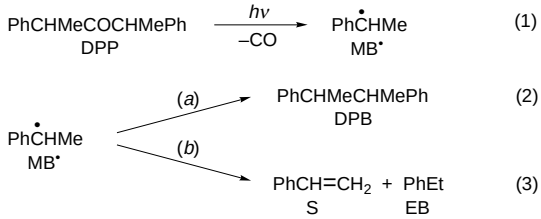
The MFI topology zeolites (*e.g.* silicalite and ZSM-5) are of technical significance in both size/shape selective catalysis and in molecular sieve separations.[1] The technically attractive properties of MFI zeolites originate from supramolecular, structural (substrates as guests, zeolite crystal as host) and dynamic (shape/size dependent supramolecular molecular diffusion) characteristics, *i.e.* substrates possess 'effective' molecular diameters comparable to the size/shape of the holes on the external surface of the zeolite crystal and/or the channels and intersections on the internal surface.[2] The siting and diffusion of a substrate are vital in determining the product selectivity in catalysis and the resolution efficiency in separations.[3]

Understanding the role of diffusion and siting requires the uncoupling of both supramolecular, structural and dynamic features from the effects of activation at active sites and rearrangements of reactive intermediates. The effects of activation are pronounced at high temperatures with zeolites possessing strongly acidic sites (*e.g.* HZSM-5).

We report a supramolecular photochemical investigation[4] at room temperature in which the activation and diffusional/siting effects of zeolite catalysis are uncoupled. Activation of the substrate towards reaction is provided by photochemical methods which (i) excite adsorbed substrates whose sitings and reaction products are directly determined by ^{2}H NMR analysis and (ii) produce persistent[5,6] adsorbed carbon-centred radical intermediates whose structure and mobility are directly determined by EPR spectroscopy. Computational methods are employed for (i) analysis of the plausibility of the siting and diffusional processes on the external and internal surfaces, (ii) rationalization of the variation of product distribution as a function of supramolecular structure, and (iii) simulation of the EPR spectra of the persistent supramolecular radical species formed upon photoexcitation of the adsorbed substrates.

In the molecular (solution) photochemistry [eqns. (1)–(3)] of 2,4-diphenylpentan-3-one (DPP) α-cleavage from T_1 produces,



after rapid loss of CO, α-methylbenzyl radicals (MB•) [eqn. (1)], which undergo random radical combination to produce 2,3-diphenylbutane (DPB) (*ca.* 95%) and disproportionates to styrene (S) and ethylbenzene (EB) (*ca.* 5%). The rates of the radical–radical reactions in eqns. (2) and (3) are close to diffusion controlled[5,8] and, in the absence of radical scavengers, determine the lifetime of the 'molecular' radicals MB•.

Results of product analysis and EPR measurements as a function of coverage [DPP/(Na)ZSM-5 (w/w), Si/Al = 80, average particle size *ca.* 0.1 μ] showed that (i) the dominant products depend on the coverage, with disproportionation to form S and EB being favored by low coverage (< 0.3%) and combination to form DPB being increasingly favored as the coverage increases,[9] and (ii) the maximum EPR intensity of the signal of the persistent MB• radicals is insensitive to loading. For example, the ratio of disproportionation to combination of MB• radicals in solution is typically of the order of 0.1; at 0.3% loading of DPP the ratio is 3.1.

The values of the half-widths ($\Delta H_{1/2}$) of the ^{2}H NMR spectra of $C_6D_5CHMeCOCHMeC_6D_5$ ([$^2H_{10}$]-DPP) as a function of coverage are shown in Fig. 1. These provide information[10] concerning both the supramolecular structure and dynamics of the [$^2H_{10}$]-DPP/ZSM-5 system as a function of coverage: (i) a 'sharp' signal (< 1 kHz) indicates rapid, isotropic motion and the lack of constraints of the molecular structure of [$^2H_{10}$]-DPP by the host ZSM-5 structure, *i.e.* the system is essentially molecular (very weak intermolecular bonds between guest and host); (ii) a 'relatively broad' signal (*ca.* 40 kHz) indicates an anisotropic and partial constraint of a weakly bonded supramolecular structure of a DPP/ZSM-5 system; (iii) a 'limiting broad' signal (*ca.* 130 kHz) indicates relatively strong intermolecular bonds which result in inhibition of motion of a supramolecular [$^2H_{10}$]-DPP/ZSM-5 system. If the ketone were located on the flat part of the external surface, its motion would be essentially isotropic, and $\Delta H_{1/2}$ would be expected to be of the

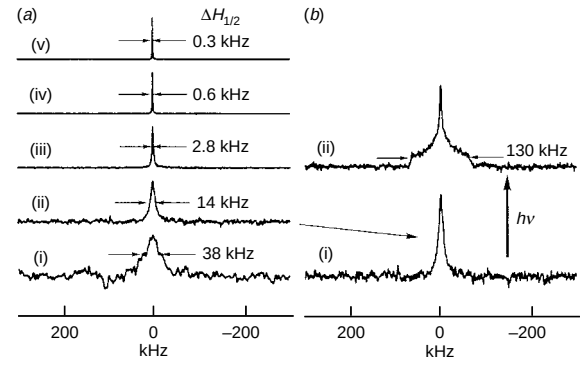


Fig. 1 (*a*) ^{2}H NMR spectra of ([$^2H_{10}$]-DPP) at (i) 0.3, (ii) 1, (iii), 2, (iv) 5 and (v) 10 wt% loading on zeolite. (*b*) Result of 1% loading sample (i) before and (ii) after photolysis.

order of 1 kHz. If the ketone were located on the inside of the zeolite $\Delta H_{½}$ would be of the order of 130 kHz. The observed value of 40 kHz is consistent with the ketone being moderately constrained in the holes on the external surface.

Before photolysis (Fig. 1), the ^{2}H NMR spectrum of the DPP/ZSM-5 system at low loading (< 1% loading) exhibits a half width of *ca*. 40 kHz, characteristic of a moderately constrained [$^2H_{10}$]-DPP molecule. Thus, we conclude that the DPP molecules at low coverage are adsorbed in the holes at the interface of the external and internal surfaces of the ZSM-5 crystal. Photolysis of [$^2H_{10}$]-DPP at room temperature results in a change in the ^{2}H NMR spectrum and the appearance of a new broad feature (*ca*. 130 kHz) which grows as the extent of photolysis increases (Fig. 2).

For high coverage before photolysis the spectrum shows mainly a sharp peak ($\Delta H_{1/2}$ < 1 kHz), with the broad peak being buried in the base line due to the [$^2H_{10}$]-DPP molecules in the holes. We conclude that photolysis of [$^2H_{10}$]-DPP at high coverage does not lead to a significant increase of the broad peak because most of the photolyzed [$^2H_{10}$]-DPP molecules occur in multilayers at high coverage, and the radicals produced in these fluid multilayers are very mobile and undergo random radical–radical combination [eqn. (2)]. This view is supported by the fact that the major product of photolysis at high coverage is that expected from 'molecular' or solution conditions, *i.e.* DPB (*ca*. 95%); most of the absorbed light excites the large excess of ketones in the multilayers rather than the relatively smaller number adsorbed in the holes at the interface.

The steady state photolysis of DPP adsorbed on ZSM-5 produced intense, long lived (many hours) EPR signals at all coverages studied. The observed spectrum fits a simulation[12] of a powder spectrum of MB$^{\bullet}$ as expected from the restricted mobility of MB$^{\bullet}$ adsorption on the internal surface. Computational analysis indicates that the lowest energy supramolecular structure of MB$^{\bullet}$ has the Ph group placed in an intersection between the channels, and the alkyl radical moiety placed in a channel between the intersections. This supramolecular geometry possesses a substantial barrier to motion, but allows the achievement of a roughly planar structure at the radical center. The hyperfine coupling constants computed and determined experimentally,[11,12] taking into account anisotropies due to restricted motion, are sufficient for the simulation. Finally, computations were made of the external surface area available for adsorption of DPP in order to estimate the relationship between the macroscopic composition (loading w/w) and the surface coverage. The measured external surface area of the ZSM-5 sample[9] is of the order of 16 $m^2\ g^{-1}$, which, when compared to the computations, implies that a monolayer of DPP will be formed when the coverage is *ca*. 0.4%, the coverage at which the experimentally observed salient effects on products and spectroscopic properties begin to change. As the coverage increases to values of *ca.* 1% and greater, the results become characteristic of a molecular, two dimensional film rather than of an adsorbed layer, because the bulk of the ketone molecules are in the multilayer and not adsorbed on the zeolite external surface. As the coverage increases, the lifetime of the radicals decreases and the ratio of disproportionation to combination decreases, *i.e.* the product distribution becomes more like that in homogeneous solution. These results are also consistent with the formation of multilayers of ketones on the external surface, so that ketone molecules finds themselves increasingly in a 'two-dimensional' liquid as the loading increases, and the results tend toward those for homogeneous solutions.

The persistence,[6,7] or lifetime, of MB$^{\bullet}$ is limited by either (i) the diffusion of two MB$^{\bullet}$ radicals into the vicinity of an intersection, or (ii) disproportionation, the lowest energy supramolecular reaction of the system within the intersection. Thus, as a consequence of their supramolecular structure, two encountering MB$^{\bullet}$ radicals to not undergo the 'molecularly favored' radical–radical combination, but instead undergo disproportionation to S and EB [eqn. (3)]. The structural basis for this selectivity may be either a supramolecular 'steric' or 'dynamic' effect. The steric effect would result from the high energy required for a C–C bond to form DPB at an intersection, as indicated by computation, and resulting from the supramolecular steric effects associated with the compression of a DPB molecule into the limited space available in the vicinity of the intersections and channels. The less sterically demanding radical–radical disproportionation in the vicinity of the intersections becomes the default supramolecularly-allowed radical–radical reaction, but even this reaction is still remarkably slow and allows the supramolecular MB$^{\bullet}$/ZSM-5 radicals to become persistent for hours at room temperature. A dynamic mechanism, termed a diffusional 'maze' effect, could also cause the persistence of otherwise reactive radicals. In the maze effect, the molecular traffic patterns of the radicals lead to rate limiting infrequent encounters in the vicinity of the intersection. In the extreme form of the maze effect an encounter leads to a 'diffusion controlled' reaction.

The ^{2}H NMR, EPR, computational and photochemical product analyses are all supported by the same supramolecular structural and dynamic interpretation of the results at high and low coverages. The supramolecular photochemistry of DPP adsorbed on ZSM-5 molecular sieve zeolites depends dramatically on the composition of the DPP/ZSM-5 system, because the supramolecular constitutional structure (connectivity relationship of the guest and host structures) depends on the system's composition. At low loading (< 0.3%) DPP is mainly adsorbed in the holes on the external surfaces that provide access to the internal surface. At intermediate loadings (*ca*. 1%), when the limited amount of holes is plugged with DPP molecules, as the coverage increases, the external framework surface between the holes becomes covered with DPP molecules until a monolayer is formed. At 'high' loadings (> 1%), both the holes and the framework's external surface are covered (a monolayer is formed) so that, as the coverage increases, multilayers or two dimensional films of DPP are formed on the external surface.

The authors thank Dr Paul Krusic (DuPont), Professors Hans Fischer and Henning Paul for enlightening discussions, and the NSF for financial support. X. G. L. and W. L. thank the Kanagawa Academy of Science and Technology for funding.

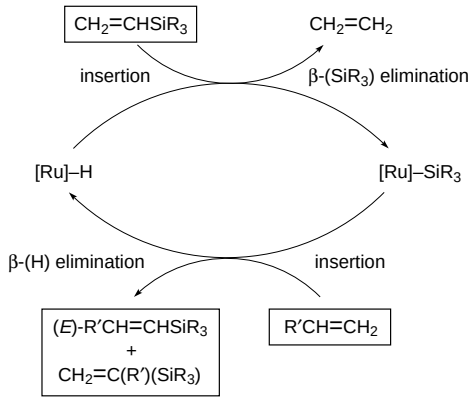
Ruthenium-catalyzed ring-closing reaction of α,ω-bis(vinylsilyl) compounds *via* a silyl transfer mechanism

Takaya Mise,*[a]† Yutaka Takaguchi,[a] Takeshi Umemiya,[b] Shoichi Shimizu[b] and Yasuo Wakatsuki[a]

[a] *The Institute of Physical and Chemical Research (RIKEN), Wako-shi, Saitama 351-0198, Japan*
[b] *Department of Industrial Chemistry, College of Industrial Technology, Nihon University, Narashino, Chiba 275, Japan*

Compounds having a vinyldimethylsilyl group at both terminals have been successfully cyclized by ruthenium hydride catalysts to give selectively disilacycles of various ring sizes *via* a metathetical reaction, *i.e.* ethene elimination from the two terminal vinyl groups, not involving metallocarbene–metallacyclobutane type intermediates.

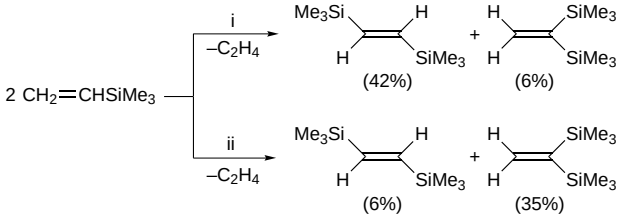
In 1991 we reported ruthenium hydride catalyzed homo- and cross-disproportionation reactions between CH_2=CH-SiR_3 and CH_2=CHR′ (R′ = SiR_3, Me, Ph, CO_2Me, OBu^n) to yield CH_2=CH_2 and R′CH=CHSiR_3.[1] When R = Me and R′ = $SiMe_3$ (homo-disproportionation), one of the disubstituted products originally assigned as the (*Z*)-isomer was subsequently identified by Marciniec and Pietrasuk as 1,1-bis(silyl)ethene.[2] We have also confirmed by NMR studies that in the case of cross disproportionations, *e.g.* R = R′ = Me, a minor product originally referred to as the (*Z*)-isomer is actually the 1,1-isomer. As a result, the catalytic sequence is now written as outlined in Scheme 1.



Scheme 1

The reaction mechanism involving β-silyl elimination and insertion of a C=C double bond into the resulting Ru–Si bond was established in the original report based on isolation of the ruthenium–silyl intermediate [RuCl(CO)$(PPh_3)_2$($SiMe_3$)] and its reaction with ethene.[1] This mechanism has been reconfirmed by a series of elaborate experiments by Marciniec and co-workers, who pointed out the possibility of involvement of metallocarbene and metallacyclobutane intermediates.[2–5] A remaining problem is that the regioselectivity of this reaction is poor in some cases, particularly for self-disproportionation-type reactions, where almost equal amounts of (*E*)-R_3SiCH=CHSiR_3 and CH_2=C$(SiR_3)_2$ are formed.[1] Apparently, the regioselection is controlled simply by the direction of insertion of the second olefin molecule into the Ru–Si bond.

Our efforts to improve the regioselectivity of the self-disproportionation of vinyltrimethylsilane, by modifying the electronic character and bulkiness of the ligands or by using coordinating additives, met with only partial success, yielding the (*E*)-1,2- and 1,1-isomers in an 88 : 12 ratio in one case and a 15 : 85 ratio at the other extreme (Scheme 2). The catalyst precursor used in the former was [RuCl(CNC_6H_4-NO_2)$(PPh_3)_3$(H)] while in the latter case, a small amount of MeCN was added to the initial reaction mixture containing [RuCl(CO)$(PPh_3)_3$(H)]: without MeCN, the isomer ratio was 44 : 56.



Scheme 2 *Reagents and conditions*: i, [RuCl$(PPh_3)_3$(CNC_6H_4-4-NO_2)(H)] (20 mg), vinylsilane (0.2 ml), toluene (2 ml), 100 °C, 20 h; ii, [RuCl$(PPh_3)_3$(CO)(H)] (20 mg), MeCN (0.1 ml), vinylsilane (0.2 ml), toluene (2 ml), 100 °C, 20 h. GLC yields in parentheses.

Table 1 Disproportionation of α,ω-bis(vinylsilyl) compounds

Entry, Catalyst[a]	Substrate	Product	Yield (%)
1[b], A	 **1**	 **2**	87[c]
2[d], A	 **3**	 **4**	75[e]
3[f], B	 **5**	 **6**	83[c]
4[g], A	 **7**	 **8**	97[c]
5[h], B	 **9**	 **10**	76[e]

[a] A: [RuCl(CO)$(PPh_3)_3$(H)], B: [RuCl(CO)$(PPr^i_3)_2$(H)]. [b] 80 °C, 24 h, toluene. [c] GLC yield. [d] 100 °C, 15 h, THF. [e] Isolated yield. [f] 60 °C, 24 h, THF. [g] 80 °C, 25 h, toluene. [h] 110 °C, 42 h, toluene.

Application of this catalytic system for intramolecular disproportionation of α,ω-bis(vinylsilyl) compounds was found to be more successful, giving disilacycles of various ring sizes: in particular, the regioselectivity was almost perfect (Table 1).‡ Only very small amounts of intermolecular reaction products was formed at normal concentrations of the reaction mixture, as detected by GC–MS, and they could be easily separated. By using either $[RuCl(CO)(PPh_3)_3(H)]$ or Werner's hydride $[RuCl(CO)(PPr^i_3)_2(H)]$ as the catalyst precursor,[6] the cyclic compounds with an *exo*-methylene unit were obtained as the sole cyclization products (Table 1, entries 1–4); the existence of the methylene unit in the products was confirmed by NMR DEPT studies. In contrast, a product which corresponds to the (*E*)-isomer, *i.e.* a 14-membered disilacycloolefin, was obtained selectively when the substrate had a longer aliphatic chain spacer (entry 5).§ In all of the cases examined, no isomeric material could be detected. Werner's hydride is in general more active as catalyst than the PPh_3 analog, but separation of the product from the catalyst and its residues is easier for the latter due to its low solubility.

The products in entries 1–4 correspond to the 1,1-isomer depicted in Scheme 2 and should not be formed in principle by the Grubbs type ring-closing metathesis using ruthenium–carbene initiators.[7] Obviously, the insertion–β-elimination mechanism shown in Scheme 1, is operating in an intramolecular fashion.

Further application of this novel ring-closing reaction to the synthesis of mono- and di-silamacrocycles, as well as to silicone-containing polymers, is now under investigation.

Highly enantioselective synthesis of dialkyl and alkyl aryl *N*-tosylsulfimides

Giuseppe Celentano, Stefano Colonna,† Nicoletta Gaggero* and Carlo Richelmi

Centro CNR and Istituto di Chimica Organica, Facoltà di Farmacia, via Venezian 21, 20133 Milano, Italy

Enantiomerically pure *S*-alkyl-*S*-[(4*S*)-4-benzyl-2-oxo-1,3-oxazolidin-3-yl]-*N*-tosylsulfimides react with Grignard reagents affording dialkyl and alkyl aryl sulfimides in high chemical yield and enantiomeric excess.

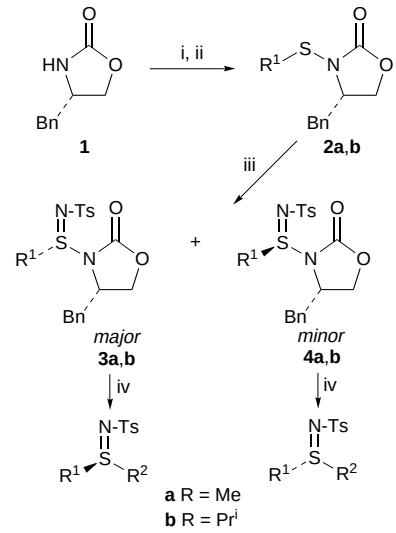
Sulfimides are a class of compounds potentially of interest in the field of medicine,[1] because of their different pharmacological properties: several families of structurally related sulfimides have shown antimicrobial, diuretic and hypotensive properties, inhibitor effects on tumor growth and activity as antidepressants and stimulants of the central nervous system.

In organic synthesis sulfimides are versatile reagents due to the presence of an S^{IV}=N moiety which provides two reaction sites susceptible to attack by both nucleophilic and electrophilic reagents. Moreover, like sulfoxides, sulfimides form stable α-carbanions. This property has recently been exploited in asymmetric methylidene transfer from the sodium salt of (*S*)-*S*-methyl-*S*-*p*-tolyl-*N*-tosylsulfimide to prochiral carbonyl groups yielding epoxides with ees of up to 70%.[2] Wider applications of sulfimides are limited, however, because of the dearth of general synthetic methodologies affording high ees. The first procedure for the preparation of optically active sulfimides took advantage of the stereospecific reaction of chiral sulfoxides with various iminating species, such as bis(*N*-tosylsulfur diimine), *N*-sulfinyltoluene-*p*-sulfonamide and toluene-*p*-sulfinyl nitrene.[3] More recently Uemura[4] reported the asymmetric synthesis of alkyl aryl sulfimides by imidation of the corresponding prochiral sulfides with [*N*-(toluene-*p*-sulfonyl)imino]phenyliodinane (PhI=NTs) in the presence of a catalytic amount of Cu^{I} salts and chiral 4,4′-disubstituted bis(oxazoline) ligands, the ee being in the range 10–71%.

N-Functionalized chiral oxazolidinones are commonly employed auxiliaries which afford excellent degrees of asymmetric induction in reactions ranging from alkylations to aldol condensations and Diels–Alder additions.[5] Their use has been highly successful in the stereoselective construction of a number of natural products, antibiotics, macrolides and other pharmacologically important compounds. Recently chiral *N*-sulfinyloxazolidinones were used by Evans[6] as sulfinylating agents of a series of organometallic nucleophiles for the synthesis of sulfoxides, sulfinate esters and sulfinamides with up to 100% ee.

Now we report a new enantioselective synthesis of dialkyl and alkyl aryl *N*-tosyl sulfimides *via S*-alkyl-*S*-[(4*S*)-4-benzyl-2-oxo-1,3-oxazolidin-3-yl]-*N*-tosylsulfimides **3** and **4** prepared from the corresponding *N*-(alkylthio)oxazolidinones[6] by reaction with chloramine T (Scheme 1).

Reagents **3** and **4**, separated by flash chromatography, reacted with a series of Grignard reagents to give the corresponding sulfimides (Tables 1 and 2).‡ The displacement reaction occurred with good chemical yields even with bulky organometallic reagents such as cyclohexylmagnesium bromide (Table 1, entry 7; Table 2, entry 7) and 2-naphthylmagnesium bromide (Table 1, entry 4; Table 2, entry 4). However, *tert*-butylmagnesium bromide did not react, even when used in a large excess (four-fold excess) and for longer reaction time. In all the cases examined, no racemization of the recovered chiral auxiliary was observed.



Scheme 1 *Reagents and conditions:* i, $Bu^{n}Li$ (1 equiv.), THF, 0 °C, 0.5 h; ii, R′S–SO_2Me (1.2 equiv.), room temp., 1 h; iii, Chloramine T (1.1 equiv.), toluene, $C_{16}H_{33}Bu_3PBr$ (0.05 equiv.), room temp., 4 h; iv, R^2MgBr (2 equiv.), THF, −78 °C, 1 h

The enantioselectivity in the formation of sulfimides was almost unaffected by the reaction temperature, indeed the ee of *S*-methyl-*S*-phenyl-*N*-tosylsulfimides obtained from diastereoisomers **3a** and **4a** with phenylmagnesium bromide was unchanged at both −78 and 0 °C. Therefore, intermediates **3a** and **4a** did not undergo epimerization, unlike *N*-sulfinyloxaz-

10[c]	Pr^i	Ph	40	78

[a] Determined by HPLC using a Chiralcel OD (entries 5, 6, 7, 8), Chiralcel OJ (entries 1, 2, 10) or Chiralpack AS columns (entry 3) with different mixtures of *n*-hexane–EtOH as the mobile phase. The optical purity of *S*-methyl-*S*-naphthyl-*N*-tosylsulfimide (entry 4) was obtained by ^{1}H NMR analysis using $Eu(tfc)_3$. [b] For 1 h at 0 °C. [c] For 8 h at 25 °C.

olidinones, which are configurationally unstable at the sulfur atom.[6] This could explain the high imidation stereoselectivity with respect to overall chemical yield.

Increasing the steric hindrance at the sulfur atom in diastereoisomers **3b** and **4b** affected the yield but not the ee of the sulfimides formed (Table 1, entries 1, 10; Table 2, entries 1, 10), thus extending this methodology to *S*-alkyl-*S*-[(4*S*)-4-benzyl-2-oxo-1,3-oxazolidin-3-yl]-*N*-tosylsulfimides having *S*-alkyl substituents other than methyl.

Diastereoisomer **3a** yielded *S*-methyl-*S*-*p*-tolyl-*N*-tosylsulfimide (Table 1, entry 2) with 87% ee and (*R*) absolute configuration according to the literature,[3] the opposite enantiomer [94% ee, (*S*)] being obtained from diastereoisomer **4a**. If we assume that the nucleophilic displacement occurred with inversion of configuration, as in the case of the *N*-sulfinyloxazolidinones,[6] the absolute configuration at the sulfur atom should be (*R*) for the diastereoisomer **3a** and (*S*) for the diastereoisomer **4a**.

In summary, this study represents a further example of the synthetic versatility of chiral oxazolidinones and describes a new approach to optically active sulfimides with good chemical yields and high ees.

‡ *Experimental procedure*: *S*-Methyl-*S*-[(4*S*)-4-benzyl-2-oxo-1,3-oxazolidin-3-yl]-*N*-tosylsulfimides **3a** and **4a** were prepared by adding chloramine T (1.1 equiv.) to *N*-(methylthio)oxazolidinone (ref. 6) (1 equiv.) and hexadecyltributylphosphonium bromide (0.05 equiv.) in toluene as solvent. After 4 h at room temperature, normal work-up afforded the diastereoisomers **3a** and **4a**. Purification by flash silica gel column chromatography (hexane–ethyl acetate 3 : 7) gave pure **3a** and **4a** in the ratio 2.3 : 1 (yield 80%.) Sulfimides were obtained by reacting diastereoisomers **3a** and **4a** (1 equiv.) with the Grignard reagents (2 equiv.) at −78 °C for 1 h in THF as solvent (ref. 6) and purification by flash silica gel column chromatography (Et_2O–MeOH 9 : 1). Diastereoisomers **3b** and **4b** were prepared in an analogous way and obtained in the ratio 1.3 : 1 (yield 72%). MeS–SO_2Me was purchased from Aldrich, and Pr^iS–SO_2Me was prepared according to the literature (ref. 7).

Chlorine abstraction by laser pyrolysis of $W(CO)_6$; a mild route to gas-phase organic radical chemistry

Grant R. Allen, Noel D. Renner and Douglas K. Russell*†

Department of Chemistry, University of Auckland, Private Bag 92019, Auckland, New Zealand

SF_6-photosensitised IR laser pyrolysis of $W(CO)_6$ in the gas phase at moderate temperatures leads to unsaturated $W(CO)_n$ species; these prove to be very effective and selective abstractors of Cl atoms from a wide range of organic substrates, and offer a low energy and clean route into gas phase organic radical chemistry.

IR laser powered homogeneous pyrolysis (LPHP)[1,2] has been successfully exploited for over 20 years in the investigation of the mechanisms of thermal decomposition of volatile organometallic[3] and organic compounds.[4] In IR LPHP, the vapour of the target species is mixed with SF_6, and the mixture exposed to the output of a CO_2 IR laser. The SF_6 strongly absorbs the laser energy, which is rapidly converted to heat *via* efficient intra- and inter-molecular relaxation.[2] The advantages of this technique are well documented; very small quantities of material are required, initiation of reaction is unambiguously homogeneous and short-lived intermediates are readily trapped (physically or chemically). Progress of reaction may be monitored by conventional analytical techniques, in the present work FTIR spectroscopy or GC–MS. The pyrolysis of many organochlorine compounds has been studied using IR LPHP, principally by Pola.[5] As in conventional pyrolysis, the chemistry of these compounds is dominated by the themes of HCl elimination (where available) and C–Cl bond homolysis.

LPHP of $W(CO)_6$ at much lower laser powers (*i.e.*, temperatures) than those required for the organochlorine compounds described below leads to copious amounts of CO and a grey deposit, shown elsewhere to be more or less pure tungsten.[6] It is usually assumed that these products result from the successive homolytic loss of carbonyl groups. In the presence of vapours of chlorinated organic compounds, the deposits also contain chlorine, XPES and reflectance IR spectroscopy indicating a composition approximating to $W(CO)_4Cl_2$. It appears, therefore, that unsaturated $W(CO)_n$ (n < 6) species are highly efficient abstractors of Cl from such compounds. Where the target compound contains both Cl and F, abstraction of Cl occurs preferentially, in accord with the relative strengths of W–X and C–X bonds.[7] Moreover, the secondary product of the $W(CO)_6$ (namely CO) is chemically inert, and highly reactive Cl atoms are effectively removed from the system. These factors lead to end products that may be ascribed unambiguously to subsequent reactions of the resultant organic radicals. Here, we report preliminary results using simple and familiar systems which confirm this point of view, and which illustrate the potential of this route into gas phase organic radical chemistry.

The thermal decomposition of the refrigerant CF_2HCl (Freon 22) has been extensively studied by both conventional methods and IR LPHP in the light of its role in destruction of stratospheric ozone.[1,8] In all cases, the observed products were HCl and C_2F_4, with further breakdown of the latter at higher temperatures. This has been ascribed to unimolecular elimination of HCl followed by recombination of the resultant difluorocarbene $:CF_2$. In the present work, the $:CF_2$ intermediate was detected directly by IR spectroscopy in an Ar matrix (dilution 100 : 1). At 15 K, a strong peak at 1220 cm^{-1} attributable to CF_2 was observed; on annealing to 40 K, this peak decayed, to be replaced by two assignable to C_2F_4 at 1178 and 1328 cm^{-1}. On co-pyrolysis with $W(CO)_6$ at much lower laser power (*i.e.*, temperature), the major products were SiF_4 and 1,1,2,2-tetrafluoroethane; no traces of HCl or C_2F_4 (or its breakdown products) were detected. These results are consistent with the selective abstraction of Cl to yield the $\cdot CF_2H$ radical; this either recombines or migrates to the cell wall, where reaction with silica results in the observed SiF_4. The decomposition of CF_2Cl_2 (Freon 12) and CH_2Cl_2 led to corresponding results, in particular the production of 1,2-dichlorotetrafluoroethane in copyrolysis of the former, and of 1,2-dichloroethane in the latter. Neither of these compounds is a major product in conventional pyrolysis, as a result of competing elimination processes and extensive secondary reactions.

The series of halogenated acetic acids provides an interesting example of a change in pyrolysis mechanism down a series.[9] Decarbonylation of the intermediate oxiranone formed by elimination of HCl from CH_2ClCO_2H yields formaldehyde, CO and HCl as the observed end products. On the other hand, C–I homolysis in CH_2ICO_2H, followed by a hydrogen shift and decarboxylation, results in CH_4 and CO_2 as the stable products; CH_2BrCO_2H follows both routes concurrently. On co-pyrolysis with $W(CO)_6$ at very low temperatures, CH_2ClCO_2H also yields the radical abstraction end-products CH_4 and CO_2. Similarly, IR LPHP of CH_3COCl alone largely follows the HCl elimination pathway, yielding the ketene observed in conventional pyrolysis.[10] Low temperature co-pyrolysis with $W(CO)_6$ completely suppresses formation of ketene, resulting instead in the CH_4 and CO characteristic of the radical route. These results are illustrated in Fig. 1.

The IR LPHP of 1,2-dichloroethene has been studied by Kubat and Pola,[11] with the conclusion that pyrolysis at low temperature leads to *Z*–*E* isomerisation; at higher laser power, this is followed by elimination of HCl yielding chloroacetylene (and, to a small extent, of Cl_2 to yield acetylene). In the present work, a sample of the slightly less stable *E*-1,2-$C_2H_2Cl_2$ alone was initially exposed to low laser power to yield an approximately equimolar mixture of the *Z* and *E* isomers. $W(CO)_6$ was then admitted to the cell, and further IR LPHP at powers insufficient to lead to further isomerisation led to decay of IR features of the two isomers at different rates. The first-order kinetic plots of Fig. 2 are consistent with reactions whose

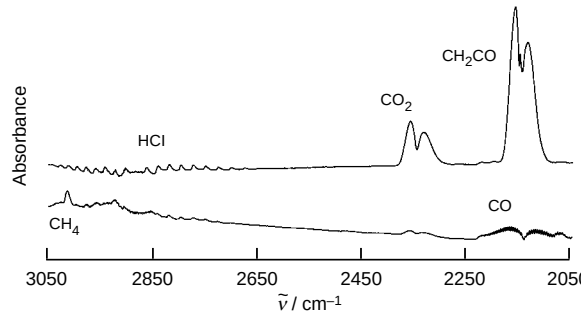

Fig. 1 Partial FTIR spectra of the products of laser pyrolysis of CH_3COCl in the absence (upper) and presence (lower) of $W(CO)_6$; the small amount of HCl evident in the lower trace was present in the original sample

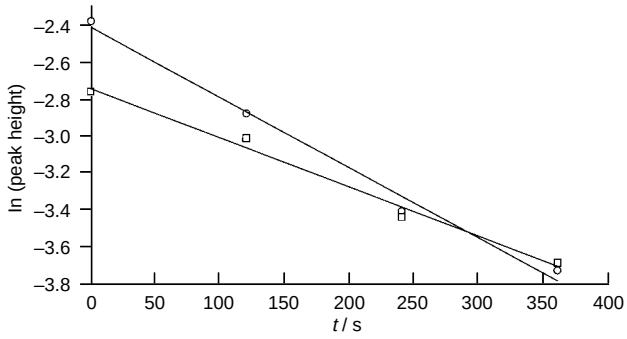

Fig. 2 First-order kinetic plots for the decay of *E*-1,2-$C_2H_2Cl_2$ (○) and *Z*-1,2-$C_2H_2Cl_2$ (□) on laser pyrolysis in the presence of $W(CO)_6$

activation energies differ by the known zero point energy difference[12] of 1840 J mol^{-1}, and an effective temperature of 650 ± 150 K. This 'kinetic isomer effect' suggests that loss reactions of the two isomers involve Cl abstraction pathways whose transition states differ little in energy.

The above preliminary results confirm that $W(CO)_n$ species do indeed act as efficient and selective abstractors of Cl from a range of organochlorine compounds under comparatively mild conditions, and that the subsequent chemistry is dominated by the resulting organic radical species. In this sense, this system may serve as a gas phase analogue of well known solution abstractors such as tri-*n*-butyltin[13] and tris(trimethylsilyl)silyl.[14] In future work, we shall investigate more complex systems; preliminary results on chlorinated xylenes, for example, have already indicated that substantially new reaction routes are opened in such species.[15]

We thank the University of Auckland for assistance with the purchase of equipment and a doctoral scholarship to G. R. A.

Two-step phosphorus-mediated substitution of hydroxy groups in selected primary alcohols for fluorinated alkyl or aryl substituents: the molecular structure of 1,1-bis(fluorosulfonyl)-1-fluoro-2-phenylethane

Alexander Kolomeitsev,*[a] Alexander Shtarev,[a] Kyrill Chabanenko,[a] Tatjana Savina,[a] Yurii Yagupolskii,[a] Michaela Görg,[b] Jan Przyborowski,[b] Enno Lork[b] and Gerd-Volker Röschenthaler*[b]†

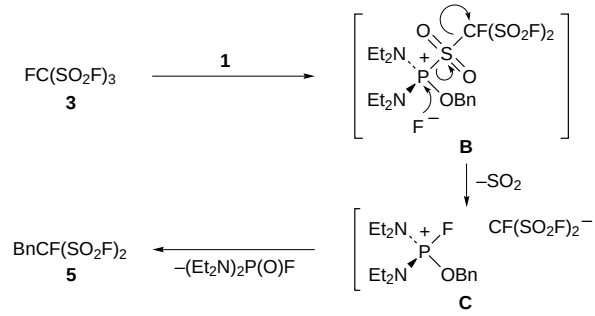
In an Arbuzov type reaction, amido phosphites $(Et_2N)_2POR^1$ and a broad range of halofluoro organic halides (X = Cl, Br) formed the corresponding alkylated derivatives R^1–R^2 [R^1 = Bn, R^2 = $C(SO_2F)_3$, CCl_2F, CCl_2CF_3, CBr_2F, $C(CF_3)_3$, C_6F_5; R^1 = Et, CH_2CF_3, Me, R^2 = CCl_2CF_3], whereas with $FC(SO_2F)_3$ and loss of SO_2, $BnCF(SO_2F)_2$ was obtained, as shown by X-ray crystallography.

