acetate (1704 and 1686 cm^{-1}) showed similar anomalous νC=O absorptions as indicated. In both cases, the νC=O absorptions are split into very weak bands, and the splitting is especially complicated in the case of propanoic acid. Nevertheless, 1:1 inclusion compounds of ethyl acrylate and ethyl propanoate with **3** showed normal strong νC=O bands at 1698 and 1712 cm^{-1}, respectively. These anomalies might not depend on the host:guest molar ratio, since the 2:1 inclusion compound of **3** with acetone also shows normal νC=O absorption.[24] As far as we are aware, such anomalous behavior has not been previously observed. Although the reason for this anomalous behavior is not clear, it is an interesting subject in solid state chemistry[20] and inclusion chemistry, and should be clarified in the future.

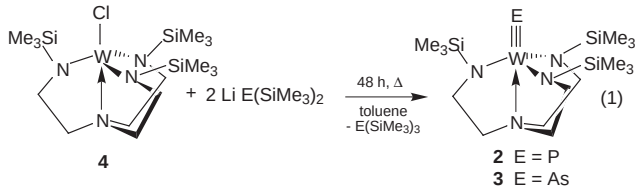
Received (in Basel, Switzerland) 20th August 1998, Accepted 13th October 1998

[LW=Sb=WL] 7 (L = $N(CH_2CH_2N(Np))_3$; Np = CH_2CMe_3) is prepared by treatment of [LWCl] 5 with $LiSb(SiMe_3)_2(dme)_n$; the ethylene complex [LWCl(C_2H_4)] 6 is a side product in the synthesis of 5; all complexes are structurally characterised.

Complexes of the general formula [$L_nM{\equiv}E$] (E = P, As) with terminal ligands represent a new class of compounds.[1] With the synthesis and structural characterisation of the phosphido complexes [(Ar′RN)$_3$Mo≡P] (Ar′ = 3,5-$C_6H_3Me_2$, R = $C(CD_3)_2CH_3$) **1**[2] and [$N(CH_2CH_2NSiMe_3)_3M{\equiv}E$] [M = W (**2a**), Mo (**2b**)][3] the speculation about the existence of stable compounds of this class was brought to an end. We have shown that one possibility to synthesise the phosphido complex **2a** is starting from Li[$P(SiMe_3)_2$] according to eqn. (1).[4] Using



Li[$As(SiMe_3)_2$] in reaction (1), we were also able to synthesise and structurally characterise the arsenido derivative **3**.[4] This raised the possibility of generating complexes with terminal antimonido and bismuthido ligands. The salts Li[$E(SiMe_3)_2$] (E = P, As, Sb, Bi) have been known for a long time for all pnictogen elements,[5] therefore this seems to be a viable route to compounds containing terminal Sb and Bi ligands.

We have found, however, that irrespective of reaction conditions, the conversion between [{$N(CH_2CH_2NSiMe_3)_3$}WCl] **4** and Li[$Sb(SiMe_3)_2(dme)_n$] did not proceed. The steric demand of the $SiMe_3$ groups in complex **4** obviously inhibits the substitution of the Cl atom by the Sb moiety. The use of a sterically less bulky tris(2-amidoethyl)amine ligand should however enable W–Sb bond formation. Herein we report the synthesis and characterisation of [{$N(CH_2CH_2N(Np))_3$}WCl] **5** (Np = $CH_2C(CH_3)_3$) and the reactivity of **5** with Li[$Sb(SiMe_3)_2(dme)_n$].

The reaction of WCl_4(dme) with $Li_3[N(CH_2CH_2N(Np))_3]$ leads to the brown compound [{$N(CH_2CH_2N(Np))_3$}WCl] **5**. A small quantity of the green ethylene complex [{$N(CH_2CH_2N(Np))_2CH_2CH_2NH(Np)$}WCl($\eta^2$-$C_2H_4$)] **6** was also isolated.[6] While complex **5** dissolves well in toluene and is moderately soluble in pentane, compound **6** undergoes decomposition even in solvents of low polarity, resulting in the formation of an insoluble solid which could not be characterised. In the mass spectra of **5** and **6** the peaks for the molecular ions are observed. The ^{1}H NMR spectrum of **5** reveals broad signals at high and low field for the paramagnetic d^2-tungsten complex.†

The source of the ethylene in **6** is uncertain. It is possibly a result of a fragmentation of the tren ligand itself. Schrock and co-workers observed C–N bond cleavage of the ligand framework of a tren complex of tantalum, yielding a N-allyl unit.[7] Moreover, the low yields generally observed in the reactions of chlorotungsten(IV) complexes with tren ligands indicate various side reactions during the synthesis.[8]

In the structure of the trigonal bipyramidal tungsten complex **5** the W–Cl and the W–N_{ax} distances [2.389(2) and 2.179(5) Å] are only slightly shorter than the equivalent distances [2.399(2) and 2.182(6) Å] in the isostructural Me_3Si substituted complex **4**.‡ In **6** (Fig. 1) the W atom exhibits a distorted octahedral coordination geometry.‡ This is one of the few examples where the tetradentate ligand tris(2-amidoethyl)amine does not bind in C_3-symmetrical fashion to a transition metal.[9] This is due to the formation of only two W–N bonds [W–N3 1.964(3), W–N4 2.002(3) Å], whereas N(2) and N(1) coordinate merely with their lone-pair to the tungsten centre [W–N1 2.254(3), W–N2 2.399(3) Å]. The ethylene experiences strong back donation from the d^2 W atom, which is evident from the elongated C–C bond [1.416(6) Å] and short W–C distances of 2.170(4) and 2.175(3) Å. The complex [$W_2(ONp)_6(\eta^2$-$C_2H_4)_2$], in which a bridging ethylene ligand forms a W_2C_2 tetrahedron with the W atoms, shows comparable bond lengths [W–C 2.14(2), C–C 1.45(2) Å].[10]

The reaction of **5** with [$LiSb(SiMe_3)_2(dme)_n$] for 48 h at 110 °C in the dark leads to Sb–W bond formation as shown in eqn. (2). Instead of a terminal antimonido complex, the symmetrically Sb-bridged complex **7** is formed, which is the first neutral Sb-containing example for this class of compounds. Cationic complexes with μ-E_1 ligands for the heavy group 15 elements were described by Huttner and co-workers.[11] Numerous compounds of the form [$L_nM{=}E{=}ML_n$] are known, which contain a symmetrical nitrogen bridge, but not for pnictogens heavier than phosphorus.[12] Stephan and co-workers succeeded in the synthesis of the complex [{Cp_2Zr}$_2$(μ-P)].[13] Cummins and co-workers isolated [{(R′RN)$_3$Mo}$_2$(μ-P)] (R = Ph; R′ = *t*-Bu) at −35 °C as a labile intermediate in the transfer reaction of a terminal P_1 ligand from the phosphido complex **1** to the d^3 complex [(R′RN)$_3$Mo] (R′ = C_6H_5, R = *t*-Bu).[14] It could not be established whether **7** is the result of such an irreversible

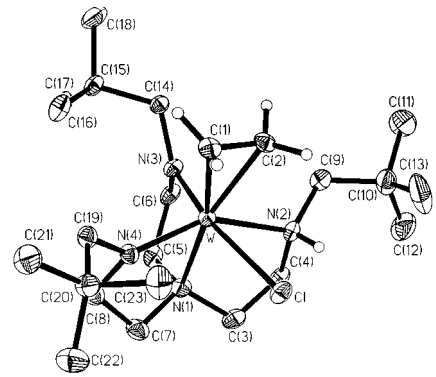


Fig. 1 Molecular structure of **6** (ellipsoids drawn at 30% probability level). Selected bond lengths [Å] and angles [°]: W–Cl 2.5116(12), W–N(1) 2.254(3), W–N(2) 2.399(3), W–N(3) 1.964(3), W–N(4) 2.002(3), C(1)–C(2) 1.416(6), W–C(1) 2.175(3), W–C(2) 2.1704(4), C(1)–W–C(2) 38.0(2), N(1)–W–Cl 94.00(9), N(1)–W–C(1) 165.64(14), N(1)–W–C(2) 156.8 (13), N(1)–W–N(2) 74.28(11), N(1)–W–N(3) 79.69(12), N(1)–W–N(4) 80.41(12), Cl–W–N(2) 74.57(8), Cl–W–N(4) 92.26(10), N(2)–W–N(3) 87.71(12), N(3)–W–N(4) 102.90(14).

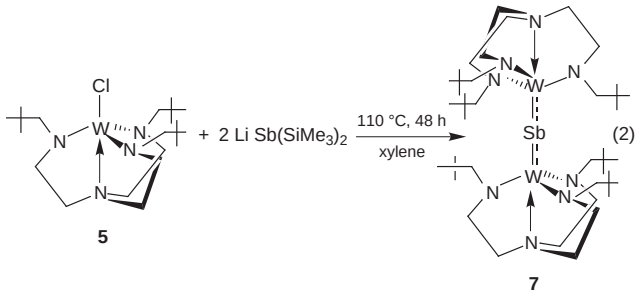

transfer reaction, or after an Sb–W bond formation an intermolecular Me_3SiCl elimination is followed. The M–E–M system of such neutral complexes possesses a $(1\pi_u)^4(1\pi_g)^3$ electron configuration with one unpaired electron. Therefore **7** is a mixed valent W(IV)/W(V) species.

The molecular structure of **7** (Fig. 2) reveals two W-tren units bonded to one Sb atom in a staggered configuration.‡ To the best of our knowledge the Sb–W bond distance of 2.5738(8) Å is the shortest Sb–W bond distance known. The $W–N_{eq}$ bond lengths are consistent with those found in **2** and **3**. The axial W–N(1) bond in **7** is 0.1 Å shorter than the equivalent distance in compounds containing a W≡E triple bond (E = P,[3] As[4]).

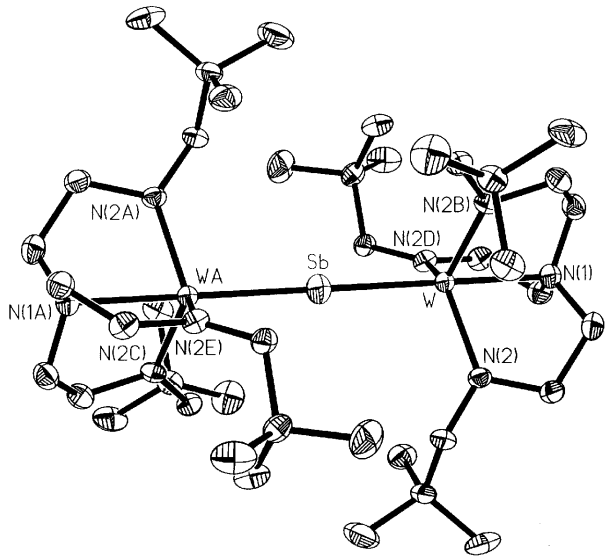

Fig. 2 Molecular structure of **7** (ellipsoids drawn at 30% probability level). Selected bond lengths [Å] and angles [°]: W–Sb 2.5738(8), W–N(1) 2.243(14), W–N(2) 2.000(7), W–Sb–W 180.0, Sb–W–N(1) 180.0, Sb–W–N(2) 101.0(2), N(1)–W–N(2) 79.0(2), N(2)–W–N(2) 116.4(1).

The equilibrium structure of **7** was calculated using the B-P86/SVP approximation.[15] The equal W–Sb bond distances of the paramagnetic compound **7** with respect to an almost linear W–Sb–W framework of 179.6° are 2.612 Å. The experimental distance of the exact linear system in **7** with a centre of inversion at the Sb atom is found to be approximately 0.04 Å shorter. According to the calculations, the corresponding Np-substituted complex with a terminal antimonido ligand possesses a W–Sb bond length of 2.514 Å, an anionic form of complex **7** reveals a W–Sb distance of 2.609 Å.

The results show that a reduction of the steric demand of the R group on the tren ligand leads to novel neutral Sb-bridged complexes. Current work is directed towards the synthesis of such complexes of the other pnictides and towards an optimisation of the size of the substituent R on the tren ligand in order to generate complexes with terminal Sb and Bi ligands.

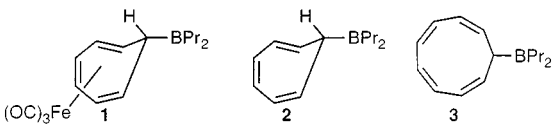
Received (in Liverpool, UK) 5th August 1998, Accepted 25th September 1998

Large-ring sigmatropic migrations do not necessarily follow the 'least motion principle' and can only be rationalized by a combination of experimental and computational techniques.

Despite the formulation of the Woodward–Hoffmann rules nearly 30 years ago,[1] the selectivities in sigmatropic migrations in conjugated carbocycles are not easily predictable. The difficulties in rationalizing a particular shift mechanism arise from the neglect of, for instance, orbital coefficients and the 'least motion principle' (LMP), when the Woodward–Hoffmann rules are applied. The possible importance of the LMP is emphasized by the large number of studies on cyclopentadienyl[2] and indenyl[3] derivatives, where mostly [1,5]- and very few [1,3]-sigmatropic migrations are observed. Since [1,5]- and [1,2]-shifts in cyclopentadienyl systems are formally equal, the LMP cannot be probed.[4] To the best of our knowledge, the [1,5]-Sn shifts in triphenyl-[5] and trimethyl-(cycloheptatrienyl)tin[6a] are the only examples violating the LMP.

Our recent studies on cycloheptatrienyl(dialkyl)boron derivatives[6] showed that both orbital *and* distance factors govern the selectivities of sigmatropic migrations. For instance, in the tricarbonyliron complex of cycloheptatrienyl(dipropyl)borane **1** both [1,3]- and [1,7]-B shifts are observed, whereas [1,5]-B shifts were not detected.[6a] This is in accord with orbital control because dialkylboryl groups migrate with inversion of configuration utilizing the unoccupied boron 2*p* atomic orbital (AO).[6b] On the other hand, the [1,7]-B shift is considerably faster than the [1,3]-B shift in **1**;[6a] the [1,7]-B migration is substantially energetically favored in uncomplexed **2**.[6b] Hence, as for the cyclopentadienyl system, the LMP seems to be effective, but could not be differentiated from other effects. We therefore present here a combined experimental and computational study on cyclononatetraenyl(dipropyl)borane **3**, which clearly displays a fast [1,3]-B shift.[7]

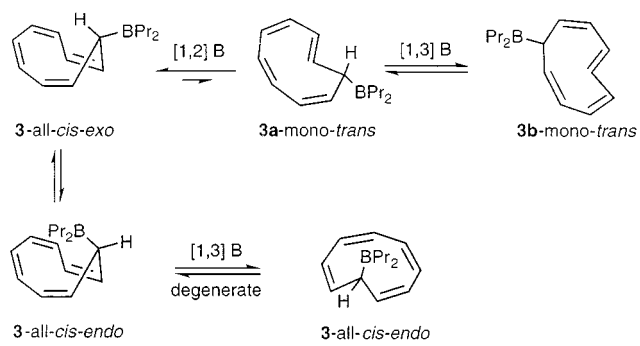


The experimental [1,3]-B shift barrier in **3** is rather low; the ^{1}H NMR data indicate dynamic processes even at −100 °C.[7] Our density functional theory (DFT) computations† show that the *endo*-conformer of **3** (the propyl groups were replaced by methyl groups to speed up the computations) is favored by only 0.3 kcal mol^{-1} over the *exo*-conformer due to overlap between the empty boron 2*p* AO and the π-system of the ring. While the degenerate [1,3] dipropylboryl migration in **3**-all-*cis-endo* could be confirmed computationally, we were unable to localize a [1,3]-B TS for **3**-all-*cis-exo*, despite extensive searches. Instead, we found that **3**-all-*cis-exo* undergoes a [1,2]-B shift to **3a**-mono-*trans-exo* (Scheme 1 and Fig. 1). However, **3**-mono-*trans* is thermodynamically unfavorable by 6.5 kcal mol^{-1} and the [1,2]-B shift is accompanied by a rather high activation barrier (17.3 kcal mol^{-1}; all energies relative to **3**-all-*cis-exo*). Hence, the observed temperature dependence of the NMR spectra and the results of EXSY experiments may be explained by degenerate [1,3]-B shifts in **3**-all-*cis-endo* only.

Although it was impossible to observe the completely averaged ^{13}C NMR spectrum due to the thermal instability of **3**, the spectrum is well resolved at low temperatures (Fig. 2). The pronounced lineshape–temperature dependence in the temperature interval 173–233 K allowed the [1,3]-B shift activation parameters in **3**-all-*cis-endo* to be determined. Lineshape calculations[8] gave: E_a = 6.2 ± 0.5 kcal mol^{-1}, $\Delta_{195\,K}G^{\neq}$ = 8.8 ± 0.1 kcal mol^{-1}; the computed E_a for **3** is 6.6 kcal mol^{-1}.

As we pointed out earlier,[6b] the dialkylboron moiety is partially positively charged; hence, one has to consider the two degenerate LUMOs (schematically depicted in Fig. 3) to determine which migrations are favorable based on orbital phases *and* coefficients. Inversion of configuration is observed for boryl group migrations (*i.e.* a *p*-orbital perpendicular to the plane of the π-system connects the migrating termini). Based on orbital phases only [1,3], [1,5] and [1,9] shifts are symmetry allowed with inversion of configuration in the cyclononatetraenyl system. LUMO 1 indistinguishably only allows for [1,3] and [1,9] shifts, while LUMO 2 permits all three. However, [1,5] migrations are highly unfavorable due to small orbital coefficients. Hence, a clear prediction cannot be made from these considerations.

For direct comparisons, we computed the transition states for [1,*j*]-B sigmatropic migrations in cyclononatetraenyl(dimethyl)borane **3**. As noted above, the E_a for the [1,3]-B shift in **3** agrees very well with the experimental value for **3**. The activation barriers for [1,9]- and [1,3]-B migrations are very



Scheme 1

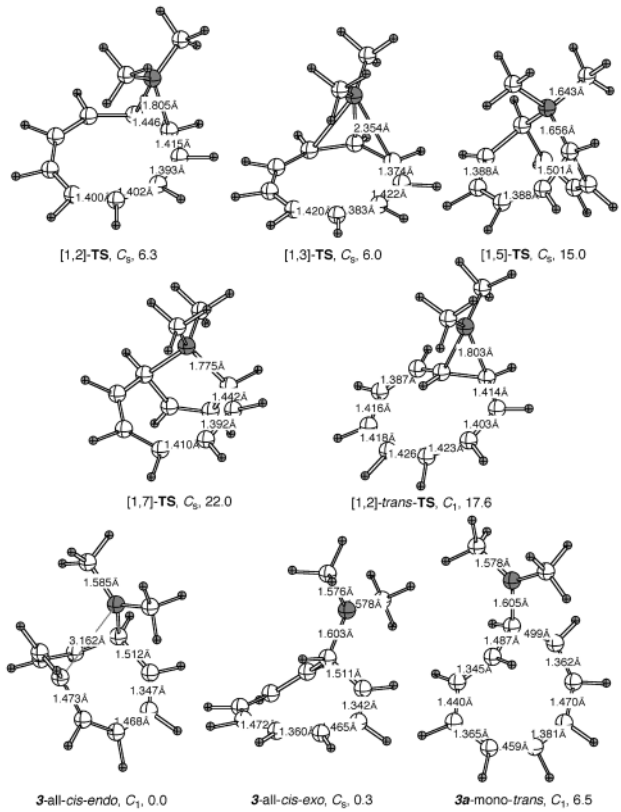


Fig. 1 B3LYP/6-311G*//B3LYP/6-31G* computed ground and transition state structures for dimethylboryl group migrations relative to **3**-all-*cis*-*endo*. Relative energies (ΔH) in kcal mol^{-1}.

similar (within 0.3 kcal mol^{-1}). It should be stressed that in symmetrically conjugated molecules like **3** only the fastest sigmatropic rearrangement can be reliably characterized by NMR analysis. At 188 K and a mixing time of 10 ms, all possible cross-peaks of comparable intensity are observed in the EXSY spectra of **3**. That means that the E_a for the [1,9]-B migration may be only about 1.1 times higher than that for [1,3]-B shifts, in agreement with the computed data. The [1,5] and [1,7] migrations are clearly disfavored by 15.0 and 22.0 kcal mol^{-1}, respectively. They also do not allow the cyclononatetraenyl moiety to become planar and therefore pseudo-Hückel-aromatic in the transition structure.

In summary, we have shown that [1,3]-dialkylboryl shifts in cyclononatetraenyl systems are facile and are slightly favored over [1,2]-shifts. Neither Woodward–Hoffmann rules nor the 'least motion principle' alone can be used for the prediction or rationalization of the migration pathways. Adequate analyses require a combination of dynamic NMR techniques and high-level *ab initio* calculations.

S. thanks the Fonds der Chemischen Industrie (Liebig-Fellowship and Sachmittel), the Deutsche Forschungsgemeinschaft, and Professor Armin de Meijere for support. Allotments of computer time from the Höchstleistungsrechenzentrum Jülich as well as the Regional Rechenzentrum Niedersachsen (RRZN Hannover) also are highly appreciated.

Notes and references

† *Computations*: Geometries of all stationary points were optimized using analytical energy gradients (ref. 9, 10). We utilized Becke's three-parameter exchange-correlation functional (ref. 11) including the nonlocal gradient corrections described by Lee–Yang–Parr (LYP) (ref. 12), as implemented in the GAUSSIAN 94 program package (ref. 13). All geometry optimizations were performed with the 6-31G* basis set (ref. 14); stationary structures were characterized by inspecting the updated Hessian matrices. Single point energies were evaluated using a standard 6-311G* basis set (ref. 15); final energies thus refer to B3LYP/6-311+G*//B3LYP/6-31G*. Standard notation is used, *i.e.* // means energy computed at // geometry (ref. 15). Computational results are available as supplementary data: see http://www.rsc.org/suppdata/cc/1998/2507.

8 The lineshapes were calculated utilizing a self-written computer program designed for direct iterative search of the activation parameters from the whole set of experimental spectra as proposed by R. Laatikainen, *J. Magn. Res*., 1985, **64**, 375. Iterations were made for two independent NMR operating frequencies (50 and 100 MHz for ^{13}C, Fig. 2; temperature calibration was carried out using a standard calibration sample (4% MeOH in [$^2H_4$]MeOH), providing an approximate accuracy of ±1 K. Temperature coefficients of the chemical shifts were determined by spatial iteration cycles where they were regarded as variable parameters. Linear coefficients were found to be approximately 1 Hz K^{-1} for C-1–4 and 2 Hz K^{-1} for C-5; second order coefficients were less than 0.001 Hz K^{-2}.

Photochemical reactions of chiral 2,3-dihydro-4(1*H*)-pyridones: asymmetric synthesis of (−)-perhydrohistrionicotoxin

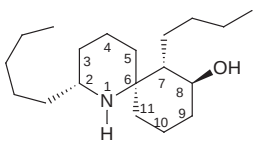
Daniel L. Comins,* Yue-mei Zhang and Xiaoling Zheng

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204, USA. E-mail: daniel_comins@ncsu.edu

Received (in Cambridge, UK) 24th September 1998, Accepted 12th October 1998

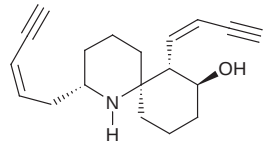
The first chiral auxiliary-mediated asymmetric synthesis of (−)-perhydrohistrionicotoxin is described.

In an effort to expand the utility of chiral 2,3-dihydro-4(1*H*)-pyridones as synthetic building blocks,[1] we are exploring their annulation using intramolecular [2+2] photocycloaddition reactions.[2] As was first demonstrated by Neier,[3] novel ring systems can be prepared from dihydropyridones using this approach. We were able to demonstrate through model studies that the skeleton of perhydrohistrionicotoxin **1** was accessible using this strategy.[4] Histrionicotoxin **2** is one of the biologically active alkaloids found in the skin secretions of the neotropical frog *Dendrobates histrionicus*.[5] Alkaloids **1** and **2** have been used in



1

perhydrohistrionicotoxin



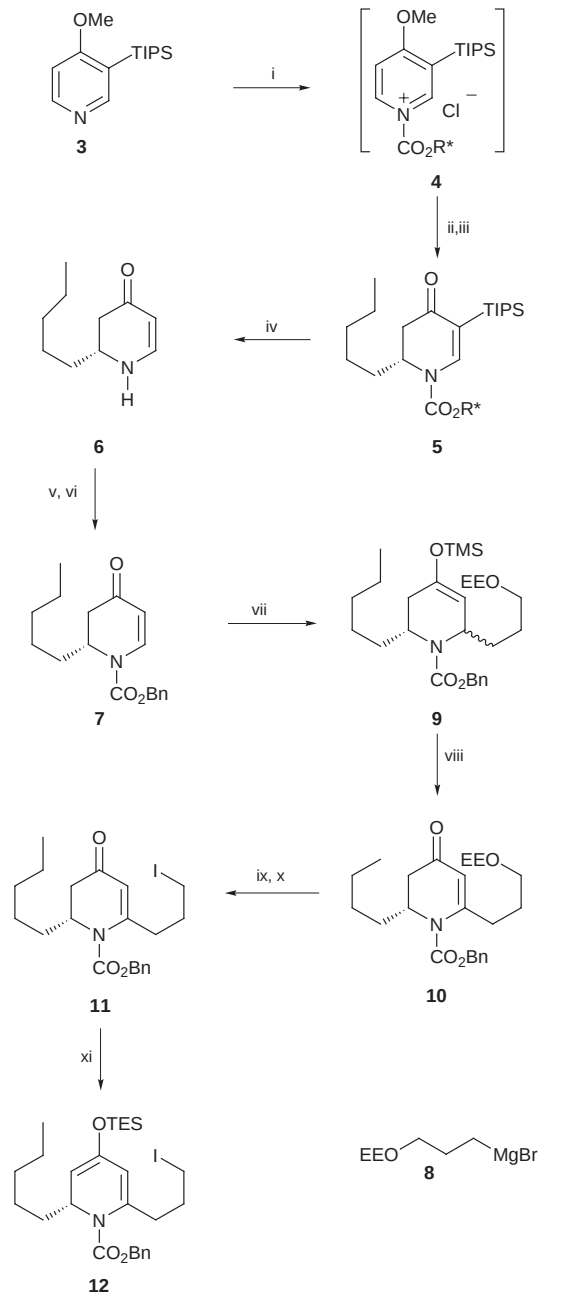
2

histrionicotoxin

studies of the mechanisms involved in transsynaptic transmission of neuromuscular impulses. The biological activity and novel structure of these alkaloids have stimulated numerous synthetic studies.[6] Several racemic and two enantioselective syntheses of **1** have been published. In addition, one asymmetric route to histrionicotoxin **2** has been reported.[6c] The enantioselective routes used enantiopure intermediates prepared by resolution[7] or derived from L-glutamic acid.[6a] Here we report a novel asymmetric synthesis of **1** using a photochemical conversion of an enantiopure 2,3-dihydro-4(1*H*)-pyridone as a key step. The enantiopure dihydropyridone was prepared by an efficient chiral auxiliary-mediated asymmetric synthesis.[1] The synthetic plan called for a stereoselective intramolecular [2+2] cycloaddition of an enantiopure dihydropyridone to set the stereochemistry at C-6 and C-7, and a subsequent cyclobutane ring opening to provide the azaspiroundecane skeleton of **1**.

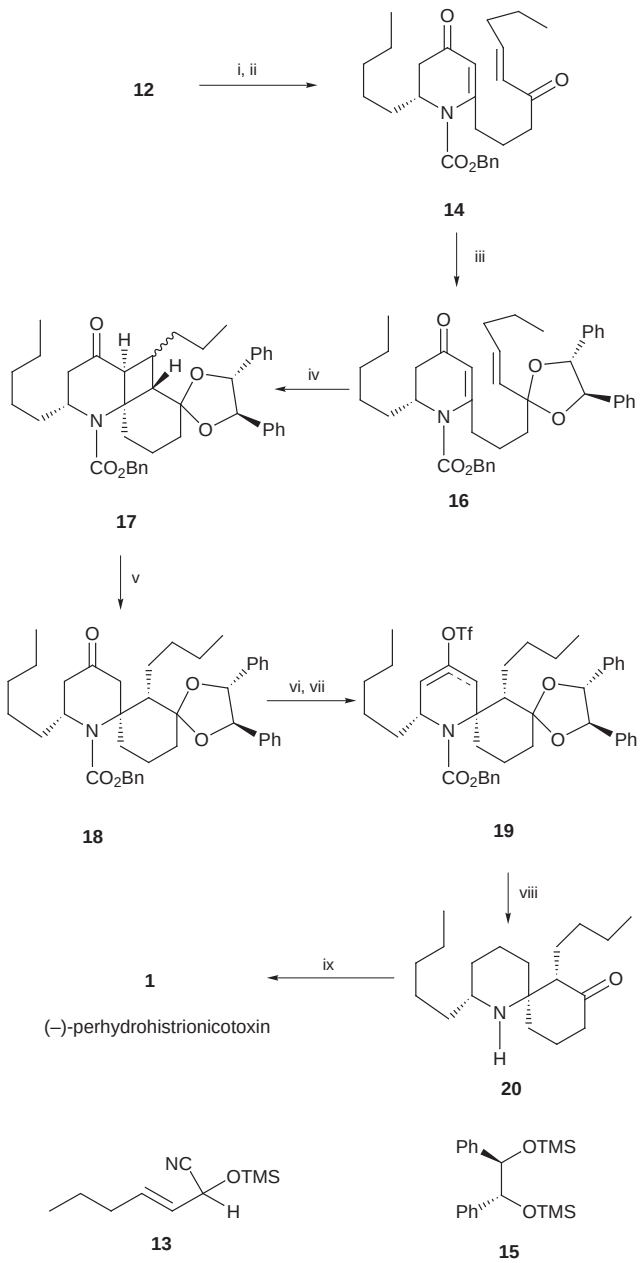
Reaction of enantiopure 1-acylpyridinium salt **4**, prepared *in situ* from 4-methoxy-3-(triisopropylsilyl)pyridine **3**[8] and the chloroformate of (−)-(1*R*,2*S*,4*R*)-2-(α-cumyl)-4-isopropylcyclohexanol (CPC),[9] with *n*-pentylmagnesium bromide in THF–toluene at −78 °C gave the crude dihydropyridone **5** in 95% yield and 90% de (Scheme 1). Purification by radial PLC (silica gel, EtOAc–hexanes) afforded a 91% yield of pure **5** [mp 75–78 °C; $[\alpha]_D^{23}$ −48.1 (*c* 0.88, $CDCl_3$)]. Treatment of **5** with NaOMe in MeOH followed by aqueous 10% HCl provided dihydropyridone **6** [$[\alpha]_D^{25}$ +353 (*c* 0.18, $CHCl_3$)] in 84% yield, and the chiral auxiliary [(−)-CPC] was recovered in 95% yield. Acylation of **6** with Bu^nLi and $ClCO_2Bn$ gave a 90% yield of enantiopure carbamate **7** [$[\alpha]_D^{23}$ −83.7 (*c* 2.24, $CHCl_3$)]. A side chain was introduced at C-6 of **7** through a 1,4-addition and oxidation sequence. In the presence of TMSCl, copper-mediated conjugate addition of Grignard reagent **8** to **7** provided silyl enol ether **9**. Oxidation of crude **9** with $Pd(OAc)_2$ gave dihydropyridone **10** in 92% overall yield for the two steps.[1c]

The acetal was hydrolyzed and the resulting alcohol was converted to iodide **11** in high yield (84%). The C-4 carbonyl of **11** was protected as the triethylsily enol ether **12**. The synthesis



Scheme 1 *Reagents and conditions*: i, $ClCO_2R^*$; ii, $C_5H_{11}MgCl$; iii, H_3O^+; iv, NaOMe, MeOH, then 10% HCl, v, Bu^nLi; vi, $ClCO_2Bn$; vii, **8**, CuBr, TMSCl; viii, $Pd(OAc)_2$, MeCN; ix, oxalic acid; x, NIS, PPh_3; xi, NaHMDS, TESCl.

was continued (Scheme 2) by treatment of crude **12** with the anion of **13**, prepared from the corresponding commercially available aldehyde, to give enone **14** in 94% yield. Protection of the ketone carbonyl using enantiopure bis-TMS ether **15**[10] provided ketal **16** (87%). Since the C-2 substituent of **16** is axial, due to $A^{1,3}$ strain,[11] photocyclization was anticipated to be highly stereoselective for the less hindered olefin face. On photolysis in acetone (460 W Hanovia Hg lamp, 16 min, 5 °C), **16** gave a 79% yield of cycloadduct **17** as the sole isolated product. The (*R*,*R*)-hydrobenzoin ketal of **16** is important for high facial selectivity, for the corresponding ethylene ketal gave only a 7:1 mixture of photoadducts. At this stage of the synthesis, installation of three stereogenic centers with the correct relative and absolute stereochemistry needed for the construction of **1** had been achieved. Treatment of **17** with SmI_2 in THF and DMPU effected cyclobutane ring opening to give spirocyclic ketone **18** in 70% yield, which was converted to a mixture of vinyl triflates **19** (90%) using LiHMDS and *N*-(5-chloro-2-pyridyl)triflimide.[12] Catalytic hydrogenation of this mixture effected vinyl triflate reduction, cleavage of the ketal, and removal of the Z group to provide the known amino ketone **20**[6a] in 81% yield. The synthesis of (−)-perhydrohistrionicotoxin **1** was completed by reduction of **20** with $LiAl(OBu^t)_3H$ according to the procedure of Winkler.[6a] Our synthetic **1** exhibited spectral data in agreement with reported data of authentic material.[5,6] The optical rotation [$[\alpha]_D$ −83.8 (*c* 0.2, CH_2Cl_2)] was also in agreement with literature values [$[\alpha]_D^{22}$ −84.1 (*c* 0.024, CH_2Cl_2); $[\alpha]_D^{22}$ −83.1 (*c* 0.0067, CH_2Cl_2)].[6a]



Scheme 2 *Reagents and conditions*: i, **13**, LHMDS, THF; ii, 10% HCl, then 2 M NaOH; iii, **15**, TMSOTf; iv, *hν*, acetone, 5 °C, 16 min; v, SmI_2, THF, DMPU; vi, LHMDS, THF; vii, *N*-(5-chloro-2-pyridyl)triflimide; viii, H_2, $Pd(OH)_2$, Li_2CO_3, EtOH; ix, $LiAl(OBu^t)_3H$.

In summary, the first chiral auxiliary-mediated asymmetric synthesis of (−)-perhydrohistrionicotoxin was accomplished in 15 steps (14% overall yield) with a high degree of stereoselectivity. Key steps include a highly stereoselective intramolecular [2+2] photocyclization of dihydropyridone **16** and a SmI_2-promoted cyclobutane ring opening, which provide the azaspiroundecane skeleton of the alkaloid.

We express appreciation to the National Institutes of Health (Grant GM 34442) and the Petroleum Research Fund (ACS-PRF #28394-AC) for financial support of this research.

Conformationally defined piperazine bis(*N*-oxides) bearing amino acid derived side chains

Ian A. O'Neil,* Andrew J. Potter,† J. Mike Southern, Alexander Steiner and James V. Barkley

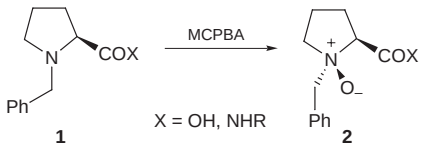
Robert Robinson Laboratories, Department of Chemistry, University of Liverpool, Crown St, Liverpool, UK L69 7ZD. E-mail: ion@liv.ac.uk

Received (in Cambridge, UK) 4th September 1998, Accepted 7th October 1998

The preparation of a number of piperazine derivatives bearing amino acid substituents on the nitrogen is described; these compounds undergo oxidation with MCPBA to yield bis(*N*-oxides) in which both oxygen atoms are axially orientated and hydrogen bonded to the amide NHs, giving highly defined conformations to the molecules; the structure of the valine derivative (8c) was confirmed by X-ray analysis.

Biological systems rely on polymers, proteins and RNA to carry out the chemical transformations necessary for life. Both proteins and RNA fold into precisely ordered structures which provide a structural framework and the catalytic site for the particular transformation. In addition to their role as catalysts, biopolymers play a central role in the maintenance of structural integrity in living systems. There is great interest in the design and synthesis of polymeric molecules which possess the ability to fold in a discrete and predictable fashion and recently several groups have shown that poly-β-amino acids adopt a stable helical structure.[1] Indeed, Gellman has coined the term 'foldamer' to describe new types of polymeric backbones with well defined and predictable folding properties.

In previous studies we have shown that *N*-alkylated derivatives of proline and pipecolic acid undergo highly diastereoselective oxidations to give tertiary amine oxides that are stabilised by hydrogen bonding (Scheme 1).[2] In most cases these systems are stabilised by the presence of six membered hydrogen bonds between the *N*-oxide oxygen and the amide NH. In addition to their fascinating structural properties, the use of chiral amine oxides as catalysts in a number of synthetically useful transformations has been reported recently.[3]

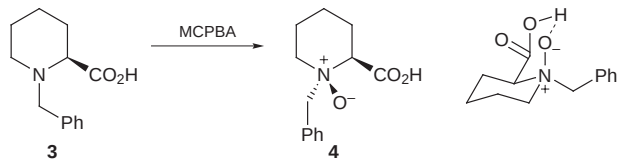


Scheme 1

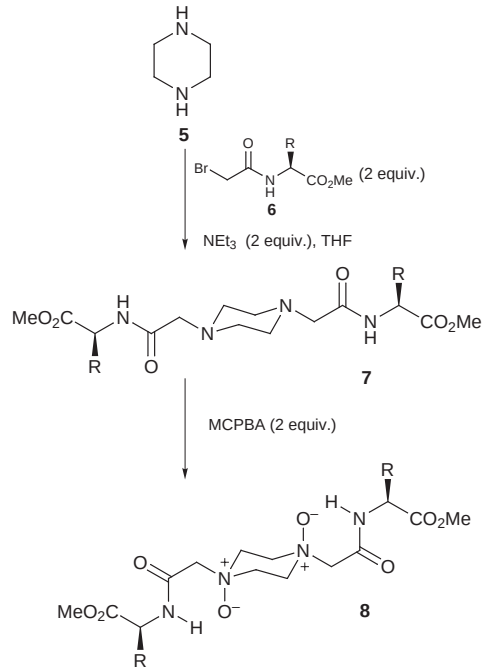
We considered that we could use this type of hydrogen bonding to enforce a conformational bias on otherwise flexible structures and give them a predictable and specific shape. We were particulary intrigued by the possibility of incorporating α-amino acid residues into the molecule since this would result in a peptide-like compound of defined structure. Earlier work from our group has shown that the oxidation of *N*-benzylpipecolic acid gave the *syn N*-oxide. Interestingly the *N*-oxide adopted an axial orientation in the crystal structure (Scheme 2).

We therefore postulated that attachment of a unit containing a peptide residue possessing an NH residue available for hydrogen bonding, followed by oxidation of both piperazine nitrogens, should yield a bis(*N*-oxide) in which both oxygens were axial and were stabilised by intramolecular hydrogen bonds to the NHs of the peptide chains. The synthesis of such compounds is show in Scheme 3.

† Present address: Ribotargets Ltd, Kett House, 1 Station Road, Cambridge, UK CB1 2JP.



Scheme 2



Scheme 3

Piperazine was alkylated on both nitrogens with α-bromo amides derived from a range of α-amino acids using literature procedures.[4] The resulting tertiary amines were treated with 2 equiv. of MCPBA. Clean oxidation was observed and the resulting *N*-oxides were isolated as stable solids. A range of different amino acids was used and the results are summarised in Table 1.

The ^{1}H NMR spectra of the *N*-oxides were highly informative. They showed that the compounds were formed as

Table 1 Synthesis of piperazine bis(*N*-oxides)

		Yield (%)	
Bis(*N*-oxide)	R	*N*-alkylpiperazine	Bis(*N*-oxide)
8a	H	73	63
8b	Me	80	72
8c	Pr^i	67	77
8d	Bu^i	84	74
8e	Ph	79	75
8f	Bn	86	81

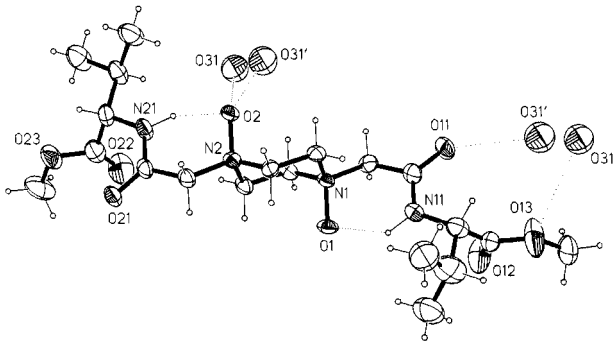


Fig. 1 Crystal structure of **8c** illustrating hydrogen bonding to the disordered water molecule. Thermal ellipsoids set at 50% probability.

single diastereoisomers; in addition the NH signals in $CDCl_3$ appeared as a singlet, which had been shifted downfield by approximately 3.5 ppm in all the compounds after *N*-oxide formation. For example, prior to oxidation, the valine derivative diamine NHs were at δ 7.63; after oxidation they had shifted to δ 11.12, and their chemical shift was found to be concentration independant in $CDCl_3$. The valine derivative gave crystals suitable for X-ray analysis‡ (Fig. 1).

The crystal structure clearly shows that both oxygen atoms are axial and are hydrogen bonded to the NH of the amides. The result is an almost linear molecule of highly defined conformation. N–O bond distances of both *N*-oxide moities are in the same range [N1–O1 1.398(5), N2–O2 1.399(5) Å]. Both hydrogen positions involved in intramolecular hydrogen bonding toward *N*-oxide moieties could be detected in difference Fourier maps and were refined freely. Both show comparable bonding distances [N11–H1 0.97(5), O1···H1 1.82(5), N21–H2 0.93(5), O2···H2 1.84(5) Å]. In addition, intermolecular interactions *via* hydrogen bonding are occuring across a water molecule which is disordered on two positions, resulting in infinite zig-zag-chains throughout the crystal lattice. One of the disordered positions (O31) bridges the amine oxide function O2 with an acyl–O (O13) [O2···O31 2.849(9), O13···O31 3.149(11) Å], while the other position forms a bridge between O2 and an amide–O (O11) [O2···O31′ 2.605(11), O11···O31′ 2.970(11) Å]. In contrast to the above described intramolecular H-bridges, hydrogen postions of the disordered water molecule could not be detected in difference Fourier maps.

In order to establish the range of the hydrogen bonding we prepared the piperazine derivative **10** which bears two amino acid substituents on each of the piperazine nitrogens (Scheme 4). Oxidation proceeded smoothly to give the bis (*N*-oxide) **11**.

NMR analysis of the product clearly showed that only the NHs of the alanine residues were hydrogen bonded to the amine oxide oxygens from their downfield chemical shift from δ 7.02 to 10.50. This specificity allows for fine-tuning of molecular shape.

We are currently examining the incorporation of these units into larger molecular structures and their use as chiral catalysts in a number of synthetic transformations.

We would like to thank the EPSRC and BBSRC for their support of this work (grants GR/K50719 and BO4940). I. O'N. would like to thank The James Black Foundation for continued financial support.

Domain formation in thin films of nonlinear optical side group polymers based on a rigid backbone

Suck-Hyun Lee,* Yong-Seok Kang and Seog-Jeong Song

Department of Applied Chemistry, Ajou University, Suwon, Korea 441-749. E-mail: hyja@madang.ajou.ac.kr

Received (in Cambridge, UK) 17th August 1998, Accepted 12th October 1998

The NLO properties of a *N*-(4-nitrophenyl)-L-prolinol substituted poly(*p*-phenylene terephthalate) polymer are investigated.

Organic polymeric NLO materials are of great interest for practical applications such as electrooptic modulators and switches, due to their fast NLO response time, low cost, ease of fabrication, and large susceptibility. Extensive research efforts have been directed at tailoring organic molecules and their incorporation into polymeric matrices, and substantial progress has been made to reduce their relaxation and improve chromophore loading in the polymer matrix.[1–3] In our studies, we have focussed on rigid chain polymers such as poly(*p*-phenylene terephthalate)s with flexibly attached NLO substituents on the terephthalate moiety. For the pendant chromophore, *N*-(4-nitrophenyl)-L-prolinol was selected. These polymers did not exhibit thermotropic mesophases and the glass transition temperature (T_g) decreased significantly with increasing alkyl tether length, as expected.[4] The present paper deals with domain formation. Most of the results were obtained from the polyester with alkyl tether length of n = 4 (**P4**). The polymer was prepared *via* solution condensation of a chromophore-containing aromatic dicarboxylic acid chloride with hydroquinone in pyridine.[4] The number average molecular weight by gel permeation chromatography was 23,000 in $CHCl_3$ solution based on the polystyrene standard, and the polydispersity of molecular weight (M_w/M_n) was 7.1. The T_g of the polymer was about 68 °C. Polymer films were prepared by spin-coating polymer solutions in tetrachloroethane onto slide glass at 2000–4000 rpm and then treating the slides in a vacuum oven at 60 °C for over 24 h to remove the solvent. Second harmonic generation (SHG) was measured using a Q-switched Nd:YAG laser (1.064 μm) with a pulse repetition rate of 10 Hz. All AFM images were recorded with a Park Scientific Instruments Autoprobe LS, operated in a contact mode.

We studied the surface topographies of the spin coated films before and after corona poling using AFM. The poling was performed in a vertical wire 1 cm above the exposed polymer film. Fig. 1(*a*) shows an AFM scan of the spin coated film (thickness = 2.5 μm). The surface of the thin unpoled film is clean and extremely flat and the root mean squared (rms) roughness value was 2.4 Å. However, this excellent quality film was drastically changed after poling. Fig. 1(*b*) shows an AFM image of the poled film. Numerous mountain-like structures, aligned along the poling direction, were formed during poling. A similar surface morphology of larger size similar to microphase-separated block copolymers[5] was also observed in other samples by optical microscopy [Fig. 1(*c*)]. For the polymer with larger tether length, hills and valleys were also observed but the steepness and curvature decreased and the domains were not well developed compared to the polymer **P4**. As the length of the alkyl side chain increases, the polymer shows decreasing T_g values,[4] suggesting less prominent side chain coupling to the main chain; the growth of domains and their tendency to form would thus decrease. Although the surface topographies of the hills and valleys were characteristic of all the samples, their statistical data were different for each of the samples and preparation conditions studied. Despite the great variations in domain size, the investigated statistical data could be taken as a qualitative indicator of domain size when comparing experimental trends for the samples and poling conditions specified. Fig. 2 shows the growth of domains as a function of poling time obtained from the controlled experiments involving growth after quenching at successive poling times. A high degree of domain growth was achieved at relatively short poling times, and the height of the domains increased only moderately upon further poling. This growth pattern is similar to the two-mode growth in the measured SHG signals, which reached their stable levels after an initial rapid growth. From our data, no apparent differences were observed in the poling dynamics between these domain forming polymers and conventional side group polymers. However, the voltage applied in this study was limited to a relatively low voltage of 6 kV by the onset of film whitening. This whitening or clouding of the film was not associated with chemical degradation of the sample since the spectroscopic analysis did not indicated

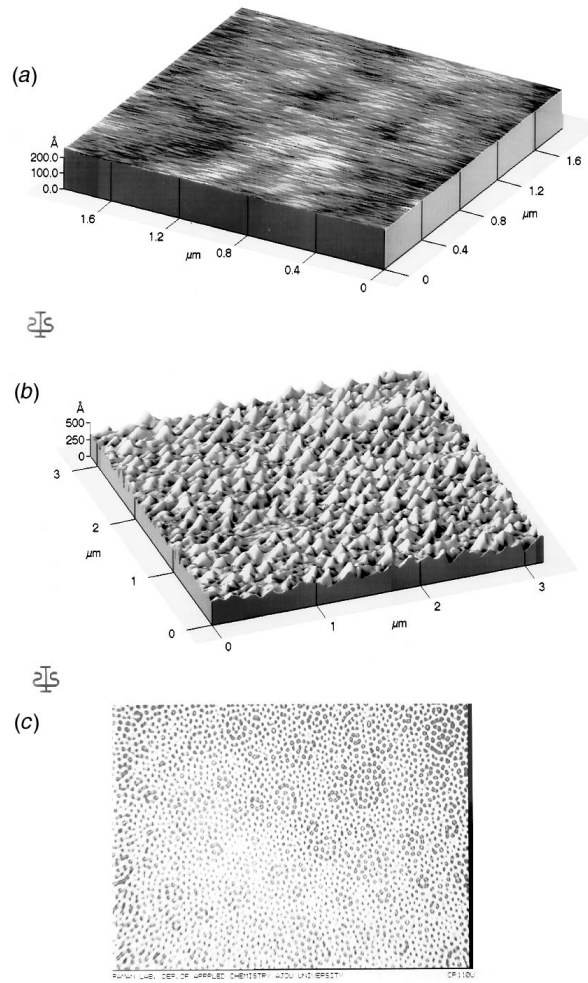

Fig. 1 AFM images for a spin coated film of 2.5 μm thickness (*a*) before and (*b*) after corona poling (92 °C, 5 kV, 15 min). (*c*) An optical micrograph recorded at a different location on the poled film exhibiting larger sizes for the same polymer **P4**.

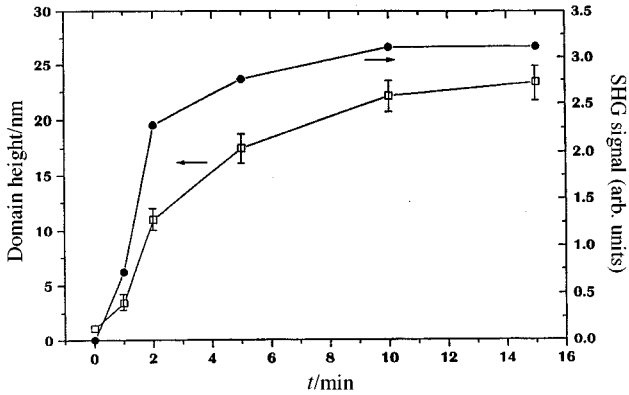

Fig. 2 SHG signal intensity and growth of the domains as a function of poling time measured after quenching at successive poling times at a poling temperature of 75 °C. The error bars were determined by repeating the measurement at five different positions on the same film.

noticeable decomposition at this poling condition. We believe this whitening is due to light scattering by chromophore domains of larger size formed during poling. One related observation for the same film is that relaxation of the SHG signal occurred by the progressive depression on the top of the domains removing the applied poling field. These results suggested that the domain size is apparently correlated with the observed SHG signal intensity.

It is interesting to note that a positive polarity was proven to work with our material much more efficiently than a negative one. When a negative polarity was applied, the observed SHG signal intensity almost vanished. The electric field in this polarity environment causes the axes of dipoles to be directed to the glass substrate, whose barrier effect hinders domain formation. In fact, the domains were not observed by AFM. A possible implication of this polarity effect is that the dipoles in this type of polymers can be oriented to form poled domains in cases where their alignment induced by the electric field facilitates cooperative movement of the rigid main chains. The attempted polings which failed confirmed this. When the corona poling was performed for films on which any barrier layers, including a vacuum deposited metallic electrode, were coated, the resulting SHG response was nearly absent, thus a sandwitch type poling was not adequate. However in cases where the films were corona poled first and then a barrier layer deposited on it, the SHG response remained almost unchanged and its temporal stability was greatly improved. This preliminary result may have important implications for obtaining stable materials for device applications. Design strategies to lock the domain itself would be valuable for improving geometrically the long term stability of second order NLO properties. We have also examined whether the roughened surface or interface had an important role in the measured SHG intensity by double coating the surface of the same polymer as the base film and then remeasuring the SHG intensity. We observed no loss in properties for this sample. This result indicates that the observed SHG should be related to the polar order effect of the chromophores in the domain rather than to the symmetry breaking nature of the roughened surface.

We have measured the SHG response of the samples for angles of incidence between −90 and 90° shortly after poling. The SHG signal of the polymer displayed no fringes, and only one peak indicative of thin sample films compared to the coherence length of the NLO process. In this case it is usual to determine the second order NLO susceptibility d_{33} by the curve fitting method using the intensity equation given by Jerphagnon and Kurtz.[6] We tried to determine d_{33} by fitting the data to the theoretical equation, but the result was not satisfactory and the experimental data systematically deviated from the theoretical values. However, the calculation at a single angle of 58° only resulted in a relatively large value of 50 pm V^{-1} referenced to a value of 0.3 pm V^{-1} for quartz, and the order parameter measured by the UV absorbance ratio was calculated to be 0.58, which to the best of our knowledge is higher than any reported values for poled polymer systems. It is still not clear if the fitting failure is a reflection of morphological changes in the polymeric films after poling. At this stage, it could be speculated that this behaviour is associated with the oriented domains largely formed on the outer surface layer and thus with the efficient second order NLO effect occurred only over a fraction of the film thickness. The SHG intensity against film thickness provides evidence of the inhomogeneous behaviour of chromophore orientations through the film thickness. As the thickness increased, the surface morphology became much rougher as a consequence of the larger sizes of the structure, and the more rugged the surface was, the greater the SHG intensity. However, the SHG intensity did not increase up to the level expected from the l^2 dependence[6] even when the film thickness was far smaller than the coherence length.

We gratefully acknowledge partial funding support from the Korea Science and Engineering Foundation (941-1100-011-2).

Imprinting chiral structures on liquid crystalline elastomers

Craig D. Hasson, Frederick J. Davis and Geoffrey R. Mitchell

Polymer Science Centre, University of Reading, Whiteknights, Reading, UK RG6 6AF.
E-mail: g.r.mitchell@reading.ac.uk

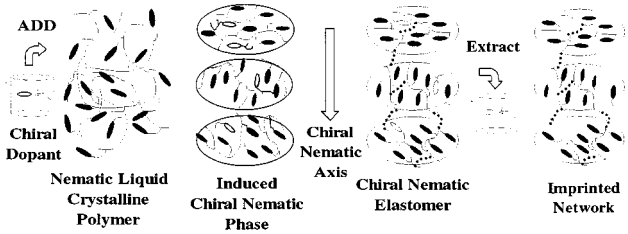
Received (in Cambridge, UK) 28th July 1998, Accepted 13th October 1998

Cross-linking achiral liquid crystalline polymers in the presence of a removable low molecular weight chiral mesogen produces a liquid crystalline elastomer in which a chiral structure has been imprinted.

In 1969 de Gennes published a paper speculating on the properties of a polymer chain lightly cross-linked in a liquid crystalline phase.[1] Using symmetry arguments, he showed that a chiral nematic would give rise to a permanent chirality of the polymer network. The essentials of de Gennes ideas[2] and other theoretical scientists[3,4] concerning nematic liquid crystalline elastomers have been confirmed experimentally,[5,6] however, we believe de Gennes's theory has remained essentially untested to date, probably because of the difficulty of incorporating a polymer backbone into a liquid crystalline phase. Some early work by Tsutsui *et al*.[7,8] attempted to resolve this issue through cross-linking an acrylate polymer in the presence of poly(benzyl-L-glutamate), however it is not clear that this system involved the types of mesogenic interaction originally envisaged by de Gennes. This issue is clearly of some importance in view of the volume of work involving cross-linking in a liquid crystalline solvent.[9] Here we show how low levels of cross-linking can be used to imprint a memory of a chiral mesophase into an elastomer with no imbalance in localised chiral centres.

Scheme 1 shows the principal features of our experiment. An achiral liquid crystalline polymer containing cross-linking sites was mixed with a chiral liquid crystal. The material was then cross-linked in the chiral nematic phase and finally the chiral liquid crystal was removed. Any chiral behaviour would then reflect a memory of the orientation imposed on the sample at the time of cross-linking in the same way that a magnetic[10] or mechanical field[11] imposes a permanent macroscopic order on the sample.

The system used was chosen to give a cholesteric phase with a helical pitch such that the material exhibited the well-known property of selective reflectivity in the visible portion of the electromagnetic spectra.[12] To this end the 4-cyanobenzoate containing acrylate **I**[13] was copolymerised with hydroxyethyl acrylate **II** (6 mol%, introduced to provide sites for cross-linking). This random atactic copolymer exhibited a nematic phase with a nematic–isotropic transition of 128 °C. Solutions were prepared in CH_2Cl_2 (dried over alumina) of this polymer and the chiral cyanobiphenyl **III** (available from Merck as CB15) and films were cast from these solutions onto glass slides



Scheme 1 Description of procedure used to imprint a chiral structure onto a liquid crystalline elastomer: a chiral dopant is added to produce a chiral nematic phase, the polymer is cross-linked and finally the dopant is removed.

coated with a rubbed film of polyimide. The composition range over which a chiral nematic phase was formed was then determined. It was found that at compositions below *ca*. 60 mol% CB15 a chiral nematic phase could be observed. At lower compositions between *ca*. 20 and 35% CB15 films of the mixture showed selective reflection of visible light. For example, the 30% sample showed a selective reflection at 730 nm at 50 °C and it is this composition which will be used for the subsequent studies. Further films were cast containing the polymer, CB15 and a sufficient quantity of the diisocyanate **IV** to react with all the hydroxy units in the polymer. The solvent was removed at room temperature and the film allowed to dry overnight before heating slowly (2 °C min^{-1}) to the required cross-linking temperature (in this example 50 °C). The sample was held at this temperature for 1 h, whereupon a polyimide sheet was placed on the surface, and 12.5 μm polyimide spacers were used to define the thickness. The material was then cross-linked for 16 days at 50 °C after which time it was found to consist of 72% gel by mass, in line with expectations based on the polydispersity of the sample.[14] The level of cross-linking was light, ~1mol% of the monomer units.

A portion of the elastomer produced from the above procedure was retained for further study, and the remainder of the sample was treated with refluxing acetone to remove both the chiral dopant and any soluble polymer. The extraction process was monitored by UV–visible spectroscopy and as Fig. 1 shows complete removal of both components was achieved after *ca*. 40 min.

The phase behaviour of the materials (*i.e*. mixture, cross-linked elastomer with dopant and cross-linked elastomer with dopant removed) was examined by optical microscopy and UV–visible spectroscopy to probe the pitch of any chiral ordering within the samples. The mixture and the elastomer samples

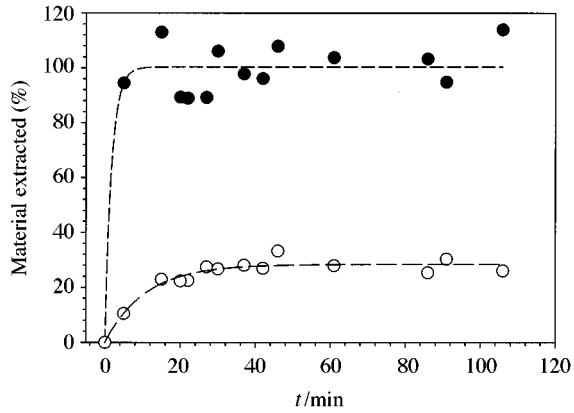

Fig. 1 Plot of the mass of the extracted material (expressed as a mass fraction relative to the initial composition) as a function of the extraction time in refluxing acetone: (●) CB15 and (○) copolymer. The solid lines serve as guides.

cross-linked at 50 °C were visibly coloured, and their absorption spectra are shown in Fig. 2. Clearly, all three samples exhibited a cholesteric reflection, and by implication a chiral nematic phase. In the case of the initial uncross-linked mixture and the cross-linked material in which the dopant was retained, the maximum absorption (λ_{max}) was at 730 nm at 50 °C, although the elastomer showed a much smaller variation of λ_{max} with temperature. Both these materials could be heated reversibly to the isotropic phase, but both passed through a biphasic region on heating in which nematic polymer coexisted with isotropic dopant. For the sample in which the dopant had been removed the maxima in the absorption spectrum moved to a much shorter wavelength, namely 500 nm at 50 °C (if this change were simply due to the presence of the dopant in lower concentrations a shift to higher wavelengths would be expected). Initial measurements suggest that the change in λ_{max} is related in a proportional manner to the change in volume of the sample arising from removal of both dopant and the sol fraction. Interestingly, λ_{max} for this sample remained invariant with temperature until the material became isotropic at 128 °C. On cooling from the isotropic the chiral nematic phase reappeared and an identical absorption spectrum to that initially observed was obtained.

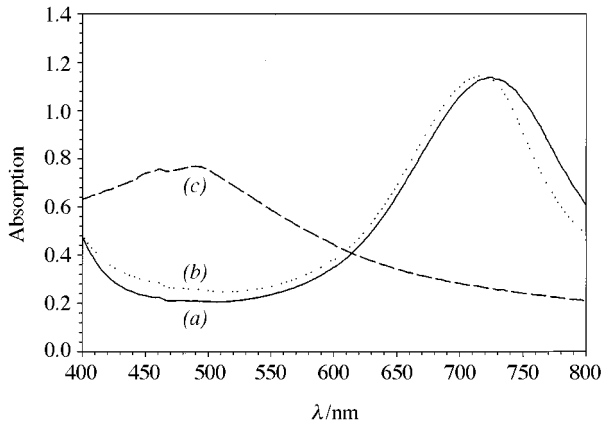

Fig. 2 Absorption spectra obtained from thin films of the liquid crystalline polymers and elastomers studied here: (*a*) mixture, (*b*) elastomer and (*c*) imprinted network. The peaks arise from selective reflection of visible light from the chiral material and are not observed for samples held at temperatures above the clearing point of the polymer.

We have shown that cross-linking an achiral side-chain liquid crystalline polymer in an induced chiral nematic phase results in material which retains a memory of the chirality upon removal of chiral dopant, by virtue of the orientation imposed on the mesogenic side-groups by the chiral nematic phase, and the coupling between the mesogenic side-groups and the polymer backbone. This is a soft imprinting and arises from subtle molecular interactions in contrast to the properties of rigid highly cross-linked networks prepared through photopolymerisation of multifunctional monomers.[9] We believe firstly, these experiments confirm the theory outlined by de Gennes; secondly, this represents a novel route to imprinted materials, not least because of the enhanced behaviour arising from the relatively low levels of cross-linking (for example, they will readily uptake solvent and are not glassy); thirdly this represents a route to materials with new properties which merit further exploration.

This work is supported by the EPSRC. We thank Dr U. Singh of the University of the West Indies for discussions and Merck R&D UK for supplying the chiral dopant CB15.

Duplex hydrogen bonding promotes intercalation of Cu(T4) in DNA hairpins (Cu(T4) = *meso*-tetrakis(4-(*N*-methylpyridyl))porphyrincopper(II))

Denise K. Crites Tears and David R. McMillin*

Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393, USA. E-mail: mcmillin@purdue.edu

Received (in Bloomington, IN, USA) 3rd August 1998, Accepted 12th October 1998

Inosine-for-guanine replacement in DNA hairpin hosts reveals that the intercalative binding of Cu(T4) depends upon strong hydrogen bonding within the stem.

Water-soluble porphyrin derivatives are of interest for photodynamic therapy,[1,2] as antiviral agents,[3,4] and, in the case of cationic systems, as versatile ligands for DNA-binding studies.[5,6] A wealth of physical data shows that metalated forms lacking axial ligands, such as Cu(T4), intercalate into DNA sequences that are rich in guanine–cytosine (G≡C) base pairs[5,6,7] (H_2(T4) = *meso*-tetrakis(4-(*N*-methylpyridyl))porphyrin). On the other hand, adenine–thymine (A=T) base pairs support external binding in groove regions. A recent report based on DNA hairpin substrates indicated that robust hydrogen bonding within the local B-form structure, not the specific base sequence, promotes intercalative binding.[8] The replacement of a guanine base by inosine provides a strict test of the hypothesis because it is a small perturbation that noticeably impacts the hydrogen bonding within DNA. The effect is to weaken the B-form structure because inosine lacks an NH_2 substituent at its C2 position and can form only two hydrogen bonds with cytosine. The following results show that even one such replacement in a six-base-pair run can dramatically alter the binding of Cu(T4).

The hexadecamers employed all came from the Macromolecular Structure Facility of Purdue University as custom syntheses. In all spectral runs the hairpin-to-copper ratio was 5 : 1. Quantification of the hairpin concentration was possible *via* the absorbance of a denatured sample at 80 °C in conjunction with the ε_{260} values (molar absorptivities at 260 nm) of the component mononucleotides. The extremum in the derivative of the absorbance *versus* temperature profile indicated the melting temperature, T_m. The sequence is normally constant except for residues 3 and 4 and their complements (positions 13 and 14). The two-letter abbreviation identifies the bases in the 3,4 positions:

$$\text{CI} = \begin{matrix}5'\text{-GA}\mathbf{CI}\text{AC}^T\text{T}\\ 3'\text{-CTICTG}_T\text{T}\end{matrix} \qquad \text{AI} = \begin{matrix}5'\text{-GA}\mathbf{AI}\text{AC}^T\text{T}\\ 3'\text{-CTTCTG}_T\text{T}\end{matrix}$$

The data in Table 1 show that replacement of a mid-stem guanine by inosine has a significant impact on the melting temperature and the reaction chemistry of the hairpin. Thus, each replacement reduces the melting temperature by about 12 °C. As a result, the CI, IC and AI hairpins all exhibit about the same T_m, presumably because they have the same number of hydrogen bonds in the stem. As previously reported, the spectral and physical data reveal that Cu(T4) intercalates into the CG hairpin.[8] In contrast, with the CI hairpin all indications point to a complete shift in the mode of binding. More specifically, the weak emission intensity from the latter adduct is a clear sign of an exposed copper center that is subject to axial attack by solvent or basic centers on the surface of the hairpin.[6] Furthermore, in the Soret region the CI adduct shows a small bathochromic shift in the absorption maximum, hyperchromism and an induced CD signal with a positive amplitude—all signs of groove binding.[5,6,9] Similar spectral changes occur in switching from the AG to the AI hairpin except for the inversion in the sign of the induced CD signal (Fig. 1). The remarkable aspect of the AG system is that the loss of just one of fifteen possible hydrogen bonds in the stem drastically alters the binding of Cu(T4).

Regardless of the mode of binding, the DNA must undergo a structural adjustment to accommodate the Cu(T4) ligand because there is no pre-organized binding site. In other words, the uptake of the porphyrin is an induced-fit process. For intercalation, the minimum necessary structural reorganization entails partial unwinding of the double helix and creation of a cavity to house Cu(T4). Even with those modifications, strain is evident,[10,11] and groove binding of Cu(T4) is a competitive phenomenon in DNA hosts containing a short run of A=T base pairs amidst long segments of G≡C steps.[6,12] Groove binding is also disruptive as Cu(T4) cannot conform to the natural contour of DNA. Consequently, uptake occurs with partial melting of the double helix and generation of an appropriate binding pocket.[6,13] Transient Raman studies of Cu(T4) by Nakamoto and co-workers reveal that a run of four consecutive adenine–thiamine (A=T) base pairs suffices to provide the surface area

Table 1 Physical data for Cu(T4) adducts with DNA hairpins[a]

and/or the flexibility necessary for groove binding.[12] From the standpoint of internalization of the ligand, intercalation and groove binding represent limiting cases of a continuum of possible interactions. Intermediate situations are certainly feasible; for example, an extruded base might stack with an externally bound porphyrin. The adduct with the IC system may, in fact, be some type of an intermediate case. To be sure, the modest hypochromism apparent in the Soret absorption is evidence for some degree of stacking with the DNA bases, and partial protection of the axial coordination positions at copper would explain the definite, albeit weak, emission signal of the adduct.[14] However, classical intercalation does not occur because the emission intensity pales in comparison with that of the GC adduct. More than one type of association may occur because the absorption and excitation maxima do not coincide for the IC or the AI adducts. Yet, the CD spectrum of the latter is clearly not the sum of the signals of a classical groove binder and a classical intercalator.

Though questions remain, the present results provide important insight into the forces influencing the binding of Cu(T4). The main conclusion is that for intercalation of Cu(T4) to occur, a robust hydrogen bonding network must exist within the B-form DNA to compensate for the steric problems posed by the bulky porphyrin. Two predictions follow. One is that the presence of a bulge in the stem may promote intercalative binding by reducing the strain and/or the energy requirement for cavity creation.[15] Indeed, comparisons of the hypochromism and the emission intensity show that Cu(T4) is a more avid intercalator for the CTA hairpin, with the bulge thymine, than the CA control (Table 1). The second prediction is that the mode of binding known as hemiintercalation, which has been observed in the solid,[11] is unlikely to occur in solution, at least in sequences rich in G≡C base pairs. The reason is that hemiintercalation would require base extrusion, but the preservation of hydrogen bonding between bases is, in reality, one of the most important factors that favors internalization over groove binding.

Dynamic kinetic resolution in the hydrolysis of an α-bromo ester

Matthew M. Jones and Jonathan M. J. Williams*

Department of Chemistry, University of Bath, Claverton Down, Bath, UK BA2 7AY.
E-mail: j.m.j.williams@bath.ac.uk

Received (in Liverpool, UK) 15th September 1998, Accepted 6th October 1998

Bromide can be employed to racemise an α-bromo ester more rapidly than the corresponding acid (carboxylate), and this rate difference has been employed as the basis of a dynamic kinetic resolution reaction.

Dynamic kinetic resolution strategies have been enjoying increasing attention in the last few years.[1] For an ideal dynamic kinetic resolution, the two enantiomers of starting material must react at very different rates. Furthermore, whilst the starting material enantiomers must be in equilibrium, the product must be essentially inert to racemisation. Recent work from this group has described racemisation procedures which strongly favour the starting material.[2]

Herein we report that the racemisation of the α-bromo ester **1** is significantly faster than for the corresponding α-bromo acid **2** under appropriate conditions. Thus, competition experiments between enantiomerically enriched ester **1** and acid **2** show that the ester racemises more quickly (Scheme 1 and Table 1).†

Scheme 1

Table 1 Racemisation of ester **1** and acid **2** with bromides

		Ee of **1** (%)		Ee of **2** (%)	
Bromide	*t*/h	Initial	Final	Initial	Final
KBr	18	38	28	34	34
CsBr	18	80	77	35	35

Wang polymer-$CH_2P^+Ph_3Br^-$	2	43	0.5	61	58

[a] Performed in H_2O–MeOH (5:1).

We rationalise that the racemisation of the ester **2** occurs *via* S_N2 displacement by bromide (Fig. 1), which is enhanced by the neighbouring carbonyl function (π* C=O). However, under the reaction conditions, the carboxylic acid will be deprotonated, and the carboxylate is less willing to assist the adjacent S_N2

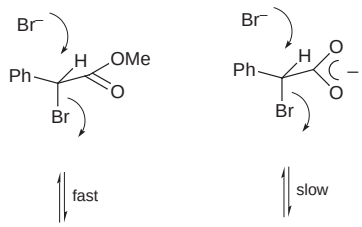

Fig. 1 Preferential racemisation by SN2 bromide displacement of an α-bromo ester.

process. We have not ruled out the possibility that racemisation occurs by simple enolisation, but the racemisation of the ester is not qualitatively dependent on pH (5–8)

The preferred sources of bromide were quaternary ammonium bromides and quaternary phosphonium bromide. In particular, the phosphonium salt produced by heating brominated Wang resin with PPh_3 in toluene for 10 h provided a particularly convenient bromide source.[3] Simple salts such as KBr were significantly less effective for the racemisation of either ester or acid.

We chose to use an enzymatic procedure for the selective hydrolysis of the bromo ester, which has some literature precedent.[4] Thus, ester **1** was hydrolysed by various enzymes in water, using a autotitrater to maintain a constant pH (7.0). A representative selection of these enzymes in a simple kinetic resolution reactions are shown in Scheme 2 and Table 2.

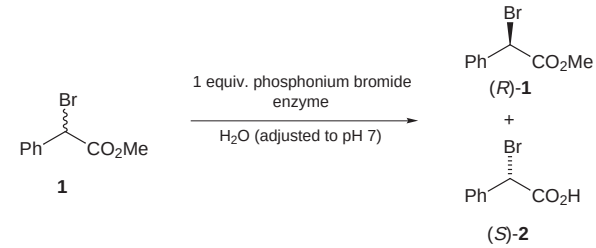
[a] Performed in H_2O. [b] *Candida rugosa* lipase. [c] CLEC-CRL - cross linked enzyme crystal (*Candida rugosa* lipase) [d] CLEC-PCL - cross linked enzyme crystal (*Pseudomonas cepacia* lipase). In this case the *R* enantiomer of acid was formed preferentially.

We favoured the commercially available cross-linked enzyme crystal, Altus 17 (*Candida rugosa* lipase, cross-linked),[5] which provided a fast reaction with reasonably good enantioselectivity in the resolution.

By combining the selective racemisation procedure with simple kinetic resolution, we proceeded to investigate the dynamic kinetic resolution reaction (Scheme 3 and Table 3). Gratifyingly, the combination of the Wang phosphonium



Scheme 3

Table 3 Dynamic kinetic resolution of ester **1**

$C_{16}H_{33}P^+Ph_3Br^-$	7	65 (70)	6	68
Wang polymer-$CH_2P^+Ph_3Br^-$	4.5	78 (80)	26	79

[a] Isolated yields. Figures in parentheses are conversions. [b] Performed in H_2O–MeOH (5 : 1).

bromide with Altus-17 afforded an effective dynamic resolution procedure. Thus at 80% conversion, the product **2** was obtained with good enantioselectivity (79% ee, essentially the same as for the simple kinetic resolution). The starting material, although not racemic, was clearly undergoing slow racemisation under the reaction conditions. Presumably the larger phosphonium salts (R^1 = $C_{16}H_{33}$) and the immobilised phosphonium salts are unable to interfere with the immobilised enzyme, which is beneficial in an effective dynamic resolution where both the enzyme and bromide source must co-exist.

In conclusion, we have shown that an α-bromo ester can be successfully racemised in the presence of an α-bromo acid (carboxylate). This provides the basis for a dynamic kinetic resolution procedure using a combination of a hydrolytic enzyme with a source of bromide. Further work extending the range of substrates will shortly be underway.

We are grateful to the EPSRC Clean Technology Unit for a studentship (to M. M. J.) and to the University of Bath for additional support.

A three-coordinate copper(I)-phenoxide complex that models the reduced form of galactose oxidase

Brian A. Jazdzewski, Victor G. Young, Jr. and William B. Tolman*

Department of Chemistry and Center for Metals in Biocatalysis, University of Minnesota, 207 Pleasant Street SE, Minneapolis, Minnesota 55455, USA. E-mail: tolman@chem.umn.edu

Received (in Bloomington, IN, USA) 28th August 1998, Accepted 12th October 1998

A novel 3-coordinate Cu(I)-phenoxide complex with N-donor supporting ligation was structurally characterized and shown to be highly reactive towards dioxygen, similar to the reduced form of galactose oxidase.

Galactose oxidase (GAO) is a fungal enzyme that couples the 2-electron oxidation of primary alcohols to aldehydes with the reduction of O_2 to H_2O_2.[1] Structural and spectroscopic studies of this enzyme[1,2] and a related system, glyoxal oxidase,[3] have shown that they belong to an important class of metalloproteins that use metal centers and proximal organic radicals together to effect multielectron redox chemistry.[4] In GAO, 2-electron transformations are mediated by a single copper ion coordinated by a cysteine-modified tyrosinate ligand (Y_{272}). A mechanistic picture has emerged from biochemical studies that involves cycling of Cu(I)/Cu(II) and $Y_{272}/Y_{272}^{\bullet}$ redox states (Fig. 1).[1,2,5] The active form (**A**) contains a unique, antiferromagnetically coupled Cu(II)–$Y_{272}^{\bullet}$ pair. After binding of substrate to **A**, proton transfer to a second tyrosinate ligand (Y_{495}) is postulated to occur, followed by an internal 2-electron oxidation (here shown as sequential H atom and electron transfers) to yield the reduced form (**R**). Oxidation of **R** by O_2 yields the important enzyme product H_2O_2 and regenerates the catalytically competent form **A**. While extensive spectroscopic and physicochemical evidence supports the postulated structure of **A**, the proposed formulation for **R** is based solely on an analysis of X-ray absorption near edge and fine structure (XANES and EXAFS) spectroscopic data.[2g] These data show that **R** contains a Cu(I) ion coordinated to 3 or 4 N,O ligands, with the favored coordination number being 3 on the basis of the XANES edge and the average Cu–N,O bond distance from EXAFS of 1.99 Å.

Further understanding of the novel properties and reactivity of the GAO active site has come from synthetic studies, which, among other things, have succeeded in providing well-characterized mononuclear Cu(II)-phenoxyl radical species analogous to **A**.[6] Few examples of monomeric Cu(I)-phenolates that might model deprotonated **R** have been reported,[6g,7] although dicopper(I) complexes with bridging phenolate ligands are relatively common.[8] Of the two monomeric compounds that have been structurally defined by X-ray crystallography, one contains soft, abiological isocyanide coligands.[7a] Sorrell *et al.* published the X-ray structure of a monocopper(I)-phenoxide supported solely by N-donors, but it is 4-coordinate and no O_2 reactivity was reported.[7b] Herein we describe the synthesis and structural characterization of a novel mononuclear Cu(I)-phenoxide complex with a coordination number and coligand complement that closely mimic those proposed for form **R** of GAO. In addition, preliminary reactivity studies show that, like **R**,[5a] the complex is extremely sensitive to oxidation by O_2.

A new sterically hindered, potentially tridentate ligand with one phenolate and two amine donors, 1-(2-hydroxy-3,5-di-*tert*-butylbenzyl)-5-isopropyl-1,5-diazacyclooctane (HL), was prepared by treatment of 1-isopropyl-1,5-diazacyclooctane[9] with 3,5-di-*tert*-butyl-2-hydroxybenzyl bromide[10] and Na_2CO_3 in CH_3CN (Scheme 1).† Attempts to generate a Cu(I) complex by reacting NaL with CuCl or $[Cu(CH_3CN)_4]X$ (X = ClO_4^- or SbF_6^-) under an inert atmosphere in a variety of solvents only led to green mixtures indicative of disproportionation. However, treatment of HL with Cu_xMes_x (x = 2 and 5)[11] in THF under stringent anaerobic conditions followed by precipitation with pentane yielded LCu (**1**) as a white powder (Scheme 1). Combined ^1H and ^{13}C NMR, UV-vis, high resolution MS, and CHN analysis data corroborate the formulation of **1**, which was ultimately confirmed by an X-ray structure on a crystal grown from toluene–pentane (Fig. 2).‡ Only one of the two independent but chemically similar molecules (rotational twins) in the unit cell is shown. A planar T-shaped coordination geometry is adopted by the complex with divergent metal–ligand bond lengths.[12] Thus, one bond is quite long [Cu(1)–N(1) = 2.279(4) Å], one is more typical of Cu(I)–N bonds in 3-coordinate complexes [Cu(1)–N(2) = 1.979(4) Å],[13] and the Cu(I)–phenoxide distance is shorter than any reported previously for such a bond [Cu(1)–O(1) = 1.878(3) Å].[7] Interestingly, the

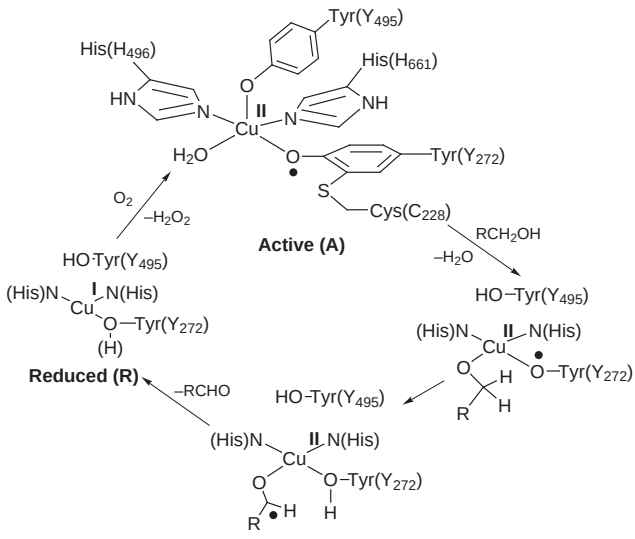

Fig. 1 Proposed mechanism for GAO (adapted from ref. 1).

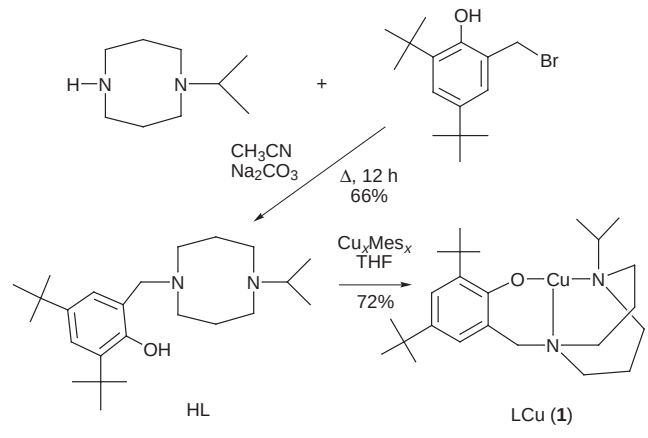

Scheme 1

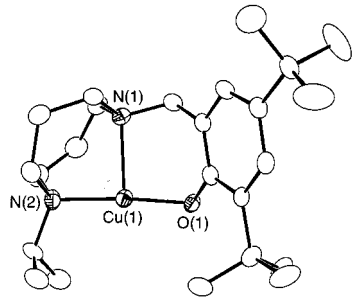

Fig. 2 Drawing of the X-ray crystal structure of LCu (**1**) (only one twin component shown). All ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): Cu(1)–O(1) 1.878(3), Cu(1)–N(1) 2.279(4), Cu(1)–N(2) 1.979(4), O(1)–Cu(1)–N(1) 96.3(2), O(1)–Cu(1)–N(2) 174.7(2).

average of these three disparate bond distances (2.05 Å) is more typical for 4- rather than 3-coordinate Cu(I) and is slightly greater than the average metal–ligand bond distance in **R** determined by EXAFS analysis (1.99 Å).[2g]

Cyclic voltammetry of **1** in THF with 0.2 M tetrabutylammonium hexafluorophosphate revealed a quasireversible wave with $E_{1/2}$ = −0.10 V *vs*. SCE (scan rate = 100 mV s^{-1}; ΔE_p = 183 mV; $i_{pa} \approx i_{pc}$) and a further irreversible oxidation at +0.32 V.[14] We have been unable to discern whether the quasireversible wave is a 1- or 2-electron process through coulometric measurements due to rapid decomposition of the product of oxidation of **1**. Consistent with a high thermodynamic driving force for oxidation reflected by the negative potential, **1** is extremely air sensitive; room temperature exposure instantly yields a light green solution [λ_{max}/nm (ε/$M^{-1}cm^{-1}$ per copper) 324 (15000), 394 (sh, 800), 656 (250)] of Cu(II) species that we presume is(are) multinuclear on the basis of its(their) EPR silence. By oxygenating a solution of **1** in THF at −72 °C a dark green intermediate was observed [λ_{max}/nm (ε/$M^{-1}cm^{-1}$ per copper) 390 (3800), 418 (3900), 670 (1900); EPR (X-band, 77 K) silent]. This intermediate is short-lived, decaying by a first order process to the aforementioned light green solution at −72 °C with $k = 3.9(1) \times 10^{-3}$ s^{-1} (UV-vis monitoring). Its spectroscopic properties are consistent with a copper-dioxygen adduct [Cu(II)-superoxo or $Cu(II)_2$-peroxo][15] or a Cu(II)-phenoxyl radical species (like **A**),[6a,b,d,e,g,i] all of which would be expected to give rise to low energy CT absorption bands and EPR silence (due to magnetic coupling) and to decay rapidly. Efforts to discern among these possibilities by further characterizing this highly reactive intermediate are ongoing.

In summary, we have prepared and structurally characterized a unique example of a three-coordinate Cu(I)-phenoxide complex supported by N-donors. Its coordination environment and high reactivity with O_2 bear striking similarities to the proposed GAO intermediate **R**. With the aim of gaining insights into the detailed role of **R** in the GAO mechanism, aspects of the reactivity of **1** will be the subject of future studies.[16]

† Characterized by ^1H and ^{13}C NMR, high resolution EI-MS, and CHN analysis.

‡ *Crystal data for* **1:** $C_{24}H_{41}CuN_2O$, M = 437.15, monoclinic, space group $P2_1$, a = 13.3193(2), b = 10.9789(2), c = 16.0969(1) Å, β = 92.349(1)°, V = 2351.89(6) $Å^3$, Z = 4, T = 173 K, μ = 0.944 mm^{-1}. The crystal used for collection was determined to be twinned (twin law −1.0, 0.0, −0.067; 0.0, −1.0, 0.0; 0.0, 0.0, 1.0; Sparks Twinning Programs, Sparks, R. A., Madison, WI, 1977). The rotational twin was modeled by converting the reflection data to the SHELXTL HKLF 5 format using the twin law, the reciprocal metric tensor, and ascending partial-overlap groupings by 0.005 $Å^{-1}$ (7 altogether), by use of the UNTWIN program (V. G. Young, Jr., 1997). Side-by-side comparison of the two twin components (0.49 : 0.21) shows only minor differences in the diazacyclooctane ring conformation, and both molecules appear to be the same enantiomer. The final cycle of full-matrix least-squares refinement (on F^2), based on 7455 reflections ($2.54 < 2\theta < 50.64°$) and 527 variable parameters, with 1 restraint, converged with $R1$ = 0.0482 and $wR2$ = 0.1121. A total of 5515 of the 7455 reflections were either exactly or partially overlapped, and 1950 reflections were considered normal data. Data were collected on a Siemens SMART system and calculations were performed using the SHELXTL-Plus V5.0 suite of programs. CCDC 182/1055.

Cationic alkyl aluminium ethylene polymerization catalysts based on monoanionic *N,N,N*-pyridyliminoamide ligands

Michael Bruce, Vernon C. Gibson,* Carl Redshaw, Gregory A. Solan, Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY. E-mail: V.Gibson@ic.ac.uk

Received (in Cambridge, UK) 13th October 1998

Treatment of the 2,6-bis(imino)pyridines {[2,6-(ArNCR)$_2$C$_5$H$_3$N]} [R = H, Ar = 2,6-*i*-Pr$_2$C$_6$H$_3$ or 2,4,6-Me$_3$C$_6$H$_2$; R = Me, Ar = 2,6-*i*-Pr$_2$C$_6$H$_3$] with AlMe$_3$ at elevated temperature gives, *via* migration of a methyl group to the ligand backbone, the pseudo-five coordinate dimethylaluminium species {2-[ArNCR(Me)],6-(ArNCR)C$_5$H$_3$N}AlMe$_2$ (1a–c); upon treatment with B(C$_6$F$_5$)$_3$, 1a–c cleanly afford the cationic methyl complexes [{2-[ArNCR(Me)],6-(ArNCR)C$_5$H$_3$N}AlMe]$^+$[MeB(C$_6$F$_5$)$_3$]$^-$ (2a–c) which are active for ethylene polymerization.

Neutral aluminium alkyls are well known to act as ethylene oligomerization[1] and polymerization[2] catalysts. However, the potential of cationic aluminium alkyls as catalysts is just emerging. Recent advances by Coles and Jordan[3] have utilised a number of chelating *N,N*-amidinate ligands, *viz.* {RC(NR′)$_2$} (R = Me, R′ = *i*-Pr, Cy; R = *t*-Bu, R′ = *i*-Pr, Cy, SiMe$_3$) which, upon reaction with Me$_3$Al, afford complexes of the form [{RC(NR′)$_2$}AlMe$_2$]. Cationic species are readily generated on further reaction with B(C$_6$F$_5$)$_3$ or [HNMe$_2$Ph][B(C$_6$F$_5$)$_4$], the latter giving amine adducts. In the case of R = *t*-Bu, R′ = *i*-Pr the derived cation [from B(C$_6$F$_5$)$_3$] polymerizes ethylene at ambient temperature, albeit with low activity.

In a separate study, we[4] and Brookhart and coworkers[5] have recently shown that iron and cobalt complexes bearing neutral, 6-electron donor 2,6-bis(imino)pyridine ligands afford exceptionally active polymerization catalysts when activated with methylaluminoxane (MAO). We became interested in extending the range of *N,N,N*-chelate ligands to monoanionic derivatives in which one of the imino groups is transformed into an amido functionality, and nucleophilic attack on the imine carbon using an alkylaluminium reagent offered a convenient approach.[6] The aluminium complexes so-derived can be used to provide a source of free pyridyliminoamine ligands (*via* hydrolysis); details of the synthetic utility of this reaction will be reported elsewhere.[7] Here, we show that the dimethylaluminium complexes bearing such tridentate *N,N,N*-ligands also can be converted cleanly to cationic alkyl derivatives which are active as ethylene polymerization catalysts. The significance of this observation is highlighted by a recent report that bidentate *N,N*-chelate ligand systems can lead to undesirable exchange reactions which thwart the generation of a polymerization-active site.[8]

Reaction of the parent 2,6-bis(imino)pyridines {[2,6-(ArNCR)$_2$C$_5$H$_3$N]} [R = H, Ar = 2,6-*i*-Pr$_2$C$_6$H$_3$ or 2,4,6-Me$_3$C$_6$H$_2$; R = Me, 2,6-*i*-Pr$_2$C$_6$H$_3$] with AlMe$_3$ in refluxing toluene (12 h) results in alkylation of the ligand backbone to give the dimethylaluminium species {2-[ArNCR(Me)],6-(ArNCR)C$_5$H$_3$N}AlMe$_2$ [R = H; Ar = 2,6-*i*-Pr$_2$C$_6$H$_3$ **1a**; R = H; Ar = 2,4,6-Me$_3$C$_6$H$_2$ **1b**; R = Me, Ar = 2,6-*i*-Pr$_2$C$_6$H$_3$ **1c**] in high yield (Scheme 1).†

Crystals of **1b** suitable for an X-ray structure determination were grown from MeCN. The molecular structure‡ of **1b** shows the N(9)–C(9)–py–C(7)–N(7) portion of the ligand to be co-planar to within 0.06 Å (Fig. 1), a geometry very similar to that observed for the closely related bis(imino)pyridine ligand in its iron complex.[4] Here the aluminium atom lies 0.33 Å out of this plane and adopts a severely distorted tetrahedral geometry with

[a] All runs performed in toluene at 5 bar of ethylene, 40 °C, 60 min, using 0.25 mmol of cation. [b] Generated *in situ* from the reaction of equimolar (0.25 mmol) amounts of **1a–c** and $B(C_6F_5)_3$. [c] Determined by GPC at 160 °C.

angles at aluminium ranging between 81.3(2) and 136.0(2)°. There is a slight asymmetry in the Al–Me distances [1.990(6) Å to C(10) and 1.951(5) Å to C(11)] but a more marked difference between the two Al–N bonds, with that to the formally negatively charged nitrogen N(7) being significantly shorter [at 1.876(4) Å] than that to the pyridyl nitrogen [2.029(4) Å]. Perhaps the most interesting feature of the structure is the directing of the imino nitrogen N(9) into the flattened 'basal' face of the tetrahedron—the aluminium atom lies only 0.3 Å out of the N(1)–C(10)–C(11) plane whereas it lies between 0.6 and 0.9 Å out of the other tetrahedral faces. The distance is long at 2.575(4) Å, but bearing in mind the potential for this nitrogen and the pyridyl nitrogen to adopt an *anti* relationship in the absence of a metal ion[7] we believe that this interaction is real and indeed a key feature in the subsequent cation formation in **2**.

The ^{1}H NMR spectra are consistent with the solid-state structures of **1** being maintained in solution. For **1a**, the pyridyl *meta*-protons resonate at δ 8.49 and 7.67 while the coordinated methyl groups appear as singlets at δ −0.67 and −0.89 reflecting the C_1 symmetry of the complex.

The cationic complexes [{2-[ArNCR(Me)],6-(ArNCR)-C_5H_3N}AlMe]$^+$ (**2a–c**) are readily generated on treatment of one equivalent of $[B(C_6F_5)_3]$ in toluene at ambient temperature (Scheme 1).† For example, the ^{1}H NMR spectrum arising from **2a** reveals a sharp singlet at δ −0.70 for the methyl group coordinated to aluminium, while the methyl group coordinated to boron of the $[MeB(C_6F_5)_3]^-$ counter-anion is clearly seen as a broad singlet at δ 0.43. The upfield shift of this resonance is consistent with a free anion[9] and contrasts with the more downfield resonance (δ 1.67) observed by Coles and Jordan in which a B–Me···Al association is invoked.[3]

All the cationic complexes **2a–c** are active for ethylene polymerization (see Table 1) affording solid polyethylene with activities between 80 and 120 g mol^{-1} h^{-1} bar^{-1}. The polymer products in each case are low molecular weight, with M_ws ranging from 33 000 (run 2) to 13 000 (run 3). It is noteworthy that by changing the ligand backbone (otherwise identical) in **2a** from a single methyl group to three methyl groups in **2c** has the effect of reducing the molecular weight by almost half (*cf.* runs 1 and 3).

In a series of experiments on the iron and cobalt catalyst systems, we have shown that the bis(imino)pyridine ligands bonded to iron and cobalt are not attacked by $AlMe_3$ or MAO under the conditions of the polymerization experiment: free bis(imino)pyridine can be isolated in quantitative yield following hydrolytic work-up after the polymerization, *i.e.* no alkylation of the ligand backbone occurs of the type described here.

BP Chemicals Ltd is thanked for financial support. Dr J. Boyle and G. Audley are thanked for NMR and GPC measurements, respectively.

Adsorption of metal cations by hydrous aluminium(III) or iron(III) hydroxide precipitates: enhancement by EDTA and related chelate molecules†

Michael G. Burnett,*[a] Cathy Faharty,[a] Christopher Hardacre,[a] James M. Mallon,[a] R. Mark Ormerod[b] and Graham C. Saunders[a]

Received (in Cambridge, UK) 14th August 1998, Accepted 15th October 1998

Stoichiometrically equivalent concentrations of ethylenediaminetetraacetate, EDTA, and of related chelating anions increase the adsorption of *ca*. millimolar concentrations heavy metal aqua-ions on amorphous precipitates of aluminium(III) or iron(III) hydroxide and, although higher concentrations decrease the adsorption, poly-EDTA, a polyelectrolyte containing EDTA functional groups, shows no such decrease.

Inorganic coagulants, such as aluminium(III) or iron(III) salts, are widely used both for cleaning potable water and also for treating a variety of aqueous effluents.[1] The gelatinous metal hydroxide or floc is also used in the treatment of effluents containing heavy metal cations since these are adsorbed[2] by the floc even though they are generally soluble at the pH used. The method is thought to be less successful in the presence of coordinating ligands since these often form soluble metal complexes which are only adsorbed by the floc at pH values[3,4] below those customarily used in water treatment by, for instance, hydrous ferric oxide.[1] However, much of the work in this area is concerned with metal adsorption in sediment or soil so that hydrated aluminium or iron oxides[5] are the absorbents usually studied. Although solutions of EDTA are believed to strip metal cations from soils[6] where they are supposed to be bound by aluminium(III) or iron(III) oxides, EDTA at concentrations comparable to those of the adsorbed metal ions, can increase their adsorption at pH values below 7 through electrostatic binding of the anionic complexes.[5] In this work we have examined the effect of EDTA on heavy metal adsorption during the precipitation of amorphous aluminium or iron hydroxide under conditions typical of those used during effluent treatment. We find that copper, nickel and cadmium show an enhanced cationic adsorption on aluminium hydroxide at pH 7, both separately and when mixed in the same solution. Enhanced adsorption at pH 7 has only been found on an iron(III) floc in the single case of mercury(II). The effect has been studied in more detail for cadmium on aluminium(III) but the similar trends observed in all cases suggest that one theoretical explanation is common to all.

The adsorption experiments were carried out by mixing reagent solutions at a pH of *ca*. 3 and then adjusting the pH to 7 sufficiently slowly to ensure that the final value during processing was 7.000 ± 0.005. The floc and supernatant solution were separated by centrifuging, the floc was redissolved in concentrated nitric acid and then analysed by ICP-AE. A correction was applied in all cases to allow for the adsorbate ions present in the solution which was trapped within the floc gel phase. In some experiments the EDTA present in each phase was estimated spectroscopically at 460 nm by complexation at pH 3 with zirconium(III).

The approach to equilibrium is rapid if all the components are present prior to the adjustment of the pH to 7 but it is slower if, for instance, the floc is formed prior to the addition of EDTA or cadmium. These results resemble the leaching experiments reported[7] previously with a range of hydrous metal oxides. A typical experiment is shown in Fig. 1 for cadmium(II) adsorbed by a floc of aluminium(III). The fraction of cadmium adsorbed decreases progressively with increasing concentration of EDTA as would be expected if the adsorbed ions were being removed from the floc because of the formation of unadsorbed EDTA–metal complexes. However the extrapolated adsorption at zero EDTA is 100% whereas the measured value is 40%. This apparent discontinuity is explained when the experiments are extended to much lower EDTA concentrations, Fig. 2. It is now obvious that the effects of trace amounts of EDTA is to increase the fraction of the metals adsorbed by the floc. The adsorption of the Cd^{2+} in the presence of a stoichiometric equivalent of EDTA increases as the pH rises showing that it occurs at a cationic site despite the anionic character of dissolved $[Cd(edta)]^{2-}$.

The concentration of aluminium found in solution increases with that of EDTA and may be calculated on the basis of the accepted values of the solubility product of aluminium hydroxide and the binding constant of the aluminium–EDTA complex,[8] as shown in Fig. 1.

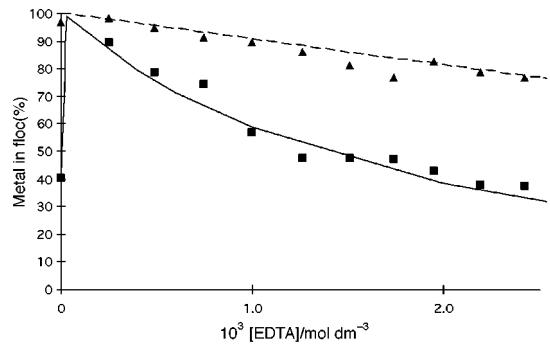

Fig. 1 Effect of EDTA at pH 7, 9.3 mM Al^{3+} and 22.2 μM Cd^{2+}: (■) % Cd(exptl.), (▲) % Al(exptl.), (——) % Cd(calc.), (- - - -) % Al(calc.).

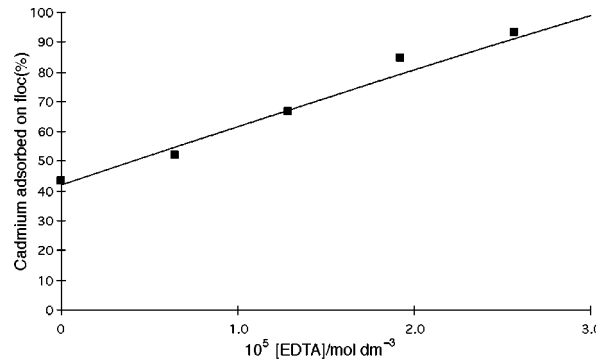

Fig. 2 Effect of low concentrations of EDTA, 12.3 mM Al^{3+} and 29.4 μM Cd^{2+}: (■) % Cd(exptl.), (——) % Cd(calc.).

† A patent has been applied for covering the material presented in this paper, Application No. GB 9817528.4, August 12th, 1998.

It has been found that changes in the EDTA structure do not prevent enhanced metal ion adsorption. Cyclohexylaminetetraacetate and nitrilotriacetate will also promote cadmium retention in aluminium floc although they are much less effective. The enhanced adsorption of cadmium also occurs when the EDTA is in the form of a polyelectrolyte, poly-EDTA, made by the condensation of polyallylamine and ethylenediaminetetraacetic dianhydride.[9] However, although the poly-EDTA enhances adsorption in the same way as does EDTA, the decline in adsorption at higher concentrations shown in Fig. 1 does not occur and the aluminium floc dissolves to a much smaller extent, by 1–2%.

The structure of the species present in the gel phase and in solution have been investigated using EXAFS which reveals the short range order within an amorphous precipitate as well as the corresponding order in the dissolved complexes. The results for cadmium adsorbed on aluminium floc show that the adsorbed metal in the absence of EDTA is identical with the aqua-cation whereas in the presence of EDTA it resembles the dissolved EDTA complex in solution. The compound adsorbed in the gel phase appears to be a six-co-ordinate complex in which the nitrogen or oxygen atoms are present at 0.24 nm from the metal atom. These results suggest that Cd^{2+},edta,Al^{3+} complexation contributes to the binding of cadmium on cationic sites but with only a slight distortion of the normal Cd^{2+},edta complexation found in solution.

The enhanced adsorption and its eventual inhibition by EDTA can be modelled by an equilibrium system provided a suitable adsorption inhibition step is postulated. The adsorption of metal aqua-ions by both aluminium and iron flocs is generally supposed to take place by binding at metal cation exchange sites. Corresponding anion binding sites are also supposed to exist to explain the removal of anions by the same floc.[5] The eventual stripping of the adsorbed metal from the floc is usually attributed to the formation of soluble metal chelates by EDTA. However if a cadmium–edta species is responsible for the enhanced binding, this no longer explains the final desorption stage. The EDTA cannot be operating by combining with the floc adsorption sites since the concentration of the chelate is more than a hundred-fold less than that of the aluminium atoms present. The simplest equilibrium step producing a satisfactory model appears to be the formation of a soluble polynuclear chelate containing both an adsorbent and an adsorbate atom together with at least two EDTA molecules. There is considerable evidence that the formation of polynuclear species is promoted by the presence of organic ligands and solid aluminium hydroxide.[10] Although EDTA complexes of this type have not previously been suggested, polynuclear carboxylate complexes are well known to exist.[11] Equilibria (1)–(7) below reproduce the essential features of our observations and the data in Figs. 1 and 2.

$$Al^{3+} + 3OH^- \rightleftharpoons G_{gel} \quad (1)$$

$$Al^{3+} + edta^{4-} \rightleftharpoons [Al^{3+}(edta^{4-})]^- \quad (2)$$

$$Cd^{2+} + edta^{4-} \rightleftharpoons [Cd^{2+}(edta^{4-})]^{2-} \quad (3)$$

$$H_2O \rightleftharpoons OH^- + H^+ \quad (4)$$

$$G_{gel} + Cd^{2+} \rightleftharpoons [Cd^{2+}(G)]_{gel} + xH^+ \quad (5)$$

$$Cd^{2+} + edta^{4-} + G_{gel} \rightleftharpoons [Cd^{2+}(edta^{4-})(G)]_{gel} + yH^+ \quad (6)$$

$$[Cd^{2+}(edta^{4-})(G)]_{gel} + edta^{4-} \rightleftharpoons [Cd^{2+}(edta^{4-})Al^{3+}(edta^{4-})]^{3-} \quad (7)$$

Gelatinous hydrous aluminium oxide is denoted by G_{gel} and all species subscripted by 'gel' are adsorbed in the floc. The number of adsorbent sites was always greatly in excess of the number of adsorbed species so that the number of sites per gm atom of aluminium could be taken to be constant. The calculated concentration of undissolved aluminium, $[Al^{3+}]_{floc,}$ was therefore assumed in eqns. (5) and (6) to be linearly related by the constant α to the concentration of free adsorption sites per unit volume of solution, Γ,

$$\Gamma = \alpha[Al^{3+}]_{floc}$$

The values for the ionic product of water, the solubility product of aluminium hydroxide and the association constants of EDTA with aluminium and cadmium were taken from the literature[8] and the constants $\alpha K_5/[H^+]^x$, $\alpha K_6/[H^+]^y$ and K_7 were fitted. There was no need to determine x or y since the pH was constant at 7. The theoretical curves in Figs. 1 and 2 were calculated by the iterative solution of the set of equations derived from equilibria (1)–(7). The agreement of experiment and theory shows that the explanation is consistent with observation although further investigation is necessary to establish the structure of the postulated polynuclear soluble species. The same model may also be used successfully to reproduce the effects of pH and the EDTA enhanced metal ion adsorption in other systems.

The fact that enhanced binding may be produced by a chelating polymer without the undesirable side-effects of aluminium and adsorbate solution eventually produced by EDTA suggests that useful new polyelectrolytes may be synthesised which could enhance the flocculative treatment of heavy metal contaminated aqueous wastes.

We thank British Nuclear Fuels plc. for their support, the Daresbury Laboratory for providing X-ray beam time and technical assistance and the Department of Education for Northern Ireland for a CAST award to J. M. M.

A hydration-controlled nano-valve in a zeolite?†

David O'Connor,[a] Paul Barnes,*[a] David R. Bates[b] and David F. Lander[b]

Received (in Bath, UK) 24th July 1998, Accepted 14th October 1998

Ion-exchange and dehydration in clinoptilolite are simulated revealing a novel feature, a hydration-controlled nano-valve, which explains hitherto anomalous behaviour of this important zeolite system.

Clinoptilolite is a naturally occurring and abundant zeolite with ideal formula $Na_6Al_6Si_{30}O_{72}{\cdot}nH_2O$ in the sodium form. It is known for its high cation exchange and water capacity and has been used[1,2] for water purification, animal feed additives, and in the treatment of nuclear waste by adsorption of heavy ions. It also has potential for gas purification, and this was the original interest behind this study: cations in clinoptilolite are known to be mobile in the hydrated state, and therefore the choice of cation and extent of hydration together offer some potential for design in the zeolite's function. One would like to fine-tune the openings within its channels so that one gas molecule is preferentially admitted over another, and be able to exploit this in gas purification through technological processes such as selective temperature/pressure swing adsorption.[3] However it is difficult to predict the ionic behaviour of a given zeolite system: for example, if two different cations are exchanged into a zeolite the resultant behaviour is not necessarily a simple mixture of those of the single cation forms—in other words, the behaviour is non-additive. This is the case with clinoptilolite: its nitrogen uptake, relative to methane, increases significantly[4] away from either the pure Ca- or pure K-form. This anomalous result typifies such non-additivity and requires an explanation that is currently lacking in the literature.

The simulation of a complete ion-exchange process is an ambitious venture requiring an adequate combination of atom potentials and simulation schedule. The exchange route from pure Ca- to a 50 : 50 Ca/K-clinoptilolite was chosen as an ideal prototype for study. The potentials used were obtained from the well characterized universal force-fields of Rappe *et al.*[5] with modifications by Burchardt *et al.*[6] for atom types which occur in zeolite frameworks, together with formal charges for the cations and partial charges for water (Jorgensen[7]), methane (Righini *et al.*[8]) and nitrogen (Murthy *et al.*[9]); cross term parameters for heterogeneous pairs (*e.g.* cation–water) were taken as the geometric mean of the corresponding homonuclear parameters given in these publications.[5,6] The simulation schedule devised (Table 1) was a combination of various Monte-Carlo and molecular dynamics stages with key features: first, the cations are allowed to be mobile, with or without their variable hydration spheres, and frequent total relaxations permit the zeolite framework to respond to this mobility; the repeated simulated annealing ensures that sufficient configurations are explored away from local minima; and the approach used in the ion-exchange (step no. 5) is pragmatic, not attempting to simulate either the thermodynamics or kinetics of the ion-exchange, but purely to obtain reasonable starting configurations for the exchanged state.

As the water content of the Ca-clinoptilolite is increased (stages 2 to 4) the Ca^{2+} cations in the main (10c) channel are progressively hydrated away from the framework oxygens towards the centre of the main channel [Fig. 1(a)]. This (50%) fraction of Ca^{2+} cations then becomes accessible and can be easily exchanged by twice the number of K^+ cations (to preserve charge neutrality) resulting in a hydrated 50 : 50 Ca : K-clinoptilolite [Fig. 1(b)]. After ion-exchange the water continues to play a key role during dehydration, firstly by allowing the newly arrived K^+ cations to gradually approach their eventual destination [Fig. 1(b), (c)]: this gradual exploration is crucial since the simulation fails if this stage is omitted or if the dehydration is performed too rapidly, and this itself reflects a well known feature that zeolite stability is generally very sensitive to mode of dehydration.[11] The water plays a second, more subtle, role during dehydration by mediating the displacement of the K^+ cations to their final (dehydrated) positions [Fig. 1(c), (d)]: the mechanism by which this occurs is that during dehydration the loss of water reduces the effective dielectric medium so that pairs of neighbouring Ca^{2+} cations experience an increasing electrostatic repulsion which is transmitted to the neighbouring K^+ cations. Thus two Ca^{2+} cations, each just inside the minor (8c) side channels, push both K^+ cations by approximately 1.7 Å so that they protrude into the main (10c)

Table 1 Summary of the 7 stages employed in the simulation schedule for modelling hydration, ion-exchange and dehydration of clinoptilolite. The starting framework structure (stage 1) is based on the published structure[10] using an ideal Si : Al ratio of 5 : 1 so that 1 in 6 tetrahedral atoms is an Al; these Al sites are chosen randomly except being subject to Loewenstein's rule.[13] Whereas various initial cation sites can be used for stages 1–4, the crucial insertion in stage 5 has so far only been attempted using positions close to those in the published structure,[10] and as illustrated in Fig. 1(b). Cations and waters can move freely during all simulated annealing (stages 2c, 6a) *and* molecular dynamics (stages 2b, 6b) cycles, whereas the framework atoms move during just the molecular dynamics (stages 2b, 6b) cycles. All stages are taken to the equilibration: Monte-Carlo (stages 2a, 6b) cycles exceed a minimum of 10^6 configurations; molecular dynamics cycles are typically 10^4 steps of 10^{-15} s; simulated annealing cycles are typically 2×10^4 steps of 10^{-15} s, generating an effective annealing temperature range of 300–600 K

Stage	Brief description
1	Start with a suitable clinoptilolite framework structure
2a	A sequence of grand canonical Monte-Carlo (GCMC) simulations at T = 300 K for increasing pressure, in which water molecules are inserted/destroyed within each fixed framework
2b	Molecular dynamics under constant N,P,T for the *whole* system (framework atoms plus waters and cations) for each pressure step
2c	Simulated annealing for mobile water molecules and cations within the fixed framework
3	Loop around steps 2a, 2b, 2c until the final water loading, N, and pressure, P, are achieved
4	Molecular dynamics under constant N,P,T for the whole system (framework atoms plus waters and cations)
5	Removal of least energetically bound Ca^{2+} cations and semi-random insertion of exchange-cations (K^+) up to electrical neutrality
6a	Simulated annealing for the mobile water molecules and cations within the fixed framework
6b	Molecular dynamics under constant N,P,T for the *whole* system: framework atoms plus waters and cations
6b	GCMC (or equivalent) simulations with decreasing pressure
7	Cycle around steps 6b + 6a to complete dehydration (N = 0)

† The term 'valve' is used here to denote adjustable flow in either channel direction.

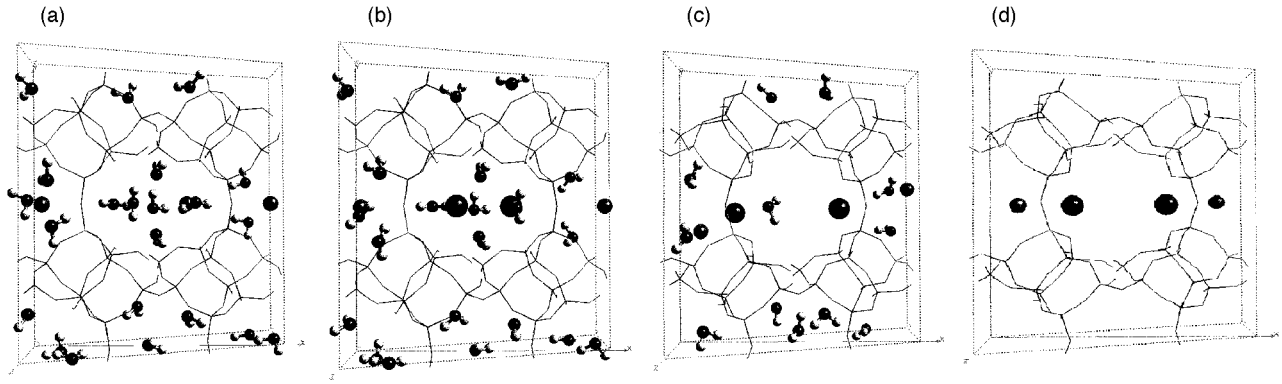

Fig. 1 Computer graphic snapshots obtained during the nano-valve simulation of clinoptilolite: (a) full hydration with the Ca^{2+} cation hydrated away from the framework; (b) a starting configuration after exchange of one Ca^{2+} by two K^+ cations; (c) during dehydration the two K^+ cations approach their framework sites; (d) on complete dehydration the Ca^{2+}–Ca^{2+} repulsion is transmitted to the K^+ cations so that they project into the main (central) 10c channel.

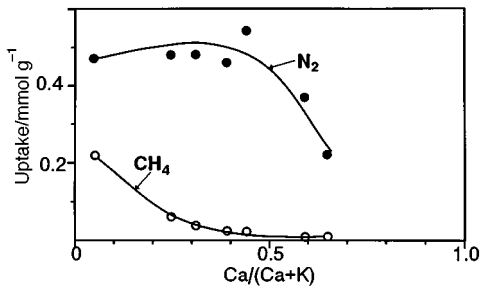

Fig. 2 Dynamic uptake, after 24 seconds exposure of activated clinoptilolite to nitrogen and methane at approximately 1 atmosphere pressure, as a function of the Ca/(Ca + K) ratio. The relative uptake increases significantly away from either the pure potassium (Ca/(Ca + K) = 0) or pure calcium (Ca/Ca + K) = 1) forms. (Data from Robinson *et al.*[4]).

channel reducing its effective diameter from *ca*. 7.2 to 3.8 Å (the actual final Ca–K separations are ~4.3 Å). This lever effect produces a constriction in the main channel which can be described as a 'nano-valve' in the sense that the degree of constriction varies with the degree of dehydration and that the ensuing flow restriction will be down the main channel in the direction of the pressure gradient driving the gas flow; the essential action is illustrated in the graphical abstract.

A difficulty with clinoptilolite is that it is extremely difficult to synthesise, yet the natural form suffers from poor crystallinity. This has prevented[11] a definitive location of cation positions by Rietveld refinement of powder diffraction data as was possible in other studies.[12] However EXAFS spectroscopy is capable of yielding one-dimensional (angle-averaged) information on the local cation environment regardless of specimen crystallinity. Calcium and potassium K-edge EXAFS measurements (Daresbury SRS) on dehydrated Ca : K-clinoptilolite yield average nearest neighbour peaks[11] which are indeed consistent with the nano-valve model described here (the operative Ca^{2+} cation coordinated to 3 framework oxygens (~2.35 Å distance) and K^+ to 4 framework oxygens (~3.0 Å); details and typical plots are available as electronic supplementary information; see http://www.rsc.org/suppdata/cc/1998/2527). However one could conceivably invoke alternative configurations which satisfy these EXAFS-deduced ion coordinations, and therefore some additional confirmation of the nano-valve action is desirable. This has been provided by gas adsorption data (Robinson *et al.*[4]) which show (Fig. 2) that the differential uptake between nitrogen and methane is maximised with the binary cation forms of clinoptilolite. We see from simulations[11] that the diffusion of methane and nitrogen (Table 2) is entirely *via* the main channel of the zeolite, and that methane diffusion is severely restricted relative to nitrogen since the constricted opening of the nano-valve falls in between the kinetic diameters of methane (3.8 Å) and nitrogen (3.0 Å, when axially aligned). Experimental measurements of gas uptake reflect a combination of such kinetic effects with thermodynamic aspects (loading capacity), though kinetic effects would dominate with pressure swing adsorption.

Table 2 Diffusion constants for methane and nitrogen down the main (10c) channel of the single (K^+) and double (50 : 50 Ca^{2+}/K^+) cation forms of clinoptilolite, obtained by *impulse molecular dynamics*. In this method, individual methane or nitrogen molecules are released within the main channel and equilibrated using a 20 ps period of molecular dynamics (individual steps of 10^{-15} s) followed by a further ≥100 ps of molecular dynamics during which the displacement down the channel is traced; the mean diffusion constant is then obtained from the straight line slope of the displacement-squared (*versus* time) plots, of which typical versions have been deposited as electronic supplementary information (see text). One notes that while the absolute values with the Ca/K form are decreased, the relative ratio of nitrogen over methane increases markedly. Diffusion constants are given in units of 10^{-9} m^2 s^{-1}.

Gas	K-clinoptilolite	K/Ca-clinoptilolite
CH_4	0.81	$< 10^{-5}$
N_2	6.48	2.88

In conclusion, this nano-valve, revealed by simulation, explains the anomalous $CH_4 : N_2$ gas adsorption by the binary (Ca/K) cation form of clinoptilolite. It also suggests that the nano-valve might even be continuously controlled by varying the degree of dehydration during calcination of the zeolite. We expect that many other properties (*e.g.* immobilisation in zeolites) might now be similarly predicted provided the effects of water are taken into account.

The authors thank EPSRC, BG plc and the Daresbury SRS.

Equilibria in the $B(C_6F_5)_3$–H_2O system: synthesis and crystal structures of $H_2O{\cdot}B(C_6F_5)_3$ and the anions $[HOB(C_6F_5)_3]^-$ and $[(F_5C_6)_3B(\mu\text{-}OH)B(C_6F_5)_3]^-$

Received (in Basel, Switzerland) 29th June 1998, Accepted 23rd September 1998

Addition of water to the Lewis acid $B(C_6F_5)_3$ gives the neutral compound $H_2O{\cdot}B(C_6F_5)_3{\cdot}2H_2O$ while the reaction between $B(C_6F_6)_3$ and KOH–H_2O in the presence of dibenzo-18-crown-6 gives $[K(dibenzo\text{-}18\text{-}crown\text{-}6)]^+[HOB(C_6F_5)_3]^-$ which crystallises together with the adduct $H_2O{\cdot}B(C_6F_5)_3$; the new binuclear borate anion $[(F_5C_6)_3B(\mu\text{-}OH)B(C_6F_5)_3]^-$ is formed as a salt with the cation $[Ir(\eta^5\text{-}C_5H_5)(C_8H_{12})H]^+$ by addition of H_2O to $B(C_6F_5)_3$ in the presence of $[Ir(\eta^5\text{-}C_5H_5)(C_8H_{12})]$.

Large and very weakly or non-coordinating anions $[BR_4]^-$ [R = 3,5-$(CF_3)_2C_6H_3$, C_6F_5] have recently attracted interest due to their ability to stabilise electrophilic metal cations containing vacant coordination sites.[1a–d] These cations can be generated by interaction of the neutral Lewis acid $B(C_6F_5)_3$ with a zirconium–methyl bond resulting in abstraction of the anionic methyl group and giving the anion $[MeB(C_6F_5)_3]^-$. Apart from the role as a co-catalyst for olefin polymerisation the Lewis and $B(C_6F_5)_3$ has been shown to have a versatile chemistry.[2] Despite the interest in $B(C_6F_5)_3$, however, little is known of its reaction with water. There is a report of the compound $[NHEt_3][HOB(C_6F_5)_3]$[3] and of the platinum complex, $[Pt\{HOB(C_6F_5)_3\}Me(Bu_2bpy)]$ (Bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine), which is formed by reaction between $[PtMe_2(Bu_2bpy)]$, $B(C_6F_5)_3$ and H_2O. This latter complex has been structurally characterised and contains the anion $[HOB(C_6F_5)_3]^-$ as a ligand co-ordinated to the platinum centre.[4] Finally, it has been reported that isobutylene and *p*-methylstyrene undergo a 'carbocationic' polymerisation initiated by $B(C_6F_5)_3$ in the presence of water.[5] This implies the presence of acidic protons as reactive species. Herein we report the isolation and full characterisation of three new boron compounds by reactions between $B(C_6F_5)_3$ and H_2O under various conditions which reveal the diverse nature of the $B(C_6F_5)_3$–H_2O system.

Slow evaporation of a $CDCl_3$ solution of $B(C_6F_5)_3$ and several equivalents of water gives colourless crystals of $[H_2O{\cdot}B(C_6F_5)_3]{\cdot}2H_2O$ **1**.[6] An X-ray crystal study reveals that one molecule of water is bound directly to the boron centre, whilst the remaining two water molecules are dispersed throughout the crystal lattice (Fig. 1).‡ All hydrogen atoms have been directly located from the difference map and bond distances indicate hydrogen bonding from the hydrogen atoms in the coordinated water molecule to the oxygen atoms of the remaining two water molecules, as shown in Fig. 1. Variable temperature multinuclear NMR studies of $B(C_6F_5)_3$ in the presence of H_2O shown that in **1** there is a rapid exchange of boron-bound water with the free water molecules.

The existence of **1** and previously reported activity of the $B(C_6F_5)_3$–H_2O system[5] imply the formation of a Lewis acid–base adduct and subsequent ionisation to generate an acidic proton and complementary anion as depicted in Scheme 1.

Further evidence for the formation of the Brønsted acid is provided by the reaction between $B(C_6F_5)_3$ and H_2O in the presence of the 'metal base' $[Ir(\eta^5C_5H_5)(C_8H_{12})]$,[7] which gives the salt $[Ir(\eta^5\text{-}C_5H_5)(C_8H_{12})H][(F_5C_6)_3B(\mu\text{-}OH)B(C_6F_5)_3]$ **2**·2$CHCl_3$, containing the previously unknown binuclear anion, $[(F_5C_6)_3B(\mu\text{-}OH)B(C_6F_5)_3]^-$. The single crystal structure of **2**§ (Fig. 2) shows that there is a large difference of size between the cation and anion. In the anion, the three pentafluorophenyl groups on each boron atom are staggered with respect to each other. The hydroxyl proton is coplanar with the B–O–B unit. The average B–O bond distance of 1.565(1) Å is consistent with other reported B–(μ-OH) bond lengths.[4,8] The B–O–B angle of 139.6(5)° is distinct from those of 144.8(5)° in a diborylcobaltocene complex[8] and 128.2(2)° in $[Pt\{HOB(C_6F_5)_3\}Me(Bu_2bpy)]$.[4]

In the cation, the hydride ligand on iridium is stereochemically active as evidenced by an angle of 20.2° between the Cp ring and the best plane of the coordinating carbon atoms in the cyclooctadiene ligand.

The only previously reported examples of hydroxy-bridged diborates are those prepared using the electrophilic chelates, *cis*-1,2-diborylalkenes[9] or in the coordination sphere of diborylcobaltocene.[8] The cation, $[Ir(\eta^5\text{-}C_5H_5)(C_8H_{12})H]^+$, has previously been synthesised by protonation of the metal base, using strong Brønsted acids such as triflic acid (CF_3SO_3H).[7]

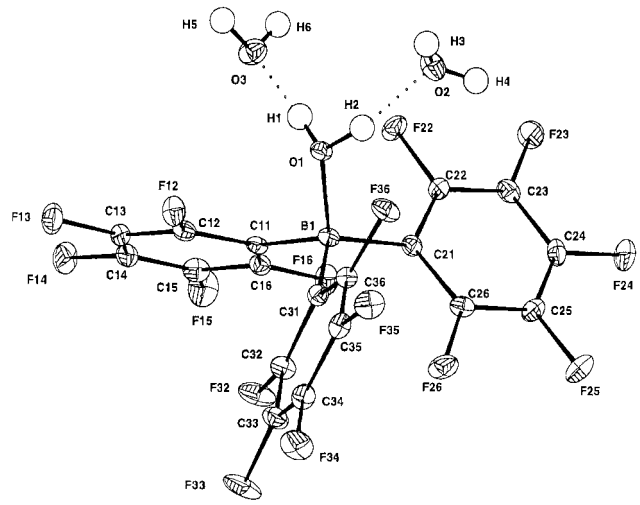

Fig. 1 Asymmetric unit in the crystal structure of **1**·2 H_2O. Selected bond lengths (Å) and angles (°): B(1)–O(1) 1.5769(14), O(1)–H(1) 0.88(2), O(1)–H(2) 0.86(2), O(1)–O(2) 2.572(2), O(1)–O(3) 2.597(2); B(1)–O(1)–H(1) 117.0(14), B(1)–O(1)–H(2) 117.8(12).

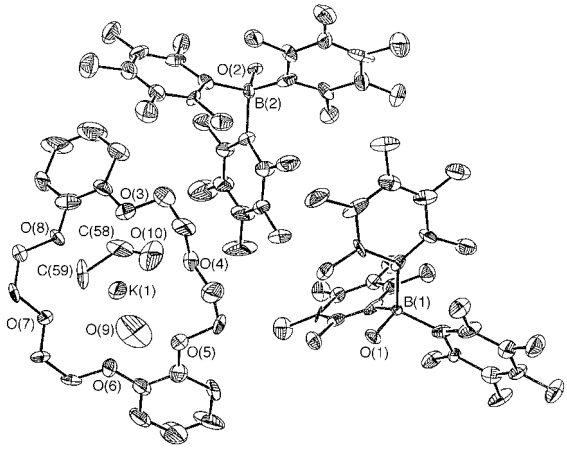

Fig. 3 Asymmetric unit in the crystal structure of **3**. Selected bond lengths (Å) and angles (°): B(1)–O(1) 1.521(10), B(2)–O(2) 1.480(11), B(1)–C 1.606–1.655, B(2)–C 1.583–1.699; C–B(1)–C 105.1–114.3, C–B(2)–C 105.6–113.6.

Formation of an anion with a bridging hydroxide between two $B(C_6F_5)_3$ groups, **B** (Scheme 1), could take place either by binding a second equivalent of $B(C_6F_5)_3$ to the monoborate anion $[HOB(C_6F_5)_3]^-$ **A**, or addition of $B(C_6F_5)_3$ to **1** to form the adduct **C** followed by ionisation to form **B**. The $[HOB(C_6F_5)_3]^-$ anion has been characterised as a ligand,[4] *vide supra*, and we now describe its independent synthesis.

In a further study, $B(C_6F_5)_3$ in a CH_2Cl_2 solution containing dibenzo-18-crown-6 was treated with solid KOH pellets and gave colourless crystals which may be formulated as $\{[H_2O{\cdot}B(C_6F_5)_3]\}\{[K(dibenzo\text{-}18\text{-}crown\text{-}6)]^+[HOB(C_6F_5)_3]^-\}{\cdot}H_2O{\cdot}MeCHO$ **3** (Fig. 3).‡ We assume the acetaldehyde present in the crystal is derived either from reaction of the solvent CH_2Cl_2 with KOH followed by decomposition of the resultant diol or by decomposition of the crown ether under highly basic conditions. There is no interaction of the aldehyde with any of the boron-containing species, although many Lewis base adducts of $B(C_6F_5)_3$ with aldehydes and ketones have been reported.[10] The structure of **3** definitively shows the presence of only one cation and charge balance therefore requires there to be only one monoanion. Hydrogen atoms cannot be located on either of the two $\{OB(C_6F_5)_3\}$ units of **3**, but we can infer that there is one molecule of $[H_2O{\cdot}B(C_6F_5)_3]$ and one of the anion $[HOB(C_6F_5)_3]^-$ present. The larger B–O distance in **3** is not consistent with that of the aqua complex **1** and it is possible that there is some mixing-in of both species at each site, particularly as the aryl ring torsion angles of the two species are equivalent to within a few degrees.

In conclusion, these preliminary studies show that reaction of H_2O with $B(C_6F_5)_3$ gives a stable adduct and that this adduct can coexist with its conjugate base although the factors affecting the equilibrium are not fully understood at present. The formation of mono- or di-borate anions may be a function of cation size or relative metal basicity under the reaction conditions. Further investigations are in progress to elucidate these factors.

Redox-active metal complexes for imaging hypoxic tissues: structure–activity relationships in copper(II) bis(thiosemicarbazone) complexes

Jason L. J. Dearling,[a] Jason S. Lewis,[b] Deborah W. McCarthy,[b] Michael J. Welch[b] and Philip J. Blower*[a]

[a] *Biosciences Dept, University of Kent, Canterbury, UK CT2 7NJ. E-mail: P.J.Blower@ukc.ac.uk*
[b] *Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO 63110, USA*

Received (in Cambridge, UK), 29th July 1998, Accepted 12th October 1998

Reduction potential and lipophilicity of the copper(II) bis(thiosemicarbazone) complexes can be independently controlled by alkylation in the diketone backbone and the N-termini of the ligand, allowing optimisation of radiopharmaceuticals strongly selective for hypoxic tissues.

Hypoxia in tumours can affect the outcome of anti-cancer treatments.[1] Hypoxic malignant tissue is relatively resistant to chemotherapy, and to irradiative therapy because of the lack of oxygen, a potent radiosensitiser. Hypoxia is also associated with other important health problems such as heart disease and stroke. Radiopharmaceuticals for imaging hypoxia have therefore been widely sought in recent years.[2] The current lead compound, ^{18}F-fluoromisonidazole,[3] shows imageable differences between normal and hypoxic tissue, but suffers from slow blood clearance and low tumour-to-muscle ratios.[4]

Copper radionuclides have attracted considerable attention in nuclear medicine because they include isotopes with both diagnostic (Cu-60, Cu-61, Cu-62, Cu-64) and therapeutic (Cu-64, Cu-67) potential. They are becoming increasingly available to the medical community through the use of generator systems and improvements in small cyclotron production.[5] The bis(thiosemicarbazone)s chelate copper(II) to form stable mononuclear, square-planar complexes. These have been investigated for use in anti-cancer chemotherapy,[6] and, in radiolabelled form, as a non-tissue-selective blood perfusion tracer $^{62/64}$Cu(PTSM).[7] The latter complex is capable of rapid entry into cells by passive diffusion as a consequence of its low molecular weight, lipophilicity and planarity.[8] It then becomes trapped intracellularly, regardless of tissue type, probably as a consequence of intracellular reduction to a copper(I) complex.[9] This redox-dependent trapping mechanism may allow, through control of redox potential, synthesis of an analogue that is trapped only in cells that provide a more reducing environment than normal, resulting from the absence of molecular oxygen). This approach could lead to design of imaging agents for hypoxia. Indeed, Cu(ATSM) has demonstrated significant selectivity for hypoxic and ischaemic tissue both *in vitro*[10] and *in vivo*,[10,11] while Cu(PTSM) has little[12] or no[13] selectivity. It has been suggested that the difference in selectivity is due to differences in redox potential.[11] Here we show that both lipophilicity and redox potential can be independently controlled through alkyl substitution at the terminal nitrogen atoms and the diketone backbone, respectively, to give complexes with and without selectivity for hypoxic cells.

We have synthesised a series of thirteen such complexes, with a variety of alkylation patterns. All gave satisfactory elemental analysis and FAB-MS results. The Cu-64-labelled complexes were identified with their non-radioactive analogues by thin-layer radiochromatography. The electrochemistry of the complexes was investigated by cyclic voltammetry using a glassy carbon working electrode in dimethyl sulfoxide containing tetrabutylammonium tetrafluoroborate as support electrolyte. The lipophilicity (log *P*) was determined by octanol extraction of the Cu-64 labelled complexes from water. The labelled complexes were screened for hypoxia selectivity using mammalian cancer cells (EMT6) in a suspension. The hypoxic cell suspension was equilibrated for 1 h with an atmosphere of

DTSM	C_2H_5	C_2H_5	CH_3	H

95% N_2–5% CO_2 while the control (normoxic) suspension was similarly equilibrated with 95% air–5% CO_2. The oxygen concentration, measured with a Mettler Toledo 4300 oxygen electrode, in the hypoxic suspension was then below 0.2% (where 100% is the equilibrium concentration under an atmosphere of air). For comparison, the upper limit defining 'radiobiological hypoxia' is 0.66%.[14] Cu-64 complexes were introduced into the suspension at tracer levels, and samples taken at time points over 1 h and centrifuged to isolate the cells. The 'hypoxia selectivity' was determined from the cell uptake ratios at 1 h incubation, and expressed as $\log_{10}$[(% uptake in hypoxic cells)/(% uptake in normoxic cells)]. Thus, hypoxia-selective complexes have positive hypoxia selectivity values while normoxia-selective complexes have negative values.[15]

Fig. 1 shows typical cell uptake *versus* time profiles for two complexes selected to represent hypoxia-selective and normoxia-selective behaviour. The cyclic voltammograms of all the complexes showed a reversible one-electron Cu(II/I) pro-

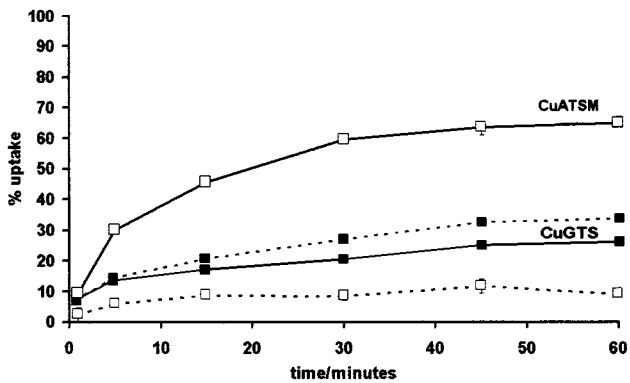

Fig. 1 EMT6 tumour cell uptake profiles selected to typify normoxia-selective (filled squares), and hypoxia-selective (open squares) copper complexes under hypoxic (solid line) and normoxic (broken line) conditions.

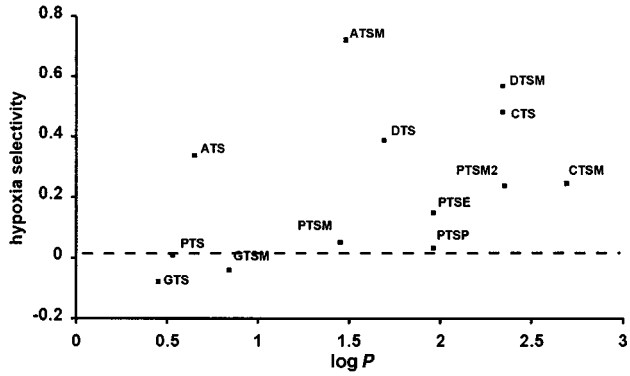

Fig. 2 Plot of hypoxia selectivity (see text for definition) for copper complexes in relation to their lipophilicity values (log *P* octanol/water).

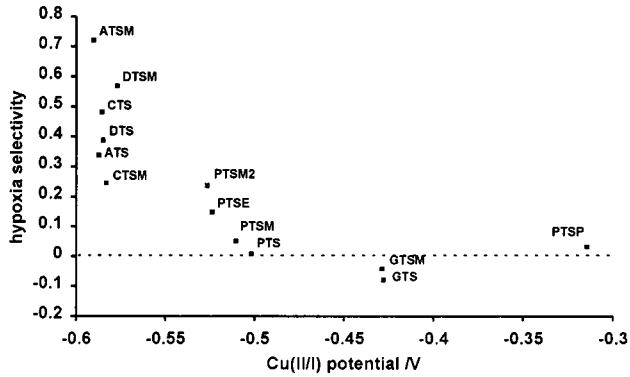

Fig. 3 Plot of hypoxia selectivity (see text for definition) for copper complexes in relation to their Cu(II/I) redox potentials *vs.* Ag/AgCl.

cess. Fig. 2 shows the relationship between lipophilicity (log *P*) and hypoxia selectivity, and Fig. 3 shows the relationship between Cu(II/I) redox potential and hypoxia selectivity.

The inter-relationships between structure, lipophilicity, redox potential and hypoxia selectivity may be summarised as follows. (1) From Fig. 3 it is evident that hypoxia selectivity is strongly dependent on redox potential. (2) On the other hand lipophilic character (Fig. 2), while presumably necessary to allow cell membrane penetration (all of the compounds have log *P* greater than zero), is not an indicator of hypoxia selectivity. (3) The overall number of alkyl groups at positions R^1–R^4 is a poor predictor of redox potential. However, the number in the diketone backbone (R^1 and R^2) is an excellent predictor: complexes with no alkylation at these sites have potentials in the range −0.42 to −0.44 V; those with one alkyl group have potentials in the range −0.50 to −0.53 V; and those with two have potentials in the range −0.57 to −0.59 V. This rule is adhered to by all except the phenyl-substituted complex Cu(PTSP). Alkyl substitution at the N-terminus, on the other hand, does not influence redox potential significantly. (4) Alkyl substitution, either in the complex as a whole or separately in the diketone backbone and N-terminus, is only a very crude predictor of lipophilicity.

These trends support the notion that the redox behaviour of transition metal complexes can be exploited to achieve hypoxia-selective targeting, and that hypoxia selectivity is a function of redox potential in these complexes. Moreover, they provide a basis for designing hypoxia-selective complexes of this type according to redox potential: it appears to be a requirement that the Cu(I/II) redox potential in dimethyl sulfoxide is more negative than −0.57 V *vs.* Ag/AgCl. It might be expected that on shifting the redox potential to much more negative values there will come a point at which the selectivity will diminish again because even hypoxic cells will be incapable of reducing the complexes. This potential is not reached in the present series.

The relationship shown in Fig. 3 suggests that redox potential is not the only factor controlling hypoxia selectivity: although complexes with potentials in the range −0.57 to −0.59 V are all hypoxia selective, they differ in degree of selectivity. Indeed it is to be expected that alkylation pattern would influence selectivity in a complex way through factors such as membrane solubility and steric effects on reaction rates as well as through redox potential. Nevertheless, an appropriate redox potential is the primary requirement for selectivity. The relationship between alkylation pattern and redox potential provides a means of controlling redox potential and lipophilicity separately: R^1 and R^2 can be varied to control redox potential, while R^3 and R^4 can be varied to control lipophilicity and other relevant pharmacokinetic parameters, to produce an ideal radiopharmaceutical for PET imaging of hypoxia.

Many facets of the mechanism of hypoxia-selectivity of these complexes remain to be investigated, including the serum stability[16] of the complexes, whether a single specific intracellular reducing agent is involved, and the reversibility of the trapping in hypoxic cells. Of the complexes investigated here, Cu(ATSM) remains the best candidate in terms of absolute selectivity *in vitro*, and ^{60}Cu(ATSM) is being investigated at the Washington University School of Medicine and Fukai Medical University[17] as an agent for the delineation of hypoxia in humans.

We thank Mr T. A. Perkins for help in producing copper-64 and Mrs E. L. C. Sherman for help with animal cell culture. J. L. J. D. is supported by a studentship and fieldwork grant from the Medical Research Council. We acknowledge the US Dept. of Energy for funding (Grant no. DE-FG02-87ER60512) work undertaken at St. Louis.

Asymmetric Baylis–Hillman reactions: catalysis using a chiral pyrrolizidine base

Anthony G. M. Barrett,* Andrew S. Cook and Akio Kamimura

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: m.stow@ic.ac.uk

Received (in Liverpool, UK) 3rd August 1998, Accepted 16th October 1998

A novel chiral pyrrolizidine base 5 derived from L-proline promotes the Baylis–Hillman reaction of ethyl and methyl vinyl ketones with electron deficient aromatic aldehydes with moderate levels of enantiomeric excess.

The Baylis–Hillman reaction is a convenient process for the preparation of a β-hydroxy-α-methylene ketone, nitrile, ester, *etc*. in one step from an α,β-unsaturated ketone, acrylonitrile or an acrylic ester and an aldehyde.[1] The reaction is mediated by a tertiary amine, and DABCO (diazabicyclo[2.2.2]octane) is the most common catalyst employed. Whilst the Baylis–Hillman reaction of chiral aldehydes or chiral Michael acceptors has been shown to proceed, in some cases, with high diastereoselectivities, the development of chiral catalysts for the Baylis–Hillman reaction is less well developed. Hirama and Markó have respectively reported the use of chiral derivatives of diazabicyclo[2.2.2]octane[2] and of quinidine or cinchonine[3] as enantioselective catalysts. However, these authors observed only modest levels of enantioselectivities (11–47 and 6–45% ee, respectively) and the requirement to use elevated pressures (3–10 Kbar) to ensure acceptable conversions. We have previously published a two step procedure to effect the enantioselective (50–96% ee) Baylis–Hillman reaction of an aldehyde with an α-methylene ketone *via* a tandem Michael addition–aldol reaction of (phenylthio)- or (phenylselenyl)-trimethylsilane catalysed by a chiral borane Lewis acid followed by oxidative elimination.[4] Recently, Soai and co-workers reported the use of (*S*)-BINAP as a catalyst for the enantioselective (9–44% ee) Baylis–Hillman reaction of pyrimidine-5-carbaldehydes with acrylate esters.[5] This work has prompted us to report the use of pyrrolizidine (1-azabicyclo-[3.3.0]heptane) derivatives as alternative chiral catalysts. We considered that such amines may function as efficient catalysts for the Baylis–Hillman reaction on account of their enhanced basicity relative to common tertiary amines[6] and the accessibility of the nitrogen lone pair. We were concerned, in our design, to seek to alleviate the known slow kinetics of the DABCO catalysed Baylis–Hillman reaction.

Swern oxidation of Boc-L-prolinol[7] **1** and direct Wittig homologation gave ester **2**[8] (81%) (Scheme 1). Subsequent hydrogenation over Raney nickel, deprotection of the Boc group, under acidic conditions, and lactamisation gave the pyrrolizidinone[9] **3** (73%). Aldol reaction of lactam **3** with 4-nitrobenzaldehyde in the presence of $BF_3{\cdot}OEt_2$ gave a mixture of four β-hydroxy lactams (94%). The less polar component consisted of a single crystalline diastereoisomer **4**†‡ which was readily isolated in 16% yield. The remaining three diastereoisomers co-chromatographed and were not separable at the lactam oxidation stage. Finally, $BH_3{\cdot}SMe_2$ mediated reduction gave the desired pyrrolizidine **5** which was initially isolated as the robust borane adduct but which could be converted into the free base following sequential reflux with methanolic TsOH and K_2CO_3.

The Baylis–Hillman reaction of ethyl vinyl ketone with 2-nitrobenzaldehyde was examined in MeCN or EtCN solution in the presence of pyrrolizidine **5** (10 mol%) at variable temperatures (−75 to 25 °C). All reactions gave rise to the corresponding β-hydroxy-α-methylene ketone **6** (R^1 = 2-$O_2NC_6H_4$, R^2 = Et) (Table 1) which was formed in variable yield and enantioselectivity.§ The yield of the reaction was significantly improved by cooling and no significant decrease in rate was observed until −50 °C. Leahy has reported unusual temperature dependence on conversions in the DABCO mediated Baylis–Hillman reaction of acrylate esters with aldehydes.[10] Although, the yield of the reaction was optimum at −40 °C, enantioselectivities were superior at higher temperatures with a maximum value at −20 °C (47% ee). Since Aggarwal has reported rate enhancements on the use of lanthanide triflates in the Baylis–Hillman reaction,[11] a series of Lewis acid co-catalysts were examined in the synthesis of **6**. Amongst diverse metal salts examined, those of the alkali metals, in particular sodium, were the most effective additives. A series of aldehydes were allowed to react with ethyl or methyl vinyl ketone in the presence of amine **5** (10 mol%) and 1 M $NaBF_4$ or $NaBPh_4$¶ in MeCN at −20 °C (Table 2). The

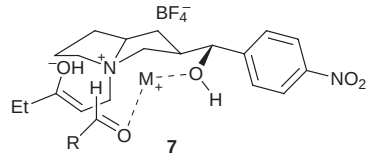
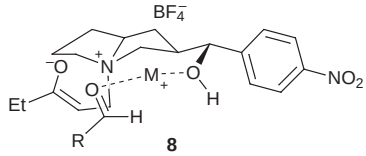
corresponding β-hydroxy-α-methylene ketones **6** were isolated in modest to excellent yields (17–93%) and with acceptable levels of enantioselectivity (21–72% ee).‖ The absolute configuration of ketone **6** (R^1 = 2-$O_2NC_6H_4$, R^2 = Me) was determined to be *R* by comparison of the sign of its specific rotation with that of the antipodal ketone.** The absolute stereochemistry of the other β-hydroxy-α-methylene ketones **6** were assigned by analogy since all were laevorotatory. It is reasonable to speculate that the reaction may proceed *via* the intermediate **7** rather than the more sterically congested system **8**. The importance of hydroxy substitution on enhancing the rate



7



8

of Baylis–Hillman reactions is well known[1] and is exemplified by the fact that 3-hydroxyquinuclidine is a superior catalyst to quinuclidine. Such an effect may also be of significance in both the catalysis by pyrrolizidine **5** and the enhancement of enantioselectivity in the presence of sodium ions. Further studies of this variant of the Baylis–Hillman reaction are now being investigated in our laboratory.

We thank Zeneca, Chiroscience, the EPSRC and the DTI for generous support under the Link Asymmetric Scheme; Glaxo-Wellcome Research Ltd for the most generous endowment (to A. G. M. B.); the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College; and George O'Doherty, Oswy Pereira and D. Christopher Braddock for helpful discussions.

Notes and references

† All new compounds were fully authenticated by spectroscopic data and microanalysis and/or HRMS.

‡ The structure of **4** and related β-hydroxy lactams and pyrrolizidines, which were confirmed by X-ray crystallography, will be reported elsewhere.

§ Enantioselectivities of all reactions were determined by HPLC analyses on Chiralcel OD-H and AD columns and, in some cases, by ^{1}H NMR spectroscopy in the presence of the chiral the shift reagent Eu(tfc)$_3$.

¶ For the use of lithium salts to enhance the rate of reactions proceeding *via* ionic intermediates, see ref. 12.

‖ *General experimental procedure* (Table 2, entry 4): **6** (R^1 = 2-ClC_6H_4, R^2 = Et)·$NaBF_4$ (27 mg, 0.25 mmol) followed by 2-chlorobenzaldehyde (26 μl, 0.22 mmol) were added to a stirred suspension of amine **5** (5 mg, 0.019 mmol) in MeCN (0.25 ml) under nitrogen at –40 °C. The reaction mixture was stirred for a further 10 min when ethyl vinyl ketone (19 μl, 0.19 mol) was added and stirring continued for 24 h. The mixture was concentrated *in vacuo* and the residue chromatographed (1:6 EtOAc–hexanes, R_f 0.3) to yield the title compound **6** (R^1 = 2-ClC_6H_4, R^2 = Et) (24.8 mg, 58%) as a colourless oil.

** The absolute stereochemistry of the major adduct **6** (R^1 = 2-$O_2NC_6H_4$, R^2 = Me) was determined by comparison of the sign of the specific rotation with literature data on (4*R*)-4-hydroxy-3-methylene-4-(2-nitrophenyl)butan-2-one, which was prepared by an enantioselective Baylis–Hillman reaction (11–42% ee) and by the partial kinetic resolution of the racemic compound by Sharpless epoxidation using L-(+)-diethyl tartrate (see ref. 2).

Application of the chelate enolate Claisen rearrangement to the modification of dipeptides

Uli Kazmaier* and Sabine Maier

Organisch-Chemisches Institut der Universität, Im Neuenheimer Feld 270, 69120 Heidelberg, Germany. E-mail: ck1@popix.urz.uni-heidelberg.de

Received (in Liverpool, UK) 23rd July 1998, Accepted 13th October 1998

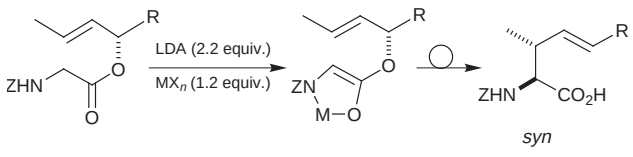
Manganese enolates of allylic esters of dipeptides are suitable to undergo Claisen rearrangements, giving rise to unsaturated peptides in excellent yield.

Peptides and cyclopeptides containing unnatural amino acids are quite common in nature, and are often found in marine organisms.[1] Many of these peptides show antibiotic activity,[2] and are therefore highly interesting from a pharmaceutical point of view.[3] For straightforward approaches towards these targets, efficient target screening and optimization of lead structures, flexible synthetic concepts are necessary. In addition to classical peptide coupling of commercially available or synthesized amino acids, the modification of existing peptides is especially suitable for this purpose. These modifications can be carried out in the side chain or directly on the peptide backbone.[4] The great advantage of side chain modifications results from the fact that the chiral center in the newly formed amino acid can be taken over from the precursor amino acid.[5] On the other hand, suitable precursors are necessary. In contrast, achiral glycine subunits can be used for backbone modifications, because the whole side chain is transferred.[6] As reactive intermediates, glycine cation equivalents[7] as well as glycine anions (glycine enolates) can be used.[8] The major drawback of this concept results from the difficulty of controlling the stereochemical outcome of the C–C coupling step.

For quite some time we have been investigating syntheses of γ,δ-unsaturated amino acids.[9] One approach towards these structures is based on a variation of the Claisen rearrangement, proceeding *via* chelated amino acid ester enolates (Scheme 1).[10]

Because of the fixed enolate geometry given by chelation, and the high preference of the Claisen rearrangement for the *chair like* transition state, the *syn* configured rearranged products are formed in a highly stereoselective fashion. If esters of chiral allylic alcohols are used, the corresponding enantiomerically pure amino acids are obtained. [11]

Therefore we were interested to see if it was also possible to transfer this Claisen protocol to peptides, and to use it for backbone modifications. Our early attempts were carried out with zinc enolates, which generally give the best results in the rearrangement of amino acids.[12] But with peptides the yields obtained were modest (20%), although they could be increased (70–80%) by addition of Pd^0 catalysts. However, under these conditions the allylation of the peptide chains proceeds *via* π-allyl–palladium intermediates. This intermolecular process results in significantly lower diastereoselectivities, and also the formation of regioisomers if substituted allylic esters are used. Therefore we undertook an intensive metal tuning to find suitable chelate complexes which undergo Claisen rearrangement without assistance from a palladium catalyst. By far the best results are obtained if manganese salts are used for chelation.[13] We investigated the rearrangement of various esters of dipeptides (Scheme 2) and the results obtained are shown in Table 1.†



Scheme 1

Independent of the protecting groups (PG) used,‡ the yields obtained with these manganese enolates were always excellent, with both esters of terminal allylic alcohols (entries 1–3) and *trans* configured substituted alcohols (entries 4–11).§ These are especially interesting, because in their rearrangement two new stereogenic centers are formed. Therefore we investigated preferentially the rearrangement of crotyl esters, because the results obtained with these esters in general can be transferred to other *trans* configured esters without problems. In all examples investigated so far, the simple diastereoselectivity of the rearrangement was very high (≥95%) and comparable to the results obtained with amino acids.¶ No significant induced diastereoselectivity was observed. Obviously the *N*-terminal amino acid has no notable influence on the rearrangement. This is also reflected in the high yields obtained, which are also nearly independent on the peptide used.

This protocol is also suitable for the direct introduction of α-alkylated amino acids into peptides (Scheme 3). These derivatives show higher resistances towards proteases, and therefore they are interesting for the development of peptide

based pharmaceuticals.[14] Because of the steric hindrance of these amino acids, their introduction into peptides by classical peptide coupling reactions often causes problems, and therefore special coupling reagents and methods have to be applied.[15] Using the peptide Claisen rearrangement even sterically hindered peptides such as **4** and **10** can be obtained. This procedure is also suitable for the rearrangement of peptides containing β-amino acids (**5**).[16] Since the influence of the adjacent amino acid on the rearrangement can be neglected, this allows for the stereoselective synthesis of peptides if esters of chiral allylic alcohols such as **7** and **9** are used.[17] The corresponding dipeptides **8** and **10** were obtained not only in good to excellent yields but also in a highly diastereoselective fashion.

These unsaturated peptides obtained by backbone modification are suitable substrates for subsequent reactions on the double bond (side chain modifications). These reactions are currently under investigation. We are also looking for chelate complexes which allow chirality transfer from the peptide chain to the new stereogenic center formed during the rearrangement.

Financial support from the Deutsche Forschungsgemeinschaft as well as the Fonds der Chemischen Industrie is gratefully acknowledged.

Notes and references

† General procedure for the peptide Claisen rearrangement: 0.2 mmol of peptide ester **1** was dissolved in 3 ml of THF, before 0.24 mmol of $MnCl_2$ was added. The mixture was cooled to −78 °C. A freshly prepared solution of 0.8 mmol LDA in 2 ml of THF was added slowly and the reaction mixture was allowed to warm to room temperature overnight. The resulting brown solution was hydrolyzed by vigorous stirring with 5 ml 1 M HCl solution, until a clear solution was obtained. After separation of the aqueous layer the rearrangement product was extracted three times with 10 ml of 1 M NaOH solution. The combined basic aqueous layers were acidified with 1 M HCl solution (pH 1) and the peptide was extracted twice with CH_2Cl_2 (15 ml each). After evaporation of the solvent, the crude product was purified by flash chromatography. For analytical purposes the rearrangement products were converted into the corresponding methyl esters with CH_2N_2.

‡ If a trifluoroacetyl group is used as protecting group, LHMDS should be applied instead of LDA.

§ The yields and selectivities obtained with *cis*-configured esters are generally lower, depending on the substituent. This can be explained by an increased rearrangement *via* the *boat like* transition state (ref. 18).

Isostructurality in crystalline oxa-androgens: a case of C–O–H···O and C–H···O interaction mimicry and solid solution formation

Addlagatta Anthony,[a] Mariusz Jaskólski,*[b] Ashwini Nangia*[a] and Gautam R. Desiraju[a]

[a] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India. E-mail: ansc@uohyd.ernet.in*

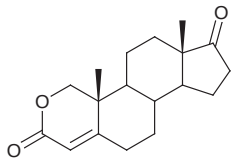
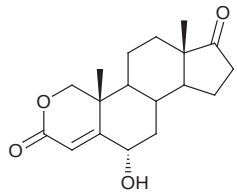
Received (in Cambridge, UK) 24th August 1998, Accepted 13th October 1998

A C–H···O interaction in 2-oxa-4-androstene-3,17-dione is replaced by a C–O–H···O hydrogen bond in the isostructural 6α-hydroxy analogue, and these compounds form a binary solid solution, showing the similarity of these two crystal structures.

As part of an ongoing study on androgens[1] and their 2-oxa analogues,[2] the crystal structures of 2-oxa-4-androstene-3,17-dione **1**[3] and 6α-hydroxy-2-oxa-4-androstene-3,17-dione



1



2

2[2] were determined. Crystals of these compounds were obtained from EtOAc–MeOH mixtures. Both these lactones were found to have similar crystal structures. Isostructurality in steroids has been studied previously for compounds that are related by an exchange of functional groups or by epimerisation. Thus, the pairs of compounds gamabufotalin/arenobufagin, cinobufagin/cinobufotalin and digitoxigenin/digirezigenin form solid solutions which are isostructural with the respective individual components while the crystal structures of epimeric 5α- and 5β-androstane-3α,17β-diol are similar, if only to a slightly lesser degree.[4] The conformation of the oxa-steroid skeletons in **1** and **2** are identical.† Accordingly, the crystal structures of **1** and **2** were scrutinised further.‡

Both **1** and **2** adopt the same monoclinic space group, $P2_1$ and the value of the *a*-axis parameter is nearly equal (6.2321 and 6.2214 Å). This is the direction of the hydrogen bond interactions and an inspection of Fig. 1–3 is instructive. In hydroxy lactone **2**, O6–H and C6–H are hydrogen bonded to the lactone carbonyl atom O3 of different screw-axis related molecules, thereby forming chains of alternating O–H···O (1.86 Å) and C–H···O (2.38 Å) hydrogen bonds§ (Fig. 1 and 3). Effectively, O6 behaves as an O–H···O donor and O3 as a bifurcated acceptor. In lactone **1**, the C6 methylene hydrogens are linked to the O3 atom of 2_1-related molecules to give chains of C–H···O hydrogen bonds (2.38 and 2.67 Å) (Fig. 2 and 3). The metrics of these hydrogen bonded chains along [100] in the two structures are given in Fig. 3, from which it is clearly seen that the shorter of the C–H···O hydrogen bonds in**1** behaves as a surrogate of the C–O–H···O bond in**2**. We note that the near equality of the *a*-axis parameter in the two structures allows for the replacement of four links between translationally related O3 atoms in **1** (two weak O···H interactions and two C–H bonds) by five links in **2** (strong O···H interaction, weak O···H interaction, C–H bond, C–O bond and O–H bond).

When a 1:1 mixture of **1** and **2** was crystallised from EtOAc–MeOH, crystals **3**‡ were obtained in the space group $P2_1$ with cell dimensions very similar to those of pure **2**. Structure solution and refinement with partial positional occupancy for O6 yielded a converged model with partial occupancies of 0.28 and 0.720(6) for **1** and **2** respectively, showing that **3** is a binary solid solution.§ While there are examples of equivalence between N–H···O and C–H···O hydrogen bonds in isostructural crystals,[6] the formation of solid solution has not been reported in these cases. Additionally, interaction mimicry between C–O–H···O and C–H···O is a novel occurrence. The present example is therefore unprecedented and offers valuable clues regarding crystal packing in general.

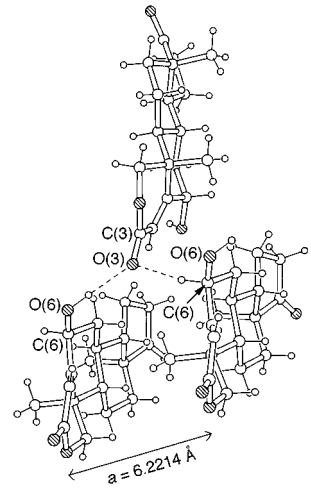


Fig. 1 Hydrogen bonding in hydroxy lactone **2** along [100] to show the O6–H···O3 and C6–H···O3 interactions between 2-related molecules. Oxygen atoms are shaded.

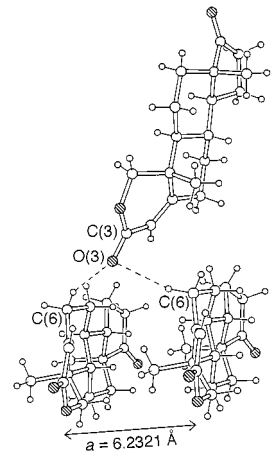

Fig. 2 Hydrogen bonding in lactone **1** along [100] between C6-methylene H-atoms and the carbonyl O3 atom of different 2_1-related molecules. Oxygen atoms are shaded. Notice the identity of *a*-axis and the similarity in hydrogen bonded chains and arrangement of molecules in the structure shown here and in Fig. 1.

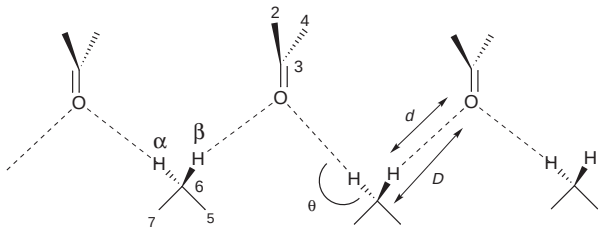
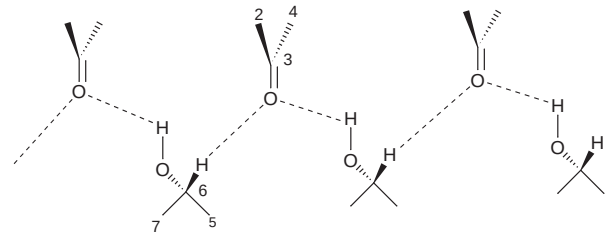


4



5

Fig. 3 Supramolecular synthons **4** and **5** in the structures of **1** and **2** along [100]. The geometrical parameters (*d*, *D*, *θ*) of the hydrogen bonds with normalised O–H and C–H distances are for **4**: C6–αH···O3: 2.38, 3.381(4) Å, 154° and C6–βH···O3: 2.67, 3.693(4) Å, 157°; **5**: O6–αH···O3: 1.8602(5), 2.831(4) Å, 171° and C6–βH···O3: 2.38 Å, 3.409(4) Å, 158°.α and β refer to the bottom and top faces of the somewhat flattened steroid skeleton.

Firstly, this example shows the equivalence of O–H···O and C–H···O hydrogen bonding and confirms yet again that the structure directing effects of these two interactions can often be the same. It is noteworthy that the C6 H-atoms in Δ^4-steroids are allylic in nature and, as such, activated as C–H donors.[7] Secondly, the formation of a solid solution in such cases is *per se* noteworthy. Binary solid solution formation is the most stringent criterion for isostructurality[8] and occurs here because **1** and **2** have similar overall molecular shapes and also because the hydrogen bonds and recognition patterns in the structure-forming domain, that is along [100], are virtually identical. These patterns are the supramolecular synthons[9] **4** and **5** and they play a significant structural role in all three crystals. Thirdly, the fact that the **3** adopts the structure of **2** rather than that of **1** could be ascribed to the larger size of the OH group compared to the H substituent,[10] while the excess of **2** over **1** in the solid solution might be because of the relative strengths of O–H···O and C–H···O hydrogen bonds in the individual structures.[11] Finally, we note that solid solution formation occurs for this pair of compounds **1** and **2** even though the *b*, *c* and β parameters are significantly different. While the unit cell similarity index Π[8,12] is fortituously close to zero (Π = 0.002), this index could be misleading here. Since the monoclinic axial lengths are quite different (9.926 and 12.050 Å), the other packing features in the crystals, in this case the general coordination arrangements of molecules, are different leading to a degree of isostructurality index,[8,12] I^{21}_{D} of only 75%. Despite this, solid solution formation has been observed leading to the thought that isostructurality along one direction is sufficient to observe mimicry effects,[13] if that direction is important as a structure determinant. The implications of such 'one-dimensional isostructurality' have a bearing on the analysis of similarities in crystal packing that are mediated by robust supramolecular synthons.[14] Such synthons could play an active role during all stages of crystallisation events from nucleation to growth to the final appearance of a single crystal.