Owing to the chemical and biological properties of organofluorine compounds,[1] considerable efforts have been made to find new reagents and methods for the fluorination of alcohols, oxy acids and glucosides. Nucleophilic fluoroalkylation is one of the most attractive routes for introducing fluorinated moieties.[2] However, to the best of our knowledge, there are no methods for substituting oxy groups in alcohols (directly or using their corresponding tosylates or triflates) for fluorinated carbon-centered anions. Phosphorus-containing reagents, *e.g.* the three component system $CF_3Br/P(NEt)_3$/electrophile or trifluoromethyl tris(dialkylamino)phosphonium salts,[3] have proven to be versatile reactants for trifluoromethylation of a variety of organic and organoelement compounds, *e.g.* Me_3SiCF_3, in its turn a powerful CF_3 transfer agent, too.[3,4] As we have recently shown, the phosphitylation of alcohols and oxy acid esters with $(Et_2N)_2PCl$, followed by the low temperature reaction of $(CF_3S)_2$ with the diamido phosphites formed, is an effective route for addition of the lipophilic SCF_3 moiety to sp^3-hybridized carbon atoms under mild reaction conditions;[5] in the case of CCl_4 and some Cl_3C group-containing species, trichloromethylated alkanes, 1,1-dichloromethyl esters and 1,1-dichloroethyl substituted phosphines were obtained.[6–8] Our preliminary results show that the reaction of $(Et_2N)_2POR^1$ (R^1 = Bn) with $XC(SO_2F)_3$ (X = F, Cl), X_3CF (X = Cl, Br), Cl_3CCF_3 and $BrC(CF_3)_3$, BrC_6F_5, and of $(Et_2N)_2POR^1$ (R^1 = Et, CH_2CF_3, Me) with Cl_3CCF_3 is a novel, convenient and generally applicable method for a two step substitution of hydroxy groups in primary alcohols for wide range of different fluorinated species; respective literature syntheses give fairly different and preparatively demanding approaches with low yields, *e.g.* $MeC(SO_2F)_3$ has been synthesized from MeI and $AgC(SO_2F)_3$,[9] $BnCCl_2CF_3$ by electrochemical cross-coupling,[10] $MeCCl_2CF_3$ from 2,2-dichloropropionic acid and SF_4,[11] $EtCCl_2CF_3$ and $CF_3CH_2CCl_2CF_3$ have been prepared photolytically,[12,13] and $BnC(CF_3)_3$ has been prepared from 1,1,3,3,3-pentafluoro-2-trifluoromethylpropene, CsF and $PhCHCl_2$.[14] For BnC_6F_5, BnCl and pentafluorobenzoyl chloride were required.[15]

In a superior general alternative to the already known methods, mentioned above, bis(diethylamido) phosphites, $(Et_2N)_2POR^1$, **1** (R^1 = Bn)[5] and the fluoro species $ClC(SO_2F)_3$ **2a**,[9] CCl_3F **2b**, CCl_3CF_3 **2c**, CBr_3F **2d**, $BrC(CF_3)_3$ **2e** and BrC_6F_5 **2f** underwent an Arbuzov type reaction to give in good yields R^1–R^2 **4a–f** [R^1 = Bn, R^2 = $C(SO_2F)_3$ (**4a**), CCl_2F (**4b**) CCl_2CF_3 (**4c**), CBr_2F (**4d**), $C(CF_3)_3$ (**4e**), C_6F_5 (**4f**)] and the corresponding halogeno amidates, $(Et_2N)_2P(O)X$ (X = Cl, Br),‡ (see Table 1). Gaseous SO_2 was formed when $FC(SO_2F)_3$ **3** was allowed to interact with **1** yielding $BnCF(SO_2F)_2$ **5**§ and $(Et_2N)_2P(O)F$. (Scheme 1) Reacting $(Et_2N)_2POR^1$ (R^1 = Et (**6**), CH_2CF_3 (**8**),[16] Me (**10**)] with **2c** gave the corresponding alkanes R^1–CCl_2CF_3 [R^1 = Et (**7c**),[12] CH_2CF_3 (**9c**),[13] Me (**11c**)[11]]. The products, either colorless liquids or low melting point solids, were easily separated from the phosphorus-containing substances by distillation or column chromatography on silica. The fluoro species R^1–$C(SO_2F)_3$ **4a**, R^1–CCl_2F **4b**, R^1–CBr_2F **4d** and R^1–$CF(SO_2F)_2$ **5** (R^1 = Bn) have not been described previously.¶ THF or triglyme were required as solvent; however, in the case of $XC(SO_2F)_3$ (X = F, Cl)[9] the reaction exclusively proceeds in aprotic, non-polar media, such as pentane. If *no* solvent is used, either no reaction occurs or products with P–C bond formation were obtained.[17]



Scheme 1

It is possible that, in a two step Arbuzov reaction *via* halogenophilic attack of phosphorus at R²–X (X = Cl, Br),

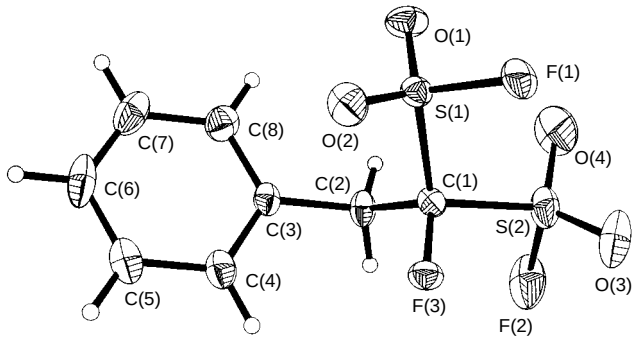

Fig. 1 Crystal structure of **5** with thermal ellipsoids. Selected bond distances (pm) and angles (°): C(1)–S(1) 183.8(3), C(1)–S(2) 183.3(3), C(1)–C(2) 151.5(4), C(2)–C(3) 151.7(4), C(3)–C(4) 138.3(4), S(1)–O(1) 140.5(1), S(2)–O(3) 141.8(2), S(1)–F(1) 154.7(2), S(2)–F(2) 152.0(2), C(1)–F(3) 137.3(3); C(2)–C(1)–S(1) 110.7(2), C(2)–C(1)–S(2) 111.8(2), F(3)–C(1)–C(2) 112.1(2), C(1)–C(2)–C(3) 114.3(2), F(3)–C(1)–S(1) 105.7(2), F(3)–C(1)–S(2) 106.2(2), S(2)–C(1)–S(1) 110.1(2), O(1)–S(1)–F(1) 107.02(12), O(3)–S(2)–F(2) 106.9(2), O(1)–S(1)–O(2) 122.36(14), O(4)–S(2)–O(3) 121.0(2), F(1)–S(1)–C(1) 100.51(12), F(2)–S(2)–C(1) 98.49(12).

unstable quasi-phosphonium intermediates $[(Et_2N)_2P(OR^1)X]^+$ $[R^2]^-$ **A** are formed, which in turn yield R^1–R^2 and $(Et_2N)_2P(=O)X$. For the reaction of **3** with **1**, a halogenophilic pathway seemed unlikely. However, the λ^3,σ^3 phosphorus nucleophile might attack sulfur (intermediate **B**) displacing a fluoride anion, which induced loss of SO_2 (intermediate **C**) and the proposed formation of $[CF(SO_2F)_2]^-$ (Scheme 1). Despite being the conjugated base of super acid (pK_a −12),[18] the tris(fluorosulfonyl)methanide anion[19] was able to be alkylated under mild conditions in pentane. Attempts to react this anion, as tetrabutylammonium tris(fluorosulfonyl)methanide, with alkyl tosylates and BnBr failed, even at elevated temperature.[18] The intermediate **A** probably exists as a tight ion pair, which facilitates the trapping of the incipient $[C(SO_2F)_3]^-$ anion *via* an intramolecular Arbuzov rearrangement. In THF or triglyme no methanide alkylation could be observed. In the case of $BrC(CF_3)_3$ **2e**, no perfluorobutene or its reaction products were found. No substitution of fluorine in the C_6F_5 moiety occurred. With C_6F_5Br **2f** the reaction was slower and accompanied by C_6F_5H formation, originating from the interaction of the corresponding anion with the solvent.[17] A concerted mechanism with λ^5,σ^5 phosphorane intermediates or a radical pathway could not be ruled out.[20]

The single crystal X-ray structure determination§ of **5** (Fig. 1), the first carried out on an alkyl derivative of $HCF(SO_2F)_2$, showed a slightly distorted tetrahedral geometry at C(1) bearing the SO_2F groups and C(2). The bond length of C(1)–S(1) corresponds to a single bond,[9] and the bond lengths C(1)–F(3), C(1)–C(2), C(2)–C(3), C(3)–C(4), S(1)–O(1) and S(1)–F(1) are all in the expected ranges.[21]

The outlined synthetic approach for introducing carbon-centered anions with a broad range of nucleophilicity to the sp^3-hybridized carbon of BnOH can be considered a simple alternative, superior to already known procedures. Preliminary positive results for EtOH, CF_3CH_2OH and MeOH promise extension of the procedure to various alkanes $R^FCCl_2(Br_2)CH_2R$, which, when successively dehydrohalogenated, offer an easy access to fluoroalkylated alkenes $R^FCCl(Br)=CHR$ and alkynes $R^FC\equiv CR$, which are in turn building blocks for fluoro heterocycles and other versatile precursors.[22]

Synthesis and crystal structure determination of sodium ozonide

Wilhelm Klein, Klaus Armbruster and Martin Jansen*†

Institut für Anorganische Chemie der Rheinischen Friedrich-Wilhelms-Universität Bonn, Gerhard-Domagk-Straße 1, 53121 Bonn, Germany

So-far-unknown ionic ozonides are accessible by a new method of synthesis; the new binary compound NaO_3 crystallizes isostructural to $NaNO_2$.

Recently, the alkali metal ozonides KO_3,[1] RbO_3[2] and CsO_3[3] have become available as bulk and pure materials, and a generally applicable route for the syntheses of ionic ozonides with relatively bulky organic group-15-'onium' cations has been developed.[4] All ozonides known so far are metastable and decompose *via* exothermal reactions.[5] Within the group of the alkali metal ozonides the stability decreases with decreasing diameter of the respective cation. As a consequence, unlike KO_3, RbO_3 and CsO_3, the lithium and sodium ozonides are not accessible *via* direct ozonisation of their peroxides or hyperoxides. However, solutions of LiO_3 and NaO_3 in liquid ammonia can be obtained by ion exchange. From these solutions the solid ozonides Li[2.2.1]O_3 and Na[2.2.2]O_3 precipitate after complexation of the cations by the appropriate cryptands.[6] In the absence of a cryptand, NaO_3 decomposes into a mixture of solid NaOH and NaO_2 upon removing the solvent. Presumably, in an initial step a proton is transferred to the ozonide anion from ammonia, which shows an increased acidity because of its coordination to the smaller and thus more strongly polarizing sodium cation, compared to K^+, Rb^+ and Cs^+. In order to circumvent this complication, we have added methylamine, which, being a stronger base than ammonia, would be the preferred ligand for the coordination of sodium, and at the same time, is less proton acidic. When evaporating the solvent mixture at −78 °C, first ammonia is removed, and upon increasing the temperature slowly up to −20 °C, pure sodium ozonide precipitates. The intensively red, air sensitive polycrystalline samples decompose slowly at room temperature into solid NaO_2 and oxygen. However, at a temperature of −18 °C, NaO_3 can be stored undecomposed for months. Surprisingly, the temperature at which rapid spontaneous decomposition starts is slightly higher for NaO_3 (37 °C) than for KO_3 (35 °C).[1]

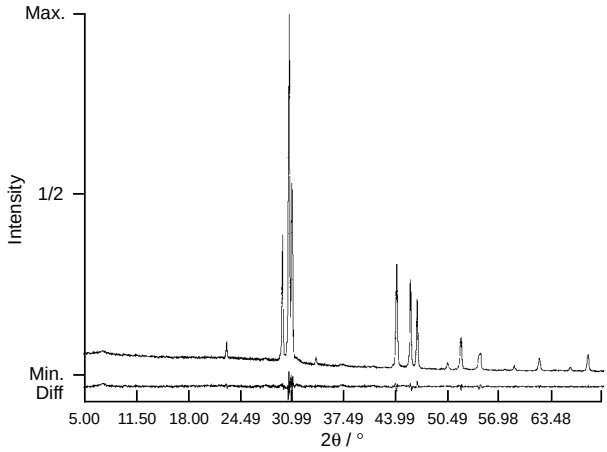

Fig. 1 Measured and calculated powder diffraction pattern of sodium ozonide and difference plot

According to a crystal structure determination by Rietveld's technique of refinement of X-ray powder data[7] (Fig. 1), NaO_3 is isostructural to sodium nitrite.‡ Thus, sodium ozonide is the first alkali metal ozonide exhibiting a ferroelectric arrangement of the anions. Generally, the crystal structure of NaO_3 can be related to the rock salt type of structure (*cf.* Fig. 2), each sodium being surrounded octahedrally by six ozonide groups. However, six negatively polarized terminal oxygen atoms belonging to only five complex anions coordinate sodium at a distance (242–244 pm) as would be expected for the first coordination sphere[8–10] (*cf.* Fig. 3). The ozonide ion exhibits the longest O–O bonds and the smallest O–O–O angle that have been seen so far. The newly determined data confirm the trend that with decreasing ionic radius of the cation the bond lengths increase and the bond angles decrease within the ozonide ion (see Table 1). Note that the differences among these values are rather close to the limits of experimental error. However, they are consistent with considerations based on Walsh's rules.[11] As in KO_3 (300.5

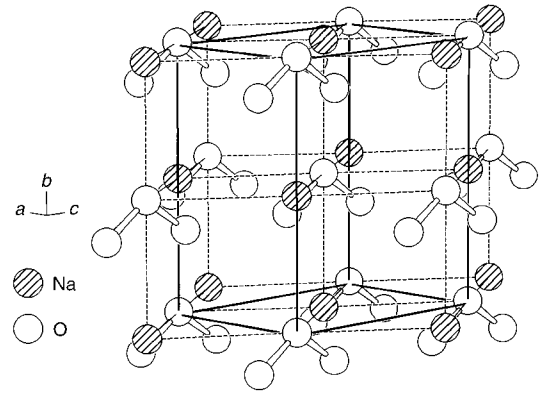

Fig. 2 Perspective view of the crystal structure of NaO_3. Bold lines: conventional unit cell, dashed lines emphasize the relation to the rock salt type of structure.

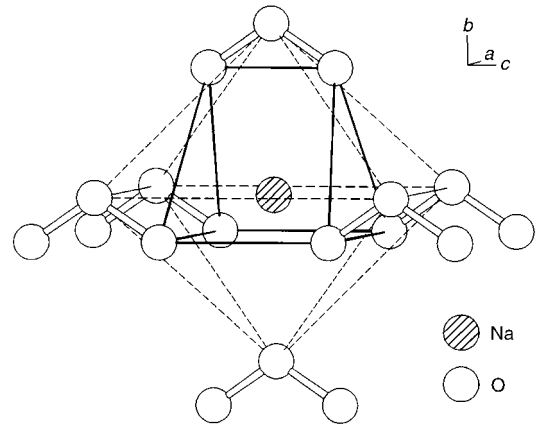

Fig. 3 Trigonal prismatic coordination of the sodium cation by six terminal oxygen atoms (bold lines), octahedral surrounding by six ozonide anions (dashed lines)

Table 1 Selected bond lengths and angles for ionic ozonides

	O–O/Å	O–O–O/°
NaO_3	135.3(3)	113.0(2)
KO_3[a]	134.6(2)	113.5(1)
RbO_3[a]	134.3(7)	113.7(5)
CsO_3[b]	133.3(9)	114.6(6)

[a] Ref. 2. [b] Ref. 13.

pm),[12] the shortest distances between different anions in NaO_3 are 301.5 pm. In contrast, for the first time the nearest oxygen atoms of different ozonide groups are terminal and negatively polarized,[13] instead of one terminal and one less negatively polarized bridging atom like in the other alkali ozonides.

Somewhat unexpectedly, the difficulties in preparing pure NaO_3 are not caused by its supposed higher intrinsic instability as compared with, *e.g.* KO_3, but probably by a stronger activation of ammonia with respect to a proton transfer when coordinated to sodium instead of potassium. Thus the synthesis method employed here might represent a general procedure for the synthesis of so far unknown ozonides. According to preliminary results $Ba(O_3)_2$ seems to be accessible *via* this novel route.

Response to steric constraint by d^{10} cations: an 'A-frame' disilver cryptate

Joanne L. Coyle,[a,b] Vickie McKee*[a]† and Jane Nelson*[a,b]†

[a] *School of Chemistry, Queens University, Belfast, UK BT9 5AG*
[b] *Chemistry Department, Open University, Milton Keynes, UK MK7 6AA*

A pair of silver(I) cations is accommodated within a small azacryptand which adopts an A-frame conformation, allowing both intra- and inter-cryptate bonding of silver cations.

In recent years we have successfully used the strategy of constraining copper ions within small azacryptand hosts in coordination geometry appropriate to overlap of d_{z^2} bonding orbitals, to generate, *via* one-electron oxidation of the dicopper(I) cryptates, metal–metal bonded dicopper cryptates of average-valence $Cu^{1.5}$ redox state.[1] This unprecedented copper–copper bond has unusual and possibly applicable spectroscopic and electrochemical properties.[1,2] The isomorphism observed between copper(I) and silver(I) cryptates elsewhere in our azacryptate series[3] encouraged us to examine the silver(I) analogues of the dicopper(I) precursors to see if similarly enforced proximity would generate delocalized metal–metal bonding in the disilver(I) pair on oxidation. This is of interest not just from the point of view of metal–metal bonding theory, but because higher redox states of silver may be of interest as replacements for chlorine-based oxidants for some specialist purposes. However, as the coordination geometry preferences of silver and copper are known to be different, a necessary first step was the structural characterisation of any disilver(I) cryptate isolated. Treatment of the free ligand imBT with silver perchlorate in either 1:2 or 1:1 stoichiometry resulted in the isolation of a pale yellow microcrystalline product $[Ag_2(imBT)][ClO_4]_2$ **2** which could be recrystallised from acetonitrile to generate X-ray quality crystals.

When copper(I) cations coordinate the tren-derived N_4 caps within the small azacryptand host imBT, steric constraint brings this pair of cations to within 2.45 Å[1] of each other, within the internuclear distance of *ca*. 2.56 Å in elemental copper. In the average-valence dicopper(1.5) state, this distance reduces only slightly, to 2.38 Å,[4] whereas within the larger (trispropylene capped) cryptate host, imbistrpn, the contraction in going from the dicopper(I) state to the average-valence $Cu^{1.5}{}_2$ state is sizeable (> 0.5 Å).[4] The lack of significant increase of internuclear distance on going to the dicopper(I) state within the imBT host suggests that the 2.45 Å separation is near the maximum achievable when the cryptand caps are used as coordination sites. As 2.45 Å would represent an improbably short Ag^I–Ag^I internuclear distance, isomorphism of polycrystalline $[Cu_2(imBT)][ClO_4]_2$ **1** and $[Ag_2(imBT)][ClO_4]_2$ **2** did not appear likely and was not, indeed, observed. Although, unexpectedly, CD_3CN solution ^1H NMR spectra of **1** and **2** show a good deal of similarity,[5] their solid state MAS NMR spectra[6] are quite different. The ^{13}C solid state NMR for **1** is simple, consistent with high symmetry of the cryptand conformation while for the disilver(I) analogue **2** it is complex, indicating lower symmetry for the cryptand host. The structure obtained by X-ray crystallography reveals the reason for these differences; the silver(I) cations have not chosen the 'pre-organised' N_4 site used by copper in its imBT, amBT and imbistrpn cryptates and adopted also in other, less constrained, disilver(I) cryptates.[7]

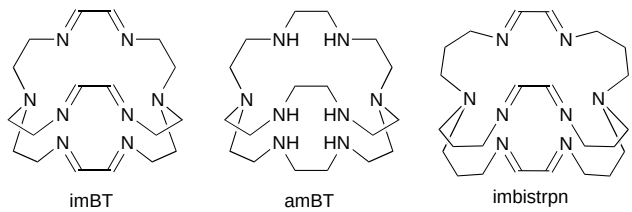

Fig. 1 illustrates the alternative site selected by Ag^I. The asymmetric unit contains two independent cations and four perchlorate anions. The cations are very similar to one another, differing only in the minor details of conformation in the cryptand strands. The Ag–Ag distances are 2.8314(8) and 2.8545(8) for Ag(1a)–Ag(2a) and Ag(1d)–Ag(2d) respectively. Two of the three strands act as bidentate diimine donors to a silver ion, while the third strand bridges the two silver ions. The bridgehead nitrogen atoms are not coordinated (Fig. 2) and the overall $N_{br}\cdots N_{br}$ distance is 6.05 Å, *vs.* 5.88 Å in **1**. The three

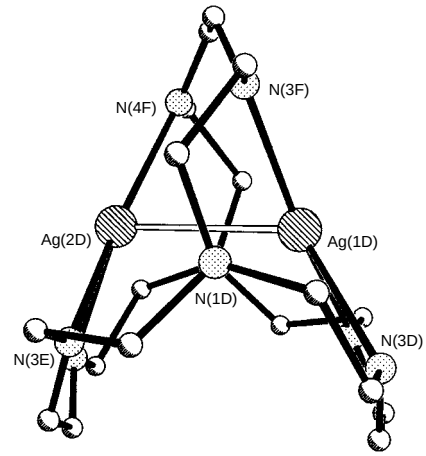

Fig. 1 View of the disilver(I) cryptate looking down the $N_{bridgehead}$ axis

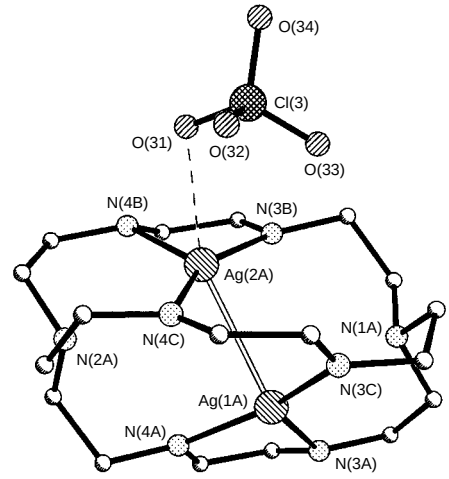

Fig. 2 View of the disilver cryptate looking sideways on to the $N_{bridgehead}$ axis. (One of the two very similar cations existing independently in the unit cell.)

imine donors take up an irregular trigonal geometry with the silver ion close to the mean plane of the nitrogen donors. The chelating diimine groups are necessarily restricted to a bite angle of *ca*. 72°. They are also asymmetric: one of the Ag–N distances is long (mean 2.405 Å) and the second is considerably shorter (mean 2.283 Å). The more tightly bound imine of the chelating imine group makes a large N–Ag–N angle [mean 158.6(2)°] with the third nitrogen donor, reflecting the preference of silver(I) for linear-based coordination.

The exposed position of the silver ions: on the outer surface of the ligand cage rather than cryptated along the main axis, allows interaction with the perchlorate anions. Ag(2a) and Ag(2d) form Ag–$OClO_3$ bonds of 2.681(6) and 2.731(5) Å, respectively while there are longer interactions with the remaining silver ions [Ag(1a)–O(22) 3.335, Ag(1d)–O(34) 3.087, Ag(2a)–O(33) 3.319 Å]. These interactions link the disilver cations in zigzag perchlorate-bridged chains, using two of the four independent perchlorate anions.

Viewed along the bridgehead–bridgehead vector the cations show A-frame geometry (Fig. 1). The top (hinge) angle is provided by the bridging diimine strand and requires a large torsion angle [46(1)° for N(3c)–C(3c)–C(4c)–N(4c) and 45(1)° for N(3f)–C(3f)–C(4f)–N(4f)]. The equivalent torsion angles for the bidentate diimine strands are in the range 28–31°.

Whether some degree of metal–metal bonding is to be implied from the observation of Ag–Ag internuclear distances shorter than those (2.89 Å) in elemental silver is a matter of debate. The rationale for the close approach of d^{10} ions observed in many systems[8] has remained a longstanding puzzle in bonding theory. To quote Hoffman[9] 'One has difficulty in seeing why two or more d^{10} ions should come near each other; after all they are filled shells'. His explanation of this behaviour relies on hybridisation of 4d with higher energy 5s and 5p orbitals which converts the closed shell repulsions into weak attractive interactions. In the case of Au^{I}, relativistic effects reduce the d–s energy gap to allow Au–Au interaction[10] of around 6–8 kcal mol^{-1} (cal = 4.184 J), but this mechanism cannot be invoked for Ag^{I}. Oxidation of the d^{10} cation should however allow stronger interaction, of the order of a one-electron bond. Preliminary electrochemical study[11] of **2** reveals a pair of overlapped and poorly reversible waves in the range 1.0–1.5 V *vs*. Ag/AgCl indicating that this disilver cryptate can be oxidised at accessible potential, apparently generating $Ag^{I}Ag^{II}$ and $Ag^{II}Ag^{II}$ products, at least in solution. Should cryptates of these redox states be isolable, the comparison of the weak $d^{10}d^{10}$ interaction with that existing in $d^{9}d^{10}$, or $d^{9}d^{9}$ where formal metal–metal bonding is theoretically possible, will assist understanding of the $d^{10}d^{10}$ situation.

The significance of the novel and unusual conformation adopted in this cryptate is that linkage of metal–metal intra-cryptate bonded entities becomes possible, *via* bridging donors coordinated at the vacant axial positions on the face of the A. Such a possibility, illustrated by the perchlorate bridging of Fig. 3, could be exploited by the use of efficient bridging ligands. In this way, cryptand-enforced metal–metal bonds could be linked together *via* unsaturated bridging groups such as CN^{-} to generate potentially exploitable oligomeric or continuous solid materials. These would still incorporate the valuable properties of the cryptand host such as steric constraint and cryptand cavity protection, while enabling propagation of bulk electronic properties such as conductivity or magnetism through the extended structure.

We thank EPSRC for support (to J. C.) and also for access to facilities: FABMS at Swansea and solid state NMR at Durham.

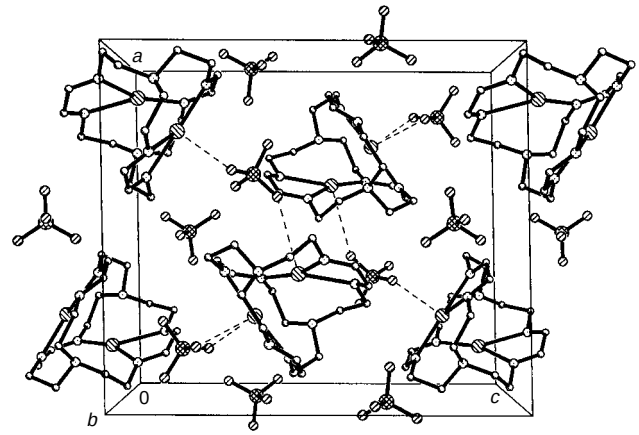

Fig. 3 Linkage of cryptate units *via* anion (perchlorate) bridging

The reductive coupling of tertiary amides to give enediamines using $PhMe_2SiLi$

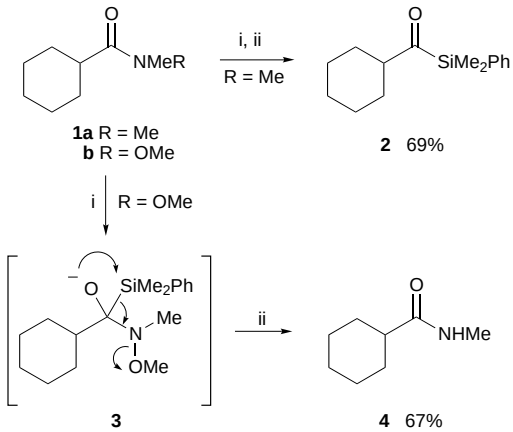
Ian Fleming,*[a]† Usha Ghosh,[a] Stephen R. Mack[a] and Barry P. Clark[b]

[a] *Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Eli Lilly and Co., Lilly Research Centre, Erl Wood Manor, Windlesham, Surrey, UK GU20 6PH*

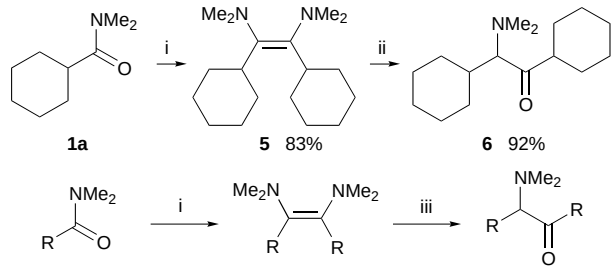
$PhMe_2SiLi$ reacts with tertiary amides to give enediamines, which can be isolated in good yield when the α-carbon is branched; the enediamines can be hydrolysed more or less easily to α-amino ketones, isomerised from *Z* to *E*, oxidised to dienediamines and isomerised to amino enamines.

We have been studying the reactions of $PhMe_2SiLi$[1] with a variety of substrates, including carbon electrophiles at the oxidation state of a carboxylic acid. One goal in this work had been to find a synthesis of acylsilanes that might be even easier than the reaction between an acid chloride and a silyl cuprate.[2] We reported almost no success, and several surprises, in the reaction between the silyllithium reagent and nitriles,[3] some success in the reaction with esters,[4] and some success with tertiary amides **1a**→**2**, *provided that the reaction is carried out and quenched at dri ice–acetone temperatures*.[4] To avoid this delicate operation, the standard device when synthesising aldehydes or ketones from amides is to use a Weinreb amide,[5] but we find that this does not work for the synthesis of acylsilanes, because the Weinreb amide **1b** gives N–O cleavage instead (Scheme 1), presumably by elimination of methoxide from the tetrahedral intermediate **3** giving the secondary amide **4**.[6] Among the variety of unexpected reactions of the silyllithium reagent that we have already reported, none has been as surprising as the reactions with tertiary amides carried out at higher temperatures, which we report here and in the following two papers.

When we treated the same *N*,*N*-dimethylamide **1a** with a little over 1 equiv. of the silyllithium reagent at −20 °C, and quenched the mixture with aq. $NaHCO_3$ at that temperature, we obtained a good yield of the crystalline enediamine **5** (Scheme 2). Although there is one precedent for this type of reaction, where a 14% yield of an enediamine was obtained from *N*,*N*-diethylbenzamide with Et_3SiLi,[7] we were at first uneasy about the structure of this compound, since it had survived dissolution in dilute hydrochloric acid overnight at room temperature—conditions that are far more vigorous than those usually needed for the hydrolysis of an enamine. An X-ray crystal structure



Scheme 1 *Reagents and conditions*: i, $PhMe_2SiLi$ (1.2 equiv.) THF, −78 °C, 1.5 h; ii, NH_4Cl, H_2O, −78 °C → room temp.



7a R = Pr^i **8a** 80% **9a** 79%
b R = Bu^t **9b** 6%
c R = Pr^n **9c** 81%
d R = $Me(CH_2)_8$ **9d** 72%
e R = $CH_2{=}CH(CH_2)_2$ **9e** 75%
f R = $CH_2{=}CH(CH_2)_3$ **9f** 59%
g R = Bn **9g** 52%
h R = $Ph(CH_2)_2$ **9h** 69%
i R = $PH(CH_2)_3$ **9i** 60%
j R = $Ph(CH_2)_4$ **9j** 46%
k R = Ph **9k** 51%

Scheme 2 *Reagents and conditions*: i, $PhMe_2SiLi$ (1.1 equiv.) THF, −78 → −20 °C, 1 h; ii, 3 M HCl, 70 °C, 18 h; iii, 3 M HCl, various times and temperatures

(Fig. 1) confirmed that it was the enediamine and showed also that it was the *Z* isomer.[8]‡

The stability in acid was now convincingly explained—the lone pairs on both nitrogen atoms are in the plane of the double bond, and not conjugated to it as they are in a typical enamine. Hydrolysis of the enediamine **5** required heating to 70 °C in dilute hydrochloric acid for 18 h in order to obtain the α-amino ketone **6**. Clearly, in contrast to the one precedent, the reductive coupling of amides can be a high-yielding reaction. We find that the amides **7a**–**k** undergo reductive coupling followed by hydrolysis to give the α-amino ketones **9a**–**k**, but the enediamines **8a**–**k**, although detectably intermediates, were only easily isolated when they carry branched substituents, as with **8a**, to confer on them this remarkable hydrolytic stability.

The enediamines **5** and **8a** showed a number of unexpected reactions (Scheme 3). When we treated the enediamine **5** with methyl acrylate, attempting to induce a cycloaddition characteristic of enamines,[9] it isomerised to the *E* isomer **11a**, which was remarkable for the substantial difference in its properties from the *Z* isomer: the R_f value on silica gel eluting with hexane changed from 0.1 to 0.7 and the mp changed from 89–90 °C to 175–176 °C. The isomerisation from the *Z* isomers **5** and **8a** to

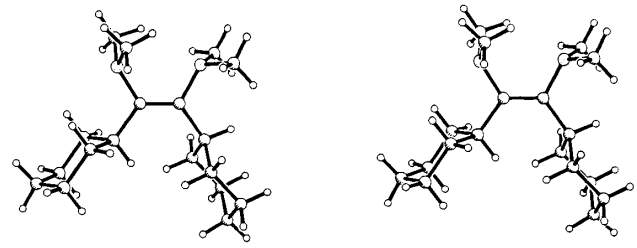


Fig. 1 Stereoview of the enediamine **5**

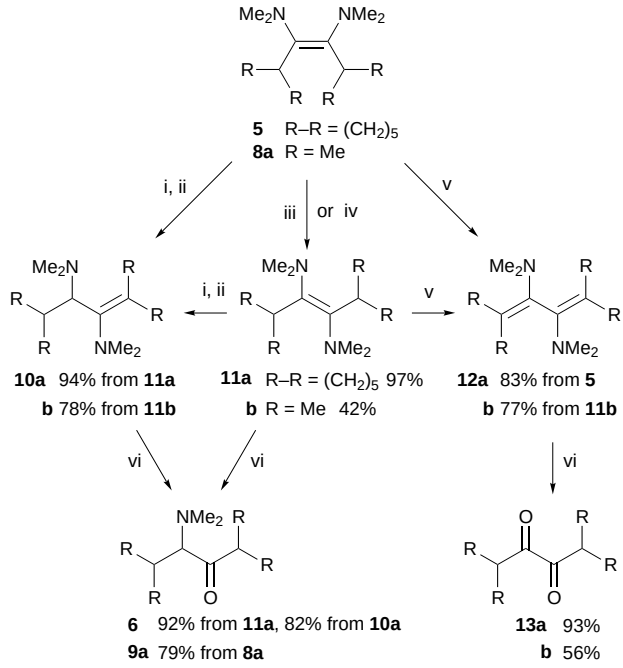

Scheme 3 *Reagents and conditions*: i, $(CO_2H)_2$, recrystallise from EtOAc; ii, NaOH, H_2O; iii, CH_2=$CHCO_2Me$, 60 °C, 24 h; iv, PtO_2, MeOH, 50 °C, 15 min; v, Pd/C, MeOH, room temp., 4 h; vi, 3 M HCl, 70 °C, 18 h

the *E* isomers **11a**, **b**, respectively, is actually better carried out using a short treatment with Adams' catalyst. The enediamines, both the *Z* and *E* isomers, gave oxalate salts, but simple recrystallisation of these salts, followed by basification, gave the isomers **10a** and **10b** of the enediamines in which the double bond had moved. All of the enediamines could be hydrolysed to the α-amino ketones **6** and **9a**, but all attempts to reduce any of them to the saturated vicinal diamine failed. Most remarkable amongst our attempts was the oxidation of the enediamines **5** or **11a** *using hydrogen and palladium on charcoal*, which gave the dienediamine **12a**. Needless to say, this oxidation was better performed without the hydrogen, and the first step, when carried out on the *Z* isomers, appears to be isomerisation to the *E* isomers. Hydrolysis of the dienediamines **12** gave the α-diketones **13**.

The reductive coupling of the amide carbonyls resembles the McMurry coupling of aldehydes and ketones, and even more closely the reductive coupling of amides using samarium and its iodide,[10] and other lanthanides and their salts.[11] While an electron transfer mechanism might be operating in our reaction, the very different reagent that we have used led us to suspect otherwise. We describe our investigations into the mechanism of the coupling in the following paper.

We thank Dr P. R. Raithby, Dr H. R. Powell and C. Wilson for carrying out the X-ray structure determination, the EPSRC and Lilly Industries for a CASE studentship for S. R. M., and Duckhee Lee for the experiment with the Weinreb amide.

α-Amino carbene or carbenoid formation in the reaction of a tertiary amide with $PhMe_2SiLi$ and its insertion into the Si–Li bond of a second equivalent

Ian Fleming,*[a]† Stephen R. Mack[a] and Barry P. Clark[b]

[a] *Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Eli Lilly and Co., Lilly Research Centre, Erl Wood Manor, Windlesham, Surrey, UK GU20 6PH*

$PhMe_2SiLi$ reacts with tertiary amides, $RCONMe_2$, to give a carbene, $RCNMe_2$, or an equivalent carbenoid, which gives enediamines, $R(Me_2N)C{=}C(NMe_2)R$, in the absence of a strong nucleophile, but is attacked by strong nucleophiles, NuLi, to give lithium reagents $R(Me_2N)CLiNu$.

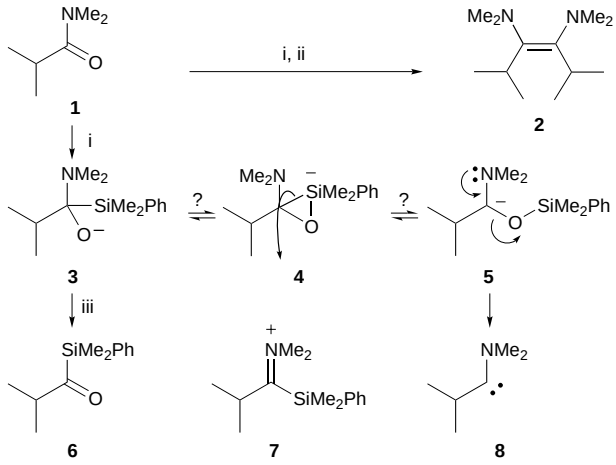
In the preceding paper[1] and its predecessor,[2] we described the reaction between 1 equiv. of $PhMe_2SiLi$ and the amide **1** giving the acylsilane **6** when the mixture was quenched at −78 °C, but giving the enediamine **2** when the mixture was warmed to −20 °C before quenching. Neither in those papers, nor in the paper describing the one precedent for this type of reaction,[3] has there been any discussion of the mechanism of the formation of the enediamine.

Among other possibilities, such reductive coupling implies that a species electrophilic at the carbonyl carbon has been attacked by an umpolung species nucleophilic at the carbonyl carbon. The latter is easily identified as the consequence of a Brook rearrangement,[4] which can be formulated as an equilibrium between an α-silyl alkoxide **3** and the α-silyloxy anion **5**,[5] with the latter the umpolung species (Scheme 1). Alternatively, it can be formulated as a single hypervalent species **4**,[6] which can react as an oxygen or a carbon (**4** arrow) nucleophile, depending upon the circumstances. It is, however, much less easy to identify the electrophilic species. Several candidates present themselves: the amide **1**, the acylsilane **6**, an iminium ion **7**, and a carbene **8**. We now report that all the evidence suggests that the carbene is the electrophile.

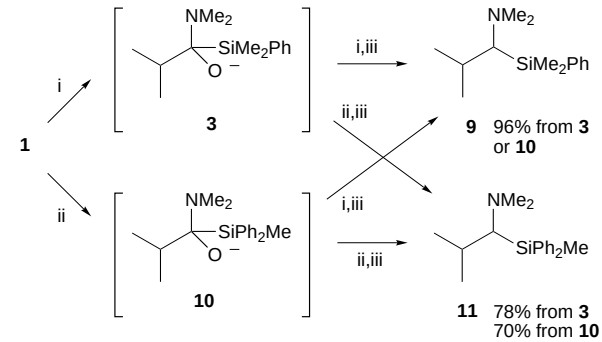
The amide itself cannot have been the electrophile—if we simply warmed the solution of the tetrahedral intermediate **3** from −78 to −20 °C, and then quenched the mixture, we obtained the enediamine **2** in good yield. The tetrahedral intermediate **3** was fully formed at the lower temperature, since on quenching it, the acylsilane **6** was obtained in reasonably good yield. It does not revert to amide and the silyllithium reagent, since adding *N*,*N*-dimethylcyclohexanecarboxamide before warming up from −78 °C gave only the homo-coupled product **2**.[7] The tetrahedral intermediate must have provided both the nucleophilic and the electrophilic species for the coupling reaction.

To trap the electrophile, we carried out the same reaction as before but with rather more than 2 equiv. of the silyllithium reagent, in the hope that the intermediate would be trapped by the second equivalent of nucleophile. The product was the α-silyl amine **9** (Scheme 2), analogous to a minor product in the Russian work.[3] If the iminium ion **7** had been an intermediate, it ought to have led to a product with two silyl groups, not just one, and the easy loss of one seems unlikely. We showed that this was not the case, by treating the tetrahedral intermediate **3** with $Ph_2MeSiLi$, and obtained this time only the α-silyl amine **11** having the Ph_2MeSi group rather than the original $PhMe_2Si$ group. We also carried out the experiment the other way round, adding $Ph_2MeSiLi$ to the amide **1** at −100 °C to give the tetrahedral intermediate **10**. This then reacted with $PhMe_2SiLi$ on warming to −20 °C to give the α-silyl amine **9**, showing that neither an α,α-disilyl amine nor the iminium ion **7** could have been intermediates—only the silyl group from the second silyllithium reagent delivered was incorporated into the product.

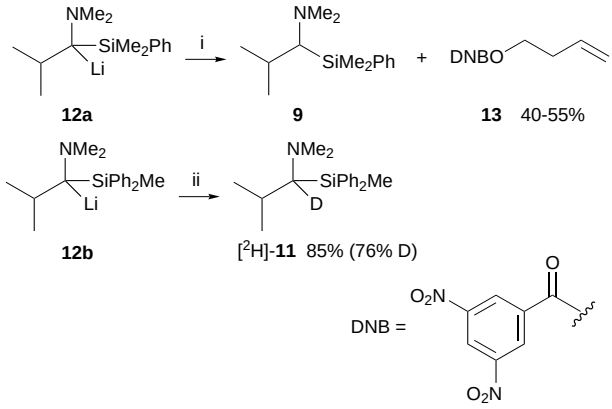
The formation of the products **9** and **11** was, however, compatible with the carbene **8** being an intermediate—it could be expected to insert into the Si–Li bond of the second lithium reagent to give an intermediate lithium reagent **12**, which would be protonated before or during the workup. Our attempts to detect the intermediate **12a** were thwarted by its evident strong basicity—it did not incorporate a deuterium label when quenched with D_2O, having already found a proton somewhere else. Nor were we at first successful in finding where that proton came from, but eventually we showed that an organolithium intermediate had been involved by trapping the corresponding Ph_2MeSi intermediate **12b** at −78 °C (Scheme 3). It is known that the more phenyl groups there are on a silyl group, effectively the faster the Brook rearrangement takes place.[8] In consequence, the intermediate **12b** was formed between −100



Scheme 1 *Reagents and conditions*: i, $PhMe_2SiLi$ (1.2 equiv.) THF, −78 °C, 1.5 h; ii, −20 °C, then $NaHCO_3$, H_2O; iii, NH_4Cl, H_2O, −78 °C → room temp.



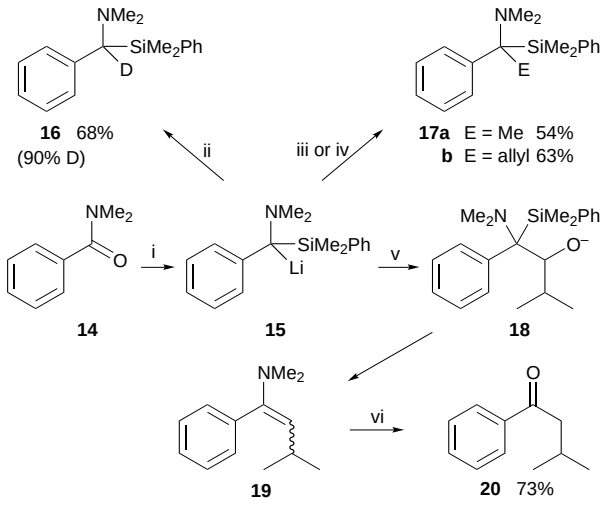
Scheme 2 *Reagents and conditions*: i, $PhMe_2SiLi$ (1.2 equiv.) THF, −78 °C, 1.5 h; ii, $Ph_2MeSiLi$ (1.2 equiv.) THF, −100 °C, 1.5 h; iii, −20 °C, then $NaHCO_3$, H_2O



Scheme 3 *Reagents and conditions*: i, 3,5-$(O_2N)_2C_6H_3COCl$; ii, D_2O

and −78 °C, at which temperature it survived long enough to be quenched with D_2O to give the deuterated α-silyl amine [^{2}H]**11**. The $PhMe_2Si$ intermediate **12a**, having been formed at higher temperature, somewhere between −78 and −20 °C, evidently found a proton before it could be quenched with D_2O. The source of that proton appears to be, at least in part, THF, which is known to react with strong bases like BuLi, losing the proton on C-2 and undergoing a retro-cycloaddition to give the enolate of acetaldehyde.[9] We detected a low level of deuterium incorporation when the reaction was carried out in [$^2H_8$]THF, and, expecting to trap the enolate of acetaldehyde, we added 3,5-dinitrobenzoyl chloride, and obtained instead the 3,5-dinitrobenzoate **13** in yields of 40–55%, with no trace of the expected product. As far as we are aware, the apparently simple E2 elimination from THF losing the proton from C-3 has not been seen before in solution chemistry, although it is thoroughly established with hydroxide ion and amide ion as bases in the gas phase,[10] and the formation of but-3-enol from the reaction between sodium and 3-chlorotetrahydrofuran is also known.[11] It is presumably unfavourable because the elimination is a retro-5-*endo*-*trig* reaction.