Received (in Cambridge, UK) 3rd September 1998, Accepted 14th October 1998

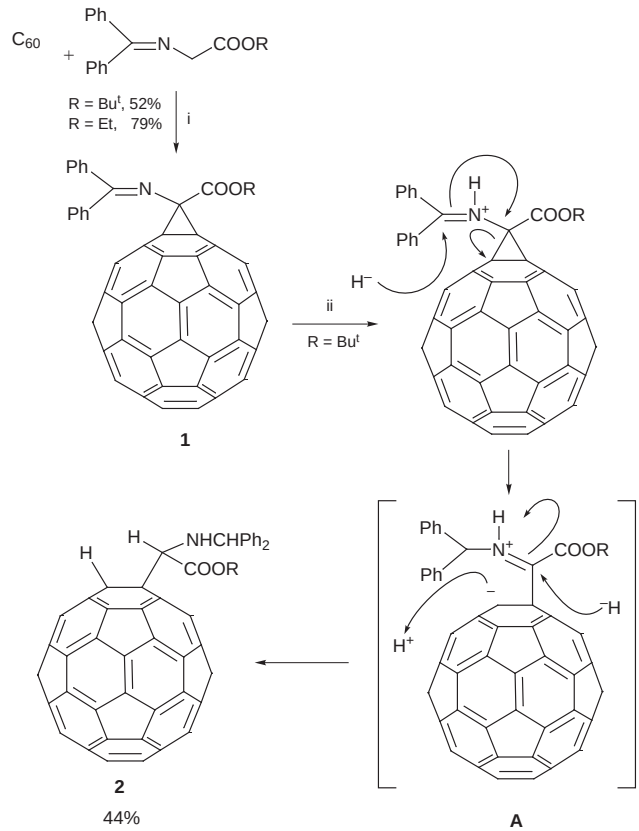
The 1,2-dihydro[60]fullerylgylcine derivative 2 has been prepared by a novel cyclopropane ring opening reaction of the methano[60]fullerene derivative 1.

[60]Fullerenes exhibit a range of interesting biological activities including inhibition of HIV-1 protease,[1] cytotoxicity[2] and the selective cleavage on DNA.[3] Furthermore, the covalent tethering of fullerenes to peptides and proteins has been the goal of a number of studies concerned with the application of fullerene–peptide conjugates to biological problems.[4–8] These conjugates not only enhance the water-solubility of the fullerene and make this molecule more amenable to biological studies, but the fullerene itself can modify the conformation of the tethered peptide and often enhance its biological activity.[6] Such investigations could be greatly enhanced if an α-substituted fulleryl amino acid was available that could be directly incorporated into a peptide sequence. The resulting fulleryl peptides would be expected to have novel secondary structures because of the possibility of π–π and hydrophobic interactions between the peptide and the fullerene surface. Furthermore, these conjugates may have unique biological properties or applications. While a number of fullerylproline derivatives have been prepared[9] the synthesis of an acyclic α-fulleryl amino acid has not been realised. We describe here the synthesis of the 1,2-dihydro[60]fullerylgylcine derivative **2** by a novel ring opening reaction of the methano[60]fullerene derivative **1** (Scheme 1).

Treatment of a solution of [60]fullerene, under Hirsch cyclopropanation conditions,[10] with *tert*-butyl *N*-diphenylmethyleneglycinate, CBr_4 and DBU gave the cyclopropane imino ester **1** in 52% yield after purification by column chromatography. Apart from the signals due to the aryl and *tert*-butyl group (δ 28.3) the ^{13}C NMR spectrum (C_6D_6–CS_2, 1:1) of **1** showed the expected downfield resonances for the sp^2 hybridized carbonyl (δ 162.3) and imine carbons (δ 153.7), 25 sp^2 fullerene carbon resonances (δ 149.3–135.0) and resonances for the quaternary sp^3 carbons at δ 95.0 (C-61), 84.3 (Me_3CO) and 83.8 (C1, C2). The electrospray ionization mass spectrum of **1**, using PhMe–MeCN (30 : 1) as solvent showed a molecular ion at *m/z* 1013. The related ethyl ester **1** (R = Et) could be obtained in 79% yield from C_{60} and ethyl *N*-diphenylmethyleneglycinate. Attempts at the acid hydrolysis (6 M HCl, TFA or TsOH) of **1** (R = Bu^t or Et) have not proven successful and none of the desired cyclopropane amino acid could be isolated.

Reduction of **1** (R = Bu^t) with $NaBH_3CN$ in THF–MeOH at pH 4 gave not the expected reduced imine compound but the novel ring opened 1,2-dihydro[60]fullerylglycine derivative **2** in 44% yield after purification by column chromatography on silica gel. The ring opened structure of **2** was evident from its ^1H NMR (C_6D_6–CS_2, 1:1) spectrum which showed a singlet resonance at δ 6.84 typical of H-2 in a 1-substituted 2-H-C_{60}.[11,12] The structure of **2** was further supported by single proton resonances at δ 5.27 (d, J = 3 Hz, Ph_2CHNH), 4.83 (d, J = 11.7 Hz, H-61) and 3.62 (dd, J = 3, 11.7 Hz, NH). The ^{13}C NMR spectrum of **2** showed 47 sp^2 fullerene resonances in the region δ 154.4–136.2 and resonances for 5 sp^3 carbons in the region δ 83–58. These latter resonances were unequivocally assigned by ^1H–^{13}C NMR correlation experiments (HMBC) as δ 82.8 (Me_3CO), 70.9 (C-61), 68.1 (C-1) , 66.7 (Ph_2CH) and 58.8 (C-2). The two fullerene carbons alpha to C-1 (C-6 and C-9) and C-2 (C-3 and C-12) were observed downfield of the other fullerene resonances and occurred in the region δ 154.4–152.4. Interestingly, C-6 and C-9 and C-3 and C-12 appeared as diastereotopic pairs due to the stereogenicity of C-61 (Fig. 1). The number of different sp^2 fullerene signals suggested that most other fullerene carbons formed diastereotopic pairs.† The assignmements made to individual carbons are shown in Fig. 1. Furthermore, the HMBC experiments confirmed that the 1,2-substituted rather than the 1,4-substituted fullerene had formed.‡

The formation of **2** can be rationalized as occuring by a mechanism similar to that shown in Scheme 1, although this process may not be concerted and the protonation steps may occur at different stages along the reaction pathway. Clearly the driving force for such a ring opening must be stabilization of the incipient C-2 fulleryl carbanion **A** by delocalization over the fullerene ring. Such ring opening of cyclopropane amino esters and acids is known when a β-electron-withdrawing group is



Scheme 1 *Reagents and conditions*: i, DBU, CBr_4, PhCl, room temp.; ii, $NaBH_3CN$, pH 4.

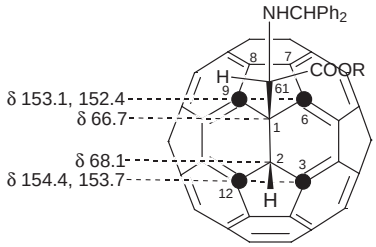


Fig. 1 ^{13}C NMR (C_6D_6–CS_2, 1:1) chemical shifts and assignments for **2** (R = Bu^t).

present on the ring that can stabilize a developing carbanionic centre.[13] The ring opening of fullerene derivatives has been observed before but not on cyclopropane derivatives or under such mild conditions.[14]

In conclusion, we have discovered a novel ring opening reaction of a methano[60]fullerene derivative under reductive conditions that allows the synthesis of 1,2-dihydro[60]fullerylglycine derivatives that would have potential for many interesting biological applications.§

We thank the Australian Research Council for financial support.

Notes and references

† Simple achiral 1-substituted 2-H fullerenes should show 30 different carbons due to their C_s symmetry (ref. 11, 12).

‡ While the structure of **2** was clear from its ^{1}H and ^{13}C NMR and IR spectral data, we have been unable to obtain a useful mass spectrum (ESMS or MALDI) of this compound.

§ To date attempts at the acid hydrolysis of the ester group (6 M HCl, TFA or TsOH) or the hydrogenolysis of the *N*,*N*-diphenylmethylamino group in **2** have not proven successful.

Received (in Liverpool, UK) 2nd September 1998, Accepted 16th October 1998

Thiophenes can be synthesised in high yields from the reaction of C_{4+} oxygenates and CS_2 at temperatures 140 °C lower than current industrial catalysts, using novel materials based upon chromium substituted iron oxide hydroxide.

Thiophene derivatives are widely used as raw materials in the production of dyes, agrochemicals and pharmaceuticals.[1] However, in recent years much research has been devoted to their catalytic destruction *via* HDS for obvious environmental reasons.[2] Conversely, the catalytic synthesis of thiophenic systems has received scant attention. Thiophene and alkylthiophenes are currently synthesised on an industrial scale (*ca*. 1000 tonnes p.a.) *via* two processes. The first involves the reaction of C_{4+} alcohols or carbonyls with CS_2 over alkali-promoted chromia alumina.[3] The second is based upon the reaction of an α,β-unsaturated aldehyde with H_2S over alkali/alkaline earth-promoted γ-Al_2O_3.[4] However, the use of alumina-based catalysts results in some disadvantages, chiefly that at the temperatures required to achieve economic yields of product (450–500 °C), cracking reactions occur with resultant losses in yields and premature catalyst deactivation through coke deposition. Hence it is desirable to design a catalyst that can operate at lower temperatures and/or give lower by-product formation. Here we address this problem and present initial data for Cr^{III}-substituted FeOOH, which has been found to be an effective thiophene synthesis catalyst at comparatively low temperatures.

Catalyst synthesis was based upon the method developed by Flanigen *et al*.[5] for the synthesis of Jarosites. This involved dissolving the required molar ratios of Fe^{III} and Cr^{III} sulfates in distilled water at 80 °C. The pH of the resulting solution was adjusted to 4 using aq. NaOH. The slurry formed was then refluxed for 20 h and the solid recovered by vacuum filtration, washed with distilled water and dried (110 °C, 12 h). Samples were then pelleted and sieved (0.6–1.0 mm), prior to testing for thiophene synthesis in a fixed bed microreactor.[6] A typical reaction involved passing a mixed vapour/gas stream of 2-methylbutanol (2MB), CS_2 and N_2 (1:1.5:80 molar ratio) at a total flow rate of 12000 h^{-1} over 1.0 g of catalyst. Product analysis was performed on-line by GC FID analysis with a carbon balance of 98–100% for all data quoted, based upon conversion of the alcohol.

A series of catalysts with increasing Cr content were prepared and tested for their efficacy in the synthesis of 3-methylthiophene (3MT), giving the results shown in Fig. 1 and Table 1. As the Cr concentration increased the yield of 3MT and conversion of alcohol were seen to increase to a maximum at *ca*. 5% Cr (57 mol% 3MT, conversion of 78 mol%), before declining to very low yields at higher Cr levels. The optimum temperature for reaction was found to be 330–350 °C, with typical temperature profile data for the reaction being shown in Table 1. Another obvious advantage of these materials was their very low by-product formation, with only minor levels of alkene formation, presumably *via* dehydration, being observed. Moreover, the proportion of cracked fractions was low and mirrored

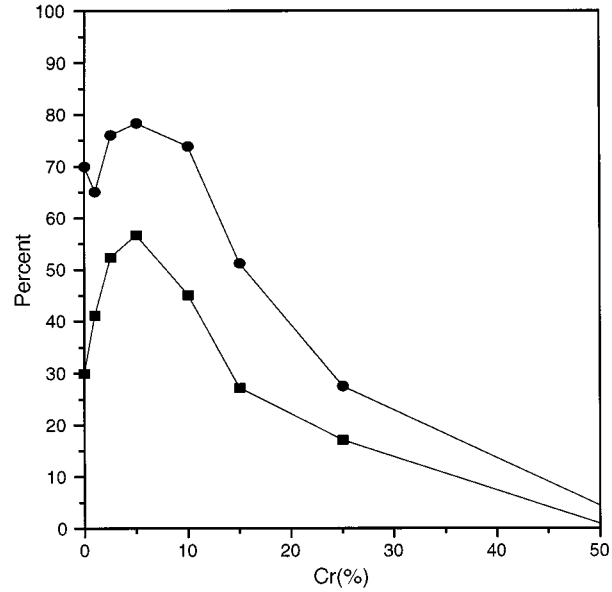

Fig. 1 The effect of Cr loading on the activity and selectivity of catalysts for the synthesis of 3-methylthiophene: (■) 3MT (mol% yield) and (●) 2MB (% conversion). Reaction conditions: 2MB:CS_2:N_2 (1:1.5:80), GHSV = 12000 h^{-1}, all samples taken at optimum temperature of activity (340–360 °C).

Table 1 The effect of Cr content and temperature on catalyst activity.

[a] Nominal Cr loading.

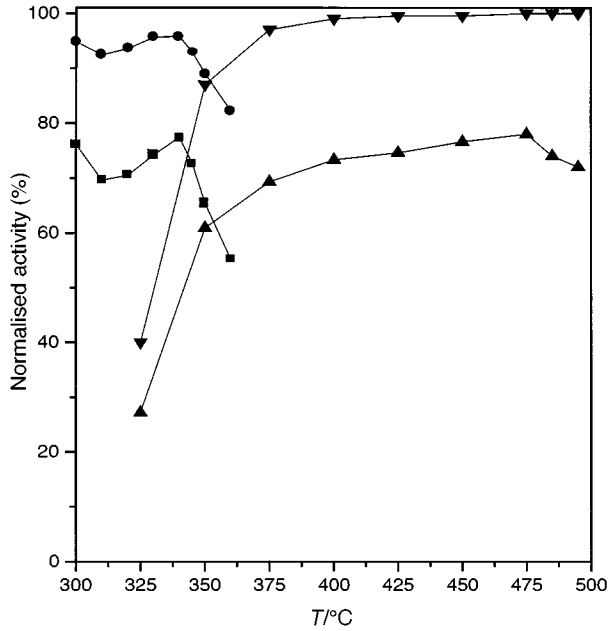

Fig. 2 Comparison of the normalised activities of α-$Fe_{0.95}Cr_{0.05}OOH$ and the current commercial catalyst for the synthesis of 3-methylthiophene: (■) 3MT (FeCrOOH, mol% yield), (●) 2MB (FeCrOOH, % conversion), (▲) 3MT, (▼) 2MB (commercial catalyst, conversion). Reaction conditions: 2MB:CS_2:N_2 (1:1.5:80), GHSV = 12000 h^{-1}, all samples taken after 15 min equilibration at each temperature.

the yield of thiophene, hence this was ascribed to β-methyl cleavage of the alcohol, rather than skeletal cracking as observed with Al_2O_3 based catalysts.

In a further set of experiments the activity of the 5% Cr catalyst (SA 103 m^2g^{-1}) was compared to that of a commercial catalyst (7.5% K_2CO_3 promoted 11% Cr_2O_3 on γ Al_2O_3, SA = 125 m^2 g^{-1}). The results, normalised to surface area, are given in Fig. 2. It is apparent that the commercial catalyst is only active at temperatures > 360 °C, and that temperatures as high as 475 °C are required to attain yields of 75 mol% 3MT, *cf.* 340 °C for the novel 5% Cr catalyst. Moreover, the commercial catalyst gave this optimum yield at a 2-methylbutanol conversion of 99 mol%, *cf.* 95 mol% for the 5% Cr catalyst, reflecting a lower selectivity and a higher formation of potentially deleterious reaction by-products for the commercial catalyst.

The changes in catalytic activity with increasing Cr content (Fig. 1) is not considered to be merely due to variation in surface area. This is confirmed by the similar BET SAs of samples with 0–10% Cr, which were all in the range 100–120 m^2 g^{-1}. However, at higher loadings of Cr, decreases in SA were recorded (15 m^2 g^{-1} for the 49% Cr sample). Hence it is clear that the intrinsic activity of the 5% Cr sample is significantly higher than that of catalysts with higher Cr loadings. Moreover, detailed powder XRD of the samples was performed which indicated that phase changes occurred as a function of Cr concentration. Thus, at 0 < Cr < 2.5% the catalyst was found to comprise of natrojarosite, with traces of α-FeOOH (Goethite) and α-CrOOH (Bracewellite).[7] However, for 3 < Cr < 10%, samples contained only a mixed α-FeOOH/α-CrOOH phase, whilst at Cr > 10% only the presence of a mixed FeCr phase supported on sodium sulfate (Thenardite) was recorded. This latter observation is consistent with the activity displayed by the intermediate Cr (15–25%) loaded samples, which exhibited performance profiles typical of supported oxides.[6] We therefore conclude that the high activities of the low Cr catalysts are related to the presence of a mixed FeOOH/CrOOH phase.

In these initial studies no attempt has been made to optimise catalyst performance by increasing the concentrations or relative proportions of the active phases. However, the data obtained demonstrate the discovery of a new class of catalysts for a lower temperature vapour phase synthesis of thiophenes[8] and may prove to be a starting point for the development of a new generation of industrial catalysts.

We are grateful for the financial support of this work by Synthetic Chemicals Ltd., now Inspec Fine Chemicals Ltd.

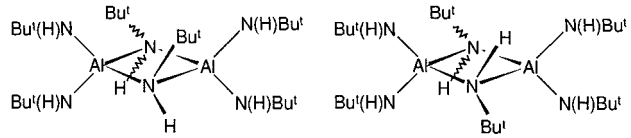
Received (in Bloomington, IN, USA) 10th September 1998, Accepted 19th October 1998

The reaction of $\{Al[N(H)Bu^t]_3\}_2$, obtained as a 1 : 2 mixture of *cis* and *trans* isomers from the addition of $AlCl_3$ to three equiv. $LiN(H)Bu^t$ in diethyl ether, with $LiBu^n$ generates a complex in which a dimeric *n*-butyllithium fragment is trapped by the trilithiated derivative $Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3$.

Current interest in amido derivatives of the Group 13 elements is stimulated primarily by possible applications in materials science.[1–3] Although there has been a recent spate of publications describing homoleptic polyimido anions of p-block elements, *e.g.* $E(NBu^t)_3^{2-}$ (E = Te,[4] Se,[5] S[6]), $Sb(NCH_2CH_2Ph)_3^{3-}$,[7] and $E(NR)_4^{x-}$ (E = S, R = Bu^t, *x* = 2;[8] E = P, R = 1-naphthyl, *x* = 3[9]), no examples of trisimido trianions, $E(NR)_3^{3-}$ (E = Group 13 element, R = alkyl or aryl group) have been reported.

Lithiation has been used to prepare complexes of the type $[R_2AlNLi(thf)_nR']_2$ from $[R_2AlNHR']_2$ (R, R′ = Me, Bu^t or Bu^i, Ph; *n* = 1), although adduct formation is observed for very bulky groups, *e.g.* $Me_2Bu^tAlNH[Li(thf)_3](C_6H_3Pr^i_2\text{-}2,6)$.[10] Nevertheless the trisamido derivatives $[Al(NHR)_3]_n$ (**1a**, R = Pr^i; **1b**, R = Bu^t) are potential precursors of $Al(NR)_3^{3-}$. The isopropyl derivative **1a** is obtained by the reaction of $AlCl_3$ with $LiNHPr^i$ in a 1 : 3 molar ratio in diethyl ether[11] whereas the analogous reaction with $LiNHBu^t$ in *toluene* gives $\{LiAl[N(H)Bu^t]_4\}_2$ rather than **1b**.[1] These observations, and the very recent report of the monomeric complex $Li(thf)Al[N(H)R]_4$ (R = 2,6-$Pr^i_2C_6H_3$),[12] prompt us to describe the formation and structure of the unusual cluster $Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3\cdot(LiBu^n)_2$ (**2**) in attempts to generate $Al(NBu^t)_3^{3-}$. Complex **2** consists of an *unsolvated n*-butyllithium dimer trapped by a trilithiated derivative of **1b**.

Treatment of $LiN(H)Bu^t$ with $AlCl_3$ (3 : 1 molar ratio) in *diethyl ether* gives the dimer **1b** as a *ca.* 1 : 2 mixture of *cis*, **1b′**



1b′ **1b″**

(C_{2v}), and *trans*, **1b″** (C_{2h}), isomers in 83% yield. The ^1H NMR spectrum of **1b** exhibits three equally intense resonances for **1b′** and two resonances in the ratio 1 : 2 for **1b″**.† The gallium analogue $[Ga(NHBu^t)_3]_2$ has been structurally characterized as the *cis* isomer.[2] The mixture of isomers **1b′** and **1b″** could not be separated by recrystallization.

The reaction of **1b** with six equivalents of $LiBu^n$ in hexane produces the novel cluster $Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3\cdot(LiBu^n)_2$ (**2**). Complex **2** is formed as the major product for stoichiometries ranging from 4 : 1 to 8 : 1, even at reflux, but the optimum yield is obtained when 5 equiv. of $LiBu^n$ are used [eqn. (1)].†

$$5\ LiBu^n + \underset{\textbf{1b}}{\{Al[N(H)Bu^t]_3\}_2} \longrightarrow \underset{\textbf{2}}{Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3\cdot(LiBu^n)_2} + 3\ HBu^n \quad (1)$$

The ^1H NMR spectrum of **2** shows five unique Bu^t environments (1 : 2 : 1 : 1 : 1) at 23 °C which resolve into six equally intense resonances at −20 °C, as well as resonances corresponding to Bu^n groups (Bu^n : Bu^t ~ 1 : 3). These puzzling observations were clarified by a single crystal X-ray structure determination, which revealed an unsolvated complex in which a trilithiated derivative of **1b** is coordinated to the dimer $(LiBu^n)_2$ (Fig. 1).‡ *n*-Butyllithium is hexameric in the solid state if crystallized from a non-coordinating solvent,[13] but the dimer is stabilized by coordination of Li^+ ions to TMEDA.[14] A solvated $(LiBu^n)_2$ moiety has been identified recently in the complex $(Ph_2NLi)[Ph(C_6H_4Li)NLi]_2(LiBu^n)_2(Et_2O)_4$ (**3**),[15] but **2** is unique in incorporating *unsolvated* $(LiBu^n)_2$ with three-coordinate Li^+ ions.

The average Li–C bond length in the puckered Li_2C_2 ring is 2.216(12) Å, *cf.* 2.268 Å for the corresponding distances for **3**.[15] Although the three N–H hydrogens in the trilithiated fragment $Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3$ were not located in the X-ray structural determination, it seems reasonable to associate them with the *three*-coordinate nitrogen atoms N(3), N(4) and N(6). Thus the static structure of **2** contains six inequivalent NBu^t groups consistent with the ^1H NMR spectrum at −20 °C (*vide supra*). However, Li(5) is disordered, with equal occupancies, over two sites in which it is in close contact with either N(1) or N(2). A fluxional process involving Li(5) will give rise to equivalence of the Bu^t groups attached to N(1) and N(2) as observed in the ^1H NMR spectrum at 23 °C. All five Li^+ ions in **2** are three-

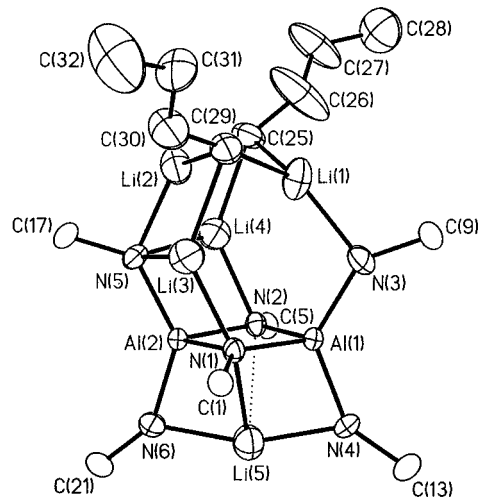


Fig. 1 Molecular structure of $Li_3Al_2[N(H)Bu^t]_3[NBu^t]_3\cdot(LiBu^n)_2$ **2** (30% thermal ellipsoids). For clarity only α-carbon atoms of Bu^t groups are shown and a second, disordered position of Li(5) is omitted. The hydrogen atoms attached to N(3), N(4) and N(6) were not located. Selected bond distances (Å) and angles (°): Li(1)–C(25) 2.262(12), Li(1)–C(29) 2.187(11), Li(1)–N(3) 2.043(12), Li(2)–C(25) 2.181(12), Li(2)–C(29) 2.236(12), Li(2)–N(5) 2.031(12), Li(3)–C(29) 2.238(11), Li(3)–N(1) 2.041(10), Li(3)–N(5) 2.080(11), Li(4)–C(25) 2.157(12), Li(4)–N(2) 2.037(10), Li(4)–N(5) 2.052(11), Li(5)–N(2) 2.303(19), Li(5)–N(4) 2.064(10), Li(5)–N(6) 2.069(11), Al(1)–N(3)–Li(1) 110.3(4), Al(2)–N(5)–Li(2) 127.4(4).

coordinate and the Li–N distances are in the normal range of 2.031(12)–2.075(10) Å with the exception of those involving Li(5) [Li(5)–N(2) = 2.303(19), Li(5)′–N(1) = 2.296(16) Å]. The geometry at aluminium is distorted tetrahedral with NAlN bond angles in the range 87.96(13)–127.90(19)° and 87.14(13)–134.80(17)° for Al(1) and Al(2), respectively. The smallest bond angle (< 90°) is found within the Al_2N_2 ring. The significant difference between the values of N(5)–Al(2)–N(6) and N(3)–Al(1)–N(4) [134.80(17)° *vs*. 127.90(19)°] presumably reflects the coordination of N(5) to Li(3) and Li(4). The Al–N distances [average value = 1.872(4) Å, range 1.833(3)–1.895(3) Å] are comparable to the values found for related lithiated AlN complexes.[10a]

Although LiBu^n has been employed successfully for the dilithiation of the dimer [Bu^{t}N(H)P(μ-NBu^t)]$_2$[16] and the trilithiation of MeSi(NHBu^t)$_3$,[17] the use of alternative metallating reagents will be necessary for the generation of $Al(NR)_3^{3-}$, an isoelectronic analogue of AlO_3^{3-}.

We gratefully acknowledge the NSERC of Canada for financial support and the Killam Memorial Foundation for a fellowship (J. K. B.).

IR (KBr, Nujol mulls): 3227 (br) cm^{-1} [ν(N–H)].

‡ *Crystallographic data* for **2**: Colourless cubic crystals of **2** (0.3 × 0.3 × 0.4 mm) were obtained from hexane and mounted on a thin glass fibre. Data were collected on a SMART CCD diffractometer with graphite-monochromated Mo-Kα radiation (0.71073 Å) at 20 °C in the range 1.98° < 2θ < 23.50° (10471 reflections collected, 6241 independent reflections, R_{int} = 0.0457). The structure was solved by direct methods and refinement, based on F^2, was by full-matrix least-squares procedures. All non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms for the Bu^t groups were treated as idealized contributions. Attempts to locate the NH hydrogen atoms were unsuccessful and were ignored. Atomic scattering factors were obtained from the SHELXTL (5.1) program library. $C_{32}H_{75}Al_2Li_5N_6$, M = 632.66, monoclinic, $P2_1/c$, a = 17.872(5), b = 11.472(3), c = 20.606(5) Å, β = 91.896(5)°, V = 4222(2) Å^3, D_c = 1.045 g cm^{-3}, Z = 4, μ = 0.099 mm^{-1}. Refinement converged at $R1$ = 0.0936, $wR2$ = 0.2962. CCDC 182/1063. See http://www.rsc.org/suppdata/cc/1998/2543, for crystallographic files in .cif format.

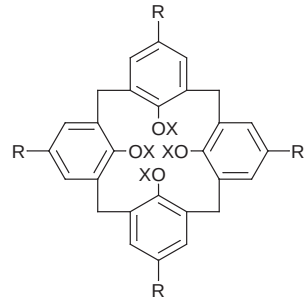
Received (in Basel, Switzerland) 23rd September 1998, Accepted 19th October 1998

Using the O-alkylation of the lower rim of the calix[4]arene to impose the 1,3-alternate conformation and the functionalisation of the upper rim to set-up four nitrile groups pointing in a divergent fashion, an *exo*-ligand capable of forming linear coordination networks was obtained; upon self-assembly of the latter and silver cation, a linear coordination polymer was obtained and structurally analysed in the solid state by an X-ray study.

Due to their foreseeable wide scope of applications, coordination polymers which may also be described as molecular networks are currently attracting much attention.[1] In these assemblies, metals in addition to their structural role might also display functional features. The dimensionality (1-, 2- or 3-D networks) as well as the topology (linear, helical) of coordination polymers may be tuned through the interplay between the metal (coordination requirements, *i.e*. coordination number and coordination geometry) and the *exo*-ligand (number of coordination sites and their location, steric control). Many examples of coordination polymers based on bis-monodentate[1,2] bis-bidentate[3,4] and bis-tridentate ligands[5] have been reported. Here we report the synthesis of an *exo*-ligand of the calix[4]arene type bearing four nitrile groups as coordination sites as well as the structural analysis of the free ligand and of its linear Ag^{I}-coordination polymer.

For the formation of molecular networks, the design of *exo*-ligands in which the coordination sites are oriented in a divergent fashion is crucial. Molecular units possessing four coordination sites occupying the apices of a pseudo-tetrahedron may be of interest for construction of linear coordination polymers using metals requiring a tetrahedral coordination geometry. The design of such a ligand may be based on a preorganised backbone offering the possibility of anchoring four coordination sites in an alternating mode below and above its main plane. This aspect was previously demonstrated in the case of mercaptocalix[4]arene derivatives for which in the lower rim the OH groups were replaced by SH moieties.[6] Another design may be based on the use of both the upper and lower rims. Indeed, one may impose the needed 1,3-alternate conformation by proper transformation of all four hydroxy groups, and on the other hand, using *para* positions one may set-up, in a controlled manner, coordination sites. This has been demonstrated in the case of catechol units as the coordination sites.[7] Again, using this strategy, we designed the *exo*-ligand **1** containing four nitrile groups as a building block for the formation of linear coordination polymers. It is worth noting that for ligand **1**, due to the donor effect of oxygen atoms, the binding ability of nitriles is considerably enhanced.

The synthesis of **1** was achieved as follows. The starting material was the *p-tert*-butylcalix[4]arene **2**[8] which after dealkylation in toluene in the presence of phenol and $AlCl_3$ afforded **3** as a mixture of conformers.[9] The O-alkylation of the latter using 2-methoxyethyltosylate in DMF in the presence of Cs_2CO_3 afforded **4** which, after recrystallisation, was shown to adopt the 1,3-alternate conformation.[10] The desired tetracyano compound **1** was obtained after bromination of **4** using NBS in butanone leading to the tetrabromo compound **5** and followed by treatment of the latter by CuCN in *N*-methylpyrrolidone.[11] The structural assignment of **1** was achieved by classical NMR studies as well as by X-ray diffraction† which indeed confirmed the 1,3-alternate conformation (Fig. 1).



1 R = CN, X = $CH_2CH_2OCH_3$
2 R = $C(CH_3)_3$, X = H
3 R = H, X = H
4 R = H, X = $CH_2CH_2OCH_3$
5 R = Br, X = $CH_2CH_2OCH_3$

The metal cation, Ag^{I}, which is already extensively used for the formation of coordination networks,[12] was chosen because it forms kinetically labile complexes. Furthermore, coordination networks based on the binding of silver by bis-,[13a] tris-[13b] and tetrakis-nitrile[13c] based ligands have been reported. However, Ag^{I} may adopt a wide range of coordination geometries. We have observed linear,[14] trigonal[15] and tetrahedral[4] coordination geometries using pyridine, benzonitrile and bipyridine based ligands respectively.

In principle, for the combination of the ligand **1** and Ag^{I}, one may envisage two types of linear coordination polymers (Fig. 2). The difference between the two possibilities resides in the difference in the coordination geometry around the silver cation. Whereas for the di-coordinated Ag adopting a linear coordination geometry, a 1 : 2 ligand : metal stoichiometry would be obtained, in the case of tetrahedral coordination geometry, a 1 : 1 metal : ligand ratio would be expected.

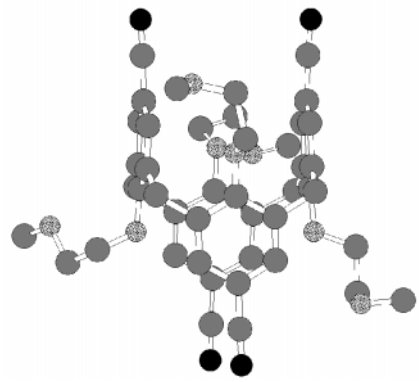


Fig. 1 X-Ray structure of the free ligand **1** adopting the 1,3-alternate conformation. H atoms are not presented for sake of clarity.

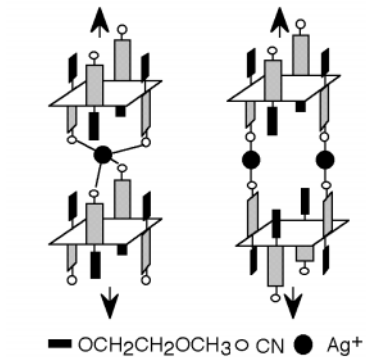

Fig. 2 Schematic representation of two types of linear coordination networks which may be envisaged for the self-assembly of the ligand **1** and Ag^{I} cation adopting tetrahedral- (left) or linear- (right) coordination geometries.

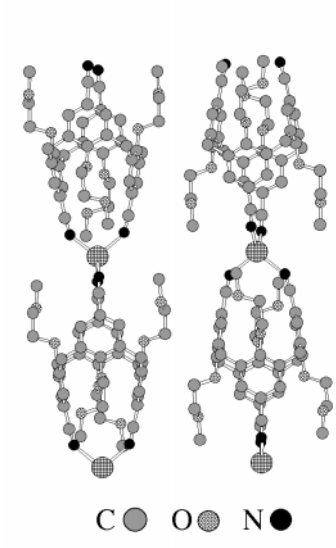

Fig. 3 A portion of the X-ray structure showing fragments of two parallel cationic linear coordination networks obtained by mutual bridging of Ag^{I} cations and ligands **1** (projection down the polymer axis). H atoms, solvent molecules and anions are not presented for sake of clarity.

Upon slow diffusion of a CH_2Cl_2 (1 ml) solution of ligand **1** (5 mg, 6.6×10^{-6} mol) into an EtOH (2 ml) solution of $AgAsF_6$ (20 mg, 6.7×10^{-4} mol) in large excess, a colourless crystalline material was obtained. The analysis of monocrystals by X-ray crystallography‡ revealed the presence of disordered H_2O and EtOH molecules in the lattice. In addition to the solvent molecules the crystal (tetragonal, space group *P*4/*nnc*) was composed of linear coordination polymers and disordered AsF_6 anions. The ligand **1**, as in the absence of Ag^{I} cation (Fig. 1), adopted a 1,3-alternate conformation (Fig. 3). The ether fragments adopted a *gauche* conformation with an OCCO dihedral angle of 73.8°. In order to bind two Ag^{I} cations in the tetrahedral mode of coordination, the calix unit was slightly pinched at the upper rim, *i.e.*, the N···N and O···O distances between nitrogen and oxygen atoms located within the same side of the calix unit were 3.533 and 5.670 Å respectively. The nitrile groups were almost linear with a CCN angle of 176.8° and CN distance of 1.104 Å. The cationic network was formed by mutual bridging between ligands **1** and Ag^{I} cations (Fig. 3). The silver cations were tetrahedrally coordinated to four nitrile groups with the NAgN angle varying from 100.9 to 121.9° (average 106.2°), CNAg angle of *ca.* 144.0° and AgN distance of *ca.* 2.292 Å. The packing of the cationic and anionic components (Fig. 4) showed parallel strands of linear coordination polymers with columns of disordered AsF_6^- anions separated by water molecules.

In conclusion, employing the self-assembly strategy, the formation of a silver coordination network using an *exo*-ligand based on calix[4]arene in the 1,3-alternate conformation and bearing at the upper rim four nitrile groups was achieved. The structure of the infinite network was established by single-crystal X-ray analysis.

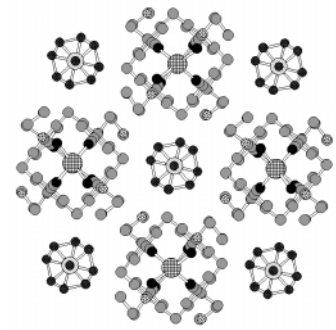

Fig. 4 A portion of the structure showing the packing of the cationic linear coordination networks and AsF_6^- anions (projection normal to the polymer axis). The AsF_6^- anions were found to be disordered. H atoms and solvent molecules (H_2O and EtOH) are not presented for sake of clarity.

Catalytic enantioselective ene reactions of imines: a simple approach for the formation of optically active α-amino acids

Sulan Yao, Xiangming Fang and Karl Anker Jørgensen*

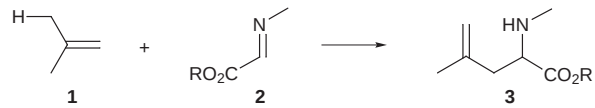
Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@kemi.aau.dk

Received (in Cambridge, UK) 15th October 1998, Accepted 21st October 1998

A highly enantioselective ene reaction of readily available tosyl α-imino esters with alkenes catalysed by only 0.1 mol% of chiral $CuPF_6$–BINAP complexes is presented.

The development of asymmetric catalytic reactions has in recent years added a new and very important aspect to chemistry as it allows one to use a small amount of chiral catalysts to form directly optically active compounds.[1]

The ene reaction of alkenes **1** with α-imino esters **2** can give α-amino acids **3** which are among the most fundamental compounds in nature (Scheme 1).



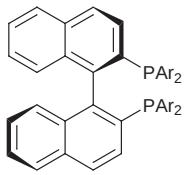
1 **2** **3**

Scheme 1

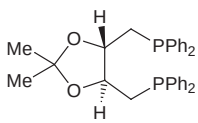
Within the last decade the asymmetric catalytic addition reactions of carbonyl compounds have been developed to a level where they can be performed with a high degree of stereoselectivity.[2–4] Compared with the highly efficient catalytic enantioselective ene reaction of carbonyl compounds, the related ene reaction of imines has only met with very limited success.[5] The catalytic enantioselective ene reaction of imines has, to the best of our knowledge, not yet been achieved regardless of its potential broad application. One of the problems with this reaction compared with the related reaction of carbonyl compounds is that the imine probably competes with the chiral ligand in coordinating to the Lewis acid and therefore suppresses the chiral information from the ligand.

Recently the first catalytic enantioselective hetero-Diels–Alder reaction,[6] addition of enol silanes[7] and alkylation[8] of α-imino esters **2** have been developed and a recent paper[9] dealing with the catalytic ene reaction of **2** with alkenes prompted us to present our results at the present stage of investigations.

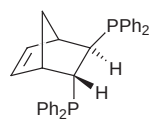
Here we present a highly enantioselective ene reaction of alkenes with tosyl α-imino esters catalysed by chiral $CuPF_6$–BINAP complexes. The strategy behind the catalytic enantioselective ene reaction of α-imino esters is the use of chiral phosphine ligands in combination with copper(I) salts. The chiral phosphine ligands (*R*)-BINAP **4a**, (*R*)-Tol-BINAP **4b**, (*R*,*R*)-DIOP **4c** and (*R*,*R*)-NORPHOS **4d** have been found to be



4a Ar = Ph
4b Ar = Tol



4c



4d

the most promising of the different ligands tested for the ene reaction of α-methylstyrene **1a** with tosyl α-imino ester **2a** in the presence of various Lewis acids. Some representative results are presented in Table 1.

The results for the screening of the various ligands and Lewis acids show that (*R*)-BINAP **4a** and (*R*)-Tol-BINAP **4b** in combination with copper(I) salts catalyse the ene reaction of α-methylstyrene **1a** with tosyl α-imino ester **2a** giving adduct **3a** in good yield and up to 95% ee (Table 1, entries 1–6). The ee of **3a** is counterion-dependent and the highest ees are obtained with PF_6 and ClO_4 as the anions; it is of practical importance that $CuPF_6$ can be used as this Lewis acid is safer, more stable and easier to handle than $CuClO_4$. Changing the catalyst to (*S*)-BINAP–$CuClO_4$ leads to the opposite enantiomer with the same yield and ee. Choosing copper(II) as the Lewis acid in combination with the BINAP ligands leads to a significant reduction in the ee of **3a** (entry 7). The combination of ligand **4b** with other Lewis acids gives only reasonable results in the case of silver(I) (entries 8–12). The application of the chiral ligands (*R*,*R*)-DIOP **4c** and (*R*,*R*)-NORPHOS **4d** leads only to very low yield and ee of **3a** when tested for the ene reaction in combination with $CuPF_6$ as the Lewis acid (entries 13, 14). The results presented in Table 1 are all performed in THF; CH_2Cl_2 can also be used and similarly good results as those presented in entries 1–6 are obtained. The latter solvent has the advantage that the reaction course can easily be monitored by the colour change; the coordination of **2a** to the catalyst complex at the reaction temperature gives a dark purple colour, and when the reaction goes to completion the colour becomes a clear light yellow. We have also tried various chiral bisoxazolines in combination with different Lewis acids but only low to moderate ees were obtained.

The potential and scope of the ene reaction of various alkenes **1a**–**e** with the tosyl α-imino ester **2a** in the presence of (*R*)-Tol-BINAP **4b**–CuX as the catalyst are presented in Table 2.[10]

The results show that both aromatic (**1a**,**b**), cyclic (**1c**,**d**) and simple aliphatic alkenes (**1e**) react with **2a** in the presence of

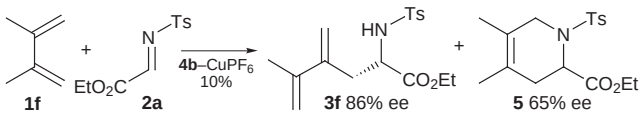

Scheme 2

(*R*)-Tol-BINAP **4b**–CuX (X = PF_6, ClO_4) as the catalyst. For alkene **1a** it appears that the reaction proceeds well using both THF and CH_2Cl_2 as these solvents, giving good yields and high ees of **3a** at room temperature in the presence of 10 mol% of the catalyst (entries 1, 2). Reducing the catalyst loading to 1, 0.5 and even 0.1 mol% causes no significant reduction in the yield of **3a** and even higher enantioselectivities (up to 99%) are obtained (entries 3–5). The *p*-methoxy substituted alkene **1b** reacts in a similar manner with **2a** and an ee of up to 91% is obtained using only 0.1 mol% catalyst loading (entry 7). Methylenecyclopentane **1c** reacts also in a highly enantioselective manner with **2a** with only 0.5 mol% of **4b**–$CuPF_6$ as the catalyst and up to 92% ee is found (entry 8), while methylenecyclohexane **1d** is less reactive and leads to a small reduction in ee compared with **1c** (entry 9). The reaction of isobutylene **1e** with **2a** in the presence of (*R*)-Tol-BINAP **4b**–$CuPF_6$ as the catalyst (entries 10, 11) gives also the corresponding ene product **3e** in reasonable yields and with high ee; the latter reaction can be performed in a gram scale with a catalytic loading of only 1 mol% without affecting the yield and ee. This reaction has been used to assign the absolute stereochemistry of the ene product **3e** as this adduct is easily transformed to the *N*-tosylleucine ethyl ester the stereochemistry of which is found to be *S* by correlation with the same compound prepared from (*S*)-leucine. The absolute stereochemistry of **3e** indicates that the alkene approaches the *si*-face of the tosyl α-imino ester **2a** when coordinated to the catalyst.

2,3-Dimethylbuta-1,3-diene **1f** reacts with the tosyl α-imino ester **2a** in the presence of (*R*)-Tol-BINAP **4b**–$CuPF_6$ (10 mol%) as the catalyst to give both the ene product **3f** and the hetero-Diels–Alder product **5**, with a preference for the latter (**3f**:**5** = 1:9) (Scheme 2). The ee of the ene adduct **3f** was 86% at room temperature, while 65% ee was found for **5**.

We have presented a highly enantioselective ene reaction of alkenes with tosyl α-imino esters catalysed by $CuPF_6$–BINAP complexes. The substrates for this ene reaction are aromatic, cyclic and simple alkenes and the reaction provides a simple method for the preparation of both optically active natural and non-natural α-amino acids; the potential of the ene reaction derives from the fact that it proceeds with only 0.1 mol% of the $CuPF_6$–BINAP catalyst. Work is in progress to develop the reaction further and to understand the mechanism.

10 *Experimental procedure*: A 0.008 M solution of the catalyst was prepared by the addition of $CuPF_6$·4MeCN (15 mg, 0.04 mmol) and (*R*)-Tol-BINAP (30 mg, 0.044 mmol) under N_2 to a flame dried Schlenk tube. The mixture was stirred for 1 h under vacuum, freshly distilled CH_2Cl_2 (5 ml) was added with a syringe under N_2 and the light yellow solution was stirred for 1–3 h until it had become absolute homogeneous. Catalytic reaction (1 mol% catalyst): To a flame dried Schlenk tube was added freshly destilled CH_2Cl_2 (1 ml) and an aliquot of the previously prepared catalyst solution (500 μl) under N_2 and stirred for 5 min; then the tosyl α-imino ester **2a** (0.4 mmol) was added at room temp. The dark purple solution was cooled to the desired reaction temperature before the alkene (0.8 mmol) was added. Then the reaction was kept at that temperature until the dark purple colour had changed into a clear yellow solution (10–65 h). After evaporation of the solvent the crude product was purified by flash chromatography (20% EtOAc–pentane) to give the ene adduct.

Received (in Cambridge, UK) 10th June 1998, Accepted 21st July 1998

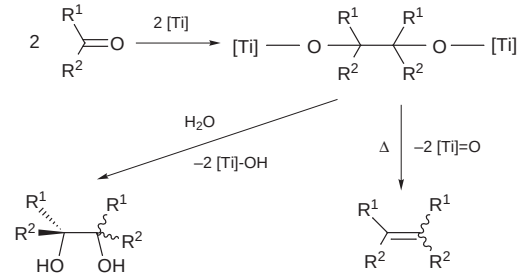
The article emphasizes the contradictory features of the McMurry reaction. The historical view shows how the chemists were firmly convinced of the occurrence of pinacolate intermediates and rejected, in spite of some evidence, the alternative pathway *via* carbenoid species. The McMurry reaction continues to find new important applications but suffers from problems of reproducibility. New practical reagents and simplified methods have been developed but rather complicated systems have been designed for obtaining higher selectivities. Recent investigations confirmed that pinacolates would be the precursors to alkenes but also revealed the possible involvement of carbenoid species, putting forward the dual nature of the mechanism of the McMurry reaction.

The huge interest in the McMurry reaction is expressed by the number of accounts devoted to its synthetic applications and, to a lesser extent, its mechanistic aspects;[1–4] an excellent review by Fürstner and Bogdanovic was published in 1996.[4] In this feature article, we would like to focus on the most recent developments but also recall some older facts, placing this field in a distinct perspective.

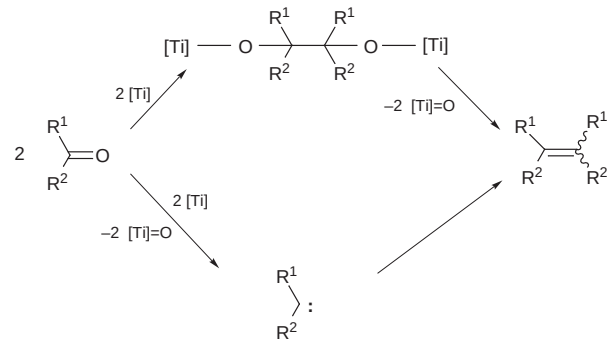
An historical view

The rich and peculiar history of the McMurry reaction will be more easily assessed after recalling the course of some important events which are not necessarily brought together, without confusion, in the chemist's memory.

In 1972, Sharpless *et al.* reported that ketones and aldehydes could be reductively coupled into alkenes by reaction with WCl_6 and RLi reagents.[5] One year after, two groups discovered that low-valent titanium complexes were also efficient in this coupling process. Tyrlik and Wolochowicz, who used the $TiCl_3$–Mg system, suggested that tetramethylethylene was obtained *via* the carbene species Me_2C:, resulting itself from deoxygenation of acetone. On the other hand, Mukaiyama *et al.* proposed that metallopinacols were intermediates in the reductive coupling of aromatic ketones by means of the $TiCl_4$–Zn system; the mechanism shown in Scheme 1 explained how benzaldehyde and acetophenone were selectively transformed into the corresponding pinacols and alkenes when the reaction was performed in THF at low temperature or in refluxing dioxane.[7] The pinacolate intermediates would be formed either by dimerization of ketyl radicals resulting from one electron transfer from the low-valent metal species to the carbonyl and/or, in the case of the more easily reducible and reactive aromatic ketones, by nucleophilic attack of a ketone dianion to the C=O bond. Therefore, at the very beginning in 1973, two mechanisms were envisaged for the reductive coupling of carbonyl molecules (Scheme 2).



Scheme 1 Reductive coupling of ketones *via* a metallopinacol intermediate.

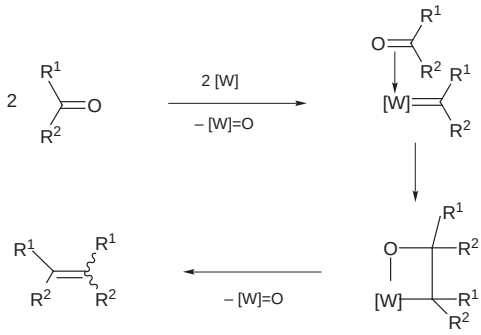


Scheme 2 The two mechanisms proposed in 1973 by Tyrlik and Wolochowicz (bottom) (ref. 6) and by Mukaiyama *et al.* (top) (ref. 7).

In 1974, McMurry and Fleming described a 'new method for the reductive coupling of carbonyls to olefins' with $TiCl_3$ and $LiAlH_4$; they also proposed that pinacolate intermediates were involved in this reaction since pinacols could be isolated as by-products in many cases.[8] The mechanism of Scheme 1 was then rapidly and generally accepted.

Meanwhile, several studies on the reductive coupling of carbonyl compounds to olefins by low-valent molybdenum and tungsten compounds revealed that this reaction involved carbenoid intermediates; the relationship with the alkene metathesis reaction was noted.[9] Such carbene species were detected by Fujiwara *et al.* in 1978,[9] before Bryan and Mayer[10] and Chisholm and co-workers[11,12] isolated in 1990 tungsten oxoalkylidene complexes resulting from reductive cleavage of the ketonic C=O bond. These compounds were found to react further with the ketone to give the olefin at room temperature, presumably *via* a metallaoxetane intermediate, and the mechanism of Scheme 3 could be proposed for the reductive coupling

Michel Ephritikhine obtained his PhD in organic chemistry in 1974 at the University of Paris under the supervision of J. Levisalles. His postdoctoral work with M. L. H. Green in Oxford confirmed his interest in organometallic and inorganic chemistry. From 1976 to 1984, he was in the group of H. Felkin in Gif sur Yvette where he studied the chemistry of rhenium polyhydrides and C–H bond activation of alkanes. In 1984, he joined the Commissariat à l'Energie Atomique in Saclay to work on uranium chemistry. He presently holds the position of Research Director in the CNRS.



Scheme 3 Reductive coupling of ketones *via* a carbenoid species.

of carbonyl substrates. It is noteworthy that Chisholm *et al.*[12] and Cotton *et al.*[13] also found that low-valent tungsten compounds could react with ketones to give metallopinacols and demonstrated that these latter species were not the source of alkenes.

Amazingly, the belief in the mechanism of Scheme 1 was so strong that another pathway for the titanium catalyzed reaction did not seem conceivable; Chisholm wrote 'superficially, the (W catalyzed) reaction would seem to provide a molecular model for the McMurry reaction...; however, the mechanisms of the two reactions differ'.[12] We note that the reductive coupling of carbonyls into pinacols and alkenes by means of titanium complexes is now called the McMurry reaction; this is justified by the leading role played by McMurry in establishing the reputation of this reaction in organic chemistry.

Recent applications

It is no longer necessary to demonstrate the remarkable efficiency of low-valent titanium compounds for carbon–carbon bond forming; their use in synthesis has been described in detail in previous reviews and only a brief reminder of the main domains of application will be given here, with recent representative examples shown in Fig. 1.

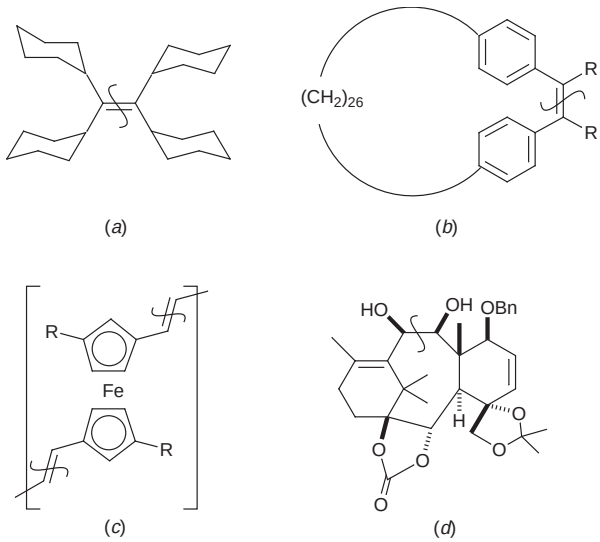


Fig. 1 Examples of compounds obtained by McMurry reactions: (*a*) a strained alkene (ref. 14), (*b*) a macrocycle (ref. 15), (*c*) a polymer (ref. 16) and (*d*) a key intermediate in the synthesis of taxol (ref. 20).

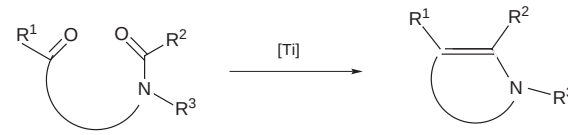
Low-valent titanium compounds served to prepare sterically hindered and/or strained olefins;[14] the driving force of the reaction is the formation of strong titanium–oxygen bonds. Many of these olefins, which exhibit specific physico-chemical properties and have a theoretical interest, could not be prepared by other methods. Also particularly notable is the effectiveness of the McMurry reaction in the synthesis of macrocycles.[15] The exceptional template effect exerted by titanium in intramolecular cyclizations of dicarbonyl molecules allowed the preparation of medium-sized and large rings; the yields are independent of the size of the cycloalkenes. A more recent application of the McMurry reaction was developed in polymer chemistry,[16] with the synthesis of polyvinylene or polypinacol derivatives and the preparation of new monomers with interesting properties.

But above all, it is with its crucial and elegant use in the key steps of numerous syntheses of natural products that the McMurry reaction has known a so great success. After the total synthesis of (+)-compactin and (+)-mevinolin by Clive *et al.*,[17] and the total synthesis of crassin by Dauben *et al.*[18] and McMurry and Dushin,[19] Nicolaou's synthesis of taxol[20] is possibly the most famous synthesis of a natural product which can be prepared with the aid of low-valent titanium compounds.

Very recently, Fürstner and co-workers considerably extended the scope of the conventional McMurry reaction: they found that titanium complexes were valuable auxiliaries for the reductive coupling of acylsilanes[21] and, more notably, the intramolecular cross-coupling reactions of ketones with amides; these substrates were previously reputed unreactive. The chemo- and regio-selective heteroarene synthesis (Scheme 4) represents a new efficient entry to a variety of substituted pyrrole and indole derivatives.[15,22,23]



Scheme 4 Reductive coupling of oxo amide molecules.

However, it is also recognized that the McMurry reaction suffers from serious problems of reproducibility, having a bad reputation as being tricky and highly 'co-worker dependent'. The chemist must be aware of the difficulties they will probably encounter in finding the suitable reagent and experimental conditions.

New reagents, new methods

Problems of reproducibility

McMurry reactions are usually carried out in two consecutive steps: reduction of $TiCl_4$ or $TiCl_3$, followed by addition of the carbonyl substrate; this procedure is imperative when the carbonyl compound is not inert towards the reducing agent. Many reducing agents were used: Li, Na, K, KC_8, Mg, Mg(Hg), Zn, Zn(Cu), $LiAlH_4$. This variety does not reflect the chemist's fantasy, but rather the problematic outcome of the reaction. The nature of the titanium reagent, as well as the solvent, temperature and reaction time, have a strong influence on the eventual formation and stereochemistry of the coupling products, diols (*dl* and *meso*) or alkenes (*Z* or *E*); as outlined by Lenoir,[2] a complete rationale for these results has to be found. In attempts to overcome these problems of reproducibility, McMurry himself proposed, after his discovery of the $TiCl_3$–$LiAlH_4$ system (1974),[8] several 'improved procedures' by using the $TiCl_3$–K, $TiCl_3$–Li (1976)[24] and then $TiCl_3$–Zn(Cu) reagents (1978),[25] and finally recommended an 'optimized procedure' with the $TiCl_3(DME)_{1.5}$–Zn(Cu) combination, which 'gave reproducibly high yields in every case it has been used' (1989).[26] The efficacy of this new procedure was illustrated by the coupling of Pr^i_2CO which afforded $Pr^i_2C{=}CPr^i_2$ in 87% yield, instead of 17% by using $TiCl_3$–$LiAlH_4$ and 37% by using $TiCl_3$–Zn(Cu). However, Letcka, a collaborator of McMurry, wrote in 1996, 'McMurry coupling does not always give high yields at the first, or even the second attempt, but with some experience, reproducibly high yields can be attained... We strongly recommend . . . several test couplings on cyclohexanone before venturing a coupling on the more complex

material'.[3] Noteworthily, inferior results were attributed to bad experimental conditions—poor quality reagents or solvents, intrusion of air—rather than a lack of control of the mechanistic course of the reaction.

With the aim of obtaining more efficient reactions and better insights into the mechanisms, new low-valent titanium species have been designed in the last few years, and simplified methods have been developed.

Synthesis of alkenes

After the successful use of titanium graphite, especially in indole synthesis, Fürstner and co-workers reported that reduction of $TiCl_3$ with high surface area sodium gave a highly active titanium species supported on Al_2O_3, NaCl or TiO_2. The titanium–alumina species, which is presumably in the +1 oxidation state, was particularly efficient for the preparation of large cycloalkenes.[21]

Barteau and co-workers found that reductive coupling of aldehydes and ketones could also be carried out as a gas–solid process on the surface of reduced titania;[27–30] the reaction could be performed catalytically in the presence of hydrogen. Such reactions are not in need of strong reducing agents and a reduced oxide catalyst would be cheaper and easier to handle than the usual McMurry reagents in liquid–solid slurries. Moreover, the gas–solid reaction represents a potential route for coating of surfaces by conducting polymers, as suggested by the reductive coupling of *p*-benzoquinone.[28]

For the first time, Fürstner and Hupperts showed that commercially available titanium powder could be used as a McMurry reagent, after destruction of the tightly bound oxide layer by chlorosilane during the activation phase.[15] The Ti–R_3SiCl reagent exerted a strong template effect for macrocyclization reactions. In contrast to other systems which were claimed to produce Ti^0, this reagent was ineffective with aliphatic substrates, thus making chemo- and regio-selective coupling possible. The reaction with the Ti–R_3SiCl reagent could be performed either in two steps, by treating the titanium powder with the chlorosilane prior to addition of the substrate, or by heating all the components together.[15] Such a one-pot procedure, which is reliable when the reducing agent is not strong enough to affect the carbonyl group, had been employed by Mukaiyama with the $TiCl_4$–Zn system[7] and was recently reintroduced by Fürstner *et al.*, with the so called 'instant method'.[23] In fact, Bogdanovic and Bolte found that $TiCl_3$ could be reduced by Zn only if its redox potential has been lowered by co-ordination to the carbonyl substrate and therefore, a two step procedure is superfluous.[31] The simple and convenient 'instant' protocol, which is suitable for conventional McMurry couplings, has been applied to the synthesis of strained indoles.[23] Moreover, the reaction was rendered catalytic in titanium when carried out in the presence of a chlorosilane which reconverted the formed titanium oxychloride into $TiCl_3$.[15]

Synthesis of pinacols

Several works were devoted to the search of low-valent titanium compounds which would be suitable for the synthesis of pinacols with high stereoselectivity; these complexes should allow the McMurry reaction to be stopped at the 1,2-diol stage. Corey *et al.*found in 1976 that aromatic and aliphatic ketones and aldehydes could be coupled into the corresponding pinacols by treatment with $TiCl_4$ and Mg(Hg), at 0 °C in THF; reaction of a cyclic ketone with an excess of acetone gave the unsymmetrical diol.[32] Porta and co-workers reported that pinacols were formed with poor stereoselectivity (*dl*/*meso* = 1.3) by coupling of aromatic carbonyl compounds with aqueous $TiCl_4$ in basic media, but with $TiCl_3$ in anhydrous CH_2Cl_2 the pinacolization was highly diastereoselective (*dl*/*meso* > 100).[33]

Most recent studies revealed that such pinacol coupling reactions could be rendered stereoselective and catalytic with the use of additives and/or modified ligands. Banerji succeeded in stopping the reductive dimerization of acetophenone at the pinacol stage by addition of 10 equiv. of pyridine to the $TiCl_3$–Mg system. Also, in the presence of a stoichiometric amount of a mono- or di-hydroxy auxiliary, pinacols were obtained in higher yields and better stereoselectivity (*dl*/*meso* = *ca*. 4–5); among these additives, catechol was the most interesting for total pinacolization of aromatic carbonyl substrates, even under refluxing conditions.[34]

Ephritikhine reported on the first pinacol coupling reactions catalytic in titanium, by using the $TiCl_4$–Li(Hg) system in the presence of $AlCl_3$; a transmetallation reaction of the titanium pinacolate intermediates with $AlCl_3$ regenerated the precatalyst $TiCl_4$ and gave aluminium diolates which were inert towards the reducing agent and not transformed into the alkene.[35]

Catalytic pinacolization of benzaldehyde was achieved by Nelson with 1% $TiCl_3(THF)_3$ in the presence of Zn and Me_3SiCl. This combination was not effective for the coupling reactions of less electrophilic aldehydes and the diastereoselection was very low, but addition of 5 mol% of Bu^tOH led to a more reactive system which catalyzed the pinacolization of aromatic and aliphatic aldehydes and aryl methyl ketones with *dl*/*meso* ratios ranging from 1.5 to 4.8. Moreover, the stereoselectivity of the homocoupling of aryl aldehydes was substantially enhanced (*dl*/*meso* = 6.7 to 10.1) when 30 mol% of 1,3-diethyl-1,3-diphenylurea was added to the $TiCl_3(THF)_3$–Bu^tOH catalyst.[36]

Pinacol coupling can be affected by organotitanium compounds, as demonstrated by Corey *et al.* with the $CpTiCl_3$–$LiAlH_4$ reagent[32] and then by Handa and Inanaga with the Cp_2TiCl_2–Pr^iMgCl system.[37] Such reactions have known a significant improvement in the last few years. Barden and Schwartz reported that $[Cp_2TiCl]_2$ was able to reductively couple aromatic and α,β-unsaturated aldehydes into 1,2-diols in either anhydrous or aqueous media; the diastereoselectivity was high, with *dl*:*meso* ratios greater than 91:9.[38] Pinacol coupling of aromatic aldehydes was catalyzed by 3 mol% of *rac*-ethylenebis(η^5-indenyltitanium) dichloride in the presence of $MgBr_2$, Me_3SiCl and Zn to give the racemic 1,2-diols in good yield and with excellent diastereoselectivity (*dl*:*meso* > 96:4). These results of Gansäuer are encouraging for the investigation of asymmetric induction using enantiomerically pure metallocene catalysts.[39]

The nature of the active species and intermediates in these pinacol coupling reactions, which are performed with the aid of rather complicated systems, is not known. It is generally proposed that the high stereoselectivity of benzaldehyde or acetophenone coupling is due to the dimerization of ketyl radicals oriented in a manner which minimizes steric interactions between the phenyl groups (Fig. 2).

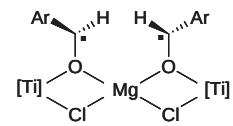


Fig. 2 Proposed intermediate for the diastereoselective coupling of benzaldehyde; [Ti] = Cp_2Ti (ref. 37) or *rac*-ethylenebis(η^5-indenyltitanium) (ref. 39).

New insights into the mechanism

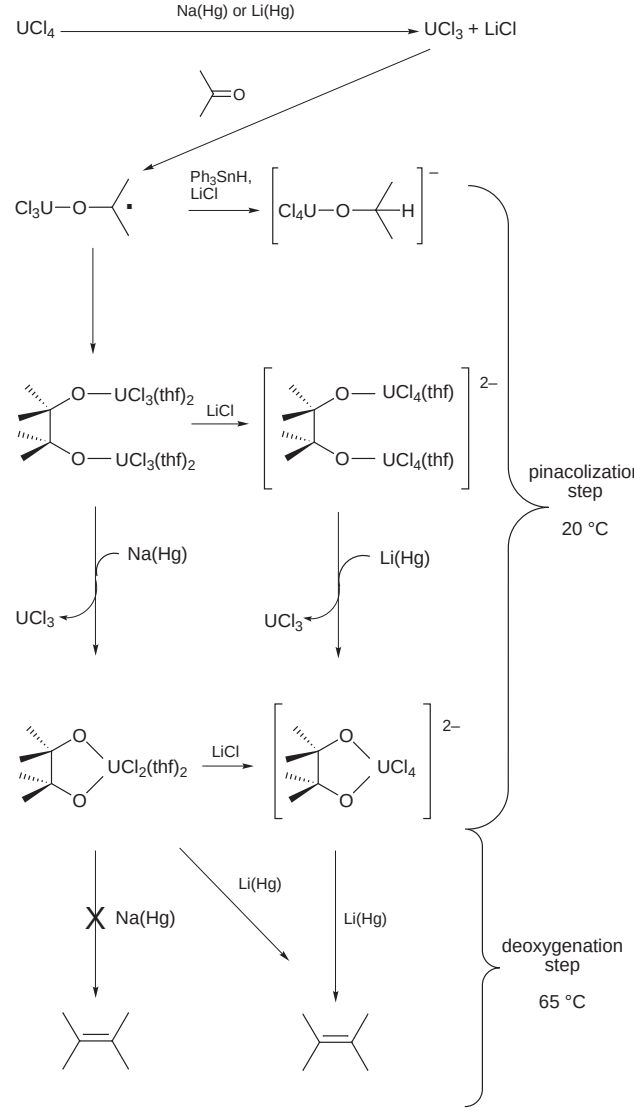
The nature of the active species

As noted above, there was apparently no doubt about the involvement of pinacolate intermediates in the McMurry reaction and the main questions rather concerned the nature of the active species, and in particular its oxidation state. Despite several indications that Ti^{III} or Ti^{II} compounds could effect the

reductive coupling of carbonyl substrates—Corey *et al.* reported in 1976 that $(C_6Me_6)Ti(AlCl_4)_2$ was able to couple acetone and cyclohexanone[32]—it has been long believed that finely divided titanium particles were the active species in McMurry reactions. This assumption was reinforced by the studies of Geise on the $TiCl_3$–M (M = Li, K, Mg) or $TiCl_3$–$LiAlH_4$ systems,[40] but it is now clearly established that the presence of Ti^0 is not a prerequisite for the McMurry reaction.

Barteau found no evidence for the presence of Ti^0 on reduced TiO_2 surfaces active for benzaldehyde coupling; X-ray photoelectron spectroscopy revealed that the active site required for gas–solid reductive coupling is an ensemble of Ti cations in the +1, +2 and +3 oxidation states which collectively effect the four electron reduction.[29]

A decisive contribution to these mechanistic investigations was made by Bogdanovic and Bolte, who identified the nature and mode of action of the active species in some classical McMurry systems.[31] The low-valent titanium species obtained by reduction of $TiCl_3$ with $LiAlH_4$ was shown to be $[HTiCl(THF)_{0.5}]_x$;[41] this titanium hydride reacted with acetophenone to give PhMeC=CMePh and behaved as a strong two electron reductant. In contrast, the $TiCl_2$·LiCl reagent proposed by Eisch *et al.*[42] acted as a one electron reductant in the coupling of PhCOMe. Titanium(II) species were also involved in both the ketone→pinacolate and pinacolate→alkene steps of the reductive coupling of acetophenone with the $TiCl_3$(DME)–Zn(Cu) system; the nucleophilic mechanism proposed for this reaction (Scheme 5) was supported by quantum mechanical calculations.[43] These coupling reactions were shown to proceed by two consecutive steps: formation of the pinacolate intermediates which occurred at room temperature, followed by alkene synthesis at reflux temperature. Their progression was determined after analysis of the products obtained by hydrolysis of aliquots, and occurrence of pinacolate intermediates was inferred from formation of 2,3-diphenylbutane-2,3-diol; however, such intermediates were not observed and characterized. In fact, a very few metallopinacols were isolated from reactions of organic carbonyl substrates with $Cp_2Ti(CO)_2$ or $CpTiX_2$ (X = Cl or Br) and no alkene was obtained from these derivatives.[44]

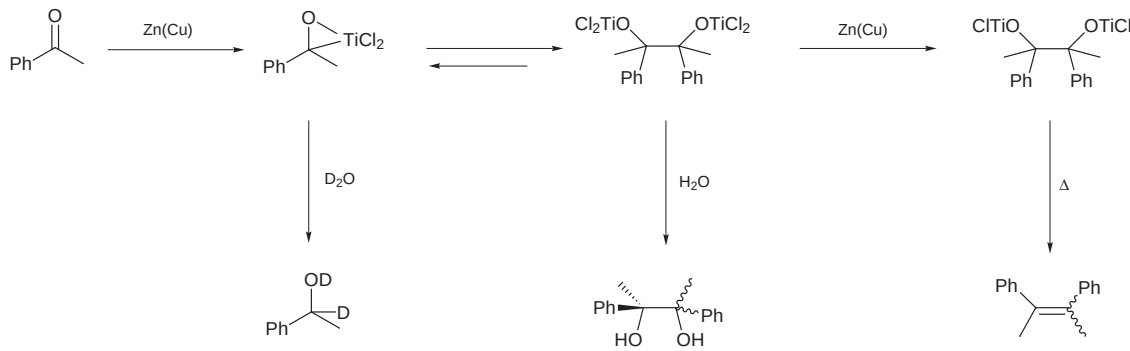


Scheme 6 Metallopinacols isolated from the reductive coupling of acetone with the UCl_4–M(Hg) systems (M = Li or Na).

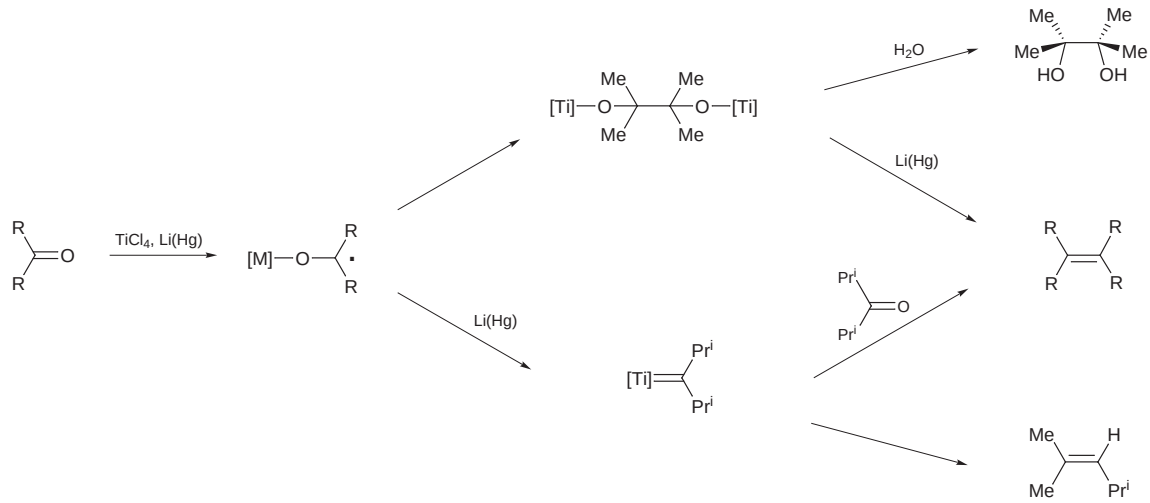
Characterization of the pinacolate intermediates

Ephritikhine considered the reactions of ketones with the UCl_4–M(Hg) and $TiCl_4$–M(Hg) systems (M = Li or Na). Uranium and titanium complexes exhibit strong similarities in structure and reactivity but uranium compounds have some advantages over their titanium counterparts: they can be easily detected by their highly-shifted paramagnetic NMR signals and they often crystallize with less difficulty. Therefore, the chances of isolating and characterizing the intermediates are greater. The active uranium species in the UCl_4–M(Hg) systems were shown to be in the +3 oxidation state; it was demonstrated by electrochemical studies that reduction of UCl_4 into UCl_4^- was rapidly followed by a chloride ion transfer from UCl_4^- to UCl_4, giving UCl_3 and the anionic U^{IV} complexes $U_2Cl_9^-$ and UCl_5^- which were then reduced at lower potentials.[45]

Reaction of benzophenone with UCl_4 and Na(Hg) afforded successively the mono- and bis-benzopinacolates $UCl_2(O_2C_2Ph_4)$ and $U(O_2C_2Ph_4)_2(THF)_2$; the latter was characterized by its X-ray crystal structure. These compounds gave benzopinacol upon hydrolysis and were transformed into tetraphenylethylene after reduction with Na(Hg).[46] Several metallopinacols were isolated from the reaction of acetone with UCl_4 and M(Hg) (Scheme 6); whatever the amalgam used, the first intermediate was the dinuclear complex $(UCl_3L_2)_2(\mu$-



Scheme 5 Proposed mechanism for the reductive coupling of benzophenone with the $TiCl_3$–Zn(Cu) system.



Scheme 7 The distinct mechanisms of the reductive coupling of acetone and diisopropyl ketone with the $TiCl_4$–Li(Hg) system.

$OCMe_2CMe_2O$) (L = THF) resulting from dimerization of the ketyl radical $[Cl_3UOCMe_2]^{\cdot}$; the crystal structure of the adduct with L = $OP(NMe_2)_3$ was determined (see front cover). The structure of the metallopinacols and their eventual transformation into $Me_2C{=}CMe_2$ were found to be strongly influenced by the molar ratio of the reactants, the nature of the reducing agent (M = Na or Li) and of the formed salt (NaCl or LiCl).[47]

Problems of reproducibility

The reductive coupling of acetone with the UCl_4–Li(Hg) system raised the problems of reproducibility. The alkene was formed in almost quantitative yield when the reaction was carried out in two consecutive steps: the pinacolization step at 20 °C and the deoxygenation step at 65 °C. However, it was much less easy, without extensive experience of the UCl_4–Li(Hg) system, to produce the alkene in a reproducible manner using a one pot procedure. This discrepancy could be related to side reactions of the different metallopinacols, which could be avoided only by determining the right time for heating the reaction mixture.[48] It was thus pointed out that, in addition to the quality of the reagents, experimental parameters like reaction time and temperature, which are directly connected to the mechanistic control of the reaction, would constitute major sources of non-reproducibility. These parameters cannot always be easily monitored in an heterogeneous medium.

Evidence of carbenoid intermediates

New facts emerged when Me_2CO was replaced with $Pr^i{}_2CO$ in its reaction with the UCl_4–Li(Hg) or $TiCl_4$–Li(Hg) systems.[49] The only coupling product was then $Pr^i{}_2C{=}CPr^i{}_2$ whereas a large amount of 2,4-dimethylpent-2-ene was formed. Control experiments showed that $Pr^i{}_2C{=}CPr^i{}_2$ did not result from the deoxygenation of pinacolate intermediates; moreover, it was found that $Cl_3TiOCPr^i{}_2CPr^i{}_2OTiCl_3$ was not stable, being readily transformed into a mixture of $TiCl_3$ and $Pr^i{}_2CO$. The facile cleavage of the titanium pinacolates and the absence of pinacol in the product mixture indicated that reductive coupling of $Pr^i{}_2CO$ would not proceed by dimerization of ketyl radicals, whereas formation of 2,4-dimethylpent-2-ene revealed the likely involvement of carbenoid intermediates.

These data put forward the dual nature of the mechanism of these McMurry type reactions (Scheme 7). Contrary to the generally accepted mechanism, metallopinacols are not the only precursors to the alkene; if the ketyl radicals can be effectively coupled into pinacolate intermediates, they can also be reduced and deoxygenated into carbenoid species which provide the alkene after further reaction with the ketone. The course of the reaction, *via* the metallopinacol or the carbenoid intermediates, is largely determined by the steric hindrance of the ketone; the most hindered ketones would follow the carbenoid route because of the difficult coupling of the ketyl radicals, and the reversible cleavage of the pinacolic C–C bond.

Now it seems that some McMurry reactions could be re-examined by considering the possible involvement of carbenoid intermediates. If the formation of 2,4-dimethylpent-2-ene was overlooked in the McMurry reactions of $Pr^i{}_2CO$, cyclohexene was detected among the products of the reductive coupling of cyclohexanone with the $TiCl_3$–K system[40] and the alkenes $RCH{=}CH_2$ (R = Me, Ph) were formed during the coupling of acetone and acetophenone on reduced alumina;[30] these alkenes would indicate the occurrence of carbenes as intermediates, even if such species could not be trapped with usual reagents. Also, Barteau observed that during the coupling of PhCOMe on reduced TiO_2 surfaces, the pinacol product was evolved at much higher temperature than $PhCH{=}CH_2$; this result was interpreted by the formation of pinacolate species at protected sites which are difficult to reduce at low temperature,[30] but it is possible that pinacols and alkenes were produced in parallel rather than sequential processes.[50]

Conclusion

The McMurry reaction represents a versatile transformation which is irreplaceable in organic synthesis. However, the huge interest and great success of this reaction conceal some experimental problems which have to be related to the difficulty in understanding the actual mechanism. Significant progress has obviously been made during the last years in the development of new reagents and methods leading to further interesting applications of low-valent titanium complexes, but these investigations also revealed that the course of the McMurry reaction is more complicated than previously assessed. The structure of the intermediates, pinacolate and/or carbenoid species, is strongly dependent on the nature of the carbonyl substrate, the titanium compound, the reducing agent and the by-products. At each stage of the process, the present intermediates can undergo side reactions which would affect the eventual formation of 1,2-diols or alkenes and give rise to problems of reproducibility. Other important aspects of the mechanism, for example the deoxygenation of the pinacolate intermediates and the role of additives in the stereoselectivity, are even more obscure. No doubt these questions will not discourage chemists, but rather incite them to consider the fascinating McMurry reaction with a more critical view.

Acknowledgments

I thank my colleagues and co-workers, whose names appear in the references, for their valuable contributions to this work.

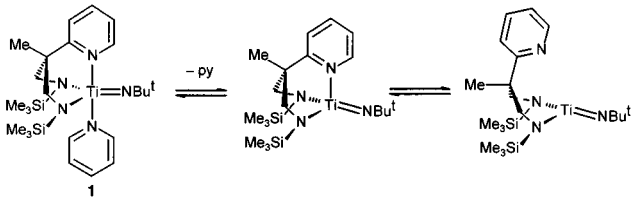
Received (in Cambridge, UK) 7th September 1998, Accepted 6th October 1998

Reaction of an imidotitanium complex, stabilized by a tridentate diamidopyridine ligand, with the methyl acetylenes MeC_2Me and MeC_2Ph led to C–H-activation of the substrate and subsequent C–N coupling to give azatitanatetracycles which may be viewed as dimetallated enamines; the same compounds were obtained in reactions with the allenes $Me(H)C{=}C{=}CH_2$ and $Ph(H)C{=}C{=}CH_2$.

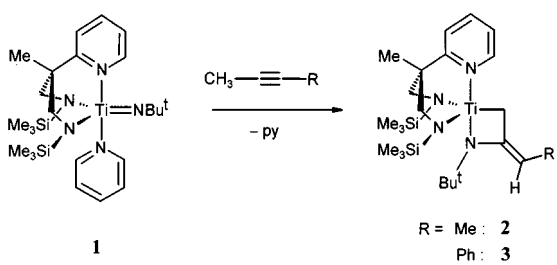
We have shown previously that the coordination of the diamidopyridine ligand system developed previously by us[1] to titanium leads to stable monomeric imidotitanium complexes such as **1**.[2] Compound **1** posseses labile pyridine and pyridyl functionalities that, under appropriate reaction conditions, may dissociate to yield an unsaturated and highly reactive imido complex of the type hitherto generally only accessible *via* irreversible thermolysis of certain precursors.[3] The facile accessibility and stability of **1** and its homologues has allowed us to undertake a systematic investigation into their reactivity, in particular C–N coupling with unsaturated hydrocarbons.



1

Heating compound **1** dissolved in neat but-2-yne or 1-phenylpropyne at 80 °C for 10 days in a sealed tube led to its complete conversion to the novel complexes **2** and **3** (Scheme 1), respectively which were isolated by direct crystallization from the reaction mixture (yields: **2** 73%, **3** 70%).

Neither **2** nor **3** contain the auxiliary pyridine ligand present in the starting material and the ^1H and ^{13}C NMR spectra indicate a transformation of a methyl group of the acetylene substrate.§Thus, new resonances for a metal bound CH_2 group were observed [$\delta(^1H/^{13}C)$ **2**: 1.77/62.4; **3**: 2.03/63.6] as well as those for an olefinic CH unit [$\delta(^1H/^{13}C)$ **2**: 4.76/86.7; **3**: 5.86/96.4]. This led to the formulation of the reaction products as depicted in Scheme 1. Unambiguous evidence for this new structural type was obtained from a single crystal X-ray structure analysis of **2** the result of which is depicted in Figure 1.¶



1

Scheme 1

The coordination geometry of the molecule is distorted trigonal bipyramidal. The two amido functions of the tripodal ligand as well as the alkyl C-atom C(45) occupy the equatorial sites while the pyridyl N-atom and the amido-N atom derived from the imido ligand represent the axial ligating atoms. The N(4)–Ti vector is significantly tilted towards the equatorial plane [N(4)–Ti–C(45) 67.6(2)°] as a consequence of the small bite angle of the coordinated chelating metalla-enamine. The bond lengths and interbond angles within the C–N-coupled organic fragment clearly support its interpretation as a metallated enamine with C(45)–C(46) 1.515(9) Å and C(46)–N(4) 1.404(8) Å representing single bonds and C(46)–C(47) 1.338(9) Å being consistent with a C–C-double bond. The {TiN(Bu^t)C(=CHR)CH_2} metalla-azetidine fragment in **2** and **3** is the first crystallographically authenticated example of this structural unit. Related oxo-metallacyclic species (*i.e.* metallaoxetanes) have only recently been fully characterized, namely [Ti(η^5-C_5Me_5)$_2${OC(=CH_2)CH_2}],[4a] [Mo(NBu^t)$_2$-Cl{OC(=CHPPh_3)CPh_2}],[4b] and [Ru(PMe_3)$_4${OC(=CH-Bu^t)CH_2}].[4c] Interestingly, the latter two complexes have a *Z*-configuration for the exocyclic C=C bond, whereas the configuration in **2** and **3** is *E*, presumably due to the steric influence of the N-*tert*-butyl group.

Although the conversion to the reaction products **2** and **3** proceeds slowly it is remarkably selective and could be monitored by ^1H NMR spectroscopy in C_6D_6. The fact that no deuterium was incorporated into the products suggests that the

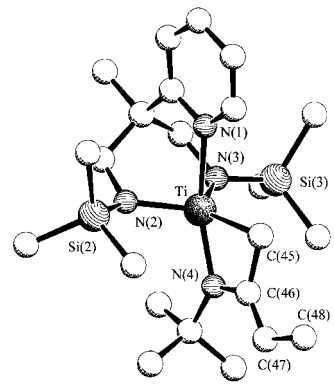


Fig. 1 Molecular structure of [TiL(NBu^t)C(CH_2)CHMe] **2**. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ti–N(3) 1.890(5), Ti–N(2) 1.903(5), Ti–N(4) 1.949(6), Ti–C(45) 2.149(7), Ti–N(1) 2.232(6), N(4)–C(46) 1.404(8), C(45)–C(46) 1.515(9), C(46)–C(47) 1.338(9), C(47)–C(48) 1.532(9), N(3)–Ti–N(2) 110.5(3), N(3)–Ti–N(4) 107.3(3), N(2)–Ti–N(4) 106.3(2), N(3)–Ti–C(45) 121.6(3), N(2)–Ti–C(45) 127.1(3), N(4)–Ti–C(45) 67.6(2), N(3)–Ti–N(1) 86.1(2), N(2)–Ti–N(1) 83.9(2), N(4)–Ti–N(1) 158.3(2), C(45)–Ti–N(1) 90.9(3), C(46)–C(45)–Ti 88.2(4), C(47)–C(46)–N(4) 131.3(7), C(47)–C(46)–C(45) 125.6(7), N(4)–C(46)–C(45) 103.0(6), C(46)–C(47)–C(48) 123.7(8).

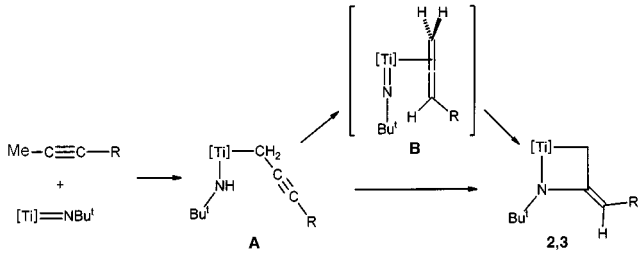
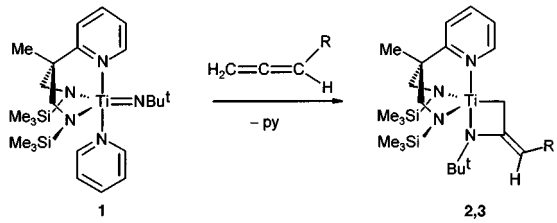


Scheme 2

hydrogen transfer involving the reaction medium does not take place. A reasonable reaction mechanism based on these results is depicted in Scheme 2.

In a first reaction step (formation of intermediate **A**) the Me-group of the methyl acetylene adds across the Ti=NR bond generating an R(H)N-amido ligand and a Ti–alkyl unit.‖ Such C–H bond activation reactions of transiently generated imido compounds have been studied extensively by Wolczanski and others in recent years.[3] In a proposed second step, H atom transfer to an acetylene C-atom leads to the re-formation of the imido unit and a π-bonded allene ligand (**B**).** These fragments couple in the third and final step to give the four-membered azatitanacycle present in **2** and **3**. Supporting evidence for this third step was obtained independently by reacting compound **1** with 1-methylallene and 1-phenylallene, respectively. In both cases the same reaction products (*i.e.* **2** and **3**, respectively) as those described above were obtained (Scheme 3). We would like to point out that, alternatively, intermediate **A** may also be directly converted to the metallacycle.



Scheme 3

The reactions of **1** with MeC≡CR and CH_2=C=CHR to form **2** and **3** are the first examples of such transformations in transition metal chemistry. Although reactions of imido complexes with internal alkynes to form metallacycles [L_nM{N(R)C(R)=CR}] are known,[7] no examples of the activation of sp^3 C–H bonds in preference to forming the simple cyclization products have been described.[8] The reaction of **1** with allenes to form a metalla-azetidine is the first fully characterized example of this type for imido complexes, although very recently the reaction of [Ti(η^5-C_5Me_5)$_2$(O)(py)] with allene to form [Ti(η^5-C_5Me_5)$_2${OC(=CH_2)CH_2}] was described.[4a]

In the more general context of organic synthesis *via* organometallics, the remarkable products of a C–N coupling reaction may be viewed as dimetallated enamines. In view of the known chemistry of *mono*-metallated enamines[9] as well as the reactive patterns established for Ti–C units,[10] a rich and varied organic chemistry is expected to derive from these preliminary results.

On intrinsic and extrinsic defect-forming mechanisms determining the disordered structure of 4-iodo-4′-nitrobiphenyl crystals

J. Hulliger* and P. J. Langley

Department of Chemistry and Biochemistry, University of Berne, Freiestrasse 3, CH-3012 Berne, Switzerland. E-mail: juerg.hulliger@iac.unibe.ch

Received (in Cambridge, UK) 4th September 1998, Accepted 12th October 1998

Following up two recent *Chemical Communications* on the structure of the title compound, a theoretical study confirms that the presence of 4,4′-dinitrobiphenyl as an impurity can give rise to disordered crystals, resulting from a chain inversion mechanism.

Recent issues of this journal have contained communications[1,2] on the disordered crystal structure of 4-iodo-4′-nitrobiphenyl (INB), in which the INB molecules pack as parallel and polar ribbons (mm2). From the original viewpoint of designing efficient nonlinear optical (NLO) materials,[1] this type of packing of dipolar entities represents an interesting and relatively seldom case[3] of a material in which all the β_{zzz} axes of the molecular hyperpolarisability β are aligned co-parallel.

The difficulties encountered initially by Sarma *et al*.[1] in obtaining a reliable structural model from X-ray data were resolved more recently by Masciocchi *et al*.[2] and Langley *et al*.[4] through careful sample purification. In interpreting the data of Sarma *et al*., the Milan group[2] identified two possible causes of defect formation in INB: (i) polarity inversion of single ribbons (chains) of INB in the presence of 4,4′-dinitrobiphenyl (DNB) impurity molecules (in analogy to 180° opposed polar macrodomain formation in perhydrotriphenylene inclusion compounds[5]); (ii) two dimensional polytypes, *i.e*. a defect paracrystal composed of many fine grains. The effect of impurity molecules on the NLO characteristics of a host crystal has been demonstrated earlier by Weissbuch *et al*.[6,7] Whilst the mechanisms which permit the favourable creation of such defects at growing crystal faces are mainly well understood,[6,7] the subsequent fates of these faults, and their distribution throughout the structures of the resulting bulk crystals, often remain elusive.

Here we discuss further using energetic arguments the relative likelihood of *intrinsic* (180° orientational disorder) and *extrinsic* [due to DNB and/or 4,4′-diiodobiphenyl (DIB) impurities] defect formation in INB, and the likely true structure of INB which results. Attachment processes during the assembly of INB crystals are driven by the alignment of INB into parallel chains, as well as collinear functional group interactions ($NO_2\cdots$I, I$\cdots$I) between molecules already attached at the {001} surfaces and incoming INB, DNB or DIB molecules (Fig. 1). The total attachment energy E_{att} per molecule in the $+c$ or $-c$ direction contains contributions from lateral and long-range interactions between chains, as well as short-range collinear interactions between the terminal moieties. With respect to the former, we can make a distinction between E_p (parallel) and E_{ap} (antiparallel), that is, the energies corresponding to preferred and defect modes of lateral attachment, respectively (Fig. 1). Values E_{AD} , E_{DD} for the terminal intermolecular interaction energies of isolated, collinear $NO_2\cdots$I (A$\cdots$D) and I$\cdots$I (D$\cdots$D) synthons have been calculated to be -5.7 (3.4 Å) and -2.8 (4.0 Å) kJ mol^{-1}, respectively.[8] The $NO_2\cdots O_2N$ (A$\cdots$A) intermolecular interaction is considered a defect configuration of low occurrence[6,8–9] because a positive interaction energy E_{AA} of $\sim$10 kJ mol^{-1} was estimated for a van der Waals contact of 3.4 Å.[8]

Intrinsic defects, *i.e*. those resulting from 180° orientational disorder during the assembly of a pure INB system, can occur at the growing faces (Fig. 2). For growth along the $+c$ and $-c$ directions, there are two non-degenerate configurations for defect attachments, represented by the energies ΔE_{defect} ($+c$ or $-c$). As a result of a Schottky-type calculation[9] accounting for the molar fraction x of orientational defects, we find that: (i) the temperature of crystal growth can significantly affect the concentration of defects; and (ii) a perfect seed crystal will during growth segregate into two adjacent volumes containing a different number of defects. The ratio of the orientational defects within these two domains can be estimated using the intermolecular interaction energies given above: $x(+c)/x(-c) \cong \exp[(E_{AA} - E_{DD})/RT]$. Since the intermolecular interaction $NO_2\cdots O_2N$ is strongly endothermic, $x(+c)/x(-c)$ is expected to vary between *ca*. 170 and 20 (300–510 K). Continuation of growth along both *c*-directions after defect formation gives rise to one of two different phenomena: *healing* (correction) of the defect or *chain inversion* (Fig. 3). With each phenomenon there are again associated two different energies, corresponding to the two different growth directions $+c$ and $-c$ [see eqn. (1) below].

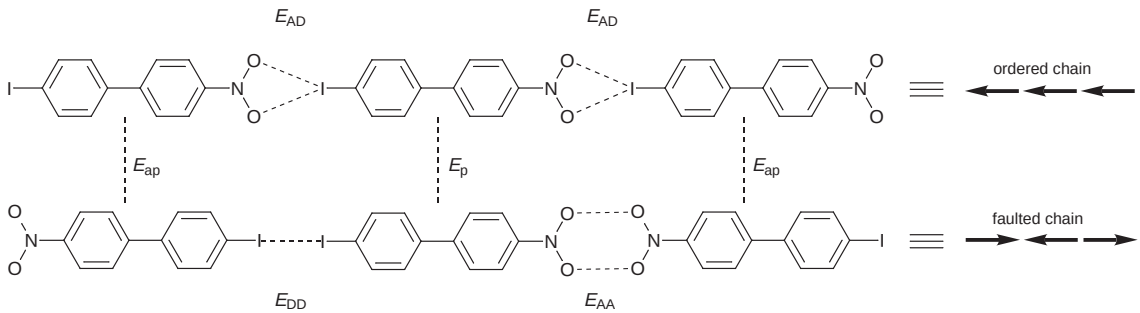

Fig. 1 Model representation of ordered and intrinsically disordered molecular chains of INB. This figure is used to illustrate the interaction energies (positive or negative; represented by dashed lines) under consideration during packing. Definition of interaction energies: $E_p \equiv$ lateral and long-range interactions between molecules (excluding collinear short-range contributions of terminal functional groups) whose dipoles are oriented co-parallel; $E_{ap} \equiv$ same as E_p but between dipoles oriented antiparallel; E_{AD}, E_{DD}, $E_{AA} \equiv$ collinear intermolecular terminal functional group interactions A$\cdots$D, D$\cdots$D, A$\cdots$A, respectively. A and D are defined in the main text. Subsequent figures employ the symbol $\rightarrow$ as a simplified representation of INB, corresponding to the intramolecular dipole orientation $O_2N\rightarrow$I.

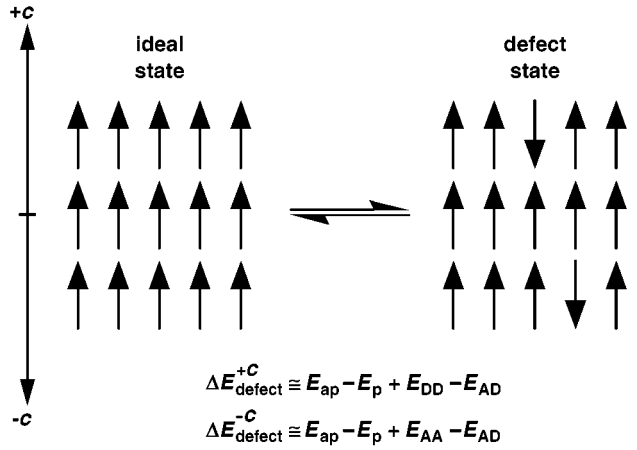

Fig. 2 Intrinsic orientational defect equilibrium at growing faces ($+c$, $-c$) of a polar crystal such as INB.

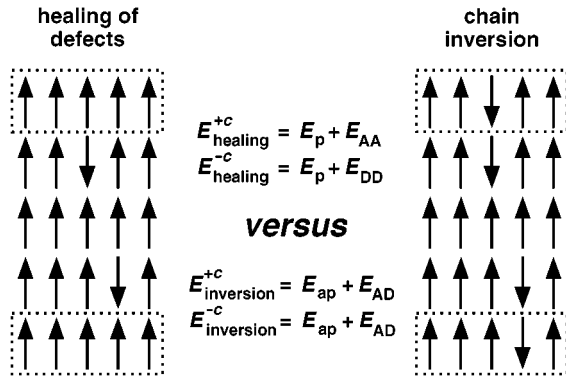

Fig. 3 Healing of defects *versus* chain inversion within the next growth layer after occurrence of primary (intrinsic) defects.

Extrinsic defects can arise due to solid solution formation of INB with DNB or DIB (Fig. 4). In the case of these symmetrically disubstituted components, the preferred mode of incorporation is driven only by the relative strengths of the terminal functional group intermolecular interactions. At an impurity level (in solution) of *ca*. 0.1, both DNB and DIB are incorporated into the growing crystal structure with different degrees of probability with respect to the $+c$ and $-c$ directions. From simplistic energy considerations it can be shown that when healing intrinsic defects, DNB attaches preferentially to defect sites along $-c$ whilst DIB attaches along $+c$. Conversely, when DNB and DIB are the defects themselves, preferred incorporations are along $+c$ and $-c$, respectively (Fig. 4).

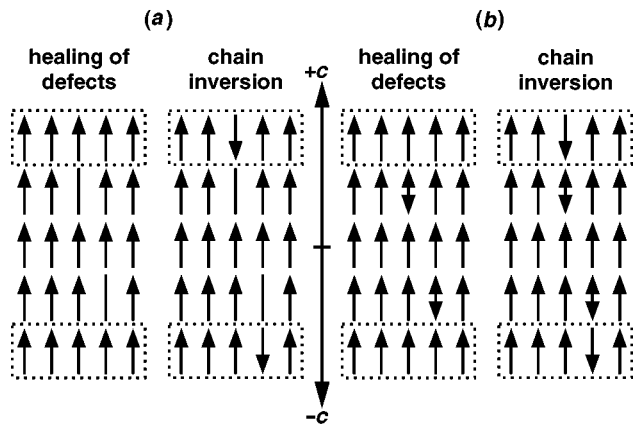

Fig. 4 Influence of DNB (—) or DIB (↔) impurities on subsequent growth layers: (*a*) healing *versus* chain inversion after preferred incorporation of DNB in the $+c$ direction; (*b*) similar scheme for DIB, where in the $-c$ direction favourable induction of a chain inversion may occur.

Which of healing or chain inversion by INB molecules in the next growth layer is the more probable is still, of course, a function of both defect (DNB or DIB) and growth direction ($\pm c$). At x_1(DNB) $\approx$ x_1(DIB), DIB can serve to heal the defects created by DNB and *vice versa*.

In the realistic case reported by Masciocchi *et al.*[2] a more complicated situation arises: preferred attachments of DNB present in the growth medium will occur along $+c$ but healing by INB in the next layer would involve unfavourable $NO_2 \cdots O_2N$ intermolecular interactions. If at this point we allow for an inversion of single chains, the energy $E_{inversion}$ would at each layer have to be lower than the energy of a configuration providing healing by antiparallel attachments (Fig. 4). The corresponding energy difference between is then given by eqn (1).

$$\Delta E(+c, \text{DNB}) \equiv E_{inversion} - E_{healing} \cong -RT\ln x(+c) + 2E_{AD} - E_{AA} - E_{DD} \quad (1)$$

The logarithmic term refers to the concentration of intrinsic defects in pure INB crystals from which an estimate of the unknown difference $E_{ap} - E_p$ has been derived. Using the calculated energy values given above it follows that chain inversion is more stable [$\Delta E(+c) < 0$] as long as the concentration of intrinsic defects in pure INB crystals (300 K) is larger than about 6×10^{-4}. A $wR2$ value of 0.032 (crystal 1 in ref. 2; see also ref. 4) sets an upper limit for $x(+c)$ to a range of a few percent. Although a lower limit cannot be extracted from the present X-ray data, we consider it a reasonable estimate that $x(+c)$ is larger than $\sim 6 \times 10^{-4}$ ($\Delta E_{defect} \leqslant 18.6$ kJ mol^{-1}).

In view of our calculations, we conclude that chain inversion provides a mechanism to continue attachments at sites where preferred intrinsic defects or substitutions by DNB have been formed. Conversely, continuation of attachments at non-preferred sites by DNB is more favoured by healing. Both primary and secondary defect formation contribute to the disordered structure of INB and possibly other structurally similar materials (*i.e.* A,D-disubstituted rod-like molecules). The main conclusion of this work is in agreement with the experimental results and mechanistic proposition given by Masciocchi *et al.*[2] However, the true structure is such that about one half ($+c$) of the crystal volume should show a significant concentration of DNB defects continued by chain inversion, whereas the other half ($-c$) should exhibit diffraction phenomena similar to a well-ordered, monodomain crystal.

We thank Dr O. König (Molecular Simulations Ltd., Cambridge, UK) for the calculated interaction energies. This work has been supported in part by the Swiss National Science Foundation (project no. 21-50828.97).

Combinatorial 'library on bead' approach to polymeric materials with vastly enhanced chiral recognition

Peter Murer, Kevin Lewandowski, Frantisek Svec and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, CA 94720-1460, USA.

Received (in Corvallis, OR, USA) 11th August 1998, Accepted 21st October 1998

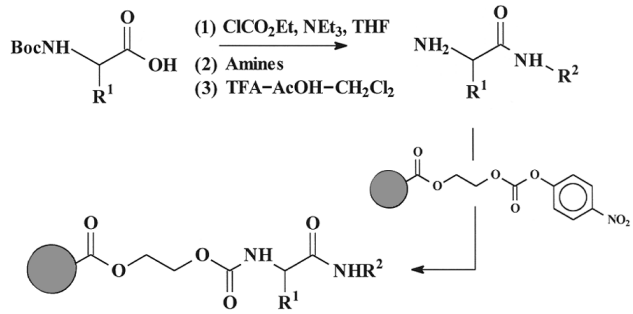
A general screening method for enantiomer recognition is introduced for the rapid preparation of novel chiral stationary phases for HPLC in which libraries of mixed chiral selectors are immobilized on polymer beads and the resulting chiral phases tested in the separation of racemic targets followed by deconvolution to afford an optimized separation medium.

Although it is well known that each enantiomer of a chiral compound may exhibit different biological activities, a number of commodity products and fine chemicals, such as drugs, agrochemicals, flavors, fragrances, and pheromones, are currently used in the form of racemic mixtures.[1] Therefore, the general trend is to replace these mixtures with single enantiomers that can be obtained directly, either by an asymmetric synthesis or by the resolution of racemates. In addition, for newly designed drugs, it may be necessary to obtain both enantiomers for pharmacological and toxicological studies. Among the separation techniques, resolution by high-performance liquid chromatography (HPLC) utilizing chiral stationary phases (CSPs) has advanced considerably in the past decade. The preparation of CSPs capable of effective enantiomer recognition is the key to this separation technique. Therefore, many CSPs for HPLC have been prepared and about 100 have been commercialized. Most are derived from various matrix-bound chiral selectors including transition metal complexes,[2] proteins,[3] antibiotics,[4] synthetic polymers and polysaccharides,[5] cyclodextrins and crown ethers,[6] or the π–π donor–acceptor complexes—'brush'-type separation media—pioneered by Pirkle.[7] Given the boundless structural and functional diversity of chiral molecules, no CSP is 'universal' and the separation of new targets may well mandate the development of new optimized complementary CSPs. Our combinatorial methods are aimed at the rapid preparation of tailor-made CSPs designed for a specific racemic solute.

Combinatorial chemistry is a very powerful tool for the preparation of large numbers of related compounds in a short period of time.[8] Today, this approach is a well-established technique used mainly to accelerate the drug discovery process. Combinatorial methods have also recently been used for the discovery of new materials.[9] Attempts to use combinatorial techniques in chromatography have focused on the field of the affinity separations employing the well-known interactions of peptides with target proteins. Typical screening methods have been used to select the most specific affinant with the highest binding constant from libraries of oligopeptides.[10]

We now report a combinatorial approach to the accelerated preparation of highly selective chiral separation media for HPLC based on chemically flexible 'brush'-type chiral selectors. The feasibility of our concept is demonstrated on model systems that involve π-basic selectors since the starting materials for these selectors are readily available in a large variety of chemistries.

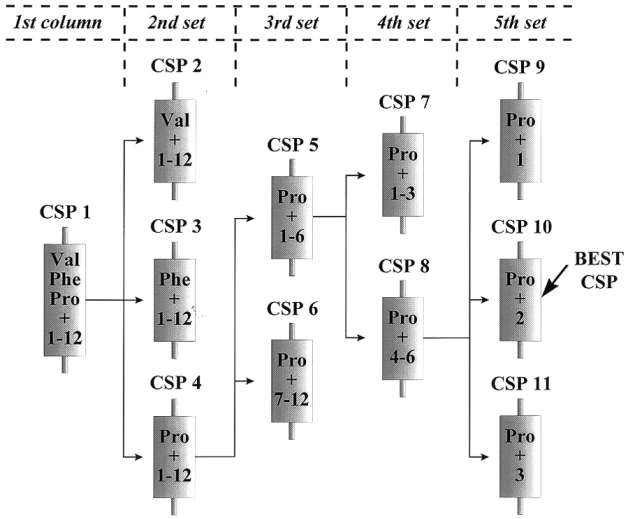
Our combinatorial approach involves the attachment of a mixed library of potential selectors to an optimized polymer support[11] followed by on-column screening for enantioselectivity, and deconvolution to identify the single best selector. A small library of amides is prepared by reaction of *N*-Boc-protected L-amino acids with a mixture of aromatic primary amines using an active ester coupling procedure (Scheme 1).† After deprotection of the amino terminus, reaction of the mixed amide library with 5 μm macroporous 4-nitrophenyl carbonate activated poly(2-hydroxyethyl methacrylate-*co*-ethylene dimethacrylate) beads[11] leads to a chiral separation medium (CSP 1) with a multiplicity of polymer-bound selectors. Synthetic polymer beads were used in this study because they provide CSPs with higher selectivities than silica as a result of the elimination of non-specific interactions.[11,12] After packing these beads into a HPLC column, selectivity is assayed by injecting various racemates of chiral targets. Although the use of columns with mixed selectors is normally not recommended for actual enantioseparations[13] it is ideally suited for our combinatorial discovery of optimized selectors.



Scheme 1

The feasibility of this 'library-on-bead' approach is demonstrated with a small model library of 36 compounds prepared by reaction of a mixture of three L-amino acids (valine, phenylalanine and proline) with 12 aromatic amines (3,4,5-trimethoxyaniline **1**, 3,5-dimethylaniline **2**, 3-benzyloxyaniline **3**, 5-aminoindane **4**, 4-*tert*-butylaniline **5**, 4-biphenylamine **6**, 1-aminonaphthalene **7**, 4-tritylaniline **8**, 2-aminoanthracene **9**, 2-aminofluorene **10**, 2-aminoanthraquinone **11** and 3-amino-1-phenyl-2-pyrazolin-5-one **12**) (Scheme 2).† Both proline and dimethylaniline are included in the library design since previous work had shown their value in the preparation of efficient CSPs.[11,12,14] Despite the presence of 36 mixed selectors within the same column, CSP 1 separates DL-(3,5-dinitrobenzoyl)leucine diallylamide‡ and other substituted amino acid amides confirming the validity of the mixed selector approach. To determine which of the 36 selectors is the most powerful, a deconvolution process involving the preparation of beads with a progressively smaller number of selectors was used. Separation factors $\alpha = (t_2 - t_0)/(t_1 - t_0)$ where t_0 is the retention time of an unretained compound (column void volume determined using 1,3,5-tri-*tert*-butylbenzene as a marker) and t_1 and t_2 are the retention times of the individual enantiomers were calculated for all the separations to demonstrate the selectivity.

In the next step, each single amino acid was coupled separately with the set of 12 amines resulting in three new polymer-based CSPs (CSP 2–CSP 4). The highest separation factor α of 13.7 was found for the proline-based column while



Scheme 2

the α values for the other two columns are close to 5. For the preparation of the third set of columns (CSP 5 and CSP 6), two proline based sub-libraries of selectors were prepared from two six-member groups of amines (**1**–**6** and **7**–**12**) and the respective columns exhibited selectivities of 13.6 and 7.3. In the next step, the six amines present in the more selective column CSP 5 were divided into two groups (**1**–**3** and **4**–**6**) and the columns CSP 7 and CSP 8 exhibited rather high α values of 17.4 and 14.9, respectively. The separation results indicate that both groups of three selectors include at least one with a very high selectivity. CSP 7 that affords somewhat higher selectivity was further deconvoluted. Three columns CSP 9–CSP 11 packed with beads containing only individual selectors were prepared. Although two of these columns (10 and 11) do not exhibit high separation factors (2.5 and 3.6, respectively), an α value of 24.7 was achieved with CSP 9 that features dimethylaniline **2** as a part of the proline selector. The rapid increase in the separation factors reflects not only the improvement in the intrinsic selectivities of the individual selectors, but also the effect of increased loading with more efficient selectors since the overall selector loading determined from nitrogen content remains virtually constant at about 0.7 mmol g^{-1} for all CSPs 1–12. NMR spectra indicate that none of the selectors binds preferentially to the support during the reaction of their mixtures.

A classical 'one column, one selector' approach would require the preparation and testing of 36 CSPs modified with each individual selector. In contrast, our combinatorial scheme documents that the parallelism advantage results in the discovery of a novel highly selective CSP from the same group of 36 selectors using only 11 columns, *i.e.* less than one third. In addition, an unlimited number of racemates may be screened through the various columns. The advantage of the mixed selector column approach becomes even more convincing with much larger sets of selectors. For example, a simple calculation reveals that the use of all 20 natural amino acids with the same 12 amines would lead to a library of 240 selectors that could be deconvoluted using only 17 columns. The question now arises as to what is the highest number of selectors that may be used simultaneously in the first column. It seems that there is no limitation from a chemical point of view. However, in a hypothetical situation in which only a single selector is active and all of the compounds are attached to the beads in equal amounts, the percentage of the active selector in the mixture decreases rapidly and despite its high specific selectivity (separation factor at a loading of 1 mmol g^{-1}), the actual selectivity of a CSP with mixed selectors may be rather small and may even vanish within the limits of experimental errors. Although the sensitivity of the chromatographic screening may somewhat limit this approach, the number of selectors that may be screened in a single column is still impressive. Obviously, the libraries of columns resulting from this approach may be used time and again for the separation of the racemates of a variety of chiral targets.

Funding of this research by the National Institute of General Medical Sciences, National Institutes of Health (GM-44885) is gratefully acknowledged. P. M. thanks the Swiss National Science Foundation for a postdoctoral fellowship.

Notes and references

† The *N-tert*-butoxycarbonyloxy-protected (Boc) amino acids (7.0 mmol) were dissolved in THF (35 ml), cooled and triethylamine (7.0 mmol) and $ClCO_2Et$ (7.0 mmol) were added slowly by syringe. After stirring at −15 °C for 1 h, a cold (−15 °C) mixture of equimolar amounts of the desired aromatic amines (total amount of amines = 7.0 mmol) in THF was admixed. Stirring continued at −15 °C for 1 h and at room temperature overnight. The organic phase was washed, dried over $MgSO_4$ and concentrated to afford the product. This product was dissolved in CH_2Cl_2 cooled to 0 °C, and treated with 1:1 mixture of TFA–AcOH for 12 h. Extraction and drying under high vacuum afforded the deprotected product mixture as a colored solid in near quantitative yield. Integration of the individual ^1H NMR signals for the amide hydrogen atoms of the compounds indicates that all expected products were formed. Et_3N (15 mmol) was added to a slurry of 4-nitrophenyl carbonate-activated poly(2-hydroxyethyl methacrylate-*co*-ethylene dimethacrylate) beads (1.6 g) (ref. 11) in THF at 0 °C. The solution of the selector mixture obtained from the deprotection step in THF was added slowly to this suspension and stirring was continued at room temperature for 3 h and then at 60 °C overnight to afford the chiral stationary phases.

‡ The chiral stationary phases were slurry packed at a constant pressure of 15 MPa into 150 × 4.6 mm i.d. stainless steel columns. Chiral separations were carried out in normal-phase mode using a 1:4 (v/v) hexane–CH_2Cl_2 mixture as the mobile phase.

Remarkable matrix effect in polymer-supported Jacobsen's alkene epoxidation catalysts

Laetitia Canali,[a] Elaine Cowan,[a] Hervé Deleuze,[b] Colin L. Gibson[a] and David C. Sherrington*[a]

[a] *Department of Pure and Applied Chemistry, Thomas Graham Building, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL. E-mail: m.p.a.smith@strath.ac.uk*

Received (in Liverpool, UK) 2nd September 1998, Accepted 16th October 1998

Adaptation of the polymer matrix has allowed high enantioselectivity to be achieved for the first time with a polymer-supported chiral Mn^{III}(salen) alkene epoxidation catalyst.

Previous attempts to immobolise Jacobsen's chiral Mn^{III}(salen) asymmetric alkene epoxidation catalyst[1,2] on polymer resins have focussed on copolymerisation of distyryl derivatives of chiral salen ligands, such that the Mn complex formed is essentially localised on a crosslink.[3,4] Perhaps not surprisingly the steric restriction of this system has led to disappointingly low levels of enantiocontrol in epoxidations. Our own first attempt to develop a polymer-supported system was also rather disappointing,[5] but encouraged us to believe that providing the following design criteria could be met, a highly active and selective heterogeneous catalyst should result: (i) the local molecular structure of the Mn complex should mimic precisely the optimum structure of Jacobsen's catalyst; (ii) the complex should be attached by a single flexible linkage to the polymer support to minimise local steric restriction; (iii) the catalyst should be attached to the polymer with sufficiently low loading to maximise site isolation of catalytic centres, hence minimising the possibility of inactive oxo-bridged dimer formation; and (iv) the morphology of the support should be such that no mass transfer limitation arises, with all active sites freely accessible. We now report on the synthesis and application of a number of polymer-supported analogues of Jacobsen's catalyst developed on the basis of the above criteria.

Polymer resin catalysts **P1**–**P5** were synthesised as shown in Scheme 1 to yield Mn complex loadings (calculated from Mn content determined by inductively coupled plasma absorption) of 0.35, 0.17, 0.08, 0.34 and 0.22 mmol g^{-1} respectively. The styrene-based resins used to prepare **P1** and **P2** employed *p*-acetoxystyrene as a functional co-monomer, commercial divinylbenzene (80% DVB grade) as the crosslinker, with styrene itself making up the co-monomer balance. The methacrylate-based resin forming the basis of **P3** likewise used *p*-acetoxystyrene as the functional co-monomer, ethane-1,2-diyl dimethacrylate as the crosslinker, and methyl methacrylate as the co-monomer balance. **P4** was derived from a resin prepared from *p*-hydroxyphenylmaleimide, divinylbenzene and styrene, while **P5** was synthesised from a resin made from 3-methacryloyoxy-2-hydroxybenzaldehyde,[7] ethane-1,2-diyl dimethacrylate and methyl methacrylate. Polymerisation compositions and resin parameters are shown in Table 1. The yields of high quality beads were good and along with subsequent chemical derivatisation confirmed good incorporation of each functional

[a] See note †. [b] Determined by GC after 2 h using PhBr as internal standard. [c] Determined by HPLC using Diacel CHIRACEL OJ column (hexane–Pr^iOH, 90:10, as eluent). [d] Absolute configuration confirmed by polarimetry. [e] Jacobsen's catalyst used as supplied from Aldrich.

co-monomer. In the case of the precursors to resin catalysts **P1**–**P3** the acetoxy group was cleaved with NH_2NH_2 and the sodium salt of the liberated phenol reacted with 3-*tert*-butyl-5-chloromethyl-2-hydroxybenzaldehyde.[4] The sodium salt of the phenolic precursor to **P4** was similarly derivatised. In all cases the immobilised salicylaldehyde residues were further elaborated as in Scheme 1. Interim elemental microanalysis of beads at various stages of the catalyst synthesis, and model reactions using 5-bromo-2-hydroxybenzaldehyde instead of the di-*tert*-butyl analogue, confirmed the success of the stepwise synthesis of the catalysts, and indicated typically ⩾90% of salen ligands to be attached pendantly (extensive details will be presented in due course in a full paper[11]). Interestingly the reactions can be monitored superficially by the succession of characteristic colour changes of the beads; acetoxy resin, white; phenolic resin, cream; phenoate resin, pale pink; salicylaldehyde resin, sandy yellow; mono-Schiff-base resin, yellow; salen resin, yellow; Jacobsen resin, dark brown.

Asymmetric epoxidations of 1-phenylcyclohex-1-ene were carried out in CH_2Cl_2 at 0 °C using MCPBA as the oxidant, and NMO as the activator. The conditions employed were typical of those reported in the use of the soluble catalyst.[6] The results obtained are shown in Table 2. In the case of polymer catalysts **P4** and **P5** both the yield and enantiomeric purity of the epoxide product are very low. With **P5** we believe this is so because attachment of the chiral Mn^{III}(salen) complex to the support is *via* the position *ortho* to the phenolic OH on one of the aromatic rings. The synthetic route to this species is facile, cost effective, and offers a highly structurally pure polymer catalyst. We had hoped the local steric restriction might reinforce the enantioselectivity. In practice this seems not to be so, and the local congestion seems so high as to inhibit any significant approach to the Mn centre, let alone an enantiocontrolled one. The poor performance of **P4** is less easily explained. The polymer matrix from which this is derived was synthesised using 60 mol% divinylbenzene crosslinker and 20 mol% *p*-hydroxyphenylmaleimide with a high level of porogen present (Table 1). The porosity characteristics suggest that mass transfer to the interior of this rather heavily crosslinked species should nevertheless be quite good. Since styrene and maleimide display a high tendency to form a 1:1 alternating copolymer structure, despite the modest loading of functional co-monomer, these residues may well therefore be in close proximity to each other in the matrix. Consequently bimolecular deactivating reactions between Mn centres might be encouraged. Since the phenylmaleimide residue is likely to be a rather rigid segment in the matrix backbone, both of these factors seem to have conspired to produce low catalytic activity and selectivity. The performance of the gel-type styrene-based resin **P1** is much better. The enantioselectivity achieved (61% ee) is as good as any previous data in the literature for polymer-supported species of this type, and far better than our earlier attempt with a gel-type resin.[5] In the latter case the polymer catalyst also displayed low activity, suggesting that deactivating dimerisation of the Mn^{III} centres was occurring. With catalyst **P1** the Mn loading level and morphological characteristics are not too different to our earlier gel-type species, but the attachment to the polymer matrix is quite different. Previously the linkage had been *via* an ether group at the position *meta* to the phenolic OH on one of the aromatic groups of the salen.[5] With **P1** the linkage is *via* an oxymethylene at the position *para* to the phenolic OH. Bearing in mind the sensitivity of these chiral salen ligands to the pattern and nature of the substitution on the aromatic rings, this simple change alone may well account for the improved catalytic performance of the gel-type species **P1**. Interestingly, catalyst **P2** is chemically similar to **P1** both in terms of the local structure in and around the catalytic centres, the Mn loading, and in terms of the longer range environment. It differs only in having a (macro)porous morphology rather than a gel-type one. Its dry porosimetry characteristics suggest mass transport should be quite good. Both the activity and enantioselectivity displayed by **P2** are very similar to those of **P1**, and suggest that further manipulations of the morphology of styrene-based resins may not alone offer significant improvement in catalyst activity and selectivity. Catalyst **P3** displays comparable activity to those of **P1** and **P2** under the conditions employed but is significantly more enantioselective (> 90% ee). Indeed the enantiocontrol displayed mirrors that of the soluble catalyst. The experimental ee is significantly higher than that reported to date for any polymer-supported system, and suggests that contrary to earlier findings a practical polymer-supported Jacobsen's catalyst may well be achievable. **P3** is prepared from a heavily crosslinked (macro)porous resin and has rather low loading of Mn sites (0.08 mmol g^{-1}). The dry resin has a good surface area and the porogen employed (toluene) is known to generate rather small pores.[12] Probably of key significance however is that **P3** is derived from a methacrylate-based resin rather than a styrene-based one, although the immediate link to the polymer is *via* a styryl residue. We believe that such a matrix, although macroscopically rigid, has considerably improved local mobility relative to a styrene-based analogue, and of course is of significantly higher polarity. These two factors, coupled with the rather low loading of catalytic sites (0.08 mmol g^{-1}), seem to be key in allowing rapid catalysis and a stereochemical outcome that are essentially analogous to those found with the soluble catalyst.

Notes and references

† Asymmetric epoxidation procedure. Resin beads (0.13 mmol Mn) were poured into a solution containing NMO (15.79 mmol) dissolved in CH_2Cl_2 (25 ml) and evacuated (water pump) for *ca*. 1 min. Phenylcyclohex-1-ene (3.16 mmol) and PhBr (2.04 mmol) were then added and the mixture was cooled to 0 °C. MCPBA (6.32 mmol) was then added in four equal portions over a 2 min period.

Application of Baylis–Hillman methodology in a novel synthesis of quinoline derivatives

Oluwole B. Familoni, Perry T. Kaye* and Phindile J. Klaas

Department of Chemistry, Rhodes University, Grahamstown, 6140, South Africa. E-mail: chpk@hippo.ru.ac.za

Received (in Cambridge, UK) 27th May 1998, Accepted 8th October 1998

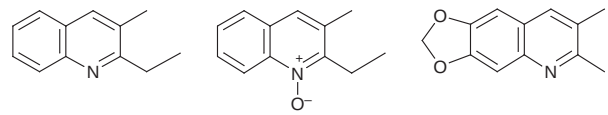
Reaction of 2-nitrobenzaldehyde with vinyl carbonyl compounds in the presence of 1,4-diazabicyclo[2.2.2]octane affords Baylis–Hillman products, catalytic reduction of which results in direct cyclisation to quinoline derivatives.

The Baylis–Hillman reaction has been the subject of two recent reviews[1,2] and continues to elicit attention.[3,4] We have demonstrated applications of this reaction in the synthesis of substituted indolizines from pyridine-2-carbaldehydes[5,6] and, in analogous reactions of salicylaldehydes, have uncovered a veritable cascade of transformations involving the formation of chromene and coumarin derivatives.[7,8] Extension of this general methodology to 2-aminobenzaldehydes was expected to provide access to quinoline derivatives.

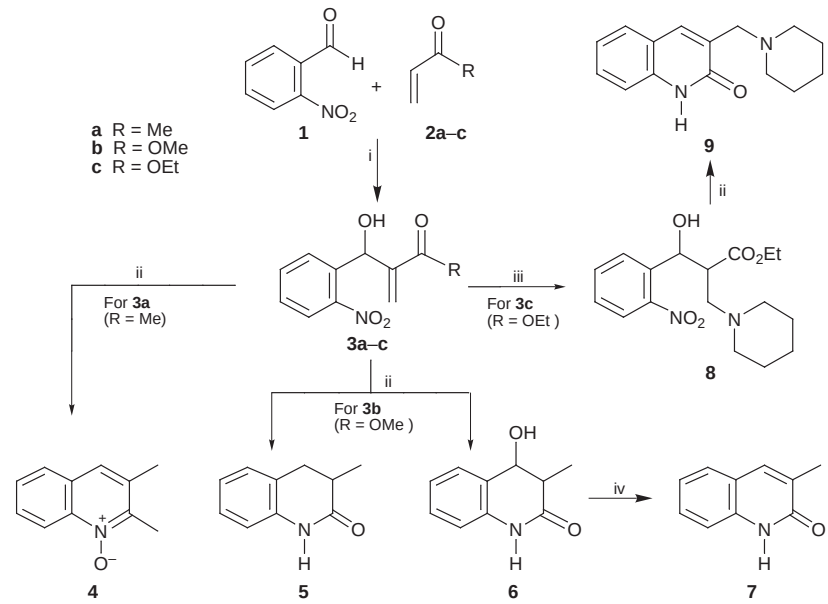
Numerous quinoline syntheses have been developed,[9] including the Friedlander synthesis (and modifications thereof) in which use is made of 2-aminobenzaldehydes. A limiting factor in the Friedlander methodology, however, is the relative inaccessibility of substituted 2-aminobenzaldehydes. This limitation, coupled with the fact that aldehyde electrophilicity is an important factor in Baylis–Hillman reactions,[10] prompted us to explore the use of 2-nitrobenzaldehyde as an activated alternative to 2-aminobenzaldehyde, subsequent reduction of the nitro group being expected to permit cyclisation *via* the resulting amine. Quinolines have, in fact, been obtained previously in yields of 27–30%, by passing mixtures of 2-nitrobenzaldehyde and various alcohols over a heterogeneous catalyst at elevated temperature (300–320 °C).[11] Here we report preliminary results which clearly illustrate the potential of the Baylis–Hillman approach to quinoline derivatives under remarkably mild conditions.

Treatment of 2-nitrobenzaldehyde **1** with methyl vinyl ketone (MVK) **2a**, methyl acrylate **2b** and ethyl acrylate **2c** in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) at, or below, room temperature† afforded the expected Baylis–Hillman products **3a–c** (Scheme 1) in moderate to good yield (68–85%). Several methods of reducing the nitro compounds **3a–c** were examined, the most efficient proving to be catalytic hydrogenation using a 10% palladium on carbon catalyst in EtOH.‡ Reduction of compound **3a** afforded, in 56% yield, a product initially presumed to be 2,3-dimethylquinoline but subsequently identified as the *N*-oxide **4**.§ Hydrogenation of the methyl ester **3b** afforded two cyclised products, *viz*. 3-methyl-2-oxo-1,2,3,4-tetrahydroquinoline **5** (22%) and the 4-hydroxy analogue **6** (59%), the latter as a diastereomeric pair, which could be readily dehydrated (in 70% yield) to the conjugated, achiral 3-methyl-2-quinolinone **7**. The α,β-unsaturated carbonyl moiety in the Baylis–Hillman products **3** is, of course, susceptible to conjugate addition, and treatment of the ethyl ester **3c** with piperidine¶ led to the diastereomers **8**, reduction of which afforded the 2-quinolinone derivative **9**;‖ in this case, cyclisation of the corresponding amino intermediate may only occur *via* acyl substitution. In principle, cyclisation of the reduced, or partially reduced, intermediates may be expected to involve *either* conjugate addition *or* nucleophilic attack at the carbonyl carbon. In practice, the latter path appears to be the dominant, if not exclusive, mode of cyclisation—somewhat surprisingly, given the lack of regioselectivity exhibited by salicylaldehyde analogues.[7,8]

Application of the methodology to the reaction of 2-nitrobenzaldehyde with ethyl vinyl ketone afforded *both* 2-ethyl-3-methylquinoline **10** (25%) *and* the *N*-oxide **11** (31%).



10 **11** **12**



Scheme 1 *Reagents and conditions*: i, DABCO, $CHCl_3$; ii, H_2, Pd-C, EtOH; iii, piperidine, THF; iv, TsOH, toluene, reflux.

Formation of the *N*-oxides **4** and **11** was established, in each case, by FAB MS analysis. Further extension of the procedure to the reaction of methyl vinyl ketone with 6-nitropiperonal gave, amongst other products, the corresponding quinoline **12** (26%).

In summary, application of the Baylis–Hillman reaction to 2-nitrobenzaldehydes provides convenient access to substituted quinoline derivatives which, in turn, constitute useful substrates for further elaboration. The results of ongoing studies, aimed at optimising reaction conditions for the selective formation of the quinolines or their *N*-oxides and exploring the generality of the method, will be reported fully in due course.

We thank the Foundation for Research Development (FRD) and Rhodes University for generous financial support, the University of Lagos, Nigeria, for study leave (to O. B. F.), Dr W. E. Molema for assistance with NMR analysis and Dr L. Fourie (University of Potchefstroom) for FAB MS data.

Notes and references

† In a typical Baylis–Hillman reaction, a solution of 2-nitrobenzaldehyde **1** (5.0 g, 33 mmol), methyl acrylate **2b** (2.95 g, 34.2 mmol) and DABCO (0.18 g, 1.6 mmol) was stirred in a stoppered flask for 3–7 d. [In the case of methyl vinyl ketone **2a**, the reaction was noticeably exothermic; use of CH_2Cl_2 as solvent and cooling the mixture (*ca*. 0 °C) during addition of the reactants resulted in a significantly cleaner product.] The solvent was evaporated *in vacuo* and the residue chromatographed [flash chromatography on silica; elution with hexane–EtOAc (3:1)] to give **3a** (6.78 g; 85%).

‡ Hydrogenation was effected in EtOH at atmospheric pressure using a 10% Pd-C catalyst (wet, Degussa type; as supplied by Aldrich Chemical Co.)

§ *Selected data* for **4**, mp 123–125 °C (Found, by FAB MS, MH^+: 174.09179. Calc. for $C_{11}H_{12}NO^+$, 174.09189.); δ_H(400 MHz; $CDCl_3$) 2.45 (3H, s, 3-Me), 2.68 (3H, s, 2-Me), 7.45 (1H, s, 4-H), 7.51 (1H, t, 6-H), 7.63 (1H, t, 7-H), 7.68 (1H, d, 5-H), 8.68(1H, d, 8-H); δ_C(100 MHz; $CDCl_3$) 14.7 (2-Me), 20.2 (3-Me), 119.6 (C-5), 125.1 (C-4), 127.1 (C-8), 127.7 (C-7), 128.1 (C-4a), 129.2 (C-6), 130.8 (C-3), 139.9 (C-8a), 146.4(C-2)].

¶ A mixture of **2c** (0.5 g), piperidine (0.5 ml) and THF (5 ml) was stirred in a stoppered flask for 24 h. Excess piperidine was evaporated *in vacuo* and the residue was chromatographed [flash chromatography on silica; elution with hexane–EtOAc (2:1)] to give **8** (0.61g, 85%).

‖ Compounds **6**, **8** and **9**, which appear to be new, and the known quinoline derivatives **4**, **5**, **7**, **10–12** were characterised by elemental (high resolution MS) and ^1H and ^{13}C NMR spectroscopic analyses.

Redox-switchable polyester dendrimers incorporating both π-donor (tetrathiafulvalene) and π-acceptor (anthraquinone) groups

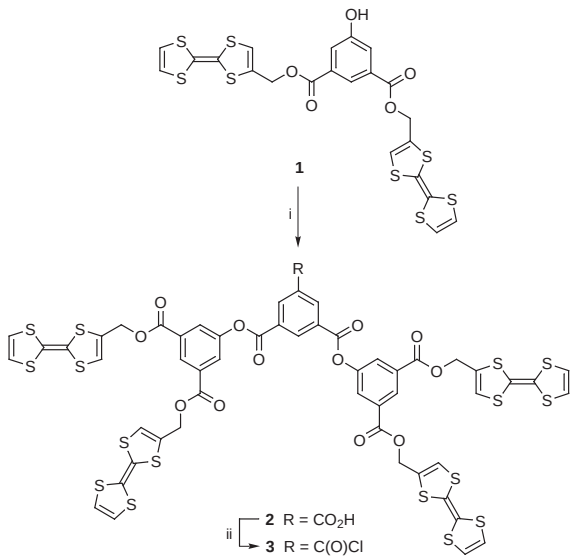
Martin R. Bryce,* Pilar de Miguel and Wayne Devonport

Department of Chemistry, University of Durham, Durham, UK DH1 3LE. E-mail: m.r.bryce@durham.ac.uk

Received (in Liverpool, UK) 9th September 1998, Accepted 16th October 1998

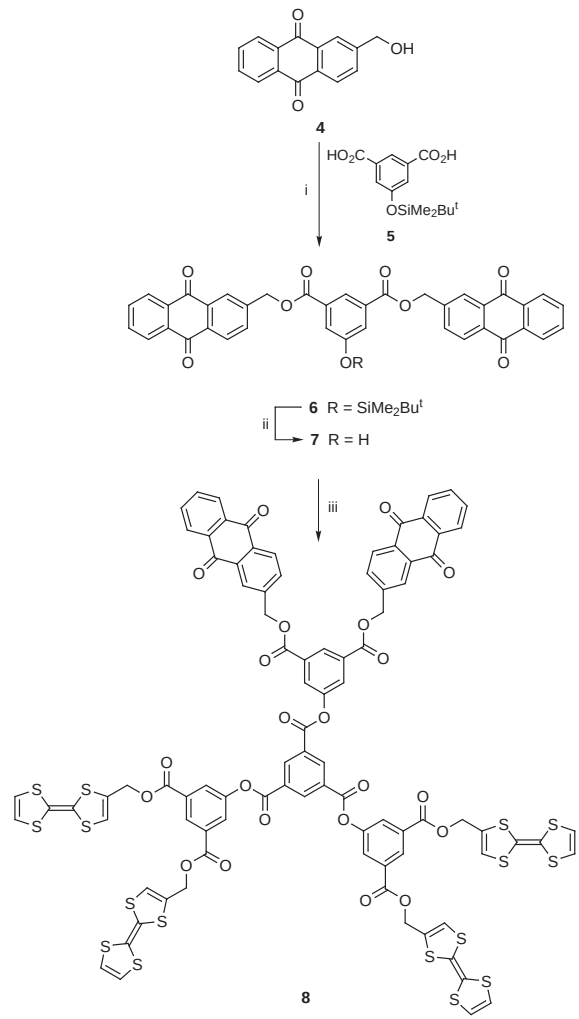
The convergent synthesis of $(TTF)_x(AQ)_y$ (TTF = tetrathiafulvalene; AQ = anthraquinone) polyester dendrimers is reported; the molecules undergo clean amphoteric redox behaviour with reversible switching between cationic and anionic states being achieved under electrochemical control; the higher generation system $(TTF)_8(AQ)_4$ displays an intradendrimer charge-transfer interaction in solution.

Dendritic molecules[1] which possess functional groups at the exterior surface and/or embedded within their structure[2] are of current interest. In this context, dendrimers which carry multiple cationic or anionic sites are attracting attention, due to their potential applications as macromolecular polyelectrolytes, catalysts and charge transfer materials. The charged sites may be introduced into the structure in two conceptually different ways: (i) during the synthesis, *e.g.* by using quaternary ammonium linkages,[3] by incorporating transition metals,[4] or by attaching polyanionic surfaces;[5] or (ii) by electrochemical redox processes or chemical doping of a neutral dendrimer which contains redox-active groups.[6] For these systems, the redox centres may behave independently in multi-electron processes (*n* identical non-interacting electroactive centres giving rise to a single *n*-electron wave) or they may interact intra- or inter-molecularly, in which case overlapping or closely-spaced redox waves are observed at different potentials. Representative electron donor groups are ferrocene,[7] metal-(bipyridyl)[8] and tetrathiafulvalene (TTF),[9] while interior anthraquinone (AQ)[10] and peripheral naphthalene diimide[11] groups have been used as electron acceptor units. Dendritic systems containing both strong π-donor and π-acceptor groups covalently bonded into their framework[12] are especially attractive targets as they should possess amphoteric redox properties under electrochemical control,[8b] and may engage in inter- and/or intra-molecular charge-transfer interactions.

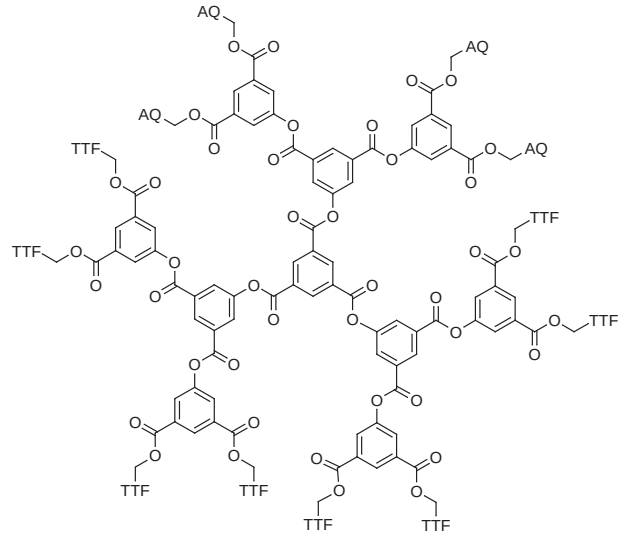


Scheme 1 *Reagents and conditions*: i, benzene-1,3,5-tricarbonyl chloride, DMAP, CH_2Cl_2, 20 °C, silica gel chromatography; ii, oxalyl chloride, toluene 80 °C.

Herein we report the prototype systems **8** and **9** containing both TTF and AQ units, built around a benzene 1,3,5-triester core. The synthesis of the $(TTF)_4$ dendron **3** is shown in Scheme 1.† The reaction of phenol derivative **1**[9a,d] (2.1 equiv.) with benzene-1,3,5-tricarbonyl chloride (1.0 equiv.) in the presence of DMAP as base (CH_2Cl_2, 20 °C) afforded the carboxylic acid derivative **2** (56% yield) after hydrolysis of the unreacted acid chloride group during workup. Reaction of **2** with oxalyl chloride in toluene afforded acid chloride derivative **3** (82% yield). The synthesis of the $(AQ)_2$ reagent **7** is shown in Scheme 2. 2-(Hydroxymethyl)anthraquinone **4** reacted with 5-(*tert*-butyldimethylsiloxy)isophthalic acid **5**[13] using the DMAP-catalysed DCC method[14] to form compound **6** in 55% yield. Attempted desilylation of **6** using TBAF in THF resulted in cleavage of the ester linkages;[15] however, heating a solution of **6** in a mixture of THF–aq. HCl (1 M) gave the alcohol derivative **7** (81% yield) which was only sparingly soluble in most organic



Scheme 2 *Reagents and conditions*: i, DCC, DMAP, CH_2Cl_2, 0–20 °C; ii, HCl (1 M)–THF (7:1 v/v), 50 °C; iii, **3**, DMAP, 1,4-dioxane, reflux.



9

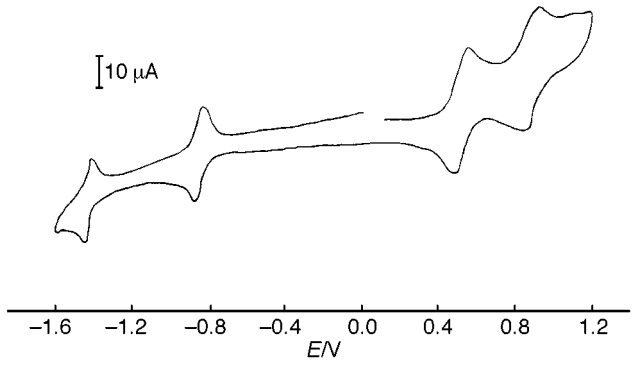


Fig. 1 Cyclic voltammogram of **8** (MeCN, 20 °C, $Bu_4N^+PF_6^-$ electrolyte, Pt electrode, *vs.* Ag/AgCl, scan rate 50 mV s^{-1}).

solvents. Esterification of **7** to afford G1 dendrimer **8** (60% yield, after column chromatography on silica gel) was achieved by reaction with acid chloride derivative **3** in the presence of DMAP in refluxing 1,4-dioxane. Analogous iterative procedures, starting with the known octa-TTF building block,[9d] gave the $(TTF)_8(AQ)_4$ G2 system **9**. Compounds **8** and **9** are soluble in a range of organic solvents (*e.g.* CH_2Cl_2, $CHCl_3$, THF, dichlorobenzene and CS_2): they darken on storage in air, and can be stored for several weeks under vacuum in the dark at 0 °C.

The solution electrochemistry of **8** and **9** has been studied by cyclic voltammetry (CV) in MeCN solution (Fig. 1). Scanning anodically, **8** exhibits two reversible four-electron oxidation waves to form, sequentially, the radical cation and dication of each of the TTF moieties;[16] scanning cathodically, two reversible two-electron waves are observed, corresponding to the reduction of each anthraquinone unit to the radical anion and the dianion.[17] Thus, **8** demonstrates clean amphoteric redox behaviour with reversible switching between the +8, +4, 0, −2 and −4 charged states being achieved. The CV of **9** is very similar (the +16, +8, 0, −4 and −8 states are clearly observed) although the second TTF wave was slightly narrower than the first wave, which was probably due to adsorption phenomena, as observed previously with some higher generation systems.[9d]

An important difference between the G1 and G2 systems **8** and **9** is manifested in their UV–VIS spectra. Compound **9** shows a very weak (ε < 250) broad absorption band in the λ 460–750 nm region in MeCN, which is not present in **8**. The solvent dependency of this band and experiments at various concentrations of **9** suggest that this low energy band arises from intramolecular (rather than intermolecular) π–π charge-transfer from TTF to anthraquinone units. Based on the different redox potentials of these donor and acceptor moieties, the degree of charge-transfer is expected to be small (< 0.1)[18] and that it is observed only in **9** appears to be an interesting consequence of the more densely packed structure of the higher generation molecule.

In summary, an efficient route has been established to polyester 'co-block' dendrimers containing both π-donor and π-acceptor moieties at the periphery. A future direction will be the incorporation into these structures of stronger π-acceptor groups,[18,19] in conjunction with TTF, enabling the study of intramolecular charge-transfer interactions within a dendritic microenvironment. Such materials could find applications in the development of electrooptical switches.

This work was funded by EPSRC (W. D.) and Universidad Complutense de Madrid (P. de. M.).

Selective ring opening cross metathesis of cyclopropenone ketal: a one step synthesis of protected divinyl ketones

Mathieu Michaut, Jean-Luc Parrain* and Maurice Santelli*

Laboratoire de Synthèse Organique associé au CNRS, Faculté des Sciences de Saint Jérôme, F-13397 Marseille Cedex 20, France. E-mail: jl.parrain@lso.u-3mrs.fr

Received (in Liverpool, UK) 9th September 1998, Accepted 16th October 1998

Grubbs ruthenium complex efficiently catalyses ring opening cross metathesis of cyclopropenone ketal and terminal olefins to afford 1,4-divinyl ketone ketals in good yields.

Since the Grubbs and Schrock groups described new alkenylidene-ruthenium and -molybdenum catalysts, olefin metathesis has attracted increasing attention.[1] The ring closing metathesis (RCM) reaction using these catalysts has in particular been studied, and syntheses of numerous cyclic structures (from five-membered rings to larger rings) have been reported.[2] In addition, ring opening metathesis of cyclic olefins has been widely used for the realisation of 'living' polymerisation.[3] Recently, the combination of ring opening metathesis (ROM) and selective cross coupling between strained bicyclic olefins and monosubstituted olefins[4,5] has shown another aspect of this powerful reaction which adheres to the 'atom economy' concept.[6] This was cleverly exemplified by Snapper in a very short synthesis of viridiene from bicyclo[3.2.0]heptadiene and butadiene.[4] So far, an identical process starting from cyclopropenes has not been reported, probably because of the steric hindrance of the substituents on the cyclopropenyl ring.[7,8]

In connection with our ongoing interest in the Nazarov cyclisation reaction,[9] an easy access to substituted divinyl ketones was desirable. Considering ring opening cross metathesis promotes selective reaction, we initiated studies on the synthesis of divinyl ketals from cyclopropenone ketals and terminal olefins (Scheme 1).

Following observations of the high reactivity of allylsilanes,[5,10] we initially employed 3 equiv. of allyltrimethylsilane and cyclopropenone propane-1,3-diyl ketal **1**[11] with 1% of Grubbs catalyst [$Cl_2(Cy_3P)_2Ru{=}CHPh$] (≡ [Ru]). The reaction was completed in less than 15 min and led only to the monomeric ring opening cross metathesis product **2i**† in 86% yield. Other possible cross metathesis or self metathesis by-products were not detected. A subsequent attempt was run with an equimolar ratio of the starting products, which provided an identical yield and selectivity for the *E* configuration of the created double bond (*E*:*Z* = 95:5). Moreover, we found that 0.04 mol% of catalyst was sufficient to complete this reaction in 2 h (Scheme 1).

In order to determine the scope and limitations of the reaction, other terminal olefins were reacted under similar conditions. The results are shown in Table 1.‡ With non-functionalized terminal olefins, optimal yields were obtained when benzene was used as solvent. High *E* selectivities were observed in all cases. The reaction was found to be extremely dependant on the substitution on carbon atoms 2 or 3 of the terminal olefins. For example, the reaction between 2-methylhexa-1,5-diene (Table 1, entry 5) and **1** occurred regioselectively on the monosubstituted olefin. On the other hand, methallyltrimethylsilane, 3,3-dimethylbutene or vinyltri-

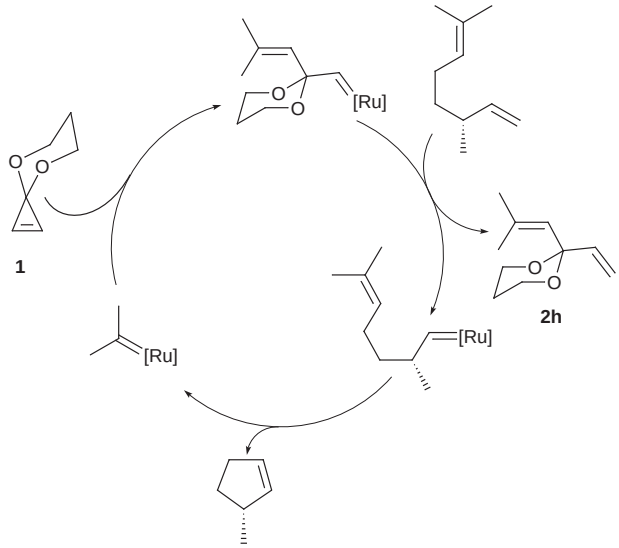
[a] Obtained as a separable 30:70 mixture of **2g** and the Diels–Alder adduct derived from **1** and butadiene (norcar-3-en-7-one propane-1,3-diyl ketal). [b] **1** was recovered after work-up.

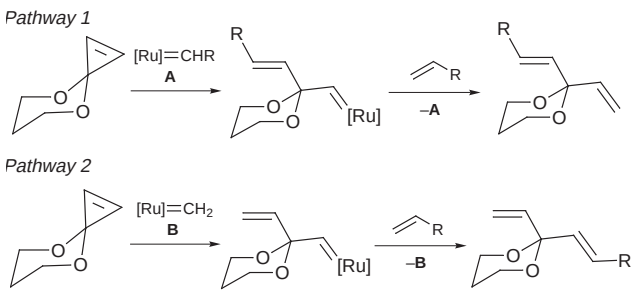


Scheme 2

methylsilane did not give metathesis products. The reaction was also found to be sensitive to electronic effects. With allyl acetate (Table 1, entry 11), no ring opening cross olefin metathesis product was detected. Only the self metathesis reaction took place, affording 1,4-diacetoxybut-2-ene.

In order to introduce a chiral center, we investigated reaction between **1** and the inexpensive (*R*)-citronellene (Table 1, entry 8). Unfortunately, the expected triene was not obtained and, instead, the reaction afforded **2h** (in 52% yield) and 3-methylcyclopentene. To explain this result, which contrasts with the others, we believe that product **2h** is obtained *via* a cascade reaction involving a ring opening cross metathesis[12] associated with a ring closing metathesis (Scheme 2). The above sequence overcomes the limitation imposed by the substitution of olefins and therefore, other 1,6-dienes could be use to introduce a disubstituted alkenyl fragment.

To better understand the reaction mechanism, stoichiometric ROM was performed in $CDCl_3$ at room temperature and examined by ^1H NMR spectroscopy. This experiment showed that cyclopropenone ketal **1** does not react with Grubbs catalyst. As a consequence, an olefin must be present to promote the metathesis reaction. This was illustrated by the reaction performed with styrene (Table 1, entry 6) where the structure of the active species is similar to that of the initial catalyst. Two credible reaction sequences could summarise the catalytic activity.[5,13] Pathway 1 (Scheme 3) utilises substituted alkylidene complex **A**, while the methylene complex **B** displays metathesis activity in pathway 2. A reaction performed with citronellene distinguished between the two mechanistic hypotheses, as the formation of divinyl ketal **2h** as the unique product strongly supports pathway 1. Moreover, we believe that the active catalytic species exhibits a structure different to the starting catalyst. According to the Chauvin mechanism[14] (formation of a metallacyclobutane followed by a cycloreversion process) and following the rational studies of Grubbs,[15] steric reasons could thus largely explain the *E* selectivity.



Scheme 3

In conclusion, under Grubbs ruthenium complex catalysis, cyclopropenone ketal reacts with terminal olefins *via* a ring opening cross metathesis reaction to provide selectively protected 1,4-divinyl ketones with a preferential *E* configuration. Studies to extend this reaction to other cyclopropene structures are currently underway and will be reported in due course.

Received (in Columbia, MO, USA) 27th July 1998, Accepted 12th October 1998

A series of novel poly(propyleneimine) dendrimers functionalized with 4, 8, 16 and 32 peripheral cobaltocenium subunits were prepared and characterized with a special focus on their electrochemical properties and binding interactions with β-cyclodextrin.

The chemistry of dendrimers[1] continues its fast development as numerous research groups take advantage of dendrimer structural frameworks for a variety of applications.[2] Recently, we have reported[3] on the preparation and properties of dendrimers functionalized with multiple ferrocene sites on their surface and shown that they may act as multisite, redox active guests[3e] for inclusion complexation by cyclodextrins.[4] Here we report the preparation and characterization of four new dendrimers **1**–**4** having 4, 8, 16 and 32 peripheral cobaltocenium subunits. While these positively charged dendrimers are not complexed by β-cyclodextrin (β-CD) in aqueous media, their electrochemical reduction triggers the formation of high molecular weight, multisite inclusion complexes with this host.

The new dendritic macromolecules **1**–**4** were synthesized by condensation reactions of 1-chlorocarbonylcobaltocenium in MeCN with poly(propyleneimine) dendrimers bearing 4, 8, 16 and 32 NH_2 groups respectively, in the presence of Et_3N. After purification by repeated column chromatography (Sephadex LH-20 with MeCN as eluent) all four organometallic dendrimers were isolated as air-stable, yellow (**1** and **2**) or green solids (**3** and **4**). Compounds **1**–**4** are soluble in solvents such as MeCN and DMSO. The structures of the new dendrimers have been straightforwardly established on the basis of ^1H and ^{13}C NMR and IR spectroscopy, MS, and elemental microanalysis.

We have previously reported the voltammetric behavior of cobaltocenium and carboxycobaltocenium in aqueous media as well as their complexation by the host β-CD.[5] We found that the reduced form, cobaltocene, precipitates on the electrode surface giving rise to strong distortions from the wave shape expected for a reversible, one-electron reduction process. The electro-

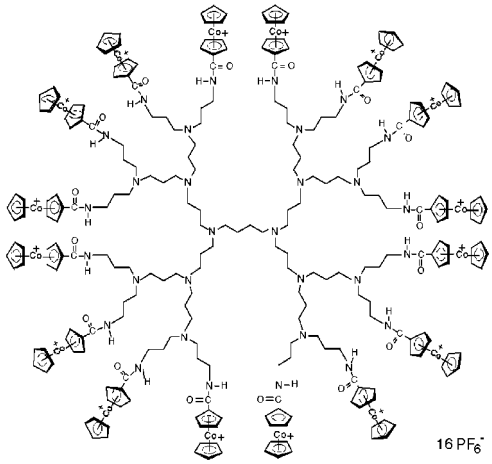
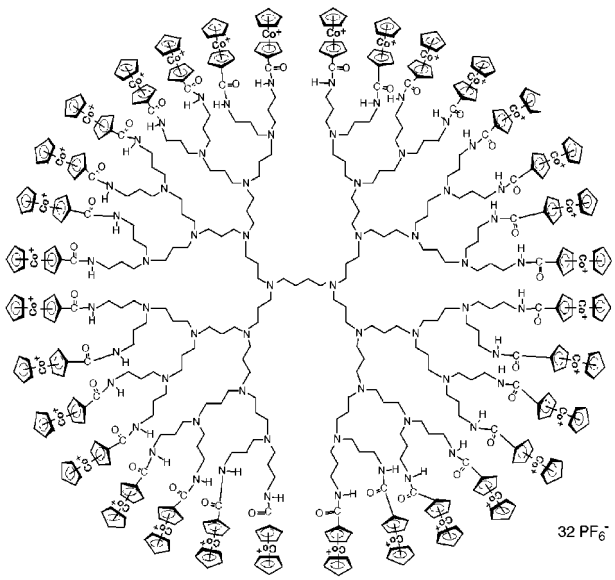
2



3



4

chemical behavior of dendrimers **1**–**4** in 0.1 M NaCl is also characterized by the deposition on the electrode surface of their reduced forms, since electrochemical reduction of the peripheral cobaltocenium subunits transforms the highly charged dendrimer structures into very hydrophobic ones. For each dendrimer, all the cobaltocenium subunits are reduced around a single half-wave potential value (see Table 1). A typical cyclic voltammogram is shown in Fig. 1(*a*) (for **1**). Although the cathodic wave departs from the shape expected for a reversible reduction process, the sharp anodic wave clearly reveals the precipitation of the reduced form on the electrode surface. Addition of β-CD to this solution gradually eliminates the sharp anodic spike on the reverse scan [Fig. 1(*b*)]. In the presence of a four-fold excess of host (compared to the total concentration of cobaltocenium subunits in the solution), the cyclic voltammogram exhibits a shape consistent with a fully reversible process [Fig. 1(*c*)]. This finding clearly indicates the solubilization of the reduced form of the dendrimer by formation of inclusion complexes between the peripheral cobaltocene subunits and the freely diffusing β-CD hosts (see Scheme 1). In order to further prove this point, we performed additional experiments with a competing guest [(ferrocenylmethyl)trimethylammonium perchlorate, Fc-$N^+Me_3 \cdot ClO_4^-$]. This ferrocene derivative is an excellent guest for binding by β-CD[6] and competes with the dendrimer cobaltocene centers for the hosts present in the solution. This is confirmed by the voltammogram in Fig. 1(*d*), which shows that the addition of Fc-N^+Me_3 leads to the behavior (sharp anodic peak) associated with the precipitation of the reduced form of **1** on the electrode.

Although dendrimers **2** and **3** are less soluble than **1** in aqueous media (probably due to the hexafluorophosphate counterions) we performed voltammetric experiments with solutions containing 0.05 mM dendrimer and obtained comparable results. Dendrimers **1**–**3** in combination with β-CD constitute a novel type of host–guest system in which the formation of multisite β-CD–dendrimer complexes is driven by the reduction of the dendrimers. These systems afford an example of high molecular weight supramolecular assemblies which undergo association upon 'electrochemical activation' of the guest.

The authors are grateful to the N.S.F. Stereocontrolled substitution of benzylic ethers complexed to tricarbonylchromium(0)

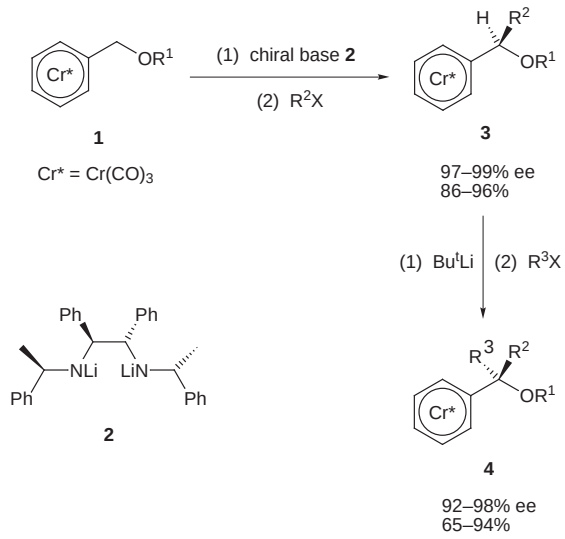
Domenico Albanese, Susan E. Gibson (née Thomas)* and Ellian Rahimian

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: s.gibson@ic.ac.uk

Received (in Liverpool, UK) 2nd September 1998, Accepted 14th October 1998

The nitrogen nucleophile HN(OH)C(O)OBu^t reacts with non-racemic chiral tricarbonylchromium(0) complexes of benzylic ethers with retention of configuration to provide a novel approach to non-racemic *N*-hydroxycarbamates and amines.

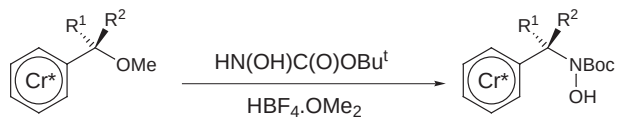
We recently demonstrated that the benzylic methylene group in tricarbonylchromium(0) complexes of benzyl ethers **1** may be functionalised asymmetrically using the non-racemic chiral base **2** (Scheme 1). Deprotonation followed by an electrophilic quench gives the substituted ethers **3** in high yield and enantiomeric excess.[1] Moreover, deprotonation of **3** with the achiral base Bu^{t}Li followed by an electrophilic quench produces the heavily substituted ethers **4** again in good yield and enantiomeric purity.[2] In view of the importance of amines as natural products, pharmaceuticals, and chiral ligands for asymmetric catalysis, we decided to determine whether or not the reliable and robust chemistry used to generate **3** and **4** could be exploited in the synthesis of chiral non-racemic amines. In principle, this could be achieved by nucleophilic substitution using a nitrogen nucleophile, but literature precedent was unpromising: although substitution of α-oxygenated arene tricarbonylchromium(0) complexes with acid/nucleophile combinations *via* a chromium-stabilised carbocation intermediate is well established for carbon, hydrogen, and oxygen nucleophiles,[3] the use of nitrogen nucleophiles is rare and inefficient. Thus, reactions of NH_3, $MeNH_2$ and Me_2NH with benzyl alcohol complexes in the presence of HPF_6 give low yields of substitution products,[4] and although introduction of nitrogen *via* the Ritter reaction works well for complexes of primary benzylic alcohols, it is inefficient for secondary alcohols and fails for tertiary alcohols.[5] We thus report herein that the nitrogen nucleophile *tert*-butyl *N*-hydroxycarbamate facilitates the introduction of nitrogen into α-oxygenated arene tricarbonylchromium(0) complexes **3** and **4** and in doing so provides a novel synthesis of non-racemic chiral *N*-hydroxycarbamates and amines.



Scheme 1

The first complex to be examined was (*R*)-**5a** (R^1 = H, R^2 = Me),[1] which was synthesised in high enantiomeric purity (99% ee) from the tricarbonylchromium(0) complex of benzyl methyl ether and MeI using the chiral base **2**. Initial reactions of **5a** with a range of nitrogen nucleophiles (*e.g.* RNH_2, R_2NH, $BocNH_2$, BocNHR, BocNHOTBDMS) in the presence of $HBF_4{\cdot}OMe_2$ were disappointing, providing only very low levels of nitrogen incoroporation and complex mixtures of products. In contrast,

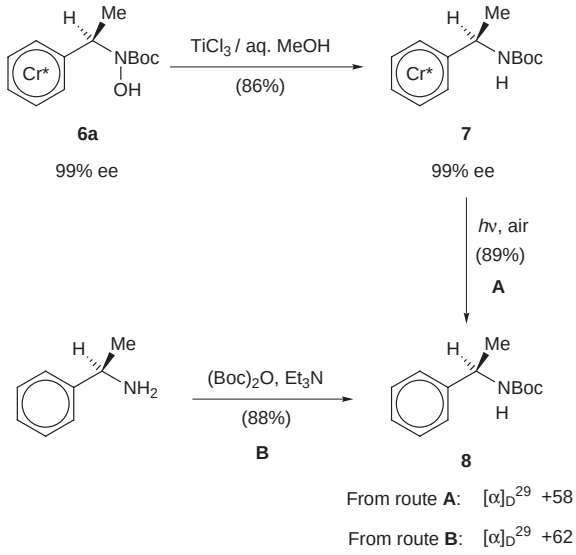
Table 1 Addition of HN(OH)C(O)OBu^t to ether complexes **5** and **7**[a]



5a–c, 9a,b **6a–c, 10a,b**

Entry	Substrate	R^1	R^2	Ee (%)[b]	$[\alpha]_D$[c]	Product	Yield (%)	Ee (%)[b]	$[\alpha]_D$[c]
1	**5a**	H	Me	99	+53	**6a**	85	99	−68
2	**5b**	H	Et	96	+66	**6b**	53	96	−40
3	**5c**	H	Pr^i	98	+43	**6c**	43	91	+18
4	**9a**	D	Me	99	+53	**10a**	79	88	−53
5	**9b**	Et	Me	99	−10	**10b**	48	80	+6

[a] The experimental procedure for the conversion of **5a** to **6a** (entry 1) is typical: $HBF_4{\cdot}OMe_2$ (0.20 cm^3, 0.26 g, 2.0 mmol) was added dropwise to a yellow solution of **5a** (0.272 g, 1.00 mmol) in CH_2Cl_2 (10 cm^3) at −40 °C under an atmosphere of nitrogen. To the resulting deep blue solution, a precooled solution of HN(OH)C(O)OBu^t (0.532 g, 4.00 mmol) in CH_2Cl_2 (5 cm^3) was added immediately *via* a cannula. The yellow mixture was stirred for 25 min at −40 °C, after which saturated aqueous $NaHCO_3$ (5 cm^3) was added and the mixture allowed to warm to room temperature. Addition of water (5 cm^3), extraction with pentane (3 × 20 cm^3), drying ($MgSO_4$), filtration through Celite and solvent removal *in vacuo* gave a yellow solid. Column chromatography [SiO_2; Et_2O–light petroleum (bp 40–60 °C) 1:5–1:1] gave **6a** as a yellow solid (0.316 g, 85%). [b] Ees measured by HPLC (Chiralcel OD-H); accuracy ±1%. [c] All values measured within the range 20–31 °C (*c* 0.5–1.0) in CH_2Cl_2.



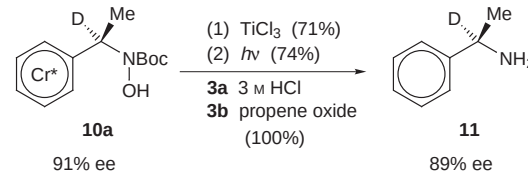
Scheme 2

protonation of **5a** at −40 °C with $HBF_4{\cdot}OMe_2$ followed by addition of commercially available *tert*-butyl *N*-hydroxycarbamate [HN(OH)C(O)OBu^t] gave the nitrogen substitution product **6a** in 85% yield. Moreover the ee of the novel† complex **6a** was measured by chiral HPLC‡ and found to be 99% (Table 1, entry 1).

The absolute configuration of the nitrogen substitution product **6a** was determined by chemical correlation. Reduction of the nitrogen–oxygen bond using $TiCl_3$ in aqueous MeOH[6] proceeded smoothly to give the novel complex **7** without loss of stereochemistry (Scheme 2).§ Oxidative removal of the tricarbonylchromium(0) unit from **7** gave carbamate **8**, the optical rotation of which was essentially identical to a sample prepared from authentic (*R*)-α-methylbenzylamine. Thus the absolute configuration of **6a** is *R* and the conversion of **5a** to **6a** proceeds with retention of configuration, presumably *via* a chromium stabilised carbocation.

In order to probe the effect on the nitrogen substitution reaction of increasing steric hindrance around the benzylic position, complexes **5b**[7] (R^1 = H, R^2 = Et) and **5c**[7] (R^1 = H, R^2 = Pr^i) were prepared and reacted with HN(OH)C(O)OBu^t. The reactions led to the novel products **6b** and **6c** in 53 and 43% yield and 96 and 91% ee respectively (Table 1, entries 2 and 3). Thus increasing steric hindrance leads to notable yield reductions and a small but significant stereochemical leakage. These effects are attributed to a reduced rate of addition of the nitrogen nucleophile to the intermediate carbocation, the increased lifetime of the latter leading to byproducts and rotation about the *ipso* carbon–benzylic carbon bond.

Subsequently, in order to test whether α,α-disubstituted benzylic ethers may be used as substrates in the reaction, complex **9a**[2] and the novel complex **9b** were synthesised from



Scheme 3

5a by Bu^{t}Li deprotonation–electrophilic quench sequences.[2] Reaction of **9a** and **9b** with HN(OH)C(O)OBu^t gave the novel complexes **10a** and **10b** in 79 and 48% yield, 88 and 80% ee respectively (Table 1, entries 4 and 5). Thus steric hindrance around the tertiary carbocation generated in the conversion of **9b** to **10b** appears to reduce the rate of nucleophilic attack by HN(OH)C(O)OBu^t allowing significant rotation around the *ipso* carbon–benzylic carbon bond to occur and hence some loss of enantiomeric purity. Finally, the deuterated product **10a** was converted into the labelled amine **11** in good overall yield and without loss of enantiomeric purity (Scheme 3).¶

The authors thank the EPSRC for a studentship (E. R.), and The Accademia Nazionale dei Lincei/The Royal Society for funding a study visit (D. A.) under the auspices of the European Science Exchange Programme.

Notes and references

† The novel complexes **6a–c**, **7**, **9b**, **10a** and **10b** all gave satisfactory spectroscopic (IR, ^{1}H NMR, ^{13}C NMR and low resolution MS) and microanalytical or high resolution MS data.

‡ Racemic products for HPLC analysis were generated by addition of HN(OH)C(O)OBu^t to ether substrates produced by Bu^{t}Li deprotonation–electrophilic quench of the tricarbonylchromium(0) complex of benzyl methyl ether.

§ The ee of **7** was measured by Boc removal, replacement with Z and HPLC analysis (Chiralcel OD-H)

¶ The ee of **11** was measured by derivatisation with 3,5-dinitrobenzoyl chloride and HPLC analysis (Phenomenex - Phase 3014).

[b] *Institut für Physikalische Chemie der Martin-Luther-Universität Halle-Wittenberg, D-06108 Halle, Mühlpforte 1, Germany*

Received (in Cambridge, UK) 28th September 1998, Accepted 26th October

The first banana-shaped molecules without Schiff-base units, with broad regions of a ferroelectric switchable liquid crystalline phase and low melting points, have been obtained.

Ferroelectricity, resulting from a spontaneous macroscopic electric polarization, is a property which was first reported by Meyer[1] to occur in a fluid, liquid crystalline phase. Until recently, ferroelectricity in liquid crystals was based on a tilted arrangement of homochiral molecules in layers (*e.g.* smectic C phase) which generates C_{2v} symmetry and allows the occurrence of a spontaneous electric polarization. In recent years such ferroelectric liquid crystals have attracted considerable interest because of their unique switching properties and their technical applications, for example, in fast-switching electrooptical devices.[2] As predicted by theory, ferroelectricity is not restricted to chiral tilted phases.[3–5] In 1996 Niori *et al*.[6] reported on ferroelectricity in a smectic phase formed by bow-shaped ('banana-shaped') non-chiral molecules. Later on, antiferroelectric switching behavior was found for these compounds.[7–9] Not only is the special electrooptical behavior of these non-conventional liquid crystals of interest. These molecules also represent a new subfield of thermotropic liquid crystals, different from the classical types such as calamitic and disc-like mesogens. Up to now, all banana-shaped liquid crystals which exhibit (anti)ferroelectric switching behavior have had a rather uniform structure. They usually comprise 1,3-phenylene bis-benzoates incorporating at least one Schiff-base unit.[6–9] Therefore, a major drawback of these compounds is their limited thermal, hydrolytic and photochemical stability. Furthermore, these special mesophases occur at rather high temperatures. Thus, the design of novel stable and low-melting materials is a topical subject in liquid crystal research.

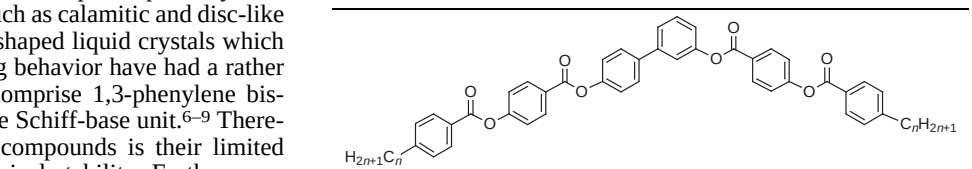
Here we describe the first banana shaped molecules without Schiff-base units which have a ferroelectric switchable liquid crystalline phase. This was achieved by combination of an angular 3,4′-disubstituted biphenyl central unit with two phenyl benzoate rigid cores *via* ester linkages. Thus the two halves of these banana-shaped molecules are different.

The transition temperatures of the compounds **1–5** are collected in Table 1.† Different mesophases were found depending on the length of the alkyl chains and the temperature. Compounds **1** and **2** with short terminal chains form only one mesophase (M_3). On cooling **1** from the isotropic liquid state at 157 °C batonnets are formed which coalesce into a mosaic-like texture. This texture is identical with that reported for some short chain banana-shaped Schiff-base derivatives,[10] and is designated an X_{B1} phase.‡ A similar texture was also observed by cooling compounds **2–4** from the isotropic liquid.

However, in the case of compound **3** two additional phase transition can be found on further cooling. At 147 °C a nonspecific texture which immediately changes into a gray schlieren texture is formed [see Fig. 2(*a*)]. This mesophase always shows a distinct birefringence and no pseudoisotropic regions can be obtained by shearing. Furthermore, this mesophase has a lower viscosity (comparable to conventional S_A and S_C phases) than the phase M_3. On heating, it directly turns into the isotropic liquid phase at 152 °C without passing the high temperature mesophase. This means that, probably for kinetic reasons, the M_3 phase can only be observed on cooling from the isotropic state. On further cooling, at 86 °C the schlieren texture turns into a mosaic-like texture with a significant increase of the viscosity.

The same trimorphism was also found for **4**, but only the mesophases M_1 and M_2 were detected for the long chain compound **5**. Here, the M_2 phase grows directly from the isotropic liquid as spherulites with a fringe pattern, characteristic of a helical structure [see Fig. 2(*b*)]. This texture is very similar to the texture of the (anti)ferroelectrically switchable mesophase (X_{B2} phase‡) of the banana-shaped Schiff-base derivatives. Slight shearing of the sample gives rise to the same

Table 1 Phase transition temperatures of **1–5**. Abbreviations: Cr = crystalline solid, M_1 = smectic low-temperature mesophase (probably S_G or S_H), M_2 = ferroelectrically switchable mesophase [X_{B2}-phase,‡ probably arrangement shown in Fig. 1(*a*)], M_3 = two-dimensionally ordered (modulated smectic) mesophase [X_{B1}-phase,‡ see arrangement in Fig. 1(*c*)], Iso = isotropic liquid.[a]



Compound	*n*	T/°C								
1		4 Cr	161					(M_3	157)	Iso
2		6 Cr	119					M_3	158	Iso
3		8 Cr	85	M_1	86	M_2	152			Iso

gray schlieren texture as observed for the M_2 phases of **3** and **4**.

X-Ray studies of non-oriented samples of compound **3** have been performed to support the phase characterization. The diffraction pattern of the high temperature phase M_3 (T = 150 °C) shows two reflections with d_1 = 3.24 and d_2 = 2.37 nm, in addition to the diffuse outer scattering. These reflections point to an undulated structure, which is already found in some banana-shaped molecules and is designated as an X_{B1} phase.‡ In the case of compound **1**, monodomains of the M_3 phase were obtained. On the basis of these oriented samples we can deduce a two-dimensional rectangular centered cell for this phase [see Fig. 1(*c*)]. Since the positions of the reflections in the M_3 phase are a linear function of the chain length, the high temperature phases of compounds **1–4** can be assumed to belong to the same type.

The phase transition from the M_3 phase to the M_2 phase is indicated by an alternation of the pattern in the small angle region. The positions of the two reflections fit now the ratio d_1:d_2 = 1:0.5 (d_1 = 2d_2 = 3.74 nm, T = 120 °C), proving a layer structure. The d value is essentially smaller than the length of the molecule (L = 5.0 nm), describing a V-shaped molecule with an angle of about 120° between the two half parts and an all-*trans* conformation of the alkyl chains. This difference leads to a tilt angle of about 41°. However a deviation of the chains from the fully stretched conformation must be assumed, so that the real tilt angle should be smaller than the estimated one. With respect to this preliminary structure the phase under consideration can belong to the type X_{B2} as reported for the Schiff-base derivatives.‡ At further cooling into the low temperature phase M_1 the layer reflections are shifted only a very little, but in the wide angle region several reflections appear. This pattern is maintained down to room temperature. The kind of reflections

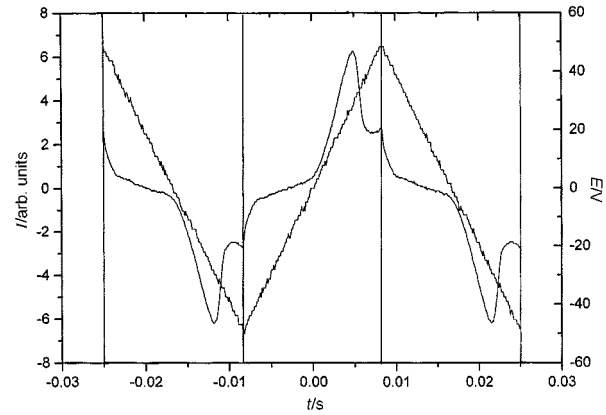

Fig. **3** Switching current response in the M_2 phase of **4** obtained by applying a triangular voltage (±50 V, 30 Hz, 125 °C).

(number, position and intensity) resembles to those of highly ordered smectic phases (S_G or S_H), but further studies are necessary to prove this analogy. Remarkably, after the first melting this compound does not crystallizes again, even after storage for several weeks at room temperature. No crystalline phases have been detected for **4** and **5**.

Preliminary investigations of the switching behavior of the M_2 phase were performed with **4**. The switching current was examined in a 5 μm thick cell by the triangular wave method. Fig. 3 shows the electric response (30 Hz) obtained in the M_2 phase at 125 °C. It can be seen that only one current peak is recorded during a half period, pointing to ferroelectric behavior. This points to the phase structure shown in Fig. 1(*a*), but it should be noted that only a schlieren texture can be obtained between the glass surfaces of the cell. Therefore more detailed electrooptical investigations with uniformly aligned samples are necessary to confirm the precise structures of the switchable mesophases.

This work was supported by the Kultusministerium des Landes Sachsen-Anhalt. We thank C. Lischka (Department of Physical Chemistry, University Halle) for help during the electrooptical investigations.

Notes and references

† The synthesis will be reported in a separate paper, satisfactory C,H analyses and ^{1}H NMR spectra were obtained. *Selected data* for **3**: δ_H(200 MHz, $CDCl_3$, 25 °C, $SiMe_4$) 0.89 (2t, 6H, CH_3), 1.2–1.8 (m, 24H, CH_2), 2.72 (t, *J* 7.7, 4H, Ar-CH_2), 7.2–7.6 (m, 14H, aromatic H), 7.68 (d, *J* 8.6, 2H, aromatic H), 8.14 (d, 4H, *J* 8.2, aromatic H), 8.32 (d, 4H, *J* 8.6, aromatic H).

Synthesis of isocyanates from carbamate esters employing boron trichloride

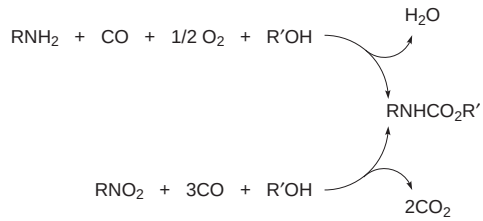
D. C. D. Butler and H. Alper*

Department of Chemistry, University of Ottawa, 10, Marie Curie, Ottawa, Ontario, Canada K1N 6N5

Received (in Corvallis, OR, USA) 17th September 1998, Accepted 21st October 1998

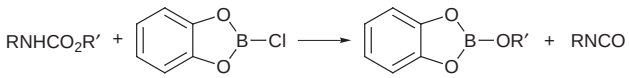
The conversion of carbamate esters to isocyanates and diisocyanates of industrial importance is possible using BCl_3 in the presence of Et_3N; the reaction is simple in execution and work-up, occurring under mild conditions and affording isocyanates in excellent yields.

Presently, isocyanates are manufactured on a commercial scale by reaction of phosgene with amine or amine salt precursors.[1] As restrictions upon the use of very toxic materials such as phosgene and other chlorine-containing compounds within the chemical industry have become more rigorously enforced, there has been increasing interest in developing alternative methods for isocyanate production.[2] One such method (Scheme 1)



Scheme 1

involves the catalytic production of carbamate esters (by reductive carbonylation of nitro derived compounds,[3] or oxidative carbonylation of amines[4,3b]), dealcoholysis of which gives isocyanates. One of us showed recently that elimination of alcohol from carbamate esters to yield isocyanates can be facilitated using chlorocatecholborane in toluene, in the presence of Et_3N (Scheme 2).[5] This paper demonstrated that the way in which the alcohol product is irreversibly removed from the reaction solution, in the form of an alkyl catecholborate, is pertinent to the significance of this method compared with those which employ the thermal decomposition of carbamate esters, in which recombination of the resulting isocyanate with alcohol is possible.



Scheme 2

Having demonstrated the use of chlorocatecholborane in this type of reaction, we reasoned that simple boron halides, BX_3 (X = Cl, Br), may also be active as cheap alternatives. Additionally, it has previously been shown that BX_3 can be generated in the production of benzyl esters by reaction of trialkyl borates with benzylic halides and CO in the presence of catalytic quantities of Pd^0 or Rh^I.[6] This offers the rather attractive option of two concomitant processes achieving commercially valuable ends together with constant recycling of boron.

Boron trihalides are known for their strong Lewis acid character, and for their ability to cleave a wide variety of ethers, acetals and esters under relatively mild conditions.[7] In pursuit of alternative methods of isocyanate production, we now report the results of our work with BBr_3 and BCl_3 in facilitating the conversion of carbamate esters to isocyanates of industrial importance.

Treatment of a carbamate ester with 0.37 equiv. of BCl_3 and 1.1 equiv. of Et_3N, for 30 min in refluxing benzene, afforded the

Table 1 Conversions of carbamate esters to the corresponding isocyanates using BCl_3

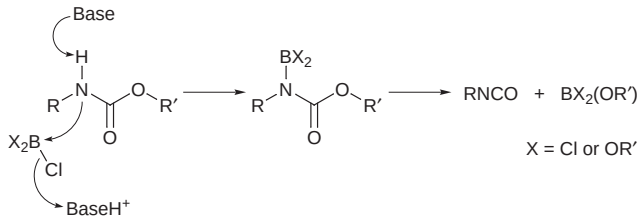
[e] Yields of pure products isolated by vacuum distillation, characterized by ^1H NMR, ^{13}C NMR, IR and MS analysis and by comparison with authentic materials.



Scheme 3

isocyanate in good yield. In most cases, quantitative or near-quantitative conversion to the product isocyanates was obtained under these relatively mild reaction conditions for a series of aryl, alkyl, alicyclic and tosyl carbamate esters. The reactions were found to be highly selective with only the product isocyanates, partially cleaved carbamate esters (where dicarbamate esters were employed as starting materials), or starting materials being observed in the final solutions. The product isocyanates can usually be easily isolated by evaporation of the solvent and trialkyl borate under reduced pressure followed by vacuum distillation at elevated temperature. For example, toluene-2,4-diyl diisocyanate (TDI), *para*-phenylene diisocyanate (PDI) and 4,4′-methylenebis(phenyl isocyanate) (MDI), which are large-scale raw materials for the manufacture of polyurethane foams,[8] can be isolated as spectroscopically pure materials from their corresponding methyl carbamate esters in 70–79% yield. Toluene-2,4-diyl diisocyanate can also be isolated in good yield from its methyl carbamate ester when the reaction is performed in toluene (65% isolated yield) or hexanes (41% isolated yield). Chlorinated solvents, however, are not suitable media for this reaction. As expected, BCl_3 is converted to trialkyl borate (identifiable by GC–MS), observed after the reaction, consistent with the reaction shown in Scheme 3.

BBr_3, a stronger Lewis acid than BCl_3, was also effective in this reaction, with isocyanate yields being similar to those quoted for BCl_3 in Table 1. However, appreciable amounts of amine were also produced in some cases bringing the selectivity of this reagent into question.

It has previously been shown that PCl_3, and other Lewis acids, can effect the removal of OH from carbamate anions to yield isocyanates by electrophilic, *oxophilic* dehydration.[9] However, we found that PCl_3, when used instead of BCl_3, is capable of less than *ca*. 5% conversion of carbamate esters to isocyanates. Similar yields were attained with $AlCl_3$, and $TiCl_4$ was found to be totally inactive. It is conceivable that PCl_3 can react as an electrophile at nitrogen in this case, and a possible reason for its overall inactivity is the inability to promote cleavage of an alkoxy group from the resulting intermediate.

In conclusion, BCl_3 is an excellent, efficient and economical reagent for the synthesis of mono- and di-isocyantes in high yield.

We are grateful to the Environmental Science and Technology Alliance Canada (ESTAC) for support of this research.

Carbohydrate based IMDA/aldol strategy towards the densely functionalized *trans*-decalin subunit of azadirachtin

Dieter Haag, Xiao-Tao Chen and Bert Fraser-Reid*

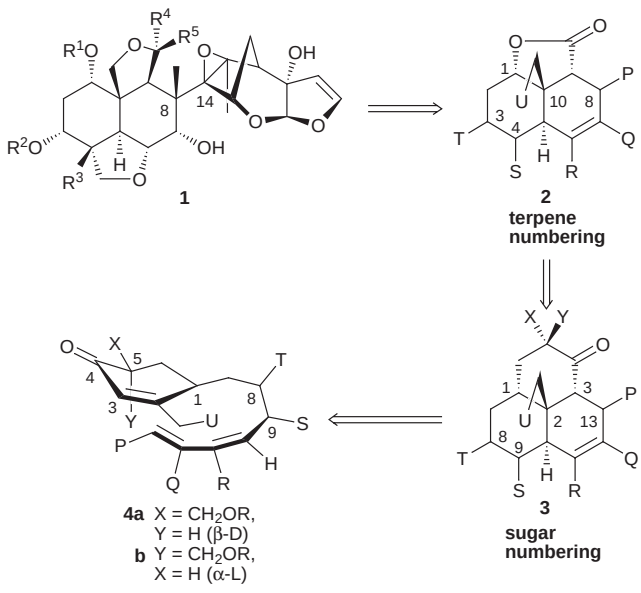
Natural Products and Glycotechnology Research Institute Inc, 4118 Swarthmore Road, Durham, NC 27707 USA. E-mail: dglucose@aol.com

Received (in Corvallis OR, USA) 10th August 1998, Accepted 14th October 1998

L-Rhamnal is converted into an hex-2-en-4-ulo *C*-glycopyranoside in which properly configured diastereomeric centers, asymmetric as well as geometric, are developed in the pendant anomeric substitutent *via* a Claisen aldol addition, and the resulting product proceeds *via* an IMDA reaction to provide a highly functionalised terpene AB ring system.

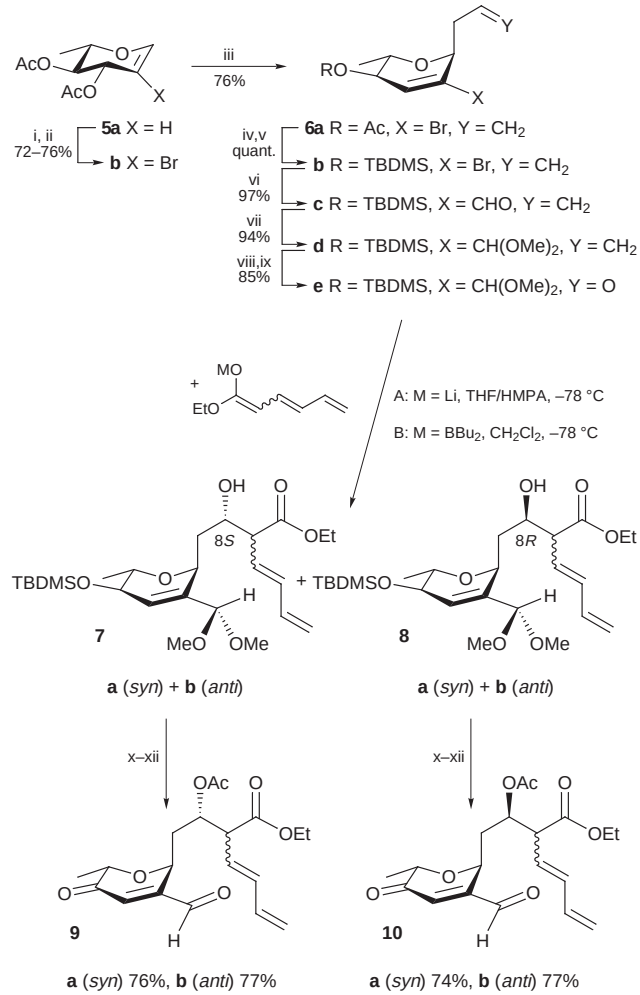
The development of synthetic routes from carbohydrates to densely functionalized carbocycles has been a sustained area of interest in our research group.[1,2] The intramolecular Diels–Alder (IMDA) strategy depicted in Scheme 1[3,4] takes advantage of the preferred β-D-face approach in reactions of pyranosidic 2-ene-4-ones. The desired (*S*)-configuration exists in β-D- and α-L-derivatives, but either may be used since the sugar's C5 stereocenter, whereby D or L is designated, does not survive in the advanced retron **2**. Thus a regioselective Baeyer–Villiger oxidation of **3** permits its ready removal. This simplifying retroanalysis also makes provisions for an array of functional groups such as is found in the clerodane family of terpenes,[5] exemplified by the 'western half' of the azadirachtins **1**.[6] An IMDA approach, based on **4** with appropriate synthons at P, Q, R, S, T and U, for this family of potent pharmacologically active compounds,[7] is therefore desirable.[8]

Dibromination of diacetyl L-rhamnal **5a**, followed by dehydrobromination, gave the 2-bromo glycal **5b** in 72–76% yield (Scheme 2). Danishefsky's version[9] of the Ferrier rearrangement[10] gave a 76% yield of α-L-*C*-glycoside **6a** (along with 19% of the corresponding β-anomer). The acetyl group was replaced by TBDMS and a THF solution of the latter was mixed with 5 equiv. of DMF, and then 6 equiv. of Bu^{t}Li were added slowly (*ca*. 2 h) at −78 °C to furnish, after aqueous work-up, enal **6c** in almost quantitative yield.



Scheme 1

The *trans*-decalin subunit of azadirachtin **1**, as well as of related terpenoids, invariably possesses hydroxy and carbon substituents at C3 and C4 respectively,[6] positions that correlate with C8 and C9 of the sugar IMDA precursor. These functionalities could conceivably be furnished by an aldol reaction. Accordingly, the aldehyde group of **6c** was first protected by acetalization. Cleavage of the terminal double bond *via* OsO_4 induced dihydroxylation followed by periodate cleavage in two discrete steps, but not in the one-pot Lemieux–Johnson protocol,[11] gave aldehyde **6e** in 85% yield.



Scheme 2 *Reagents and conditions*: i, Br_2, CH_2Cl_2; ii, A: one-pot, DBU, 76% + 14% of **5a**, or B: work-up, then DBN, toluene–DMSO, 72% + 4% of **5a**; iii, allyltrimethylsilane, $BF_3{\cdot}Et_2O$, CH_2Cl_2, 0 °C to room temp.; iv, NaOMe, MeOH; v, NaH, TBDMSCl, THF; vi, THF, DMF (5.0 equiv.), −78 °C, then Bu^{t}Li (6.0 equiv.); vii, CSA, $Me_2C(OMe)_2$, reflux; viii, NMO, 1% OsO_4, THF–H_2O; ix, $NaIO_4$, THF–H_2O; x, Ac_2O, Py, cat. DMAP, CH_2Cl_2, 0 °C to room temp.; xi, HF·Py, THF, room temp.; xii, PCC, SiO_2, CH_2Cl_2, room temp.

Our next task was to elaborate the anomeric *C*-substituent into the required dienic tether. A Claisen-type aldol addition with ethyl sorbate seemed an ideal approach. Indeed that an 8-hydroxy-9-ethoxycarbonyl addition product had formed was apparent from NMR examination of the crude material. Separation of the four diastereomeric aldol adducts was achieved by (repeated) flash chromatography, and *syn*- and *anti*-configuration were easily distinguished on basis of the coupling constant between the protons attached to C8 and C9 (*syn*: ^3J ~ 5.0 Hz, *anti*: ^3J ~ 9.0 Hz). However, the absolute configuration at C8 and C9 was assigned in retrospect upon isolation of IMDA products **11**–**14** (Table1).

For proof-of-concept, the major component (assigned in retrospect as **7a**, *vide infra*) was acetylated and treatment of the crude material with HF–pyridine in THF for one day at ambient temperature effected desilylation as well as cleavage of the rather acid-sensitive dimethyl acetal. Final activation was accomplished by oxidation with PCC on silica gel to furnish the corresponding aldehyde enone **9a** in 76% yield for the whole four-step sequence. Heating of **5a** in toluene at reflux for 30 h afforded a 23% yield of **11**, the structure being confirmed independently by NMR (Table 1) and X-ray analyses.

Conceivably, the efficiency of the IMDA step, as well as the correct C3 configuration in the resultant product, could both be ensured by fine-tuning the preparative procedures. Thus under conditions A (Scheme 2) variations in the equivalents of enolate, and the duration of the reaction revealed that rapid equilibration was occuring at −78 °C (Table 2). Our studies also showed (*a*) that compounds **7a**+**b**, having the undesired (8*S*)-configuration, were kinetically favored, and (*b*) that the *syn*:*anti* ratios were generally poor. We therefore examined the *syn*-selective protocol of Evans[12] (conditions B) on **6e**, and were rewarded with a 61% yield of **8a**+**b** in an 11:1 ratio.

Steric factors on the tether can substantially affect the course of IMDA reactions.[4,13] We were therefore pleased to see, from the formation of **13** and **14** (Table 1), that the required (*R*)-configuration at C8 of precursors **10a**+**b** presents no obstacle to the success of the IMDA reaction. Conceptually, either configuration at C9 is acceptable in view of the future quaternization at C4 of compounds **13** and **14**. Furthermore, the results in Table 1 suggest that selective formation of the IMDA products may be possible by judicious choice of temperature and duration of the reaction. The bulk of the C8-hydroxy protecting group might also have a salutary effect.

These and other refinements for this IMDA/aldol approach to compounds such as **1** are underway.

We are grateful to Professor A. T. McPhail of Duke University for X-ray structure determination of **14**, and to Dr Ken Henry for insight and helpful suggestions. D. H. thanks the Alexander von Humboldt Foundation for a Feodor Lynen Fellowship. Partial support from the National Institutes of Health (GM 51237) is acknowledged. Dedicated to the memory of Professors H.-D. Scharf and D. H. R. Barton.

Table 1 Influence of the configuration of C8 and C9 in the dienic tether on the course of the IMDA reaction (E = CO_2Et)

IMDA precursor	Conditions	Yield	Product	^3J/Hz
9a	toluene reflux, 30 h	23%	 **11**	7,8: 12.4 7',8: 5.0 8,9: 6.0 9,10: 5.6

Received (in Basel, Switzerland) 29th July 1998, Accepted 21st September 1998

High-temperature reaction of $NbTe_4$ with KCN at 450 °C and further crystallization from aqueous solution produces an oxygen-centered tetranuclear niobium cubane-type complex, isolated here as $K_6[Nb_4OTe_4(CN)_{12}]\cdot K_2CO_3\cdot KOH\cdot 8H_2O$, and characterized by X-ray crystallography.

Many small clusters of the electron poor transition metals in groups 3 and 4 are stabilized by an interstitial atom, Z,[1] which serves as an electron donor to stabilize metal–metal bonds and/or stabilizes the cluster by the formation of strong M–Z bonds. A few examples of group 5 transition metal cluster complexes, discrete and extended, containing interstitial atoms have been reported, among them $Nb_4OTe_9I_4$,[2] $Nb_6I_{11}H$,[3] $[M_6S_{17}]^{4-}$ (M = Nb, Ta),[4] $[V_4O(edt)_2Cl_8]^{2-}$ (edt = ethane-1,2-dithiolate),[5] $[Nb_4(\mu_4\text{-}O)(\mu\text{-}Cl)_4\{\mu\text{-}(PhC)_4\}_2Cl_4]^{2-}$,[6] Ta_4SiTe_4[7] and $[Nb_6SBr_{17}]^{3-}$.[8]

The metal atoms in the cuboidal cluster complexes $[M_4(\mu_3\text{-}Q)_4L_n]$ (Q = S, Se, Te; L denotes ligating atoms with either neutral or anionic ligands) with four μ_3-Q bridging chalcogenide ligands generally have enough electrons to support metal–metal bond formation. These cluster complexes are known for a wide variety of transition metals, and they appear to be one of the most important common basic structures of small-sized transition metal cluster complexes.[9] So far only one example of a cubane-type niobium compound $Nb_4Se_4I_4$ has been reported.[10] There are as yet no examples of cuboidal clusters M_4ZQ_4 stabilized by an interstitial atom Z.

In the course of our study on the syntheses and reactivities of solid-state molybdenum and tungsten chalcogenides, we recently obtained new cyanocomplexes with cubane-type W_4S_4, W_4Se_4, W_4Te_4 and Mo_4Te_4 cluster cores.[11] Here we report the synthesis and characterization of the first oxygen-centered cubane-type complex $[Nb_4(\mu_4\text{-}O)(\mu_3\text{-}Te)_4(CN)_{12}]^{6-}$. Tetrameric metal complexes which have a $M_4(\mu_4\text{-}O)(\mu\text{-}L)_6$ core are not uncommmon.[2,12] These complexes are known for a wide variety of metals with six μ-bridging ligands, but they are not known for tetranuclear clusters with four μ_3-bridging ligands (cuboidal complexes).

Dark brown crystals of $K_6[Nb_4(\mu_4\text{-}O)(\mu_3\text{-}Te)_4(CN)_{12}]\cdot KOH\cdot K_2CO_3\cdot 8H_2O$ (**1**)† were obtained in moderate yield by high-temperature reaction of $NbTe_4$ with KCN at 450 °C in a sealed ampoule and further crystallization within 5–7 days from aqueous solution. The source of oxygen was presumed to be water/oxygen contamination of the ampoule/reagents. In related studies it has already been reported that it was almost impossible to obtain an oxide-free product even under rigorous oxygen-free/anhydrous conditions.[2,6,12d] Furthermore, hydrolysis and oxidative degradation of KCN may explain the existence of CO_3^{2-} anions in the structure of **1**.

Owing to the presence of H_2O and CO_3^{2-} intense bands were observed in the IR spectra of **1** in KBr or Nujol. The cyanocomplex can be easily identified since it exhibits ν(CN) at 2095 cm^{-1} and also a ν(NbC)/δ(NbCN) band at 410 cm^{-1}.[11b,13] Another band in the low-energy region at 510 cm^{-1} belongs to the asymmetrical vibration of the Nb_4O core.[12c]

The crystal structure of the compound $K_6[Nb_4(\mu_4\text{-}O)(\mu_3\text{-}Te)_4(CN)_{12}]\cdot KOH\cdot K_2CO_3\cdot 8H_2O$ (**1**) contains two independent cluster anions $[Nb_4Te_4(\mu_4\text{-}O)(CN)_{12}]^{6-}$ with similar geometries (one of which is shown in Fig. 1), carbonate anion, some K^+ cations and solvent water.‡ One K^+ and one O form a pair ($K\cdots O$ of 2.7 Å) which is disordered over two positions with site occupancies 0.643(8) and 0.357(8). The overall content of K^+ in the unit cell is 36 (9 per formula unit). The pH of the solution during crystallization was greater than 7 and therefore the carbonate anion must not be protonated (CO_3^{2-}, not HCO_3^-). This means that we have 7 K^+ per cluster anion and oxygen atoms which may be H_2O or OH^-. Quantum chemical calculations on the diamagnetic compound **1** gave a total cluster anion charge of −6 (see below). In accordance with this, we assume that one of the independent oxygen atoms corresponds to OH^- and the remainder to H_2O. It is possible that OH^- corresponds to the oxygen in the disordered pair $K^+\cdots O$, since their observed interatomic distance is close to that which is found for $K^+\cdots OH^-$ in KOH (2.57–2.83 Å[14]).

The cluster anion (Fig. 1) has a structure which is similar to the well-known $[M_4Q_4(CN)_{12}]^{n-}$ cubane-type clusters (M = Mo, W, Re, Q = S, Se, Te[11,13,15]). As usual, the metal and chalcogen atoms form a distorted cube surrounded by 12 terminal CN ligands. The main difference is the presence of a μ_4-oxygen atom in the center of the Nb_4 tetrahedron with Nb–μ_4-O distances at 1.941(7)–1.98(1) Å. The Nb–Nb distances (3.189(2)–3.211(2) Å) are longer than in those compounds which formally possess a Nb–Nb single bond.[16]

Quantum chemistry calculations for the cluster anion $[Nb_4Te_4(CN)_{12}]^{6-}$ were performed with the extended Hückel method using the CACAO program.[17] Frontier orbital energies for **1** reveal a substantial gap (0.54 eV) between the 21e MO and the top of the lower-lying non-bonding block as well as a large (1.62 eV) 21e (HOMO)–18a_1 (LUMO) separation (Fig. 2). The

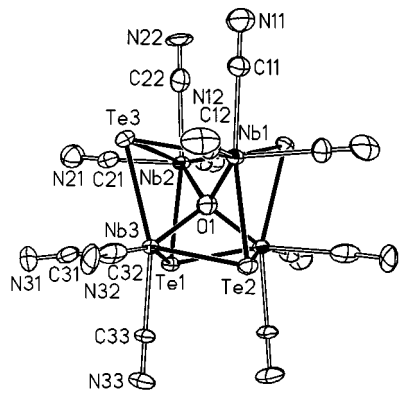

Fig. 1 Anion in **1** (a.d.p. ellipsoids at 50% probability level). All Nb–Nb bonds are omitted for clarity. Some geometrical parameters (Å): Nb–Nb, 3.189(2)–3.211(2), av. 3.202[7]; Nb–μ_4-O, 1.941(7)–1.98(1), av. 1.96[2]; Nb–μ_3-Te, 2.832(2)–2.859(1), av. 2.849[7]; Nb–C, 2.20(2)–2.29(1), av. 2.25[3], C–N, 1.11(2)–1.19(2), av. 1.15[3].

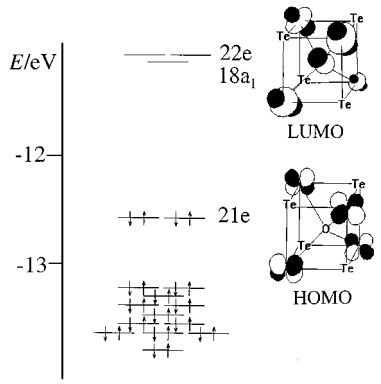

Fig. 2 Extended Hückel MO results for **1**. The corresponding LUMO and HOMO are depicted on the right of the scheme. Only the cluster core Nb_4Te_4O is shown for clarity.

formally non-degenerate $18a_1$ LUMO has both weak Nb–O antibonding and Nb–Nb nonbonding character. The doubly degenerate empty 22e MO, which is very close to $18a_1$ in energy, has a similar bonding pattern. Similarly the degenerate 21e HOMO with a zero contribution of oxygen orbitals is slightly Nb–Nb bonding. The contribution of Te, C and N atomic orbitals in the frontier MOs is negligibly low. According to a bond overlap population analysis Nb–Te bond orders are approximately 1 and Nb–O bond orders are slightly less then 1, generally supporting the model of the centered cubane-like framework tightened with single bonds.

EHMO calculations are in agreement with simple qualitative concepts. Counting oxygen and cyanide as O^{2-} and CN^- and the bridging Te groups as Te^{2-} leads to the formulation $[(Nb^{4+})_4(O^{2-})(Te^{2-})_4(CN^-)_4]^{6-}$, where four electrons are shared by four Nb atoms in the tetrahedral Nb_4 fragment.

Preliminary characterization of the redox behaviour of **1** was performed by cyclic voltammetry (scanning interval: −600 to 1000 mV *vs.* NHE in 0.1 M Na_2SO_4). The oxidation potential occurring at 309 mV has quasi-reversible behaviour. Further oxidation occurring at 900 mV is irreversible.

The authors are grateful to Dr. Davide Proserpio (University of Milano) for the CACAO program package and Dr. M. N. Sokolov for CV experiments. † *Preparation of* $K_6[Nb_4OTe_4(CN)_{12}]\cdot K_2CO_3\cdot KOH\cdot 8H_2O$ (**1**). $NbTe_4$ was synthesized directly from the elements.[18] A mixture of $NbTe_4$ (2.00 g; 3.31 mmol) and KCN (2.00 g; 30.7 mmol) was heated (450 °C; 48 h) in a sealed Pyrex tube. The product of the reaction was added to 30 ml of water and the mixture was refluxed for 2 h. After filtration, the green-brown solution was allowed to stand at 20 °C for 5–7 days. During this time, the volume was decreased to 3 ml. Dark brown crystals, together with some colourless powder, were isolated by filtration, washed by 60% methanol in order to remove the colourless powder, and dried in air. Yield 0.42 g of $K_6[Nb_4OTe_4(CN)_{12}]\cdot K_2CO_3\cdot KOH\cdot 8H_2O$ (29%). Satisfactory elemental analyses (C, H, N, K, Nb and Te) were obtained. The UV–VIS absorption spectrum of **1** in H_2O gave peak positions [λ/nm (ε/M^{-1} cm^{-1}) per Nb_4] at 450 (1300) and 564 (640). The magnetic susceptibility was measured at 300 K: $\chi_M = -590 \times 10^{-6}$ cm^3 mol^{-1}.

‡ *Crystallography:* a dark brown crystal of $K_6[Nb_4(\mu_3\text{-}Te)_4(\mu_4\text{-}O)(CN)_{12}]\cdot KOH\cdot K_2CO_3\cdot 8H_2O$ (**1**) (0.56 × 0.32 × 0.14 mm) was prepared as described above. X-Ray structural analysis was carried out at room temperature on an Enraf-Nonius CAD4 four-circle diffractometer (MoKα, λ = 0.7107 Å, graphite monochromator, standard techniques). *Crystal data*: $C_{13}H_{17}K_9N_{12}Nb_4O_{13}Te_4$, M = 1783.33, monoclinic, space group $P2_1/m$, a = 12.4688(9), b = 22.658(4), c = 16.318(2) Å, β = 91.584(9)°, U = 4608(1) Å^3, Z = 4, D_c = 2.570 g cm^{-3}. A total of 8724 reflections were collected up to $2\theta_{max}$ = 50°, of which 8316 were unique (R_{int} = 0.0144). Absorption corrections (μ = 4.325 mm^{-1}) were applied by integration from the crystal shape, transmission factors ranging from 0.5629 to 0.2942. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 with an anisotropic approximation using SHELX-97.[19] Hydrogen atoms were not located. One of the potassium cations and one oxygen atom appeared to be disordered. Their occupancy factors were refined together with other parameters. Final R values: $R1$ = 0.0490, $wR2$ = 0.1151 for 5272 $F_o \geqslant 4\sigma(F)$, $R1$ = 0.0823, $wR2$ = 0.1347, GOF = 1.022 for all unique data. CCDC 182/1068. See http://www.rsc.org/suppdata/cc/1998/2579/, for crystallographic files in .cif format.

A new strategy for preparing macroporous materials: using a colloidal gas aphron to create an oriented crystal network

R. J. Davey, H. Alison, J. J. Cilliers and J. Garside

Colloids, Crystals and Interfaces Group, Department of Chemical Engineering, UMIST, Manchester, UK M60 1DQ. E-mail: r.j.davey@umist.ac.uk

Received (in Cambridge, UK) 14th September 1998, Accepted 22nd October 1998

We report a simple and generic means of using a static colloidal foam to create a novel porous material, having porosity on the micrometer size scale, that arises from the creation of an oriented crystal network.

The development of materials science over the last decade owes much to our increased understanding of the structural and stereochemical factors which drive molecular recognition[1] processes in the creation of such supramolecular assemblies as crystals,[2] surfactant structures,[3] and colloidal aggregates.[4,5] This progress has been stimulated by the desire to understand and mimic biomineralisation phenomena,[6] to control morphology and polymorphic form of molecular solids,[7] and to synthesise a new generation of functional materials having nanoscale dimensions.[8] One particularly elegant example of this progress has been the discovery that monolayers of amphiphilic molecules at the air/solution interface can be effective in templating nucleation in supersaturated subphases. Thus, for example the control of polymorphic form, crystal size and orientation of calcium carbonate precipitating from aqueous solution have been demonstrated[9] as has[10,11] the catalysed nucleation of α-glycine as {010} pyramids and plates.

The application of this work either for large scale manufacture of particulate products or in the preparation of novel materials has hardly been addressed,[13] largely because it relies on the use of a small scale, static interface between templating monolayer and supersaturated subphase for its viability. In an attempt to demonstrate the potential of this scientific discovery in the preparation of materials we carried out the preliminary experiments reported here in an attempt to make a macroporous material. Control of porosity in the size range 1–100 nm has been demonstrated previously[15,16] but we believe the work reported here to be the first to address porosity in the micrometer size range.

The concept underlying this innovation is that since a foam consists of a high surface area of gas bubbles dispersed in a liquid then, with amphiphilic molecules located at the bubble surfaces, the liquid lamellae separating the bubbles might be used as locations for templated crystallisation. In experiments with single air bubbles in supersaturated glycine solutions we showed previously[12] that, in the presence of an amphiphile chosen to template the nucleation of glycine [*e.g.* (*R*)-leucine[10]] and a surfactant appropriate for stabilising a foam, it was possible to encapsulate a bubble with a crystalline layer of (010) oriented glycine crystals. This oriented nucleation results from the prochiral nature of the {010} faces and their stereochemical relationship to (*R*)-leucine, which segregates at the air/solution interface: it is consistent with earlier reports.[10,11] If this effect could be reproduced throughout the bulk of a stable static foam then it should be possible to utilise such a methodology to create a three dimensional material which has pore sizes corresponding to the bubble size of the foam and a network of solid walls composed of an interconnected array of ordered microcrystals. Such a process is shown schematically in Fig. 1.

In order to realise this concept we first created a colloidal gas aphron. This was achieved following the experimental method of Sebba[13] together with a combination of stabilising surfactant and nucleation inducing template molecules. Thus, for example, a solution of glycine containing 200 μM of either surfactant or a 50 : 50 wt% surfactant/template mixture was prepared at 60 °C and agitated, so as to entrain air, for 15 min at 4500 rpm. This produced a gas aphron with bubble sizes between 10 and 30 μm and 90% volume fraction of air, which under static conditions was stable for *ca.* 1 h. Cooling of this foam then initiated supersaturation and subsequent crystallisation of the glycine. We found that TTAB [$CH_3(CH_2)_{13}N(CH_3)_3Br$] was a particularly effective surfactant for stabilising these aphrons while the hydrophobic α-amino acids (*R*)-leucine and (*R*,*S*)-norleucine were used to template the nucleation at the bubble surface.[11] Control experiments were also carried out in which glycine crystals were prepared by cooling a bulk saturated solution of glycine containing the surfactant mixture. These gave crystals with an (010) plate morphology, as expected from previous work.[10]

When crystallised within the stable aphron containing a templating molecule, glycine was found to nucleate at temperatures between 8 and 15 °C higher than in corresponding bulk solutions (the value depending on the level of supersaturation which varied[12] between 1.01 and 1.20 at 25 °C) indicating that nucleation was catalysed. It was observed that almost no three dimensional growth took place within the bulk solution: glycine crystals grew around and out from the air-solution phase boundaries. This led to the formation of a 'solid foam', consisting of an interconnected glycine crystal network. As crystallisation proceeded a point was reached at which the gas aphron collapsed and liquid drained to the bottom of the sample. This left a 'skeleton' comprising a solid framework of oriented glycine crystals with pore sizes identical to, or slightly larger than, the original aphron bubble sizes. This is seen in

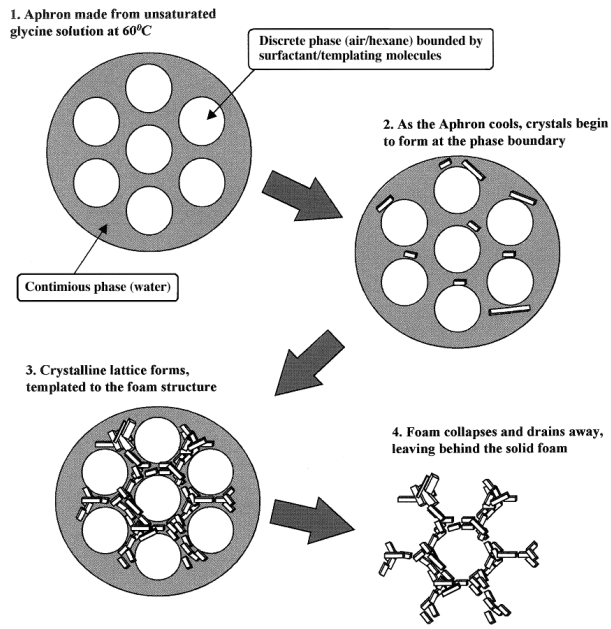

Fig. 1 Schematic depiction of crystallisation in a gas aphron showing the creation of an oriented crystal network and solid foam.

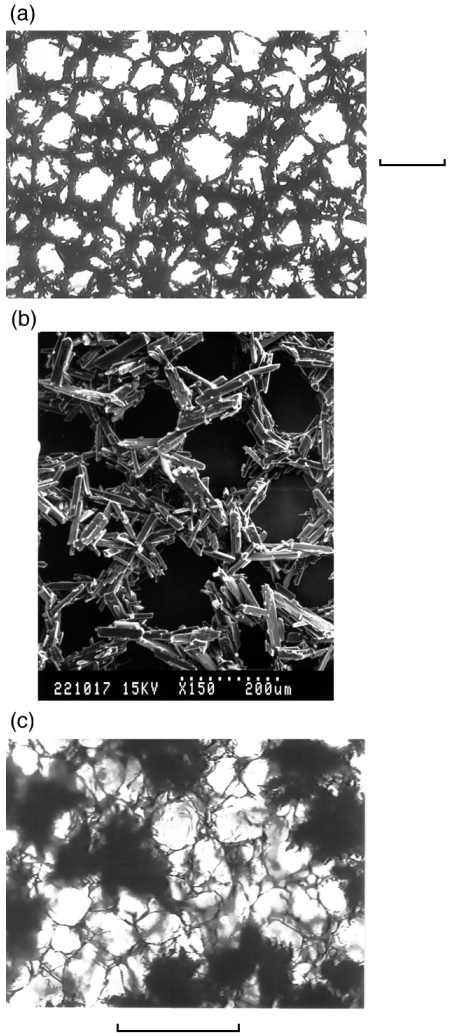

Fig. 2 α-Glycine crystal networks in solid foams prepared from supersaturated aqueous solutions of glycine in a gas aphron using TTAB as a stabilising surfactant and (*R*)-leucine [(a) and (b)] and (*R*,*S*)-norleucine as templating molecules: (a) templated by (*R*)-leucine, an optical micrograph (scale bar 150 μm), (b) templated by (*R*)-leucine, a scanning electron micrograph, (c) templated by (*R*,*S*)-norleucine, and optical micrograph (scale bar 100 μm).

Fig. 2(a), an optical micrograph, and Fig. 2(b), an electron micrograph. Crystals of sizes between 10 and 50 μm are oriented with their (010) facets bounding the pores. Two further observations were evident from the work. Firstly, crystallisation from a stable aphron was not in itself sufficient to create this microstructure: if the templating molecule was not present the oriented nucleation was lost and the foam and crystals collapsed to an unoriented powder. Secondly, when the templating molecule was present as a racemic mixture [(*R*,*S*)-norleucine in this case] not only were crystals templated with (010) orientation but growth was also inhibited in both directions along the *b*-axis yielding thin plate-like crystals. As seen in Fig. 2(c) this again forms a solid foam but now with significantly thinner walls.

It is our belief that this surprisingly simple experimental methodology may now be extended, not only to other solid phases such as fats, waxes, or inorganics but also to employ alternative disperse phases.[14] For example, we performed a preliminary experiment crystallising glycine from aqueous solution in the presence of hexane as the dispersed phase. In this case the size scale of the final crystal network can be reduced since oil drops in the size range 0.1–10 μm may be stabilised and it appears that the oil droplets themselves may be encapsulated by the crystal network. From this we conclude that such structures may have significant potential not in the conventional market place for porous structures, such as catalysis and ceramics but in the equally important arena of formulated products where the crystal network would impose overall structural properties with the release of active components such as agrochemicals, pharmaceuticals or cosmetics, controlled by its porosity, wall thickness and encapsulation properties.

The authors would like to acknowledge the support of EPSRC through its ROPA programme.

1,6-Bis(2,4,6-tri-*tert*-butylphenyl)-1,6-dibora-2,5-diaza-hexa-1,5-diine, the first compound containing two B≡N triple bonds

Thomas Albrecht, Gernot Elter and Anton Meller*

Institut für Anorganische Chemie der Universität, Tammannstr. 4, D-37077 Göttingen, Germany. E-mail: punger@gwdg.de

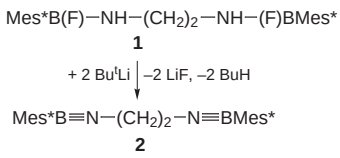
Received (in Cambridge, UK) 21st September 1998, Accepted 21st October 1998

The elimination of hydrogen fluoride from *N*,*N*′-bis[(2,4,6-tri-*tert*-butylphenyl)fluoroboryl]ethylenediamine 1 gives the title compound 2 as a thermally very stable moiety; water is easily added across the B≡N triple bonds.

Iminoboranes R–B≡N–R′[1] and aminoiminoboranes R_2N–B≡N–R′[2] are now quite well known species,[3] particularly due to the work of Paetzold[1] and Nöth.[2] Iminoboranes are kinetically stabilized species and their thermal and hydrolytic stability is dependent upon the steric requirement of the substituents and their resistance against intramolecular chemical attack from the thermodynamically unstable (BN) triple bond. In the past we have studied systematically the stabilization of these moieties by the 2,4,6-tri-*tert*-butylphenyl (supermesityl, Mes*) group.[4,5] If iminoboranes carrying the supermesityl group have the methyl group as the other substituent, their stability against dimerization is retained up to 100 °C. While if the other substituent is ethyl, benzyl, phenyl, *tert*-butyl or trimethylsilyl these iminoboranes will not dimerize, but upon heating will rearrange to give the corresponding benzo[1]borolanes at temperatures between 170 and 350 °C.

Our attempts to prepare a bis(imino)borane by HF-elimination from Mes*BF–NHNH–FBMes*[6] upon treatment with Bu^{t}Li, MeLi or $MN(SiMe_3)_2$ (M = Li, Na) failed. Apparently the two supermesityl groups are too large to permit the necessary approach considering the short bond lengths in the corresponding bis(imino)borane.

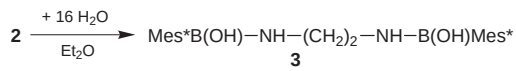
By using an ethylene bridge as a spacer to avoid excessive steric interference we have now prepared the first bis(imino)-borane, containing two isolated B≡N triple bonds (Scheme 1).†



Scheme 1

The bis(imino)borane **2** is thermally stable up to its melting point of 311 °C. It neither dimerizes or oligomerizes nor reacts in an intramolecular fashion to give a benzo[1]borolane derivative. Heating above its melting point, however, delivers several decomposition products, which we could not identify until now. The ^{11}B NMR signal for **2** is at δ 5.9 (for Mes*B≡NMe, δ 5.3[5]) and the IR spectrum shows ν (^{11}BN) = 2020 and ν (^{10}BN) = 2066 cm^{-1}, typical for iminoboranes.[5]

Compound **2** reacts readily with water to yield the corresponding *N*,*N*′-bis[(2,4,6-tri-*tert*-butylphenyl)hydroxyboryl]ethylenediamine derivative **3** (Scheme 2).‡



Scheme 2

Notes and references

† Preparative details and selected spectroscopic data for **1** and **2**: All reactions under dry nitrogen. Mes*BF_2 was obtained as described.[4]

1: to 1.2 g (0.02 mol) ethylenediamine dissolved in 100 ml hexane, 17 ml of a solution (23% in hexane) of BuLi (0.04 mol) were added with stirring. The mixture was refluxed for 2 h and then cooled to −15 °C. To the stirred suspension was added 11.8 g (0.04 mol) Mes*BF_2 dissolved in 80 ml hexane and the reaction mixture warmed to ambient temperature and then refluxed (2 h). The solvent was removed under reduced pressure and volatile byproducts removed at 160 °C (0.01 Torr). Sublimation in a three-bulb tube yielded 6.9 g (57%) of yellowish **1**, subl.p 240 °C (0.01 Torr) (air bath temp.). After short path resublimation the mp was 208 °C. $C_{38}H_{64}B_2F_2N_2$ (608.61): satisfactory analytical results. EIMS: *m/z* (%) = 608 (4) $[M]^+$, 551 (3) $[M - CMe_3]^+$, 57 (100).

NMR data: ^{1}H ($CDCl_3$, $SiMe_4$, 250 MHz) δ 1.34 (s, 18H, CMe_3 : 4), 1.43 (d, $^6J_{HF}$ 1.1 Hz, 36H, CMe_3 : 2/6), 3.22 (m, 4H, CH_2), 3.34 (br, d, $^3J_{HF}$ 17.6 Hz, 2H, NH), 7.40 (s, 4H : 3/5); ^{13}C ($CDCl_3$, TMS, 100.6 MHz) δ 31.3 (C*Me*$_3$: 4), 33.0 (d, $^5J_{CF}$ 2.5 Hz, C*Me*$_3$: 2/6), 34.9 (*C*Me$_3$: 4), 37.5 (*C*Me$_3$: 2/6), 41.6 (d, $^3J_{CF}$ 2.1 Hz, CH_2), 121.0 (3/5), 127.5 (br, 1), 149.8 (d, $^5J_{CF}$ 0.6 Hz : 4), 153.6 (d, $^3J_{CF}$ 2.1 Hz : 2/6); ^{11}B ($CDCl_3$, BF_3·OEt_2 ext., 80.25 MHz) δ 33.0; ^{19}F ($CDCl_3$, C_6F_6 int., 188.3 MHz) δ 70.3.

2: to a suspension of 4.0 g (0.0066 mol) of **1** in 70 ml hexane, 9 ml of a 15% solution of Bu^{t}Li in pentane (0.0132 mol) was added dropwise with stirring at 0 °C. The pentane was distilled off and the reaction mixture refluxed for 2 h. The solution was filtered through a pressure funnel, the residue washed with three portions of hexane (20 ml each) and the solvent distilled off under reduced pressure. By short path sublimation in a high vacuum the remainder yields 1.5 g (41%) of colourless **2**; mp 311 °C, subl.p 180 °C (0.0001 Torr) (bath temp.). **2** is only sparingly soluble in organic solvents. $C_{38}H_{62}B_2N_2$ (568.55). Satisfactory elemental analyses were obtained. EIMS: *m/z* (%) = 568 (2) $[M]^+$, 511 (5) $[M - CMe_3]^+$, 284 (100) $[M/2]^+$; FDMS: *m/z* (%) = 568 (100). *NMR data*: ^{1}H ($CDCl_3$, $SiMe_4$, 250 MHz) δ 1.33 (s, 18H, CMe_3 : 4), 1.57 (s, 36H, CMe_3 : 2/6), 3.73 (s, 4H, CH_2), 7.33 (s, 4H : 3/5); ^{13}C ($CDCl_3$, $SiMe_4$, 100.6 MHz) δ 31.3 (C*Me*$_3$: 4), 31.9 (C*Me*$_3$: 2/6), 35.3 (*C*Me$_3$: 4), 36.7 (*C*Me$_3$: 2/6), 44.9 (CH_2), 114.0 (br, 1), 119.6 (3/5), 152.4 (4), 159.1 (2/6); ^{11}B ($CDCl_3$, BF_3·OEt_2 ext., 80.25 MHz) δ 5.9. IR: ν (^{11}BN) = 2020 cm^{-1}, ν (^{10}BN) = 2066 cm^{-1} (in KBr).

‡ Preparative details and selected spectroscopic data for **3**: to a stirred suspension of 2.0 g (0.0035 mol) of **2**, suspended in 30 ml Et_2O was added 1 ml H_2O (0.055 mol, excess). The mixture was refluxed for 2 h and the liquids removed under reduced pressure leaving colourless **3**. Yield: 1.9 g (91%), mp 221 °C; **3** is fairly soluble in THF. $C_{38}H_{66}B_2N_2O_2$ (604.58). Satisfactory elemental analyses were obtained. EIMS: *m/z* (%) = 604 (1) $[M]^+$, 547 (3) $[M - CMe_3]^+$, 302 (15) $[M/2]^+$, 257 (100) $[Mes*BO - Me]^+$. *NMR data:* ^{1}H (THF-d_8, $SiMe_4$, 250 MHz) δ 1.28 (s, 18H, CMe_3 : 4), 1.44 (s, 36H, CMe_3 : 2/6), 3.22 (m, 4H, CH_2), 3.47 (m, br, 2H, NH), 6.46 (d, $^4J_{HH}$ 1.5 Hz, 2H, OH), 7.31 (s, 4H : 3/5); ^{13}C (THF-d_8, $SiMe_4$, 100.6 Hz) δ 31.8 (C*Me*$_3$: 4), 34.0 (C*Me*$_3$: 2/6), 35.4 (*C*Me$_3$: 4), 38.5 (*C*Me$_3$: 2/6), 43.2 (CH_2), 121.4 (3/5), 134.8 (br, 1), 148.7 (4), 153.5 (2/6); ^{11}B (THF-d_8, BF_3·OEt_2 ext., 80.25 MHz) δ 32.7. IR: ν (OH) = 3605 cm^{-1} (in KBr). No dehydration was observed up to the mp.

Quantitative gas-phase electrophilicities of the dihalogen molecules XY = F_2, Cl_2, Br_2, BrCl and ClF

A. C. Legon

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: A.C.Legon@exeter.ac.uk

Received (in Cambridge, UK) 18th September 1998, Accepted 20th October 1998

Intermolecular stretching force constants k_σ determined from the rotational spectra of complexes B···XY, where B is one of the Lewis bases CO, C_2H_2, C_2H_4, HCN, H_2S and NH_3 and XY is a dihalogen F_2, Cl_2, Br_2, BrCl and ClF, are used to establish a quantitative scale of gas-phase electrophilicities E_{XY} of the halogens.

The nature of the initial interaction of homo- or heteronuclear diatomic halogen molecules XY with simple Lewis bases B in chemically reactive mixtures of the two components is a matter of fundamental interest in chemistry.[1] It has recently proved possible to isolate pre-reactive complexes of the type B···XY in gaseous mixtures and then characterise them through their rotational spectra by using a fast-mixing nozzle[2] in combination with a Fourier-transform microwave spectrometer.[3,4] Thereby precise values of several properties of the isolated species B···XY become available, including its angular and radial geometry, the strength of binding (as measured by the intermolecular stretching force constant k_σ), and the extent of electric charge redistribution within XY on complex formation. The efficacy of the fast-mixing nozzle is such that even pre-reactive complexes formed by NH_3, CO, H_2S, C_2H_2 or C_2H_4 with F_2 or ClF can be detected,[5–11] despite the rapid and violent reactions that would attend mixing of the components under normal conditions. Consequently, trends in the properties of B···XY may be identified not only by variation of the Lewis bases over a wide range of types but also by examining complexes with halogens as reactive as fluorine and chlorine monofluoride.

Such an approach has already revealed[12] a remarkable parallelism between the angular geometries of B···XY and B···HX (X,Y = F, Cl or Br). Thus, the pair B···HX and B···XY are isostructural for a given B over the range of XY and HX. This parallelism establishes that some simple rules first proposed for predicting angular geometries of hydrogen-bonded species B···HX,[13,14] and based on simple electrostatic considerations, also apply to the halogen complexes B···XY. The question then arises: Does the parallelism extend to other properties?

Another property of B···HX complexes that was found to vary systematically with B and HX is k_σ, which is the restoring force per unit infinitesimal displacement of the hydrogen bond along its dissociation co-ordinate and, therefore, one measure of the strength of the interaction. In particular, it was discovered[15,16] that k_σ could be partitioned between B and HX to define a nucleophilicity N_B of the proton acceptor region of B and the electrophilicity E_{HX} of HX. The relationship between N_B, E_{HX} and k_σ was established to be[15]

$$k_\sigma = cN_BE_{HX} \quad (1)$$

where c is constant. This empirical equation could be used to predict k_σ of a large number of B···HX from a few N_B and E_{HX} values. For the particular scales of nucleophilicities and electrophilicities chosen, the value c = 0.25 N m^{-1} was appropriate. The advantage of the N_B and E_{HX} thereby established is that they define the propensity of a molecule to interact with either an electrophile or a nucleophile, respectively, in the limit where one molecule probes the other with only minor perturbation, and in isolation in the gas phase. The empirical eqn. (1) has been rationalised on the basis of the electrostatic model of the hydrogen bond elsewhere.[15]

The purpose of this communication is to examine whether the k_σ values of B···XY complexes, where B is CO, C_2H_2, C_2H_4, HCN, H_2S or NH_3 and XY is F_2,Cl_2, Br_2, BrCl or ClF, obey eqn. (1) and, if so, to establish a scale of electrophilicities E_{XY} for halogens and interhalogens. Another aspect of interest is whether a common set of nucleophilicities N_B applies to both the B···HX and B···XY series.

Table 1 displays a matrix of k_σ values for the series of B···XY defined earlier.[5–11,17–32] All values were derived from centrifugal distortion constants D_J or Δ_J established from analyses of rotational spectra, the latter usually observed with the fast-mixing nozzle/FT microwave spectrometer combination. Relationships between k_σ and D_J or Δ_J valid in the quadratic approximation for rigid, unperturbed subunits B and HX or XY have been derived by Millen for complexes of various symmetries.[33]

To test the validity of eqn. (1) for the B···XY in Table 1, the following procedure was used. First, the electrophilicity of BrCl was arbitrarily assigned the value E_{BrCl} = 9.0. Then E_{BrCl} was used with the k_σ values of all but one member of the series B···BrCl and c = 0.25 N m^{-1} to generate the nucleophilicities N_B for the Lewis bases B = CO, C_2H_2, C_2H_4, HCN and H_2S. This approach was not used for N_{NH_3} because there is evidence (see later) that H_3N···BrCl (and H_3N···ClF) involve significant

charge transfer in addition to a simple electrostatic interaction.

Next, the N_B values so generated and recorded in Table 2 were used to establish E_{XY} for XY = F_2, Cl_2, Br_2 and ClF. For example, the appropriate N_B and k_σ pair was substituted into eqn. (1) to give one E_{ClF} value for each member of the series B···ClF. The mean value was then taken. Values of E_{F_2}, E_{Cl_2}, E_{Br_2} and E_{ClF} obtained in this way are included in Table 2 with the set of nucleophilicities N_{CO}, $N_{C_2H_2}$, $N_{C_2H_4}$, N_{HCN}, N_{H_2S} and N_{NH_3}. For the series B···Cl_2, B = NH_3 was not used to give a value of E_{Cl_2}, but instead the mean value of E_{Cl_2} from the remaining members was combined with k_σ of H_3N···Cl_2 to define N_{NH_3}. This approach was preferred because N_{NH_3} could not be satisfactorily obtained from H_3N···BrCl, for reasons alluded to earlier. Likewise, H_3N···ClF was not used in the evaluation of E_{ClF}.

As a check on the procedure, the N_B and E_{XY} of Table 2 were employed in eqn. (1) to generate k_σ for all complexes implied in Table 1. The predicted k_σ, shown in Table 1 in parentheses, are in good agreement with the experimental values when available, except for H_3N···BrCl and H_3N···ClF, whose large k_σ are seriously underestimated. These disagreements can be understood when the electric charge redistribution in the XY subunit, as estimated from the halogen nuclear quadrupole coupling constants, is considered for each member of the series B···Cl_2,[34] B···BrCl[35] and B···ClF.[12] Only a few hundredths of an electronic charge is transferred from X to Y in most complexes except H_3N···BrCl and H_3N···ClF and, in particular, it was shown to be necessary to assume a significant contribution of the ionic structure $[H_3NCl]^+$···F^- in a valence bond description of the latter complex.[9] Presumably a similar assumption is appropriate to the strongly bound H_3N···BrCl[11] but all other B···XY can be understood on the basis of the simple electrostatic model without invoking such charge transfer.[12,34,35]

Some interesting conclusions about B···XY interactions are available by reference to Tables 1 and 2. First, the fact that eqn. (1) applies to the two series of complexes B···HX and B···XY (with exceptions noted) suggests that the intermolecular binding is of a common type in both. For B···HX, the hydrogen bond interaction is well established to be of the simple electrostatic type B··$^{\delta+}$H–X$^{\delta-}$, where $^{\delta+}$H interacts with a nucleophilic region of B.[13,14,36] Presumably, this is also the case for the halogen complexes, with interactions of the type B··$^{\delta+}$X$^{\delta-}$–X$^{\delta+}$ or B··$^{\delta+}$X–Y$^{\delta-}$. It is noteworthy that the order of the electric quadrupole moments of the homonuclear dihalogens is F_2 < Cl_2 < Br_2, while BrCl and ClF have electric dipole moments of similar magnitude.[37] This order of electric moments is consistent with the order F_2 < Cl_2 < Br_2 < BrCl < ClF established here for the electrophilicities E_{XY} of the halogens (see Table 2).

The second conclusion is that, with one exception, the nucleophilicity N_B obtained for each B from the experimental k_σ of Table 1 and eqn. (1) is similar to that established from the B···HX series. The exception is HCN. The N_B and E_{HX} from the B···HX series are included in Table 2 for convenience. Evidently, HCN is a better nucleophile with respect to the hydrogen halides than to dihalogen molecules.

Table 2 Nucleophilicities N_B and electrophilicities E_{XY} of a series of Lewis bases B and dihalogen molecules XY

Nucleophilicities N_B

Crystalline silica prepared at room temperature from aqueous solution in the presence of intrasilica bioextracts

Carole C. Perry* and Tracey Keeling-Tucker

Department of Chemistry and Physics, The Nottingham Trent University, Clifton Lane, Nottingham, UK NG11 8NS. E-mail: Carole.Perry@ntu.ac.uk

Received (in Bath, UK) 23rd September 1998, Accepted 20th October 1998

Silica, exhibiting crystalline texture has been prepared from aqueous solution at pH *ca.* 7 in the presence of intrasilica biomolecules extracted from the primitive plant *Equisetum telmateia*; some of the silica shows interplanar lattice spacings of 3.5 Å and is present in lath-like objects up to *ca.* 20–30 nm wide and more than 100 nm in length; an electron diffraction pattern obtained from this material also shows interplanar spacings of 3.46, 2.13 and 1.70 Å suggesting that the material might be quartz.

In the field of biomineralization where biological organisms are able to regulate the formation of both crystalline and amorphous composite mineral phases there is much interest in understanding how mineralization occurs.[1] The process requires the concentration of selected elements, the nucleation, growth and moderation of growth of the mineral phase in predefined locations at specific times during the lifetime of a particular organism. Biominerals are usually composite phases containing organic components such as membranes and/or proteins and carbohydrates together with the mineral phase. The relationship between the two is thought to be important in the regulation of mineral composition, crystallographic phase and morphology.[2] The organic phase is largely found external to the mineral phase but low levels (*ca.* 0.03% by weight) of acidic proteinaceous biopolymers can also be found intercalated within the mineral phase, perhaps at crystal domain boundaries.[3] The intercalated biopolymers may have fundamental roles to play in nucleation and/or crystal growth and their presence has also been shown to have dramatic effects on the mechanical properties of crystalline biominerals.[4] For amorphous biominerals such as silica, biopolymers are also found in intramineral locations,[5–7] however, their role in nucleation, particle growth and aggregation remains unclear.

We are interested in extending our understanding of how biosilicas with specific form[8,9] are laid down and additionally we are interested in the preparation of novel silica phases using knowledge gained from the study of biological systems. To this end we have extracted protein-containing biomolecules from intrasilica locations in the branches of *Equisetum telmateia*[5] and used them in the study of silica precipitation at circumneutral pH.† The biopolymer extract used in this study was released by solubilization of the siliceous phase with buffered solutions of HF following treatment of plant materials with a mixture of concentrated nitric and sulfuric acids. The amino acid composition of this extract was rich in serine, glutamine/glutamic acid and glycine and had associated with it a carbohydrate component enriched in glucose and xylose. The 'model' system used to study particulate silica precipitation utilized a catecholato complex of silicon, $K_2[Si(C_6H_4O_2)_3]\cdot xH_2O$ as the source of soluble silicon.[10] At *ca.* physiological pH the complex partially decomposes to yield orthosilicic acid which immediately undergoes polycondensation reactions to relieve any resultant supersaturation.

50 mM solutions of potassium silicon catecholate were used with/without the biopolymer extract at 1% w/w, the pH of the solution was lowered to *ca.* 7.0 by the addition of a predetermined quantity of HCl and the concentrations of orthosilicic acid measured as a function of time by a colorimetric molybdenum blue method.[11] Kinetic analysis of the solution data was carried out in accordance with our previous studies.[12]‡

The effect of the biosilica extracts on both the early oligomerization reactions (*e.g.* the formation of dimers and trimers of orthosilicic acid) and on particle growth by precipitation/dissolution reactions was studied. Electron microscopy studies of the precipitates gave information on the effect of solution additives on nucleation, particle growth and aggregation.

Statistical analysis (students t-test and Mann Whitney U-test)[13] of the kinetic data‡ showed that the addition of 1% w/w of the *Equisetum telmateia* intrasilica extract to the silica oligomerization medium results in a *ca.* 22% increase in the rate of trimer formation (the second reaction in the oligomerization process). The rate constant for the addition of a monomer to an oligomer larger than a trimer is statistically no different for samples including the proteinaceous extract but the rate of removal of monomers from oligomers is reduced by *ca.* 33%. The effect of these changes is to increase the rate at which orthosilicic acid is removed from solution and to reduce the amount of silicon left in solution at the end of the experiment. Fig. 1 shows the increase in the levels of oligomerized silica at all sampling points. Electron microscopy of the precipitated silica shows evidence for aggregates built up from small particles *ca.* 1–2 nm in diameter, much smaller than is expected for the 'blank' system (data not shown, see ref. 10 for an example). Other structures present include ribbon-like (lath-like) objects and curved loops which often show characteristic fringes of *ca.* 3.50 Å. Energy dispersive X-ray analysis of all such areas indicates that the material contains silicon and oxygen.† The ribbon-like structures and loops, Fig. 2(a)–(c), are found in all samples from 1 h after initiation of the precipitation reaction. Samples taken at 48 h after the start of the experiment occasionally exhibit order over distances > 600 nm in length and *ca.* 20–30 nm in width. The images obtained suggest a 'soft' or perhaps 'layered' material (for an example, see ref. 14) but the electron diffraction patterns obtained from some areas with *d*-spacings of 3.46, 2.13 and 1.70 Å are compatible with quartz [PDF 5-490], Fig. 2(d). X-Ray diffraction data could not be obtained from silica collected by centrifugation 7 days after initiation of the reaction (even after an extended scan over 8 h) indicating that the silica sample prepared in the presence of the

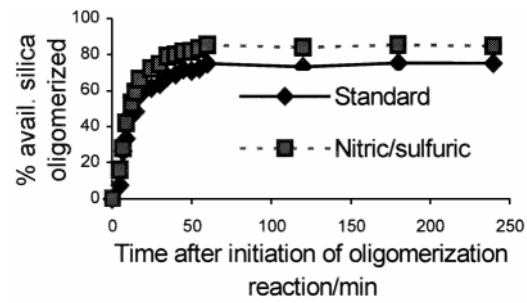

Fig. 1 Plot of % of oligomerized silica (not detectable by the molybdate method) *vs.* time.

biopolymer extract contains only low levels of crystalline material. No additional information was obtained from diffraction studies at low values of 2θ suggesting that the siliceous materials are not mesoporous, lamellar phases.

The presence of the protein-containing extract in the oligomerizing mixture clearly had some effect on nucleation with the formation of (a) smaller particles of silica (the majority of fundamental particles are smaller than 2 nm in diameter as opposed to particles up to 4 nm in diameter for the blank system) and, (b) silica with a crystalline appearance. The presence of the latter material from the earliest analysis point (as assessed by electron microscopy) suggests that this material is formed very early in the reaction profile and is not the result of structural rearrangement with time.

Biopolymers can be removed from the silica precipitated in the 'model' reaction system utilizing the same methods used for their initial production. The levels of proline are decreased and the levels of glycine are *ca*. doubled in the proteinaceous material extracted from the 'model' silica precipitated materials. The amino acid composition of the biopolymer extracts is rich in amino acids known to form β-sheet or β-turn secondary structures. For such structures, the spacing between successive layers is a minimum of 3.5 Å when only glycine is involved but may be 5.7 Å for chains rich in alanine as is found in the silk protein fibroin.[15] It is possible that the observed silica structures are either crystalline silica formed *de novo* from aqueous solution, or more likely, the observed structures are generated by epitaxial matching of the organic and inorganic matrices with the silica structure continuing to develop from the initial biopolymer-controlled nucleation event. It is evident that in the biological environment additional controls must be exerted during the process of silica precipitation in order to prevent the formation of crystalline phases as they are much more difficult to mould into the macroscopic structures produced by living organisms.

Further work will involve identification of the biopolymer component(s) (preliminary studies have shown that the extracts contain both high molecular weight proteins and low molecular weight glycoproteins) which are most effective in the spontaneous generation of crystalline silica structures from supersaturated solutions at room temperature, neutral pH and in the absence of multicharged cations, conditions which would not be expected to yield crystalline silica.[11,16]

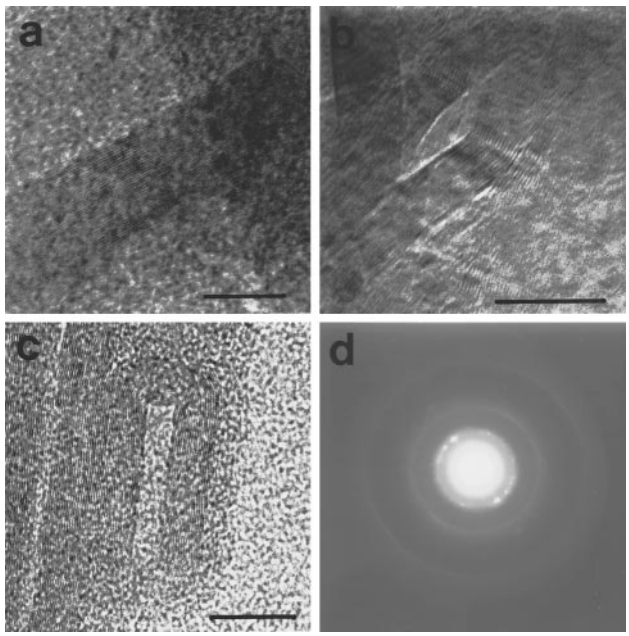

Fig. 2 (a)–(c) Transmission electron microscopy data for unusual silica structures precipitated in the presence of 1% w/w biopolymer extracts. All images shown are from microscope grids prepared by the 'dipping' method. Scale bars represent 10 nm; (d) electron diffraction pattern from (b). Pattern was recorded using a camera length of 100 cm.

Notes and references

† Precipitation experiments were conducted using biopolymer extracts from two separate extractions. The amino acid compositions were measured using an Applied Biosystems 420a amino acid analyser operated by A. C. Willis of the MRC Immunochemistry Unit, Oxford University. For the kinetic measurements, four sample runs were completed for each experiment on the same day using a temperature controlled reaction vessel set at 23 ± 0.1 °C. Samples for electron microscopy studies were taken from parallel experiments by dipping carbon coated formvar covered copper electron microscope grids into the reaction vessel at 1, 4, 24, 48 h and 7 days after the experiment was initiated and allowing the grids to air dry. Samples for electron microscopy were investigated using a JEOL 2010 analytical electron microscope (Link ISIS system) fitted with a LaB_6 filament operating at 200 keV. Magnifications of 200 000 × were necessary to see the lattice fringing present and areas of interest were subjected to energy dispersive X-ray analysis to identify the elements with atomic number ⩾6 present in the sample. A minimum of 10 analyses for each sample area showed that the precipitated material contained Si and O together with traces of K and Cl (N.B. the grids were not washed after sampling by dipping). Crystalline structures as presented in this paper have not been observed by transmission electron microscopy in any of our other model precipitation experiments performed in the presence of a range of singly and multiply charged metal ions, carbohydrates and proteins such as bovine serum albumin, zein, concanavalin A and cytochrome c. Silica samples were also analysed by powder X-ray diffraction; Siemens D500 diffractometer operating in the range 2θ = 1–80° by Professor Mark Weller and Dr Adam Whitehead of Southampton University. The Visual Services Department at The Nottingham Trent University are thanked for printing of the electron micrographs for publication. BBSRC and Crosfield Chemicals are thanked for their funding.

EPR study of platinum supported on NaY

Thorsten Schmauke, Einar Möller and Emil Roduner*

Institut für Physikalische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70550, Germany. Tel: +49 711 685 4490; Fax: +49 711 685 4495. E-mail: roduner@indigo01.chemie.uni-stuttgart.de

Received (in Bristol, UK) 1st July 1998, Accepted 26th October 1998

Pt/NaY was prepared by the aqueous ion-exchange method and investigated by EPR spectroscopy. After reduction with H_2 using a static system, an orthorhombic EPR signal was observed with g_1 = 2.531, g_2 = 2.322, g_3 = 2.062, coaxial with the hyperfine components a_1 = 64.9 G, a_2 = 74.6 G, a_3 = 72.6 G; this signal is assigned to Pt^+ ions. Typical cation sites for location in the supercages are excluded for symmetry reasons.

Hetereogenous catalysts consisting of transition metal ions or small clusters supported on zeolites play a key role in important petrochemical reactions.[1] Since the activity and the selectivity of catalytic reactions depend on the size of clusters, characterization of the size, location, electronic and atomic structure by techniques such as TEM, EXAFS, XRD, XPS, TPR, TPD, H_2 chemisorption, ^{129}Xe NMR, IR or electron paramagnetic resonance (EPR) is indispensable. EPR has been shown to be an important tool for the characterization of many transition metals in zeolites.[2] In many cases it is possible to distinguish between different oxidation states, coordination numbers, complex symmetries and crystal field strengths. It is of importance for a further understanding of heterogenous catalysis to observe changes of the catalytically active transition metal centers during reactions. The site determines the accessibility by reacting molecules. In view of the importance of Pt on zeolites it is surprising that there have been no publications of EPR studies until today.

Samples were prepared *via* ion-exchange at 343 K over 48 h by dropwise addition of 0.003 M $[Pt(NH_3)_4]Cl_2$ solution to NaY slurry, resulting in a Pt loading of 4%. The exchanged zeolite was filtered, washed with deionized water in order to remove Cl^- ions, and dried at 296 K in air. Calcination was conducted by heating Pt/NaY from room temperature to 563 K at 0.5 K min^{-1} in flowing O_2 (270 ml min^{-1} g^{-1}), and holding at 563 K for 3 h. After this treatment platinum is located as PtO in the supercages of Y zeolite as has been shown using X-ray methods, electron microscopy and gas adsorption.[3,4] The zeolite was pumped at 523 K to remove water, and reduction was performed by heating from 296 K to 563 K at 0.5 K min^{-1} in a closed EPR tube with different molar ratios of Pt : H_2 (1 : 3 or 1 : 6), and holding at the final temperature for 6 h. X-Band EPR spectra were recorded on a Bruker EMX spectrometer in the temperature range 4 K to 150 K in H_2 atmosphere.

For reduction at a molar ratio of Pt : H_2 = 1 : 6, no EPR spectrum is observed. For a molar ratio Pt : H_2 = 1 : 3, the EPR spectrum at 4 K shows overlapping signals (Fig. 1). The spin concentration corresponds to about 0.5% of the total Pt loading. The main signal is orthorhombic with resolved ^{195}Pt hyperfine splitting (natural abundance 33.8%, $I = \frac{1}{2}$). Simulation[5] yields the spin Hamiltonian parameters g_1 = 2.531, g_2 = 2.322, g_3 = 2.062, a_1 = 64.9 G, a_2 = 74.6 G, a_3 = 72.6 G with coaxial *g*- and *a*-tensors. The orthorhombic symmetry allows us to exclude the possibility that the species is located at a typical cation site,[6] since axial symmetry should be expected for these sites. Going to higher temperatures, the lines broaden and the intensity decreases. Above 100 K only a very weak and broad spectrum is observed. This behavior may be caused by dynamic effects, for example by jump exchange of the observed species between different sites. At this point we have no explanation for the remaining minor features, which are superimposed mainly on the central line.

Several EPR spectra of formal Pt(I) complex compounds with organic ligands have been described.[7] The general sequence of *g*-values in all these spectra is $g_1 > g_2 \approx g_e >> g_3$, and the authors assign them to Pt^+, in contrast to expectation since for a d^9 system all *g*-values should be larger than g_e due to spin–orbit coupling.[8] Other authors[9] assume that during electrochemical preparation of these complexes a reduction of the organic ligands occurs, leading to species which are better described as $Pt^{II}(L^-)$ than as $Pt^I(L)$. The present case is different since a reduction of the zeolite lattice is more difficult than a reduction of unsaturated organic ligands. Indeed, *g*-values in the sequence $g_1 > g_2 > g_3 > g_e$ indicate the presence of platinum in the formal oxidation state of +1. For Pt^{3+} ions (d^7) $g_i > g_e$ is expected as well as for all ions with a more than half filled d-shell. Since we used an excess of hydrogen for the reduction of PtO it is unlikely that Pt^{3+} is formed.

Axial EPR spectra of Pt^+ ions with spin Hamiltonians characterized by $g_\parallel$ = 3.29, $g_\perp$ = 2.261, $a_\parallel \leqslant$ 10 G and $a_\perp$ = 229 G for an Ar matrix and $g_\parallel$ = 3.13, $g_\perp$ = 2.214, $a_\parallel \leqslant$ 10 G and $a_\perp$ = 311 G for a Kr matrix were reported.[10] Compared with the observed platinum species in Y zeolite, the *g*-anisotropy of Pt^+ was larger in the rare gas matrices because of the weaker crystal field.

The ^{195}Pt hyperfine splitting of about 70 G in NaY is equivalent to an s-orbital contribution of 0.6%, which is similar to the 1.4% for Pt^+ in Ar and 1.9% in Kr matrices.[10] The formation of Pt clusters during reduction is a well known process,[12] but based on the isotropic hyperfine coupling constant[11] of about 12000 G for Pt^0 a much higher s-character is expected for neutral clusters. We therefore exclude the possibility that the spectrum observed here represents clusters. The contribution of d-orbitals of Pt^+ in rare gas matrices is 54% for Ar and 76% for Kr.[10] The observed d-orbital contribution for Pt^+/NaY is only about 2%, possibly because of the contribution of excited p-orbitals.[10,13,14] Another possibility is the delocalization of spin density to ligands since the d-orbital contribution is smaller by about a factor 30 for Pt^+ in NaY than for Pt^+ in rare gas matrices. On the other hand, the high *g*-value allows us to exclude the possibility that the radical is localized on oxygen since $O^{\cdot-}$ or $O_2^{\cdot-}$ have *g*-values near g_e.[15,16] A more attractive interpretation is based on the assumption that one (or two) of the

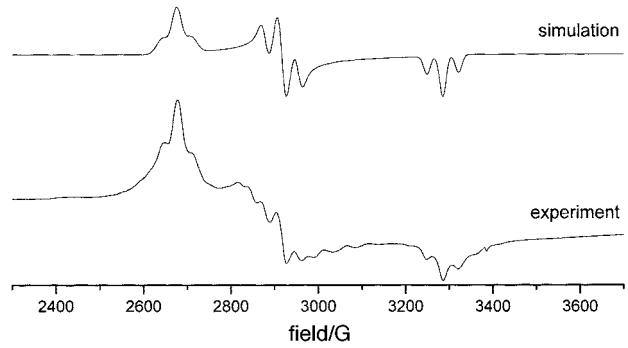

Fig. 1 Simulation and X-band EPR spectrum of Pt/NaY observed at 4 K.

hyperfine components is of negative sign, which is experimentally not distinguishable. This leads to near-zero s-character and somewhere of the order of 36% d-character, which is much closer to the results reported for Pt^+/Ar, and also compatible with the high g-values.

The present results introduce a new, non-invasive tool for the characterization of one of the most important catalysts. Further EPR experiments aiming at a better understanding of reaction mechanisms of heterogenous catalysis on Pt exchanged zeolites are in progress. This includes other preparation conditions and examinations of further zeolites which lead to Pt cations located at different sites, for example in sodalite cages,[3,4] and consequently to other environments which can be studied by EPR. Adsorption of organic compounds or oxidation may lead to the disappearance of the observed EPR signals, and perhaps to the appearance of other EPR active species. ESEEM experiments may give more detailed information about the nature of ligands around the observed species.

We thank M. Munzarová for valuable comments.

The preference for terminal rather than bridging {*i.e.* $[(silox)_2Re]_2(\mu\text{-}O)_2$} oxo ligands in C_2 $(silox)_2(O)Re{\equiv}Re(O)(silox)_2$ is electronic, not steric, in origin.

Use of the bulky siloxide $^tBuSiO^-$ (silox) ligand has enabled investigations of several low coordinate, monomeric complexes of groups 4–6,[1–4] but metal–metal bond formation cannot always be averted. $[(silox)_2MH_2]_2$ (M^{IV} = Nb, Ta)[5] dimers form upon reduction of $(silox)_2MCl_3$ under H_2 when M^V trihydride derivatives were expected, and while sterically protected $(silox)_2W{=}N^tBu$,[4] an unusual three-coordinate W^{IV} derivative, was isolable, a less hindered W^{III} environment encouraged triple-bond formation, *i.e.* $(silox)_2XW{\equiv}WX(silox)_2$ (X = Cl, H, Me, Et).[6] Attempts to extend the theme of low-coordination to Re[7] have instead resulted in the synthesis of C_2 $(silox)_2(O)Re{\equiv}Re(O)(silox)_2$, whose terminal oxo groups are an apparent oddity.

In contrast to metatheses within groups 4–6, treatments of various rhenium chlorides with Na(silox) were ineffective. Utilization of Tl(silox), prepared *via* metathesis of Hsilox with TlOEt, mitigated some of the undesired redox processes. Addition of Tl(silox) to $ReCl_3(PEt_3)_3$[8] (100 °C, 12 h, C_6H_6) afforded orange $(silox)ReCl_2(PEt_3)_2$ **1** (60%), and a similar treatment (100 °C, 2 d, C_6H_6) of Cl_4ReL_2 (L = THT,[9] THF)[10] gave the blue, trigonal bipyramidal (X-ray) Re^V complex, $(silox)_3ReCl_2$ **2** (33%) upon chromatographic work-up in air. Metathesis of Re_3Cl_9 with 3 equiv. Tl(silox) (100 °C, 12 h, C_6H_6) provided dark green, C_s (X-ray) $[(silox)ReCl]_3(\mu\text{-}Cl)_3$ **3** (85%); further incorporation of silox into **1–3** could not be effected.

Treatment of *cis*-$ReOCl_3(PEt_3)_2$[11] with 3 equiv. of Tl(silox) afforded orange $(silox)_2(O)Re{\equiv}Re(O)(silox)_2$ **4** [eq (1)] in moderate yield (38%) after extensive trituration with hydro-

$$cis\text{-}ReOCl_3(PEt_3)_2 + 3\ Tl(silox) \xrightarrow[\text{benzene, -3 TlCl}]{\text{160 °C, 3 d}} \underset{\mathbf{4}}{(silox)_2(O)Re{\equiv}Re(O)(silox)_2} + \ldots. \quad (1)$$

carbons and crystallization from THF. Two singlets in its ^1H NMR spectrum suggested C_2 symmetry, and IR spectroscopy revealed a moderate band at 944 cm^{-1} tentatively assigned to ν(ReO). An X-ray diffraction study of **4** confirmed the molecular C_2 symmetry, terminal oxo and silox ligands, and distorted tetrahedral geometry about each Re (Fig. 1). Inter-silox angles O1–Re1–O4 [124.9(2)°] and O2–Re2–O3 [123.1(2)°] are significantly splayed due to a steric interaction. While O4–Re1–Re2 110.8(2)° and O3–Re2–Re1 112.5(2)° are relatively normal, they contrast with O1–Re1–Re2 [92.8(2)°] and O2–Re2–Re1 [93.0(2)°], which cant toward more open space between the silox and oxo groups. The d(Re≡Re) of 2.3593(6) Å is long compared to common Re^{II} d^5–d^5 ($\sigma^2\pi^4\delta^2\delta^{*2}$) triple bonds and related C_2 ditungsten species.[12] The Re–oxo bond lengths of 1.690(5) and 1.729(6) Å are slightly longer than average, but most comparisons are with oxo ligands on higher valent derivatives,[13,14] where shorter bonds are expected. Two Re-silox distances are normal [d(Re1–O1) = 1.822(5), d(Re2–O2) = 1.819(5) Å], while the remaining Re1–O4 [1.875(6) Å] and Re2–O3 [1.909(6) Å] linkages are quite long due to the respective *trans*-influences of the O6 and O5 oxo groups transmitted through the Re≡Re bond.

$(silox)_2(O)Re{\equiv}Re(O)(silox)_2$ **4** was remarkably inert toward simple donors (*e.g.* CO, py, alkenes), reducing agents (*e.g.* H_2, Me_3SiH), common oxidants (*e.g.* I_2, $BrCH_2CH_2Br$, pyO, Me_3NO, H_2CCH_2O, N_2O) and heterocumulenes (*e.g.* CS_2, PhN=C=O), and reacted with a few substrates or reagents (*e.g.* $PhPH_2$, Na/Hg, O_2) to give mixtures. Terminal rhenium–oxo bonds have been noted to be strong and inert in mononuclear complexes [*cf.* $(MeC_2Me)_2RReO$],[14] yet aggregation *via* μ-oxo formation is common.[15] Since **4** could have adopted a $[(silox)_2Re]_2(\mu\text{-}O)_2$ **5** configuration without undue steric strain {*cf.* $[(silox)_2W]_2(\mu\text{-}CMe)_2$},[16] calculations were employed to assess the terminal oxo electronic structure preference.

Fig. 2 illustrates truncated extended Hückel MO diagrams for the model complex $(HO)_2(O)Re{\equiv}Re(O)(OH)_2$ **4′**, which was given the structural parameters of **4** and adjusted to be C_2, and $[(HO)_2Re]_2(\mu\text{-}O)_2$ **5′**, whose optimized geometry [*e.g.* d(ReRe) ≒ 2.53 Å, d(Re–O_b) = 1.94 Å] was determined from density functional theory (DFT). The EHMO calculations revealed **5′** to be *ca.* 4 eV less stable than the observed **4′** system, with a very small HOMO–LUMO gap of *ca.* 0.5 eV. The extreme discrepancy in total energy is due to a tremendous increase of Re–O and Re–Re π* character realized in the three highest occupied orbitals of **5′**. In the unbridged geometry **4′**, the Re≡Re bond is comprised of the usual σ- and two π-bonding orbitals,[17] and while the d^3 fragment MOs have a significant amount of Re–O π*-character, it is largely dissipated upon forming the

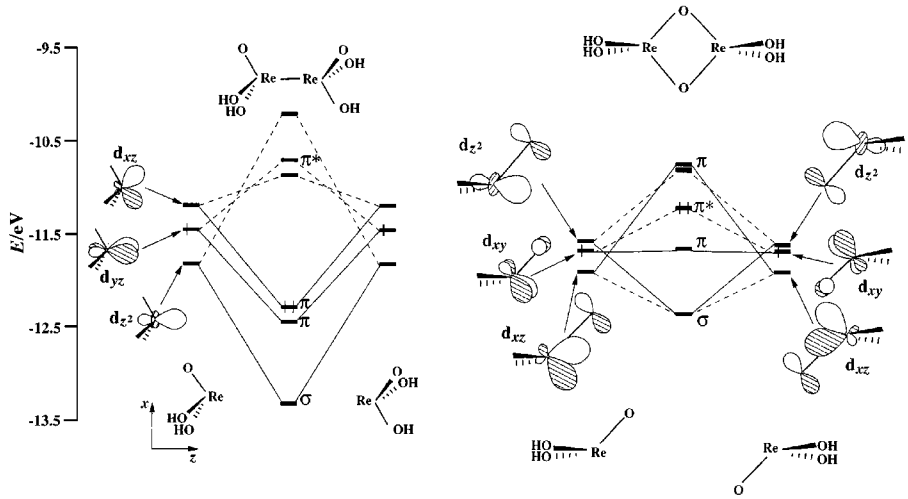

Fig. 2 Truncated MO diagrams for $(HO)_2(O)Re{\equiv}Re(O)(OH)_2$ **4′** and $[(HO)_2Re]_2(\mu{-}O)_2$ **5′**, modeling $(silox)_2(O)Re{\equiv}Re(O)(silox)_2$ **4** and hypothetical $[(silox)_2Re]_2(\mu{-}O)_2$ **5**, respectively.

metal–metal bond. In the μ-oxo version **5′**, dimerization of the $(HO)_2ReO$ fragments affords a Re–Re σ-bonding (σ) orbital that is principally d_{z^2} and a Re–Re π-bonding (π) orbital based on d_{xy}, but both have significant Re–O π* character, and the latter is rendered virtually non-bonding relative to the fragment MOs. Another Re–Re π-bonding orbital derived from d_{xz} contains so much Re–O π* character that it is destabilized relative to a Re–Re π* orbital that is populated instead. The net $\sigma^2\pi^2\pi^{*2}$ ordering describes a single Re–Re bond, and an assessment of the core orbitals (not shown) indicates that the Re–O antibonding π-interactions are not compensated enough by the two additional Re–O σ-interactions. Interestingly, the calculated minimum energy configuration of **4′** does not have a classical ethane-like geometry,[17] but optimizes with an HO–Re–Re angle near 90°, as in the crystal structure of **4**.

The cylindrical symmetry accorded the terminal oxos in **4** permits four significant π-bonds, whereas disruption of virtually all Re–O π-bonding in the bridged form is poorly balanced by additional σ-interactions; the terminal oxo structural preference of **4** is electronic in character. Thermodynamic preferences of $[(EtC_2Et)_2(O)Re]_2$ over $[(EtC_2Et)_2Re](\mu\text{-}O)(\mu\text{-}EtC_2Et)[Re(O)(EtC_2Et)]$,[18] and $(RO)_2(^tBuC{\equiv})Re = Re(\equiv C\text{-}^tBu)(OR)_2$[19] over μ-alkylidyne bridged forms, may be similarly ascribed. In compounds that lack additional terminal π-donors, or contain two less electrons {*e.g.* d^2-d^2 $[(Me_3SiCH_2)_2Re]_2(\mu\text{-}CSiMe_3)_2$},[20] the bridged form of multiple metal–ligand bond may prevail.[15]

Decarboxylation of an α-amino acid coordinated to cobalt(III): kinetic stabilisation and molecular structure of a Co–C–N three-membered ring incorporated into a cobalt(III) macrocyclic ligand complex†‡

Received (in Cambridge, UK) 22nd September 1998, Accepted 28th October 1998

Photochemically-induced decarboxylation of a cobalt(III) cyclam complex bearing two coordinated *N*-carboxymethyl pendant arms results in kinetic stabilisation of the resulting aminoalkyl three-membered Co–C–N ring, which has been characterised by an X-ray crystal structure determination.

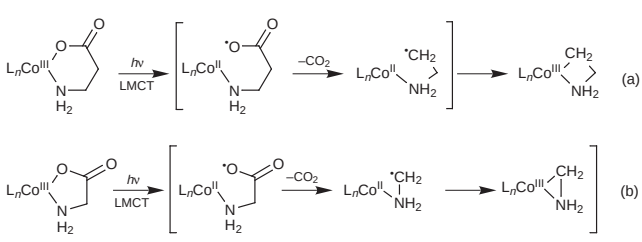
Cobalt(III) complexes containing chelated amino acids have been subjected to intense investigation, with most attention being paid to α-amino acid complexes. They have been used as activating and protecting groups in peptide synthesis, and they undergo a variety of useful reactions, many of which cannot be achieved with non-complexed α-amino acids.[1] These include alkylation at the α-carbon, imine formation, and condensation, oxidation and decarboxylation reactions.

The mechanism proposed for the photochemical decarboxylation of cobalt amino acid complexes involves, in sequence, excitation into the LMCT band, homolytic cleavage of the cobalt–oxygen bond, loss of carbon dioxide and recombination to produce a new cobalt(III)–carbon bond as part of a chelating aminoalkyl group (Scheme 1).[2,3] When the substrate contains a β-amino acid the resulting aminoalkyl group comprises a four-membered Co–C–C–N ring [Scheme 1(a)], and several such examples have been structurally characterised.[4] However, the corresponding three-membered rings that would result from decarboxylation of a chelated α-amino acid ligand [Scheme 1(b)] have proved to be more elusive.[2] In just one case, the use of the π-acids bipyridine or phenanthroline as the ancillary ligands on cobalt led to isolable products containing three-membered Co–C–N rings.[5] The compound resulting from the decarboxylation of the glycinato ligand in $[Co(gly)(bipy)_2]^{2+}$ was characterised by crystallography. Although the hydrogen atoms in the cobalt aminoalkyl moiety were not located and the structural and spectroscopic data were not fully reconciled, this structure did serve to demonstrate the formation of a three-membered ring by a decarboxylation reaction.

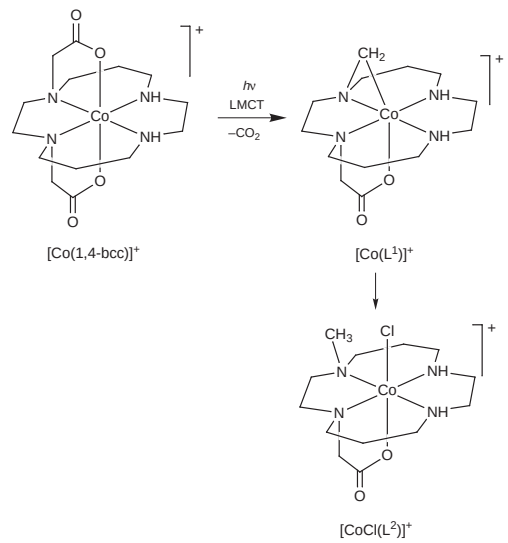
We have investigated kinetic stabilisation of the Co–C–N three-membered ring. As part of our interest in reactions of ligands coordinated to cobalt(III) we have prepared complexes of macrocyclic and acyclic hexadentate ligands bearing pendant coordinated α-amino acid groups.[6,7] They are ideal substrates for investigation of decarboxylation reactions, as the resulting aminoalkyl group would be appended to a macrocyclic ligand. One such candidate is $[Co(1,4\text{-bcc})]ClO_4$ (1,4-bcc = 1,4-bis-(carboxymethyl)cyclam) which contains a cyclam-based tetra-azamacrocycle bearing two *N*-carboxymethyl substituents.[7] An aqueous solution containing $[Co(1,4\text{-bcc})]ClO_4$ was irradiated for 120 minutes at 0 °C, resulting in a colour change from pink to pale orange. The product was purified by ion exchange chromatography, isolated as the salt $[Co(L^1)]BPh_4$, and characterised by elemental analysis, cyclic voltammetry, UV-visible, ^1H and $^{13}C\{^1H\}$ NMR spectroscopy and an X-ray crystal structure determination.§ The complex contains a substituted cyclam macrocycle bearing one intact *N*-carboxymethyl arm, but loss of CO_2 from the other *N*-carboxymethyl group results in a three-membered ring containing a cobalt σ-alkyl group (Scheme 2).

The molecular structure of the $[Co(L^1)]^+$ cation is shown in Fig. 1. The four nitrogens of the cyclam ring remain coordinated in the equatorial plane and the axial sites are occupied by an oxygen of the one remaining *N*-carboxymethyl group and the newly formed σ-bonded CH_2 group. The presence of the strained three-membered Co–C–N ring results in very irregular geometry around the cobalt atom, as exemplified by the O(1)–Co–C(13) and N(1)–Co–C(13) angles. The C(13)–N(1) bond length is shorter than the other C–N bond lengths in this complex but is still within the range observed for a C–N single bond (1.47 Å).[8] Both hydrogen atoms on C(13) were located crystallographically. The C(1)–N(1)–C(10) and H(13A)–C(13)–H(13B) angles of 110.4(2)° and 108(3)°, respectively, indicate sp^3 hybridization at N(1) and C(13).

Relative to the precursor $[Co(1,4\text{-bcc})]^+$, the lengthening of the Co–O(1) bond,[4] the shift of the d–d bands in the UV-visible spectrum[9] and the more negative reduction potential observed by cyclic voltammetry[7] are all consistent with the presence of the strong-field σ-bonded alkyl ligand in $[Co(L^1)]^+$. The cation has C_1 symmetry and the $^{13}C\{^1H\}$ NMR spectrum exhibits a unique signal for each of the 13 carbon atoms.



Scheme 1



Scheme 2

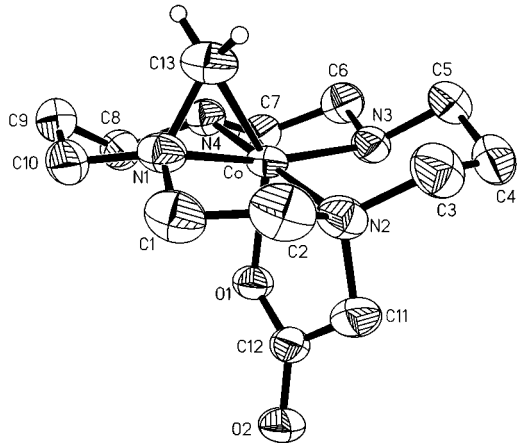


Fig. 1 Molecular structure of $[Co(L^1)]BPh_4$. Selected bond lengths (Å) and angles (°): Co–O(1) 1.993(2), Co–N(1) 1.920(2), Co–N(2) 1.993(2), Co–N(3) 1.987(2), Co–N(4) 1.961(2), Co–C(13) 1.980(3), C(13)–N(1) 1.447(4), C(13)–H(13A) 0.93(4), C(13)–H(13B) 0.96(4), O(1)–Co–C(13) 143.90(12), N(1)–Co–C(13) 43.52(12), Co–N(1)–C(13) 70.44(17), Co–C(13)–N(1) 66.06(15), O(1)–Co–N(1) 100.54(9).

Only two other structurally characterised examples of a Co–CH_2–NR_2 ring have been reported, both incorporated into a polydentate ligand, although they were prepared by quite different routes to that reported here.[10,11] In one of these examples, the ring was formed by C–H activation of an N–CH_3 group incorporated in a tetraaza macrocycle.[11] We observe the complementary reaction to this, wherein $[Co(L^1)]BPh_4$ undergoes Co–CH_2 bond cleavage upon heating in aqueous dilute HCl. The product, $[CoCl(L^2)]^+$, was characterised by an X-ray crystal structure determination§ and contains a chloro ligand *trans* to the N-carboxymethyl pendant arm and an N–CH_3 group derived from the CH_2 group (Scheme 2).

$[Co(L^1)]^+$ arises from the decarboxylation of a coordinated α-amino acid. Its successful isolation is attributed to the fact that the nitrogen atoms of the α-amino acid moieties in the $[Co(1,4\text{-bcc})]^+$ precursor are attached to a macrocyclic ligand, resulting in kinetic stabilisation of the aminoalkyl three-membered ring. This complements the earlier report concerning the photochemical decarboxylation of $[Co(gly)(bipy)_2]^{2+}$ in which stabilisation of the Co–C–N three-membered ring in the product has been attributed to the presence of the π-acid bipyridine ligands.[2] Our result is general and we have isolated further examples of Co–C–N three-membered rings resulting from photochemical decarboxylation of cobalt(III) complexes containing coordinated α-amino acid groups incorporated into other macrocyclic ligands.

D. M. T. is grateful to The University of Auckland for the award of a doctoral scholarship.

Microwave activation of electrochemical processes at microelectrodes

Richard G. Compton, Barry A. Coles and Frank Marken*

Physical and Theoretical Chemistry Laboratory, Oxford University, UK OX1 3QZ.
E-mail: Frank@physchem.ox.ac.uk

Received (in Exeter, UK) 17th August 1998, Accepted 26th October 1998

Electrochemical experiments at platinum microdisc electrodes are shown to be possible in an environment of intense microwave radiation and a considerable current enhancement observed for the ferrocyanide/ferricyanide redox couple in aqueous 1 M KCl is shown to be Faradaic in nature consistent with a rapid heating effect causing the temperature in the liquid phase at the electrode/solution interface to locally superheat.

By combining the use of a source of activation with the range of known electrochemical methodology new types of experiments and in some cases novel applications of electrochemistry, *e.g.* in photoelectrochemistry and in sonoelectrochemistry, have been developed. The interaction of microwave radiation with electrochemical systems, that is with redox and chemical processes at solid/liquid and liquid/liquid interfaces, is to date unexplored, although the interest in microwave enhanced chemistry[1] and the use of microwave radiation and microwave technology have become widespread over the recent decades. The use of *low* power microwave radiation in electrochemical systems is of considerable importance in areas of research such as *in-situ* electrochemical EPR[2] (typically X-band, 9.5 GHz) and microwave reflectance characterisation[3] of semi-conducting electrodes. The activation of the electrochemical system due to absorption of microwave radiation can in these cases usually be ignored due to the rather low intensities involved. However, microwave radiation is known to interact not only with molecules in the gas phase but also with condensed materials and interfaces with sufficient dielectric loss, ε'',[4] and may therefore be employed to activate an electrochemical system.

An 800 W, 2.45 GHz domestic multi-mode microwave oven has been modified† to supply constant power or pulsed microwave radiation of variable power and to allow an electrochemical cell to be inserted into a high intensity region. In Fig. 1 a schematic drawing of the experimental arrangement is shown. In Fig. 2(a)–(c) voltammograms for the one electron oxidation of 2 mM $Fe(CN)_6^{4-}$ at a 25 μm diameter Pt disc electrode in aqueous 1 M KCl are shown. The observed limiting current, I_{lim} = 6.4 nA, is slightly higher than that expected for the known diffusion coefficient, $D(Fe(CN)_6^{4-}) = 0.63 \times 10^{-9}$ $m^2\ s^{-1}$,[5] presumably due to micro-electrode imperfection. The expression for quasi-steady-state voltammetry at a microdisc

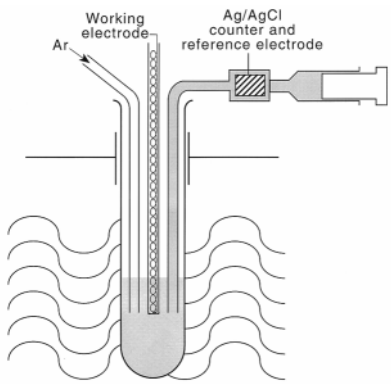

Fig. 1 Schematic representation of the electrochemical cell used for experiments in the presence of microwave radiation.

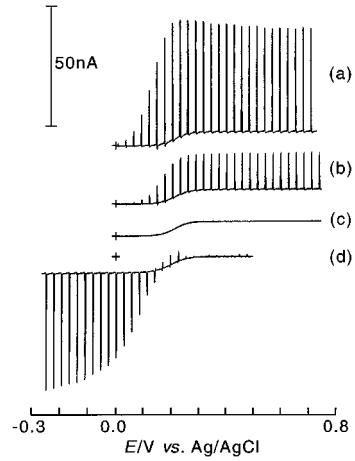

Fig. 2 Voltammograms obtained for (a)–(c) the oxidation of 2 mM $Fe(CN)_6^{4-}$ and (d) the reduction of 2 mM $Fe(CN)_6^{3-}$ in aqueous 1 M KCl at a 25 μm diameter Pt disc electrode and with a scan rate of 10 mV s^{-1}; 0.6 s microwave pulses with (a) and (d) 24 W and (b) 16 W microwave intensity.

electrode[6] has been shown to be $I_{lim} = 4nFDcr$. In this expression n denotes the number of electrons transferred per molecule, F, the Faraday constant, c, the concentration, and r, the radius of the electrode. Pulsed microwave radiation can be seen to induce current pulses which are superimposed on the quasi-steady-state current response.

In Fig. 2(a) the effect of 24 W (absorbed microwave power, see Table 1) microwave pulses of 0.6 s duration is shown. Current pulses are observed at potentials well negative of those of the current response in the absence of microwave radiation. The equilibrium potential for the $Fe(CN)_6^{4-/3-}$ redox couple is known to be affected by the temperature and data for the equilibrium potential–temperature dependence determined in the same cell over a 70 °C range and with the temperature of the reference electrode kept constant at 25 °C suggest a linear dependence with $dE/dT = -1.53$ mV K^{-1} consistent with published data.[7] Therefore at higher temperature the current response for the oxidation of $Fe(CN)_6^{4-}$ is expected to occur at a more negative potential in qualitative agreement with the

Table 1 The rate of microwave heating of 5 cm^3 water or aqueous solution in the electrochemical cell placed in a high intensity area of the modified microwave oven

	Pure water		1 M aqueous KCl	
Microwave power level	Rate of heating/ K s^{-1}	Absorbed energy[a]/W	Rate of heating/ K s^{-1}	Absorbed energy[a]/W
A	0.15	4	0.26	7

[a] Calculation based on a calibration procedure in which joule heating with a resistor is used to induce a temperature change.

Table 2 The temperature measured potentiometrically after *ca.* 0.2 s in a solution of 5 mM $Fe(CN)_6^{4-}$, 5 mM $Fe(CN)_6^{3-}$, and 1 M KCl at a 25 μm diameter Pt disc electrode when a 0.6 s pulse of microwave radiation is applied

Microwave pulse intensity/W	7	16	24	33
Temperature/°C	60 ± 6	87 ± 9	120 ± 12	150 ± 15

experimental observation [Fig. 2(a)]. From the current trace in Fig. 2(a) it can be concluded that the temperature of the bulk solution is not significantly affected by the pulsed microwave radiation. The current immediately returns to the expected value, I_{lim}, after each microwave pulse. The rate of heating observed independently in an experiment monitoring the bulk solution temperature was 1 K s^{-1} for the 24 W microwave intensity setting (see Table 1). Therefore it appears to be possible that the intensity of the microwave radiation is considerably higher at the electrode/solution interface compared to the average intensity experienced by the solution phase. A lower microwave intensity of 16 W induces a smaller current response as shown in Fig. 2(b). More importantly, microwave pulses of 24 W intensity applied to the reduction process of 2 mM $Fe(CN)_6^{3-}$ in 1 M KCl at a 25 μm diameter Pt disc electrode [Fig. 2(d)] also induce current jumps superimposed on the quasi-steady-state voltammetric response with complementary features. The cathodic current increases by a similar factor compared to the increase of the anodic current [Fig. 2(a)] and the shift of the half wave potential towards more negative potentials upon irradiation with microwaves is apparent. From this observation and from the linear dependence of both the quasi-steady-state current and the microwave enhanced current on the concentration of the redox reagent it can be concluded that the observed current for the $Fe(CN)_6^{4-/3-}$ redox couple in 1 M KCl in the presence of microwave radiation is purely *Faradaic*.

In order to achieve a more quantitative description of the heat pulse induced by microwave radiation at the electrode/solution interface the temperature can be estimated potentiometrically based on the equilibrium potential for a solution of 5 mM $Fe(CN)_6^{4-}$, 5 mM $Fe(CN)_6^{3-}$, and 1 M KCl under zero current condition. This measurement allows the temperature at the electrode/solution interface to be measured simultaneously with applying microwave pulses and data for the observed trend are given in Table 2. These data are valid only for the 25 μm diameter Pt disc electrode and cell geometry used in this set of experiments. However, the data suggest an approximately linear dependence of the microwave intensity absorbed by the bulk solution and the heating induced by the microwave radiation focused by the micro-electrode. Further, for short periods of time superheating of the solution phase can be observed.

The diameter of the working electrode also is a crucial factor in determining the magnitude of the heating effect. In experiments with a 50 μm diameter Pt disc electrode higher microwave intensities were required in order to give similar temperature jumps compared to those observed at the 25 μm diameter Pt disc electrodes. In experiments conducted with a 1 mm diameter Pt disc electrode the heating effect remained negligible even at the highest microwave intensity settings. In general, the temperature measured at the electrode strongly depends on (i) the microwave intensity, (ii) the cell geometry and positioning of the electrode, (iii) the type of solvent and solute used and produced during the course of the electrode reaction. The use of organic solvent systems is possible and the parameter characterising the microwave absorption has been shown to be the dielectric loss.[4]

The 0.6 s pulse which has been employed in the experiments shown in Fig. 2 is sufficient for thermal equilibrium to be achieved, at least locally at the electrode surface. With the knowledge of the approximate temperature at the electrode/solution interface it is possible to calculate the mass transport limited current based on the temperature dependence of the diffusion coefficient of $Fe(CN)_6^{4-}$. The limiting current observed for the oxidation of 2 mM $Fe(CN)_6^{4-}$ in 1 M KCl shows an Arrhenius type increase consistent with an activation energy of 14.3 kJ mol^{-1} and in agreement with Walden's rule[8] and literature data.[5] The expected mass transport controlled limiting current for the oxidation of 2 mM $Fe(CN)_6^{4-}$ at 120 °C can be calculated to I_{lim} = 26 nA. In the corresponding voltammogram [Fig. 2(a)] the observed limiting current is 50 nA and therefore higher. For a temperature of 90 °C the limiting current for the oxidation of 2 mM $Fe(CN)_6^{4-}$ is expected to be 18 nA which is slightly lower than the experimentally observed current in the presence of microwave radiation of 20 nA [Fig. 2(b)]. Therefore under conditions employed in Fig. 2 the temperature jump induces a current response with transient characteristics especially for very large temperature jumps. Further indications for the non-steady-state behaviour are the microwave induced *anodic* current in Fig. 2(d) at 0.22 V *vs*. Ag/AgCl for the reduction of $Fe(CN)_6^{3-}$ and the maximum observed at 0.24 V *vs*. Ag/AgCl for the microwave induced current associated with the oxidation of $Fe(CN)_6^{4-}$ [Fig. 2(a)].

The time scale for a steady-state current to be achieved at a microdisc electrode within ε% has been shown[9] to be approximately $t_\varepsilon = 10^4 r^2/\pi^3 \varepsilon^2 D$. In this expression the time t_ε is related to the electrode radius, r, and the diffusion coefficient, D. For a microdisc electrode of 25 μm diameter the expected time scale for the transient current to settle within 5% of the steady-state current is in the order of 2 s. Therefore the time scale for current transient after a temperature jump is expected to be larger compared to the time scale needed for the temperature to settle.

It has been shown both that microwave activation is an interesting new tool for enhancing and controlling processes in electrochemical systems and that electrochemical detection may be employed for microwave induced chemical processes.

Notes and references

† The intensity distribution in a Panasonic NN-3456 multi-mode microwave oven with modified electric power supply and fitted with a water load was mapped. A hole through the cavity wall extended by a 14.7 mm inner diameter brass tube, 50 mm long, which acted as a waveguide below cutoff, allowed a 1.41 cm diameter electrochemical cell to be inserted into a high intensity region (Fig. 1). A special working electrode design with a range of Pt disc electrodes of 25, 50, and 1000 μm diameter sealed into glass was used to prevent both radiation from escaping through the inlet and sparking. The lead-out from the micro-electrode was in the form of a helix made by winding 0.19 mm diameter platinum wire on a 0.46 mm diameter mandrel with 28 turns per cm. A test with a radiation meter (Apollo XI microwave monitor, Apollo Ltd.) confirmed this design to act as a filter and to stop microwave radiation from being conducted out of the cavity. In electrochemical experiments an Autolab PGSTAT 20 system (Eco Chemie, NL) was used for recording voltammetric and microwave intensity data. Reagents of analytical grade purity and demineralised water of conductivity not less than 18 MΩ cm were used. If not stated otherwise experiments were conducted under an inert atmosphere of argon and at a temperature of 25 ± 2 °C.

Dramatic increase of the DNA cleavage activity of Cu(Clip-phen) by fixing the bridging linker on the C^3 position of the phenanthroline units

Marguerite Pitié, Brigitte Sudres and Bernard Meunier*

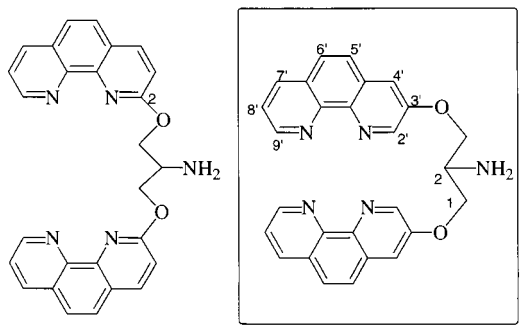
Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse cedex 4, France. E-mail: bmeunier@lcc.toulouse.fr

Received (in Cambridge, UK) 7th October 1998, Accepted 28th October 1998

The synthesis of a new ligand with two phenanthrolines bridged on their C^3 carbon by a serinol is reported; Cu(3-Clip-phen) cleaves DNA more efficiently than the parent Cu(2-Clip-phen) bridged on the C^2 carbon.

The redox activity of cuprous complexes of 1,10-phenanthroline (phen) is well known as artificial nuclease. They are able to realise single-strand cleavages of DNA in the presence of H_2O_2 by oxidative attack on deoxyribose units from the minor groove of DNA.[1,2] $Cu^I(phen)_2$ is significantly more reactive[3] than $Cu^I(phen)$ but the association constant for the second phenanthroline ligand is only $10^{5.5}$ dm^3 mol^{-1} which is too low for a biological use at submicromolar concentrations of these complexes.[4] For this reason, we have recently prepared Clip-phen (renamed 2-Clip-phen in the present study, Scheme 1) with two phenanthroline entities linked *via* their C^2 carbon by a short flexible arm in order to favor the 2 : 1 phen–Cu stoichiometry.[5] In the presence of a reductant and air, we observed an increase of DNA cleavage activity on ΦX174 by a factor two for Cu(2-Clip-phen) compared to $Cu(phen)_2$. In addition, the serinol bridge between the two phenanthrolines of 2-Clip-phen allowed further functionalisation on its primary amino group with different possible vectors (polyamines, intercalators, oligonucleotides) in order to increase or to modulate the binding domain of these DNA cleavers. So, the attachment of the natural polyamine spermine (a minor groove binder) to 2-Clip-phen afforded a new conjugate with enhanced nuclease efficiency.[6]

The bridging serinol was fixed on the C^2 carbon of phen units in 2-Clip-phen, near the chelating nitrogen atoms, in order to decrease the length between the two phen entities. But, having in mind that this substitution on C^2 carbon has been observed to disactivate the DNA cleavage activity of Cu–phen complexes,[1,7] we decided to prepare a new bis-chelating ligand, 3-Clip-phen, with the serinol bridge between the C^3 carbons of phen units. The 3-position is known to have fewer effects on redox activity[4] and may also allow the use of a small bridge like serinol between the two phen units in order to favor a mononuclear Clip-phen complex $[Cu^{II}(Clip\text{-}phen)]^{2+}$. However the C^3 monosubstitution of the phen ligand, which limits steric constraints for DNA interactions and for conformational changes during the reduction of Cu^{II} to Cu^I, has been little studied although a conjugate of acridine on the C^3 carbon of phen has been described to cleave DNA.[8]



Scheme 1 Structures of 2-Clip-phen and 3-Clip-phen. Numbering corresponds to NMR assignments.

The synthetic strategy used to prepare 3-Clip-phen was based on the synthesis of the 2-Clip-phen parent compound. Two equivalents of halogenated phenanthroline (600 mg, 2.3 mmol of 3-bromophenanthroline prepared according to ref. 9) and one equivalent of serinol (109 mg, 1.18 mmol) were stirred for 24 h in dry DMF (14 mL) in presence of 9 equivalents of NaH (423 mg, 10.5 mmol of a 60% dispersion in mineral oil). At 0 °C, 2-Clip-phen was obtained in good yield, but 3-Br-phen gave only 4% of 3-Clip-phen under the same conditions. The low reactivity of 3-Br-phen for nucleophilic aromatic substitution required warming of the reaction mixture.[10] Unfortunately the quantitative reduction of 3-Br-phen by NaH at 80 °C forced us to choose intermediate heating conditions at 50 °C. Under these conditions 3-Clip-phen was only obtained in 27% yield after purification [addition of ethanol and water in the reaction mixture in order to destroy the excess of NaH, then extraction with chloroform, precipitation with hexane to remove unreacted 3-Br-phen and phen and a neutral alumina column ($CHCl_3$ with 0–5% of methanol)].†

3-Clip-phen was metallated with one equivalent of $CuCl_2$ and its DNA cleavage activity was compared to that of $[Cu(2\text{-}Clip\text{-}phen)]Cl_2$. Relaxation of supercoiled ΦX174 DNA (form I) into relaxed circular (form II) and linear (form III) conformations was used to quantify the relative cleavage efficiency of these copper complexes. The nuclease activity of these Cu(II) complexes (1 μM) was initiated by addition of 5 mM mercaptopropionic acid (MPA) in the presence of air. Fig. 1 summarises the results obtained.‡

As expected, no degradation of DNA was observed in the absence of reductant. The comparison of lanes 4 and 5 shows that Cu(3-Clip-phen) complex exhibited a significantly higher activity than Cu(2-Clip-phen) since all form I disappeared, to give forms II and III (50% of the starting material) and a smear (corresponding to multifragmented DNA), whereas form I was

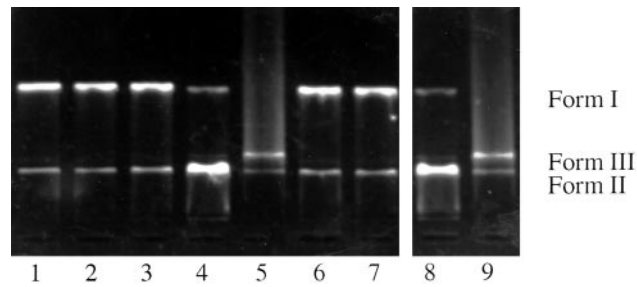


Fig. 1 Comparison of ΦX174 cleavage efficiency between 2-Clip-phen and 3-Clip-phen in the presence of $CuCl_2$ and 5 mM MPA. Lane 1: control DNA. Lane 2: 1 μM 2-Clip-phen and $CuCl_2$ without MPA. Lane 3: 1 μM 3-Clip-phen and $CuCl_2$ without MPA. Lane 4: 1 μM 2-Clip-phen and $CuCl_2$. Lane 5: 1 μM 3-Clip-phen and $CuCl_2$. Lane 6: control DNA with 5 mM MPA. Lane 7: control DNA with 1 μM $CuCl_2$ and 5 mM MPA. Lane 8: 1 μM 2-Clip-phen and 2 μM $CuCl_2$. Lane 9: 1 μM 3-Clip-phen and 2 μM $CuCl_2$.

still present for the same concentration of Cu(2-Clip-phen) under identical conditions. Assuming a non-specific single-strand cleavage of the DNA double-helix, as previously observed for Cu(2-Clip-phen),[6] the number of single-strand breaks per ΦX174 DNA molecule was calculated according to ref. 11. Cu(3-Clip-phen) gave 32 ± 4 single strand breaks per ΦX174 DNA compared with 1.4 ± 0.2 for Cu(2-Clip-phen). The comparison of lanes 5 and 9 shows also that Cu(3-Clip-phen) gave the same number of single strand breaks when metallated by 1 equivalent of copper salt [1 Cu for 2 phen entities, corresponding to a Cu(3-Clip-phen) complex] or 2 equivalents of copper salt [1 Cu per phen entity, corresponding to a putative Cu_2(3-Clip-phen) compound] as expected for a ligand able to chelate the same copper ion with its two phen subunits.

In order to understand this high DNA cleavage activity of Cu(3-Clip-phen), work on interactions of the complex with DNA are in progress. New conjugates of 3-Clip-phen with DNA binders are also in preparation in order to increase the nuclease activity of this promising new family of DNA cleavers.

Dr Jean-Pierre Sauvage (Université Louis Pasteur, Strasbourg) is gratefully acknowledged by the authors for fruitful discussions on phenanthroline reactivity which initiated the preparation of 3-Clip-phen.

Notes and references

† 3-Clip-phen has been characterised by ^{1}H NMR (250 MHz, $CDCl_3$) δ 9.14 (dd, 2H, *J* 4.3, 1.7 Hz, H9′), 8.96 (d, 2H, *J* 2.9 Hz, H2′), 8.20 (dd, 2H, *J* 8.1 and 1.7 Hz, H8′), 7.78 and 7.72 (AX, 2H, *J* 8.9 Hz, H5′, H6′), 7.60 (d, 2H, *J* 2.9 Hz, H4′), 7.56 (dd, 2H, *J* 8.1, 4.3 Hz, H7′), 4.36 (m, 4H, H1), 3.82 (q, 1H, *J* 5.4 Hz, H2); MS (CDI, NH_3): *m*/*z* (%) = 448 (M + H, 100), 268 (14.0), 252 (22.7), 197 (75.9); UV–VIS (MeOH) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 240 (59 500), 272 (44 100), 294 (23 900, sh), 314 (8200, sh), 328 (5700), 344 (3800). Received (in Cambridge, UK) 25th September 1998, Accepted 19th October 1998

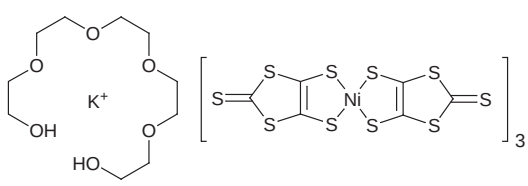
The X-ray structural analysis of the title compound revealed the formation of segregated [Ni(dmit)$_2$] (dmit = 2-thioxo-1,3-dithiol-4,5-dithiolate) columns and dimeric K$^+_2$[PEG]$_2$ (PEG = pentaethylene glycol) supramolecular cations in the crystal; the interaction between K$^+$ and acyclic PEG was found to be weaker that that between K$^+$ and cyclic polyether 18-crown-6.

Composite organic polymer electrolytes are promising candidates for applications in high energy density electrochemical batteries.[1] Polyethylene oxide (PEO) derivatives especially have been extensively examined as non-crystalline polymeric ion-conducting materials. The crystal structure of a uniaxially oriented PEO–NaI ionic conductor has been reported previously.[2] The structure of a single crystal of PEO as an ion-transport environment has not been reported. The classification of the nature of the coordination in PEO–ion moieties will assist in the construction of organic crystalline ionic conductors.

Organic π-molecular systems have a tendency to form a one-dimensional columnar stack structure, in which electrons can move along the stack through overlap of the π-systems.[3] We have been attempting to construct electron–ion hybrid conducting systems based on crystalline molecular conductors, and have reported the formation of supramolecular cation (SC$^+$) structures within organic conductors.[4] For example, a typical cation complex of a cyclic polyether, K$^+$(18-crown-6), can be incorporated into a highly conducting [Ni(dmit)$_2$] (dmit = 2-thioxo-1,3-dithiol-4,5-dithiolate) salt as K$^+$(18-crown-6)[Ni(dmit)$_2$]$_3$ with a room temperature conductivity (σ_{RT}) of 0.08 S cm^{-1}.[5] We report here the incorporation of a cation complex of an acyclic polyether as a new SC$^+$ unit in a [Ni(dmit)$_2$] organic conductor, in which the potassium cation is included within the cyclic pentaethylene glycol (PEG) (Scheme 1).

Single crystals of K$^+$(PEG)[Ni(dmit)$_2$]$_3$ were prepared by the electrocrystallization method.† The unit cell contains three crystallographically independent [Ni(dmit)$_2$] units **A–C** and one K$^+$(PEG) unit. A segregated non-uniform [Ni(dmit)$_2$] column is observed with the stacking order of **A–C–B** along the *c*-axis; the molecular planes of [Ni(dmit)$_2$] are nearly parallel to the *ab*-plane (Fig. 1). Each [Ni(dmit)$_2$] molecule is connected by side-by-side S···S interactions, forming a layer structure within the *ac*-plane, and the K$^+$(PEG) units exist in the interlayer space. The plane of K$^+$(PEG) is inclined at 45° to the *b*-axis. A weak interatomic contact is found between the terminal sulfur of [Ni(dmit)$_2$] **C** and K$^+$(PEG), K$^+$···S(30) = 3.282(7) Å. This distance is *ca*. 0.15 Å longer than the sum of the van der Waals radius of S and the ionic radius of K$^+$.[6]



K$^+$(PEG)[Ni(dmit)$_2$]$_3$

Scheme 1

The mean interplanar distances of [Ni(dmit)$_2$] within a column are 3.50 (**A–B**), 3.65 (**A–C**), and 3.45 Å (**B–C**) with overlap modes of slipped metal–ring (**A–B**), metal–metal (**A–C**), and metal–ring (**B–C**) types, respectively [Fig. 1(b)]. A

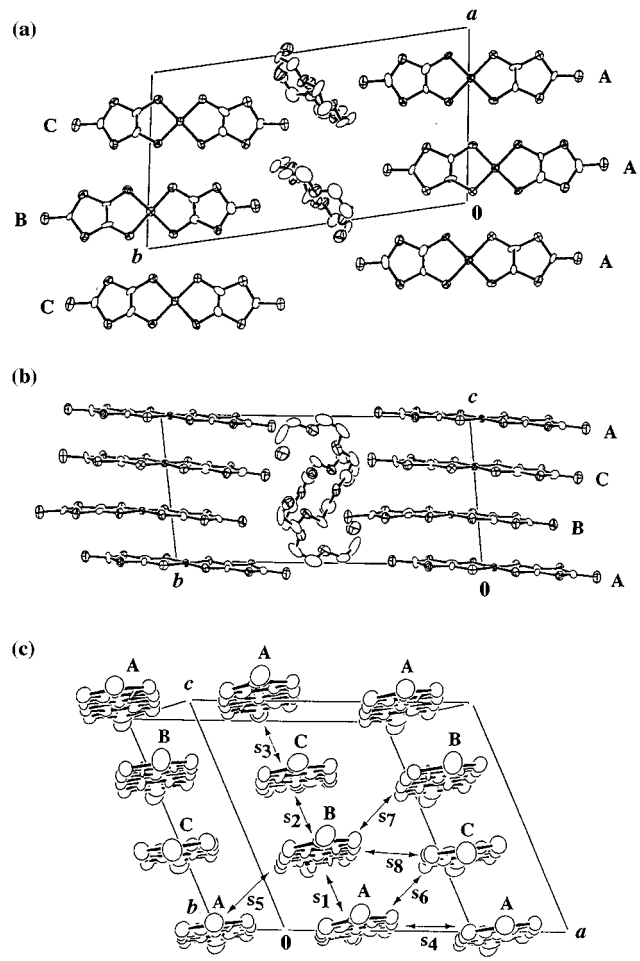


Fig. 1 Crystal structure of K$^+$(PEG)[Ni(dmit)$_2$]$_3$, (a) viewed along the *c*-axis, (b) along the *a*-axis. (c) [Ni(dmit)$_2$] layer viewed along the long axis of [Ni(dmit)$_2$] together with the numbering scheme of overlap integrals (s_1–s_8).

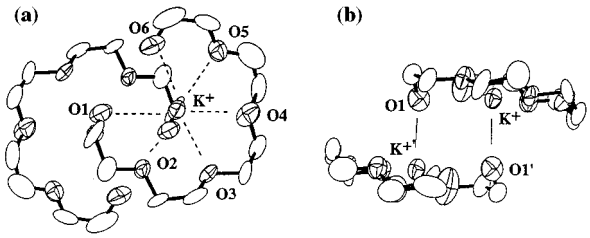

Fig. 2 Supramolecular cation (SC^+) unit of $K^+_2(PEG)_2$, (a) viewed along the perpendicular direction to the K^+(PEG) plane, (b) side view of K^+(PEG) dimer with the oxygen atom numbering scheme. Primes indicate atoms generated by passing through the inversion center. Dashed and solid lines indicate the $K^+\cdots O$ interactions.

similar trimer structure was also observed in K^+(18-crown-6)[Ni(dmit)$_2$]$_3$ with an **A–B–A** stacking arrangement. Fig. 1(c) shows the intermolecular interactions within the [Ni(dmit)$_2$] layer viewed along the long axis of [Ni(dmit)$_2$]. The overlap integrals (s_1–s_8 × 10^{-3}) were obtained by using extended Hückel molecular orbital calculatons.[7] Since the **A–B** interaction (s_1 = 19.07) is significantly larger than **A–C** (s_2 = −1.05) and **B–C** (s_3 = 2.47), the [Ni(dmit)$_2$] column mainly consists of **A–B** dimers and weakly interacting **C** molecules between the **A–B** dimers in the order –(**A–B**)–**C**–(**A–B**)–. In the case of K^+(18-crown-6)[Ni(dmit)$_2$]$_3$, the intratrimer *s* value (s_{intra} = 15.3) indicated the formation of tightly bounded **A–B–A** trimers within the column. By replacing the SC^+ unit of the cyclic [K^+(18-crown-6)] with the acyclic [K^+(PEG)], the stacking mode of [Ni(dmit)$_2$] within the column is changed from the trimer to the dimer.

Within the *ab*-plane, the [Ni(dmit)$_2$] molecules form a sheet-like structure of –**A–A–A–** and –**B–C–B–** arrangements along the *a*-axis [Fig. 1(a)]. Owing to the symmetry of the LUMO of [Ni(dmit)$_2$], the interstack interactions along the *a*-axis are small (s_4 = 0.10 and s_8 = 0.20), resulting in weak interactions within the sheets. The interactions along the $a + c$ direction (s_5 = 0.50, s_6 = 0.86, and s_7 = −0.33) also do not effectively increase the interstack interactions.

Fig. 2 shows the SC^+ unit viewed along the orthogonal [Fig. 2(a)] and parallel [Fig. 2(b)] directions to the molecular plane of K^+(PEG). The SC^+ unit has two K^+(PEG) units which are related by the inversion center, and are connected by two axial K^+ (K^+)$\cdots$O1′ (O1) interactions [solid lines in Fig. 2(b)] to form a dimerized $K^+_2(PEG)_2$ supramolecular cation. The K^+ is coordinated by six PEG oxygen atoms [dashed lines: $K^+\cdots$O1 = 3.00(1), $K^+\cdots$O2 = 2.90(1), $K^+\cdots$O3 = 2.81(1), $K^+\cdots$O4 = 2.86(1), $K^+\cdots$O5 = 2.90(1), $K^+\cdots$O6 = 2.77(2) Å] and an axial oxygen of another PEG unit [solid lines: $K^+\cdots$O1 = 2.86(2) Å]. The average $K^+\cdots$O distance within the PEG unit (2.87 Å) is in the same range as the sum of the van der Waals radius of oxygen and the ionic radius of K^+ (2.85 Å). In the case of K^+(18-crown-6), the average $K^+\cdots$O distance (2.804 Å) is*ca*. 0.07 Å shorter than that in the acyclic K^+(PEG) system, indicating a weaker cation binding ability of the acyclic polyether relative to the corresponding cyclic one due to the *macrocyclic effect*.[8] The weaker cation binding ability (10 000×) should be more appropriate to ionic conductivity in the solid.

The K^+(PEG)[Ni(dmit)$_2$]$_3$ salt showed semiconducting behavior over the temperature range 150–300 K, which is consistent with the non-uniform dimerized stack of [Ni(dmit)$_2$]. Fig. 3 shows the log(resistivity/Ω cm) *vs*. T^{-1}/K^{-1} plots of (i) K^+(PEG)[Ni(dmit)$_2$]$_3$ and (ii) K^+(18-crown-6)[Ni(dmit)$_2$]$_3$.[5] The room temperature conductivity (σ_{RT} = 0.001 S cm^{-1}) is two orders of magnitude lower that that of K^+(18-crown-6)[Ni(dmit)$_2$]$_3$ (σ_{RT} = 0.08 S cm^{-1}). The activation energy E_a (0.17 eV) of the acyclic system is intermediate in range between the high (0.28 eV) and low (0.12 eV) temperature semiconducting phases of K^+(18-crown-6)[Ni(dmit)$_2$]$_3$.

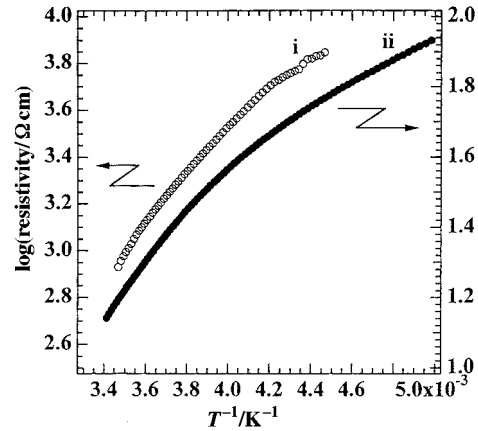

Fig. 3 Log(resistivity/Ω cm) *vs*. T^{-1}/K^{-1} plots of (i) K^+(PEG)[Ni(dmit)$_2$]$_3$ (○) and (ii) K^+(18-crown-6)[Ni(dmit)$_2$]$_3$ (●).

In conclusion, the supramolecular cation of acyclic K^+(PEG) has been incorporated into the electrically conducting [Ni(dmit)$_2$] salt. The coordination ability of PEG to K^+ is smaller that that of 18-crown-6 due to the loss of macrocyclic effect, which helps to construct the ion-conducting field within the crystalline solid. Attempts to insert shorter or longer polyethylene glycol chains into the conducting [Ni(dmit)$_2$] salts are now in progress to construct ion-conducting paths.

Received (in Cambridge, UK) 25th August 1998, Accepted 26th October 1998

A visible light-induced desulfurization process for light oil, effected by electron-transfer photooxygenation and liquid–liquid extraction, allows the deep desulfurization of light oil under moderate conditions and without hydrogen.

The desulfurization of light oil has become one of the urgent problems of the world.[1] In order to protect against environmental contamination, the sulfur level in diesel fuels is presently limited to 0.05 wt% in Japan and Europe, and this will certainly be tightened in the near future. The current technology of hydrodesulfurization (HDS), when adopted on an industrial scale, can desulfurize aliphatic and acyclic sulfur-containing compounds adequately. The above process, however, when treating dibenzothiophene and its derivatives (DBTs),[2–4] apparently fails to reach the new specifications imposed by recent Clean Air Regulations. Thus, to produce light oil containing a very low level sulfur requires inevitably rather severe conditions. For the development of an energy-saving desulfurization process, a new approach is needed which isn't limited to the conventional HDS method.

As reported by Berthou and Vignier,[5] DBTs in spilled crude oil are sunlight-photooxidized to DBT sulfoxide (DBT-O) and DBT sulfone (DBT-O_2) in sea water. These sulfur-oxygenated DBTs are highly polarized and are water-soluble. The application of this photochemical oxidation to desulfurization has been realized in our previous studies, using oil–water[6,7] and oil–polar solvent[8] two-phase systems, and in which the desulfurization of light oil to a sulfur content of less than 0.05 wt% has been achieved successfully. However, UV irradiation was found to be essential to oxidize DBTs and desulfurization hardly progressed at wavelength of $\lambda > 400$ nm.

Electron-transfer type photosensitizers, such as cyano-substituted anthracene, differ from the usual energy-transfer type photosensitizers, and act as the anode by absorbing the wavelength of light equivalent to their lowest excitation energy. The sulfur-containing compounds, having the free electron on the S atom, are thought to be readily one-electron oxidized by this type of photosensitizer. In this work, we consider such a photoprocess applied to the indirect photooxygenation of DBTs and thus to the desulfurization of DBTs in light oil.

A schematic electron-transfer process between 9,10-dicyanoanthracene (DCA) and DBT in MeCN is shown in Fig. 1. DCA has a relatively low reduction potential and can be excited at wavelengths greater than 400 nm. DCA exhibits a strong, blue fluorescence in both polar and non-polar solvents. This blue fluorescence is quenched by adding DBT with the rate constant of $k_{q,\,DBT} = 1.75 \times 10^{10}$ L mol^{-1} s^{-1}, and a yellow fluorescence is then exhibited. Exciplex emission is observed only in non-polar solvents, and not in MeCN and MeOH; this suggests that dissociation of the ion pairs occurs only in the most polar solvents.

An MeCN solution containing DBT and DCA was irradiated to visible light of wavelength $\lambda > 400$ nm (main emission peak: 406 nm), generated by a high-pressure mercury lamp with a 3 wt% $NaNO_2$ solution filter.[9] As shown in Fig. 2, only in MeCN were the corresponding sulfoxide (DBT-O) and sulfone (DBT-O_2) photogenerated at high yield, whereas no reaction was

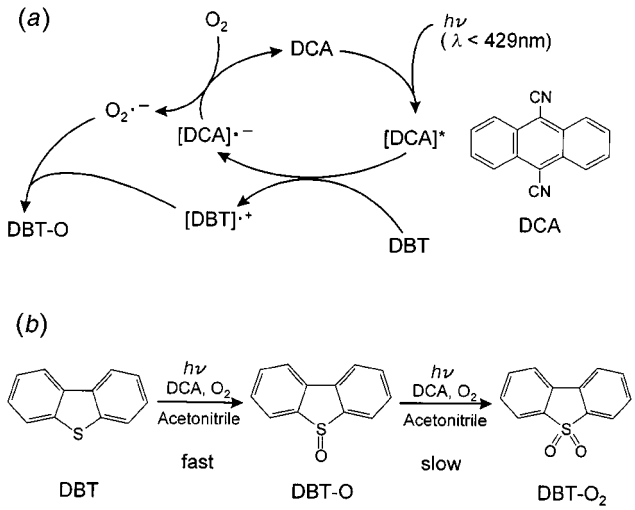

Fig. 1 (*a*) Electron-transfer process occurring in MeCN between DCA, DBT and oxygen. (*b*) Schematic representation of the reaction route of DBT by DCA sensitized photooxygenation.

observed in protic solvents such as MeOH and Pr^{i}OH or in non-polar solvents. This behavior is expected for a process proceeding *via* an intermediate ion pair, since such a pair will be too poorly solvated in non-polar solvents to be separated. Other photosensitizers such as *p*-benzoquinone or 1-cyanonaphthalene are not applicable to this process, since the oxidation potential of the former is lower than the reduction potential for O_2 and the latter is excited at wavelength shorter than 320 nm. These findings suggest that DCA is the most suitable photosensitizer for the photooxygenation of DBT, which seems to proceed *via* the three steps shown schematically in Fig. 1. These are (i) photoexcitation of DCA, (ii) one-electron oxidation of DBT and one-electron reduction of O_2 (generation of superoxide ion $O_2^{\cdot -}$) and (iii) combination of radical ion pairs (DBT$^{\cdot +}$

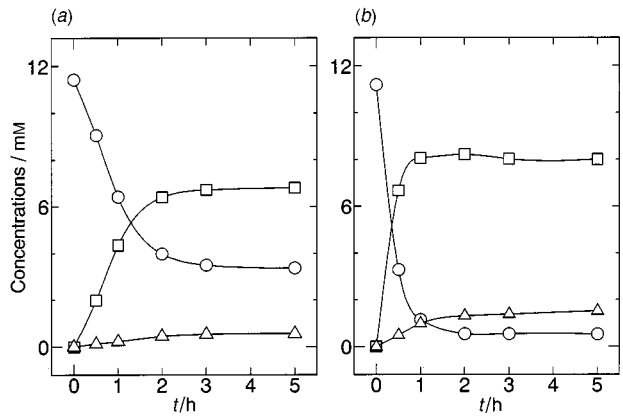

Fig. 2 Time-course variation for the concentrations of (○) DBT, (□) DBT-O and (△) DBT-O_2 by DCA photosensitized reaction in MeCN. The initial concentrations of DCA are (*a*) 0.02 and (*b*) 0.1 mM.

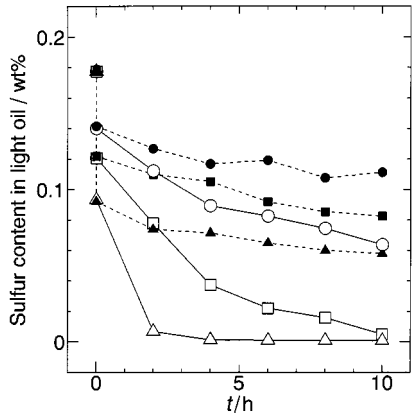

Fig. 3 Time-course variation of sulfur content in light oil for differing solution volume ratios: MeCN:light oil = (○,●) 1:1, (□,■) 3:1 and (△,▲) 7:1; filled symbols = without DCA, open symbols = with DCA.

and $O_2^{\cdot -}$). In alcoholic solvents, the oxygenation seems to be prevented, owing to the shorter lifetime for $O_2^{\cdot -}$. Bacciochi *et al.*[10] have suggested the C–S cleavage mechanism for the electron-transfer reaction of benzyl phenyl sulfide, but DBT gave only the S oxidation product, as mentioned in the case of diphenyl sulfide.[11] This is attributable to a stabilization of the C–S bond of DBT by thiophenic heterocycles. The rate of DBT oxidation decreased with photoirradiation time, as shown in Fig. 2(*a*), since the DBT-O formed also quenches the DCA fluorescence ($k_{q,\,DBT\text{-}O} = 7.37 \times 10^9$ L mol^{-1} s^{-1}) and competitive electron-transfer occurs. This problem can be solved by adding a larger quantity of DCA [Fig. 2(*b*)]. The two photoproducts of DBT, DBT-O and DBT-O_2, are both highly polarized and insoluble in non-polar light oil.[12] Thus the process has potential for the desulfurization of light oil.

The above photoprocess was applied to the desulfurization of light oil containing ca. 0.18 wt% sulfur, which is below the previous regulation in Japan (0.2 wt%). Light oil (50–200 ml) and MeCN (200–350 ml) saturated with DCA were introduced into the reaction vessel at MeCN:light oil volume ratios of 1:1, 3:1 or 7:1 v/v. The solutions were photoirradiated using a high-pressure mercury lamp with a 3 wt% $NaNO_2$ solution filter, combined with air bubbling at atmospheric pressure.

Certain quantities of DBTs from the light oil in the light oil–MeCN two-phase system transfer into the MeCN phase, together with other aromatics. The photoirradiation of the two-phase system thus causes the oxidation of the DBTs in the MeCN, resulting in the successive removal of the DBTs from the light oil phase.[8] Fig. 3 shows the effect of the addition of DCA on the time-course variation of the sulfur content in the light oil, with respect also to variations in the MeCN:light oil volume ratio. The data points, at an irradiation time of zero, show the distribution equilibria for the sulfur contents in the two-phase systems. Without DCA, the sulfur content was reduced only slightly, since the light oil contains three-ring aromatics which absorb visible light only weakly. The reduction rate for the sulfur content was enhanced drastically however by the addition of DCA. For an MeCN:light oil volume ratio of 3:1, 2 h of irradiation decreased the sulfur level to 0.05 wt%, and 10 h of irradiation decreased the value to 0.005 wt%, which is the value presently strictly legislated in Sweden. Light oil containing such a low sulfur level has not been achieved so far by the HDS method, even under severe operating conditions at 673 K.[3] Thus, the present method is applicable as an energy-saving deep desulfurization process to meet with the newest regulation for sulfur content in light oil, and requires only air bubbling and irradiation with visible light, avoiding the use of hydrogen and high pressure.

The present study thus describes a novel desulfurization process for light oil, effected by the combination of electron-transfer photooxygenation and liquid–liquid extraction using an oil–MeCN two-phase system. This could be developed as a desulfurization process utilizing solar irradiation as a light source. Work is in progress to develop the overall process, including a method for subsequent recovery of DCA from the resulting solutions.

The fixation and reduction of dinitrogen using lanthanides: praseodymium and neodymium *meso*-octaethylporphyrinogen–dinitrogen complexes

Elisa Campazzi, Euro Solari, Carlo Floriani* and Rosario Scopelliti

Institut de Chimie Minérale et Analytique, BCH, Université de Lausanne, CH-1015 Lausanne, Switzerland. Phone: +41 (21) 692 39 02; Fax: +41 (21) 692 39 05. E-mail: carlo.floriani@icma.unil.ch

Received (in Basel, Switzerland) 23rd September, Accepted 26th October 1998

The *meso*-octaethylporphyrinogen–sodium–lanthanide complexes, [{(η^5 : η^1 : η^5: η^1-Et_8N_4)M}Na$(thf)_2$], in the presence of Na metal and under a nitrogen atmosphere, fix and reduce dinitrogen to the $[N_2]^{2-}$ anion, as shown by the isolation of the dinuclear complexes containing the [M(μ-η^2 : η^2-N_2)M] moiety [M = Pr, Nd].

Lanthanide metals can be particularly appropriate in the exploitation of the electron-rich nature of the *meso*-octaalkylporphyrinogen tetraanion. The ligand in turn can provide between 8 and 24 electrons as it adapts the bonding mode of each pyrrolyl anion from η^1 to η^5 based on the requirements of the metal.[1,2] The unique nature of this ligand, which has been recently widely explored in early transition metal organometallic chemistry, centers on its ability to function in a bifunctional manner[1,2] when bonded to acid metals, and through its peculiar redox chemistry.[3] These properties seem to be particularly suitable for exploring the reactivity of lanthanide–porphyrinogen complexes towards dinitrogen. Surprisingly, only one dinitrogen–lanthanide derivative is known for samarium.[4]

Herein we report dinitrogen complexes of Pr and Nd. The synthesis of the unknown starting compounds **3** and **4** has been carried out according to the sequence in Scheme 1. Owing to the potential complication of using lithium, which could eventually reduce N_2,[4b] all preparations and subsequent reactions involved the use of sodium.

Complexes **3**† (light-yellow crystals) and **4**† (light-blue crystals) can occur either in the monomeric or dimeric form, depending on the solvent used during their crystallization. The bonding mode of the lanthanide ion and the sodium cation has been proved by an X-ray analysis on **4**. Complexes **3** and **4** were reduced in THF under a nitrogen atmosphere with sodium, in the presence of small amounts of naphthalene and led to the yellow, **5**,‡ and green, **6**,‡ microcrystalline solids, respectively. Two different solid state forms of the N_2 derivatives have been obtained, depending on the crystallization solvents. Thus, complexes **5** and **6**, when recrystallized from dimethoxyethane (DME) and dioxane, gave **7**‡ and **8**,‡ respectively.

The structures of **7**§ and **8**§ are shown in Figs. 1 and 2 along with selected structural parameters. In both compounds, the porphyrinogen is η^5 : η^1 : η^5 : η^1 bonded[1,2] to the lanthanide ion. Both compounds show two sodium cations η^1 : η^3 bonded to the porphyrinogen and complete their hexacoordination with DME in **7** or two dioxane molecules in **8**. Two additional sodium cations function as countercations in **7**, while in **8** they interact with N_2. The N–N axis is perpendicular to the lanthanide–lanthanide direction, displaying a μ-η^2 : η^2 bonding mode.[4a,5] In both compounds **7** and **8**, unlike in [{(η^5-$C_5Me_5)_2$Sm}$_2$(μ-η^2 : η^2-N_2)][4a] [N–N, 1.088(12) Å] or [{UN($CH_2CH_2NSiBu^tMe_2)_3$}$_2$(μ-η^2 : η^2-N_2)] [N–N, 1.109(7) Å] the N–N distance is in good agreement with a bielectronic reduction of N_2.[6] The magnetic moments at 298 K of the complexes **3** and **5**, **4** and **6**, are very close [μ_{eff} = 3.53, **3**; 3.44, **5**; 3.29, **4**; 3.18 μ_B, **6**] and they remain constant over a wide range of temperature (50–320 K). These results allows the assignment of the +III oxidation state to all metal ions in **3–6**, and rules out any significant coupling between the two paramagnetic centres. In compounds **7** and **8** the lanthanide–N distances are relatively short and comparable to those of amido derivatives.[7] The rather short Na–N(N_2) distances support the interaction of the alkali cation with an anionic form of N_2. Unlike in [{(η^5-$C_5Me_5)_2$Sm}$_2$(μ-η^2 : η^2-N_2)] or in [{UN($CH_2CH_2NSiBu^tMe_2)_3$}$_2$(μ-η^2 : η^2-N_2)], no loss of N_2 was observed, though complexes **5–8** were kept under vacuum for a rather long time. Dinitrogen was evolved from **5**

and **6** in the expected amount only after oxidation with I_2. The present report deals with some important issues and in particular the use of an electron-rich ligand like porphyrinogen and its role in the fixation of dinitrogen in a reduced form bound to lanthanides like Pr and Nd, which are generally difficult to reduce.

Notes and references

† *Procedures for* **3** *and* **4**: [$PrCl_3$·thf$_2$] (11.2 g, 28.6 mmol) was added to a light-yellow solution of **2** (22.3 g, 28.9 mmol) in THF (600 cm³). The resulting yellow-green suspension was kept stirring for 12 h at room temperature. The solid, mainly NaCl, was filtered off and the resulting solution evaporated to dryness. The yellow solid was recrystallized from THF–pentane (18.2 g, 75%). (Found: C, 62.63; H, 7.67; N, 6.71. $C_{44}H_{64}N_4NaPrO_2$ requires C, 62.55; H, 7.63; N, 6.63%). Complex **4** was obtained following the same procedure. (Found: C, 62.22; H, 7.36; N, 6.66. $C_{44}H_{64}N_4NaNdO_2$ requires C, 62.30; H, 7.60; N, 6.61%).

‡ *Procedures for* **5**–**8**: Na metal (0.21 g, 9.26 mmol) and naphthalene (0.30 g, 2.31 mmol) were added to a THF (200 cm³) suspension of **3** (6.51 g, 7.70 mmol) in a 3 dm³ flask. Stirring gave a red solution after 2 h and was continued for 24 h. Standing for 2 more days resulted in a yellow microcrystalline solid. The amount of solid was increased by partial evaporation of THF until 70 cm³ and addition of pentane (100 cm³) (5.8 g, 73%). (Found: C, 60.81; H, 7.60; N, 6.91. $C_{104}H_{160}N_{10}Na_4Nd_2O_8$ requires C, 60.87; H, 7.86; N, 6.86%). The reaction of **5** (1.44 mmol) in THF (100 mL) with I_2 (4.33 mmol) gave N_2 (1.39 mmol). Complex **5** recrystallized from DME gave crystals of **7** suitable for X-ray analysis. The synthesis of **6**, obtained as green crystals, was carried out following the procedure reported for **5**. (Found: C, 60.51; H, 7.95; N, 6.95. $C_{104}H_{160}N_{10}Na_4Nd_2O_8$ requires C, 60.67; H, 7.83; N, 6.80%). Oxidation of **6** (1.43 mmol) with I_2 in THF evolved 1.34 mmol of N_2. The recrystallization of **6** from dioxane gave crystals of **8**, analyzed by X-ray diffraction.

§ *Crystal data* for **7**: $C_{104}H_{176}N_{10}Na_4O_{16}Pr_2$, M = 2196.33, monoclinic, space group $P2_1/c$, a = 20.1877(14), b = 19.2513(14), c = 29.745(2) Å, β = 94.134(6)°, V = 11529.8(14) Å³, Z = 4, D_c = 1.265 g cm^{-3}, F(000) = 4640, λ(Mo-Kα) = 0.71073 Å, μ = 0.912 mm^{-1}; crystal dimensions 0.51 × 0.44 × 0.53. Diffraction data were collected on a KUMA CCD at 173 K. For 16219 observed reflections [$I > 2\sigma(I)$] the conventional R is 0.0687 ($wR2$ = 0.1668 for 22661 independent reflections). *Crystal data* for **8**: $C_{124}H_{200}N_{10}Na_4Nd_2O_{26}$, M = 2627.38, monoclinic, space group $P2_1/c$, a = 12.908(3), b = 15.537(2), c = 32.885(9) Å, β = 94.02(2)°, V = 6579(3) Å³, Z = 2, D_c = 1.326 g cm^{-3}, F(000) = 2772, λ(Mo-Kα) = 0.71070 Å, μ = 0.865 mm^{-1}; crystal dimensions 0.40 × 0.38 × 0.27. Diffraction data were collected on a mar345 area detector at 173 K. For 8471 observed reflections [$I > 2\sigma(I)$] the conventional R is 0.0546 ($wR2$ = 0.1623 for 10692 independent reflections). Received (in Liverpool, UK) 8th September 1998, Accepted 26th October 1998

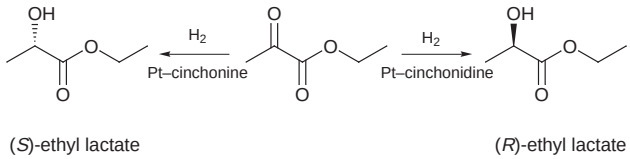
The hydrogenation of ethyl pyruvate to (*S*)-ethyl lactate (up to 70% ee) over a Pt/Al_2O_3 catalyst using α-isocinchonine as a modifier strongly supports the structure of the intermediate complex [cinchona alkaloid (open conformer)–pyruvate 1:1 complex] of this type of reactions.

As is well known, one of the most important fields in contemporary chemical research is the preparation of chiral compounds. The potential of asymmetric catalytic processes is especially high, since in this way large amounts of chiral products can be prepared using catalytic amounts of chiral modifier.[1,2] As a result of industrial and economical requirements the major aim is to develop heterogeneous catalytic asymmetric syntheses.[3–6] In this respect, the hydrogenation of pyruvates is one of the most frequently studied reactions.[7,8] After optimization 95[9]–97% ee[10] was achieved over Pt/Al_2O_3 catalyst using cinchonidine (CD) as the modifier in the preparation of (*R*)-ethyl lactate and 90%[11] ee using cinchonine (CN) for (*S*)-ethyl lactate (Scheme 1).



Scheme 1

Since pyruvate hydrogenation is one of the two[12,13] good ee producing heterogeneous chiral hydrogenations (α-keto esters,[12] β-keto esters and 1,3-diketones[13]), extensive efforts have been made to gain insight into the mechanism. Many mechanistic details of the pyruvate hydrogenation are known, however, there is no agreement concerning the structure of the intermediate (CD–pyruvate 1:1 complex) responsible for chirality. The intermediate complexes (depending on the reaction conditions) published recently are summarized in Fig. 1.

As shown, there is no significant conceptional difference between the structures in each groups [group I: Fig. 1(*a*),[14] (*b*),[15] (*c*),[16] (*f*);[17] group II: (*d*),[18] (*e*)[19]]. The CD in all intermediates in group I is in the 'open' conformation, while in group II it is in the 'closed'conformation. Between the two groups, however, there is a huge difference. The intermediates belonging to group I are anchored to the surface of the platinum catalyst by a multicenter π-bond from the quinoline skeleton and the conjugated σπ systems of pyruvate. In contrast, the structures belonging to group II are already formed in the solution and the complex most likely adsorbs through the conjugated σπ system of the substrate and the non-bonding electron pairs of the quinoline nitrogen due to the so-called 'shielding effect'. It has been clearly proven[7,8,15] that the conformation of the modifier plays a determining role in the chiral induction.

Here we provide new information about the structure of the intermediate complex and experimental proof of whether the 'closed' conformation of the cinchona alkaloids is necessary for chiral induction. For this reason, two cinchona alkaloids, CN and α-isocinchonine (ICN) were selected as chiral modifiers.

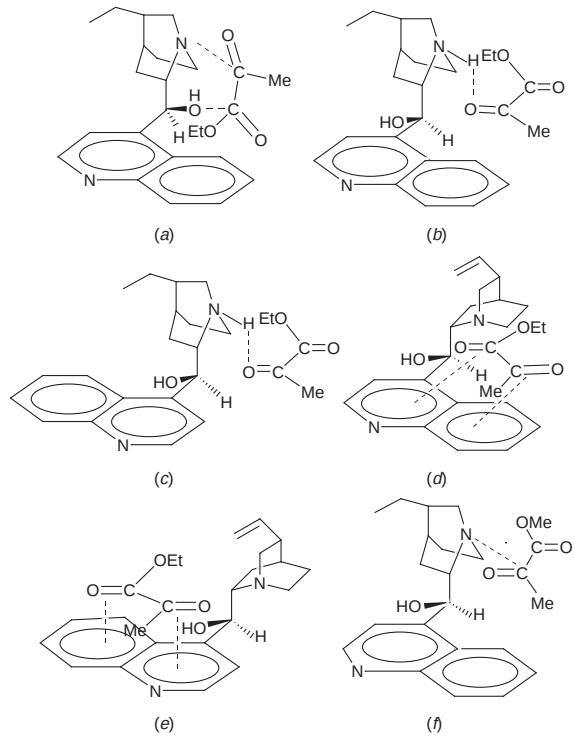


Fig. 1 The structures of the cinchonidine–ethyl pyruvate intermediate complexes.

Although the mechanistic proposals mentioned above are related to the platinum–CD system,[7,8,14,17,18] there is no reason to assume that when using CN the mechanism should be basically different.[11,12,15] Fig. 2 illustrates the most stable

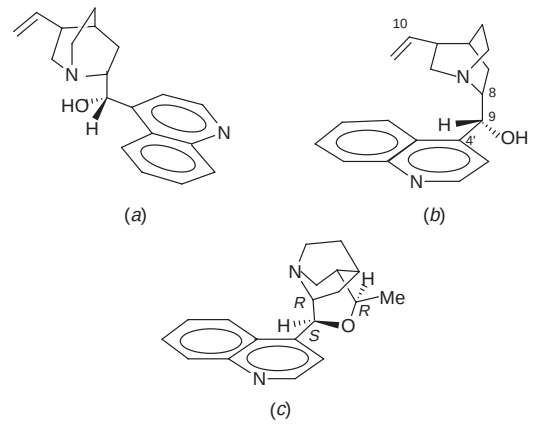

Fig. 2 The conformations of cinchonine [(*a*) 'open' conformer, (*b*) 'closed' conformer] and (*c*) α-isocinchonine.