We also found that the presence of a phenyl group in the *N*,*N*-dimethylbenzamide **14** stabilised the corresponding intermediate **15**, which survived even at −20 °C, and gave a deuterated α-silyl amine **16** on quenching with D_2O (Scheme 4). The intermediate **15** also reacted with alkyl halides giving the amines **17a** and **17b**, and with isobutyraldehyde giving, initially, an alkoxide **18** that undergoes a Peterson elimination giving the enamine **19**, which is easily hydrolysed to the ketone **20**. These reactions illustrate an umpolung of reactivity in the amide **14**.



Scheme 4 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.) THF, −78 → −20 °C, 1.5 h; ii, D_2O; iii, MeI; iv, allylBr; v, Pr^{i}CHO; vi, HCl, H_2O

The carbene intermediate **8** could be formed by Brook rearrangement, followed by or concerted with the elimination of silane oxide (Scheme 1). This pathway is, as far as we are aware, a new one for reactions taking place within the Brook rearrangement manifold, and is a new route to carbene or carbene-like intermediates. The nearest analogy is the formation of an oxygen-stabilised carbene when the acetals of acylsilanes are heated to 190 °C.[12] Our reaction takes place, presumably, because of the extra electronic push (**5**, arrows) from the Me_2N lone pair. It could equally be derived by cheletropic extrusion of $PhMe_2SiO^-$ directly from the intermediate **4**. It is not clear what the structure of the carbene is in detail—it could be the carbene itself **8**, as we have drawn it here for simplicity, or it could be an equivalent species such as an α-lithio iminium ion. A carbene was also invoked by Ogawa and Sonoda in their work using samarium iodide induced coupling of amides.[13] Whatever its nature, our carbene was not trapped by a silicon hydride—only the enediamine **2** was formed, and not the silyl amine **9**, when the tetrahedral intermediate **3** was warmed to −20 °C in the presence of $PhMe_2SiH$, nor have we found at any stage products that might have been derived by insertion of the carbene into the neighbouring C–H bond, nor into a well-placed C=C bond, as described in the following paper. The enediamine could be produced from the carbene or carbenoid by dimerisation, or, more likely in view of the probable low concentration of such a species, by attack upon it by the *C*-nucleophilic intermediate **4** or **5** of the Brook rearrangement, followed by β-elimination of a second silyloxy anion.

The following paper describes some other remarkable reactions that can be ascribed to the presence of intermediate lithium reagents like **12** and **15**. They add further support to this being the correct mechanism, at least in outline.

We thank the EPSRC and Lilly Industries for a CASE studentship for S. R. M.

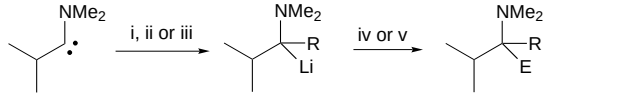
Formation of α-dialkylamino alkyllithium intermediates in the reaction of *N*,*N*-dialkylamides with $PhMe_2SiLi$ followed by a second lithium reagent, and their alkylation, fragmentation, cyclisation and rearrangement by proton transfer

Ian Fleming,*[a]† Stephen R. Mack[a] and Barry P. Clark[b]

[a] *Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Eli Lilly and Co., Lilly Research Centre, Erl Wood Manor, Windlesham, Surrey, UK GU20 6PH*

Tertiary amides ($RCONMe_2$) react with $PhMe_2SiLi$, followed by a second lithium reagent NuLi, to give α-dialkylamino alkyllithium intermediates $R(Me_2N)CLiNu$ that undergo protonation 2 → 3, alkylation 2a → 3ab, β-elimination 5 → 6, intramolecular attack on an isolated double bond 9 → 10, intramolecular proton transfer 12, 17 and 22 (arrows), and fragmentation 28 and 34 (arrows), depending upon the structures of the various components R and Nu.

In the preceding paper[1] we described how an intermediate carbene **1** derived from the remarkable reaction between 1 equiv. of $PhMe_2SiLi$ and *N*,*N*-dimethylisobutyramide could be trapped by a second equivalent of the silyllithium reagent. We now report that when we prepared the tetrahedral intermediate from the amide with 1 equiv. of $PhMe_2SiLi$ at −78 °C as usual, and then added PhLi, Bu^nLi or Bu_3SnLi, before warming the mixture to −20 °C, we obtained the amines **3aa**, **3ba** and **3ca**, presumably by way of the intermediate lithium reagents **2a**–**c**. We also quenched the phenyl-stabilised lithium reagent **2a** with allyl bromide to give the amine **3ab** (Scheme 1). These reactions establish a new way of assembling secondary alkyl and, more remarkably, tertiary alkyl tertiary amines, and an α-stannyl tertiary amine.



1

2a R = Ph
b R = Bu^n
c R = $SnBu_3$

3aa R = Ph, E = H 68%
ab R = Ph, E = allyl 60%
ba R = Bu^n, E = H 42%
ca R = $SnBu_3$, E = H 21%

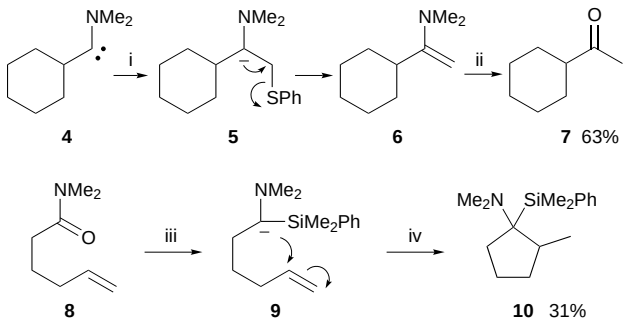
Scheme 1 *Reagents and conditions*: i, PhLi; ii, Bu^nLi; iii, Bu_3SnLi; iv, $NaHCO_3$, H_2O; v, allylBr

We achieved umpolung in another way, by building a leaving group into the nucleophile (Scheme 2). We treated *N*,*N*-dimethylcyclohexanecarboxamide with 1 equiv. of the silyllithium reagent, followed by 1 equiv. of $PhSCH_2Li$, and then warmed to −20 °C to give the lithium reagent **5**, drawn here and from now on as an anion, in order to allow us to use uncomplicated curly arrows. β-Elimination gave the enamine **6**, and hence the ketone **7** on hydrolysis. We also intercepted the intermediate anion **9**, setting it up with 2 equiv. of the silyllithium reagent, and found that nucleophilic attack by the anion (arrows) is possible on the isolated double bond built in to be at the appropriate distance for a known[2] type of 5-*exo*-*trig* reaction of α-amino alkyllithium reagents (Scheme 2). The isolated cyclopentane product **10** was a single diastereoisomer, but we do not know which one. These simple extensions of the pathways recorded in the preceding paper confirm the intermediacy of α-amino alkyllithium intermediates **2**, **5** and **9**.

We also report that the generality of these routes is compromised by the ease with which the intermediate anion, suitably constituted, undergoes proton transfer to give better stabilised anions, and how other similarly constituted anions suffer extraordinary elimination reactions with a benzyl anion leaving group. The intermediate lithium reagents are evidently unstable, and find a disconcerting variety of ways to decompose.

Thus, the phenylacetamide **11** gave, as well as the normal product **13**, small amounts of a cyclic product **15** (Scheme 3). This appears to be a result of a proton transfer **12** → **14**, to give a phenyl anion, followed by displacement of the phenyl group from silicon (**14** → **15**). Displacement of a phenyl group from silicon with an oxy anion nucleophile is well established,[3] and there are a few examples of the displacement of a phenyl or vinyl group by a carbon–lithium reagent.[4]

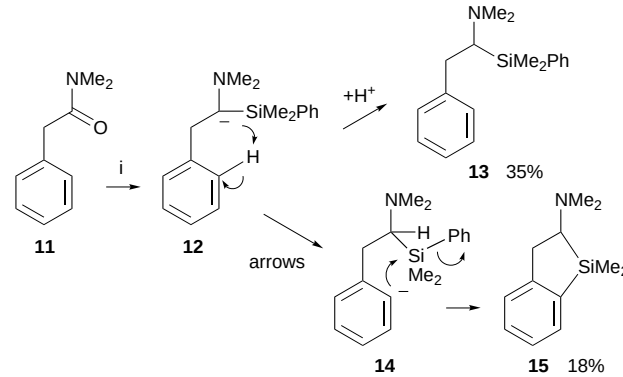
Similarly, the bis-homologue **16** gave the normal product **18** together with a product of proton transfer (**20**) in this case with a benzyl anion displacing the phenyl group (**19** → **20**) (Scheme 4).



4 **5** **6** **7** 63%

8 **9** **10** 31%

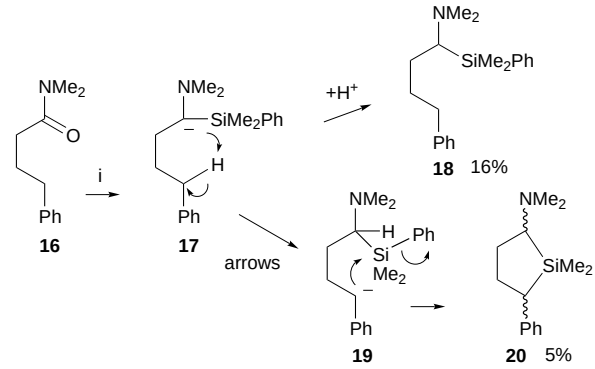
Scheme 2 *Reagents and conditions*: i, $PhSCH_2Li$, −20 °C; ii, HCl, H_2O; iii, $PhMe_2SiLi$ (2.4 equiv.) THF, −78 → −20 °C, 1.5 h; iv, $NaHCO_3$, H_2O



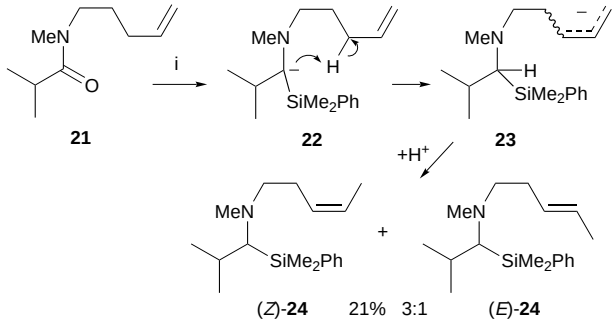
11 **12** **13** 35%

14 **15** 18%

Scheme 3 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.), THF, −78 → −20 °C, 1.5 h



Scheme 4 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.), THF, −78 → −20 °C, 1.5 h

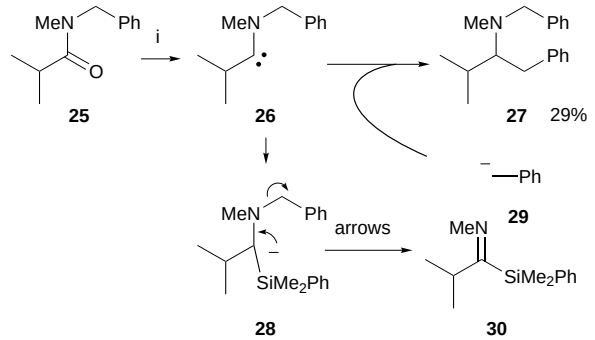


Scheme 5 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.), THF, −78 → −20 °C, 1.5 h

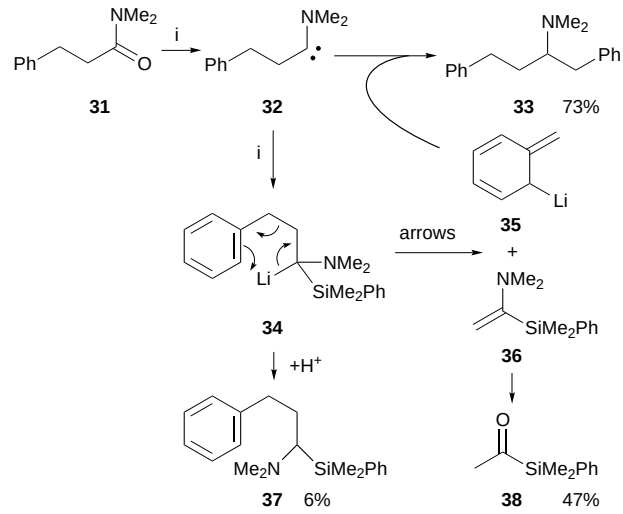
Proton transfer within a five-membered ring also took place from the pentenyl substituent in the amide **21**, where the minor, but the only recognisable, basic products were the pent-3-enylamines (*Z*)-**24** and (*E*)-**24**, similar to what we might call the normal product, except that the double bond had moved (Scheme 5). Proton transfer **22** → **23**, with the formation, as usual,[5] of more of the sickle-shaped allylic anion than of the W-shaped anion, accounts for this curious reaction.

We saw yet another pathway in the reaction with *N*-benzyl-*N*-methylamide **25** (Scheme 6), where the only basic product that we were able to identify from the reaction with 2 equiv. of $PhMe_2SiLi$ was the tertiary amine **27**. This can be accounted for by elimination **28** → **30** to release a benzyl anion **29**, followed by the attack of the benzyl anion on the carbene intermediate **26** and subsequent protonation.

Elimination to give a benzyllithium intermediate also explains what is perhaps the most remarkable reaction in the



Scheme 6 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.), THF, −78 → −20 °C, 1.5 h



Scheme 7 *Reagents and conditions*: i, $PhMe_2SiLi$ (2.4 equiv.), THF, −78 → −20 °C, 1.5 h

cornucopia of remarkable reactions, both those described in this series of papers and those for which we have no room here. When we treated the amide **31**, intermediate between the amides **11** and **16**, with 2 equiv. of $PhMe_2SiLi$, the major basic product was the amine **33** (Scheme 7). Elimination from the usual intermediate **34** would give the enamine **36**. The elimination is drawn here (**34** arrows) as a retro metalla-ene reaction, and the elimination product is drawn as the 'allylic' isomer **35** of benzyllithium, to illustrate an alternative perception to that drawn for the related elimination **28** → **29** + **30** in Scheme 6. The benzyllithium or its allylic isomer **35** might then trap the carbene **32** to give, after protonation, the major product **33**. In support of this sequence, we also isolated the acylsilane **38** from the basic fraction, into which, presumably, it had been extracted as the enamine **36**. We are not aware of any precedent for carbon–carbon bond cleavage with a benzyllithium leaving group.

We thank the EPSRC and Lilly Industries for a CASE studentship for S. R. M.

Hybridization properties of nucleic acid analogs containing β-aminoalanine modified with nucleobases

Masayuki Fujii,*[a]† Kohya Yoshida,[a] Jinsai Hidaka[a] and Takayuki Ohtsu[b]

[a] *Department of Industrial Chemistry, Faculty of Engineering in Kyushu, Kinki University, 11-6 Kayanomori, Iizuka, Fukuoka 820, Japan*

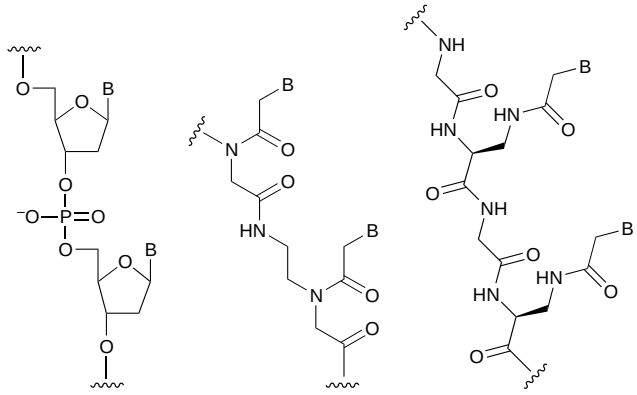
[b] *Department of General Education, Faculty of Biological Science and Engineering, Kinki University, 930 Nishimitani, Uchida, Naka-gun, Wakayama 649-64, Japan*

Oligopeptides containing *N*β-(thymin-1-ylacetyl)-β-aminoalanine and *N*β-(cytosin-1-ylacetyl)-β-aminoalanine moieties synthesized on a solid phase using standard Boc chemistry showed hybridization properties with single stranded DNA and RNA, and also with double stranded DNA, at pH 7.0.

The development of artificial regulatory molecules for specific gene expression is of special interest from the medicinal and biological points of view.[1] In particular, nucleic acids and their analogs, such as antisense or triple-helix forming oligonucleotides, ribozymes and decoy RNAs, are promising reagents as genetic medicines. In spite of intensive efforts to improve their chemical and biological properties, several problems still remain to be solved, which include degradability by cellular nucleases, impermeability through cell membranes and low hybridization affinity caused by electrostatic repulsion between phosphate backbones.[2]

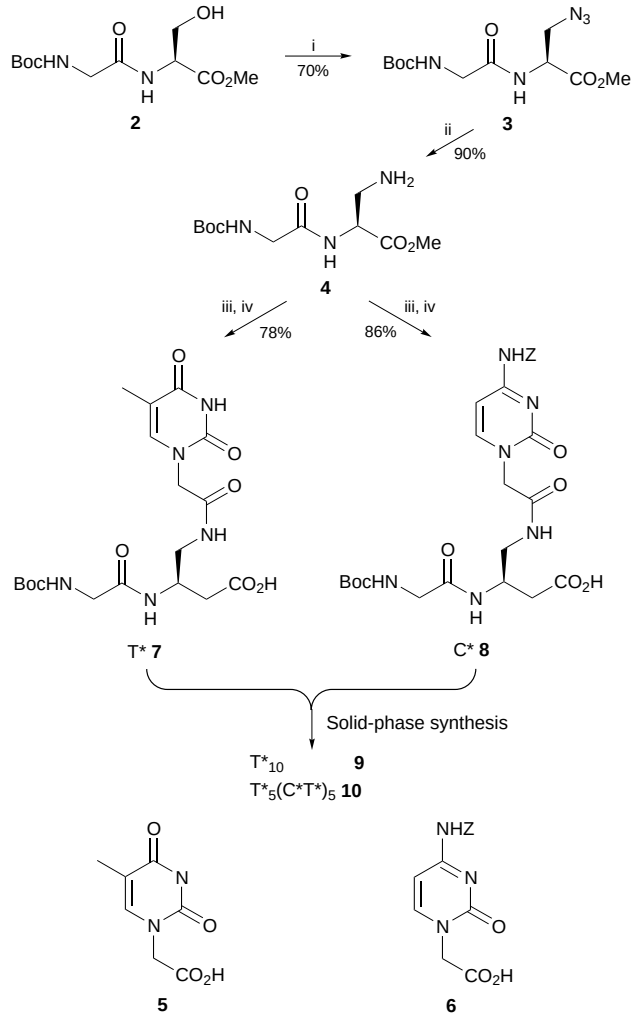
Among various chemical modifications that could be performed on such synthetic DNAs and RNAs, introduction of a peptide backbone into such molecules seems to be attractive because peptide compounds can be expected to have such preferable properties as nuclease resistance, membrane permeability and a good affinity and specificity to nucleic acids, as can be seen in a number of DNA binding proteins.

In this study, oligopeptides **1** containing β-aminoalanine bearing a nucleobase were synthesized and their hybridization properties with ssDNA, ssRNA and dsDNA were examined *via* T_m measurement.



Syntheses of *N*-*tert*-butoxycarbonylglycyl-*N*β-(thymin-1-ylacetyl)-L-β-aminoalanine **7** (T*) and *N*-*tert*-butoxycarbonylglycyl-*N*β-(cytosin-1-ylacetyl)-L-β-aminoalanine **8** (^{Z}C*) were achieved as shown in Scheme 1.[3] These protected amino acids **7** and **8** were readily applicable to solid-phase peptide synthesis using standard Boc chemistry on methylbenzhydrylamine (MBHA) resin.[4] The obtained 20-mer peptide T^*_{10} (**P**) and 30-mer peptide $T^*_5(C^*T^*)_5$ (**Q**) were purified by RP HPLC and confirmed by FAB mass spectrometry {**P**: $C_{122}H_{154}N_{52}O_{51}$ calc. 3164.9, found 3165.9 $[(M + H)^+]$; **Q**: $C_{177}H_{224}N_{82}O_{71}$ calc. 4636.2, found 4637.2 $[(M + H)^+]$}.

As shown in Table 1, formation of a hybrid double strand by **P** and dA_{10} was confirmed by observing a hypochromic effect at pH 7.0. It should be noted that the melting temperature (T_m) was higher than that for the natural DNA double strand by 13.5 °C (1.35 °C base^{-1}).[5] The stability of the hybrid was not affected by salt concentration. The peptide **P** also formed a double strand with rA_{10}, and the T_m was 21 °C. Moreover, it was shown that **P** could bind to double stranded DNA by triple helix



Scheme 1 *Reagents and conditions*; i, Ph_3P, NaN_3, CBr_4, DMF, room temp., 24 h; ii, Pd/C, H_2, MeOH, room temp., 20 h; iii, **5** or **6**, HOBt, DCC, CH_2Cl_2, 0 °C to room temp., 5 h; iv, 1 M NaOH, room temp., 12 h

Table 1 Double and triple helix formation by peptide DNA analogs **P** and **Q**

Strand	Target	T_m[a]/°C	Δ T_m/°C
dT_{10}	dA_{10}	23	—
PNA	dA_{10}	73[b]	+50
P	dA_{10}	36.5	+13.5
P	dA_{10}	36.2[c]	+13.2
P	dA_{10}	36.4[d]	+13.4
P	rA_{10}	21.4	—
dT_{10}	5′-GCTA_{10}TCG-3′/3′-CGAT_{10}AGC-5′	20.9	—
P	5′-GCTA_{10}TCG-3′/3′-GCAT_{10}AGC-5′	19.3	−0.4
5′-T_5-$(CT)_5$-3′	5′-GCT$A_5$$(GA)_5$TCG-3′/3′-CGA$T_5$ $(CT)_5$AGC-5′	21.3	
Q	5′-GCT$A_5$$(GA)_5$TCG-3′/3′-CGA$T_5$ $(CT)_5$AGC-5′	22.8	+1.5

[a] Measured in a buffer containing 50 mM Tris, pH 7.0, 20 mM $MgCl_2$, 100 mM NaCl, [Strand] = [Target] = 0.5 mM. [b] 140 mM NaCl, 10 mM sodium phosphate, pH 7.2. [c] 20 mM $MgCl_2$, 1.0 M NaCl, pH 7.0. [d] 0 M $MgCl_2$, 0 M NaCl, pH 7.0.

formation with comparable affinity (T_m = 19.3 °C, ΔT_m = −0.7 °C).

Oligopeptide **Q** containing mixed pyrimidine bases was also shown to form a triple helix with double stranded DNA (T_m = 22.8 °C, ΔT_m = +1.5 °C).[6]

Studies on the pH dependence of these hybridization properties revealed that the peptide **P**, which contains only thymine bases, binds to ssDNA and dsDNA with an affinity independent of pH, whereas the peptide **Q**, which contains thymine and cytosine bases, binds to dsDNA with less affinity as the pH value increased (Fig. 1). This pH dependency was interpreted to mean that triple helix formation by **Q** with dsDNA required protonation of the cytidine bases in **Q**. These results strongly suggested that **P** and **Q** are binding to dsDNA in the major groove by Hoogsteen hydrogen bonding.

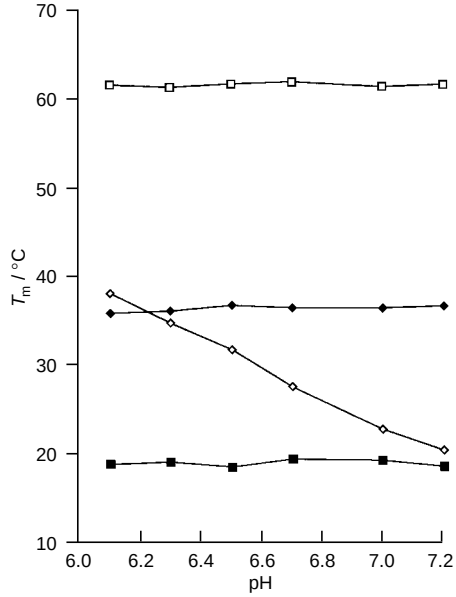


Fig. 1 pH dependence of hybridization: (□) dsDNA, (◆) **P**/ssDNA, (◇) **Q**/dsDNA and (■) **P**/dsDNA

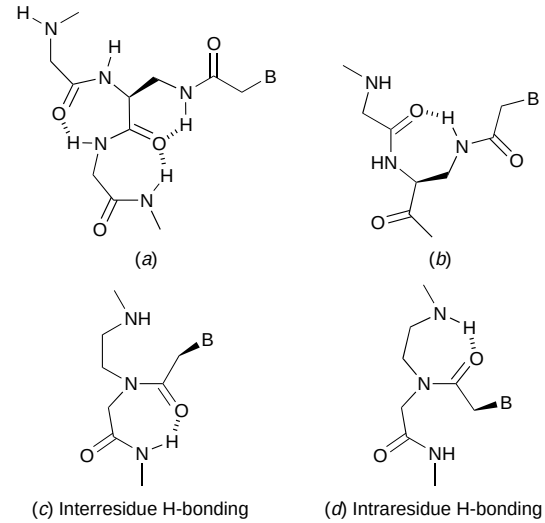

Fig. 2 Intramolecular hydrogen bonding in **1** [(*a*) and (*b*)] and PNA [(*c*) and (*d*)]

The oligopeptides **P** and **Q** were designed to have nucleobase moieties at an interval of six atoms on the backbone, which was previously demonstrated to be critical for hybrid formation with DNA or RNA by Nielsen.[7] The linkage between the nucleobase and the backbone in **P** and **Q** is longer than that in DNA or PNA by two atoms. It was also pointed out by Nielsen's group that the linkage is slightly flexible. It can be postulated that Watson–Crick base pairing in the duplex and Hoogsteen base pairing in triplex by **P** and **Q** is made possible because of the favorable orientation of the base moieties caused by intramolecular hydrogen bond, as shown in Fig. 2.[8]

The present study demonstrates that these novel peptide DNA analogs are promising candidates for antisense and triple helix forming molecules. Further studies to reveal the chemical and biological properties of the peptide DNA analogs are now in progress in our laboratory.

The authors are grateful for financial support from the Chugai Pharmaceuticals Award in Synthetic Organic Chemistry, Japan and from the Fukuoka Industry, Science and Technology Foundation (IST).

Efficient near IR sensitization of nanocrystalline TiO_2 films by ruthenium phthalocyanines

Md. K. Nazeeruddin,†[a] R. Humphry-Baker,[a] M. Grätzel*[a] and Barry A. Murrer[b]

[a] *Laboratory for Photonics and Interfaces, Institute of Physical Chemistry, Swiss Federal Institute of Technology, CH-1015 Lausanne, Switzerland*

Bis(3,4-dicarboxypyridine)(1,4,8,11,15,18,22,25-octamethylphthalocyaninato)ruthenium(II) (JM3306) anchored to nanocrystalline TiO_2 films through the axial pyridine 3,4-dicarboxylic acid ligands is an efficient near IR sensitizer for photovoltaic injection cells based on nanocrystalline TiO_2 films.

Nanocrystalline solar cells have attracted significant attention as low cost alternatives to conventional solid state photovoltaic devices.[1] The most successful charge transfer sensitizers employed so far in these cells are polypyridyl-type complexes of ruthenium[2,3] yielding overall AM 1.5 solar to electric power conversion efficiencies of up to 10–11% and stable operation for millions of turnovers.[4] In order to improve further the performance of these devices it is imperative to enhance their near IR response which is weak owing to the small absorption coefficient of such ruthenium complexes above 650 nm. Phthalocyanines possess intense absorption bands in the near IR region and are known for their excellent stability rendering them attractive for photovoltaic applications.[5] They have been repeatedly tested in the past as sensitizers of wide band gap oxide semiconductors.[6,7] However, poor incident photon to electric current conversion yields were obtained remaining under 1% with these systems which is insufficient for solar cell applications. Here we report on the use of ruthenium phthalocyanines (RuPC) as a charge transfer sensitizer. While RuPC derivatives have been tested as agents for photodynamic cancer therapy[8,9] they have not been employed as redox sensitizers so far. The choice of Ru as a central metal offers the advantage to attach the chromophore through axial ligands to the surface of the oxide semiconductor. Using 3,4-dicarboxypyridine to anchor the dye to mesoscopic TiO_2 films we have achieved for the first time strikingly high photocurrent yields with phthalocyanines exceeding 60% in the near-IR region.

Bis(3,4-dicarboxypyridine)(1,4,8,11,15,18,22,25-octamethylphthalocyaninato)ruthenium(II) (JM3306) was synthesized according to literature procedure[10] and isolated as $[(PCMe_8)Ru\{3,4\text{-}py(CO_2)_2H\}_2]\cdot 3THF$. Elemental analysis (calculated mass% in parentheses): C, 62.05 (62.11); H, 4.86 (4.86); N, 10.79 (10.98). The absorption and emission spectra of an ethanol solution of this dye are shown in Fig. 1. The absorption band in the visible [Fig. 1(*a*)] has a maximum at 650 nm (ε = 49 000 $dm^3\ mol^{-1}\ cm^{-1}$) and that of the phosphorescence [Fig. 1(*b*)] is located at 895 nm the triplet state lifetime being 474 ± 5 ns under anaerobic conditions. The emission is entirely quenched [Fig. 1(*c*)] when JM3306 is adsorbed onto a nanocrystalline TiO_2 film. The dye was deposited by dipping a mesoscopic anatase film (thickness *ca.* 10 μm, coated onto conducting glass, LOF TEC 10, fluorine doped SnO_2 sheet resistance 10 $\Omega\ \square^{-1}$) as previously described[2] for several hours in a 2×10^{-5} M solution in ethanol containing 40 mM 3α,7α-dihydroxy-5β-cholic acid (Cheno) and 2.5% Me_2SO. The presence of Cheno is necessary to avoid surface aggregation of the sensitizer. The vibible band in the absorption spectrum of JM3306 is red shifted by 10 nm upon adsorption.

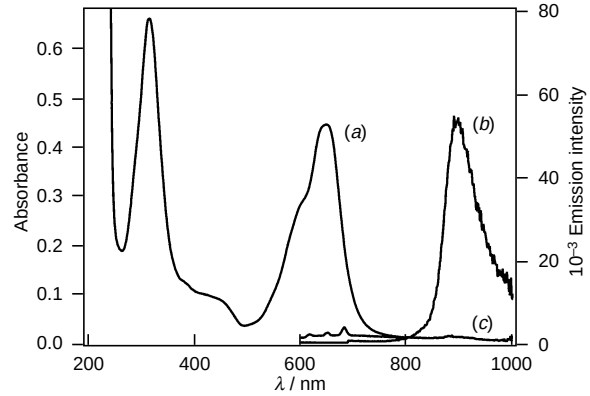

Fig. 1 Absorption (*a*) and emission (*b*) spectra of JM3306 in ethanol, concentration = 9×10^{-6} M; (*c*) quenched emission of JM3306 adsorbed onto the nanocrystalline TiO_2 film

The very efficient quenching of the emission of JM3306 was found to be due to electron injection from the excited triplet state of the phthalocyanine into the conduction band of the TiO_2. The photocurrent action spectrum is shown in Fig. 2 where the incident photon to current conversion efficiency (IPCE) is plotted as a function of wavelength. The feature is extending well into the near IR region displaying a maximum

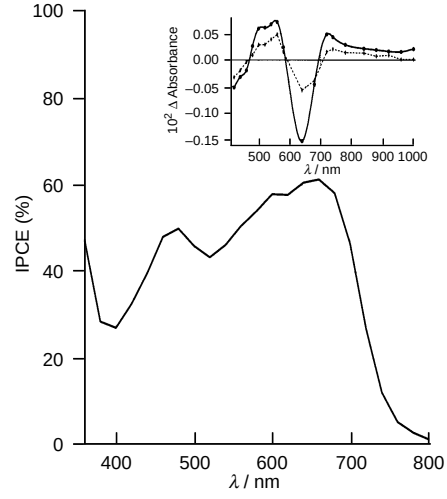

Fig. 2 Photocurrent action spectrum obtained with a nanocrystalline TiO_2 film supported onto a conducting glass sheet and derivatized with a monolayer of JM3306 and coadsorbed with Cheno. The incident photon to current conversion efficiency is plotted as a function of wavelength. A sandwich type cell configuration was used to measure this spectrum. The redox electrolyte was 0.5 M LiI–0.05 M LiI_3 in propylene carbonate solvent. Insert shows the transient spectra of JM3306 on a TiO_2 film, at time slices of 8 and 32 μs after the 532 nm (0.3 mJ) exciting pulse from a Nd-YAG laser.

around 660 nm where the IPCE exceeds 60%. Despite the fact that the pyridyl orbitals do not participate in the π–π*-excitation which is responsible for the 650 nm absorption band of JM3306, electronic coupling of its excited state to the Ti 3d conduction band manifold is strong enough through this mode of attachment to render charge injection very efficient. Bignozzi and coworkers[11] achieved very recently sensitization of TiO_2 with ruthenium polypyridyl type complexes where the coupling of the MLCT excited state to the conduction band manifold was through space and did not involve the anchoring group.

The occurrence of electron transfer was further confirmed by time resolved nanosecond laser experiments shown in the inset of Fig. 2. The end of the pulse transient spectrum indicates bleaching of the ground state absorption of JM3306 and the appearance of new features in the wavelength range 700–800 and 480–580 nm. These bands are attributed to the formation of the cation radical of the phthalocyanine.[9] The recovery of the ground state specrum due to charge recombination occurs on a time scale of several hundred microseconds indicating that recapture of the conduction band electron by the oxidized dye is a relatively slow process.

Our results establish a new pathway for grafting phthalocyanines to oxide surfaces through axially attached pyridine ligands. Using such a film in a sandwich type cell configuration[2] in conjunction with a 1 M LiI–0.05 M LiI_3 redox electrolyte photocurrents close to 10 mA cm^{-2} were readily obtained under simulated AM 1.5 solar radiation. These are by far the highest conversion efficiencies obtained with phthalocyanine type sensitizers. These findings open up new avenues for improving the near IR response of our nanocrystalline injection solar cell. In addition, important applications can be foreseen for the development of photovoltaic windows transmitting part of the visible light. Such devices would remain transparent to the eye, while absorbing enough solar photons in the near IR to render efficiencies acceptable for practical applications.

Partial financial support of this work by the Swiss Federal Institute for Energy is gratefully acknowledged.

Single-molecule magnets: out-of-phase ac susceptibility signals from tetranuclear vanadium(III) complexes with an $S = 3$ ground state

Ziming Sun,[a] Craig M. Grant,[b] Stephanie L. Castro,[b] David N. Hendrickson*[a] and George Christou*[b]†

[a] *Department of Chemistry-0358, University of California at San Diego, La Jolla, CA 92093-0358, USA*
[b] *Department of Chemistry, Indiana University, Bloomington, IN 47405-4001, USA*

The salts of the tetranuclear vanadium(III) ions $[V_4O_2(O_2CEt)_7(L–L)_2]^z$ (L–L = bpy, $z = +1$; L–L = pic$^-$, $z = -1$) with a V_4 butterfly topology and a $S = 3$ ground state have been found to exhibit out-of-phase ac susceptibility signals, a signature of single-molecule magnets.

The study of molecules possessing unusually large spin values in their ground state is an area of intense current research, particularly since the realisation in recent years that some species with this property exhibit the new phenomenon of single-molecule magnetism.[1–4] Such molecules provide a new approach to nanoscale magnets, and one with the major advantage that it provides 'magnetic particles' that are both soluble and are composed of a single, sharply defined size. As such, they hold the promise of numerous technological applications, including access to the ultimate high-density memory device.

The first single-molecule magnet (SMM) to be discovered was $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]\cdot 2MeCO_2H\cdot 4H_2O$ with $S = 10$.[1–6] The related complexes $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_x]$ (R = Et, $x = 3$;[2] R = Ph, $x = 4$[2]) with $S = 9$ or 10 also show SMM properties, as does $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$, the first ionic SMM.[2] More recently, a second class of SMM has been discovered, the family of Mn molecules of formulation $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ (X = various; dbm = anion of dibenzoylmethane) with a $[Mn_4(\mu_3\text{-}O)_3(\mu_3\text{-}X)]^{6+}$ highly distorted cubane core and an $S = 9/2$ ground state.[7] Additionally, $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ (tacn = 1,4,7-triazacyclononane) has been reported to exhibit SMM behaviour.[8] We recently reported the synthesis of $[V_4O_2(O_2CEt)_7(bpy)_2][ClO_4]$ **1** (bpy = 2,2′-bipyridine)[9] with a $[V_4O_2]^{8+}$ butterfly core and a $S = 3$

ground state, and we have now discovered that **1** and the related complex $[NEt_4][V_4O_2(O_2CEt)_7(pic)_2]$ **2** (pic = 2-picolinate) are new additions to this small family of SMMs.

Ac magnetic susceptibility studies, which monitor the response of a material's magnetic moment to an applied oscillating magnetic field, are an excellent way to detect the slow relaxation of magnetisation characteristic of a SMM. Ac susceptibility data were collected on **1** and **2** in a 1.0 G ac field oscillating at 250, 500 or 1000 Hz with a dc field of zero. In the range 10–30 K, the value of χ'_mT (χ'_m is the in-phase ac susceptibility) for **1** is constant at $\sim$4.8 cm^3 K mol^{-1} (μ_{eff} = 6.20 μ_B) consistent with an $S = 3$ ground state and $g \approx 1.8$. Below 4.0 K, χ'_mT decreases from 4.13 cm^3 K mol^{-1} at 4.0 K to 3.47 cm^3 K mol^{-1} at 1.7 K [Fig. 1(top)] suggesting that at these temperatures the magnetisation of the complex cannot reverse its direction fast enough to keep in phase with the oscillating ac field. If this is the case, an out-of-phase magnetic susceptibility (χ''_m) signal should be seen; indeed, a χ''_m signal is observed [Fig. 1(bottom)] and found to be frequency dependent. Such behaviour is characteristic of single-molecule magnets, corresponding to superparamagnet-like behaviour normally associated with large, but single-domain collections of interacting spin carriers. However, the χ''_m signal for **1** is quite weak at the lowest temperature attainable with present instrumentation, the χ''_m value at 1.7 K being only *ca.* 1–2% of the χ'_m signal. Complex **2** gives similar results but a stronger χ''_m signal of *ca.* 0.05 cm^3 K mol^{-1} at 1.7 K and a 1000 Hz ac field oscillation frequency.