Table 1 Enantioselective hydrogenation of ethyl pyruvate over a 5% Pt/Al_2O_3 catalyst (Engelhard 4759) in AcOH at room temperature [50 mg of catalyst (as received), 5 mg of modifier, 5 ml of solvent and 0.25 ml of ethyl pyruvate][a]

Modifier	H_2 pressure/bar	Conversion (%)	Ee (%) (configuration)
CD	1	100	80 (*R*)
CD	50	100	90 (*R*)
CN	1	95	72 (*S*)
CN	50	98	67 (*S*)
ICN	1	94	67 (*S*)
ICN	50	98	69 (*S*)

[a] Analysis: ee (%) = 100{[*R*] − [*S*] (or [*S*] − [*R*])}/([*R*] + [*S*]), chiral GC (HP 5890 GC-FID, 30 m long Lipodex-A column), HPLC-MS (HP1090 Ser.II HPLC-HP5989B MS with an HP5987A ES interface).

conformations of CN [Fig 2(*a*)] and ICN [Fig. 2(*c*)] alkaloids suggested and verified by combined NMR and X-ray analysis and molecular mechanical calculations.[20–22] Conformational changes in CN are possible by rotation along the C(4′)–C(9) and C(8)–C(9) bonds. [It should be noted that in the case of flat adsorption of the quinoline skeleton on platinum, as already pointed out,[17,23] the C(4′)–C(9) rotation is hindered.] To realize our aim mentioned above, ICN was selected because it cannot rotate around C(8)–C(9). It is also known that ICN exists only in '*anti*-open' conformation.[22]

The enantioselective hydrogenation of ethyl pyruvate (EtPy) was performed either in a conventional atmospheric hydrogenation apparatus or in a Berghof Bar 45 autoclave at room temperature (25 °C). The results are shown in Table 1.

As the HPLC–ESMS measurements revealed, the ICN modifier did not revert back to CN, *i.e*. the cyclic ether structure remained stable during the hydrogenations. As the results clearly show the ICN modifier of fixed conformation showed practically the same performance (conversion, ee) as CN during the hydrogenations.

The proposed intermediate complex of the chiral hydrogenation carried out in the presence of ICN is illustrated in Fig. 3. It should be mentioned that only the existence of the '*anti*-open' conformer was proven in solution;[22] the formation of the '*syn*-open' conformer during the adsorption cannot be excluded.

These experimental data strongly support the existence of the structures in Fig.1(*b*) and (*c*) when working under acidic conditions. Further measurements are necessary, however, to distinguish between the two structures. Although the reaction conditions are not fully optimized in the case of CN and ICN it is unambiguously proven that the formation of a cinchona alkaloids(closed)–EtPy complex is not a precondition for chiral induction. On the other hand, extensive studies with respect to cinchona-modified pyruvate hydrogenation in AcOH, accompanied by the present results, strongly supports the 1:1 adsorptive interaction model[7,8] of Baiker, Blaser and co-workers. In neutral solvents, the recently revised mechanistic proposal by Wells[17] and co-workers seems most likely.

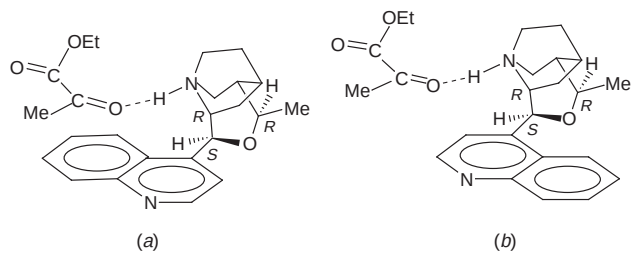

Fig. 3 The structures of α-isocinchonine–ethyl pyruvate intermediate complexes [(*a*) '*anti*-open' complex, (*b*) '*syn*-open' complex].

Our results obtained with ICN suggest further mechanistic studies of cinchona-modified asymmetric syntheses utilising other cinchona alkaloids of rigid conformation. The results of this work provide further proof of our earlier statement[24] that the conformation of the reactants is of crucial importance in determining the selectivity of metal-catalyzed transformations.

Financial support by the Hungarian National Science Foundation (OTKA Grant T016109) and the Hungarian Academy of Sciences (AKP 97-4 2,4) is highly appreciated. Our most sincere thanks are due to Dr J. Thiel (A. Miczkiewicz University, Poznan, Poland) for the donation of the α-isocinchonine sample used to start these investigations.

Calix[4]arenes with perfluorinated alcoholic functions at the upper rim: a new class of neutral anion receptors

N. Pelizzi, A. Casnati and R. Ungaro*

Dipartimento di Chimica Organica e Industriale dell'Università, Viale delle Scienze, 43100-Parma, Italy. E-mail: ungaro@ipruniv.cce.unipr.it

Received (in Liverpool, UK) 2nd September 1998, Accepted 22nd October 1998

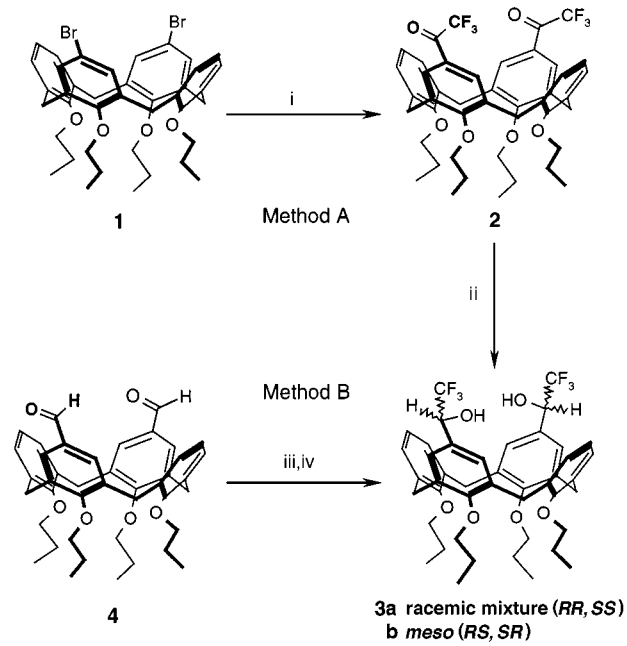
Two or four perfluorinated alcoholic functions were successfully introduced at the upper rim of calix[4]arenes, affording a new type of neutral receptor for anion recognition; preliminary binding studies indicate that the difunctionalized receptors 3a and 3b are selective for Y-shaped carboxylate ions over spherical anions which are, on the contrary, more efficiently bound by the tetraalcohol 6.

Compared with cation complexation, anion recognition represents a less explored area of research, in spite of the important role played by anionic species both in chemistry and biology. However, very recently interest in this field has grown and several new hosts which specifically recognize anions have been synthesized.[1] Most of the organic synthetic receptors for anions are charged species[2] or contain a metal center which directly coordinates to the anion[3] or increases the binding ability of other functional groups.[3] Nevertheless, neutral hosts which complex anions *via* hydrogen bonding are known.[4] So far mainly amides[5] and (thio)ureas[6] or a combination of the two[7] have been used as hydrogen bonding donor groups for the synthesis of electroneutral organic receptors. These groups have also been linked to calixarenes, at either the upper or lower rim, for the synthesis of selective anion receptors. It is well known that perfluoro alcohols are very good anion solvating agents,[8] and that they can affect the kinetics of chemical processes by specific anion solvation.[9] Moreover Pirkle *et al*. used chiral fluoro alcohols as chiral solvating agents and were able to determine the enantiomeric compositions of chiral Lewis bases.[10] Surprisingly, nobody has exploited so far the fluoro alcohol function as a binding site in the design of more complex receptors for anions and polar organic molecules.

We explored the possibility of introducing two or four fluoro alcohol functions at the upper rim of calix[4]arenes blocked in the cone conformation, and report here our successful synthetic results together with some preliminary anion binding properties of the new ligands synthesized.

The difunctionalized anion receptors **3a**,**b** are obtained by two different methods (Scheme 1). Method A exploits the known procedure reported in the literature for the synthesis of simple fluoro ketones.[11] The reaction of the dibromotetrapropoxycalix[4]arene **1**[6b] with Bu^{t}Li in dry THF gives the diketone **2** in 18% yield. The subsequent reduction of **2** with $NaBH_4$ in dry MeOH gives the fluorinated calix[4]arene dialcohol **3** as 1:1 mixture of **3a** (*RR, SS* racemic mixture) and **3b** (*RS, SR meso*). Better yields (85%) are obtained by Method B, reacting the tetrapropoxy calix[4]arene dialdehyde **4**[12] with trifluoromethyltrimethylsilane in the presence of a catalytic amount of TBAF.[13] The two diastereoisomers **3a** (racemic mixture) and **3b** (*meso*) can be separated by column chromatography (SiO_2, hexane–EtOAc 9:1) and their structure assigned by NMR analysis in $CDCl_3$.† The racemic mixture **3a** and the *meso* compound **3b** are easily distinguished by the multiplicity of the signals of the unsubstituted aromatic nuclei; **3a** presents a C_2 axis and gives three doublets of doublets, while **3b** has a symmetry plane and generates two doublets and two triplets.

Since it has been shown that calixarenes bearing strong hydrogen bonding groups like (thio)urea[14] form in apolar solvents dimeric molecular capsules we have studied solvent



Scheme 1 *Reagents and conditions*: i, Bu^{t}Li, CF_3CO_2Et, THF, −80 °C; ii, $NaBH_4$, MeOH; iii, CF_3SiMe_3, TBAF, THF; iv, 4 M HCl.

effects on **3a** and **3b**. The independency upon diluition of NMR spectra in $CDCl_3$ and the osmometric determination of the molecular weight indicate that there are no *inter*molecular hydrogen bonds and that **3a**,**b** are monomeric in solution. However a significant conformational rearrangement is observed in the ^1H NMR spectra of the diastereomeric mixture passing from $CDCl_3$ to [$^2H_6$]DMSO: the hydrogens *ortho* to the trifluoromethyl alcohol give signals between δ 6.2 and 6.6 in $CDCl_3$, whereas they are shifted to between δ 7.1 and 7.3 in [$^2H_6$]DMSO. On the contrary the signals of the unsubstituted aromatic rings, which are between δ 6.8 and 7.1 in $CDCl_3$, shift to the region between δ 6.0 and 6.7 in [$^2H_6$]DMSO. This behaviour is due to two different pinched cone conformations adopted in $CDCl_3$ and in [$^2H_6$]DMSO (Fig. 1). In $CDCl_3$ the upfield shift of the aromatic hydrogens of the nuclei bearing the fluorinated alcohols indicates that an intramolecular hydrogen bond is present between the two OH groups which keeps these

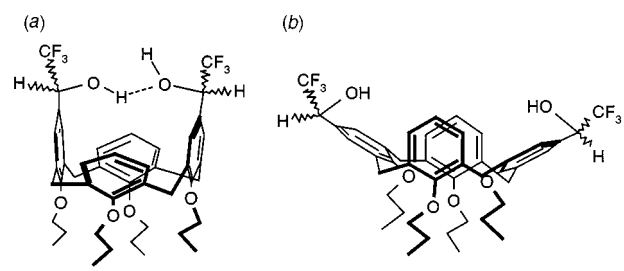


Fig. 1 The two pinched cone conformations adopted by **3a**,**b** in (*a*) $CDCl_3$ and (*b*) [$^2H_6$]DMSO.

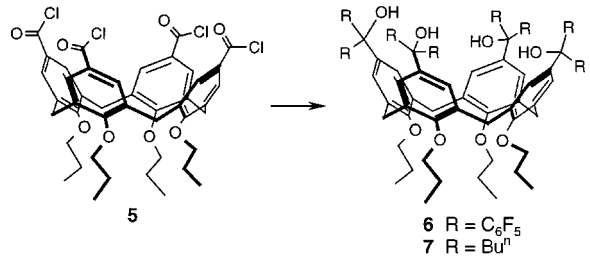

Scheme 2 *Reagents and conditions*: i, RI, Li.

two functionalized aromatics in the shielding cone of the other two. On the contrary in [$^2H_6$]DMSO the intramolecular hydrogen bonding is prevented by solvation and the calixarene adopts a piched cone conformation where the unsubstituted aromatic rings are in the shielding cone of the other two.

We have also synthesized the calix[4]arene derivative **6** (Scheme 2), which bears four perfluorinated alcoholic functions at the upper rim, by reacting the tetraacyl chloride **5**[15] with C_6F_5I and lithium in dry Et_2O (yield 15%)† and, for comparison, compound **7** (yield 95%).†

Preliminary binding studies using titration NMR experiments‡ reveal that both receptors are able to complex anions in $CDCl_3$. Difunctionalized receptors **3a** and **3b** show selectivity in the recognition of carboxylate over spherical anions with the racemic compound **3a** binding acetate anion (K_{ass} = 435 M^{-1}) more efficiently than the *meso* compound **3b** (K_{ass} = 200 M^{-1}). Also in the case of a chiral guest like the anion of *N*-lauroyl-L-phenylalanine we have observed a stronger association of the racemic compound **3a** (K_{ass} = 165 M^{-1}) with respect to the *meso* compound **3b** (K_{ass} = 40 M^{-1}), the latter probably giving rise to unfavorable steric interactions. On the other hand the tetrafunctionalized receptor **6** binds spherical anions such as bromide (K_{ass} = 480 M^{-1}) more efficiently than acetate anion (K_{ass} = 90 M^{-1}). Although these data may be negatively affected by the presence of intramolecular hydrogen bonding, a comparison with the data reported in the literature for the interactions between anions and other hydrogen bonding donor groups[5,16] seems to indicate that the strength of the interaction between the perfluorinated alcoholic functions and anions is smaller than that of the same anions with urea or sulfonamide groups, but comparable with carboxamides. The importance of the perfluorinated groups for anion binding is however indicated by the fact that compound **7** shows no interaction with either bromide and acetate anions under the same conditions.

We are currently working on the synthesis of more rigid calixarene receptors in order to avoid intramolecular hydrogen bonding.

This research was supported by MURST (Supramolecular Devices Project) and by CNR. We also thank C. I. M. (Centro Interdipartimentale Misure) for the use of NMR and mass spectrometry instruments.

‡ Association constants (K_{ass}) were determined by ^{1}H NMR titration experiments in $CDCl_3$; stock solutions of host and guest in $CDCl_3$ at different concentrations were prepared and mixed together in the NMR tube in various molar ratios. ^{1}H NMR spectra were recorded at 300 K and the chemical shift of some protons were plotted *versus* guest concentration. Non-linear regression analyses allowed the determination of K_{ass} (accuracy ±10%).

Received (in Liverpool, UK) 23rd September 1998, Accepted 26th October 1998

Ti-beta catalyses the oxidation of small- and medium-sized silanes to the corresponding silanols by aqueous (30%) H_2O_2 as oxygen donor with high conversions and excellent selectivity (no disiloxane).

Although organosilanols have been of continual interest since their discovery,[1] only a limited number of methods for their selective preparation are available. Sterically exposed silanols are especially problematic as they readily dimerize with traces of acid or base to the disiloxanes. Therefore, the commonly used method, *i.e.* the hydrolysis of chlorosilanes,[2] is only applicable for sterically encumbered derivatives. Currently one of the best methods of making silanols is the oxidation of silanes with dioxiranes,[3] but the disadvantage is that this reagent is used stoichiometrically. Catalytic Si–H insertions have also been reported for nickel, palladium, chromium, rhodium, and copper complexes,[4] but these reactions are either limited to special substrates or produce disiloxanes in high amounts.

Recently we developed the first *selective* metal-catalysed Si–H insertion by using the methyltrioxorhenium/urea–H_2O_2 adduct (MTO/UHP) oxidant[5] and proposed that the observed selectivity derives from oxidation in the urea channels (host–guest chemistry), which suppresses the subsequent dimerization of the silanol to the disiloxane. Since the redox molecular sieves TS-1 and Ti-beta are known to catalyse efficiently a variety of oxidations by H_2O_2,[6–9] it was of interest to explore whether such Ti-doped zeolites could serve as catalyst as well as host for the selective oxyfunctionalisation of silanes without disiloxane formation. Indeed, that this is the case is demonstrated herein for Ti-beta, which effectively catalyses the selective oxidation of silanes to silanols by H_2O_2. Most conveniently, our titanium zeolite-catalysed Si–H insertions [eqn. (1)] may be conducted at room temperature with H_2O_2, an environmentally benign oxygen source since its reduction product is water.

$$\underset{\textbf{1a–f}}{R^1R^2R^3SiH} \xrightarrow[\text{MeCN, 20 °C, 24}]{\text{Ti zeolite, } H_2O_2} \underset{\textbf{2a–f}}{R^1R^2R^3SiOH} + \underset{\textbf{3a–f}}{[R^1R^2R^3Si]_2O} \quad (1)$$

The Ti-beta samples used throughout this study were provided by Professor A. Corma, Valencia, Spain, with a Ti content of 2 wt% (as TiO_2) and an aluminium content of 0.29 wt%, and were cation-exchanged by 0.16 M aq. NaOAc. In a typical experiment, the substrate (*ca*. 330 μmol) was dissolved in 1 ml of MeCN, 1.1 equiv. of H_2O_2 (85% or 30% aq. solution) was added while stirring, followed by 30–50 mg of titanium catalyst. The slurry was stirred at ambient temperature (*ca*. 20 °C) for 24 h, subsequently the zeolite was removed by means of a membrane filter (millipore HV, 0.45 μm pore size) and washed three times with 2 ml of acetone. The product mixture was analysed by capillary gas chromatography (Fisons HRGC 5160 Mega Serie, 30-m HP-5 capillary column, FID) and the products were identified by comparing the GC retention times with authentic samples. Conversions and mass balances were calculated relative to an internal standard (Table 1).

Table 1 Conversions, mass balances and product selectivities of the oxidation of silanes **1** to silanols **2** by titanium catalysts

Entry	Substrate	Catalyst	Oxygen source	Conversion[a] (%)	Mass balance[a] (%)	Selectivity[b] **2**:**3**

[a] Entries 1,2: determined by ^1H NMR spectroscopy directly on the crude reaction mixture, error ±5% of the stated values; entries 3–10: mass balances and conversions were determined by gas chromatography against an internal standard, error ±1% of the stated values; conditions for **2a**: 35 °C (8 min)→[30 °C min^{-1}]→100 °C (1 min)→[30 °C min^{-1}]→160 °C (2 min), flow 0.5 kg cm^{-2}, against toluene; for **2b**: 40 °C (7 min)→[30 °C min^{-1}]→100 °C (2 min)→[30 °C min^{-1}]→150 °C (5 min)→[30 °C min^{-1}]→240 °C (1 min), flow 0.5 kg cm^{-2}, against ethylbenzene; for **2c**: 35 °C (14 min)→[30 °C min^{-1}]→240 °C (5 min), flow 1.0 kg cm^{-2}, against toluene; for **2d**: 80 °C (4 min)→[30 °C min^{-1}]→130 °C (1 min)→[30 °C min^{-1}]→240 °C (1 min), flow 0.4 kg cm^{-2}, against *n*-hexadecane; for **2e**: 40 °C (3 min)→[30 °C min^{-1}]→100 °C (1 min)→[30 °C min^{-1}]→160 °C (1 min), flow 1.2 kg cm^{-2}, against *n*-dodecane; entry 13: determined by HPLC analysis with Chiralcel® OD-H column with *n*-hexane–Pr^iOH (9:1) as eluent and dimethyl isophthalate as internal standard, error ±2% of the stated value. [b] Selectivities were determined by gas chromatography under the conditions and with the internal standards specified in footnote *a*, error ±1% of the stated values. [c] Recycled catalyst. [d] Catalyst was stirred for 24 h with 1 equiv. H_2O_2 in MeCN and recycled as described. [e] In the presence of diethyl L-tartrate.

For our studies, two titanium-doped zeolites were used, namely TS-1 (5.3 × 5.6 Å)[10] and Ti-beta-Na (6.4 × 7.6 Å).[10] Control experiments showed that no reaction occurred in the absence of the titanium zeolite. This clearly indicates that the oxidative species requires the titanium metal for the activation of H_2O_2 and that direct oxidation of the silane by H_2O_2 does not take place. For comparison with a homogeneous Ti^{IV} catalyst, we employed the well-known $Ti(OPr^i)_4$/Bu^tOOH oxidant.

When Ti-beta was used as oxidation catalyst, good to excellent conversions of the silanes **1a–e** to the corresponding silanols **2a–e** were obtained (Table 1, entries 1–3,5–7,11,12). In contrast, the conversion of the model substrate **1d** with the homogeneous system was lower by 20% (entry 10 compared to entries 5,6). Notably, the silane **1f** is not oxidised because it is sterically too encumbered to enter the zeolite channels (entry 13). Steric hindrance is also the reason why the silane **1d** is not oxidised when the TS-1 zeolite is employed as catalyst (entry 4). The latter results provide unequivocal evidence that these oxidations take place inside the zeolite and not on the outer surface. In addition, if any oxidation of the silanes were to occur on the outer surface of the zeolite, significant amounts of the corresponding disiloxane products should have been formed, in analogy to the Si–H insertion in solution with $Ti(OPr^i)_4$/Bu^tOOH (entry 10).

A major advantage of the Ti-beta/oxidant system for the transformation of silanes to silanols is the fact that excellent product ratios of silanol *versus* disiloxane were obtained for all the silanes studied. This is in stark contrast to the silanol/disiloxane product distributions which have been observed in most previous studies.[4] A further benefit is the fact that the 85% aq. H_2O_2 solution may be substituted by 35% aq. H_2O_2 solution without any loss of selectivity and reactivity (entry 5 *vs*. 6 and entry 11 *vs*. 12).

Since the inorganic framework of the zeolite is quite resistant to oxidative degradation, it was of interest to explore the possibility of catalyst recycling. Indeed, we found that the Ti-beta zeolite may be re-used several times by heating the filtered catalyst at 240 °C for several hours. Interestingly, the recycled catalyst showed even higher catalytic activity (entry 7). It is known that calcination reduces the coordination number of the lattice-bound titanium[11] from 5 or 6 to 4, and thus it seemed likely that the increase in activity is due to the loss of coordinated water; thus more activated sites for H_2O_2 are generated. However, an independently calcinated (*ca*. 500 °C) sample of Ti-beta did not show enhanced catalytic activity (entry 8); moreover, a lower silanol selectivity was observed (59:41). Furthermore, when a sample of Ti-beta was stirred in MeCN with 1 equiv. H_2O_2 for 24 h and recycled as described above, a moderate silanol selectivity (entry 9) was obtained. We propose that the increased catalytic activity is due to *in situ* silylation of free OH groups in the zeolite lattice. The beneficial effect of silylation on the enhancement of catalytic activity has previously been reported for Ti-MCM-41[12] and was assigned to a change to a less polar zeolite interior. The lower silanol selectivity in entries 8 and 9 might be caused by a higher zeolite acidity due to loss of coordination water on calcination, which would promote silanol dimerisation.

Recently, a peracid-type transition-state structure for the Ti-beta-catalysed epoxidation of chiral allylic alcohols with H_2O_2 has been assessed.[8] In analogy, we propose also for the Si–H insertion a five-membered ring peracid-type geometry, as shown in Fig. 1.

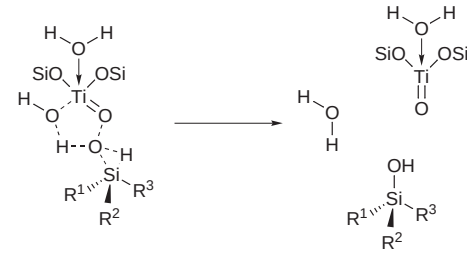

Fig. 1 Proposed transition-state structure for the titanium-catalysed Si–H oxidation.

In conclusion, the well-known Ti-beta/H_2O_2 oxidant is an excellent system for the catalytic conversion of silanes selectively into silanols. This catalytic oxidation takes place inside the zeolite channels and the observed selectivity (no disiloxane) is due to prevention of the dimerization of the silanol.

The authors thank the Deutsche Forschungsgemeinschaft (SFB 347 'Selektive Reaktionen Metall-aktivierter Moleküle'), the Bayerische Forschungsstiftung (Bayerischer Forschungsverbund Katalyse - FORKAT), and the Fonds der Chemischen Industrie for generous financial assistance. A gift of Ti-beta-Na zeolite from Professor A. Corma is greatly appreciated.

New efficient synthesis of phosphonofluorodithioates ROP(S)(S$^-$)F and their structural analogues

Izabela Tworowska and Wojciech Dąbkowski*

Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, 90–363 Łódź, Sienkiewicza 112, Poland. E-mail: wdabkow@bilbo.cbmm.lodz.pl

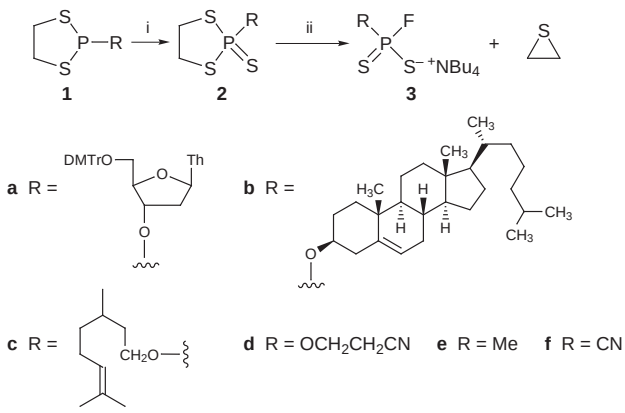
Received (in Liverpool, UK) 7th September 1998, Accepted 26th October 1998

The title compounds 3 are formed in very high yield from a one-pot sequential reaction of 1,3,2-dithiaphospholane P^{III} derivatives 1, which are transformed into the corresponding P^{IV} compounds 2 by addition of elemental sulfur and finally into fluoridodithioates 3 by TBAF.

Phosphorus dithioacids play an important role as reagents, ligands and stereochemical probes in ^{31}P NMR spectroscopy.[1] Dithioacids containing a fluorine ligand attached directly to the phosphorus atom are rare.[2] The method of choice for the preparation of simple phosphonofluoridodithioates is not applicable for the preparation of phosphonofluoridodithioate monoesters derived from natural products. Unlike for nucleoside phosphonofluoridate[3a–c] or phosphonofluoridothioate[3d] monoesters, there is only one synthetic method available for the preparation of nucleoside phosphonofluoridodithioate monoesters.[3e] Stawinski and Bollmark have devised a synthesis of nucleoside phosphonofluoridodithioate monoesters *via* oxidation of nucleoside phosphonodithioate with I_2 in pyridine in the presence of TMSCl, followed by addition of triethylamine trishydrofluoride (TAF) to give the nucleoside phosphonofluoridodithioate.[3e]

The importance of phosphoro-fluorine compounds in pure and applied chemistry stimulated our interest in the synthesis of phosphorus dithioacids with P–F bonds. Our studies on the synthesis of phosphonodithioates from 3′-thiothymidine by anhydro-ring opening of 2,3′-anhydrothymidine[4] required an efficient synthesis of *O*,*O*-disubstituted phosphonodithioic acids. We now disclose a novel synthesis of the title compounds **3** containing a wide variety of substituents attached to the phosphorus center (Scheme 1). Our method is based on 1,3,2-dithiaphospholane derivatives **1** which are readily available from ethane-1,2-dithiol and an appropriate P^{III} compound.

The protocol we have developed involves two consecutive reactions carried out in one pot: sulfurization of compound **1** to form compound **2** and finally the reaction with TBAF to open the dithiaphospholane ring with spontaneous elimination of ethylene sulfide and formation of the desired acid **3** (Scheme 1). The roots of this approach are derived from methodology described by Stec.[5]



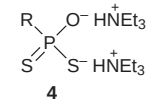
Scheme 1 *Reagents and conditions*: i, S_8, benzene; ii, TBAF, THF.

To illustrate the power and versality of this strategy several examples are presented which include the fluoro dithioacids **3** containing alkyl and alkoxyl (nucleosidyloxy) moieties attached to the phosphorus center. The first example comes from nucleotide chemistry (Scheme 1).† The compounds **1a** and **2a** have been prepared according to the modified procedure of Okruszek and Olesiak.[5b] The condesation of **1** (R = NPr$^i_2$) with 5′-dimethoxytritylthymidine was performed in the presence of TMSCl yielding **1a** in very high yield.[6]†

According to this method *O*-cholesteryl phosphonofluoridodithioate **3b** was obtained in quantitative yield (Scheme 1).‡ 2-Cholesteryloxy-2-thioxo-1,3,2-dithiaphospholane **2b** was the first prepared by Stec and coworkers.[7]

An analogous synthetic pathway led to **3c**§ starting from **1c** (Scheme 1). Synthesis of the 2-citronellyloxy-1,3,2-dithiaphospholane **1c** was achieved by the coupling of **1** (R = NPr$^i_2$) with citronellol in the presence of TMSCl as activator.[6]

The phosphonofluoridodithioate **3d**¶ can be conveniently prepared from **1d**, which is readily available from **1** (R = NPr$^i_2$) *via* condensation with 2-cyanoethanol in the presence of TMSCl. Compound **1d** was transformed into **2d**¶. Ring opening with TBAF gave the dithioacid **1d** (Scheme 1) which, after removal in the presence of Et_3N of the 2-cyanoethyl group, gave the phosphonofluoridodithioic acid **4** [δ_P($CDCl_3$) 67.50(d); δ_F($CDCl_3$) −0.42 (d, $J_{P–F}$ = 1108.96)].



4

The methylphosphonofluoridodithioate **3e**‖ was prepared from compound **1e**[8] (Scheme 1). The preparation of the latter involves the condensation of ethane-1,2-dithiol with methyl(dichloro)phosphine.

The same strategy allowed us to prepare a novel inorganic structure, the cyanophosphonofluoridodithioate **3f**** (Scheme 1). The cyano derivative **1f** was prepared by the reaction **1** (R = Cl) with trimethylsilyl cyanide.

In summary we have developed a novel, efficient and general method for the synthesis of phosphonofluorodithioates **3**. Yields of the final products are very good, exceeding 95%. They show high stability at ambient temperature and can be conveniently converted into free acids by the action of toluene-*p*-sulfonic acid. Acids **3** are strong nucleophiles and thus serve as useful precursors to a wide variety of hitherto unknown functionalized heteroatom systems and ligands. The new route leading to phosphonofluorodithioic acids **3** described here is noteworthy in its flexibility. It can also be extended to analogues of **2** containing a P=Se group.

This work was supported by the German–Polish project (POI-211-96).

Notes and references

† The solvents were reagent grade and were distilled and dried by conventional methods before use. NMR spectra were recorded on a Bruker AC200 spectrometer (^{31}P 81.014 MHz, H_3PO_4 external standard; ^{19}F

188.15 MHz, $CFCl_3$). The compounds **1a** and **2a** were prepared according to the modified procedure of Okruszek and Olesiak [ref. 5(*b*)]. *Typical procedure* for **1** (R = NPr^i_2): A solution of $Pr^i_2NPCl_2$ (10 mmol) in dry THF (10 ml) was added dropwise at room temperature under a nitrogen atomosphere to the solution of ethane-1,2-dithiol (10 mmol) and Et_3N (20 mmol) in dry THF (50 ml) with stirring for 2 h. After 2 h, $Et_3N{\cdot}HCl$ was filtered off and the filtrate evaporated *in vacuo*. The residue was distilled under reduced pressure.

For **1a**: A solution of 5′-DMTr-thymidine (10 mmol) in dry THF (10 ml) was added dropwise at room temperature under a nitrogen atmosphere to a solution of **1** (R = NPr^i_2) (10 mmol) and TMSCl (0.6 mmol) in dry THF (20 ml). After 1 h the mixture was evaporated *in vacuo* and the residue was purified by column chromatography [$\delta_P(CDCl_3)$ 150.67].

For **2a**: To a solution of **1a** in THF was added elemental sulfur, and the mixture was stirred overnight at room temperature. The solvent was evaporated and the residue was chromatographed using acetone–CH_2Cl_2 as eluent to give pure **2a** [$\delta_P(CDCl_3)$ 122.65].

For **3a**: To a solution of **2a** (10 mmol) in dry THF was added a solution of TBAF (11 mmol) in THF at room temperature. After 1 h the mixture was evaporated *in vacuo* and the residue was purified by column chromatography [$\delta_P(CDCl_3)$ 119.64 (d); $\delta_F(CDCl_3)$ −4.92 (d, J_{PF} 1103.74)].

‡ *Selected data* for **1b**: $\delta_P(CDCl_3)$ 147.24. For **2b** $\delta_P(CDCl_3)$ 118.33. For **3b**: $\delta_P(CDCl_3)$ 118.65 (d); $\delta_F(CDCl_3)$ −3.36 (d, J_{PF} 1096.38). Compounds **1b**, **2b** and **3b** were prepared according to the procedure described in note †.

§ *Selected data* for **1c**: $\delta_P(CDCl_3)$ 142.75. For **2c**: $\delta P(CDCl_3)$ 120.53. For **3c** $\delta_P(CDCl_3)$ 120.24 (d); $\delta_F(CDCl_3)$ −8.53 (d, J_{PF} 1094.22). Compounds **1c**, **2c** and **3c** were prepared according to the procedure described in note †.

¶ *Selected data* for **1d**: $\delta_P(CDCl_3)$ 150.19. For **2d**: $\delta_P(CDCl_3)$ 123.34. For **3d**: $\delta_P(CDCl_3)$ 120.84 (d); $\delta_F(CDCl_3)$ −6.07 (d, J_{PF} 1096.30). Compounds **1d**, **2d** and **3d** were prepared according to the procedure described in note †.

‖ *Selected data* for **1e**: $\delta_P(CDCl_3)$ 42.78. Compound **1e** was prepared as described by Peake *et al.* (ref. 7). For **2e**: $\delta_P(CDCl_3)$ 90.58. For **3e**: $\delta_P(CDCl_3)$ 129.8 (d); $\delta_F(CDCl_3)$ −25.55 (d). Compounds **2e** and **3e** were prepared according to the procedure described in note †.

** *Selected data* for **1f**: $\delta_P(CDCl_3)$ 10.71. Compound **1f** was prepared by the reaction of **1** (R = Cl) with TMSCN. For **2f**: $\delta_P(CDCl_3)$ 108.0. For **3f**: $\delta_P(CDCl_3)$ 60.18 (d), $\delta_F(CDCl_3)$ −41.01 (d, J_{PF} 1070.1). Compounds **2f** and **3f** were prepared according to the procedure described in note †. For **2f**, the sulfurization procedure using B_2S_3 is superior to that employing elemental sulfur.

A significant effect of anion binding ureas on the product ratio in the palladium(II)-catalyzed hydrocarbonylation of alkenes

Jan Scheele, Peter Timmerman and David N. Reinhoudt*

Laboratory of Supramolecular Chemistry and Technology, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands. E-mail: smct@ct.utwente.nl

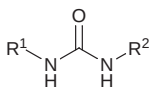
Received (in Cambridge, UK) 27th August 1998, Accepted 21st October 1998

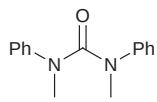
Hydrogen bonding of urea derivatives to the anionic ligands X of (dppp)PdX_2 catalysts significantly increases the hydroacylation of cyclopentene relative to the hydroformylation, most probably due to a decreased coordination strength of the anionic ligands.

Transition metal complexes are important homogeneous catalysts for alkene polymerization[1] and alkene/CO copolymerization reactions.[2] In the L_2PdX_2-catalyzed hydrocarbonylation of alkenes with synthesis gas (CO/H_2) either aldehydes (hydroformylation), ketones (hydroacylation), or polyketones (copolymerization) are formed. The type of reaction is determined mainly by the coordination strength of the anionic ligands X in L_2PdX_2.[3] Only Pd^{II} catalysts with weakly coordinating anions (*e.g.* X = TFA) show sufficient activity in such hydrocarbonylation reactions. These catalysts are prepared by anion metathesis reactions of L_2PdX_2 with the corresponding silver salt (X = Cl)[4] or Brønsted acid (X = OAc).[5] Alternatively, strong Lewis acids like methylalumoxane (MAO)[6] or $SnCl_2$[7] are added.

Our group has developed a variety of anion receptors based on multiple hydrogen bonding to (sulfon)amides[8] or (thio)ureas,[9] or coordination to a Lewis acidic uranyl center.[10] These anion receptors have been applied for anion-selective sensors (CHEMFETs)[11] and in membrane transport studies. Recently, we have described the catalytic activity of anion receptors in acyl transfer reactions.[12]

Here we show that *N*,*N*′-disubstituted urea derivatives **1**–**5**





6

1 $R^1 = R^2 = Ph$
2 $R^1 = p\text{-}F_3CC_6H_4$, $R^2 = Ph$
3 $R^1 = R^2 = p\text{-}F_3CC_6H_4$
4 $R^1 = Bu^n$, $R^2 = Ph$
5 $R^1 = R^2 = Bu^n$

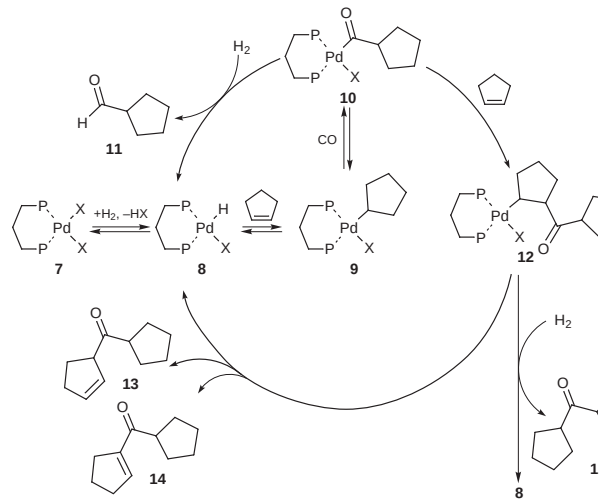
significantly influence the performance of the (dppp)PdX_2 catalyst [dppp = 1,3-bis(diphenylphosphino)propane] in hydrocarbonylation reactions. The effect is attributed to the interaction[13] of the acidic urea protons with the counterions (X = OAc, TFA, OTs) leading to a decrease in their coordination strength. There are reports of hydrogen bonding to the anionic ligands of transition metal complexes in the solid state.[14] To the best of our knowledge this is the first report in which hydrogen bonding to the anionic ligands of a homogeneous catalyst alters the product ratio of the reaction.[15]

As a model reaction we used the Pd^{II}-catalyzed hydrocarbonylation of cyclopentene with synthesis gas in anisole.† The mechanism for this reaction[3] is depicted in Scheme 1. Hydride **8** is formed by reaction of precatalyst (dppp)PdX_2 with H_2. The rate of the subsequent exchange reaction of cyclopentene for X depends strongly on the coordination strength of the counterion to the Pd center.[4,16] Migratory insertion gives the σ-alkyl–Pd complex **9** and consecutive CO insertion yields the acyl–Pd intermediate **10**. The formation of **10** from **8** is monitored by the turnover number of CO (TON_{CO}), *i.e.* the number of CO insertions per Pd center. Intermediate **10** can react further in two different ways, either giving cyclopentanecarbaldehyde **11** or yielding one of the ketones **13**–**15** after insertion of a second molecule of cyclopentene. In all cases **8** is regenerated either by β-elimination or by oxidative addition of HX to the Pd^0 complex formed.

The selectivity for ketones increases from 14 to 98% reflecting the decrease in coordination strength of the anionic ligands X in the series of (dppp)PdX_2 (X = TFA, OMs, OTs, OTf, entries 1–4 in Table 1) with $6.0 \times 10^2 < TON_{CO} < 9.2 \times 10^2$ mol (mol Pd)$^{-1}$ h^{-1}. With (dppp)Pd$(OAc)_2$ (entry 5) the TON_{CO} is reduced to 0.2×10^2 mol (mol Pd)$^{-1}$ h^{-1} because of the stronger coordinating acetate, and the selectivity for ketones is 24%. Weaker coordinating anions may enhance the (intrinsic) electrophilicity of the Pd^{II} center and, of course, these anions are more easily displaced from the (fourth) coordination site which facilitates the formation of intermediates **10** (increased TON_{CO}) and **12** (increased selectivity for ketones).

We found that in the presence of 0.6 mol% [7.5 equiv. with respect to the (dppp)Pd$(TFA)_2$ catalyst] of *N*,*N*′-diphenylurea **1** the selectivity for ketones increases from 14 to 25% (entry 6 in Table 1), whereas the TON_{CO} increases from 6.0×10^2 to 7.8×10^2 mol (mol Pd)$^{-1}$ h^{-1}.‡ With 0.6 mol% of the urea derivatives **2** and **3**, containing either one or two electron-withdrawing substituents at the phenyl rings that will increase the anion affinity of the urea moiety,[17] the selectivity for ketones shows a sharp increase from 14 to 49 and 61%, respectively (entries 7 and 8). In both cases the TON_{CO} is similar to that in the presence of urea **1**. Both *N*-butyl-*N*′-phenylurea **4** and *N*,*N*′-dibutylurea **5** do not significantly change the selectivity for ketones (entries 9 and 10), which is in accordance with the much lower acidity and anion binding strength of (di)alkyl ureas compared to diaryl ureas.[18]

The altered selectivities of the catalyst upon addition of diarylureas **1** or **3** were also observed for the catalysts



Scheme 1 Catalytic cycle for the Pd^{II}-catalyzed hydrocarbonylation of cyclopentene.

Table 1 Selectivity for ketones and turnover number for the hydrocarbonylation of cyclopentene with CO and H_2 in the presence of urea derivatives **1**–**6**[a]

Entry	Anion	Receptor[b]	Selectivity (%)[c]	$TON_{CO}/10^2$ mol (mol Pd)$^{-1}$ h^{-1} [d]
1	OTf	—	98	8.7
2	OTs	—	54	8.2
3	OMs	—	41	9.2
4	TFA	—	14	6.0
5	OAc	—	24	0.2
6	TFA	**1**	25	7.8
7	TFA	**2**	49	7.8
8	TFA	**3**	61	8.3
9	TFA	**4**	16	5.9
10	TFA	**5**	10	5.1
11	OAc	**1**	45	0.4
12	OAc	**3**	80	0.4
13	OTs[e]	**1**	82	7.0
14	OTs	**3**	95	10
15	TFA	**6**	14	6.4
16	TFA[f]	**6**	12	5.8
17	OAc	**6**	25	0.3
18	OTs	**6**	51	9.6

[a] Cyclopentene (5 ml), anisole (10 ml), (dppp)PdX_2 (0.08 mol%), 110 °C, 80 bar (CO:H_2 = 1:1), analysis by GC FID, integrals were not corrected for sensitivities. [b] 7.5 equiv. cocatalyst compared to Pd catalyst. [c] Percentage of hydroacylation products (**13–15**) of the total amount of products formed, accuracy ±2%. [d] Turnover number of CO determined as the sum of TONs of all products **11**, **13**, **14** and **15**; accuracy ±5% (see note ¶). [e] 10 equiv. cocatalyst **5**. [f] 13 equiv. cocatalyst **6**.

(dppp)Pd(OAc)$_2$ (entries 11 and 12) and (dppp)Pd(OTs)$_2$ (entries 13 and 14). In both cases the stronger anion binding urea **3** causes the largest change in the selectivity for ketones, *i.e.* from 24 to 80% for (dppp)Pd(OAc)$_2$ and from 54 to 95% for (dppp)Pd(OTs)$_2$. The TON_{CO} is enhanced from 0.2×10^2 to 0.4×10^2 and from 8.2×10^2 to 10×10^2 mol (mol Pd)$^{-1}$ h^{-1}, respectively. These results suggest that the observed increase in ketone formation is the result of complexation of the anionic ligands by the urea derivatives **1**–**3** *via* hydrogen bonding which decreases the coordination strength of the counterions to the Pd center.

Experiments carried out in the presence of a large excess of tetrasubstituted urea **6**, which is unable to bind anions *via* hydrogen bonding, show that neither the selectivity for ketones nor the TON_{CO} is affected to a significant extent (entries 15–18 in Table 1). This excludes the possibility that the observed effect is due to coordination of the urea carbonyl to the Pd center or to a change in the polarity of the reaction medium.§

Our results show that hydrogen bond formation to the anionic ligands X of (dppp)Pd catalysts can significantly change the selectivity of the catalyst in the hydrocarbonylation of cyclopentene with synthesis gas. Addition of *N*,*N*′-diarylureas **1**–**3** strongly favours hydroacylation with respect to hydroformylation. The maximum effect is observed with the stronger anion binding urea **3**.

We thank the Shell Research & Technology Centre, Amsterdam, for financial support and Professor Dr E. Drent and Dr W. P. Mul for helpful discussions.

Notes and references

† *Experimental procedure*: Hydrocarbonylation experiments were performed in a 100 ml autoclave at 110 °C. 10 ml anisole, 5 ml cyclopentene, 0.08 mol% of (dppp)PdX_2 catalyst, and urea cocatalyst were brought under a H_2 atmosphere whereafter the autoclave was pressurized with 40 bar CO and 40 bar H_2. After a reaction time of 20 h the autoclave was cooled down and the gas (pressure drop < 15 bar) was vented off. The products were analysed by GC FID (CPSIL-5, 50 m).

‡ The amount of added *N*,*N*′-diphenylurea **1** correlates well with the selectivity for ketones formed in the reaction and the TON_{CO}. With varying amounts (2–18 equiv.) of **1** as cocatalyst in the (dppp)Pd(TFA)$_2$ catalyzed reaction both the selectivity for ketones and the TON_{CO} are increased. A maximum of 37% and 8.9×10^2 mol (mol Pd)$^{-1}$ h^{-1} was reached with 1.5 mol% (18 equiv.) of **1** (limited by the solubility of **1** in the reaction medium).

§ Additional evidence for hydrogen bond formation of **1**–**5** to the anionic ligands X of (dppe)PdX_2 (X = Cl, TFA, OTs) was obtained by IR, ^{1}H and ^{31}P NMR spectroscopic studies in $CDCl_3$ at room temperature (ref. 19). Addition of 2 equiv. (dppe)$PdCl_2$ to an 1 mM solution of *N*,*N*′-diphenylurea **1** (free N–H vibration at 3422 cm^{-1}) gave rise to an additional N–H stretch frequency at 3330 cm^{-1} in the FT–IR spectrum. The ^{1}H NMR spectra of ureas **1**–**5** show in all cases downfield shifts ($0.40 > \Delta\delta > 0.15$ ppm) for the urea proton signals upon addition of 1 equiv. of (dppp)PdX_2, which is indicative for hydrogen bond formation. Furthermore the ^{31}P NMR resonances of the (dppe)PdX_2 complexes shift over 1 ppm downfield upon addition of 2 equiv. of **1**. Similar downfield shifting of the ^{31}P NMR resonances is also observed upon weakening of the coordination strength of the anions of (dppe)PdX_2 (X = TFA: δ 63.1; X = OTs: δ 69.9). In contrast to this the addition of 1,3-dimethyl-1,3-diphenylurea **6** to the Pd complexes did not induce any significant shift of the ^{31}P NMR resonances.

¶ The TONs based on conversion of cyclopentene ($TON_=$).can easily be calculated from Table 1 according to $TON_= = TON_{CO} \times (1 +$ selectivity).

Synthesis of cross-conjugated trienes by dimerization of allenes with palladium-phenol catalyst

Mieko Arisawa, Takumichi Sugihara† and Masahiko Yamaguchi*

Faculty of Pharmaceutical Sciences, Tohoku University, Aoba, Sendai 980-8578, Japan.
E-mail: yama@mail.pharm.tohoku.ac.jp

Received (in Cambridge, UK) 28th September 1998, Accepted 26th October 1998

Cross-conjugated trienes were synthesized by dimerization of monosubstituted allenes in the presence of a catalyst system consisted of $Pd_2(dba)_3$, *p*-nitrophenol, and P(*p*-Tol)$_3$.

Cross-conjugated trienes have attracted considerable interest in polymer chemistry[1] and theoretical chemistry[2] as well as in synthetic chemistry, and various methods have been developed for the preparation of the parent 3-methylenepenta-1,4-diene and its derivatives.[3] Although catalytic dimerization of substituted allenes can directly provide such trienes, an effective method has as yet not been developed. The dimerization reaction of 3-methylbuta-1,2-diene was reported to give 2,5-dimethyl-3,4-bismethylenehex-1-ene, which was promoted by a stoichiometric amount of a nickel(0) complex.[4] The reaction, however, gave a very low yield of the cross-conjugated triene when other allenes were employed. Although palladium complexes are known to catalyze dimerization of propa-1,2-diene in the presence of water or amine giving hydroxylated or aminated 2,3-dimethylbuta-2,3-diene,[5] the method was not applied to the synthesis of cross-conjugated trienes. Described here is an efficient synthesis of the trienes by catalytic dimerization of monosubstituted allenes, alka-1,2-dienes. A novel combination of $Pd_2(dba)_3$ (dba = dibenzylideneacetone), *p*-nitrophenol, and P(*p*-Tol)$_3$ was employed for the catalyst.

When undeca-1,2-diene **1** was treated with $Pd_2(dba)_3$ (5 mol%), P(*p*-Tol)$_3$ (15 mol%) and *p*-nitrophenol (10 mol%) in refluxing THF for 12 h, (9*E*,12*E*)-10-methyl-11-methyleneicosa-9,12-diene **2** was obtained in quantitative yield (Table 1, entry 5). The structure including the stereochemistry was determined unambiguously by spectroscopic methods. Added phenol played an important role, and no reaction took place in its absence (entry 1). This reaction was effectively promoted by phenol possessing an electron-withdrawing group (*p*-nitrophenol) while the yield of **2** decreased when phenol, alkylphenol, or methoxyphenol was used (entries 2–4). Considerable amounts of adducts **3** or **4** derived from **2** and the phenols were formed in the latter cases. Since AcOH also promoted the reaction (entry 10), phenol appeared to function as the Brønsted acid.[6] The dimerization reaction did not occur with sodium phenoxide or tributyltin phenoxide. Use of P(*p*-Tol)$_3$ was also essential, and the reaction was retarded by the introduction of electron-withdrawing substituents on the aromatic ring (entry 7). Bidentate phosphines gave 1,3-diene without forming the dimeric product (entries 8 and 9).

The dimerization reaction of other methylene-substituted allenes under the above reaction conditions proceeded stereoselectively to give the cross-conjugated (*E*,*E*)-trienes in quantitative yields (Table 2). With this catalyst system, a product–catalyst ratio of 1000:1 could be reached (entry 2). Dimerization of a methyne substituted allene, 1-cyclohexylpropa-1,2-diene, was sluggish, although the stereoselectivity was retained (entry 8).

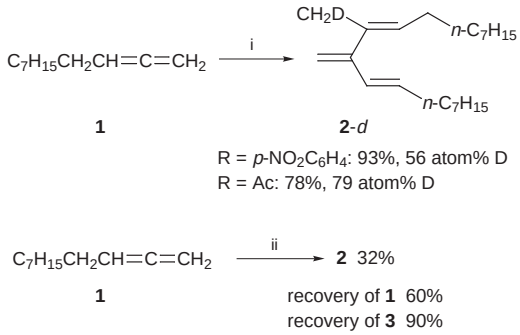
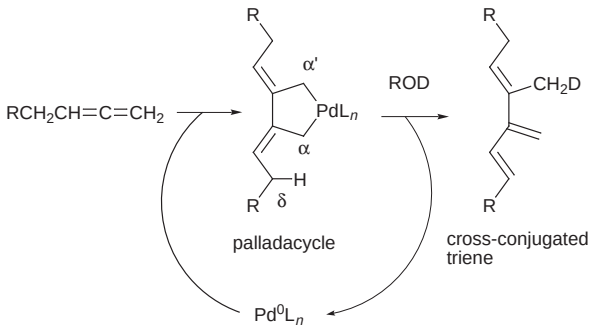
[a] The reaction was carried out using 5 mmol of **1** in the presence of 0.1 mol% of $Pd_2(dba)_3$, 0.3 mol% of P(*p*-Tol)$_3$ and 0.2 mol% of *p*-nitrophenol. [b] Starting material was recoverd in 32% yield.



Scheme 1 *Reagents and conditions*: i, $Pd_2(dba)_3$ (5 mol%), P(p-Tol)$_3$ (15 mol%), ROD (100 mol%), THF, reflux, 12 h; ii, $Pd_2(dba)_3$ (5 mol%), P(p-Tol)$_3$ (15 mol%), **3** (R = p-Tol) (10 mol%), THF, reflux, 12 h.

atom% D) yield, respectively (Scheme 1). A ^{2}H NMR experiment revealed deuteration at the methyl group. A considerable part of the proton was thus introduced from the external proton source. In order to know the role of the adducts **3** and **4** in the reaction, the dimerization of **1** was conducted in the presence of a catalytic amount of **3** (R = p-Tol) instead of p-nitrophenol. After reacting for 12 h, only 32% yield of the dimer **2** was obtained with **1** recovered in 60% yield. Approximately 90% of the adduct **3** (R = p-Tol) was also recovered unchanged. The result, compared to that of Table 1, entry 3, indicated that the formation of **3** and **4** was not the major process of the present catalytic reaction.

Although the dimerization reactions of propa-1,2-diene and 3-methylbuta-1,2-diene was studied to some extent,[4,5] the mechanism still remained unclear. Based on our experiments and the results of the $(R_3P)_3Ni$-promoted stoichiometric dimerization reaction of 3-methylbuta-1,2-diene, the following working hypothesis was presented (Scheme 2). Since the nickel reaction took place *via* a nickelacycle,[4] it may be likely that the present palladium-catalyzed dimerization involved a palladacycle.[7] The reductive elimination with concomitant proton transfer from the δ-carbon atom to the α′-carbon atom gave the cross-conjugated triene. Our deuteration experiments showed that the δ-proton in the palladacycle was not transferred



Scheme 2

intramolecularly. The process appeared to be catalyzed by phenol.

Polymerization of the cross-conjugated trienes obtained in the present study was also examined. Triene **2** was treated with $SnCl_4$ and Bu^{t}Cl in CH_2Cl_2 at −50 °C for 1 min.[8] After aqueous workup and purification by gel permeation chromatography, soluble polymer was obtained in 30% yield (M_n = 1.9 × 10^4, M_w/M_n = 1.93). Use of protic acid (H_2SO_4, $HClO_4$, TfOH) gave insoluble materials. The cationic conditions turned out to be suitable for the polymerization of **2**, and radical conditions (AIBN, 80 °C), anion treatment (Bu^{n}Li or Bu^{t}Li, THF, −78 °C) or thermal treatment (80 °C, 24 h, under argon or oxygen) gave low molecular weight oligomers.

The dimerization reaction of **1** is representative. Under an argon atmosphere, a mixture of $Pd_2(dba)_3$ (45.7 mg, 5 mol%), P(p-Tol)$_3$ (45.6 mg, 15 mol%), **1** (152 mg, 1.0 mmol) and p-nitrophenol (13.9 mg, 10 mol%) in THF (5 ml) was heated at reflux for 12 h. THF was then removed under reduce pressure, and the residue was purified by flash chromatography (hexane) over silica gel giving **2** (145.9 mg, 96%).

The authors thank Professor Tokuji Miyashita (Institute for Chemical Reaction Sciences, Tohoku University) for obtaining M_w and M_n values for the polymer. This work was supported by grants from the Japan Society of Promotion of Science (RFTF 97P00302) and the Ministry of Education, Science, and Culture, Japan.

On the cyclization mechanism of squalene: a ring expansion process of the five-membered D-ring intermediate

Tsutomu Sato,[a] Takamasa Abe[b] and Tsutomu Hoshino*[ab]

[a] *Graduate School of Science and Technology, and*
[b] *Department of Applied Biological Chemistry, Faculty of Agriculture, Niigata University, Ikarashi, Niigata 950-2181, Japan. E-mail: hoshitsu @agr.niigata-u.ac.jp*

Received (in Cambridge, UK) 7th September 1998, Accepted 26th October 1998

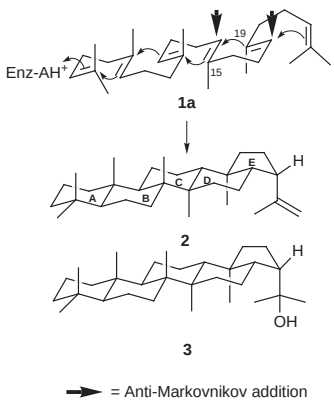
Site-directed mutagenesis experiments with W169F, W169H and W489F for the squalene-hopene cyclase, and the formation of 10 possessing the five-membered D-ring and a tetrahydrofuran moiety as the enzyme product of the analogue 8 with a hydroxy group, strongly suggest that a ring expansion reaction from the five- to the six-membered ring is responsible for the D-ring formation of hopene.

The cyclization of squalene **1** into pentacyclic triterpenes, hop-22(29)-ene **2** and hopan-22-ol **3**, is an outstanding reaction from the point of view of both stereo- and regio-chemical specificity, with the formation of five new carbon–carbon bonds and nine new chiral centers.[1] Oxidosqualene also undergoes the polyolefin cyclization analogous to squalene.[1] Recent progress on the two cyclases of squalene and oxidosqualene has spurred mechanistic studies of the polycyclization reactions. Squalene-hopene cyclase (SHC) is believed to fold the linear molecule **1** into an all pre-chair conformation **1a** inside the enzyme cavity, leading to **2** and **3** through the generation of a series of carbocation intermediates (Scheme 1).[2] Scheme 1 also shows that the C- and D-rings are formed by anti-Markovnikov closures. Site-directed mutagenesis experiments of SHC revealed that both D-376 and D-377 were crucial for the catalysis.[3] Recently, an X-ray analysis of *Alicyclobacillus acidocaldarius* SHC has been reported.[4] We have independently succeeded in an overexpression of the SHC and reported the first identification of the tryptophan residues 169 and 489 as components of the active sites; substitution of these tryptophans with valine and leucine by point mutations resulted in complete loss of the enzyme activity.[5] Here, we report that mutants of W169F, W169H and W489F produce the normal cyclization products **2** and **3** together with an abnormal tetracyclic product **4** consisting of a 6/6/6/5-fused ring system, the formation of **4** being in agreement with the Markovnikov rule. This finding leads us to propose that a ring expansion reaction is involved in the D-ring formation of **2** and **3**.

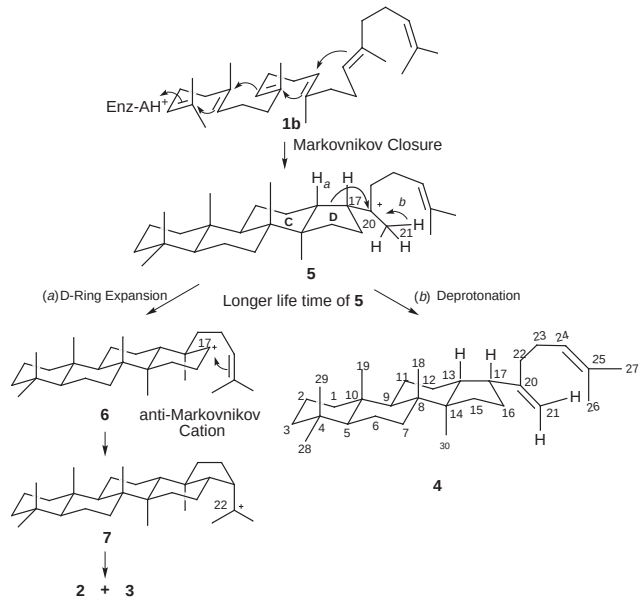
Cell-free homogenates of the mutants prepared by site-directed mutagenesis were incubated with **1** at optimal temperatures (45 °C for W169F and W169H, and 53 °C for W489F). The wild-type has a catalytic optimum at 60 °C and pH 6.0.[3,5] A large scale incubation of **1** (150 mg) for 16 h with a cell-free extract from a 6 l culture of W169F afforded **2**, **3** and **4** (an oil) (100.5, 10 and 6 mg, respectively) after the separation with a SiO_2 column (hexane–EtOAc). The incubation of other mutants conducted with the same quantities of **1** and cell-free extracts as for W169F gave the following isolated yields: for mutant W169H: **2** (73.5 mg), **3** (6.3 mg) and **4** (33.0 mg), and for mutant W489F: **2** (36.8 mg), **3** (3.3 mg) and **4** (9.8 mg). Detailed 2D NMR analyses[6] revealed that **4** had a dammarene skeleton with an exomethylene group, but the 17-side chain had an α-orientation (17-*epi*-dammarene). No other product was detected in the reaction mixtures except for recovered **1**.

Concomitant production of **4** together with the two normal products **2** and **3** indicates that a common intermediate **5** is being produced during the polyolefin cyclization process (Scheme 2). Formation of the dammarene cation **5** having a 6/6/6/5-fused ring system is thermodynamically favored by Markovnikov control. Proton elimination from the methyl group would give **4** [path (*b*)], while the ring expansion process from a five- to six-membered D-ring would give the hopanyl C22-cation **7** *via* a disfavored anti-Markovnikov C-17 cation **6** [path (*a*)], the latter being formed after the ring expansion of **5** has been processed. The ring expansion competes with the deprotonation. Steric factors also favor the formation of **5**; given that the cyclization reaction proceeds by adopting a pre-chair conformation **1a** for the D-ring construction, greater repulsion would occur due to the 1, 3-diaxial arrangement between the two methyls at the 15- and 19-positions (squalene numbering), thus resulting in the less hindered conformation **1b**.

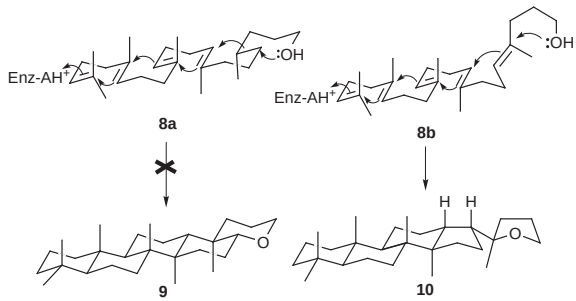
A similar ring expansion has been proposed for the C-ring formation in lanosterol biosynthesis, based on the trapping of



Scheme 1



Scheme 2



Scheme 3

the five-membered C-ring intermediate (a 6/6/5-fused ring) from incubation experiments with substrate analogues.[7] Incubation of the squalene analogue **8** (C_{27}-OH), prepared *via* treatment of H_5IO_6 with 2,3-oxidosqualene followed by reduction with $LiAlH_4$, with the wild-type SHC afforded **10**[6] almost quantitatively (Scheme 3). Compound **9** and other products were not detected. Formation of **10** strongly supported the suggestion that the cyclization reaction proceeded *via* the prefolded **8b** (like **1b**), but not through **8a** (like **1a**), and also gave unequivocal evidence for the involvement of a discrete metastable C-20 carbocation intermediate like **5** prior to the ring expansion and further cyclization; the hydroxy group would have attacked the tertiary C-20 cation thus produced due to its highly nucleophilic nature, resulting in the formation of a tetrahydrofuran ring in **10**. A dammarene cation similar to **5** was postulated for the cyclization mechanism of 2,3-dihydrosqualene[8] and 29-methylidene-2,3-oxidosqualene[9] by SHC.

Since the mutants of W169V and W489L were completely inactive,[5] it appears that the tight binding to **1** comes from the aromatic ring residue, not from the hydrophobic aliphatic residues of SHC. To date, cation–π interactions induced by aromatic moieties, resulting in the carbocation stabilization, have been proposed for the catalysis and/or acceleration of the polycyclization reaction.[10] Kinetic values for the mutants were compared with that of the wild-type.[11] For the mutant W169F, K_m increased 17-fold, but V_{max} remained unchanged. On the other hand, for the mutant W489F, K_m increased 5.5-fold, but V_{max} was only 14% of the wild type. These kinetic results imply that the W169 would bind to **1** rather than stabilizing the carbocation, while W489 may exhibit both binding and cation stabilization, and also suggest that the higher electron density of the π-electrons, the greater affinity to **1**. The looser binding of the phenylalanine or histidine residues to **1**, near the D-ring, in the mutant SHCs would lead to the longer lifetime of **5**, as inferred from the thermodynamic and steric preferences. Compared to W169F, W169H significantly increased the amount of **4** 5.5-fold; the histidine residue may abstract a proton from the 21-methyl [path (*b*)], indicating that the position of W169 in the cavity may possibly be close to the 21-methyl of **5**, but further evidence is required to confirm this.

Synthesis of novel 'supercharged' analogues of pyrophosphoric acid

Xiaohai Liu, Harry Adams, and G. Michael Blackburn*

Krebs Institute, Department of Chemistry, University of Sheffield, Brook Hill, Sheffield, UK S3 7HF. E-mail: g.m.blackburn@sheffield.ac.uk

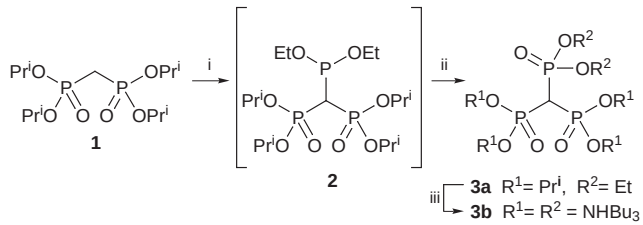
Received (in Liverpool, UK) 11th September 1998, Accepted 26th October 1998

Syntheses of two novel halomethanetriyltrisphosphonic acids are based on an improved preparation of methanetriyltrisphosphonic acid: pK_as for their second acidic dissociations show they are 'supercharged' relative to pyrophosphoric acid, PP_i, while X-ray crystallographic analysis of fluoromethanetriyltrisphosphonic acid establishes its isosteric character relative to PP_i.

Many of the functions of ATP in cellular chemistry have been explored by nucleotide analogues containing phosphonate moieties stable to hydrolysis.[1] By contrast, the dinucleoside 5′,5″-polyphosphates, also a ubiquitous component of all cells, have biological functions that are not yet adequately understood,[2] although some of them (*e.g.* Ap_5A,[3] Ap_5U,[4] Ap_5dT[5]) have proved valuable as transition state mimics for investigation of a range of kinases and show that multiplicity of anionic charge is a major factor in protein affinity. We[6] and others[7] have generated a variety of analogues of ATP and of diadenosine 5′,5″-polyphosphates, Ap_nA, designed to resist specific or general enzymatic hydrolysis, some of which have shown promising therapeutic activity.[8] In an ongoing programme to synthesise analogues of nucleotides with enhanced affinity for receptors[9] and better charge correlation with transition states for selected kinases,[10] we have developed new organophosphorus mimics of pyrophosphoric acid by the substitution of the carbon of methylenebisphosphonic acid by anionic functions. These species should have additional anionic charge relative to simple methylenebisphosphonates and also when incorporated into ATP and Ap_nA analogues.

We envisaged that methanetriyltrisphosphonic acid **3b** and its α-chloro **5** and α-fluoro **7** derivatives would best fulfil this specification, firstly because the introduction of a third ionizable phosphonate (PO_3H_2) group into methylenebisphosphonic acid **1** would be expected to deliver additional anionic charge at physiological pH and secondly because it has been well-established that α-halogenation can enhance the acidity of an alkylphosphonic acid while retaining the stability of its P–C bond to enzymatic cleavage.[11] Since the published procedure[12] for the preparation of hexaethyl methanetriyltrisphosphonate proved of uncertain utility in our hands, we developed[9] an independent multi-step route to this compound, but this gave only low yields of **3b**. We here describe a significantly improved synthesis of methanetriyltrisphosphonic acid and its esters using a modification of Gross's original procedure[12] on which we have established the preparation of novel chloro- and fluoro-methanetriyltrisphosphonic acids. Their physical properties and X-ray structure analysis demonstrate that they are 'supercharged' analogues of pyrophosphoric acid having isosteric character relative to pyrophosphate.

Tetraisopropyl methylenebisphosphonate **1** was reacted with diethyl chlorophosphite in the presence of NaHMDS (in contrast to NaH) (Scheme 1).[12] The reaction quickly reached equilibrium when 4 equiv. of diethyl chlorophosphite and NaHMDS were used to drive the equilibrium towards product **2**. Intermediate **2** was found to be unstable during either acidic (AcOH quench) or basic (sat. $NaHCO_3$ quench) work-up and decomposed to give starting material **1**. Therefore, it was oxidised *in situ* with iodine in pyridine–THF–water to give the desired product **3a** in 72% yield.[13] This provides a significant



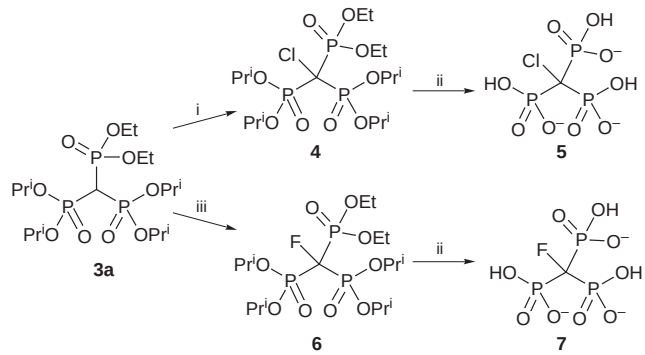
Scheme 1 *Reagents and conditions*: i, NaHMDS, $(EtO)_2PCl$, toluene, room temp.; ii, 0.5 M I_2 solution in Py–THF–H_2O (40:9:1); iii, Me_3SiBr, CH_2Cl_2, reflux overnight, then MeOH, Bu_3N.

improvement for the general synthesis of esters of methanetriyltrisphosphonic acid. When **3a** was heated with TMSBr[14] in CH_2Cl_2 overnight at reflux, methanetriyltrisphosphonic acid was isolated in 98% yield as its tris(tributylammonium) salt **3b** following solvolysis in the presence tri-*n*-butylamine. This product was converted quantitatively into its trisodium salt by precipitation from MeOH with NaI solution (0.5 M in acetone).

Chloromethanetriyltrisphosphonate ester **4** was obtained in 97% yield after treatment of the methanetriyltrisphosphonate ester **3a** with NaOCl solution (Scheme 2).[15] Deprotection of the ester functions was achieved by refluxing with TMSBr and tri-*n*-butylamine in CH_2Cl_2 in 98% yield. (The addition of 1.5 equiv. of base was necessary for clean deprotection of **4** to avoid loss of phosphoric acid from the product **5**, which we observed under acidic conditions, as has been noted elsewhere[16]).

Fluoromethanetriyltrisphosphonate **6** was prepared from **3a** in 77% yield using perchloryl fluoride[17] at −78 °C in the presence of NaHMDS. Substituting *N*-fluorobis(benzene)-sulfonimide for $FClO_3$ gave no product even at room temperature. Presumably this is a consequence of the extreme steric hindrance to electrophilic substitution at the central carbon in **3a**.

Deprotection of **6** was effected in quantitative yield under the conditions used for **4** and the structure of product **7** (as its trisodium salt) confirmed by X-ray crystallography (Fig. 1). From the X-ray crystallographic data of fluoromethanetriyltrisphosphonate, it is clear that the P–C–P geometry (both the P–C bond distance and the P–C–P bond angle)[18] is close to that in



Scheme 2 *Reagents and conditions*: i, 4–20% NaOCl, $NaHCO_3$, 0 °C, 1.5 h; ii, TMSBr, Bu_3N, CH_2Cl_2, reflux overnight; iii, $FClO_3$, NaHMDS, THF, −75 °C.

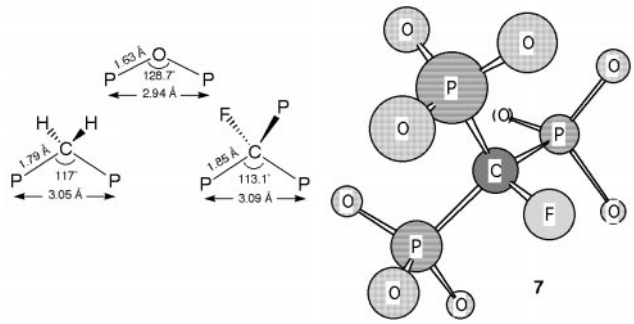


Fig. **1** A comparison of bond angles and bond distances in pyrophosphate, methylenebisphosphonate and fluoromethanetriyltrisphosphonate salts (left) and the X-ray crystallographic structure of the trisodium salt of **7** (right).

methylenebisphosphonate salts[7,19] while the overall phosphorus–phosphorus separation is very close to that observed for methylenebisphosphonate and pyrophosphate salts, largely as a result of compensation between a smaller P–C–P angle and longer P–C bonds (Fig. 1). The crystal lattice of **7** can be considered as a layered structure where one face of the anion coordinates to the sodium ion layer whilst the other face interacts *via* hydrogen bonding to the next anionic layer. This is illustrated in the packing diagram (Fig. 2).

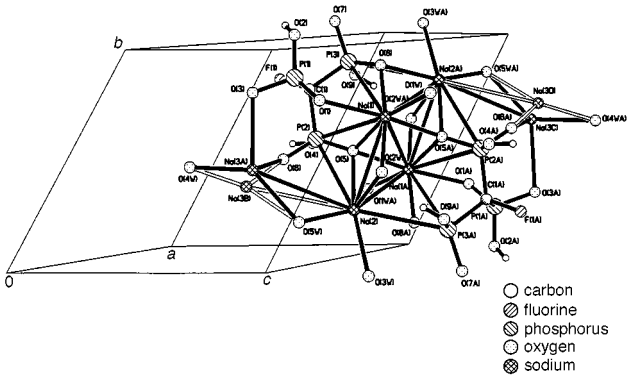

Fig. **2** Crystal packing diagram for **7** illustrating the layered structure and the intermolecular interactions described in the text.

The pK_as of these methanetriyltrisphosphonic acid analogues together with those for α-sulfonylmethylenebisphosphonic acid and α-carboxymethylenebisphosphonic acid[9] were measured under physiological conditions (37 °C, 0.152 M NaCl), which called for deconvolution of titration curves for multiple overlapping pK_as. The ionic state of these trisphosphonates calculated for pH 7.0 (Table 1) show clearly that all five species are 'supercharged' at physiological pH. Methanetriyl-, chloromethanetriyl- and fluoromethanetriyl-trisphosphonic acids have at least one more negative charge than pyrophosphate at pH 7.0. By comparison, α-sulfonylmethylenebisphosphonic acid[9] has a charge of 3.71 minus and α-carboxymethylenebisphosphonic acid[9] 3.3 minus at pH 7.0. It is to be expected that this charge differential will be maintained or enhanced in analogues of ATP and Ap$_n$A containing these trisphosphonates, thereby underpinning the investigation of the role of anionic charge in nucleotide binding to enzymes and receptors.

Table 1 Ionisation constants for polyphosphonic acids determined in the range 3.5 < pH < 10.5 at 37 °C and 0.152 M NaCl

Entry	pK_a3	pK_a4	pK_a5	Net charge at pH 7.0
Pyrophosphoric acid	6.6	9.4	—	2.72
Methanetriyltrisphosphonic acid **3b**	—[a]	6.46	9.90	3.77
Chloromethanetriyltrisphosphonic acid **5**	—[a]	5.92	9.08	3.92
Fluoromethanetriyltrisphosphonic acid **7**	—[a]	5.77	8.86	3.95
α-Sulfonylmethylenebisphosphonic acid[b]	—[a]	6.61	10.57	3.71
α-Carboxymethylenebisphosphonic acid[b]	—[a]	7.24	10.11	3.35

[a] The first three ionisation constants were too low to be accessed in the pK_a titrations employed. pH titration curves were deconvoluted for multiple overlapping pK_a values using a programme written for an Apple Macintosh computer. [b] Ref. 9.

Syntheses of such supercharged analogues of ATP and of Ap$_n$As, determination of their physical characteristics, and studies on protein binding is under active investigation. These results also identify these trisphosphonic acids as strong candidate ligands for calcium ion ligation and as potential bone affinity agents.

We gratefully acknowledge financial support from BBSRC (ROPA/MOLO4558).

Efficient synthesis of β-substituted α-chloro enones by rhodium(II)-catalyzed reactions of cyclic diazodicarbonyl compounds with acid chlorides

Yong Rok Lee* and Jung Yup Suk

Received (in Cambridge, UK) 8th September 1998, Accepted 26th October 1998

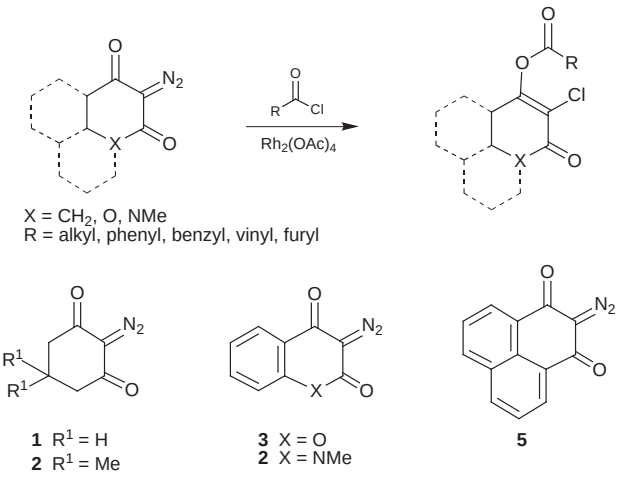
An efficient synthesis of α-chloro α,β-enones is achieved by rhodium(II)-catalyzed reaction of cyclic diazodicarbonyl compounds with a variety of acid chlorides in good yield.

α-Halo enones have been widely used as valuable and versatile intermediates in the synthesis of α-carbon substituted enones[1] and biologically active natural products.[2] There are many convenient methods available for the preparation of α-bromo and α-iodo enones.[3] However, these procedures are not suitable for the preparation of α-chloro enones. α-Chloro enones are typically prepared by an addition–elimination reaction of enones with PhSCl,[4] ring opening of dichlorocyclopropane with aq. AcOH,[5] and oxidative chlorination of enones with HCl/MCPBA/DMF.[6] Although several methods for the synthesis of these compounds have been developed, their synthetic exploitation has been limited by the difficulties in handing the required strong acidic conditions, and side reactions involving over-oxidation. The necessity for overcoming these serious problems has prompted a search for new methods for the preparation of α-chloro enones.

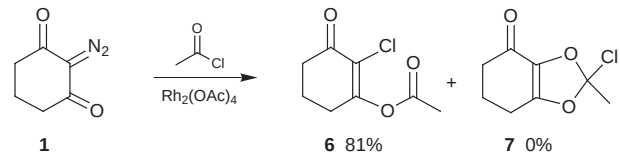
We have been interested in rhodium-catalyzed reactions of diazodicarbonyl compounds with several substrates.[7] Recently, the rhodium-catalyzed reaction of diazocarbonyl compounds with furans, pyrroles, alkynes and nitriles has been widely studied by several groups.[8] However, the rhodium-catalyzed reaction of diazocarbonyl compounds with acid halides has not been investigated. We report here a new and efficient synthesis of β-substituted α-chloro enones utilizing rhodium(II)-catalyzed reactions of cyclic diazodicarbonyl compounds with a variety of acid chlorides.

The strategy that we have developed begins with the reaction of cyclic diazodicarbonyl compounds **1–5** and acid chlorides (ten-fold excess), which serve as a solvent and a reactant, in the presence of 1 mol% of $Rh_2(OAc)_4$, as shown in Scheme 1.

Treatment of 2-diazocyclohexane-1,3-dione **1** with AcCl at room temperature for 3 h gave the 3-acetoxy-2-chlorocyclohex-2-enone **6** in 81% yield, without a trace of expected 1,3-dioxole



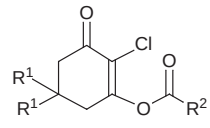
Scheme 1



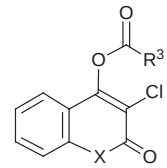
Scheme 2

7 (Scheme 2).[9] Support for the structural assignment comes from spectroscopic analysis. The enone **6** is identified by the IR carbonyl absorptions of the enone at 1693 cm^{-1} and the vinyl ester at 1777 cm^{-1}, and the ^1H NMR peak of the methyl group of the vinyl acetate as a singlet at δ 2.26. Further support for the structural assignment of **6** is obtained from its ^{13}C NMR spectrum, which clearly shows the expected eight carbons, including the two carbonyl carbons of the enone at δ 191.31 and the vinyl ester at δ 166.15.

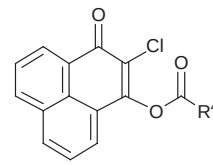
Reaction of diazodicarbonyl compounds **1** and **2** with a range



8	R^1 = H, R^2 = Pr	96%
9	R^1 = H, R^2 = Ph	35%
10	R^1 = Me, R^2 = Pr	92%
11	R^1 = Me, R^2 = Bn	71%
12	R^1 = Me, R^2 = (*E*)-prop-1-enyl	70%
13	R^1 = Me, R^2 = 2-furyl	20%



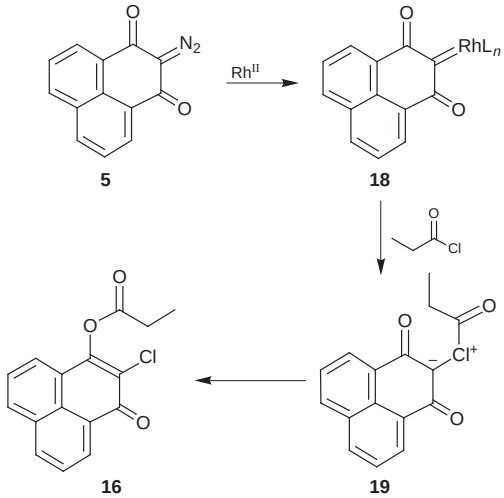
14	R^3 = Me, X = O	35%
15	R^3 = Et, X = NMe	70%



16	R^4 = Et	74%
17	R^4 = Pr	74%

of acid chlorides gave compounds **8–13**. In all cases, only a single product was seen. In particular, reaction of diazodicarbonyl compound **2** with crotonyl chloride gave the enone **12** in 70% yield. In this reaction, no addition product to the C=C bond could be detected. Reaction of diazodicarbonyl compounds **2** and **3** with acid chlorides such as PhCOCl, 2-furoyl chloride and AcCl gave the expected enone **9** (35%), **13** (20%) and **14** (35%) in low yields. This is likely to be due to the instability of products. Importantly, our result is in clear contrast to that of Alonso who reported that the copper(II)-catalyzed reaction of acyclic methyl 2-diazo-3-oxobutyrate with carbonyl compounds such as aldehydes or ketones afforded 1,3-dioxole adducts in moderate yields.[9]

In order to extend the utility of this methodology, reactions of more complex diazodicarbonyl compounds **3–5** with acid chlorides were examined. In these cases, only a single product was also detected. In particular, there is no direct precedent for Rh^{II}-catalyzed reactions of diazodicarbonyl compounds **3–5**



Scheme 3

with other substrates such as alkenes, alkynes, furans, and carbonyl compounds, so it is noteworthy that reaction of **3–5** with acid chlorides give the α-chloro enone **14–17** in 35–74% yields.

Although the exact mechanism of the reaction is still not clear, it is best described as shown in Scheme 3. The diazodicarbonyl compound **5** first gives a carbenoid **18** (or a carbene) by displacement of nitrogen by $Rh_2(OAc)_4$. Nucleophilic addition of acid chloride to the electrophilic carbenoid **18** yields an ylide **19**, which subsequently undergoes intramolecular nucleophilic addition of oxygen to the carbonyl group and the cleavage of the acyl–Cl bond to give product **16**.

In conclusion, rhodium-catalyzed reaction of cyclic diazodicarbonyl compounds with a variety of acid chlorides offers a simple and facile method for the synthesis of α-chloro α,β-unsaturated ketones. Further application of this reaction will be investigated, and is now in progress in our laboratory.

Received (in Cambridge, UK) 7th October 1998, Accepted 30th October 1998

Using the tropp^{Ph} ligand 1, stable monomeric d^8-Ir^{+I}, d^9-Ir^0 and d^{10}-Ir^{-I} complexes could be isolated and structurally characterized; in all complexes, the metal centre lies within a coordination sphere intermediate between a square plane and a tetrahedron.

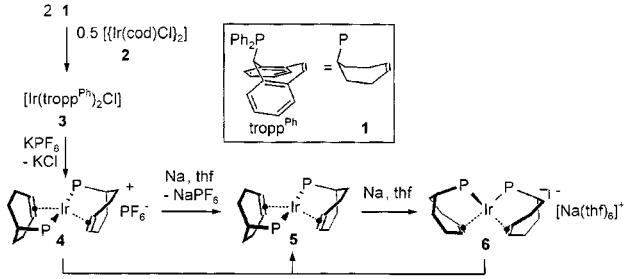
Upon stepwise reduction of a square planar d^8-metal complex, electrons are filled into metal–ligand antibonding orbitals, which eventually will lead to structural distortion towards a tetrahedron.[1] Qualitative MO-arguments indicate, that strong σ-donors will induce a preference for a tetrahedral structure while π-acceptor ligands may give rise to a more square planar structure. In line with these predictions pioneering electrochemical and EPR studies by Pilloni *et al.*[2] and Orsini and Geiger[3] showed that while d^9-[Rh(cod)$_2$] and d^9-[Rh{P(OR)$_3$}$_4$] probably have almost planar structures, [Rh(PPh$_3$)$_4$] is likely to have a tetrahedral co-ordination.

Using the new ligand (dibenzo[*a*,*d*]cycloheptene-5-yl)diphenylphosphine **1** (dibenzo*trop*ylidenyl *p*hosphine = tropp^{Ph}, the superscript indicates substituents bonded to phosphorus),[4,5] we were able to isolate a series of stable mononuclear [Ir(tropp^{Ph})$_2$] complexes were the metal centre formally adopts a d^8, d^9, and d^{10} valence electron configuration.

Thus, we prepared the lemon yellow pentacoordinated chloro iridium complex [Ir(tropp^{Ph})$_2$Cl] **3** and the orange–red tetracoordinated complex [Ir(tropp^{Ph})$_2$]$^+$ PF$_6^-$ **4** using standard synthetic methods as shown in Scheme 1. Both the neutral complex **3** and the cationic species **4** are easily reduced by lithium or sodium metal in thf to give the deep green paramagnetic iridium(0) complex **5** (μ_{eff} = 1.7 μ_B). Further reduction with sodium metal leads to the diamagnetic burgundy red iridate complex [Na(thf)$_6$]$^+$ [Ir(tropp^{Ph})$_2$]$^-$ **6**. A comproportionation reaction between **6** and **4** is the preferred synthetic method for radical **5**, which is isolated in almost quantitative yield because of its low solubility.†

X-Ray structural studies‡ for **4**, **5** and **6** show structural changes caused by the stepwise addition of two electrons without changing either the number or the coordination mode of the metal bound ligands.[6]

The structures of the d^8-Ir cation **4** and that of d^9-**5** are remarkably similar and are superimposed in Fig. 1. In both compounds two phosphorus centres of each tropp^{Ph} ligand are coordinated in *trans*-positions at the iridium centre. The Ir–P and Ir–C distances (see Table 1) lie within the expected range.



Scheme 1

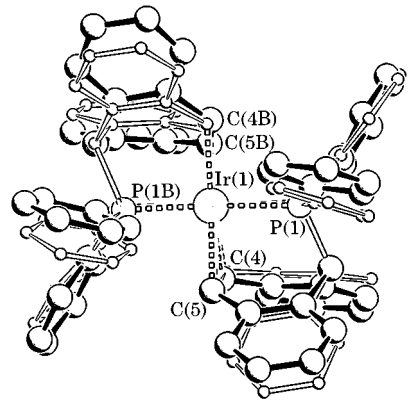


Fig. 1 Overlaid molecular structures of cation **4** (filled lines) and radical **5** (unfilled lines). Selected bond lengths and angles are given in Table 1.

Table 1 Selected bond lengths (Å), bond angles (°) and interplane angles φ (°) of **4**, **5** and **6**

	Ir–P	Ir–C4/C4A	Ir–C5/C5A	C4/C4A–C5/5A	α/°	β/°	φ
4	2.308(3)	2.18(1)	2.19(1)	1.42(2)	169.7(1)	143.5(5)	38.0
5	2.272(3)	2.21(1)	2.15(1)	1.46(2)	165.5(1)	149.4(5)	33.8
6	2.241(1)	2.171(6)	2.127(6)	1.472(9)	98.5(7)	101.0(4)	50.6

The iridium centres deviate significantly from square planar arrangements even in the cation for which planar coordination is expected.[7] Also, the P–Ir–P angles α [**4**: 169.7(1)°; **5**: 165.5(1)°] and (•)–Ir–P angles β [**4**: 143.5(5)°; **5**: 149.5(5)°; (•) = midpoint of the coordinated C=C unit] deviate significantly from 180°. Furthermore, the interplane angles φ (**4**: 38°; **5**: 34°) between the intersections of the P–M–(•) planes show this distortion. A plot of the structure of the iridate anion of [Na(thf)$_6$]$^+$ [Ir(tropp^{Ph})$_2$]$^-$ **6** is shown in Fig. 2.

Both phosphorus centres now occupy mutually *cis*-positions in the distorted coordination sphere which remains intermediate

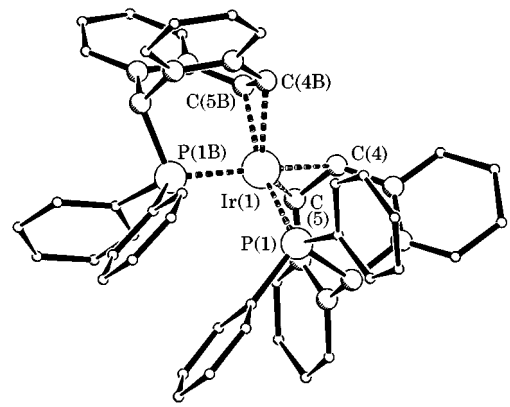

Fig. 2 Molecular structure of the anion of **6.** Selected bond lengths and angles are given in Table 1.

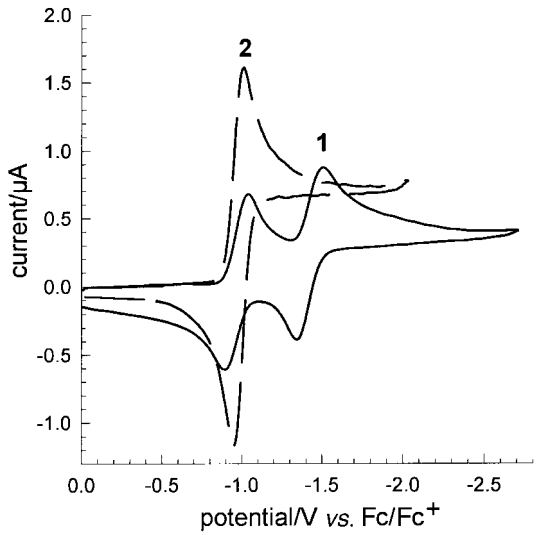

Fig. 3 Cyclic voltammogram of **4** in th–$Bu^n_4NPF_6$ electrolyte (trace 1) or MeCN–$Bu^n_4NPF_6$ electrolyte (trace 2); 298 K, 100 mV s^{-1}; Pt working electrode (0.785 mm^2/ Pt counter electrode/ Ag reference electrode, ferrocene as internal standard for calibration (+0.352 V *vs*. Ag/AgCl).

between a square plane and a tetrahedron (φ = 50.6°). Selected structural data are also listed in Table 1. The Ir–P and Ir–C bond distances do not show significant changes with the formal metal oxidation state in $[Ir(tropp^{Ph})_2]^{+1/0/-1}$ complexes. A slight lengthening of the co-ordinated C=C bond [C4–C5 1.42(2) Å in **4** *vs*. 1.472(9) Å in **6**] indicates increasing metal to ligand d–p(π)-back-donation. Hence, the only significant change is found in the interplane angle φ which changes by about 15° towards a more tetrahedral structure when d^8-**4** and d^9-**5** ($\varphi \approx 36°$) are transformed into d^{10}-**6** ($\varphi \approx 51°$). Note that both centro-symmetric planar structures (φ = 0°) or tetrahedral structures (φ = 84°) are found in $[M(tropp^{Ph})_2]^n$ complexes for M = Rh, n = +1, or Co, n = 0, respectively.[5,8] Hence, the structural features of the iridium complexes described in this work are not merely caused by steric requirements of the ligand. The Ir^{+1}/Ir^0 and Ir^0/Ir^{-1} redox couples are shifted to remarkably low potentials. The cyclic voltammogram of **4** in a $Bu^n_4NPF_6$–THF (trace 1) and $Bu^n_4NPF_6$–MeCN electrolyte (trace 2) is shown in Fig. 3.

While in thf the Ir^{+I}/Ir^0 and Ir^0/Ir^{-I} redox couples ($E^1_{\frac{1}{2}}$ = −0.97 V, ΔE = 149 mV; $E^2_{\frac{1}{2}}$ = −1.426 V; ΔE = 165 mV) appear separately, proving an overall stepwise EE mechanism, a further cathodic shift of the second wave is observed in MeCN leading to only one two-electron wave at $E^{1,2}_{\frac{1}{2}}$ = −0.982 V (ΔE = 91.4 mV).[9] It will be now interesting to study the application of tropp type complexes in electrocatalytic cycles running over four formal oxidation states at the metal centre (*i.e.* Ir^{+III}–Ir^{-I}).

Bond energy of complexes of neon with aromatic molecules: rotational spectrum and dynamics of pyridine–neon

Assimo Maris, Walther Caminati* and Paolo G. Favero

Dipartimento di Chimica 'G. Ciamician', Università di Bologna, Via Selmi 2, I-40126 Bologna, Italy. E-mail: caminati@unibo.it

Received (in Exeter, UK) 18th September 1998, Accepted 30th October 1998

The equilibrium configuration of the very weakly bonded pyridine···Ne complex has been deduced from its free jet millimeter-wave spectrum; the three van der Waals motions have approximated fundamentals in the range 19–31 cm^{-1} and the dissociation energy has been estimated to be 1.1 kJ mol^{-1}.

At very low pressures and temperatures, conditions similar to those of interstellar space, rare gases (RG) form stable adducts with various molecules.[1] It can be questionable if these processes are real chemistry, but we will see that the difference with respect to 'normal' chemistry is quantitative rather than qualitative. The combination of supersonic expansion with spectroscopic techniques[2] has allowed an extensive investigation of the chemistry of these adducts.

Jet cooled rotationally resolved spectra supply the most detailed information on the dynamics (and thus on the binding energy) of the van der Waals motions: the measured distortion from a rigid rotor behaviour is in fact mainly due to the van der Waals vibrations (see for example refs. 3–6).

Taking into account the van der Waals complexes between a RG atom and an aromatic ring molecule investigated with such techniques, about twenty complexes involve an Ar atom while only one (benzene–Ne[7]) involves a Ne atom.[1] This is likely to be due to the lower interaction energy of Ne.

Most of these studies have generally been performed with pulsed molecular beam microwave Fourier transform, as for example benzene–RG[7,8] (RG = Ne, Ar, Kr, Xe) and pyridine–RG[9,10] (RG = Ar, Kr). Recently a direct absorption technique, free jet millimeter-wave absorption spectroscopy, has also been applied to the investigation of such complexes, as, for example, pyrimidine–Ar[6] and pyridazine–Ar.[11]

Here we report the rotational spectrum of pyridine–neon (PYR-Ne), investigated with the latter technique. Fig. 1 shows PYR–Ne, PYR, the switching of the principal axes upon formation of the adduct, and the van der Waals structural parameters.

The Stark and pulse modulated free jet absorption millimeter-wave spectrometer used in this study has already been described elsewhere.[12] The complex was formed by flowing neon at a pressure of *ca.* 1.5 bar over the sample at room temperature, and expanding the mixture through a pulsed nozzle (repetition rate 5 Hz) with a diameter of 0.35 mm, reaching an estimated 'rotational' temperature of *ca.* 7–8 K. Neon (99.995%) was supplied by Linde, and pyridine by Aldrich. The accuracy of the frequency measurements is about 0.05 MHz.

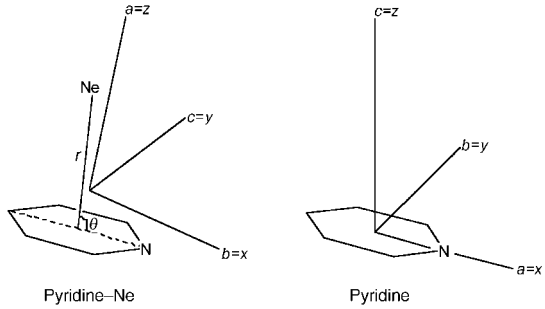

Fig. 1 Geometry and principal axes system in PYR···Ne and PYR.

The first estimate of the rotational constants of PYR–Ne has been based on a model similar to that of Fig. 1, with Ne positioned 3.4 Å above the PYR plane, along the perpendicular to the center of mass (c.m.), and with the r_0 geometry of PYR as in the isolated molecule.[13] The spectrum has been assigned and the 43 measured transitions (available upon the authors) have been fitted with Watson's 'S' reduced Hamiltonian (I^r representation).[14] Quartic and sextic centrifugal distortion parameters where required to fit the spectrum, in accord with the large amplitude inherent in the Ne motions. Only μ_b-type transitions have been observed. Owing to the low value of the μ_a-dipole component and to the high J values involved, μ_a-type transitions were too much weak to be detected with our spectrometer. Table 1 collects the determined parameters.

The three translational motions of the isolated Ne are replaced by three low energy vibrational modes upon formation of the complex. Because of the low energy and large amplitude of these van der Waals motions, which bring Coriolis coupling contributes to the moments of inertia, usual methods for structure determination supply poor results. Here we will apply a method which takes into account these effects. One of the van der Waals motions can be considered the stretching between the two centers of mass of the two constituent molecules, while the remaining ones can be thought of as two internal rotations of Ne around PYR.

The stretching (radial part of the Ne motions) can be, in a first approximation, isolated from the other motions. For asymmetric top complexes in which the stretching coordinate is near-parallel to the inertial a-axis the stretching force constant (k_s) can be estimated by approximating the complex to a molecule made of two rigid parts, by using equations of the type:[3]

$$k_s = 16\,\pi^4\,(\mu_D\,R_{CM})^2\,[4B_D^4 + 4C_D^4 - (B_D - C_D)^2(B_D + C_D)^2]/(hD_J) \qquad (1)$$

The subscript D denotes a dimer quantity, μ_D is the pseudo diatomic reduced mass, R_{CM} is the distance between the centers of mass of the monomers (3.386 Å for PYR–Ne), and D_J is the centrifugal distortion constant. k_s, the corresponding harmonic stretching fundamental (ν_s), the dissociation energy (E_B) and the equilibrium distance of Ne (r_e) from the center of mass of PRM are reported in Table 2, and compared to the correspond-

ν_X/cm^{-1}	19.6	34.1	E_B/cm^{-1}	90	259

[a] From ref. 4. [b] The equilibrium position of the noble gas is shifted in the direction from the center of mass of the ring towards the nitrogen atom, forming an angle ϕ_e (= 90 − θ of Fig. 1) with the perpendicular to the ring.

ing values for the related complex PYR–Ar.[4] E_B and r_e have been adjusted within a Lennard-Jones type potential in such a way to reproduce ν_s and $(B + C)_0$. A one-dimensional flexible model[15] has been used to calculate rotational and vibrational energy levels. Fig. 2 shows the Lennard-Jones potential energy curves for PYR–Ne and PYR–Ar.

As to the two Ne internal rotations their effects are reflected either in the anomalous high values of the Δ_{JK} and Δ_K centrifugal distortion parameters, as outlined in several of the complexes of aromatic molecules with rare gases (see, *e.g.* refs. 4, 5, 11), and in the negative changes of the planar moments of inertia M_{xx} and M_{yy} (Fig. 1) in going from isolated PYR to PYR–Ne. The procedure to extract the bends van der Waals potential energy parameters from centrifugal distortion is rather complex for low symmetry complexes as PYR–Ne. For this reason we extracted this information for the C_s symmetry PYR–Ne complex from the ΔM_{xx} and ΔM_{yy} values of Table 3. The planar moments of inertia are defined and related to the rotational constants through eqn (2):

$$M_{aa} = \Sigma_i m_i a_i^2 = h/(16\pi^2)\,(-1/A + 1/B + 1/C),\ etc. \quad (2)$$

They represent the mass extension along the principal axes. Their shifts on going from the isolated molecule to the complex (Fig. 1) are shown in Table 3 for the PYR/PYR–Ne and PYR/PYR–Ar systems. Owing to the axis switching upon formation of the complexes the more consistent quantities ΔM_{xx}, ΔM_{yy} and ΔM_{zz} (Fig. 1) are reported there. The smaller value of ΔM_{zz} for PYR–Ne is in accord with the fact that Ne is lighter than Ar, and closer to the ring center of mass. By contrast, it is difficult, at first sight, to understand the negative value of ΔM_{yy}, and why this value for PYR–Ne is more negative than that of PYR–Ar. A rather simple interpretation of this effect has been given for pyrimidine–Ar,[6] in terms of mass dispersion and vibrational Coriolis couplings associated with the two bendings. The two motions are considered local harmonic oscillations on one side of the ring, by a model that describes the A′ type mode in the *xz* plane by the displacement *X* and the A″ type displacement in the *y* direction by *Y*:

$$V(X,Y) = (1/2)\,[k_x\,(X - X_e)^2 + k_y Y^2] \quad (3)$$

where X_e is the displacement, within the symmetry plane, of the neon atom from the *z* axis at equilibrium. The calculations were

	PYR→PYR–Ne	PYR→PYR–Ar[a]
ΔM_{xx}	−1.838	−1.081
ΔM_{yy}	−1.123	−0.697
ΔM_{zz}	186.775	335.404

[a] From data of refs. 12 and 13.

made by using the two-dimensional version of the above mentioned flexible model,[15] resolving the range (−2.0 Å, +2.0 Å) into 21 mesh points for each of the *X* and *Y* displacements. X_e, k_x, and k_y have been adjusted in order to reproduce ΔM_{xx} and ΔM_{yy}. Since the two pieces of data do not allow one to estimate more than two of the three parameters, we assumed $k_x = k_y$, a condition nearly fulfilled for this kind of complexes.[4] The results are shown in Table 2. Although $X_e = \pm 0.245$ Å was obtained, a comparison with other complexes[4,6] suggests the minus rather than the plus sign and yields $X_e = -0.245$ Å, which means that the vertical on the ring plane passing through the equilibrium position of the neon atom, at 3.316 Å above the ring plane, is tilted by about 4.2° from the center of mass of the ring towards the nitrogen atom. The 'equilibrium' values discussed above refer to the limit situation without van der Waals vibrations, but with half a quantum of each ring vibrations. Despite the fact that Ne is much lighter than Ar, the bend vibrational fundamental frequencies of 19.6 and 19.9 cm^{-1}, are considerably lower than the values of 34.1 and 34.5 cm^{-1} for PYR–Ar,[4] indicating that PYR–Ne is much floppier than PYR–Ar (see Table 2 for a comprehensive comparison).

As a conclusion we can remark that Ne has a binding energy to aromatic molecules which is about 1/3 of that of Ar, and about two–three orders of magnitude smaller of that of normal chemical bonds.

We thank Mr A. Millemaggi for technical help, and the Ministero dell'Università e della Ricerca Scientifica e Tecnologica, and the CNR for financial support.

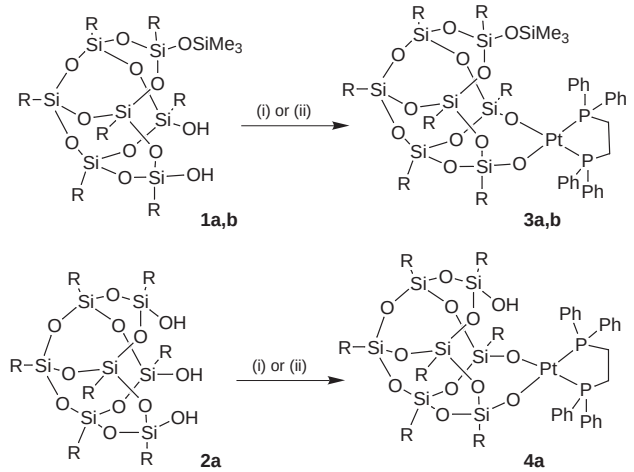
Received (in Cambridge, UK) 19th October 1998

The reaction of partially condensed silasesquioxanes of the type $[R^1{}_7Si_7O_9(OH)_2(OR^2)]$ (R^1 = *c*-C_5H_9, *c*-C_6H_{11}; R^2 = H, $SiMe_3$) with either $[Pt(dppe)(CO_3)]$ or $[Pt(dppe)Cl_2]/Ag_2O$ leads to the formation of $[R^1{}_7Si_7O_9(OR^2)O_2Pt(dppe)]$, crystallographically characterised for R^1 = *c*-C_5H_9; R^2 = $SiMe_3$, providing unprecedented routes to late transition metal silasesquioxane complexes.

Currently, metallasilasesquioxanes are considered as the best soluble models for silica-supported transition metal species and an increasing number of examples of *early* transition metal compounds based on these ligands is being reported.[1] In contrast, metallasilasesquioxanes involving *late* transition metals are considerably rarer, and to date no such examples of mononuclear platinum group complexes have been characterised crystallographically. Transmetallation reactions have briefly been reported to give platinum silasesquioxane complexes,[1] though no experimental details were published and the reported transmetallations suffer from requiring the use of thallium or tetraalkylstibonium intermediates. Here we detail two simple routes to platinum silasesquioxane complexes and present the first example of an X-ray single crystal structure of a mononuclear platinum metal silasesquioxane complex.

Platinum silasesquioxane complexes can be conveniently prepared (Scheme 1) by utilising the reactivity of the acidic silasesquioxane silanol groups[2] with the carbonate functionality in $[Pt(dppe)(CO_3)]$ [dppe = bis(diphenylphosphino)ethane].[3] In all cases the reactions are slow with full conversion only occurring after several days, but yields are good with no by-products observed.† $^{31}P\{^1H\}$ NMR spectroscopy provides a useful method for following the reactions, and resonances for the silasesquioxane derivatives **3** and **4** occur in all cases upfield and with larger ^1J(PPt) coupling constants than for $[Pt(dppe)(CO_3)]$.‡ Both chemical shifts and ^1J(PPt) coupling constants for **3** and **4** fall within a narrow range [δ between 26 and 28, referenced to external 85% phosphoric acid, and ^1J(PPt) between 3730 and 3780 Hz]. The chemical shifts are similar to those reported previously for $[Pt(dppe)(OSiMe_3)_2]$ [δ 27.1, ^1J(PPt) 3595][4] and $[Pt(dppe)(OMe)_2]$ [δ 28.5, ^1J(PPt) 3342][5] though the coupling constant is somewhat larger, reflecting the lower *trans* influence of the silasesquioxane. The reactivity of $[Pt(dppe)(CO_3)]$ is in marked contrast to that of $[Pt(PPh_3)_2(CO_3)]$, for which no reaction with **1** was observed after several days. A similar pattern was observed in the reaction of these platinum carbonates with ethane-1,2-diol, for which the equilibrium constant was approximately 27 times greater for $[Pt(dppe)(CO_3)]$ than for $[Pt(PPh_3)_2(CO_3)]$.[6]



Scheme 1 (i) $[Pt(dppe)CO_3)]$, CH_2Cl_2; (ii) $[Pt(dppe)Cl_2]$, Ag_2O, CH_2Cl_2, Δ (**a**, R = *c*-C_5H_9; **b**, R = *c*-C_6H_{11}).

A second useful preparative route utilises the reaction of the silasesquioxane silanol groups with the chlorides on $[Pt(dppe)Cl_2]$ in refluxing dichloromethane in the presence of the base silver(I) oxide.[7] Again the reaction is slow, though more general than the carbonate route as it allows $PMePh_2$ analogues of **3** and **4** to be prepared.

Single crystals of complex **3a** were grown from the slow diffusion of acetonitrile into a toluene solution, and the molecular structure is shown in Fig. 1.§ The co-ordination geometry around the platinum centre is distorted square planar,

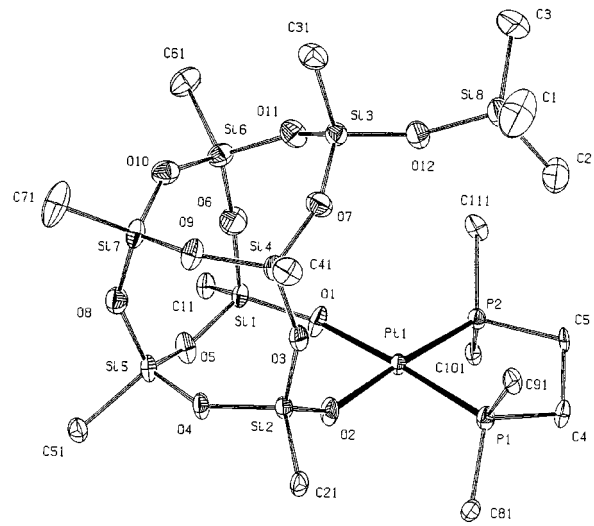


Fig. 1 Perspective ORTEP plot of **3a**. For clarity, thermal ellipsoids are shown at 50% probability; no H and only C attached to Si and P are shown. Selected interatomic distances (Å) and interbond angles (°) are: Pt–O(1) 2.031(6), Pt–O(2) 2.036(4), Pt–P(1) 2.195(2), Pt–P(2) 2.204(2), Si(1)–O(1) 1.573(6), Si(2)–O(2) 1.566(6), other Si–O 1.597(7)–1.647(7), O(1)–Pt–O(2) 90.3(2), O(2)–Pt–P(1) 90.2(2), P(1)–Pt–P(2) 86.90(8), P(2)–Pt–O(1) 92.5(2), Pt–O(1)–Si(1) 146.2(4), Pt–O(2)–Si(2) 148.3(4), Si(3)–O(12)–Si(8) 152.8(5), other Si–O–Si 140–170.

with *cis* angles ranging from 86.9 to 92.5°. The Pt–O and Pt–P distances compare well with those found in the isoelectronic compound [Pt(dppe)$(OCH_3)_2$] [Pt–P = 2.222(3), 2.228(3) Å, Pt–O = 2.037(7), 2.041(7) Å][5] with the slight shortening of the Pt–P bonds in complex **3a** with respect to [Pt(dppe)$(OCH_3)_2$] again consistent with the lower *trans* influence of the silasesquioxane. The Si–O distances in the platinum siloxy functions [Si(1)–O(1) = 1.573(6) Å; Si(2)–O(2) = 1.566(6) Å] are significantly shorter than those present in the silasesquioxane skeleton [1.597–1.647 Å; typical 1.63 Å], while in the silasesquioxane silanol **1a**, these distances are 1.619(7) and 1.616(7) Å (*vide infra*). This bond shortening may be ascribed to the absence of electron donation of the oxygen lone pairs to the electron rich platinum centre which will lead to a stronger Si–O bond by enhanced electron donation to silicon; this effect is absent or the reverse in high oxidation state early transition metal silasesquioxanes.[8]

In order to make a better evaluation of the structural features of the silasesquioxane unit present in **3a**, we determined the molecular structure of the silasesquioxane disilanol **1a** (Fig. 2); single crystals were prepared by allowing acetonitrile to diffuse slowly into a toluene solution of **1a**.§ This disilanol was found to be a monomeric compound that crystallises into two distinct isomers that differ mainly by the orientations of the, highly disordered, cyclopentyl units. Although the quality of the structure determination is poor ($R1$ = 0.1423), the conformation of the Si/O skeleton of **1a** can be discussed with regard to that present in **3a**. Such a comparison reveals that the Si/O skeletons of both compounds are remarkably similar. For instance, the intramolecular distance of the ligating oxygen atoms O(1) and O(2) in **3a** is 2.88(1) Å *versus* 2.67(1) Å in **1a**, while the intramolecular distance Si(1)–Si(3) in **3a**, which can be considered as a measure for the binding cavity, of 5.22(1) Å is virtually equal to that of 5.21(1) Å measured in **1a**. As a result, one might conclude that the silasesquioxane diol is ideally preorganised for co-ordination to a Pt(II) centre following deprotonation.

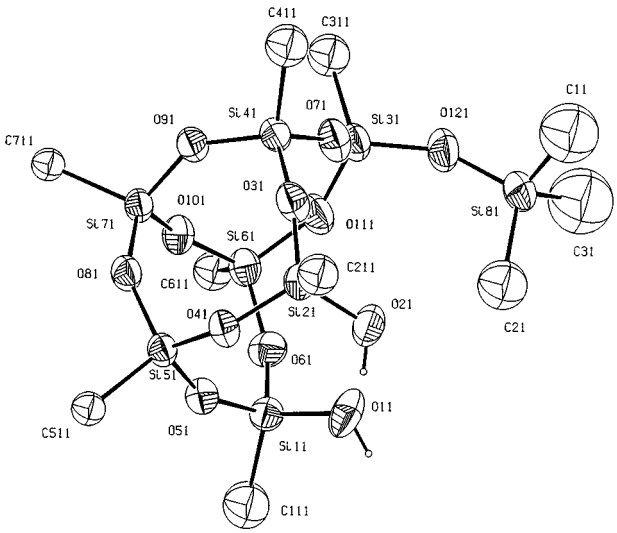

Fig. 2 Perspective ORTEP plot of one of the independent molecules of **1a**. For clarity, thermal ellipsoids are shown at 50% probability; no H and only C attached to Si are shown. Selected interatomic distances (Å) and interbond angles (°) are: Si(11)–O(11) 1.650(8), Si(21)–O(21) 1.619(8), other Si–O 1.579(10)–1.650(8), Si–O–Si 149–156.

We are currently investigating the reactivity of the hydroxyl group in **4** and those of the known silasesquioxane tetrasilanol (c-$C_7H_{13})_6Si_6O_7(OH)_4$[9] with a view to preparing bimetallic metallasilasesquioxanes.

L.) by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organisation for Scientific Research (NWO). The British Council and NWO are thanked for financial support to HCLA and ADB (Grant JRP313).

Notes and references

† A typical preparation (**3a**): Silasesquioxane **1a** (294 mg, 0.304 mmol) was added to a solution of [Pt(dppe)(CO_3)] (200 mg, 0.306 mmol) in dichloromethane (20 cm^3) and the mixture stirred at room temperature (typically 7 days). The solvent was removed under reduced pressure, the crude solid washed with acetonitrile, and recrystallised from toluene–acetonitrile to give colourless crystals of **3a** (90% yield). (Anal. Found: C, 49.8; H, 6.25%; $C_{62}H_{96}Si_8O_{12}P_2Pt$ requires C, 49.8; H, 6.41%). Silasesquioxane silanols **1b** and **2a** were prepared according to ref. 2 and 9, respectively. The new silasesquioxane **1a** was prepared by an identical method as reported for **1b** starting from 17.0 g of **2a**, 25 mL of Et_3N and 2.20 mL of Me_3SiCl to give 13.6 g (75%) of **1a;** ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C) δ 4.22 (s, 2H, SiOH), 1.76–1.48 (m, 56H, C_5H_9), 1.49 (m, 7H, C_5H_9), 0.16 (s, 9H, $SiMe_3$). ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C) δ 27.6–27.0 (CH_2), 23.7, 22.7, 22.4, 22.3, 22.1 (1 : 2 : 2 : 1 : 1 for CH), 1.7 ($SiMe_3$).

Synthesis of alkenyl-substituted cyclic enol ethers by catalytic ring-closing metathesis of alkynyl ethers

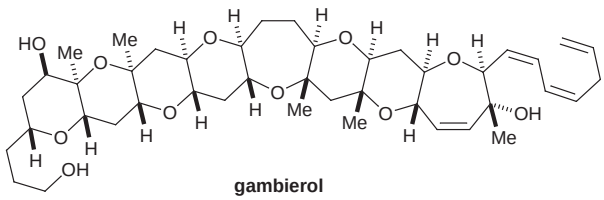
J. Stephen Clark,*[a] Graham P. Trevitt,[a] Dean Boyall[a] and Blanda Stammen[b]

[a] *School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: j.s.clark@nottingham.ac.uk*
[b] *Discovery Chemistry, Pfizer Central Research, Sandwich, Kent, UK CT13 9NJ*

Received (in Cambridge, UK) 2nd October 1998, Accepted 28th October 1998

Ring-closing enyne metathesis can be used to prepare alkenyl-substituted six- and seven-membered cyclic enol ethers in moderate to good yield.

Over the past two decades, fused polycyclic ether natural products, such as the brevetoxins and the ciguatoxins,[1] have attracted considerable attention because of their fascinating structures and potent biological activities.[2] Many of the natural products of this type possess arrays of *trans*-fused six- and seven-membered cyclic ethers, as exemplified by gambierol.[3]



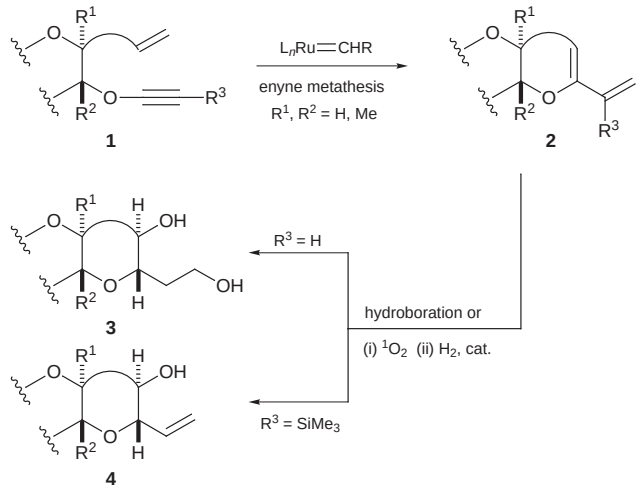
gambierol

Recently, we[4] and others[5] have found that ring-closing metathesis reactions offer a powerful and general approach to the synthesis of cyclic ether sub-units found in the brevetoxins and ciguatoxins. We have demonstrated that the sequence of ring-closing metathesis[6] and hydroboration can be used to prepare six- and seven-membered cyclic ethers[4a] and that ring-closing metathesis of allylic ethers[4b] can be used to prepare eight- and nine-membered cyclic ethers in excellent yield.

In connection with our continuing studies directed towards the synthesis of the brevetoxins and the ciguatoxins, we became interested in exploiting ring-closing enyne metathesis reactions to complement the enol ether and allylic ether ring-closing metathesis reactions that we have already developed.[4] Our interest in the use of ring-closing enyne metathesis reactions was stimulated by recent promising reports from the groups of Murai,[7] Mori,[8] and Barrett and Gibson[9] who have described the preparation of carbocycles and nitrogen heterocycles using ruthenium-catalysed enyne metathesis reactions.

The general strategy for the preparation of sub-units of the brevetoxins and ciguatoxins using a ring-closing enyne metathesis reaction is shown in Scheme 1. We envisaged subjecting a suitably functionalised alkynyl ether **1** to a ruthenium-catalysed ring-closing metathesis reaction to obtain the alkenyl-substituted enol ether **2**. Elaboration of this product (R^3 = H) by hydroboration or by reaction with $^1O_2$ and hydrogenation of the resulting cyclic peroxide,[10] would provide the diol **3**. Application of the same reactions to the vinylsilane-substituted cyclic enol ether **2** (R^3 = SiR_3) would afford the vinyl-substituted cyclic ether **4** by Peterson elimination of the resulting β-hydroxy silane.[11] The pendant vinyl group of this compound would then provide scope for construction of an additional cyclic ether by a subsequent ring-closing metathesis reaction.

We wanted to ascertain whether alkynyl ethers would undergo reaction with the Grubbs catalyst, $Cl_2Ru(PCy_3)_2$-CHPh,[12] in contrast to enol ethers, which were unreactive to this catalyst or the metal alkylidenes generated from it. We also wanted to determine whether terminal alkynyl ethers would



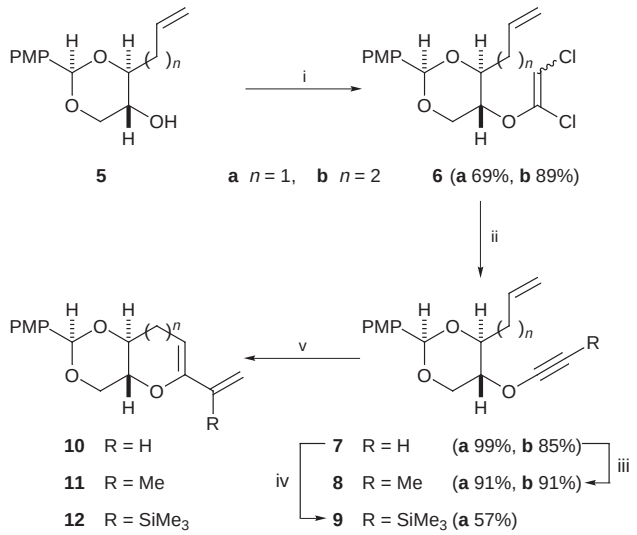
Scheme 1

undergo efficient ring-closing metathesis because there was evidence to suggest that terminal alkynes are not generally good substrates for this reaction.[8,9]

The alkynyl ethers required for our study were prepared from the alcohols **5a** and **5b**, which are readily available from (*R*)-2,3-*O*-isopropylideneglyceraldehyde (Scheme 2).[4b,13] The cyclisation substrates **7a** and **7b** were prepared by an adaptation of Greene's method for the synthesis of alkynyl ethers.[14] This method involves deprotonation of an alcohol with KH and reaction of the resulting alkoxide with Cl_2C=CHCl to give a mixture of dichloro enol ethers that are then converted to the required alkynyl ether by treatment with *n*-butyllithium.[14] Greene has demonstrated that this sequence of reactions can be performed in a one-pot fashion without isolation and purification of the intermediate dichloro enol ethers, and that it can be used to convert hindered secondary alcohols into alkynyl ethers.

Initially, we used Greene's one-pot procedure to convert the alcohols **5a** and **5b** to the required alkynyl ethers **7a** and **7b**. However, only modest yields of the products were obtained, so we opted to isolate the dichloro enol ethers produced upon reaction of Cl_2C=CH_2 with the sodium alkoxides generated from the alcohols **5a** and **5b**. Enol ether formation proceeded in reasonable yield and the products **6a** and **6b** were isolated as stable crystalline solids. Treatment of these dichloro enol ethers with *n*-butyllithium provided the alkynyl ethers **7a** and **7b** in very high yield. The yields over two steps, including isolation of the intermediate dichloro enol ethers, were only marginally lower those obtained by Greene when he used his one-pot procedure for the preparation of related systems.[14]

Having prepared the ethers **7a** and **7b**, we then obtained the other substrates of interest by alkylation of these terminal alkynes. Thus, the substrates **8a** and **8b** were prepared by deprotonation of the alkynyl ethers **7a** and **7b** followed treatment with methyl iodide, and the silyl-substituted alkynyl



Scheme 2 *Reagents and conditions*: i, NaH, THF, rt, then $CHClCCl_2$ (3 equiv.), −50 °C→rt; ii, *n*-BuLi, Et_2O, −78 °C→rt; iii, *n*-BuLi, DMPU, −78 °C, Et_2O, then MeI, −10 °C→rt; iv, *n*-BuLi, Me_3SiCl, Et_2O, −78 °C→rt; v, $Cl_2Ru(PCy_3)_2CHPh$ (10 mol%), CH_2CH_2 (10 min), CH_2Cl_2, rt or reflux, 4 h or 14 h.

ether **9a** was prepared by deprotonation of the alkyne **7a** and reaction of the resulting anion with trimethylsilyl chloride.

The ring-closing metathesis reactions of the alkynyl ethers **7**–**9** were explored (Scheme 2). Treatment of each substrate with the Grubbs catalyst, $Cl_2Ru(PCy_3)_2CHPh$,[12] in CH_2Cl_2 at reflux led to successful ring-closing metathesis and afforded the alkenyl-substituted cyclic enol ethers **10**–**12** (Table 1).† The highest yields for the ring-closing enyne metathesis reaction were obtained upon cyclisation of the alkynyl ethers **7a** and **8a** to give the six-membered cyclic enol ethers **10a** and **11a**. Interestingly, the terminal alkynyl ether **7a** underwent efficient cyclisation, although a higher yield was obtained upon reaction of the substrate **8a**, containing a non-terminal alkyne. The silyl-substituted alkynyl ether **9a** also underwent cyclisation, but in low yield; it is likely that the poor yield for this reaction can be attributed to the steric bulk of trimethylsilyl substituent.[8a]

The ring-closing enyne metathesis reactions to produce seven-membered cyclic enol ethers proved to be less successful than those to produce the alkenyl-substituted dihydropyrans. The reactions were slow, and prolonged reaction times were required for complete reaction. There was little difference between the yield obtained upon cyclisation of the terminal alkynyl ether **7b** to give the diene **10b** and that obtained upon cyclisation of the methyl-substituted substrate **8b** to give the diene **11b**.

In all the enyne metathesis reactions, the ruthenium catalyst was 'pre-activated' by the passage of ethene through the solution of the catalyst prior to addition of the substrate, and reactions were then performed under an atmosphere of ethene. Inferior yields were obtained upon cyclisation of the substrates **7b** and **8b** when the reactions were performed in the absence of ethene.

Table 1 Results of ring-closing enyne metathesis reactions of the alkynyl ethers **7**–**9** catalysed by $Cl_2Ru(PCy_3)_2CHPh$ (10 mol%)

Substrate	Reaction time/h	Product	Yield (%)[a]
7a	4[b]	**10a**	65
7b	14[c]	**10b**	33
8a	4[b]	**11a**	77
8b	14[c]	**11b**	27
9a	4[b]	**12a**	20

[a] Yield of isolated product after chromatography on silica gel. [b] Reaction performed in CH_2Cl_2 at reflux. [c] Reaction performed in CH_2Cl_2 at room temperature.

Our results show that ring-closing metathesis of alkynyl ethers can be used to prepare alkenyl-substituted cyclic enol ethers. Although the yields of seven-membered cyclic enol ethers were low, we have demonstrated that the reaction is a synthetically viable one for the preparation of alkenyl dihydropyrans in good yield. We have also shown that the Grubbs catalyst, $Cl_2Ru(PCy_3)_2CHPh$,[12] can be used for ring-closing enyne metathesis of alkynyl ethers, which contrasts with the lack of reactivity exhibited by this catalyst towards related enol ethers.[4a,15]

The cyclic ethers **10a** and **10b** are potentially useful enantiomerically pure chiral building-blocks for the synthesis of sub-units of the brevetoxins and ciguatoxins. The elaboration of these compounds (*e.g.* **2**→**3**) is currently under investigation, and the results of these studies will be reported in due course.

We thank the Engineering and Physical Sciences Research Council for the award of a CASE Studentship (to D. B.) and the University of Nottingham for financial support.

Notes and references

† Typical procedure for the ring-closing enyne metathesis of the substrates **7**–**9**: The catalyst, $Cl_2Ru(PCy_3)_2CHPh$ (38 mg, 0.045 mmol, 10 mol%), was dissolved in dry CH_2Cl_2 (60 mL) and a stream of ethene passed through the solution for 10 min (the solution turned from purple to orange in colour). A solution of the alkyne (0.45 mmol) in dry CH_2Cl_2 (5 mL) was added by cannula to the solution of the catalyst under an atmosphere of ethene at room temperature. The flask was then washed with further CH_2Cl_2 (3 mL) and this was added to the reaction mixture. The mixture was then stirred under a static atmosphere of ethene at reflux (4 h) or room temperature (21 h). On completion of the reaction, the solvent was then removed *in vacuo* and the residual material was purified by flash column chromatography on silica gel (hexane–Et_2O, 4:1 with 1% triethylamine) to afford the product as a colourless solid.

Difluorotoluene, a thymine isostere, does not hydrogen bond after all

Xue Wang and K. N. Houk*

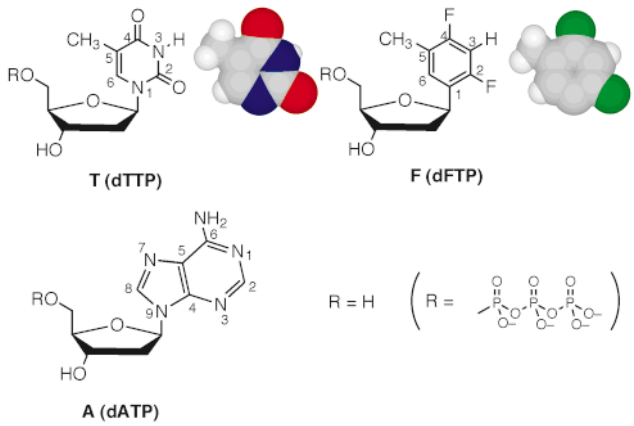
Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095, USA. E-mail: houk@chem.ucla.edu

Received (in Corvallis, OR, USA) 26th June 1998, Revised Manuscript Received 20th October 1998, Accepted 21st October 1998

The lack of significant hydrogen bonding by 2,4-difluorotoluene, an isostere of thymine, is confirmed by *ab initio* calculations and force field modelling of nucleic acids.

Watson–Crick base-pairing is the information code which directs replication, transcription and translation.[1] Base-pairing is produced by hydrogen-bonding which stabilizes the DNA double helical structure.[2] The free energy differences between matched and mismatched base pairs in aqueous solution are estimated to be in the range of 0.2 to 0.4 kcal mol^{-1} for terminal base pairs[3] and 1 to 3 kcal mol^{-1} for internal base pairs.[4] In 1988, Echols and Goodman noted that the energy difference between hydrogen bonding of matched and mismatched terminal pairs is insufficient to account for the remarkably high fidelity of Watson–Crick base pairing in DNA replication by the DNA polymerase (10^4 to 10^5).[5] It was proposed that the geometry of the complex between the template and substrate on DNA polymerase was more important than hydrogen bonding in controlling polymerase fidelity.

In 1994, Kool and co-workers proposed that there is no significant hydrogen bonding between adenine (**A**) and the



thymine (**T**) isostere, **F**.[6] Nevertheless, numerous studies now show that **F** can be readily incorporated in place of **T** by DNA polymerase.[7] In **F**, fluorines replace oxygens, and carbons replace nitrogens. Much evidence has been amassed in accord with the idea. ^{1}H NMR and X-ray data indicated that **F** does not H-bond with natural nucleotides in solution.[8] Single nucleotide insertion and 'running start' experiments demonstrated that **F** expressed similar selectivity to **T** during the replication of a DNA strand in the presence of Klenow fragment (KF) of *Escherichia coli* DNA polymerase.[7] The geometry of the reaction complex, not hydrogen bonding, seems of principal importance in the fidelity of the DNA polymerase.

However, Evans and Seddon proposed that the hydrogen bonding between **A** and **F** still plays an important role in DNA replication even with templates containing **F**.[9] In their communication, *ab initio* RHF/6-31G**, semi-empirical AM1 and PM3 calculations were presented which reveal large dipole moments of the methyl derivative of 2,4-difluorotoluene **1** (1.86 D) in comparison to H_2O (1.82 D). They suggested that the polar nature of 2,4-difluorotoluene is important for hydrogen bonding and hence, DNA replication. They reported the electrostatic potential surfaces of **1** and N^1-methylthymine **2** [Fig. 1(*a*)]. These are clearly similar, suggesting that **F** mimics the shape, the charge distribution and hydrogen-bonding patterns of **T** [Fig. 1(*b*)]. Evans and Seddon supported the 'status quo' concerning the major role of hydrogen-bonding on replication fidelity, even with **F**.

We have reinvestigated these issues with quantum mechanics and molecular mechanics, to test the ability of hydrogen-bonding by **F** and the potential role in base-pairing interactions in DNA.

It is well known that fluorinated olefins and aromatic compounds are poor hydrogen bond acceptors. Fluorine has a greater electronegativity and lower polarizability than oxygen, which renders it a much poorer hydrogen bond acceptor. At the MP2/TZV++(3d,1f,1p) level of theory, vinyl C(sp^2)–F forms hydrogen bonds with water with a strength of only 1.5 kcal mol^{-1}, significantly lower than typical hydrogen bonds of 5 to 10 kcal mol^{-1}.[10] **F** contains two aromatic C(sp^2)–F moieties. The hydrogen bonding strength of **F** with water should be even less.

We recomputed **1** and **2** with semi-empirical PM3, *ab initio* RHF/3-21G and RHF/6-31G** calculations.[11] At the RHF/6-31G** level, the electrostatic charges of fluorines in **1** are both 0.21, and the dipole moment of **1** is 1.90 D. The electrostatic charges of the oxygens in **2** are both 0.61, and the dipole moment of **2** is 4.83 D. The dipole moment of the water molecule has also been calculated using the RHF/6-31G** method for comparison, giving a value of 2.15 D. In spite of the representation displayed in Fig. 1(*a*), the fluorines of **F** and oxygens of **T** have significantly different electrostatic charges. The electrostatic potential range used in the published pictorial representation for **1** is from −19 to +27 electron per atomic unit, while it is from −46 to +51 electron per atomic unit for **2**.

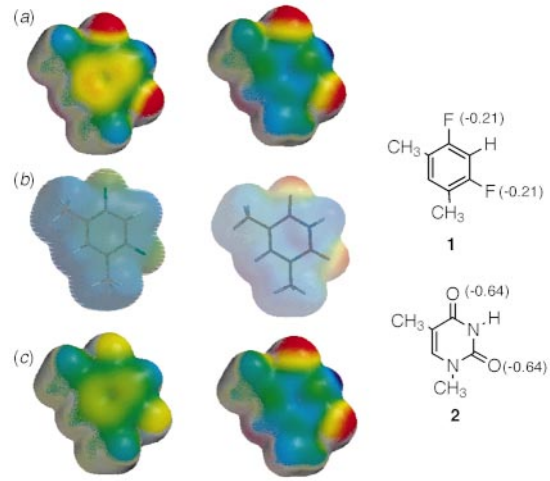


Fig. 1 The electrostatic potential surfaces of **1** and **2**: (*a*) as presented in ref. 9 [the range of electrostatic potential shown in thymine is from red (−46.0) to blue (+50.5) and in difluorotoluene is from red (−19.0) to blue (+27.3); the units are electrons per atomic unit), (*b*) PM3 model and (*c*) RHF/6-31G** model [both (*b*) and (*c*) using the same potential range (−46.1 to +50.5 from red to blue for RHF) for both structures from our calculations; the units are electrons per atomic unit and charges are given in parenthesis].

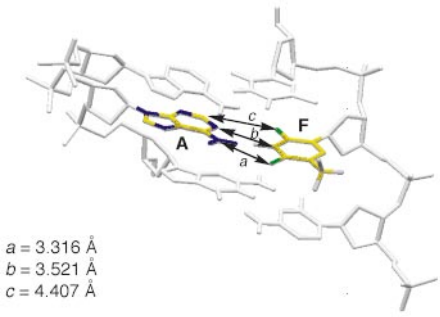

Fig. 2 Molecular modelling shows no obvious hydrogen bonding of **F** with **A**.

Because of this, the color pictures in Fig. 1(*a*) provide the incorrect impression that the electrostatic potentials are very similar. When plotted on the same color scale [Fig. 1(*b*),(*c*)], it is obvious that the electrostatic potential range of **1** is much more limited than that of **2**. Hydrogen bonds involving **F** will be very weak, perhaps impossible to detect in solution. Indeed, this is the conclusion of Kool *et al*. based upon experimental data.[8] The dipole moment of **1** is also significantly smaller than **2**, even smaller than H_2O. Since replication experiments are performed in aqueous solution, DNA strands are solvated. Hydrogen bonding between **F** and **A** is not competitive with hydrogen bonding between solvent water molecules and **A**, even if **F** can weakly complex with **A** in the gas phase.

Since the Evans–Seddon paper, others have tested the ideas computationally.[12,13] Meyer and Sühnel did calculations on **F**–**A** and **T**–**A** complexes using the RHF, B3LYP and MP2 methods and the 6-31G** basis set.[12] Without zero point correction, the complexation energy for **T**–**A** is 11.7 kcal mol^{-1}, significantly larger than the complexation energy for **F**–**A** (−3.8 kcal mol^{-1}).

However, in aqueous solvent, the loosely complexed **F**–**A** is readily dissociated. Santhosh and Mishra did calculations on **F**–**A** and **T**–**A** systems in a solvent cavity model (PCM) at the 4-31G level with AM1 geometries.[13] The complexation energy of **F**–**A** becomes repulsive (3.5 kcal mol^{-1}) in aqueous media, while it is attractive for the **T**–**A** complex (−11.1 kcal mol^{-1}). The best distance for fluorine of **F** and nitrogen of **A** is 3.533 Å (calculated from their graph), significantly longer than that of **T**–**A** (3.0 Å). We performed RHF/6-31G* optimizations and SCI-PCM solvent cavity model calculations on **F**–**A** and **T**–**A** as well. With RHF/6-31G* optimized geometries, and SCI-PCM solvation calculations at the RHF/6-31G* level, the energy difference between **F**–**A** and uncomplexed **A** and **F** is −1.4 kcal mol^{-1}. This means that the **F**–**A** complex becomes repulsive in aqueous solution, as Santhosh and Mishra showed.[13] The complexation energy for **T**–**A** in water is computed to be −5.2 kcal mol^{-1}. **F** does not hydrogen bond with **A** in aqueous solution.

We have also modelled the polydeoxynucleotides containing **F**–**A** or **T**–**A** complexes. The AMBER* force field was employed in these calculations.[14] The charges on the oxygens in **T** are −0.47 and −0.53, respectively, and the charges on the fluorines in **F** are both −0.25. A strand of 3-nt DNA is shown in Fig. 2. Whereas the distances between O^4 of **T** and NH_2 of **A**, and between N^3 of **T** and N^1 of **A**, are computed to be 2.832 and 2.851 Å respectively, the distance between F^4 of **F** and NH_2 of **A** is 3.316 Å, and the distance between C^3 of **F** and N^1 of **A** is 3.521 Å. These are 0.484–0.670 Å longer, a clear indication of the absence of hydrogen-bonding in the small DNA oligomer. Importantly, the distance between N^3 of **T** and N^1 of **A** calculated with the AMBER* force field (2.851 Å) is close to those measured from high resolution DNA X-ray structures (2.82 ± 0.07 Å),[12] and the distance between F^4 of **F** and N^1 of **A** calculated with the AMBER* force field (3.521 Å) is close to the value obtained from RHF/4-31G//AM1 calculations by Santhosh and Mishra (3.533 Å).[13]

Force field calculations of a 12-nt DNA fragment with the GB/SA* solvation model[15] also show that there is no hydrogen-bonding between **F** and **A** (Fig. 3). In DNA double helices, the

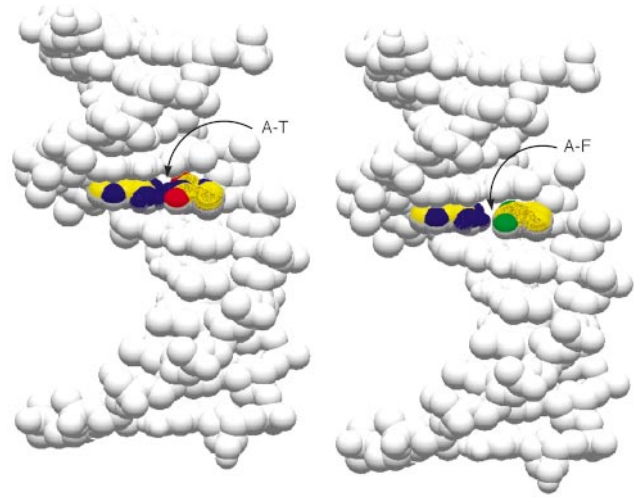

Fig. 3 The structure of 12-nt DNA with **A**–**T** or **A**–**F** base pairs.

base pairs adjacent to **F**–**A** are strongly hydrogen bonded. This, along with π-stacking to **F** and **A**, keeps the **F**–**A** base pair from separating. Aqueous solvation also keeps DNA strands tightly coiled. Even with the assistance from neighboring base pairs, the **F**–**A** hydrogen bonding distances are still 0.6–0.7 Å longer than those of **T**–**A**. All evidence suggests that there is no hydrogen bonding between **F** and **A**. However, the π-stacking and the shape of the whole DNA strands are not distorted significantly with **F** in place of **T**. As a nearly perfect isostere, **F** should be able to fit into the DNA template-polymerase-substrate complex without disturbing the structure.

The experimental and theoretical studies support the conclusion of Kool *et al*. that the hydrogen bonding of **F**–**A** is very unlikely to play an important role in DNA replication. Geometrical effects must account for the high fidelity of DNA replication in the presence of polymerase.

Nitrile functionalised pendant-arm derivatives of [9]aneN$_3$ as new multidentate ligands for inorganic crystal engineering ([9]aneN$_3$ = 1,4,7-triazacyclononane)

Lorenzo Tei, Vito Lippolis, Alexander J. Blake, Paul A. Cooke and Martin Schröder*

School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: m.schroder@nottingham.ac.uk

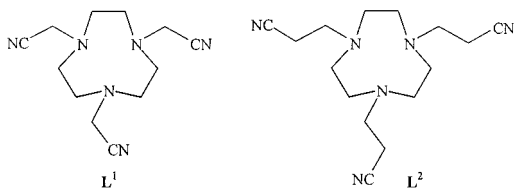
Received (in Cambridge, UK) 23rd September 1998, Accepted 12th October 1998

Functionalised pendant-arm derivatives of [9]aneN$_3$ have been used as building blocks for the synthesis of inorganic multi-dimensional networks in the presence of Ag^I.

Crystal engineering and the design of solid-state architectures have become areas of increasing interest over recent years.[1–4] Initially, attention was focused mainly upon the use of supramolecular contacts (particularly hydrogen bonding and π–π interactions) between suitable organic molecules to generate multi-dimensional arrays and networks.[1–3] More recently, the design of three-dimensional inorganic coordination polymers has become a rapidly expanding area[4,5] with transition metal ions such as Cu^I and Ag^I and multidentate ligands derived from 4,4′-bipy being used as building blocks for different network topologies and structural motifs.[6–8] Although subtle factors such as π–π interactions between ligand units and/or the nature of the anion may have profound effects on the topology of the cationic coordination array, the design and synthesis of new multidentate ligands that can be used as building blocks for the construction of desired solid-state architecture is still the major target.

Functionalised pendant arm derivatives of aza-crown ether macrocycles have long been used as ligands for producing complexes of low nuclearity and of high kinetic and thermodynamic stability, with the coordinated transition-metal ion(s) adopting specific coordination and redox properties which make them relevant as models for metallobiosites or catalytic reagents.[9,10] The pendant groups are carefully chosen and are often attached to the macrocyclic framework to give endocyclic complexes. However, functionalised pendant arms have not been previously intentionally attached onto aza-crown ether rings for the purpose of assembling a multidentate ligand to be used in the construction of three-dimensional exocyclic solid-state architectures.

We report herein the synthesis† and coordination properties of the new ligands L^1 and L^2 with Ag^I. We argued that nitrile functionalised pendant arms would prevent these polydentate



ligands from encapsulating tetrahedral metal centres (Ag^I, Cu^I) or forming sandwich complexes with them, but would promote the formation of multinuclear or polymeric compounds.

Reaction of L^1 with 1 molar equivalent of $AgPF_6$ in MeCN at room temperature gives colourless plate crystals following partial removal of the solvent and diffusion of Et_2O vapour into the remaining solution. A single crystal X-ray determination‡ confirms the product to be a three-dimensional polymer, $\{[Ag(L^1)](PF_6)\}_\infty$ **1**. Each Ag^I ion is coordinated to six N-donors in a distorted octahedral coordination geometry, with one face taken up by the three N-donors of the triaza ring [Ag–N 2.523(4)–2.547(4) Å]. The remaining three positions are occupied by the N-donors of nitrile groups belonging to three different molecules of $[Ag(L^1)]^+$ [Ag–N 2.311(4)–2.486(4) Å] (Figs. 1 and 2). A three-dimensional inorganic network is therefore formed in which each molecule of L^1 is a node linked to four different Ag^I centres (Fig. 2) and each Ag^I ion represents a six-connected junction *via* NCH_2CN linkers to six other Ag^I ions in the overall 3D single network. Six-connected single networks at Ag^I consisting of a cationic frame linked by molecular rods are very rare in the literature, the only reported example being the complex $[Ag(pyz)_3]SbF_6$ which is topologically related to the structures of ReO_3 or Prussian blue.[7c]

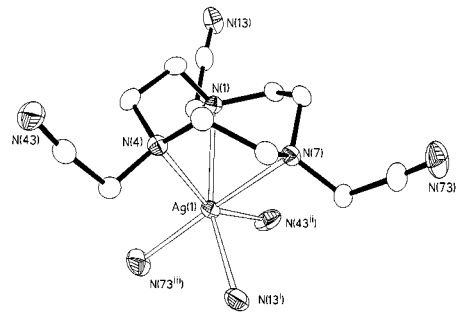


Fig. 1 View of the coordination sphere around the Ag^I ion in the $[Ag(L^1)]^+$ cation with numbering scheme adopted. The nitrogen atoms N(13^i), N(43^{ii}) and N(73^{iii}) belong to three different symmetry related molecules of L^1 [i = $x+1/2, -y+3/2, z-1/2$; ii = $x-1/2, -y+3/2, z-1/2$; iii = $-x+1/2, y+1/2, -z+1/2$]. Hydrogen atoms are omitted for clarity and displacement parameters are drawn at 50% probability.

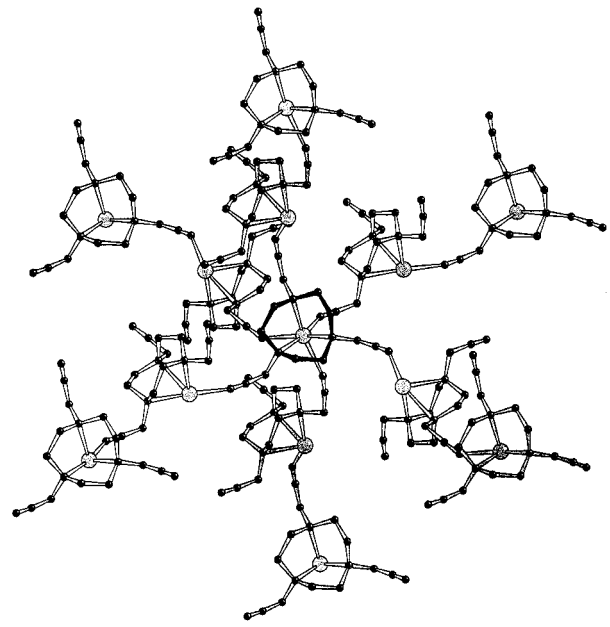

Fig. 2 View of part of the $\{[Ag(L^1)]^+\}_\infty$ three-dimensional polymer. Counter-anions are omitted for clarity and chains running through the structure are distinguished by the colour of their bonds.

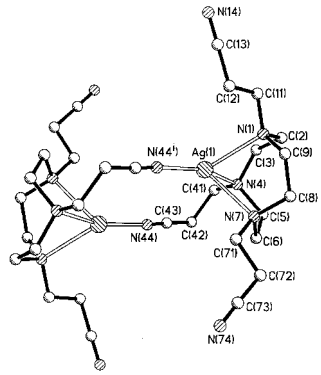

Fig. 3 View of the $[Ag_2(L^2)_2]^{2+}$ dinuclear cation with numbering scheme adopted. Hydrogen atoms are omitted for clarity. Symmetry operation i = $-x+1, -y+1, -z$.

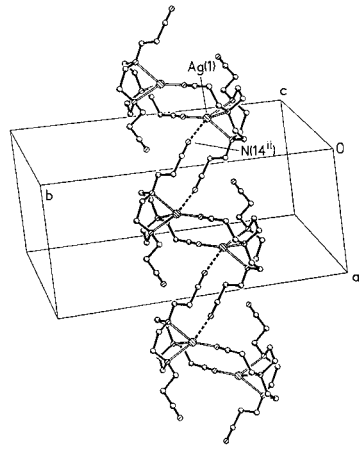

Fig. 4 Packing diagram for the $\{[Ag_2(L^2)_2]^{2+}\}_\infty$ polymeric chain. Counter-anions are omitted for clarity. Symmetry operation ii = $-x+2, -y+1, -z$.

Using the same synthetic procedure as for **1**, colourless crystals were obtained from the reaction of L^2 with $AgBF_4$ in 1:1 molar ratio in MeCN. Although analytical and mass spectroscopic data for the product were consistent with the stoichiometry $[Ag(L^2)]BF_4$, a single crystal structure determination was undertaken to ascertain the ligation and nuclearity of the complex. The structure confirms the product to be a one-dimensional zigzag polymer, $\{[Ag_2(L^2)_2](BF_4)_2\}_\infty$ **2** in which the repeating unit is the binuclear complex cation $[Ag_2(L^2)_2]^{2+}$ which lies across a crystallographic inversion centre (Fig. 3). Each Ag^I ion in the binuclear fragment is coordinated to four N-donors in a distorted tetrahedral geometry with N–Ag–N angles ranging from 74.0(2) [N(4)–Ag(1)–N(7)] to 159.1(2)° [N(4)–Ag(1)–N(44^i), i = $-x+1, -y+1, -z$] and Ag–N bond distances from 2.192(6) [Ag(1)–N(44^i)] to 2.504(5) Å [Ag(1)–N(7)]. Three out of four N-donors are provided by the [9]aneN_3 framework of a molecule of L^2 and the fourth, which completes the coordination sphere around the metal centre, belongs to the nitrile group of a pendant arm of the symmetry related $[Ag(L^2)]^+$ unit (Fig. 3). One of the remaining two pendant arms of L^2 interacts with a Ag^I centre of an inversion-related $[Ag_2(L^2)_2]^{2+}$ binuclear fragment [Ag(1)–N(14^{ii}) 2.779(7) Å, ii = $-x+2, -y+1, -z$] to give an infinite zigzag polymer along the *a* axis (Fig. 4). Thus, simply altering the pendant arm length, from C_2 in L^1 to C_3 in L^2, affords a different network motif for the resultant coordination polymer.

The work described herein represents the first attempt to use properly designed functionalised pendant-arm derivatives of aza crown ethers as building blocks for the synthesis of extended inorganic architectures. We have also shown that the potential of this type of ligand can be increased further by the fine-control over the nature of the resulting inorganic network offered by varying the length of the pendant arms.

We thank the EPSRC for financial support.

Notes and References

† The ligands L^1 and L^2 were prepared in 53 and 95% yield, respectively, starting from [9]aneN_3·3HBr and [9]aneN_3, respectively, according to procedures adapted from the literature.[11] L^1: Found (calc. for $C_{12}H_{18}N_6$): C, 58.2 (58.5); H, 7.6 (7.4); N, 34.0 (34.1%); ^{1}H NMR ($CDCl_3$, 298 K, 300 MHz), δ 2.85 (12H, s), 3.59 (6H, s); ^{13}C NMR ($CDCl_3$, 298 K, 75 MHz), δ 54.12, 46.49, 116.14. L^2: Found (calc. for $C_{15}H_{24}N_6$): C, 61.80 (62.50); H, 8.22 (8.33); N, 28.88 (29.17%); ^{1}H NMR ($CDCl_3$, 298 K, 300 MHz), δ 2.44 (6H, t, *J* 6.67 Hz, CH_2CN), 2.79 (12H, s), 2.86 (6H, t, *J* 6.62 Hz, NCH_2CH_2CN); ^{13}C NMR ($CDCl_3$, 298 K, 75 MHz), δ 17.06, 54.06, 55.71, 119.26.

‡ Stoe Stadi-4 four-circle diffractometer, Mo-Kα radiation, ω–θ scans, θ_{max} = 25°. Both structures were solved using direct methods[12] and all non-H atoms were located using subsequent difference Fourier methods.[13] Hydrogen atoms were placed in calculated positions and thereafter allowed to ride on their parent atoms.

Communication 8/07409G

A new chiral ligand for the Fe–Lewis acid catalysed asymmetric Diels–Alder reaction

Marion E. Bruin and E. Peter Kündig*

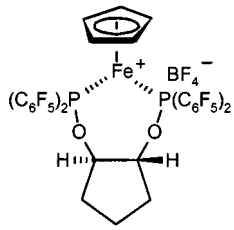
Département de Chimie Organique, Université de Genève 30 Quai Ernest Ansermet, CH-1211 Genève 4, Switzerland. E-mail: peter.kundig@chiorg.unige.ch

Received (in Basel, Switzerland) 17th August 1998, Accepted 23rd October 1998

The readily accessible enantiopure hydrobenzoin forms the backbone of the new bidentate ligand BIPHOP-F that is shown here to provide the chiral environment for a highly enantioselective Fe–Lewis acid catalysed Diels–Alder reaction between α,β-enals and dienes.

The high versatility of the Diels–Alder reaction in the synthesis of six-membered ring compounds and the potential for the control of up to four stereogenic centres make this transformation one of the key reactions in organic synthesis. Lewis acid catalysis has further enhanced its scope. Recent focus in this area has been on the use of chiral Lewis acids as catalysts and both main group and transition metal Lewis acids have yielded impressive results.[1,2]

Our earlier report in this area centred on the chiral Cp iron(II) Lewis acid **1** containing the electron poor C_2-symmetric



(*R*,*R*)-**1**

bidentate phosphorus ligand CYCLOP-F derived from *trans*-cyclopentane-1,2-diol **2**.[2a,3a] While both enantiomers of **2** are available by diastereoselective synthesis[3b] or enzymatic resolution,[4] the synthesis of **2** in larger quantities is time consuming and costly.

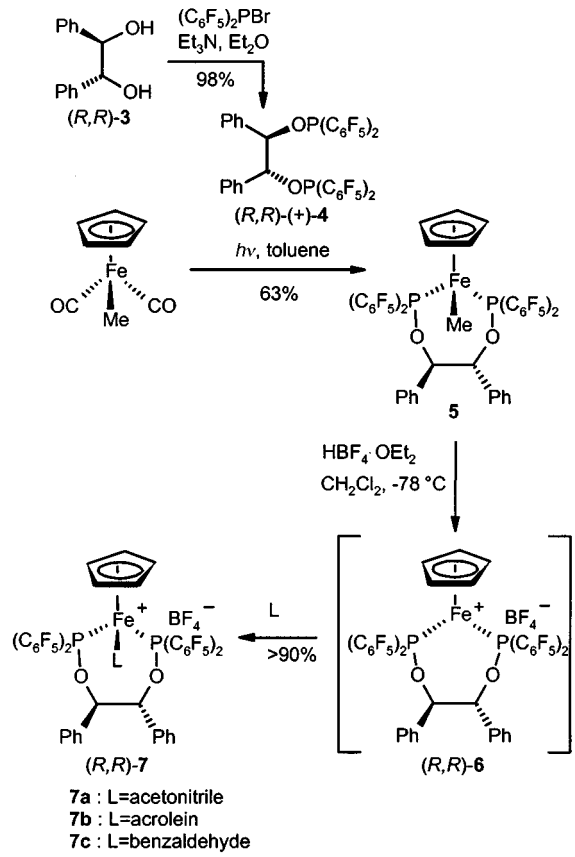
We here report on the new ligand BIPHOP-F (**4**) and on its use in the Fe–Lewis acid catalysed Diels–Alder reaction. Models suggested that hydrobenzoin **3** would be a good candidate for replacement of the cyclopentanediol backbone. As diol **3** is readily synthesised *via* Sharpless dihydroxylation,[5] we were surprised to find that its previous use in the synthesis of bidentate phosphorous ligands is limited to a single report.[6]

Ligand **4**† was prepared in near quantitative yield by reaction of (*R*,*R*)- or (*S*,*S*)-hydrobenzoin [(*R*,*R*)-**3** or (*S*,*S*)-**3**] with *bis*(pentafluorophenyl)phosphorus bromide[7] in the presence of triethylamine. The Lewis acid catalyst **6** was obtained by photolytic ligand exchange in [$CpFe(CO)_2Me$] followed by protolytic demethylation of complex **5**[2a] (Scheme 1). The unsaturated Fe complex **6** was trapped *in situ* with either acetonitrile, acrolein, or benzaldehyde to give, after precipitation with hexane, complexes **7a**–**c**, respectively.

Complex **7a** is stable and is readily characterised. The acetonitrile ligand is strongly bound and the complex does not exhibit catalytic activity towards the Diels–Alder reaction between enals and dienes. Complexes **7b** and **7c** are stable at ambient temperature in the solid state and can be weighed out in air without degradation. In CH_2Cl_2 solution, the aldehyde ligands in **7b** and **7c** are labile and in the absence of excess free aldehyde, the complexes slowly decompose at temperatures above −20 °C. Both **7a** and **7b** can be used as precatalysts in Diels–Alder reactions between α,β-enals and dienes (Table 1). 2,6-Di-*tert*-butylpyridine was added to scavenge residual acid impurities that adversely affected enantioselectivities. We subsequently found that 2,6-dimethylpyridine was equally efficient.

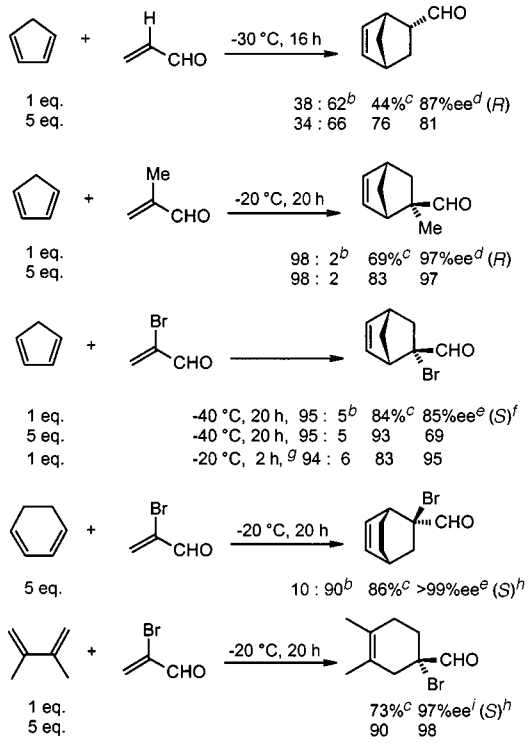
The results in Table 1 show that *exo/endo* ratios, yields, and enantiomeric excess obtained matched, and in some cases slightly exceeded, those realised with catalyst **1**. Increasing the quantity of diene led to a faster reaction and to higher yields but in some cases, *e.g.* the reactions between cyclopentadiene and acrolein or α-bromoacrolein, resulted in a drop of enantioselectivity. This presumably is due to the competitive uncatalysed background reaction. The sense of asymmetric induction observed is the same for both Lewis acids **1** and **6**. Indeed, the chiral catalyst sites are very similar. Fig. 1‡ shows the chiral pocket of the catalysts **6** and **1**[2a] and the postulated position of methacrolein in the transition state assembly.§ The diene approaches the alkene C_α-*si*-face of the *s*-trans conformer of the coordinated enal. The *re*-face is shielded by a pentafluorophenyl ring of the ligand and the ligand backbone.

In summary, the new C_2-symmetric bidentate phosphorus ligand BIPHOP-F **4** derived from (*R*,*R*)- or (*S*,*S*)-hydrobenzoin **3** described here proved to be an effective ligand in the Fe^{II}



Scheme 1

Table 1 Diels–Alder reactions with complex **7b**[a]



[a] The Diels–Alder reactions were carried out in freshly distilled CH_2Cl_2 (1 M solution) with 5 mol% precatalyst **7b** and 5 mol% of 2,6-di-*tert*-butylpyridine or 2,6-dimethylpyridine. Analogous results were obtained with **7c**. [b] *exo/endo* Ratio. [c] Isolated yield after flash-chromatography. [d] The ee was determined by GC analysis of the diasteromeric acetals obtained by reaction with (2*R*,4*R*)-pentanediol.[8] The absolute configuration was assigned by comparing the sign of $[\alpha]_D^{20}$ with literature values.[8,9] [e] The enantiomeric excess was determined from the ^{1}H NMR spectrum in the presence of the chiral shift reagent Eu(hfc)$_3$. [f] The absolute configuration was assigned by comparison with literature data.[10] [g] Slow addition of the diene (1 h). [h] The absolute configuration assigned is based on the presumption of attack of the enal C_α-*si*-face (same as in the first three examples in the Table). [i] The enantiomeric excess was determined by GC analysis on a chiral column (MN FS-Lipodex E).

catalysed asymmetric Diels–Alder reaction of α,β-enals with dienes and its ease of synthesis merits attention for other applications in asymmetric catalysis.

We thank the Swiss National Science Foundation for support of this work. (SNSF grants 20-045291.95 and 20-52478.97). We also thank Ms Maria Mayor Lopez and Professor Jacques Weber for carrying out computational studies on the catalysts.

2,2′-Bi-1,6-naphthyridine metal complexes: a new ligand and a novel 2 × 2 inclined interpenetration of (4,4) nets or formation of helicoidal chains†

He-Ping Wu,[a] Christoph Janiak,*[a] Lars Uehlin,[a] Peter Klüfers[b] and Peter Mayer[b]

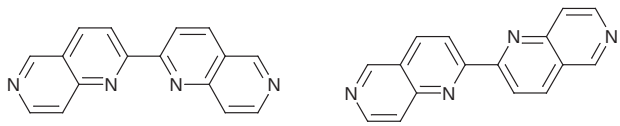
[a] *Institut für Anorganische und Analytische Chemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany. E-mail. janiak@uni-freiburg.de*

[b] *Institut für Anorganische Chemie, Universität Karlsruhe, Kaiserstr. 12, D-76131 Karlsruhe, Germany*

Received (in Cambridge, UK) 28th September 1998, Accepted 29th October 1998

Cobalt(II), zinc(II) and cadmium(II) salts react with the new spacer ligand 2,2′-bi-1,6-naphthyridine 1 to give 2D-planar (4,4) frameworks which interpenetrate such that each grid window of each sheet has two other sheets passing through it with all sheets being equivalent whereas copper(I) tetrafluoroborate and 1 form a 2_1-helicoidal chain with neigboring chains interlocking through an aromatic π–π interaction.

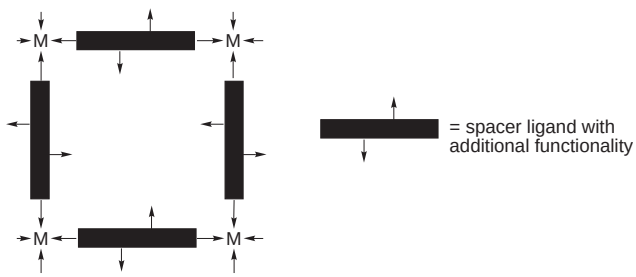
The synthesis of interpenetrating nets and the elucidation of the factors leading to a periodic entanglement is an area of increasing interest.[1] Many interpenetrating structures were obtained from attempts to create porous solid bases on metal coordination polymers.[2] As nature tends to avoid vacuum, identical copies of the frameworks with large openings interpenetrate to fill this empty space rather than to create a single network.[3] In the design of metal–ligand networks rigid and multidentate ligands with pyridine groups feature prominently as building blocks.[4] In our study of functionalized 2,2′-bipyridine-type ligands[5] we look here at the self-assembly process of the new spacer 2,2′-bi-1,6-naphthyridine **1**[6] with various metal salts.



s-cis *s-trans* conformation

1

The choice of functionalized 2,2′-bipyridine building blocks stems from the aim to supply functional groups within the inner walls of a porous coordination polymer as is schematically depicted in **2**. Such functionalities should eventually interact with organic guest molecules, *e.g.* through hydrogen bonding, or allow for the anchoring of additional metal ions.



2

Spacer **1** reacts with cobalt chloride, zinc or cadmium perchlorate in the presence of a slight excess of KSCN in water–ethanol (1 : 1) to give well formed crystals in yields of 50% and above. The products were investigated by single crystal X-ray analysis† and correspond to the formula $^2_\infty$[M(NCS)$_2$(μ-**1**)$_2$] (M = Co, Zn, Cd) (matching the C,H,N analytical data‡). The three M(II) compounds are isostructural. The binaphthyridine ligand assumes the *s-trans* conformation and bridges between the metal centers. Four ligands of **1** are arranged around the metal in a square-planar fashion and two *trans* (nitrogen-bound) isothiocyanato ligands complete the octahedral metal coordination sphere. The bonded metal–**1** arrangement leads to planar (4,4) nets. Fig. 1 shows an individual metal–ligand grid. The bridged metal–metal distances along the edges of the parallelograms are around 15.76–16.05 Å and the distances along the shorter and longer diagonals are 21.44–21.95 and 23.10–23.43 Å, respectively, depending on the metal. The 2D framework from Fig. 1 is interpenetrated in an inclined mode[1] by symmetry related, identical sheets to give an interlocked 3D structure. The manner of interpenetration is such that each window of each grid has parts of two other sheets passing through it, which we would like to call a 2 × 2 interpenetration (Figs. 2 and 3). It was surprising at first that the rings were large enough and the binaphthyridine rods slim enough to allow the passage of two sheets, when considering the van der Waals surfaces of the aromatic system and the NCS group. A space-

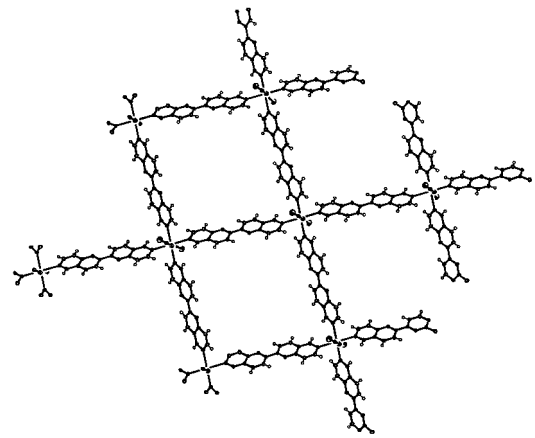


Fig. 1 View of a section of the planar individual metal–ligand network in $^2_\infty$[M(NCS)$_2$(μ-**1**)$_2$] (M = Co, Zn, Cd).

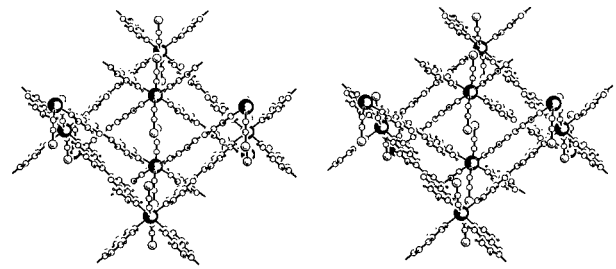

Fig. 2 Stereoview along *b* of the interpenetration of parts of two sheets through a grid window in $^2_\infty$[M(NCS)$_2$(μ-**1**)$_2$] (M = Co, Zn, Cd).

† Dedicated to Professor Dr Bernt Krebs on the occasion of his 60th birthday.

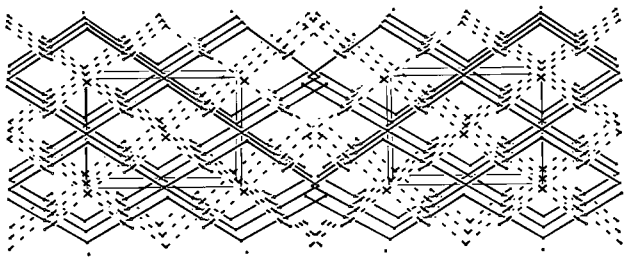

Fig. 3 Stereoview along *c* of the schematic framework of $^{2}_{\infty}$[M(NCS)$_2$(μ-**1**)$_2$] (M = Co, Zn, Cd), with only the metal center and the central C–C unit of the binaphthyridine moiety shown. Sheets of different inclination are drawn with solid or dashed lines, respectively.

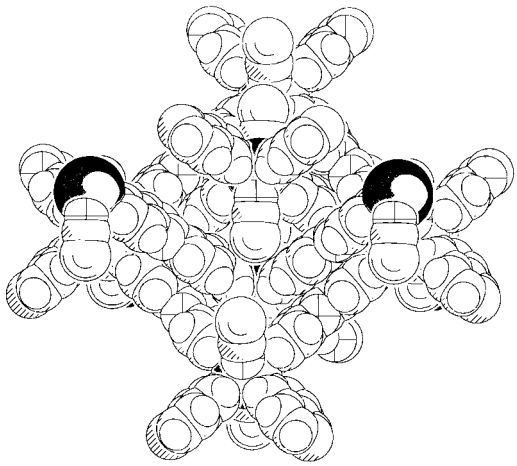

Fig. 4 Space-filling drawing of the interpenetration of parts of two sheets through a grid window in $^{2}_{\infty}$[M(NCS)$_2$(μ-**1**)$_2$] (M = Co, Zn, Cd).

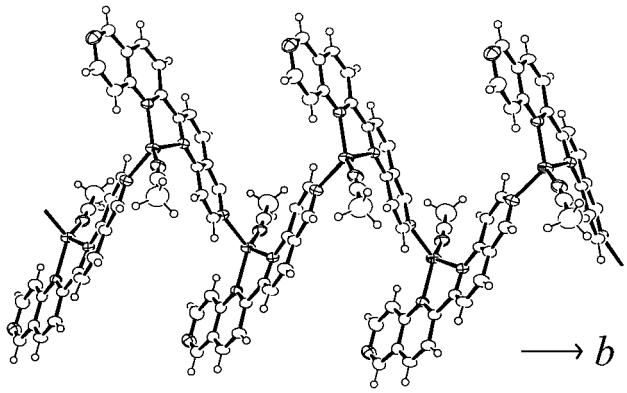

Fig. 5 Section of the 2_1-helical coordination polymer of $^{1}_{\infty}$[Cu(MeCN)(μ-**1**)]BF_4·0.5CH_2Cl_2. Anion and solvent molecule have been omitted for clarity.

filling model then illustrated the close π–π contact of the naphthyridine moieties (Fig. 4). The knots or metal centers of the intersecting networks do not lie within the plane of the pierced ring but above and below. The nets run either parallel to the (021) or to the (02 − 1) plane. The inclination of the sheets is almost perpendicular, the angle ranges from 92.9° for the cobalt to 93.7° for the cadmium grids. A similar mode of interpenetration was so far only reported in the structure of [Cd(py)$_2${Ag(CN)$_2$}$_2$],[7] for the more common type of a 1 × 1 interpenetration in (4,4) square grid sheets, the structure of $^{2}_{\infty}$[M(4,4′-bipy)$_2$]SiF_6 (M = Zn, Cd) is a typical example.[8]

The anellated arene substituents in the α position to the bipyridine nitrogen donor atoms prevent the chelating coordination of two or three ligands of **1** with its bipyridine unit in an octahedral complex. A bipyridine selectivity in **1** (cuproin group) can, however, be expected towards copper(I). An X-ray study† revealed that the reaction of **1** with [Cu(MeCN)$_4$]BF_4 in MeCN–CH_2Cl_2 led to a compound of formula $^{1}_{\infty}$[Cu(MeCN)(μ-**1**)]BF_4·0.5CH_2Cl_2. A 1D-coordination polymer (Fig. 5) originates from the chelation of the copper center by **1** in its *s-cis* conformation together with the bridging action of the ligand to the next metal through one of its exodentate nitrogen donors. The distorted tetrahedral coordination sphere at copper is completed by an acetonitrile ligand. The copper–ligand strand assumes a helicoidal conformation following a 2_1 screw axis. The neighboring parallel strands are of opposite helicity and interlock (interdigitate) through π–π interactions of the extended aromatic binaphthyridine system.

We acknowledge the support by the Humboldt Foundation (fellowship for H.-P. W.), the Fonds der Chemischen Industrie, the DFG, and the graduate college 'Unpaired Electrons'.

Formal stereoselective synthesis of (±)-akagerine

M.-Lluïsa Bennasar,* Bernat Vidal, Bilal A. Sufi and Joan Bosch*

Laboratory of Organic Chemistry, Faculty of Pharmacy, University of Barcelona, Barcelona 08028, Spain. E-mail: jbosch@farmacia.far.ub.es

Received (in Cambridge, UK) 9th October 1998, Accepted 30th October 1998

A stereoselective synthesis of pentacyclic dilactam 1, a known precursor of the indole alkaloid akagerine, involving addition of the enolate of 1-acetylindole 2 to 3-acetyl-2-fluoropyridinium salt 3, cyclization of the resultant 1,4-dihydropyridine, elaboration of the (*E*)-ethylidene substituent and closure of the C ring by Pummerer reaction, is reported.

Akagerine is a tetracyclic indole alkaloid isolated in 1975 from *Strychnos usambarensis*[1] and later from several *Strychnos* species.[2] This Corynanthean[3] alkaloid has a peculiar skeleton lacking the characteristic piperidine (D) ring and containing an additional link between N-1 and C-17 (biogenetic numbering);[4] consequently, it incorporates a perhydroazepine ring fused to a tetrahydro-β-carboline unit. Akagerine has received little attention from the synthetic standpoint: only one total synthesis in the racemic series *via* dilactam **1**[5] (Scheme 1) and one enantioselective synthesis of (−)-akagerine[6] through a completely different route have been reported to date.

We present here a short, stereoselective route to pentacyclic dilactam **1**. Our approach takes advantage of our previously developed methodology for the synthesis of bridged indole alkaloids, based on the addition of indole-containing enolates to *N*-alkyl-3-acylpyridinium salts, with subsequent acid-promoted cyclization of the resultant 1,4-dihydropyridine.[7] Taking into account the easy hydrolysis of the C–F bond in 2-fluoropyridines,[8] we thought that the use of a pyridinium salt bearing a fluorine atom at the 2-position in the above two-step sequence would lead to a bridged tetracyclic intermediate embodying the required 2-piperidone moiety present in **1**. On the other hand, the closure of the C ring would be effected by electrophilic cyclization of a thionium ion generated by Pummerer rearrangement,[9] taking advantage of the functionalized two-carbon substituent present at the piperidone nitrogen.

The synthetic sequence is outlined in Scheme 2. Thus, reaction of the enolate derived from 1-acetylindole **2** with 3-acetyl-2-fluoropyridinium salt **3** gave (25%) 1,4-dihydropyridine **4**,[10] which underwent cyclization (58% yield) upon the indole 2-position with concomitant cleavage of the C–F bond by treatment with TsOH in the presence of LiI.[11] The spectroscopic data of the resulting tetracyclic lactam **5**[12] clearly showed that the acetyl carbonyl group was in an enolized form, presumably with a *Z* double bond configuration.

The elaboration of the C-20 (*E*)-ethylidene double bond was effected in a stereoselective fashion by conversion of the 1-hydroxyethylidene group of **5** into the corresponding triflate, followed by Pd^0 catalyzed reduction with Bu_3SnH.[13] Following this protocol **6** was obtained in 45% overall yield from **5**.

MCPBA oxidation of tetracyclic sulfide **6** gave the corresponding sulfoxide (mixture of stereoisomers), which smoothly underwent Pummerer rearrangement with TFAA in CH_2Cl_2 in the presence of 2,6-di(*tert*-butyl)pyridine at room temperature.[14] When the presumed acyloxy sulfide intermediate was refluxed in CH_2Cl_2 the desired pentacyclic sulfide **7** (a single diastereomer, undetermined configuration at C-6) was obtained in 71% overall yield from **6**.

Finally, desulfurization of **7** with Bu_3SnH–AIBN gave the desired pentacyclic dilactam **1** in 72% yield. The ^1H NMR data of **1** are in agreement with those previously reported.[5,15] Taking into account the previous work by Winterfeldt,[5] the synthesis of **1** represents a formal total synthesis of (±)-akagerine.

Double diastereocontrol in the synthesis of enantiomerically pure polyoxamic acid

Laurence M. Harwood* and Sarah M. Robertson

Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 6AD.
E-mail: l.m.harwood@reading.ac.uk

Received (in Liverpool, UK) 24th September 1998, Accepted 26th October 1998

Polyoxamic acid 4 is prepared by a short and efficient process involving diastereochemically matched cycloaddition of 5-(*S*)-phenylmorpholin-2-one 1 with (*S*)-glyceraldehyde acetonide 2, followed by sequential hydrolysis and hydrogenolysis of the adduct.

We have demonstrated the use of 5-(*S*)-phenylmorpholin-2-one **1**† as a chiral template in the rapid, diastereo- and enantiocontrolled synthesis of β-hydroxy-α-amino acids.[1] In this process, the chiral azomethine ylide intermediate generated by condensation with an aldehyde is trapped by excess of the aldehyde to furnish a cycloadduct which can be subsequently dismantled to lead to *threo*-(2*S*, 3*R*)-configured products of high stereochemical integrity (Scheme 1).

In the cycloaddition step, stereochemical discrimination arises from the chiral azomethine ylide reacting with an achiral aldehyde dipolarophile. Utilizing a chiral aldehyde in such a reaction therefore poses the question as to whether there might be diastereochemical 'match' or 'mismatch' in either the ylide generation step or the cycloaddition step between the chiral reacting partners.

We now report an efficient synthesis of polyoxamic acid **4**,[2] the unique polyhydroxyamino acid constituting the side chain moiety of the antifungal polyoxin antibiotics.[3] The key conversion in our synthesis involves reaction of 5-(*S*)-phenylmorpholin-2-one **1** with excess (*S*)-glyceraldehyde acetonide **2** (obtained from commercially available 5,6-*O*-isopropylidene-L-gulono-1,4-lactone.[4]) in refluxing toluene with removal of water.‡ It would appear that this combination of starting materials leads to matched diastereocontrol as close examination of the crude product mixture isolated from reaction between (*S*)-**2** with 5-(*S*)-phenylmorpholin-2-one **1** indicated the presence of only a single product. This could be isolated in 53% yield and showed spectroscopic features consistent with those expected of a cycloadduct resulting from highly diastereoselective reaction of two equivalents of (*S*)-**2** with (*S*)-**1**.

By analogy with our earlier rationale for stereocontrol in both ylide generation and trapping steps, cycloaddition of the aldehyde dipolarophile to the *E*-isomer of the azomethine ylide from the face opposite the 5-phenyl substituent would be predicted to furnish cycloadduct **3** (Scheme 2).[1]

Although a solid, crystals of sufficient quality for X-ray structural analysis could not be obtained. A combination of 2-dimensional ^{1}H NMR and NOE difference studies supported the predicted stereochemical outcome of the cycloaddition step, enhancements of signals corresponding to H_2 and $H_{3\beta}$ on irradiating H_7 proving diagnostic of their mutual *syn*-relationship, but the stereochemistry at C-9 remained unresolved.‡

Final confirmation of the stereochemical outcome of the ylide generation and trapping sequence came by conversion of **3** to polyoxamic acid as its natural (2*S*,3*S*,4*S*) enantiomer. Treatment of the cycloadduct with aqueous methanolic HCl gave the deketalized methyl ester which was not isolated but subjected immediately to hydrogenolysis (H_2, Pearlman's catalyst, aq. MeOH, TFA) leading to the isolation of a homogeneous material in 95% overall yield with a specific rotation $[\alpha]_D^{24}$ +2.4 (*c* 1.0, H_2O), [lit.,[2d] +2.2 (*c* 1.0, H_2O)] and spectroscopic data identical with those of authentic polyoxamic acid **4** (Scheme 3).§ In the same manner, the non-natural enantiomer

of polyoxamic acid was obtained by reacting (*R*)-glyceraldehyde acetonide (prepared by oxidative cleavage of 1,2:5,6-di-*O*-isopropylidene-D-mannitol[5]) with (*R*)-**1**, followed by sequential degradation of the cycloadduct. Pure *ent*-polyoxamic acid was isolated in excess of 50% yield over the whole sequence, with a specific rotation, $[\alpha]_D^{24}$ −2.5 (*c* 1.0, H_2O).

Having successfully prepared polyoxamic acid and its enantiomer it was decided to investigate the synthesis of diastereoisomers by employing the alternative combination of reactant enantiomers. However, under the same conditions as before, reaction of 5-(*S*)-phenylmorpholin-2-one **1** with (*R*)-**2** resulted in a product mixture consisting of roughly equal quantities of three products which were found to be diastereoisomers of **3** by spectroscopic analysis. Unfortunately none could be isolated with sufficient purity to permit definitive structural assignment, nor was it possible to separate the deprotected acids at the ultimate stage of the synthetic route. However, the observation of three cycloadducts indicates diastereochemical mismatch in more than one element of the ylide generation and trapping sequence, be it reactant ylide geometry, diastereofacial control or *exo*/*endo* approach of the dipolarophile.

In conclusion, we have demonstrated that diastereochemically matched and mismatched reactions can occur in the generation and trapping of azomethine ylides in which both starting materials are chiral and have established a rapid diastereocontrolled synthesis of polyoxamic acid *via* a diastereochemically matched reaction of 5-(*S*)-phenylmorpholin-2-one with (*S*)-glyceraldehyde acetonide. We are currently investigating the scope of this process and applying it to the synthesis of other enantiomerically pure β-hydroxy-α-amino acids with additional stereogenic centres.

We thank the University of Reading for postgraduate support under the R.E.T.F. framework (to S. M. R).

The biosynthesis of pramanicin: intact incorporation of serine and absolute configuration of the antibiotic

Petar Duspara, Stephen I. Jenkins, Donald W. Hughes and Paul H. M. Harrison*

Department of Chemistry, McMaster University, 1280 Main Street West, Hamilton, Ontario, L8S 4M1, Canada. E-mail: pharriso@mcmaster.ca

Received (in Corvallis, OR, USA) 21st September 1998, Accepted 21st October 1998

Biosynthetic incorporation of isotopically labelled serines into pramanicin 1 in *Stagonospora* sp. ATCC 74235 shows that L-serine is incorporated as an intact entity with all four bonds to the α-carbon retained; thus 1 is assigned the 5*S* absolute configuration.

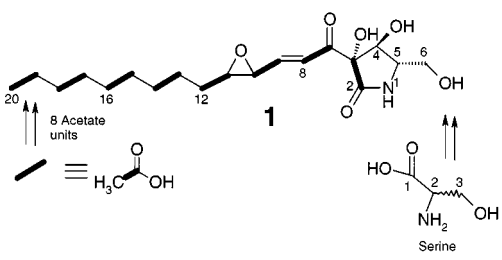
We have recently described the biosynthesis of pramanicin[1] **1** (Scheme 1) in *Stagonospora* sp. ATCC 74235.[2] Eight acetate units combine in the 'head-to-tail' manner typical of fatty acids and polyketides[3] prior to cyclization with the three-carbon precursor corresponding to carbon atoms 4 to 6 in **1**. The resulting putative tetradeca-2,4-dienoyltetramic acid[1] is then presumably further modified to furnish **1**. We demonstrated that incorporation of DL-[1-^{13}C]serine proceeded very efficiently: only C-4 of **1** was labelled, suggesting that serine is the direct amino acid precursor of **1**. However, serine can be converted to a number of metabolites *in vivo*, and we thus sought further evidence for the proposed intact incorporation of a serine entity into **1**. We also wished to establish which enantiomer of serine is utilised in the biosynthetic pathway and to correlate these results with the as yet unknown absolute configuration of pramanicin. Experiments directed toward these issues are described herein.

Cultures of *Stagonospora* sp. ATCC 74235 were grown,† precursors were added, and pramanicin was isolated as described previously.[1,2] Incorporations of L-[2,3,3-$^{2}H_3$]serine, L-[1,2,3-$^{13}C_3$,^{15}N]serine, and the separated D- and L-enantiomers of [2-^{2}H,3-^{13}C]serine‡ furnished samples of pramanicin **2–5**, respectively (Scheme 2).

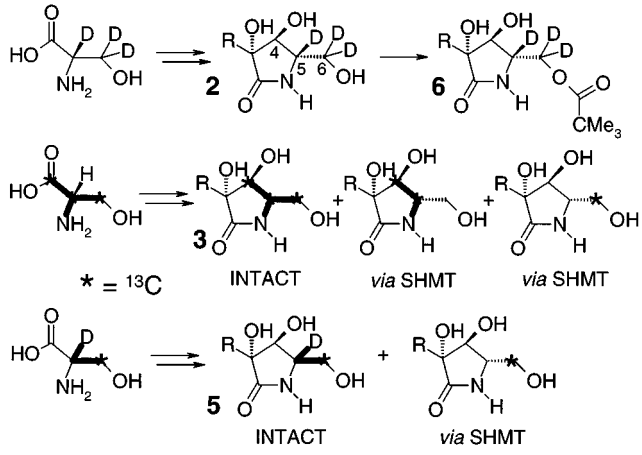
Pramanicin **2** derived from L-[2,3,3-$^{2}H_3$]serine exhibits two resonances in the ^{2}H{^{1}H} NMR spectrum in MeOH. One signal corresponds in chemical shift to one of the two diastereotopic protons at C-6 (δ 3.79), which is well separated from other resonances in the proton NMR spectrum. The other deuterium signal, somewhat larger than the first, correlates with the proton chemical shift of the other C-6 proton and to that of H-5; these two resonances are close in proton chemical shift (δ 3.55 and 3.49, respectively), and the breadth of the signals in the deuterium NMR spectrum precluded their resolution. These resonances remained unresolved in acetone, but the spectrum in DMSO, where the difference in shift between the two protons is larger,[2] did exhibit a clear shoulder, most notably when the sample was heated to 85 °C to reduce viscosity and enhance ^{2}H relaxation. Nonetheless, we sought to clarify this result, and thus **2** was converted to the mono-pivaloyl derivative **6** (pivaloyl chloride, TEA, 70 °C, 30 min, Scheme 2). In the proton NMR spectrum of **6**, the two C-6 protons are shifted downfield by 0.58 and 0.51 ppm, relative to **1**, while H-5 gives a unique resonance which is shifted downfield by only 0.13 ppm. The deuterium NMR spectrum of **6** exhibited three resonances, corresponding to the two H-6 (δ 4.30 and 4.00), and the H-5 (δ 3.55) resonances [Fig. 1(A)].§ However, the D-5 signal intensity was significantly weaker than either of the D-6 resonances, and integration showed that only about 0.5 deuterons were present at this site.

These results clearly show that L-serine is a viable precursor to pramanicin: a strong deuterium signal was observed although the precise incorporation could not be measured in this experiment. Further, there is no cryptic oxidation state change at C-3 of serine since both of the diastereotopic deuterons at this position are incorporated. The retention of some deuterium at C-5, derived from H-2 of serine, is most readily explained by direct incorporation of the L-enantiomer. The observed loss of deuterium would arise from an incidental, reversible process which results in net exchange of the α-proton. This solvent exchange could conceivably be accomplished by the action of a serine racemase;[9,10] a transaminase (to interconvert serine and 3-hydroxypyruvate);[9] serine hydroxymethyl transferase (SHMT), which interconverts serine with glycine and methylene-tetrahydrofolate (CH_2-THF);[9,11] or any of several enzymes which catalyse β-elimination or β-replacement reactions on serine or its derivatives.[9] Extensive investigations of amino acid racemases [whether double-base or pyridoxal phosphate (PLP) dependent] have shown that this process invariably occurs with substantial or complete loss of the substrate α-proton.[10] However, the PLP-dependent SHMT catalyses several processes, including racemisation of alanine and the exchange of both the prochiral α-protons of glycine, and thus this enzyme could possibly lead to deuterium-labelled D-serine which could then be incorporated into **1**.

To resolve these issues, we next incorporated L-[1,2,3-$^{13}C_3$,^{15}N]serine. Analysis of the extensive coupling pattern [Fig. 1(B)] in the ^{13}C{^{1}H} NMR spectrum of the derived pramanicin **3** showed the labelling pattern of [4,5,6-$^{13}C_3$,^{15}N]pramanicin, derived from an intact serine molecule, along with the [6-^{13}C]- and [4,5-$^{13}C_2$,^{15}N]-iso-



Scheme 1



Scheme 2

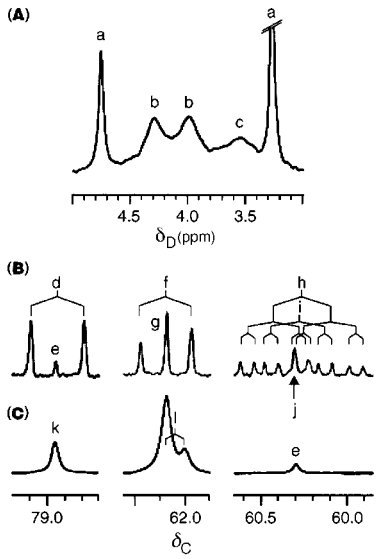


Fig. 1 (A) $^{2}H\{^{1}H\}$ NMR spectrum of 6-pivaloylpramanicin **6** derived from L-[2,3,3-$^{2}H_3$]serine: (a) natural abundance signals from MeOH solvent; (b) diastereotopic deuterons at C-6; (c) 5-D. (B), (C) Partial $^{13}C\{^{1}H\}$ NMR spectra of pramanicin **1** derived from (B) L-[1,2,3-$^{13}C_3$,^{15}N]serine and (C) L-[2-^{2}H,3-^{13}C]serine mixed with DL-[1-^{13}C]serine. Left: C-4; centre: C-6; right: C-5. For complete assignments, see ref. 1,2. Traces in (B) have the same scaling for both axes, as do those in (C), but (B) and (C) have different natural abundance peak heights. (d) $^{1}J_{^{13}C\text{-}4\text{-}^{13}C\text{-}5}$ = 38 Hz; (e) natural abundance signal; (f) $^{1}J_{^{13}C\text{-}5\text{-}^{13}C\text{-}6}$ = 40 Hz; (g) enriched singlet from action of SHMT on labelled CH_2—THF and unlabelled glycine; (h) coupled signals from [4,5,6-$^{13}C_3$,^{15}N]pramanicin from an intact serine unit, $^{1}J_{^{13}C\text{-}4\text{-}^{15}N}$ = 10 Hz; (i) signals for [4,5-$^{13}C_2$,^{15}N]pramanicin from action of SHMT on unlabelled CH_2—THF and labelled glycine; (j) natural abundance signal plus coupled component; (k) enhanced singlet from [1-^{13}C]serine; (l) β-deuterium isotope shift, $\Delta\delta$ 74 ppb.

topomers. The ^{15}N NMR spectrum showed only a coupled signal,¶ so all molecules labelled at C-2 are attached to ^{15}N and all enriched ^{15}N atoms are adjacent to ^{13}C. Thus there is no detectable action of either transaminase or serine β-elimination enzymes *en route* to **1**. However, SHMT is present in this microbial strain, and gives rise to the two non-intact isotopomers *via* cleavage of serine to [^{13}C]CH_2-THF and [$^{13}C_2$,^{15}N]glycine, followed by re-condensation of each fragment with the corresponding unlabelled partner. Nonetheless, the observation of substantial intact incorporation shows that SHMT is not required for the biosynthesis of **1** from serine. The results also exclude biosynthetic mechanisms in which the polyketide component is produced as an amide, and subsequent condensation with an α-keto acid leads to **1**.

When the L-enantiomer of [2-^{2}H,3-^{13}C]serine was mixed with DL-[1-^{13}C]serine (32 mol%) as internal standard and incorporated into **1**, C-4 and C-6 [18 and 82%, respectively, of total ^{13}C incorporated, Fig. 1(C)] were labelled with carbon-13, and the C-6 resonance exhibited a shifted signal ($\Delta\delta$ 74 ppb, 28% of total C-6 enrichment) due to a β-deuterium isotope shift. The corresponding D-[2-^{2}H,3-^{13}C]serine similarly mixed with DL-[1-^{13}C]serine gave product labelled with carbon-13 only at the control site, C-4.‖ Thus, the D-enantiomer is not a significant precursor for **1**, while the C-3:C-2:H-2 unit of L-serine is partially incorporated in an intact manner into C-6:C-5:H-5 of **1**. The remaining enrichment of the C-6 signal without concomitant incorporation of deuterium can be accounted for by the reversible action of SHMT.

In summary, L-serine is the true biosynthetic precursor for **1**, and is converted with all four atoms which are attached to the α-carbon atom retained. SHMT is not required in the pathway. These results are completely consistent with the proposed route to **1** *via* an acyltetramic acid.[1] The simplest conclusion is that the absolute configuration of pramanicin at C-5 is the same as that of L-serine, *i.e.* 5*S*; the remaining chiral centres in the tetramic acid moiety of **1** are then defined by the work of Schwartz *et al.*,[2] who determined the relative configurations of C-3 to C-5. The absolute configuration of the *trans*-epoxide remains undetermined. There is no evidence for racemisation of L-serine, or epimerisation of other biosynthetic intermediates in the pathway to **1**, which would lead to the opposite configuration of **1**, *i.e.* 5*R*. Although this possibility cannot be rigorously excluded by these or indeed by other whole-cell isotope labelling experiments, it would require the action of an enzyme which alters the configuration yet proceeds with substantial retention of the α-proton; there is little precedent for such an activity.[10] Further work on the pathway to the polyketide moiety of **1**, as well as the X-ray crystal structure of **1**, will be described shortly.

Financial support by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged. Part of this work was undertaken through the Co-operative Education Program, Hamilton-Wentworth Catholic District School Board, St. Jean de Brébeuf High School, Hamilton.

Notes and references

† *Stagonospora* was cultured in liquid medium LCM (100 ml in 500 ml Erlenmeyer flasks). Labelled serines (12–20 mg per culture flask) were added as sterile solutions in water at 24 h intervals over days 2–6. After 7 days, work-up as previously described gave *ca*. 10 mg of **1** per flask.

‡ The samples of D- and L-[2-^{2}H,3-^{13}C]serine were prepared from DL-[3-^{13}C]serine using the pyridoxal-dependent exchange of the α-proton in D_2O as described for [2-^{2}H]serine by Miles and McPhie (ref. 4), using some of the modifications of de Kroon *et al*. (ref. 5), as well as those of Townsend *et al*. (ref. 6), who prepared [2-^{3}H,1-^{14}C]serines; some minor modifications designed to conserve the yield based on labelled serine were also used. For the same reason, the resolution method of Velluz *et al*. (ref. 7) as modified by Gorissen *et al*. (ref. 8) was used in preference to the multi-step chemical and enzymatic resolution used by the former workers. All new compounds and isotopomers gave satisfactory spectral data; for serine hydrochlorides, $[\alpha]_D^{30}$: D, −9.0 ± 0.5; L, +10.0 ± 0.5 (*c* 1, H_2O).

§ The measured shifts in the deuterium NMR spectrum are 0.005–0.006 ppm upfield of those in the proton spectrum; this can be ascribed to the method of referencing the two spectra. Proton spectra in CD_3OD are referenced to C*H*D$_2$OD at δ 3.30, while the deuterium spectra in CH_3OH are referenced to natural abundance CH_2*D*OH; the observed solvent nuclei thus experience different isotope shifts.

¶ The ^{15}N NMR spectrum was recorded in DMSO-d_6, using polarisation transfer by the INEPT sequence: δ −256.4 relative to CH_3NO_2 at δ 0 (lit.[2] −229.1, converted from a different external standard), dd ($^{1}J_{^{15}N\text{-}^{1}H}$ 93 Hz, lit.[2] 92 Hz, $^{1}J_{^{15}N\text{-}^{13}C}$ 9 Hz).

‖ A small enhancement (0.14%) at C-6 was observed; this may however be accounted for by traces of the L-enantiomer present in the sample (< 2% required).

Received (in Cambridge, UK) 2nd September 1998, Accepted 27th October 1998

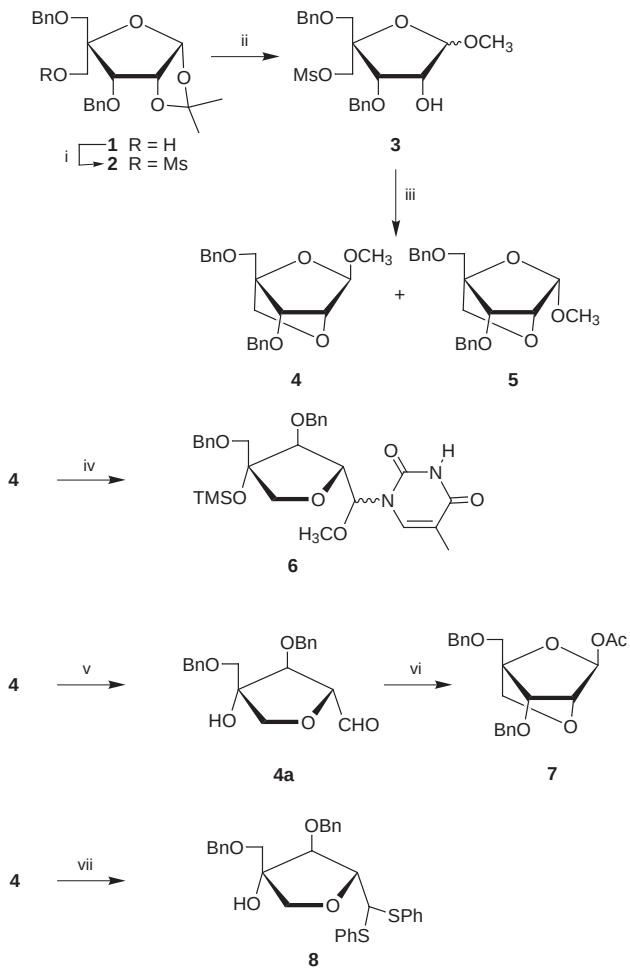
A bicyclic thiofuranoside (phenyl 3,5-di-*O*-benzyl-2-*O*,4-*C*-methylene-β-D-ribofuranoside) was efficiently synthesized and introduced as the key synthon in a method for convergent synthesis of α- and β-LNA nucleosides; acid-induced ring-opening reactions of the corresponding bicyclic methyl furanoside are also described.

In the search for an ideal nucleic acid mimic, intensive research towards conformationally restricted oligonucleotide analogues has been carried out during the last years.[1] We have recently introduced LNA (Locked Nucleic Acid) as a novel class of preorganized oligonucleotide analogues showing very interesting properties.[2–4]† In our initial synthetic approaches, monomeric β-configurated LNA nucleosides (*e.g.* the thymine derivative **13**, 5-methyl-2′-*O*,4′-*C*-methyleneuridine or (1*S*,3*R*,4*R*,7*S*)-7-hydroxy-1-hydroxymethyl-3-(thymin-1-yl)-2,5-dioxabicyclo[2.2.1]heptane, Scheme 2) were synthesized by stereoselective condensation of appropriately protected 4-*C*-hydroxymethyl-1,2-di-*O*-acetyl furanoses with silylated nucleobases and subsequent base-induced ring-closure and deprotection;[2,3] linear syntheses of LNA nucleosides have also been accomplished.[5–7] Here, a novel synthetic strategy is introduced, involving the use of a bicyclic carbohydrate precursor for nucleobase coupling reactions thus revealing the first synthesis of α-configurated LNA nucleosides. Our interest in these α-anomers, and in α-LNA, was stimulated by reports that α-DNA, in comparison with β-DNA, forms a more stable duplex with complementary RNA.[8,9]

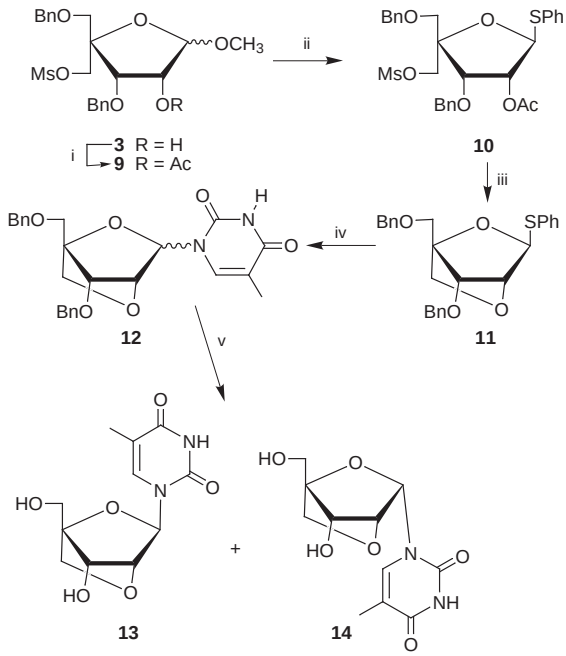
The protected 4-*C*-hydroxymethyl furanose **1** was synthesized according to the known method[3,10] and converted to the methanesulfonate **2** in 99% yield (Scheme 1). This compound was treated with HCl in MeOH–H_2O (7 : 1 v/v) to give the anomeric mixture of methyl furanosides **3** in 95% yield. Treatment with NaH gave the two isomeric bicyclic methyl furanosides **4** and **5** in 60 and 30% yield, respectively. The structures of the two products were verified using NMR experiments. Thus, mutual NOE contacts between H-1, H-2 and H-3 verified the α-configuration of **5** and the absence of NOE contacts between H-1 and H-3 verified the β-configuration of **4**. The coupling constants $^3J_{H1,H2}$ and $^3J_{H2,H3}$ were in both cases extremely small (~ 0 Hz) confirming the bicyclo[2.2.1]heptane structures. An attempt to use these bicyclic methyl furanosides as precursors for synthesis of LNA nucleosides failed. Thus, coupling of thymine to furanoside **4** using a modified Vorbrüggen methodology[11] [*N*,*O*-bis(trimethylsilyl)acetamide (BSA) and Me_3SiOTf in MeCN] afforded in 59% yield one major product which was assigned as the ring-opened derivative **6** existing as a mixture of diastereoisomers.[12] The considerable ring strain in the bicyclic structure is a plausible explanation for the favouring of the Lewis acid mediated ring-opening reaction over the cleavage of the anomeric bond.

As an attempt to overcome this problem, better leaving groups were introduced at the anomeric position (Scheme 1 and 2). In order to obtain a mixture of 1′-*O*-acetyl derivatives, methyl furanoside **4** (and/or **5**) was treated with 80% aq. AcOH to give a deprotected intermediate, which was subsequently acetylated. The latter reaction was slow and problematic giving a major product in only 23% yield, which was assigned as the pure β-anomer **7**. NMR spectra of the deprotected intermediate showed distinctive aldehyde signals suggesting ring strain and the predominance of the monocyclic intermediate **4a** to be responsible for the slow and low-yielding conversion to furanose **7**. Summarizing, the strategies depicted in Scheme 1 are not convenient for synthesis of the bicyclic nucleosides.

Thioglycosides have been intensively investigated for glycosylation reactions due to their ability to react with sulfur-specific electrophiles, thereby creating sulfonium cations readily displaced as leaving groups.[13,14] In the case of phenyl thioglycosides, there have been reports of nucleobase coupling reactions yielding natural as well as modified nucleosides.[15,16]



Scheme 1 *Reagents and conditions*: i, MsCl, pyridine; ii, 20% HCl in MeOH, H_2O; iii, NaH, DMF; iv, thymine, BSA, Me_3SiOTf, MeCN; v, 80% AcOH; vi, Ac_2O, pyridine; vii, Me_3SiSPh, Me_3SiOTf, CH_2Cl_2.



Scheme 2 *Reagents and conditions*: i, Ac_2O, pyridine; ii, Me_3SiSPh, Me_3SiOTf, CH_2Cl_2; iii, NH_3, MeOH, then NaH, DMF; iv, thymine, HMDS, then NBS, **11**, 4 Å molecular sieves, CH_2Cl_2; v, H_2, $Pd(OH)_2$/C, EtOH, CH_2Cl_2.

Furthermore, oxidized phenylsulfenyl glycosides have been used in glycosylations[17] and in nucleobase coupling reactions.[18,19] Thioglycosides have been obtained from *O*-glycosides,[13] but treatment of the bicyclic methyl furanoside **4** with Me_3SiSPh and Me_3SiOTf[13] gave the ring-opened dithioacetal derivative **8** in 61% yield (Scheme 1). However, after protection of the methyl furanoside **3** to give 2′-*O*-acetyl derivative **9** in 97% yield (Scheme 2), the β-thiofuranoside **10** was obtained in 66% yield using Me_3SiSPh and Me_3SiOTf (25% of starting material **9** was recovered). Only trace of the α-anomer of **10** was detected due to the expected anchimeric assistance from the 2′-*O*-acetyl group. The acetyl group was removed with methanolic ammonia and direct ring-closure was very efficiently performed using NaH affording phenyl 3,5-di-*O*-benzyl-2-*O*,4-*C*-methylene-β-D-ribofuranoside **11**‡ in 95% yield.

Condensation of the bicyclic phenyl thiofuranoside **11** with silylated thymine[20] using NBS as a thiophilic activator[13,16] gave an inseparable mixture of anomeric nucleosides **12** (α:β ~ 2:1) in 61% yield (or 100% yield based on the recovery of 39% starting material). This mixture was directly deprotected by hydrogenation to give the known β-LNA nucleoside **13** and its α-LNA nucleoside analogue **14**§ (in preliminary yields of 12 and 25%, respectively). The expected bicyclic structure of **14** was verified by mass spectrometry and NMR spectroscopy which revealed, as for **13**,[2,3,5] negligible $^3J_{H1',H2'}$ and $^3J_{H2',H3'}$ coupling constants (~0 Hz). Importantly, no ring-opening reactions were detected using this nucleobase coupling method taking advantage of the chemoselective cleavage of the anomeric bond by NBS.

A general bicyclic thioglycoside synthon **11** for nucleobase coupling reactions has been efficiently synthesized. The applicability of thiofuranoside **11** has been demonstrated by the synthesis of the known β-LNA nucleoside **13** and the first α-LNA nucleoside **14**, and analogous thioglycosides may prove useful for convergent syntheses of other constrained bicyclic nucleoside derivatives. The general use of **11** as a precursor for synthesis of α- and β-LNA nucleosides is currently under investigation.

The Danish Natural Science Research Council, The Danish Technical Research Council and Exiqon A/S, Denmark, are thanked for financial support.

Notes and references

† LNA is defined as an oligonucleotide (analogue) containing one or more monomeric LNA nucleosides. These LNA monomers are preorganized in a 3′-*endo* conformation as shown by X-ray crystallography (see ref. 5) and NMR studies (see ref. 2 and 3).

Received (in Cambridge, UK) 28th September 1998, Accepted 3rd November 1998

Isovalent substitution of Mn(II) for Mg(II) in the oxide ion conductor, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$, yields a new oxide ion conductor which exhibits an ionic conductivity (σ = 4.6 × 10^{-2} S cm^{-1} at 800 °C) that is comparable to the conductivity of the Mg(II) analogue; interestingly, the Mn(II) oxide has a lower activation energy for conduction (E_a = 0.47 eV) than the Mg(II) oxide.

The strontium- and magnesium-substituted lanthanum gallate perovskite, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{3-z}$ **I**, first reported by Ishihara *et al.*[1] has turned out to be an excellent oxide ion conductor[2] that promises to replace yttria-stabilized zirconia (YSZ) in solid oxide fuel cells (SOFCs) operating at relatively low temperatures (600–800 °C).[3,4] Besides providing an optimal concentration of oxide ion vacancies, the exact role of strontium and magnesium toward the high oxide ion conductivity of phase **I** is unclear at present. While it is known[1,5] that substitution of other cations (such as Ca, Ba, lanthanides) for La/Sr adversely affects the ionic conductivity of **I**, the effect of other divalent cations substituting for Mg(II) in **I** has, to our knowledge, not been investigated.† We considered that Mn(II) would be an effective replacement for Mg(II) in **I**, in view of its size‡ and stability under reducing conditions. Also a Mn(II)-derivative of **I** is likely to have a better compatibility as electrolyte material in SOFCs using $La_{1-x}Sr_xMnO_3$ (LSM) as cathode material.[6] Accordingly, we investigated Mn(II)-substituted derivatives of **I** having the general formula, $La_{1-x}Sr_xGa_{1-y}Mn_yO_{3-z}$ **II**, for several values of x and y. Since Mn(II) is not stable under the normal synthetic conditions employed for the preparation of **I**, we developed a special route for the synthesis of members of **II** that involves preparation of a higher valent Mn perovskite first, followed by its subsequent reduction to the Mn(II) phase in hydrogen. Stabilization of lower/unusual oxidation states of transition metals under reducing conditions has been reported for several perovskite-related oxides.[7] Typical examples are stabilization of Ni(I) in $LaNiO_2$, $YSr_5Ni_3O_8$ and $LaSrCr_xNi_{1-x}O_{4-y}$.

Our results, which are reported here, show that the Mn(II)-derivative of **I** is indeed an excellent oxide ion conductor whose conductivity (σ = 4.6 × 10^{-2} S cm^{-1} at 800 °C) is comparable to that of **I**, but with a lower activation energy E_a for conduction (E_a = 0.47 eV).

$La_{1-x}Sr_xGa_{1-y}Mn_yO_z$ **II** oxides were prepared for various values of x and y between $0 < x, y \leqslant 0.2$ by reacting dry La_2O_3, $SrCO_3$, Ga_2O_3 and $MnC_2O_4{\cdot}2H_2O$ in the required proportions at 1100 °C (12 h), 1400 °C (12 h) and 1450 °C (36 h) in air, with intermittent grindings. At the last stage, the samples were made into pellets (0.9 cm diameter and *ca.* 0.2 cm height) suitable for electrical conductivity measurements. Powder X-ray diffraction (XRD) patterns (Siemens-D5005 X-ray diffractometer, Cu-Kα radiation) revealed formation of nearly single-phase perovskite-like materials for x = 0.1; y = 0.2 (**IIa**) (Fig. 1) and x = 0.2; y = 0.2 (**IIb**). All the major reflections could be indexed on a rhombohedral perovskite cell, excepting the weak ones at $d \approx$ 3.15 and 2.98 Å. These impurity reflections, which are likely due to La_4SrO_7, are weaker in **IIa** than in **IIb** indicating that the composition of **IIa** is closer to a single-phase perovskite than **IIb**. This observation is consistent with the formation of a single-phase perovskite in the Mg(II) system for the composition $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$.[1,8–10]

Considering that manganese in these oxides would be in a higher oxidation state, we investigated reduction of **IIa** and **IIb** in a thermogravimetric (TG) balance (Cahn TG-131 system) in flowing hydrogen (10 ml min^{-1}). Reduction occurs in two stages (*ca.* 250 and 500 °C) with weight losses of 0.30 and 0.15% respectively. These weight losses are consistent with the compositions $La_{0.9}Sr_{0.1}Ga_{0.8}Mn_{0.2}O_{2.92}$ for **IIa** and $La_{0.9}Sr_{0.1}Ga_{0.8}Mn_{0.2}O_{2.85}$ for **IIIa**, where the oxidation state of manganese is Mn(II). The reduced sample (**IIIa**) is oxidized in air back to the original stoichiometry in a single step around 200 °C. Accordingly, the average oxidation state of manganese in the precursor oxide **IIa** is 2.7+, which would correspond to the formula $La_{0.9}Sr_{0.1}Ga^{III}_{0.8}Mn^{III}_{0.14}Mn^{II}_{0.06}O_{2.92}$. Powder XRD patterns show that the reduced materials retain the rhombohedral perovskite structure,§ albeit with a slight increase in the unit cell parameters (Table 1), that is consistent with the reduction of Mn(III) to Mn(II).

Ionic conductivity of both as-prepared (**IIa** and **IIb**) and hydrogen-reduced samples (**IIIa** and **IIIb**) was measured on sintered pellets coated with gold paste. Impedance data were obtained in air (as-prepared samples) or in flowing argon (reduced samples) at 100 Hz–15 MHz and 60–800 °C employing a HP4194A Impedance/Gain-Phase Analyzer interfaced with an IBM-PC. For each sample, measurement was made for at least two heating and cooling cycles. Impedance plots at low temperatures could be resolved into two semicircles corresponding to the bulk and grain-boundary contribu-

Reflections due to impurity phase are marked by asterisks.

Table 1 Chemical composition, lattice parameters and ionic conductivity data for $La_{1-x}Sr_xGa_{1-y}Mn_yO_z$ perovskites[a]

Composition	Lattice parameters[b]			$\sigma_{800\ °C}$/S cm^{-1}	E_a[c]/(eV)
	a/Å	c/Å	V/Å^3		
$La_{0.9}Sr_{0.1}Ga_{0.8}Mn_{0.2}O_{2.85}$ (**IIIa**)	5.524(2)	13.360(7)	353.0(2)	4.60×10^{-2}	0.47
$La_{0.8}Sr_{0.2}Ga_{0.8}Mn_{0.2}O_{2.80}$ (**IIIb**)	5.525(1)	13.381(1)	353.7(1)	3.00×10^{-2}	0.57
$La_{0.9}Sr_{0.1}Ga_{0.8}Mn_{0.2}O_{2.92}$ (**IIa**)	5.518(1)	13.335(4)	351.6(2)	3.03×10^{-2}	0.38
$La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$ (**I**)		[d]	358.14[e]	1.00×10^{-1}	1.07[f]

[a] For comparison, the data for $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$ **I** are also included. [b] Rhombohedral lattice parameters are given for the hexagonal setting. [c] 60–800 °C. [d] The lattice parameters of **I** are a = 7.816, b = 5.539, c = 5.515 Å, β = 90.06° (ref. 10). [e] Equivalent volume. [f] Data taken from ref. 2.

tions to the resistivity. We have uniformly obtained the conductivity from the low-frequency intercept of the impedance plots, that includes both bulk and grain-boundary contributions. Accordingly, the values quoted here would correspond to a lower estimate of the actual conductivity of the samples.

The Arrhenius plots of the conductivity of the **III**-series of oxides are shown in Fig. 2. The conductivity (σ) at 800 °C and the activation energy (E_a) values obtained from the Arrhenius plots are given in Table 1. We see that among the samples investigated, sample **IIIa**, which is the Mn(II) analog of the well known oxide ion conductor, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$, shows the highest conductivity of 4.6×10^{-2} S cm^{-1} at 800 °C. The corresponding conductivity for the Mg(II) oxide[2] is *ca.* 1.0×10^{-1} S cm^{-1} at 800 °C. The E_a value for the Mn(II) derivative (0.47 eV) is however significantly lower than the corresponding E_a for the Mg(II) oxide[2] (1.07 eV). Accordingly, we see that isovalent substitution of Mn(II) for Mg(II) in the oxide ion conductor, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$, produces a new oxide ion conductor whose conductivity is of the same order of magnitude as the Mg(II) parent oxide, but lowers the activation energy E_a. Interestingly, as-prepared samples (**IIa** and **IIb**) where manganese occurs in a mixed-valent state [Mn(II)/(III)] also exhibit considerable conductivity. Both ionic as well as electronic contributions to the conductivity most likely exist in these phases.

We have investigated the oxygen partial pressure dependence of the conductivity of the sample **IIIa**. The results show a slight increase in the conductivity at higher oxygen pressures [$p(O_2) > 10^{-8}$ atm], indicating the appearance of a p-type electronic contribution. We therefore believe that the conduction of the Mn(II) oxide reported here would be purely ionic only at low oxygen partial pressures [$p(O_2) < 10^{-10}$ atm].

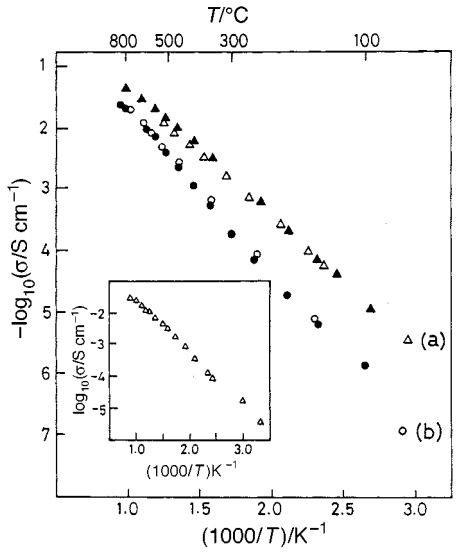

Fig. 2 Arrhenius plots for the electrical conductivity of (a) $La_{0.9}Sr_{0.1}Ga_{0.8}Mn_{0.2}O_{2.85}$ **IIIa** and (b) $La_{0.8}Sr_{0.2}Ga_{0.8}Mn_{0.2}O_{2.80}$ **IIIb**. Closed and open data points correspond to second heating and cooling cycles respectively. The data for sample **IIa** are shown in the insert.

In conclusion, we have shown that isovalent substitution of Mn(II) for Mg(II) in 'the most promising oxide ion conductor', $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{2.85}$ **I** yields a new oxide ion conductor exhibiting a comparable conductivity with a lower activation energy. The present work suggests that substitution of other divalent cations such as Co(II), Ni(II), Zn(II) and Cd(II) in **I** is worthy of exploration, especially to understand the role of ionic radius and electronic configuration in determining σ and E_a.

Influence of hemicyanine dye structures on spectral properties of their supramolecular complexes with amylose

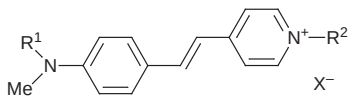
Received (in Columbia, MO, USA) 30th June 1998, Revised Manuscript Received 14th October 1998, Accepted 22nd October 1998

Hemicyanine chromophores bearing long-chain alkyl substitutents on the donor and/or acceptor ends have been prepared, and absorption and emission spectra of their supramolecular complexes with amylose have been studied in order to relate them to their supramolecular structures.

We have developed a novel strategy[1] based on supramolecular complexation of alkyl-substituted hemicyanine dyes (guest) by amylose (host). This not only prevents chromophore aggregation but also provides many added advantages such as improved thermal stability[2] and enhanced hyperpolarizabilty.[3] The unique feature of this system is the development of a supramolecular self-poling[4] in solution-cast thin films.

Since the guest dye fluoresces strongly in the inclusion,[1,5,6] the dye itself can be utilized as a probe to monitor the binding interaction with the host amylose, depending on external conditions such as temperature (thermochromism).[7] Hemicyanine dyes have also been studied as potential voltage-sensitive probes in biomembranes.[8,9] The dyes exhibit a negative solvatochromism,[10,11] in that spectral shifts of absorption and fluorescence, in response to the solvent polarity, occur to the blue and to the red, respectively. However, in lipid membranes, their spectral behavior is reversed, exhibiting a further blue-shift beyond the absorption in water. This is interpreted to be due to the differential solvation of the chromophore oriented in a lipid bilayer.[12] Here we discuss spectral properties of the supramolecular chromophores (which are uniaxially oriented in the host cavity) when they (dyes **1** and **2**) are mono-functionally



1 R^1 = Me, R^2 = $C_{16}H_{33}$, X = Br
2 R^1 = $C_{16}H_{33}$, R^2 = Me, X = I
3 R^1 = R^2 = $C_{16}H_{33}$, X = Br

derived by blocking one of the sensing partners (amino head and pyridinium tail) with a long alkyl chain and retaining (deactivating) it inside the cavity, thereby allowing the other unit to function for polar sensing. In this respect, one of the present hemicyanine–amylose supramolecules, which contains dye **2**, can be regarded as a model of the dye probe imbedded in the lipid bilayer. Spectral results are compared to demonstrate how the chromophore structure is reflected in the sensing activity of their supramolecular complex.

Visible absorption and emission spectra of dyes **1**–**3** in various DMSO–water mixtures (without amylose) reveal significantly different aggregation tendencies. While dye **1** exhibits negligible aggregation even at Φ_{DMSO} = 0.2, spectral data indicate that aggregation (*ca*. 420 nm) of dyes **2** and **3** occurs below Φ_{DMSO} = 0.55 and 0.75, respectively. This suggests that for the fixed alkyl chain length, substitution at the amine end of the chromophore (relative to the pyridinium end) has a greater influence on the overall hydrophobic character of the molecule.

The spectral properties of dyes **1**–**3** in DMSO-rich mixtures ($\Phi_{DMSO} \geqslant 0.75$) containing amylose† are nearly identical to those of comparable mixtures without amylose, since no inclusion (only free dye state) occurs even in the presence of amylose. However, significant differences due to the presence of amylose are observed as the Φ_{DMSO} of the solvent mixture is decreased. In particular, a dramatic enhancement of fluorescent emission (Fig. 1) is observed at $\Phi_{DMSO} \approx 0.6$ for all three dyes, indicative of supramolecular confinement of the chromophore by the helical amylose.[3] The greater fluorescence enhancement due to the inclusion complexation of dyes **2** and **3** relative to **1** presumably reflects stronger binding of more hydrophobic amino residue by amylose. For all three dyes, the full inclusion of amylose is attained at $\Phi_{DMSO} \approx 0.5$, as evidenced by the

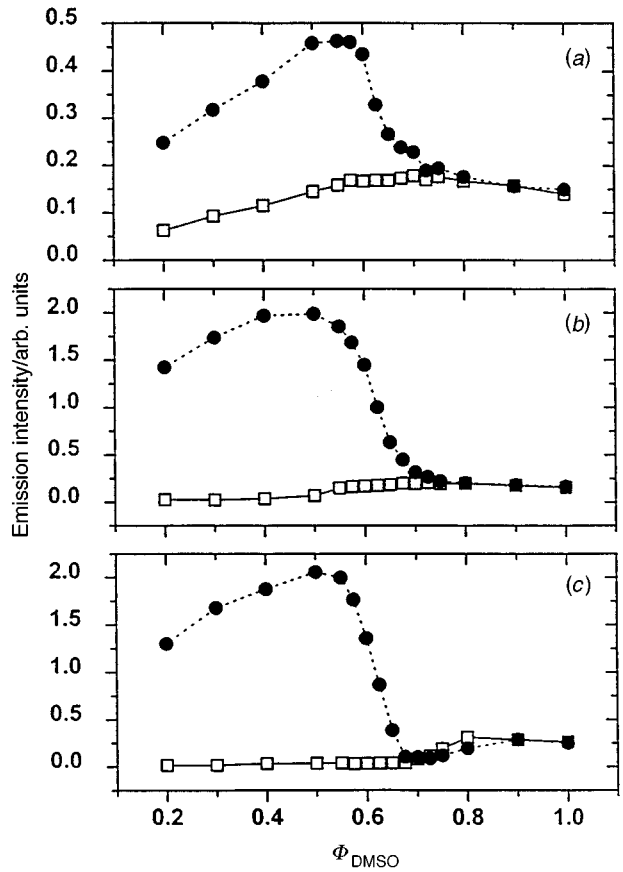


Fig. 1 Integrated fluorescence intensity (480–760 nm) *vs*. Φ_{DMSO} (volume fraction of DMSO) for dyes **1**–**3** in DMSO–H_2O mixtures with (●) and without (□) added amylose: (*a*) dye **1**, (*b*) dye **2** and (*c*) dye **3**. [Dye] = 1.5 × 10^{-5} M in all cases, and [Amylose] = 1.0 × 10^{-3} M for solutions containing amylose. Excitation wavelength = 425 nm.

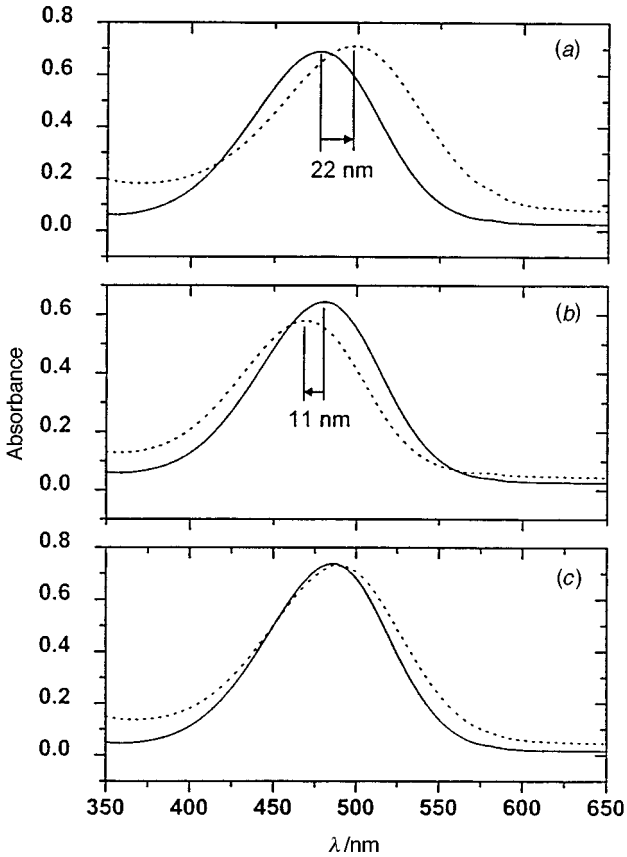

Fig. 2 Visible spectra of dyes **1**–**3** in the free state (—) compared with those of their inclusion complexes (···): (*a*) dye **1**, (*b*) dye **2** and (c) dye **3**. Free dye spectra were recorded at Φ_{DMSO} = 0.90. Spectra of included dyes were recorded at Φ_{DMSO} = 0.50, [amylose] = 1.0×10^{-3} M and [dye] = 1.5×10^{-5} M in all cases.

maximum fluorescence emission‡ of the supramolecular complex. The gradual decrease in emission intensity of the included dye in water-rich mixtures ($\Phi_{DMSO} < 0.50$) is not due to the separation of the dye from the amylose inclusion. It can be therefore attributed, as previously suggested,[3] to conformational changes (*i.e.* swelling) of the amylose helix induced by increasing the solvent polarity of the medium.

The characteristic free dye absorption (at *ca.* 475 nm) of dyes **1**–**3** undergoes a spectral shift (Fig. 2) upon complexation with amylose. This is associated with the difference in intramolecular charge-transfer (ICT) transitions between the free dye state and the inclusion state. The ICT band-shifts due to the complexation of the dyes (**1**–**3**), which are determined by comparing visible spectra of each dye in the fully-included and free (unincluded) states, differ in both magnitude and direction, depending on the dye structure. In view of the fluorescence results (*vide supra*), a fully-included dye can be represented by the spectra recorded at Φ_{DMSO} = 0.5 in the presence of amylose. However, it is difficult for dyes **2** and **3** to represent the free dye state in the spectra recorded under identical solvent condition (Φ_{DMSO} = 0.5), due to aggregation of the dyes. Alternatively, the free state of each dye can be best represented by its spectrum recorded at Φ_{DMSO} = 0.90, where no aggregation occurs even in the presence of amylose (mentioned above).

Thus, as shown in Fig. 2, complexation of dye **1** induces a 22 nm red-shift, but a 11 nm blue-shift is observed upon the complexation of dye **2** under comparable conditions. In contrast, the visible λ_{max} for the inclusion state of dye **3** is red-shifted by only 3 nm relative to the free dye. For dye **1**, the position of the alkyl substituent ensures that the charged pyridinium group resides completely within the nonpolar host cavity in the inclusion state. Exclusion of the pyridinium moiety from solvent contact results in the red-shift in visible absorption of the included dye relative to the free dye in this case. In contrast, inclusion of dye **2** confines the alkyl-substituted amino donor in the host cavity, while the pyridinium cation end resides near the edge of the host, being in contact with the bulk solvent polarity. This situation leads to a blue shifting of the absorption band. The common feature in both cases is that the local environment of the sensing units (amino donor and pyridinium acceptor) is differentiated by inclusion formation. Unlike the case of dyes **1** and **2**, both the donor and acceptor moieties of dye **3** are confined in the same environment in the inclusion. This situation seems to have little influence on the ICT in the excited state, leading to a negligible spectral shift.

In solutions of non-inclusion free dye, both the donor-head and acceptor-tail of dye molecules are exposed to a homogeneous environment. The fact that hemicyanine dyes exhibit negative solvatochromism (blue-shift of λ_{max} with increasing solvent polarity)[10,11,13] and that charge-shift occurs in the chromophore by excitation, suggests that the ground state is more stable than the excited state, and that the pyridinium cation in the ground state has a greater influence on the spectral shift relative to the neutral amino donor in the excited state. The opposite spectral shifts of the supramolecules can therefore be interpreted as being due to the fact that, when the pyridinium cation is exposed to a polar environment (dye **2** case), the ground state has a stronger influence on ICT, whereas when it is disposed in a nonpolar environment (dye **1** case), the excited state has a stronger influence on ICT. Accordingly, the spectral behavior of the present amylose–hemicyanine supramolecular complex bearing dye **2** shows a close resemblance of the membrane-embedded case, *i.e.* blue shifts in both absorption and fluorescence spectra relative to the free molecular state.

In summary, the direction of absorption band-shift upon inclusion of amphiphilic hemicyanine dyes by amylose has been related to the dye structure. This is interpreted in terms of the difference in local environments surrounding the sensing units of the chromophore in the inclusion. The charged pyridinium (acceptor) group, being more strongly influenced by the environmental polarity, plays a dominant role in determining the ICT band shift.

Notes and references

† A low molecular weight (4500 D) amylose (Aldrich) was used for a 1:1 complexation (ref. 1) with the dyes, except for dye **3** with which a 2:1 complexation seems to be more favorable.

‡ The emission band shift due to the inclusion is significant and the direction of the shift depends on the dye structure; the shift of dye **1** is to the red and that of dye **2** to the blue. A minor band shift occurs between different Φ_{DMSO} regions.

Enantiomerically pure 1,3,2-dioxaborolanes: new reagents for the hydroboration of alkynes

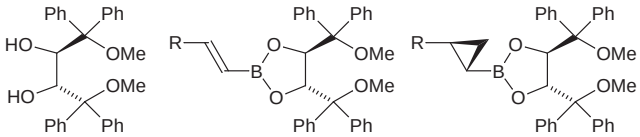
Joachim E. A. Luithle, Jörg Pietruszka* and Andreas Witt

Institut für Organische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70569 Stuttgart, Germany. E-mail: joerg.pietruszka@po.uni-stuttgart.de

Received (in Liverpool, UK) 14th September 1998, Accepted 26th October 1998

Stable, enantiomerically pure alkenylboronic esters 2 are conveniently prepared by direct hydroboration employing the new 1,3,2-dioxaborolane 4; their highly diastereoselective cyclopropanation can be achieved.

Alkyl- and alkenyl-boronic esters are versatile intermediates in organic syntheses, readily available *via* several well established routes.[1] Arguably, the direct hydroborations of alkenes and alkynes using either catechol-[2] or pinacolborane[3] are the most straightforward method to accomplish their preparation. However, the products are frequently water-sensitive[2] or thermolabile[4] and as such they are not always easy to handle, purify and store. Recently, we reported on the high stability of boronates formed by the condensation of alkenylboronic acids with diol **1**,[5] which was conveniently synthesized from dimethyl tartrate.[6] The cyclopropanation of alkenylboronic ester **2** with CH_2N_2 (Pd^{II} catalyzed) was a high yielding process giving readily separable cyclopropylboronic esters **3**, albeit the diastereomeric ratio was low.[5]

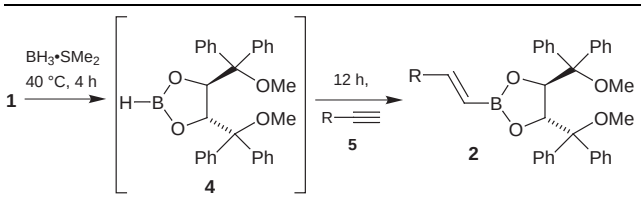


1 **2** **3**

In order to improve the overall efficiency of these reactions, we were not only interested in increasing the selectivity of the cyclopropanation, but especially in omitting the somewhat laborious sequence of alkyne hydroboration, hydrolysis and condensation to give **2**.[3,7] In addition, boroxine formation[5b,8] and their sluggish reaction with diol **1** made us look for alternatives. We envisaged a direct hydroboration with a chiral hydroborating reagent. Although several attempts to make use of, for example, pinanediol failed in the past,[3,9] we were encouraged by the findings of Knochel *et al*. who utilized pinacolborane under exceptionally mild conditions.[3]

The preparation of the hydroborating reagent **4** was straightforward (Table 1). On the other hand, hydroboration of alkyne **5** with **4** did not occur either at room temperature, or in refluxing CH_2Cl_2. After hydrolysis, 1-hydroxy-1,3,2-dioxaborolane **6** was the only isolated product, whose structure was unequivocally determined by X-ray crystallography† after recrystallization from MeOH (formation of ester **7**; Fig. 1). It was established that the desired hydroboration could be achieved to give **2** by heating the alkyne **5** with **4** neat at higher temperature (120 °C).‡ The stable alkenylboronic ester **2a** was directly crystallized† from the reaction mixture (Fig. 2). Only traces of a regioisomer (< 1%) could be detected. It proved advantageous to use two equivalents of alkynes in cases where the starting materials, *e.g*. **5b**,**c**, have relatively low boiling points and consequently the reaction temperatures needed to be decreased (90 °C). This was probably also the reason for the failure of all attempts to hydroborate 3,3-dimethylbutyne **5d**. Protected propargyl alcohols are valuable starting materials that were also successfully employed in this sequence. Both, *tert*-butyldiphenylsilyl (TBDPS) and *tert*-butyldimethylsilyl (TBDMS) protected alcohols **5e**,**f** gave microanalytically pure esters **2e**,**f** in good yield (66–83%). Increasing the reaction temperature, which is compatible with high-boiling compounds like **5g**, not only decreased the reaction time, but also allowed for better yields.

Table 1 Synthesis of highly stable alkenylboronic esters **2** *via* direct hydroboration using the new reagent **4**



Compound	R	*T*/°C	Yield of **2** (%)
a	Ph	120	82
b	n-C_5H_{11}	90	68
c	Bu^n	90	70
d	Bu^t	40–90	—
e	$TBDPSOCH_2$	120	66
f	$TBDMSOCH_2$	120	70
g	$TBDPSO(CH_2)_3$	135	83

The following experiments proved that this method is rather general. (1*R*,2*R*,3*S*,5*R*)-Pinanediol[9] and (*R*)-1,1,2-triphenyl-

Fig. **2** Molecular structure of **2a**.

ethane-1,2-diol[10] furnished the corresponding alkenylboronic esters **8** and **9** in good yield (81 and 67%), respectively. Diastereoselective cyclopropanation using CH_2N_2 and $Pd(OAc)_2$ yielding cyclopropanes **10** and **11** was also possible (> 95%), however, the diastereomeric ratio was relatively low (Fig. 2; major diastereomers shown).§ Furthermore, we observed that ester **11** slowly hydrolyzes on silica. While cyclopropane **10** is perfectly stable under these conditions, separation of diastereomers cannot yet be achieved. Under the same, now optimized conditions (0 °C, slow addition and 5–10 mol% catalyst), we obtained cyclopropanes **3a** and **3b** in superior selectivity (86:14 and 93:7) as white solids that were easily separable from their diastereomers (> 95%).

The reason for the good selectivity is not well understood. Examining the X-ray structures of compounds **2a** and **7** (Fig. 1 and 2), it is obvious that the conformation of the 1,3,2-dioxaborolane rings with the bulky substituents is in both cases very similar, efficiently blocking three quadrants. This should also be true for the reactive conformation and consequently one face of attack should be favoured.

In summary, we have demonstrated that direct hydroboration with chiral hydroborating reagents leads to enantiomerically pure, highly stable alkenylboronic esters. These building blocks should prove versatile for a plethora of further transformations, *e.g*. cycloaddition reactions. We have shown that cyclopropanation can easily be achieved in excellent yield and good diastereomeric ratio. This short sequence furnishing enantiomerically pure cyclopropylboronic esters should allow access to a variety of different stereochemically homogeneous 1,2-disubstituted cyclopropanes utilizing the vast synthetic potential of boronic esters.[1,5]

Financial support by the Fonds der Chemischen Industrie (doctoral fellowship for J. E. A. L. and Liebig fellowship for J. P.) and the Deutschen Forschungsgemeinschaft (fellowship for J. P.) is gratefully acknowledged. We also thank the Institut für Organische Chemie der Universität Stuttgart (Professor Dr F. Effenberger and Professor Dr V. Jäger), Dr W. Frey for performing the X-ray crystal structure analyses, and Degussa AG (Hanau) and Boehringer Ingelheim KG (Biberach) for their ongoing support.

Refined by full-matrix least-squares on F^2 for all data weights to R = 0.057, wR = 0.094, S = 1.067, H atoms riding, max. shift/error 0.001, residual ρ_{max} = 0.117 e Å^{-3}.

For **7**: $C_{31}H_{31}BO_5$, M_r = 494.4, colourless, crystal size 0.5 × 0.5 × 0.35 mm, a = 11.839(2), b = 8.6176(9), c = 13.7172(11) Å, β = 110.526(8)°, U = 1310.7(3) Å^3, T = 293 K, monoclinic, space group $P2_1$, Z = 2, D_c = 1.253 mg m^{-3}, μ = 0.083 mm^{-1}. 3197 measured reflections, 3054 independent reflections. Refined by full-matrix least-squares on F^2 for all data weights to R = 0.050, wR = 0.095, S = 1.043, H atoms riding, max. shift/error 0.001, residual ρ_{max} = 0.216 e Å^{-3}. CCDC 182/1066.

‡ Procedure for alkenylboronic ester **2a** is representative: Diol **2** (4.55 g, 10.0 mmol) was carefully dried at 50 °C under reduced pressure for 1 h. Under an atmosphere of nitrogen, CH_2Cl_2 (5 cm^3) was added and the solution cooled to 0 °C. $BH_3{\cdot}SMe_2$ (1.2 cm^3, 12 mmol, 10 M in SMe_2) was added dropwise with vigorous stirring, followed by refluxing the mixture for 4 h. The solvent was removed, the reagent cooled to 0 °C and alkyne **5a** (2.2 cm^3, 20 mmol) slowly added. The flask was closed with a septum, slowly heated to 120 °C and kept at this temperature for 12 h. After cooling to room temperature usual work-up and purification under standard conditions followed [ref. 5(*a*)]. Alternatively, the product **2a** could be directly crystallized (MeOH–light petroleum) from the resulting oil, furnishing a colourless solid (1.90 g, 3.40 mmol, 34%). From the remaining mother liquor additional product **2a** (2.70 g, 4.80 mmol, 48%) was obtained after chromatography (silica, eluent: Et_2O–pentane, 1:6). All spectra were in agreement with published data [ref. 5(*a*)].

§ Diastereomeric ratios of cyclopropylboronic esters were determined by ^{1}H NMR analysis using a Bruker ARX-500 spectrometer. Conversion to cyclopropanols with known configuration allowed the unambiguous stereochemical assignment of the cyclopropanes [ref. 5(*a*)].

Received (in Cambridge, UK) 29th September 1998, Accepted 30th October 1998

In the templated aluminophosphate, DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$, the water molecules mediate the template–layer interaction: through a molecular dynamics simulation of the water molecule dynamics we have assigned the librational modes of water in the inelastic neutron scattering spectrum to motions of water molecules in three different environments.

In chemical self-assembly molecular sub-units spontaneously form supramolecular frameworks. For zeolites and microporous aluminium phosphates self-assembly is achieved using organic molecules and coordination compounds as structure directing templates.[1] Recently the use of chiral cobalt complexes in directed synthesis of layered aluminophosphates (ALPOs) has been described. One such ALPO is DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$,† which consists of ALPO layers with $[Co(en)_3]^{3+}$ cations and water molecules in the interlayer region.[2] We are currently investigating the nature of the interactions between the templating cations, the water molecules and the ALPO layers. A question of current interest is whether the interlayer water molecules have a structural role. Water is known to play an important role in biological self assembly, for example by stabilising biopolymer conformations through hydrogen bonding:[3] may water similarly mediate interaction between the templating $[Co(en)_3]^{3+}$ cation and the ALPO layer? Although X-ray crystallography located the oxygen atoms of the interlayer water molecules in our templated ALPO the positions of the hydrogen atoms could only be inferred. We now describe how a combination of inelastic neutron scattering (INS) and molecular dynamics (MD) simulations has revealed the location and hydrogen bonding interactions of the water molecules. The water molecules, which have a structural role in the interlayer region, occupy three different sites.

INS spectra of the templated ALPO, DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$, and the templating complex, $[Co(en)_3]Cl_3$, both hydrated ($2H_2O$) and anhydrous, were recorded on the TFXA spectrometer at the Rutherford Appleton Laboratory ISIS facility.[4] The compounds (10 g) in aluminium foil sachets were measured at 20 K over energy transfers in the range 16–4000 cm^{-1}. Molecular dynamics calculations were carried out on the templated compound using the program DL_POLY.[5] Initial coordinates were taken from the X-ray crystal structure.[1] The force-field for interactions within the ALPO layers was adapted from van Beest *et al.*[6–8] while for the templating cation, $[Co(en)_3]^{3+}$, we used Lennard-Jones (12–6) atomic potentials with CHARMM parameters[9] supplemented with partial charges calculated using DGauss; water was modelled with the SPC potential.[10] Previously we had validated this force-field in simulations of $[Co(tn)_3]Al_3(PO_4)_4{\cdot}2H_2O$.[11]†

We focus on the librational motions of the water molecules, which occur in the region 250–1000 cm^{-1}. The calculated density of states, $G(\omega)$, was obtained as the Fourier transform of the auto-correlation function $\langle \boldsymbol{v}_a(0){\cdot}\boldsymbol{v}_a(t)\rangle$ of velocities $\boldsymbol{v}_a(t)$ for atoms α,

$$G(\omega) = \frac{1}{N}\sum_{\alpha}\frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-i\omega t}\langle \boldsymbol{v}_\alpha(0)\cdot\boldsymbol{v}_\alpha(t)\rangle \mathrm{d}t$$

where ω is frequency.[12] Experimentally, the density of states is weighted by the scattering cross sections of the atoms and so is completely dominated by hydrogen atom motions; thus calculations of $G(\omega)$ are reported only for α = hydrogen.

The INS spectra of DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$, $[Co(en)_3]Cl_3$ and $[Co(en)_3]Cl_3{\cdot}2H_2O$ are shown in Fig. 1. The main features of these spectra arise from H atoms, associated with either ethylenediamine ligands or water molecules. Bands arising from ethylenediamine, Fig. 1, were found to be coincident in all three spectra. Thus the experimental spectrum for water in the hydrated AlPO was obtained by subtracting the $[Co(en)_3]Cl_3$ spectrum from the templated ALPO, DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$ (with intensities normalised to the ethylenediamine peak at 320 cm^{-1}). This spectrum is presented in Fig. 2 along with a smoothed spectrum obtained by Gaussian deconvolution of the experimental difference spectrum; peak positions are listed in Table 1.

In Fig. 2 we also show the vibrational density of states for water calculated from our molecular dynamics simulations. There is a good correlation between the experimental and calculated spectra. Both exhibit one broad and three sharp peaks, and the positions of the latter are in good agreement. The main discrepancy is that the broad peak is harder to resolve in the experimental spectrum, and this subsequently affects the comparison of relative intensities, so it has been considered as a single feature. We conclude that the simulations reproduce the essential features of the experiment, and so enable a more detailed assignment of these peaks from the simulated motions of the water molecules.

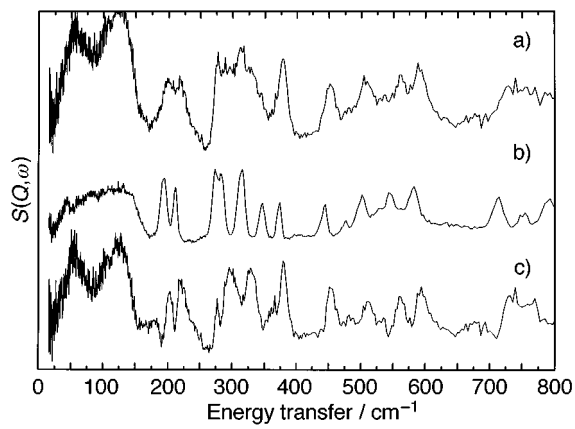

Fig. 1 Experimental INS spectra, (a) templated ALPO DL-$[Co(en)_3]Al_3(PO_4)_4{\cdot}3H_2O$, (b) dehydrated template $[Co(en)_3]Cl_3$ and (c) the hydrated template $[Co(en)_3]Cl_3{\cdot}2H_2O$.

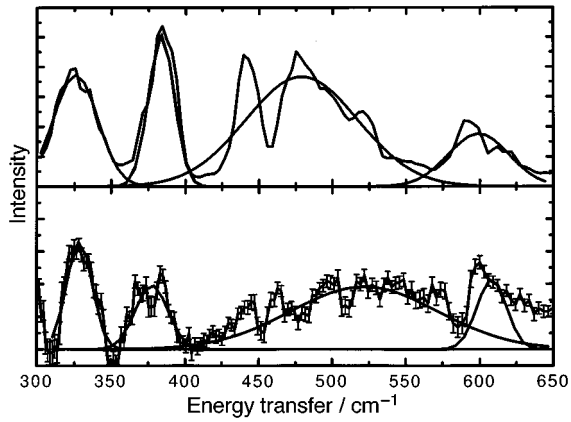

Fig. 2 Calculated (top) and experimental (bottom) difference spectra in the 300–650 cm^{-1} region. Gaussians are indicated to show the four major peaks.

Table 1 Experimental and calculated INS frequencies and relative intensities for $300 < \omega < 650$ cm^{-1}. Peak intensities have also been decomposed into contributions from the three principal librational modes, see Fig. 3

Experiment		Simulation				
				Fractional contribution to intensity[a]		
Frequency/ cm^{-1}	Relative intensity[a]	Frequency/ cm^{-1}	Relative intensity[a]	ω_x	ω_y	ω_z
328	0.16	326	0.19	0.00	0.05	0.95
376	0.13	387	0.18	0.24	0.04	0.72
400–575	0.51	420–550	0.50	0.34	0.02	0.64
599	0.20	599	0.13	1.00	0.00	0.00

[a] Integrated area under the peak.

To obtain a detailed assignment of the water frequencies, the calculated spectrum has been decomposed into contributions from librations about the three principal molecular axes (defined in Fig. 3). From Table 1 it can be seen that the density of states is dominated by librations around the *x* and *z* axes, with no intensity in the *y*-axis librations. All three components do exhibit three separate peaks, indicating three distinct environments for the water molecules. The main features of the broad peak exhibit a more complex structure in the experiment as well as in the simulation.

Our simulation of the structure of DL-$[Co(en)_3]Al_3(PO_4)_4 \cdot 3H_2O$ in comparison with the INS spectrum has revealed three different environments for the three water molecules. By combining our analysis of the experimental INS spectrum and molecular dynamics simulations we are able to locate the water molecules, in particular the hydrogen atoms, in a way not possible from the X-ray structure alone. These results now open up the possibility of identifying how water mediated interactions between the AlPO layers and the templating cation determine the structure of the layered solid.

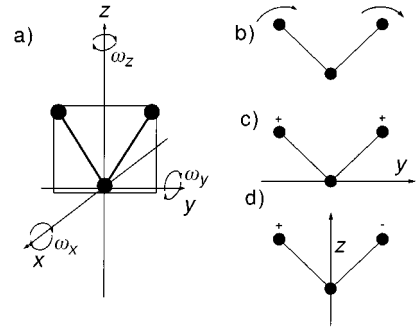

Fig. 3 Three principal rotational/librational modes for water.

Electroactive dendritic π-conjugated oligothienylenevinylenes

Isabelle Jestin, Eric Levillain and Jean Roncali*

Ingénierie Moléculaire et Matériaux Organiques, CNRS UMR 6501, Université d'Angers, 2 Bd Lavoisier, 49045 Angers, France. E-mail: jean.roncali@univ-angers.fr

Received (in Cambridge, UK) 7th October 1998, Accepted 30th October 1998

Electroactive π-conjugated oligothienylenevinylenes end-capped with dendritic branches of generation one to three have been synthesized.

Thienylenevinylene oligomers (*n*TVs) have recently emerged as a new class of extensively π-conjugated systems.[1] Whereas at a molecular level *n*TVs are interesting models of molecular wires, they also open interesting potentialities as advanced materials for electronic and photonic applications. Progress in these areas implies a supramolecular control of interchain interactions in order to develop at will either compact materials with high electron mobility or, in contrast, single molecular wires.

We report here the synthesis of monodisperse electroactive *n*TVs end-capped with dendritic chains[2] and preliminary results on their electrochemical behavior. Previous examples of incorporation of linear π-conjugated systems within dendritic structures involved dendrimers with poly(*p*-phenylene)[3] and oligotriacetylenes[4] cores.

In order to analyze the effect of progressive steric shielding of the *n*TV system, Fréchet type dendrons[5] of generation 1, 2 and 3 have been attached at both ends of a tetrathienylenevinylene (4TV) derived from 3,4-dihexylthiophene to afford the target compounds **1–3**. While the construction of dendrons from 1-trifluoromethyl-4-bromomethylbenzene **5** is based on the Fréchet type convergent approach,[5] the originality of our strategy lies in the conversion of each generation of dendron into a phosphonate (**Gn-W**) with final assembly of the target system *via* a two-fold Wittig–Horner olefination of dialdehyde **4** with phosphonates **G1-W**, **G2-W** and **G3-W** (Scheme 1).

Reaction between **5** and 3,5-dihydroxybenzyl alcohol in the presence of K_2CO_3 and 18-crown-6 afforded the benzylic alcohol of the first generation (**G1-OH**) which was then converted into the bromomethyl derivative (**G1-Br**) by reaction with PBr_3. Repetition of the procedure followed by re-crystallization at each step gave successively **G2-Br** and **G3-Br** in high yields. Reaction of **G1-Br** and **G2-Br** with diethyl phosphite in the presence of NaH led to phosphonates **G1-W** and **G2-W** while **G3-W** was prepared by reaction of **G3-Br** with phosphite (yields ⩾ 90%). Compounds **1–3** were obtained in 50–60% yield by double Wittig–Horner olefination of dialdehyde **4** with phosphonates **G*n*-W**. The target compounds were fully characterized by ^1H and ^{13}C NMR analyses, elemental analyses, FAB and MALDI-TOF mass spectroscopies.†

Compounds **1–3** exhibit identical UV–VIS spectra with λ_{max} at 542 nm and ε_{max} = 100000. Owing to the extension of the conjugation length by the grafting of two styryl groups, these values are larger than those for the 4TV core and are close to those for 6TV.[1] All spectra exhibit a well-resolved vibronic fine structure which indicates that the increase of **G*n*** does not alter the planarity and rigidity of the π-conjugated backbone.

Compounds **1–3** show identical cyclic voltammograms (CV) with two reversible one-electron oxidation waves corresponding to the formation of the cation radical and dication at redox potentials $E°_1$and $E°_2$ of 0.53 and 0.65 V (Fig. 1). Both $E°_1$and $E°_2$ values were fully independent of **G*n***. Furthermore, the linear dependence of the intensity of the first anodic peak of compound **3** *vs*. the square root of scan rate between 25 and 5000 mV s^{-1} shows that the charge-transfer process between

the electrode and the core electrophore is not subject to kinetic limitation. This behavior contrasts with that of redox active metal centers encapsulated in dentridic structures for which the increase of **G*n*** leads to a progressive decrease of the reversibility of the oxidation and/or reduction process and to a positive and/or negative shift of the corresponding potential.[6] The independence of the electroactivity of the π-conjugated system on **G*n*** observed here may be related to the length of the electrophore which prevents complete steric burial within the dendritic structure. We also observed that the $E°_1$ value for **3** was independent of substrate concentration in the range of 5 10^{-5} to 5 10^{-3} M. This result is consistent with an absence of follow-up reaction of the cation radical such as formation of a π-dimer;[7] however, this hypothesis needs further confirmation.

Work is now underway to extend this approach to longer *n*TVs and to analyze in more detail the effects of the dendritic branches on inter-chain interactions.

Received (in Cambridge, UK) 10th September 1998, Accepted 19th October 1998

The solid-phase synthesis of asymmetric oligothiophenes on a chloromethylated macroporous resin, using an alternating sequence of bromination and Stille coupling reactions, has been used to afford oligomers up to the pentamer in excellent yield and purity.

Polythiophenes[1] and the related oligothiophenes[2] have received considerable attention due to their interesting optical and electronic properties, as well as their high environmental stability both in the neutral and oxidized state. Unfortunately, the coupling reactions used to prepare oligothiophenes (*i.e.* Kumada, Stille, Suzuki and Negishi)[3] are plagued by undesirable side-reactions such as homocoupling and loss of functionalization, thus making the purification and isolation of pure oligomers in high yield a difficult task. The pioneering work of Merrifield in the area of solid-phase synthesis has provided the synthetic chemist with a powerful tool for the rapid and frequently automated synthesis of oligomeric organic compounds.[4] Solid-phase synthesis is ideal for multi-step syntheses[4–6] since the isolation of intermediates is not required, and rapid purification is easily achieved by simply washing impurities and excess reagents away from the insoluble polymeric support.

Most of the published work employing organometallic cross-coupling reactions on solid supports has focused on one-step syntheses leading to simple bis-aryl or vinyl-aryl compounds.[7] Palladium mediated cross-couplings such as the Heck, Stille and Suzuki reactions have become increasingly important for the solid-phase synthesis of clinically useful compounds.[8] Recently, palladium catalyzed cross-coupling reactions have been employed[9] independently by Moore and Tour to prepare phenylacetylene oligomers on solid support. Herein, we report the first solid phase synthesis of oligothiophenes in which an alternating sequence of bromination and Stille coupling reactions provides an efficient, high-yielding synthesis of oligothiophenes from the dimer to the pentamer with excellent purity.

The solid phase synthesis is depicted in Scheme 1. The 2,2′-bithiophene-5-carboxylic acid moiety **1** was bound to a macroporous Merrifield-type chloromethylated resin using a standard nucleophilic displacement of the resin's benzylic chloride in DMF.[10] While gel resins, in their swollen state, are generally more reactive than their macroporous counterparts, the latter have a more rigid structure with permanent pores that allows their use in almost any solvent and may facilitate reactions involving ionic or sparingly soluble species. Therefore, the high crosslink density/constant-porosity of the macroporous resin is expected to render it less susceptible to both fouling by low solubility by-products and potential side reactions such as homocoupling that may accompany the coupling step. Such side-reactions would increase the cross-linking of a gel resin, limiting both swelling and reaction conversion, while also reducing the ability to wash out any trapped impurities. The use of a macroporous resin also allows relatively high resin loadings while minimizing[10b,11] the potential for the site–site interactions that would lead to attachment to multiple sites.[12] A macroporous resin, Argopore-Cl, with Merrifield-type $ClCH_2$ functionality at a loading level of 1.03 mequiv. Cl g^{-1} met our needs. The extent of loading of **1** determined by cleavage of the dimer from the support using NaOMe in THF was 0.73 mequiv. g^{-1} suggesting that 84% of the sites of the starting resin had been functionalized to **2**. The coupling step itself was readily monitored by FT-IR spectroscopy as the CH_2Cl peak at 1265 cm^{-1} disappeared while a new peak at 1712 cm^{-1} corresponding to the bound bithiophene ester **2** appeared. Bromination of **2** at the terminal α-position using excess NBS in DMF, followed by coupling to 2-(trimethylstannyl)-4-octylthiophene[13] using $Pd(PPh_3)_2Cl_2$ in DMF as the catalyst afforded the resin-bound trimer **4**. A systematic study involving the coupling step followed by cleavage and quantitative analysis of the product showed that a minimum of 4 equiv. of stannane is required to maximize the conversion of the dimer bromide **3** to the trimer. The monobromination of **4** to the trimer bromide **5** using NBS in DMF was only accomplished in high yield when a stoichiometric amount of NBS was used. The use of an excess of NBS leads to a dibromination product, as confirmed by EI-MS and HPLC analysis of the product isolated after cleavage from the resin. ^{1}H NMR analysis of the cleaved product suggests that the second bromine atom is introduced into the thiophene ring and not at the allylic position of the octyl chain. Attempts at monitoring the bromination on solid support by FT-IR proved fruitless as bands characteristic

Table 1. Purity and yield of methyl ester oligothiophenes cleaved from the resin

Entry	Oligomer	HPLC purity[a] (% yield)
1	Dimer **2e**	98
2	Dimer bromide **3e**	97
3	Trimer **4e**	95
4	Trimer bromide **5e**	95
5	Tetramer **6e**	93
6	Tetramer bromide **7e**	95
7	Pentamer **8e**	89 (90)[b]

[a] Reverse phase HPLC analysis was performed by UV–VIS spectroscopy at 254 nm using THF–ACN as the eluant. [b] The acid/ester cleavage product was converted exclusively to the ester *in situ* by treatment with 18-C-6 and MeI. Loading of the linker was determined by cleavage (0.73 mequiv. g^{-1}). Yield of **8e** (from **2**) is based on the theoretical loading of **8** (0.486 mequiv. g^{-1}) itself calculated assuming quantitative conversion at every step from **2** to **8**.

of the transformations are located in the fingerprint region and thus overlap with strong resin background absorbance. Reaction of trimer bromide **5** with 2-(trimethylstannyl)-4-octylthiophene in DMF using $Pd(PPh_3)_2Cl_2$ as the catalyst afforded the resin-bound tetramer **6**. A final iteration involving successive activation and coupling steps finally afforded the resin bound pentamer **8**. All of the above reactions were performed without stirring since the Argopore macroporous resins are very fragile and are readily ground to a fine powder if magnetic stirring is used. Destruction of the resin beads makes handling difficult and leads to losses since resin fragments can make their way through the filter during work-up.

Cleavage from the resin can be accomplished at any stage in the synthesis, using NaOMe in THF,[10c] to afford the cleaved oligomer as a mixture of the methyl ester and a lesser amount of the sodium carboxylate product. In typical control experiments, 100–200 mg aliquots of the resins were subjected to cleavage and the resulting methyl ester dissolved in CH_2Cl_2 was isolated by filtration through silica prior to analysis by reverse phase HPLC. Entries 1–7 in Table 1 represent a sequence in which the synthesis of the pentamer was monitored at each step through HPLC analysis of the cleaved ester products. Although this HPLC analysis only allows an evaluation of the purity of the cleaved ester product, our findings clearly suggest that all reactions reached a high level of conversion. To accurately measure the yield of pentamer **8e,** the cleaved product mixture (ester and carboxylate) was treated with MeI under phase transfer conditions with 18-crown-6 to ensure conversion of the sodium carboxylate fraction to its methyl ester derivative. This transformation is conveniently accomplished directly as part of the cleavage step even while the resin is still present. After washing the resin with THF, CH_2Cl_2 and MeOH, concentration of the organic phase *in vacuo*, and filtration of the CH_2Cl_2 solution through a short silica plug, pentamer **8e** was isolated in 90% yield and in high purity as assessed by HPLC, ^1H NMR and elemental analysis.[14] This high yield of pentamer is remarkable considering that both the activation and coupling steps are susceptible to side reactions and that no purification, other than a simple filtration, was done after each of the six steps.

Oligothiophene syntheses are notorious for the need of extensive chromatographic purification and the *ease* of purification with the solid-phase protocol is clearly an advantage over the traditional solution phase purification methods. This solid-phase synthesis approach, affording easy access to oligomeric materials, complements our recently demonstrated[13] solution-phase fragment coupling approach in which brominated asymmetric building blocks can be used to prepare longer symmetric oligothiophenes in a single step. Finally, it should be noted that cleavage from the resin affords oligomers with a functional handle that may be exploited later to attach the oligomers to a variety of substrates in order to exploit their intrinsic properties or to impart such properties as enhanced solubility and/or novel optical and electronic properties.[13]

Financial support of this research by the AFOSR MURI program and partial support by NSF (DMR- 9796106) is gratefully acknowledged. Stimulating discussions with Dr Lambertus Groenendaal and the gift of Argopore-Cl resin from Argonaut Technologies Inc. are also acknowledged with thanks.

Solvent control in the formation of mononuclear and dinuclear double-helical silver(I)-2,2′:6′,2″-terpyridine complexes

Gerhard Baum,[b] Edwin C. Constable,*[a] Dieter Fenske[b] Catherine E. Housecroft[a] and Torsten Kulke[a]

[a] *Institut für Anorganische Chemie, Spitalstrasse 51, CH-4056 Basel, Switzerland. E-mail: constable@ubaclu.unibas.ch*

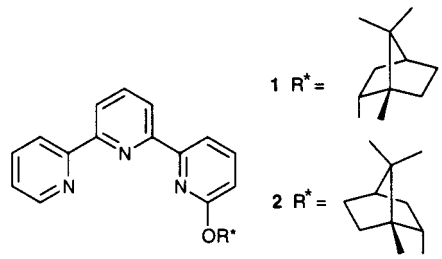
Received (in Cambridge, UK) 17th September 1998, Accepted 2nd November 1998

The coordination behaviour of chiral 2,2′:6′,2″-terpyridines with silver(I) is solvent dependent; in acetonitrile, mononuclear [Ag(L)(MeCN)]$^+$ complexes are formed, whereas in less coordinating solvents such as methanol or nitromethane, solid state tetranuclear bis(double helices) [{Ag_2L_2}$_2$]$^{4+}$ are obtained.

It is well established that oligopyridines and related ligands form helicates with a variety of metal centres.[1–3] Although copper(I) forms dinuclear double-helicates with 2,2′:6′,2″-terpyridines (tpy),[4,5] we have been unable to isolate analogous silver(I) species.[6] To date, the only oligopyridine system for which solution equilibria between {ML}$_n$ species have been established involves 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridines and cobalt(II).[7] In the course of our studies on chiral helicates[5,8] we have revisited the 2,2′:6′,2″–terpyridine–silver(I) system and now show that both mononuclear and dinuclear double-helical species may be isolated and that the equilibrium between mono- and dinuclear species is solvent dependent.



The chiral ligands 1*S*-(−)-**1** and 1*R*-(+)-**2** (L)[8] reacted with Ag(O_2CMe) in MeOH to give colourless solutions from which white solids were precipitated by the addition of [NH_4][PF_6]. Both solutions and solids were photosensitive and turned yellow and then brown upon several hours exposure to sunlight. The electrospray mass spectra of these solids in MeOH or MeCOMe exhibited peaks assigned to {AgL}, {AgL_2} and {$Ag_2L_2(PF_6)$} whereas in acetonitrile, predominantly mononuclear species were observed. Recrystallisation from MeOH, $MeNO_2$ or MeCN gave solids with a 1 : 1 ratio of silver to L but which were qualitatively and quantitatively different. The ^{1}H NMR spectra of solutions of these solids were solvent dependent, although identical spectra were obtained in a given solvent for both crude and recrystallised materials. Reversible changes occurred upon adding CD_3CN to CD_3OD solutions. The magnitude of these changes suggested that different chemical species might be present in solvents of varying donor ability and the spectra in acetonitrile resembled those of the known [Ag(tpy)(MeCN)]$^+$.[6]

The ligands are chiral and CD spectroscopy proved useful. In [Ag(L)(MeCN)]$^+$, the only source of chirality is the ligand and the CD spectra of MeCN solutions of any of the solids are compatible with this formulation; the spectra exhibit $\Delta\varepsilon$ values of ± 2 mol^{-1} l cm^{-1} {$[\alpha]_D$ (MeCN) = ± 60°, $[M]_D$ (MeCN) = ± 420°}, similar to those of the free ligands and with equal and opposite responses for **1** and **2** compounds. We have previously shown that related dicopper(I) double helicates are formed with good diastereoselectivity for the *P* or *M* helicates and have CD responses with characteristic bands at 320 nm allowing the assignment of *P* or *M* helical chirality.[5,8,9] Solutions in MeOH or $MeNO_2$ of the crystals obtained from $MeNO_2$ showed equal and opposite responses at 329 nm {$\Delta\varepsilon$ ± 20 mol^{-1} l cm^{-1}; $[\alpha]_D$ = ± 200°; $[M]_D$ = ± 2530°} for the compounds derived from **1** and **2**; addition of MeCN to the MeOH solution resulted in a decrease in the CD response and eventually the development of the same spectrum as observed for pure MeCN solutions (Fig. 1). Similar changes were observed upon adding MeOH to MeCN solutions. On the basis of these observations we propose the formation of mononuclear [Ag(L)(MeCN)]$^+$ species in MeCN but of double-helical complexes in $MeNO_2$ and MeOH; the sign of the CD response at 329 nm[5,8,10] and the observation of only a single solution species by NMR in MeOH suggest diastereoselective formation of *M*-[Ag_2(**1**)$_2$]$^{2+}$ and *P*-[Ag_2(**2**)$_2$]$^{2+}$.

The recrystallisation of silver(I) complexes of simple 2,2′:6′,2″-terpyridines from MeCN leads to solvento species [Ag(L)(MeCN)]$^+$ [6] and this proved also to be the case with **1**. Fig. 2(a) shows the molecular structure of one of the two mononuclear [Ag(**1**)(MeCN)]$^+$ cations present in [Ag(**1**)(MeCN)][PF_6]·Et_2O. The silver is four coordinate and bonded to the three nitrogen donors of **1** and an acetonitrile molecule; the coordination geometry is distorted square planar and the silver lies 0.13–0.15 Å out of the plane defined by the three tpy nitrogen donors and the acetonitrile nitrogen donor lies 0.51–0.66 Å from this plane. The planar cations are stacked within the lattice [Fig. 2(b)] with a zigzag arrangement of silver centres (Ag···Ag = 5.277, 5.577 Å) resulting in efficient π-stacking of the tpy domains. The zigzag structure results in π-bonding interactions between silver and the central ring of the tpy in the adjacent cations to give a sandwich structure (Ag···centroid, 3.646, 3.514 Å).

X-Ray quality crystals of the product formed in $MeNO_2$ were obtained by the diffusion of Et_2O into an MeCOMe solution. The crystal structure of one of the cations found in the solid state

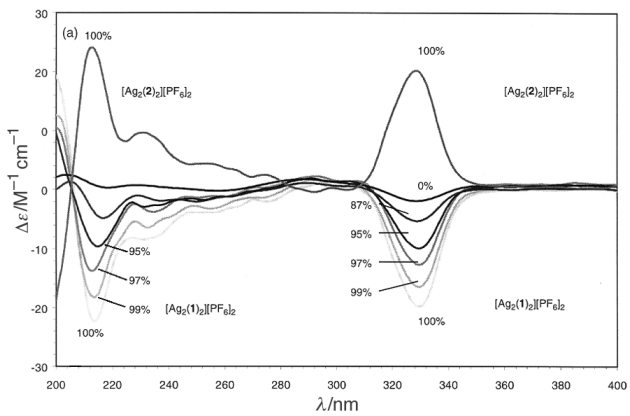


Fig. 1 CD spectra of MeOH solutions of the complexes formed with **2** and **1** and the effect of adding MeCN to the complex with **1**.

in the compound $[Ag_2(\mathbf{1})_2][PF_6]_2\cdot$MeCOMe is presented in Fig. 3. Firstly, a disilver head-to-head double helicate is present with Ag···Ag distances of 2.914–2.940 Å. Each silver is effectively two coordinate with short Ag–N bonds (2.146–2.616 Å) to terminal pyridine rings of each of two ligands and two longer Ag···N contacts to the central rings (3.1–3.2 Å). However, the structure is rather more complex; each of the double helicates forms a short (3.107, 3.156 Å) tail-to-tail Ag···Ag contact with a second dinuclear unit to give a tetranuclear unit. Each of the dinuclear subunits possesses the same helical chirality (both *M* in the case of Fig. 3). The tail-to-tail arrangement results in π-stacking of the terminal pyridine rings of the two dinuclear subunits (3.669–3.783 Å).

As discussed above, solution measurements indicated diastereoselective formation of *M*-$[Ag_2(\mathbf{1})_2]^{2+}$ and *P*-$[Ag_2(\mathbf{2})_2]^{2+}$ helicates; however, in the solid state, there are two tetranuclear

units within the lattice, one of which has two *P* and the other two *M* helicates as dinuclear subunits–a diastereomeric excess of 0%! This illustrates the subtlety of the interactions controlling stereoselectivity in helicates. Although the formation of the tetranuclear units can be understood in terms of the favourable stacking and Ag···Ag interactions, the formation of both*P* and *M* helices in the solid state (but not in solution) is unexpected. A similar observation has been reported for mononuclear complexes[10] and it appears to be a consequence of a low energy barrier for the interconversion of diastereomers combined with crystal packing effects of the same order as the energy difference between the diastereomers. There are no short contacts between chiral substituents of adjacent tetranuclear subunits.

In conclusion, we have now established that silver(I) behaves in a similar manner to copper(I) and forms double helical complexes with tpy ligands. However, the tendency for the formation of Ag···Ag interactions results in a subsequent aggregation process to give tetranuclear species.

We should like to thank the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung and the University of Basel for support.

Divergent assembly of a starburst tetracosacobalt compound

Edwin C. Constable,* Oliver Eich, Catherine E. Housecroft* and Lesley A. Johnston

Institut für Anorganische Chemie, Universität Basel, Spitalstrasse 51, CH-4056 Basel, Switzerland.
E-mail: housecroft@ubaclu.unibas.ch

Received (in Cambridge, UK) 8th October 1998, Accepted 30th October 1998

The syntheses of $C[\{p\text{-}C_6H_4C{\equiv}C\}_nH]_4$ (n = 1,2,3) and their reactions with $Co_2(CO)_8$ have led to the formation of starburst molecules with rigid, cluster-containing arms; up to twelve cluster units have been incorporated.

We are currently developing synthetic strategies for the preparation of monodispersed dendritic and starburst molecules containing metal centres,[1–3] with a view to developing novel materials. Here, we report initial studies on the synthesis of metal-rich species containing low oxidation state carbonyl clusters with precise spatial distribution. We hope to use molecules of this type, which exhibit distinct onion-like shells of 'organic' and 'inorganic' components, for the formation of metal oxide nanospheres with precise dimensions.

Very recently, there has been active interest in the use of multifunctional alkynes containing 1,3,5-triethynylbenzene

cores as building blocks for starburst systems.[4–7] Here, we focus on multifunctional alkynes radiating from a tetrahedral carbon centre; the compound $C(p\text{-}C_6H_4I)_4$[8] has previously been recognised as a precursor for the assembly of nanostructures such as organometallic tripodaphyrins.[9,10] We report here the reaction of alkynes **1**–**3**, (prepared by a divergent strategy), with dicobalt octacarbonyl to give starburst molecules **4**–**6** which possess rigid, cluster-containing arms. The synthetic procedure may be extended to allow the incorporation of any desired number of alkyne substituents. Reactions between alkynes and $Co_2(CO)_8$ are well established, and provide a useful means of entry into this novel area.[11–13] More recently, Diederich and coworkers have shown that cyclic systems containing $\{C_2Co_2(CO)_6\}$ units are stabilised with respect to the corresponding polyalkynes.[14,15]

Compound **1** was prepared as previously reported,[8–10] and reaction of **1** with an excess of $Co_2(CO)_8$ gave **4** as a brown solid in 46% isolated yield after chromatographic purification.† The IR spectrum showed the expected absorptions in the carbonyl region. In the ^{1}H NMR spectrum, the change in the chemical shift of the alkyne proton from δ 3.06 in **1** to δ 6.37 in **4** was consistent with the incorporation of the RC≡CH group into a $Co_2(CO)_6$(RCCH) cluster unit. Both the ^{1}H and ^{13}C NMR spectra were in accord with a symmetrical product, *i.e.* reaction of all four alkyne functionalities with $Co_2(CO)_8$ and this was supported by the observation in the MALDI-TOF mass spectrum of a parent ion corresponding to **4**.

Systematic growth of each polyyne chain from the carbon core of **1** was achieved‡ by sequential divergent reaction as shown in Scheme 1. Compounds **2** and **3** were characterised by NMR spectroscopy and mass spectrometry. Reaction of each alkyne generation with an excess of $Co_2(CO)_8$ (Scheme 2) gave moderately good yields of compounds **5** and **6**.§ The spectroscopic data for **5** and **6**, and mass spectrometric data for **6** (no parent ion could be obtained for **5**) were fully in accord with cluster formation at each of the alkyne functionalities of the respective precursors. ^{13}C NMR chemical shift correlations across the series of compounds **1**–**6** provided additional support for their formulation. A schematic representation of compound **6** is given in Fig. 1. In going from **3** to **6**, each carbon incorporated into a Co_2C_2-cluster core undergoes a change in local geometry and the C_{ring}–$C_{cluster}$–$C_{cluster}$–C_{ring} is no longer linear. Crystallographic determinations of [1,4-$\{Co_2(CO)_6CHC\}_2C_6H_4$][16] and $[Co_2(CO)_6C_2Ph_2]$[17] show the C_{ring}–$C_{cluster}$–$C_{cluster}$ angles to be *ca.* 140°. We estimate from molecular modelling studies that the radius of compound **6** is in the range 1.6–2 nm.

We are currently extending these studies to higher generations and to the oxidative degradation of the compounds.

This work was supported by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung, the University of Sydney (Eleanor Sophia Wood Travel Scholarship, L. A. J.), and the University of Basel. We thank Dr W. Amrein (ETH, Zürich) for obtaining mass spectrometric data for **4**.

Notes and references

† **4**: Alkyne **1** (19 mg, 0.046 mmol) and $Co_2(CO)_8$ (94 mg, 0.27 mmol) were stirred in CH_2Cl_2 (or acetone) for 1 h, the solvent removed, and the residue purified by column chromatography [SiO_2, hexane:CH_2Cl_2 (1 : 1)] to give a dark brown solid (33 mg, 46%). IR ($CHCl_3$, cm^{-1}) ν_{CO} 2092s, 2057vs, 2027vs. ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.44 (d, 8H, *J* 8.1 Hz), 7.22 (d, 8H, *J* 8.1 Hz), 6.37 (s, 4H); ^{13}C NMR (101 MHz, $CDCl_3$) δ 199.4 (CO), 145.8, 135.5, 131.4, 129.5, 89.5 ($C_{cluster}$), 73.0 ($C_{cluster}$), 64.9 (C_{quat}); MS (MALDI-TOF) *m/z* 1532 $[M - CO]^+$.

‡ **2**: Alkyne **1** (83 mg, 0.20 mmol), *p*-$IC_6H_4C{\equiv}CSiMe_3$ (251 mg, 0.837 mmol), CuI (15 mg, 0.080 mmol) and $[(PPh_3)_2PdCl_2]$ (56 mg, 0.080 mmol) were stirred in dry, degassed NEt_3 (10 ml) under argon for 42 h at 41 °C. Chromatographic work-up [alumina, hexane–CH_2Cl_2 (4 : 1)] gave the TMS-protected intermediate as a yellow crystalline solid; it was dissolved in THF (30 ml), and 1 M NaOH (30 ml) added; the solution was stirred for 1 h at room temperature. Water was added and after extraction with CH_2Cl_2, the residue was purified by column chromatography [SiO_2, hexane–CH_2Cl_2 (1:1)] to give a yellow crystalline product (107 mg, 66 %). ^{1}H NMR (250 MHz, $CDCl_3$) δ 7.47–7.43 (m, 24H), 7.20 (d, 8H, *J* 8.3 Hz), 3.18 (s, 4H); ^{13}C NMR (63 MHz, $CDCl_3$) δ 146.1, 132.1, 131.5, 131.2, 130.9, 123.6, 122.0, 121.1, 90.9 (C_{alkyne}), 89.3 (C_{alkyne}), 83.3 (C_{alkyne}), 78.9 (C_{alkyne}), 65.0 (C_{quat}); MS (MALDI-TOF) *m/z* 816 $[M]^+$, 614 $[M - 2C_6H_4CCH]^+$, 413 $[M - 4C_6H_4CCH]^+$.

3: Alkyne **2** (47 mg, 0.058 mmol), *p*-$IC_6H_4C{\equiv}CSiMe_3$ (72.5 mg, 0.242 mmol), CuI (4.4 mg, 0.023 mmol) and $[(PPh_3)_2PdCl_2]$ (16.2 mg, 0.023 mmol) were stirred in dry, degassed NEt_3 (5 ml) under argon for 12 h at 35 °C. Work-up similar to that for **2** gave a white crystalline solid (37 mg, 53 %). ^{1}H NMR (250 MHz, $CDCl_3$) δ 7.50–7.44 (m, 40H), 7.22 (d, 8H, *J* 8.3 Hz), 3.18 (s, 4H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 146.1, 132.1, 131.6, 131.5, 131.2, 130.9, 123.5, 123.3, 122.1, 121.2, 91.0 (C_{alkyne}), 90.9 (C_{alkyne}), 90.7 (C_{alkyne}), 89.6 (C_{alkyne}), 83.2 (C_{alkyne}), 79.0 (C_{alkyne}), 65.0 (C_{quat}); MS (MALDI-TOF) 1217 $[M]^+$, 915 $[M - \{C_6H_4C_2\}_3H]^+$, 613 $[M - 2\{C_6H_4C_2\}_3H]^+$.

Stereocontrolled synthesis and reactivity of sugar acetylenes

Minoru Isobe,† Rena Nishizawa, Seijiro Hosokawa and Toshio Nishikawa

Laboratory of Organic Chemistry, School of Bioagricultural Sciences, Nagoya University, Chikusa, Nagoya 464-8601, Japan. E-mail: isobem@agr.nagoya-u.ac.jp

Received (in Cambridge, UK) 29th June 1998, Accepted 17th August 1998

C-Glycosidation is of great significance in the organic synthesis of optically active materials, since it allows the introduction of carbon chains to sugar chirons and the use of sugar nuclei as a chiral pool as well as a carbon source. Silylacetylenes are sufficiently reactive to form 'sugar acetylenes' for the selective introduction of various acetylenic groups in an *alpha-axial* manner at the anomeric position of D-hexopyranose rings. 1,4-*Anti* induction, on the other hand, gives a different stereochemical outcome in the case of C-glycosidation of pentopyranose glycals. The mechanism of these reactions includes oxonium cation intermediates in which stereoelectronic and/or steric factors drive the direction of the incoming silylacetylene. Bis-C-glycosidation allows the introduction of sugars at both ends of some bis(trimethylsilyl)acetylenes. A 2,3-dideoxyglucose derivative provides the corresponding C-1 α-acetylenic compounds, which would increase the scope of C-glycosidation with silylacetylenes. In sugar acetylenes, the alkynyl group at the anomeric position of a pyranose ring is epimerized *via* a hexacarbonyldicobalt complex by treatment with trifluoromethanesulfonic acid. The three steps—cobalt complexation, acidic transformation and decomplexation—afford overall epimerization and thus one can obtain either the α- or β-alkynyl C-glycoside as desired. Ring opening of a dihydropyran derivative using Nicholas-type cation intermediates is also part of this study. Several sets of decomplexation conditions for *endo*-type acetylene–cobalt complexes provide various olefins possessing potential utility for synthesis. These methodologies have been utilized for the synthesis of polyoxygenated natural products and derivatives.

Introduction

In target-orientated synthesis, continuous efforts have provided organic chemistry with a considerable number of new synthetic methodologies. These include new concepts for multistep syntheses that achieve the desired target in a more straightforward manner. Syntheses of optically active natural products have posed many problems despite there being numerous methodologies available to the organic chemist. Sugars have been used as chirons as well as carbon sources in many organic syntheses.[1] The induction of one or more stereogenic centers onto a side chain extending from a sugar ring is another application which has attracted much attention.[2] We have designed and developed C-glycosidation (alkynylation) as a key reaction for the introduction of a carbon chain onto sugars. Those alkynylated compounds are called 'sugar acetylenes' for short,[3] and they have been applied to syntheses of natural products such as tautomycin[4] and ciguatoxin.[5]

Professor Minoru Isobe was born in Nagoya, educated in Nagoya and found his academic position in Nagoya University. He received his PhD degree with Professor Toshio Goto (silkworm diapause hormone) in 1973, and moved to Columbia University in New York as a postdoctoral researcher under the guidance of Professor Gilbert Stork (Prostaglandin F_2a). He was appointed an Associate Professor (1975–1991) in Professor Goto's group after Dr Yoshito Kishi left for Harvard University, and then Professor of Organic Chemistry (1991). His synthetic interests have mostly focused on the total synthesis of natural products, such as vernolepin, maytansine, okadaic acid, tautomycin and allo-yohimbane, and he is currently involved in the total synthesis of tetrodotoxin, ciguatoxin etc. *He has expanded his interests in bioorganic chemistry into the fields of bioluminescence, insect diapause, protein phosphatase inhibitors* etc. *and into those mechanistic elucidation processes including the counter proteins. He has received awards from the Agricultural Chemical Society for young chemists in 1980 and from the Society of Synthetic Organic Chemistry, Japan in 1996. He is currently a project leader at JSPS-RFTF.*

Rena Nishizawa was born in Osaka, Japan, in 1974. She received her BS degree from Nagoya University in 1997 and is currently an MS student under the supervision of Professor Minoru Isobe at the School of Bioagricultural Sciences of Nagoya University, involved in the study on the chemistry of C-glycosidation.

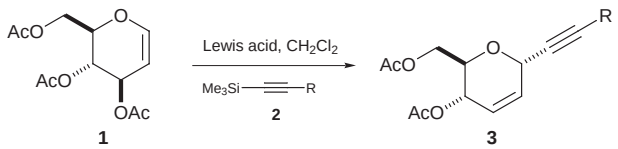
Dr Seijiro Hosokawa was born in Kurashiki, Japan, in 1968. He received his BS and MS degrees from Hokkaido University under the supervision of Professor Haruhisa Shirahama, and his PhD from Nagoya University under the supervision of Professor Minoru Isobe in 1996. After a year of postdoctoral research at Nagoya University and an additional one year at the Scripps Research Institute under the supervision of Professor K. C. Nicolaou, he became an Assistant Professor of Chemistry in 1998 in the Faculty of Pharmaceutical Sciences, Science University of Tokyo. His research interests include organic synthesis and bioorganic chemistry.

Dr Toshio Nishikawa was born in Nagano, Japan, in 1962. He received his BS degree in 1985 from Shizuoka University under the direction of Professor Daisuke Uemura and his MS degree in 1987 from Nagoya University. After spending time as a research associate at the research institute of the Sapporo Brewery Company (1987–1988), he returned to Nagoya University and received his PhD in 1995 from the same University under the supervision of Professor Minoru Isobe. Currently he is an Assistant Professor in the School of Bioagricultural Sciences at Nagoya University. His research interests include the development of new synthetic methods and the organic synthesis of nitrogen-containing natural products for the elucidation of biological problems.

C-Glycosidation with silylacetylene

During the course of our synthetic studies on okadaic acid,[6] an oxygenated marine natural product, we used the Hosomi–Sakurai reaction for the coupling of allyltrimethylsilane and tri-*O*-acetyl-D-glucal to prepare one of the starting materials.[7] We came across with a similar C-glycosidation under acidic conditions with silylacetylenes instead of allylsilane (R = $SiMe_3$).[8] The stereoselectivity of this reaction is excellent, giving only the α-acetylene, and is better than that in the allylsilane case (α:β = 96:4). C-Glycosidation with silylacetylenes allows a wide variety of substituents on the other end of the acetylene, and the resulting alkynylated sugar derivatives are of great potential utility as starting materials for natural product synthesis in optically active form.[9] Examples with different substituents are listed in Table 1.[8–10] In the reaction, R

Table 1 Alkynylation of tri-*O*-acetyl-D-glucal with silylacetylenes



Entry	R	Lewis acid	*T*/°C	Yield (%)
1	H	$TiCl_4$	0	0
2	Me	$SnCl_4$	−15	99
3	$SiMe_3$	$TiCl_4$	−20	75
4	$SiMe_3$	$SnCl_4$	−20	99
5	Bu^n	$TiCl_4$	−20	68
6	CH_2SPh	$TiCl_4$	−20	15
7	CH_2OAc	$TiCl_4$	−20	0
8	$(CH_2)_2OAc$	$TiCl_4$	−20	22
9	$(CH_2)_3OAc$	$TiCl_4$	−20	36
10	$(CH_2)_4OAc$	$TiCl_4$	−20	59

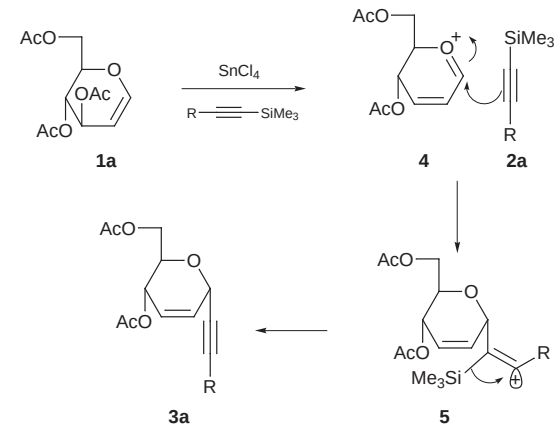
has to be larger than Me to afford alkynylation in reasonably good yield. The yield with R = H (entry 1) is almost 0%.[10a] On the other hand, the stronger Lewis acid $SnCl_4$ seems to work better than $TiCl_4$ in the case of R = $SiMe_3$ (entries 3 and 4). When R is a methylene group with an OAc moiety at the terminal position, *e.g.* the reaction with prop-2-ynyl acetate (entry 7), no alkynylated product is given. The yields of products increase with the higher homologous acetates (entry 8–10). This is due to the moderating effect of the methylene group(s) on the OAc moiety, which destabilizes the cationic transition state. These results suggest that the mechanism of this alkynylation reaction involves cationic charge development at the 2′-carbon in the transition state. In case of the phenylthio group (R = SPh, discussed later), the product is unstable with the stronger acids, and high yield is observed only with milder Lewis acid such as $BF_3{\cdot}OEt_2$; the nucleophilicity of (phenylthio)silylacetylene is high enough to yield the phenylthioethynylation product in good yield.[11]

Possible mechanism of C-glycosidation and proof of stereochemistry

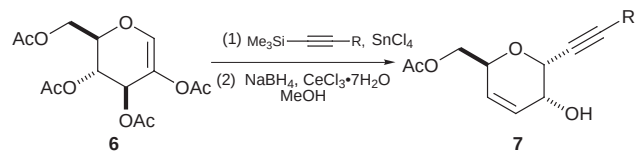
This C-glycosidation includes eliminative formation of the enonium ion (as shown in Scheme 1) to which silylacetylene can coordinate from the α side. The stereochemistry should largely be determined by the coordination between two π-electron orbitals of the onium and acetylene groups, while the stereoelectronic control allows the α-pseudo-axial orbital to make the bond, as shown in Fig. 1.

In 2,3,4,6-tetra-*O*-acetyl-D-glucal the C-glycosidation took place in a similar fashion to that in the tri-*O*-acetyl-D-glucal cases above with silylacetylenes (Scheme 2).[9] In this particular reaction, as shown in **8** and **9** (Scheme 3), the primary products are all unstable under the work-up conditions and/or silica gel chromatography. The reaction mixture is immediately subjected to hydride reduction ($NaBH_4$ and $CeCl_3$ in MeOH; or $LiAlH_4$, < −40 °C), in which the reagent accelerates elimination of the 4-OAc group (**8**) and then attacks the resultant ketone from opposite side of the *axially* oriented α-alkynyl group, thus giving a 2α-hydroxy group.

Incidentally, reduction with $LiAlH_4$ at higher temperature (*ca*. 0 to −10 °C) is usually followed by hydroalumination of the acetylene **8**, resulting in the formation of *trans* olefin **10**. The acetylene group in **3** can be partially reduced into *cis* olefin **11** with diimide (Fig. 2). These partial reduction products give NOEs in their NMR spectra between H-5 and H-1′ to prove the



Scheme 1



Scheme 2

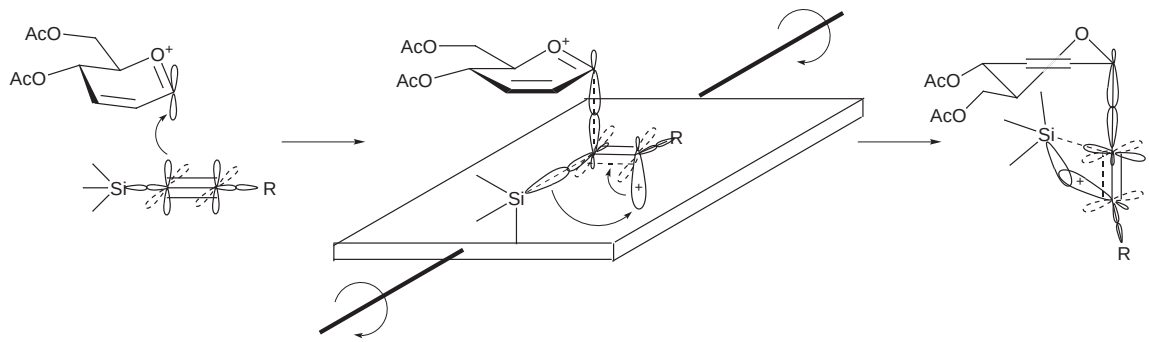


Fig. 1

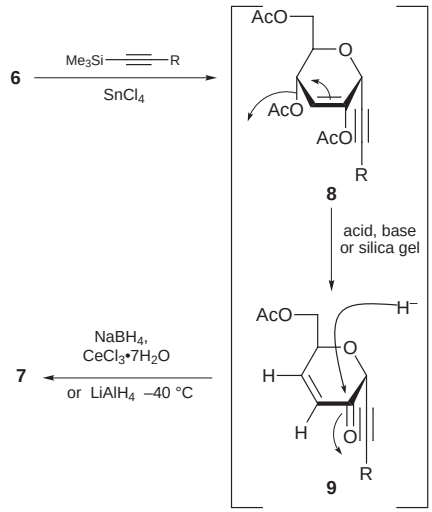

Scheme 3

α stereochemistry of the original acetylene (Fig. 2).[9] Hydrosilylation of the benzylidene acetylene **21** (in Scheme 4) also gives two products (**12a** and **13a**), providing further evidence for the stereochemistry; thus, similar NOEs are observed. These benzylidene compounds have the bulky olefinic group in the α axial position in **12** or the α equatorial position in **13**, the latter showing an NOE between H-1 and H-4 due to the boat conformation of the tetrahydropyran ring.

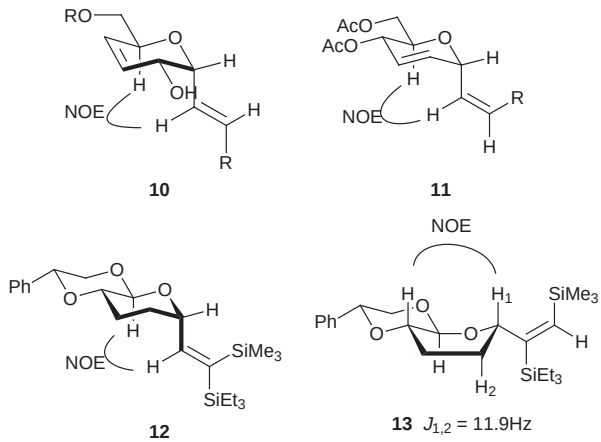

Fig. 2

Expansion of C-glycosidation to similar systems

In Table 2 other examples of C-glycosidation of 2,3-dideoxyglucose derivative **14** with silylacetylene are shown. The acetylation of the glycoside is critical to provide the C-1 leaving group which generates the oxonium ion, with which silyl acetylenes can react to form the α sugar acetylene. Scheme 4 illustrates the preparation of these compounds in order to prove the stereochemistry, and includes C-glycosidation of the saturated pyran ring. In this case the C-1 OAc group in **14** is necessary to provide a good leaving group, to generate the oxonium cation **17** to which the silylacetylene coordinates. After conversion to the corresponding 4,6-benzylidene derivative **21**, its acetylene group was subjected to hydrosilylation to provide a mixture of regioisomers **12a** and **13a**.[12]

Table 2 C-glycosidation of 2,3-dideoxyglucose derivative **14** with silylacetylene **15**

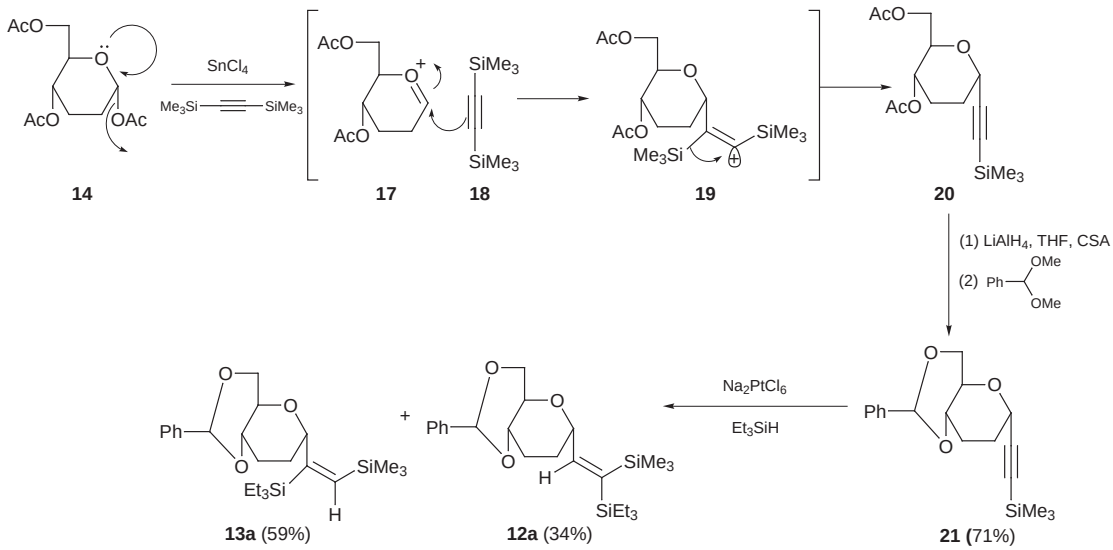
Sugars at both ends of an acetylene

In the C-glycosidation of silylacetylenes with glucal type compounds, both of the examples in Schemes 1 and 2 afford different sugar products (R = $SiMe_3$) bearing trimethylsilylacetylene moieties, respectively. But these silylacetylenes do not react further with another equivalent of glycal. This lack of reactivity is observed for prop-2-ynyl acetate (entry 7, Table 1); thus no double C-glycosidation product was obtained in this particular case, presumably due to the presence of an electron-



Scheme 4

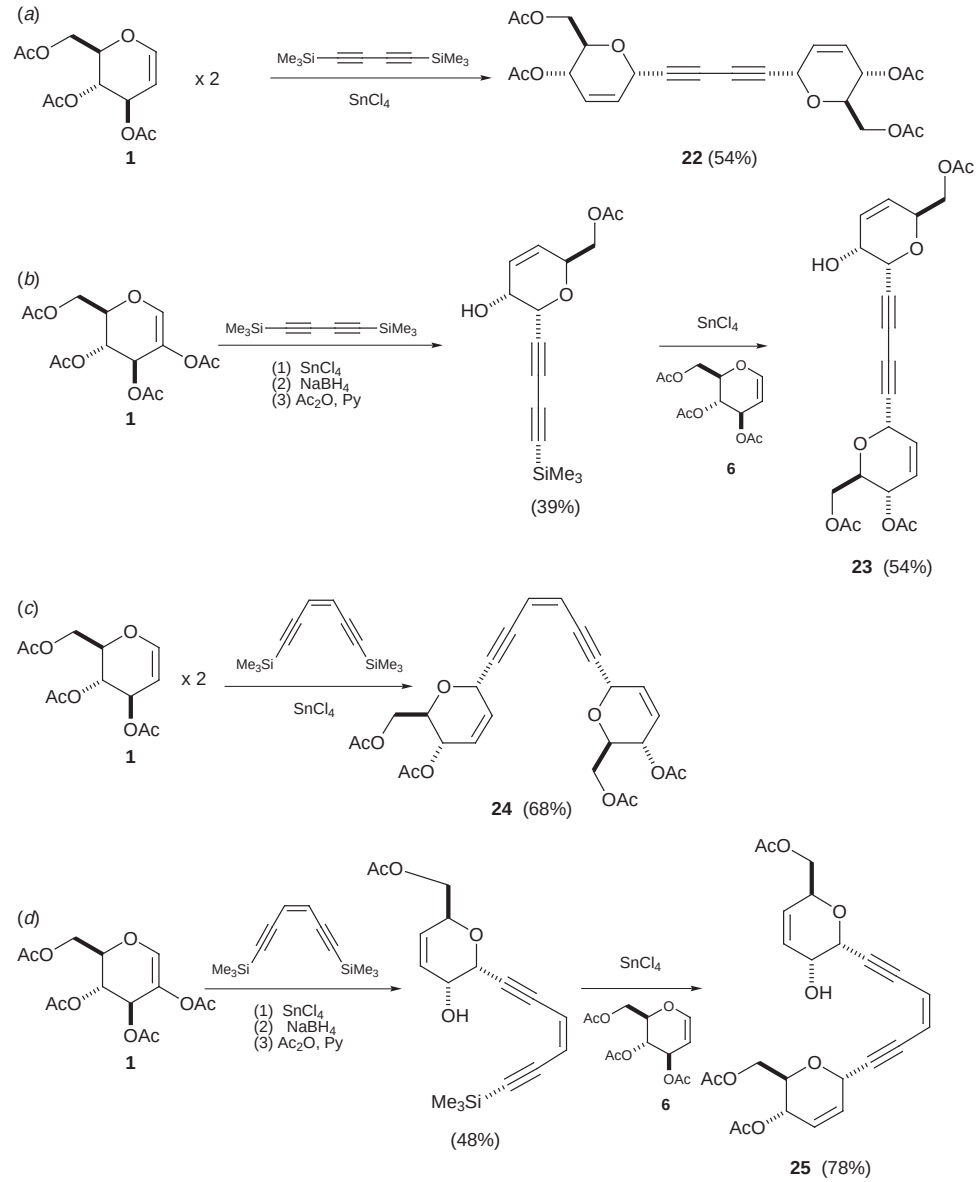
withdrawing oxygen atom at the properglic position, that destabilizes the cationic intermediates. However, further examination of some other reactions provided several good examples of double C-glycosidation between two glycals and bis(silylacetylene)s connected by longer carbon chains. Scheme 5(*a*) and (*b*) show the first examples of disilylacetylenes with sugar rings to both ends. The reaction process is stepwise, providing first mono- and then di-glycosidation products. This fact suggests that the second C-glycosidation is slower than the first,[13] and that it is possible to attach two different kinds of sugar ring, as in Scheme 5(*b*) and (*d*). The silylacetylene moieties can also form the ends of endiyne compounds [Scheme 5(*c*) and (*d*)].

Phenylthioacetylenes

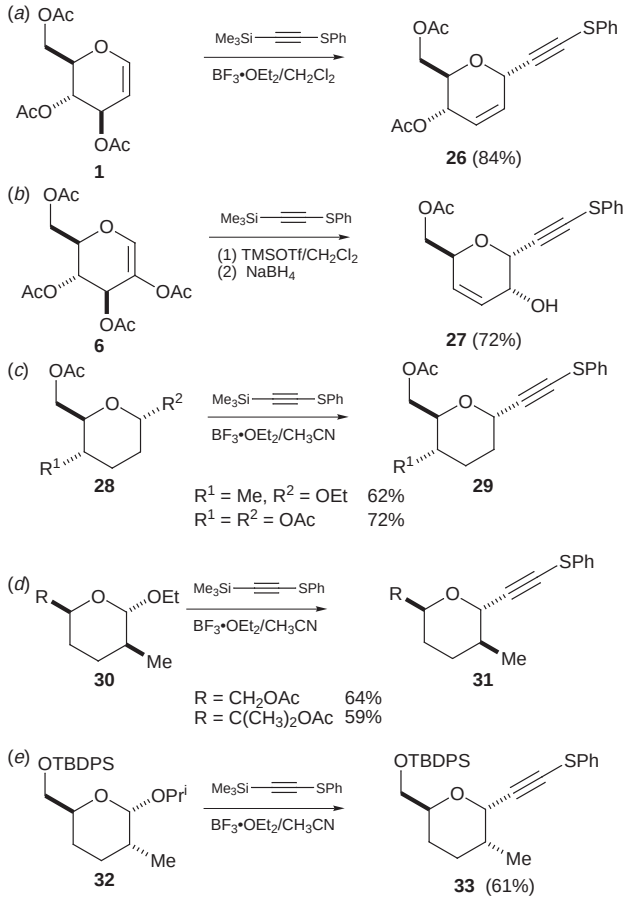
Higher reactivity is observed for silylacetylenes carrying a phenylthio group at the other end. The reagent 1-trimethylsilyl-2-phenylthioacetylene is prepared from the lithium salt of ethynyltrimethylsilane and *S*-phenyl benzenethiosulfonate.[14] In this case high yields are obtained with a weaker Lewis acid catalyst such as $BF_3{\cdot}OEt_2$ by stirring for 20 min in MeCN. In Scheme 6(*a*) and (*b*)[12,15] are demonstrated the first two examples, with quantitative formation of the phenylthioacetylenes. Similar C-glycosidations are possible from *O*-glycosides [Scheme 6(*c*)–(*e*)].[4b,15,16] Most of these examples give high yields with 1-trimethylsilyl-2-phenylthioacetylene in the presence of $BF_3{\cdot}OEt_2$. Mechanistically, the phenylthio group can provide electrons which help develope cationic charge at the adjacent carbon in the transition state of the C-glycosidation. The product, a phenylthioacetylenic sugar, does not react further with $BF_3{\cdot}OEt_2$, but does with $SnCl_4$. The yields dramatically drop with stronger Lewis acid catalyst (such as $SnCl_4$ or $TiCl_4$) and/or by prolonging the reaction period.

Other interesting examples

Nicolaou *et al*. reported a similar example of silylacetylene addition to methylated glucal acetate [**34** in Scheme 7(*a*)].[17] Williams demonstrated that bromide (in **36** and **38**) is a better leaving group, using an alkynyltin species and zinc chloride as the Lewis acid catalyst [Scheme 7(*b*) and (*c*)].[18] They reported high α selectivity with hexose (**37**), but variable selectivity with pentofuranose (**39**). Recently Veyrieres described the reaction of 2-deoxy-2-azido-1-bromo compound **40** with an alkynyltin species in the presence of silver tetrafluoroborate catalyst [Scheme 7(*d*)].[19] Martin found that the selectivity of the



Scheme 5



Scheme 6

reaction of (±)-1-formyl-2-alkoxypentopyranose with various silylacetylenes varied with the substituent on the other end of the acetylene moiety; thus, 1,2-*syn* and 1,2-*anti* selectivities were observed as shown in Scheme 7(*e*).[20]

1,4-*anti* Selectivity of silylacetylene to pentopyranoside

We expanded the *C*-glycosidation reaction to pentopyranose derivatives such as di-*O*-acetyl-D-xylal **45** and di-*O*-acetyl-L-arabinal **47** during the course of synthetic studies on the ABC segment of ciguatoxin (CTX, see compounds **109**–**111**), a polyether marine natural product.[21] This glycosidation provides a single stereoisomer.[22] During the CTX synthesis, this stereogenic center is destroyed and is thus not significant in the above mentioned synthesis (we did not even determine whether the stereochemistry was α or β at first). Recently, the stereochemical induction turned out to be in striking contrast to the previous cases. Namely, tri-*O*-acetyl-D-glucal **1** and bis-trimethylsilylacetylene react in the presence of a Lewis acid in a highly stereospecific manner to give exclusively the α-axial orientation in the product **3**.[9] The examples of silylacetylene addition to hexopyranoglycals occur under various acidic conditions but they all produce only the α-acetylene products with 1,4-*syn* selectivities higher than 95%. On the other hand, similar addition of silylacetylene to pentopyranoglycal diacetates (such as **45** and **47**) and dipivalates (**51** and **56**) affords the opposite results; thus, 1,4-*anti* stereochemistry is observed with the exclusive products **46**, **48**, **49**, **50**, **53**, **55**, **57** and **58** in the pentopyranose cases as shown in Table 3. Various nucleophiles add to the same pentopyranose glycals to afford similar results.[23]

	LA	yield (%)	**43** : **44**

R = Ph	$SnCl_4$	71	95 : 5

Scheme 7

Application of the Hosomi–Sakurai reaction to this system provides the 1,4-*anti* products [Scheme 8(*a*) and (*b*)]. The reaction of a vinylsilyl ether with **45** also affords a 1,4-*anti* product **61** [Scheme 8(*c*)]. An oxygen nucleophile (propan-2-ol) mainly yields a 1,4-*anti* product, although the *syn*:*anti* selectivity was 25:75 [Scheme 8(*d*)].[23]

Stereochemical control

Miljkovic *et al*. reported a 1,4-position stabilization effect for the oxocarbenium intermediate in a hydrolysis of pentopyranoside[24] [Scheme 9(*a*)]; thus, the benzyloxy group of **63** (R = Bn) sits in an axial orientation [**64**(**4*ax***) in Fig. 3] to stabilize the oxocarbenium ion through space rather than in an equatorial position **64**(**4*eq***). On the other hand, an acyloxy group such as an acetyl group provided no stabilizing or even destabilizing

Table 3 1,4-*anti* Selecvtivity in the reaction of silylacetylene with pentopyranoside

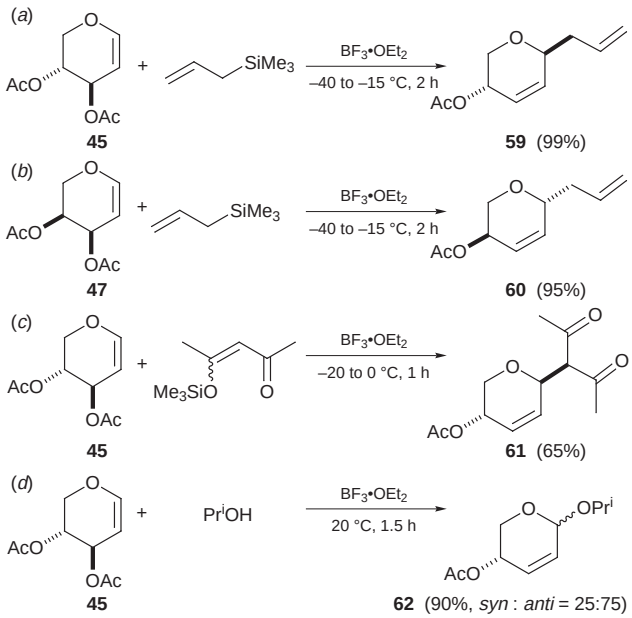
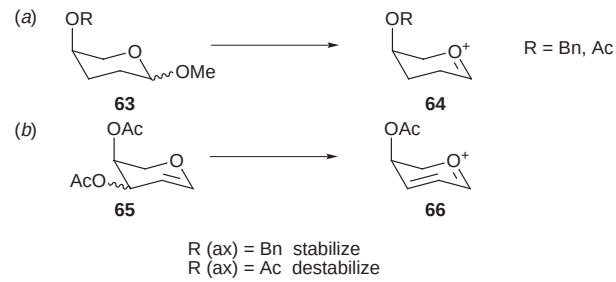


Scheme 8



Scheme 9

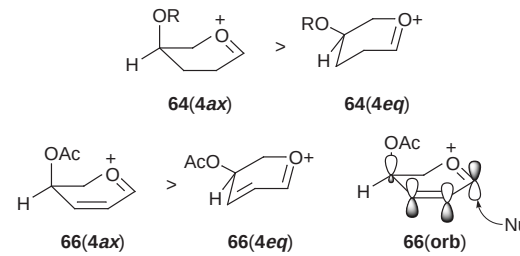


Fig. 3

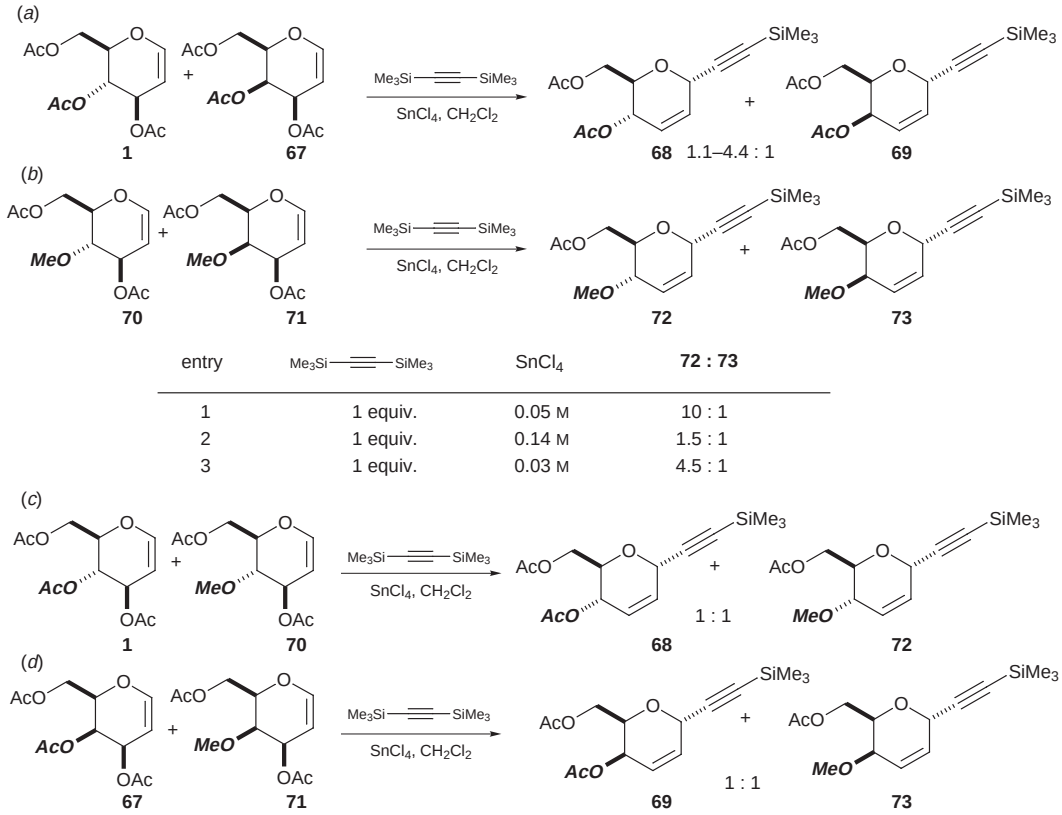
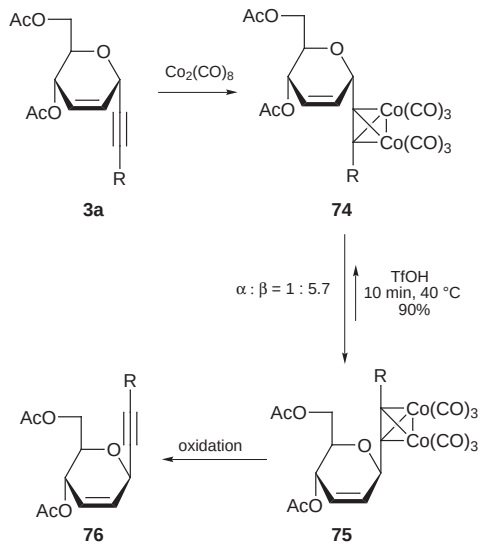
effect during the hydrolysis. A similar explanation might be possible in the enoxocarbenium ion **66** formed during pentose C-glycosidation [Scheme 9(*b*)]. The suggestion that the reaction proceeds *via* **66**(**4*ax***) and not **66**(**4*eq***) would explain the 1,4-*anti* orientation, because the nucleophile silylacetylene would approach from the α side (*anti* to the acetoxy group). An alternative explanation may be due to orbital interaction; thus, the axially orientated 4β-acetoxy group reduces the electron density in the π-electron lobe at C-2 in the β-face, making the *anti*-lobe at C-1 more reactive [**66**(**orb**)]. We must await further experimental results before deciding which mechanism is operative.

These results prompted us to do mixing experiments with glucal and galactal derivatives (Scheme 10) in our laboratory to



Scheme 10



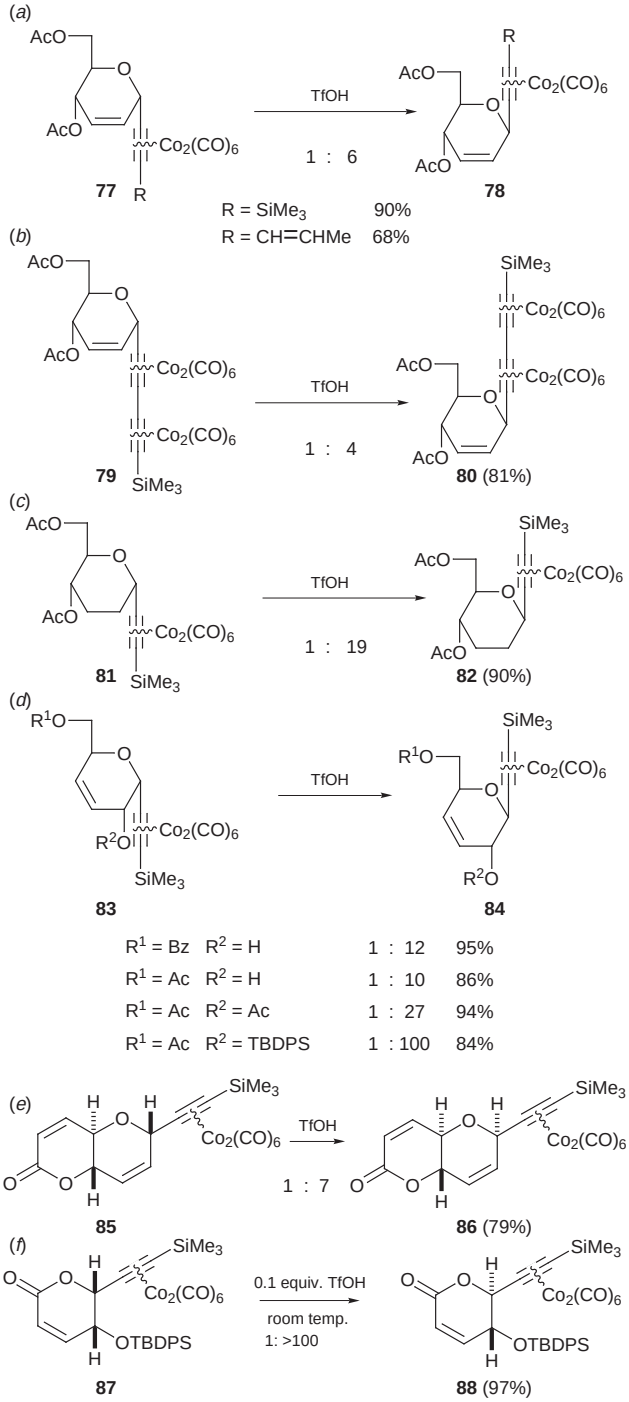
Scheme 11

determine the relative rates of C-glycosidation in pentopyranose systems, to thus avoid conformational problems. Glucals always give higher yields than galactals in C-glycosidations, even with the reaction being interrupted after only a short reaction time [Scheme 10(*a*) and (*b*)]. When mixtures of the 4-acetoxy and 4-methoxy substituted glucals or galactals were subjected to the C-glycosidation conditions [Scheme 10(*c*) and (*d*)], the ratio of the products was 1:1. These results for the bond formation process are striking different to those of the hydrolysis case, although similar oxocarbenium ions are involved. The mechanism and kinetics of these C-glycosidations need to be studied further.

Epimerization of the C-1 alkynyl group on the pyranose ring using an acetylenehexacarbonyldicobalt complex

The stereoselectivity of these C-glycosidations with silylacetylenes exclusively leads to products with the α-axial orientation. If an epimerization were possible which gave products with β orientation, this methodology would be more useful, giving access to both α and β configurations. Nicholas reported that complexation of an alkynyl group with octacarbonyldicobalt provides a hexacarbonyldicobalt complex which stabilizes the carbocation at the proparglic position.[25] Application of the Nicholas reaction to α-sugar acetylenes under acidic conditions would give the thermodynamically more stable β-equatorial isomer at equilibrium under the reaction conditions.[26] In fact the overall process including cobalt complexation, acid epimerization and oxidative decomplexation can take place as illustrated in Scheme 11. Reagents often used for the decomplexation include *N*-methylmorpholine *N*-oxide, cerium(IV) ammonium nitrate, ferric nitrate, iodine *etc*. Among these oxidants, iodine reacts very fast even at 0 °C to finish the reaction in 36 min, providing the acetylene in quantitative yield even with large excess of iodine. Often the last two steps can be carried out in one pot.

Examples of epimerization of the α sugar acetylenes into β ones are shown in Scheme 12(*a*) and (*b*), in which the 2,3-dehydro ring systems are involved with different acetylene cobalt complexes. The ratios of equilibration in these cases are 1:4–6, rather low values which may be due to the single pairs of 1,3-diaxial interactions since they have an energy difference of only *ca*. 1 kcal mol^{-1}. The saturated ring system in Scheme 12(*c*) gives a higher ratio (1:19) due to three pairs of 1,3-diaxial interactions (Fig. 4). The ratios vary in Scheme 12(*d*) which includes 3,4-en-2-ol system; the ratios increase in accordance with the size of the alkoxy substituents. The major cause in this case may be due to 1,2-strain, as shown in Fig. 5.[26]



Scheme 12

Conformational preferences are not the only necessary factors for a high equilibrium ratio for the acetylene cobalt complex. The bicyclic example shown in Scheme 12(*e*) may have a rigid ring system, but the important thermodynamic factor is once again a single 1,3-diaxial interaction, resulting in a 1:7 ratio. Evidences of this 1,2-strain is clearly demonstrated in Scheme 12(*f*), where the ring system does not have the carbon corresponding to C-6. A Nicholas reaction makes the epimerization possible.[26]

Opening of the pyranose ring and re-cyclization

The above epimerization *via* the cation intermediate is an important characteristic of the cobalt complex in sugar acetylenes. The same cation intermediate is potentially applicable to medium ether ring formation and other useful protocols. Oxepane ring formation from six-membered ether precursors is usually impractical due to thermodynamic constraints. In Scheme 13, oxepene **89** is planned to cyclize from **92** *via* the cation **90** derived from the sugar acetylene hexacarbonyldicobalt complex **91**. The overall reaction is shown in Scheme 14; opening of the ring of the 3,4-unsaturated glucose derivative **83** takes place under acetolysis conditions (TfOH in Ac_2O at −40 °C) for a few hours to provide **93** as a diastereomeric mixture at the C-3 position. The *cis* olefinic compound **93** is decomplexed (**94**) and further manipulated *via* the protecting groups of the hydroxy moieties (**95**), cyclizing into the corresponding oxepene compound **96**. Decomplexation gives **97**, which has *syn-trans* stereochemistry.[27]

Ring opening also takes place with the 2,3-unsaturated system, as shown in Scheme 15. In this case, acid treatment of **98** generates the enoxocarbenium ion at the anomeric position (original sugar numbering C-1) and epimerization is followed by ring opening (**99**). The process is different from the above cases with 3,4-double bonds because the *cis*-2,3-unsaturated system has the cation at the allylic position, which can equilibrate into the more stable *trans* allylic cation, resulting in the acetylation of the 7-hydroxy group. If this occurs, one can make produce a spontaneous ring-recyclization by positioning a nucleophilic hydroxy group at the other side of the acetylene hexacarbonyldicobalt group.

Scheme 16 illustrates this plan; the substrate, unsaturated six-membered **101**, should transform into **104** *via* the cation intermediates **102**, in which the *cis* allylic cation at the C-1 position can equilibrate to the more stable *trans* allylic cation **103**. The latter cannot re-cyclize back to **101** and waits for the addition of the hydroxy group on the other side to afford **104** with various ring sizes, such as seven-, eight-, nine- and ten-membered rings, depending upon the number of methylenes.

The multistep sequence of reactions (**1**→**101**) includes C-glycosidation with silylacetylene, and Pd-catalyzed ene–yne coupling with the *cis* vinyl iodide to provide the precursor **101**.[5]

The resulting ring compounds (**104**) are a new type of acetylene cobalt complex with the complex inside the ring system; thus, the *endo*-complex cannot be decomplexed under oxidative conditions as for the *exo*-complex. Finally, Rh-C was found to be effective for the synthesis of the decomplexed dienes **105**–**108** under high pressure H_2.[5] The carbons corresponding to the original acetylene complex end up as the olefinic carbons (except for the double bond transposition in the seven-membered system). Incidentally, the rhodium catalyst thus formed during the decomplexation of hexacarbonyldicobalt fulfils the reductive function of the cobalt complex into olefins, but did not reduce the double bonds under the reaction conditions.