As was the case for the $[Mn_{12}O_{12}]$ and $[Mn_4O_3X]$ complexes, the slow relaxation of **1** and **2** can be rationalized as due to a barrier to magnetisation reversal arising from a sufficiently large S coupled with negative magnetic anisotropy ($D < 0$, where D is the zero-field splitting (ZFS) parameter). For **1** and **2**, the potential energy plot of Fig. 2 then applies and indicates that the barrier to magnetisation reversal from, say, 'up' ($M_s = -3$) to down ($M_s = +3$) is $|9D|$. Fitting of dc magnetisation *vs.* field data (not shown) collected in the 0.500–50.0 kG and 2.00–30.0 K ranges gave $S = 3$, $g = 1.93$ and $D = -1.52$ cm^{-1} for **1**, and $S = 3$, $g = 2.00$ and $D = -1.50$ cm^{-1} for **2**. Thus, the barrier to magnetisation reversal in the ac experiments is $|9D| \approx 13.5$ cm^{-1}, a relatively small number that rationalises only a weak χ''_m signal at 1.7 K. In contrast, the $S = 10$ and $D \approx -0.5$ cm^{-1} values for certain $[Mn_{12}O_{12}]$ complexes give a barrier of $|100D| \approx 50$ cm^{-1} and χ''_m signals in the range 6–8 K under comparable conditions.[1–6]

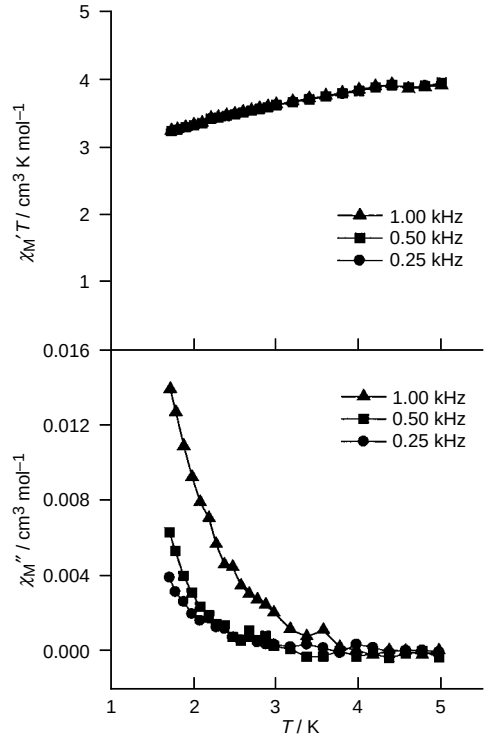

Fig. 1 Plots of χ'_mT *vs.* T (top) and χ''_m *vs.* T (bottom) for $[V_4O_2(O_2CEt)_7(bpy)_2][ClO_4]$ **1** in a 1.0 G ac field oscillating at the indicated frequencies (and with no applied dc field)

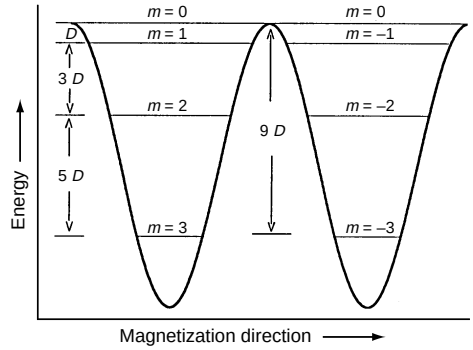

Fig. 2 Double-well potential energy *vs.* magnetisation direction diagram for an $S = 3$ system with a negative ZFS parameter D

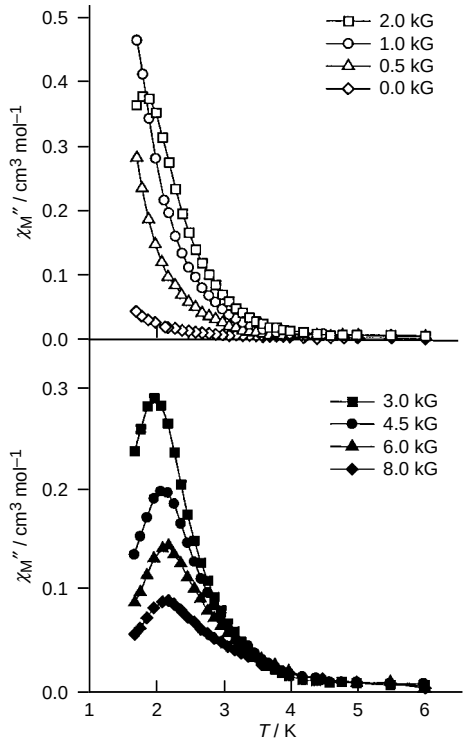

Fig. 3 Plots of χ''_m *vs.* T for $[NEt_4][V_4O_2(O_2CEt)_7(pic)_2]$ **2** in a 1.0 G ac field oscillating at 1000 Hz and applied dc fields of 0–2.0 kG (top) and 3.0–8.0 kG (bottom)

To better observe the χ''_m signals at $\geqslant$1.7 K, an external dc field was applied: this makes the double-well potential energy diagram of Fig. 2 asymmetric and slows down the relaxation rate by (*i*) increasing the barrier to (thermally activated) relaxation (originally $|9D|$), and (*ii*) making the energy levels on one side of the double-well no longer equienergetic to those on the other side, thus decreasing the rate of resonant quantum tunneling of magnetisation through the barrier. As a result, the χ''_m signal should move to higher temperatures. This is indeed observed for **1** and **2**. The data for **2** at different dc fields are shown in Fig. 3 and it can be seen that the χ''_m signal at 1.7 K increases in strength with increasing dc field, presumably as a χ''_m peak moves closer to the observable temperature range. Eventually, a peak does become visible at 1.8 K at 2.0 kG dc field, moving to 2.2 K at 8.0 kG field. The peak position represents the temperature at which the relaxation rate equals the ac field frequency.

To probe the stability of complex **1** in solution, ^{1}H NMR spectra were recorded in CD_2Cl_2. A total of 20 peaks were observed in the range δ +90 to −50 assignable to the $[V_4O_2(O_2CEt)_7(bpy)_2]^+$ cation. This is exactly the number expected for effective C_2 solution symmetry: eight bpy resonances, four CH_3 resonances in a 2:2:2:1 relative integration ratio, and eight CH_2 resonances in a 2:2:2:2:2:2:1:1 relative ratio resulting from the diastereotopic nature of the CH_2 hydrogen atoms. The resonances were fully assigned by 2D COSY and T_1 studies, together with Me-substitution on the bpy rings: full details will be provided elsewhere.[10] Similar results were obtained for **2**. The ^{1}H NMR studies thus show that these cations retain their structures on dissolution.

The combined data described above establish that the $[V_4O_2]^{8+}$ complexes are new examples of single-molecule magnets and that they retain their structural and therefore magnetic integrity in solution. The latter is noteworthy, given that, in addition to a small, sharply defined size, solubility is one of the greatest advantages of SMMs over conventional magnetic particles of nanoscale dimensions.

Reversible five-component assembly of a [2]catenane from a chiral metallomacrocycle and a dinaphtho-crown ether

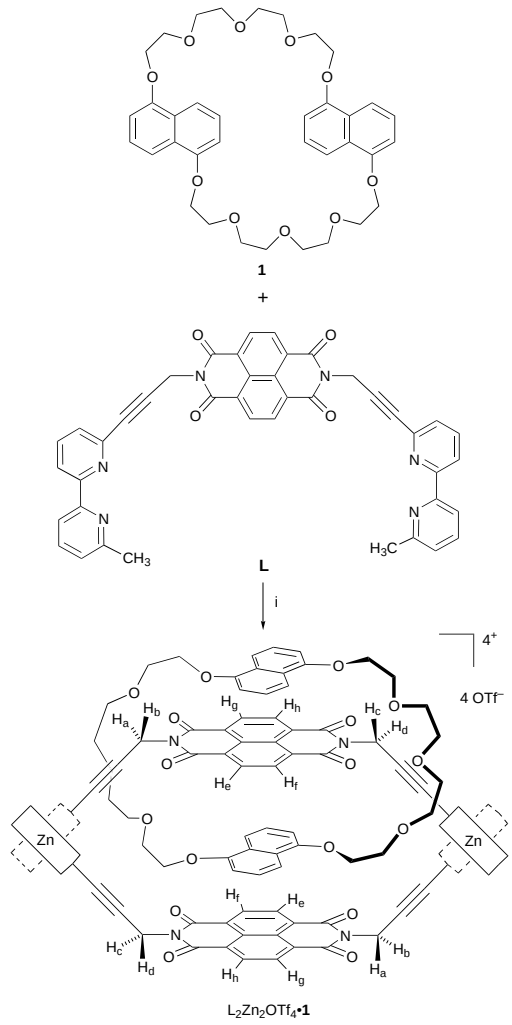
Addition of a dinaphtho-crown ether to the components of a chiral metallomacrocycle affords a [2]catenane as the exclusive thermodynamic product; the reversible assembly process is driven by a combination of zinc(II)–bipyridyl ligation and π-donor/π-acceptor interactions between the electronically complementary aromatic components.

In recent years a range of non-covalent interactions have been employed in the template directed kinetically controlled syntheses of wholly organic catenated structures, including π-association of aromatic rings,[1] metal–ligand coordination[2] and hydrogen-bonding interactions.[3–5] The application of these strategies results in mechanically interlocked ring systems, whose separation would require the cleavage of a covalent bond.[6] Catenanes incorporating an organic ring and a magnesium metallomacrocycle,[7] as well as interlocked metallomacrocyclic structures,[8,9] have also been reported: incorporation of labile metal coordination sites into the ring introduces the possibility of reversibility into the threading process, although this feature has not hitherto been fully explored.[10] We now report the use of both metal ligation and donor–acceptor interactions to achieve quantitative catenane synthesis under reversible, thermodynamically controlled conditions.

We reported the design and synthesis of ligand L which assembles exclusively into a helical [2 + 2] metallomacrocycle in the presence of zinc(II) ions and a complementary aromatic substrate.[11,12] The π-electron rich aromatic guest plays a crucial role in the assembly process, effecting the selection of its optimal metallomacrocycle host from the range of geometries and oligomers present in solutions containing only L and Zn^{II}. The driving force for the formation of the supramolecular complex is provided by the π-donor/π-acceptor stacking interactions present in the final complex. Similar programmed recognition features between π-electron deficient aromatic diimides and the π-electron rich dinaphtho-crown ether **1** have been used to prepare neutral [2]catenanes in good yield *via* irreversible acetylenic couplings.[13–15] In light of these results we have utilised the electron-deficient diimide present in L and the electron-rich diethers of crown **1** to promote the assembly of a chiral [2]catenane in a thermodynamically controlled association process.

Titration of a solution of **1** into a CD_3CN solution of $L_2Zn_2OTf_4$ (in equilibrium with other oligomers)[11,12] resulted in a change from pale yellow to purple–maroon, indicative of the formation of a π-donor/π-acceptor complex (Scheme 1). Electrospray mass spectrometry of the complex was consistent with formation of the catenane, with peaks at *m/z* 530.8 $[L_2Zn_2\cdot\mathbf{1}]^{4+}$, 757.8 $[L_2Zn_2OTf\cdot\mathbf{1}]^{3+}$ and 1210.8 $[L_2Zn_2OTf_2\cdot\mathbf{1}]^{2+}$; no peaks corresponding to the individual components were detected.

Unambiguous evidence for formation of the catenane‡ was obtained by analysis of the ^1H NMR spectra obtained on titration of **1** into a solution of L and zinc(II) triflate. The resulting spectrum exhibits a new set of sharp signals [Fig. 1(*b*)]; an identical spectrum was also obtained upon dissolution of equimolar amounts of L, zinc(II) triflate and 0.5 equiv. of **1** in CD_3CN. Two distinct environments for the 'inner' and 'outer' naphthyl protons of **1** were detected,‡ both sets of signals resonating at higher field to those of 'free' **1**, an observation consistent with slow exchange of the crown naphthyl rings on the NMR chemical shift timescale. In the methylene region of the spectrum the predominant AB system of the $L_2Zn_2OTf_4$ host [Fig. 1(*a*)] is split into two AB systems upon interlocking with **1** [Fig. 1(*b*)], consistent with the helical catenated structure§ being templated out of the equilibrating mixture of complexes. Similar distinct changes were observed in the aromatic region of the spectrum where the protons of the naphthalenediimide spacer evolved from a singlet in the equilibrating pre-complexation mixture [Fig. 1(*a*)] to four doublets in the interlocked complex [Fig. 1(*b*)]. These observations taken in isolation suggest that the two diimide units of $L_2Zn_2OTf_4\cdot\mathbf{1}$, like the crown naphthyl rings, exist in 'inner' and



Scheme 1 *Reagents and conditions*: i, $Zn(OTf)_2$, acetonitrile

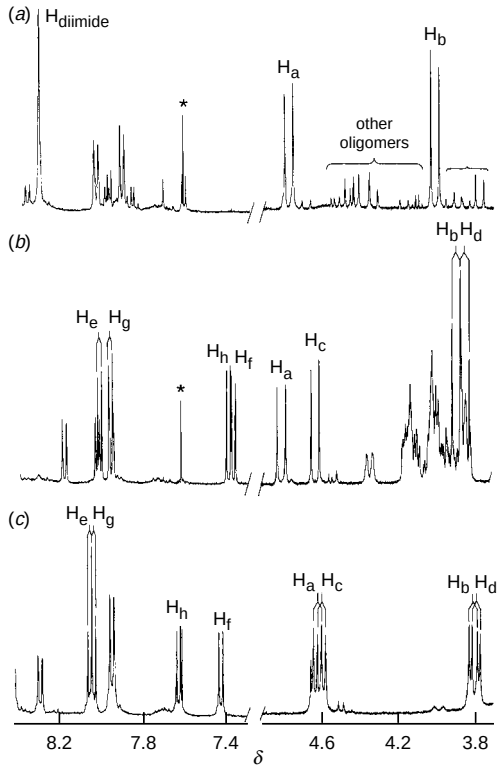


Fig. 1 ^{1}H NMR spectra (400 MHz, CD_3CN) of the methylene and aromatic regions of (*a*) $L_2Zn_2OTf_4$ (in equilibrium with oligomers) at 300 K, (*b*) $L_2Zn_2OTf_4$·**1** at 300 K and (*c*) $L_2Zn_2OTf_4$·**2** at 235 K; * impurity

'outer' environments (with respect to **1**). However, the appearance of similar splitting patterns in the complex formed between $L_2Zn_2OTf_4$ host and 1,5-dimethoxynaphthalene **2** at 235 K [Fig. 1(*c*)] indicates that the two diimide units of $L_2Zn_2OTf_4$·**1** are in the same environment (assigned as shown in Scheme 1).¶‖ This observation is consistent with an exchange process in which the 'outer' naphthyl ring of **1** is able to sweep around the periphery of $L_2Zn_2OTf_4$, rendering the two diimide components equivalent. This behaviour parallels that displayed by our recently reported neutral [2]catenanes.[13,14]

The catenane is remarkably stable: up to 350 K the maroon colour of the interlocked complex is retained and no signal coalescence is observed in the NMR spectrum. For comparison, the analogous complex formed with **2** contained exchange broadened resonances at room temperature; these coalesce on heating to 350 K to give two methylene doublets and a broad signal for the diimide protons, while at 235 K sharp, slowly-exchanging multiple resonances are observed [Fig. 1(*c*)]. Although the exact orientation of the bound naphthyl rings between the two aromatic diimide spacers is unknown, the optimal stacking of **1**, and also **2** (at 235 K), with $L_2Zn_2OTf_4$ results in overall asymmetry in this system.

We have shown that a stable [2]catenane can be non-covalently assembled from five components using pre-programmed recognition sites. The lability of the zinc(II)–bipyridyl coordination complex is an important feature of this system as it facilitates opening of the [2 + 2] metallomacrocycle to allow the thermodynamically favourable interlocking process in the presence of the crown. The access to a range of coordination geometries for zinc(II) is probably also important in optimising the electrostatic interactions between the π-complementary components. The principles embodied in the reversible nature of this assembly process should facilitate template-directed syntheses of more complex organic and supramolecular structures that would otherwise be difficult to obtain, and dynamic combinatorial libraries of mechanically interlocked structures.[16]

$Rb_2Au_6Sb_4S_{10}$: a novel sulfosalt with two different interpenetrating anionic frameworks: $[Au_3Sb_4S_8]^-$ and $[Au_3S_2]^-$

Jason A. Hanko and Mercouri G. Kanatzidis*†

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824, USA

The layered compound $Rb_2Au_6Sb_4S_{10}$ consisting of two interpenetrating $[Au_3Sb_4S_8]^-$ and $[Au_3S_2]^-$ frameworks was prepared from the reaction of Au with a polythioantimonate flux.

Polychalcoantimonate fluxes can be used for the synthesis of new ternary and quaternary thioantimonate and selenoantimonate compounds.[1–4] This method is complementary to conventional direct combination of the binary sulfides[5] or hydro(solvento)thermal synthesis.[6] The polychalcoantimonate fluxes are formed by the *in situ* fusion of $A_2Q/Sb/Q$ and contain $[Sb_xQ_y]^{n-}$ ligands (A = Na, K, Rb, Cs; Q = S, Se) as well as polychalcogenide ligands. The key feature of this method is that the polychalcoantimonate units form and coordinate to metal ions to build up extended lattices. Examples include A_2AgSbS_4 (A = K, Rb, Cs),[3,4] $Cs_3Ag_2Sb_3Q_8$ (Q = S, Se),[3,4] $KThSb_2Se_6$,[2] A_2AuSbS_4 (A = Rb, Cs)[3b] and $KHgSbS_3$.[7] Continuing our investigations of the coinage metals, particularly Au, we report here, the synthesis, structural characterization, and physical properties of a novel quaternary gold thioantimonate compound, $Rb_2Au_6Sb_4S_{10}$.‡ The novelty in this two-dimensional compound derives from the fact that its layers are comprised of two different and independent interwoven frameworks. The only other structurally characterized example of two interpenetrating frameworks is K_2PdSe_{10}.[8]

The strikingly complex structure of $Rb_2Au_6Sb_4S_{10}$§ is composed of two different interpenetrating layered frameworks, $[Au_3Sb_4S_8]^-$ and $[Au_3S_2]^-$, Fig. 1. As a result, $Rb_2[Au_3Sb_4S_8][Au_3S_2]$ is a more descriptive formula, and to the best of our knowledge, represents the first reported example of a compound in which a binary framework is interpenetrating with a ternary one. The $[Au_3Sb_4S_8]^-$ layer is strongly undulating and consists of infinite $[Sb_4S_7]^{2-}$ one-dimensional chains bound to $[Au_3S]^+$ units. The $[Sb_4S_7]^{2-}$ chain [Fig. 2(*a*)] is comprised of four condensed SbS_3 pyramids forming a twelve membered Sb–S ring. Two of the SbS_3 units share two corners leaving one terminal sulfide while the other two SbS_3 units share all three corners. The dimensions of the ring are 6.49(3) Å [Sb(4)–Sb(2)] by 7.83(3) Å [Sb(1)–Sb(3)]. The chains alternate above and below the layer in a staggered fashion [Fig. 2(*b*)]. The Sb atoms are in pyramidal coordination with Sb–S distances in the range from 2.21(6) to 2.65(6) Å [mean 2.46(3) Å] and compare well with those reported for $Cs_2Sb_4S_8$[1] and $Cs_3Ag_2Sb_3S_8$.[3,4] The discrete $[Au_3S]^+$ unit has a pyramidal sulfide linked to three linear Au^+ cations. The Au–S distances range from 2.28(4) to 2.46(5) Å and compare well with those found in $CsAu_3S_2$,[9a] AAuS[9b] (A = Na, K, Rb, Cs), $KAuS_5$[10] and $AAuSbS_4$[3] (A = Rb, Cs). The S–Au–S angles range from 170 to 174°.

The second framework, which is interwoven with the one described above is a $[Au_3S_2]^-$ layer. The $[Au_3S_2]^-$ layer is puckered with twelve-membered Au–S rings in an *anti*-B_2O_3 motif {ring dimensions: 6.91(2) Å [Au(4)···Au(4)] by 7.19(3) Å [Au(3)···Au(3)]}. Fig. 3(*a*) highlights the pyramidal sulfide and the puckered nature of the layer and Fig. 3(*b*) shows a perpendicular view. The Au–S distances are in the range from 2.25(4) to 2.46(5) Å and the S–Au–S angles range from 165 to 178°. The $[Au_3S_2]^-$ layered structure is similar but not identical to that observed in $CsAu_3S_2$.[9a]

Upon further inspection, it was observed that the Au^+ centers in $Rb_2Au_6Sb_4S_{10}$ aggregate to form a column that runs along the *c*-axis. There are two types of Au···Au interactions: those at ≤3.25 Å and those between 3.25 and 3.6 Å. Fig. 3(*c*) shows a view perpendicular to these Au-based columns. In Fig. 3(*c*) the interactions ≤3.25 Å are represented as solid lines while the Au···Au interactions between 3.25 and 3.60 Å are represented as dashed lines. The layers are separated by ten-coordinate $Rb(1)^+$ [Rb(1)–S (mean) 3.59(3) Å] and eight-coordinate Rb(2) [$Rb(2)^+$ [Rb(2)–S (mean) 3.50(3) Å].

The optical spectrum of $Rb_2Au_6Sb_4S_{10}$ reveals the presence of a sharp optical gap of 1.37 eV, suggesting the material is a semiconductor.

The far-IR spectrum¶ of $Rb_2Au_6Sb_4S_{10}$ displays absorptions at *ca*. 377 and 350 cm^{-1} which can be tentatively assigned to Sb–S stretching modes in the 'Sb_2S_4'-like backbone of the $[Au_3Sb_4S_8]^-$ framework.[1,3] Absorptions in the range 381–347 cm^{-1} are tentatively assigned to the Sb–S vibrational stretching modes by analogy with the $Cs_2Sb_4S_8$[1] and $Cs_3Ag_2Sb_3S_8$.[3] Absorptions below 347 cm^{-1} are assigned to Au–S vibrations as compared to Rb_2AuSbS_4.[3] By comparison with $KAuS_5$ the absorption at *ca*. 323 cm^{-1} is assigned as an Au–S stretching vibration.[10] The Raman spectrum¶ of $Rb_2Au_6Sb_4S_{10}$ displays absorptions in the range 377–350 cm^{-1} which are assigned to

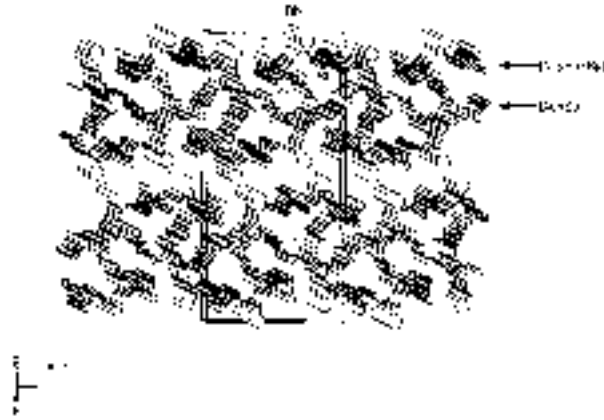

Fig. 1 Structure of $Rb_2Au_6Sb_4S_{10}$ viewed down the *c*-axis. Selected distances (Å) and angles (°) with esds in parentheses: Au(1)–S(3) 2.32(1), Sb(1)–S(6) 2.43(2), Au(1)–S(5) 2.30(1), Sb(1)–S(8) 2.47(1) (×2), Au(2)–S(2) 2.28(2), Sb(2)–S(5) 2.54(2), Au(2)–S(4) 2.30(2), Sb(2)–S(1) 2.48(1) (×2), Au(3)–S(3) 2.32(1), Sb(3)–S(6) 2.58(2), Au(3)–S(7) 2.31(1), Sb(3)–S(1) 2.48(1) (×2), Au(4)–S(3) 2.29(2), Sb(4)–S(4) 2.40(2), Au(4)–S(7) 2.30(2), Sb(4)–S(8) 2.47(1) (×2), Au(1)–Au(3) 3.192(3), Au(1)–Sb(1) 3.393(5), Au(1)–Au(4) 3.060(4), Au(1)–Sb(3) 3.233(5), Au(2)–Au(4) 3.593(1), Au(2)–Sb(2) 3.091(6), Au(1)–Au(1′) 3.588(4), Au(2)–Au(3) 3.389(4), Au(3)–Au(3′) 3.461(5), Au(3)–Au(4) 3.558(3); S(2)–Au(1)–S(5) 170.9(7), S(1)–Sb(3)–S(1′) 89.4(7), S(2)–Au(2)–S(4) 173.9(8), S(1)–Sb(3)–S(6) 95.6(5), S(3)–Au(3)–S(7) 178.4(7), S(1′)–Sb(3)–S(6) 95.6(5), S(3)–Au(4)–S(7) 170.0(8).

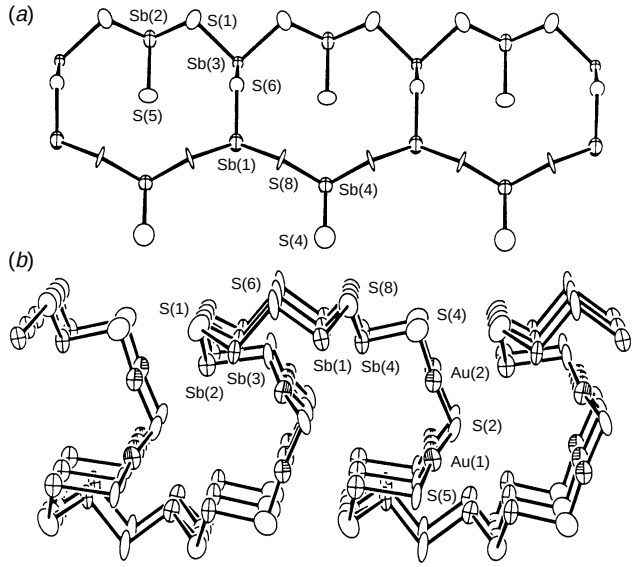

Fig. 2 (*a*) ORTEP view of the $[Sb_4S_7]^{2-}$ chain with labelling; (*b*) ORTEP view of the complete $[Au_3Sb_4S_8]^-$ framework with labelling

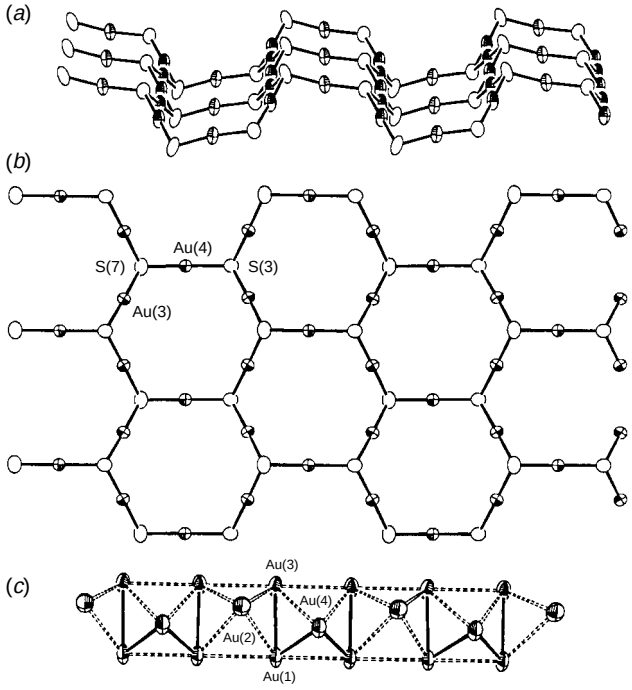

Fig. 3 (*a*) ORTEP view of the $[Au_3S_2]^-$ layer highlighting the pyramidal sulfides in the undulating layer; (*b*) perpendicular view of the $[Au_3S_2]^-$ layer with labelling; (*c*) Au···Au interactions of the Au column

Sb–S modes and the absorptions below 350 cm^{-1} are assigned to Au–S stretching vibrations.

DTA data, followed by careful XRD analysis of the residues, show that $Rb_2Au_6Sb_4S_{10}$ melts incongruently at *ca*. 442 °C. Examination of the residue by powder XRD revealed that the compound decomposes to an amorphous material and Au metal.

In conclusion, $Rb_2Au_6Sb_4S_{10}$ represents the first example of a sulfosalt with two different interpenetrating anionic frameworks. Although one of the frameworks $[Au_3S_2]^-$ can exist by itself, efforts to isolate the second framework alone are in progress.

‡ $Rb_2Au_6Sb_4S_{10}$ was synthesized from a mixture of Rb_2S (0.102 g, 0.5 mmol), Au (0.098 g, 0.5 mmol), Sb (0.031 g, 0.25 mmol) and S (0.064 g, 2 mmol) sealed under vacuum in a Pyrex tube and heated to 350 °C for 4 days followed by cooling to 150 °C at 4 °C h^{-1}. The excess $Rb_x[Sb_yS_z]$ flux was removed by washing with DMF to reveal analytically pure black needles in low yield (20% yield based on Sb). The crystals are air- and water-stable. Microprobe analysis carried out on several randomly selected crystals gave an average composition of $RbAu_{4.6}Sb_{2.7}S_9$. This technique tends to underestimate the amount of Rb.

§ *Crystallography*: A Siemens SMART Platform CCD diffractometer equipped with Mo-Kα was used for a crystal of 0.400 × 0.010 × 0.005 mm. An empirical radiation (λ = 0.710 73 Å) absorption correction was applied to the data during data processing. *Crystal data* at −120 °C: a = 12.4402(2), b = 26.0790(4), c = 6.9614(1) Å, U = 2258.3(7) $Å^3$, Z = 4, D_c = 4.043 g cm^{-3}, space group *Pnnm* (no. 63), μ = 48.83 cm^{-1}, index ranges $-14 \leqslant h \leqslant 14$, $-31 \leqslant k \leqslant 28$, $-8 \leqslant l \leqslant 8$; total data 15609; unique data 2340 (R_{int} = 0.146), data with $F_o^2 > 3\sigma(F_o^2)$ 1181; no. of variables, 124; final R, R_w = 0.080, 0.096; GOF 2.66; max. peak in difference electron density map = 7.97 e^- $Å^{-3}$. The structure was solved with SHELXS-86 and refined with the TEXSAN Structure Analysis Package (Molecular Structure Corporation, 1985) of crystallographic programs. CCDC 182/760.

Inclusion processes based on molecular recognition processes may be used as a design principle for the generation of molecular networks in the solid state. Hollow tuneable molecular modules (koilands) based on fusion of pre-organised cavities were shown to be assembled in the solid state into one-dimensional molecular arrays (koilates) either by self-inclusion or by interconnection using connector molecules. The formation of the molecular networks in the crystalline phase was established by X-ray studies.

Introduction

Molecular solids are defined by the chemical nature of their molecular components and by their interactions with respect to each other in the crystalline phase. With our present level of knowledge, the complete understanding and therefore prediction of all intermolecular interactions in the crystalline phase seems unreachable. Therefore, it appears that crystal structures are not predictable.[1] However, following the statement by Jack Dunitz:[2] 'A crystal is, in a sense, the supramolecule *par excellence*', using appropriate molecular modules, one may predict some of the intermotive interactions. Molecular networks are defined as supramolecular structures, theoretically composed of infinite number of molecules, possessing translational symmetry.[3] Whereas molecules are described as assemblies of atoms interconnected by covalent bonds, by analogy, one may describe molecular networks as hypermolecules in which the connectivity between the elementary components (molecular modules) is ensured by non-covalent intermotive interactions.

The construction of large molecular networks (10^{-6}–10^{-3} m scale) with predicted and programmed structure may hardly be envisaged through step by step type strategy. However, the preparation of such higher-order materials may be reached through iterative self-assembling processes engaging individual modules. This strategy relies on a double analysis. One is at the molecular level, dealing with the individual modules composing the solid, and the other is at the supramolecular level, dealing with the intermotive or intermolecular interactions.[4,5] Obviously the latter type of analysis is more subtle. For the design and synthesis of molecular networks, the approach called molecular tectonics,[6] which is based on the self-assembly[7] of structurally defined and energetically programmed complementary tectons[8] (from Greek *tekton*: builder), seems to be the most viable one. The synthesis of solids based on iterative assembling of individual complementary tectons still remains a challenge. A strict control of the self-assembly of molecular modules in the solid state should lead to structurally strictly controlled molecular networks (one-, two- and three-dimensional solids).

Dealing with design, whereas an endo molecular receptor forms discrete molecular complexes with a selected exo-substrate, an exo-receptor may form either discrete species with substrates acting as stoppers or molecular networks in the presence of appropriate connectors (Fig. 1). Thus, in order to achieve an iterative assembling process, the building blocks or tectons must fulfil both structural and energy criteria. In particular, the complementary tectons must recognise each other (molecular recognition) and furthermore should allow the repetition of the recognition patterns which may be designed as assembling cores. These two requirements lead to molecular modules possessing connecting points or interaction sites located in a divergent fashion. We have previously reported exo-ligands based on mercaptocalix[4]arenes,[9a] calix-[4]arene,[9b] tetraarylporphyrin[9c] bearing bidentate catechol units and macrocyclic frameworks containing bipyridine units.[9d]

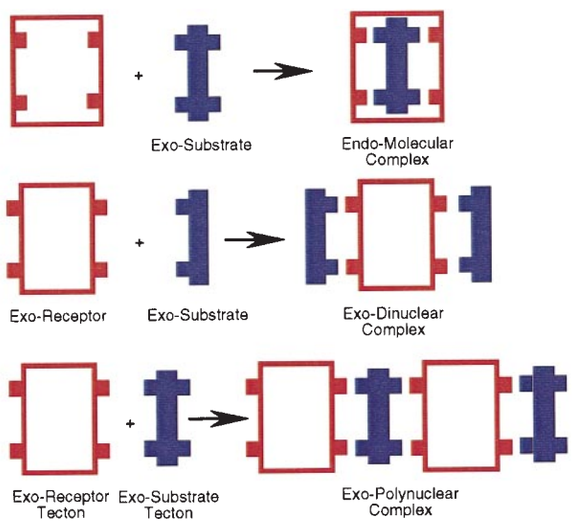

Fig. 1 Schematic representation of the formation of discrete molecular complexes by an endo-receptor and a substrate (top), by an exo-receptor and two stoppers (middle) or of a linear molecular network by an exo-receptor and a connector (bottom)

Thus, the most important operational concepts in molecular tectonics are molecular recognition between tectons and geometrical features, encoded within their frameworks, allowing the iteration of the recognition processes. Molecular networks may be obtained by an iterative assembling process of either self-complementary, or of several complementary tectons.

In terms of interaction energy between molecular modules governing the recognition and assembling processes, hydrogen[10] and coordination[11] bonds have been almost exclusively used for the formation of molecular networks. However, some time ago, we proposed the use of rather weak van der Waals interactions responsible for the inclusion processes between concave and convex molecules.[12,13] Although, based on the above mentioned approach, molecular networks were obtained using all three types of interactions, *i.e.* hydrogen bond,[14] coordination bond[15] and van der Waals interactions[12,13] the present article shall be mainly devoted to molecular networks based on inclusion phenomena in the solid state.

Design of koilands

The chemistry of inclusion complexes based on concave and convex molecules, *i.e.* the inclusion of a substrate within the cavity of a receptor molecule, is an established area. One may extend the concept of inclusion in solution to the construction of new networks in the solid state. Koilands[12,13] (from Greek *koilos*: hollow) were defined as multicavity receptor molecules composed of at least two cavities arranged in a divergent fashion. Since each individual cavity offers the possibility of forming inclusion complexes with a convex molecules, fusing, in a rigid framework, two or more of such cavities may lead in the presence of an appropriate connector to a non-covalently assembled polymeric species which may be called a koilate. For example, linear koilates (one dimensional linear molecular arrays or α-networks) may be assembled in the solid state using non-covalent van der Waals interactions between a rigid and compact direceptor possessing two divergent cavities with an angle of 180° between them (linear koiland) and a linear connector, possessing two extremities each capable of being included within the cavities of the direceptor (Fig. 2).

For the design of koilands, calix[4]arene derivatives[16] appeared to be candidates of choice (Fig. 3). Indeed, these compounds offer a preorganised and tuneable hydrophobic pocket surrounded by four aryl moieties as well as four hydroxy groups for further functionalisation. Furthermore, both the entrance and the depth of the preorganised cavity of calixarenes may be controlled by the nature of the substituent R at the *para* position (Fig. 4), *i.e.* Bu^t (**1**), H (**2**), Me (**3**), Ph (**4**). Whereas for the parent compounds **1**, **2** and **4** the cone conformation was established in the solid state by X-ray studies, to our knowledge, for compound **3** no X-ray data are available so far. The basket-type cavity of calix[4]arene derivatives such as **1** resulting from the cone conformation has been shown to accommodate in the solid state a variety of neutral guests.[17]

The design of koilands was based on the fusion of two calix[4]arenes derivatives in the cone conformation by two silicon atoms (Fig. 4).[12] Examples of fused calix[4]arenes using titanium(IV), niobium(V), aluminium(IV) and more recently zinc have been reported.[18] Two calix[4]arenes have also been interconnected by organic[19] and organometallic bridges.[20]

Tuning the cavity

The general strategy for the synthesis of koilands was based on treatment of the calix derivatives by NaH in dry THF followed by addition of $SiCl_4$. The desired compounds were usually obtained after chromatography on silica or by crystallisation. The starting material for the synthesis of all koilands reported was the *p-tert*-butylcalix[4]arene **1** prepared according to the published procedure.[21] The calix[4]arene **2** was obtained by aluminium chloride de-*tert*-butylation of **1**.[22] The latter was the common starting material for the synthesis of both *p*-methylcalix[4]arene **3** and *p*-phenylcalix[4]arene **4**. Although the syntheses of **3**[23] and **4**[24] were first reported by Gutsche *et al.*, the procedures by Ungaro and coworkers[25] and by Atwood and coworkers[26] respectively were found to be more convenient. The koilands **9**[27] (42%), **12**[12] (60%) and **14**[27] (17%) based on the double fusion of two *p*-methylcalix[4]arenes **3**, *p-tert*-butylcalix[4]arene **1** and *p*-phenylcalix[4]arenes **4**, respectively

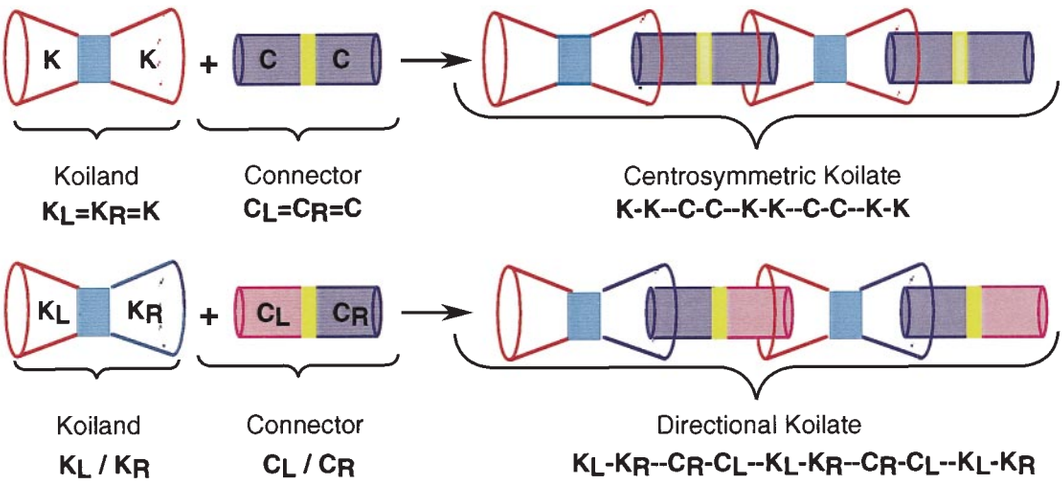

Fig. 2 Schematic representation of the formation of centrosymmetric (top) and directional (bottom) koilates (linear molecular network) by centrosymmetric (top) or non-centrosymmetric (bottom) linear koilands and connectors

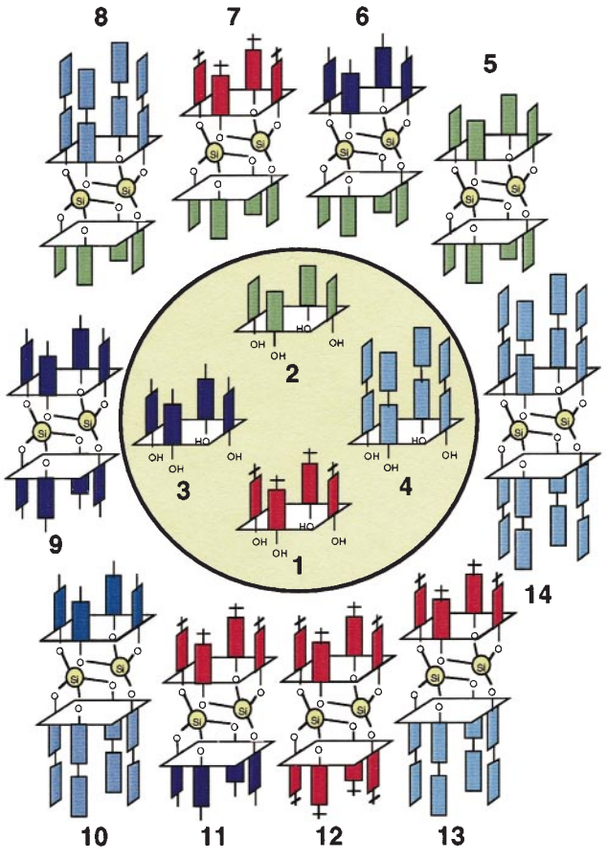

Fig. 4 Schematic representation of parent calix[4]arene derivatives **1**–**4** used as preorganised cavities and of centro-symmetric (**5**, **9**, **12**, **14**) and non-centrosymmetric (**6**–**8**, **10**, **11**, **13**) koilands formed by fusion of two calix units by two silicon atoms

with two silicon atoms were obtained as colourless stable crystalline solids.