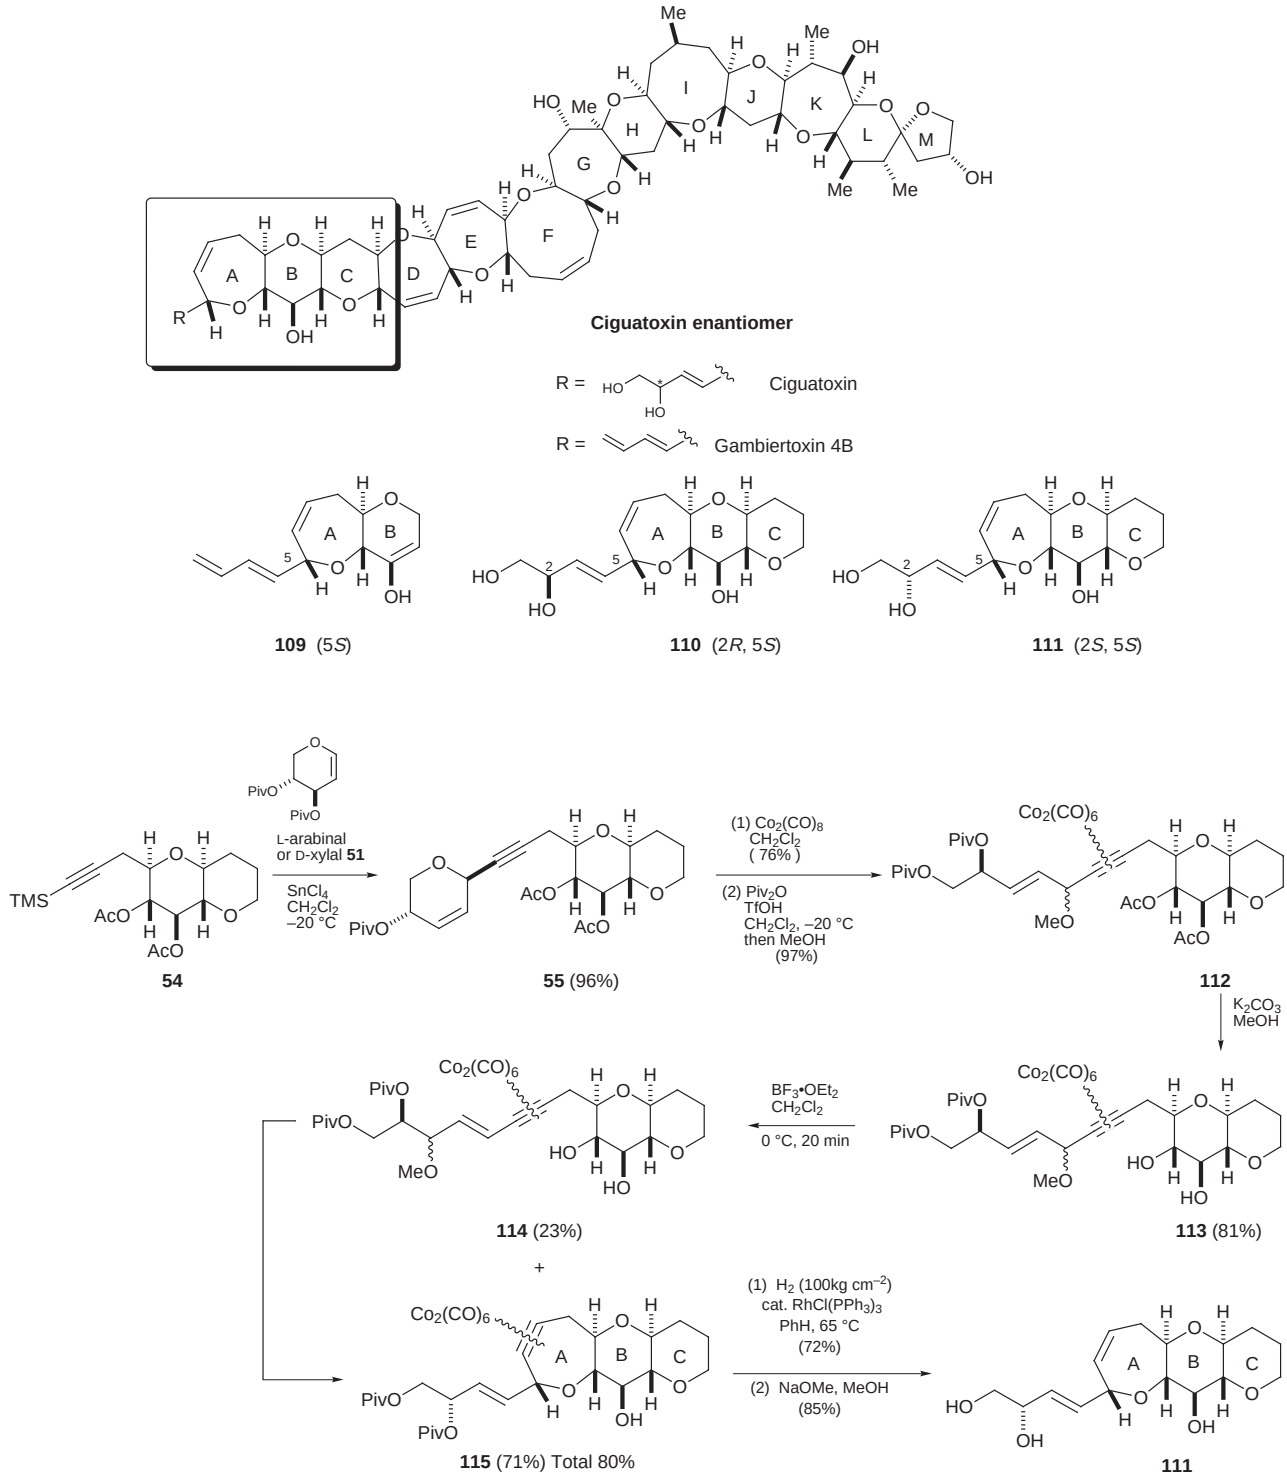
Application to ciguatoxin synthesis

Above methodologies have been developed for application to the synthesis of ciguatoxin and gambiertoxins, potent toxins causing marine ciguatera poisoning. When this synthesis was started, the absolute configuration and part of the relative

configuration had not been determined. Recently, Yasumoto reported that the absolute configuration of ciguatoxin is that of the opposite enantiomer.[21] Various side chains are attached to the 5 position of the A-ring, such as a 1,3-diene or 1-en-3,4-diol. We have demonstrated the synthesis of the AB(C) ring system with three possible side chains (**109**–**111**).[23] The synthesis of one of these compounds is shown in Scheme 17. The silylacetylene moiety was attached to the bicyclic compound **54**, which added to D-xylal **51** to afford the coupling product *anti*-acetylene as a single stereoisomer **55**. The cobalt complex of **55** was treated with pivalic anhydride in the presence of TfOH to afford the *trans* olefin (**112**). This was followed by hydrolysis of the acetate protecting group to give the hydroxy group (**113**) and then by a second treatment with acid to provide the tricyclic compound (**115**) together with some isomeric compound (**114**). Decomplexation of the *endo*-cobalt complex was achieved to give **111** using Wilkinson's catalyst under the high pressure hydrogen atmosphere.[5,23]

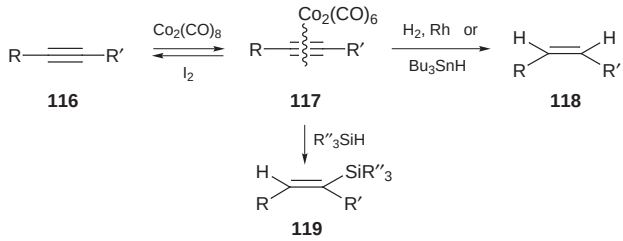
Novel reductive decomplexation of acetylene hexacarbonyldicobalt complex

Acetylene hexacarbonyldicobalt complexes[28] have mostly been used for the protection of triple bonds as well as for C–C bond



Scheme 17

and C–O bond formation reactions,[23,29] and thus they have been applied to natural product syntheses.[30] The most common decomplexation is an oxidative procedure leading to the original triple bond, but this is limited to the exocyclic cases as discussed previously. In endocyclic complexes only decomplexation under high pressure hydrogen using a Rh catalyst provides olefinic cyclic ethers.[5,23] Recently Kuwajima reported a Birch reduction for such decomplexation.[31] Here we describe two additional decomplexation protocols applicable to either *exo*- or *endo*-cyclic acetylene cobalt complexes, as shown in Scheme 18.[32]



116 **117** **118** **119**

Scheme 18

The new method is applicable to either *endo*- or *exo*-complexes to provide simple *cis*-olefins (with tri-*n*-butyltin hydride) or *cis*-vinyl silanes (with trialkylsilanes or triarylsilanes) at the original position of the acetylene (Scheme 18). Various examples using SnH are shown in Table 4. A simple terminal acetylene–dicobalt complex is converted to a terminal olefin (entry 1). Two examples of *exo*-complexes gave *cis*-olefins (entries 2 and 3). *endo*-Complexes of seven- and nine-membered rings are also shown (entries 4–7). Of particular interest is the bis(hexacarbonyldicobalt) complex of the nine-membered ring, which is only able to decomplex under these conditions, since using rhodium under high pressure conditions failed to give the diene.[32] This method was applied to the synthesis of ABC fragment **109** of gambiertoxin.[33]

Table 4 Decomplexation of acetylene hexacarbonyldicobalt with Bu^n_3SnH

Entry	Substrate	Product	Yield (%)
1	 **120**	 **121**	60

5	 **129**	 **110**	82
6	 **130**	 **131**	61
7	 **132**	 **131**	35

Table 5 Decomplexation of acetylene hexacarbonyldicobalt with R_3SiH

Entry	Substrate	Silane/solvent	Product (% yield, ratio)
1	 **122**	Et_3SiH C_6H_6	 **133** **134** (65%, ~1:1)
2	 **122**	Ph_3SiH C_6H_6	 **135** **136** (49%, ~1:1)
3	 **122**	Ph_3SiH C_6H_6–EtOH	 **137** **138** (64%, ~6:4)
4	 **139**	Et_3SiH C_6H_6	 **140** (78%)
5	 **141**	Et_3SiH C_6H_6	 **142** (87%)
6	 **143**	Et_3SiH C_6H_6	 **144** (74%)

Similarly the acetylene hexacarbonyldicobalt *endo* or *exo* complexes can be converted into the corresponding *cis*-vinylsilanes. In entries 1 and 2 in Table 5, alcohol (**122**) is converted using triethyl- or triphenyl-silanes into *cis*-vinylsilanes as the silyl ethers. When this reaction is carried out in EtOH–benzene, the corresponding alcohols (**137**, **138**) are obtained in free form. A symmetric precursor (**139**) affords a single product (**140**). A sterically unequal acetylene **141** is converted into a single hydrosilation product (**142**). The *endo* complex **143** also gives a single product (**144**) in which the silyl group is situated away from the neighboring substituent. Thus, the hydrosilylation of cobalt complexes becomes synthetically very useful.

Summary

This review describes new aspects of sugar acetylenes, including their preparation (C-glycosidation with silylacetylene), epimerization and medium ring re-cyclization *via* acetylene hexacarbonyldicobalt complexes. Expansion of these synthetic concepts demonstrates some applicability to the synthesis of ciguatoxin. New reactions have been developed for decomplexation of the cobalt acetylene complexes, particularly for both the *endo*- and *exo*-complexes. This chemistry will further develop towards better synthetic methods for natural product synthesis.

Acknowledgments

This review is a summary of recent studies largely achieved in our laboratory. The authors are gratefully indebted to Dr Yoshiyasu Ichikawa, Mr Takahiro Tsukiyama, Dr Shigeyoshi Tanaka, Dr Jiang Ymin, Dr Steven Peters and Dr Chavie Yenjai for participating in the above experiments and/or the earlier stages of the program. Miss R. Saeeng, Mr T. Liu and Mr K. Kira are thanked for contributing to related chemistry. Dr V. Rukachaisirikul, Dr T. Franz and Mrs Jianmin Li are thanked for their help in the preparation of this manuscript. This research was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan, JSPS-RFTF program, and scholarships from the Hitachi International Foundation, JSPS and Monbusho.

Received (in Cambridge, UK) 28th August 1998, Accepted 16th October 1998

A bis(tosyl)amidoruthenium(III) complex of 1,4,7-trimethyl-1,4,7-triazacyclononane (Me_3tacn) is prepared, and its crystal structure revealed the two tosylamido ligands in a *cis* configuration; the '[Ru^{III}(Me_3tacn)$(NHTs)_2$(OH)] + Ag(I) or PhINTs' protocol can effect amidation of saturated C–H bonds, and an electrophilic tosylimidoruthenium intermediate is implicated based on Hammett correlation studies and trapping experiments.

Amidation of saturated C–H bonds is an appealing route to amides and amines.[1] To our knowledge, only a handful of catalytic systems involving [*N*-(toluene-*p*-sulfonyl)imino]phenyliodinane (PhINTs) as a nitrogen source have been reported for this transformation,[2] and a highly reactive metal tosylimido (M=NTs) species is usually postulated to be the active intermediate. To date, few M=NTs complexes are known to react with saturated C–H bonds.[3] We reason that those M=NTs species capable of acting on saturated C–H bonds would be highly oxidizing and react readily with organic solvents rendering their isolation and/or investigation difficult. A way to tackle this problem would be to prepare structurally characterized metal–tosylamido complexes. Through proton-coupled oxidations, either chemically[4] or electrochemically,[5] it may be feasible to *in situ* generate and study the highly reactive M=NTs species from its tosylamido precursor. Herein is described the first tosylamidoruthenium(III) complex that can mediate amidation of saturated C–H bonds.

[Ru^{III}(Me_3tacn)$(NHTs)_2$(OH)] (**1**; Me_3tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane) was prepared by reacting [(Me_3tacn)$Ru^{III}Cl_3$][6] (0.1 g, 0.26 mmol) with TsNHNa (0.4 g, 2.1 mmol) in methanol (20 cm^3) at room temperature for 3 hours and was isolated as a yellow crystalline solid.† Magnetic susceptibility measurement gave μ_{eff} = 1.8 μ_B, consistent with a Ru(III) formulation. The infrared spectrum of **1** shows the N–H stretch at 3400 cm^{-1}. Fig. 1 shows the structure of complex **1** established by X-ray crystallography.‡ The two tosylamido ligands are in a *cis* configuration [N–Ru–N bond angle = 80.4(2)°]. The Ru^{III}–N(tosylamido) distances of 2.072(5) and 2.140(5) Å are in between the related values of 2.025(1) Å in [Ru^{IV}(Por)(NHTs)(pz)] (Por = porphyrinato ligand; pz = pyrazolate)[7] and 2.21(1) Å in [Ru^{II}(Et_2dtc)$(PPh_3)_2$(CO)(NH-$SO_2C_6H_2Pr^i_3$-2,4,6)] (Et_2dtc = *N*,*N*′-diethyldithiocarbamate).[8] The observed Ru–OH distance of 1.947(4) Å is comparable to the related value of 1.904(2) Å found for [Ru^{III}(N_2O_2)($O-H_2$)(OH)]$(ClO_4)_2$ (N_2O_2 = 6,7,8,9,10,11,17,18-octahydro-6,10-dimethyl-5*H*-dibenzo[*e*,*n*][1,4,8,12]dioxadiazacyclopentadecine).[9] The Ru–N–S angles of 144.3(3)° and 132.3(3)° suggest that the nitrogen atom is sp^2 hybridized.

We found that addition of weakly oxidizing $AgClO_4$ to **1** in acetonitrile gave a red species (λ_{max} = 480 nm), which would react with PPh_3 to produce TsN=PPh_3 and [Ru^{II}(Me_3tacn)-$(MeCN)_3$]$(ClO_4)_2$ quantitatively. Likewise, other oxidants such as PhI$(OAc)_2$ and $(CPh_3)(PF_6)$ are equally effective for this transformation. On the other hand, (1-cyclohexenyloxy)trimethylsilane was found to be converted to α-*N*-tosylaminocyclohexanone§ under '**1** + $AgClO_4$' conditions comparable to the related transformations by the '[(L)Mn^V≡N] + $(CF_3CO)_2O$' (L = Schiff base)[10*a*] and 'Cu(I) + PhINTs'[10*b*] systems. These findings imply that a reactive Ru=NTs species might have been generated upon chemical oxidation of **1** presumably *via* oxidative deprotonation of the coordinated amido ligands. Although attempts to isolate and characterize the Ru=NTs species of Me_3tacn have proved futile, the '**1** + Ag(I)' protocol was found to carry out facile C–H amidation of allylic and aromatic hydrocarbons to afford the corresponding tosylamides (RNHTs).

When cyclohexene (1 mmol) was treated with **1** (0.16 mmol) and $AgClO_4$ (0.2 mmol) in acetonitrile (5 cm^3), a red solution resulted. The red color slowly disappeared upon stirring for 3 h at room temperature to form a yellow to brown solution with metallic silver deposited at the bottom of the reaction vessel. After GLC analysis, allylic toluene-*p*-sulfonamide was produced in 63% yield based on the Ru complex (Table 1). Ethylbenzene, cumeme, indane and tetralin also reacted similarly to afford the corresponding benzyl tosylamide derivatives in 41–75% yield. It is noteworthy that adamantane can also be converted to 1-adamantane tosylamide selectively in 59% yield by the **1**/$AgClO_4$/MeCN system. In all cases, $TsNH_2$ was detected as well, and the 'RNHTs + $TsNH_2$' production reached a total of 200% for two tosylamido moieties per ruthenium complex.

The effect of *para*-substituents (*p*-Y-$C_6H_4CH_2CH_3$; Y = MeO, Me, H, F, Cl) on the amidation of ethylbenzene by employing **1**/$AgClO_4$ conditions has been studied. The relative rates (k_{rel}) were established under competitive conditions where equimolar amounts of ethylbenzene and its substituted derivative were used. We found that both electron-donating and -withdrawing substituents can promote the reaction, and a straight line (R = 0.99) results using Jiang's σ_{JJ}•[11] and

Table 1 Ruthenium amidation of saturated C–H bonds

			'**1** + Ag(I)'	'**1** + PhINTs'
Entry	Substrate	Product	Yield (%)[a,b]	Yield (%); turnover number[c,d]
1			63	52; 29
2			59	50; 25
3			75	72; 48
4			41	30; 23
5			60	49; 25
6			52	45; 25
7			65	55; 37

[a] Reaction conditions: to an acetonitrile suspension (5 cm^3) containing hydrocarbon substrate (1 mmol) and **1** (0.16 mmol) was added $AgClO_4$ (0.2 mmol); the resulting red solution was stirred for 3 h at room temperature. Aliquots were analyzed by GLC for product identification and quantification. [b] Yields are based on the amount of Ru complex used. [c] Reaction conditions: an acetonitrile mixture (10 cm^3) of hydrocarbon substrate (1 mmol) and **1** (2 mol%) was treated with PhINTs (6 mmol), and the reddish brown solution was stirred at room temperature for 12 h. After rotary evaporation to dryness, the amide product was extracted with diethyl ether. Aliquots were taken from the organic extracts and analyzed by GLC for product identification and quantification. [d] Yields are based on the amount of PhI formed.

Hammett σ^+ substituent constants, and $\rho_{JJ}\bullet$ = +0.85 and ρ^+ = −0.67 ($|\rho_{JJ}\bullet/\rho^+|$ = 1.27) are obtained (Fig. 2). The correlation suggests that the ruthenium-mediated amidation reaction should involve a benzylic radical intermediate produced by H-atom abstraction of ethylbenzene. The negative ρ^+ value is indicative of an electrophilic nature of the active ruthenium species. The results of the correlation studies and the trapping experiments imply that a highly oxidizing Ru=NTs species was generated upon oxidation of complex **1**.

The amidation reaction can become catalytic when PhINTs was utilized as the terminal nitrogen source and **1** as the catalyst in acetonitrile at room temperature (see Table 1). The reaction of hydrocarbon substrates with PhINTs in the presence of 2 mol% of **1** in acetonitrile afforded the corresponding amides in moderate to good yields. Up to 75 turnovers could be achieved for the amidation of ethylbenzene when a lower catalyst loading (**1** : PhINTs : ethylbenzene = 1 : 100 : 200) was employed.

Catalytic benzene coupling on caesium/nanoporous carbon catalysts

Mark G. Stevens,[a] Keith M. Sellers,[a] Shekhar Subramoney[b] and Henry C. Foley*[a]

Received (in Bloomington, IN, USA) 24th August 1998, Accepted 19th October 1998

Caesium/nanoporous carbon materials have a very high affinity for hydrogen, breaking the extremely energetic C–H bond in benzene and promoting its condensation to biphenyl, opening a new class of chemical reactions to heterogeneous catalysis.

Graphite intercalation compounds of alkali metals have been extensively studied[1] and shown to have very high affinity for hydrogen. The compound $C_{24}K$ promotes deuterium exchange with methane[2] and hydrocarbons having acidity equal to or greater than that of benzene.[3] Béguin and Setton[4] found C_8K could condense benzene to biphenyl at 298 K. However, these materials are pyrophoric, have relatively low surface area, and exfoliate at reaction temperature.[5] In a previous paper[6] we revealed caesium entrapped in high-surface-area ($\sim$1000 $m^2\ g^{-1}$) nanoporous carbon is an excellent catalyst for double-bond migration in olefins but, unlike alkali-metal graphite intercalation compounds, is not pyrophoric and is thermally stable towards desorption up to 773 K.

By preparing nanoporous carbon (NPC) from poly(furfuryl alcohol)–poly(ethylene glycol) mixtures[7–10] we obtain chemically inert solids that contain nanopores,[7,8] with sizes distributed around 0.5 nm, and transport pores[11] with sizes distributed around 10 nm that allow access to catalytic sites contained by the nanopores.[12] Since caesium's atomic diameter (0.48 nm covalent) is close to the mean nanopore size of the NPC, the vapor of elemental caesium is rapidly and strongly adsorbed.[6] By this means we have produced materials containing up to 42% caesium by weight.

Through magnetic-susceptibility measurements and electron-paramagnetic-resonance spectroscopy studies[6] of these Cs/NPC materials, we have shown them to contain unpaired electrons. Significantly, an identical *g* factor value of 2.0026 was obtained† both for the free radicals in the carbon precursor, as well as those present in material loaded with 15% Cs by weight. The *g*-shift is roughly proportional to the mean spin–orbit coupling constant, which in the case of caesium should be large. The EPR data, however, are not indicative of such an effect. Instead the *g*-value demonstrates that caesium's orbitals do not participate; hence, the electrons from caesium are donated to the carbon. These two facts, along with their demonstrated ability to promote the double-bond migration in olefins,[6] suggest that the Cs/NPC materials should have an affinity for hydrogen similar to, or higher than, their purely graphitic analogues. In 1976, at least two studies[3,4] found that potassium graphite would couple benzene to biphenyl. Béguin and Setton[4] found that a proton donor/acceptor solvent (THF) was required to promote the reaction and that water was required to extract the biphenyl product from the alkali-metal graphite. Matsuzaki and coworkers[13] performed a detailed study of the polymerization of benzene over alkali-metal graphite compounds. Based on a series of experiments, they proposed a polymerization mechanism: two benzene radical anions $C_6H_6^{\cdot -}$ form, then couple and lose dihydrogen forming $C_{12}H_{10}^{2-}$ the dianion of biphenyl, a species they observed by Raman spectroscopy. This dianion loses an electron to produce the biphenyl radical anion, $C_{12}H_{10}^{\cdot -}$, which reacts with another benzene radical anion to propagate the chain and to produce polyphenyl. Finally, caesium metal alone, when reacted with benzene in THF and then washed with water, yielded 1,1′,4,4′-tetrahydrobiphenyl.[14]

In our study, batch reactions‡ of benzene over a 10% Cs/NPC produced biphenyl and terphenyl products. Fig. 1 displays results of several experiments at various temperatures. From these data the apparent first-order activation energy can be calculated as 34 kJ mol^{-1}, indicating a coupling-limited, free-radical reaction or that the reaction is taking place in the internal diffusion limited regime. Table 1 displays the typical carbon selectivity. Gas chromatography measurements of the vapor phase over the products confirmed the presence of hydrogen. Control experiments using pure NPC produced no detectable biphenyl. Finally, long-term experiments (8 g benzene reacted over 0.5 g 10% Cs/NPC at 450 °C for 72 hours)confirmed the catalytic nature of the reaction, by acheiving over 5 turnovers, based on the *total* molar caesium content.

To confirm the catalyst is not some form of caesium metal that has leached into the liquid phase, we performed a second set of experiments (Table 2), in which benzene was converted to biphenyl in the vapor phase. A mixture of benzene in argon (5 mol%) was circulated over the catalyst at 450 °C and 2 bar.§ By means of a continuous separation built into this recirculating reactor, nearly 100% selectivity to biphenyl was achieved at

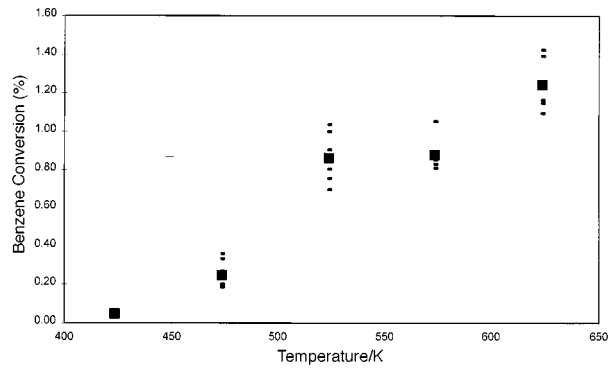

Fig. 1 In each experiment 8 g benzene was reacted for three hours over 0.5 g of a 10% Cs by weight catalyst: (−) indicates individual experiments, (■) indicates average for a given temperature.

Table 1 Average carbon selectivity of reaction at 1–3% conversion of benzene

Product	Carbon selectivity (%)
Biphenyl	75
o-Terphenyl	4

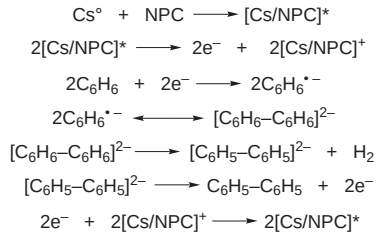

Scheme 1 Plausible catalytic mechanism.

near 2.5% benzene conversion. In this manner 29.8 mmol of benzene were converted to biphenyl in 96 hours over 1.46 mmol of caesium supported on NPC. This amounts to more than 20 turnovers based upon the *total* molar caesium content of the catalyst. The experiment was repeated twice with essentially the same result. Again, a control experiment using pure NPC did not produce detectable levels of biphenyl.

Since Cs/NPC can facilitate the breaking of the C–H bond in benzene (460 kJ mol^{-1}), we conclude that the metal provides, through its powerful electropositive nature, the electrons necessary to initiate the process. The carbon mediates the reaction by acting as the electron repository, stabilizing the intermediate radical anions. In the mechanism proposed by Matsuzaki and coworkers,[13] hydrogen and electron transfer are critical steps. The carbon may aid in these steps by promoting the net redox chemistry. Protons generated in the reaction can couple to produce dihydrogen with the carbon supplying the electrons to mediate the process. Additionally, the electron exchange between neutral benzene and the radical anion is facile ($E_a \approx 12$ kJ mol^{-1}),[15] and the carbon may stabilize the intermediate radical anions produced in this chemistry, making the net chemistry catalytic rather than stoichiometric. A plausible catalytic mechanism is shown in Scheme 1. Since the EPR measurements indicate caesium promotes its electron into the local carbon structure, in essence NPC acts as a macro radical anion that may be thought of as [Cs^+/$NPC^{\cdot -}$]. From this vantage point we can begin to see why the material may be so able to promote demanding redox chemistry.

Finally, we have previously shown that caesium, when loaded at high ratios (2/1 Cs^0/C w/w), promotes the rearrangement of the amorphous NPC to nanotubes, polyhedra and other crystalline structures;[16] transmission electron microscopy¶ of the catalyst before and after benzene treatment indicates that approximately 5% (by volume) of the carbon has transformed to ordered structures. This limited conversion of the amorphous NPC as compared to previous work[16] may be attributed to the combined effects of lower caesium content and the competitive reaction with benzene. In conclusion, since the phenyl radical anion is extremely difficult to produce and especially considering that deuterium exchange with methane has been shown,[2] these results indicate an entirely new class of radical chemistry may be open to heterogeneous-catalytic exploration in the future.

Notes and references

† EPR experiments were performed on a Bruker ER-200D electron-paramagnetic-resonance analyzer at 298 K. The authors wish to thank Dr. Paul Krusic and Mr. Steven Hill of the DuPont Company for their assistance with these measurements.

‡ Batch reactions were performed in a stainless-steel, 'tubing-bomb' reactor (2.54 cm o.d., 1.77 cm i.d. 15 cm long, capped with a hex nut and plug, internal volume: 12 cm^3). Catalyst and benzene were loaded in an argon-atmosphere glove box. Extreme care was taken to eliminate air and water contamination of the experiment. The reactor was sealed with a titanium gasket, removed from the glove box and placed in a fluidized sand bath maintained at the reaction temperature. After the desired reaction time was reached, the reactor was quenched in water and the products were analyzed by gas chromatography, confirmed by mass spectrometry.

§ A recirculating vaporizer/condenser reactor was constructed for the experiments. Catalyst was loaded in an argon atmosphere glove box. Extreme care was taken to eliminate air and water contamination of the experiment. Argon cycled through the system at 1500 sccm in the following order: bubbled through a temperature controlled (298 K) vessel containing 100 ml of benzene that was dried and deoxygenated over molecular sieves and lithium ribbon; the benzene rich (5 mol%) argon passed through a flow controller, a diaphragm pump and to the catalyst bed; the stream was heated to 723 K and flowed through the catalyst bed (1.5 g of catalyst containing 15% by weight Cs, 0.025 s per pass contact time); the reacted stream then returned to the bottom of the benzene vessel in which the biphenyl was trapped due to its low vapor pressure (0.005 bar at 298 K) to repeat the cycle. Products were analyzed by gas chromatography. No terphenyl was detected.

¶ The control (untreated catalyst) and benzene treated samples were prepared for transmission electron microscopic (TEM) studies by depositing them dry on carbon-coated Cu TEM grids. The grids were examined in a JEOL 2000FX S/TEM fitted with a Noran energy dispersive spectroscopic elemental analyzer. The control sample consisted of disordered appearing carbon with the Cs dispersed uniformly throughout the support. While we were not able to image individual particles of Cs on the carbon support, elemental analysis confirmed the presence of Cs everywhere in the sample. The used catalyst appeared similar to the control sample in microstructure as well as elemental composition with the Cs dispersed uniformly throughout the support. However, we observed a small fraction of the carbon to have ordered to graphitic nanoparticles and microscopic sheets of graphitic/turbostratic carbon during the benzene reaction process. No Cs was detected in these ordered pockets of carbon. Based on the TEM analysis, we estimate the amount of ordered carbon in the benzene-treated sample to be approximately 5% on a volume basis.

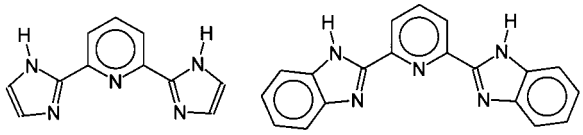
Received (in Basel, Switzerland) 21st September 1998, Accepted 2nd November 1998

Remote site deprotonation of a coordinated imidazole ligand switches the reduction potential of coordinated iron over a narrow pH range from +0.920 to −0.460 V.

A fundamental concept of coordination chemistry is that ligand type may favour one oxidation state of a metal over another. Thus π-acceptor ligands such as CO and PF_3 stabilise low oxidation states, whereas high oxidation states are favored by π-donor ligands such as fluoride or anionic oxygen donors. Implicit in this concept is the idea that chemical modification of the ligand may change its ligating properties, and thereby modify the reduction potential of the metal to which it is coordinated. Protonation or deprotonation of the ligand at a site remote from the metal–ligand bond is a simple, reversible method of modification, and in this communication we show how the deprotonation of a coordinated imidazole ligand can influence dramatically the redox potential of iron bound to the ligand as well as influencing the spin state.

Ligand **1** in acetonitrile forms the complex $[Fe(\mathbf{1})_2]^{2+}$ expected by analogy with the related benzimidazole ligand **2**



1 **2**

whose complexes with iron(II) have been studied previously.[1–3] The dark red complex† showed a strong MLCT band in methanol at 520 nm (ε = 5900 l mol^{-1} cm^{-1}). Upon treatment with Bu^{t}OK in methanol under nitrogen the solution became dark purple and showed the red shift and increase in intensity previously observed[1,2] for $[Fe(\mathbf{2})_2]^{2+}$ upon deprotonation; at the end points corresponding to $[Fe(\mathbf{1} - H)_2]$ the MLCT was at 536 nm (ε = 6220 l mol^{-1} cm^{-1}) and for $[Fe(\mathbf{1} - 2H)_2]^{2-}$ 538 nm (ε = 7620 l mol^{-1} cm^{-1}). Admission of air to the basic solution or addition of base in presence of oxygen gave a sky blue solution showing two weaker bands at 588 nm (ε = 870 l mol^{-1} cm^{-1}) and 730 nm (ε = 790 l mol^{-1} cm^{-1}) typical of low spin iron(III) coordinated by a diimine,[4] and no Fe(II) MLCT. The blue complex could be isolated as a sodium salt‡ either from the iron(II) complex after treatment with base or by reaction of $FeCl_3$ with **1** in presence of base. Elemental analysis and ESMS confirmed the presence of iron(III), and X-ray crystallography§ showed the expected pseudo-octahedral structure of the deprotonated complex $[Fe(\mathbf{1} - 2H)_2]^-$ (Fig. 1) and showed only slightly shorter Fe–N bond lengths [Fe–N_{py} 1.920(6) Å, Fe–N_{imid} 1.935(7) Å] than those observed for $[Fe(\mathbf{2})_2]^{2+}$.[2]

Since iron(II) coordinated to unsaturated nitrogen heterocyclic ligands is generally very hard to oxidise, the observation of spontaneous oxidation by air was surprising, especially since $[Fe(\mathbf{2})_2]^{2+}$ is not oxidised in base. Cyclic voltammetry studies in acetonitrile (glassy carbon electrode, 0.1 M NEt_4ClO_4 electrolyte , scan rate 200 mV s^{-1}) showed a reversible Fe^{III}–Fe^{II} wave at +0.920 mV *vs.* NHE for $[Fe(\mathbf{1})_2]^{2+}$, typical for an iron(II)–diimine complex. Upon deprotonation however, the Fe^{III}–Fe^{II} wave shifted to −0.460 mV for $[Fe(\mathbf{1} - 2H)_2]^-$ confirming the dramatic shift in redox potential, and explaining the observed sensitivity to oxidation by air. Reaction of iron(III) with two equivalents of **1** gave a yellow solution which darkened on standing as a result of reduction to $[Fe(\mathbf{1})_2]^{2+}$. No complex $[Fe(\mathbf{1})_2]^{3+}$ could be isolated, but a complex analysing as $[Fe(\mathbf{1})Cl_3]$ analogous to that formed by **2**[1] could be isolated.

Magnetic moments measured in methanol solution by the Evans method showed $[Fe(\mathbf{1})_2]^{2+}$ to have spin crossover behaviour analogous to $[Fe(\mathbf{2})_2]^{2+}$ [1,3] with a room temperature value of μ_{eff} = 3.6 μ_B, falling close to zero at 200 K. The change in UV–VIS spectrum of $[Fe(\mathbf{1})_2]^{2+}$ upon deprotonation at room temperature is consistent with the transition to a fully low spin state. $[Fe(\mathbf{1} - 2H)_2]^-$ in methanol gave μ_{eff} = 1.92 μ_B consistent with low spin Fe(III), while a solution of stoichiometric composition $[Fe(\mathbf{1})_2]^{3+}$ gave μ_{eff} = 6.3 μ_B, indicating high spin Fe(III). It is thus possible to switch the spin states by pH changes.

Deprotonation of coordinated imidazole at the pyrrolic hydrogen has been reported on many occasions[5] and often results in the imidazolate acting as a bridging ligand with formation of binuclear species.[6] For **1** − 2H this is impossible as a result of steric hindrance from the pyridyl moiety, but the basic nature of the deprotonated nitrogens is shown by the strong hydrogen bonds formed between N3 and N5 and the water molecules bound to sodium in $[Fe(\mathbf{1} - 2H)_2][Na-$

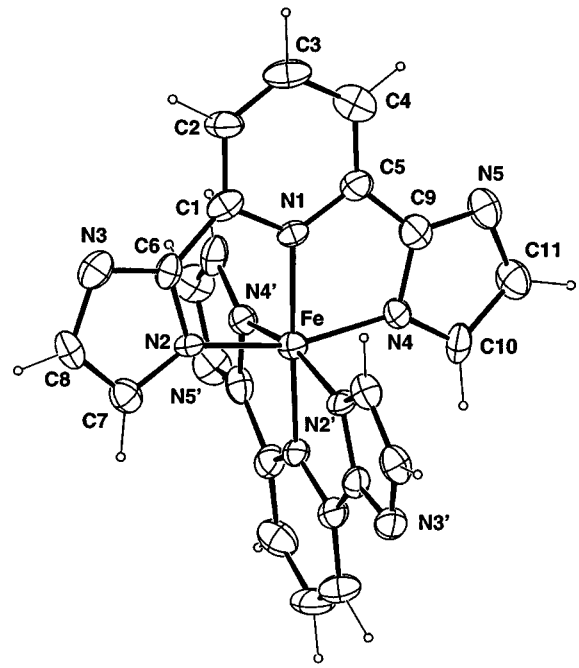


Fig. 1 Structure of the $[Fe(\mathbf{1} - 2H)_2]^-$ ion. A crystallographic twofold axis passes through the iron atom perpendicular to the pyridine–pyridine axis. Ellipsoids are shown at the 40% probability level.

$(H_2O)_4]_{0.5}[Na(MeCN)_4(THF)_2]_{0.5}$ [distances N···O 2.78(1) and 2.81(1) Å]. Potentiometric titration of a solution of $[Fe(\mathbf{1})_2]^{2+}$ [DMF–H_2O (4 : 1), I = 0.1 M KNO_3, in presence of air] with KOH showed the loss of four protons with pK values (estimated by a least squares fitting of the titration curve) of 8.19(5), 8.67(7), 9.86(10) and 9.92(9). These values should be interpreted with some caution since oxidation probably occurs before dissociation of all the protons. After removal of two protons the spectrum of the mixture is very similar to a superposition of the spectra of $[Fe(\mathbf{1})_2]^{2+}$ and $[Fe(\mathbf{1} - 2H)_2]^{-}$.The p$K_a$s are close to those previously reported for imidazole bound to Fe(II).[5]

We have found no reference to the effect of imidazole deprotonation upon redox potential in the literature. Although we would intuitively expect that the progressive introduction of negative charge onto the ligand would favour the higher oxidation state, the magnitude of the effect, some 1380 mV, is much greater than we anticipated. Haga *et al.* have studied the effect of deprotonation of coordinated benzimidazole ligands in ruthenium and osmium complexes[7] and has shown a shift of the reduction potential to more negative values upon deprotonation of *ca.* 300 mV per proton. This is broadly consistent with the effect observed here for the removal of four protons. It is of course well known that deprotonated pyrrolic ligands such as porphyrins and phthalocyanines allow stabilisation of iron(III) in a low spin state.

In conclusion, we have shown that it is possible to switch the redox potential of the iron(III)/iron(II) couple from strongly oxidising to strongly reducing over a limited range of pH (between 8 and 10). There is consequently a strong coupling between electron and proton transfer: proton loss from the ligand is followed by electron loss from iron(II), and proton capture by the ligand makes the iron(III) oxidising. We believe that this may be significant for biological oxygen chemistry, where reduction of dioxygen is accompanied by proton transfer to the dioxygen moiety, and oxidation of water requires concomitant deprotonation. It is to be noted that in many oxygen-reducing enzymes, iron is coordinated by imidazole ligands from histidine residues,[8] while in photosystem II the manganese ions are equally thought to have imidazole in the coordination sphere.[9] In such systems deprotonation of the imidazole might allow the attainment of a high oxidation state for manganese; proton transfer from coordinated water to the imidazole would then raise the oxidation potential of the metal to a degree where oxidation of the coordinated oxygen would be possible. Experiments to test this hypothesis are in progress. Finally, we may note that the protonation–deprotonation equilibrium also switches the spin state of the iron, and the affinity of the ligand for the metal, notably in the Fe(III) state.

Photoreductive dechlorination of chlorinated benzene derivatives catalyzed by ZnS nanocrystallites

Yuji Wada,[a] Hengbo Yin,[b] Takayuki Kitamura[a] and Shozo Yanagida*[a]

[a] *Material and Life Science, Graduate School of Engineering, Osaka University, Suita, Osaka 565-0871, Japan*
[b] *Department of Chemical Engineering, Shenyang Institute of Chemical Technology, Shengyang, China*

Received (in Cambridge, UK) 3rd August 1998, Accepted 28th October 1998

ZnS nanocrystallites effectively enhanced photo-reduction of chlorinated benzene derivatives in the presence of triethylamine as a sacrificial electron donor under UV irradiation (λ > 300 nm), leading to selective and stepwise dechlorination to give benzene at the final stage.

Photochemical detoxification of halogenated compounds, such as PCB, dioxin, and DDT, has been attracting much attention because this can be regarded as a promising process to eliminate C–Cl bonds under environmentally relevant and mild conditions. In particular, TiO_2-catalyzed photoprocesses involving oxidation and reduction in aqueous systems have been extensively investigated.[1] In such systems, however, photooxidation proceeds through the formation of hydroxyl radical (HO•), leading to unavoidable formation of unknown photoproducts especially from polychlorinated compounds.[2,3] Further, the rate of such photodegradation often slows in the case of polychlorinated compounds because they are electron-deficient molecules, *i.e*. their oxidation potentials are very positive in nature, showing resistance to the electrophilic attack of HO•.[4] Therefore, reductive processes with semiconductors should be investigated practically for the purpose of detoxification of chemicals.[5,6]

In this paper, we show that photoreduction induces selective dehalogenation of chlorinated benzene derivatives, providing more favorable dehalogenation processes than the photooxidative ones. In particular, ZnS nanocrystallites stabilized in *N*,*N*-dimethylformamide (DMF)[7] catalyze photoreduction of chlorinated benzene derivatives, leading to their step-wise dechlorination under UV-irradiation at ambient temperature.

A DMF solution of ZnS nanocrystallites was prepared by the reaction of $Zn(ClO_4)_2$ with H_2S under cooling with ice and water as described elsewhere.[7] Photoreactions were carried out under cooling with water by UV irradiation of a DMF solution (2 ml) containing a substrate (25 mM), ZnS nanocrystallites (2.5 mM in diatomic concentration as ZnS) and triethylamine (TEA, 1 M) in a Pyrex glass tube using a 500 W high pressure mercury lamp. The reaction mixtures were analyzed by gas chromatography with a fused silica capillary column (HiCap-CBP20, 25 m × 0.2 mm, Shimadzu) using dodecane as an internal standard.

Fig. 1 shows time conversion plots of the photoreaction of 1,4-dichlorobenzene. The concentration of 1,4-dichlorobenzene decreased during irradiation with and without ZnS nanocrystallites. However, the rate of the conversion in the presence of ZnS nanocrystallites was twice that at the beginning and several times faster at the later stages than that in the absence of ZnS crystallites. In parallel with the consumption of 1,4-dichlorobenzene the formation of chlorobenzene was observed and benzene was formed at the final stage, *i.e*. after the induction period of 1 h with the decreased rate of formation of chlorobenzene, indicating that 1,4-dichlorobenzene is dechlorinated successively to benzene through chlorobenzene. Hydrogen was formed competitively but in a small amount (2–3 μmol in 5 h) in the presence of ZnS nanocrystallites. No other byproducts, such as biphenyl derivatives and chlorophenol, were detected by GC analysis, showing a consistent material balance between the consumed substrate and the products.

The dechlorination proceeded at a relatively high rate even without ZnS nanocrystallites. The absorption spectrum measured for the mixture of 1,4-dichlorobenzene and TEA showed the appearance of a shoulder at the long wavelength edge of the absorption of 1,4-dichlorobenzene, suggesting the formation of the exciplex between the two compounds. The formation of the exciplex should contribute to the photochemical dechlorination without the catalyst.[8,9] On the other hand, the photocatalytic dechlorination in the presence of ZnS nanocrystallites should mainly proceed through the excitation of ZnS, since ZnS nanocrystallites absorb most light in this region when they are present in the system.

In our earlier report, ZnS nanocrystallites prepared in DMF act as a photocatalyst for the two-electron reduction of CO_2 to HCOOH or CO in the presence of triethylamine.[7] The photogenerated electrons on ZnS nanocrystallites possess such a high reducing power (< -2.2 V *vs*. SCE) that the substrates are subject to successive two-electron reduction, causing the stepwise dechlorination. This fact suggests that the anion radicals first formed should be readily dechlorinated to the radicals, which may undergo further reduction and protonation. The electrons can be supplied by photooxidation of TEA. The resulting TEA^{+}• works as a proton source giving $[Et_2NHCHCH_3]$• which can also function as a good electron source in the system.[7]

In Table 1 are listed the conversions and the product distributions for the photodechlorination of various chlorobenzene derivatives observed in the presence of ZnS nanocrystallites with their reduction potentials.[10,11] The distribution of the products observed for the reactions of polychlorobenzenes well confirmed the successive and stepwise dechlorination reactions. For example, in the reaction of 1,2,3,4-tetrachlorobenzene, 1,2,4-trichlorobenzene formed preferentially is dechlorinated at the 2 position giving 1,4-di-

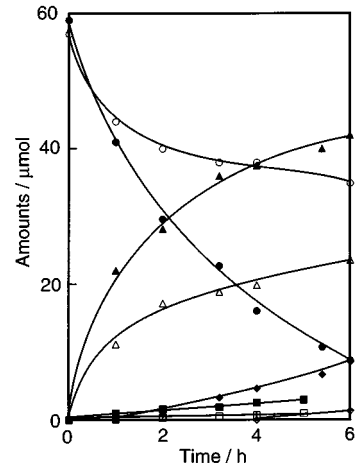

Fig. 1 Time profile of the photocatalytic dechlorination of 1,4-dichlorobenzene by ZnS nanocrystallites. In the presence of ZnS: 1,4-dichlorobenzene (●), chlorobenzene (▲), benzene (◆), hydrogen (■); in the absence of ZnS: 1,4-dichlorobenzene (○), chlorobenzene (△), benzene (◇), hydrogen (□).

[a] Reaction solution containing substrate (25 mM), TEA (1 M) and ZnS (2.5 mM) in DMF was irradiated with UV light (λ > 300 nm) under N_2. Abbreviations: ben, benzene; m, chlorobenzene; 1,4-di-, 1,4-dichlorobenzene; 1,3-di, 1,3-dichlorobenzene; 1,2-di, 1,2-dichlorobenzene; 1,2,3-tri, 1,2,3-trichlorobenzene; 1,2,4-tri, 1,2,4-trichlorobenzene; tetra, 1,2,3,4-tetrachlorobenzene. [b] Starting substrates. [c] From ref. 9 and 10; measured in DMSO solution containing TEABr (0.1 M) as electrolyte. [d] Irradiation time. [e] Conversion of substrates.

chlorobenzene as the predominant product in the isomers of dichlorobenzene, and is further dechlorinated to benzene through chlorobenzene.

The order of the photocatalytic dechlorination rates was 1,2,3-trichlorobenzene > 1,4-dichlorobenzene > 1,2,3,4-tetrachlorobenzene > 1,2,4-trichlorobenzene ≈ 1,3-dichlorobenzene ≈ 1,2-dichlorobenzene >> chlorobenzene. This order is roughly explained by the order of the redox potentials shown in Table 1, in other words, ease of reduction of the substrates.

In conclusion, the reduction of polychlorobenzene photocatalyzed by ZnS nanocrystallites gives selective and successive dechlorination without formation of any unidentified byproducts containing chlorine atoms. This photoreduction should provide a new strategy for detoxification of hazardous chlorinated aromatics under minimum-energy conditions.

Stabilization of the merocyanine form of photochromic compounds in fluoro alcohols is due to a hydrogen bond

Takayuki Suzuki, Fu-Tyan Lin, Satyam Priyadashy and Stephen G. Weber*

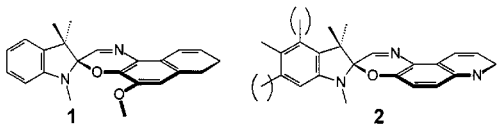
Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 5260, USA. E-mail: sweber+@pitt.edu

Received (in Columbia, MO, USA) 10th August 1998, Accepted 3rd November 1998

Fluoroalcohols [1,1,1,3,3,3-hexafluoropropan-2-ol (HFP), 2,2,2-trifluoroethanol (TFE) and 2-fluoroethanol (FE)], acting as Lewis acids, stabilize the π-conjugated, colored merocyanine forms of spiropyran and spirooxazine photochromic compounds as metal ions do.

We[1] and others[2] have been interested in the interactions of metal ions with photochromic compounds such as spiropyrans, spironaphthoxazines, and chromenes for potential applications in optical switching, memory and sensors. In these photochromic compounds, light is used to cleave a single C–O bond in the pyran or oxazine ring (so-called closed form) which results in the creation of a relatively more polar species (so-called open or merocyanine form). Metals influence this process by associating with this now electron-rich oxygen atom in the open form. It has been reported that 1,1,1,3,3,3-hexafluoropropan-2-ol (HFP) stabilizes the merocyanine form of polymer-bound nitrospiropyran through a general effect of the solvent's 'polarity'.[3] We wondered if HFP and other fluoro alcohols[4] known as good H-bond donors could stabilize the open form of spirooxazines in particular, and other similar photochromics in general, and if so, do they work as the metal ions do, through a specific Lewis acid/Lewis base interaction?

Compound **1**, 1,3-dihydro-5-methoxy-1,3,3-trimethylspiro-



1 **2**

[2*H*-indole-2,3′-[3*H*]naphtho[2,1-*b*][1,4]oxazine] is purple at room temperature at equilibrium without photolysis in HFP-*d* (2 atom% ^{1}H on the hydroxy group). ^{1}H NMR integration shows that about 50% of **1** exists in the open form(s) **1′**. ^{1}H ROESY spectra for these solutions have cross peaks between the solvent hydroxy proton and the *N*-methyl protons in **1**. There is also a cross peak between the solvent hydroxy proton and the methoxy methyl in the merocyanine form of the molecule **1′**. There is evidence for both so-called TTC[5] and TTT isomers of **1′**; cross peaks are indicated as arrows in Fig. 1.

Compound **2** (1,3,3-trimethyl 5,6-dimethylspiro[2*H*-indole-2,3′-[3*H*]pyrido[3,2-*f*][1,4]benzoxazine][6]) also opens to the merocyanine form(s) **2′** in fluoro alcohols. Compound **2′** comprises 70 mol% in HFP, 15 mol% in TFE, 9 mol% in FE, and 2 mol% in EtOH in the dark. A TFE-d_3 (5 atom% ^{1}H) solution containing **2** is also purple at equilibrium at room temperature, although it is only about 15% open form. A signal is observed between the hydroxy proton of TFE and the 2′-proton of **2′** (ring proton *ortho* to the oxygen) in the ^{1}H NOESY spectrum. Furthermore, the resonance of the hydroxy proton of TFE is deshielded (δ 5.4) in comparison to pure TFE (δ 5.2) as shown in Fig. 2. When the solution is irradiated with UV (300–400 nm) light, the resonance becomes more deshielded (Fig. 2). We infer that TFE interacts with **2′** *via* an H-bond to the oxygen with rapid exchange on the NMR time scale (500 MHz). Additionally, we note a signal between the *N*-methyl protons at the indole group and the imine proton for **2′** in the ^{1}H NOESY spectrum, while there are no signals between the imine proton and the geminal methyl protons, nor are there signals between the imine proton and the 2′-proton; thus, for **2′**, TTC is the only isomer in TFE. In a solution of **2** in HFP, which is 70% ring-opened, there are several cross peaks (^{1}H ROESY) indicating the presence of both the TTC and TTT isomers. The cross peaks are illustrated schematically in Fig. 3. There is also a cross peak between the solvent hydroxy proton and the open-form *N*-methyl protons, once again indicating a possible H-bond to the former oxazine ring oxygen. If, as implied in the ^{1}H NMR studies, the stability of the open forms is due to H-bonding, there should be additional manifestations of the H-bond on the properties and spectroscopy of the compounds.

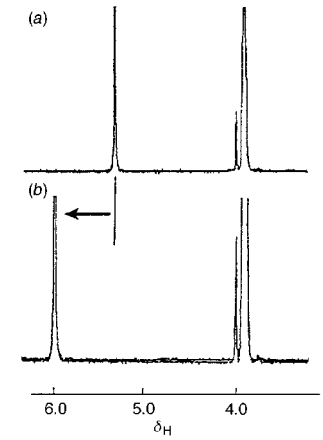


Fig. 2 ^{1}H NMR spectra (500 MHz) of the hydroxy proton of (*a*) TFE equilibrated in the dark, and (*b*) the same solution measured after irradiation with UV light. The TFE-d_3 solution contains **2**/**2′** (15 mM) and TFE (0.5 mM).

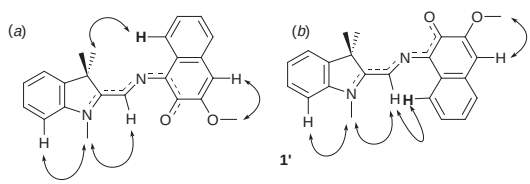

Fig. 1 (*a*) TTC and (*b*) TTT merocyanines **1′**. Cross peaks in the ^{1}H ROESY spectrum used to assign the structure are shown as curved arrows. The cross peaks of the bold H atoms are particularly diagnostic.

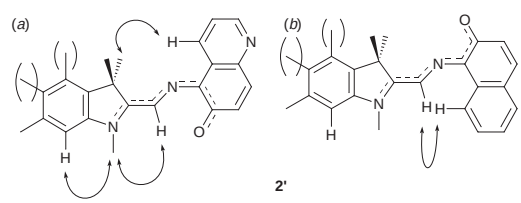

Fig. 3 (*a*) TTC and (*b*) TTT merocyanines **2′**. Cross peaks in the ^{1}H ROESY spectrum used to assign the structure are shown as curved arrows.

By perturbing a solution of **2**/**2′** in TFE with the appropriate wavelength range of light, excess **2** or **2′** can be formed. Both time courses can be analyzed as first order reactions within the temperature range of 15–40 °C (Fig. 4). Both activation energies are equal (25 ± 1 kcal mol^{-1} **2**→**2′**, 25 ± 1 kcal mol^{-1} **2′**→**2**), so the resulting difference is the enthalpy difference between **2** and **2′** which is 0 ± 1.4 kcal mol^{-1}. Typical values for similar molecules are *ca.* 4 kcal mol^{-1} in most solvents, from the non-polar benzene and toluene to the polar EtOH and MeCN.[7] The difference of 4 kcal mol^{-1} is consistent with the enthalpy of an H-bond in general[8] and with those between TFE and various acceptors in noncompetetive solvents[9] in particular.

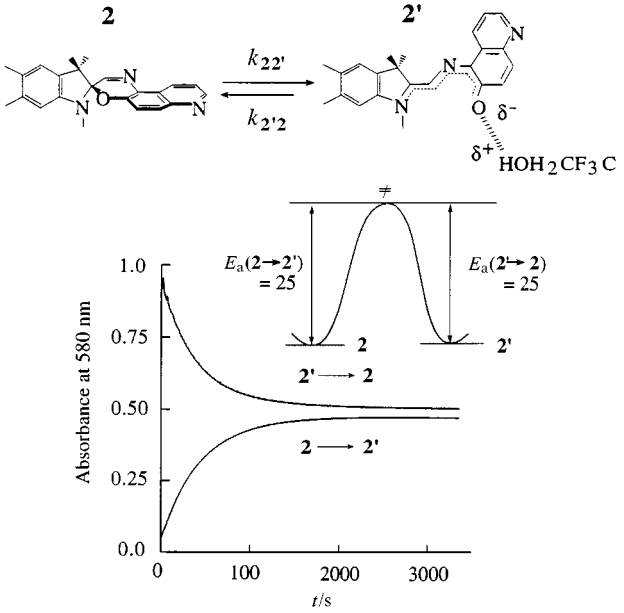

Fig. 4 Kinetics of the opening and closing reactions of **2**/**2′** in TFE (0.7 mM) at 22 °C. Activation energies are in kcal mol^{-1}.

If there is a specific H-bond formed as hypothesized, then there should be a shift in the λ_{max} of the long wavelength band of the merocyanine.[6] In common solvents, the long wavelength band of the merocyanine is weakly solvatochromic (*e.g.* λ_{max} in toluene, MeCN and MeOH for **2′** is 602 nm, EtOH, 605 nm, ethylene glycol and 3-methyloxazolidin-2-one, 610 nm). However, in the fluoro alcohols there is considerable solvatochromism (λ_{max} values: HFP, 534 nm; TFE, 582 nm; FE, 590 nm). The values of $E_T(30)$ as a benchmark for the strength of hydrogen-bond donation and polarity of the fluoro alcohols are also in the order HFP > TFE > FE [$E_T(30)$: 63.3, 59.8, 55.5 respectively].[4f] Furthermore, there is a good correlation between the energy of the long wavelength band of the merocyanine and the logarithm of the equilibrium constants (estimated as [**2′**]/[**2**] from the NMR data). Thus, changes in the energy of the ground state, through solvent H-bonding to the oxygen, influence the spectroscopy and the equilibrium consistently.

We have performed *ab initio* calculations[13,14] on all the solvent molecules and the solute **2′**. We also performed preliminary calculations on the H-bonded complexes at the semiempirical quantum level using PM3 parameterization. Full geometry optimizations of the complexes with the solvents HFP, TFE and FE were performed. The calculated H-bond distance between the O of the **2′** carbonyl and the H of the hydroxy hydrogen of the solvent are 1.7729, 1.818 and 1.820 Å for HFP, TFE and FE, respectively. The calculations support the observed order in the effectiveness of the fluoro alcohols in stabilizing the merocyanine form. Theory also shows very little change in the O–H bond distances in the fluoro alcohols (difference: complex-free solvent (Å) HFP: 0.014, TFE: 0.0163, FE: 0.0058).

Finally, we note that the behavior in the Lewis acid solvents differs dramatically from the behavior in the weak Brönsted acid, glacial acetic acid (AA). A sample of **2**/**2′** in AA, after a considerable time, yields a band at 420 nm. This solution is not photoactive. The band at 420 nm arises from protonated **2′** with TTT geometry [Fig. 3(*b*)].[1b] When a quantity of Et_3N equivalent to the AA is added to the solution, the band due to the protonated form disappears. There is no significant absorbance in the visible region. Illumination with UV light yields a transient absorption peak at 610 nm, which is characteristic of **2′** in polar solvents.

The Lewis acid Zn^{II} causes the ring opening reaction **2**⟶**2′**. The complex is stable, as is the solvate of HFP. The visible wavelength is 538 nm, between that of HFP and TFE solutions. Thus, the original hypothesis that Lewis acids of different sorts similarly influence the structure and properties of the photochromic species is confirmed.

We are grateful to Dr Barry van Gemert and Mr David Knowles at PPG, Inc., Chemicals Division, for providing **1** and **2**. This work was supported by the Office of Naval Research and the National Science Foundation (CHE-9710213).

Received (in Cambridge, UK) 26th October 1998, Accepted 6th November 1998

The synthesis and characterisation of a novel microporous niobium silicate (AM-11), an excellent catalysts for the conversion of alcohols, are reported.

Recently, the synthesis of microporous framework titanium silicates, displaying zeolite-type properties and containing Ti(IV) usually in octahedral coordination, has attracted much interest.[1–4] As a natural extension of this work, we have embarked on a systematic study aimed at preparing novel microporous zirconium[5] and niobium[6] silicates. Here we report the synthesis and structural characterisation of a novel microporous niobium silicate denoted AM-11 (Aveiro-Manchester microporous solid no. 11).

AM-11 was prepared in Teflon-lined autoclaves under static hydrothermal conditions. An alkaline solution was made by mixing 1.27 g tetraethylorthosilicate (Aldrich), 2.40 g ethanol, 6.40 g H_2O, 1.68 g NaOH (Merck) and 0.53 g NaF (Aldrich). A second solution was made by mixing 20.0 g H_2O, 3.00 g oxalic acid (Panreac), 1.00 g niobium oxalate (Niobium Products) and stirred overnight. These two solutions were combined, seeded with 0.1 g ETS-4[1] and stirred thoroughly. The pH (after a 1 : 100 water dilution) was adjusted to 10.2 by adding an ammonia solution (25%, Merck). The gel, with a composition 1.0 Na_2O : 1.0 SiO_2 : 0.15 Nb_2O_5 : 240 H_2O, was autoclaved for 15 days at 200 °C. The crystalline product was filtered off, washed with distilled water and dried at ambient temperature, the final product being an off-white microcrystalline powder.

AM-11 samples were characterised by powder X-ray diffraction (XRD), scanning electron microscopy (SEM), ^{93}Nb, ^{29}Si and ^{23}Na magic-angle spinning nuclear magnetic resonance (MAS NMR), Raman spectroscopy, thermogravimetry (TG), adsorption isotherms and catalytic tests.

SEM (not shown) reveals that AM-11 crystals are needles *ca.* 10 μm in length. Energy dispersive absorption of X-rays yields Si/Nb and Na/Nb molar ratios of *ca.* 4.6 and 0.3, respectively.

The total AM-11 mass loss between 30 and 700 °C is *ca.* 16.5%. Two stages of dehydration are observed (not shown): between 30 and 270 °C the solid loses *ca.* 10.5% while between 270 and 700 °C the mass loss is *ca.* 6%. The adsorption behaviour of AM-11 was investigated in order to assess the porosity of the material. Nitrogen and methanol adsorption isotherms are both type I with maximum uptakes of *ca.* 0.15 and 0.11 g g^{-1}, respectively. Although the material is microporous, the propane uptake was found to be negligible suggesting a very small pore size. However, ethanol, *n*-propanol and 2-methylpropan-1-ol have uptakes of *ca.* 0.6–0.7 g g^{-1} at $P/P^0 = 0.5$. This conflicting behaviour may originate in the polarity of the sorbate.

The powder XRD pattern of AM-11 is shown in Fig. 1, while the *d*-spacings and intensities of the main reflections are collected in Table 1. Peak intensities were altered by changing the method of sample preparation indicating the occurrence of preferred orientation effects. *In situ* powder XRD patterns recorded under vacuum at temperatures up to 650 °C (not shown) are similar to the pattern given by the parent hydrated material. The water in AM-11 is zeolitic and its removal is not permanent. This was confirmed by first heating a sample at 650 °C and then keeping it, for several hours, in contact with air at room temperature. The powder XRD patterns and TG curves of the parent and calcined hydrated materials were found to be identical.

The ^{29}Si MAS NMR spectrum of AM-11 [Fig. 2(*a*)] displays a resonance at δ −95.6, a group of (at least) three overlapping peaks at δ −105.5, *ca.* −106.7 and −108.1 and a sharp signal at δ −111.1. The attribution of these resonances is difficult because, to the best of our knowledge, no systematic study is available on the relationship between the ^{29}Si NMR chemical shift and the number of niobium polyhedra coordinating a given silicon tetrahedron. Our previous study on synthetic analogues of the mineral nenadkevichite, containing framework niobium,[6] suggests that this relationship may be similar to that found for titanium silicates where a systematic downfield chemical shift is observed when increasing numbers of titanium polyhedra coordinate a given silicon tetrahedron.[7] We assign the peak at δ −111.1 to Si(4 Si, 0 Nb) environments. The resonances at δ −105.5, *ca.* −106.7 and −108.1 are tentatively assigned to Si(4 Si, 0 Nb) or Si(3 Si, 1 Nb) environments,[3] while that at δ −95.6 is attributed to Si(3 Si, 1 Nb) or Si(2 Si, 2 Nb) sites.

The central-transition ^{93}Nb MAS NMR spectrum [Fig. 2(*b*)] of AM-11 contains a broad (full-width at half maximum, FWHM, *ca.* 127 ppm) resonance centred at δ −100 relatively to solid Nb_2O_5 (the other peaks are spinning sidebands). Considering the few ^{93}Nb NMR spectra reported for niobium

3.571	43	2.125	20

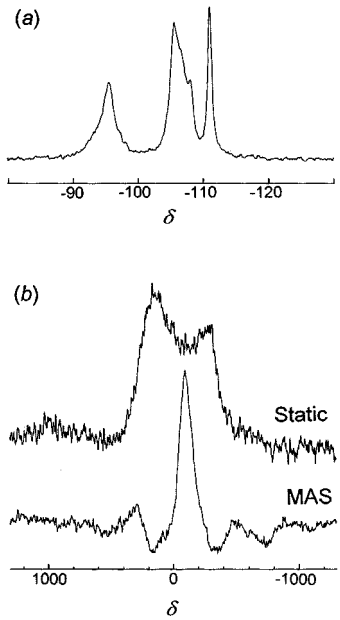

Fig. 2 (*a*) ^{29}Si MAS, (*b*) ^{93}Nb MAS and static NMR spectra of AM-11, recorded at 79.50 and 97.84 MHz on a Bruker MSL 400P spectrometer using spinning rates of 5 and 32 kHz, respectively.

Table 2 Conversions and product distributions (wt%) of isopropanol and *tert*-butanol over AM-11[a]

	Isopropanol[b]	*tert*-butanol[c]
Conversion	99.9	99.9
Propene	85.7	
Acetone	14.2	
Isobutene		98.9
C_5–C_9		1.0

[a] Catalyst activation at T = 400 °C and P = 1 atm for 3 h. [b,c] P = 1 atm, WHSV = 2 h^{-1}, TOS = 60 min; [b] T = 350 °C, Ar carrier gas flow 10 ml min^{-1}; [c] T = 250 °C, Ar carrier gas flow 30 ml min^{-1}.

silicates containing hexa-coordinated niobium which give resonances at *ca.* δ 0,[6] this value is slightly shifted to low frequency. This may be due to a large quadrupole coupling constant, (simulation of the static spectrum in Fig. 2(*b*) indicates a rather large value, in excess of 26 MHz) which results in a significant low-frequency shift. The FWHM of the static spectrum is *ca.* 640 ppm. Hence, MAS narrows the NMR resonance by a factor of five. Now, when second-order quadrupole effects dominate, MAS only narrows the peaks by a factor of *ca.* 3.6. We conclude that other line broadening mechanisms, such as chemical shift anisotropy and dipolar interactions are in operation.

The central-transition ^{23}Na MAS NMR spectrum of AM-11 (not shown) contains a broad peak centred at δ −6 with a faint shoulder at *ca.* δ −12 (relatively to aqueous NaCl).

The Raman spectrum of AM-11 (not shown) displays a main, strong and sharp, band at 687 cm^{-1} and several fainter bands in the range 100–300 cm^{-1}. The former peak is typical of NbO_6 octahedra in porous niobium silicates: the synthetic analogues of nenadkevichite give a similar peak at 668 cm^{-1} and weak bands at 100–300 cm^{-1}.[6]

A preliminary charcterisation of the acid–base properties of AM-11 was performed by means of isopropanol conversion, a probe reaction which is tailored for both acidity and basicity.[8] The main products of this catalytic process are propene and acetone resulting from acid dehydration and base-catalysed dehydrogenation respectively. The product distributions are given in Table 2 and indicate that this material exhibits both acidic and basic active sites in its as-synthesised form. Further studies of the catalytic properties of AM-11 were carried out using *tert*-butanol. From the results given in Table 2, it is apparent that AM-11 dehydrates *tert*-butanol to isobutene with remarkably high activity and selectivity. This finding coupled with the large pore volume of this material point to its potential in catalysis. Moreover, conventional ion-exchange experiments may enhance both its basic and acidic properties.

In conclusion, we report the synthesis and characterisation of AM-11, a novel microporous niobium silicate which is a promising catalyst for the dehydration of alcohols. Work is in progress in order to solve the crystal structure of this material.

Fast and selective homogeneous hydrogenation with nickel(II) phosphane catalysts

Ingrid M. Angulo, Alexander M. Kluwer and Elisabeth Bouwman*

Leiden Institute of Chemistry, Gorlaeus Laboratories, Leiden University, PO Box 9502, 2300 RA Leiden, The Netherlands. E-mail: bouwman@chem.leidenuniv.nl

Received (in Cambridge, UK) 25th September 1998, Accepted 28th October 1998

Nickel(II) phosphane complexes are able to hydrogenate oct-1-ene to *n*-octane with high turnover numbers and high selectivities at low temperature and moderate pressure.

From recent research it is known that the active site of the enzyme hydrogenase contains nickel.[1] This enzyme, present in some bacteria, activates molecular hydrogen at atmospheric pressure and room temperature. However, although nickel is widely used as a heterogeneous catalyst for hydrogenation reactions (Raney nickel), homogeneous hydrogenation catalysts containing nickel are scarcely found in the literature.[2] Yet, homogeneous nickel catalysts are known for related reactions like isomerisation, oligomerisation, polymerisation, hydrosilylation and hydrocyanation.[3]

Herein we report on a novel *homogeneous in situ* nickel catalyst for the hydrogenation of linear olefins. In this research nickel(II) acetate in combination with several diphosphane ligands was tested on catalytic activity in the hydrogenation of oct-1-ene (Scheme 1).

In our search for homogeneous nickel hydrogenation catalysts, initially nickel(II) salts in the absence of any ligands were tested. Nickel(II) acetate, without addition of ligand, showed some hydrogenation activity at a reaction temperature of 373 K. It has been reported that nickel(II) acetate in methanol in reductive reaction conditions at elevated temperatures may form colloidal nickel,[4] which is an active, but heterogeneous hydrogenation catalyst. The presence of a black precipitate in the reaction mixture after the hydrogenation reaction at 373 K indicates that also in this case some colloidal nickel was formed. However, this hydrogenation activity drops to zero when the reaction temperature is lowered to 323 K; even after 20 h no hydrogenation activity was observed and no colloidal nickel was formed.

Subsequently, some didentate phosphane ligands were added to nickel(II) acetate, to investigate their influence on catalytic activity.† The results of the hydrogenation reactions are presented in Table 1.

Initially, two simple phosphane ligands, dppe and dppp (for abbreviations see Scheme 1), were used (Table 1, entries 1 and 2). Whereas nickel(II) acetate alone shows some hydrogenation activity at 373 K (probably heterogeneous), the presence of dppe or dppp leads to an unreactive complex. When dppe or dppp is added to the green nickel(II) acetate solution, almost immediately a yellow complex is formed. The fact that the colour of this solution does not change during the hydrogenation experiment and that no black precipitate is observed, indicates that the phosphane ligands prevent the formation of colloidal nickel. As the simple phosphane ligands dppe and dppp did not lead to active hydrogenation catalysts, it was decided to use some more complex phosphane ligands, and methoxyphenyl and cyclohexyl derivatives were selected (Scheme 1).

$R_2P(CH_2)_nPR_2$

Ligand[a]	R	*n*
dppe	Ph	2
dppp	Ph	3
dcpe	*c*-C_6H_{11}	2
dcpp	*c*-C_6H_{11}	3
o-MeO-dppe	*o*-$MeOC_6H_4$	2
o-MeO-dppp	*o*-$MeOC_6H_4$	3
m-MeO-dppe	*m*-$MeOC_6H_4$	2
m-MeO-dppp	*m*-$MeOC_6H_4$	3
p-MeO-dppp	*p*-$MeOC_6H_4$	3

Scheme 1 Structure of the ligands. dppe = 1,2-bis(diphenylphosphino)-ethane, dppp = 1,3-bis(diphenylphosphino)propane, dcpe = 1,2-bis(dicyclohexylphosphino)ethane, dcpp = 1,3-bis(dicyclohexylphosphino)propane, *o*-MeO-dppe = 1,2-bis(di-*ortho*-methoxyphenylphosphino)ethane, *o*-MeO-dppp = 1,3-bis(di-*ortho*-methoxyphenylphosphino)propane, *m*-MeO-dppe = 1,2-bis(di-*meta*-methoxyphenylphosphino)ethane, *m*-MeO-dppp = 1,3-bis(di-*meta*-methoxyphenylphosphino)propane, *p*-MeO-dppp = 1,3-bis(di-*para*-methoxyphenylphosphino)propane.

First, *o*-MeO-dppe was tested in combination with nickel(II) acetate for hydrogenation activity at 373 K in methanol. The formed catalytic species was very active, so that within 15 min, all the oct-1-ene had reacted. Therefore the hydrogenation reaction was performed at a lower temperature of 323 K (Table 1, entry 3). After 1 h the reaction mixture contained, besides *n*-octane and unreacted oct-1-ene, also some isomerisation products, mainly *cis*- and *trans*-oct-2-ene. The propane-bridged analogue *o*-MeO-dppp was also tested on hydrogenation activity in combination with nickel(II) acetate (Table 1, entry 4). With this ligand the activity is increased to 350 turnovers h^{-1}. Furthermore, when ethanol is used as the solvent the activity increased further to 410 turnovers h^{-1} (Table 1, entry 5).

Application of the cyclohexyl ligand dcpe leads to a very active catalyst (Table 1, entry 6). The reaction temperature had to be lowered even further, to 298 K, to be able to follow the reaction course. Even at this low temperature a high turnover number of 460 after 1 h was reached. In contrast to the results obtained with the *ortho*-methoxy ligands the propane-bridged analogue dcpp leads to a somewhat less active catalyst with 350 turnovers h^{-1} (Table 1, entry 7).

In order to establish the homogeneity of the catalysts, the catalytic activity as a function of the amount of catalyst was determined. Only in the case of a homogeneous catalyst is the activity expected to be directly proportional to the catalyst concentration. We performed this test with the *in situ* catalyst formed with nickel(II) acetate and *o*-MeO-dppe; we found that

Table 1 Nickel-catalysed hydrogenation of oct-1-ene[a]†

Entry	Ligand	TON[b]	*T*/K	Solvent
1	dppe	0	373	EtOH
2	dppp	0	373	EtOH
3	*o*-MeO-dppe	220	323	MeOH
4	*o*-MeO-dppp	350	323	MeOH
5	*o*-MeO-dppp	410	323	EtOH
6	dcpe	460	298	MeOH
7	dcpp	350	298	MeOH
8	*m*-MeO-dppe	0	373	MeOH
9	*m*-MeO-dppp	0	373	EtOH
10	*p*-MeO-dppp	0	373	EtOH

[a] *Reaction conditions*: oct-1-ene/Ni = 500, Ni/ligand = 1, [Ni] = 0.005 M, *t* = 1 h, $p(H_2)$ = 50 bar. [b] Turnover number in mol *n*-octane per mol $Ni(OAc)_2$ after 1 h.

the activity of the catalyst increased linearly (correlation coefficient = 0.997) with the catalyst concentration. It is possible that the reaction conditions, dihydrogen, electron-rich phosphine plus an alcohol solvent, can cause reduction of nickel, leading to a heterogeneous catalyst, but even when a non-coordinating, electron-rich phosphine, such as tris(*ortho*-methoxyphenyl)phosphine, is used under identical reaction conditions, no hydrogenation activity is observed. These results, in combination with the observation that pure nickel(II) acetate does not lead to an active catalyst under the reaction conditions, lead to conclusion that genuine homogeneous catalysts are observed here.

The positive effect of the *ortho*-methoxyphenyl and the cyclohexyl groups in the diphosphane ligands on the hydrogenation activity compared to dppe and dppp could be due to either steric or electronic effects. Both the *ortho*-methoxyphenyl group and the cyclohexyl group are weaker π-acceptors than a simple phenyl group. As a consequence the basicity of the phosphorus atoms in the corresponding diphosphane ligands is higher, which will influence the electrophilic nature of the nickel(II) ion. This extra electron density at the metal increases its ability to interact with dihydrogen. Furthermore, *ortho*-methoxyphenyl and cyclohexyl groups are much more bulky than the phenyl group.

In an initial attempt to separate electronic from steric effects of the methoxyphenyl group the *meta* and *para* analogues of these phosphane ligands were also tested for hydrogenation activity in combination with nickel(II) acetate (Table 1, entries 8, 9 and 10). None of the formed complexes showed any hydrogenation activity even at higher reaction temperatures. Only some isomerisation was observed in the case of *p*-MeO-dppp. This indicates that the positive effect of the *ortho*-methoxyphenyl groups on the hydrogenation activity is predominantly steric. It is known that the ligands dppe and dppp can form bis(ligand) complexes with nickel such as in $[Ni(dppe)_2][NO_3]_2$.[5] A positive influence because of steric properties may be explained by a lower probability of the formation of inactive bis(ligand) complexes with the bulkier *ortho*-methoxyphenyl- or cyclohexyl-derived ligands. So far, no X-ray structures of bis(ligand) complexes containing the *ortho*-methoxyphenyl and the cyclohexyl groups in the diphosphane ligands have been reported.

It is assumed that the catalytic cycle for isomerisation at least partly coincides with that of the hydrogenation reaction. With some of the catalysts reported here, a considerable amount of the oct-1-ene is initially isomerised; However, over time the amount of these internal olefins also decreases suggesting that either the catalyst is able to hydrogenate these or isomerisation back to the terminal olefin occurs. Further investigations will concentrate on elucidating the mechanism of the hydrogenation reaction and isomerisation, with these nickel catalysts by variation of the substituents on the phosphane ligand and by changing the reaction conditions.

In conclusion, novel truly homogeneous nickel containing hydrogenation catalysts are described, which show faster and more selective catalytic activity compared to known homogeneous nickel containing hydrogenation catalysts.[2] In the future, a further improved nickel catalyst may replace the more expensive rhodium and ruthenium catalysts which are currently used. Even enantioselective nickel hydrogenation catalysis complexes can be envisaged.

This research has been financially supported by the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CNWO). We thank Dr J. Reedijk and Dr E. Drent for fruitful discussions. Shell International Chemicals B. V. kindly provided some phosphane samples.

Notes and references

† In a typical experiment, 0.1 mmol nickel(II) acetate tetrahydrate and 0.1 mmol of the ligand were mixed in 20 ml of dry solvent for 10 min at room temperature under an argon atmosphere. For *o*-MeO-dppe or *p*-MeO-dppp mixing was performed at elevated temperatures and/or for prolonged times, until the ligand was completely dissolved. Solutions containing ligands *o*-MeO-dppp, *m*-MeO-dppe or *m*-MeO-dppp had to be refluxed for 5 h. Then, 50 mmol of oct-1-ene was added to the yellow–orange solution and mixing continued for 5 min. The mixture was transferred into the autoclave, under oxygen-free conditions, and a hydrogen pressure of 50 bar applied. The reaction was initiated by heating the autoclave to the desired temperature. Samples were taken every 15 min over 1 h and were analysed using gas chromatography.

Practical radical cyclisations leading to the construction of near-stereopure quaternary carbon stereogenic centres

Raymond McCague,[a] Robin G. Pritchard,[b] Richard J. Stoodley*[b] and Douglas S. Williamson[b]

Received (in Liverpool, UK) 12th October 1998, Accepted 2nd November 1998

The 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl auxiliary is effective in directing bromopropargyloxy additions to the olefinic bonds of vinylogous esters/carbonates; in the presence of AIBN and 1-ethylpiperidinium hypophosphite, the adducts undergo highly stereoselective reductive radical cyclisations in which quaternary carbon stereogenic centres are generated.

The control of the absolute stereochemical outcome of reactions that generate quaternary carbon stereogenic centres is an important requirement in synthesis which is receiving much attention.[1] For radical methodology to provide a contribution, it is necessary to effect stereoselective additions of tertiary carbon radicals to carbon-based radical acceptors or of carbon radicals to tertiary olefinic acceptors. The ability to direct such radical additions by the use of temporarily attached auxiliaries† would offer notable synthetic versatility. To date, however, very few examples of such processes have been reported.[2]

Recently, we have shown that vinylogous esters/carbonates bearing the 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl auxiliary react with NBS and primary alcohols with excellent regioselectivity, high *anti* stereoselectivity and reasonable facial selectivity.[3] For example, in reactions involving PrOH, the olefins **1a–c** gave rise to *ca*. 6:1 mixtures of the bromopropoxy derivatives **2a–c** and **3a–c** (Scheme 1), from which the major products **2a–c** could be isolated in near-stereopure states and satisfactory yields by fractional crystallisation. Seeking to stereoselectively replace the bromine atoms by functional carbon substituents, we have studied the radical reactivity of bromides of type **4**. We now report our findings.

As outlined in Scheme 2, it was envisaged that, in the presence of a radical reducing agent, bromides of type **4** would afford tertiary radicals of type **5** which would undergo 5-*exo*-*dig* cyclisations and acceptance of hydrogen atoms to give products of types **6** and/or **7**. In an initial experiment, it was found that the vinylogous ester **1a** was converted into a 4:1 mixture of the requisite bromide **4a** and a diastereomer by the action of NBS and propargyl alcohol; fractional crystallisation provided **4a**,‡ mp 169–170 °C, $[\alpha]_D$ −68 (*c* 0.54, CH_2Cl_2), in 54% yield. When heated in toluene under reflux with AIBN and Bu_3SnH, **4a** was transformed into one major product (35% yield after chromatography and crystallisation), mp 94–95 °C, $[\alpha]_D$ −23 (*c* 0.25, CH_2Cl_2), that clearly possessed the structure **6a** or **7a** on the basis of its analytical and spectral properties.

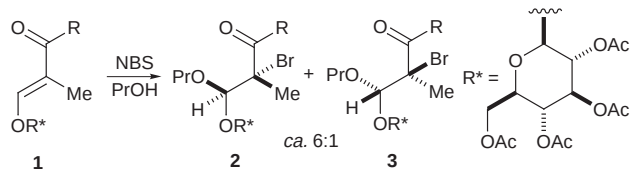
That the radical cyclisation product possessed the stereostructure **6a** was established by an X-ray crystallographic analysis of a derivative. Thus, catalytic hydrogenation (H_2, 5% Pd–C, EtOAc) afforded a 3:1 mixture of dihydro derivatives, from which the major diastereomer, mp 151–152 °C, $[\alpha]_D$ +40 (*c* 0.25, CH_2Cl_2), was isolated by fractional crystallisation. The product possessed the stereostructure **8** on the basis of the X-ray analysis§ (Fig. 1). Clearly, the radical **5a** had undergone a reductive cyclisation to give **6a** rather than **7a**. Moreover, there was a preference for hydrogen addition to **6a** to occur *syn* to the acyl group. Finally, the presumed stereochemical outcome of the initial bromopropargyloxylation reaction was substantiated.

Numerous attempts were made to improve the efficiency of the **4a**→**6a** transformation and to avoid the handling of toxic tin-based reagents. The use of AIBN and tris(trimethylsilyl)-silane[4] in toluene under reflux provided a cleaner raw product but chromatography was still required to remove impurities; **6a** was then isolated in 65% yield. However the best result was achieved when **4a** was heated with AIBN and 1-ethylpiperidinium hypophosphite[5] in toluene under reflux; the crude product, obtained in essentially quantitative yield after work-up, was very largely **6a**.

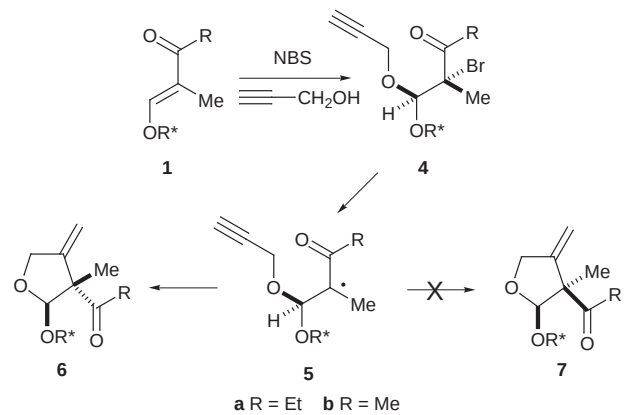
The effectiveness of the overall technology was demonstrated further by its application to the vinylogous ester **1b**. Thus, subjection of **1b** to the action of NBS and propargyl alcohol gave **4b**‡ (47% yield after crystallisation), mp 133–134 °C, $[\alpha]_D$ −82 (*c* 0.25, CH_2Cl_2), which underwent the hypophosphite-induced reductive radical cyclisation to give largely **6b** almost quantitatively; crystallisation provided **6b**,‡¶ mp 133–134 °C, $[\alpha]_D$ −28 (*c* 0.28, CH_2Cl_2), in 61% yield.

The excellent stereoselectivity observed in the aforecited radical cyclisations can be accommodated by an extension of a stereoinduction model proposed by Giese.[6] Thus, it is envisaged that the cyclisation occurs by way of the conformer **9** in which the acetal hydrogen atom is *syn* to the olefinic bond of the delocalised radical. A prediction of this model is that the stereochemical outcome is determined solely by the acetal configuration and that the auxiliary plays no direct role in the stereoinduction process.

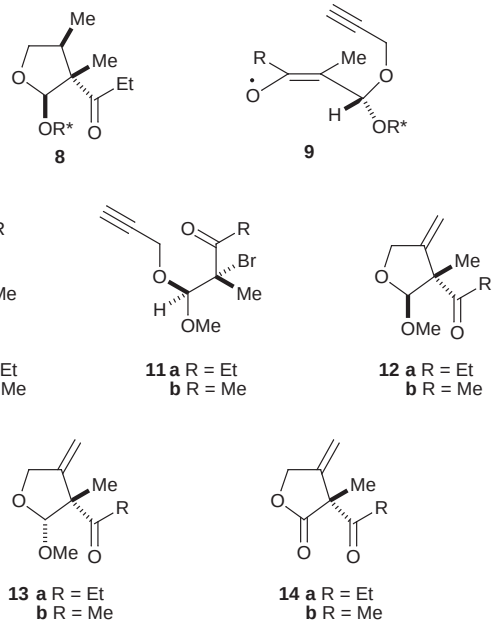
The vinylogous ester **10a**‖ was converted into the acetylenic bromide *rac*-**11a**‡ (73% yield after chromatography) which



Scheme 1



Scheme 2



underwent radical cyclisation to give compound *rac*-**12a**‡ (77% yield after chromatography) [a comparative NOE difference spectroscopic study on *rac*-**12a** and *rac*-**13a** (obtained by equilibration of *rac*-**12a** using TsOH and MeOH) left little doubt about the stereochemical assignments]. Similarly, **11b**‡ (obtained in 78% yield after chromatography by bromopropargyloxylation of **10b**‖) afforded *rac*-**12b**‡ (74% yield after chromatography). Clearly, the configuration of the acetal stereocentre of the reactants *rac*-**11a** and *rac*-**11b** determines the configuration of the quaternary carbon stereocentre of the products *rac*-**12a** and *rac*-**12b**, providing strong support for the stereoinduction model **9**.

To complete the study, it was appropriate to remove the sugar auxiliary from **6a** and **6b** and to determine the enantiomeric purities of the products. In preliminary experiments, it was shown that *rac*-**12a** and *rac*-**12b** could be oxidised (CrO_3, H_2SO_4, Me_2CO, ultrasound)[7] to the γ-lactones *rac*-**14a** and *rac*-**14b**,** the enantiomers of which were separable by GC.††

Under methanolysis conditions (TsOH, MeOH), **6a** was transformed into a 1:1 mixture of the methoxy derivatives **12a** and **13a**‡ (84% yield after chromatography), $[\alpha]_D$ −110 (*c* 0.16, CH_2Cl_2), whereas **6b** afforded a 3:1 mixture of the methoxy derivatives **12b** and **13b**‡ (79% yield after chromatography), $[\alpha]_D$ −142 (*c* 0.30, CH_2Cl_2). Following Jones' oxidation of the mixtures, the γ-lactones **14a** and **14b**** were isolated, each with 96% ee. Since the ee analyses were conducted on products that had been obtained from raw samples of **6a** and **6b**, it is clear that the hypophosphite-induced radical cyclisations displayed excellent stereoselectivities; moreover, the diastereomeric purities of the precursors **4a** and **4b** were high. When a crystallised sample of **6b** was employed, the derived γ-lactone **14b** possessed an ee of >99%.

The aforecited findings are significant in the following respects. In the presence of AIBN, 1-ethylpiperidinium hypophosphite offers marked advantages over Bu_3SnH or tris(trimethylsilyl)silane in effecting 5-*exo*-*dig* reductive radical cyclisations‡‡ of acetylenic bromides. The high stereoselectivities observed in the radical cyclisations are striking; they can be accommodated by a simple stereoinduction model dictated by allylic strain considerations. As well as providing a further illustration of the versatility of vinylogous esters/carbonates of type **1** in asymmetric synthesis, the technology enables units featuring quaternary carbon stereogenic centres with three functional arms to be assembled in multigram quantities.

We thank the DTI and EPSRC for subsidisation of a studentship (to D. S. W.) under the Link Asymmetric Synthesis Programme. We are also grateful to P. D. Tiffin for relevant preliminary studies and to Dr G. Potter for helpful advice.

Experimental evidence of partially rate limiting ion-pair interconversion in a base catalyzed 1,3-proton transfer reaction

Anita Hussénius,* Olle Matsson and Göran Bergson

Institute of Chemistry, Uppsala University, Box 531, S-751 21 Uppsala, Sweden. E-mail: anitah@kemi.uu.se

Received (in Liverpool, UK) 7th October 1998, Accepted 26th October 1998

The relative rates for interconversion and reprotonation of the ion-pair intermediates are of the same order of magnitude in the piperidine catalyzed 'degenerate' rearrangement of 1,3-dimethylindene, as investigated using ^{1}H and ^{2}H NMR spectroscopy by letting the 1,3-hydron transfer reaction compete with isotope (^{1}H/^{2}H) exchange.

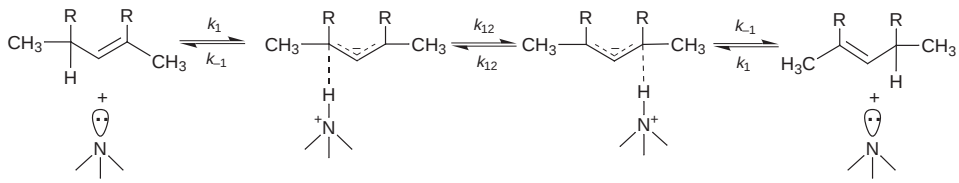
Many organic and biochemical reactions involve the transfer of a proton from a carbon acid to a base. Hydrogen bonded carbanions have been postulated as intermediates in essentially all hydron transfer reactions from carbon acids.[1] Therefore, mechanistic interpretations of observed phenomena such as kinetic isotope effects and enantioselectivities require detailed knowledge of processes involving carbanion ion pairs. The simple example shown in Scheme 1 illustrates this point (the 'degeneracy' of this rearrangement reduces the number of different rate constants, thus simplifying the kinetic analysis). Application of the steady-state approximation to the two reactive ion-pair intermediates gives the relation [eqn. (1)]

$$k = k_1/[2 + (k_{-1}/k_{12})] \quad (1)$$

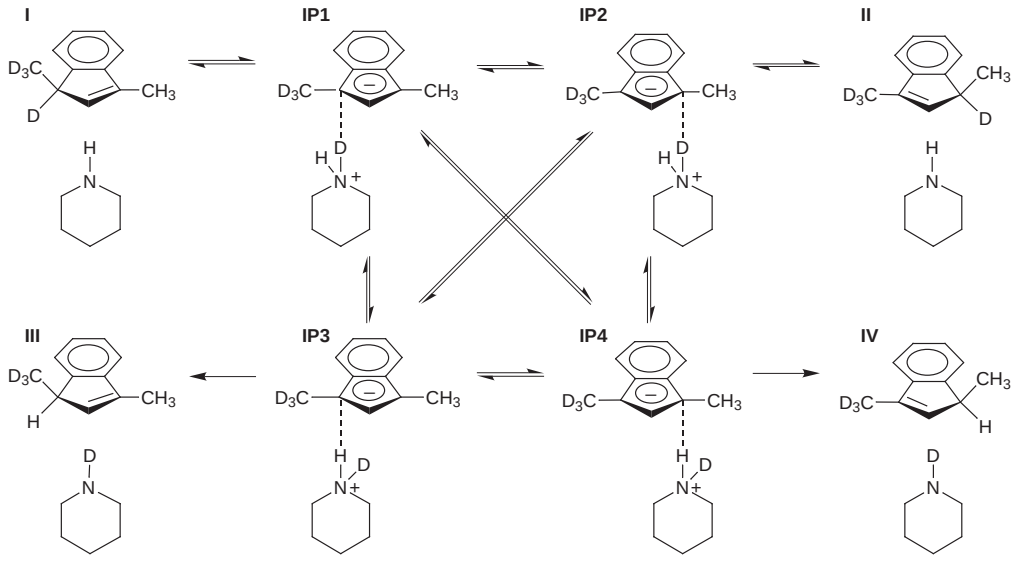
between the phenomenological rate constant k (which can be determined experimentally) for this 1,3-proton transfer reaction, and the mechanistic rate constants, k_1, k_{-1} and k_{12}. If and only if the interconversion of the ion pairs (k_{12}) is much faster than collapse back to a covalent entity (k_{-1}), can observed effects on k be discussed straightforwardly in terms of the proton abstraction step (k_1). Thus, it is of great importance to know the magnitude of the rate constant ratio (k_{-1}/k_{12}).

Arguments for rapid interconversion ($k_{12} >> k_{-1}$) of the intermediates arise from the fact that no covalent bonds are formed or broken in this process, making it plausible that the ammonium ion, once formed, should be able to slide between the 1- and 3-positions with very low activation energy. Evidence for the existence of two ion-pair intermediates not in equilibrium with each other has, however, been presented by Ahlberg and Thibblin.[2,3] Thus, the assumption of rapid interconversion of ion pairs has to be tested, if possible, for each specific system.

Herein, we report on an experimental investigation aimed at retrieving information about the relative rates referred to above. The crucial point is that the 1,3-hydron transfer is allowed to compete with isotopic exchange of the 'mobile' hydron mediated by ammonium ion rotation within the ion pair.[4–6] Our system (Scheme 2) mimics the simple case given in Scheme 1. 1,3-Dimethylindene, in which a trideuteriomethyl group is substituted for one of the methyl groups, was used as a substrate. The CD_3 group served only as a label making it possible to distinguish between the 1- and 3-positions and to follow the time evolution of the concentrations of all four species (**I**–**IV**) by ^{1}H and ^{2}H NMR spectroscopy. The expected small secondary isotope effects due to this labelling can be neglected



Scheme 1



Scheme 2

in the present context. The reaction was run in benzene solution and the secondary amine piperidine was used as base-catalyst and (^{1}H/^{2}H) −exchange agent. If the substrate is deuteriated in the C1 position, the use of protic base results in incorporation of protium in the dimethylindene due to rotation of the ammonium ion within the ion pair. If the base is used in large excess, the ^{1}H/^{2}H exchange is practically irreversible. The kinetics of this protium incorporation, in the 1- and 3-positions respectively, provides a measure of the relative rates of ion-pair equilibration and collapse.

In Scheme 2 a mechanistic model for our system is depicted. Starting at the upper left corner, the amine abstracts a deuteron from 1,3-dimethylindene **I** and an ion-pair intermediate **IP1** is formed. Either the hydron transfer proceeds, *via* interconversion to the ion pair **IP2**, to the rearranged product **II** without deuterium/protium exchange, or a new ion pair **IP3** is formed through ammonium ion rotation (a direct route from **IP2** to **IP4** cannot be excluded, but the presence of such a route does not influence our conclusions). Now, the ion pairs **IP3** and **IP4** can interconvert, just as **IP1** and **IP2**. If the ion-pair interconversion is much faster than collapse, the two exchange products **III** and **IV** will appear in equal amounts (or more precisely in the ratio 1.04, which is the magnitude of the secondary equilibrium isotope effect, determined as the average from several kinetic experiments) from the very start of the reaction. On the other hand, if these products, **III** and **IV**, appear in unequal amounts, the assumption of fast ion-pair interconversion is not valid. Thus, by studying the kinetics of formation of the exchange products **III** and **IV**, information can be obtained regarding the relative rates of ion-pair interconversion and ion-pair collapse.

The present kinetic data have been obtained from ^{1}H and ^{2}H NMR spectra of quenched and concentrated samples, taken at regular time intervals from the reaction mixture. The experiments were performed in benzene solution at 20 °C. The secondary amine piperidine was used as base catalyst, in an excess of 45–50 equiv. of the substrate concentration. The use of a large excess of base permits the ^{1}H/^{2}H exchange reaction, to a good approximation, to be regarded as irreversible. In principle it is possible to start from either of the four different isotopically substituted 1,3-dimethylindenes but all kinetic experiments reported here have started from the substrate 1-[^{2}H$_3$]methyl-3-methyl[1-^{2}H]indene[7–9] and protic piperidine.

In the kinetic procedure, the isotopically substituted 1,3-dimethylindene (70–100 mg) was weighed into a calibrated 10 ml volumetric flask. A stock solution of piperidine in benzene was prepared in a volumetric flask which was then sealed with a tight PTFE septum and a screwcap. Both flasks were thermostatted at 20.00 °C. The temperature was measured with a calibrated mercury thermometer with an absolute accuracy of 0.02 °C. The temperature did not deviate more than 0.02 °C from the average value during the kinetic runs and was thus 20.00 ± 0.04 °C. Base solution was withdrawn by means of a nitrogen flushed syringe and the 10 ml flask was filled to the mark. A clock was started when half of the base solution had been added. The flask was sealed with a septum and a screwcap and was then rapidly shaken and replaced in the thermostat bath. Samples (1–1.5 ml) were taken at regular time intervals. The reaction was quenched with 2–3 ml of 5 M HCl, which was cooled to at least −10 °C. The organic phase was separated and washed with brine and distilled water. The solution was concentrated by evaporation and ^{2}H NMR spectra were recorded. Residual solvent was removed at reduced pressure, the residue was dissolved in C^{2}HCl$_3$ (Ciba-Geigy, > 99.9 atom% ^{2}H) and finally the ^{1}H NMR spectra were recorded. When the pure substrate was subjected to the work-up conditions it was recovered unchanged.

The samples of the quenched reaction contain four different isotopically substituted 1,3-dimethylindenes resulting from rearrangement and exchange reactions (see Scheme 2). There are three signals of interest in the NMR spectra: the signal at δ 1.28 from the methyl group at the C1 position of the indene ring system, the signal at δ 2.13 from the methyl group at the C3-position, and the signal at δ 3.40 from the protium (deuterium) at C1. Computer resolution of the ^{1}H signals at δ 1.28 was performed using a curve fitting routine, to be able to solve for the four unknown concentrations. The signal at this shift consists of a doublet from **IV**, a singlet from **II** (see Scheme 2) and also a signal from traces of protium in the trideuteriomethyl group at the 1-position. Utilizing computer resolution the ^{1}H NMR spectrum is, in principle, sufficient for determination of the content of each species. The ^{2}H NMR spectra have been recorded in order to allow for a double check of the relative concentrations.

Table 1 Relative concentrations[a] of the four 1,3-dimethylindenes in the reaction mixture at different tmies, in a piperidine[b] catalyzed rearrangement/exchange experiment starting from 1-[^{2}H$_3$]methyl-3-methyl[1-^{2}H]indene **I** in benzene at 20 °C

[a] The total concentration of substrate was 0.0677 M. The concentration is normalized to 1 in the table. [b] [Piperidine] = 3.149 M.

In Table 1 the results from a typical kinetic experiment are displayed. In the beginning of the experiment (18% reaction) the isotopically exchanged indene **III**, produced by collapse of **IP3**, appear in the reaction mixture in a concentration almost twice as high as that of indene **IV**, produced from **IP4** ([**III**]/[**IV**] = 1.97). The concentration ratio of the exchanged indenes then gradually decreases towards the secondary equilibrium isotope effect (for simplicity, the reversible piperidine catalyzed rearrangement between **III** and **IV** has been omitted from Scheme 2). The conclusion is thus that the assumption of fast ion-pair equilibration is not valid for the system studied. This is in accordance with recently published theoretical calculations for a similar rearrangement.[10] In that study it was found that the relevant activation barriers were dependent of the structure of the catalyzing base as well as on the solvent. A full account including a detailed kinetic analysis of the present reaction system will be published in due course.

A new redox-tunable near-IR dye based on a trinuclear ruthenium(II) complex of hexahydroxytriphenylene

Anita M. Barthram, Rosemary L. Cleary, Ralph Kowallick and Michael D. Ward*

School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: mike.ward@bristol.ac.uk

Received (in Cambridge, UK) 8th October 1998, Accepted 10th November 1998

The complex $[\{Ru(bipy)_2\}_3(\mu^3\text{-}L)]^{3+}$ (H_6L = hexahydroxytriphenylene), in which the tris-dioxolene bridging ligand is formally in the tris-semiquinone oxidation state [sq,sq,sq], undergoes three reversible ligand-centred oxidations to the [q,q,q] state (q = quinone); it exhibits very strong NIR absorption arising from Ru → L charge transfer whose maximum wavelength may be tuned over a wide range according to oxidation state.

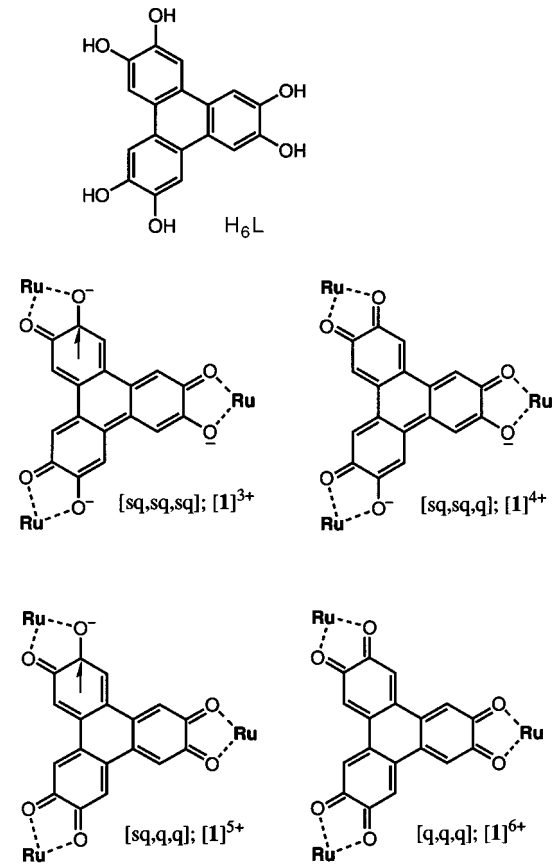
Compounds which absorb light strongly in the near IR (NIR) region of the spectrum have numerous potential applications, including (i) optical data storage devices, in which reading and writing is performed by diode lasers; (ii) Q-switching of lasers, whereby continuous low-energy output in the NIR region is converted to very short, intense bursts; and (iii) photodynamic therapy, which takes advantage of the relative transparency of living tissue to NIR radiation.[1] Prominent examples of such compounds include nickel(II)–dithiolene complexes[2] and extended quinones.[3] If the strong NIR absorption is not permanent but may be switched on by some external perturbation, then the compound is of additional interest as a switchable electrochromic dye; such compounds are relatively rare.[4]

The simple complex $[Ru(bipy)_2(sq)]^+$ (bipy = 2,2′-bipyridine; sq = 1,2-benzosemiquinone monoanion) is of potential interest in this regard, having a NIR transition at about 900 nm (ε *ca.* 10^4 dm^3 mol^{-1} cm^{-1}) arising from a $Ru[d_\pi] \rightarrow sq(\pi^*)$ MLCT process.[5] It undergoes ligand-centred redox behaviour, being oxidised to $[Ru(bipy)_2(q)]^{2+}$ (q = 1,2-benzoquinone) and reduced to $[Ru(bipy)_2(cat)]$ (cat = catecholate dianion), in both of which forms this NIR transition is absent.[5] We have recently been interested in the electrochemical and spectroscopic properties of dinuclear complexes in which two such Ru(II) fragments are linked by bridging ligands containing two dioxolene termini.[6] We describe here the synthesis, electrochemical and UV–VIS–NIR properties of $[\{Ru(bipy)_2\}_3(\mu\text{–}L)]^{n+}$ (**1**$^{n+}$, n = 3–6) in which three such redox-active Ru(II) fragments are linked in a triangular array by the bridging ligand hexahydroxytriphenylene (H_6L).[7] Spectroelectrochemical analysis in four oxidation states reveals an exceptionally strong absorbance in the NIR region which may be tuned over a wide range according to oxidation state.

Reaction of hexahydroxytriphenylene[7] with 3 equiv. of $[Ru(bipy)_2(OH_2)_2]^{2+}$ (ref. 8) in refluxing ethanol–water–KOH at reflux in air for 2 h, followed by precipitation of the complex with NH_4PF_6 and chromatographic purification (alumina; CH_2Cl_2–MeOH, 19 : 1 v/v), afforded in 50% yield $[\mathbf{1}][PF_6]_3$ (Scheme 1) as a black solid. Characterisation was on the basis of FAB mass spectrometry [*m/z* 1848 {70%, $M - PF_6$}, 1703 {100%, $M - 2PF_6$}] and a satisfactory elemental analysis. The +3 charge implies that each of the three dioxolene fragments is in the semiquinone oxidation level (denoted sq-sq-sq) following synthesis in air, which is to be expected.[5,6] Individual $\{Ru(bipy)_2(sq)\}^+$ units have one unpaired electron on the semiquinone ligand, but when two such units are linked in a *para* substitution pattern by a suitable conjugated bridge, the two electrons pair up to give diamagnetic dinuclear complexes with formation of an additional π-bond resulting in a quinonoidal bridging ligand.[6] In $[\mathbf{1}]^{3+}$ any two of the semiquinone sites can be spin-paired, resulting in a monoradical.†

Cyclic and square-wave voltammetry of $[\mathbf{1}][PF_6]_3$ was performed in MeCN. If each dioxolene site showed the expected cat/sq and sq/q interconversions characteristic of mononuclear $[Ru(bipy)_2(sq)]^+$ then we would expect to see six redox processes linking seven oxidation states of the bridging ligand ranging from [cat,cat,cat] to [q,q,q]. Six waves were indeed observed, whose potentials (from a square-wave voltammogram) are +0.66, +0.36, −0.03, −0.43, −0.70 and −0.97 V *vs.* ferrocene–ferrocenium. The approximately constant and quite substantial spacing between these redox potentials is to be expected given the proximity of the dioxolene sites to one another.[6] Of these six processes only the first four appeared fully reversible (equal cathodic and anodic peak currents, ΔE_p 60–80 mV) by cyclic voltammetry using a Pt-wire working electrode (Fig. 1); the two processes at most negative potentials showed stripping peaks on the return waves, characteristic of absorption on the Pt electrode surface after generation of the [cat,sq,sq] and more reduced oxidation states. Despite this it is apparent that all seven oxidation states are in principle accessible.

We therefore subjected $[\mathbf{1}][PF_6]_3$ to a spectroelectrochemical study in an OTTLE cell (MeCN, −30 °C) spanning the oxidation states sq,sq,sq (**1**$^{3+}$), sq,sq,q (**1**$^{4+}$), sq,q,q (**1**$^{5+}$) and q,q,q (**1**$^{6+}$). For all three interconversions clean isosbestic points



Scheme 1 Ru ≡ $\{Ru(bipy)_2\}^{2+}$.

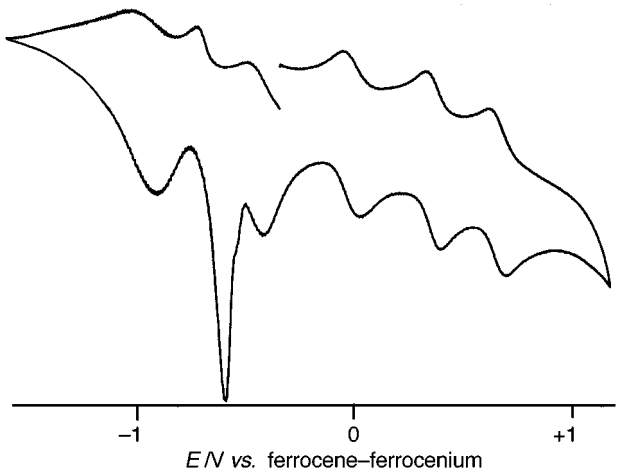


Fig. 1 Cyclic voltammogram of $[\mathbf{1}]^{3+}$ in MeCN, showing the stepwise interconversions between the [cat,cat,cat] and [q,q,q] states of the bridging ligand. Only the three most positive processes, from [sq,sq,sq] to [q,q,q], are fully reversible at a Pt electrode.

were observed, and after the final oxidation to $[\mathbf{1}]^{6+}$, re-reduction regenerated exactly the spectrum of the starting $[\mathbf{1}]^{3+}$. The results (Fig. 2) show that (i) the redox chemistry is indeed ligand-centred, and (ii) the complex has exceptionally strong absorption in the near-IR region whose absorption maximum varies monotonically with oxidation state. It is helpful to recall that for mononuclear $[Ru(bipy)_2(sq)]^+$, the MLCT transition at 900 nm shifts to *ca.* 640 nm on oxidation to $[Ru(bipy)_2(q)]^{2+}$.[5] For $[\mathbf{1}]^{3+}$, the MLCT transition involving the delocalised [sq,sq,sq] bridging ligand occurs at 1170 nm (ε = 40 000 $dm^3\ mol^{-1}\ cm^{-1}$). As the ligand is oxidised in steps to the [sq,sq, q], then [sq,q,q] and finally [q,q,q] oxidation states this absorption maximum moves in steps to 1083 (ε = 74 000), 909

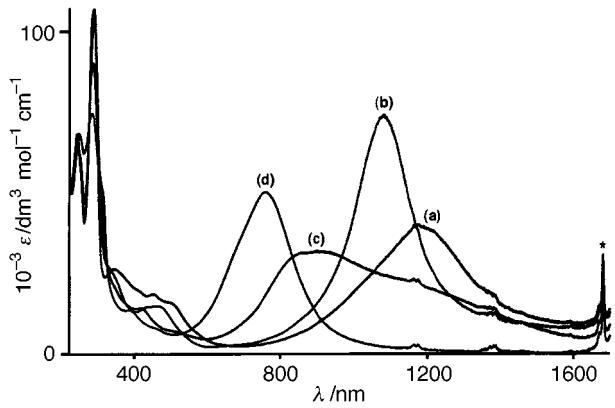

Fig. 2 Electronic spectra of (a) $[\mathbf{1}]^{3+}$, (b) $[\mathbf{1}]^{4+}$, (c) $[\mathbf{1}]^{5+}$ and (d) $[\mathbf{1}]^{6+}$ (MeCN, −30 °C); * denotes a solvent-based IR overtone.

(ε = 32 000) and finally 759 nm (ε = 50 000 $dm^3\ mol^{-1}\ cm^{-1}$). The 'mixed-valence' [sq,sq,q] and [sq,q,q] states must therefore be delocalised, because a single transition at a 'weighted average' position occurs in each case rather than two separate transitions characteristic of distinct sq and q sites in the bridging ligand. These transitions are remarkably intense and broad: the absorption coefficients of 32 000–74 000 $dm^3\ mol^{-1}\ cm^{-1}$ are comparable to those of commercially useful NIR dyes,[1,2] and the lower-energy three transitions have long low-energy tails (extending to 1700 nm and over) such that in these oxidation states the molecule is effectively a panchromatic NIR absorber. This complex therefore shows an unusual combination of very strong NIR absorbance and tunability of the absorption maximum over a wide range using four readily accessible oxidation states.

We thank the EPSRC for Ph.D. studentships (A. M. B. and R. L. C.).

Notes and references

† That $[\mathbf{1}][PF_6]_3$ is a monoradical and not a triradical was confirmed both experimentally and theoretically. An EPR spectrum (frozen MeCN solution, 77 K) has a near-symmetric signal at g = 2.017 characteristic of a semiquinone-based monoradical with no evidence for Δm_s = 2 or Δm_s = 3 transitions. A MOPAC calculation on $[L]^{3-}$ in the [sq,sq,sq] state showed that the three frontier orbitals involved in conversion between the [cat,cat,cat] and [q,q,q] states are non-degenerate, such that the [sq,sq,sq] state (as well as the [sq,q,q] and [sq,cat,cat] states) are monoradicals, whilst the others are diamagnetic, as in Scheme 1.

Synthesis of a ferrocene bridged cyclam: a new redox-active macrocycle and the structure of a nickel(II) complex with strongly coupled metal centers

Herbert Plenio* and Clemens Aberle

Institut für Anorganische und Analytische Chemie, Albertstr. 21, 79104 Freiburg, Germany. E-mail: plenio@uni-freiburg.de

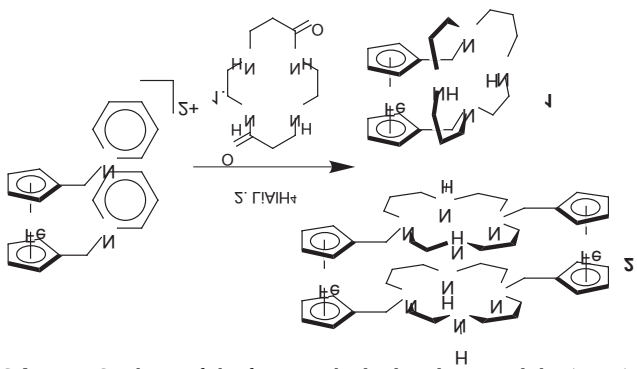
Received (in Basel, Switzerland) 16th September 1998, Accepted 30th October 1998

The reaction of 1,1′-ferrocene-bis(methylenepyridinium) with 1,4,8,11-tetraazacyclotetradecane-5,12-dione followed by reduction of the product with $LiAlH_4$ results in a ferrocene bridged cyclam, which is a very efficient redox-switch for transition metal ions due to the short iron-to-metal ion distances.

Cyclam (1,4,8,11-tetraazacyclotetradecane) and its numerous derivatives are among the most important macrocyclic ligands;[1] its coordination chemistry is well explored[2] and a number of cyclam–metal complexes are catalytically active.[3]

We were interested in synthesizing a ferrocene-bridged cyclam, since we anticipated that this would result in short distances between the ferrocene iron and any metal ion coordinated within the tetraaza-macrocycle. Consequently the interactions between the different metal centers are expected to be very strong and redox reactions at the ferrocene should have a pronounced effect on the properties of cyclam and those of the metal ions coordinated by it. This should add a new dimension to the coordination chemistry of cyclam and allow the design of new molecules for the electrochemical sensing of transition metal cations[4] and anions,[5] redox-switched catalysis,[6] the redox-switched bonding of metal ions[7] and biomimetic chemistry.[8]

However, partially substituted cyclams are less easily available and only recently a very convenient synthesis utilizing 1,4,8,11-tetraazacyclotetradecane-5,12-dione was presented by Guilard and coworkers.[9] In order to generate the ferrocene bridged cyclam, 1,1′-ferrocene-bis(methylenepyridinium) was reacted with 1,4,8,11-tetraazacyclotetradecane-5,12-dione in refluxing acetonitrile (Scheme 1).† After chromatographic work-up two main products were isolated: the 1 + 1-addition product (yield *ca.* 50%), the 2 + 2-addition product (yield *ca.* 24%) and a small amount of 3 + 3-product (*ca.* 5%). The total yields and the ratios of the different oligomers depended on the concentration of the reactants in the reaction mixture and it is possible to raise the amount of the 2 + 2- and 3 + 3-product significantly by decreasing the amount of solvent. Ferrocene-cyclam **1** can be synthesized in 86% yield from the initial 1 + 1-product by reduction with $LiAlH_4$. The 2 + 2-product can also be reduced in this manner resulting in the respective cofacial bis(ferrocene-cyclam) **2**.



Scheme 1 Synthesis of the ferrocene bridged cyclam **1** and the (2 + 2)-addition product **2**.

Initially we were interested in the electrochemical properties of the ferrocene-cyclam and its transition metal complexes. Table 1 lists redox data obtained by cyclic voltammetry in acetonitrile from which it is obvious that the magnitude of the redox shifts and hence the redox-switching effect per single metal ion is enormous, when for example compared to the $\Delta E_{½}$ values of related ferrocenyl-substituted cyclams[10,11] ($\Delta E_{½}$ < 100 mV) and is significantly larger than those of aminoferrocene metal complexes synthesized by us.[12]

To better understand the coordinating properties of **1** as well as the origin of the extremely large redox shifts we attempted to crystallize a metal complex of this ligand and were successful with $Ni(CF_3SO_3)_2$ (Fig. 1).‡ In the crystal, nickel is coordinated in the center of the tetraazamacrocycle in a square-planar environment, which is only slightly distorted, even though the oxygen atom of an acetone molecule displays a weak contact to Ni^{2+} [Ni1–O2 320.8(9) pm]. This square-planar geometry also appears to be present in solution as evidenced by the diamagnetic nature of the complex in acetonitrile. The stereo-

Table 1 Electrochemical data of **1** and transition metal complexes as determined by cyclic voltammetry in MeCN using NBu_4PF_6 as supporting electrolyte *vs.* cobaltocene ($E_{½}$ = −0.94 V) or ferrocene ($E_{½}$ = +0.40 V) reference

Important bond lengths, interatomic distances (pm) and bond angles (°): Ni–N1 195.9(4), Ni–N2 194.8(5), Fe1–Ni1 385.4(8), N1–Ni–N1a 166.1(3), N2–Ni–N2a 162.4(3), N1–Ni–N2a 95.1(2), N1–Ni–N2 87.0(2).

chemistry of **1**·Ni(CF_3SO_3)$_2$ in the solid state is *trans*-I according to the Bosnich classification[13] and consequently both N–H vectors point approximately towards the ferrocene. Another unusual feature of this crystal structure is the rather short distance between iron and nickel [385.4(8) pm] and this can easily explain why upon Ni^{2+}-coordination the iron redox potentials are perturbed drastically. The above mentioned distance might be too long to account for a significant interaction (other than electrostatic) between the metals, but it once again raises the question about the possibility of bonding interactions between the iron in ferrocene and metal cations.[14] The fact that the ferrocene HOMO is predominantly localized on iron has nurtured speculation about donor–acceptor type interactions between the ferrocene iron and other metal ions. Investigations of metal ion complexes of ferrocene-cyclam **1** could provide a more conclusive answer to this question. The geometry of the ferrocene unit itself is essentially unremarkable though not ideal as evidenced by the small tilt (6.4°) of the respective planes of the two cyclopentadienyl rings; a more significant distortion is observed in the methylene groups (C6, C6a) which deviate from the respective cyclopentadienyl plane by 10.5°.

In conclusion this communication offers a simple two step synthesis of a redox-active cyclam ligand in which, owing to the intimate coupling of the metal centers, redox reactions at the ferrocene will strongly alter the coordination characteristics of the ligand.

Notes and references

† *Synthesis of ferrocene cyclam*. **A.** 1,1′-ferrocene-bis(methylenepyridinium) chloride tosylate (5.12 g, 9.02 mmol), 1,4,8,11-tetraazacyclotetradecane-5,12-dione (2.06 g, 9.02 mmol) and Na_2CO_3 (7.0 g) were added to acetonitrile (300 mL) and heated under reflux for 60 h. The cold reaction mixture was filtered and the filtrate evaporated to dryness. The residue was purified by chromatography ($CHCl_3$–MeOH = 10 : 1) to yield ferrocene–cyclamdione (2.0 g, 50%), 2 + 2-product (0.94 g, 24%) and 3 + 3-product (*ca*. 0.20 g, 5%). EIMS: 438 (M^+); ^{1}H NMR ($CDCl_3$) δ 2.11–2.29 (m, 6H), 2.58–3.36 (m, 10H), 3.82–4.08 (m, 12H), 8.97 (s, NH), 9.02 (s, NH). **B**. Ferrocene–cyclamdione (4.4 g, 10 mmol) was dissolved in a mixture of thf (100 mL) and $CHCl_3$ (200 mL). To the ice-cooled solution was added $LiAlH_4$ (7.6 g, 200 mmol) and stirring continued for 48 h. After careful hydrolysis of excess $LiAlH_4$ with water (70 mL), 15% aq. NaOH (200 mL) were added and the product extracted with $CHCl_3$. The organic layer was separated, dried over $MgSO_4$, filtered and the filtrate evaporated to dryness. The residue was purified by chromatography (MeOH–Et_2NH = 10 : 1) to yield 3.5 g (86%) of **1**. ^{1}H NMR ($CDCl_3$) δ 1.40 (d, 14 Hz, 2H), 1.85 (d, 12 Hz, 2H), 2.14 (d, 11 Hz, 4H), 2.46–2.95 (m, 14H), 3.22 (td, 7 Hz, 3 Hz, 2H), 3.73 (s, 2H), 3.93–4.08 (m, 10H). ^{13}C NMR ($CDCl_3$) δ 25.64, 47.02, 51.55, 53.40, 53.49, 58.20, 65.37, 65.76, 67.40, 70.26, 88.35. All compounds have been characterized by elemental analysis and NMR spectroscopy.

Iron complexes of the $N(CH_2CH_2S)_3^{3-}$ ligand; a paramagnetic, trigonal bipyramidal Fe(II) CO complex as a chelate ligand

Sian C. Davies, David L. Hughes, Raymond L. Richards and J. Roger Sanders

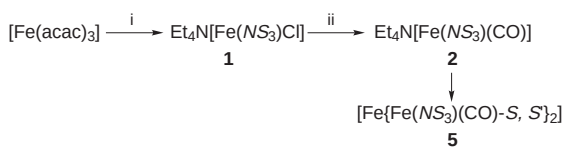
Nitrogen Fixation Laboratory, John Innes Centre, Colney Lane, Norwich, UK NR4 7UH.
E-mail: ray.richards@bbsrc.ac.uk

Received (in Cambridge, UK) 1st October 1998, Accepted 6th November 1998

The paramagnetic complex anions $[Fe(NS_3)Cl]^-$ [NS_3 = $N(CH_2CH_2S)_3^{3-}$] and$[Fe(NS_3)(CO)]^-$ have been prepared and structurally characterised; with $FeCl_2$, $[Fe(NS_3)(CO)]^-$ gives the structurally characterised, linear, paramagnetic cluster complex $[Fe\{Fe(NS_3)(CO)\text{-}S,S'\}_2]$.

A number of metal sites in enzymes carry three sulfur-donor ligands. These include the low-spin Fe centre of nitrile hydratase,[1] which is bound to three cysteine sulfur and two amide nitrogen atoms, and the cofactor of molybdenum nitrogenase, FeMoco, an $MoFe_7S_9$ cluster in which the six central iron atoms are each coordinated by three sulfides.[2] The Mo atom in FeMoco is coordinated by three sulfides as well as two oxygens from homocitrate and one histidine nitrogen[2] and it is thought that the vanadium atom in vanadium nitrogenase[3] and one iron atom in the 'iron-only' nitrogenase[4] are in similar environments. We are particularly interested in models for the trigonally S-coordinated Fe centres in the central portion of FeMoco and the S_3-coordinated Mo, V or Fe centres at the histidine end of nitrogenase cofactor clusters. Following our investigation of the nitrogen chemistry of vanadium coordinating the tetradentate tripodal ligand $N(CH_2CH_2S)_3^{3-}$ (NS_3),[5] we report iron chemistry of this ligand which, because its ligation involves three sulfur atoms, relates to the metal environments in the enzymes mentioned above. In the course of this work we have discovered a novel, paramagnetic carbonyl complex of iron which acts as a chelate ligand, as described below.

The starting point of our iron chemistry is the Fe(III) complex anion $[FeCl(NS_3)]^-$ **1**, obtained as shown in Scheme 1, which on reduction under CO gives the Fe(II) anion $[Fe(NS_3)(CO)]^-$ **2**. The NEt_4 salts of **1** and **2** {also the vanadium complex $NEt_4[VCl(NS_3)]$[5]} are isostructural; in both structures, the anion lies disordered about a crystallographic mirror plane.† Figs. 1 and 2 show the iron atoms to have trigonal bipyramidal geometry. In the solid state, both complexes are paramagnetic, The NEt_4 salt of **1** has μ_{eff} = 5.87 μ_B, S = 5/2. Mössbauer data at 77 K, (rel. natural Fe), are; isomer shift (IS) 0.37 mm s^{-1} and quadrupole splitting (QS) 1.00 mm s^{-1}. The NEt_4 salt of **2** has μ_{eff} = 2.79 μ_B, S = 1; IS = 0.22, QS 0.99 mm s^{-1}. Comparison of the anions in Figs. 1 and 2 shows that in the carbonyl **2** the Fe–N distance [2.035(8) Å] and the average Fe–S distance [2.278(3) Å] are shorter than the corresponding distances in the chloride **1** [2.273(3) and 2.316(2) Å respectively], despite the higher formal oxidation state of the metal in **1**. This is probably a consequence of the higher spin state of **1** and electron withdrawal by CO in **2**, and results in a relative distortion of the trithiolate ligand; the mean S–Fe–N angle contracts from 87.8(1)° in **2** to 83.6(2)° in **1**.



Scheme 1 *Reagents and conditions*: i, $N(SH)_3$ + Et_4NCl in MeCN; ii, Na/CO in MeCN; iii, $FeCl_2$ (0.5 mol ratio) in MeCN or Me_2SO.

Paramagnetic CO complexes of iron are extremely rare and as far as we are aware only two other examples, $K[Fe\{N(CH_2CONPr^i)_3\}(CO)]$[6] **3** and $Et_4N[Fe\{P[C_6H_3S\text{-}2(Ph\text{-}3)]_3\}(CO)]$[7] **4**, are known. Both have similar magnetic and Mössbauer properties to those of **2** but both have ν(CO) at 1940 cm^{-1}, a notably higher frequency than that of **2** (1885 cm^{-1}). Evidently the $FeNS_3^-$ site in **2** is more electron releasing to CO than are the corresponding iron sites in **3** and **4**.

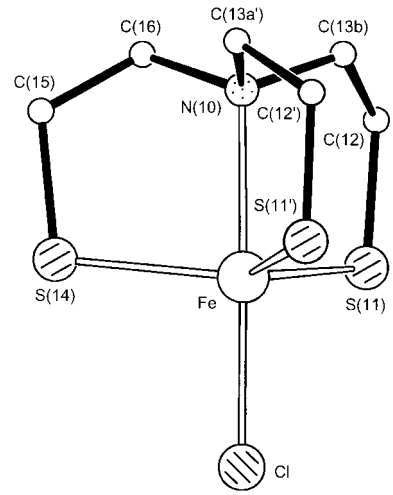


Fig. 1 The molecular structure of anion **1**. The disorder about the mirror symmetry plane is not shown; the atoms C(13a′), C(13b) and C(16) have half occupancy of the sites shown. Selected molecular dimensions: Fe–N(10) 2.273(3), Fe–Cl 2.3120(14), Fe–S(11) 2.3143(9), Fe–S(14) 2.3193(12) Å; N(10)–Fe–Cl 179.00(9), N(10)–Fe–S(average) 83.6(2)°.

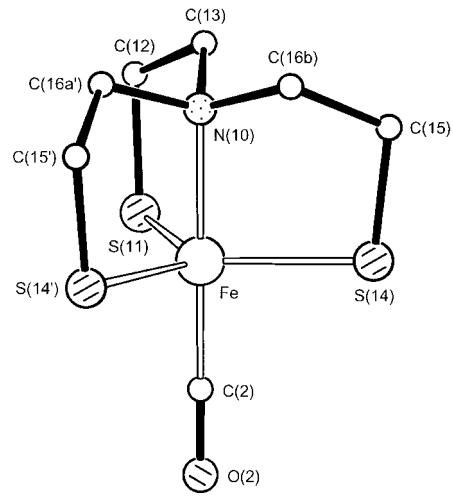

Fig. 2 The molecular structure of anion **2** which has disorder similar to that described in Fig. 1. Selected molecular dimensions: Fe–N(10) 2.035(8), Fe–C(2) 1.720(14), C(2)–O(2) 1.154(14), Fe–S(11) 2.281(3), Fe–S(14) 2.272(2) Å; N(10)–Fe–C(2) 179.7(5), N(10)–Fe–S(av.) 87.8(1)°.

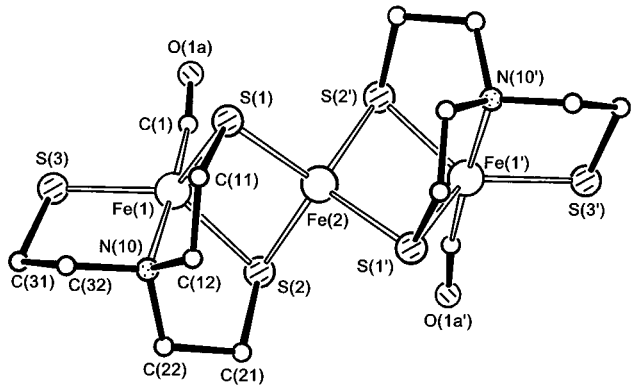

Fig. 3 The molecular structure of **5**, viewed down the twofold symmetry axis through Fe(2). Selected molecular dimensions: Fe(1)–N(10) 2.052(3), Fe(1)–C(1) 1.765(4), C(1)–O(1a) 1.13(1) (major component in disordered carbonyl group), C(1)-O(1b) 1.22(2), Fe(1)–S(1) 2.2677(10), Fe(1)–S(2) 2.2563(10), Fe(1)–S(3) 2.2139(9), Fe(2)–S(1) 2.2774(9), Fe(2)–S(2) 2.2928(10), Fe(1)···Fe(2) 2.6663(5) Å; N(10)–Fe(1)–C(1) 175.67(13), N(10)–Fe(1)–S(av.) 88.1(3), Fe(1)–S(1)–Fe(2) 71.84(3), Fe(1)–S(2)–Fe(2) 71.76(3), S(1)–Fe(1)–S(2) 107.79(3), S(1)–Fe(2)–S(2) 106.21(3), S(1)–Fe(2)–S(2') 105.93(3), S(1)–Fe(2)–S(1') 121.89(6), S(2)–Fe(2)–S(2') 110.50(6)°.

The latter sites are sterically hindered and **3** and **4** are made by CO addition to trigonal pyramidal iron-complex precursors. We have not been able to isolate the monomeric precursor to **2**, $[Fe(NS_3)]^-$. Instead, we obtain as yet uncharacterised products which appear to be multinuclear, probably because sulfur acts as a bridging group in them. However, the bridging ability of its sulfur ligands allows **2** itself to function as a ligand in a controlled way. Thus treatment of **2** with $FeCl_2$ (Scheme 1) affords the novel green, paramagnetic, linear Fe_3S_4 carbonyl cluster $[Fe\{Fe(NS_3)(CO)\text{-}S,S'\}_2]$ **5** [ν(CO) 1937 cm^{-1}. Mössbauer consistent with two different iron(II) sites: IS = 0.60, QS = 1.96 (intensity 1); IS = 0.22, QS = 1.17 mm s^{-1} (intensity 2)].

The structure of **5** (Fig. 3)† shows that this complex is made up from two trigonal bipyramidal $Fe(NS_3)(CO)$ units, each of which bridges through two of its sulfur atoms to a central Fe, which thus has distorted tetrahedral geometry and lies on a crystallographic twofold symmetry axis. Within the $Fe(NS_3)$-(CO) units, the Fe-S distances involving the four bridging S atoms are 2.256(1) and 2.268(1)Å, but those to the non-bridging S atoms are shorter [2.214(1) Å]. The Fe-S distances about the central Fe are 2.277(1) Å and 2.293(1) Å. All the iron atoms can be regarded as formally in oxidation state two, but solid **5** has μ_{eff} = 1.54 μ_B per molecule at 20 °C showing considerable electron coupling. The molecule is disordered with two distinct sites for the O atoms of the CO ligands; the C–O distances are 1.131(12) and 1.22(2) Å, with corresponding Fe–C–O angles of 168.8(6) and 161.4(9)°.

We note that the C–O stretching frequencies in the IR spectra of **2** (1885 cm^{-1}) and **5** (1937 cm^{-1}) are in the region of several frequencies observed in stopped-flow FTIR studies of CO complexes of *Klebsiella pneumoniae* nitrogenase (1880, 1906, 1936 and 1958 cm^{-1}).[8]

We also point out that treatment of the NEt_4 salt of **1** with NaN_3 gives $NEt_4[Fe(NS_3)N_3]$, which has relevance to azide inhibition of the iron site in nitrile hydratase.[1] This and other complexes of inhibitors of nitrile hydratase are under investigation, although MeCN appears to bind very weakly to the $FeNS_3^-$ site.

The shape of our iron cluster is reminiscent of those of the linear trinuclear complexes $[Et_4N]_3[Fe_3S_4(SPh)_4]$[9] and $[Et_4N]_3[VFe_2S_4Cl_4]$.[10] We anticipate in our future work that **2** and related complex anions such as $[Fe(NS_3)(CNR)]^-$ will function as ligands to allow assembly of a range of multinuclear complexes of iron with other metals. Already, we have obtained the analogue of **5**, $[Fe_3(NS_3)_2(CNC_6H_{11})_2]$, [from $Fe(acac)_3$, NS_3H_3, and CNC_6H_{11},[11] and $[Fe_2Co(NS_3)_2(CO)_2]$ (by use of $CoCl_2$ in place of $FeCl_2$ in step iii of Scheme 1).

We thank the BBSRC for support of this work and Dr D. J. Evans for Mössbauer spectroscopic measurements.

Acetaldehyde hydration by zinc–hydroxo complexes: coordination number expansion during catalysis

Xiaodong Xu, Ajay R. Lajmi and James W. Canary*

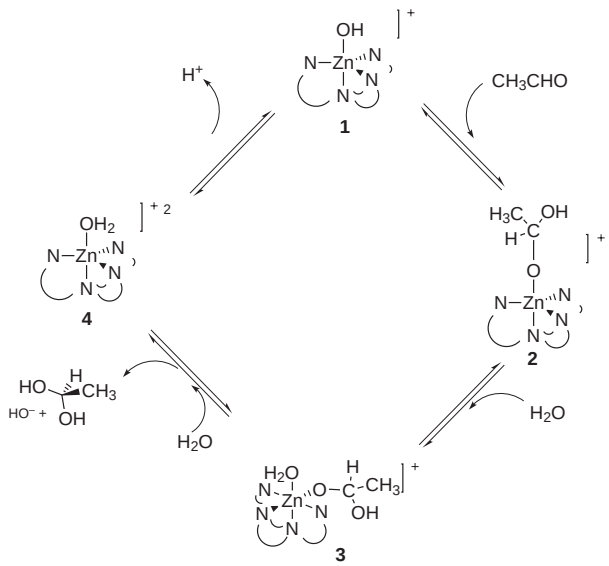
Department of Chemistry, New York University, New York, NY 10003, USA. E-mail: james.canary@NYU.edu

Received (in Bloomington, IN, USA) 17th August 1998, Accepted 6th November 1998

The complexes [Zn(tren)(OH)]$^+$ and [Cd(Me$_6$tren)(OH)]$^+$ are excellent catalysts for the hydration of acetaldehyde while the closely related complex [Zn(Me$_6$tren)(OH)]$^+$ does not catalyze the reaction, consistent with the notion that zinc ions require the ability to accommodate expanded coordination numbers in hydrolytic reactions such as those catalyzed by the enzyme carbonic anhydrase.

Carbonic anhydrases are widely occurring Zn(II) metalloenzymes that catalyze the interconversion of CO_2 and HCO_3^-. The catalytic zinc ion in human carbonic anhydrase II is ligated by three histidine residues and a water molecule in its resting state. Most detailed mechanisms postulated for carbonic anhydrases[1] require expansion of the coordination sphere of the zinc ion from four to five (or six) during the catalytic cycle for addition of zinc-bound hydroxide to the CO_2 with concomitant polarization of the carbonyl group by zinc, and for associative displacement of the bicarbonate product by water.[2] Higher coordination number intermediates are suggested by crystallographic analyses,[3,4] but little functional data is available that bears on the significance of this issue. In this paper, we test the hypothesis that zinc ions require coordination number increases in hydrolysis catalytic cycles, specifically the hydrolysis reaction of acetaldehyde catalyzed by zinc complexes of the synthetic ligands tris(2-aminoethyl)amine (tren) and tris(2-dimethylaminoethyl)amine (Me$_6$tren).

The hydration of acetaldehyde is catalyzed by carbonic anhydrase and has also been studied extensively with several synthetic catalysts and buffers.[5,6] A plot of log(k_{cat}) *vs.* pK_a (k_{cat} = dk_{obs}/d[ZnL]) yields a linear relationship suggesting that the mechanism of the reaction is simple nucleophilic attack upon the carbonyl. A simplified mechanistic scheme for the reaction is shown in Scheme 1, with the zinc-hydroxo form of the catalyst shown as the catalytically active species. Associative exchange is generally observed for substitution reactions of zinc complexes of these ligands;[7] formation of intermediate **3** requires an expanded coordination sphere.



Scheme 1 Proposed mechanism for hydration of acetaldehyde catalyzed by Zn(II) or Cd(II) complexes.

The ligands tren and Me$_6$tren offer an opportunity to examine this question since zinc complexes of tren can form six-coordinate complexes but those of Me$_6$tren cannot. In five-coordinate complexes, both ligands adopt a C_3-symmetric conformation [Fig. 1(a)].[8] However, in six-coordinate complexes, tren adopts a C_σ conformation [Fig. 1(b)] that is sterically inaccessible to Me$_6$tren due to the steric hindrance caused by the bulky dimethylamino substituents. A search of the Cambridge Structural Database[9] yielded over 20 structures of tetradentate complexes of Me$_6$tren, all of which showed the ligand in a C_3-conformation while tren complexes showed both five-coordinate (C_3) and six-coordinate (C_σ) complexes. Thus the zinc ion in [Zn(Me$_6$tren)(OH)]$^+$ should be limited to

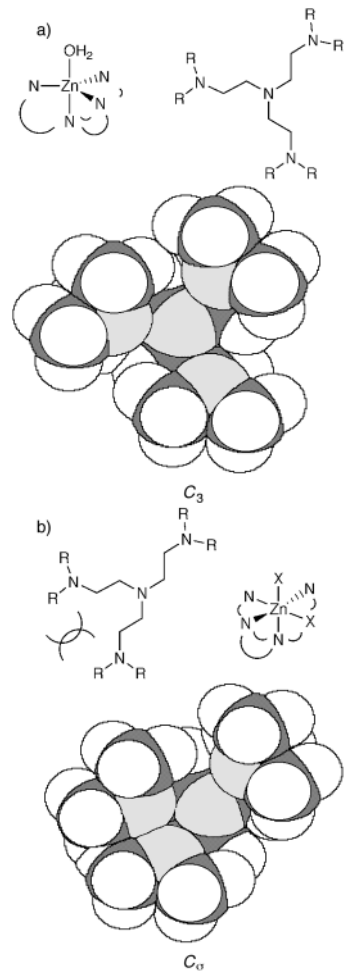


Fig. 1 C_3 (a) and C_σ (b) conformations observed for penta-coordination and hexa-coordination. Steric hindrance in Me$_6$tren precludes hexa-coordination.

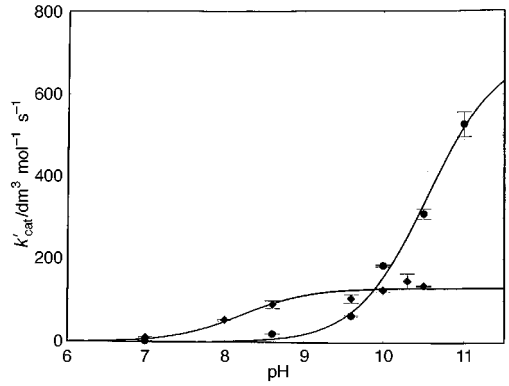

Fig. 2 pH–rate profiles for $[Zn(tren)(OH)]^+$ (●) and $[Cd(Me_6tren)(OH)]^+$ (◆).

maximal five-coordination while in $[Zn(tren)(OH)]^+$ six-coordination should be readily achievable. Thus, intermediate **3** should be accessible only for the tren complex, and the Me_6tren complex should not catalyze the reaction.

The hydration rate of acetaldehyde in aqueous solution was determined using stopped flow UV–VIS detection, monitoring the decrease of the carbonyl band at 278 nm. The solution used in this work was 10% aq. MeCN {0 °C, 0.1 M $NaClO_4$; $[CH_3CHO]$ = 36 mM, $[[Zn(L)(OH)]^+]$ = 0.25–5 mM}.[5,10] The results are shown in Fig. 2, where each data point represents 3–5 experiments at different catalyst concentrations, each run in triplicate; The line is a non-linear least-squares fit of $k'_{obs} = k_{cat}\chi_{[Zn(L)OH]^+}$ where $\chi_{[Zn(L)OH]^+}$ is the mole fraction of catalytically active species. The observed pH–rate profile for $[Zn(tren)(OH)]^+$ reveals a point of inflection at pH 10.5 similar to the published pK_a.[11] The log(k_{cat}) is 2.84, consistent with that predicted from the Brønsted analysis (2.9).[6] However, for the complex $[Zn(Me_6tren)(OH)]^+$, no catalysis was observed even though it should be easily seen under these conditions [predicted log(k_{cat}) = 2.0].

It was reasoned that although the hydration reaction is not catalyzed by $[Zn(Me_6tren)(OH)]^+$, it should be catalyzed by $[Cd(Me_6tren)(OH)]^+$ complex since the Cd(II) ion may have an expanded coordination number due to its large ionic radius.[8] The observed pH–rate profile is shown in Fig. 2. The pK_a value from curve fitting is 8.2 which compares favorably with that determined by pH titration.[12] The log(k_{cat}) is 2.12 as expected from the Brønsted relationship discussed above.

Based on the available data, the most likely explanation for the inactivity of $[Zn(Me_6tren)(OH)]^+$ is the inability of water to displace the hydrated acetaldehyde intermediate due to the steric bulkiness of the ligand that prevents hexa-coordination of the Zn(II) ion. Formation of **2** should not be hindered by the methyl groups in Me_6tren as indicated by examination of models and calculations of heats of formation (Spartan: MNDO)[13] of **2** and various similar compounds that failed to show any significant steric interaction between the atoms of the acetaldehyde and the ligand.

It is widely believed that one reason that enzymes maintain low coordination numbers to catalytic zinc ions is to increase the acidity of the zinc-bound water molecule.[14–16] The implication of the present study is that zinc ions involved in hydrolytic reactions require access to an expanded coordination sphere for catalyst turnover. This requirement may be an additional reason for the frequent observation of four-coordinate zinc ions in crystal structures of resting state enzyme active sites, and higher coordination numbers in corresponding enzyme-inhibitor complexes.

We thank the National Institutes of Health (GM 49170) for support of this work.

Solution and soluble polymer syntheses of 3-aminoimidazoline-2,4-diones

Juyoung Yoon,† Chang-Woo Cho, Hyunsoo Han and Kim D. Janda*

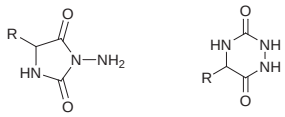
Department of Chemistry, The Scripps Research Institute and The Skaggs Institute for Chemical Biology, 10550 N. Torrey Pines Road, La Jolla, CA 92037, USA. E-mail: kdjanda@scripps.edu

Received (in Corvallis, OR, USA) 9th September 1998, Accepted 6th November 1998

3-Aminoimidazoline-2,4-dione derivatives have been synthesized from a combination of α- and aza-amino acids by both solution phase and soluble polymer supported approaches; this soluble polymer methodology combines clean product isolation with recycling of the original matrix.

Molecular diversity based on combinatorial organic synthesis is now being used for rapid lead generation in both drug discovery and the development of biologically active compounds with potential therapeutic value.[1] Recently, solid-phase synthesis of heterocycles bearing one or more nitrogen atoms such as diketopiperazines,[2] diazines,[3] and hydantoins[4] has received considerable attention due to their medicinal importance. Hence, development of strategies for the mixture/parallel synthesis of additional heterocyclic structures either in solution or on a polymer support is of key interest.

The synthesis and structure assignment of hexahydro-1,2,4-triazine-3,6-dione **2**, isomeric with 3-aminoimidazoline-2,4-dione **1**, has been rather cryptic for over 30 years.[5–7] It has been demonstrated[6,7] that a hexahydro-1,2,4-triazine-3,6-dione could be prepared by the reaction of *N*-[*N*-(phenylthiocarbonyl)glycyl]-*N*′-(benzyloxycarbonyl)hydrazine with lead acetate.[8] A similar cyclization of ethyl semicarbazinoacetate [$H_2NNHC(O)NHCH_2CO_2Et$] with NaOEt[9] was discovered to lead to **1** rather than **2**. A more recent attempt[10] to synthesize 1,2,4-triazine-3,6-diones by the reaction of hydrazine with α-lactams gave mainly **1**.[11] If **1** or **2** could be made in a controlled

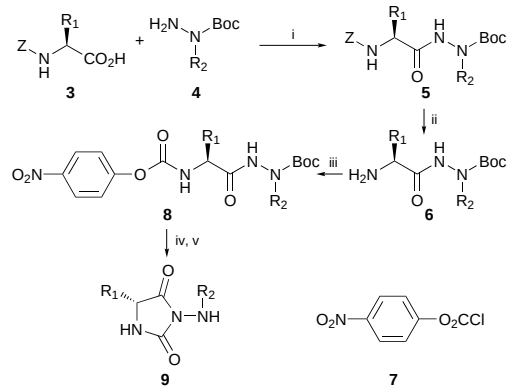


1 **2**

fashion they should make interesting targets for combinatorial synthesis/drug discovery as they are structurally rigid, possess ample hydrogen donor/acceptor functionality and contain two points for diversity generation. Herein we describe our synthetic approach to 3-aminoimidazoline-2,4-diones **1**, our application of this strategy to a soluble polymer support, and our ability to design a methodology that allows regeneration of the resin.

As detailed *vide supra* examples relating to the controlled syntheses of 3-aminoimidazoline-2,4-dione derivatives have been sparse. In 1985, a concise one step synthesis from α-amino acids and *tert*-butyl carbazate was reported by Lalezari,[12] however, this report also detailed a major problem with this synthetic tack which induced racemization of the product. To avoid this unwanted racemization, our solution phase approach utilized Et_3N or Pr^i_2NH at room temperature for the cyclization step, allowing optical activity‡ to be preserved.

As shown in Scheme 1, *N*-benzyloxycarbonyl protected amino acids were used as convenient starting materials in the solution phase synthesis. Thus, protected amino acids were coupled with our previously described Boc-protected aza-amino acids[13] using DCC and DMAP in typically 95% yield.



Scheme 1 *Reagents and conditions*: i, DCC, DMAP; ii, H_2/Pd-C; iii, **7** (1.1 equiv.), Et_3N (1.1 equiv.); iv, TFA–CH_2Cl_2 (1:1 v/v); v, dilution, Et_3N (1.1 equiv.).

After removal of the benzyloxycarbonyl (Z) group, nitrophenyl chloroformate was introduced to generate an activated intermediate for the cyclization reaction. Removal of the Boc group was performed using TFA–CH_2Cl_2 (1:1), followed by cyclization in Et_3N–CH_2Cl_2 (1:100 v/v) at 25 °C, and the desired unracemized 3-aminoimidazoline-2,4-diones **9** were obtained in approximately 75% yield.

With a sound solution phase strategy in hand we extended our methodology to a soluble polymer supported synthesis. In this scenario linear homopolymer [polyethylene glycol monomethyl ether (MeO-PEG)] served as our carrier for polymer synthesis and purification. We have demonstrated the advantages of using liquid phase synthesis through the construction of both peptide/small molecule combinatorial libraries[14] and as a reagent/catalyst support.[15]

Linker **10** was prepared *via* the oxidation of 4-(*tert*-butoxy)benzaldehyde with Ag_2O. This acid was coupled to MeO-PEG5000-amine and upon deprotection with TFA gave phenol **11** which was now ready for the first diversity step coupling (Scheme 2). The amino acid was introduced in the form of isocyanate **12**[16] and this building block was attached to **11** granting **13**; the second point of diversity, Boc-aza-amino acid **4** was added to deprotected **13** providing PEG-**14**. It should be stressed that the unique physical properties of the MeO-PEG homopolymer allowed each coupling/deprotection reaction to be purified by precipitation of the modified homopolymer. Furthermore, reaction progress was conveniently monitored by ^1H and ^{13}C NMR spectroscopy. Finally, after removal of the Boc group, **14** could be base-cyclized and thus cleaved from the support generating a variety of 3-aminoimidazoline-2,4-diones in greater than 90% purity and in 62–80% yield (Table 1). The structures of the products were confirmed by ^1H, ^{13}C NMR and FAB mass as well as IR spectroscopy.§ For example, ^1H NMR analysis of **9d** in [$^2H_6$]DMSO clearly shows a doublet at δ 2.49 for NCH_3 and a quartet for NH at δ 5.43. Also, all of the compounds showed distinct peaks in their IR spectra at 1775 and 1725 cm^{-1} which is indicative of a 3-aminoimidazoline-2,4-dione structure.[5] Lastly, it was possible to regenerate PEG-**11** and reapply this material in another round of synthesis. This was accomplished by simple treatment of the isolated reaction PEG-**11** with 1 M NaOH which in effect removed any previous

materials that had accumulated during the synthesis of **9**. We could use this PEG-**11** again without any significant reduction in loading or yield, which was confirmed by ^{1}H NMR analysis.

In conclusion, we have shown both solution and liquid phase methodologies for the controlled stepwise synthesis of 3-aminoimidazoline-2,4-diones. In our strategy we have provided a method that allows for the incorporation of two points of diversity which can be drawn from a large pool of building blocks. Finally, our approach allows for polymer regeneration and its reuse.

Iron-catalyzed allylic amination by nitroorganics

Radhey S. Srivastava† and Kenneth M. Nicholas*

Received (in Corvallis, OR, USA) 15th September 1998, Accepted 28th October 1998

$[CpFe(CO)_2]_2$ catalyzes the reaction of nitroaromatics with olefins under CO to produce allyl amines regioselectively; a coordinated organonitrogen species is implicated as the active aminating agent.

In contrast to oxygenation, synthetically useful methods for the direct introduction of nitrogen into hydrocarbons (nitrogenation) are few. Metal-mediated nitrogenation reactions have been receiving increasing attention, as evidenced by recent reports of metal-catalyzed aziridinations[1] and hydroaminations[2] of olefins, both of which involve addition to the double bond. Processes for the direct *allylic* nitrogenation of hydrocarbons, which could expand the scope of the commercially important ammoxidation of propylene to acrylonitrile,[3] also hold considerable appeal. Recent efforts in this laboratory and others have led to the development of Mo-[4] and Fe-catalyzed[5] reactions of olefins with aryl hydroxylamines, which provide *N*-aryl-*N*-allyl amines in generally moderate yields and with excellent regioselectivity. A novel azodioxide–iron complex has been implicated as the active aminating agent in the allylic aminations catalyzed by iron salts.[5b]

In order to enhance the synthetic utility of metal-catalyzed allylic aminations and to further explore the reactivity of coordinated organonitrogen species, we have been interested in the use of more readily available prospective aminating agents, including amines[6] and, here, nitroorganics. The metal-catalyzed reactions of nitroarenes and CO can produce various useful organonitrogen compounds, including amines, urethanes, ureas and isocyanates.[7] We now report the discovery of a new allylic amination system, which employs nitroarenes as aminating

agents and inexpensive $[CpFe(CO)_2]_2$ as the catalyst [eqn. (1)]. Initial experiments indicate that this system is distinct, both mechanistically and chemoselectively, from the recently reported $Ru_3(CO)_{12}$/(α-diimine)-catalyzed system for allylic amination.[8]

The reactions of olefins with nitroarenes catalyzed by $[CpFe(CO)_2]_2$ (5 mol%) were carried out in dioxane at 150–180 °C under 50–75 atm of CO.‡ Representative results for a number of olefins and nitro compounds are summarized in Table 1. The desired allyl amines were the only olefin-derived products detected, generally constituting 75–95% of the volatile N-containing products; *N*,*N*-diaryl ureas are the principal byproducts.§ The yield of allyl amine depends markedly on the structure of both the olefin and the nitro compound. Among the small set of test olefins 1,1-disubstituted derivatives were aminated most efficiently (entries 1,2) while 1,2-disubstituted, trisubstituted and terminal olefins were aminated less efficiently (entries 3–5). With unsymmetrical alkenes (entries 1–5) single regioisomers were obtained which are derived from introduction of nitrogen at the less-substituted vinylic carbon with double bond transposition, characteristic of ene reactions.[9] Probing the structure/reactivity correlation of the nitroarene component with α-methylstyrene (AMS) as the substrate (entries 1, 6–9), nitrobenzene gave a nearly quantitative yield, nitroarenes bearing electron-withdrawing groups gave moderate yields, and nitroanisole afforded a poor yield of the corresponding allyl amine.

Initial screening experiments demonstrated that the dinuclear **1** is the most active among several related complexes tested as amination catalysts. In the reaction of nitrobenzene with AMS (dioxane, 160 °C, 70 atm CO) neither bimetallic $Cp_2Mo_2(CO)_4$ nor other mono-iron complexes, *e.g.* $Fe(CO)_5$, $CpFe(CO)_2Br$ or $CpFe(CO)_2(THF)^+$, produced appreciable quantities of allyl amine. However, a 52% yield of the allyl amine from AMS was obtained using $CpFe(CO)_2(\eta^1\text{-allyl})$ (**2**, 5 mol%) as (pre)-catalyst. The documented ability of the two active (pre)-catalysts, **1** and **2**, to generate the $CpFe(CO)_2$ radical[10,11] suggests that this species may be involved in the catalytic mechanism.

Given the unprecedented catalytic activity of **1** and the distinctive regioselectivity of the amination reaction several experiments were conducted to probe the nature of the actual aminating species. Firstly, evidence was gathered indicating that two potential reactive free organonitrogen species are not involved. Nitrosobenzene, an established enophile,[12] was excluded as an intermediate since the amination of AMS by nitrobenzene proceeded cleanly in the presence of the PhNO-trapping agent, 2,3-dimethylbutadiene [eqn. (2)],[13] with none of the corresponding hetero-Diels–Alder adduct being produced.¶

Table 1 Allylic amination by nitroarenes catalyzed by $[CpFe(CO)_2]_2$

Entry	Alkene	Nitroarene	Allylamine	Yield[a,b] (%)

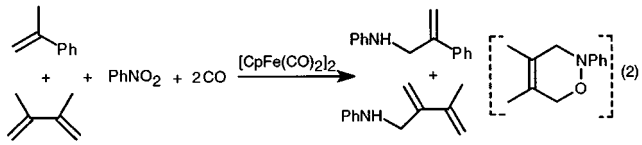
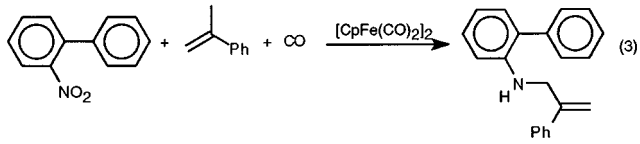
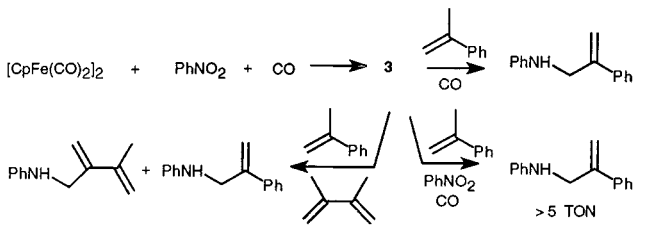
† Present address: Department of Chemistry, University of Southwestern Louisiana, Lafayette, LA 70504, USA.





Similarly, amination of AMS by 2-nitrobiphenyl afforded the corresponding *N*-biphenyl-*N*-allyl amine exclusively [eqn. (3)], but no detectable carbazole, the established product of intramolecular nitrene trapping.[14] Together these results suggest that a coordinated organonitrogen species serves as the active aminating agent in the reactions catalyzed by **1**.

More direct information on the iron species involved in the catalytic reaction was obtained by examining a dark red paramagnetic compound **3** which can be isolated from the stoichiometric reaction of **1** with nitrobenzene in the absence of olefin (dioxane, 100 °C, 75 atm CO, Scheme 1). Although we have not yet established the structure of **3**,‖ this compound appears to be catalytically relevant since it both stoichiometrically (in the absence of nitrobenzene) and catalytically (in the presence of nitrobenzene) efficiently aminates AMS (dioxane, 160 °C, 60 atm CO, TON *ca*. 8). Moreover, **3** aminates AMS in the presence of the nitrosobenzene trap, 2,3-dimethylbutadiene, again suggesting that the nitrogen fragment is transferred in the coordination sphere of the metal.



Scheme 1

In summary, $[CpFe(CO)_2]_2$ has been found to be an effective catalyst for the regioselective allylic amination of olefins by nitroarenes. It is significant that iron-catalyzed reactions involving nitroorganics and CO are rare.[15] Moreover, the differing chemoselectivity and trapping results between the present system and the $Ru_3(CO)_{12}$/α-diimine-catalyzed aminations[8]** suggests the involvement of distinctly different active aminating agents. Further insight into the mechanism of this new catalytic amination process, including the nature of the active iron species involved, awaits the results of studies in progress.

We are grateful for support provided by the National Science Foundation (CHE 9610277). We also thank Professors F. Ragaini and S. Cenini (Milan) for discussions and communication of their recent results prior to publication.

Notes and references

‡ *General procedure*: $[CpFe(CO)_2]_2$ (0.15 mmol), nitrobenzene (2.9 mmol), olefin (3.8 mmol) and dioxane (10 ml) were placed in the glass liner of a stainless steel autoclave under nitrogen. The autoclave was charged with CO (900–1000 psi) and then heated at 160–180 °C for 22–24 h, during which time aliquots were withdrawn *via* dip tube for GC analysis. The autoclave was cooled, the solution was transferred into a Schlenk tube, and the volatiles were removed *in vacuo*. The residue was triturated with light petroleum–Et_2O. The insoluble residue contained the *N*,*N*-diaryl ureas. The extracts were chromatographed on silica gel using light petroleum–Et_2O as eluent to afford the allyl amine. New compounds were characterized by NMR and MS analysis.

§ Small amounts of aryl amine (1–20%), azoarene (1–5%), and azoxyarene (1–5%) were also detected by GC–MS analysis. Non-volatile *N*,*N*-diaryl urea by-products were isolated by crystallization/chromatography.

¶ The hetero-Diels–Alder adduct was shown to be stable under the conditions of the catalytic reaction.

‖ *Selected data* for **3**: ν_{max}(KBr)/cm^{-1} 2033 and 1965; EPR (CH_2Cl_2)/G 3525 (bs); *m*/*z* (FAB) 628, 471, 396, 342, 288, 195; the elemental analysis of **3**, while indicating the presence of C, H, N and Fe, suggests contamination by an organic impurity.

** In the $Ru_3(CO)_{12}$/diimine-catalyzed reactions, aryl amines are the major byproducts (ref. 8) and amination in the presence of dimethylbutadiene affords substantial quantities of the hetero-Diels–Alder adduct. F. Ragaini and S. Cenini, personal communication, 1998.

Preparation of a silica-supported peroxycarboxylic acid and its use in the epoxidation of alkenes†

Jacob A. Elings, Rachida Ait-Meddour, James H. Clark* and Duncan J. Macquarrie

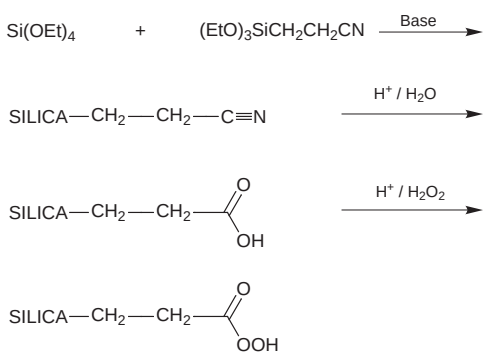
Green Chemistry Group, Department of Chemistry, University of York, Heslington, York, UK YO1 5DD. E-mail: jhc1@york.ac.uk

Received (in Cambridge, UK) 28th September 1998, Accepted 3rd November 1998

A new solid peroxyacid based on organically modified silica has been prepared and successfully applied to the epoxidation of alkenes.

Peroxyacids are active straightforward epoxidation reagents with wide application.[2] They do not require catalysts and are often excellent epoxidation reagents for unfunctionalised alkenes. Their use in epoxidation, however, is disputed because of the requirement of at least stoichiometric amounts in the reaction, resulting in the production of large amounts of acid waste. Although recycling of these acids to peroxyacids is possible by treatment with hydrogen peroxide in the presence of concentrated acids, this is normally not attractive for present-day homogeneous processes. An additional problem is that some types of the more active peroxyacids are not stable and therefore unsafe for use on a large scale. Because of these drawbacks the use of peroxyacids is not popular in industry.[3] The use of heterogeneous peroxyacids can deliver important improvements with respect to workup, recycling and stability. Heterogenisation of peroxyacids has, however, scarcely been studied and in the literature only a few examples are known where peroxyacids were supported on polystyrene resins.[4–8] Although these polymer-supported peroxyacids are active epoxidation reagents, their performance is poor due to the electron-releasing effect of the polymer backbone and their need for swelling. Furthermore, the close contact of easy oxidisable polymer backbones with strongly oxidative peroxyacids can potentially be dangerous (explosive). We now report a novel robust heterogeneous peroxyacid based on chemically modified silica, which is an active, selective and effective reagent for alkene epoxidation.

The preparation of the silica-supported peroxyacid is summarised in Scheme 1. The preparation of the cyanoethyl silica was partially based on a previously reported sol-gel method for MCM-type silicas.[9] Typically, tetraethyl orthosilicate (TEOS, 20.4 g, 98 mmol) and 2-cyanoethyltriethoxysilane (CETS, 21.3 g, 98 mmol) were added, separately, to a mechanically stirred mixture of ethanol (104 ml), water (106 ml) and *n*-dodecylamine (10 g, 54 mmol) at room temperature. A milky solution was rapidly formed, followed by precipitation. The stirring was continued for 21 h, yielding a thick white suspension. This was filtered and *n*-dodecylamine was removed by heating the solid at reflux in absolute ethanol (200 ml) for 3 h. This extraction was repeated three times. The solid was then dried in a vacuum oven at 95 °C for one night, yielding 15.2 g of a fine white solid (CN-silica). The CN-silica (10.0 g) was hydrolysed by heating it in 50% (v/v) aqueous sulfuric acid at 150 °C for 3 h. After cooling to room temperature, the silica was filtered and washed with an excess of water. Drying in a vacuum oven at 95 °C for one night afforded 10.3 g of COOH-silica. To 1 g of the COOH-silica were successively added methanesulfonic acid (3.0 g, 31 mmol) and hydrogen peroxide (70 wt% aqueous solution, 1.75 g, 36 mmol). This mixture was stirred at room temperature for 5 h. After this, the mixture was combined with 50 ml of water and filtered. The residue was thoroughly washed with an excess of water. The COOOH-silica (**1**) obtained was dried in a desiccator over KOH under vacuum for one night. Approximately 0.25 g of this desiccator-dried material was used to determine the number of peroxyacid groups by reductive titration with 0.1 M aq. $Na_2S_2O_3$ in the presence of I^-. Similarly prepared were **2** (ratio CETS:TEOS = 1:2) and **3** [3-cyanopropyltriethoxysilane (CPTS) instead of CETS, ratio CPTS:TEOS = 1:1].



Scheme 1

The epoxidation of *cis*-cyclooctene and cyclohexene to their corresponding oxides was carried out as follows. To a solution of the alkene (4 mmol) in 50 ml $CHCl_3$ was added the remaining part of the desiccator-dried COOOH-silica (0.75 g). This mixture was stirred at 30 °C for 24 h, after which it was filtered. The silica residue was washed with 25 ml $CHCl_3$. The combined filtrates were analysed by GC using 1,4-dichlorobenzene as an internal standard.

Table 1 shows that the treatment of the COOH-silicas with hydrogen peroxide in the presence of an acid resulted in materials containing peroxy groups. We confirmed that these were really supported peroxyacids by checking a blank silica. When a silica comprising TEOS only was treated in a similar way with hydrogen peroxide, no oxidation activity was found, which rules out the possibility of physically adsorbed hydrogen peroxide as the active reagent. Comparison of the peroxyacid loadings of **1** and **2** shows an interesting phenomenon. Despite the fact that the relative number of CETS groups in the synthesis of **2** was decreased by a factor 2 with respect to that of **1**, this resulted only in a reduction of the number of peroxyacid groups

Table 1 Epoxidation of *cis*-cyclooctene with silica-supported peroxyacids

Silica	**1**	**2**	**3**
Number peroxyacids/mmol g^{-1}	3.54	2.88	3.31
Specific surface area/m^2 g^{-1} [a]	426	1080	597
Conversion *cis*-cyclooctene (%)	55	57	62
Selectivity to cyclooctene oxide (%)	100	88	96
Efficiency of oxygen transfer (%)[b]	81	87	91

[a] Determined for the parent COOH–silica using the BET isotherm with dinitrogen as adsorbate. [b] 100 × (mmol epoxide formed)/(mmol COOOH groups per g dried silica × exact amount COOOH-silica).

Table 2 Reagent recyclability in the epoxidation of cyclohexene with COOOH-silica **2**

Cycle	Number peroxyacids/mmol g^{-1}	Conversion (%)	Selectivity (%)	Efficiency of oxygen transfer (%)
0	2.95	57	77	81
1[a]	2.97	55	77	76

[a] The spent reagent of cycle 0 was removed by filtration, washed with $CHCl_3$, dried and subsequently regenerated. The amounts of reactant used in the regeneration process and epoxidation were adapted to the amount of spent reagent which remained after its recovery.

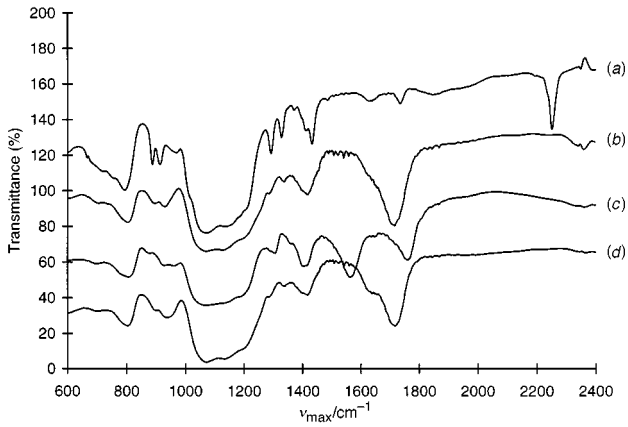

Fig. 1 DRIFT spectra of silica-supported peroxyacid **1** and its precursors: (*a*) CN-silica, (*b*) COOH-silica, (*c*) COOOH-silica **1** and (*d*) spent COOOH-silica.

in the final product by a factor of 1.2. This result may indicate a better accessibility of the carboxylic groups in the precursor of **2**, which is supported by its higher surface area.