The solid state structures of **9**[27] and **12**[12] were confirmed by X-ray studies which revealed that both compounds were indeed centrosymmetric aryloxy dimers consisting of two Si and two calixarenes. Both calixarene units were in cone conformation, thus presenting two divergent cavities (Fig. 5).

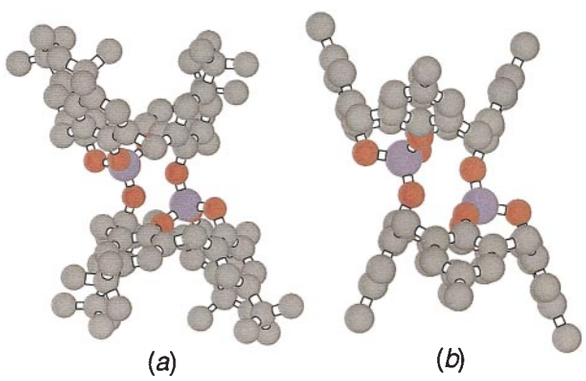

Fig. 5 X-Ray structures of linear koilands **9** (*a*) and **12** (*b*) showing the interconnection of two cavities in a linear fashion. For the sake of clarity, solvent molecules and hydrogen atoms are not presented.

Formation of discrete binuclear inclusion complexes

In order to ascertain the possibility of double inclusion, discrete binuclear complexes composed of koiland **12** and $CHCl_3$,[12] anisol[28] and *p*-xylene[28] were prepared (Fig. 6). The crystal study showed that in all three cases, each cavity accommodates,

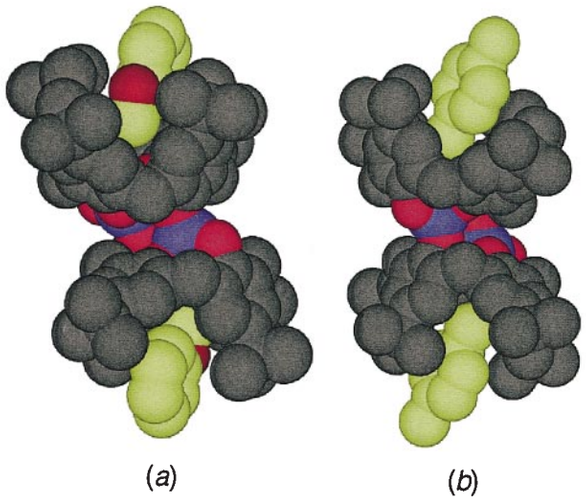

Fig. 6 X-Ray structures of discrete binuclear inclusion complexes formed by the linear koiland **12** and anisol (*a*) and *p*-xylene (*b*). For the sake of clarity, the carbon atoms of the substrate are coloured in green and the hydrogen atoms are not presented.

in a inclusive fashion, a solvent molecule. For the anisol co-crystals, amongst the four anisol molecules present in the lattice, only two of them, one at each side, were deeply inserted through their Me groups into the cavities of the hollow module [Fig. 6(*a*)]. In the case of *p*-xylene, although a sandwich complex composed of the parent compound **1** and the solvent with a 1 : 1 ratio was reported in the solid state,[29] with the koiland **12**, again a discrete binuclear inclusion complex in the solid state was obtained [Fig. 6(*b*)]. Again, amongst the three *p*-xylene molecules present, two of them penetrate deeply into the cavities of **12** through one of their Me groups. Whereas the formation of discrete binuclear complexes with $CHCl_3$ and anisol may be explained by their restricted dimension and unfavourable geometry, in the case of *p*-xylene possessing the right topology, one could, *a priori*, expect the formation of a koilate. However, it appeared from the X-ray study that the distance between the two Me groups ($d_{C–C}$ = 5.83 Å) was too short to allow the interconnection of two consecutive units and thus the formation of the koilate.

Formation of koilates

Hexadiyne, a rod type molecule, possessing both the requested linear geometry and distance between its two terminal Me groups ($d_{C–C}$ = 6.65 Å) leads indeed to the formation of the desired koilate (Fig. 7). The latter crystallises out from either

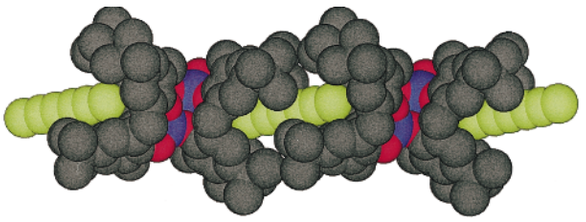

Fig. 7 A portion of the X-ray structure of the koilate formed between the koiland **12** and hexadiyne as the connector. The one-dimensional network is obtained by a single translation of the assembling core defined by the inclusion of the connector into the cavity of the receptor. For the sake of clarity, the carbon atoms of the connector are coloured in green and the hydrogen atoms are not presented.

$CHCl_3$–MeOH or $CHCl_3$–hexane mixtures of koiland **12** and hexadiyne in large excess.[28] The X-ray analysis revealed that in the crystal, in addition to **12** and hexadiyne present in 1 : 1 ratio, two $CHCl_3$ molecules were also present. The lattice is indeed composed of molecular linear arrays of koilates formed between

koilands **12** and hexadiyne as connectors. Each connector bridges two consecutive hollow bricks by penetrating their cavities through its terminal Me groups. The methyl groups of hexadiyne are deeply inserted into the cavity of the koiland. Indeed, the shortest distance between the Me group of the connector and the aromatic carbon atom (CO) of the koiland is 3.64 Å. It is worth noting that the hexadiyne molecules are extremely well encapsulated by two consecutive koilands **12** forming a sandwich, the shortest distance between the Me groups of the *tert*-butyl moieties of **12** being 3.51 Å.

Functionalisation of koilands

Calix[4]arene, in addition to the features stated above, presents further advantages by being readily modified at the *para* position by a large variety of substituents bearing functionalities. In particular, one may introduce at the *para* position functional groups such as allyl moieties.[30] It has been shown previously that although the compound **15** shows temperature-dependent conformational mobility, below room temperature it adopts a cone conformation.[30] The design of the new koiland **16** [Fig. 8(*a*)] possessing functional groups at both faces of the

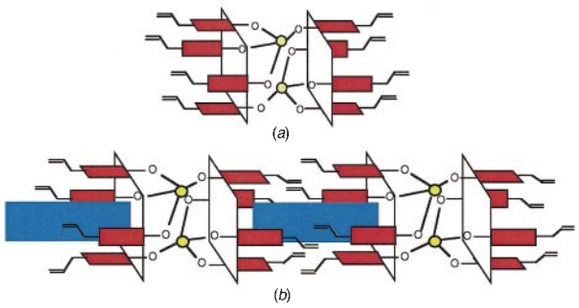

Fig. 8 Schematic representations of the doubly fused tetraallylcalix[4]arene **16** (*a*) and of the linear koilate formed in the presence of connector molecules (*b*)

molecule was based on the double fusion of the parent compound **15** with two silicon atoms.[31] Compound **15** was prepared according to published procedures[30] starting from compound **1**[21] which was dealkylated leading thus to the compound **2** and the latter was first converted into the allyl ether and then, by a Claisen rearrangement, to the desired compound **15**. The doubly fused compound **16** was obtained after column chromatography in 53% yield upon treatment of compound **15** in dry THF by NaH followed by addition of $SiCl_4$.[31]

Since it has been previously observed that *p*-xylene, a rigid, compact and ditopic molecule, forms in the solid mononuclear and binuclear inclusion complexes with *p-tert*-butylcalix[4]arene[17,29] **1** and with the koiland **12**[28] respectively, the formation of a one-dimensional network using compound **16** as the koiland and *p*-xylene as the connector was investigated [Fig. 8(*b*)]. Suitable crystals were obtained from a mixture of compound **16** and *p*-xylene in excess and Pr^iOH at room temperature. The X-ray analysis[31] showed the following features (Fig. 9). The crystals were composed exclusively of **16** and *p*-xylene disposed in an alternate fashion. Both the connector and the koiland were centrosymmetric, the latter offering two divergent cavities. The coordination geometry around the silicon atoms was tetrahedral. As predicted, a linear koilate was formed through the interconnection of two cavities belonging to consecutive koilands **16** with the *p*-xylene molecule. In the crystal one could identify an assembling core which could be defined as the inclusion of a Me group of the connector within a cavity of **16**. The shortest C–C distance of 3.63 Å between the Me groups of the connector and one of the carbon atoms belonging to one of the phenolic group at the bottom of the cavity indicated a high degree of inclusion. The formation of the α-network resulted from a single translation of the assembling core.

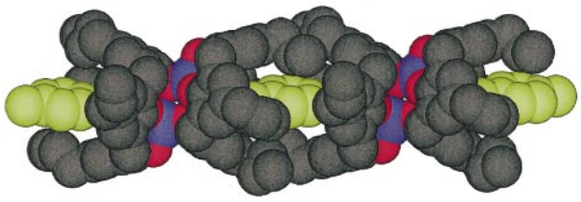

Fig. 9 A portion of the X-ray structure of the koilate formed between the koiland **16** and *p*-xylene as the connector. The one-dimensional network is obtained by a single translation of the assembling core defined by the inclusion of the connector into the cavity of the receptor. For the sake of clarity, the carbon atoms of the connector are coloured in green and the hydrogen atoms are not presented.

Although the formation of the α-network was predicted, the X-ray analysis revealed another unexpected feature. Due to the large number of rotations available for the allyl moieties, one cannot in fact predict their conformations in the crystal lattice. Interestingly, when looking at lateral packing of consecutive linear koilates, it was observed that among the eight allyl groups present in each koiland **16**, two of them were oriented centrosymmetrically in a peculiar manner (Fig. 10). Indeed, two

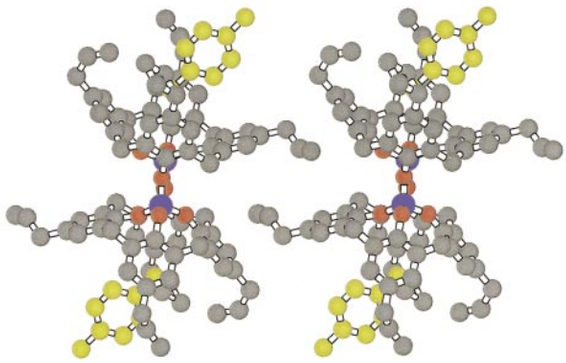

Fig. 10 A portion of the X-ray structure of the koilate formed between the koiland **16** and *p*-xylene as the connector showing the lateral packing of linear koilates leading to parallel disposition of the allyl moieties

alkene moieties belonging to two consecutive koilands were located perfectly parallel to each other with a alkene-to-alkene distance of 4.52 Å between them. Although the observed distance seems slightly too long, the proximity of the two double bonds suggests the possibility to interconnect covalently the koilates by performing a [2 + 2] cycloaddition reaction in the solid state.

It is interesting to notice that although, using compound **12** and hexadiyne, the first fully characterised linear koilate was obtained in the solid state,[28] one could nevertheless argue that, owing to the presence of $CHCl_3$ molecules in the lattice, the formation of the koilate was governed by solvent molecules. The formation of the koilate with compound **16** and *p*-xylene precludes this objection since in that case the linear koilate was formed in the solid without the presence of any solvent molecules in the lattice.

Formation of koilates by self-inclusion

As demonstrated above, koilands may lead in the solid state either to discrete molecular complexes in the presence of molecules acting as stoppers [Fig. 11(*a*)] or to linear molecular networks in the presence of appropriate connectors [Fig. 11(*b*)]. Another alternative route to the formation of linear koilate may be based on the use of self-complementary koilands possessing simultaneously two divergent cavities and connecting moieties [Fig. 11(*c*)]. Compound **16** fulfils these requirements. Indeed, the latter possesses two preorganised cavities resulting from the fusion of two calix units in cone conformation, as well as allyl groups at both faces of the molecule which may act as connectors.[32]

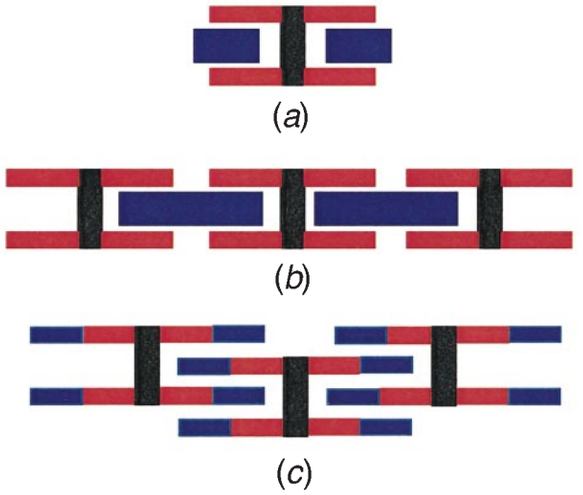

Fig. 11 Schematic representation of discrete binuclear inclusion complexes formed between koilands and stopper molecules (*a*) or of infinite linear molecular networks formed by koilands in the presence (*b*) and absence (*c*) of connector molecules

A study based on X-ray diffraction on single crystals obtained under various conditions for the compound **16** revealed indeed the formation of an α-network in the solid state. Upon slow liquid–liquid diffusion at room temperature of EtOH into a $CHCl_3$ solution of compound **16**, suitable large, colourless, air stable at room temperature, mono-crystals of the same morphology (rhombic) were obtained. The X-ray analysis revealed that the crystal was exclusively composed of compound **16**. The latter, offering two divergent cavities, was centrosymmetric. As in the case of other koilands presented above, the coordination geometry around the silicon atoms was tetrahedral. In the crystalline phase, the self-complementary koiland **16** formed a linear koilate (Fig. 12) through the

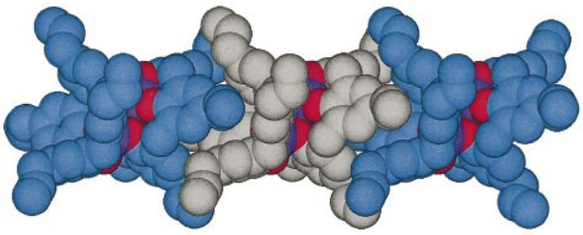

Fig. 12 A portion of the X-ray structure of the koilate formed by self-inclusion of the koiland **16**. The one-dimensional network is obtained by a single translation of the assembling core defined by the inclusion of the allyl moieties acting as internal connector into the cavity of the consecutive koiland **16**. For the sake of clarity, the carbon atoms of the consecutive koilands are differentiated by colour and the hydrogen atoms are not presented.

interconnection of two cavities belonging to consecutive koilands **16** by van der Waals interactions. The assembling core leading by a single translation to the α-network, could be identified as the inclusion of one of the four allyl groups located at one of the two faces of the molecule **16** by one of the two cavities of the consecutive self-complementary compound **16**. The shortest C–C distance between the terminal CH_2 of the allyl group acting as connector and carbon atoms of one of the aromatic moieties of the cavity belonging to the next unit varied from 3.63 to 3.92 Å, including a rather high degree of inclusion. Interestingly, when crystals of compound **16** were grown from other solvent systems such as toluene–EtOH, $CHCl_3$–Pr^iOH and toluene–Pr^iOH, in all cases, crystals of the same morphology and stability were obtained and their investigation by X-ray (lattice parameters) confirmed that they were the same. However, when crystals of **16** were grown by the same technique from a CH_2Cl_2–EtOH mixture, two types of crystals, one with a rod-type morphology and the other with rhombic shape, were observed. Whereas the crystals with rhombic morphology were stable at room temperature and proved by X-ray analysis to be of the same type as those mentioned above, the rod-shape crystals were unstable outside the solution. Their analysis by X-ray diffraction revealed the presence of **16** and three molecules of CH_2Cl_2. In the lattice two types of discrete inclusion complexes were present and therefore no network based on inclusion processes could be identified (Fig. 13). The

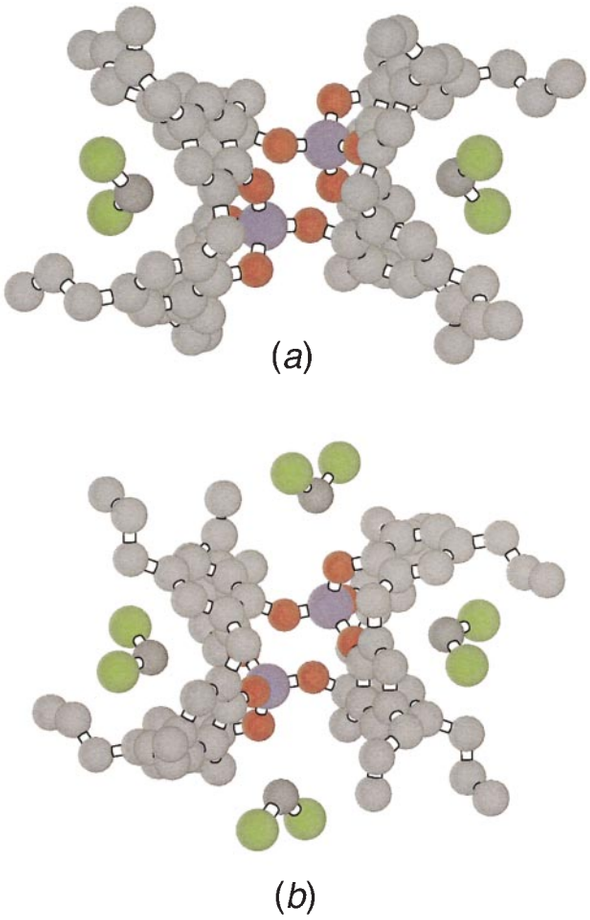

Fig. 13 X-Ray structures of the discrete bi- (*a*) and tetra-nuclear (*b*) inclusion complexes formed by the linear koiland **16** and CH_2Cl_2. For the sake of clarity, the hydrogen atoms are not presented.

two types of units were a binuclear [Fig. 13(*a*)] and a tetranuclear [Fig. 13(*b*)] CH_2Cl_2 inclusion complex. For the binuclear complex, both cavities of compound **16** were occupied by a CH_2Cl_2 molecule. For the tetranuclear species, among the four CH_2Cl_2 present, as in the case of the binuclear complex, two of them occupied the two preorganised cavities, whereas the remaining solvent molecules were located within the two 'pockets' resulting from the positioning of the allyl groups. The difference between the two discrete complexes observed in the lattice may be assigned to two different conformations adopted by the allyl groups.

It is worth noting that in the case of the self-complementary compound **16** depending on composition of the solution, all three situations (Fig. 11), *i.e.* discrete inclusion complexes and one-dimensional networks formed either by interconnection of consecutive units by connectors or by self-interconnection, were obtained.

Towards directional koilates

In dealing with one-dimensional networks, the control of the directionality of the assembly remains an important and

challenging issue. In all cases of koilates mentioned above, although the dimensionality of the molecular assembly could be controlled (α-network) by the geometrical features of the building blocks, due to their centrosymmetric nature, no particular directionality could be obtained (Fig. 1). In order to control both the dimensionality and the directionality of koilates, one may use non-symmetric koilands (Fig. 14). The design of non-centrosymmetric koilands may be based either on electronic or on geometric differentiation.

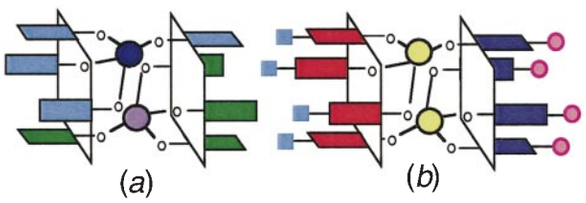

Fig. 14 Schematic representation of non-centrosymmetric koiland based either on electronic (*a*) or geometric (*b*) differentiation of the two cavities

Electronic differentiation [Fig. 14(*a*)] may be achieved by using two different fusing atoms with the same oxidation state IV such as Si and Ti or with different oxidation states III and IV such as B and Si. The non-symmetric nature of the Si–Ti heterobinuclear koiland is based on the induced difference between the two calix units by their coordination to two different metals with different electronegativity. Indeed, one of the calixes is triply coordinated to a Si atom whereas the other unit is triply coordinated to a Ti atom. The synthesis of the Si–Ti heterobinuclear koiland **17** [Fig. 15(*a*)] was achieved.[33] The stepwise strategy used was based on the preparation of the mono-fused compound **18** [Fig. 15(*b*)] which was shown by NMR ROESY experiments to adopt a face to face '*syn*' conformation. Upon treatment of the latter by $TiCl_4$ the desired compound **17** was obtained in high yield.

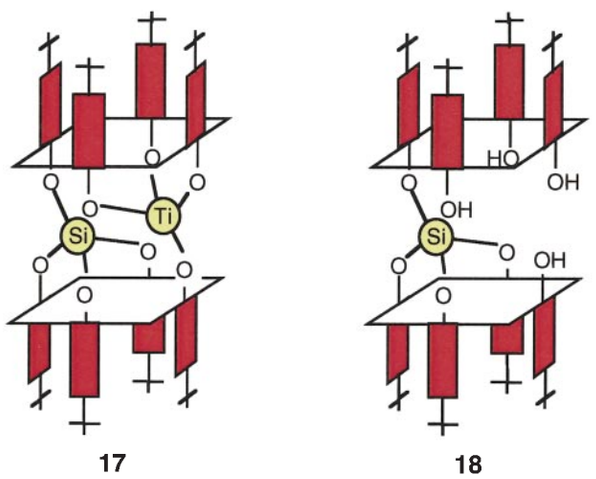

Fig. 15 Schematic representation of the koiland obtained by double fusion of two *p-tert*-butylcalix[4]arenes by silicon and titanium atoms **17** and of the mono-fused compound **18**

Geometric differentiation [Fig. 14(*b*)] may be accomplished, while keeping the same fusing element such as Si, by connecting two different calix units. Mixed compounds based on the double fusion of two different calix units by two Si atoms have been prepared. The general strategy for the preparation of non-symmetric koilands **6**–**8**, **10**, **11** and **13** (Fig. 4) was based on a combinatorial approach. Upon treatment of a combination of two different calix[4]arenes [X,Y] (X = Y = **1**–**4**) with base, followed by reaction with $SiCl_4$, as expected, three different koilands [X–X], [Y–Y] of the homo type (centrosymmetric) and [X–Y] of the hetero type (non-centrosymmetric) were obtained.[34]

In solution, as expected, ^{29}Si NMR studies revealed the presence of two signals for the non-centrosymmetric heterodimers, whereas for the centrosymmetric koilands a unique signal was observed. In the solid state structures of compounds **6** and **7** were confirmed by X-ray analysis (Fig. 16). For both

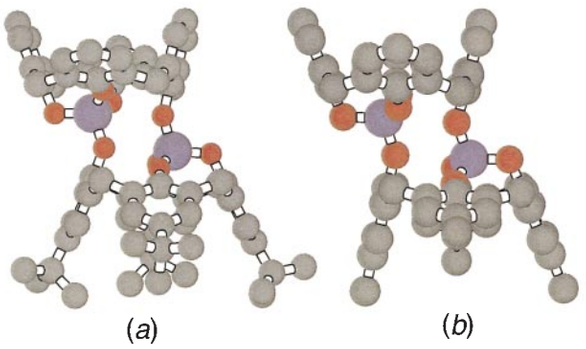

Fig. 16 X-Ray structures of linear koilands **6** (*a*) and **7** (*b*) showing the interconnection of two different calix units by two silicon atoms. For the sake of clarity, solvent molecules and hydrogen atoms are not presented.

compounds, the coordination geometry around the silicon atoms was tetrahedral. The Si–Si distance varied only slightly from 3.84 Å for **6** to 3.77 Å for **7**. These values are similar to those previously observed for compounds **9** and **12**.

Formation of directional koilates using the non-centrosymmetric koilands mentioned above is under current investigation.

Conclusions

In conclusion, it has been demonstrated that hollow molecular modules may be assembled in the solid state into one-dimensional molecular arrays either by self inclusion or by interconnection using connector molecules. Thus, inclusion processes based on van der Waals interactions may be used as a design principle for the generation of molecular networks in the solid state. Although at the present state of affairs, this approach remains essentailly structural, by using molecular building blocks possessing specific magnetic, photonic or electric properties, one may extend this strategy to the preparation of functional solids. Work along these lines is in progress.

He was mainly educated at the Louis Pasteur University, Strasbourg where he obtained his PhD degree in 1983 working with Jean-Marie Lehn. In 1981 he joind the French National Research Centre as a permanent member. After a postdoctoral fellowship spent in 1985 with Kenneth Raymond at Berkeley, he returned to Strasbourg where he continued to work with Jean-Marie Lehn. In 1990 he was appointed as a Professor of Organic Chemistry at Louis Pasteur University. In 1992 he was nominated for a period of five years at the Institut Universitaire de France. He was invited Professor at the University of Western Australia at Perth, University of Geneva, The Institute of Materials and Chemical Research, Tsukuba, Japan and University of Tokyo. His main research interests are in the area of molecular architecture and range from molecular receptors and catalysts to molecular networks and molecular materials.

André De Dian was born in 1942 in Aumetz, France. He completed his undergraduate and graduate studies at Louis Pasteur University, Strasbourg, he obtained his PhD degree at the same institution in 1972 working with Raymond Weiss.

After a postdoctoral fellowship with M. L. H. Green at Oxford, he returned to Strasbourg as a permanent researcher (French National Research Centre, CNRS). He is a chemist and crystallographer and his main scientific interests are in the area of porphyrins and mixed porphyrin/phthalocyanine derivatives as well as in the field of crystal engineering.

Novel ferrocene-based chiral Schiff's base derivative with a twist-grain boundary phase (TGBA) and a blue phase

Tarimala Seshadri*† and Hans-Jürgen Haupt

Department of Inorganic and Analytical Chemistry, University of Paderborn, Warburger Straße 100, 33098 Paderborn, Germany

Synthesis of a monosubstituted ferrocene-based chiral Schiff's base derivative with unusual mesomorphic behavior is reported namely the first metallomesogen which exhibits TGBA and blue phases apart from S_C*, S_A and N* phase transformations.

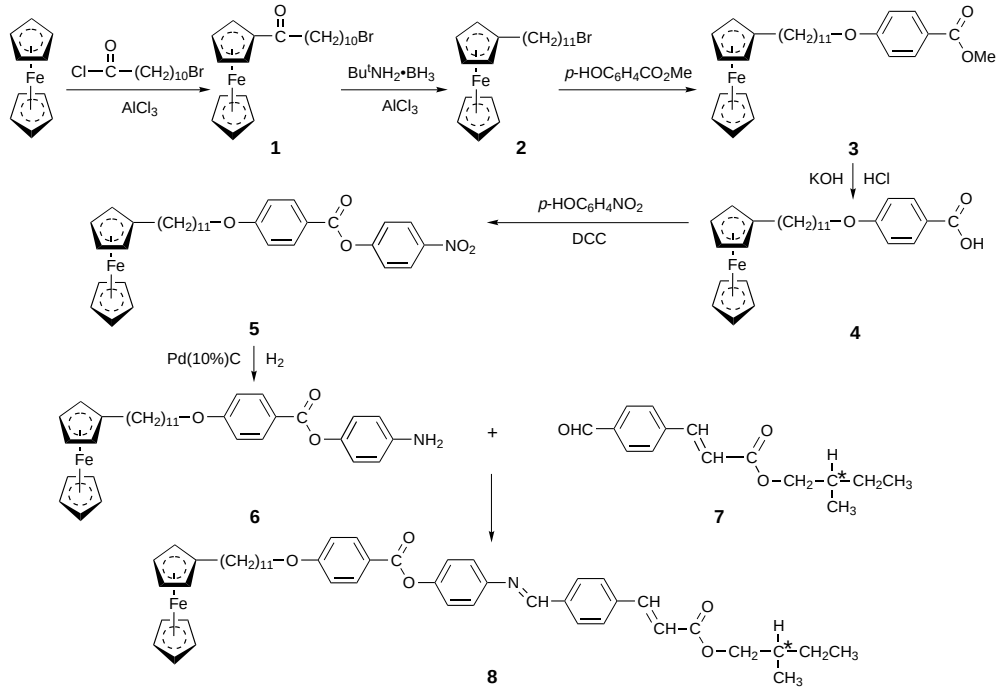
Chirality in ordered fluids has become one of the most fascinating and innovative fields of current research in liquid crystals. The quest to develop new chiral mesomorphic compounds led to the serendipitous discovery of new types of physical behavior namely the twist grain boundary (TGB)[1] and the blue phases[2] apart from the ferri- and antiferro-electric[2,3] liquid crystalline phases. The TGBA phase first discovered by Goodby *et al.*,[4] in 1989 was initially predicted by Gennes[5] in 1972. The appearance of the TGB phase[6] has induced enormous interest due to the formal analogy of its Landau free energy to that of the Shubnikov phase occurring in the type II superconductors.[5,7] Renn and Lubensky[7] in 1988 described this phase as a frustrated intermediate between N* and S_A phases. Since then, several new organic compounds showing such a phase were synthesized by different workers and their phase sequences were identified.[6]

Both the TGB and the blue phases are two kinds of frustrated phases which are found exclusively in chiral organic compounds. None of the chiral metallomesogens reported until now exhibited such phase formation, although several of their Pd, Cu and V complexes bearing one or more stereocenters were synthesized.[8] Nevertheless, incorporation of metals into the structures of low molar mass chiral liquid crystals to attain such phases must be a very challenging and attractive subject for study from both the academic and the applications point of view. Especially, introduction of ferrocene units as components of chiral liquid-crystalline materials may bring about high thermal stability and other additional properties among which its ability to undergo reversible one-electron transfer processes is one of the most important.[9]

However, studies on the synthesis of chiral smectic C mesophases comprising monosubstituted ferrocenyl group are scanty except the one reported by Imrie and Loubser.[10] The limited studies in this direction are attributed to the fact that monosubstituted ferrocenes, because of their unfavourable molecular shape (L-shape) and also due to repulsive steric effects of the ferrocene unit which hinders the ability of the molecules to pack in layers thus favouring mostly the formation of nemetic phases.[11–13]

We therefore attempted to prepare several ferrocene based chiral mesophases and surprisingly synthesized a compound that exhibits enantiotropic S_C*, S_A, a twist grain boundary phase (TGBA), a cholesteric as well as a blue phase. This is the first chiral metallomesogen which exhibits a TGBA and a blue phase.

The synthesis of the chiral Schiff's base derivative **8** is described in Scheme 1. To start with, we used the readily available (*S*)-(−)-2-methylbutan-1-ol for this purpose. In **8** the chiral centre with a small terminal chain is located adjacent to the rigid molecular core in order to couple strongly with the



Scheme 1

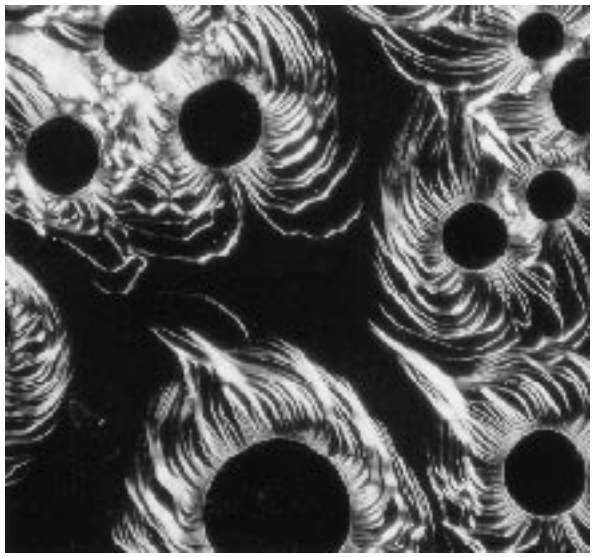


Fig. 1 Polarized optical micrograph of the TGBA phase on heating to 143.8 °C; magnification × 100

dipolar regions of the core. The phase assignments and transition temperatures (°C) of **8** shown below were determined by polarized optical microscopy using clean, untreated glass microscopic slides and cover slips as well as by differential scanning calorimetry (DSC) measurements.

C 116 S_C* 136 S_A 143.8 TGBA 144.9 N* 158 BP 159.2 I
I 157.2 BP 154.6 N* 143.1 TGBA 141.2 S_A 132.6 S_C* 77.9 C

At the S_A–S_C* transition, a dramatic textural change was observed whereby the dark homeotropic texture of the S_A phase gives rise to a *schlieren* texture characteristic of the S_C phase. The thermogram indicates that owing to the small enthalpy associated with these transitions, some of the peaks could not be detected. The calculated enthalpies (kJ mol^{-1}) are as follows. S_C*–S_A, 0.28; S_A–TGBA–N*, 0.55 and BP–I, 0.81.

When heating slowly (0.2° min^{-1}), the filament structure of the TGBA phase shown in Fig. 1, grows slowly in the homeotropic regions of the smectic A phase and ends up in a fire ball which coalesces into a cholesteric phase with a fan-shaped texture. Also oily streaks are seen upon subjecting the preparation to mechanical stress.

Both during heating and cooling cycles (0.2° min^{-1}), the formation of the blue phase is clearly seen as a platelet texture which is shown in Fig. 2.

The influence of orientation of ester linkages which directs the electron delocalization and the coplanarity of the two aromatic rings of benzylideneaniline (the angle between the two planes of these rings deduced from X-ray[14] and UV data[15] was found to be 66°) probably enhances the polarisability of the rigid core due to extended conjugation. This in turn enhances the preponderance of smectic phases and also creates favourable packing conditions. Furthermore, the presence of the flexible spacer between the phenyl ring and the ferrocenyl unit in **8** is primarily responsible for the formation of highly ordered phases, in the absence of which only a cholesteric phase was observed.

Compound **8** is very stable and no decomposition was seen during repeated heating and cooling cycles. Furthermore, a free-standing film can be prepared by heating the compound into its smectic state (130 °C) without any decomposition.

In conclusion, we report here a monosubstituted ferrocene-based metallomesogen with a chiral Schiff's base which shows for the first time a relatively long S_C* domain, a TGBA phase which mediates between S_A and N* and a blue phase just before the clearing point, in spite of a bulky pendant ferrocene unit on the one side and a relatively small terminal group appended to the chiral centre on the other side. This ferrocene derivative and derivatives thereof should be interesting candidates for preparing ferroelectric smectic C* materials useful in fast switching electro-optic devices.

‡ Detailed synthetic procedures for the intermediate ferrocenyl derivatives **1**–**6** will be reported separately. The final Schiff's base compound **8** is obtained by refluxing equimolar amounts of **6** and **7** in ethanol containing a few drops of acetic acid for 1 h and filtered hot through a sintered glass. The precipitate obtained after cooling was dissolved in dichloromethane and reprecipitated by the addition of heptane. Yield: 82%. Anal. Calc. for $C_{49}H_{57}FeNO_5$: C, 73.95; H, 7.22; N, 1.76. Surprises in enolate binding at high valent molybdenum

Paul A. Cameron, George J. P. Britovsek, Vernon C. Gibson,*† David J. Williams and Andrew J. P. White

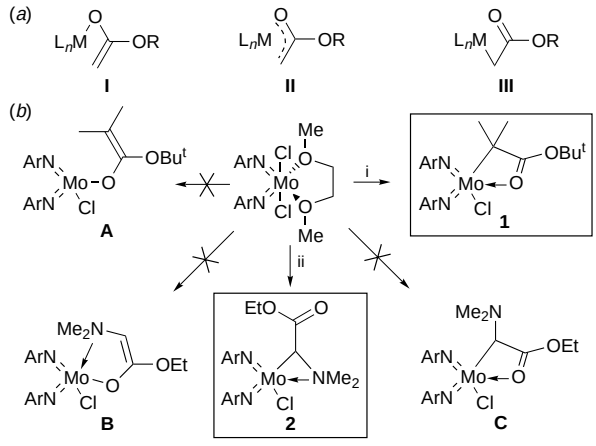
Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, London, UK SW7 2AY

Treatment of $[Mo(NAr)_2Cl_2(DME)]$ (Ar = 2,6-diisopropylphenyl; DME = 1,2-dimethoxyethane) with $LiOC(O\text{-}Bu^t)CMe_2$ at low temperature affords the unexpected carbon-bound molybdenum(VI) enolate complex $[Mo(N\text{-}Ar)_2Cl\{\eta^2\text{-}C(Me_2)CO_2Bu^t\}]$ 1; the novel α-aminoenolate derivative $[Mo(NAr)_2Cl\{\eta^2\text{-}CH(NMe_2)CO_2Et\}]$ 2 is obtained under analogous conditions using $LiNPr^i_2/Me_2NCH_2CO_2Et$; the structures of 1 and 2 confirm the carbophilic nature of the $[Mo(NAr)_2]$ core.

Transition metal enolate chemistry nowadays features prominently in organic synthetic methodology. The enolate ligand, an intermediate between an allyl and an acetate unit, has two different binding modes. Depending on the oxophilicity/carbophilicity of the metal centre, the enolato functionality can bind either *via* the 'CH_2' unit or *via* its oxygen atom [Scheme 1(*a*)], giving rise to different reactivity in further transformations. In general, the oxygen binding mode **I** predominates for early transition metals, whereas M–C bonding **III** is favoured by the softer late transition metals. A number of oxygen bound enolate complexes of early transition metals have been isolated and structurally characterised.[1–4] For molybdenum, only low valent molybdenum enolate complexes as in $[MoCp(CO)_3R]$ (R = enolate ligand) have been made and these are exclusively carbon bound.[5–9]

With a view to exploiting the isolobal relationship between the Cp_2M^{IV} and the $(RN)_2M^{VI}$ cores,[10,11] we became interested in establishing whether or not the relatively 'hard' high valent molybdenum centre would promote a switch from a carbon-bound to an oxygen-bound enolate binding mode, since oxygen-bound enolate complexes of early transition metal[12,13] and rare earth metallocenes[14,15] are implicated as the active species in the polymerisation of methyl methacrylate (MMA). Here, we describe the first examples of high valent molybdenum enolate complexes and their unusual and unanticipated structures.

Complex **1** was prepared according to Scheme 1(*b*), from $[Mo(NAr)_2Cl_2(DME)]$ and $[LiOC(OBu^t)CMe_2]$[16] at −78 °C. Recrystallisation from pentane at −30 °C afforded **1** as an orange crystalline product.‡ A second recrystallisation from heptane gave X-ray quality crystals of **1** and the molecular structure is shown in Fig. 1.§ Compound **1** decomposes slowly in solution ($t_{1/2}$ *ca.* 1 week) but can be stored for weeks in the solid state at −20 °C.



Scheme 1 (*a*) Potential binding modes of the ester enolate ligand. (*b*) *Reagents and conditions*: i, $LiOC(OBu^t)CMe_2$ (1 equiv.), Et_2O, −78 °C → room temp.; ii, LDA, $Me_2NCH_2CO_2Et$, THF, −78 °C → room temp.

The X-ray analysis of **1** reveals the unexpected bidentate coordination of the enolate ligand *via* the carbonyl oxygen atom O(2) and the α-carbon atom C(1). The geometry at Mo, although five-coordinate, is probably best described as distorted tetrahedral with the chelating enolate ligand occupying one of the tetrahedral sites; the angles subtended at Mo by the two imido N atoms and the Cl atom range between 105.4(4) and 111.3(3)°. The Mo–N distances are typical of 'linear' imido ligands, the angles at the N atoms being 157.6(8) [N(10)] and 158.5(8)° [N(23)].[17,18] The feature of most interest is the pattern of bonding to, and within, the enolate ligand. The 'stronger' coordination is to the α-C atom [Mo–C(1) 2.208(11) Å] whereas that to the carbonyl O atom is 2.370(6) Å. The C(1)–C(2) linkage [1.50(2) Å] has lost all its double bond character, though there is not a full pyramidalisation at C(1), the sum of the C–C(1)–C angles being *ca.* 342°. There is evidence for delocalisation between the two O atoms of the ester, the C(2)–O(2) and C(2)–O(3) distances being 1.24(2) and 1.29(2) Å, respectively.

Interestingly, complex **1** unveils a fundamental difference between the isolobal Cp_2M^{IV} and the $(ArN)_2M^{VI}$ cores. Whereas the analogous Cp_2M^{IV} complex $[Cp_2Ti\{O\text{-}C(OMe)CMe_2\}Cl]$ was found to be an O-bound enolate complex,[4] complex **1** does not bind similarly *via* the O atom as in complex **A**, but clearly establishes the carbophilic nature of the $(ArN)_2Mo^{VI}$ core.