Fig. 1 shows the DRIFT spectra of COOOH-silica **1** and its precursors. The precursors display the expected bands for CN (2252 cm^{-1}) and COOH (1715 cm^{-1}), respectively. Conversion of the COOH group into its corresponding peracid resulted, as expected,[2] in a shift of the band for the carbonyl group to higher frequencies (1760 cm^{-1}) and a spectrum consistent with that found for peracetic acid.[10] Interestingly, DRIFT also shows that the supported peroxyacid is converted into its parent acid during the epoxidation process (and neutralisation of the unreacted groups by reductive titration). This indicates that recycling is in principle possible.

Tables 1 and 2 show that the new COOOH-silicas were capable of epoxidising *cis*-cyclooctene and cyclohexene with high to excellent selectivities. In neither of the cases could by-products be detected by GC. Table 2 also shows that by giving spent COOOH-silica **2** another treatment with hydrogen peroxide/methanesulfonic acid, we managed to fully recycle the former number of peroxy groups, resulting in a silica which was still capable of epoxidising cyclohexene. Comparison of the oxygen transfer efficiencies of the silica materials with known polymer systems shows that the silica materials were much more effective in their transfer of oxygen to *cis*-cyclooctene. For example, Harrison and Hodge found for their polymer-supported peroxyacid (loading 3.5–4.0 mmol g^{-1}) a maximum efficiency of 48% only.[6] Despite the fact that we used an excess of alkene in our epoxidation experiments, the peroxy oxygens were not fully transferred to the substrate. Although decomposition of the supported peroxyacids may be responsible for the loss of oxygens (reminiscent of epoxidation with conventional peroxyacids[2]), we found in the case of **1**, by reductive titration of spent material, that the 'missing oxygens' could mainly be attributed to unreacted peroxyacid groups, indicating the presence of groups inaccessible to the alkene.

The new peroxyacid reagents have several important characteristics including loadings and activities which approach those found for conventional homogeneous peroxyacids (*e.g.* 70% MCPBA $\approx$ 4 mmol g^{-1}). Also, these materials appear to be stable under anhydrous conditions at room temperature (no loss in activity on drying and on storing the dry material over at least 24 h). We are currently optimising the performance of above mentioned supported peroxyacids. For this purpose, the effect of solvent and temperature will be studied in detail. Preliminary results show that epoxidation of a range of alkenes can be achieved using the new solid peroxyacid, that these materials are also effective in benign solvents such as EtOAc and that the oxygen transfer efficiencies can be further enhanced by fine-tuning of the silica synthesis and porosity.

We are grateful to the European Commission for a TMR Marie Curie Grant (to J. A. E.), to the Royal Academy of Engineering/EPSRC for a Clean Technology Fellowship (to J. H. C.) and the Royal Society for a University Research Fellowship (to D. J. M.).

α-Carbonyl radical cyclization approach toward spiro[4.4]nonene: total synthesis of dimethyl gloiosiphone A

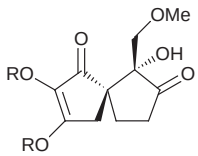
Chin-Kang Sha* and Wen-Yueh Ho

Department of Chemistry, National Tsing Hua University, Hsinchu 300, Taiwan, ROC.
E-mail: cksha@chem.nthu.edu.tw

Received (in Cambridge, UK) 2nd November 1998, Accepted 9th November 1998

The total synthesis of dimethyl gloiosiphone A 2 was achieved *via* an α-carbonyl radical spirocyclization.

Gloiosiphone A **1** and its dimethyl derivative **2** were isolated from red marine algae *Gloiosiphonia verticillaris*.[1] Crude lipid collections of *Gloiosiphonia verticillaris* were found to exhibit profound antimicrobial activity against several *Staphylococcus*,

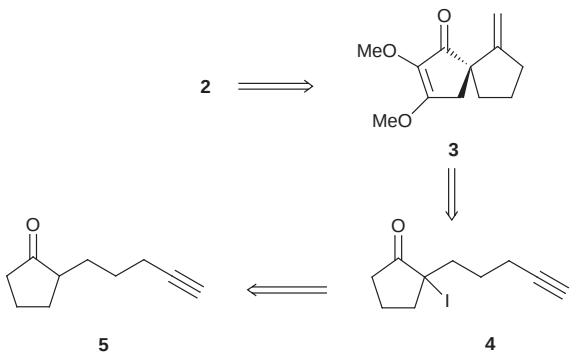


1 R = H
2 R = Me

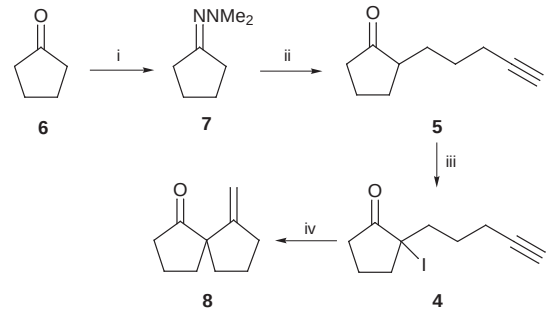
Bacillus and *Salmonella* species. Since the causative agent **1** was not stable enough for isolation, the crude collections were treated with CH_2N_2 to furnish the more stable dimethyl derivative **2**.

Compounds **1** and **2** comprise a new structural class featuring a highly oxygenated spiro[4.4]nonene system. Due to their potential antimicrobial activity and novel molecular skeleton, these compounds are challenging synthetic targets. The first total synthesis of dimethyl gloiosiphone A **2** has been achieved recently by Paquette's group.[2] As an extension of our work on the α-carbonyl radical cyclization reaction,[3] we report herein the total synthesis of **2** using an α-carbonyl radical cyclization as the key step. The retrosynthetic analysis is outlined in Scheme 1. The spirononene structure in **2** could be produced by an α-carbonyl radical cyclization followed by appropriate oxidation (**4**⟶**3**). The radical precursor iodo ketone **4** would be generated according to our method[4] from **5**, which in turn could be prepared from cyclopentanone **6** according to Yamashita's procedure.[5]

Treatment of cyclopentanone **6** with *N*,*N*-dimethylhydrazine in the presence of TFA as catalyst furnished hydrazone **7** (Scheme 2). Deprotonation of **7** with Bu^{n}Li at 0 °C followed by alkylation with 5-iodopent-1-yne and hydrolysis yielded the required ketone **5**. Ketone **5** was sequentially treated with HMDS/TMSI and NaI/MCPBA in THF to afford iodo ketone **4**.



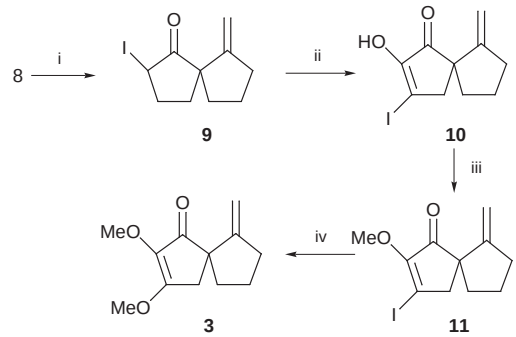
Scheme 1



Scheme 2 *Reagents and conditions*: i, H_2NNMe_2, 90%; ii, Bu^{n}Li, 0 °C, 5-iodopent-1-yne, then 10% HCl, 1 h, 80%; iii, HMDS, TMSI, CH_2Cl_2, then NaI, MCPBA, THF, 82%; iv, $(Bu_3Sn)_2$ (0.1 equiv.), sun lamp, C_6H_6, 1.5 h, then Bu_3SnH (1.05 equiv.), AIBN, C_6H_6, 87%.

Treatment of **4** with Bu_3SnH under standard conditions furnished the required spirocyclic compound **8** in 50% yield. To improve the yield, an atom transfer radical reaction was adopted.[6] Thus, irradiation of a benzene solution of ketone **4** at reflux with a sun lamp in the presence of $(Bu_3Sn)_2$ (0.1 equiv.) followed by reduction of the resulting vinyl iodide with Bu_3SnH (1.05 equiv.) using AIBN as initiator furnished spiro compound **8** in 87% overall yield.

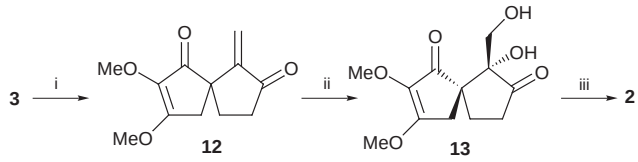
We then focused our attention on the introduction of enol ether moieties into **8**. First, iodo ketone **9** was generated from **8** by the same method used for the transformation of **5**⟶**4** (Scheme 3).[3] The iodo ketone **9** was then converted into unsaturated ketone **10** *via* a modified version of Sato's method.[7] Accordingly, **9** was oxidized with DMSO at 70 °C followed by addition of I_2 (1 equiv.) to provide **10**.



Scheme 3 *Reagents and conditions*: i, HMDS, TMSI, CH_2Cl_2, then NaI, MCPBA, THF, 82%; ii, DMSO, I_2, 86%; iii, NaH, MeI, DMF, 95%; iv, NaOMe (10 equiv.), MeOH, 92%.

Compound **10** was subsequently methylated with NaH and MeI to give methoxy iodo enone **11**. Nucleophilic displacement of iodide in **11** with NaOMe then furnished dimethoxy enone **3**.

Allylic oxidation of **3** with SeO_2 gave diketone **12** (60%) (Scheme 4). Treatment of **12** with a catalytic amount of OsO_4 with NMO as the co-oxidant gave dihydroxy ketone **13**. Finally, selective methylation of the primary alcohol with dimethyl sulfate in presence of excess K_2CO_3 (10 equiv.) afforded



Scheme 4 *Reagents and conditions*: i, SeO_2, dioxane, reflux, 60%; ii, OsO_4, NMO, Bu^{t}OH, THF, H_2O, 87%; iii, K_2CO_3 (10 equiv.), Me_2SO_4, 75%.

dimethyl gloiosiphone A **2**. All spectral data for **2** are in good agreement with those reported in the literature.[1,2]

In summary, a total synthesis of dimethyl gloiosiphone A **2** has been accomplished in a stereoselective manner in which an α-carbonyl radical cyclization reaction was employed to facilitate the construction of the key spiro[4.4]nonene skeleton. Application of this versatile α-carbonyl radical cyclization methodology toward the total synthesis of more complex natural products is under current investigation.

We thank the National Science Council of the Republic of China for financial support (NSC87-2113-M-007-043).

Molecular design of thermotropic liquid crystalline polyhydroxy amphiphiles exhibiting columnar and cubic mesophases of the normal type

Konstanze Borisch,[a] Carsten Tschierske,*[a] Petra Göring[b] and Siegmar Diele[b]

[a] *Institute of Organic Chemistry, University Halle, Kurt-Mothes-Str. 2, D-06120 Halle, Germany. E-mail: coqfx@mlucom6.urz.uni-halle.de*

[b] *Institute of Physical Chemistry, University Halle, Mühlpforte 1, D-06099 Halle, Germany*

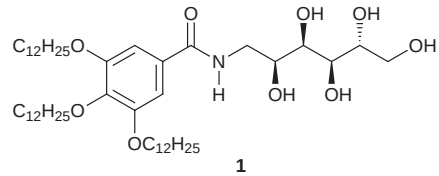
Received (in Cambridge, UK) 26th October 1998, Accepted 5th November 1998

The phase sequence Col_{h1}–Cub_{V1}–S_A–Col_{h2}–Cub_{I2}, which represents a major part of the theoretical lyotropic phase diagram of detergent solvent systems, was realized for the first time in a binary mixture of two thermotropic amphiphilic liquid crystals without any solvent.

The molecular self-organization of amphiphilic molecules in aqueous systems with formation of micelles and lyotropic mesophases is a well known phenomenon.[1] Different types of lyomesophases can be detected depending on the amphiphile structure,[2] the concentration and the temperature. Beside the layer-like lamellar phase (L_α, smectic A: S_A) other mesophases consisting of curved aggregates occur. Cylindrical aggregates organize into hexagonal columnar phases (H, Col_h) and globular or non-globular spheroids can build cubic mesophases (discontinuous cubic phases, Cub_I). Another type of cubic mesophase consisting of two mutually interwoven networks of branched cylinders (bicontinuous cubic mesophases, Cub_V) occurs at the transitions between smectic and columnar phases. For each of the non-lamellar mesophases two different types are possible. Normal phases (type 1) have the stronger cohesive forces located in the continuum surrounding the aggregates. In the reversed (or inverse) phases (type 2) they are located inside the aggregates.

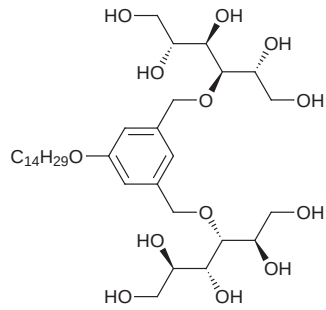
Many amphiphilic molecules can form not only lyotropic phases in aqueous systems, but also thermotropic mesophases as pure materials.[3] In particular, amphiphilic polyhydroxy compounds[3] and carbohydrate derivatives can have a wide variety of different thermotropic mesophases.[4] The formation of large dynamic hydrogen bonding networks between the hydroxy groups and the micro-segregation of the hydrophilic and the lipophilic parts of the individual molecules into separate regions are important driving forces for their self-organization. The kind of mesophase formed depends on the temperature and the chemical structure of the amphiphiles. Double chain compounds usually form columnar mesophases (Col_{h2}) or bicontinuous cubic mesophases (Cub_{V2}). Amphiphiles with three long aliphatic chains, such as **1** (see Fig. 1), can form micellar cubic mesophases built up from spheroidic closed micelles (Cub_{I2}).[5,6] Because the stronger cohesive forces (hydrogen bonding) are located inside the aggregates surrounded by the flexible alkyl chains the thermomesophases of these molecules are similar to the reversed lyotropic mesophases of detergent solvent systems. Interestingly, most non-lamellar thermomesophases of pure amphiphiles belong to the reversed type.† In particular, the concept of taper-shaped molecules[7] is based on this type of molecular organization.

Therefore we set out to design novel amphiphilic polyhydroxy compounds which can organize to thermotropic mesophases which represent analogues of normal lyotropic systems. Their aggregates should consist of micro-segregated lipophilic cores surrounded by polar shell regions providing cohesive forces *via* dynamic hydrogen bonding. To achieve this, we have synthesized the amphiphilic molecule **2**‡ consisting of two large hydrophilic polyhydroxy units and a single lipophilic chain connected *via* an aromatic linking unit (**2**, Fig. 1).



1

Cr 94 °C Cub_{I2} 227 °C Iso



2

Fig. 1 Thermotropic phase transitions of **1** and **2**. The transition temperatures of **2** from the Col_{h1} phase to the Cub_{V1} phase depend on the cooling rate. Abbreviations: Cr = crystalline solid; Col_{h1} = normal hexagonal columnar phase,; Cub_{V1} = normal bicontinuous cubic phase; Cub_{I2} = reversed discontinuous cubic mesophase; Iso = isotropic liquid state.

Compound **2** was studied by polarizing microscopy and X-ray diffraction. On heating, the material melts at 78 °C into a birefringend mesophase with a non-specific texture. This mesophase turns into the isotropic liquid state at 212 °C. On cooling from the isotropic melt the formation of a spherulitic texture can be observed at the same temperature. Immediately after its occurrence optically isotropic domains appear and rapidly coalesce to a highly viscous optically isotropic phase. On further cooling a mosaic-like texture occurs at 202 °C. On re-heating this texture remains without changes up to the isotropization temperature at 212 °C. The X-ray diffraction pattern of this birefringent phase is characterized by three sharp reflexes in the small angle region and a diffuse scattering in the wide angle region. The ratio of the positions of the small angle reflections is $1:3^{1/2}:2$, proving a hexagonal two-dimensional lattice with a hexagonal lattice parameter of a_{hex} = 4.66 nm at T = 80 °C and a_{hex} = 4.49 nm at T = 180 °C (hexagonal columnar mesophase). The diameter of the columns (*ca.* 4.5 nm) is in good agreement with a radial arrangement of the molecules (L = 3.0 nm in their most extended conformation) in cylinders with the fluid alkyl chains assembled in their centers. The number of molecules which should be arranged on average in the cross-section of a 0.45 nm thick slice of the columns is about 8.§

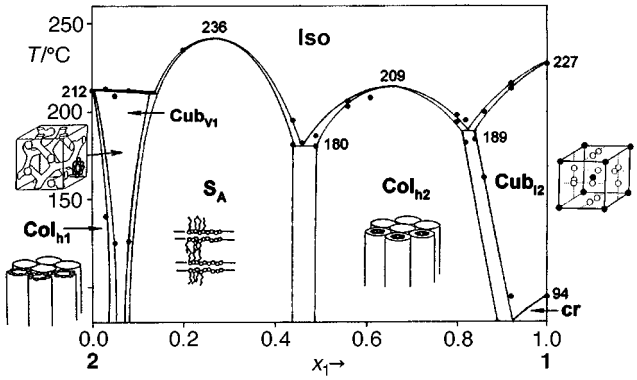


Fig. 2 Phase diagram of the binary system **1/2**. The transition temperatures observed in the heating scans (polarizing microscopy) are shown. In the cooling scans a Cub_{V1}/Col_{hl} dimorphism is found for the pure compound **2** (Fig. 1) and the Cub_{V1}–Col_{h1} transition is shifted to lower temperatures and lower concentrations of **1**. A *Ia3d* cubic lattice is shown as an example for the bicontinuous Cub_{V1} phase (the cylinders are filled with the alkyl chains). The Cub_{I2} phase is described in ref. 5(*c*),(*d*). Abbreviations: S_A = smectic A phase, Col_{h2} = reversed hexagonal columnar phase. Other abbreviations, see Fig 1.

The optically isotropic mesophase should be a cubic mesophase as indicated by the optical isotropy, the high viscosity and the cornered phase boundaries which occurring during its growth. Proof of this using X-ray scattering was not possible because of the high temperatures required. Remarkably the cubic mesophase is only formed on cooling the sample from the isotropic liquid state after passing the small range of a columnar mesophase. It seems that the cubic phase is the thermodynamical stable phase in the temperature range between 202 and 212 °C, however the formation of this three-dimensionally ordered mesophase is hindered for kinetic reasons, and its formation from the columnar phase is more strongly hindered in the heating cycles.¶

The normal type of the mesophases of **2** was proven by means of miscibility experiments.[5b,d] The phase diagram of **2** with the triple chain amphiphile **1**[5b] is shown in Fig. 2. In the contact regions of the hexagonal columnar mesophase of **2** with the reversed micellar cubic phase (Cub_{I2}) of **1**, the columnar phase of **2** is lost and is completely replaced by the cubic mesophase. In a concentration range between X_1 = 0.1 and 0.4 a broad region of a smectic A layer structure is found. The stability of this mesophase is significantly higher than those of the mesophases of the pure compounds. Upon a further increase of the content of **1** a second columnar mesophase is induced. Because the interface curvature changes continuously from left to right, the induced columnar phase which is intermediate between the S_A and the reversed micellar Cub_{I2} phase should be a reversed columnar phase (Coh_{h2}). Thus, in the contact region between **2** and **1**, five different mesophases can be observed:‖ Col_{h1}–Cub_{V1}–S_A–Col_{h2}–Cub_{I2}. This sequence represents a major part of the theoretical lyotropic phase diagram of detergent solvent systems, which was realized for the first time in a binary system of two different amphiphiles in the absence of any solvent and is a proof of the normal type of the mesophases of **2**. Thus, with exception of normal cubic mesophases consisting of spheroidic closed micelles (Cub_{I1}) all the main mesophase types found in lyotropic systems were successfully realized as their thermotropic closed analogues.‖

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Notes and references

† The first amphiphilic compound which could have a normal (probably bicontinuous) cubic mesophase was recently reported (ref. 8), furthermore some polysaccharides with cubic or columnar mesophases have been described (ref. 9); however, no experimental proof of the normal type phase structure was given in these references.

‡ Synthesized by etherification of 3,5-bisbromomethyl-1-tetradecyloxybenzene (obtained by reduction of methyl 3,5-tetradecyloxybenzene-1,3-dicarboxylate with $LiAlH_4$, followed by treatment with PBr_3) and 1,2:5,6-di-*O*-isopropylidene-D-mannitol (NaH in DMF) followed by deprotection (10% HCl in MeOH). Expected C, H analyses, mass and ^1H and ^{13}C NMR spectra were obtained: δ_H(400 MHz, DMSO-d_6, 27 °C, $SiMe_4$) 0.83 (t, 3 H, *J* 6, CH_3), 1.22–1.38 (m, 22 H, CH_2), 1.65–1.69 (m, 2 H, CH_2), 3.31–3.67 (m, 16 H, C*H*$_2$OH, C*H*OH, CH_2OC*H*), 3.91 (t, 2H, *J* 7, OCH_2), 4.18 (d, 2H, *J* 7, OH), 4.30 (t, 2H, *J* 6, OH), 4.45 (t, 2H, *J* 6, OH), 4.50–4.59 (m, 8H, OH, C*H*$_2$OCH), 6.81 (s, 3H, aromatic H); δ_C(126 MHz, DMSO-d_6, 30 °C, $SiMe_4$) 13.9 (CH_3), 22.0, 25.5, 28.6, 28.7, 28.8, 28.9, 29.0, 31.2 (CH_2), 67.3 (OCH_2), 64.0, 63.0 (*C*H_2OH), 70.4, 71.0, 71.1, 77.9 (*C*HOH, CH_2O*C*H), 73.0 (*C*H_2OCH) 158.5, 140.5, 118.4, 112.2 (aromatic C); *m*/*z* (ESI-MS) 701 ([M + Na]$^+$, 100%).

§ $n = (a_{hex}^2/2)h(N_A/M)\rho$ with ρ = 1 g cm-3, N_A = Avogadro constant, *M* = molecular mass, *h* = 0.45 nm (diffuse scattering in the wide angle region of the X-ray pattern).

¶ No prolonged heating is possible at these temperatures due to decomposition.

‖ As in other binary mixtures of amphiphilic polyhydroxy compounds [ref. 5(*b*)] no reversed bicontinuous cubic mesophase (Cub_{V2}) could be detected between the S_A phase and the reversed Col_{h2} phase, although the reason for this is not yet clear. However, this phase was realized with other polyhydroxy amphiphiles [ref. 5(*b*),(*d*)].

ChemComm

A formal synthesis of both atropenantiomers of desertorin C

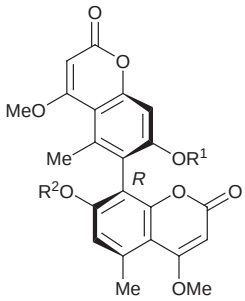
Rekha V. Kyasnoor and Melvyn V. Sargent*

Department of Chemistry, University of Western Australia, Nedlands, Western Australia, 6907, Australia. E-mail: mvs@chem.uwa.edu.au

Received (in Cambridge, UK) 20th October 1998, Accepted 6th November 1998

Asymmetric synthesis of both enantiomers of 1,1′-(2′,4-dihydroxy-6,6′-dimethoxy-2,4′-dimethylbiphenyl-3,3′-diyl)-bisethanone allows the formal synthesis of both enantiomers of 4,4′,7,7′-tetramethoxy-5,5′-dimethyl-6,8′- bicoumarin (desertorin C).

The desertorins A **1**, B **2** and C **3** are a family of unsymmetrical coumarin dimers of fungal origin which are optically active on account of restricted rotation about their stereogenic axes.[1]



1 $R^1 = R^2 = H$
2 $R^1 = H$, $R^2 = Me$
3 $R^1 = R^2 = Me$
4 $R^1 = R^2 = Bz$

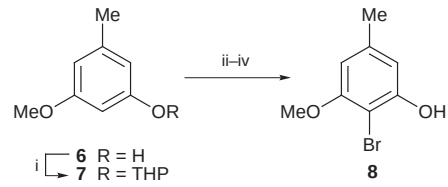
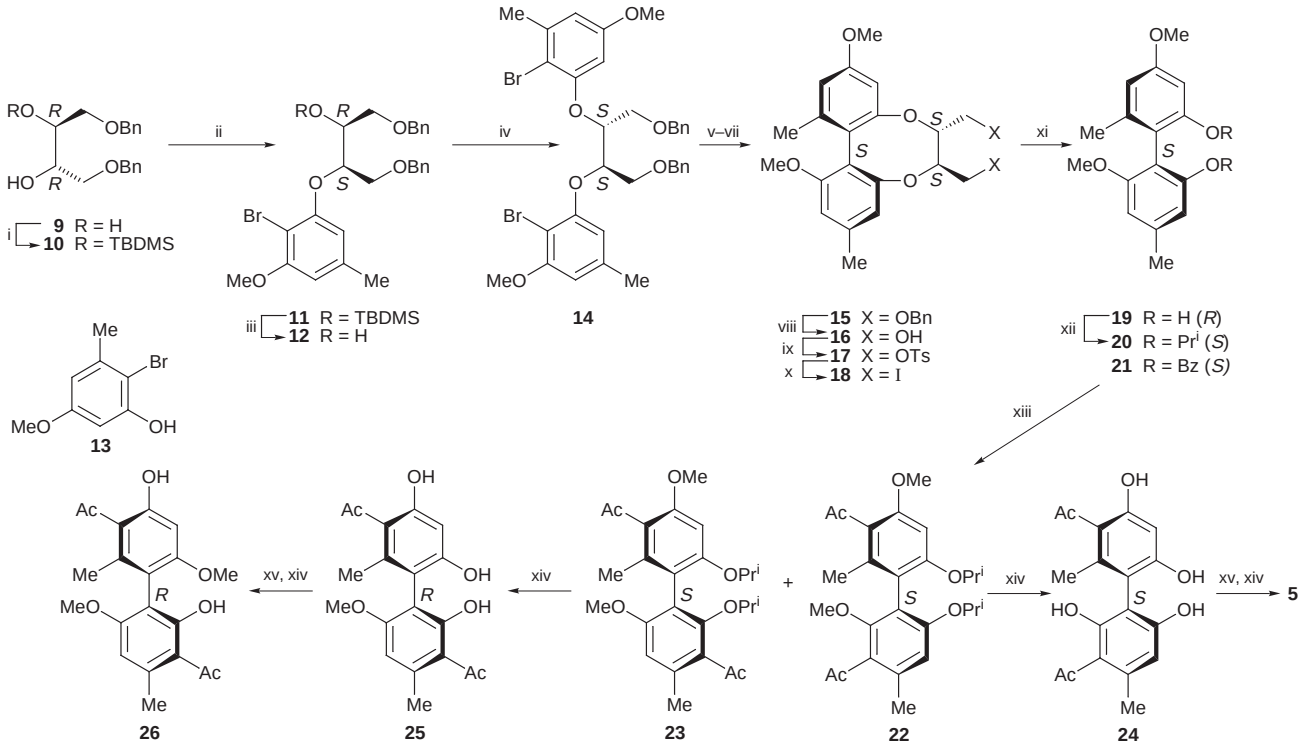


Scheme 1 *Reagents and conditions*: i, TsOH, dihydropyran, THF, 0 °C, 20 h; ii, BuLi, Ar, THF, TMEDA, 25 °C, 4 h; iii, $BrCF_2CF_2Br$, 25 °C, 1 h; iv, H^+, H_2O.

Methylation of both desertorins A and B provides desertorin C which on base hydrolysis yields the diketone **5**.[1] We have previously synthesized desertorin C in racemic form using the (±)-diketone **5** as the key intermediate.[2] Subsequently the absolute configuration of the desertorins was established as *R* by an X-ray crystal structure determination of the bis-bromobenzoate **4**.[3] We now describe a synthetic approach to both enantiomers of desertorin C.

O-Methylorcinol **6** (Scheme 1) was protected as its tetrahydropyranyl ether **7** which on lithiation and subsequent treatment with 1,2-dibromotetrafluoroethane and acidic work-up gave the bromophenol **8**,[4] mp 71–72 °C, in 60% overall yield. Mitsunobu reaction (Scheme 2) between this bromo-



Scheme 2 *Reagents and conditions*: i, TBDMSCl, imidazole, DMF, 25 °C, 15 h, 76%; ii, **8**, Bu_3P, DEAD, THF, 25 °C, 24 h; iii, Bu_4NF, THF, 25 °C, 1 h; iv, **13**, Bu_3P, DEAD, THF, 25 °C, 48 h; v, BuLi, Ar,THF, −78 °C, 1 h; vi, CuCN, TMEDA, −78 to −40 °C, 15 min; vii, O_2, −78 °C, 3 h; viii, H_2, Pd/C, EtAc, 94%; ix, TsCl, C_5H_5N, 0 °C, 7 h, 78%; x, NaI, Me_2CO, reflux, 5 h, 91%; xi, Zn, EtOH, reflux, 1 h, 80%; xii, Pr^iBr, K_2CO_3, DMF, 45 °C, 48 h, 68%; xiii, TFAA, AcOH, CH_2Cl_2, 25 °C, 7h, 69%; xiv, BCl_3, CH_2Cl_2, 0 °C, 2 h; xv, MeI, K_2CO_3, DMF, 40 °C, 15 h.

phenol **8** and the mono(*tert*-butyldimethylsilyl)ether **10** of 1,4-di-*O*-benzyl-L-threitol **9**[5] gave the ether **11** (68%) which on deprotection afforded the alcohol **12** (90%). This alcohol was caused to react in another Mitsunobu reaction with the bromophenol **13**.[6] The resultant D-threitol derivative **14**, mp 54–56 °C (45%), was subjected sequentially to lithiation, copper(I) cyanide and dry oxygen after the manner of Lipschutz *et al*.,[7] which gave the cyclized product **15** (40%). Deprotection was achieved by hydrogenolytic debenzylation and tosylation of the resultant diol **16**. The tosylate **17** was converted into the iodide **18**, mp 155–157 °C, which on reductive elimination with activated zinc supplied the diol **19**, mp 134–136 °C, $[\alpha]_D^{20}$ −27 (*c* 0.67, $CHCl_3$).

In order for the intramolecular coupling **14**→**15** to occur the aryloxy substituents in the intermediate higher order cyanocuprate[7] are predicted to adopt, on account of the anomeric effect, the *gauche* conformation depicted in Fig. 1. Hence the axial configuration of the intermediate cyclic compound **15** is *S* and that of the diol **19** is *R*. The diol appeared to be enantiomerically pure since it was not resolved on HPLC on two chiral columns[8] nor did the ^1H and ^{19}F NMR spectra of the derived Mosher diester show the presence of the other enantiomer even in the presence of a lanthanide shift reagent. The CD spectrum (MeCN) of the derived dibenzoate **21** showed exciton splitting centred at λ 226 nm with a positive first Cotton effect (λ 237 nm, $\Delta\varepsilon$ 24.3) and a negative second effect (λ 215 nm, $\Delta\varepsilon$ −9.0) in keeping with the *R* configuration of the diol **19**.[9]

Since *O*-methylorcinol **6** undergoes *C*-monoacetylation at both positions *ortho* to the hydroxy group, the diol **19** was isopropylated and the resultant ether **20** was acetylated with AcOH and TFAA, which supplied an inseparable mixture of the diketones **22** and **23**. Selective dealkylation of this mixture with BCl_3 yielded the tetrol **24** (30%), mp 198–200 °C, $[\alpha]_D^{20}$ 32.8 (*c* 0.86, Me_2CO), $\delta_{OH}(CDCl_3)$ 8.46, 8.54, 11.80 and 13.42, and the triol **25** (35%), mp 120 °C decomp., $[\alpha]_D^{20}$ −61.0 (*c* 1.05, Me_2CO), $\delta_{OH}(CDCl_3)$ 8.36, 11.87 and 12.45. Methylation and selective demethylation of the tetrol **24** gave the (*S*)-diketone **5** (69%), mp 147–149 °C (lit.,[1] 149–150 °C), $[\alpha]_D^{20}$ 34.0 (*c* 0.94, Me_2CO),[10] which had previously been obtained by basic hydrolysis of desertorin C.[1] The (*R*)-diketone **26** (82%), mp 145–146 °C, $[\alpha]_D^{20}$ −53.0 (*c* 0.80, Me_2CO),[11] was obtained in a similar fashion from the triol **25**. Since the racemic diketone has been converted into desertorin C this constitutes a formal synthesis of both of the enantiomers of this metabolite.

Both the synthetic diketone **5** and the degradation product **5** appear to have undergone some racemisation, the former presumably at the tetrol stage, and the latter under the harsh conditions of the hydrolysis.

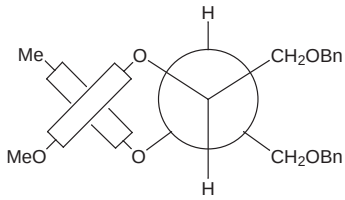


Fig. 1 Newman projection along the 2,3-bond of the D-threitol **14** in the conformation for the coupling reaction leading to **15**.

Vicinal diamination of 1,4-dihydropyridines

Rodolfo Lavilla,* Rakesh Kumar, Oscar Coll, Carme Masdeu and Joan Bosch

Laboratory of Organic Chemistry, Faculty of Pharmacy, University of Barcelona, 08028 Barcelona, Spain. E-mail: lavilla@farmacia.far.ub.es

Received (in Liverpool, UK) 6th October 1998, Accepted 10th November 1998

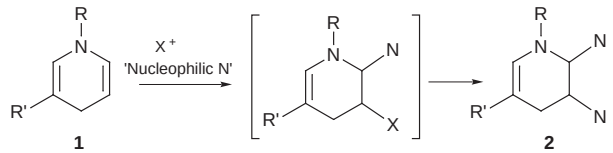
Electrophilic interaction of iodine with *N*-alkyl-1,4-dihydropyridines 1 in the presence of secondary amines stereoselectively leads to the corresponding *trans*-2,3-diamino-1,2,3,4-tetrahydropyridines 2 in satisfactory yields (79–94%); the method allows the synthesis of piperidine, pyrrolidine, morpholine and piperazine derivatives.

Continuing our research on the development of new transformations of 1,4-dihydropyridines,[1] we have recently described some 'non-biomimetic' oxidations of these compounds, in which the normal production of the corresponding pyridinium salt is avoided.[2–4] As a consequence, several unusual transformations of these heterocyclic systems have emerged as useful synthetic tools. For instance, the oxidative addition of halonium ions (*N*-halosuccinimide or related alkoxyhalogenations) was investigated, and the method was successful for the preparation of 2-substituted 3-halo-1,2,3,4-tetrahydropyridines, which, in turn, may be considered as valuable synthetic intermediates.[3] In these reactions, we observed the formation of some byproducts, arising from the nucleophilic trapping of the iminium ion produced in the interaction of the enamine moiety with the halogenating agent. We reasoned that the use of nitrogenated species in these processes would result in the formation of interesting tetrahydropyridines bearing amino substituents at positions 2 and 3 (Scheme 1).[5]

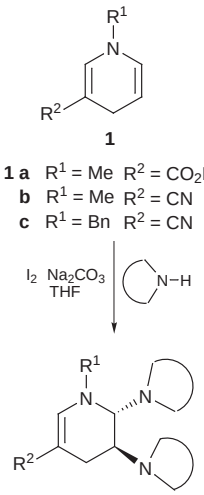
The use of amines as nucleophiles in this type of transformation is normally avoided,[6,7] because of the easy oxidation of the nitrogen atom or its coordination with the electrophile. We felt, however, that this process could be dramatically reduced due to the high reactivity of the enamine moiety present in dihydropyridines **1**, which may rapidly attack the halogen to form a 3-halo-3,4-dihydropyridinium ion. In good agreement with our expectations, when dihydropyridine **1a**[8] was treated in THF solution with iodine (3.5 equiv.) in the presence of an excess of pyrrolidine, the 2,3-diaminotetrahydropyridine **2a**† was stereoselectively formed in 87% yield (Scheme 2 and Table 1).‡ The stereochemistry of the addition was ascertained by NMR methods (including homo- and hetero-correlation techniques). The small H^2–H^3 coupling constant observed suggests a *trans* relationship between the two pyrrolidine groups and a major conformation in which these substituents are axial (it should be noted that in a tetrahydropyridine ring such a substitution pattern displays no serious 1,3-diaxial interactions).

The formation of **2a**§ could be rationalized by considering the initial formation of a *trans*-2-amino-3-iodotetrahydropyridine, which would undergo an internal nucleophilic substitution reaction followed by a stereoselective ring opening of the resulting aziridinium ion promoted by a second equivalent of the secondary amine.[9]

The reaction seems to be quite general, and works well with different alkyl groups at the dihydropyridine nitrogen (methyl and benzyl) and electron-withdrawing groups at the 3 position (methoxycarbonyl and cyano). Several cyclic secondary amines¶ were tested, including pyrrolidine, piperidine, morpholine and *N*-methylpiperazine, and the corresponding *trans* vicinal diamines were isolated in good yields. It should be noted that the diamination of olefins usually involves multistep sequences and/or the use of expensive organometallic reagents. The yields were slightly improved by adding solid Na_2CO_3 to the reaction mixture, but efforts to reduce the amount of iodine and/or secondary amine to stochiometric amounts resulted in decreased yields, even after longer reaction times.



Scheme 1



Scheme 2

This remarkable process is also suitable for the formation of cyclic adducts. Thus, when **1a** was allowed to react with iodine in the presence of *N*,*N*′-dimethylethylenediamine, the bicyclic adduct **3** was obtained (80% yield) as a slightly unstable oil, probably as a mixture of two isomers. Column chromatography (SiO_2, elution with CH_2Cl_2–EtOAc) allowed the purification of the major component. The stereochemistry of the ring fusion in

Table 1 Vicinal diamination reactions from dihydropyridines **1**

4

the major isomer was determined to be *cis*,‖ as the coupling constant between the ring fusion hydrogens is small (J < 1 Hz; a *trans*-decalin type fusion would result in a much larger coupling constant). This was confirmed by NOE and NOESY experiments. The difference with respect to the previous acyclic systems (where only *trans* products **2** were obtained) may reflect the fact that, in the present case, the intramolecular nucleophilic attack in the initially formed *trans*-2-amino-3-iodotetrahydropyridine takes place faster from the remaining secondary amino group to form the more stable 6-membered ring. Alternatively, an aziridinium intermediate could undergo ring-opening to give a 3-amino-3,4-dihydropyridinium cation, which could be intramolecularly trapped by the remaining secondary amino group.

The use of this methodology with enol ethers was tested next, and when 3,4-dihydro-2*H*-pyran was treated with iodine and pyrrolidine, an unstable compound was obtained (presumably the corresponding 2,3-diaminotetrahydropyran), which decomposed during column chromatography to furnish the hemiacetal **4**** (27%, non-optimized yield) as an anomeric mixture.[10] It is worth mentioning that cyclohexene failed to yield significant amounts of the corresponding addition product[11] on treatment with iodine and pyrrolidine under the usual reaction conditions, thus suggesting that only electron-rich olefins are good substrates for this kind of oxidative additions.

In summary, we have described a new 'non-biomimetic' oxidation of 1,4-dihydropyridines that allows the vicinal diamination of these substrates in an efficient and stereocontrolled manner.

This work was supported by the DGICYT, Spain (project PB94-0214). Thanks are also due to the Comissionat per Universitats i Recerca (Generalitat de Catalunya) for Grant SGR97-00018. O. C. and R. K. thank the 'Ministerio de Educación y Cultura', Spain, for fellowships.

Notes and references

† All new compounds were characterized by ^{1}H and ^{13}C NMR, IR, UV, MS and HRMS or elemental analysis.

‡ *General procedure* for oxidative diamination reactions. A solution of iodine (3.5 mmol) in THF (50 ml) was added dropwise under N_2 atmosphere to a stirred suspension of dihydropyridine **1** (1 mmol), secondary amine (25 mmol), and Na_2CO_3 (95 mmol) in THF (50 ml) kept at 0 °C, and stirring was continued at room temperature until no dihydropyridine is detected by TLC (usually 1–3 h). Water (150 ml) was added, and the mixture was extracted with EtOAc (3 × 75 ml). The combined organic extracts were washed with aq. $Na_2S_2O_3$ solution (100 ml, 0.5 M) and brine (100 ml), and dried (Na_2SO_4). The solvent was removed under reduced pressure, and the residue was purified by column chromatography (SiO_2, elution with CH_2Cl_2–EtOAc) to yield pure 2,3-diaminotetrahydropyridines.

Methylation of zinc bound thiolates; a model for cobalamine independent methionine synthase

Udo Brand, Michael Rombach and Heinrich Vahrenkamp*

Institut für Anorganische und Analytische Chemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany. E-mail: vahrenka@uni-freiburg.de

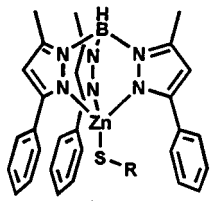
Received (in Basel, Switzerland) 21st September 1998, Accepted 10th November 1998

Pyrazolylborate–zinc–thiolate complexes react under mild conditions with methyl iodide, dimethylsulfate and trimethylsulfonium iodide, liberating the corresponding methyl thioethers; the driving force for these reactions lies in the high nucleophilicity of the zinc-bound thiolates and the low donor quality of thioethers toward zinc.

Methylation of thiols is an essential biological process,[1] being required *inter alia* for the biosynthesis of methionine or during DNA repair by the Ada protein. It is becoming evident that zinc plays an important rôle in this process,[2] being involved catalytically in Ada,[3] cobalamine independent methionine synthase,[4] or methanol–CoM–methyltransferase.[5] A common source of the methyl group is methyltetrahydrofolate, in the form of a methylammonium cation. Frequently methylcobalamine is the methyl group transfer agent, but in the world of plants which lacks vitamin B_{12} the methylating enzyme catalyzes the direct alkyl transfer from the methyl source to the thiol.

Model studies involving zinc complexes were published by Walker and Lippard[6] [reactions of $Zn(SPh)_4^{2-}$, $LZn(SPh)_3^-$ or $L_2Zn(SPh)_2$ with trimethyl phosphate] and by Darensbourg and coworkers[7] [reactions of a solvated tetradentate-N_2S_2 zinc complex with iodomethane and dibromopropane]. In the former case it was concluded that the thiolate dissociates from zinc prior to alkylation, and in the latter case the intermediate replacement of a thiolate ligand by a solvent molecule could not be ruled out. We now present evidence for the intramolecular alkylation of zinc bound thiolates and show how the ligand environment of zinc as well as the nature of the thiolates and the methylating agents affect the group transfer reactions.

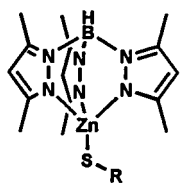
Based on the proposal[8] that in cobalamine independent methionine synthase the reacting thiol homocysteine is activated as a protein–zinc–thiolate in a neutral or monoanionic L_3Zn–SR complex, we chose again substituted pyrazolylborates Tp* to mimic the protein L_3 environment, thereby ensuring that the Tp*Zn thiolates are uncharged and that the zinc ion is encapsulated by the 3-substituents of the Tp* ligands. Complexes **1** and **2** were used as model compounds. Such complexes form spontaneously from the corresponding Tp*Zn–OH complexes (our 'enzyme models')[9] and thiols at neutral pH,[10] as verified here for **1a** and **1b**. **2a** and **2b**, whose corresponding $Tp^{Me,Me}Zn$–OH complex is unstable, were prepared from $Tp^{Me,Me}Zn$–Cl and the sodium thiolates.†



L^1Zn–SR

1a: R = Et

1b: R = CH_2Ph



L^2Zn–SR

2a: R = Et

2b: R = CH_2Ph

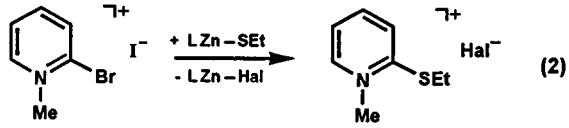
All four complexes **1** and **2** reacted with methyl iodide in a 1:1 ratio in chloroform at room temperature according to eqn. (1).‡ There can be no doubt that the methylations occur at

$$LZn-SR + MeX \longrightarrow LZn-X + MeSR \qquad (1)$$

the zinc bound thiolates, the main pieces of evidence being the non-polar reaction conditions and the fact that cationic Tp*Zn•L complexes can exist only in the presence of very good donor ligands and only in the absence of even weakly coordinating anions.[11] It was verified that the free thiols do not react with methyl iodide under the given reaction conditions. Furthermore, the intermediate existence of free thiolates was deemed unlikely by an exchange experiment: replacement of SEt^- in **1a** by SCH_2Ph^- to form **1b**‡ is about 20 times slower than methylation of SEt in **1a** under the same conditions. Preliminary kinetic data indicate that, as expected, the reactions are bimolecular. Surprisingly, the reactions of **1a** and **1b** are about ten times faster than those of **2a** and **2b**. This indicates that the higher hydrophobicity around zinc in complexes **1** due to encapsulation by the phenyl groups outweighs their lower accessibility due to steric hindrance by the same phenyl groups as a rate-determining factor. An important part of the driving force for these reactions must be ascribed to the poor donor quality of the resulting thioethers toward zinc. It is extremely unlikely that they would form the above-mentioned cationic Tp*Zn–L complexes, and we are actually not aware of any structurally characterized zinc complex with a monodentate thioether ligand.

Methylation reactions according to eqn. (1) were also achieved with dimethylsulfate in chloroform.‡ Although dimethylsulfate is known to be a stronger methylating agent than methyl iodide, it did not react faster here. This is further evidence for the intramolecular nature of these methylations: in a four-center Zn–S/C–X transition state of a bimolecular reaction there is more driving force to proceed *via* a soft–soft interaction (Zn–I) than *via* a soft–hard interaction (Zn–OSO_2OMe). In line with this the related Tp*Zn–OSO_2Me complexes[11] were found to be difficult to handle. $Tp^{Ph,Me}Zn$–OSO_2OMe has so far been characterized only in solution, and instead of $Tp^{Me,Me}Zn$–OSO_2OMe the complex $(Tp^{Me,Me})_2Zn$ was isolated, which is a known dismutation product of unstable $Tp^{Me,Me}Zn$–X complexes.[12]

In an attempt to apply more 'natural' methylating agents, complex **1a** was treated with trimethylsulfonium iodide as a model for the biological methyl donor *S*-adenosyl methionine[4] and with *N*-methylpyridinium iodide as a model for methyltetrahydrofolate. These reactions required higher temperatures and the more polar solvent acetonitrile for the ionic reagents. A clean methylation was achieved with trimethylsulfonium iodide, leaving $Tp^{Ph,Me}Zn$–I. The *N*-methylpyridinium reagent did not transfer a methyl group. When the more electrophilic reagent 2-bromo-*N*-methylpyridinium iodide was used its bromide substituent was replaced by the ethylthio group according to eqn. (2). Thus the zinc bound thiolate of **1a** is a strong enough nucleophile to attack halopyridinium systems. In



this case the remaining zinc species was a mixture of $Tp^{Ph,Me}Zn$–Br and $Tp^{Ph,Me}Zn$–I.‡

The methylation reactions reported here are the closest representations of their biological models yet, specifically of cobalamine independent methionine synthase. The precursors of the Tp*Zn thiolate complexes, the Tp*Zn hydroxide complexes which exist at neutral pH and which may represent the resting enzymes, incorporate the thiols spontaneously with liberation of H_2O, *i.e.* without pH effects. The thiolate complexes react with neutral and ionic methylation reagents in a sterically restricted situation reminiscent of that in the enzymes. An important factor driving the reactions must be the high nucleophilicity of the zinc bound thiolate groups, as we previously found for the zinc bound hydroxide in analogous Tp*Zn–OH complexes.[9,13] Coupled with the low donor strength of thioethers toward zinc, again analogous to the leaving tendency of H_2O from $[Tp^*Zn–OH_2]^+$, this makes the methylation reactions facile and rapid.

At this stage of the investigation we see two challenges. One concerns the choice of alkylating agents which should be closer relatives of methyltetrahydrofolate or *S*-adenosyl methionine. The other concerns the testing of a mechanistic implication of the intramolecular alkylations by methyl iodide. A four-center transition state Zn–O/E–O has been found likely for hydrolytic cleavages of $R_nE(O)$–X substrates by Tp*Zn–OH.[14] If an analogous Zn–S/C–I transition state is implied for the reactions between Tp*Zn–SR and CH_3–I, then this corresponds to front-side attack of the nucleophile at the C-I unit which means retention of configuration at carbon. A mechanistic investigation is indicated which should answer this question as well as that of possible ionic intermediates of the methylation reactions.

This work was supported by the Deutsche Forschungsgemeinschaft.

Notes and references

† The constitution of Tp*Zn–SR complexes has been established by structure determinations of $Tp^{tBu,Me}$Zn-SEt[9a] and $Tp^{Cum,Me}$Zn–SPh.[10c] The new species **1** and **2** were characterized by analyses, spectra and a structure determination of **2a**.

‡ On the millimolar scale the methylations by methyl iodide take 1–2 h for **1a**, **b** and about 1 day for **2a**, **b**. The quantitative nature of the methylation reactions and the identity of the resulting thioethers were ascertained by NMR. In those cases where Tp*Zn–Hal or Tp^*_2Zn complexes resulted these were isolated by crystallization and identified by comparing their spectra with data from the literature. The reaction between **1a** and an excess of $[N(PPh_3)_2][SCH_2Ph]$ leads to *ca*. 10% of **1b** after 3 days and takes weeks to reach equilibrium.

The electrochemistry of tetramesityldisilene, $Mes_2Si{=}SiMes_2$

Zeng-Rong Zhang,[a] James Y. Becker*[a] and Robert C. West[b]

[a] *Department of Chemistry, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel. E-mail: becker@bgumail.bgu.ac.il*

[b] *Department of Chemistry, University of Wisconsin, Madison, WI 53706, USA*

Received (in Cambridge, UK) 22nd October1998, Accepted 4th November 1998

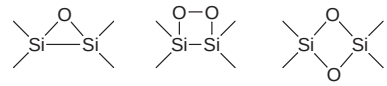
The outcome of the controlled potential oxidation and reduction of a disilene, tetramesityldisilene (TMDS), indicates that the main silicon containing products involve only one silicon atom and have the general structure $Mes_2SiX(Y)$, X and Y being H, OH or F.

A great deal of progress has been made in disilene chemistry since the isolation of the first stable disilene in 1981.[1] Advances in the chemistry of stable (and marginally stable) disilenes are described in a recent review,[2] and several other reviews covering Si=Si double bonds have been published.[3–6] The disilenes are far more reactive than their alkene counterparts. Even though the stable disilenes are sterically hindered, they are remarkably reactive toward many electrophilic and nucleophilic reagents, providing a complex and elaborate chemistry of the Si=Si double bond.[2–6]

Information in the literature on the electrochemical behavior of disilenes is very limited. To the best of our knowledge, the only published work related to cyclic voltammetry measurements.[7] All tetraaryl- and dialkyldiaryl-disilenes investigated exhibited one irreversible oxidation wave and one irreversible reduction wave. The oxidation potentials were similar (0.4–0.5 V *vs.* SCE), indicating that the highest occupied molecular orbital (HOMO) of each species lies at approximately the same energy level. However, their reduction potentials were found to be dependent on the substitution pattern, −2.0 to −2.2 V for tetraaryldisilenes and about −2.6 V (*vs.* SCE) for dialkyldiaryldisilenes. These results indicate that the lowest unoccupied molecular orbital (LUMO) of tetraaryldisilenes is lower in energy than the LUMO of dialkyldiaryldisilenes,

The present communication reports for the first time results of the controlled potential electrolysis of a disilene. Tetramesityldisilene, $Me_2Si{=}SiMes_2$ (TMDS) was studied by both anodic oxidation and cathodic reduction. The products obtained upon electrochemical oxidation of TMDS in MeCN using Bu_4NPF_6 as the supporting electrolyte are shown in Fig. 1. Interestingly, all of the detected products contain only one silicon atom. It seems that the anodic process invovles the cleavage of both the π and σ bonds. This behavior is remarkably different from what has been observed by chemical oxidation.

For example, reactions of disilenes with the single-oxygen transfer agents N_2O or azoxybenzene[8] give three-membered rings of type **I**. Disilenes react with oxygen[8,9] of the air to give compounds **I** and/or 1,2-disiladioxetanes **II**; the latter undergo rearrangement to cyclodisiloxanes **III** in a subsequent step.[10]



I **II** **III**

Upon comparing the results described in Table 1, column A (in THF) with those in column B (in MeCN), in both cases, the same six products were formed (**1**–**6**), but the ratio of products which contain fluorine atoms (**1**–**3**) to those without fluorine atoms (**4**–**6**) is higher in MeCN. When the electrolyte was changed from Bu_4NPF_6–MeCN (column B) to Et_4NBF_4–MeCN (column C), only five products were obtained (**1**–**5**), the fluorinated ones becoming even more predominant. In Bu_4NClO_4–MeCN solution (column D), the reaction became more selective to yield three products only, **4**–**6**. Upon changing the Pt anode material (column C) to glassy carbon (column E), leavng all other conditions the same, the reaction became somewhat less selective and yielded more non-fluorinated products at the expense of the fluorinated ones. Evidently, the preferred products in THF or in the presence of ClO_4^- are **5** and **6**, whereas **3** is favored in the presence of BF_4^-. The above results indicate that solvent, electrolyte and anode material all play a role in the product outcome upon electrochemical oxidation of tetramesityldisilene.

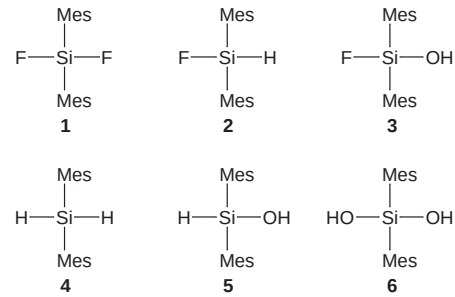


Fig. 1 Molecular structures of products obtained by anodic oxidation of TMDS.

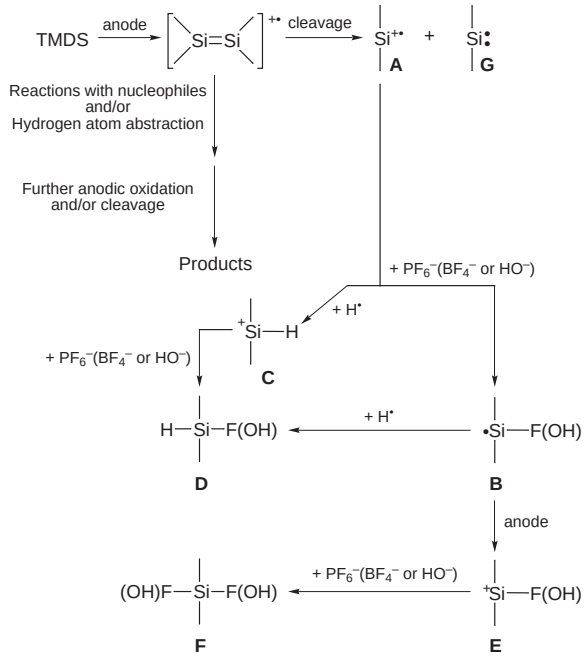

Scheme 1 Mechanism for the electrochemical oxidation of TMDS.

A plausible mechanism which accounts for the formation of all products in the electrochemical oxidation process is outlined in the over simplified Scheme 1. The initially formed unstable radical cation from TMDS is a highly reactive species and could undergo a number of different reactions, *i.e.* reactions with nucleophiles, abstraction of hydrogen atoms, cleavage, *etc*. For example, the direct cleavage may lead to a radical cation **A** and silylene **G**. The radical cation **A** may undergo an attack by PF_6^- (BF_4^- or HO^-) anion to form the radical **B**, or abstract a hydrogen atom (from solvent or electrolyte) to generate a silylenium cation **C**, followed by a chemical reaction with a nucleophile to yield **D** (products **2** and **5**). Intermediate **B** could undergo further anodic oxidation to the cation **E**, or abstract a hydrogen atom from its surroundings to generate **D**. Cation **E** may react with PF_6^- (BF_4^- or HO^-) anion to form **F** (products **1**, **3** and **6**). It is noteworthy that the formation of some of the products outlined in Fig. 1, as well as **4**, could also originate from silylene **G**.

Results of the controlled potential electrochemical reduction[12] of TMDS in both THF and acetonitrile are shown in Scheme 2. A major product found was mesitylene. As in the anodic process, the silicon products (except for compound **8**) contain only one silicon atom, probably due to fragmentation of the initial electrochemically generated anion radical. The same four products (**1**, **2**, **7** and **8**) were obtained both in THF and MeCN. However, an additional product, **4**, was detected in THF.

Surprisingly, some of the products (**1**, **2** and **4**) observed by the electrochemical reduction process are identical to those obtained by the anodic oxidation. Therefore, it is reasonable to suggest that these products could stem from the same intermediate, which might be generated in both types of reactions. Attempts to trap such intermediate and characterize its nature are underway,

The electrochemical reduction of TMDS in MeCN–Bu_4NClO_4 (0.1 mol l^{-1}) solution was also attempted. The GLC chromatogram indicated the formation of a very complex mixture of products (> 20 peaks!), which has yet to be analysed, among which Mes_2SiH_2 and $Mes_2Si(H)(OH)$ could be detected.

	A: 0.1 mol l^{-1} Bu_4NPF_6–THF	**B**: 0.1 mol l^{-1} Bu_4NPF_6–MeCN
1	9%	31%
2	18%	25%
4	20%	—

11 All experiments were carried out in a drybox ([H_2O] < 1 ppm; [O_2] < 1 ppm), employing controlled potential electrolysis (on Pt) in an 'H' type two-compartment cell and pulsing from 0 to 0.5 V (*vs.* Ag wire) every 0.5 s. Typically, the working compartment contained 0.1–0.2 mmol of disilene dissolved in 25 ml solution. Electricity consumption is *ca.* 1 F mol^{-1}. Solvents MeCN and THF were distilled over P_2O_5 and benzophenone/Na, respectively. All electrolytes were dried under vacuum (*ca.* 30 mmHg) at 105 °C for 48 h. HRMS results for MH^+: Found (calc. for M). **1**: 305.1547 (305.1547 for $C_{18}H_{23}F_2Si$); **2**: 287.1620 (287.1640 for $C_{18}H_{24}FSi$); **3**: 303.1590 (303.1595 for $C_{18}H_{24}FOSi$); **4**: 269.1733 (269.1745 for $C_{18}H_{25}Si$); **5**: 285.1500 (285.1694 for $C_{18}H_{25}OSi$); **6**: 301.1420 (301.1643 for $C_{18}H_{25}O_2Si$); **7**: 120.0910 (120.0948 for C_9H_{12}); **8**: 470.2155 (470.2120 for $C_{27}H_{33}F_3Si_2$).
12 The chemical reduction of sterically congested disilenes by alkali metals has not been studied. Formation of disilene anion radicals is reported to result from reductions of the corresponding dichlorodisilenes by alkali metals,[13] but to the best of our knowledge there is no report on the nature of products obtained by reaction/decomposition of this type of anion radical.

Received (in Cambridge, UK) 16th September 1998, Accepted 29th October 1998

Spectroscopic studies of the reaction of $[Os_3(CO)_{11}MeCN)]$ with *para*-thiocresol to form $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}SC_6H_4Me\text{-}p)]$ indicate that the reaction proceeds *via* a two-step consecutive process involving the intermediate $[Os_3(CO)_{11}(MeC_6H_4SH\text{-}p)]$, in which there is an agostic Os–H–S interaction.

Hydrodesulfurization (HDS) processes are used to remove sulfur from organosulfur compounds in fossil fuels.[1] These catalytic processes are subject to intensive investigation because of the widespread use of HDS and its economic and environmental importance. Although structures of the active components of HDS catalysts have been proposed,[1] the exact nature of the interaction between sulfur-containing hydrocarbons and the catalyst(s), and the mechanism of the catalytic reaction(s), have not been elucidated.

Friend *et al*.[2] have studied the adsorption and desulfurization of thiols on Mo(110) surfaces. The cleavage of the sulfur–hydrogen bond to form a metal-bound thiolate has been found to be rapid whereas the cleavage of the carbon–sulfur bond appears to be the rate-limiting step. Several metal complexes containing sulfur ligands have been synthesized as both structural and functional models for HDS processes.[3] We are currently studying whether it is possible to monitor the initial coordination of thiols to polynuclear metal complexes and to relate these phenomena to HDS processes.[4] Here we wish to describe how the reaction between $[Os_3(CO)_{11}(MeCN)]$ **1** and *para*-thiocresol proceeds *via* the intermediate $[Os_3(CO)_{11}(MeC_6H_4SH\text{-}p)]$ **2** to form the final product $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}SC_6H_4Me\text{-}p)]$ **3**. The intermediate (**2**) is proposed to contain an agostic Os–H–S interaction; to our knowledge, this is the first example of an agostic interaction involving a thiol hydrogen.

Two resonances could be detected at high field when the reaction of stoichiometric equivalents of **1** and *para*-thiocresol was monitored by ^{1}H NMR at ambient temperature. Fig. 1(a) shows the variation of the intensities of the two signals with time. There is a relatively rapid build-up of the resonance at δ −4.81 followed by a slower decay of the intensity of this signal, while there is a gradual build-up of the signal at higher field. This implies that the resonance at lower field is due to an intermediate which is gradually converted to the final product with a resonance at δ −17.00. The high-field resonance may be ascribed to the bridging hydride of the final product **3**† by comparison to previously known $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}SR)]$ clusters.[4,5] The shift of the second resonance occurs at lower field than may be expected for a hydride coordinated to a triosmium cluster;[6] the signal is assigned to the thiol hydrogen and it is suggested that the shift arises from an agostic interaction of this hydrogen with one of the osmium atoms. The T_1 relaxation times for the two signals are similar, although not identical, being 2.08 s for the intermediate **2** and 4.37 s for the final species **3**. Greater discrepancies in relaxation times for the two signals have been observed for the same type of reaction involving other thiols.[7]

It was possible to slow down the above reaction so that the intermediate was the predominant species by mixing the reactants and rapidly cooling the solution to −60 °C; at this temperature, **2** was found to be stable for several hours. A ^{13}C NMR spectrum‡ of a carbon-13 enriched sample of **2** at −60 °C showed that the intermediate possesses eleven carbonyls, consistent with the proposed formula $[Os_3(CO)_{11}(MeC_6H_4SH\text{-}p)]$. On the basis of the ^{13}C–^{13}C and ^{13}C–^{1}H coupling pattern, several ^{13}CO resonances have been assigned. Moreover, a 2D-EXSY experiment showed that all CO ligands (except one at δ 171.54) exchange pair-wise, suggesting the possible occurrence

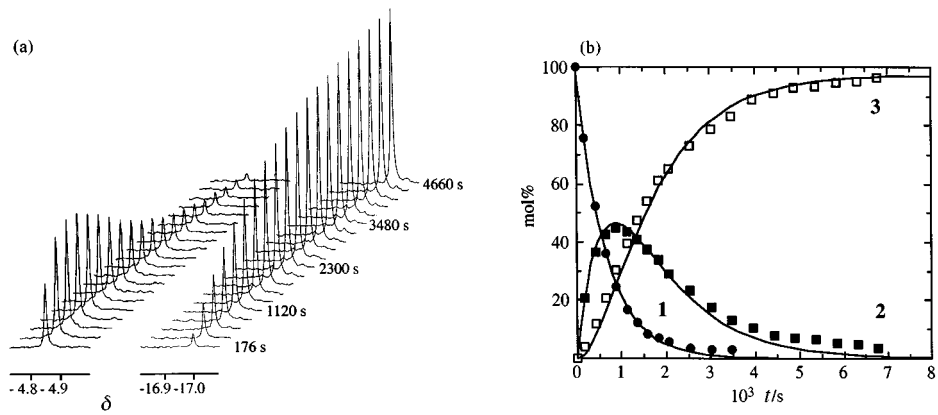

Fig. 1(a) ^{1}H NMR signal variations *vs.* time for compounds **2** and **3** in the reaction of **1** with RSH (t_s = 236 s; RSH = *para*-thiocreosol; [**1**] = 0.012 M; [RSH] = 0.053 M; [MeCN] = 0.054 M; solvent = $CDCl_3$; T = 295.2 K). (b) Time dependence of the concentrations of the species **1**–**3**.

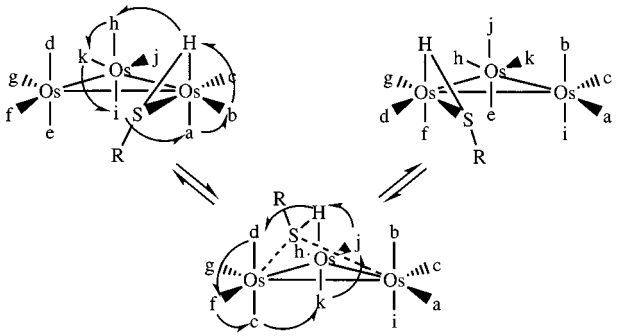


Scheme 1 Proposed fluxional mechanism for ligand exchange in the intermediate $[Os_3(CO)_{11}(MeC_6H_4SH\text{-}p)]$ **2**. This mechanism is in agreement with the following pairwise exchange for all carbonyls except k, which stays in the same magnetic environment: a ↔ f, b ↔ d, c ↔ g, e ↔ i, h ↔ j.

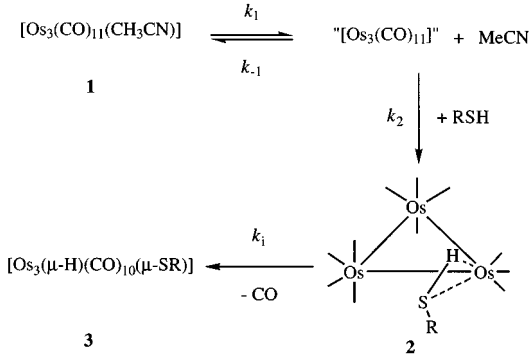
of a sliding motion of the thiol moiety on the surface of the cluster accompanied by two successive, one-step-only, merry-go-round processes as depicted in Scheme 1. This exchange process is reminiscent of that observed in the enantiomerization of $[Os_3H(\mu\text{-}H)(CO)_{11}]$.[6] Further (indirect) evidence for an agostic Os–H–S interaction could be derived from the reaction of **1** with PhSeH which proceeds *via* an intermediate with a characteristic ^{1}H NMR resonance at δ −5.4. This resonance contains satellites due to ^{1}H–^{77}Se coupling and the value of the coupling constant is unusually low ($^1J_{SeH}$ = 38.1 Hz), which is consistent with elongation of the Se–H bond.

The kinetics of the reaction of **1** with *para*-thiocresol were measured by UV–VIS, IR and NMR spectroscopy. Two consecutive reactions were observed in dichloromethane at 298.2 K. Analysis of the changes of the IR and ^{1}H NMR spectra during the course of the reaction showed that the processes under study involve fast thiol addition to **1** and subsequent slow cleavage of the S–H bond with concomitant dissociation of a carbonyl ligand to yield the final product [eqn. (1)].

$$\mathbf{1} + \mathrm{RSH} \xrightarrow[-\mathrm{MeCN}]{k_{obs1}} \underset{\mathbf{2}}{[Os_3(CO)_{11}(RSH)]} \xrightarrow[-\mathrm{CO}]{k_{obs2}} \mathbf{3} \quad (1)$$

The first step could be observed by rapid-mixing UV–VIS spectroscopy in the range 300–480 nm and the kinetics of the two steps were studied spectrophotometrically at different ligand concentrations under pseudo-first-order conditions. The observed rate constants, k_{obs1} = (1.52 ± 0.1) × 10^{-2} s^{-1} and k_{obs2} = (1.09 ± 0.08) × 10^{-3} s^{-1}, were found to be independent of ligand concentration. On the other hand, studies carried out in the presence of different concentrations of free acetonitrile indicated consecutive processes. Immediately after mixing the reactants, the ^{1}H NMR spectra showed the presence of resonances belonging to the starting cluster **1**, the intermediate **2** and the final product **3**. The concentrations of the three species were evaluated from the integrals of the signals at δ 2.72 for C*H*$_3$CN in **1** and of the agostic hydrogen (**2**) and hydride (**3**) resonances [*cf.* Fig 1(a)]. The time dependence of the concentrations for the three species is shown in Fig. 1(b).

The dissociative natures of the transition states for both steps are confirmed by the fact that (i) both rate constants are independent of ligand concentration, (ii) the activation parameters§ obtained from the temperature dependence of k_{obs1} and k_{obs2} [*cf.* eqn. (1)] are consistent with a dissociative process, and (iii) in the first step, the displacement of the acetonitrile by the sulfur donor ligands is retarded by the addition of the free leaving group; a plot of the rate constants for the *para*-thiocreosol at different acetonitrile concentrations shows saturation, with a curvilinear dependence on the concentration of the entering thiol. Scheme 2 shows the overall mechanism proposed for these reactions. The first step is a reversible dissociation of acetonitrile from **1**, to give a labile and coordinatively unsatured intermediate, '$[Os_3(CO)_{11}]$', which



Scheme 2 Proposed mechanism for the formation of $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}SC_6H_4Me\text{-}p)]$ **3** *via* the intermediate $[Os_3(CO)_{11}(MeC_6H_4SH\text{-}p)]$ **2**.

undergoes either acetonitrile addition to form the starting cluster or thiol addition to form the intermediate $[Os_3(CO)_{11}(RSH)]$ **2**. The latter loses carbon monoxide to form the final compound $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}SC_6H_4Me\text{-}p)]$ **3**.¶ The mechanism depicted in Scheme 2 appears to be general. Thus far, similar kinetics and the same type of intermediate have been detected for all thiols that we have reacted with $[Os_3(CO)_{11}(NCMe)]$, including ethanethiol, *ortho*- and *meta*-thiocresol, 2-naphthalenethiol and *tert*-butylthiol.[7]

This research has been supported by grants from the Swedish Natural Science Research Council (to L. I. E. and E. N.), the Consiglio Nazionale delle Ricerche (to M. M and S. A.), the European Union (TMR Network Metal Clusters in Catalysis and Organic Synthesis - MECATSYN, to E. N and S. A.; a postdoctoral Human Capital and Mobility (HCM) fellowship to M. R. P.) and the Metal Cluster network of the European Science Foundation (travel grant to F. P.). We are indebted to Dr Jason King for assistance with the NMR measurements.

$CsFeSiO_4$: a maximum iron content zeotype

Paul F. Henry and Mark T. Weller*

Chemistry Department, University of Southampton, Highfield, Southampton, UK SO17 1BJ. Tel and Fax No. 00 44 1703 593592. E-mail: mtw@soton.ac.uk

Received (in Bath, UK) 21st September 1998, Accepted 9th November 1998

The alkali-metal iron silicate, $CsFeSiO_4$, has been synthesised, using a gel decomposition method followed by high temperature annealing, and shown to adopt the zeolite ABW structure constructed from alternating FeO_4 and SiO_4 tetrahedra surrounding caesium.

Substitution of iron into zeolitic frameworks using hydrothermal methods has been investigated by several groups[1–5] but with limited success due to the difficulty of attaining purely tetrahedral Fe(III) in an aqueous environment. Levels of tetrahedral iron that can be incorporated into the framework, replacing aluminium, are generally restricted to a few percent and octahedral iron species often block the zeolite pores. The main motivation behind substitution of transition metal centres (particularly Fe, Co, Mn and Cr) into frameworks lies in the attempt to build selective redox catalysts by utilising the channels inherent within zeolite structures. A secondary idea is the possibility of producing new pigments by incorporating coloured species into frameworks rather than intercalating coloured species into the channels within frameworks.[6–9]

Some complex tetrahedra based iron silcate materials have been previously reported in the literature: $KFeSiO_4$ exists in three forms,[10] α-$KFeSiO_4$ is orthorhombic but of unknown structure, β-$KFeSiO_4$ adopts the stuffed tridymite structure and γ-$KFeSiO_4$ has the kaliophilite structure. Studies into the K_2O-Fe_2O_3-SiO_2 phase field[11,12] have also shown the existence of iron leucite, $KFeSi_2O_6$, and iron feldspar, $KFeSi_3O_8$, which show analogous polymorphism with their corresponding aluminium compounds.

A polycrystalline sample of $CsFeSiO_4$ was prepared as follows. Stoichiometric quantities of LUDOX (40% by weight SiO_2 in water, Aldrich) and $Fe(NO_3)_3{\cdot}9H_2O$ (99.9%, Aldrich) were dissolved in 50 ml of 2M HNO_3. A 1.5-fold excess of $CsCO_3$ (99.9%, BDH) was then added to the solution; excess was added to compensate for the high volatility of caesium salts at the intermediate temperatures used in the experimental procedure. 100 ml ethanol was added under constant stirring followed by 10 ml of .880 ammonia solution, added dropwise. A brown spongy material was seen to precipitate from the solution as the ammonia was added, which partially redissolved on addition of further ammonia solution. The mixture was heated to dryness over a period of 12 h. The resultant solid was then partially decomposed in an alumina crucible at a temperature of 250 °C for a further 12 h. The brown powder obtained was thoroughly ground and heated for a further 16 h at 600 °C, then 850 °C and finally 1000 °C. After each heat treatment a powder X-ray diffraction (PXD) pattern was collected, using a D5000 Siemens diffractometer (Cu-Kα_1 radiation) operating in reflection geometry. The annealing at 1000 °C was repeated until there was no observable change in the powder diffraction pattern. The final product was found to be mustard yellow in colour. Data, for Rietveld analysis using the GSAS suite of programs,[13] were obtained over 16 h for the 2θ range 10–110° using a step size of 0.02°.

The initial PXD pattern collected from $CsFeSiO_4$ after annealing at 600 °C was found to contain no discernible Bragg reflections. The PXD pattern collected after annealing at 850 °C showed a new phase to be present, although the diffraction pattern was very weak. Repeated annealing at 1000 °C gave a crystalline material with sharp Bragg reflections, which were indexed on an orthorhombic unit cell using the PC program TREOR90.[14] Comparison of the PXD pattern with that simulated for a material adopting the zeolite ABW structure with the calculated lattice parameters gave very good agreement. No evidence of leucite or feldspar type impurities were found in the pattern.

Full Rietveld analysis was then performed using the structure of the known ABW material $LiAlSiO_4$[15] as the starting model but with iron on the aluminium position and caesium replacing lithium. In this model the silicon and aluminium positions are distinct, *i.e.* the framework is ordered with alternating tetrahedral ions in accordance with Loewenstein's rule.[16] The framework was refined, subject to some hard and soft constraints; these constraints are necessary due to the in-

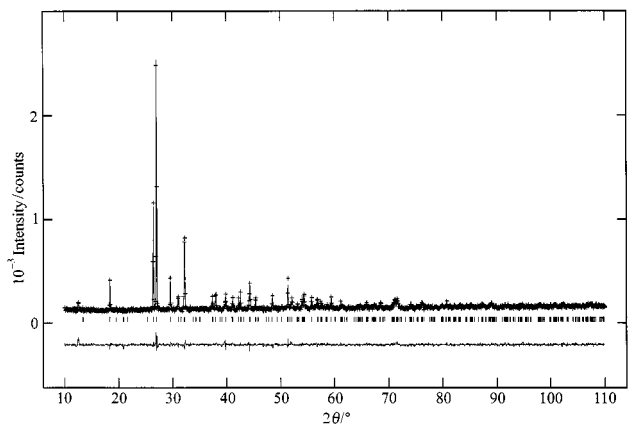

Fig. 1 Final Rietveld refinement profile of $CsFeSiO_4$. The observed data are crosses, the calculated pattern a solid line, the tick marks show the allowed reflections and the lower line is the difference plot; R_{wp} = 6.85%, R_p = 5.24%, R_e = 5.63% and $R_{F^{**}2}$ = 13.52% for 355 observations.

sensitivity of the technique for a caesium containing material. The thermal factors of the oxygen sites were constrained to be identical, as were those of the silicon and iron sites. The Si–O and Fe–O bond lengths were refined with a soft constraint (standard deviation of 0.005 Å) at 1.625 and 1.825 Å respectively. The refinement converged smoothly to give the excellent final profile fit illustrated in Fig. 1. Atomic data and cell data are given in Tables 1 and 2. Refinement was also attempted using the disordered framework ABW model of $CsAlTiO_4$[17] in the space group *Imma* but this gave much poorer profile fit parameters and was discarded. The refined structure is constructed of alternating SiO_4 and FeO_4 vertex linked tetrahedra with the alkali-metal cation occupying the large 8-ring cavities parallel to the crystallographic *b*-axis. Channels also exist along the *a*-direction (4-rings) and *c*-direction (6-rings) as illustrated in Fig. 2.

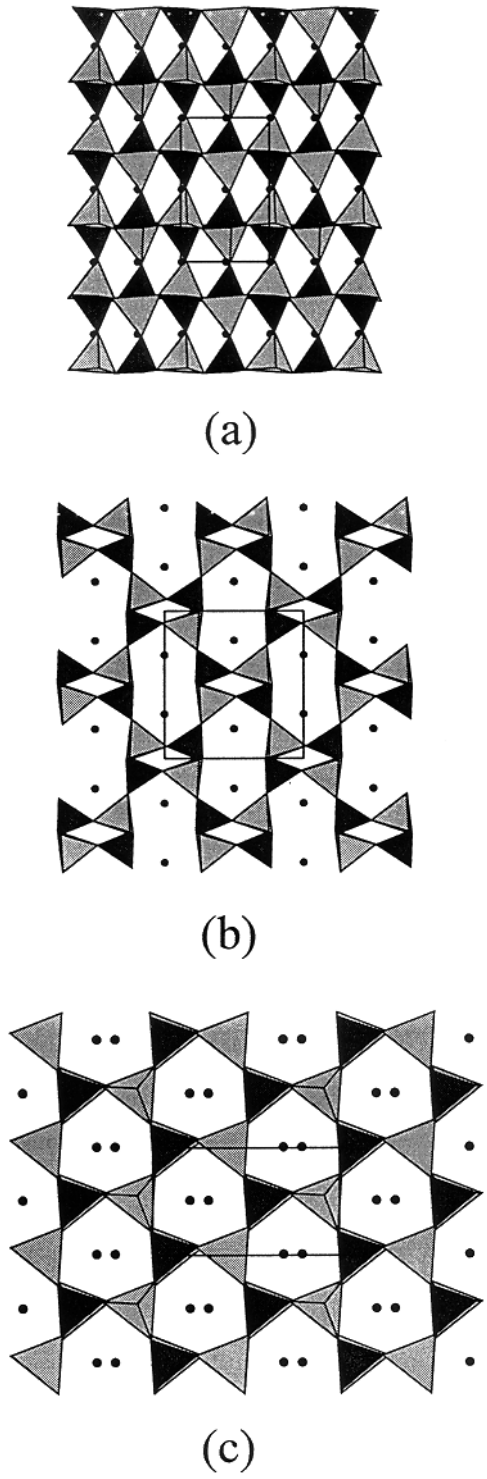

Fig. 2 Representations of the structure of $CsFeSiO_4$ along (a) [100], (b) [010] and (c) [001] illustrating the channels. Dark tetrahedra represent SiO_4, light tetrahedra represent FeO_4 and the black spheres are caesium.

The stability of the product material to moisture was studied by stirring in deionised water for 3 days at 45 °C. Residual water content was measured by thermogravimetric analysis (TGA) using an STA1500 TGA/DSC. Elemental analysis was carried out using a JEOL JSM-6400 SEM equipped with a TRACOR series II energy dispersive X-ray analysis system. TGA showed the as-made material to contain no residual water. Attempts were made to hydrate the material by exposure to water vapour for 3 days but subsequent TGA measurements showed no weight loss up to 1000 °C indicating no water uptake. The material was also found to be air and moisture stable. EDAX on $CsFeSiO_4$ showed the ratio of Cs : Fe : Si to be approximately 1 : 1 : 1 in accordance with that expected for an ABW product stoichiometry.

Further, $AFeTiO_4$ (A = Cs, Rb) have been synthesised using the same experimental technique as dark brown powders. Rietveld analysis on $CsFeTiO_4$ using powder X-ray data show this material also adopts the zeolite ABW structure and TGA reveals no residual water within the structure. Attempts to synthesise the germanium analogues have met with limited success. Further structural characterisation of materials using powder neutron diffraction data is planned to investigate the framework ordering in detail.

$CsSiFeO_4$, with a structure based on alternating FeO_4^{5-} and SiO_4^{4-} tetrahedra, is the first framework material having the maximum level of iron in a zeotype. The ability to incorporate such high levels of iron is a result of templating at high temperatures using caesium rather than in aqueous solution where six coordinate iron is unavoidable and influences the nature of the zeolite product.

The financial support of EPSRC is gratefully acknowledged.

Plasmacatalytic low-temperature conversion of NO_x to N_2 by ammonium-loaded zeolites in a dielectric barrier discharge

H. Miessner,*[a] R. Rudolph[a] and K.-P. Francke[b]

[a] Institut für Umwelttechnologien GmbH and [b] Gesellschaft zur Förderung der naturwissenschaftlich-technischen Forschung e.V., Rudower Chaussee 5, D-12489 Berlin, Germany. E-mail: info@iut-berlin.com

Received (in Cambridge, UK) 28th September 1998, Accepted 13th November 1998

The direct application of a silent electrical discharge on an ammonium-loaded zeolite as catalyst to remove NO in excess oxygen results in a synergetic improvement of NO_x abatement at temperatures below 373 K.

The selective catalytic reduction (SCR) of NO using the addition of reductants like NH_3, urea, hydrocarbons, alcohols, *etc*. has been studied intensively as a potential method to remove NO_x from exhaust gases with excess oxygen.[1] Depending on the type of catalysts and the reductant used, SCR is effective in a temperature range between 450 and 900 K.

In a recent publication, Richter *et al*.[2,3] have described a catalytic low-temperature conversion of NO_x to N_2 using NH_4^+ ions fixed in zeolites as reductant. NO is converted in these systems to N_2 in excess oxygen even at temperatures as low as 373 K. The intermediate oxidation of NO to NO_2 is believed to be the key step limiting the reaction rate of the reaction sequence. As we will show here, the abatement of NO in oxygen excess can be significantly enhanced further by applying a silent electrical discharge immediately on the ammonium-loaded zeolite as catalysts.

For the experiments a reactor was used that enables a dielectric barrier discharge (DBD) directly on the catalyst bed. A glass tube as dielectric is surrounded by a copper grid as ground electrode and contains an inner electrode, which consists of a rod with equidistant steel discs leaving a gap to the glass tube of 0.5 mm. Between these discs the catalyst can be positioned. As catalyst, a mordenite with a Si : Al ratio of 11 was used in the ammonium form. The mordenite has been shown to be effective in the low temperature conversion of NO_x, but also other zeolites (*e.g.* Y, ZSM-5) could be used.[2,3] The electric discharge was initiated by a high-voltage pulse generator with 20 kV peak voltage, 20 μs rise time and a repetition rate up to 115 Hz. The gas composition (NO, NO_2, N_2O, HNO_x) was determined by an FTIR spectrometer equipped with a long-path (20 m) gas cell (Perkin Elmer) and a NO_x-analyser (ECO-Physics). The energy deposited into the discharge was determined by integrating the voltage–charge traces monitored with a digitising oscilloscope (Tektronics TDS 520 C).

Fig. 1 shows the dependence of the conversion of 500 ppm NO in N_2–O_2 (5 vol%) on the applied energy both with and without the catalyst. Without the NH_4-mordenite, NO is partly removed by reactions with the active species from the electric discharge, but at the same time NO_2 is formed and the overall NO_x concentration remains nearly constant. Using the catalyst alone, part of the NO is removed already without an electric discharge. This is due to the reaction described by Richter *et al*.[3] and also by adsorption phenomena at 343 K. At 373 K *ca.* 400 ppm and at 423 K 450 ppm NO remain in the gas phase without electric discharge. Applying additionally the DBD, a complete conversion of NO without the formation of a significant amount of NO_2 was observed. For comparison it should be noted that the energy input of 20 W h m^{-3} is equivalent to an adiabatic temperature increase of *ca.* 70 K.

The conversion of NO to N_2 strongly depends on the oxygen concentration in the gas. Fig. 2 shows this dependence again with and without NH_4-mordenite as catalyst. Whereas the conversion without catalyst declines with increasing oxygen concentration (the NO is converted to NO_2 *vide supra*), the behaviour in the presence of NH_4-mordenite is just the opposite: The conversion strongly increases with the oxygen content. This is in line with the proposal[3] of the intermediate oxidation of NO to NO_2 as the rate limiting step in the reaction mechanism. The electric discharge obviously promotes this intermediate NO-oxidation, resulting in an enhanced overall reaction rate.

To analyse the influence of the electric discharge in more detail, the local position of the catalyst was varied in order to have the discharge in front of, behind and directly on the catalyst bed. Fig. 3 shows the effect of these combinations on

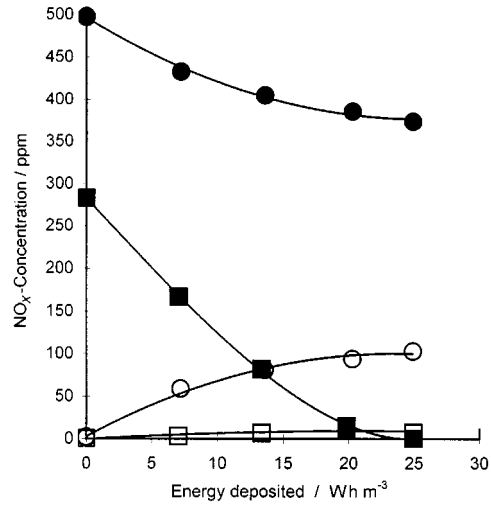

Fig. 1 NO_x concentration after conversion of 500 ppm NO in N_2–O_2 (5 vol%) with (■ : NO, □ : NO_2) and without (● : NO, ○ : NO_2) NH_4-mordenite as catalyst at 343 K and GSHV = 3000 h^{-1}.

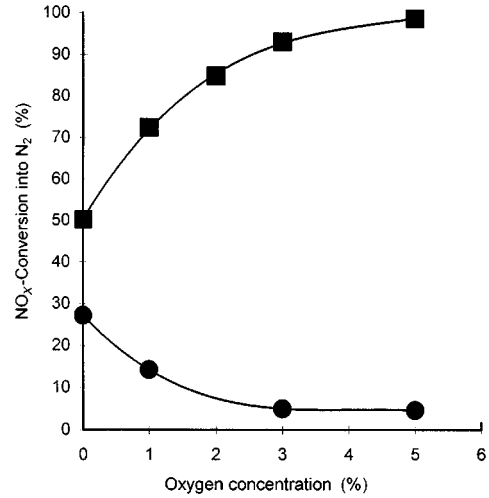

Fig. 2 Conversion of 500 ppm NO into N_2 at DBD (25 W h m^{-3}) without (●) and with (■) NH_4-mordenite as catalyst at 343 K and GSHV = 3000 h^{-1}.

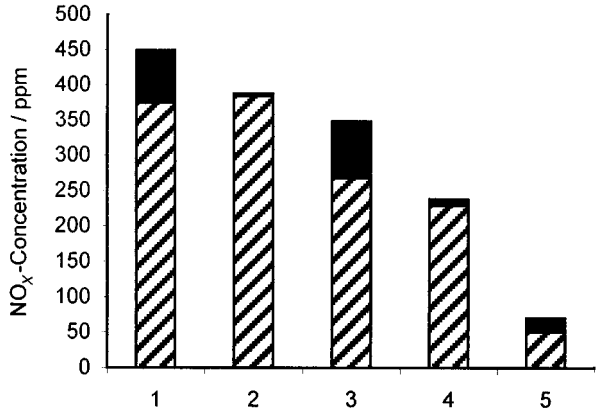

Fig. 3 NO_x concentration after conversion of 500 ppm NO in N_2–O_2 (2 vol%): DBD, without catalyst (1); with NH_4-mordenite, no DBD (2); DBD behind the catalyst (3); DBD in front of the catalyst (4); DBD over the catalyst (*in situ*) (5). Conditions at the catalyst: 343 K, GSHV = 3000 h^{-1}, DBD: *ca*. 25 W h m^{-3}, NO: hatched, NO_2: black.

the NO_x concentration. The application of the DBD behind the catalyst (column 3) converts a part of the remaining NO to NO_2 as should be expected (*cf*. column 2). If the DBD is applied in front of the catalyst, the NO_2 formed in the electric discharge (*cf*. column 1) is converted by the catalyst to nitrogen (column 4). Finally, the *in situ* application of the discharge directly on the catalyst bed results in a synergetic increase of the NO conversion to a degree much higher than the sum of the individual effects (column 5).

This synergy can be explained by the interaction of discharge-induced plasmachemical reactions with the catalysis on the zeolite. A silent electrical discharge in an oxygen-containing gas mixture produces mainly oxygen radicals as active species.[4] Atomic oxygen leads to fast oxidation by the three body reaction (1). In case of the discharge alone without any catalyst, NO removal is limited because of back-reaction (2) and only a part of NO can be converted to NO_2 (Fig. 3, columns 1 and 3). In the presence of NH_4-zeolite, however, NO_2 is removed from the gas stream by the fast catalytic reaction (3),[3] thus preventing the undesirable back conversion (2) of NO_2 to NO.

$$NO + O + M \rightarrow NO_2 + M \quad (1)$$

$$NO_2 + O \rightarrow NO + O_2 \quad (2)$$

$$NO + NO_2 + 2\ NH_3 \rightarrow 2N_2 + 3H_2O \quad (3)$$

The ammonia bonded to the zeolite is consumed during the reaction with NO_x, leaving the zeolite in the H-form. To maintain the catalytic activity, the zeolite has to be reloaded from time to time with gaseous NH_3 or by ion exchange. Initial experiments have demonstrated that this can be done without loss of activity.

The authors thank M. Richter and R. Eckelt (Berlin) for helpful discussions and for supplying the sample of the NH_4-mordenite. Prof. Dr. J. Leonhardt (Berlin) is acknowledged for his encouragement of the work and for useful discussions. Received (in Cambridge, UK) 5th October 1998, Accepted 29th October 1998

An anionic semiquinone radical of 6-azaflavin (6-AzaFl) was found to be stabilized by hydrogen bonding of a melamine derivative bearing an *N*-phenylguanidinium ion in $CHCl_3$, but not by the correponding *N*-unsubstituted guanidinium ion.

Flavin conenzymes such as FMN and FAD exhibit diverse functions through interactions with apoproteins, in which hydrogen bondings play important roles in the regulation of redox prperties.[1] Flavin semiquinone radicals are known to be stable when bound to apoproteins, whereas non-bound semiquinone radicals are unstable due to disproportionation.[2] Yoneda *et al*. reported that the anionic semiquinone radical of flavin 6-carboxylate is stabilized by intramolecular hydrogen bonding of the 6-CO_2H group at the N(5) position even in aqueous solution.[3] This suggests that the hydrogen bonding to the N(5) position is essential for stabilization of an anionic semiquinone radical of flavin. This was tested by employing 6-AzaFl and a melamine derivative bearing an *N*-phenylguanidinium ion **1** in $CHCl_3$. We report herein that receptor **1** is able to stabilize the anionic semiquinone radical of 6-AzaFl in $CHCl_3$, whereas receptor **2** is unable to stabilize it.

Receptor **1** was prepared by reaction of 2-butylamino-4-diethylamino-6-(3-aminomethyl-benzylamino)-*s*-triazine[4] with *S*-methyl-*N*-phenylisothiouronium iodide[5] in EtOH, and **3** was prepared from dodecylamine and *S*-methyl-*N*-phenylisothiouronium iodide, followed by counteranion exchange with KPF_6.† The pK_a value of the guanidinium hydrogen of **1** was determined to be 10.7 by spectroscopic pH titration at 280 nm in buffer solutions containing 20% MeCN,‡ which is considered to be lower than that of **2** by at least 1–2 pK_a units.[6]§ The binding constant of 6-AzaFl·**1** was determined spectrophotometrically [K = (5.3 ± 0.3) × 10^3 dm^3 mol^{-1} in $CHCl_3$] as described previously.[4] Despite of more acidic guanidinium hydrogen of **1**, the K value of 6-AzaFl·**1** is smaller than that of 6-AzaFl·**2** [K = (1.4 ± 0.1) × 10^5 dm^3 mol^{-1} in $CHCl_3$].[4] This requires an explanation, since a more acidic H-donor is known to give a larger binding constant for H-bonded complexation.[7] The thermodynamic parameters for the complex formation (ΔH and $T\Delta S_{298}$: −27 and −6.0 kJ mol^{-1} for 6-AzaFl·**1**; −34 and −5.0 kJ mol^{-1} for 6-AzaFl·**2**)¶ indicated that the complex formation is mainly controlled by the enthalpy term. The ^{1}H NMR study of the complexes implied steric hindrance for complexation of 6-AzaFl and **1**. Namely, as shown in Fig. 1, the larger upfield shifts of C(7)-H of 6-AzaFl upon addition of **1** rather than **2** suggest that C(7)-H is situated in a position close enough to feel the ring current of the *N*-phenyl ring of **1** due to the steric hindrance between C(7)-H and the *ortho*-H of the *N*-phenyl ring.

Redox potentials of 6-AzaFl were determined by cyclic voltammetry in CH_2Cl_2.[8]‖ In the absence of the receptors, 6-AzaFl showed a reversible redox couple ($E_{1/2}$ = −971 mV *vs*. ferrocene/ferrcenium). Upon increasing the concentration of the receptors, the redox potentials shifted in a positive direction in both receptors, finally leading to fixed potentials; $E_{1/2}$ = −738 mV for **1** (5 equiv.), and −767 mV for **2** (3 equiv.). The shifts of the potentials due to the receptors ($\Delta E_{1/2}$) are 233 mV for **1** and 204 mV for **2**, corresponding to stabilization of the 6-AzaFl radical anion by 22 and 20 kJ mol^{-1}, respectively. It should be noted that the cyclic voltammogram of 6-Aza-MeFl was not affected by addition of **1**.

Formation of a semiquinone radical of 6-AzaFl was detected spectrophotometrically by employing the oxidation of dithiothreitol (DTT) in $CHCl_3$ under anaerobic conditions as shown in Fig. 2. In the presence of **2** or a mixture of **3** (K = 180 ± 2 dm^3 mol^{-1}) and **4** (K = 150 ± 6 dm^3 mol^{-1}),[4] the absorption spectrum of 6-AzaFl [Fig. 2(*a*)] was changed to that of 2e-reduced 6-AzaFl [Fig. 2(*b*)]. On the other hand, in the presence of **1**, the spectrum shown in Fig. 2(*c*) was observed, suggesting formation of the anionic semiquinone radical of 6-AzaFl,[2,9] which was confirmed to be stable for at least 48 h. With a large

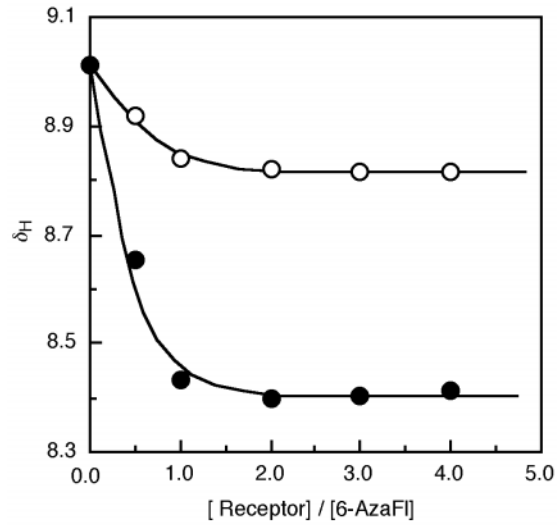

Fig. 1 Changes of chemical shifts of C(7)H in $CDCl_3$ upon addition of the receptors at 25 °C: (●) **1**, (○) **2**.

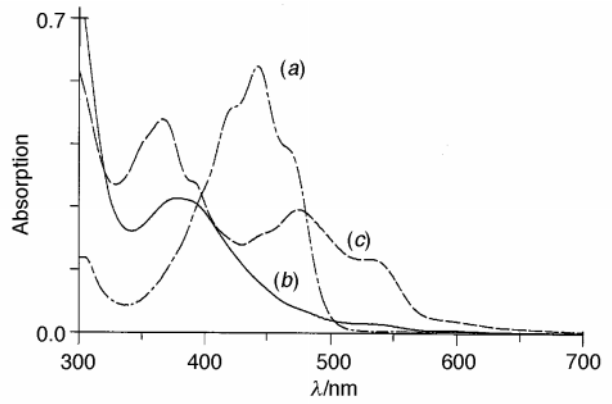

Fig. 2 Absorption spectra of 6-AzaFl in the reaction with DTT. [6-AzaFl] = 5.0×10^{-5} mol dm^{-3}, [DTT] = [Bu_3N] = 5.0×10^{-4} mol dm^{-3} in the presence of **1** or **2** (1.0×10^{-4} mol dm^{-3}) in $CHCl_3$ at 25 °C under N_2; (*a*) oxidized form, (*b*) reduced form, and (*c*) anionic semiquinone radical.

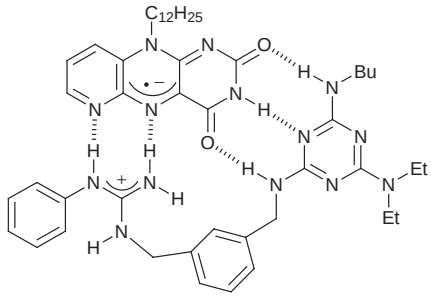

Fig. 3 Structure of 6-AzaFl$^{\cdot-}$ **1**.

excess of DTT, the spectrum shown in Fig. 2(*c*) changed to that shown in Fig. 2(*b*). The spectrum shown in Fig. 2(*b*) was found to give that in Fig. 2(*c*) after O_2 bubbling only with the receptor **1**, suggesting formation of the radical by coproportionation of reduced 6-AzaFl and oxidized 6-AzaFl, or direct electron transfer from the reduced 6-AzaFl to O_2.[2b] Plots of the amount of the anion radical (absorption at 525 nm) *vs*. [**1**] allowed us to calculate the binding constant as 7.7×10^5 dm^3 mol^{-1} which is much larger than that of 6-AzaFl·**1** due to stronger hydrogen acceptability of the anionic radical (6-AzaFl$^{\cdot-}$) as shown in Fig. 3.

Formation of 6-AzaFl radical anion in the presence of **1** was also confirmed by EPR spectroscopy in $CHCl_3$ under anaerobic conditions (Fig. 4). Although hyperfine lines could not be obtained, a *g* value of 2.0040 is in reasonable agreement with those obtained for other flavin radicals.

In summary, we have demonstrated that the acidity of a H-donor of a receptor molecule plays a crucial role in the stabilization of the anionic semiquinone radical of 6-azaflavin. This is the first example showing that intermolecular hydrogen bonds are able to stabilize the anionic semiquinone radical. The receptor molecule could be regarded as an apoprotein model. Furthermore the present results are of use for understanding the functional groups at the active sites of flavoenzymes which give a stable anionic semiquinone radical.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan.

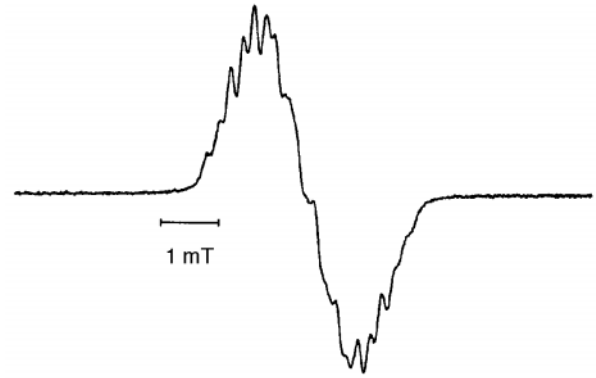

Fig. 4 EPR spectrum of the radical generated by reaction of 6-AzaFl (5.0×10^{-3} mol dm^{-3}) with DTT (5.0×10^{-3} mol dm^{-3}) and Bu_3N (5.0×10^{-3} mol dm^{-3}) in the presence of **1** (5.0×10^{-3} mol dm^{-3}) in $CHCl_3$ at 25 °C under N_2.

Notes and references

† Compound **1**: Yield 54%, mp 178–179 °C (EtOH–diethyl ether). Satisfactory elemental analyses and ^{1}H NMR data were obtained. Compound **3**: Yield 70%, mp 63–65 °C. Receptors **2** and **4**, and 6-azaflavins were supplied from our previous study (ref. 4).

‡ MeCN was added to improve the solubility of **1**.

§ The pK_a for **2** could not be determined by spectroscopic pH titration because of the lack of noticeable absorption changes, but was estimated to be 12–13 (ref. 6).

¶ The thermodynamic parameters were calculated from the following data: 6-AzaFl·**1**; 9.1×10^3 dm^3 mol^{-1} (10 °C), 4.2×10^3 (20), 3.9×10^3 (30), 2.8×10^3 (40). 6-AzaFl·**2**; 1.5×10^5 dm^3 mol^{-1}(20 °C), 1.1×10^5 (30), 7.2×10^4 (40), 5.0×10^4 (50).

‖ To compare the potentials, we used conditions similar to those of ref. 8. [6-AzaFl] = 1.0×10^{-3} mol dm^{-3}, [$Bu_4N^+ClO_4^-$] = 0.1 mol dm^{-3}, 25 °C. Scan rate: 100 mV s^{-1}.

Synthesis and X-ray structure of a complex containing two (η^3-allyl)Mo^{II} units bridged by $Mo^{VI}O_4^{2-}$ and exhibiting an unusual type of aggregation

Cornelia Borgmann, Christian Limberg* and László Zsolnai

Universität Heidelberg, Anorganisch-Chemisches Institut, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. E-mail: Limberg@sun0.urz.uni-heidelberg.de

Received (in Basel, Switzerland) 3rd July 1998, Accepted 26th October 1998

Treatment of the $[Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2(Me_2CO)]^+$ cation with an aqueous MoO_4^{2-} solution enabled the first structural characterisation of an (η^3-allyl)MoO complex, which aggregates to a dimer showing Mo=O···H–C contacts in the solid state.

Organotransition-metal chalcogenide complexes are noteworthy in representing a link between solid, more or less ionic, metal chalcogenides and low-valent molecular organometallic systems.[1] Despite the potential importance of organomolybdenum oxo systems containing molybdenum in the highest oxidation states +5 and +6 as catalytic intermediates in industrial processes,[2] there are known as yet few model complexes of this sort.

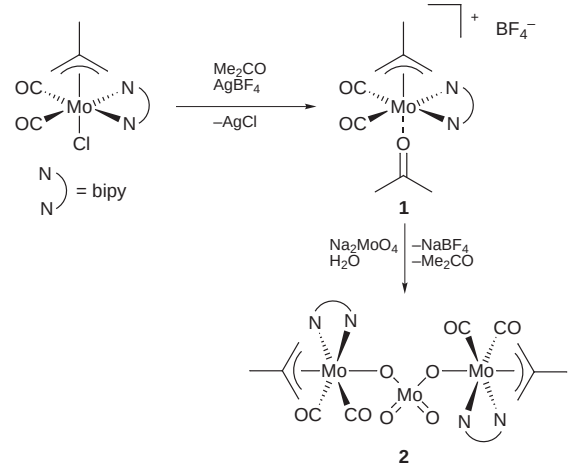
One example of heterogeneous catalysis where such species might play a significant role entails the oxidation of propene to acrolein using MoO_3/Bi_2O_3 as the catalyst and this has gained considerable technical importance. Nontheless, the reaction mechanism has remained for the most part speculative. The results of their experiments on isotopic enrichment lead Grasselli and Burrington to suggest the intermediate formation of symmetric π-allyl complexes (or the chemisorption of delocalised allyl radicals) to Mo centres of the catalyst's surface.[3] Furthermore recent investigations suggest that in heterogeneous oxidation catalyses where Mo-oxides are employed the oxygen atoms found in the organic oxidation products have their origin in previously *bridging* positions.[4]

So far there are no compounds existent in the literature which could be regarded as functional models for the oxo molybdenum π-allyl surface intermediates under discussion. Only few allyl molybdenum compounds containing ligands with oxygen donor functions of any kind have been synthesised and characterised structurally,[5] and none of those bear the terminal or bridging O^{2-} ligands characteristic to the catalyst.

We have shown that complexes with (η^3-allyl)Mo units in oxygen-rich coordination spheres containing RO^- ligands (R = Me, H) can be obtained if cationic complexes with labile ligands are employed as starting materials.[6] Making use of the same principles we have now achieved for the first time the synthesis and structural characterisation of an allyl–Mo complex containing an O^{2-} link to another Mo centre.

The interface reaction of a $[Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2(Me_2CO)]BF_4$ **1** solution in acetone—prepared by treatment of $[Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2Cl]$ with $AgBF_4$ as established for the corresponding $\eta^3\text{-}C_3H_5$ complex[7]—with a solution of Na_2MoO_4 in water leads to the precipitation of a crystalline maroon solid insoluble in all common organic solvents. However, its elemental analysis suggested the composition $[\{Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2\}_2(\mu\text{-}MoO_4)]$ **2**† which had been aimed at (Scheme 1).

An X-ray diffraction analysis‡ of a single crystal yielded the structure shown in Fig. 1, which clearly proves the presence of an O–MoO_2–O moiety bridging two $Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2$ units. One of the latter [Mo(3/4)] was disordered through a rotation by 0.5° around the Mo(1)–O(2) axis and in Fig. 1 for clarity only the Mo(4) fragment is shown. The Mo(3/4)–O(2) and Mo(2)–O(1) distances [2.092(3) and 2.107(3) Å] lie within a range characteristic for bonds of the molybdate unit



Scheme 1

to other Mo centres (2.02–2.15 Å)[8] indicating a real bonding situation rather than a weak coordination of the MoO_4^{2-} unit. The Mo(1)–O(1/2) bridging distances [1.795(3) and 1.797(2) Å] are also typical (1.75–1.85 Å) and the angles found within the central unit of **2** are all very close to the perfect tetrahedral angle. However, if just the solid state structure of the *individual* molecule is considered it does seem surprising that the two organometallic fragments coordinated to the MoO_4^{2-} unit are not oriented symmetrically with respect to the latter: Mo(1/2/4) and O(1/2) are almost in a plane intersecting the C(13)–Mo(2)–C(15) angle while the corresponding C(55)–Mo(4)–C(53) angle of the other subunit escapes intersection by a rotation of this fragment by *ca.* 90° around the Mo(4)–O(2) bond.

An explanation can be found if the structure as a whole is considered: As obvious from Fig. 2 the molecules can pack very efficiently through an internal rotation as described and this

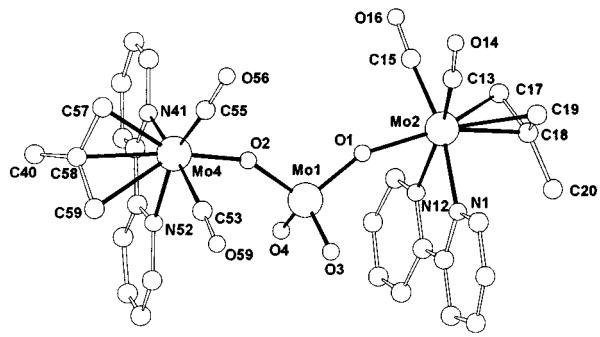


Fig. 1 Structural representation of $[\{Mo(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2\}_2(\mu\text{-}MoO_4)]$ **2**. Selected bond lengths (Å) and angles (°): Mo(1)–O(3) 1.731(3), Mo(1)–O(4) 1.739(3), Mo(1)–O(1) 1.795(3), Mo(1)–O(2) 1.797(3), Mo(2)–O(1) 2.107(3), Mo(3/4)–O(2) 2.092(4); Mo(1)–O(1)–Mo(2) 156.8(2), Mo(1)–O(2)–Mo(3/4) 150.8(2), O(3)–Mo(1)–Mo(4) 107.6(2), OC–Mo(2)–CO 78.7(2), OC–Mo(3/4)–CO 76.2(5); averaged distances and angles: Mo(2)–C_{meso} 2.243(4), Mo(2)–C_{term} 2.323(5), Mo–N 2.254(9), Mo–CO 1.97(1), OC–Mo–N_{trans} 168.9(5), OC–Mo–N_{cis} 104.1(5).

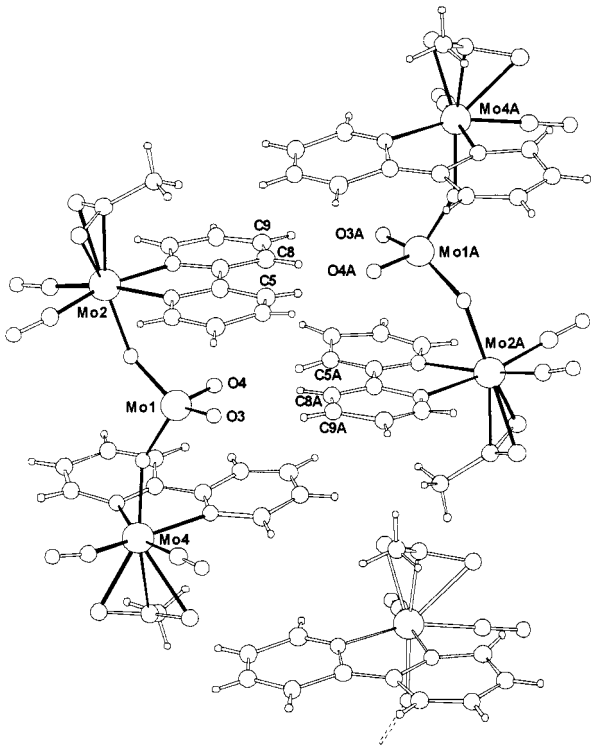

Fig. 2 Structural arrangement of the molecules of **2** in the unit cell. Selected bond lengths (Å): O(3)–C(9A) 3.180, O(3)–C(8A) 3.279, O(4)–C(5A) 3.213, O(4)–C(8A) 3.421.

leads to symmetric dimeric aggregates. These show very short Mo=O···C distances suggesting that there are intermolecular contacts between the protons of the bipy ligands and the Mo=O groups (compare Fig. 2 where the calculated H positions are shown; the Mo=O···H distances were calculated to lie between 2.39 and 2.77 Å). Of course the short C–H···O=Mo distances neither have to be indicative of attractive interactions,[9] nor is the presence of the corresponding contacts necessary to explain the structural features observed, so that attention now focused on the Mo=O bonds. The Mo=O bond lengths in d^0 molybdenum dioxo complexes usually fall in a narrow range and are not strongly effected by the nature of the other ligands at the metal.[10] It has been shown, though, that *classical* H-bridging to a $HNEt_4^+$ cation[8c] can selectively lengthen one of two Mo=O bonds in a MoO_2 unit by *ca.* 0.03 Å. The Mo=O distances observed in **2** [1.731(3) and 1.739(3) Å] are certainly located at the 'tail' of the d(Mo=O) distribution and have to be described as long, which may support the idea of attractive interactions.

Complex **2** is EPR silent and magnetic measurements showed it to be diamagnetic at room temperature, which suggests the presence of a hitherto unknown Mo^{II}–O–Mo^{VI}–O–Mo^{II} unit. Few compounds possessing two oxo bridged Mo centres differing in their oxidation states by *two* are known. An organometallic representative involving a bridging MoO_4^{2-} unit, too, is the complex $[(Cp^{Me}{}_2Mo^{IV})_2(\mu\text{-}Mo^{VI}O_4)_2]$.[8a] In **2** the difference in oxidation states amounts to *four*, which is unusual and had to find an explanation in the redox potentials of the two subunits. Indeed—probably due to the strongly π-accepting ligands—the $[Mo^{II}(\eta^3\text{-}C_3H_4Me)(bipy)(CO)_2(Me_2CO)]^+$ cation showed a reversible oxidation wave at a potential as high as 0.88 V (*vs.* SCE), which cannot be reached by molybdate[11] and this fact allowed the isolation of **2**.

The molybdate complex reported here contains π-allyl–Mo fragments which are bonded *via* 'pure' oxygen bridges to Mo^{VI} centres also providing Mo^{VI}=O groups in close proximity. It therefore already meets some of the requirements to serve as a structural model complex for surface intermediates during molybdenum oxide catalysed propene oxidation. However, other important features like the high oxidation states of all metal centres are still missing so that **2** is not suitable to simulate the properties of these intermediates. Methallyl radicals are released at 193 °C but no oxidation or allyl shift occurs, probably due to the large intramolecular separation of the coordinated allyl ligands from the oxo groups.

C. L. is grateful to the Deutsche Forschungsgemeinschaft for a scholarship and C. B. acknowledges financial support through the Landesgraduiertenförderung Baden-Württemberg. We also wish to thank Professor Dr G. Huttner for his generous support.

Received (in Bath, UK) 8th October 1998, Accepted 10th November 1998

Self-assembled thin films of metallo-supramolecular complexes were prepared and characterized by synchrotron based X-ray reflectivity and fluorescence techniques.

In recent years, layer-by-layer self-assembly has become a very useful technique as an easy and inexpensive method for the preparation of functional thin films.[1] Monolayers and multilayers containing *e.g*. organics, polymers or nanoparticles have been prepared providing a potential approach towards advanced materials or devices with molecularly engineered properties.[2] However, to date, this method has not been used for the defined arrangement of special functional supramolecular units with nanometer dimensions into ordered molecular architectures on surfaces.[3] Here, we report the successful extension of the self-assembly technique to such metallo-supramolecular systems.

We used metal–ligand interactions as non-covalent forces to assemble well-ordered metallo-supramolecular architectures. Such metal coordination arrays ([1 × 1] or [2 × 2] grid-type architectures) based on transition metal ions with octahedral coordination and terpyridine or 4,6-bis(6′-(2′,2″-bipyridyl))-pyrimidine ligands were found to present interesting electronic, magnetic, and structural properties, such as electronic interactions between the metal centers and antiferromagnetic transitions at low temperatures.[4,5] These complexes are formed by spontaneous self-assembly of the corresponding ligands and suitable metal ions such as Co(II), Cd(II), Zn(II) or Hg(II) (see Fig. 1 for [2 × 2] grids). Besides the design and synthesis of 'isolated' grid units, the ordered and stable arrangement of such metallo-supramolecular architectures on surfaces or thin films is of special interest. Two approaches were recently described: (a) hydroxy-terminated grids could be organized on a water trough using the Langmuir–Blodgett (LB) technique and transferred onto substrates;[6] (b) unfunctionalized ligands were self-assembled in the presence of metal ions at the air–water interface.[7] However, both methods are rather complicated and not applicable for larger areas. We used the self-assembly into thin monomolecular films by adsorption onto polyelectrolyte covered substrates. As model systems for the film growth we chose the [1 × 1] Zn(II) and [2 × 2] Cd(II) complexes (Fig.1).†

First we prepared a thin cushion of polyelectrolytes onto a glass or silicon substrate using poly(ethyleneimine) hydrochloride (PEI) followed by the adsorption of a layer of poly(styrenesulfonate) (PSS) which reversed the surface density (Fig. 2).‡ In the next step the supramolecular units were adsorbed on the PSS layer. Owing to the counterions used the complexes were not soluble in water. However, the procedure could be also performed in acetone.§

To characterize the obtained layers we performed both specular and non-specular X-ray reflectivity measurements:¶ Examples of the reflectivity profiles are displayed in Fig. 3 as a function of vertical momentum transfer q_z after normalization by the Fresnel reflectivity $R_F(q_z)$. The response is proportional to the squared Fourier transform of the density gradient along the interface normal[8] and hence reflects the vertical film structure. The three data sets are shifted by arbitrary factors for clarity and correspond to films composed of the polyelectrolyte layers PSS/PEI/Si (a) without any metal complexes, (b) with [1 × 1] Zn complexes, and (c) with [2 × 2] Cd complexes adsorbed on top. The spacing of the minima is given by the inverse $2p/d$ of the total layer thickness d, yielding (a) d = 30 Å, (b) 46 Å and (c) 66 Å, respectively. Note the large thickness increase when [2 × 2] Cd grids are adsorbed, indicating an upright position of the grids (see Fig. 2). The observed differences in the oscillation amplitude reflects the different density contrasts and interfacial widths. The most pronounced fringes in Fig. 3(b) indicate particularly well defined interfaces for the adsorbed [1 × 1] Zn complexes. A more complete data analysis will be presented elsewhere.[9] Similar curves have been measured with [1 × 1] Cu(II), [1 × 1] Hg(II) and [1 × 1] Cd(II) adsorbed onto the polyelectrolytes. From the typical mass densities of the adsorbed [1 × 1] metal complexes, molecular

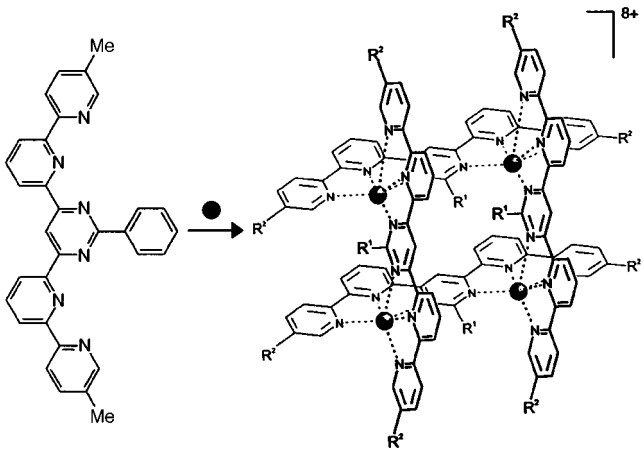

Fig. 1 Schematic representation of the *bis*-terdentate ligands leading to the formation of the [2 × 2] grid type complexes $[Cd_4L_4]^{8+}$ (R^1 = Ph, R^2 = Me). The terpyridine ligand (5,5″-dimethyl-2,2′:6′,2″-terpyridine) and the complexes are not shown.

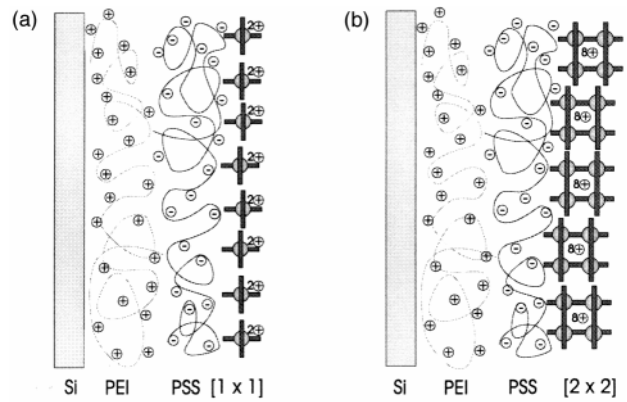

Fig. 2 Schematic drawing illustrating the build-up of the complex layers: (a) [1 × 1] metal grids; (b) [2 × 2] metal grids. Si, PEI and PSS refer to silicon substrate, poly(ethyleneimine) and poly(styrene-4-sulfonate), respectively. The filled circles denote the metal ions.

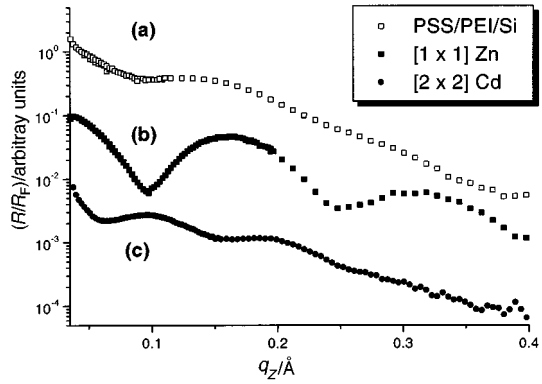

Fig. 3 Typical X-ray reflectivity profiles $R(q_z)/R_F(q_z)$ of the self-assembled films after normalization by the Fresnel reflectivity $R_F(q_z)$. The three data sets are shifted by arbitrary factors for clarity and correspond to films composed of the polyelectrolyte layers PSS/PEI/Si (a) without any metal complexes, (b) with [1 × 1] Zn complexes, and (c) with [2 × 2] Cd complexes adsorbed on top. The curves reflect the laterally averaged density profiles of the film along the interface normal (see text). The total film thickness can be derived directly from the spacing of the minima.

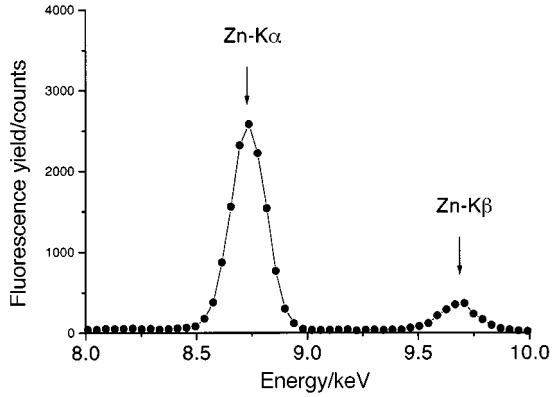

Fig. 4 The successful adsorption of complexes is evidenced most directly by the measured X-ray fluorescence. Typical spectra of monomolecular layers are collected on the time scale of a few min. For the case of [1 × 1] Zn the corresponding Kα and Kβ emission lines are observed.

volumes of *ca*. 1700 Å^3 can be inferred, yielding a mean intermolecular distance of *ca*. 11 Å. This value is in good agreement with the metal–metal distance in the crystals indicating an essentially closed packed complex layer.[10] Furthermore, to investigate the lateral structural parameters of the complex layer (two-dimensional order) we performed grazing incidence X-ray diffraction on the [2 × 2] Cd complexes. However, as yet, we could not find a long-range ordering within the layer.‖

Simultaneously to the specular reflectivity, the X-ray fluorescence of the metal ions in the complexes adsorbed on the surface has been measured.** X-Ray fluorescence under grazing incidence has been shown to be a very powerful tool of surface chemical analysis. By means of the characteristic fluorescence energies (Kα and Kβ lines for Co, Cu, Zn, Lα for Hg) excitable at an incident energy of 12.5 keV, this provides the most direct proof of the complex adsorption. Moreover, the variation of the fluorescence yield with α_i contains quantitative information on the position and width of the metal distribution with respect to the substrate. A typical curve of the energy dispersive spectrum for the [1 × 1] Zn complex is shown in Fig. 4.

At this stage, we use the data as additional, unequivocal proof that the complexes of different types have been adsorbed. Except for the peaks of the corresponding elements the spectra were clean, indicating no contamination of other transition metals or cross-contamination in sample preparation.

The present results demonstrate a simple entry to an ordered arrangement of metallo-supramolecular systems on surfaces. Using X-ray reflectivity we could establish the controlled adsorption of one layer of metal complexes onto a PSS/PEI substrate. Furthermore, the structures of the films have been characterized by synchrotron based X-ray reflectivity and fluorescence techniques. The layer-by-layer adsorption method together with the described analytical techniques opens new avenues for the construction of novel metallo-supramolecular thin film materials which could find potential applications in the preparation of various optical, electronic, or magnetic devices.

This study was supported by the Bayerisches Staatsministerium für Unterricht, Kultus, Wissenschaft und Kunst, the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (DFG).

Notes and references

† The ligands were synthesized and characterized as described elsewhere.[4–6] The reaction of suitable quantities of the ligands and the corresponding metal acetates in refluxing methanol or water exclusively leads to the formation of the monomolecular or tetranuclear complexes (isolated as PF_6 salts and recrystallized twice from acetone–ether).

‡ The silicon or glass substrates were washed extensively in trichloroethylene, methanol, and Millipore water followed by treatment with 5 M KOH (glass) and a saturated KOH solution in ethanol (silicon), respectively, for 1 min. Subsequently, they were washed with water. All samples were then kept in a 0.5% solution of poly(ethyeneimine) hydrochloride (PEI) for 20 min. Then the samples were rinsed in water followed by adsorption of a layer of poly(styrenesulfonate) (PSS) in a 3 mg ml^{-1} solution of PSS in water. The samples were again washed with water.

§ The metal complexes were adsorbed on the PSS layer by immersing the samples in 0.5 mg ml^{-1} solutions of the complexes in acetone for *ca*. 20 min and subsequent rinsing in acetone and water before drying (acetone did not destroy the polyelectrolyte layers, as shown by *ex situ* and *in situ* measurements).

¶ X-Ray experiments were carried out at the D4 bending magnet station of the storage ring DORIS at HASYLAB/DESY with a monochromatic X-ray beam of 12.5 keV. Typically, the reflectivity can be recorded over eight orders of magnitude, after correction for diffuse scattering background.

‖ The surface diffuse scattering (non-specular scattering) has been measured both in the plane of incidence and out of the plane of incidence.

** The X-ray fluorescence under grazing angles was recorded simultaneously with the reflectivity measurements. The detector was placed at 90° opposite the sample surface at a distance of a few centimeters.

Hydrothermal assembly and structural characterisation of one- and two-dimensional organic/inorganic hybrid materials constructed from diphosphopentamolybdate(VI) clusters and $\{Cu(en)\}^{2+}$ complex groups

Jianjiang Lu, Yan Xu,* Ngoh K. Goh and Lian S. Chia

Received (in Cambridge, UK) 30th September 1998, Accepted 10th November 1998

Three novel low-dimensional organic/inorganic hybrid materials, assembled hydrothermally, are constructed from diphosphopentamolybdate(VI) clusters linked through $\{Cu(en)\}^{2+}$ groups; the initial Mo/Cu and Mo/en ratios and the use of F^- ions control the connectivity between the phosphomolybdate clusters and $\{Cu(en)\}^{2+}$ groups, and hence the dimensionality of the solid architectures.

Self-assembly of inorganic molecular precursors in a quest for supramolecular chemistry is one of the highly recognised areas of chemical research. The significant contemporary interest in the transition polyoxometalate–phosphorus based solid materials[1–5] reflects their diverse applications in the areas such as catalysis, sorption and molecular electronics.[6–9] These solids are noted not only for their rich chemical reactivity and structural complexity, but for their unique capability of allowing a variety of chemical reactions to take place in the intracrystalline region. It is evident that chemically robust clusters of polyoxometalates can be assembled through charge compensating cations forming extended structures, though the mechanism by which the assembly is organised remains elusive. A popular strategy in the realisation of materials engineering involves combined applications of hydrothermal synthesis method and structure-directing templates. The feasibility of this strategy can be demonstrated by the advancement in porous materials[10] and the development of low-dimensional and microporous transition metal phosphates.[2–5]

The chemistry of polyoxomolybdate–phosphorus has been extensively studied due to their inherent potential for the development of supramolecular chemistry.[11] The recent success in the hydrothermal assembly of low-dimensional and microporous heteropolymolybdate-based hybrid materials using transition metal coordination complexes suggests a novel approach towards rational synthesis of metal oxide/organic solids.[12] As a continuation of our effort in the hydrothermal assembly of polyoxomolybdate(VI)-based solid materials,[13] we seek to explore the assembly of phosphomolybdates in the presence of Cu^{2+} and en under the influence of a F^- switch. Here, we report the hydrothermal synthesis and structural characterisation of three novel one- and two-dimensional hybrid solids, $[H_2en]_2[\{Cu(en)(OH_2)\}Mo_5P_2O_{23}]\cdot 4H_2O$ **1**, $[H_2en][\{Cu(en)_2\}Mo_5P_2O_{22}(OH_2)]\cdot 2H_2O$ **2** and $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]\cdot 3H_2O$ **3**.

Solids **1**-**3** were synthesised from the hydrothermal reactions of $MoO_3\cdot H_2O$, H_3PO_4, $CuSO_4\cdot 5H_2O$, en, H_2O with and without the use of F^- ions at 160 °C for 72 h.† The concentration of F^- ions in the initial mixtures was found to be critical for the synthesis of **1**. Solid **2** was obtained from similar reaction mixtures to **1** in the absence of F^- ions. Solid **3** was obtained from reaction mixtures containing much higher Cu^{2+} and en concentrations in comparison to those of **1** and **2**. *In situ* PXRD studies‡ showed that the crystal structures of solids **1**-**3** remained intact until *ca.* 400 °C. The synthesis of the three solids is sensitive to the specific reaction conditions such as the Mo/Cu and Mo/en ratios, suggesting a kinetically controlled crystallisation mechanism.

The structure of $[H_2en]_2[\{Cu(en)(OH_2)\}Mo_5P_2O_{23}]\cdot 4H_2O$ **1**§ is constructed from linking of the $[Mo_5P_2O_{23}]^{6-}$ clusters and $\{Cu(en)(OH_2)O_2\}^{2+}$ square pyramids into spiral-shaped chains of $[\{Cu(en)(OH_2)\}Mo_5P_2O_{23}]^{4-}$ as shown in Fig. 1. The geometry of the $[Mo_5P_2O_{23}]^{6-}$ cluster[11] can be described as a ring of five distorted MoO_6 octahedra with two PO_4 tetrahedra capped on each side. Two adjacent $[Mo_5P_2O_{23}]^{6-}$ clusters are connected through a $\{Cu(en)(OH_2)\}^{2+}$ unit *via* corner-sharing interactions of the type PO–Cu with Cu–O 1.949(5), 2.014(5) Å. The copper site is defined by two nitrogen donors from an en molecule, two *cis*-oxo groups from two adjacent $[Mo_5P_2O_{23}]^{6-}$ clusters and one oxygen donor from a H_2O molecule. The axial Cu–O bond [Cu-OH_2 2.432(7) Å] is considerably longer than the equatorial Cu–O bonds [Cu–O 1.949(5), 2.014(5) Å] owning to Jahn–Teller distortion. The $[\{Cu(en)(OH_2)\}Mo_5P_2O_{23}]^{4-}$ chains align in parallel and are packed such that each chain is circumscribed by two groups of four alike chains, which are related by a *pseudo* 4-fold axis, giving rise to an elongated cylindrical unit. As a result, pseudo-one-dimensional channels are formed that are filled with the charge-compensating Hen_2^{2+} cations.

Modifying the reaction mixture of **1** by reducing the F^- ion content leads to the co-crystallisation of solids **1** and **2**. Monophasic crystals of **2** are produced by removing F^- ions from the reaction mixtures. Examination of the structure of $[H_2en][\{Cu(en)_2\}Mo_5P_2O_{22}(OH_2)]\cdot 2H_2O$ **2**§ reveals that it consists of the $[Mo_5P_2O_{22}(OH_2)]^{4-}$ clusters[11] linked through the $\{Cu(en)_2O_2\}^{2+}$ octahedra into a virtual one-dimensional chain of $[\{Cu(en)_2\}Mo_5P_2O_{22}(OH_2)]^{2-}$ as shown in Fig. 2. Each $[Mo_5P_2O_{22}(OH_2)]^{4-}$ cluster is connected to two $\{Cu(en)_2O_2\}^{2+}$ octahedra through the two terminal oxo groups of a common MoO_6 octahedron forming weak interactions of the type Cu–OMo with Cu–O 2.490(6), 2.503(6) Å. The two axial Cu–O bonds of the $\{Cu(en)_2O_2\}^{2+}$ octahedron are, as expected, elongated. The adjacent chains of $[\{Cu(en)_2\}Mo_5P_2O_{22}(OH_2)]^{2-}$ are in close contact forming pseudo-two-dimensional layers through weak interactions of the type P···O 3.325(6) Å as shown in Fig. 2. The striking differences between the structures of **1** and **2** lie in (i) the number of en molecules

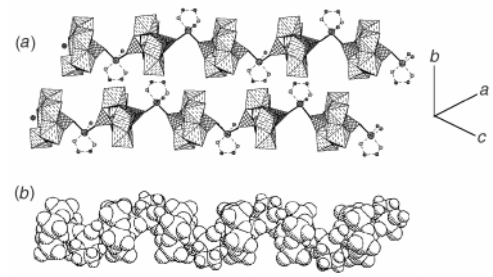

Fig. 1 (a) A polyhedral and ball-and-stick packing view of the $\{[Cu(en)(OH_2)\}Mo_5P_2O_{23}]^{4-}$ chains of **1** showing the connectivity between the $[Mo_5P_2O_{23}]^{6-}$ clusters and $\{Cu(en)(OH_2)O_2\}^{2+}$ square pyramids and orientation of the chains. Octahedra and tetrahedra represent Mo and P atoms respectively. Cu atoms are shown by large ahtched circles. (b) The space-filling plot of the spiral-shaped chains of **1**.

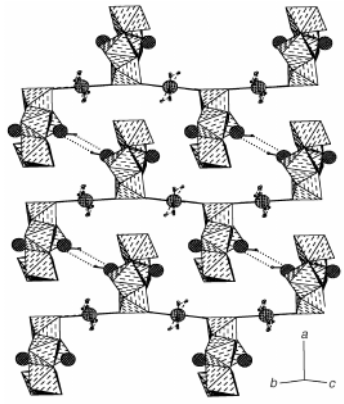

Fig. 2 A polyhedral and ball-and-stick representation of **2** showing (i) the connectivity between the $[Mo_5P_2O_{22}(OH_2)]^{4-}$ clusters and $\{Cu(en)_2O_2\}^{2+}$ octahedra; (ii) the packing and orientation of the $[\{Cu(en)_2\}Mo_5P_2O_{22}(OH_2)]^{2-}$ chains and the pseudo-layers formed as a result of interchain interactions. Octahedra represent Mo atoms. P and Cu atoms are shown by large heavy-crossed and heavy-shaded circles.

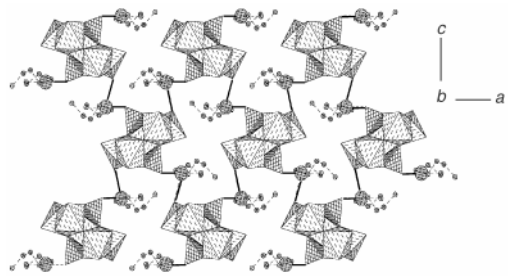

Fig. 3 A polyhedral and ball-and-stick representation of the $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]$ layer of **3** showing the connectivity between the $[Mo_5P_2O_{23}]^{6-}$ clusters and $\{Cu(en)(Hen)O_2\}^{3+}$ square pyramids and the 12-membered rings. Octahedral and tetrahedra represent Mo and P atoms respectively. Cu atoms are shown by large dotted circles.

participated in forming $\{Cu(en)\}^{2+}$ building blocks and (ii) the connectivity between $[Mo_5P_2O_{23}]^{6-}$ clusters and $\{Cu(en)\}^{2+}$ groups, namely, PO–Cu in **1** and MoO–Cu in **2**. The packing of chains gives rise to an elongated cylindrical unit in **1** and pseudo-layers in **2**. We believe that the strong coordination effect of F^- ions plays a role in controlling the reaction between Cu^{2+} center and the N donors of en molecules, and between Cu^{2+} center and the O donors of $[Mo_5P_2O_{23}]^{6-}$ clusters or H_2O molecules.

The solid architectures of **1** and **2** provide examples of different ways of connecting $[Mo_5P_2O_{23}]^{6-}$ clusters and $\{Cu(en)\}^{2+}$ groups. It suggests that further condensation of $[Mo_5P_2O_{23}]^{6-}$ clusters into higher dimensional solids through the linkage of $\{Cu(en)\}^{2-}$ groups could be feasible. Reducing the initial Mo/Cu and Mo/en ratios results in the successful crystallisation of solid **3**. The structure of $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]\cdot 3H_2O$ **3**§ is constructed from $[Mo_5P_2O_{23}]^{6-}$ clusters[11] linked through $\{Cu(en)(Hen)\}^{3+}$ groups into two-dimensional layers of $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]$ as shown in Fig. 3. Each $[Mo_5P_2O_{23}]^{6-}$ cluster is bonded to four $\{Cu(en)(Hen)\}^{3+}$ groups through two PO_4 tetrahedra and two MoO_6 octahedra forming two pairs of covalent interactions of the types Cu–OP and Cu–OMo with Cu–O 1.952(2), 2.557(2) Å respectively. The Cu^{2+} center of $\{Cu(en)(Hen)O_2\}^{3+}$ square pyramid receives contributions from three nitrogen donors belonging to one and half en molecules, one oxygen donor from a PO_4 unit and one oxygen donor from a MoO_6 unit with Cu–N 1.991(3), 2.011(3), 2.020(3) Å and Cu–O 1.952(2), 2.557(2) Å. This results in the 12-membered rings ($Mo_4P_4Cu_4$) of the $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]$ layers of **3**. Adjacent $[\{Cu(en)(Hen)\}_2Mo_5P_2O_{23}]$ layers are separated by H_2O molecules with small interlamellar separation owing to the presence of extensive network of H-bonds. The coexistence of Cu–OP and Cu–OMo linkages plays a critical role in constructing the layer structure of **3** which contrast strikingly to the Cu–OP and Cu–OMo linkages in building up the chain structures of **1** and **2** respectively.

The successful isolation of solids **1**–**3** provides novel examples of assembling phosphomolybdate clusters through the templating effects of $\{Cu(en)\}^{2+}$ groups for design of composite oxide materials. It demonstrates that the use of hydrothermal techniques is essential for the realisation of materials design. The dimensionality of solid architectures is, to certain degree, tailorable while the key leading to the success lies on the kinetic aspect of assembly process. While the mineralising mechanism of F^- ions remains debatable, its critical role in constructing solid architectures is manifest. The present study reveals the rich hydrothermal chemistry of the phosphomolybdate–Cu–en system and the structural versatility evolving from altering reaction kinetics. This highlights the feasibility of engineering metal–organoamine–phosphomolybdate solids with potentially interesting and useful properties.

Aromatic inclusion within a neutral cavity-containing rectangular grid

Ryan H. Groeneman, Leonard R. MacGillivray and Jerry L. Atwood*

Received (in Cambridge, UK) 5th October 1998, Accepted 9th November 1998

Reaction of $CoCl_2·6H_2O$ with pyrazine and disodium terephthalate in water results in the formation of a neutral cavity-containing rectangular grid, $[Co(pyz)(terph)(H_2O)_2]$, which includes a tightly bound aromatic as a guest; classification of these frameworks also provides targets for chemical synthesis.

In a recent report, we demonstrated the one-pot synthesis of a cationic cavity-containing rectangular grid, $[M(4,4'\text{-bipy})(pyca)(H_2O)_2]^+$ **1** [where M = Co(II) or Cd(II); 4,4′-bipy = 4,4′-bipyridine; pyca = pyridine-4-carboxylate], which self-assembles in the solid state to form stacked layers.[1] The stacking exhibited by this framework yielded interconnected microchannels which include highly disordered neutral (*i.e.* solvent H_2O) and charged (*i.e.* NO_3^- ions) guest species. In this contribution, we now extend the chemistry of these materials to neutral frameworks and demonstrate, for the first time, the ability of a cavity-containing rectangular grid, $[Co(pyz)(terph)(H_2O)_2]$ **2** (where pyz = pyrazine, terph = 1,4-benzenedicarboxylate), to include an aromatic (*i.e.* pyz) as a guest. We also demonstrate that it is possible to classify these and related square grids based on simple charge considerations which we anticipate will aid in the synthesis and sorting of these compounds as new members of each family continue to emerge.

There are, in principle, only four ways in which either a cationic or neutral rectangular grid may be constructed using a M^{2+} ion (M = transition metal) (Table 1).† In the first case, both bridging ligands, in terms of charge, must be neutral. In the second case, one bridging ligand must possess a − 1 charge. In the third case, both bridging ligands must possess a − 1 charge. Finally, in the fourth case, one bridging ligand must possess a − 2 charge. In each case, either a square planar or octahedral metal center may be employed for the assembly process. In this study, an example of case 4, which is based upon an octahedral metal center, is presented. Notably, for a square grid, there are only two ways in which such a framework may be constructed. Either the bridging ligand must possess a − 1 charge or be neutral. This latter observation is due to the fact that only a single bridging ligand may be used to construct a square grid framework.

When a hot, aqueous solution (5 mL) of $CoCl_2·6H_2O$ (238 mg, 1.0 mmol) was added to a hot, aqueous solution (4 mL) of pyrazine (160 mg, 2.0 mmol) and disodium terephthalate (210 mg, 1.0 mmol) according to eqn (1), crystals of **2**·pyz suitable for X-ray analysis formed, after cooling, within a period of approximately 1 week (yield 16.2 %, single product). The formulation of **2**·pyz was confirmed by single-crystal X-ray analysis‡ and thermogravimetric analysis.

$$CoCl_2·6H_2O + 2\ pyz + Na_2(terph) \rightarrow \mathbf{2}·pyz \qquad (1)$$

A view depicting the metal ion coordination in **2** is shown in Fig. 1. In a similar way to **1**,[1] the metal center is coordinated to two *trans* μ-pyz ligands, two *trans* μ-terph ions, and two *trans* water molecules that form a slightly distorted octahedral coordination environment. As a result, a cavity-containing rectangular grid has formed. Unlike **1**, however, the anion possesses a −2 charge and the framework is therefore neutral. Notably, the grids lie parallel to the crystallographic *ab* plane and exhibit intragrid M···M separations of 7.2× 11.3 Å across each pyz ligand and terph ion, respectively. In a similar way to **1**, the anion participates in two O–H···O hydrogen bonds with two coordinated water molecules [O···O 2.683(2) Å] such that the carboxylate moieties of the ligand lie approximately orthogonal to the MN_2O_2 plane.

Table 1 Summary of rectangular grids

Case	Metal[a]	Ligand I	Ligand II	Ref.
1	M^{2+}	Neutral	Neutral	2
2	M^{2+}	−1	Neutral	1
3	M^{2+}	−1	−1	–
4	M^{2+}	−2	Neutral	3, this study

[a] Square planar or octahedral transition metal center.

As shown in Fig. 2, the bridging ligands of **2** have generated a cavity with dimensions suitable to accommodate a molecule of pyz. The included guest, which, in contrast to **1**,[1] is well ordered, participates in π-π interactions (centroid···centroid 3.34 Å) and C–H···N hydrogen bonds§ (C···N 3.34 Å) with the anion and bridging pyz ligand, respectively. Although aromatic guest inclusion has been demonstrated in discrete[7,8] and infinite square assemblies,[9,10] these observations illustrate, for the first time, the ability of a rectangular framework to host an aromatic guest.

A view depicting the extended structure of **2** is shown in Fig. 3. As in **1**[1] and $Cu(4,4'\text{-bipy})(pyz)(H_2O)_2(PF_6)_2$ **3**,[2] the grids self-assemble in the solid state such that they form stacked layers. Notably, the grids of **2** interact by way of O–H···O hydrogen bonds [O···O 2.808(3) Å], which involve coordinated water molecules and carboxylate moieties of the terph ion, such that adjacent layers lie offset. This, in turn, generates guest-

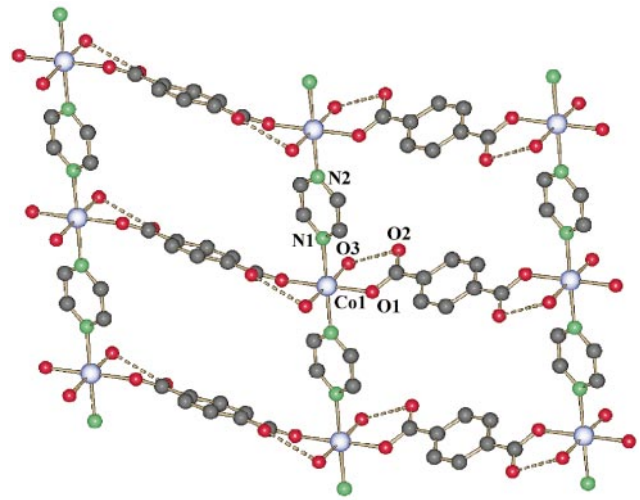

Fig. 1 A view of **2** depicting the coordination environment around the Co(II) metal centres. Selected interatomic distances (Å): Co(1)–O(1) 2.059(2), Co(1)–O(3) 2.121(2), Co(1)–N(1) 2.190(3), Co(1)–N(2) 2.163(3), O(2)···O(3) 2.683(2). All bond distances are within expected ranges. The guest has been omitted for clarity.

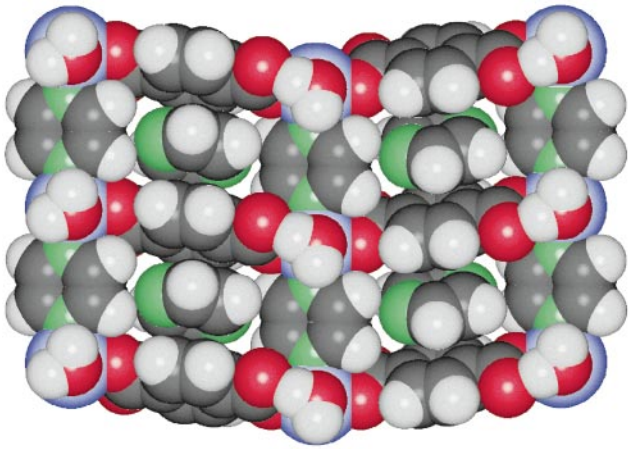

Fig. 2 A space-filling model of **2**·pyz. The guest is held within the cavity by a combination of π–π interactions and C–H···N hydrogen bonds.

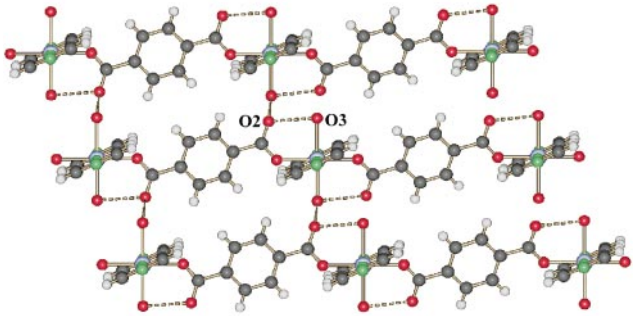

Fig. 3 A view depicting the O–H···O hydrogen bonds [O(2)···O(3) 2.808(3) Å] which occur between the stacked layers of **2**.

filled microchannels which run in an oblique direction with respect to the layers. Interestingly, thermal analysis of **2**·pyz reveals that, in contrast to **1**, the guest is tightly bound within the lattice. The TGA trace displays a rapid weight loss of 20.0% (calculated 19.1%), from 107 to 252 °C, which corresponds to one molecule of pyz.§ The resulting material, [Co(pyz)(terph)(H_2O)$_2$], then slowly decomposes with loss of pyz and the terph ion to yield the metal oxide.

The results reported herein illustrate the utility of using the process of self-assembly for the construction of *multi*-component host–guest architecture. By selecting appropriately functionalized components, we have shown that it is possible to extend the chemistry of rectangular grids involving bridging pyridines/diazines and carboxylate moieties to neutral frameworks. Considering the relatively small number of cavity-containing rectangular frameworks which have been synthesized to date (Table 1), it also now possible to target certain grids, for chemical synthesis, which have not yet been constructed (*e.g.* case 3), in which case members of each family may display similar properties. We are also currently exploring further inclusion properties of **2**, with a view to determine whether other aromatic guest molecules can be isolated within the framework.

We are grateful for funding from the National Science Foundation (NSF) and the Natural Sciences and Engineering Research Council of Canada (NSERC) for a doctoral scholarship (L. R. M.).

Notes and references

† To place our results in the context of those obtained to date, we limit our discussion to M^{2+} ions (M = transition metal) and exclude anionic frameworks.

‡ *Crystal data* for **2**·pyz: monoclinic, space group *C*2/*c*, a = 11.415(1), b = 7.161(1), c = 20.585(2), β = 96.189(2), U = 1682.8(3) Å^3, D_c = 1.66 g cm^{-3}, Mo-Kα radiation (λ = 0.71070 Å) for Z = 4. Least-squares refinement based on 1496 reflections with $I_{net} > 2.0\sigma(I_{net})$ (out of 1835 unique reflections) led to a final value of R = 0.039. Aromatic hydrogen atoms were placed by modeling the moieties as rigid groups with idealized geometry, maximizing the sum of the electron density at the calculated hydrogen positions. Structure solution was accomplished with the aid of SHELXS-86[4] and refinement was conducted using SHELXL93[5] locally implemented on a Pentium-based IBM compatible computer. CCDC 182/1084.

§ For comparison, **1** exhibits an initial weight loss at 25 °C. Similar square-based systems have been shown to exhibit initial guest weight losses below 70 °C.[10–12]

The nature of the interaction of molecular fluorine and Lewis bases B from a comparison of the properties of B···F_2 and B···HF

A. C. Legon

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD E-mail: a.c.legon@exeter.ac.uk

Received (in Cambridge, UK) 7th October 1998, Accepted 4th November 1998

Comparison of angular geometries, radial geometries and intermolecular stretching force constants k_σ of the two series of complexes B···F_2 and B···HF, where B is H_2S, HCN, CH_3CN, H_2O, $(CH_2)_2O$ or NH_3, allows conclusions about the nature of the interaction in B···F_2 and the shape of the F atom in F_2.

The reactivity of elemental fluorine is legendary. It results from the ease with which the F–F bond is broken, coupled with the great strength of the bonds E–F (E = H,C or N) that are formed. Hence, the reactions of F_2 with many simple compounds are highly exothermic. Once sufficient concentrations of F atoms have been produced, presumably initially at surfaces and then through the temperature rise as the reaction begins, self-acceleration sets in through chain processes. Explosions can then result. But what of the interactions of the difluorine molecule F_2 itself with other molecules B when the possibility of reactions proceeding through fluorine atoms is precluded?

We have recently demonstrated that, by using a simple device, the complexes B···F_2 formed by simple Lewis bases B with F_2 may be isolated and characterised before any chemical reaction can occur.[1–6] The device is called a fast-mixing nozzle.[7] It consists of a pair of concentric, coterminal tubes of circular cross section that issue into the evacuated Fabry–Pérot cavity of a Fourier-transform microwave spectrometer.[8] The inner tube is a glass capillary of 0.3 mm internal diameter but the outer is constructed from Teflon. A dilute mixture of F_2 in argon is pulsed *via* a solenoid valve down the outer tube while the pure Lewis base B is flowed continuously into the vacuum chamber through the glass capillary. The coaxial gas flows undergo adiabatic expansion as they emerge from the tubes and so molecules of B and F_2 meet only when F_2 is moving away from surfaces at rate of *ca.* 5×10^4 cm s^{-1}, which is the terminal speed of the gas pulse for argon as carrier gas.[8] Complexes B···F_2 so formed are rapidly cooled to their lowest rotational and vibrational energy states and achieve collisionless expansion in *ca.* 10 μs. Thereafter, the complexes are effectively frozen and no chemical reaction is possible. The B···F_2 can then be characterised through their rotational spectrum in the relatively long period before the gas encounters a vessel wall, *etc*.

Analysis of the rotational spectrum of B···F_2 leads to details of the radial and angular geometry and to the strength of the interaction, as discussed elsewhere for complexes B···HX.[9] Sufficient B···F_2 have now been characterised to allow general conclusions about the nature of the interaction of F_2 with simple Lewis bases B. Table 1 summarises the radial and angular geometries of the six complexes B···F_2[1–6] and the six analogous hydrogen-bonded complexes B···HF,[10–16] where B is H_2S, HCN, CH_3CN, H_2O, $(CH_2)_2O$ or NH_3. Also included in Table 1 are the intermolecular stretching force constants k_σ. These are available from the centrifugal distortion constants D_J or Δ_J for weakly bound complexes in the quadratic approximation with the assumption of rigid, unperturbed subunits B and F_2 by using expressions developed by Millen[17] and provides one measure of the strength of the B–F_2 interaction.

Several general points emerge from Table 1. First, the angular geometries of the pair B···F_2/B···HF are isomorphous for a given B. The detailed similarity within the pair for H_2O···XF (X = F or H), for H_2S···XF and for $(CH_2)_2O$···XF, in each of which the geometry is not dictated by the symmetry of B, is remarkable. Although both H_2O···F_2 and H_2O···HF are

recorded as effectively planar, $H_2O\cdots HF$ has been shown[18] to have a small potential energy barrier (126 cm^{-1}) to the planar C_{2v} conformation that separates the two equivalent equilibrium geometries of C_s symmetry having a pyramidal configuration at O. The top of the barrier lies only slightly above the zero-point energy level and the vibrational wavefunctions have C_{2v} symmetry. In view of the much weaker bond in $H_2O\cdots F_2$, it is likely that the barrier in this species is even lower. This interpretation is reinforced by the fact that a low-lying vibrational satellite attributed to internal rotation of the H_2S subunit is observed in $H_2S\cdots F_2$ but not in $H_2S\cdots HF$, which is rigidly pyramidal.

Secondly, we note from Table 1 that the k_σ for the $B\cdots F_2$ are smaller than those of the $B\cdots HF$ by a factor of 6 to 8. Indeed, the $B\cdots F_2$ are so weak that their k_σ values are closer to those of $B\cdots Ar$ complexes. For example, k_σ = 3.6(4) N m^{-1} and 2.18 N m^{-1} for oxirane$\cdots F_2$[6] and oxirane$\cdots$Ar,[19] respectively.

Thirdly, the distance $r(Z\cdots F)$ from the acceptor atom Z in B to the nearest F atom is almost identical within a given pair $B\cdots F_2$/$B\cdots HF$.

What explanation can be offered for these observations? The behaviour of the $B\cdots HF$ complexes was interpreted[20,21] on the basis of a simple electrostatic interaction of B and HF, *i.e.* between unperturbed electric charge distributions. The angular geometries of $B\cdots HF$ were first rationalised[20] on the basis of the simple rule which states that in the equilibrium geometry the axis of the HF molecule coincides with the axis of a non-bonding electron pair on the acceptor atom Z in forming a hydrogen bond with B. This rule was subsequently given a quantitative basis by a simple electrostatic model.[22] The variations of the k_σ in $B\cdots HF$ complexes has also been interpreted in terms of an electrostatic interaction.[23]

The results in Table 1 suggest a similar approach for $B\cdots F_2$. In that case, the fact that the leading term in the Taylor series expansion of the electric charge distribution of F_2, namely its electric quadrupole moment Q = 2.76 × 10^{-40} C m^2, is very small[24] while HF has an electric dipole moment[25] μ = 1.8265 D (6.0925 × 10^{-30} C m) ensures that the interaction $B\cdots{}^{\delta+}F\overset{\delta-}{\delta+}F^{\delta+}$ will be much weaker than in $B\cdots{}^{\delta+}H\text{–}F^{\delta-}$. This is borne out by the k_σ values of Table 1. Moreover, the nearly spherical F_2 electric charge distribution explains why the magnitudes of k_σ for $B\cdots F_2$ are like those of $B\cdots Ar$. Presumably, the London dispersion interaction is more significant for $B\cdots F_2$ than for $B\cdots HF$, for which the preponderant contribution is electrostatic. In some ways F_2 behaves like its united atom Ar in complexes with B.

Evidently, the electrostatic part of the energy of interaction in $B\cdots F_2$ is still definitive of the angular geometry and hence the latter is of the same form for a given pair $B\cdots F_2$/$B\cdots HF$. Nevertheless, the weaker electrostatic term in the $B\cdots F_2$ is consistent with a lower barrier to internal rotation of the H_2S subunit in $H_2S\cdots F_2$ than in $H_2S\cdots HF$.

Given that the $B\cdots F_2$ interaction is weak, it seems likely that the distance $r(Z\cdots F)$ will be determined by the sum of the van der Waals radii $\sigma(Z)$ and $\sigma(F)$ of the atoms Z and F. Values of $\sigma(Z) + \sigma(F)$ generated from Pauling's radii[26] are given in Table 1. If a range of 0.05 Å is assigned to the Pauling radii, the $r(Z\cdots F)$ for both $B\cdots F_2$ and $B\cdots HF$ are identical with the sum $\sigma(Z) + \sigma(F)$, since the mean difference $\Delta r = \{\sigma(Z) + \sigma(F)\} - r(Z\cdots F)$ is only 0.07(6) for the $B\cdots F_2$ and 0.09(4) for the $B\cdots HF$. It was suggested earlier[22] that the distance $r(Z\cdots F)$ in hydrogen-bonded complexes can be taken as the sum of the van der Waals radii of Z and F, in view of the lack of a repulsive electron shell for the nearly bare proton $^{\delta+}H$ in HF. This is illustrated graphically in Fig. 1, in which the netted spheres of appropriate van der Waals radius drawn on the O and F atoms in the scale diagrams of $H_2O\cdots F_2$ and $H_2O\cdots HF$ just touch in each case.

The fact that Δr is effectively zero for $B\cdots F_2$ suggests that F_2 may not be 'snub-nosed' in the sense that Cl_2 is, *i.e.* that the van der Waals radius along the axis is not shorter than the value perpendicular to it. For several $B\cdots Cl_2$, the mean value of Δr is found to be *ca.* 0.5 Å. *Ab initio* calculations of the type[27] used to establish the anisotropy of the van der Waals radius of Cl_2 would settle this.

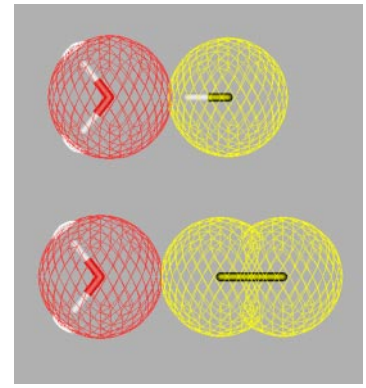

Fig. 1 Stick models of $H_2O\cdots HF$ (upper) and $H_2O\cdots F_2$ (lower) drawn to scale, with the experimental intermolecular separations $r(Z\cdots F)$ given in Table 1. The nets are spheres having the appropriate van der Waals radii (red for oxygen, yellow for fluorine, white for hydrogen). The sphere for the H of HF is not drawn, for the reason discussed in the text. For convenience, both molecules are depicted as planar. Note that the van der Waals spheres of oxygen and the inner fluorine atom just touch in each case.

The author thanks the EPSRC for the award of a Senior Fellowship.

Received (in Cambridge, UK) 21st September 1998, Accepted 13th November 1998

The rigid bis-porphyrinic host 2 forms 1:1 complexes with rigid 5,15-bis(4-pyridyl)porphyrins and both 1:1 and 2:1 complexes with tetrapyridylporphyrin 4, with the latter complex providing a new example of a self-assembled system containing an enclosed molecular environment.

Strategies for self-assembly are receiving increasing attention for the construction of multichromophoric supramolecular arrays involving porphyrins.[1] In particular, metal ion co-ordination utilising ligation of the metallated porphyrin nucleus has proven efficient for positioning photoactive components.[2,3] Systems exerting co-operativity between two or more non-covalent interactions provide access to self-assembled arrays with increased stability compared to systems relying on a single interaction alone.[3] The construction of such porphyrinic arrays is a key to the development of synthetic models which mimic the manner in which nature assembles the photoactive components within the photosynthetic apparatus and produces charge separation in high quantum yield.[4]

Here, we show that the rigid bis-porphyrin **2** can react with rigid dipyridyl porphyrins to form 1:1 complexes, and that the tetrapyridylporphyrin component **4** can form both 1:1 and 2:1 complexes;† the latter porphyrin array **7** has a shape and mobility reminiscent of a universal joint.‡ While such a structure is novel and aesthetically intriguing, its value is conceptual; it may have interesting photophysical properties and its formation suggests similar methodologies for the assembly of other large covalent capsules.

Molecular modelling (AM1) revealed that a self-assembled host–guest arrangement between bis-porphyrin **2** and rigid dipyridyl rod **3** or tetrapyridyl rod **4** should be feasible, based on the following dimensions: a porphyrin centre-to-centre distance in **2** of 22 Å (Fig. 1); pyridine N–N distances in 5,15-dipyridyl substituted porphyrins **3** and **4** of 15.7 and 15.5 Å, respectively; and an average zinc porphyrin to pyridyl bond distance of 2.2 Å.[7]

Mixing equimolar amounts of rigid bis-porphyrin **2** [formed from **1**[8] by treatment with $Zn(OAc)_2$ in CH_2Cl_2–MeOH] and dipyridyl porphyrin rod **3**§ ($CDCl_3$ or CD_2Cl_2) resulted in the formation of a 1:1 complex **5** (C_{2v}). Examination by ^{1}H NMR spectroscopy revealed sharp resonances for **3** complexed on the inside of **2** in which the resonances for **2** were slightly broadened. Such broadening has been observed previously in complexation studies involving **3**,[9] and in both cases these signals were sharpened by cooling the solution to 263 K or below.

The α- and β-pyridyl resonances of **3** within **5** are drastically affected by the host porphyrin system's magnetic anisotropy, shifting upfield by 5.74 and 1.66 ppm respectively. In contrast, the proton resonances of the fused carbocyclic framework in **5** are only slightly affected by the guest porphyrin (*ca.* $\Delta\delta$ 0.14). Such large pyridyl shifts are indicative of coordination of the bis-pyridyl porphyrin guest with the bis-zinc porphyrin host.[3]

UV spectroscopic titrations carried out in CH_2Cl_2 at 298 K (424 and 433 nm) yielded a Job plot with a maximum at $x = 0.5$, confirming the 1:1 stoichiometry of complexation in **5**. Analysis of the titration data by non-linear least-squares revealed an empirical association constant of *ca.* 10^8 M^{-1}. This association constant is considerably stronger than that observed for pyridine itself with a zinc porphyrin precursor (10^4 M^{-1}) indicating strong chelation within **5**.