Fig. 1 Molecular structure of **1**. Subsequently, an attempt was made to force the enolate ligand into an O-bound coordination mode, by using an α-aminoester enolate ligand [Scheme 1(*b*)]. It was anticipated that this ligand should produce a five-membered chelate, bound *via* the N and the carbonyl O donor to the metal centre as in complex **B** [Scheme 1(*b*)]. However, the strong carbophilic nature of the $(ArN)_2Mo^{VI}$ fragment again became apparent, resulting in the C-bound enolate complex **2**. Moreover, a three-membered chelate with an intramolecular coordination of the amine donor is formed. Thus, chelation of the carbonyl O to give a four-membered ring as in complex **C** is not observed [Scheme 1(*b*)]. Similar preferred arrangements have been reported previously for low valent Mo complexes.[19,20]

The preparation of complex **2** involved the *in situ* formation of the lithium enolate from LDA and $Me_2NCH_2CO_2Et$ in THF at −78 °C. Addition to $[Mo(NAr)_2Cl_2(DME)]$ at this temperature and extraction of the product with pentane at room temp. gave complex $[Mo(NAr)_2\{CH(NMe_2)CO_2Et\}Cl]$ **2** as a dark red crystalline solid.‡ Suitable crystals for X-ray analysis were obtained from pentane, and the molecular structure is given in Fig. 2.§

The X-ray structure of **2** again reveals an unexpected coordination of the α-aminoenolate ligand, with chelation *via* the amino atom N(1) and the α-C atom C(1) [with consequent loss of double bond character for C(1)–C(2)], rather than the carbonyl O atom O(2). As in **1**, the coordination at Mo can be considered as distorted tetrahedral, the enolate occupying a single coordination site [the N–Mo–N and N–Mo–Cl angles are in the range 106.9(1)–113.2(2)°]. The Mo–N(imido) distances are again typical of 'linear' species, with angles at N of 161.0(4) and 171.1(4)° for N(2) and N(3) respectively. As in **1**, the 'strong' bond to the α-aminoenolate ligand is to the α-C atom [2.149(6) Å] whereas that to N(1) is 2.198(4) Å. This contrasts with the pattern observed for related chelation to a Mo^{II} centre where the Mo–C bond is noticeably longer than that to N.[20] In the absence of coordination to the ester carbonyl O atom there is no delocalisation between the two O atoms.

In conclusion, we have shown that enolate complexes of the bis(imido)Mo^{VI} core are readily accessible and that the metal–carbon bonded form is favoured over the oxygen-bonded arrangement, confirming the surprisingly carbophilic nature of the Mo^{VI} centres in these complexes.

A method for obtaining stable, high activity for NO_x reduction at low temperatures

Robert Burch,*† Paolo Fornasiero and Barry W. L. Southward

Catalysis Research Centre, Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 6AD

Very high and stable low temperature activity for the reduction of NO by *n*-octane on a 0.3 mass% Pt/Al_2O_3 catalyst operating under lean burn conditions may be achieved by secondary injection of micropulses of clean-burning thermal promoters into the gas stream.

Oxides of nitrogen (NO_x) formed in the combustion of diesel fuel are recognised as severe atmospheric pollutants and are the subject of increasingly stringent emissions control legislation[1,2] and so diesel engines will soon require comparable exhaust emissions technology to that used for petrol engines. However, although there has been much research on NO_x removal in fuel-lean exhaust streams,[3–6] to date no suitable material has been developed which will attain the levels of activity required under diesel operating conditions. Of the various materials examined, supported Pt catalysts appear to offer the best low temperature activity, are resistant to poisoning by SO_x, and are hydrothermally stable.[1,2,4,5] However, the goal of obtaining high activity at low temperatures, without rapid deactivation, has yet to be realised. Here, we address this problem and present preliminary data concerning the use of microinjection techniques to achieve highly active low temperature $DeNO_x$ catalysts.

The catalyst used in this study was the commercial catalyst CK303, ex Akzo (0.3 mass% Pt on Al_2O_3, pre-reaction surface area 226 $m^2\ g^{-1}$, metal surface area 0.48 $m^2\ g^{-1}$, Pt particle diameter 1.7 nm). It was chosen primarily as a low cost material having modest low temperature activity.[3,4] All catalyst testing was performed in a standard microreactor system described elsewhere.[3] Prior to testing, all samples were aged overnight in a standard reaction mixture (100 mg catalyst, 500 ppm NO, 500 ppm *n*-octane, 5% O_2, balance He, total flow 200 ml min^{-1}) at 500 °C and then 'cleaned' (550 °C in 5% O_2 in He for 1 h). *n*-Octane was chosen as a reductant to simulate a real fuel. NO_x conversions were determined by on-line analysis using a standard chemiluminescence detector (Signal series 4000), with samples logged onto a PC at 6 s intervals. CO_2 analysis was performed using a Signal series 2000 IR analyser. No reaction was observed in the absence of a catalyst.

The profile for the $DeNO_x$ reaction over a range of temperatures was analysed and gave results typical of those found in the literature with the conversion to N_2 rising to a maximum at *ca*. 220 °C[3,4–8] (results not shown). However we have previously shown that temperature programming studies may not be a reliable measure of catalyst activity[7] because of deactivation as the catalysts is heated up from lower temperatures. Therefore we have examined the lifetime of clean catalysts under isothermal conditions at temperatures close to the *n*-octane light-off point (*ca*. 220 °C when using CK303 as the catalyst, defined as the temperature required for >20% conversion of *n*-octane). The activity was clearly sensitive to temperature (Fig. 1). Indeed, only at 220 °C was the activity stable, whilst at lower temperatures the timescale for steady activity became increasingly small. Hence at 170 °C catalyst deactivation occurred so rapidly that reactor response lag and NO_x adsorption mask any NO_x reduction. This was reflected in the low amount of CO_2 produced, and the absence of an in-bed exotherm.[3,7] In contrast, reaction at 185 °C [steady activity for *ca*. 65 min, see Fig. 1(*c*) and Fig. 2(*a*)] was ascribed to catalytic reaction only. The decline in activity is ascribed to surface deposition of unreacted (carbonaceous) intermediates.

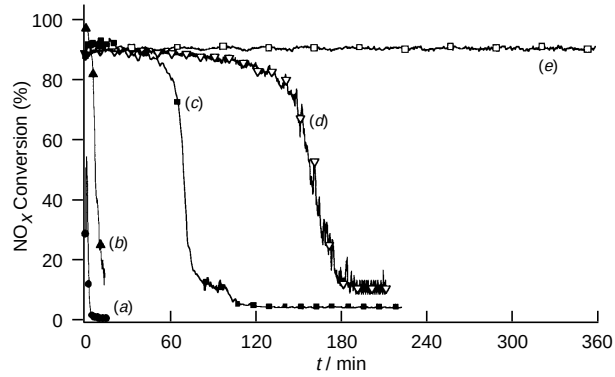

Fig. 1 Effect of temperature on the activity of CK303 (0.3 mass% Pt on Al_2O_3) under standard reaction conditions (100 mg catalyst, 500 ppm NO, 500 ppm *n*-octane, 5% O_2–He, balance He, total flow 200 ml min^{-1}). (*a*) 170 °C (●), (*b*) 180 °C (▲), (*c*) 185 °C (■), (*d*) 200 °C (▽), (*e*) 220 °C (□)

To circumvent this process of deposition leading to deactivation the method of micropulse injection was devised. This entailed injection of minute quantities of 'thermal promoters', *i.e.* readily combustible molecules, into the standard reaction mixture. It was envisioned that the combustion of these molecules would create an exotherm within the catalyst bed, and more specifically at the reaction centres. The ensuing temperature rise would promote reaction/desorption of any deposits located thereon.

The injection of small quantities of H_2 [Fig. 2(*b*)], gave no significant improvement in lifetime. However a bed exotherm of *ca*. 20 °C was recorded some 10 s after the injection, although it is clear that the temperature rise at any active site would be significantly larger, with associated desorption of surface NO_x as evidenced by the sharp (negative) peaks. However, the use of

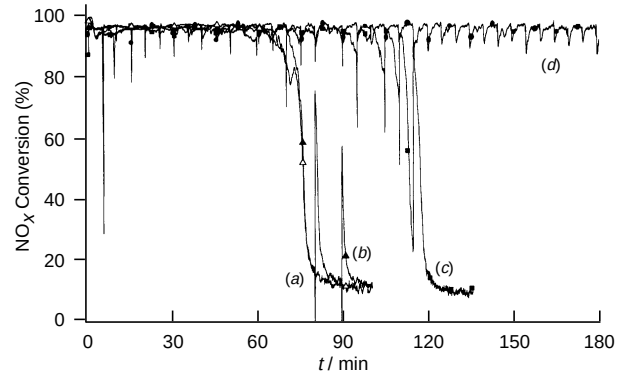

Fig. 2 Effect of microinjection on the activity of CK303 under standard reaction conditions, at 185 °C. (*a*) No injection (▽), (*b*) 0.5 ml H_2 every 10 min (▲), (*c*) 2 ml of H_2 every 5 min (■), (*d*) 1 μl of MeOH every 5 min-(●)

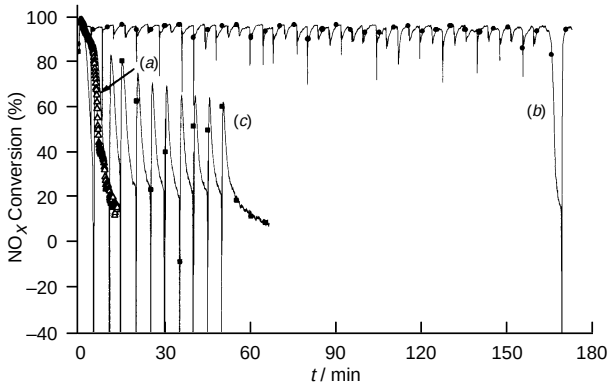

Fig. 3 Effect of microinjection on the activity of CK303 under standard reaction conditions at 180 °C. (*a*) No injection (▽), (*b*) pulse feed of 2 μl MeOH only every 4 min (■), (*c*) 2 μl MeOH every 4 min (●). Note after 160 min injections stopped and then recommenced at 169 min.

larger, more regular pulses of H_2 was found to be beneficial [Fig. 2(*c*)], and increased catalyst lifetime by *ca*. 30 min. This was consistent with the increased and more regular exotherm (bed temperature increase of *ca*. 30 °C) and associated desorption/reaction of NO_x and other adsorbates.

The use of pulses of methanol was even more successful [Fig. 2(*d*)] with no deactivation being observed for > 4 h on line (associated bed exotherm 40–45 °C). This is clearly a very significant result and suggested a means for obtaining high activity with no deactivation at low temperatures.

Given the successful application of methanol micropulsing at 185 °C its use at 180 °C was attempted. Previously, complete deactivation of CK303 had been observed in *ca*. 6 min [Fig. 3(*a*)] but by pulse injection (2 μl every 4 min, bed exotherm *ca*. 45 °C) deactivation was circumvented [Fig. 3(*b*)]. Injection was ceased after 160 min and deactivation occurred within 6 min in exactly the same manner as observed earlier with the clean catalyst [Fig. 3(*a*)]. Injection of MeOH at 169 min however, resulted in complete recovery of activity. These data confirm that the methanol effectively cleans the Pt surface to enable $DeNO_x$ to occur.

The methanol pulse itself is not the primary reductant as can be seen from the reaction of MeOH pulses in the absence of the *n*-octane feed [Fig. 3(*c*)]. In this case there is some $DeNO_x$ activity but this decreases rapidly to a low value. Thus it is clear that the very high activity obtained when MeOH is injected into a gas stream containing *n*-octane is due to the micropulsing in conjunction with the *n*-octane feed.

These results provide a novel, practical method for obtaining high activity for $DeNO_x$ reactions under diesel exhaust conditions at low temperatures.

We are pleased to acknowledge the financial support for this work through EU grant EV5V-CT94-0535.

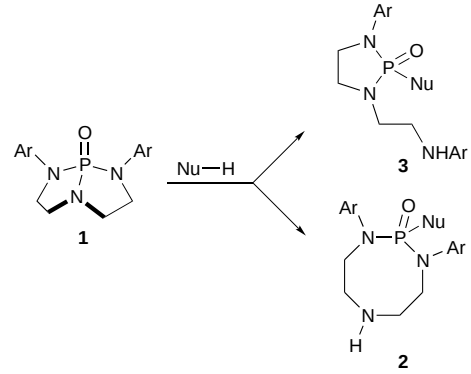
Solvolysis of 1-oxo-2,8-diphenyl-2,5,8-triaza-1λ⁵-phosphabicyclo[3.3.0]octane: new rearrangement of an eight- to a five-membered phosphodiamidate system

Xavier Y. Mbianda, Tomasz A. Modro*† and Petrus H. Van Rooyen

Centre for Heteroatom Chemistry and Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

The alcoholysis of the title compound with RO⁻/ROH gives the 1,3,2-diazaphospholidine derivative *via* the cleavage of the P–N(2) bond, while under acidic catalysis the P–N(5) bond is broken leading to the eight-membered monocyclic product, which can isomerize *via* a new type of rearrangement to the former five-membered system.

We have recently reported the preparation of the bicyclic phosphoric triamides **1** *via* the base-promoted cyclization of the corresponding 3-(2-chloroethyl)-2-oxo-1-aryl-2-arylamino-1,3,2-diazaphospholidines.[1] Nucleophilic cleavage of one of the P–N bonds in **1** can lead to another 1,3,2-diazaphospholidine derivative ['*exo*' departure of N(2)], or to a novel, eight-membered heterocyclic system **2** ['*endo*' departure of N(5)] (Scheme 1). We present here the results of the acid-catalyzed or base-promoted alcoholysis of **1a** (Ar = Ph). It was expected that under acidic conditions the regioselectivity governed by the first protonation site of the substrate[2] should involve the departure of the more basic N(5) atom. Our recent ^{15}N NMR spectroscopic studies[3] indicated a high degree of 'p³' character, hence high basicity, of N(5) in **1**. Alcoholysis of **1a** carried out in an alcohol containing 1 equiv. of dry HCl led, as expected, to the exclusive cleavage of the P–N(5) bond, yielding the corresponding 1-oxo-1-alkoxy-2,8-diphenyl-2,5,8-triaza-1λ⁵-phosphacyclooctane **2a** (Ar = Ph; Nu = OMe) or **2b** (Ar = Ph; Nu = OEt).‡ Amido esters **2** are, however, rather unstable compounds and undergo further changes upon purification (*vide infra*); they could be converted into stable derivatives *via* acylation of the N(5) atom.§ Unambiguous evidence for the structure of the primary product of the solvolysis was obtained from the crystal structure of the *N*⁵-Bz derivative of **2b** (Fig. 1).¶ Structural parameters of the phosphodiamidate function in *N*⁵-Bz**2b** are similar to those reported for related structures, except for two points. First, we observe the short P···N(2) non-bonded distance of 3.242 Å, which should be even shorter in free, nonbenzoylated **2b**. Second, the two P–N bonds are non-equivalent: while one (1.651 Å) lies well within a typical bond distance for phosphoramidates,[4] the other (1.688 Å) indicates a significantly lower bond order.



Scheme 1

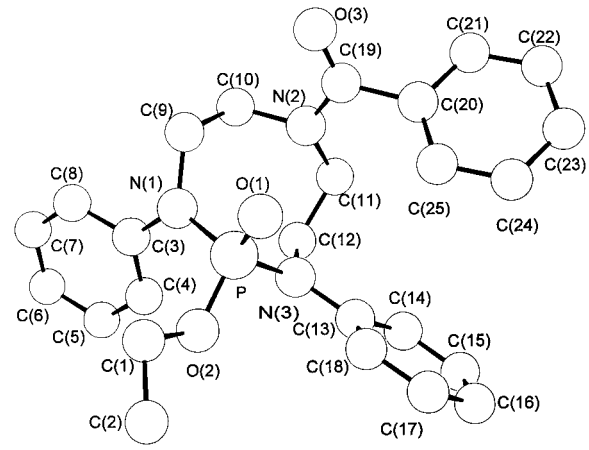


Fig. 1 ORTEP plot of the structure of the *N*-benzoyl derivative of **2b**

When free cyclic diamido phosphates **2** were stored as neat substances, or as solutions in aprotic solvents, they underwent slow change yielding another phosphorus-containing product. Full conversion could be achieved by refluxing **2** in benzene or THF and, for **2b**, the product, after isolation and purification, was identified as the isomeric 3-[2-(phenylamino)ethyl]-2-oxo-2-ethoxy-1-phenyl-1,3,2λ⁵-diazaphospholidine **3b**.‖ The structure of this product was determined by X-ray diffraction (Fig. 2),** demonstrating unambigously the 8 → 5 ring contraction nature of the rearrangement. The only reported structure closely related to **3b** is that of Jones *et al.*,[5] the molecular parameters of both compounds correspond well to each other.

This new ring contraction **2b** → **3b** can be conveniently followed *via* ^{31}P NMR spectroscopy ($\Delta\delta_P$ = 6.4 ppm). Reactions carried out in refluxing THF with variable initial concentrations of **2b** showed clearly the first order kinetics, with $k_1 = (4.1 \pm 0.1) \times 10^{-5}$ s^{-1}. The rearrangement can be explained in terms of intramolecular 1,5-nucleophilic attack of the amine nitrogen at the phosphoryl centre, followed by proton transfer and P–N bond cleavage (Scheme 2); this mechanism is also supported by the structural characteristics of *N*⁵-Bz**2a** discussed above. Similar transannular N–P interaction in an eight-membered heterocyclic system was postulated for the

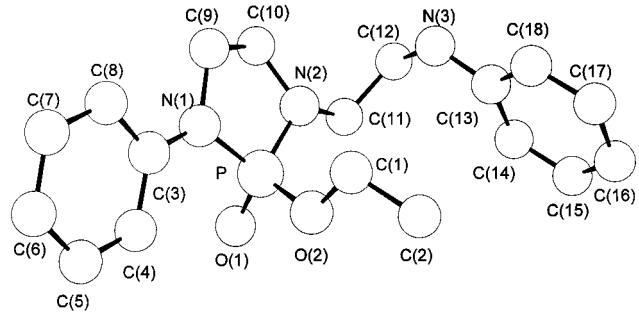

Fig. 2 ORTEP plot of the structure of **3b**

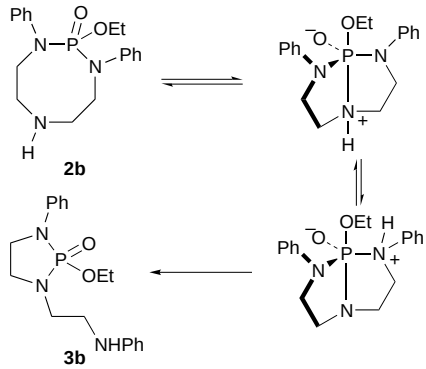

Scheme 2

mechanism of the hydrolysis of medium-ring phosphate esters.[6] In that case, however, as well as in other cases of transannular interactions involving nitrogen and a carbonyl group,[7] the ring structure of the substrate remains intact, while for **2** we observe a change in the cyclic skeleton of the molecule. To the best of our knowledge, this is the first reported case of a rearrangement of this type.

Methanolysis of **1a** in MeO^-/MeOH led directly to the formation of **3a** (Ar = Ph; Nu = OMe) as a result of nucleophilic cleavage of the P–N(Ph) bond. In the absence of the activation of the N(5) atom in **1** *via* protonation, it is the leaving ability of the departing nitrogen (NPh) that determines the regioselectivity of the P–N bond cleavage. In the presence of an excess of MeO^- ions, **3a** undergoes the opening of the second 1,3,2λ^5-diazaphospholidine ring, yielding dimethyl di(2-phenylaminoethyl)phosphoramidate **4a**.††

The **2** → **3** rearrangement reported here indicates greater thermodynamic stability of the latter heterocyclic system. The structure and conformational behaviour of **2**, as well as the mechanism of its rearrangement to **3**, is currently being studied in this laboratory.

‡ *Acid-catalysed alcoholysis* of **1a**: a solution of **1a** (0.50 g, 1.67 mmol) in anhydrous alcohol (15 ml) containing dry HCl (1.67 mmol) was kept at room temperature for 16 h, diluted with water (10 ml) and neutralised with aq. Na_2CO_3. The solution was extracted with $CHCl_3$ (3 × 10 ml), dried (Na_2SO_4) and evaporated under reduced pressure yielding **2** as a solid (**2a**) or a viscous oil (**2b**). Data for **2a** (0.55 g, 100%): mp 91.5–92.7 °C; δ_H (300 MHz, $CDCl_3$) 2.04 (1 H, br s), 2.87 (4 H, ddd, *J* 14.6, 6.7, 3.1), 3.50 (3 H, d, *J* 5.6), 3.60–3.85 (4 H, m), 7.08–7.50 (10 H, m); δ_C 47.4 (s), 51.8 (s), 53.2 (d, *J* 5.7 Hz), 123.5 (s), 124.1 (s), 129.2 (s), 143.3 (d, *J* 4.2); δ_P 13.6. For **2b** (0.58 g, 100%): oil; δ_H 0.99 (3 H, t, *J* 7.1), 2.06 (1 H, br s), 2.87 (4 H, ddd, *J* 14.6, 6.7, 3.1), 3.55–3.80 (4 H, m), 3.87 (2 H, dt, *J* 7.1), 7.08–7.50 (10 H, m); δ_C 15.6 (d, *J* 6.7), 47.3 (s), 51.5 (s), 62.9 (d, *J* 5.4), 123.4 (s), 123.9 (s), 129.1 (s), 143.2 (d, *J* 4.2); δ_P 12.1.

§ *Selected data* for N^5-Bz**2a**: (66%), mp 148.2–149.7 °C (from MeCN–hexane, 1 : 1); δ_P 12.0; Found: C, 66.22; H, 6.17; N, 9.50; $C_{24}H_{26}N_3O_3P$ requires: C, 66.19; H, 6.01; N, 9.64%. For N^5-Bz**2b**: (74%), mp 144.2–145.6 °C (from MeCN); δ_P 10.6; Found: C, 67.07; H, 6.29; N, 9.34. $C_{25}H_{28}N_3O_3P$ requires: C, 66.80; H, 6.27; N, 9.34%.

¶ *Crystal data* for N^5-Bz**2b**: $C_{25}H_{28}N_3O_3P$, *M* = 449.49, monoclinic, space group $P2_1/n$ (No. 14), *a* = 9.743(1), *b* = 12.443 (2), *c* = 19.334(2) Å, β = 104.34(1)°, *U* = 2271(1) Å^3, *F*(000) = 952, λ(Mo-Kα) = 0.7107 Å, μ(Mo-Kα) = 1.13 cm^{-1}, *T* = 295(1) K, *Z* = 4, D_c = 1.30 g cm^{-3}. Data were collected on an Enraf Nonius CAD4 diffractometer in the range $3 \leqslant \theta \leqslant 30°$ (7072 reflections). The structure was solved by direct methods (ref. 8) and refinement, based on *F*, was by full-matrix least-squares methods (ref. 9) to R = 0.057, R_w = 0.065 {weighting scheme $[\sigma^{-2}(F_o) + 0.000699F^2]$} for 293 parameters using 4047 unique reflections with $I > 3\sigma(I)$.

‖ *Rearrangement* of **2b** to **3b**: **2a** (0.345 g, 1 mmol) in dry benzene (15 ml) was heated under reflux for 18 h. After concentrating to *ca*. 1/4 volume, the solution was poured into dry Et_2O (20 ml) with vigorous stirring. The precipitate (0.318 g, 92%) was filtered off and crystallized from MeCN. 1-Phenyl-2-ethoxy-2-oxo-3-[2-(phenylamino)ethyl]-1,2,3λ^5-diaza-phospholidine **3b**, mp 129.4–130.1 °C; δ_H 1.17 (3 H, t, *J* 7.1), 3.24–3.46 (6 H, m), 3.57–3.70 (2 H, m), 3.97 (2 H, dt, *J* 7.1), 6.60–7.30 (10 H, m); δ_C 16.2 (d, *J* 7.2), 41.6 (d, *J* 2.4), 43.1 (s), 43.3 (s), 44.4 (d, *J* 4.9), 63.6 (d, *J* 7.2), 112.5 (s), 115.9 (s), 122.9 (s), 129.2 (s), 129.3 (s), 141.3 (d, *J* 6.3), 148.0 (s); δ_P 18.5; Found: C, 62.18; H, 7.16; N, 12.08; $C_{18}H_{24}N_3O_2P$ requires: C, 62.59; H, 7.00; N, 12.16%.

** *Crystal data* for **3b**: $C_{18}H_{24}N_3O_2P$, *M* = 345.38, monoclinic, space group $P2_1/n$ (No. 14), *a* = 13.902(2), *b* = 6.046(5), *c* = 22.110(5) Å, β = 94.59(3)°, *U* = 1852(1) Å^3, *F*(000) = 736, λ(Mo-Kα) = 0.7107 Å, μ(Mo-Kα) = 1.24 cm^{-1}, *T* = 295(1) K, *Z* = 4, D_c = 1.22 g cm^{-3}. Data were collected on an Enraf Nonius CAD4 diffractometer in the range $3 \leqslant \theta \leqslant 30°$ (6077 reflections). The structure was solved by direct methods (ref. 8) and refinement, based on F^2, was by full-matrix least-squares methods (ref. 9) to R = 0.063, R_w = 0.040 {weighting scheme $[\sigma^2(f_o)]$} for 221 parameters using 2522 unique reflections with $I > 3\sigma(I)$. An intermolecular bond O(1)···H–N(3) of 2.042 Å is observed. Perspective drawings were prepared using ORTEP (ref. 10). CCDC 182/772.

†† *Base-promoted alcoholysis* of **1a**: a solution of **1a** (0.300 g, 1 mmol) and MeONa (3 mmol) in MeOH (20 ml) was kept at room temperature for 28 days (full conversion, as shown by ^{31}P NMR spectroscopy), neutralised with methanolic HCl, filtered and evaporated under reduced pressure. The crude product (0.336 g, oil) consisted of two phosphorus-containing compounds (δ_P 19.9, 55%; δ_P 14.4, 45%) which were separated by column chromatography (SiO_2, Et_2O). *Selected data* for **3a**, oil; δ_H 3.39 (6 H, m), 3.61 (3 H, d, *J* 12.3), 3.63 (2 H, m), 4.42 (1 H, br s), 6.63 (2 H, d, *J* 7.6), 6.68 (1 H, t, *J* 7.5), 6.98 (1 H, t, *J* 7.3), 7.15 (4 H, m), 7.29 (2 H, t, *J* 7.9); δ_C 41.7 (s), 43.2 (d, *J* 7.7), 43.4 (d, *J* 6.5), 44.5 (s), 54.3 (d, *J* 7.8), 112.8 (s), 115.7 (s), 117.4 (s), 121.7 (s), 129.3 (s), 129.4 (s), 137.6 (d, *J* 5.2), 147.8 (s); δ_P 19.9; Found: C, 63.20; H, 7.48; N, 11.45. $C_{19}H_{26}N_3O_2P$ requires: C, 63.50; H, 7.29; N, 11.69%. For **4a**: oil; δ_H 3.28 (8 H, m), 3.69 (6 H, d, *J* 11.2), 6.56 (4 H, d, *J* 7.7), 6.68 (2 H, t, *J* 7.4), 7.15 (4 H, m); δ_C 41.5 (s), 45.8 (d, *J* 4.4), 53.5 (d, *J* 6.2), 112.7 (s), 117.9 (s), 129.3 (s), 147.8 (s); δ_P 14.2.

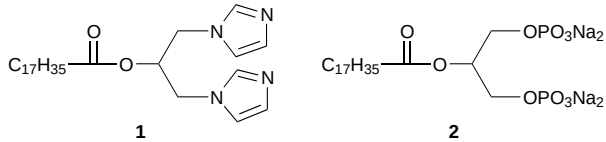
Dicephalic surfactants

Nico A. J. M. Sommerdijk,† Theo L. Hoeks, Kees Jan Booy, Martinus C. Feiters, Roeland J. M. Nolte* and Binne Zwanenburg*

Department of Organic Chemistry, NSR-Institute for Molecular Structure, Design and Synthesis, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands

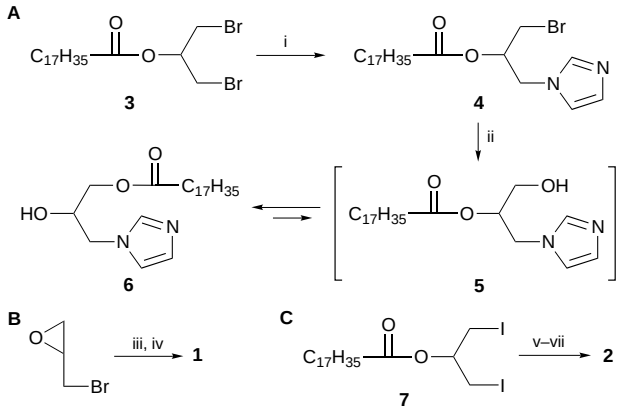
Two examples of dicephalic surfactants, a new class of two-headed amphiphiles, were prepared and demonstrated to exhibit unexpected aggregation behaviour.

Recently several research groups have studied the aggregation behaviour of surfactants with unusual structural features in order to further understand the relationship between the structure of the amphiphile and the type of aggregates it forms. Examples include surfactants with hyperextended[1] and spiro[2] hydrocarbon chains, gemini surfactants[3] and super surfactants, *e.g.* block copolymers of polystyrene and poly(propyleneimine) dendrimers.[4] Gemini surfactants, a new class of amphiphilic molecules with two hydrocarbon chains and two polar head groups connected by a linker, display aggregation behaviour that is distinctly different from that of the constituting 'parent' surfactants.[5] The interesting properties of gemini surfactants prompted us to design and synthesise another type of amphiphilic molecule for which we propose the name dicephalic (two-headed) surfactant. Molecules of this type consist of a single hydrocarbon chain and two polar head groups (**1** and **2**).‡ Both compounds can complex metal ions: the former binds transition metals to its imidazole groups, the latter calcium ions to its phosphate functions.[6] Here we report on the unusual self-assembling properties of the dicephalic surfactants.



1 **2**

The synthesis of compound **1** was initially tried by treating 1,3-dibromopropan-2-yl stearate **3**§ with imidazole in MeCN. Instead of the desired product **1** a mixture of compounds **4** and **6** was isolated. A mechanistic explanation is presented in Scheme 1A. Direct nucleophilic replacement of the second halogen atom in **3** by imidazole is difficult due to considerable steric hindrance as was evident from examination of CPK models.¶ During aqueous work-up a hydroxy group is probably introduced which gives **5** and after acyl migration[7] the α-hydroxystearate **6**. Compound **1** could, however, be synthesised *via* a double nucleophilic attack of sodium imidazolide on epibromohydrin, followed by acylation of the alkoxide intermediate (Scheme 1B).



Scheme 1 (i) Imidazole–CH_3CN; (ii) aqueous work-up; (iii) NaH–imidazole–DMF; (iv) $C_{17}H_{35}COCl$; (v) $AgOP(O)(OBn)_2$–toluene, reflux; vi H_2/Pd/C; (vii) Dowex-Na^+

Reaction of **3** with tetraalkylammonium salts of mono- and di-benzyl phosphate, for similar steric reasons as mentioned above, did not lead to satisfactory yields of the respective desired bis-phosphates.‖ Compound **2** was prepared therefore by phosphorylation of the diiodide **7**§ with silver dibenzyl phosphate[8] followed by catalytic hydrogenation over Pd/C and subsequent cation exchange (Scheme 1C). This indirect displacement of the halogen atoms by the dibenzyl phosphate ions is promoted by the formation of an AgI complex and the neighbouring group participation of the ester carbonyl function.

Inspection of CPK models of **1** and **2** revealed that both compounds have a very large head group section compared to their lipophilic part. According to the structure–shape concept,[9] the formation of micelles may therefore be expected when these compounds are dispersed in water. Dispersion of **1** in water at pH 7.0 (0.1%, w/w) did not, however, lead to the formation of micelles, but to well defined multilayered platelets of micrometer size [Fig. 1(*a*)]. Powder diffraction experiments revealed a repetitive distance of 31 Å, indicating a structure in which the hydrocarbon chains are interdigitated. Electron diffraction showed several bands, indicative of the polycrystalline nature of the sample, and a strong phase transition at 58 °C (ΔH = 60 J g^{-1}) was observed by DSC. The pK_a values of **1** (3.6 and *ca.* 7), make it likely that the platelets consist of a mixture of protonated and deprotonated surfactant molecules. The possibility of intermolecular hydrogen bond formation over long distances, may account for the remarkable stability of these lamellar structures.

When 0.25 equiv. of $CuSO_4$ were added to a dispersion of **1** in water, vesicles with diameters of 50–250 nm were formed [Fig. 1(*b*)]. EPR and FTIR titration experiments showed that a complex of the type $Cu(Imidazole)_4^{2+}$ had been formed,** but it was not possible to differentiate between a monomeric Cu^{II} $\mathbf{1}_2$

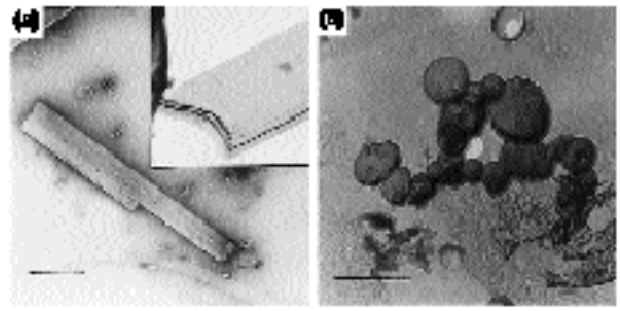


Fig. 1 Electron micrographs of (*a*) **1** (negative staining, inset Pt shadowing technique) and (*b*) a 2:1 complex of **1** and $CuSO_4$ (freeze fracture technique) in water. Bars represent 250 nm.

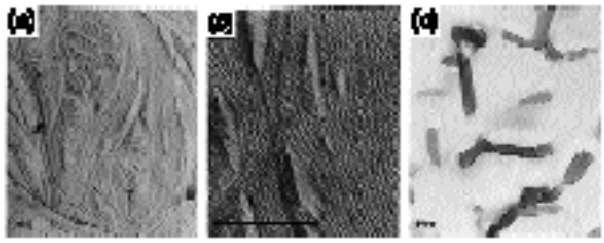

Fig. 2 Electron micrographs of **2** in (*a*, *b*) aqueous 2 mM PIPES buffer (pH 7.0, freeze fracture technique) and (*c*) aqueous 2 mM PIPES buffer containing 0.5 mM $CaCl_2$ (pH 7.0, Pt shadowing technique). Bars represent 100 nm.

complex and a polymeric coordination network. According to powder X-ray diffraction these vesicles had an interdigitated bilayer with a thickness of 32 Å. DSC revealed a phase transition at 15 °C (ΔH = 15 J g^{-1}), indicating that copper complex formation caused a dramatic change in the molecular packing.

For 0.1% (w/w) dispersions of **2** in an aqueous buffer of pH 7.0, electron microscopy [Fig. 2(*a*),(*b*)] revealed the formation of bundles of fibres each with a diameter of 65 Å, (approximately twice the molecular length) and lengths up to 15 μm (aspect ratio >2000). These fibres showed a faint phase transition at 23 °C (ΔH = 1.5 J g^{-1}) in DSC. The formation of very long structures suggests that intermolecular interactions must also play an important role in stabilising these aggregates. Since at pH 7.0 the phosphate groups will be in their monoprotonated form,[10] a network of hydrogen bonds can be formed between protonated and unprotonated P–OH groups of neighbouring molecules (Fig. 3), which could account for the observed stability of these large structures.

Compound **2** is expected to form a 1:1 complex with calcium, either intramolecularly by chelation or intermolecularly by formation of a linear polymeric complex.[11] Addition of calcium chloride ([Ca^{2+}] = 0.5 mM) to aqueous dispersions of **2** led to the formation of a precipitate consisting of small (200–500 nm) and irregularly shaped multilayered platelets [Fig. 2(*c*)]. These platelets were shown to be polycrystalline by electron diffraction and displayed a sharp phase transition at 148 °C (ΔH = 17 J g^{-1}) in DSC. Considering the relative volumes of the hydrophilic and hydrophobic parts of **2** it is reasonable to assume that the lamellar structures formed upon complexation of calcium ions consist of intercalated bilayers.

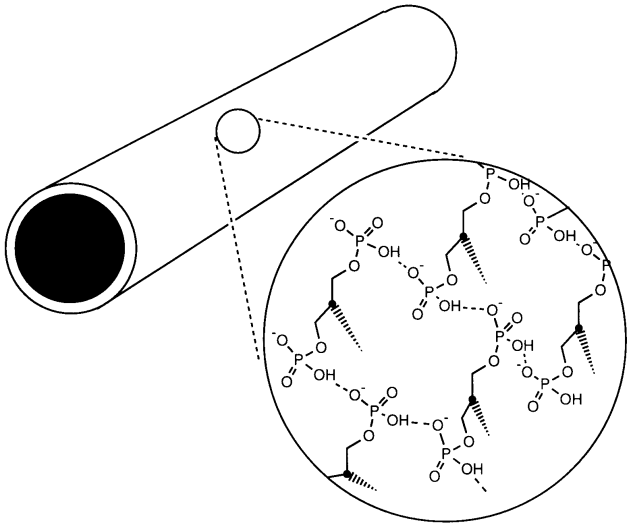

Fig. 3 Schematic representation of the possible hydrogen bonding arrangement of molecules of **2** in the fibers presented in Fig. 2(*a*,*b*). The dashed lines represent the lipophilic parts of the molecules, pointing towards the interior of the fiber.

In summary, **1** and **2** are examples of a new class of amphiphiles whose aggregation behaviour in water does not follow the structure–shape concept.[9] The extended intermolecular interactions which are possible because of the dicephalic character of the molecules lead to the formation of lamellar platelets in the case of **1** and fibres in the case of **2**. Complexation of metal ions, *i.e.* Cu^{II} ions to **1** and Ca^{2+} ions to **2**, gives rise to a change in molecular organisation resulting in the generation of lamellar structures in both cases. Further studies are underway and will be presented elsewhere.

Found: C, 70.67; H, 10.20; N, 11.99%.); *m/z* (EI) 458 (M^+); $\delta_H(CDCl_3)$ 0.88 (t, *J* 6.7, 3 H, C*H*$_3$), 1.25 [m, 28 H $CH_2(CH_2)_{14}CH_3$], 1.56 [m, 3 H, C(O)CH_2CH_2], 2.31 [t, *J* 7.5, 2 H, C(O)CH_2], 4.07 (*ABX*, 4 H, CH_2N), 5.33 (AB*X*, 1 H, C*H*–O), 6.92 (s, 1 H, 5-ImH), 7.11 (s, 1 H, 4-ImH), 7.47 (s, 1 H, 2-ImH); ν(KBr)/cm^{-1} 3100 (C–H_{Im}), 2910, 2840 (C–H), 1740 (C=O), 1530–1490 (Im).

Physical data for **2**: R_f 0.17 (silica, BuOH–AcOH–H_2O 4:1:1) (Calc. for $C_{21}H_{40}P_2O_{10}Na_4 \cdot H_2O$: C, 39.2; H, 6.84; Na, 14.3. Found: C, 39.0; H, 6.74; Na, 14.0%.); *m/z* (FB^+, free acid) 541 ($M + Na^+$); $\delta_{31P}(D_2O)$ −2.27; ν(KBr)/cm^{-1} 2910, 2860 (C–H), 1740 (C=O), 1200 (P=O).

§ **3** and **7** were prepared by acylation of the corresponding alcohols using stearoyl chloride and a catalytic amount of $AlCl_3$ (ref 12). The alcohols were prepared according to literature procedures (refs. 13, 14).

¶ The molecular structure of **3** is such that one of the bulky groups on the C(2) atom, *i.e.* the stearoyloxy group or the methylene imidazole group, blocks the incoming second imidazole group.

‖ Tetra-*n*-butylammonium dibenzyl phosphate (ref. 15) and tetraethylammonium (ref. 16) monobenzyl phosphate were used, respectively, following modified literature procedures.

** The stoichiometry of the complex was determined by monitoring the intensity of a new imidazole vibration at 1521 cm^{-1} in the FTIR spectrum upon addition of Cu^{II} ions. In addition a signal attributed to free $CuSO_4$ was observed in the EPR spectrum when the Cu^{II}:**2** ratio exceeded 0.5.