When the dipyridylporphyrin guest was replaced by the tetrapyridylporphyrin **4**,[10] the ^{1}H NMR spectrum at 303 K for a 1:1 mixture of host **2** and guest **4** in $CDCl_3$ revealed sharp

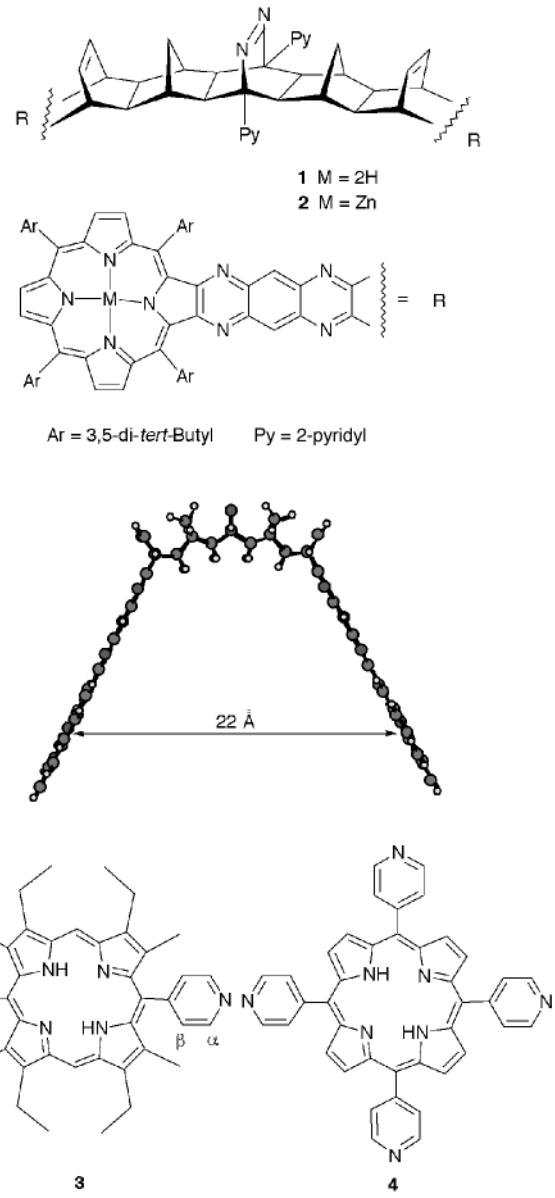

Fig. 1 Molecular modelling of the skeletal backbone of **1** reveals the overall U-type geometry.

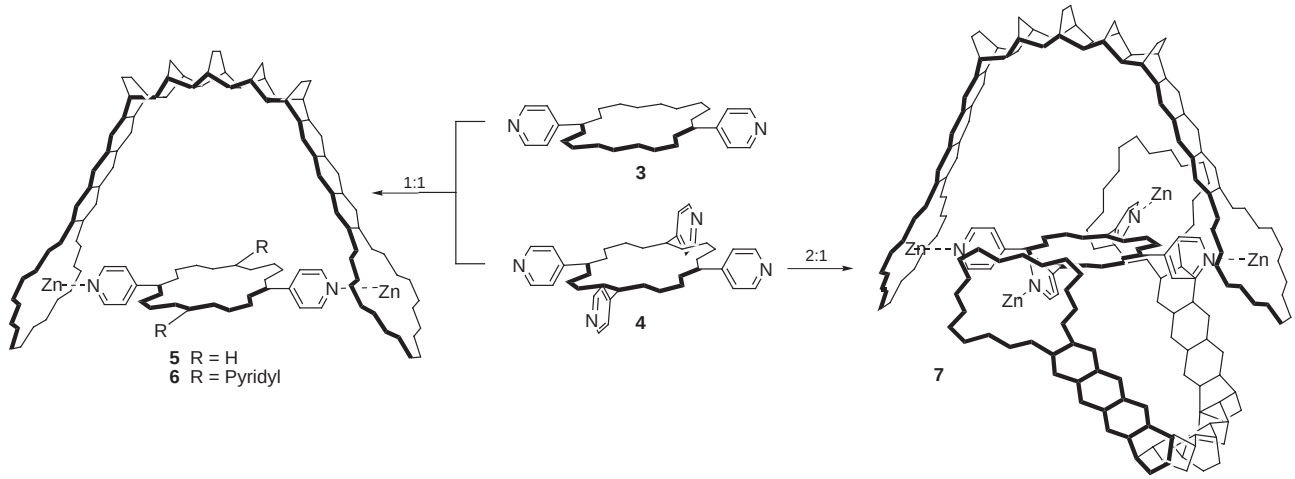

Scheme 1

resonances for **2** and, surprisingly, only a single resonance for **4**, the pyrrole NH (δ −3.77, $\Delta\delta$ −0.89 ppm). The resonances for the protons of the norbornyl backbone of cavity molecule **2** are again only slightly affected by the addition of **4** (*ca*. $\Delta\delta$ 0.04 ppm), but the fact that those on the inside face of the backbone are most affected is consistent with the formation of an internal 1:1 complex. Cooling this solution to 233 K produced a new set of proton resonances where the resonances for α- and β-protons of **4** now reflect their new complexed environment. Two unique sets of resonances for the pyridyl ring protons were observed with the most shielded set occurring at δ 3.19 ($\Delta\delta$ −5.9 ppm) and 6.35 ($\Delta\delta$ −1.8 ppm).

The second set of pyridyl ring protons for **4** in the 1:1 complex **6** are less shielded (*viz*. α $\Delta\delta$ −0.2 ppm, β $\Delta\delta$ −0.49 ppm) from the resonances of uncomplexed **4** and this smaller shift is consistent with the uncoordinated pyridyl groups being in a complexed environment such as **6**. Saturation transfer experiments revealed that the two sets of pyridyl ring proton resonances undergo rapid exchange. The above data support **4** being complexed within the cavity of **2** yet with an uncoordinated environment for the second set of pyridyl rings, as illustrated in Scheme 1. The formation of the 1:1 complex in solution is consistent with electrospray mass spectrometry of the complex, which yielded peaks for **6** (*m/z* 1837 $[M + 2H]^{2+}$).

We were intrigued by the possibility of encapsulating the tetratopic guest **4** within two of the ditopic host units **2**. ^{1}H NMR examination at 303 K of a solution containing a 2:1 ratio of **2** to **4** revealed a similar situation to the 1:1 case, *i.e*. complete absence of any resonances for **4** except for the pyrrole NH resonance (δ −4.05 $\Delta\delta$ −1.17 ppm) and small but significant changes for the resonances of **2** (*ca*. $\Delta\delta$ 0.09 ppm). Cooling the solution to 233 K again yielded new resonances derived from guest **4**, *i.e*. two sets of resonances for the pyridyl protons of **4**, but now both sets of resonances indicate porphyrin coordination ($\Delta\delta$ α −5.76, −6.17 and β −1.67, −2.99 ppm). Furthermore, two resonances were observed for the β-pyrrole resonances of **4** in **7** compared to a single resonance for uncomplexed **4**.

We interpret these data as follows. The two α- and β-pyridyl proton resonances are a result of the assymmetry enforced by the horizontal and rotationally rigid positioning of **4** within **7**. The two β-pyrrole resonances can result from either of two effects, (a) the formation of a distorted complex (Scheme 1) where the complexation of the second equivalent of **2** is forced to adopt an eccentric position owing to the steric interactions between the *tert*-butyl substituents on the porphyrin subunits¶ and where the subunits are reciprocating slowly on the NMR timescale, or (b) the result of slow NH tautomerism in the central free-base porphyrin unit, with fast exchange between the two possible eccentric conformations of **7**.‖ We also note that free-base **2** shows evidence of NH tautomerism at similar low temperatures. In either case, the result is an intriguing arrangement resembling a molecular scale mechanical universal joint.

The concept of organising two host molecules around a central template has been successfully employed by others to create enclosed molecular environments.[5,6] The ability of **2** to act as a host for other porphyrinic guests opens the way for non-covalent positioning of photoactive components and such studies are underway in our laboratories.

Notes and references

† Crossley *et al*. have recently reported the first 2:1 complex involving the self-assembly of rigid bisporphyrins (2 equiv.) using a flexible tetratopic amine (ref. 5).

‡ This complex also bears some resemblance to the topology of the Rebek 'ball-like' molecules, although the latter assemble independently of guest inclusion in contrast to the templated assembly described here (ref. 6).

§ The synthesis of the dipyridylporphyrin rod **3** was achieved by the acid-catalysed condensation of 3,3′-diethyl-4,4′-dimethyldipyrromethane and pyridine-4-carbaldehyde followed by oxidation with chloranil (ref. 9).

¶ Such an off-centre arrangement is also supported by molecular modelling.

‖ We thank the referee for suggesting this alternative. Experiments are currently underway to differentiate between (a) and (b).

A strong-base induced [4+2] cycloaddition of homophthalic anhydrides with enolizable enones: a direct and efficient synthesis of *peri*-hydroxy aromatic compounds

Namakkal G. Ramesh, Kiyosei Iio, Akiko Okajima, Shuji Akai and Yasuyuki Kita*

Received (in Cambridge, UK) 11th September 1998, Accepted 28th October 1998

A direct and efficient synthesis of *peri*-hydroxy aromatic compounds *via* a strong-base induced [4+2] cycloaddition of homophthalic anhydrides with α-phenylsulfinyl enolizable enones has been accomplished.

In the past two decades, considerable effort has been devoted to the synthesis of biologically important polycyclic *peri*-hydroxy aromatic compounds which include anthracyclines,[1] fredericamycin A,[2] granaticin,[3] bostrycin,[4] olivin[5] and other polycyclic antibiotics. Among the methods known for the construction of the key *peri*-hydroxy aromatic frameworks,[6] the strong-base induced [4+2] cycloaddition reaction of homophthalic anhydrides to dienophiles[7] continues to dominate, due to the generality and efficiency of the reaction as well as ready accessibility of the starting materials. An added advantage is the direct synthesis of *peri*-hydroxy compounds in a single step. The applicability of this methodology has already been realized in the total synthesis of a variety of natural products such as anthracyclines,[1i,8] galtamycinone[9] and dynemicin A.[10] However, all these examples utilize non-enolizable dienophiles such as quinone-type compounds or α,β-unsaturated esters.[7b] On the other hand, the strong-base induced reaction of homophthalic anhydride with enolizable enones such as cyclohex-2-en-1-one or its β-substituted derivatives did not give any of the cycloaddition products[7b] although in some cases the expected product was obtained in low yield.[11] This is probably due to extensive enolization under the basic reaction condition, which might in turn retard the cycloaddition step.

Since the discovery of this reaction by us in 1982,[7a] we have been engaged in developing its variants and utilizing this methodology for the synthesis of natural compounds. We have now extended this reaction to enolizable enones. We reasoned that the aforesaid problem could be readily overcome by the introduction of a suitable functional group at the α-position of the enone moiety which should be electron deficient in order to increase dienophilicity and should also behave as a leaving group, to provide directly the *peri*-hydroxy aromatic compounds.

A number of functional groups such as Br, SPh, S(O)Ph, SO_2Ph were considered and among them, the sulfinyl group, which fulfils the above-mentioned criteria, was found to be the substituent of choice. Here we report an efficient, strong-base induced [4+2] cycloaddition of various homophthalic anhydrides with α-sulfinyl substituted enones providing directly the *peri*-hydroxy aromatic compounds in moderate to good yields.

The homophthalic anhydrides **1a**–**d** were prepared according to the reported method.[7] The strong-base induced reaction of homophthalic anhydride **1a** with 2-phenylsulfinylcyclopent-2-en-1-one **2a** was investigated in detail in order to optimize the reaction conditions. Similar to our earlier work,[7d] we have found that NaH is more suitable than other bases (Bu^{t}OK, LDA *etc*.). As can be seen from Table 1, among the various sets of reaction conditions tried, use of 1.1 equiv. of NaH in refluxing dioxane was adjudged the best, affording after acylation the *peri*-hydroxy compound as its acetate **3a** in good yield. In a typical experiment, to a slurry of NaH in dry dioxane was added a solution of homophtahlic anhydride **1a** in dioxane. The resulting slurry was stirred at room temperature for 30 min and then for 20 min each at 80 °C and 120 °C (bath temperature). Enone **2a** was then added and the reaction mixture was stirred for 20 min., cooled, quenched with aq. NH_4Cl and extracted with EtOAc. The crude reaction mixture, after evaporation of the solvent, was treated with Ac_2O and pyridine and left overnight at room temperature. Column chromatography afforded the *peri*-hydroxy aromatic compound as its acetate **3a**. Subsequently, all the reactions were performed using the same conditions, except for the final reaction time.

This base catalyzed [4+2] cycloaddition reaction was found to be general for a range of substituted homophthalic anhydrides **1a**–**d** as well as with different sulfinyl substituted enones **2a**–**e**, including that having an acetal functional group, affording the respective products in moderate to good yields (Table 2). Noteworthy is the success of the reaction with acyclic enone **2e**, which is a rewarding result given the report that no reaction was observed between homophthalic anhydride and methyl but-2-enoate.[11a] It is highly relevant that the reactions of homophthalic anhydrides **1a** and **1b** with cyclohex-2-en-1-one and cyclopent-2-en-1-one were not successful. The reactions under identical conditions resulted only in complex mixtures and no useful product could be isolated, indicating the possibility of a base-induced enolization in these cases. Thus, it is clearly evident that the sulfinyl group present at the α-position of the enone moiety plays an important role in directing the course of the reaction. Furthermore, the highlight of the reaction is the rapid *syn*-elimination of the phenylsulfinyl moiety under the reaction conditions, a unique characteristic of this functional group,[7d] providing directly the *peri*-hydroxy aromatic compounds in a single step. The advantages of the sulfinyl group are emphasized by the fact that the strong-base induced reaction of homophthalic anhydride with 2-bromocyclohex-2-en-1-one was not successful. Reaction of **1a** with 2-bromocyclohex-2-en-1-one, under identical conditions for 7 h, afforded after acylation acetate **3e** in only 7% yield with the recovery of a large amount of unreacted bromocyclohexenone. Use of an additional equivalent of base (2.2 equiv.) in order to bring about the *trans*-elimination of HBr from a possible non-aromatized cycloadduct, did not lead to any significant improvement in the yield. The reaction afforded, after 3 h, the acetate **3e** in only 10% yield.

The generality and efficiency of the reaction, ready availability of the starting materials coupled with the unique activating as well as leaving ability of the sulfinyl group renders this method an attractive one for the synthesis of *peri*-hydroxy aromatic compounds using enolizable enones. The application of this methodology for the synthesis of natural products is in progress and will be reported in a forthcoming paper.

Synthesis of extended α,α′-oligo(silylthiophenes) by cerium(IV) oxidative coupling reactions

Ali H. Mustafa and Michael K. Shepherd*

School of Biological and Applied Sciences, University of North London, UK N7 8DB. E-mail: m.shepherd@unl.ac.uk

Received (in Liverpool, UK) 21st August 1998, Accepted 9th November 1998

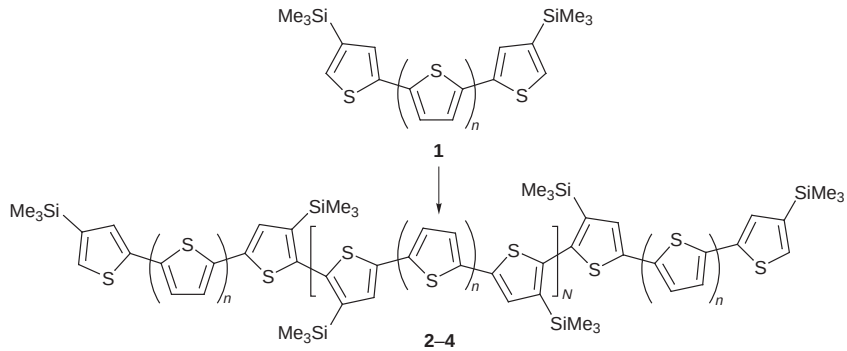
Cerium(IV) oxidative dimerisations of 4,4′-bis(trimethylsilyl)-2,2′:5′,2″-terthiophene and the quaterthienyl analogue 1c gave the corresponding sexi- and octi-thiophenes; the latter have been used to prepare α-linked hexadecithiophene and tetracosithiophene derivatives.

The extreme insolubility of extended oligothiophenes renders purification and spectral analysis increasingly difficult for unsubstituted systems containing more than six α-linked thiophene units. Only two literature citations can be found for oligomers beyond octithiophene, namely decithiophene, obtained by electrochemical oxidation of quinquithiophene and characterised by absorption spectra in the solid state,[1] and dodecithiophene, identified as an impurity in crude samples of octithiophene by mass spectroscopy.[2] Oligo(alkylthiophenes) bearing long-chain β-substituents are much more soluble, and derivatives containing up to sixteen rings have been characterised.[3–5] The longest of these, an octadodecylhexadecithiophene, was obtained in 19% yield after coupling of the corresponding lithiooctithiophene with $CuCl_2$.[5] We reasoned that silylated oligomers should be soluble enough to aid purification and, *via* electrophilic displacement of silicon, subsequently afford straightforward access to the unsubstituted analogues and other derivatives required for physical studies. We describe here our results to date, culminating in the isolation of the twentyfour-ring dodecakis(trimethylsilyl)tetracosithiophene **4d**, the longest oligomer yet reported.

We obtained β,β-disilylated thiophenes **1b–e**† by the $NiCl_2$(dppp)-catalysed couplings[6] of 2 equiv. of the Grignard reagent prepared from 2-bromo-4-trimethylsilylthiophene‡ with 2,5-dibromothiophene, 5,5′-dibromo-2,2′-bithiophene, 5,5′-dibromo-2,2′:5′,2″-terthiophene and 5,5‴-dibromo-2,2′:5′,2″:5″,2‴-quaterthiophene,‡ respectively. The yields increase on moving from **1b** to the quinquithienyl **1d**, but the very low solubility of both the sexithienyl **1e** and the dibromoquaterthienyl precursor rendered this route impractical for the preparation of oligomers containing more than five rings.

To circumvent this problem we turned our attention to coupling the readily-soluble quaterthienyl **1c**. We were encouraged by the observation that aged thin-layer chromatograms of **1c** showed progressive formation of a lower R_f component on re-elution. This was attributed (and subsequently confirmed by comparison with pure samples) to photo-oxidation of **1c** to the dimer **4a** on the silica surface. A reaction of **1c** with ceric ammonium nitrate gave moderate yields (*ca.* 15%) of **4a**, the major product being 3,4‴-bis(trimethylsilyl)-5-nitro-2,2′:5′,2″:5″,2‴-quaterthiophene (43%). When using ceric ammonium sulfate as the oxidising agent the octithiophene **4a** was isolated in up to 66% yield,§ with varying amounts of the dodecithiophene **4b** (4–7%) and hexadecithiophene **4c** (0.5–2%) as byproducts (Scheme 1). The high yield of dimer obtained under these conditions is surprising, bearing in mind that oxidation potentials for these systems should be inversely related to the size of the oligomer.[6,7] Cerium(IV) sulfate oxidations were more rapid, but the relative proportions of **4b**,**c** and other higher molecular weight products increased with respect to **4a**. The oligomers **4a–c** are bright yellow crystalline solids which exhibit intense greenish fluorescence in dilute solution. The UV–VIS absorption spectra show only a small bathochromic shift on moving from **1c** (λ_{max} 389 nm) to **4c** (λ_{max} 419 nm), in contrast to the n-dodecyl derivatives,[5] which move from yellow (λ_{max} 379 nm) to violet (λ_{max} 464 nm) along the same sequence. In our series, the closer proximity of the bulky silyl substituents to the point of coupling presumably leads to a higher degree of twisting about every fourth α,α′-linkage, reducing through-conjugation. This may be fortuitous—levelling the oxidation potentials of these systems and hence suppressing their tendency to polymerise.

Coupling of the terthiophene **1b** under conditions as described above gave the sexithiophene **3a** (48% yield) and the nonithiophene **3b** (11%) as major products,¶ along with higher oligomers. This reaction proved more sluggish than that above, probably as a consequence of the higher energy of the terthienyl cation radical intermediate. A reaction of 4-trimethylsilyl-2,2′:5′,2″-terthiophene resulted in coupling in even lower yield



1a *n* = 0

Scheme 1

(8%), between the two α-positions adjacent to the β-silyl group; the sexithiophene **1e** and its 4,3‴-disilyl isomer were not detected. These observations are in line with a recent study on the stabilising effect of progressive β-methylation on cation radicals derived from 5,5′-dimethyl-2,2′-bithiophene.[8] Attempts to dimerise 4,4′-bis(trimethylsilyl)-2,2′-bithiophene **1a** to **2** in like manner resulted in quantitative recovery of the starting material.

The octithiophene **4a** oligomerised on reaction with cerium(IV) sulfate in 1,2-dichloroethane at room temperature to give the sexadecithiophene **4c** (35% yield), the tetracosithiophene **4d** (11%), and a mixture of higher oligomers (*ca*. 20%) after column chromatography on silica. The dotriacontithiophene **4e** appears to be the major constituent of the residue, corroborated by TLC studies of dimerisation attempts using **4c**, but we have not yet been able to isolate pure samples. The relative insolubility of the higher oligomers of **4** has prevented preparative separation by chromatography, while the more soluble analogues **3** are not satisfactorily resolved beyond **3b**. We anticipate that replacement of either or both trimethylsilyl substituents in **1c** by more lipophilic alkylsilyl groups should circumvent this problem and ultimately, *via* protodesilylation, enable preparation of the parent systems. Preliminary studies indicate that compounds **3a** and **4a** give quantitative yields of analytically pure sexithiophene and octithiophene respectively, on treatment with TFA in CH_2Cl_2.

Notes and references

† New compounds have been characterised by spectroscopic and microanalytical data.

‡ Prepared by bromination of the appropriate disilyl derivative: NBS, aq. THF, 0 °C.

§ Preparation of **4a**: Finely ground cerium ammonium sulfate (10.5 g) was added in portions over *ca*. 6 h to a stirred solution of **1c** (3.0 g) in C_6H_6 (40 cm^3). The resulting suspension was stirred at room temperature for *ca*. 30 h, the solvent removed under reduced pressure, and the solid residue extracted with pentane (100 cm^3). The extract was chromatographed directly on silica (the column should be shielded from light) eluting with pentane to give unreacted **1c** (0.72 g). Further eulution with 4% CH_2Cl_2 in pentane gave **4a** (1.87 g, 62%, 82% based on consumed **1c**), bright yellow crystals, mp 147–149 °C (Found: C, 55.9; H, 5.3. $C_{44}H_{50}S_8Si_4$ requires C, 55.8; H, 5.3%); δ_H(250 MHz, $CDCl_3$) 7.29 (2 H, d, α-H, A,H-rings), 7.20 (2 H, d, β-H, A,H-rings), 7.13 (2 H, s, D,E-rings), 7.08 (8 H, m, B,C,F,G-rings), 0.29 (18 H, s, $SiMe_3$, A,H-rings), 0.17 (18 H, s, $SiMe_3$, D,E-rings); δ_C 130.8, 129.3, 128.3, 124.7, 124.6, 124.3, 124.2 (C-H), 143.7, 143.2, 140.6, 137.9, 137.8, 136.4, 136.1, 135.8, 135.6 (quaternary carbons), 0.6, −0.7 (CH_3); *m/z* (LSI) 947 $(M + 1)^+$ (100%). Further gradient elution up to 25% CH_2Cl_2 in pentane gave **4b** (125 mg, 4%), followed by **4c** (14 mg, 0.5%) and a mixture of higher oligomers (15 mg).

¶ The yields for coupling reactions of **1b** and **4a** have not been optimised, and do not take into account recovery of the precursors.

Received (in Cambridge, UK) 5th October 1998, Accepted 12th November 1998

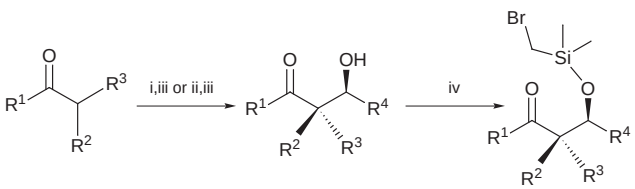
A new SmI_2-promoted intramolecular reductive cyclization of β-(α-bromo siloxy) carbonyl compounds is reported.

In the last decade, SmI_2 has become one of the most developed reagents in organic synthesis due to the oxophilicity of samarium metal and its powerful one election donor reactivity with various functional groups.[1] Reductions, reductive cyclizations or coupling reactions using SmI_2 have been intensively studied. In particular, intramolecular reductive cyclizations have brought noticeable results in the formation of highly functionalized carbocycles[1,2] and heterocycles.[1,3] Barbier type reactions,[1c,4] Reformatsky type reactions,[1c,5] pinacolic coupling reactions[1c,6] and ketone-olefin coupling reactions[1b,c,7] have been investigated for intramolecular reductive cyclization. Aryl radical cyclization,[8] halide induced cyclization,[1b,c,9] and sequence cyclization[1a,10] have also been reported. Of these reactions, Barbier type reactions give excellent results for cyclization with high stereoselectivity.[1c]

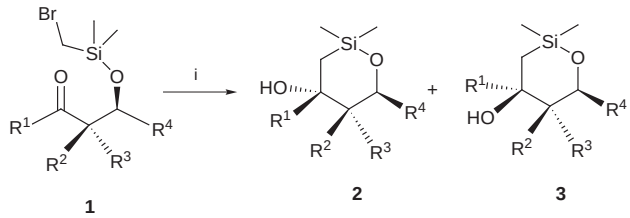
Intramolecular cyclizations of β-(α-bromo siloxy) alkenes or alkynes or vinyl bromo siloxy derivatives *via* a free radical process by treatment with Bu_3SnH gave various useful cyclic silyl ethers[11] with high degrees of regio-, chemo- and stereoselectivity; the reaction products are potentially useful intermediates which can be converted to triols by Tamao oxidation.[12]

Although many attempts have been made to construct functionalized carbocycles or heterocycles by ring closure of a ketyl radical or anion with a ketene or alkyne, there is no reported example of radical or anion cyclization of β-(α-bromo siloxy) carbonyl derivatives mediated by SmI_2. Matsuda and co-workers examined cyclization of β-(α-bromo siloxy) carbonyl derivatives in sugar moieties, and demonstrated that no cyclization occurred.[13]

We were intrigued by the possibility of another Barbier type reaction, this time with β-(α-bromo siloxy) carbonyl substrates using SmI_2. The β-(α- bromo siloxy) carbonyl substrates were prepared *via* two steps as shown in Scheme 1. The ketones were condensed with aldehydes or ketones under typical aldol conditions.[14] For the preparation of α-substituted aldol products, Bu^n_2BOTf was used and the *erythro* product was obtained as the major product. The resulting β-hydroxy ketone was treated with bromomethyl(dimethyl)chlorosilane in the presence of pyridine at 0 °C to provide the desired product **1** in excellent yields as shown in Scheme 1. Their structures were identified by ^1H and ^{13}C NMR and mass spectroscopy.



Scheme 1 *Reagents and conditions*: i, LDA, THF, −78 °C; ii, Bu^n_2BOTf, Pr^i_2NEt, THF, −78 °C; iii, R^4CHO, −78 °C; iv, $ClMe_2SiCH_2Br$, pyridine, CH_2Cl_2, 0 °C.



Scheme 2 *Reagents and conditions*: i, SmI_2 (2 equiv.), HMPA (4 equiv.), THF, −78 °C.

Here we describe a new intramolecular reductive cyclizations of β-(α-bromo siloxy) carbonyl compounds **1** with SmI_2 in the presence of HMPA to **2**, as shown in Scheme 2.

In order to generalize the cyclization of β-(α-bromo siloxy) carbonyl substrates, both acyclic (**1a–j**) and cyclic substrates (**1k–n**) were subjected to the cyclizations under the optimized reaction conditions [SmI_2 (2.2 equiv.), HMPA (4 equiv.), THF, −78 °C]. The results obtained are summarized in Table 1.

Formation of two stereoisomers is possible; one is the *syn* isomer, which has the R^3 and OH groups pointing in the same direction, and the other is *anti* isomer, which has the R^3 and OH groups pointing in opposite directions. As a result the *syn* isomer **2** was obtained together with trace amount of the *anti* isomer **3**. The configuration of **2** (**2f**) was identified by ^1H and ^{13}C NMR and NOE experiments (Fig. 1) and mass spectroscopy. The *syn* isomer conformation obtained could be explained by steric hindrance in the transition state. In the four possible transition states, conformation **A** seems to be the most favorable due to steric effects, as suggested by Molander.[9]

In the absence of HMPA, the yield of **2** is low and desilylated aldol products were obtained as the major product. *Erythro* or *threo* cyclohexanone substrates gave the corresponding *erythro* or *threo* products respectively in good yields. The substrate **1d** gave the desired cyclized product **2d** (44%) together with olefin

Table 1 Cyclization of siloxy derivatives using SmI_2[a]

Substrate	R^2	R^1	R^3	R^4	*t*/min	Ratio **2**:**3**	Yield (%)[b]
1a	H	Ph	H	Et	10	> 99:1	61
1b	H	Ph	H	Pr	15	> 99:1	75
1c	H	Me	H	Pr	30	> 99:1	72
1d	H	Pr^i	H	Pr	30	> 99:1	44[c]
1e	H	Me	H	c-Hex	30	> 99:1	57
1f	Me	Et	H	Ph	30	95:5	65 (15)[d]
1g	Me	Et	K	Pr	30	90:10	67
1h	Me	Et	H	Bu^t	30	95:5	62
1i	Me	Ph	H	H	15	92:8	71
1j	Me	Ph	H	Ph	10	95:5	35
1k	$-(CH_2)_4-$		H	Ph	10	> 99:1	74
1l	H		$-(CH_2)_4-$	Ph	10	> 99:1	69
1m	$-(CH_2)_3-$		H	Ph	10	> 99:1	80
1n	$-(CH_2)_3-$		H	Et	30	> 99:1	63

[a] All reactions were carried out using SmI_2 (2.2 equiv.) in THF and HMPA (4 equiv.) at −78 °C. [b] Isolated yields. [c] Eliminated olefin was obtained in *ca.* 20% yield. [d] The reaction was carried out in the absence of HMPA.

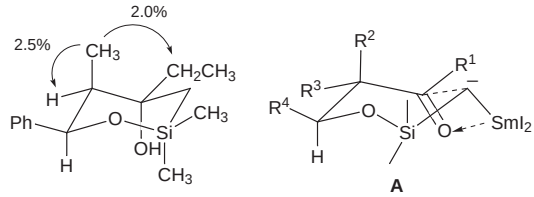


Fig. **1** NOE correlations of β-hydroxy cyclic silyl ether.

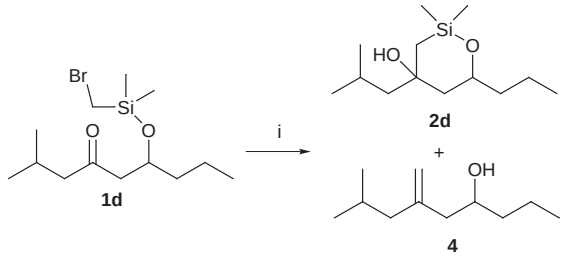
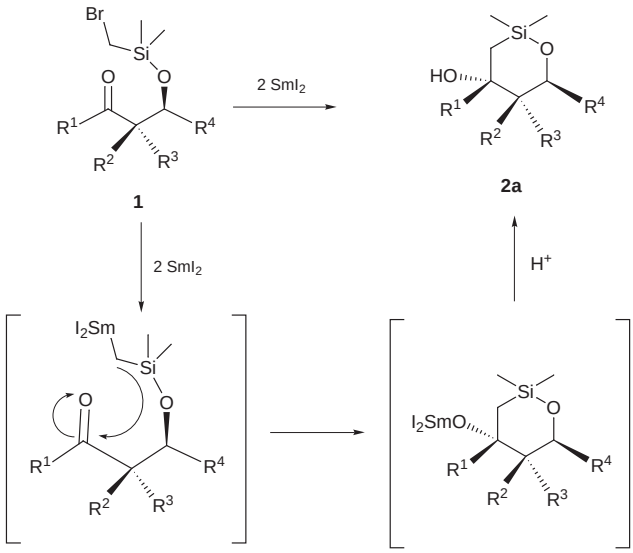


Scheme 3 *Reagents and conditions*: i, SmI_2 (2.2 equiv.), HMPA (4 equiv.), THF, −78 °C.

4 (20%) which is formed by elimination of the siloxy moiety as shown in Scheme 3.

In the reaction mechanism, there are two possible process; a radical–radical coupling process and a samarium Grignard-type anion process (Scheme 4). In the radical–radical coupling reaction, 2 equiv. of SmI_2 generates both a ketyl radical and an alkyl radical which couple each other. On the other hand, the organosamarium Grignard-type species, which could be generated from an alkyl radical by one more electron transfer from SmI_2, could add to the carbonyl group. Since the reactivity of primary alkyl bromides with SmI_2 is higher than that of carbonyl groups, it can be considered that the organosamarium Grignard-type process is more favorable.



Scheme 4

The α-effect of the silicon moiety may also help to promote the organosamarium pathway. Most of the reactions gave the reduced aldol products in *ca*. 20% yield as a side product. Formation of the aldol side product also supports the organosamarium pathway. If the reaction occurs *via* a diradical pathway, the carbonyl moiety might be reduced to a β-OH moiety. However, only the desilylated aldol products (up to 20%) were obtained and confirmed.

Synthesis and characterization of a novel bipolar polymer for light-emitting diodes

Yunqi Liu, Hong Ma and Alex K-Y. Jen*

Department of Chemistry, Northeastern University, 360 Huntington Avenue, Boston, Massachusetts 02115, USA. E-mail: ajen@lynx.neu.edu

Received (in Cambridge, UK) 14th October 1998, Accepted 10th October 1998

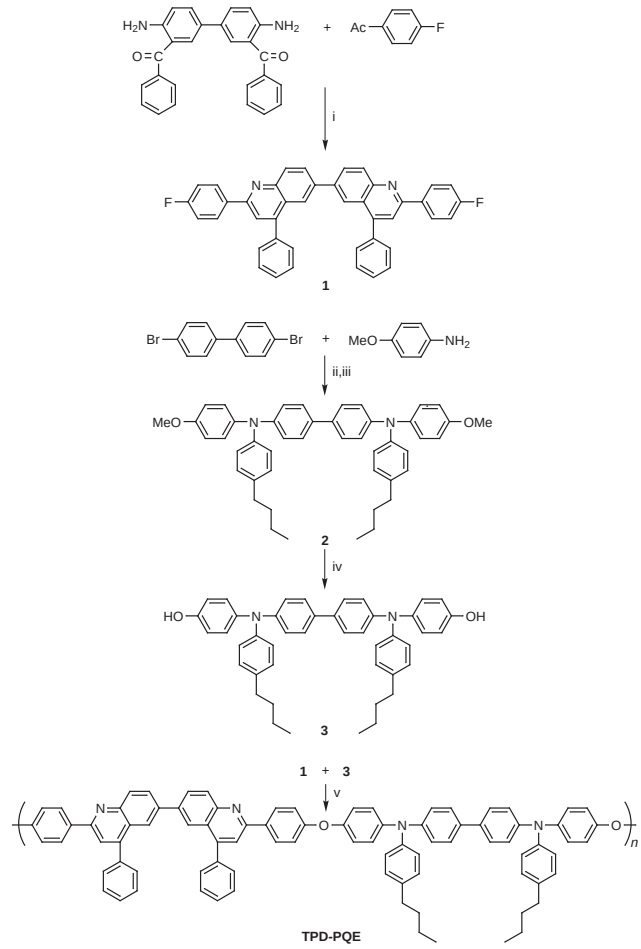
A novel bipolar light-emitting polymer containing both efficient hole and electron injecting/transporting segments exhibiting high thermal stability (T_d = 445 °C), good electrochemical reversibility, excellent thin film-forming and light-emitting properties (bright yellow emission, a rectification ratio greater than 10^5 and a low turn-on voltage of 3.7 V) is reported.

For most of the conjugated polymers that are reported in the literature, the hole injection/transport is more favorable than the electron injection/transport due to the electron-richness of the π-conjugated systems. To facilitate the electron injection, metals with low work functions, such as calcium and magnesium, have been used as cathodes. However, the stability of the resulting devices is severely compensated for by the sensitivity of these metals to both oxygen and moisture. To circumvent these problems, several approaches have been utilized, such as synthesizing highly electron-affinitive polymers,[1] inserting an additional electron injecting/transporting layer between the emitter and the cathode[2] and blending small molecules into the polymer matrix.[3] Although some success has been achieved, several deficiencies are associated with these methods. For example, more tedious and complex multilayer structures were needed to offset the poor hole injection of the highly electron-affinitive polymers for achieving high device efficiency. In addition, phase separation often occurs when the dopant concentration is high. Recently, Bao *et al*.[4] reported the results of light-emitting polymers containing both electron and hole transporting moieties that achieved efficient device performance. Thus, it is desirable to design and synthesize a bipolar polymer that possesses both a hole injecting/transporting segment and an electron-affinitive segment in order to enhance the charge injecting/transporting ability. Polyquinolines (PQs) are a class of heteroaromatic polymers that possess excellent thermal stability, good thin film processibility, high electron affinity and unique nonlinear optical properties.[5,6] A blue electroluminescent (EL) device using a fluorinated polyquinoline (PQ-100) as the emitting layer has been reported that possessed a very high turn-on voltage (50 V) due to difficulties achieving efficient/balanced charge injection.[7] On the other hand, tetraphenyldiaminobiphenyl (TPD) has been widely used as an excellent hole-transport material in fabricating small molecule EL devices.[8] In the hope of combining both the blue light-emitting and good electron-affinitive properties of the bisquinoline and the efficient hole-injecting/transporting properties of the TPD into a single bipolar material to enhance the overall performance of an EL device, we have copolymerized these two functional moieties *via* a nucleophilic replacement reaction/polycondensation. Here we report the excellent thermal, electrochemical and EL results obtained from this polymer.

The synthesis of the copolymer (TPD-PQE) is outlined in Scheme 1. Compound **1** was synthesized (80% yield) from 4,4′-diamino-3,3′-dibenzoyldiphenyl ether and 4-fluoroacetophenone.[9] Compound **2** was synthesized (50% yield) from the modified Buchwald coupling reaction[10,11] between 4-anisidine and 4,4′-dibromobiphenyl in the presence of tris(dibenzylideneacetone)dipalladium [$Pd_2(dba)_3$], 1,1′-bis(diphenylphosphino)ferrocene (dppf) and NaOBu^t, followed by the addition of 1-bromo-4-butylbenzene and additional NaOBu^t. Compound **3** was obtained (72% yield) from **2** by a demethylation reaction.[12] Polymerization between **1** and **3** was carried out in the presence of K_2CO_3 in a NMP–toluene solvent mixture.[13] The resulting viscous polymer solution was precipitated into MeOH, followed by Soxhlet extraction with MeOH to afford polymer **4** (78% yield). The chemical structures of monomers and polymer were confirmed by ^{1}H NMR and elemental analyses.

TPD-PQE was a pale-grey fibrous solid. As a result of the two n-butyl groups attached on the TPD moiety, the TPD-PQE was readily soluble in common organic solvents, such as $CHCl_3$, THF and cyclopentanone. The weight average molecular weight (M_w = 58400 with a polydispersity index of 5.76) was determined by gel permeation chromatography using THF as eluent and polystyrene as standard.

The thermal properties of TPD-PQE were determined by thermal gravimetric analysis (TGA) and differential scanning



Scheme 1 *Reagents and conditions*: i, conc. H_2SO_4, AcOH; ii, $Pd_2(dba)_3$, dppf, toluene, NaOBu^t, 90 °C; iii, 4-BrC_6H_4Bu, NaOBu^t; iv, $BBr_3{\cdot}SMe_2$, $ClCH_2CH_2Cl$; v, K_2CO_3, toluene, NMP.

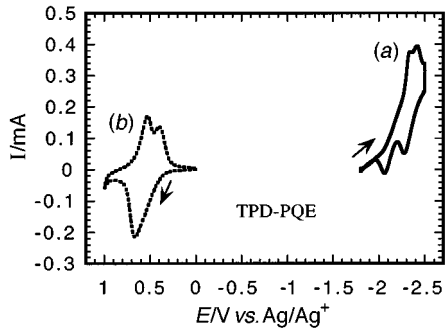


Fig. 1 Cyclic voltammetry of TPD-PQE spun-coated on ITO glass in an MeCN solution of TBAP (0.1 M) at a scan rate of 40 mV s^{-1}: (*a*) reduction and (*b*) oxidation.

calometry (DSC). The TPD-PQE possessed excellent thermal stability with a glass transition temperature (T_g) of 196 °C, and a T_d (onset of the decomposition temperature) of 445 °C.

The energy levels of TPD-PQE were investigated by cyclic voltammetry (CV). A thin film of the polymer was spin-coated onto pre-cleaned indium-tin-oxide (ITO) glass as a working electrode (~3 cm^2) from a cyclopentanone solution (concentration ~ 3 mg ml^{-1}). The reference and counter electrodes were Ag/Ag^+ (non-aqueous) and Pt gauze, respectively. The experiment was carried out under nitrogen with tetrabutylammonium perchlorate in anhydrous MeCN (TBAP, 0.1 M) as the supporting electrolyte. A typical CV curve is shown in Fig. 1. Two redox-active moieties were revealed for the copolymers. It is worth pointing out that the oxidative (*p*-doping) process was highly reversible and the reductive (*n*-doping) process was quasi-reversible for TPD-PQE. As a matter of fact, such a bipolar ability is beneficial to the performance of LEDs. The energy values of the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO) for TPD-PQE were calculated using the ferrocence (FOC) value of −4.8 eV below the vacuum level.[14] The onset potentials of oxidation and reduction of TPD-PQE (Fig. 1) were determined as +0.39 and −2.07 V *vs.* Ag/Ag^+, corresponding to +0.27 and −2.19 V *vs.* FOC (EFOC = 0.12 V *vs.* Ag/Ag^+). Thus, the HOMO and LUMO levels and the HOMO–LUMO gap should be −5.07, −2.61 and 2.46 eV, respectively. The optical E_g calculated from the onset (426 nm) of the UV–VIS absorption spectra of the spin-coated films for TPD-PQE was 2.91 eV.

To fabricate LED devices, copper phthalocyanine (CuPc), tris(8-hydroxyquinoline)aluminium (Alq_3) and Al layers were evaporated in a vacuum (10^{-6} Torr). Thin films of poly(9-vinylcarbazole) (PVK) and TPD-PQE were spin-coated from a 1,2-dichloroethane solution and from a $CHCl_3$ solution, which were filtered through a 0.2 μ Teflon filter before spin-coating. Three types of LEDs with the structure of ITO/CuPc/TPD-PQE/Al (**A**), ITO/PVK/TPD-PQE/Alq_3/Al (**B**) and ITO/TPD-PQE/Alq_3/Al (**C**) were employed in this study. The thickness of the TPD-PQE was the same (~35 nm) for all three types of LEDs, while the thickness of CuPc, PVK, Alq_3 and Al were ~35, ~40, ~50 and ~100 nm, respectively. The active area of the resulting devices was 7.07 mm^2. All of the fabrication processes

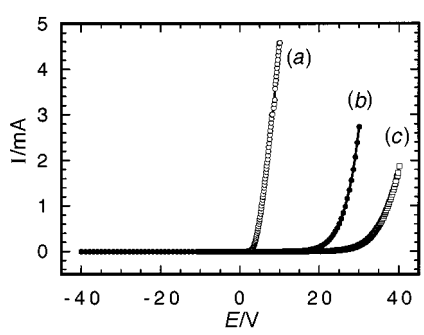

Fig. 2 Current–voltage characteristic for the light emitting devices. (*a*) ITO/CuPc/TPD-PQE/Al **A**, (*b*) ITO/PVK/TPD-PQE/Alq3/Al **B** and (*c*) ITO/TPD-PQE/Alq3/Al **C**.

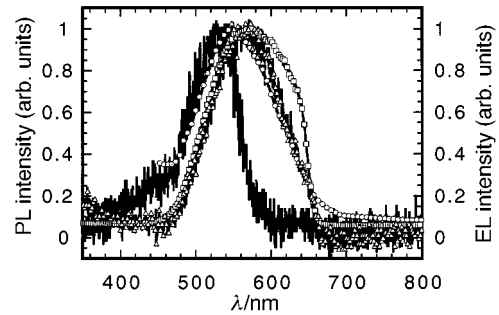

Fig. 3 (○) Photoluminescence spectrum of TPD-PQE and electroluminescence spectra of (—) ITO/CuPc/TPD-PQE/Al **A**, (□) ITO/PVK/TPD-PQE/Alq3/Al **B** and (△) ITO/TPD-PQE/Alq3/Al **C**.

(except for vacuum evaporation) and measurements were performed in air and at room temperature.

Fig. 2 shows the current–voltage characteristics of the LEDs. Excellent diode behavior was found for these devices. The turn-on voltage and rectification ratio were determined to be 3.7 V, and 5.1×10^4 (at 4.5 V) for **A**, 21.0 V and 4.2×10^5 (at 30.0 V) for **B**, and 30.1 V and 6.0×10^4 (at 36.0 V) for **C**, respectively. It is worth noting that, for these devices using PVK or CuPc as hole injecting/transporting layers, the turn-on voltages were decreased, while using Alq_3 as an electron injecting/transporting layer, the turn-on voltages were increased. This indicated that the TPD-PQE polymer has a good electron injecting/transporting ability. When the hole injecting/transporting (PVK or CuPc) layers were introduced, the overall charge injection/transport of the devices were balanced, which led to the decrease of the turn-on voltages.

Fig. 3 shows the photoluminescence (PL) spectrum of a TPD-PQE film and EL spectra of the LEDs. The PL spectrum of TPD-PQE had an emission peak at 547 nm when it was excited at 366 nm. The EL spectrum from device **A** is blue-shifted (λ_{max} = 530 nm) compared to the PL spectrum of the TPD-PQE. In particular, its long wavelength side became much steeper. This was due to partial absorption by CuPc in the 520–680 nm region.[15] The shape of the EL spectrum from device **C** is similar to the PL spetrum of TPD-PQE, however, it is red-shifted to 568 nm. In the case of device **B**, the EL emission shows a peak at 570 nm with a shoulder at ~620 nm. The shoulder is probably due to emission from aggregates of carbazole groups.[19] Bright light emission can clearly be seen under room light at forward bias for all three types of LEDs.

In conclusion, a bipolar copolymer was synthesized and characterized. This polymer showed high thermal stability, good electrochemical reversibility and excellent thin film-forming ability. In addition, very good LED performance was obtained with a low turn-on voltage, high rectification ratio, and bright light emission.

Received (in Cambridge, UK) 13th October 1998, Accepted 16th November 1998

Catalytic enantioselective addition of (4-trimethylsilylbut-2-ynyl)tributylstannane to aldehydes provides trimethylsilylmethylallenyl alcohols in high enantioselectivity which can be converted with a second electrophile to the corresponding dienyl alcohols.

There is considerable interest in the development of catalytic process utilizing chiral Lewis acids to realize efficient and practical asymmetric syntheses.[1] In previous studies, we have demonstrated that the utilization of molecular synergetic reagents for catalytic asymmetric allylic transfer reactions resulted in not only a significant increase in the reaction rate but also a reduced dosage of chiral catalyst. Our approach involves the use of BINOL–Ti^{IV} complex as a chiral promoter along with Et_2BSPr^i or Me_3SiSPr^i as an accelerating synergetic reagent that has recently shown to provide highly enantioselective versions of allylic transfer reactions of achiral aldehydes such as allylation,[2] propargylation[3] and allenylation.[4] The efficiency of this protocol in terms of enantioselectivity and catalytic ability has encouraged us to apply the extension of this method to more versatile systems which would expand the scope and utility of allylic transfer reactions.[5] Described herein is an extension of the molecular accelerating strategy aimed at finding new reagents and realizing useful and practical ways to advance new levels of asymmetric synthesis. In this study we focus on the addition of a bifunctional reagent to an aldehyde and subsequent attack by a electrophile to form dienyl alcohols. The realization of an efficient method in this reaction should be valuable because many useful functional group transformations can be foreseen for chiral alcohols.[6] In the present research, the following observations were made: (i) (4-trimethylsilylbut-2-ynyl)stannane is effective as a new reagent; (ii) dramatic solvent effects are observed when using $PhCF_3$; (iii) the efficient chemical transformation of homoallenylsilane into dienyl alcohols.

Our initial studies began with 1,4-bis(tributylstannyl)but-2-yne **1** as the allylic transfer reagent, which was prepared from the reaction of Bu_3SnLi (2 equiv.) with 1,4-dichlorobut-2-yne at −78 °C in THF.[7] The chiral catalyst, BINOL–Ti^{IV} complex **3**, was prepared by the reaction of (*S*)-BINOL (BINOL = 2,2′-dihydroxy-1,1′-binaphthol) and $Ti(OPr^i)_4$ (2:1) in the presence of 4 Å molecular sieves at 25 °C for 2 h.[8] Initial reactions of **1** and **2** in the presence of chiral catalyst **3** afforded none of the adduct **5** under various conditions. Fortunately, this lack of reactivity was overcome by introducing synergetic reagent Et_2BSPr^i **4**. Treatment of **1** with **2** (R = $PhCH_2CH_2$) and then **4** in the presence of **3** (10 mol%) at −20 °C for 20 h in CH_2Cl_2 afforded **5** along with undesired **6** in 58% combined yield in a ratio of 2:1 as judged by 500 MHz ^1H NMR analysis of the crude product (Scheme 1). Treatment of **5** with 10% HCl in THF cleanly gave dienyl alcohol **6** without loss of optical purity. Using heptanal as substrate under the same conditions, similar results were obtained but the formation of dienyl alcohol **6** still remained a problem. However, attempts at further conversion with benzaldehyde gave very poor results (< 10% conversion, at −20 °C for 36 h).

The formation of dienyl alcohol **6** from **5** was attributed to the acidic reaction media (Pr^iOH with Ti^{IV} species).† We speculated that the limited scope of the reaction and the side reaction with **1** can be solved by introducing the relatively less bulky and more stable silyl substituent instead of the stannyl group at C-4 on **1**. The new reagent **7**, a crucial compound in the present research, was prepared from propargyltrimethylsilane by the following sequences. Lithiation of propargylsilane with BuLi in THF (−78 °C, 1 h) followed by addition of paraformaldehyde (−78 to −20 °C, 2 h) gave (4-hydroxybut-2-ynyl)silane in 74% yield after distillation.[9] Treatment of (4-hydroxybut-2-ynyl)silane with BuLi at −78 °C for 1 h in THF followed by reaction with TsCl at −78 °C for 1 h and then −20 °C for 2 h gave the corresponding tosylate which used in the next reaction without isolation. Subsequent treatment of the tosylate with Bu_3SnLi at −78 °C for 2 h afforded **7**. Final purification of **7** was effected by distillation (75–82% yield, bp 121–122 °C at 0.4 mmHg).‡ Initial experiments on the allylic transfer reaction of **7** with various aldehydes promoted by **3** along with **4** under similar conditions (−20 °C for 18–24 h in CH_2Cl_2) afforded encouraging but marginal results. Although no or trace amounts (> 30:1) of dienyl alcohols **6** were produced during the reaction, the product yields for **8** ranged from 39 to 72% with 83–92% ee, as indicated in Table 1. After exploring numerous sets of conditions, we were delighted to find that the use of α,α,α-trifluorotoluene ($PhCF_3$) as solvent led to the best results in terms of chemical yields and enantioselectivities.[10] Under optimal conditions, the allylic transfer reaction was carried out according to the following procedure: The red–brown mixture of (*S*)-BINOL–Ti^{IV} complex (10 mol%) was cooled to −20 °C, and **2** (R = $PhCH_2CH_2$) was added. To this mixture was added dropwise **7** (1.2 equiv.) in $PhCF_3$ followed by **4** (1.2 equiv.) in $PhCF_3$ using a gas-tight syringe *via* a syringe pump over 1 h along the wall of the flask while keeping the temperature below −20 °C. After 18 h at −20 °C, the mixture was quenched by the addition of a saturated aqueous $NaHCO_3$. After work up, chromatography on Et_3N treated silica gel gave **8** (R = $PhCH_2CH_2$) in 78% yield with 97% ee. Additional experiments with various aldehydes were carried out and representative

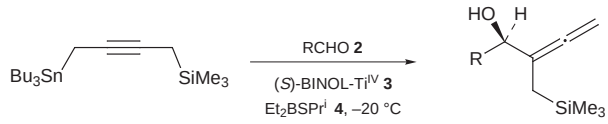
Table 1 Allylic transfer reactions of **7** with achiral aldehydes[ab]



7 **8**

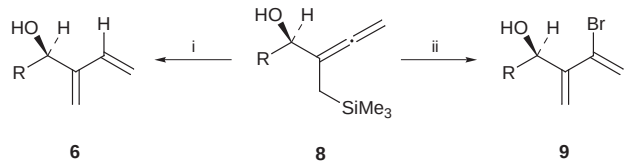
Entry	R	Solvent	*t*/h	Yield (%)[c]	Ee (%)[d]
1	$PhCH_2CH_2$	CH_2Cl_2	18	62	92
2	$PhCH_2CH_2$	$PhCF_3$	18	78	97
3	C_6H_{13}	CH_2Cl_2	18	60	90
4	C_6H_{13}	$PhCF_3$	18	83	97
5	Ph	CH_2Cl_2	24	39	84
6	Ph	$PhCF_3$	24	54	91
7	$Me_3SiC{\equiv}C$	CH_2Cl_2	24	50	83
8	$Me_3SiC{\equiv}C$	$PhCF_3$	24	62	88

[a] All reactions were carried out at −20 °C in indicated solvent. [b] BINOL:Ti(OPr^i)$_4$ = 2:1 (10 mol%). [c] Yields refer to isolated and purified products. [d] Ees were determined by preparation of (+)-MTPA ester derivatives, analysis by 500 MHz ^{1}H NMR spectroscopy, and comparison with corresponding diastereomers which were prepared from (*R*)-BINOL-Ti^{IV}.

results are summarised in Table 1. It is noteworthy that the formation of bis-allylated diol was not detected. Also, reduced dosage of chiral catalyst **3** (5 mol%) resulted in diminished chemical yield and longer reaction time (**2**, R = $PhCH_2CH_2$, −20 °C, 36 h, 34%).

The absolute configuration of the predominating enantiomer of the adducts **8** was unambiguously established after conversion to **6** by comparison of their specific rotations with that of known alcohols.[11] The absolute sense of the asymmetric induction parallels previous observations on catalytic allylations that employed the (*S*)-BINOL–Ti^{IV} catalyst.[2–4]

The adducts **8** are readily amenable to further conversion with electrophiles to give the useful synthetic intermediates, dienyl alcohols, with retention of enantiopurity, as described in Scheme 2. For example, the alcohol **6** was obtained from the reaction of **8** (R = $PhCH_2CH_2$) with acidic media in 78% isolated yield (a 4:1 mixture of aqueous HF and HCl at 0 °C in THF). Treatment of **8** (R = $PhCH_2CH_2$) with bromine (1.1 equiv.) in the presence of pyridine (5 equiv.) in CH_2Cl_2 at −78 °C for 1 h afforded **9** along with the corresponding silyl ether (less than 10%) which was readily desilylated with Bu_4NF in THF (over all 71% yield).



6 **8** **9**

Scheme 2 *Reagents and conditions*: i, aq. HF/HCl (4:1), 0 °C, THF (R = $PhCH_2CH_2$, 78%; R = C_6H_{13}, 81%; R = Ph, 68%); ii, Br_2 (1.1 equiv.), pyridine (5 equiv.), −78 °C, 1 h, CH_2Cl_2, then TBAF, THF (R = $PhCH_2CH_2$, 71%; R = C_6H_{13}, 74%).

In summary, this paper describes a new bifunctional reagent for the catalytic asymmetric allylic transfer reaction in a very general and efficient way which promises to be widely applicable. We believe that the products can serve as synthetic intermediates for the synthesis of chiral substances by selective functional group transformations.

Notes and references

† Removal of Pr^{i}OH under reduced pressure after formation of catalyst resulted in significantly diminished chemical yields. Also, according to the results of control experiments under identical conditions except for the use of aldehyde, we did not observe formation of any buta-2,3-dienylstannane from **1**.

‡ Compound **7** was prepared in quantity, purified by distillation, and is stable to storage, whereas compound **1** could not be distilled and is somewhat unstable to storage at −20 °C over more than a week.

Ab initio structure determination of norbornene from powder diffraction data using molecular packing analysis method

Jinrong Min, Jordi Benet-Buchholz and Roland Boese*

Institut für Anorganische Chemie, Universität-GH Essen, D-45117 Essen, Germany.
E-mail: boese@structchem.uni-essen.de

Received (in Cambridge, UK) 8th October 1998, Accepted 17th November 1998

The previously unknown crystal structre of the low temperature ordered phase of norbornene was solved from a set of powder diffraction data with severe preferred orientation collected on a laboratory X-ray diffractometer by first predicting the starting model by means of molecular packing analysis method, which was then refined against the experimental data by means of Rietveld method.

Norbornene, bicyclo[2.2.1]-2-heptene, belongs to a family of compounds which have a globular molecular shape, form orientational disordered plastic crystals and undergo phase transitions from high temperature disorderd phases to low temperature ordered phases. During the phase transition, plastic crystals usually shatter and it is very difficult to obtain single crystals from the ordered phases. For norbornane (C_7H_{12}),[1] the crystal structure of the low temperature ordered phase was solved by model building due to the special geometrical arrangement of molecules in the unit cell and refined against high-resolution synchrotron powder diffraction data. For norbornadiene (C_7H_8),[2] the crystal structure of the low temperature ordered phase was solved from single crystal grown by means of the *in situ* technique[3] from solution. This technique, however, failed so far for norbornene.

There is currently a major renaissance in the use of powder diffraction techniques for determining crystal structures at atomic resolution.[4] In this paper, we report the crystal structure of the low temperature ordered phase of norbornene (commercial product) solved from powder diffraction data at 105 K on an ordinary laboratory X-ray diffractometer (Siemens D5000, 7° position-sensitive detector, curved graphite monochromator and Cu-Kα_1 radiation). The structure only exists in an ordered form at low temperatures. The sample was sealed inside a capillary (d = 0.3 mm) and data were collected in steps of 0.0166° from 10.40 to 110.40° in 2θ, counting time 200 s per step. Indexing based on a monoclinic unit cell (TREOR90[5]) and refinement of unit cell dimensions with the whole pattern gave: a = 7.6011(7), b = 8.5985(8), c = 8.7290(8) Å, β = 97.313(3°), V = 565.87(9) Å^3. Systematic absences suggested that the possible space group was $P2_1/c$, although $P2_1$, $P2$, Pc, $P2/c$ could not be excluded for sure in the beginning. $P2/m$, Pm and $P2_1/m$ are excluded from symmetry considerations.

The sample has severe preferred orientation and contains a little impurity of the hexagonal high temperature disordered phase because not all of the sample has transformed into the ordered phase when cooling through the phase transition point at 145.3 K.[6] Preferred orientation, a well known problem that can seriously undermine structure solution attempts, is present in this sample. Therefore, the conventional structure determination method[7] did not succeed in this case, and we turned to molecular packing analysis method.[8] We first predicted structure models by molecular packing analysis method in possible space groups, simulated the diffraction patterns which were then compared to the experimental pattern. Subsequent Rietveld refinement[9] led to a final model.

The only inputs required by molecular packing analysis method are the molecular structure and an intermolecular force field. This method is used to predict the structure of crystals or molecular clusters by energy minimization, based on a variety of published force fields or a user-defined force field. The intermolecular or nonbonded energy of the molecular assembly is represented by a pairwise sum over atoms in different molecules. Crystal lattice sums are accurately evaluated using the accelerated convergence method.[10] The structural variables considered by the program are the rotations and translations of several molecules, and selected internal rotations. Molecules may be related by space group symmetry operations. In our case, we constructed the molecular structure from norbornadiene.[2] The energy minimization was implemented using the fixed unit cell dimensions and on different possible space groups. Rotation and translation parameters of the independent molecule were allowed to vary, while the symmetry-related molecules moved in a dependent way. We just considered the VDW energy term, because Coulomb energy is insignificant for this compound. The final minimized energies are listed in Table 1. From this table, we can see that $P2_1/c$ has the lowest packing energy. These predicted models were used to simulate the powder diffraction patterns, which are shown in Fig. 1. From this figure, we can exclude the space groups $P2$, $P2_1$, and Pc. When we tried to refine the structure in $P2/c$, it did not

Table 1 Molecular packing energies of the low temperature ordered phase of norbornene assuming different space groups at fixed cell dimensions

Space group	$P2_1/c$	$P2/c$	Pc	$P2_1$	$P2$
Packing energy/kJ mol^{-1}	−56.2	−43.9	−32.7	−19.1	22.4

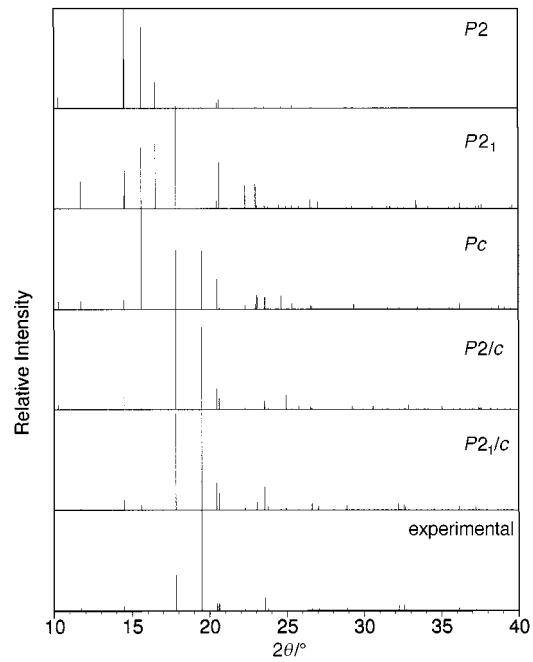

Fig. 1 Simulated powder diffraction patterns from predicted models by molecular packing analysis method on different space groups.

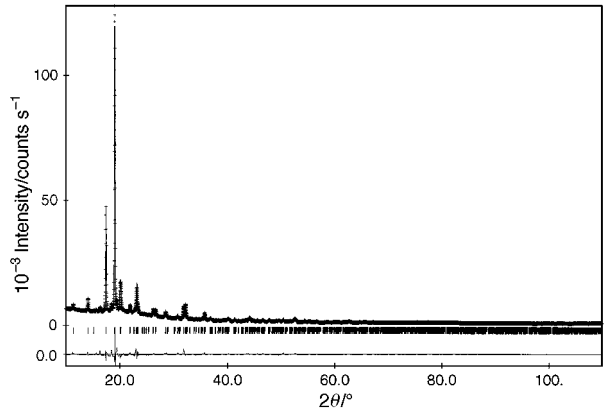

Fig. 2 Observed (plus marked line), calculated (solid line) and difference patterns (at the bottom) for the low temperature ordered phase of norbornene at 105 K. The short vertical lines mark the positions of possible Brag reflections.

converge. Therefore, we can conclude that the correct space group of the low temperature phase of norbornene is $P2_1/c$.

The atomic coordinates of the model predicted by molecular packing analysis method were input into the Rietveld refinement program FULLPROF.[11] A pseudo-Voigt profile function was selected to describe the diffraction peak profiles. After some cycles of refinement, the difference pattern between the observed and calculated patterns shows obvious preferred orientation along [111], which was modelled using Marsh–Dollase function.[12] At the beginning of refinement, only the positions of the carbon atoms were refined with an overall isotropic thermal parameter and without any constraints on the bond distances. After some cycles, one C–C bond became remarkably shorter than the other C–C bonds, indicating its

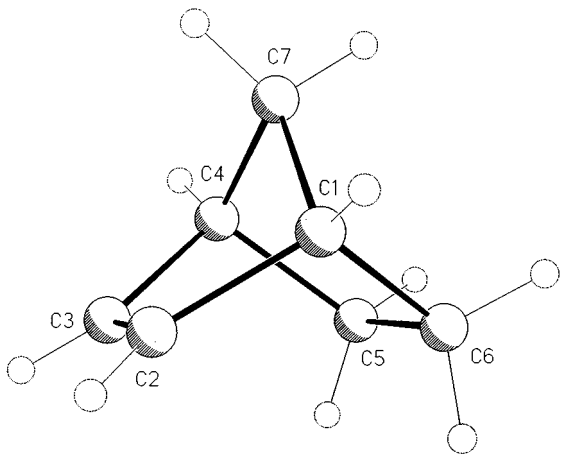

Fig. 3 Molcular structure of low temperature ordered phase of norbornene.

double bond characteristic. The positions of the hydrogen atoms were generated using the SHELXTL utilities XP[13] on the ideal positions after each cycle of refinement of carbon atoms. Fig. 2 shows the Rietveld refinement pattern. The remarkably good fit between the observed and calculated patterns supports the structure model.[14] Fig. 3 shows the molecular structure of the low temperature ordered phase of norbornene.

In summary, from the successful structure determination of norbornene, we wish to encourage the scientific community to exploit the structural information which can be readily obtained from powder diffraction data with inhouse techniques.

The determination of gaseous molecular density using a hybrid vapour sensor

Marcus J. Swann, Andrew Glidle, Li Cui, John R. Barker and Jonathan M. Cooper*

Department of Electronics and Electrical Engineering, University of Glasgow, Glasgow, Scotland, UK G12 8QQ. E-mail: jmcooper@elec.gla.ac.uk

Received (in Exeter, UK) 19th October 1998, Accepted 9th November 1998

The simultaneous responses from a conductance sensor and a gravimetric quartz crystal sensor can be combined as a hybrid measurement which yields the analyte vapour's molecular density.

The measurement of odours is of importance in the monitoring of industrial, bio-agricultural and environment processes. Traditionally analytical methods, including gas chromatographic mass spectrometry[1] or optical measurements,[2] have made use of inherent physical characteristics of the vapour. In other gas sensing systems, such as electronic noses,[3–5] where the instrumentation and methodology may be more simple, there is often a lack of detailed mechanistic knowledge as to what determines the sensor response. As a consequence, one of the greatest challenges in artificial olfaction is the development of a convenient sensor technology where the analytical response results from an intrinsic molecular signature or property of the gas. Here, we show how a hybrid device, comprising a conductimetric and gravimetric sensor pair, can, through the simple ratioing of their responses, determine the molecular density of one or more vapour(s). The method that we propose has an advantage over existing olfactory techniques in that it generates quantitative physical information describing the gas composition (analogous to, for example, an IR stretch).

Much work on the development of electronic noses[3–9] has focused on two distinct sensing methods, namely, conductivity measurements based on chemoresistors[3–5] and the (mass sensitive) quartz crystal microbalance (QCM).[6–9] In both technologies, a transducing element is coated with a membrane, which may be either an organic polymer, an inorganic oxide, or simply a functionalised self assembled monolayer.[3–9] Responses are measured, either by an increase in mass (as is the case for a QCM), or by a change in electrical resistance (exemplified by the chemoresistor) due to the interaction of the gas with the overlayer. A notable difference, however, between the two systems is the common use of non-conducting overlayers in QCM sensors, and of conducting polymers or metal oxides in the chemoresistor systems.

Both the QCM[9–11] and conductimetric techniques[3–5] have been expanded to utilise arrays of different sensors. Consequently, commercial instruments have exploited signal processing as a means of producing an olfactory image and hence identifying the composition of an unknown vapour stream.[12]

A recent innovation has resulted in the manufacture of conductimetric sensors, fabricated using a dispersion of carbon-black[13] or any other finely divided conducting material[14] in a non-conducting polymer (so forming a conducting membrane). Sorbtion of a vapour into such a composite matrix causes a change in the electrical resistance by influencing the length of percolation paths between conducting particles within the polymer film. A consequence of this methodology for sensor fabrication has been to greatly extend the variety of polymers and deposition methods which can be used in these sensor systems. Additionally, by using these composites, interpretation of the measured resistance changes becomes simplified through the finding that changes in conductivity are linear with the (single component) vapour phase concentration[13] (below the percolation threshold). Importantly, it has been proposed[13,14] that the resistance change is proportional to the change in polymer-composite's volume, due to swelling.

In producing our sensors, we have exploited the possibility of measuring resistance changes in thin films of carbon black composite materials at a conductimetric sensor, on exposure to a range of vapours (due to changes in the polymer-volume) whilst simultaneously determining increases in mass at a similarly coated QCM (due to vapour sorbtion). Thus, we have developed a device which is capable of determining the molecular density of an odour (as a vapour's mass divided by its volume). This measurement, which can be determined by ratioing the voltage outputs from the QCM and the conductimetric sensor pair using a simple potential divider, provides a straightforward method to obtain an intrinsic physical signature of a gaseous species.

In the series of experiments described below, conductimetric sensors (Fig. 1, left) were fabricated as interdigitated electrodes with gap sizes of either 20 or 40 μm and an effective length of 10 cm. These electrodes have the advantage that they can be functionalised by spin coating (2000 rpm) or by an ink jet printer, from a solution containing both dissolved polymer and a carbon-black dispersion. The gravimetric (QCM) sensors (Fig. 1, right) were 10 MHz AT cut quartz crystals (ICM Co., Oklahoma, USA) and were spin coated using a solution of the polymer alone. Typical coating solutions contained 200 mg poly(ethylene oxide) (Aldrich) with/or without 50 mg carbon black (Cabot Co., Bilerica, USA), in 10 g of chloroform.

Vapours were passed over the sensor pair using a regulated flow system enabling the simultaneous measurement of QCM and conductimetric responses. Fig. 2 shows the changes in frequency and resistance of the QCM and interdigitated sensors

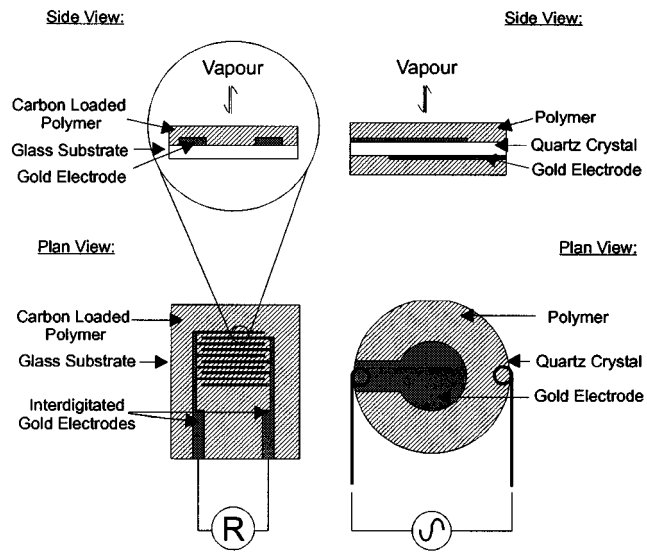

Fig. 1 Schematic diagram of the two sensor types. The conductimetric sensor (left) is a molecular volume sensitive transducer, consisting of two interdigitated electrodes. The quartz crystal microbalance (right) is a mass sensitive transducer, based on the change in resonant frequency of a quartz crystal.

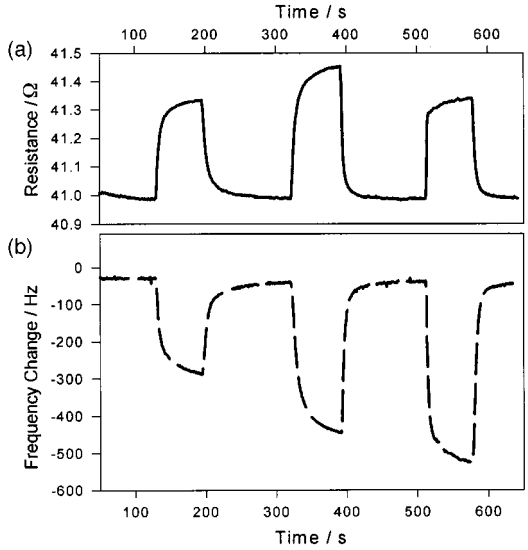

Fig. 2 Response of poly(ethylene oxide) coated (a) conductimetric and (b) QCM sensors to *n*-hexane (13 mmHg), water (9 mmHg) and chloroform (6 mmHg) in nitrogen as a function of time. Between exposure to vapour samples, the sensors were purged with dry nitrogen.

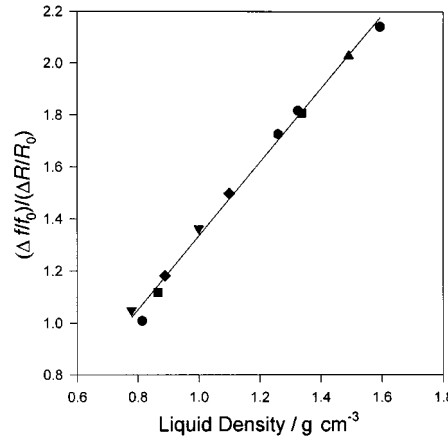

Fig. 3 A plot of $[(\Delta f/\Delta f_0)/(\Delta R/R_0)]$ *vs.* the vapour's liquid density for a range of different solvents, where f_0 is the film's dry mass, and R_0 is its initial resistance. The solvents were cyclohexane (ρ = 0.779 g cm^{-3}), hexanol (0.814), toluene (0.865), THF (0.889), water (1.00), deuterium oxide (1.10), dichloroethanene (1.26), dichloromethane (1.33), trichloroethane (1.338), chloroform (1.49) and carbon tetrachloride (1.59). The straight line is a linear regression fit to the data, (r^2 = 0.99).

on exposure to vapours of *n*-hexane, water and chloroform (at different selected, partial pressures). As can be seen, chloroform gives the largest frequency (mass) change for the given resistance change, and hexane the smallest. Although the rate of change of the response of the sensors is different for each vapour, the time dependent responses of a conductimetric and QCM sensor pair follow each other closely. Indeed, division of the temporal responses from each of the sensors in the pair is linear for a given gas, indicating that the output of the hybrid device is constant for different amounts of sorbed vapour (the actual amount of sorbed vapour can still be determined from the individual conductimetric, or gravimetric responses).

Confirmation that the sorbtion of gas does lead to a volume change in the sensing layer, as proposed by others,[13,14] has been investigated by simple neutron and X-ray reflectivity experiments (not detailed here) showing that thin films of polymers swell to as much as 150% of their original thickness on exposure to suitable vapours.

To demonstrate the independence of the ratio of conductimetric to gravimetric responses, with amount of sorbed vapour, we measured the percentage frequency change and percentage resistance change for different vapour pressures of dichloromethane (9.2 mm–138 mm Hg). The relationship is linear over the concentration range studied, although the non-zero intercept obtained from an unconstrained best fit line may reflect the influence of the bath gas (N_2) on polymer swelling.

To examine the hypothesis that the sorbed species' molecular density can be calculated from a simultaneous measurement dependent on the volume change in the conductance sensor and a corresponding gravimetric measurement, we investigated a hybrid device's response to a variety of vapours generated from volatile liquids. Fig. 3 illustrates the ratio of gravimetric change to the polymer volume increase by showing the ratio of QCM frequency change to interdigitated electrode resistance change as a function of the density of the sorbed vapour. To demonstrate that the hybrid sensor response was independent of vapour–polymer interactions, the odours were chosen in order to be representative of hydrophobic, hydrophilic, polar, non-polar, and isotopically substituted molecules. The wide range of liquid densities covered by these species (0.78–1.59 g cm^{-3}) further emphasises the versatile nature of the methodology in monitoring different vapours, including light hydrocarbon gases and heavier halogenated species. Ultimately, these techniques may be extended to (volatile) metal complexes (*e.g.* UF_6).

In conclusion, we have shown that by combining carbon-black loaded polymer conductimetric and QCM sensors, we can greatly augment the information obtained when compared with the use of either one sensor material, or one measurement system alone. This simplicity of signal processing is not found in current array based conductimetric electronic noses, owing to the numerous factors influencing conductivity mechanisms in, for example, the family of poly(pyrroles).[12] Although QCM and chemoresistance measurements have previously been made simultaneously,[15,16] giving responses which are linear with respect to the amount of (single component) vapour species adsorbed, the magnitude and sign of their proportionality coefficients are not readily related to the molecular species involved. This clearly contrasts with the novel sensor configuration that we have demonstrated here.

The authors wish to thank both MAFF and The Leverhulme Trust for supporting this work.

The synergetic effect of cobalt and indium in ferrierite catalysts for selective catalytic reduction of nitric oxide with methane

B. Sulikowski,*[a] J. Janas,[a] J. Haber,*[a] A. Kubacka,[a] Z. Olejniczak[b] and E. Wloch[a]

Received (in Cambridge, UK) 27th October 1998, Accepted 17th November 1998

A pronounced synergetic effect was found in the title reaction when indium and cobalt ions were present simultaneously in zeolite ferrierite.

A number of catalysts have been tested in the SCR of NO_x, including mixed oxides, supported metals and zeolites of different compositions.[1] While the SCR of NO with olefins proceeds usually smoothly on zeolite catalysts,[2] it is much more difficult to perform the title reaction using methane, a very stable molecule, and to achieve the reduction of NO while preventing total oxidation of the organic molecule by oxygen. Li and Armor showed that methane can be successfully used as a reductant of NO on Co^{2+}, Mn^{2+} and Ni^{2+}-exchanged ferrierites.[3] Ga and In/H-ZSM-5 were active catalysts in the title reaction.[4] Indium oxide supported on TiO_2–ZrO_2 showed significant activity for reduction of NO with propene, but not with methane, ethene, propane or alcohols.[5] We wish to report on the characterization and performance of Co^{2+} and/or In^{3+} containing ferrierite in the SCR of NO with CH_4, in the presence of excess oxygen.

Ferrierite was synthesized hydrothermally by using pyrrolidine (pyr) or piperidine (pip) and Ludox AS-40. The gels having compositions of (10–12) SiO_2 : (4.8–7.0) pyr : (0.48–0.64) NaOH : 1.0 Al_2O_3 : (380–460) H_2O and (11–12) SiO_2 : (4.0–6.0) pip : (6.5–7.5) NaOH : 1.0 Al_2O_3 : (160–220) H_2O have been homogenized for few hours and allowed to crystallize in the Teflon-lined stainless-steel autoclaves under autogenous pressure for 2–13 days at 160–200 °C. After calcination at 550 °C ferrierite was ion-exchanged with ammonium acetate (twice) and transformed into the hydrogen form (H-FER) by calcination. The Si/Al ratio of H-FER (I) was 6.1 and BET (Ar) = 335.7 $m^2\ g^{-1}$; for H-FER (II) the Si/Al ratio was 7.8 and BET = 321.1 $m^2\ g^{-1}$, respectively. XRD showed both samples contained pure ferrierite phase (no mordenite or other phases were present).

^{29}Si MAS NMR spectra of both hydrogen forms were typical for pure ferrierite phase,[6] giving three signals at −108.2, −113.6 and −117.5 ppm. A fourth weak signal was found at −102.7 ppm. ^{27}Al MAS NMR revealed that aluminium in all the samples is present in tetrahedral positions. More detailed discussion of silicon and aluminium NMR spectra of ferrierites will be given elsewhere.

H-FER was modified further by Co(II) and In(III) ions using standard and solid-state ion exchange (s.s.i.e.) procedures.[7] Cobalt acetate (Merck, p.a.) was mixed with H-FER (I) in an agate mortar and calcined in air (heating rate 50 °C h^{-1}) at 550 °C for 2.5 h to yield Co-FER (I) with Co/Al molar ratio of 0.27. The sample In-FER (1) was obtained by ion exchange from indium nitrate solution at pH = 2.1, washed, dried and calcined in air at 550 °C for 2 h (In/Al = 0.12). Another catalyst was prepared by grounding zeolite and indium(III) oxide, heating in He to 400 °C and reducing with hydrogen at this temperature for 2 h. The sample was cooled down to ambient temperature in the He flow to give In-FER (2) with In/Al = 0.99. Finally, Co,In-FER was prepared from the Co-FER (I) sample by applying the additional s.s.i.e. procedure. Thus Co-FER (I) was ground with In_2O_3, heated in the helium flow to 400 °C, reduced with hydrogen for 2 h and cooled to room temperature in He. The catalyst labelled Co,In-FER had Co/Al = 0.27 and In/Al = 0.23.

The catalytic tests were performed in the continuous flow microreactor connected on-line with a gas chromatograph, at GHSV = 10 000 h^{-1}. All the data in Tables 1–3 are related to steady-state conditions. After these conditions were established (*ca.* 2 h) no measurable loss of catalysts activity was observed up to two days on stream (except H-FER).

The selective catalytic reduction (SCR) of NO by a hydrocarbon molecule (here methane) in the presence of oxygen proceeds according to eqn. (1):

$$2\ NO + CH_4 + O_2 \rightarrow N_2 + CO_2 + 2\ H_2O \quad (1)$$

In addition to reaction (1), at least two other parallel processes can be envisaged. First, the hydrocarbon can be fully oxidized by the molecular oxygen [eqn. (2)]:

$$CH_4 + 2\ O_2 \rightarrow CO_2 + 2\ H_2O \quad (2)$$

Second, NO can be oxidized to NO_2 instead of being reduced [eqn. (3)]:

$$NO + 1/2\ O_2 \rightarrow NO_2 \quad (3)$$

Table 1 A comparison of the selective catalytic reduction (SCR) of NO on indium forms of ferrierite. The oxidation of NO to NO_2 without methane in the feed is also shown (*O*)[a]

Third, the partial reduction of NO to N_2O may proceed. However, in the presence of methane and ethene the yield of N_2O was low (up to 5%). Accordingly, the following three reactions have been studied on ferrierite-based catalysts: (i) the SCR of NO; (ii) the oxidation of NO to NO_2 in the absence of methane; and (iii) the combustion of CH_4 to CO_2 and H_2O (without NO in the feed).

On pure hydrogen form of ferrierite the conversion (*X*) of NO at 250–300 °C was *ca.* 20% (Table 2). However, the zeolite loses its activity relatively quickly (< 1 h on stream). Moreover, the conversion of NO decreases sharply with the temperature. Above 400 °C the solid becomes essentially inactive. In the absence of CH_4 the oxidation of NO to NO_2 proceeds at low temperatures and above 450 °C is negligible (Table 2, column *O*).

The activity of the catalysts containing indium shows much more pronounced conversion in the temperature range 250–350 °C (Table 1). Contrary to the H-FER sample, the oxidation of NO to NO_2 was observed on In-FER (1) in the whole temperature range studied, up to 525 °C. However, under the SCR conditions, the oxidation of NO prevails only at temperature 200–250 °C, while above 350 °C the SCR of NO was the main process. The conversion level of NO does not exceed *ca.* 40% at 500–525 °C. The sample In-FER (2) is much less active; the oxidation of NO to NO_2 above 350 °C becomes negligible, while the total conversion of NO is nearly the same as found for H-FER. Finally, the oxidation of methane on this catalyst rises quickly with the temperature. As is seen from Table 1, no simple parallelism exists between the ability of catalysts to oxidize CH_4 and its performance in the SCR of NO.

The activity of pure Co-FER (I) under the same conditions is similar to the In-FER (1) sample. The catalyst shows an ability to oxidize NO (Table 2, column *O*). Thus summarizing, moderate conversions of NO have been obtained on the catalysts containing either cobalt or indium cations in the zeolite matrix [In-FER (1), Co-FER (I)].

We have found, however, that when cobalt and indium ions were present simultaneously in ferrierite, a very significant synergetic effect was observed. The conversion of NO increases sharply from 20 to 98% in the temperature range 300–425 °C (Table 3, column *X*). It is also remarkable that on Co,In-FER no NO_2 was found in the effluents above 300 °C. As the conversion of methane reveals, at 300–425 °C the SCR of NO proceeds predominantly. This is confirmed further by a very low combustion of methane in the absence of NO (for example, combustion of CH_4 without NO was < 1% at 300 °C and 6% at 400 °C). Above 400 °C the competition between reactions (1) and (2) becomes more important. As a result the combustion of methane by molecular oxygen increases with temperature. We note, however, that even at 500 °C methane is still able to reduce NO. Another interesting feature of the Co,In ferrierite is low yield of N_2O, decreasing continuously from 5.6% at 350 °C to 0% at 500 °C.

The activity of Co,In-FER catalyst was measured for comparison purposes using ethene in the stream instead of methane. The results are summarized in Fig. 1. Surprisingly, the conversion of NO is lower at high temperatures when using ethene as the reductant. Moreover, high (> 90%) conversion of NO on the Co,In-FER catalyst in the presence of methane was observed in a broader range (400–500 °C). Two remarkable features of our catalyst formulation are seen: (i) higher activity at high temperatures when using methane as the reductant; and (ii) still high activity in the de-NOx process with ethene. Typical behaviour of other zeolite catalysts investigated by us (mordenite and ZSM-5) was different: high activity in the presence of ethene and *lower* when using methane.[8]

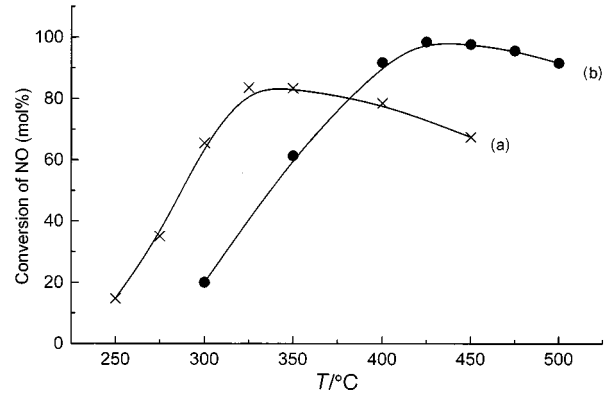

Fig. 1 Conversion of NO (mol%) on the Co,In-FER in the presence of ethene (a) and methane (b).

Finally, it is interesting to speculate on the surface species, as revealed in Co,In-FER by ESCA. We found the following concentrations of the catalyst components—Si : Al : O : In : Co = 0.261 : 0.045 : 0.647 : 0.031 : 0.016. The Si/Al ratio was 5.8 (in bulk, 6.1 was found by atomic absorption). Analysis of cobalt species gave Co(II) : Co(III) = 0.99. Upon heating to 400 °C, concentration of In and Co on the surface decreases to 0.023 and 0.013, respectively. This is in a very good agreement with higher initial activity of the catalyst (75.2% at 300 °C) in comparison with 65.5% steady-state value reached after 2 h on stream. Distribution of Co ions in crystals is very homogeneous, as seen by comparing Co/(Si+Al) = 0.038 (bulk) and 0.036 (surface). Contrary to this, even after heating at 400 °C the surface of ferrierite is enriched with indium oxide species [In/(Si+Al) = 0.064 (surface) and 0.033 (bulk)], at variance with the case demonstrated for large crystals of H-ZSM-5.[9]

We are grateful to Dr. Jerzy Stoch for ESCA analysis. We thank the State Committee for Scientific Research (KBN), Warsaw, for support (grants no. 2P 303 053 07 and no. 2 P03B 077 13).

1,2-Bis(4,4′-dipyridinium)ethane: a versatile dication for the formation of [2]rotaxanes with dibenzo-24-crown-8 ether

Stephen J. Loeb* and James A. Wisner

School of Physical Sciences, Chemistry & Biochemistry, University of Windsor, Windsor, Ontario, Canada N9B 3P4. Fax: + (519) 973-7098. E-mail: loeb@uwindsor.ca

Received (in Cambridge, UK) 24th September 1998, Accepted 9th November 1998

The 1,2-bis(4,4′-dipyridinium)ethane dication threads through dibenzo-24-crown ether (DB24C8) to form a [2]pseudorotaxane which is easily stoppered to form [2]rotaxanes either by alkylation or coordination of a transition metal complex.

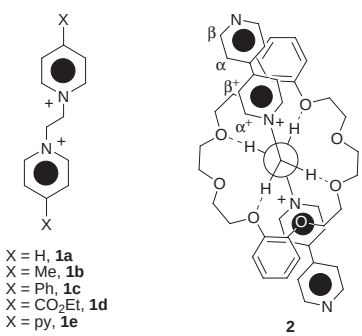
To date, most [2]rotaxanes involving crown ethers have been templated by either the stacking interactions between π-electron rich and π-electron poor aromatic rings[1] or hydrogen bonding between secondary dialkylammonium ions and crown ether oxygen atoms.[2] We have recently demonstrated that various 1,2-bis(pyridinium)ethane dications **1a**–**d** will thread through the 24-membered crown ethers 24C8, B24C8 and DB24C8 to form [2]pseudorotaxanes in which the major templating forces are $N^+\cdots O$ and C–H···O interactions.[3] By adding various substituents (X) to the 4-position of the pyridinium ring, it was possible to prepare a series of interlocked molecules containing DB24C8 with K_a values ranging from 105 $dm^3\ mol^{-1}$ for **1a** to 1200 $dm^3\ mol^{-1}$ for **1d** in MeCN solution.

We have now turned our attention to converting these [2]pseudorotaxanes into permanently interlocked [2]rotaxanes. Our strategy was to prepare an appropriate 1,2-bis(pyridinium)ethane dication which could form a stable [2]pseudorotaxane and be easily stoppered to form a [2]rotaxane. In a straightforward variation of our previous work, these criteria were met by using 4,4′-bipyridinium units; X = 4-pyridine, **1e**.[4] The 1:1 interaction of **1e** with DB24C8 resulted in formation of the [2]pseudorotaxane **2** (Scheme 1) as identified by ^1H NMR spectroscopy, ESI-MS and an association constant of 920 $dm^3\ mol^{-1}$ measured at 298 K in MeCN. Spectroscopic data are consistent with binding *via* $N^+\cdots O$ interactions, C–H···O hydrogen bonds and π-stacking analogous to that found in solution for **1a**–**d** and in the solid state, by X-ray crystallography, for **1d** (X = CO_2Et).[3]

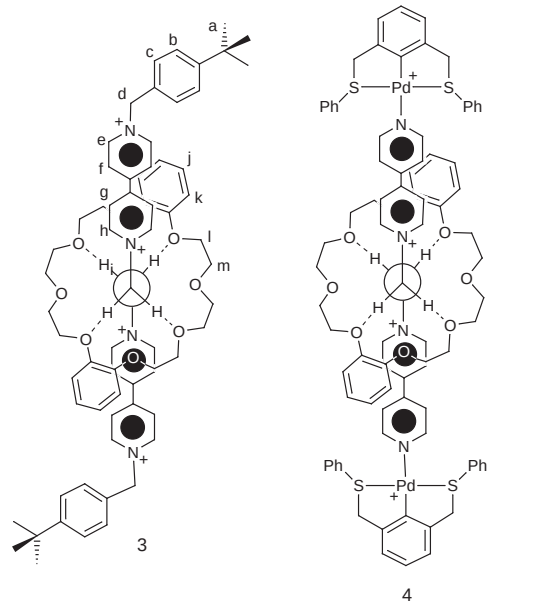
Two routes were used to convert the [2]pseudorotaxane **2** to a permanently interlocked [2]rotaxane. First, **2** was alkylated at the terminal, pyridine nitrogen atoms with bulky *tert*-butylbenzyl groups by vigorously stirring a two-phase $MeNO_2$–saturated $NaBF_4(aq)$ solution containing 1 equiv. of **1e**, 6 equiv. of *tert*-butylbenzyl chloride and 3 equiv. of DB24C8. The [2]rotaxane **3** was isolated in 46% yield by extraction of the product into CH_2Cl_2 (Scheme 2). Significant *downfield* shifts (ppm) for α^+ (0.34) and $^+NCH_2$ (0.33) protons were indicative of C-H···O hydrogen bonding to crown ether O-atoms and *upfield* shifts were observed for the α (0.03), β (0.28), β^+ (0.27) and crown aromatic protons (0.26, 0.50) indicating π-stacking between the catechol and bipyridinium aromatic rings. An X-ray crystal structure determination† of **3** verified the nature of the interaction and an ORTEP diagram is shown in Fig. 1.

The [2]rotaxane, **3** exhibits $N^+\cdots O$ interactions ranging from 3.41 to 4.50 Å and eight C–H···O hydrogen bonds with C···O distances in the range 3.18–3.69 Å. The orange colour of the solid material is consistent with charge transfer interactions between the normally colourless crown ether and dipyridinium fragments. The S-shaped conformation of the dibenzo-24-crown ether molecule allows this π-stacking phenomenon to occur through both *intra*molecular and *inter*molecular interactions as shown in Fig 2.

In a metal–ligand, self-assembly reaction, the [2]pseudorotaxane **2** was used as a ligand and stoppered with organopalladium fragments to form the metallo-[2]rotaxane **4**. This was done by simply mixing 1 equiv. of **1e**, with 2 equiv. of $[Pd\{C_6H_3(PhSCH_2)_2\}(MeCN)]BF_4$ and 3 equiv. of DB24C8 in MeCN solution. The ^1H NMR spectrum of this solution showed that the [2]rotaxane **4** was formed in quantitative yield. As for **3**, significant *downfield* shifts for α^+ (0.41) and NCH_2 (0.38) protons were observed indicative of C–H···O hydrogen bonding to crown ether O-atoms, while *upfield* shifts were observed for the α (0.24), β (0.32), β^+ (0.38) and crown aromatic protons (0.31, 0.58) indicating π-stacking between the two sets of



Scheme 1 Formation of [2]pseudorotaxane **2** from the 1,2-bis(4,4′-dipyridinium)ethane dication **1e** and DB24C8. **2** is viewed along the $^+NCH_2CH_2N^+$ vector in a Newman type projection emphasizing four of the stabilizing C–H···O interactions.



Scheme 2 [2]Rotaxanes can be formed from **2** by adding 'stopper' groups.

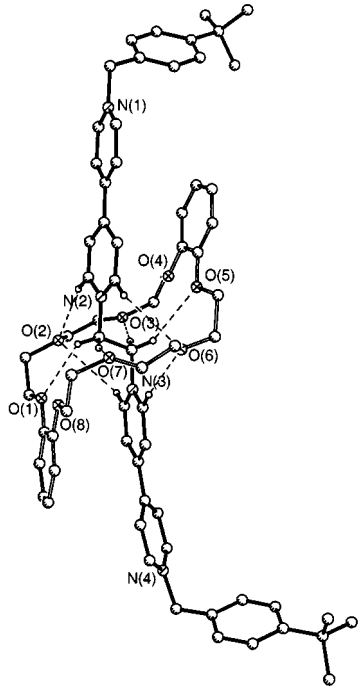


Fig. 1 An ORTEP diagram of the [2]rotaxane **3** showing the basic numbering scheme. $N(2)^{+}\cdots O$ distances; O(1) 4.52, O(2) 3.79, O(3) 3.93, O(4) 3.41, O(5) 3.55, O(6) 4.06, O(7) 3.80, O(8) 4.50 Å. $N(3)^{+}\ldots O$ distances; O(1) 3.43, O(2) 3.97, O(3) 4.05, O(4) 4.68, O(5) 4.64, O(6) 3.74, O(7) 4.22, O(8) 3.65 Å. C–H···O bonds: C(19)···O(2) 3.33, C(20)···O(6) 3.62, C(24)···O(2) 3.69, C(28)···O(6) 3.18, C(22)···O(1) 3.29, C(22)···O(7) 3.27, C(23)···O(3) 3.24, C(23)···O(5) 3.54 Å.

aromatic rings. An X-ray crystal structure determination of **4** verified the nature of the interaction and an ORTEP diagram is shown in Fig. 3.

The [2]rotaxane, **4** shows a series of $N^{+}\cdots O$ interactions ranging from 3.51 to 4.90 Å and eight C–H···O hydrogen bonds with C···O distances in the range 3.18–3.62 Å. The SPh rings of the metal fragment do not interact with the rest of the molecule. The organopalladium fragment is large enough to prevent unthreading and acts as a stopper in the designed manner.

The ability of the 1,2-bis(4,4′-dipyridinium) dication to form [2]rotaxanes using simple synthetic methodologies demonstrates that this component has the potential to be an important building block for the construction of more complex mechanically linked systems such as [2+*n*]rotaxanes, molecular necklaces[5] [*n*]MN and [*n*]catenanes.

We thank the Natural Sciences and Engineering Council of Canada for financial support of this research.

Synthesis of 2-deoxy and 2,6-dideoxy glycosides under neutral conditions in $LiClO_4/Et_2O$ mixtures

Heidrun Schene and Herbert Waldmann*

Universität Karlsruhe, Institut für Organische Chemie, Richard-Willstätter-Allee 2, D-76128 Karlsruhe, Germany. E-mail: waldmann@ochhades.chemie.uni-karlsruhe.de

Received (in Cambridge, UK) 5th October 1998, Accepted 6th November 1998

Glycosides of 2-deoxy and 2,6-dideoxy carbohydrates were built up in high yields and with high stereoselectivity in 0.1 M $LiClO_4/Et_2O$ mixtures; the glycosidations proceed under neutral conditions and without need for an additional promoter such as a strong Lewis acid, a heavy metal salt or an alkylating reagent.

2-Deoxy and 2,6-dideoxy glycosides are important substructures of antitumor drugs, antibiotics active against Gram-positive bacteria and drugs used in the treatment of cardiac insufficiency. Owing to this biological relevance the development of methods for the efficient and stereoselective construction of deoxyglycosidic linkages is of great relevance to organic synthesis, medicinal and bioorganic chemistry.[1] In comparison to the synthesis of other glycosides this problem is particularly challenging, since 2-deoxy glycosides are more acid-labile. Furthermore no stereodirecting neighboring group adjacent to the anomeric center is available that may direct the steric course of the glycosidation reaction. To circumvent these problems for deoxy glycoside synthesis, mostly electrophile-mediated addition of acceptor alcohols to the double bond of glycals followed by reductive removal of the C-2 substituents introduced into this position is employed.[2] Alternatively, glycosyl donors with 2-substituents acting as a neighboring group[3] or 1,2-anhydropyranoses[4] are used followed by reductive removal of the 2-substituent. Clearly, the application of direct methods for the efficient construction of 2-deoxy and 2,6-dideoxy glycosides is highly desirable.[5] These transformations should proceed under very mild and preferably neutral conditions without the use of strong Lewis acids or other promoters such as toxic and expensive heavy metal salts. We now report that trichloroacetimidates and fluorides of 2-deoxy and 2,6-dideoxy carbohydrates are activated under neutral conditions in solutions of $LiClO_4$ in Et_2O to give the correspondig deoxyglycosides with pronounced stereoselectivity and in high yields (Scheme 1).[6]

If benzyl-protected 2-deoxyglucosyl trichloroacetatimidate **1**[7] was treated with 6-O-deprotected benzylated glucoside **5a** in Glycosides of 2-deoxy and 2,6-dideoxy carbohydrates were built up in high yields and with high stereoselectivity in 0.1 M $LiClO_4/Et_2O$ mixtures; the glycosidations proceed under neutral conditions and without need for an additional promoter such as a strong Lewis acid, a heavy metal salt or an alkylating reagent.solutions of metal perchlorates in different solvents, the desired disaccharide **11** was formed smoothly. A brief survey of the reaction conditions (solvent, metal perchlorate, other metal salts, concentration of the salt) revealed that the best results were recorded in 0.1 M $LiClO_4$ in Et_2O. Under these conditions the desired glycoside was formed in 89% yield with a slight preference for the α-anomer (Table 1, entry 1). At lower or higher perchlorate concentration (0.03–0.5 M), in CH_2Cl_2, toluene or MeCN and in the presence of $Ba(ClO_4)_2$, $Zn(ClO_4)_2$ or $Mg(ClO_4)_2$, the yield was lower and the α/β selectivity remained almost unchanged. $LiClO_4$ could be replaced by $Li(NTf)_2$,[8] $LiBF_4$ or $LiPF_6$; however in the presence of these salts the results were not improved. Also the β-imidate corresponding to **1** gave inferior yields and the α/β selectivity remained unchanged. Therefore, all further reactions were conducted with the α-anomer **1** in 0.1 M $LiClO_4/Et_2O$ solutions.

[a] All glycosides were chromatographically purified and identified by ^1H NMR spectroscopy (250, 400 or 500 MHz). [b] Determined by integration of the relevant signals in the ^1H NMR spectra of the anomeric mixtures after chromatographic purification. [c] 0.15 M $LiClO_4$. [d] In CH_2Cl_2.

Under these gentle conditions glycosyl donor **1** reacts with galactose derivative **6a**, serine imine **7** and cholesterol **8a** to give the desired glycosides **12–14** in high yields, while glucosyl disaccharide **15** is obtained with lower yield (Table 1, entries 1–5). Thus 2-deoxyglycosyl imidate **1** is efficiently activated in the absence of a strong Lewis acid. The rate-accelerating effect of this reaction medium may be attributed to the ability of $LiClO_4/Et_2O$ solutions to stabilize polar or ionic transition states or intermediates like glycosyl cations.[6,9]

Although with imidate **1** the desired glycosides were formed in high yields the stereoselectivity remained low (Table 1, entries 1–4, see, however, entry 5). Therefore other glycosyl donors were investigated. Whereas use of the diethyl phosphite analogous to **1** did not improve this situation, 2-deoxyglycosyl fluoride **2** led to significantly higher anomer ratios. Glycosyl donor **2** is also activated in 1 M $LiClO_4$ in Et_2O under very mild conditions and reacts with selectively deprotected glucose **5a**, galactose **6a** and cholesterol **8a** to give glycosides **11**, **12** and **14** in useful yields. However, in these cases the α-anomers are formed with ratios ranging from 6:1 to 13.4:1 (Table 1, entries 6–8). Thus, by means of this method 2-deoxyglycosides can be constructed under very gentle conditions and with pronounced stereoselectivity.

In order to extend the scope of this very mild method, glycosylation of 2,6-dideoxy carbohydrates was investigated. Since in the case of 2-deoxyglucose the glycosyl fluoride had shown the most advantageous results, deoxy-L-fucosyl fluoride **3** and D-digitoxosyl fluoride **4** were prepared[7] and subjected to the glycosidation reactions.† As glycosyl acceptors silyl ethers **5b**, **6b** and **8b** were employed to facilitate the reactions by formation of the very stable Si–F bond. Lactose derivative **10** was used to investigate if regioselectivity can be achieved. Upon treatment of benzyl-protected 2-deoxyfucosyl fluoride with glucose derivative **5b**, galactosyl acceptor **6b**, cholesteryl silyl ether **8b** and lactose derivative **10** in 0.1 M $LiClO_4$ in Et_2O, glycosides **16–19** were smoothly formed in moderate to high yields. In all cases the anomer ratio was gratifyingly high (Table 1, entries 9–12). Whereas the glucose and the galactose disaccharides were obtained with α/β ratios of 8.1 to 12.7, cholesteryl glycoside **18**‡ and trisaccharide **19** were formed with complete α-selectivity. Furthermore, the glycosylation of lactose acceptor **10** proceeded with complete regioselectivity to deliver exclusively the 4′-deoxyfucosyl trisaccharide. Thus, under these reaction conditions glycosides of 2-deoxy-L-fucose can be prepared with high selectivity and the method is applicable to the construction of oligosaccharides.

D-Digitoxosyl fluoride **4** reacted with glucosyl and galactosyl silyl ethers **5b** and **6b** under the mild conditions provided by the $LiClO_4/Et_2O$ systems to give the corresponding disaccharides **20** and **21** in satisfying yields (Table 1, entries 13 and 14). Whereas with glucose acceptor **5b** the anomers were formed in nearly a 1:1 ratio, for galactose disaccharide **21** a high α/β ratio was once more recorded.

In conclusion the results detailed above demonstrate that in 0.1 M $LiClO_4/Et_2O$ mixtures glycosides of 2-deoxy and 2,6-dideoxy carbohydrates are formed in useful yields and with high stereoselectivity. The glycosidation reactions proceed under neutral conditions and without need for an additional promoter usually applied in glycoside synthesis, *i.e.* a strong Lewis acid, a heavy metal salt or an alkylating reagent.

Notes and references

† *General procedure* for the glycosydations with the fluorides **2**, **3** and **4** as donors. Pulverized, freshly activated molecular sieves (4 Å) (70 mg), $LiClO_4$ or $Ba(ClO_4)_2$ (0.2 mmol) and acceptor (0.2 mmol) were stirred in Et_2O, CH_2Cl_2 or MeCN (1 ml) for 30 min under argon. To this suspension was added a solution of the donor (0.1 mmol) in the same solvent (1 ml). In the case of acceptors without a TMS group, CsF (0.1 mmol) was used as an acid scavenger. After stirring for 3 d (2 d with the donors **3** and **4**) at room temperature, the reaction mixture was diluted with CH_2Cl_2 (50 ml), filtered and washed with water. The organic layer was dried over Na_2SO_4 and concentrated *in vacuo*. The crude product was purified by flash chromatography.

Are vinylidenes possible intermediates in thermal rearrangements of substituted cyclopropenes? A theoretical study†

Norman Goldberg* and Wilhelm Graf von der Schulenburg

Institute of Organic Chemistry, Technical University Braunschweig, Hagenring 30, D-38106 Braunschweig, Germany. E-mail: n.goldberg@tu-bs.de

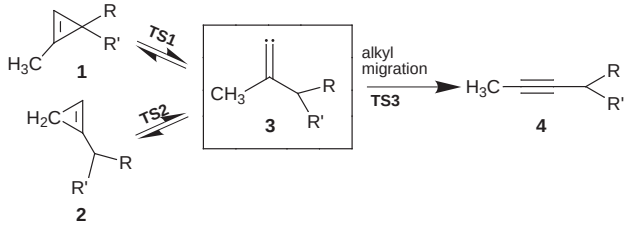
Received (in Liverpool, UK) 11th September 1998, Accepted 17th November 1998

The thermally induced ring-opening reactions of substituted cyclopropenes to the corresponding vinylidenes have been investigated computationally; the alkyl-substituted singlet vinylidenes have been found to lie in potential wells of 7–11 kcal mol^{-1} (DFT calculations; 1 kcal = 4.184 kJ).

Vinylidenes, unsaturated carbenes of the type $R_2C{=}C{:}$, have received a great deal of attention during recent years. They have been postulated as reactive intermediates in organic reactions[1] and the simplest member of this family of compounds, $H_2C{=}C{:}$, was characterised by mass spectrometry[2] and negative ion photoelectron spectroscopy[3] of the corresponding vinylidene anion, $H_2C{=}C^{-\cdot}$. These experimental as well as several theoretical studies[4] demonstrate that the singlet vinylidene, $H_2C{=}C{:}$, lies in a very shallow potential energy well and readily rearranges to acetylene on the picosecond time scale.[3b] Thus, the observation of a vinylidene species in the mass spectrometric studies was attributed to a long-lived, excited triplet species.

Another experimental entry into the chemistry of vinylidenes was predicted by Yoshimine and co-workers[4b] in a theoretical study on the thermal ring opening of cyclopropene. Based upon their calculations, the authors proposed that cyclopropene may not only rearrange to propyne *via* a homolytic bond cleavage to vinyl carbene and subsequent hydrogen migration (as previously assumed[5]), but that methylvinylidene also constitutes an energetically viable intermediate. Recent experimental studies on the pyrolysis of substituted cyclopropenes[6] have furnished the first experimental evidence for the involvement of vinylidene carbenes as intermediates in the thermal rearrangements of highly strained cyclopropenes. Hopf *et al.*[6d] found that isomeric cyclopropenes can be thermally interconverted and proposed that the common intermediates in these reactions are vinylidenes. However, to the best of our knowledge the only singlet vinylidene that has been successfully trapped and characterized is difluorovinylidene, $F_2C{=}C{:}$, which was recently observed by matrix isolation and theoretical studies.[7]

These interesting experimental results have prompted us to investigate the possible intermediates in the thermal isomerizations (Scheme 1) of a number of substituted cyclopropenes [Structures **1**, **3** and **4**, where R = R′ = H (**1a**, **3a**, **4a**), R = H, R′ = CH_3 (**1b**–**4b**) and R = R′ = CH_3 (**1c**–**4c**)] by means of



Scheme 1 Thermally induced formation of vinylidenes (**3**) from cyclopropenes (**1** and **2**) and alkyne formation (**4**) *via* alkyl migration.

† Details of the theoretical study are available from the RSC web page, see http://www.rsc.org/suppdata/cc/1998/2761

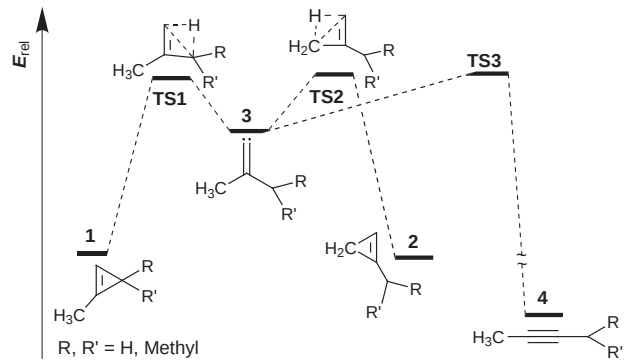


Fig. 1 Schematic singlet potential energy surface of alkyl-substituted cyclopropenes (**1**, **2**), vinylidenes (**3**), alkynes (**4**) and transition states (**TS1**,**TS2** and **TS3**).

hybrid density-functional (B3LYP) and *ab initio* (CCSD(T)) methods.[8]

A schematic potential energy surface for the important pathways leading to vinylidenes and the subsequent formation of alkynes upon alkyl migration is shown in Fig. 1. Formation of the corresponding vinylidenes occurs *via* a transition state involving the simultaneous breaking of a bond and a hydrogen shift, which for the reverse reaction is best described as an intramolecular insertion of the vinylidene carbene into the C–H bond (Fig. 2). Both types of substituted cyclopropenes, **1** and **2**, thus give rise to identical vinylidenes.

Our theoretical results (Table 1) indicate that the alkyl-substituted vinylidenes **3a**–**c** are all intermediates in the ring-opening reactions of alkylcyclopropenes (**1a**–**c** and **2a**–**c**). In the case of dimethylvinylidene **3a**, the symmetry-allowed 1,2-migration of a methyl group (**TS3a**) (with retention of its configuration), lies 11.1 kcal mol^{-1} above the vinylidene, while the transition state for the cyclization reaction (**TS1a**) giving

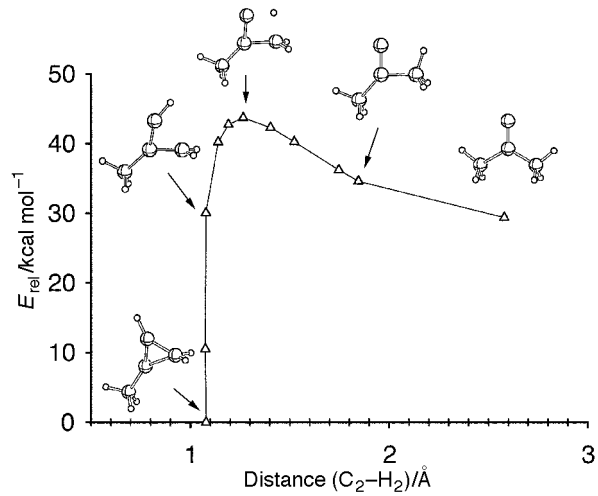

Fig. 2 Intrinsic reaction coordinate (IRC) for the formation of dimethylvinylidene (**3a**) from 1-methylcyclopropene (**1a**) *via* **TS1a** (B3LYP/6-31G*).

Table 1 Relative energies [in kcal mol^{-1}; B3LYP/6-311+G(2d,p) and CCSD(T)/6-31G(d) level of theory] of alkylvinylidenes (**3a–c**) with respect to their cyclopropene precursors (**1a–c** and **2b**,**c**), their connecting transition states (**TS1a–c** and **TS2b**,**c**) and the transition states for the alkyl migrations leading to alkynes (**TS3a–c**)

	1a		**3a**	**TS1a**		**TS3a**	
B3LYP	−25.9		0.0	12.5		11.1

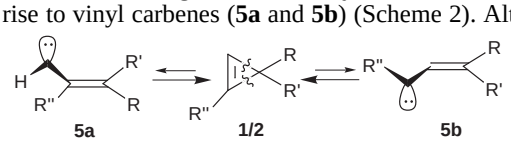
	1b	**2b**	**3b**	**TS1b**	**TS2b**	**TS3b-Me**	**TS3b-Et**
B3LYP	−28.4	−26.0	0.0	9.4	12.5	11.3	9.6
CCSD(T)	−29.1	−26.6	0.0	12.3	15.4	13.8	12.0
	1c	**2c**	**3c**	**TS1c**	**TS2c**	**TS3c-Me**	**TS3c-Pr^i**
B3LYP	−30.4	−26.3	0.0	7.3	12.5	10.9	9.7
CCSD(T)	−31.3	−27.1	0.0	9.8	15.1	13.1	11.1

rise to the 1-methylcyclopropene is 12.5 kcal mol^{-1} higher in energy (all B3LYP results). The lowest exit channel for ethylmethylvinylidene **3b** lies 9.4 kcal mol^{-1} above the vinylidene and the lowest isomerization pathway of methylisopropylvinylidene **3c** requires 7.3 kcal mol^{-1}. Thus all three investigated vinylidenes correspond to minima on their energy surfaces, substantiating the proposal that these reactive species are indeed common intermediates in the isomerization of cyclopropenes.[6d]

Overall, the good correlation of *ab initio* and density-functional results lends confidence to the quality of our thermochemical predictions. Further support for the reliability of the B3LYP data comes from comparison of these results with experimentally determined activation energies. The average deviation of the calculated barrier heights from the experimentally obtained values for the cyclopropene-to-vinylidene transition states **TS1b–c** and **TS2b–c**[6d,9] is found to be 2.4 kcal mol^{-1} at the B3LYP/6-31G* level and 0.1 kcal mol^{-1} at the B3LYP/6-311+G(2d,p) level. The results of the B3LYP/6-311+G(2d,p) calculations lie within the experimental error bars. This means that, given an average experimental error of 0.4 kcal mol^{-1},[6d,9] the relative error in the B3LYP/6-311+G(2d,p) must be smaller than 0.5 kcal mol^{-1}. The deviation of the *ab initio* results [CCSD(T)/6-31G*] from the experimental values is about 3.5 kcal mol^{-1}. Similar excellent agreement between activation energies obtained with the B3LYP method and experimental values has recently been noted for [3,3]-sigmatropic rearrangements.[10]

The experimentally observed formation of alkynes from vinylidenes involves a rate-affecting alkyl migration. With unsymmetrically substituted vinylidenes (**3b–c**) either a methyl (**TS3b-Me** and **TS3c-Me**) or an alkyl (**TS3b-Et** and **TS3c-Pr^i**) migration can occur. The calculations show that alkyl migration **TS3b-Et** and **TS3c-Pr^i** is preferred over the methyl shift (**TS3b-Me** and **TS3c-Me**), although the differences in the activation energies for these processes are small [ΔE_a(B3LYP) = 1.7 and 1.2 kcal mol^{-1}, respectively]. This agrees with experimental results from the pyrolysis of ^{13}C-labelled cyclopropenes **1b** and **1c**,[6e] where the ratio of **TS3b-Et** and **TS3b-Me** is found to be 3:1 and of **TS3c-Pr^i** and **TS3c-Me** is 1.4:1. The reasons for these small energetic differences, although difficult to pinpoint, most likely result from a combination of hyperconjugation, which stabilizes the three-centre two-electron bonds in these transition states, and steric effects, leading to a destabilization of the TS for the migration of higher substituted alkyl groups.

We have also investigated the homolytic bond-cleavage that gives rise to vinyl carbenes (**5a** and **5b**) (Scheme 2). Although



Scheme 2

this reaction is in some cases energetically preferred over vinylidene formation, it leads to an energetic dead end.[11] Subsequent hydrogen shifts of these vinyl carbenes that would lead to the corresponding allenes or dienes are all found to lie higher in energy than the corresponding vinylidene pathways and the transition states for the direct formation of alkynes from these conjugated carbenes all lie approximately 20 kcal mol^{-1} above the transition states for the alkyne formation from the corresponding vinylidenes.

These findings agree well with the experimentally observed product distributions in the pyrolysis of various cyclopropenes where the main decomposition channel was found to lead to alkynes.[6a–d,9]

The theoretical results support the proposed mechanistic pathway for the thermal ring-opening of highly strained cyclopropenes, and demonstrate that alkyl-substituted singlet vinylidenes correspond to intermediates that lie in potential energy wells deep enough to allow their characterization by spectroscopic methods. Experiments aimed at further characterisation of these interesting sub-valent carbon species thus seem promising. In contrast to previous assumptions, our theoretical investigations indicate that vinyl carbenes are not intermediates in the formation of alkynes from cyclopropenes.

N. G. kindly thanks Professor H. Hopf for his continuing support and interest in our work and the DFG for a fellowship.

Stereoselective sulfoxidation of α-mannopyranosyl thioglycosides: the *exo*-anomeric effect in action

David Crich,*[a] Jan Mataka,[a] Sanxing Sun,[a] K.-C. Lam,[b] Arnold L. Rheingold[b] and Donald J. Wink[a]

[a] *Department of Chemistry, University of Illinois at Chicago, 845 West Taylor Street, Chicago, IL 60607-7061, USA. E-mail: dcrich@uic.edu*

[b] *Department of Chemistry and Biochemistry, University of Delaware, Academy Street, Newark, DE 19716, USA*

Received (in Corvallis, OR, USA) 29th May 1998, Accepted 10th November 1998

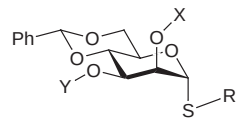
As a consequence of the *exo*-anomeric effect, and in contrast to their β-anomers, α-thioglycosides undergo stereoselective oxidation to give very predominantly the *R*-sulfoxides, as revealed by X-ray crystallography.

The sulfoxide method is a very powerful tool for the formation of glycosidic linkages to even very sterically hindered, unreactive glycosyl acceptors.[1–3] In most of the work described in the literature β-thioglycosides are oxidized to mixtures of sulfoxides,[3–5] which are used as such in the coupling reaction. In contrast, we have noted that a range of differentially protected α-mannopyranosyl thioglycosides are oxidized with excellent stereoselectivity to give essentially diastereomerically pure sulfoxides. These may then be employed productively in the efficient synthesis of β-mannopyranosides.[6–9] We now report the configuration of three α-mannopyranosyl sulfoxides, as determined by X-ray crystallography and chemical correlation, and discuss a possible reason for the stereoselectivity.

Initially, we noted that thioglycoside **1** was oxidized stereoselectively by magnesium monoperoxyphthalate (MMPP) in aqueous THF to give a single sulfoxide **8** in excellent yield, but were unable to assign configuration.[10] Similar results were obtained with MCPBA in CH_2Cl_2. Subsequently, the same phenomenon was observed with thioglycosides **2**–**7** and **15**–**17**, giving the corresponding sulfoxides **9**–**14** and **18**–**20**.[6–9,11,12] In view of the mechanism of the stereoselective β-mannosylation process,[9] in which the sulfoxide simply serves as a convenient precursor to the actual glycosylating species, the α-mannosyl triflate, the configuration at sulfur is of no consequence. However, curiosity dictated that we seek the origins of this unanticipated stereoselective sulfoxidation. Eventually, we were rewarded by the growth of single crystals of **20** (mp 109–111 °C) suitable for X-ray crystallographic analysis from EtOH solution. In due course the configuration at sulfur was revealed to be *R* (Fig. 1).

In an attempt to obtain an isomeric sulfoxide, **16** was oxidized with $NaIO_4$ and with Oxone, but in each case only **19** was obtained. It was therefore apparent that the stereoselectivity was not a function of the reagent and, for example, hydrogen bonding to the ring oxygen. We next submitted thioglycoside **21** to oxidation with MCPBA and again were rewarded by the formation of one major sulfoxide (> 10:1). Crystals suitable for X-ray analysis were again obtained (mp 190 °C, EtOH) and the structure consequently revealed to be **22** (Fig. 2), with the same configuration at sulfur as **20**. Again, a diverse range of oxidants provided the same major sulfoxide. Treatment of **22** with NaH and then BnBr in THF provided sulfoxide **10**, albeit in only 35% yield, so fixing its configuration at sulfur as *R*. Thus, we have established that three of the eleven sulfoxides in question have the same *R*-configuration and see no reason to doubt that the remainder follow the pattern.

In view of the range of different oxidants and solvents employed, each giving the same result, we conclude that the stereoselectivity of the oxidation is dictated predominantly by



1 R = Et, X = TBDMS, Y = Bn

steric effects[13] and the conformation imposed on the thioglycosides by the *exo*-anomeric effect.[14–16] Thus, as seen from the Newman projection in Fig 3, in the conformation imposed by the *exo*-anomeric effect the *pro-R* lone pair of the α-thioglycosides is exposed to attack. On the other hand oxidation of the *pro-S* lone pair would be substantially hindered by the pyranose ring, and especially by the axial hydrogens, H-3 and H-5. In the case of the β-thioglycosides, the two lone pairs are less sterically differentiated and mixtures of sulfoxides result.

Finally, we note that the two crystalline sulfoxides both adopt the same conformation (Fig. 1 and 2) about the C1–S bond, which roughly mirrors that imposed on the original thioglyco-

sides by the *exo*-anomeric effect. However, in this instance, it seems likely that this is more a consequence of minimization of repulsion between the C1–O5 and S–O dipoles.[17]

We thank the NSF (CHE 9625256 and NIH GM57335) for partial support of this work.

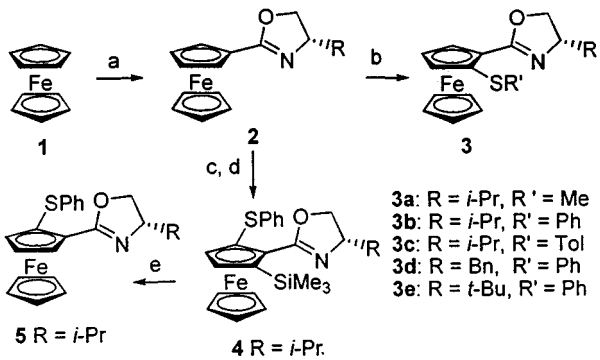
A series of chiral thioether dervatives of ferrocenyl-oxazolines, prepared with diastereoselectivities > 95 : 5, have been shown to be highly efficient catalysts for a palladium catalyzed allylic substitution reaction, with enantioselectivity of 81–98% ee, and the role of planar chirality in these ligands was also discussed.

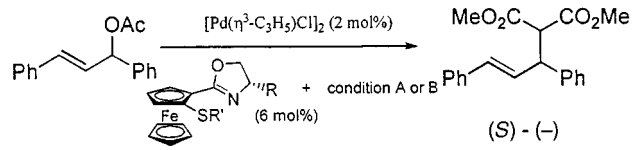
In the past few years, palladium catalyzed allylic substitutions[1] have been used extensively in asymmetric carbon–carbon bond formation to provide chemo-, regio-, diastereo-, and enantioselectivity.[2] A variety of chiral ligands have been studied. In addition to the widely used phosphine or phosphite ligands, sulfur–nitrogen ligands have recently been proved to be successful.[3] For example, Williams explored thioether of phenyloxazoline ligands for the palladium catalyzed allylic substitution,[13a,b] good to excellent enantioselectivities were obtained. Other groups also showed the high enantioselectivity obtained with this type of N,S-bidentate ligand. Recently, planar chiral bidentate ligands have been successfully applied in many asymmetric reactions. The work of Fu and coworkers showed that the single planar chiral bidentate ligands were highly efficient catalysts for several asymmetric reactions.[4] In conjunction with our group's interest on asymmetric sulfonium ylide reaction[5] and transfer hydrogenation with planar chiral ferrocene derivatives[6] as ligands, we disclose a preliminary result of our studies on the synthesis of chiral thioether derivatives of ferrocenyl-oxazoline and application in palladium catalyzed allylic substitution. The role of planar chirality in this reaction was also studied.

Recently, Ahn *et al.* have reported an efficient diastereoselective synthesis of chiral oxazolinylferrocene compounds.[7] According to Ahn's method and our own experience, a series of chiral thioether derivatives of ferrocenyl-oxazoline were synthesized as follows: oxazolinylferrocene **2** was treated with *n*-BuLi and equimolar amount of TMEDA in Et_2O at −78 °C for 2 h (Scheme 1), the resulting mixture quenched with electrophiles (Me_3SiCl, $PhSO_2SR'$ or R'SSR'), then usual work-up to give the pure products. The diastereoselectivities of **3** and **5** determined by 300 MHz ^1H NMR were > 95 : 5.



Scheme 1 *Reagents and conditions*: a, See refs. 7–9; b, (1) *n*-BuLi, TMEDA, Et_2O −78 °C, 2 h; (2) $PhSO_2SMe$ or R'SSR' 67–91%; c, (1) *n*-BuLi, TMEDA, Et_2O, −78 °C, 2 h; (2) TMSCl 93%; d, (1) *n*-BuLi, Et_2O, −78 °C, 2 h; (2) PhSSPh 70%; e, TBAF, THF, reflux, 6 h 88%.

To assay the effectiveness of ligands and other factors in palladium catalyzed alylic substitution, we chose the usual test reaction, the reaction of 1,3-diphenylprop-2-enyl acetate with the nucleophile derived from dimethyl malonate. Conditions A [$NaCH(CO_2Me)_2$, THF, r.t.] or B [$CH_2(CO_2Me)_2$, BSA, LiOAc, DCM, r.t.] were used in the reaction (Scheme 2).



Scheme 2 Condition A: $NaCH(CO_2Me)_2$, THF, r.t. Condition B; $CH_2(CO_2Me)_2$, BSA [*N*,*O*-Bis(trimethyl)acetamide], LiOAc, CH_2Cl_2, r.t.

First, we investigated the effect of different salts on reaction yields and enantioselectivies under condition B with the catalyst derived from **3c** and $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$. The results are summarized in Table 1, and it was found that ee values did not change in the presence of the salts listed in Table 1 (88.1–89.9%), but that the reaction time varied significantly (3–48 h). In view of the reaction time, yield and ee value, the lithium acetate (Table 1, entry 4) was used throughout this work.

Using the above conditions, a variety of ligands and conditions in the palladium catalyzed asymmetric allylic substitutions are summarized in Table 2. The sense of enantioinduction was determined by HPLC and confirmed by specific rotation of the product methyl-2-carbomethoxy-3,5-diphenylpent-4-enolate[10] and was found to be *S* in all cases. Comparing conditions A and B, we obtained higher enantioselectivities with the latter, which is consistent with most literature reports.[1,2] From entries 1–6 we found that ligands **3b** and **3c** are superior to **3a**. The chiral thioether of ferrocenyl-oxazolines derived from different amino alcohols show different effectiveness for enantioselectivities. The results showed that R = *t*-Bu (entries 9,10) is superior to R = *i*-Pr (entries 3,4) or Bn (entries 7,8). Entry 11 showed that the palladium complex with ligand **4** could mediate the allylic substitution reaction

Table 1 Asymmetric palladium catalyzed allylic substitution with different salts under condition B[a]

Entry	Salt	*t*/h	Yield (%)[b]	Ee (%)[c]

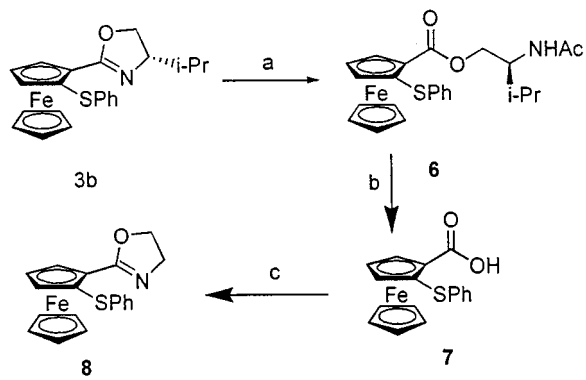
smoothly, while the bulkier trimethylsilyl group may decrease the enantioselectivity of the product.

Compared with the palladium complexes of chiral thioethers of phenyloxazoline ligands reported by Williams,[3a] the palladium complexes with chiral thioethers of ferrocenyl–oxazolines are more efficient. The allylic substitution reaction catalyzed by the latter under our conditions is much faster and gives almost quantitative yields.

In order to investigate the effect of planar chirality on the absolute configuration and enantioselectivity of this reaction, diastereoisomer **5** was also synthesized, and subjected to palladium catalyzed allylic substitution. Under essentially similar conditions (condition B), a similar enantioselectivity (89.4% in entry 4 *vs.* 90.4% in entry 12, Table 2) and the same absolute configuration was obtained. It seems that the absolute configuration is governed mainly by the central chirality of the oxazoline ring. (It seems that planar chirality plays a much less important role in palladium catalyzed allylic substitution.) This phenomenon was also found in our previous work on ruthenium-catalyzed asymmetric transfer hydrogenation with ferrocene derived catalysts.[6]

In order to further clarify the role of the planar chirality in this reaction, we may remove the central chirality on the oxazoline ring. For this purpose, the single planar chiral thioether of ferrocenyl-oxazoline (**8**) was designed and synthesized[11] (Scheme 3). Ligand **8** was subjected to palladium catalyzed allylic substitution under essential similar conditions as above (condition B) but only 8.5% ee was obtained and the absolute configuration is *R*. This result can explain why diastereosiomer



Scheme 3 *Reagents and conditions*: a, (1) TFA, H_2O, Na_2SO_4, THF; (2) Ac_2O, Py, CH_2Cl_2, 88%; b, (1) 2.5 M NaOH (aq), THF, 55 °C (2) H_3O^+, 85%; c, (1) $(ClCO)_2$, $NH_2(CH_2)_2OH$, Et_3N, CH_2Cl_2, (2) TsCl, Et_3N, DMAP, CH_2Cl_2, 63%.

Entry	Ligand	Condition[b]	*t*/h	Yield (%)	Ee (%)[c]
1	**9a**[a]	A'	36	91	78
2	**3b**	A	2	98	84.0
3	**9a**[a]	B'	36	96	90
4	**3b**	B	3	98	89.4
5	**9b**[a]	B'	96	92	96
6	**3e**	B	12	98	98.0

[a]  **9a**: R = *i*-Pr; **9b**: R = *t*-Bu. [b] Condition A': $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (2.5 mol%), 9 (10 mol%), $NaCH(CO_2Me)_2$, THF, 20 °C. Condition B': $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (2.5 mol%), 9 (10 mol%), KOAc (3 mol%), BSA, $CH_2(CO_2Me)_2$,CH_2Cl_2, 20 °C. [c] Absolute configuration of product was *S* for all cases.

5 achieved only a little higher ee than ligand **3b** (90.4% entry 12 *vs.* 89.4% entry 4 in Table 2); the planar chirality matched the central chirality in **5** for the oxazoline ring whereas they are mismatched in ligand **3**. The ee obtained with ligand **8** was low but did have an influence in this asymmetric allylic substitution reaction. Furthermore, it is noteworthy to compare the reaction rate of the reaction catalyzed by **3** with the counterpart of the thioether of phenyloxazoline **9** (Table 3). For all the reactions catalyzed by **9**, the rates are much slower than those of the ferrocene derivatives.[12]

Received (in Cambridge, UK) 14th October 1998, Accepted 9th November 1998

Computational methods based on the density functional theory have been employed in the search for new ferromagnetic molecules and several compounds are predicted to exhibit stronger ferromagnetic coupling than the known hydroxo-bridged complexes, especially remarkable is the very strong coupling predicted for oxo-bridged Cu(II) or Ni(II) dimers.

One of the strategies applied to obtain new materials with interesting magnetic properties consists of increasing their structural dimensionality by combining binuclear building blocks to form chains, layers or tridimensional networks.[1] The choice of binuclear transition metal building blocks with different exchange coupling patterns opens up a number of possibilities in this area.[2] Hence, the magnetic behavior of a variety of such compounds has been explored during the last decades[3] with the aim of designing molecular magnets or molecule-based magnets. However, the large number of known antiferromagnetic complexes is in sharp contrast with the paucity of ferromagnetic systems. Up to now, the search for ferromagnetic coupling in binuclear transition metal complexes has been based on the synthesis of heteronucler complexes with strictly orthogonal singly-occupied molecular orbitals (SOMOs) or of complexes with accidentally degenerate SOMOs. Theoretical studies are therefore of great help in establishing the factors that lead to such accidental degeneracy in a given compound.

In recent work[4,5] we have shown the ability of hybrid density functional-Hartree–Fock methods to provide good numerical estimates of the exchange coupling constant J (defined in the Heisenberg hamiltonian $H = -JS_1S_2$) by using the B3LYP method[6] implemented in the GAUSSIAN package,[7] combined with a modified broken-symmetry approach.[8] The excellent results obtained so far prompted us to apply such methodology in search for new complexes with ferromagnetic behavior. A reasonable starting point for this search is to chemically modify Cu(II) systems already known to behave ferromagnetically, such as the hydroxo- or the end-on azido-bridged complexes. In particular, the hydrogen atom of the hydroxo bridging group offers a wider choice for chemical substitution. For hydroxo-bridged Cu(II) binuclear complexes, a classical correlation between the experimental exchange constant and the Cu–O–Cu bond angle θ indicates that those complexes are antiferromagnetic for $\theta > 98°$, but ferromagnetic for smaller angles.[9] In our previous work, we have shown that for these complexes the out-of-plane shift (τ) of the hydrogen atoms on the bridge also plays a crucial role in determining the magnetic behavior, since the ferromagnetic coupling increases with τ.[4,5]

We started by analyzing the influence of the substituent at the oxygen atom on the value of J, using the model compounds $[(NH_3)_2Cu(\mu\text{-}OR)_2Cu(NH_3)_2]$ **1**, with the bond angles θ and τ fixed at 101 and 0°, respectively. From now on we will refer to this particular structure as geometry **A**. In spite of the antiferromagnetic character found for the hydroxo-bridged complexes with this structure, we compare the calculated value of J with that of the hydroxo derivative with the same geometry as a criterion for selecting the best candidates. The calculated exchange constants for the different models with geometry **A**[10] are presented in Table 1, together with an indication of the pertinent structural data for the related compounds found in the Cambridge Structural Database (CSD).[11] From the calculated values of J some conclusions can be drawn: (1) all the alkoxo- and phenoxo-bridged complexes show stronger antiferromagnetic coupling than the hydroxo-bridged ones, in agreement with the experimental results. (2) For the methoxo-bridged compounds, substitution of the hydrogen atoms by alkyl groups weakens the antiferromagnetic coupling. (3) In general, the larger the electronegativity of the substituent, the stronger the antiferromagnetic coupling (*i.e.*, the values of $-J$ appear in the order OF > OCR_3 > OH ≈ OBR_3 > $OSiR_3$ ≈ $OGeR_3$ > $OAlR_3$ > OLi), although there are a few exceptions to this rule. The effect of substituents at a distance of two bonds cannot be rationalized according to the same electronegativity criterion, as seen for the two R groups in $OSiR_3$ and $OGeR_3$.

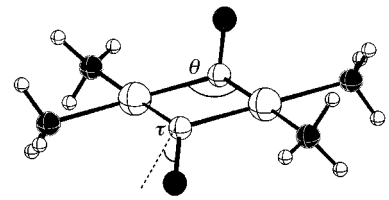

Table 1 Calculated coupling constants (cm^{-1}) for $[(NH_3)_2Cu(\mu\text{-}OR)_2Cu(NH_3)_2]^{n+}$ with structure **1** (n = 0, OR = O, OSO_3, OBR_3 and $OAlR_3$; n = 4 for OR = OPy; n = 2 for all other OR) in geometries **A** (θ = 101°, τ = 0°) and **B** (θ = 96°, τ = 50°)

[a] The experimental structural data have been obtained with the help of the CSD.[11] The number (N) indicates the structures with planar Cu_2O_2 rings. An all electron double-ζ basis has been employed in the calculations.[12]

Since the angles θ and τ adopted in the model structure **A** are not expected to favor ferromagnetism, we selected the least antiferromagnetic or most ferromagnetic compounds for further exploration with a structure more likely to favor ferromagnetism. For them, a second set of calculations was performed with θ and τ fixed at 96 and 50°, respectively (geometry **B**), and the calculated coupling constants are also presented in Table 1. In practically all cases, the new geometry results in a decrease of the antiferromagnetic contribution, as expected for the smaller energy gap of the SOMOs obtained by reducing θ while simultaneously increasing τ.[13] The exceptions (O and $OSOCH_3$) should be attributed to the fact that the energy ordering of the SOMOs is inverted in these compounds. As a consequence, the energy gap between these two orbitals increases with the Cu–O–Cu bond angle and a stronger antiferromagnetic contribution results.[4] From the calculated exchange coupling constants, one can conclude that the sulfato and OX bridges with X = Li, BR_3, AlR_3, SiR_3 or GeR_3 could yield ferromagnetic complexes. Especially remarkable is the fact that the OBH_3-bridged compound is made much more ferromagnetic upon changing its geometry from **A** to **B**. However, we could only detect one case of a related complex in the literature, having an OB(R)=O bridge and quite large Cu–O distances. In summary, our results indicate that copper(II) binuclear complexes bridged by oxygen bonded to an electropositive atom, such as an alkali, alkaline-earth, group 13 or group 15 element, are good candidates to present a strong ferromagnetic coupling. Notice that our prediction of ferromagnetic systems is based on a particular set of structural parameters (θ = 96° and τ = 50°). Thus, we are investigating whether such structures are energetically feasible for the selected compounds by optimizing model structures of increasing complexity. Preliminary results show that the selected systems adopt structures close to that corresponding to geometry **B** and a strong ferromagnetic coupling should be expected.

A particularly surprising result is the exceptionally strong ferromagnetic coupling constants obtained for the oxo-bridged complex of copper (+989 and +782 cm^{-1} for geometries **A** and **B**, respectively), as compared to the largest values reported in the literature for azido- and hydroxo-bridged complexes (+170 and +172 cm^{-1}, respectively).[14,15] To obtain a more realistic model of an oxo-bridged complex, we have repeated the calculations adding an NH_3 ligand in the fifth coordination position of each copper atom, whereupon the calculated exchange constant for geometry **B** is reduced to +661 cm^{-1}, exhibiting still a very strong ferromagnetic character, comparable to the calculated value (+685 cm^{-1}) for the optimized structure of the penta-coordinate copper model. In agreement with the Hay–Thibeault–Hoffmann model,[13] all the oxo-bridged model calculations reveal a near-degeneracy of the two SOMOs. Unfortunately, no oxo-bridged Cu(II) complexes have been described in the literature to the best of our knowledge. An indication of the ability of the oxo bridge to induce ferromagnetic coupling is provided by the μ-aqua–μ-oxo complex described by Chaudhuri *et al.*,[16] which is tautomeric to the corresponding bis(μ-hydroxo) complex. The latter presents a coupling constant of −90 cm^{-1} whereas the former shows a ferromagnetic behavior with a singlet–triplet gap of +74 cm^{-1}. Recently, Root *et al.* reported the structure of a trinuclear complex containing a Cu_3O_2 core with two Cu(II) and one Cu(III) ion showing a singlet–triplet gap of +14 cm^{-1}.[17]

Similar bis (μ-oxo) complexes with transition metals other than copper have been described, mainly with manganese[18,19] and iron.[20] In sharp contrast to our theoretical prediction for copper, these complexes show antiferromagnetic coupling. To verify our predictions against the experimental data for Mn and Fe, we have studied the dependence of **J** on the angle θ for the model complex $[(NH_3)_4M(\mu\text{-}O)_2M(NH_3)_4]$, where M = Cu, Ni or Mn. The results, represented in Fig. 1, show a parabollic dependence of J on θ, with the maximum value of J appearing at smaller angles in the order Mn > Ni > Cu, similar to that we previously found for the end-on azido-bridged complexes.[21]

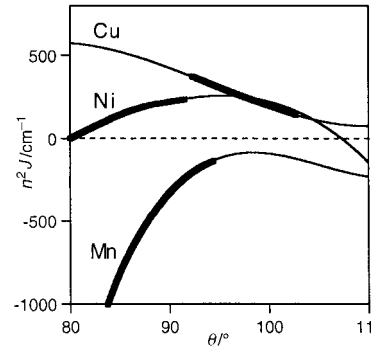

Fig. 1 Total exchange constants (n^2J, where n is the number of unpaired electrons per metal atom) for bis μ-oxo complexes of Cu(II), Ni(II) and Mn(II) as a function of the bridging angle θ. The outlined parts of the curves correspond to those geometries within 3 kcal mol^{-1} of the calculated energy minima (1 cal = 4.184 J).

The main difference is that for the azido complexes ferromagnetic coupling is found for the three metals while the oxo-bridged Mn(II) complexes show antiferromagnetic behavior, consistent with the available experimental data for the d^5 Fe(III) oxo-bridged complex.[20] The values of the optimized θ angles are also different for the two bridges with the same metal. Thus, for the end-on azido complexes the order Mn > Ni > Cu was found for such angle, whereas for the oxo-bridged complexes the largest value is that for Cu. As a conclusion, Ni(II) and Cu(II) complexes with an oxo bridge or with electropositive substituents at the bridging oxygen constitute interesting synthetic goals for new potentially ferromagnetic systems.

Inhibitors of DNA polymerase β from *Schoepfia californica*

Jie Chen, Yu-Huan Zhang, Li-Kai Wang, Steven J. Sucheck, Angela M. Snow and Sidney M. Hecht*

Departments of Chemistry and Biology, University of Virginia, Charlottesville, Virginia 22901, USA. E-mail: sidhecht@virginia.edu

Received (in Corvallis, OR, USA) 8th September 1998, Accepted 18th November 1998

Fractionation of a hexane extract prepared from the plant *Schoepfia californica* was carried out by bioassay guided fractionation, affording five inhibitors of DNA polymerase β; four of these were shown to be anacardic acid and structurally related derivatives, while the fifth was oleic acid.

In addition to their role in DNA replication, at least three eukaryotic DNA polymerases participate in the repair of damaged DNA.[1] Given that elements in our environment such as sunlight and pollution provide a steady source of DNA damage, the repair of damaged DNA must be essential to maintain cell viability.[2] There is, however, at least one context in which DNA damage repair is not beneficial, namely following the clinical administration of antitumor agents that function by damaging DNA. The repair of DNA damage inflicted by these agents on cancer cells must mitigate their therapeutic potency.

DNA polymerase β is believed to have primary responsibility for supporting short patch DNA base excision repair.[3–5] This pathway has specifically been implicated in the repair of DNA damage caused by agents such as *cis*-platinum, bleomycin and neocarzinostatin.[3,4,6–8] To identify non-toxic compounds that can block the function of DNA polymerase β selectively, and which may thereby be able to potentiate the action of anticancer agents such as bleomycin, we have surveyed plant extracts for naturally occurring inhibitors of polymerase β.[9] Presently we describe five natural inhibitory principles from *Schoepfia californica* that can potentiate the action of bleomycin and *cis*-platinum.

A hexane extract prepared from the twigs, leaves and fruit of *Schoepfia californica* was partitioned between hexane and MeOH; the hexane phase contained most of the polymerase β inhibitory activity. Successive bioassay-guided fractionations on two silica gel columns and then by preparative silica gel TLC afforded an active fraction that effected 94% inhibition of polymerase β function at 5 μg ml^{-1} *vs.* 38% inhibition for the initial extract.† Fractionation (C_8 column, 80% MeOH) then afforded pure compounds **1–5**; all were obtained as colorless needles except **3**, which was a colorless oil.

The structures were determined by spectroscopic analysis. Compound **1** was found to have a molecular ion at *m/z* 374.2822, establishing the molecular formula as $C_{24}H_{38}O_3$. The ^{13}C NMR spectrum of **1** displayed six resonances (δ 110.31, 115.87, 122.74, 135.38, 147.76 and 163.65) assigned to an aromatic ring and a resonance at δ 175.67 assigned to a carboxylate carbon, thus accounting for five of the six units of unsaturation implied by the molecular formula. The presence of three aromatic resonances in the ^{1}H NMR spectrum at δ 6.77 (d, *J* 7.5), 6.87 (d, *J* 7.5) and 7.36 (dd, *J* 7.5, 7.5) indicated that the aromatic ring was trisubstituted; the multiplicities of the proton resonances were consistent with a 1,2,3-trisubstituted benzenoid system.‡

The chemical shift of the carboxylate at δ 175.67 was typical of a carboxylate attached to an aromatic ring; the downfield shift of the aromatic H at δ 7.36 (dd) suggested the *para* relationship of this H to the carboxylate moiety. That the remaining O atom was present as part of a phenolic substituent was suggested by the downfield shift of one ring carbon (δ 163.65). The *ortho* relationship of this OH to the ring carboxylate was supported by the upfield shift of the ring C atom (δ 110.31), consistent with the known (δ 12.7) shielding effect of *ortho* phenolic OH groups.[15]

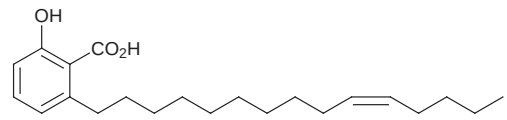
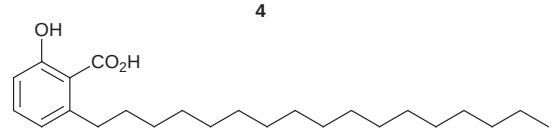
3



4

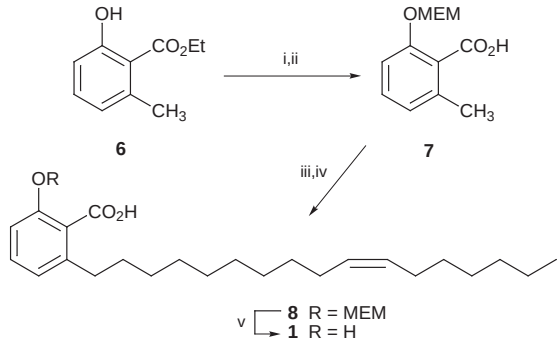


5

These data suggested that **1** was a 6-substituted salicylic acid; the ^{1}H and ^{13}C NMR spectra were consistent with an unbranched alkyl substituent containing a single double bond. The double bond configuration was assigned as *cis* based on the ^{13}C NMR resonances of the allylic carbon atoms.[16] Determination of the olefin position was made by modification of published procedures.[17]

The structure assigned to **1** was confirmed by chemical synthesis, as outlined in Scheme 1. Ethyl 2-hydroxy-6-methylbenzoate **6**[18] was protected as the corresponding MEM ether[19] and the ethyl ester was saponified, affording carboxylic acid derivative **7** as colorless prisms (71% yield). Treatment of **7** with LDA (2 equiv., THF), followed by admixture of (9*Z*)-hexadec-9-enyl bromide at 0 °C,[20] afforded homologated salicylic acid derivative **8** (68% yield). MEM deprotection[19] provided **1**[14] as colorless needles (80% yield). The synthetic and naturally derived samples were found to be identical as judged by their behavior on silica gel TLC, and by their identical ^{1}H and ^{13}C NMR and mass spectra, as well as their equal abilities to inhibit DNA polymerase β (*vide infra*).

Compounds **2**, **4**, and **5** were found to have spectroscopic properties most similar to **1**. The structures were assigned in the same fashion as for **1**, a process facilitated by previous reports



Scheme 1 *Reagents and conditions*: i, MEMCl, Pr^i_2NEt; ii, Bu^tOK, 61% over 2 steps; iii, LDA; iv, (9*Z*)-hexadec-9-enyl bromide, 68% over 2 steps; v, $ZnBr_2$, 80%.

of each of these compounds.[21] Verification of the structure assignments was accomplished by total chemical synthesis of each. The mass spectrum of **3** contained a molecular ion having *m/z* 282. The ^1H and ^{13}C NMR spectra of **3** were found to be identical with those of oleic acid.[13]

The activities of **1**–**5** as inhibitors of DNA polymerase β are shown in Table 1. Compound **1** exhibited an IC_{50} of 1.4 μM in the absence of bovine serum albumin (BSA). BSA reduced the IC_{50} to 9 μM, undoubtedly reflecting the binding of **1** to this (basic) protein. Unsaturated analogues **1** and **4** were found to have the greatest potencies in the presence of BSA (9 and 19 μM, respectively), and to be reproducibly more active than saturated derivatives **2** and **5**. Oleic acid, which is a simple fatty acid, was active only at significantly higher concentration. Methylation of the phenol or carboxylic acid moieties essentially eliminated inhibitory activity as did conversion of the carboxylate of **5** to the respective carboxamide, demonstrating that the anacardic acids are specific inhibitors rather than simple denaturants.§

2	30
3	72
4	19
5	25

[a] Determined as described in footnote †. [b] Determined in the absence of bovine serum albumin.

Compound **1** and a few structurally related species were evaluated in more detail as DNA polymerase β inhibitors. In both short and long term mammalian cell culture, these compounds potentiated the action of DNA damaging agents such as bleomycin (Table 2) and *cis*-platinum, and inhibited bleomycin-induced unscheduled DNA synthesis. They also blocked DNA polymerase β-mediated gap filling of a DNA duplex substrate.[12] Thus specific inhibitors of DNA polymerase β may well be able to potentiate the effects of the DNA damage caused by clinically used antitumor agents that function at this locus.

Table 2 Potentiation of the cytotoxicity of bleomycin (BLM) by **1**[a]

Compounds present	Viable cells (% of control)
—	100

50 μM **1**	98
50 μM BLM + 50 μM **1**	68

[a] P388D, cells were cultured in suspension in the presence of the test compounds for 6 h, then assessed for viability by trypan blue exclusion staining.

We thank Ms Shelley Starck, University of Virginia, for biochemical evaluation of these agents and Dr Mark Hemling, SmithKline Beecham Pharmaceuticals, for the high resolution mass spectrometry data. We thank Dr Akio Matsukage, Aichi Cancer Center Research Institute, Nagoya, for providing us with a source of cloned rat DNA polymerase β. This work was supported by NIH Research Grant CA50771 from the National Cancer Institute.

Notes and references

† Inhibition of polymerase β was assayed in 62.5 mM ammediol buffer, pH 8.6, containing 10 mM $MgCl_2$, 1 mM dithiothreitol, 50 μg ml^{-1} of BSA, 6.25 μM deoxynucleotide triphosphates including [^{3}H]thymidine triphosphate and 12.5 μg of DNase I-treated calf thymus DNA. The reactions were initiated with 0.2 μg of rat liver DNA polymerase β (ref. 10,11), incubated at 37 °C for 1 h, and monitored as described (ref. 12).

‡ The assignments of the H3, H4 and H5 resonances in the NMR spectra of **1**, **2**, **4** and **5** were further supported by HMQC spectroscopy. The spectra also proved useful for assigning proton and carbon resonances in the aliphatic substituents of **1–5**, used in combination with the full ^{13}C NMR assignments of a number of common fatty acids (ref. 13) and the ^{1}H-coupled ^{13}C NMR spectra of several compounds structurally related to **1**, **2**, **4** and **5** (ref. 14).

§ Also determined was the selectivity of inhibition. A number of derivatives were found to be essentially inactive as inhibitors of calf thymus DNA topoisomerase I, AMV reverse transcriptase, DNA polymerase I (Klenow fragment) and restriction endonuclease *Hin*dIII at concentrations at which those compounds strongly inhibited DNA polymerase β.

ChemComm

A unique mode of molecular recognition in palladium(II) metallacrown ethers

Dale C. Smith, Jr., Charles H. Lake and Gary M. Gray

Department of Chemistry, University of Albama at Birmingham, Birmingham, AL 35294, USA. E-mail: gmgray@uab.edu

Received (in Bloomington, IN, USA) 15th September 1998, Accepted 26th October 1998

Metallacrown ethers of the type $[PdX_2\{Ph_2P(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$ (X = Cl, I) exhibit a unique and reversible mode of molecular recognition in which PdX_2 units are incorporated into the metallacrown ether ring *via* a ring-expansion reaction to form dimetallacrown ethers.

Molecular receptors are of interest as chemical sensors, catalysts and models for complex biochemical receptors.[1] Recently, molecules with multiple receptor sites have received considerable attention. The multiple receptor sites can give rise to unusual catalytic properties[2] or allow the molecules to function as highly selective sensors.[3]

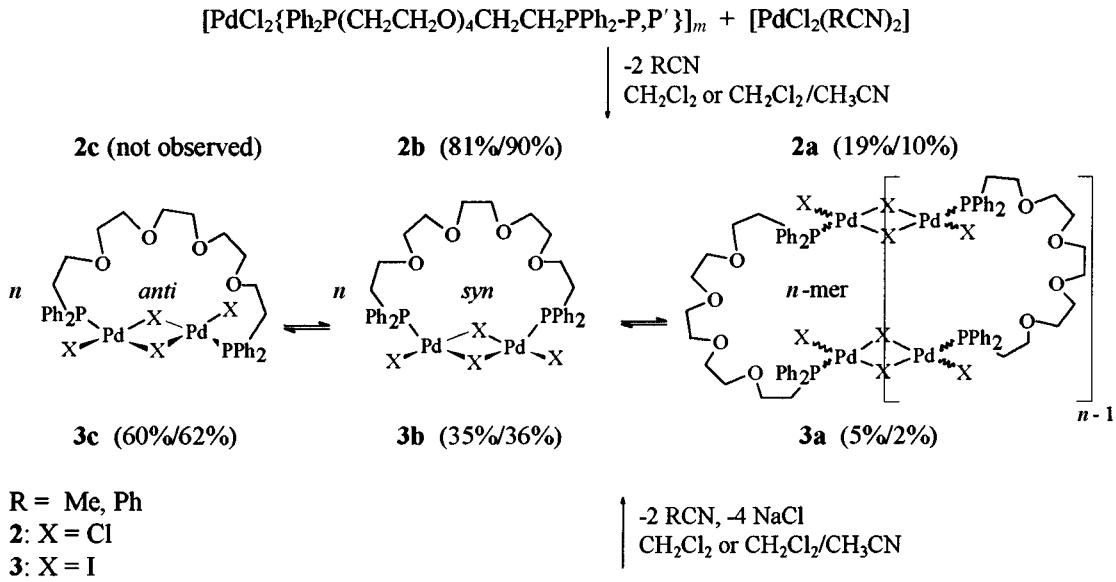
Metallacrown ethers are a class of molecular receptors with both crown ether- and transition metal-receptor sites.[4,5] We now report that the metallacrown ether $[PdCl_2\{PPh_2(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$, **1**,[6] exhibits a unique mode of molecular recognition in which the metallacrown ether ring is expanded by the incorporation of a $PdCl_2$ moiety. The product of this reaction is the first reported example of a dimetallacrown ether.

In a typical experiment, the metallacrown ether $[PdCl_2\{PPh_2(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$ **1**, which is mixture of *cis*- and *trans*-monomers and cyclic *n*-mers,[6] is reacted with either $[PdCl_2(PhCN)_2]$ or $PdCl_2$. This reaction is rapid with soluble palladium salts, *i.e.* $PdCl_2$ in acetonitrile or $[PdCl_2(PhCN)_2]$ in dichloromethane, but takes place even when the palladium salt is insoluble, *i.e.* $PdCl_2$ in chloroform. Both reactions give high yields of the dimetallacrown ether $[Pd_2Cl_2(\mu\text{-}Cl)_2\{PPh_2(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$, **2**, (Scheme 1). A similar reaction of **1** with either $[PdCl_2(PhCN)_2]$ or $PdCl_2$ and excess NaI in an acetonitrile–dichloromethane mixture gives a high yield of the dimetallacrown ether $[Pd_2I_2(\mu\text{-}I)_2\{PPh_2(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$, **3**. The latter reaction is of interest because it demonstrates that it is possible to exchange the anion in the dimetallacrown ether without exchanging the cation.

Comparison of the rates of $PdCl_2$ binding by **1** and $[PdCl_2(PPh_2Et)_2]$ **4**[7] in chloroform-*d* solutions clearly demonstrates the importance of the metallacrown ether receptor in **1**. After 20 h at ambient temperature, **1** is completely converted into **2**. In contrast, after 20 h at ambient temperature, only 10.5% of **4** is converted into the corresponding dinuclear palladium complex, $[Pd_2Cl_4(PPh_2Et)_2]$.

The binding of $PdCl_2$ by the metallacrown ether, **1**, is strong and reversible. It is not possible to remove the $PdCl_2$ from **2** by extracting chloroform-*d* solutions of **2** with 0.5 M aqueous HCl solutions. However, the $PdCl_2$ can be completely removed from **2** *via* chromatography, with the $PdCl_2$ remaining on the silica and **1** eluting from the column.

Chloroform-*d* solutions of **2** and **3** contain multiple resonances in their $^{31}P\{^1H\}$ NMR spectra (Fig. 1) indicating that these complexes, like **1**, exhibit both geometrical and monomer/*n*-mer equilibria in solution.[6] The major resonance in the $^{31}P\{^1H\}$ NMR spectrum of **2** is assigned to the monomeric *syn*-dimetallacrown ether **2b** while the minor resonances are assigned to *n*-meric dimetallacrown ethers **2a**. This assignment is supported by the decrease in ratio of the major resonance **2b** to the minor resonance **2a** both as the concentration increases (8.0/1 at 0.0175 M *versus* 4.3/1 at 0.0350 M) and as the



Scheme 1 Proposed equilibria for the dimetallacrown ethers. The relative species percentages were determined by integration of the quantitative $^{31}P\{^1H\}$ NMR spectra and are given for both 0.0350 M and 0.0175 M solutions of **2** in chloroform-*d* and for both 0.0350 M and 0.0175 M solutions of **3** in (1 : 1) dichloromethane/chloroform-*d* at 295 K.

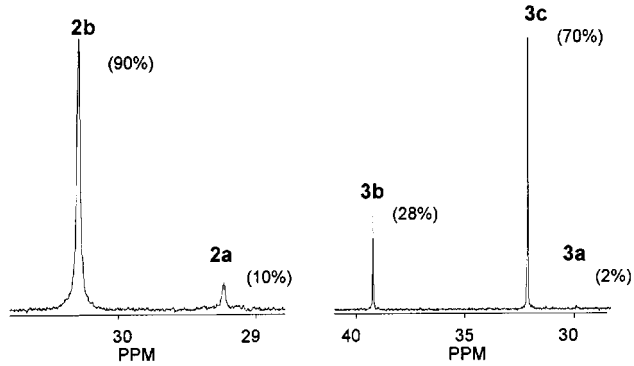


Fig. 1 $^{31}P\{^{1}H\}$ NMR spectra of 0.0175 M solutions of the dimetallacrown ethers, **2** and **3**, in chloroform-*d* at 295 K. {Spectral parameters: $^{31}P\{^{1}H\}$, 121.498 MHz, number of scans 256, line broadening 1.0 Hz, sweep width 2439.02 Hz, 30° inverse gated pulse, pulse delay 30 sec}.

temperature decreases (11.3/1 for a 0.0175 M solution at 331 K *versus* 8.0/1 for a 0.0175 M solution at 295 K).[8] The assignment of **2b** as the *syn* isomer is based on the similarity of the chemical shift of its $^{31}P\{^{1}H\}$ NMR resonance to those of *syn*-$Pd_2Cl_4L_2$ (L = monodentate phosphine) complexes.[9]

The major resonance in the $^{31}P\{^{1}H\}$ NMR spectrum of **3** is assigned to the monomeric *anti*-dimetallacrown ether **3c**, and the minor resonance is assigned to the *syn*-dimetallacrown ether **3b** (Fig. 1). This assignment is supported by the increase in the ratio of the major resonance **3c** to the minor resonance **3b** as the polarity of the solvent decreases (1.8/1 in a 1 : 1 dichloromethane–chloroform mixture *versus* 2.4/1 in chloroform). The very small, upfield resonances **3a** appear to be due to *n*-meric

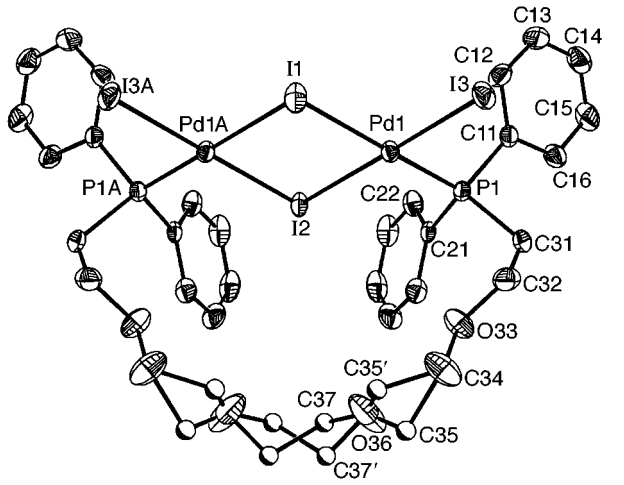

Fig. 2 Molecular structure of **3c**. For clarity the hydrogen atoms are removed, and the complete molecule (two asymmetric units) is shown. Selected bond lengths [Å] and angles [°]: Pd1–I1 2.667(1), Pd1–I2 2.602(1), Pd1–I3 2.598(1), Pd1–P1 2.264(2), P1–C11 1.822(7), P1–C21 1.819(6), P1–C31 1.815(7); I1–Pd1–I2 84.0(1), I1–Pd1–I3 91.3(1), I2–Pd1–I3 173.9(1), I1–Pd1–P1 177.4(1), I2–Pd1–P1 94.7(1), I3–Pd1–P1 90.1(1), Pd1–I1–Pd1A 94.3(1), Pd1–I2–Pd1A 97.4(1), Pd1–P1–C11 115.1(2), Pd1–P1–C21 113.6(2).

dimetallacrown ethers. The very different behavior of **2** and **3** in solution demonstrates that the halide ligand has a surprising effect on both the isomerization and *n*-merization equilibria in dimetallacrown ethers.

The X-ray crystal structure of **3c**,[10] shown in Fig. 2, suggests that this dimetallacrown ether could have quite different receptor properties from those of the previously reported metallacrown ethers, *cis*-[$PtCl_2\{PPh_2(CH_2CH_2O)_4$-$CH_2CH_2PPh_2$-P,P′}], **5**, and *trans*-[$Mo(CO)_4\{PPh_2(CH_2$-$CH_2O)_4CH_2CH_2PPh_2$-P,P′}], **6**.[4d,4e] The average cross-ring oxygen–oxygen distance in **3c** (O33–O36A and O33A–O36, 5.27 Å), which provides a measure of the ring size, is intermediate between that in **5** (4.66 Å) and that in **6** (5.87 Å).[4d,4e] The angle of intercept between the least squares planes through the ether oxygens (O33, O36, O33A, O36A) and that containing the Pd_2I_2 fragment is 42° in **3c**. In contrast, the angle between the least squares planes through the ether oxygens and the $PtCl_2$ center in **5** is 60°. The smaller angle means that an alkali metal cation in the dimetallacrown ether receptor site would be in closer proximity to the transition metal center in **3c** (the distance from the centroid of the four ether oxygens to Pd1 is 4.984 Å). A bifunctional molecule, such as CO, could easily coordinate to both the Pd and the alkali metal cation in the dimetallacrown ether.