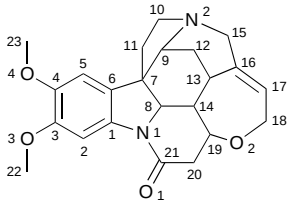
Promiscuous recognition of the hexapyranose epimers α,β-D-glucuronic and α,β-D-galacturonic acids between corrugated brucine sheets

Fokke J. J. Dijksma,[a] Robert O. Gould,*[a]† Simon Parsons,[a] Paul Taylor[b] and Malcolm D. Walkinshaw[b]

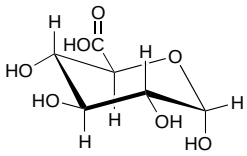
[a] *Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, Scotland, UK EH9 3JJ*
[b] *Department of Biochemistry, University of Edinburgh, Michael Swann Building, Edinburgh, Scotland, UK EH9 3JR*

The crystal structures of brucinium glucuronate and galacturonate are reported, both of which show layers of uronate between identical corrugated brucine sheets; the change of configuration at C(4) of the acid engineers a reversal in the packing mode of these sheets, while differences at C(1) appear to be relatively unimportant.

For many years the alkaloid brucine **1** has been used to separate racemic mixtures by co-crystallisation, generally with molecules containing acidic functional groups. We have previously reported a motif common to many brucine co-crystals;[1,2] this feature makes it attractive to examine the possibilities of using brucine as a co-crystallising agent for determining the structures of molecules which crystallise on their own with difficulty or not at all. Carbohydrates provide many examples of this type, and in a preliminary study, we have crystallised glucuronic **2** and galacturonic **3** acids with brucine to examine the specific interactions made. The acids **2** and **3** differ only in the configuration of the OH group at C(4). In addition, both exist in aqueous solution as an equilibrium of anomers [opposite configuration at C(1)] with the approximate anomeric ratio[3] α:β = 3:2. Advances in methods of crystal structure determination, particularly as applied to those structures containing substantial fragments of fixed and known stereochemistry,[4] make the use of brucine as a co-crystallising agent particularly attractive.

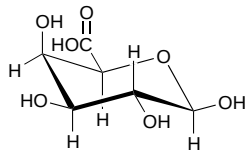


1



2

α-D-Glucuronic acid



3

β-D-Galacturonic acid

Crystals of brucinium D-glucuronate **4** and brucinium D-galacturonate **5** were obtained from an aqueous solution of an equimolar mixture of **1** and **2** or **1** and **3**. Crystals of **5** were readily obtained within two days as well-formed colourless blocks. Crystals of **4** were only obtained with much greater difficulty as colourless laths after acetonitrile was added to the solution. Both give monoclinic crystals, space group $P2_1$, with unit cell dimensions for **4**: a = 7.946(1), b = 12.660(1), c = 14.814(2) Å, β = 93.676(9)°; and for **5**: a = 7.958(4), b = 12.366(5), c = 27.639(10) Å, γ = 93.57(3)° (in order to emphasise the relationship of the two structures, **5** has been referred to a cell with c as the unique axis).‡

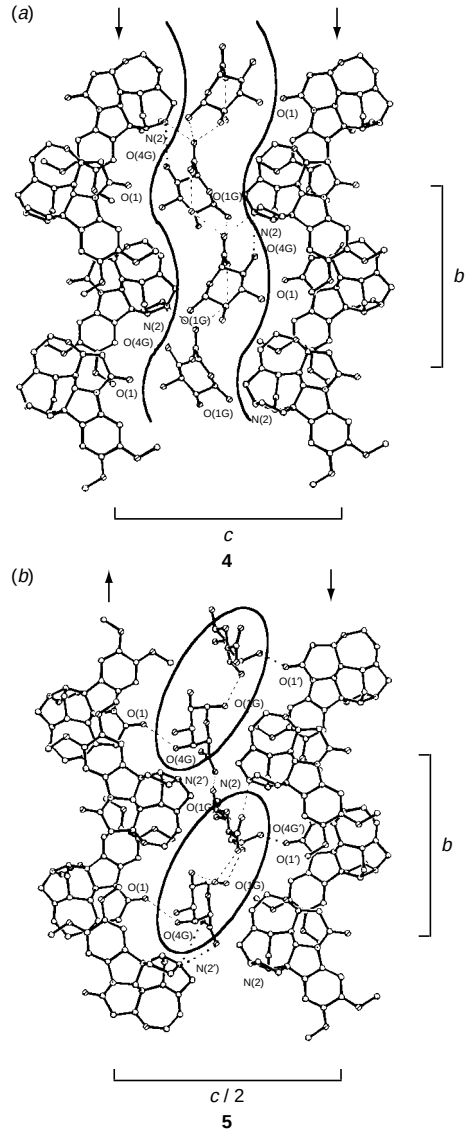


Fig. 1 A view parallel to a brucinium layer (along the *a*-axis) of the major components of **4** and **5** showing the relative polarities of the brucine sheets, the interstices between them and significant hydrogen bonds. (*a*) **4**: N(2)···O(6G): 2.851(4), N(2)···O(4G): 3.065(4), O(3W)···O(1) [$\bar{1}-x, \frac{1}{2}+y, -z$]: 2.812(4),[a] O(1G)···O(6G) [$1-x, \frac{1}{2}+y, 1-z$]: 2.794(4) O(4G)···O(3W) [$x-1, y, z$]: 2.796(4)[a]. (*b*) **5**: N(2)···O(6G): 2.719(5), N(2)···O(5G): 2.976(5), N(2′)···O(6G) [$2-x, 1-y, \frac{1}{2}+z$]: 2.781(5), N(2′)···O(7G) [$2-x, 1-y, \frac{1}{2}+z$]: 3.184(5), O(1G′)···O(7G): 2.656(5), O(4G′)···O(1) [$x, y-1, z$]: 3.035(5), O(1G)···O(3G) [$x, 1+y, z$]: 2.731(5), O(4G)···O(1) [$1-x, 1-y, z-\frac{1}{2}$]: 2.832(5), O(1W)···O(1) [$\bar{1}-x, 1-y, z-\frac{1}{2}$]: 3.169(5)[a].

[a] Not shown in figure.

Both structures show layers of brucinium ions reported previously,[1,2] with anions and solvent between the layers as shown in Fig. 1. While the uronates give many opportunities for donation and acceptance of hydrogen bonds, the brucinium ions are limited to two: donation by N(2) and acceptance by O(1) (see Fig. 1). In both structures, O(1) in brucine accepts from water, and in **5** additionally from the hydroxy group (axial) at C(4) of both independent galacturonates, which do not accept hydrogen bonds. In **4** these hydroxy groups (equatorial) donate to water and accept bifurcated bonds from N(2) of a brucinium. This proton is shared in both structures by the O(6) of a uronate; it is shared in **5** with O(5) or O(7) of a uronate. The only disorder in the crystal structures is in the region of the anomeric carbon atoms. In **4** the glucuronate ion is 82.7(8)% in the α-anomeric form. In **5** one of the galacturonate ions is essentially all in the α-anomer, while the other exists as 89.3(8)% β-anomer. These hydroxy groups show hydrogen bonding only with neighbouring uronate ions or water molecules. The water molecules are present mainly as a connecting medium for the uronates. In **5** there are three molecules of water for every one in **4**, and they partially compensate for the poorer fit of glucuronate to brucinium layers. Their requirement may explain the much slower formation of **5**.

In **4**, with one brucinium ion per asymmetric unit, the layers simply repeat along the *c*-axis, giving parallel sheets of brucinium ions and an interstice of roughly uniform thickness [Fig. 1(*a*)]. In **5**, with the unit cell nearly twice as large, there are two bruciniums in the asymmetric unit, the layers being related by the 2_1 axis parallel to the *c*-axis, while the two crystallographically independent ions in each layer are related by an approximate screw axis parallel to the *b*-axis. This antiparallel packing of layers results in the division of the interstices into channels [Fig. 1(*b*)].

The crystal structures are remarkable in showing a conserved packing of brucine moieties, although the packing and the hydrogen bonding of the sheets of water and uronate ions is very different. The configuration at C(4), which distinguishes the two ions, is crucial while the configuration at C(1) is practically irrelevant.

Reaction of phosphinoyl-activated imines: stereocontrolled synthesis of either *trans*- or *cis*-vinylaziridines

Xue-Long Hou,*† Xiao-Fang Yang, Li-Xin Dai and Xian-Feng Chen

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032, PR China

Phosphinoyl imines react with allylsulfonium ylide to provide *trans*-aziridines at room temperature and *cis*-aziridines at low temperature, in high yields and good to excellent stereoselectivities.

Aziridines are versatile building blocks that have found many uses in organic synthesis.[1] They are also an important subunit in many natural products.[2] All these factors make the synthesis of aziridines an active field of research, and recently, a number of methods have appeared in the literature for the preparation of these useful compounds. Among them the direct approach to ring formation *via* a carbene or nitrene route is more attractive because of its efficiency.[3] Similar to the carbene approach, ylide attack at a C=N bond is another useful possibility,[1b] however, the synthesis of substituted aziridines *via* an ylide route is less well explored. For example, only a few procedures have been reported for the synthesis of vinyl-substituted aziridines,[4] although the versatility in synthesis of this kind of aziridine is well documented.[5] As part of a programme aimed at the application of imines to organic synthesis, we studied the aziridination reaction using normal and *N*-tosyl-activated imines as starting materials and semi-stabilized and stabilized sulfonium ylides as reagents,[3a,b,6] and found that the ylide route is a convenient way to prepare aziridine derivatives.

In the presence of Lewis acids, aldimines reacted with allyl- and prop-2-ynyl-sulfonium ylides to deliver the corresponding *cis*-aziridines as the sole products when the substituent at nitrogen was an aryl group.[6] On the other hand, the reaction of *N*-tosyl imines with allyl- and prop-2-ynyl-sulfonium ylides also provided the corresponding aziridines, but high stereoselectivities were obtained only in the case of prop-2-ynylsulfonium ylides;[3b] *cis*- and *trans*-aziridines were afforded with lower selectivity when trimethylsilylallylsulfonium ylide was used as the starting material.[3a] Unlike the ylide epoxidation reaction, where the *trans* isomer is usually the preferred configuration, the former reaction afforded the *cis*-isomer exclusively. In order to improve the stereoselectivity of the latter reaction another imine activation group was sought. It was found that when phosphinoyl-activated imines reacted with allylsulfonium ylides, both *cis*- and *trans*-aziridines were formed with high stereoselectivity. Here we disclose the results of our studies on the stereocontrolled aziridination of phosphinoyl-activated imines *via* the ylide route.

N-Phosphinoyl imines **1**[7] reacted with [3-(trimethylsilyl)-allyl]dimethylsulfonium bromide **2** in the presence of base at room temperature to provide *trans*-vinylaziridines **3** predominantly. On the other hand, *cis*-vinylaziridines **4** were the main products when the preformed ylide prepared from [3-(trimethylsilyl)allyl]diphenylsulfonium perchlorate **5** reacted with the same imines **1** (Scheme 1, Table 1). The operation was simple and the yields of both reactions were excellent.‡

From Table 1, it can be seen that all reactions furnished the desired aziridines in satisfactory yields. Stereocontrol is realized *via* simply changing the ligands on the sulfur atom (that is, Ph or Me) and the reaction conditions. Reaction at room

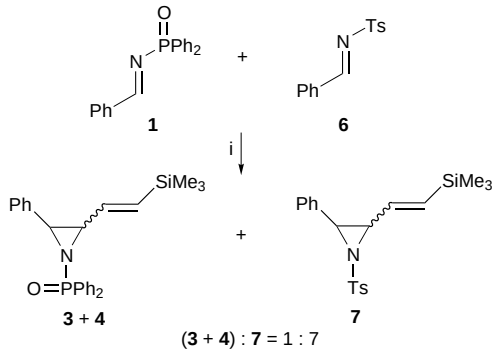

Scheme 2 *Reagents and conditions*: i, **2**, NaH, CH_2Cl_2, room temp.

temperature with the dimethylsulfonium salt provided *trans*-aziridines **3** (*trans* : *cis* = 78 : 22 to 90 : 10), even though *cis*-aziridines are considered thermodynamically more stable.[8] In this reaction, the selection of base is important. High stereoselectivity is obtained when NaH is used (entry 1), but it is lowered if KOH is used (entry 2). This might be because the use of NaH avoids the formation of water in the reaction. It was also observed that the stereoselectivity of the reaction in CH_2Cl_2 was better than that in MeCN or benzene. At low temperature, reaction of the ylide preformed from diphenyl sulfide with imines **1** gave rise to *cis*-aziridines with high stereoselectivity. Lower temperatures favored the *cis*-isomers (entries 6 and 12). In some cases the reaction furnished the *cis*-products almost exclusively (entries 7, 8 and 10). Unlike epoxidation and cyclopropanation reactions,[9] the presence of LiBr is not crucial and the stereochemistry of this reaction does not depend on whether LiBr is present or not (entries 12 and 13).

The improvement of stereoselectivity in the case of the *N*-diphenylphosphinoyl imines as compared with the *N*-tosyl imines is probably due to their different reactivity toward the attack of the allylsulfonium ylide. A competition reaction involving phosphinoylimine, tosylimine and allylsulfonium ylide shows that phosphinoylimine is less reactive than tosylimine (Scheme 2).

In summary, the $Ph_2P(O)$ moiety is a good activating group of imines for the reaction with sulfonium ylides. The advantages are (i) the stereochemistry can be greatly improved and tuned to either the *cis*- or *trans*-isomer, (ii) the *cis*- and *trans*-aziridines are easily separated by simple chromatography and (iii) the $Ph_2P(O)$ group is easily removed using acid.[10] Further investigations on the reaction mechanism and asymmetric synthesis of aziridines using *N*-phosphinoyl imines are underway.

‡ *General experimental procedure* for room temperature reaction: To a solution of sulfonium salt **2** (0.44 mmol) and phosphinoyl imine **1** (0.4 mmol) in CH_2Cl_2 (4 ml) was added NaH (15 mg, 0.6 mmol) at room temp. The resulting mixture was stirred at room temp. until the starting material **1** disappeared (monitored by TLC). Water (10 ml) was added and the mixture was extracted with CH_2Cl_2 (15 ml × 3). The organic solutions were combined and dried ($MgSO_4$). Removal of solvent under reduced pressure and chromatography (silica gel, light petroleum–EtOAc 5 : 1) afforded pure *trans*-aziridine **3** and *cis*-aziridine **4**.

General procedure for low temperature reaction: To a solution of sulfonium salt **5** (0.48 mmol) in THF (6 ml) under argon at −100 °C was added NaHMDS (2 M in THF, 0.24 ml, 0.48 mmol). The resulting mixture was stirred for 10 min. A solution of imine **1** (0.4 mmol) in THF (2 ml) was added and the stirring continued for another 1 h. The reaction temperature was then allowed to rise to room temp. Work up as above and chromatography provided pure *trans*-aziridine **3** and *cis*-aziridine **4**.

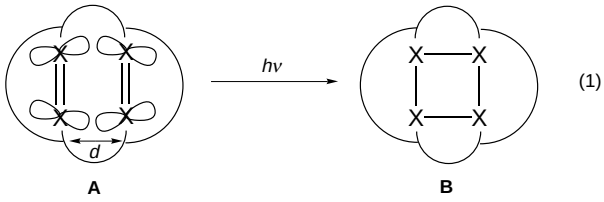
Highly efficient photometathesis in a proximate, synperiplanar diazene-diazene oxide substrate: retention of optical purity, mechanistic implications

Kai Exner and Horst Prinzbach*†

Institut für Organische Chemie und Biochemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany

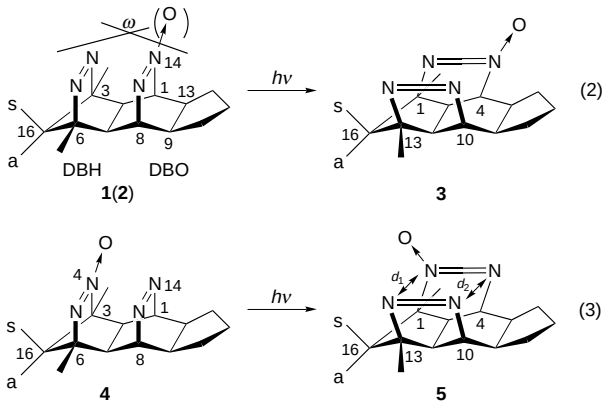
In a specifically designed proximate and almost perfectly synperiplanar diazene–diazene oxide substrate, metathesis is the exclusive photoreaction and occurs with retention of optical purity, providing support for the [π2 + π2]photocycloaddition pathway (tetrazetidine oxide intermediate).

An intriguing discrepancy between rigid, proximate (*d*), synperiplanar (*ω*) dienes **A** (X = CR) and bisdiazenes **A** (X = N) is the contrasting propensity for [π2 + π2] photocycloaddition (**A** → **B**).[1] The ease of N_2 extrusion is the main reason for the repeated failure to achieve diazene + diazene → tetrazetidine photocycloaddition [reaction (1)].[2,3]



(1)

We have recently reported that in the specifically designed very proximate and nearly synperiplanar bisdiazene **1** with its very favourable stereoelectronic prerequisites (*d* = 2.822 Å, *ω* = 174.2°, X-ray), N_2 elimination still precludes the [π2 + π2] photocycloaddition, but that some photometathesis of its oxide **2** (→ **3**) does occur (2%) [reaction (2)], most probably through the tetrazetidine oxide.[4] Given the quantum yields Φ_{-N_2} of 1.00 and 0.02, respectively, for the N_2 elimination from the parent 2,3-diazabicyclohept-2-ene (DBH) and 2,3-diazabicyclooct-2-ene (DBO),[5] the cycloaddition (metathesis) of the isomeric oxide **4** with its oxidized DBH- and 'reluctant' DBO-subunits was expected to be more successful [reaction (3)]. The synthesis of **4** as a racemate and as the (+)-enantiomer and the experimental verification of the above hypotheses are the subjects of this communication.[6]

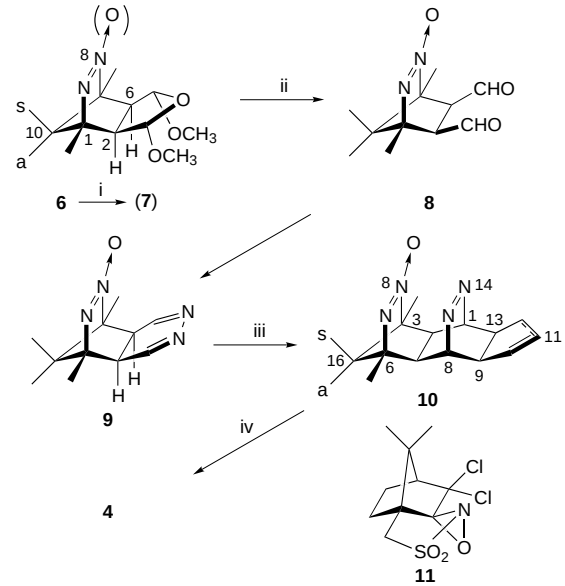


(2)

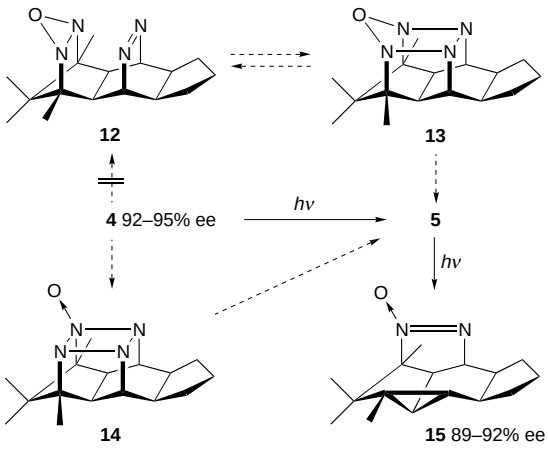
(3)

Since monooxidation of bisdiazene **1** had exclusively occurred in the DBO section to give **2**, the isomer **4** was prepared starting with **6**[4] (Scheme 1). The quantitatively obtained oxide *rac*-**7** [λ_{max} (CH_3CN)/nm 230 (ε/dm^3 mol^{-1} cm^{-1} 5980)] was then transformed into the diazene-diazene oxide **10** (mixture of diastereomers [λ_{max} (CH_3CN)/nm 236 (ε 3340), 387 (82)] *via* dialdehyde **8** and dihydropyridazine **9** (mixture of trimers) following the procedure for the preparation of **1**. Yet, hydrogenation (catalytic, N_2H_2) of the cyclopentene ring in **10** could not be effected without partial deoxygenation (→ **1**). Typical for the rigid, colourless, crystalline *rac*-**4**, obtained in *ca.* 50% yield after chromatography and crystallisation ($CHCl_3$–*n*-hexane), are *inter alia* the small H,H coupling constants ($J_{1,2\ (1,13)}$ = $J_{7,8\ (8,9)}$ = 1.6 Hz) and the *m*/*z* = 141 fragment in the EIMS spectrum (3,4,4,5-tetramethyl-4*H*-pyrazole 1-oxide + H$^+$, 100%). In the UV spectra (CH_3CN) of **10** (**4**) the distinct N=NO π,π* maxima at 237(236) nm [ε 3780(2340)] and the N=N n,π* maxima at 387(387) nm [ε 82(81)], when compared with the N=NO absorption of **7** and the n,π* maximum for the parent DBO [λ_{max}(*n*-hexane)/nm 378 (ε 182)], can be taken as evidence for a weak transannular N=N/N=NO interaction. Note that **2** and **4**, upon heating to their melting temperature (260/264 °C), remained unchanged; there was no indication for their interconversion or for their common [4 + 2] oxazolidine cycloadduct;[7] at even higher temperatures neat N_2 elimination (**2**) or oligomerization (**4**) occurred.

In line with expectation n,π* excitation (solidex vessel, CH_3OH, 150 W Hg high pressure lamp, 25 °C) for several hours left **4** unchanged; denitrogenation was obviously very much slower than in isomer **2**. Monochromatic π,π* excitation (254 nm, quartz vessel, CH_3OH, Hanau TNN 15 lamp, 25 °C)



Scheme 1 *Reagents and conditions*: i, (±)-**7**: DMDO, CH_2Cl_2–Me_2CO, rt, quant.; (+)-**7**: (+)-**11**, 14 kbar, 65 °C, 12 d, ethyl acetate, 75%, 92–95% ee; ii, 1 M H_2SO_4, reflux, used as CH_2Cl_2 solution of the hydrate; N_2H_4, 10 equiv., K_2CO_3, 100 equiv. CH_2Cl_2, 0 °C; iii, TFA (1 equiv.), cyclopentadiene (*ca.* 500 equiv.), CH_2Cl_2, 4 °C, 62%; iv, H_2/MeOH/Pd/C (10%), rt, 66%



Scheme 2 Photochemistry of (chiral) bisdiazene oxide **4** and its isomer **5** (254 nm low pressure Hg lamp, MeOH, rt)

generated, in up to *ca.* 10% conversion exclusively, the metathesis isomer **5** (TLC, NMR) which was chromatographically isolated as colourless crystals [λ_{max} (CH_3CN)/nm 239 (ε 5510, π,π* N=NO), 346 (ε 172, n,π* N=N)]. With increasing conversion, denitrogenation of **5** to give **15** (70–75% was isolated in the crystalline form) and oligomers (25–30%) became important (Scheme 2). By separate irradiation of **5** it was ascertained that **15** indeed was a secondary photoproduct. The skeletal changes in going from **4** to the more mobile **5** with the most stable calculated (B3LYP/6-31G*) conformation at d_1 = 3.142 and d_2 = 2.950 Å (ω = 161.4°) are manifested *inter alia* by the relatively large H,H coupling constants $J_{4,5}$ = 5.9, $J_{4,15}$ = 6.4, $J_{9,10}$ = 9.2, $J_{10,14}$ = 7.0 Hz and the hypsochromic displacement of the N=N n,π* absorption.[8]

Of the two pathways shown in Scheme 2 for the metathesis **4** → **5**, the route featuring the C_s symmetrical **12** and **13** as intermediates could be put to experimental test with optically active **4**. After futile attempts to oxidize **6** enantioselectively using Sharpless[9] and Jacobsen[10] methods, with percamphanic acid[11] or the chiral oxaziridine **11**,[12] the application of high pressure to the reaction of **6** with **11** brought the solution: chiral oxide **7** was isolated with 92–95% ee (Chiralcel AD, propan-2-ol–*n*-hexane 1 : 3). After standard synthesis of (+)-**4** and photolysis, the retention of the optical purity was established for (−)-**15** (89–92% ee, Chiralcel AD, the enantiomers of **4** and **5** could not be sufficiently separated). Experiments for the low-temperature (matrix) characterisation of the tetrazetidine oxide **14** as the most plausible intermediate are in progress.[13]

The synthesis and structure of $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$: a bridging oxo complex in a system that yields terminal sulfido and selenido counterparts

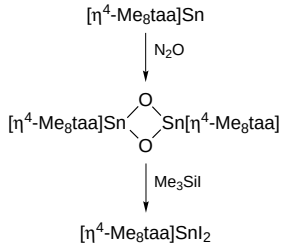
Matthew C. Kuchta, Tony Hascall and Gerard Parkin*†

Department of Chemistry, Columbia University, New York, New York 10027, USA

Oxo transfer from N_2O to divalent $[\eta^4\text{-}Me_8taa]Sn$ (Me_8taaH_2 = octamethyldibenzotetraaza[14]annulene) yields the oxo complex, $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$; the bridging nature of the oxo ligand provides a marked contrast with the terminal sulfido and selenido counterparts, $[\eta^4\text{-}Me_8taa]SnE$ (E = S, Se).

Terminal chalcogenido complexes of the transition[1] and main group[2] elements are presently a major focus of our research. For example, with respect to the main group elements, we have employed (*i*) the sterically demanding tris(3,5-di-*tert*-butyl)pyrazolylhydroborato ligand to enable the isolation of terminal chalcogenido complexes of gallium and indium, *i.e.* $[Tp^{Bu^t_2}]GaE$ (E = S, Se, Te),[3] and $[Tp^{Bu^t_2}]InSe$,[4] and (*ii*) the macrocyclic octamethyldibenzotetraaza[4]annulene ligand to support terminal chalcogenido complexes of germanium and tin, *i.e.* $[\eta^4\text{-}Me_8taa]GeE$ (E = S, Se, Te)[5] and $[\eta^4\text{-}Me_8taa]SnE$ (E = S, Se).[6,7] In this paper, we report the synthesis of the tin oxo counterpart, and describe X-ray diffraction studies which demonstrate that, unlike the [Sn=S] and [Sn=Se] functionalities, the corresponding terminal [Sn=O] moiety is unstable with respect to bridging.

Considering that the terminal sulfido and selenido complexes, $[\eta^4\text{-}Me_8taa]SnE$ (E = S, Se) are readily obtained by reaction of $[\eta^4\text{-}Me_8taa]Sn$ with the elemental chalcogens,[6] it was anticipated that the related oxo species could be generated by the reaction of $[\eta^4\text{-}Me_8taa]Sn$ with an appropriate oxo transfer reagent. Indeed, $[\eta^4\text{-}Me_8taa]Sn$ was found to react cleanly with N_2O to give the orange oxo complex, $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$ (Scheme 1).[8] However, in contrast to the monomeric terminal sulfido and selenido complexes, X-ray diffraction studies revealed that the oxo counterpart is dimeric, with bridging oxo ligands (Fig. 1).[9,10] Tin complexes with bridging oxo ligands are common, as illustrated by the cyclic 'stannoxanes', $[R_2Sn(\mu\text{-}O)]_n$, but are typically obtained by hydrolysis of tetravalent halide precursors, R_2SnX_2,[11] rather than by reactions of divalent precursors with oxo transfer reagents. A notable exception, however, is Lappert's synthesis of $\{[(Me_3Si)_2CH]_2Sn(\mu\text{-}O)\}_2$ by reaction of $[(Me_3Si)_2CH]_2Sn$ with Me_3NO.[12,13] In addition to the similar method of synthesis, another feature that is common to both $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$ and $\{[(Me_3Si)_2CH]_2Sn(\mu\text{-}O)\}_2$ is the presence of a four-membered $[Sn_2O_2]$ ring. More typically, stannoxanes exist as cyclic trimers with six-membered $[Sn_3O_3]$ rings, as exemplified by $[Mes_2Sn(\mu\text{-}O)]_3$,[14] $[R_2Sn(\mu\text{-}O)]_3$ (R = Bu^t, Me_2EtC),[15] $[(Me_3Si)_3C(Me)Sn(\mu\text{-}O)]_3$,[16] $[\{2,4,6\text{-}(CF_3)_3C_6H_2\}_2Sn(\mu\text{-}O)]_3$,[17] and $[(2,6\text{-}Et_2C_6H_3)Sn(\mu\text{-}O)]_3$.[18,19]



Scheme 1

The observation that the oxo ligand in the $\{[\eta^4\text{-}Me_8taa]SnE\}$ system bridges more readily than does either the sulfido or selenido ligands is particularly interesting, especially in view of the notion embodied by the so-called 'classical double bond rule', one version of which cites: 'elements having a principal quantum number greater than 2 should not be able to form $(p\text{–}p)\pi$ bonds to themselves or with other elements.[20] Furthermore, it is noteworthy that all other structurally characterized multiply bonded terminal chalcogenido complexes of tin are restricted to the heavier congeners,[21] with no examples of terminal oxo derivatives; as noted above, however, bridging oxo complexes of tin are well precedented. Regardless of whether or not monomeric $\{[\eta^4\text{-}Me_8taa]SnO\}$ is an intermediate in the reaction of $[\eta^4\text{-}Me_8taa]Sn$ with N_2O, the structures of $\{[\eta^4\text{-}Me_8taa]SnE\}_n$ suggest that the terminal [Sn=O] moiety is significantly more prone to participate in bridging than is either the [Sn=S] or [Sn=Se] functionalities. Albeit limited, there are other observations which also suggest that the oxo ligand shows a greater propensity to act as a bridging functionality in main group chemistry than do the heavier chalcogenido ligands. For example, the germanium sulfido complex $[\eta^3\text{-}\{(\mu\text{-}Bu^tN)_2(SiMeNBu^t)_2\}]GeS$ exists as a monomer, whereas the oxygen analogue is dinuclear with oxo bridges.[22] Likewise, the sulfido and selenido complexes $Ph(\eta^2\text{-}C_{10}H_6NMe_2)SiE$ (E = S, Se) are monomeric, while the oxygen counterpart is trinuclear with a six-membered Si_3O_3 ring.[23] Such behaviour is completely counter to that observed in transition metal systems, where the oxo ligand shows the least tendency to bridge,[24] with terminal oxo complexes being considerably more abundant than terminal sulfido, selenido, and tellurido derivatives.[1] A possible explanation for this difference between oxo complexes of the main group and transition elements is associated with the polarity of

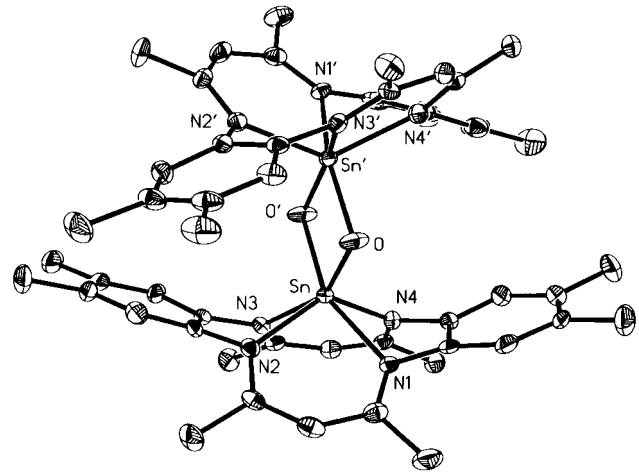


Fig. 1 Molecular structure of $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$. Selected bond lengths (Å) and angles (°): Sn–O 2.001(5), Sn–O′ 1.987(5), Sn–N1 2.220(6), Sn–N2 2.142(7), Sn–N3 2.256(7), Sn–N4 2.169(7); O–Sn–O′ 80.1(2), Sn–O–Sn′ 99.8(2).

the M–O bonds. Specifically, oxo ligands bound to electropositive main group elements may be expected to bear a substantial negative charge,[25,26] especially if the metal center has a coordination number greater than three, such that p_π–p_π overlap is unfavourable. For such a situation, the resonance structure $[\overset{+}{M}–\overline{O}]$ is an appropriate description of the bonding, and the existence of this dipole would be expected to promote oxo bridging. Transition metal oxo complexes, however, do not normally exhibit such a high degree of polarity due to favourable d_π–p_π overlap (*i.e.* a contribution from the resonance structure $[\overset{-}{M}\equiv\overset{+}{O}]$) which serves to reduce the $[\overset{\delta+}{M} \sim \overset{\delta-}{O}]$ polarity of the bond.[27,28] Since the $[\overset{+}{M}–\overline{E}]$ resonance structure for main group chalcogenido complexes would be expected to be most significant for oxo derivatives,[29] the propensity for bridging is likewise expected to be greater for oxo complexes than for the heavier chalcogenido counterparts.

Finally, it is noteworthy that the bridging oxo ligand of $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$ is readily abstracted by treatment with excess Me_3SiI to give $[\eta^4\text{-}Me_8taa]SnI_2$ (Scheme 1), a complex that has previously been synthesized by oxidative addition of I_2 to $[\eta^4\text{-}Me_8taa]Sn$.[30]

In summary, oxo transfer from N_2O to divalent $[\eta^4\text{-}Me_8taa]Sn$ yields the bridging oxo complex, $\{[\eta^4\text{-}Me_8taa]Sn(\mu\text{-}O)\}_2$. Since the sulfido and selenido counterparts are mononuclear, it is evident that the oxo ligand in this system shows the greatest propensity to bridge. Such behavior is in marked contrast to that typically observed in transition metal systems.

We thank the National Science Foundation (CHE 96-10497) for support of this research. G. P. is the recipient of a Presidential Faculty Fellowship Award (1992–1997).

24 For example, compare the terminal oxo complexes $[Cp^{Me}]_2MoO$[24a] and $[Cp^{Bu^t}]_2MoO$[24b] with the bridging chalcogenido complexes $\{[Cp^{Bu^t}]_2\text{-}Mo(\mu\text{-}E)\}_2$ (E = S, Se, Te). (*a*) N. D. Silavwe, M. Y. Chiang and D. R. Tyler, *Inorg. Chem.*, 1985, **24**, 4219. (*b*) J. H. Shin and G. Parkin unpublished results.

25 Furthermore, theoretical studies on three-coordinate $H_2M{=}O$ (M = Ge, Sn, Pb) complexes have indicated that both the σ- and π-bonds are polarized towards oxygen. See: J. Kapp, M. Remko and P. v. R. Schleyer, *J. Am. Chem. Soc.*, 1996, **118**, 5745; G. Trinquier, M. Pelissier, B. Saint-Roch and H. Lavayssiere, *J. Organomet. Chem.*, 1981, **214**, 169; G. Trinquier, J.-C. Barthelat and J. Satge, *J. Am. Chem. Soc.*, 1982, **104**, 5931.

26 For additional theoretical studies on $H_2M{=}O$ (M = Si, Ge, Sn, Pb), see: J. Kapp, M. Remko and P. v. R. Schleyer, *Inorg. Chem.*, 1997, **36**, 4241.

27 W. A. Nugent and J. M. Mayer, *Metal–Ligand Multiple Bonds*, Wiley-Interscience, New York, 1988.

28 Certain early and late transition metal oxo complexes are, however, believed to be best represented by the $[\overset{+}{M}–\overline{O}]$ resonance structure, *e.g.* $Cp^*_2Zr(O)(NC_5H_5)$[28a] and (dppp)(L)PtO.[28b] (*a*) W. Howard and G. Parkin, *J. Am. Chem. Soc.*, 1994, **116**, 606; (*b*) M. A. Andrews, G. L. Gould and E. J. Voss, *Inorg. Chem.*, 1996, **35**, 5740.

29 The relative contribution of the $[\overset{+}{M}–\overline{E}]$ resonance structure would be most significant for the oxo derivative due to (*i*) the greater electronegativity of oxygen which stabilizes the negative charge, and (*ii*) the shorter M–O bond length which results in a greater Coulombic stabilization. See ref. 28(*a*).

A Ga_4N_8 cage structure formed by reaction of trimethylgallium with phenylhydrazine

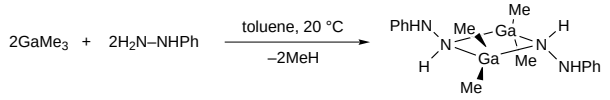
David W. Peters,[a,b] Maurice P. Power,[a] Edith D. Bourret[b] and John Arnold*[a,b]†

[a] *Department of Chemistry, University of California, Berkeley, California 94720-1460, USA*
[b] *Materials Sciences Division, Lawrence Berkeley National Laboratory, California 94720, USA*

Methane elimination during thermolysis of $GaMe_3$ with $PhHNNH_2$ yields sequentially dimeric $[Me_2Ga\{\mu\text{-}N(H)N(H)Ph\}]_2$, tetrameric $[MeGa\{\mu\text{-}N(H)NPh\}]_4$ and, ultimately, GaN; the X-ray structure of the tetramer shows a novel Ga_4N_8 cage.

A number of research groups have investigated the chemistry of molecules containing Ga–N bonds,[1–5] with most of the recent emphasis directed at using these compounds as single-source precursors to the wide bandgap semiconductor GaN.[6–13] Here we describe some new results on the use of hydrazines as a source of nitrogen including the formation of two intermediates formed on elimination of 1, then 2 equiv. of methane during the thermolysis reaction between $GaMe_3$ and $PhHNNH_2$. Both complexes have been isolated and fully characterized and the latter is shown to have an unusual structure featuring a cage with a Ga_4N_8 core;[14] this species eliminates a final equivalent of methane to form GaN at higher temperatures.

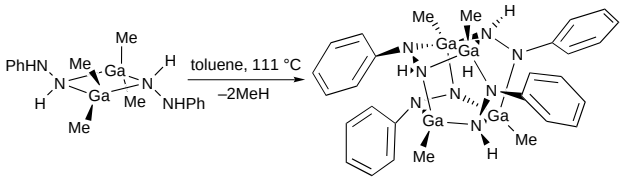
As shown in Scheme 1, 1 equiv. of methane is eliminated in the reaction of $GaMe_3$ and $PhHNNH_2$ at room temperature in toluene. We saw no evidence for the presumed monomeric intermediate 'Me_2Ga–N(H)N(H)Ph', instead the colorless dimeric product was isolated in 88% yield.[15]



Scheme 1

The solid-state structure of the dimer is very similar to that of the closely related species $[Et_2Ga\{\mu\text{-}N(H)NPh_2\}]_2$, prepared by the metathesis reaction between Et_2GaCl and $LiN(H)NPh_2$,[11] with both compounds crystallizing as *anti* conformers.[16]

Upon further heating, the dimer undergoes a second methane elimination reaction as shown in Scheme 2.



Scheme 2

As monitored by ^1H NMR spectroscopy, the reaction proceeds in a quantitative fashion and microcrystalline product, which is much less soluble than the starting material, precipitates from the reaction solvent in 84% yield.[15] The ^1H NMR spectrum shows a simple pattern consistent with only single methyl, N–H and phenyl environments[15] and we saw no evidence of fluxional behavior between −80 and 110 °C. Since these data were insufficient to unambiguously determine the structure of the molecule, an X-ray study was carried out.

Crystals of $[MeGaN(H)NPh]_4$ were grown by thermolysis of $[Me_2GaN(H)N(H)Ph]_2$ in toluene at 105 °C.[17] The solid state structure, shown in Fig.1, consists of a tetrameric unit that resides on the intersection of three mutually perpendicular mirror planes. The geometry about gallium is distorted tetrahedral, with angles ranging from 121.3(1) [N(1)–Ga(1)–C(1)] to 94.4(1) [N(2*)–Ga(1)–N(2*)]. The bond length of Ga to the four-coordinate N(2*) [1.993 (3) Å] is longer than that to the three-coordinate N(1) [1.914(2) Å], although the mean Ga–N distance of 1.966(3) Å falls within the reported range for gallium amido complexes.[1–5] The N–N bond length of 1.489(3) Å is longer than in the only other crystallographically characterized Ga hydrazide complex $[Et_2Ga\{\mu\text{-}N(H)NPh_2\}]_2$, [1.457(8) and 1.446(8) Å][11] and is somewhat longer than predicted for a N–N single bond (1.454 Å), a result that may be attributed to the bridging nature of the hydrazine ligand[18] in the cage species. Owing to the high quality of the data obtained, the hydrazine hydrogen was located in the Fourier difference map and refined isotropically. Fig. 2 shows a view of the unit cell which highlights the rather large open core of the structure (*ca.* 4.5 Å) and the fact that there are no unusually short intermolecular contacts. We are unaware of previous reports of such a cage structure for Ga, although we note that a related boron compound $[Bu^tBN(H)N(H)]_4$ was characterized some time ago.[19]

Thermolysis of the cage complex at 700 °C under a hydrogen atmosphere leads to the formation of hexagonal GaN (identified

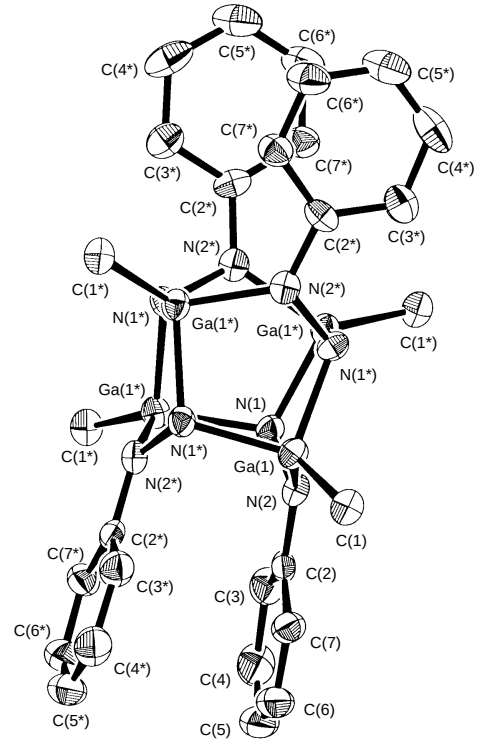


Fig. 1 X-Ray crystal structure of $[MeGaN(H)NPh]_4$

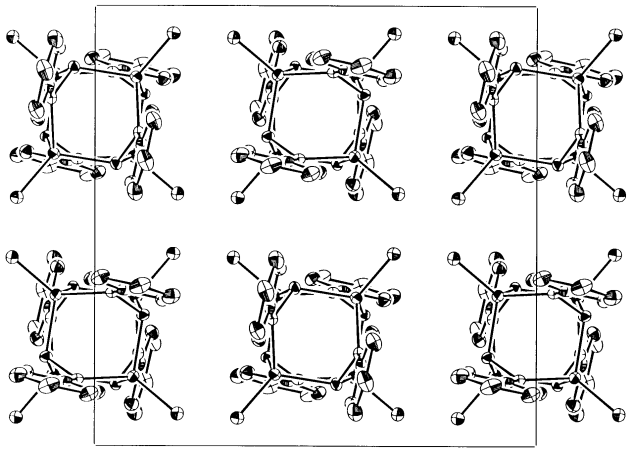

Fig. 2 Unit cell of $[MeGaN(H)NPh]_4$

by powder X-ray diffraction by comparison to a standard sample in the JCPDS database) along with a mixture of unidentified volatile organic fragments. Further studies are in progress and will be described in a more detailed account.

We thank the donors of the Petroleum Research Fund (administered by the American Chemical Society) for partial support of this work.

Side-chain hydrophobicity controls the activity of proton channel forming rigid rod-shaped polyols

Chiyou Ni and Stefan Matile*†

Department of Chemistry, Georgetown University, Washington, D.C. 20057-1227, USA

Increased activity, facile incorporation into lipid bilayers and intact active structure and transport selectivity are the consequences of modifications of the side-chain hydrophobicity of a proton channel-forming octa(*p*-phenylene).

Rigid-rod molecule **1**[1,2] represents a promising new class of non-peptide ion channel models[3–5] with unique properties, but unfortunately it does not incorporate well into lipid bilayers (Fig. 1). Although the incorporation of artificial ion channels into lipid bilayers is a general problem, it is often bypassed by using high temperatures or constructing the entire supramolecular assay system in the presence of the test sample for every new experiment. Rational design strategies to tune partition without changing desired properties of a parent model have not been established so far, in spite of the fact that poor incorporation may prevent potential biological studies and pharmaceutical applications. Here we present our efforts to solve this problem by increasing the hydrophobicity of lateral side-chains attached to oligo(*p*-phenylene)s without destructive effects on active structure or transport selectivity.

In addition to the general aim to increase the lipophilicity of octamer **1**, the following considerations were taken into account for the design of the new side-chains in **2** and **3** (Fig. 1). We anticipated that length and flexibility of the propylene spacer in polyol **2** could facilitate the arrangement of the diols to form the transmembrane hydrogen-bonded chain[6] essential for proton selectivity.[2] It further may enlarge the ionophoric tube between the rigid-rod scaffold and 'proton wire'. The additional propyl group at the terminus of each side-chain in **3** possibly covers the hydrophilic 'proton wire' with an external lipophilic layer.

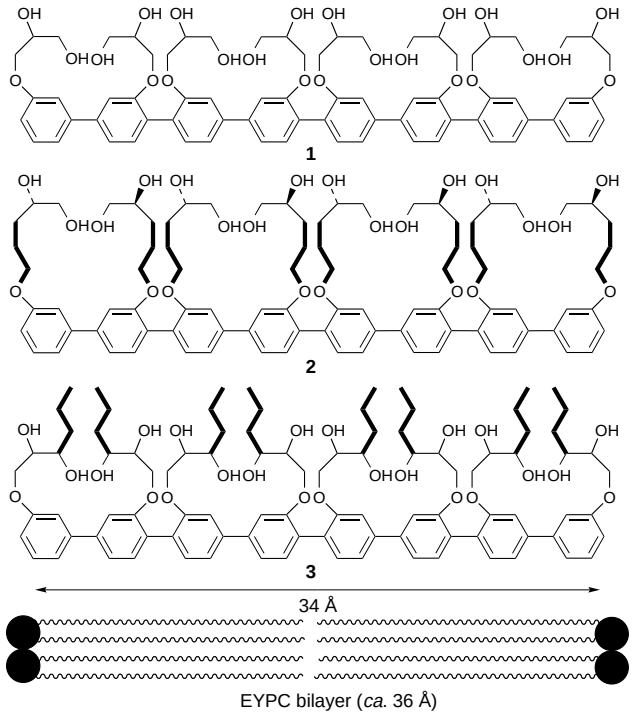

Fig. 1 In-scale planar structures of membrane-bound octa(*p*-phenylene)s **1**–**3**. Structural modifications of the side-chains are emphasized with bold lines.

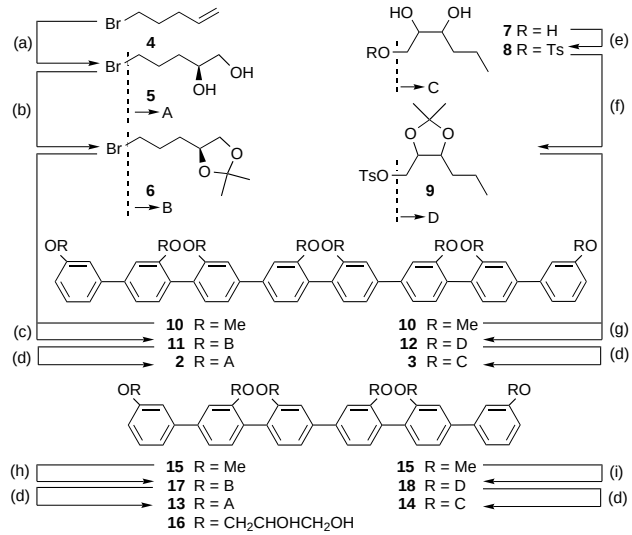
Syntheses of the octamers **2** and **3** are shown in Scheme 1. For **2**, bromide **4** was subjected to Sharpless asymmetric dihydroxylation,[7]‡ and the resulting diol **5** was converted to acetonide **6**. For **3**, the diastereomeric mixture of triol **7** was selectively tosylated, and protection of the resulting diol **8** afforded **9**. Williamson ether synthesis using **6**/**9** and the crude octaphenol prepared by treatment of **10** with BBr_3,[1] followed by deprotection of **11**/**12**, yielded the polyols **2**/**3**, respectively. The corresponding hexamers **13** and **14** were prepared identically from hexaanisole **15**.§

The interaction of the fluorophores **1**–**3** with lipid bilayers was examiend using uniformly sized (68 ± 3 nm) EYPC-SUVs labeled with either 2 mol% 5- or 12-DOXYL-PC.[8,2]¶ Quenching of *ca.* 60% of the red-shifted emission of **2** and **3** by 5-DOXYL-PC labeled EYPC-SUVs proved facile incorporation compared to **1** (Fig. 2). Nearly identical quenching of **1**–**3** by 5-DOXYL-PC and 12-DOXYL-PC (not shown) confirmed that variation of side-chain hydrophobicity does not disturb the preferred transmembrane orientation of **1**–**3**.

In sharp contrast to the membrane-spanning octamers **1**–**3** (34 Å), the side-chain structure governs the organization of the corresponding hexamers (26 Å) in EYPC-bilayers. Namely, **16** was found at the membrane/water interface (quenching by 12-DOXYL-PC < 5-DOXYL-PC),[2] **13** in transmembrane orientation [12-DOXYL-PC (67%) ≈ 5-DOXYL-PC (69%)], and **14** between the two leaflets of the lipid bilayer [12-DOXYL-PC (49%) > 5-DOXYL-PC (26%)].



Scheme 1 *Reagents and conditions*: (a) AD-mix-α, 71%; (b) 2,2-dimethoxypropane, H_2SO_4, 80%; (c) (1) BBr_3; (2) **6**, Cs_2CO_3, 66%; (d) TFA (quant.); (e) TsCl, pyridine, 65%; (f) 2,2-dimethoxypropane, H_2SO_4, 83%; (g) (1) BBr_3; (2) **9**, Cs_2CO_3, 27%; (h) see (c), 15%; (i) see (g), 27%

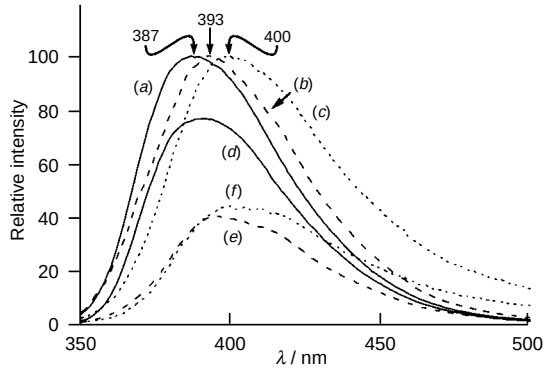


Fig. 2 Relative emission intensities [I/I (λ^{e}_{max}) × 100%, λ_{ex} = 328 nm) of 5 μM solutions of **1** (*a*), **2** (*b*), and **3** (*c*) with 0.5 mM of unlabeled EYPC-SUVs, and of **1** (*d*), **2** (*e*) and **3** (*f*) with 5-DOXYL-PC labeled EYPC-SUVs (100 mM KCl, 100 mM HEPES, pH 7.1)

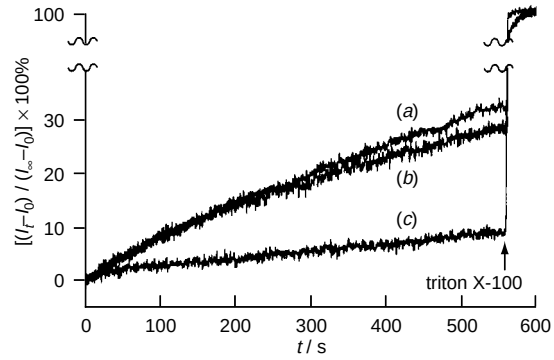

Fig. 3 Change in fluorescent intensity {[(I_t–I_0)/(I_∞–I_0)] × 100%, λ_{ex} = 460 nm, λ_{em} = 510 nm} of EYPC-SUV-entrapped HPTS (100 mM KCl, 100 mM HEPES, pH_{in} = 7.0, pH_{out} = 7.6) as a function of time after the addition of 10 nmoles of octa(*p*-phenylene)s **1** (*c*), **2** (*b*) and **3** (*a*) in 20 μl MeOH followed by 40 μl of 1.2% triton X-100¶

The ion transport activity of polyol **1** was originally assessed in comparison with the structurally related antifungal polyol amphotericin B (AmB).[1] Both mediated intravesicular pH changes with comparable exchange rates (**1** > AmB) when added to EYPC-SUVs having entrapped pH sensitive fluorophore HPTS and a transmembrane pH gradient.[1] The K^+/Na^+ > H^+ selectivity of AmB was shown by accelerated internal pH changes in the presence of a selective H^+ carrier,[9,1] while similar enhancements induced by the presence of the K^+ carrier valinomycin demonstrated proton selectivity for **1**.[2]

For direct comparison with incorporation efficiencies of polyols **1**–**3** (Fig. 2), we conducted the activity measurements summarized above under the conditions used for fluorescence quenching, *i.e.* reduced polyol and increased lipid concentrations compared to previous reports.[1,2] Under these conditions, the transport activity of **1** without additional valinomycin is nearly identical with the negative control ($k = 9.0 \times 10^{-6}$ s^{-1}, Fig. 3).‖ Improved incorporation (Fig. 2) resulted in significantly increased ion flux rates for octamer **2** ($k = 2.2 \times 10^{-4}$ s^{-1}) and **3** ($k = 2.4 \times 10^{-4}$ s^{-1}, Fig. 3). For all octamers (**1**–**3**), accelerated internal pH changes in the presence of 12 nM valinomycin were observed as reported before for polyol **1** (not shown).[2] Thus, the difference in side-chain lipophilicity of **2** and **3** does not significantly alter the proton selectivity previously observed for **1**.‖

These results demonstrate that the incorporation of proton channel forming rigid-rod octa(*p*-phenylene)s into lipid bilayers can be precisely tuned without significant disturbance of active structure and transport selectivity. The erratic interactions of identically modified hexa(*p*-phenylene)s with lipid bilayers further corroborate the importance of the length of the rigid-rod scaffold for controlled, transmembrane binding of substituted oligo(*p*-phenylene)s. Ion channel formation of octamers **1**–**3**, but not hexamer **16** in planar lipid bilayers supports these conclusions and will be reported in due course.

We thank NIH (GM56147-01), the donors of the Petroleum Research Fund, administered by the American Chemical Society, Suntory Institute for Bioorganic Research (SUNBOR Grant), and Georgetown University for support of this work. Both authors thank Dr Naomi Sakai for invaluable discussions and experimental advise.

Notes and References

‡ The stereochemistry of the side-chain is with all likelihood irrelevant for the transport activity of rigid-rod polyols.[2] However, judging from the outcome of osmium-catalyzed asymmetric dihydroxylation of terminal olefins, formation of the *S*-enantiomer **5** in 78–97% ee can be expected using AD-mix-α.[7]

§ All final products were purified by reverse-phase HPLC and gave satisfactory spectroscopic data.

¶ Abbreviations: AmB: amphotericin B; 5-DOXYL-PC: 1-palmitoyl-2-stearoyl(5-DOXYL)-*sn*-glycero-3-phosphocholine; 12-DOXYL-PC: 1-palmitoyl-2-stearoyl(12-DOXYL)-*sn*-glycero-3-phosphocholine; EYPC: egg yolk phosphatidylcholine; HPTS: 8-hydroxypyrene-1,3,6-trisulfonic acid; SUV: small unilamellar vesicle.

‖ In all experiments conducted with HPTS, the intensity change was confirmed to be the consequence of internal pH change by simultaneous measurement of the time course of emission intensity at 510 nm due to excitation at 460 nm as well as 405 nm. The contribution of the negative control was eliminated for the calculation of the initial first-order rate constants. The effect of valinomycin further corroborates the absence of HPTS-leakage.[2]

Novel synthesis and new chemistry of naphthochlorins

Bénédicte Krattinger, Daniel J. Nurco and Kevin M. Smith*†

Department of Chemistry, University of California, Davis, CA 95616, USA

Reactions of 2-nitro-5,10,15,20-tetraphenylporphyrin with alkyl α-isocyanoacetates afford naphthochlorins (in addition to the expected pyrroloporphyrins) which undergo free radical dimerization; the X-ray structure of one such naphthochlorin dimer is reported.

Tetrapyrrole macrocycles bearing fused aromatic rings have attracted considerable attention, with examples including benzoporphyrins,[1] benzochlorins,[2] pyrroloporphyrins,[3a,b] naphthoporphyrins,[4] naphthochlorins[5] and others.[6] Many of these possess long wavelength absorptions and are therefore potential candidates as second generation photodynamic therapy photosensitizers.[7] The approaches to naphthochlorins described to date have involved acid-catalyzed intramolecular cyclizations. Thus, naphthochlorins were prepared from Ni^{II} and Cu^{II} 2-formyl-TPPs[5b–d] and from Ni^{II} 2-vinyl-TPPs.[5a] Herein we report a novel base-promoted reaction which affords naphthochlorins; we also show that naphthochlorins possess novel free-radical chemistry wherein, in the presence of oxygen, a unique covalently linked naphthochlorin dimer is obtained. This naphthochlorin dimer represents the first example of a β–β′ linked bis(chlorin).

Nitroalkenes have been shown to react with α-isocyanoacetates to give pyrroles.[3c] Treatment of nitroporphyrin **1** with methyl or ethyl α-isocyanoacetate has been shown to afford pyrroloporphyrins **2** and **3**.[3a,b] Under similar reaction conditions we have now discovered that reaction of **1** with *tert*-butyl α-isocyanoacetate affords the expected pyrroloporphyrin **4**‡ in 32% yield and an additional porphyrinic product, the naphthochlorin **5**,‡ in 19% yield. Since our reaction conditions involved basic rather than acidic conditions it is necessary to postulate a new mechanistic route for naphthochlorin formation (Scheme 1). We propose that addition of the *tert*-butyl α-isocyanoacetate anion to nitroporphyrin **1** gives nitrochlorin **6** which eliminates HNO_2 to afford porphyrin **7**. Further reaction of DBU with porphyrin **7** yields chlorin **8** which subsequently undergoes two electrocyclic rearrangements (Scheme 1) to afford naphthochlorin **5**. Test reactions confirmed that naphthochlorin **5** did not arise from pyrroloporphyrin **4**. Further reaction of nitroporphyrin **1** [refluxing 10 : 1 THF–EtOH, DBU (4 equiv.)] with ethyl α-isocyanoacetate (2 equiv.) yielded a mixture of naphthochlorin **10** and pyrroloporphyrin **3**; when EtOH was replaced with BnOH a mixture of naphthochlorin **11** and pyrroloporphyrin **12** was obtained. A test reaction to prepare naphthochlorin free of pyrroloporphyrin was undertaken; isopropyl cyanoacetate (2 equiv.) was used instead of an alkyl α-isocyanoacetate [refluxing 10 : 1 THF–Pr^iOH, nitroporphyrin **1**, DBU (4 equiv.)] and formation of naphthochlorin **13** was observed. Although we were able to isolate naphthochlorins **10**, **11** and **13**, yields for each were < 1% [λ_{max}/nm (rel. int.) (CH_2Cl_2); **10**: 440 (1), 604 (0.08), 662 (0.15); **11**: 444 (1), 606 (0.08), 662 (0.18); **13**: 440 (1), 604 (0.08), 668 (0.16); these optical data agree well with those of naphthochlorin **5** (the structure of which has been confirmed by the crystal structure of naphthochlorin dimer **14**) and with those of previously reported naphthochlorins[5]]. Full characterization of naphthochlorins **10**, **11** and **13** was not possible owing to the scarcity and instability of these compounds.

Attempted crystallization of naphthochlorin **5** from $CDCl_3$–MeOH afforded crystals of naphthochlorin dimer **14**.‡ We were able to reproduce the dimerization *via* the following methods. A solution of naphthochlorin **5** in 1 : 1 CH_2Cl_2–MeOH (MeOH optional) was stirred while exposed to the air. After 5 days the presence of **5** was no longer detectable and naphthochlorin dimer **14** was isolated in 37% yield. Alternatively, refluxing **5** in dry benzene under argon with benzoyl peroxide (0.5 equiv.) afforded **14** in 53% yield. The reaction presumably proceeds by way of a π-stabilized radical on the non-aromatic β-carbon, followed by a radical dimerization. There is ample precedent for this type of reaction in the porphyrin literature; π-stabilized radicals have been obtained from oxophlorins[8] and some of them dimerize[9] by a mechanism similar to those involved in phenolic chemistry.[10]

The identity of naphthochlorin dimer **14**‡ was confirmed by a crystal structure, as shown in Fig. 1. This structure is unique among porphyrinoid crystal structures in that the dimeric linkage features a direct C_β–$C_{\beta'}$ bond. The macrocycles are both

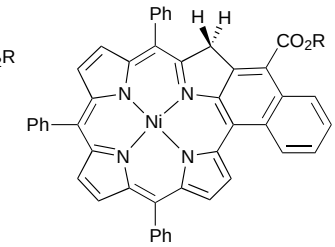
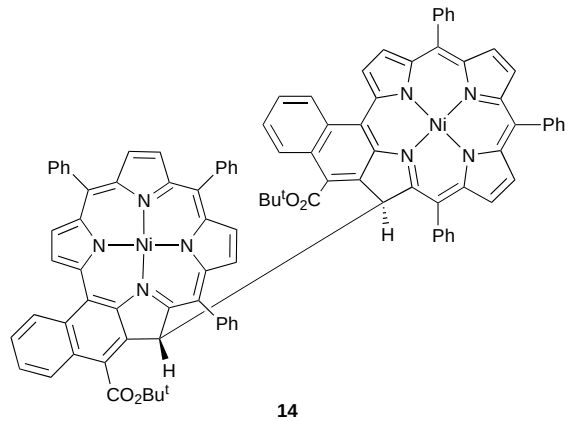
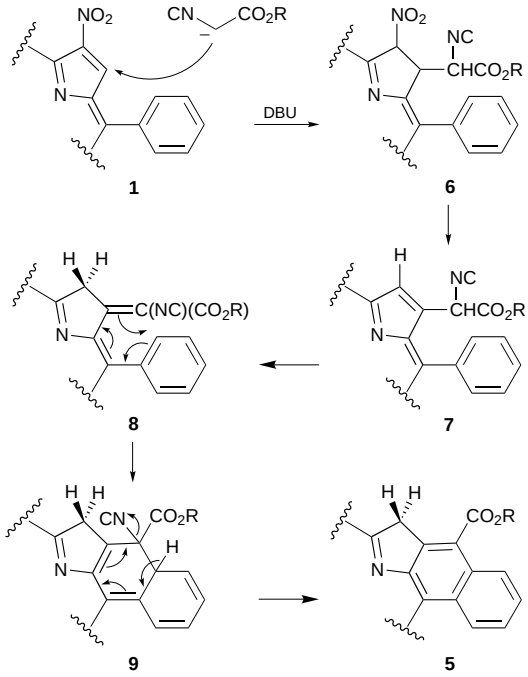
2 R = Me
3 R = Et
4 R = Bu^t
12 R = Bn



5 R = Bu^t
10 R = Et
11 R = Bn
13 R = Pr^i



14



Scheme 1

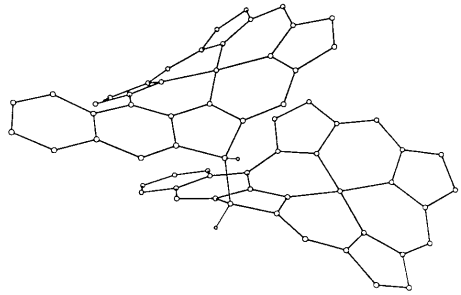


Fig. 1 Molecular structure of naphthochlorin dimer **14**;‡ esters, non-fused phenyl rings and hydrogen atoms (with the exception of those associated with the direct dimer link) have been omitted for clarity

significantly ruffled[11] with 0.33 and 0.36 Å mean deviations of the macrocyclic atoms from their least-squares planes (calculated based upon the 24 core carbon and nitrogen atoms); the average Ni–N bond length was 1.914(6) Å. The two macrocycles were nearly coplanar and exhibited an interplanar angle of 30.1°, a mean plane separation of 3.70(14) Å, and a metal to metal distance of 5.68 Å. Macrocyclic overlap was limited to one pyrrolic subunit of each naphthochlorin monomer. A lateral shift of 4.54 Å and a slip angle of 53(13)° were observed; in this regard this structure bears a marked similarity to the bacterial PRC 'special pair' which exhibits an overall geometry which is generally similar and a lateral shift of *ca*. 6.6 Å.[12]

This work was supported by grants from the National Science Foundation (CHE-96-23117) and the National Institutes of Health (HL-22252). We thank Dr Timothy P. Forsyth for carrying out the cyclic voltammetry experiments.

Notes and References

† E-mail: kmsmith@ucdavis.edu

‡ *Selected data* for **4**: $\lambda_{max}(CH_2Cl_2)$/nm 444 (ε 182 000), 538 (9400), 558 (9800), 606 (14 200); *m/z* (LSIMS) 809.3 (M^+ 100%). C,H,N combustion analysis satisfactory.

For **5**: $\lambda_{max}(CH_2Cl_2)$/nm 444 (ε 153 000), 614 (11 000), 662 (29 000); $\delta_H(CDCl_3)$ 5.19 (s, 2 H, reduced pyrrole ring H); *m/z* (LSIMS) 782.3 (M^+ 100). C,H,N combustion analysis satisfactory. Cyclic voltammetric measurements were carried out with a Cypress Systems CS-1087 computer controlled potentiostat. Naphthochlorin **5** undergoes two one electron oxidations at $E_{1/2} = -1.14$ and 0.74 V; a single compartment cell was used with a platinum disk working electrode, Ag/AgCl reference electrode, and silver wire auxiliary electrode. Measurements (scan rate 110 mV s^{-1}) were made in CH_2Cl_2, with Bu_4NPF_6 as supporting electrolyte. Ferrocene was added as an internal reference.

For **14**: $\lambda_{max}(CH_2Cl_2)$/nm 440 (ε 109 000), 668 (16 500), 712 (6800). Crystals of *meso*-**14** ($C_{100}H_{70}N_8O_4Ni_2 \cdot 3.4CHCl_3 \cdot 0.5MeOH$) were grown by the slow diffusion of MeOH into a $CHCl_3$ solution of **5**. The selected crystal (0.20 × 0.25 × 0.50 mm) had a triclinic unit cell, space group $P\bar{1}$ and cell dimensions a = 14.925(3), b = 17.025(3), c = 18.395(3) Å, α = 90.896(12), β = 99.902(13), γ = 105.083(13)°, V = 4436.9(12) Å^3 and Z = 2 (FW = 1987.0). Data were collected on a Siemens P4 diffractometer with a rotating anode [λ(Cu-Kα) = 1.54178 Å] at 130(2) K in $\theta/2\theta$ scan mode to $2\theta_{max}$ = 112°. Of 12 130 reflections measured ($+h,\pm k,\pm l$) 11 578 were independent (R_{int} = 0.090) and 8509 had $I > 2\sigma$ (T_{min} = 0.50, T_{max} = 0.56, ρ_{calc} = 1.487 g cm^{-3}, μ = 3.85 mm^{-1}). The structure was solved by direct methods and refined (based on F^2 using all independent data except for two suppressed reflections) by full-matrix least-squares methods with 1038 parameters (Siemens SHELXTL V. 5.03). Hydrogen atom positions were generated by their idealized geometry and refined using a riding model. An empirical absorption correction was applied (ref. 13). All of the solvate molecules were disordered; further description of the solvate disorder and how it was treated is given in the supplementary material. Final R factors were $R1$ = 0.092 (observed data) and $wR2$ = 0.25 (all data). CCDC 182/768.

Dodecasubstituted metallochlorins (metallodihydroporphyrins)

Kalyn M. Shea, Laurent Jaquinod, Richard G. Khoury and Kevin M. Smith*†

Department of Chemistry, University of California, Davis, CA 95616, USA

Regioselective bromination of 2-nitro-5,10,15,20-tetraphenylporphyrin, cyclopropa[*b*]chlorins, or *trans*-bis-(dicyanomethyl)chlorins occurs in the pyrrole subunit opposite the substituted ring; exhaustive bromination of functionalized tetraphenylchlorins provides a route to dodecasubstitued dihydroporphyrins for the first time.

The existence of nonplanar hydroporphyrins in photosynthetic chromophores is increasingly evident in X-ray structures of protein complexes.[1] A series of synthetic nonplanar porphyrin models, obtained by steric crowding of β- and *meso*-positions, has established that such conformational variations can have significant effects on the physical and chemical properties of nonplanar porphyrins.[2,3] Results show that the excited state properties of some of these chromophores are exquisitely sensitive to structural and vibrational variations.[4] The synthesis of such model systems often requires the relatively inaccessible 3,4-disubstituted pyrrole for condensation with aldehydes.[5] Nonplanar β-brominated porphyrins, on the other hand, are easily accessed *via* controlled bromination of porphyrins[6] or metalloporphyrins,[7] and have since provided intermediates for a range of nonplanar β-arylporphyrin syntheses.[8] Extension of these synthetic efforts to hydroporphyrin systems will allow facile entry into highly nonplanar dihydroporphyrins (chlorins) and thus provide a means to more effectively test the theoretical predictions[9] of the consequences of nonplanar distortions in this biologically important class of compounds.

2-Nitro-5,10,15,20-tetraphenylporphyrins have been shown to undergo nucleophilic attack at the β–β′ bond bearing the nitro group leading to a range of β-substituted porphyrins,[10] and more recently, work completed in our laboratory has provided new methodology for the preparation of a wide range of highly substituted dihydroporphyrin systems by way of nucleophilic attack of 2-nitro-5,10,15,20-tetraphenylporphyrin **1** (2-nitroTPP), with 'active' methylene compounds.[11] It has also been shown that regiospecific functionalization of pyrrolic positions on the porphyrin periphery occurs *via* fixation of the delocalization pathway.[12]

Here we show that either a nitro group or a reduced pyrrole substituents directs the bromination to the antipodal pyrrolic ring, leading to 12,13-dibromoporphyrin products. We also demonstrate that, *via* hexabromination of metallated dihydroporphyrins, highly nonplanar dodecasubstitued dihydroporphyrins can be prepared for the first time.

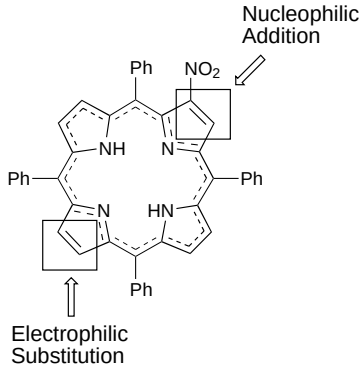

Fig. 1 Regioselective reactivity in 2-nitroTPP

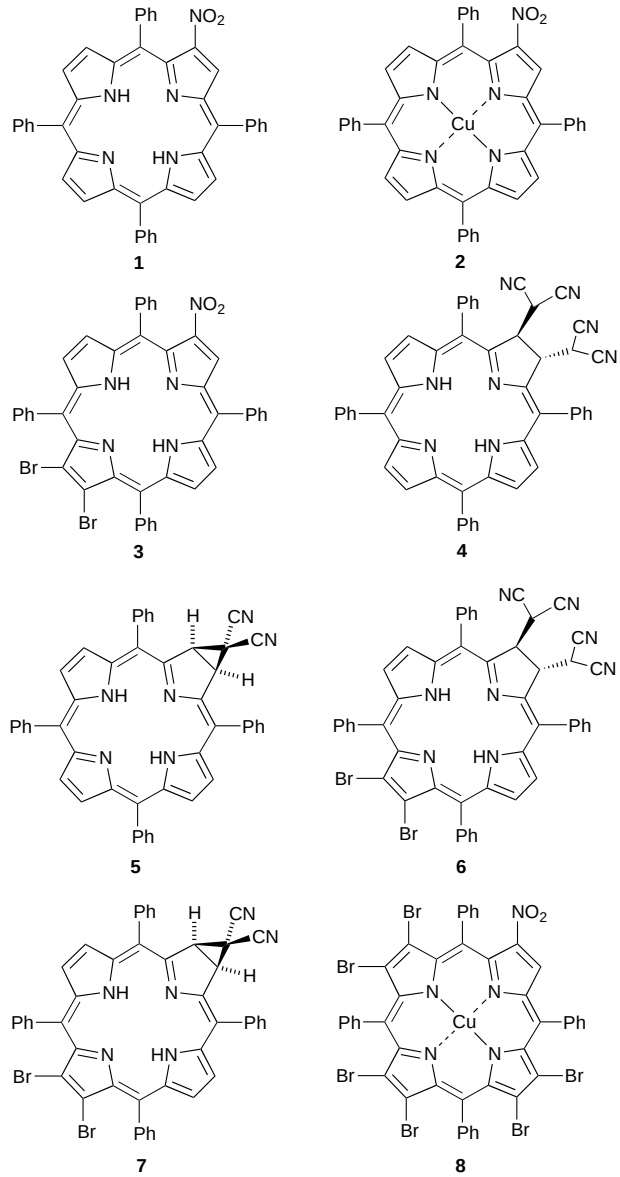
Treatment of 2-nitroTPP **1** (2 g scale) with 2.5 equiv. of NBS in refluxing $CHCl_3$ afforded 2-nitro-12,13-dibromoTPP **3** in good yield (82%). Reaction of **3** (100 mg scale) with malononitrile (10 equiv.) and K_2CO_3 in THF afforded the cyclopropyl derivative **7** in 65% yield. The ^{1}H NMR spectrum of **7** displayed a singlet at δ 5.08, characteristic of the reduced pyrrole protons, and two doublets at δ 8.43 and 8.71. Similar treatment of **3** at 60 °C led to a second chlorin compound, **6**, in 62% yield. This set of reactions reveals the bimodal reactivity of 2-nitroTPP: (i) nucleophilic attack at the double bond bearing the nitro group and (ii) electrophilic regiospecific attack at the antipodal double bond (Fig. 1). The molecular structure of compound **6** was further confirmed by X-ray crystallography [Fig. 2(*a*)].‡



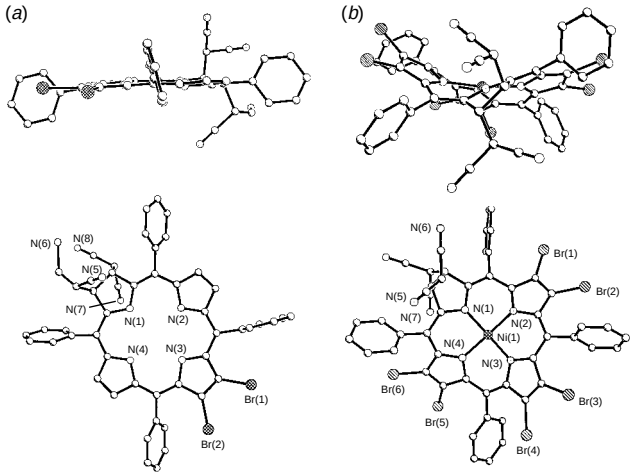


Fig. 2 Molecular structure of (*a*) **6** (below: from top; above: edge-on view) and (*b*) **11** (below: from top; above: edge-on view). Hydrogen atoms have been omitted for clarity.

A second route leading to dibromochlorin compounds involves initial formation of the chlorin chromophore.[11] In this case, the reduced pyrrole functionality induces a favored delocalization pathway, *via* thermodynamically more stable N(22)H–N(24)H tautomerism, allowing regiospecific bromination to take place. Treatment of **5** (200 mg scale) with 2.5 equiv. of NBS in $CHCl_3$ at 65 °C afforded **7** quantitatively. Dropwise addition of bromine (2.5 equiv. in $CHCl_3$) to **4** afforded the desired brominated product **6** in 91% yield. A characteristic 10 nm red shift of the Soret band was observed (λ_{max} 408 to 418 nm) as a result of this reaction. As expected, reaction of a Ni–chlorin **7** with 2.5 equiv. of bromine led to a mixture of brominated products.[12]

Reaction of the metal-free nitroporphyrin **1** with excess NBS (or chlorin **4**, with excess bromine, 10 equiv.) afforded only dibrominated products **3** (or **6**). In contrast, subjecting metallated 2-nitroTPP and metallated dihydroporphyrins to excessive bromination conditions produced the desired hexabrominated products. When Cu-nitroTPP **2** was allowed to react with 16 equiv. of NBS in refluxing 1,2-dichloroethane, hexabromo-2-nitroTPP **8** was produced in 70% yield.

Initial preparation of Ni^{II}–chlorins **9** and **10**,[11] followed by excessive bromination, afforded the desired hexabromochlorins, providing the first route to dodecasubstituted dihydroporphyrins. Dropwise addition of bromine (10 equiv.) in $CHCl_3$ to **9** and **10** (100 mg scale) produced **11** and **12** in 88 and 84% yields, respectively. Hexabromination of **11** resulted in a 26 nm red shift of the Soret band (λ_{max} 414 to 440 nm) and a 56 nm shift for the Q band (λ_{max} 604 to 660 nm). The ^{1}H NMR spectrum of **11** displayed two doublets at δ 3.52 and 4.83, characteristic of the *trans* chlorin functionality, and no peaks in the aromatic β proton region. The molecular structure of compound **11** was further confirmed by X-ray crystallography (Fig. 2).‡ The macrocycle exhibits a ruffled-type conformation with a mean deviation of 0.536 Å for the 24 core atoms from their least-squares plane, and is significantly more nonplanar than dibromochlorin **6** [Fig. 2(*a*)].

Total synthesis of (+)-furanomycin

Sung Ho Kang*† and Sung Bae Lee

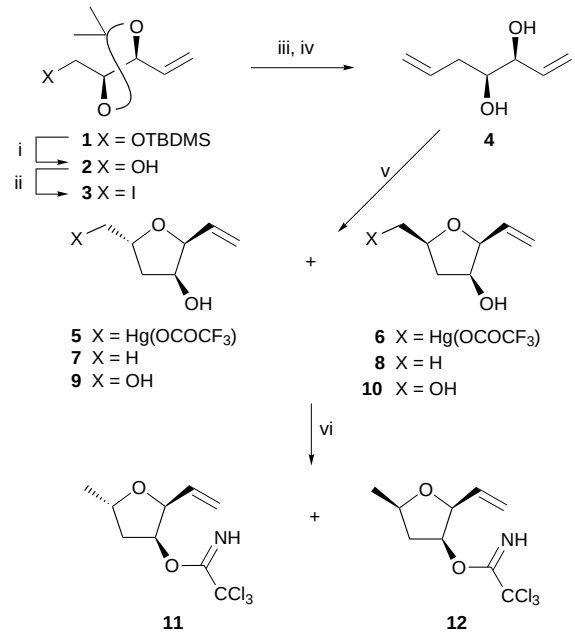
Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea

A highly enantioselective total synthesis of (+)-furanomycin 24 has been achieved *via* the mercury cation-mediated cyclizations of γ-hydroxy alkene 4 and homoallylic trichloroacetimidate 11 to install the *trans*-2,5-disubstituted tetrahydrofuran and the (α*S*)-amino acid side chain, respectively.

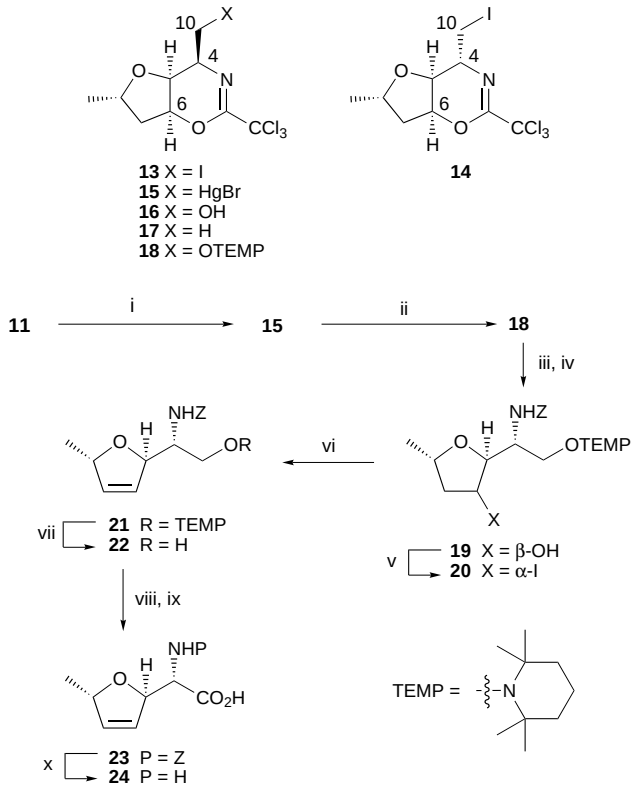
In 1967 Katagiri *et al.* discovered a novel antibiotic (+)-furanomycin from a culture filtrate of *Streptomyces threomyceticus* (ATCC 15795),[1] which binds to *E. coli* isoleucyl-tRNA synthetase, to be charged to *E. coli* isoleucine tRNA and subsequently incorporated into protein.[2] Biosynthetically it is believed to be derived from two acetetes and one propionate.[3] The antibiotic also functions as a competitive antagonist of isoleucine and suppresses the growth of T-even coliphage more effectively than T-odd.[1] Originally its molecular structure was assigned as (+)-(2*R*)-2-amino-2-[(2*R*,5*R*)-2,5-dihydro-5-methyl-2-furyl]acetic acid by spectroscopic data and chemical degradation experiments,[1] but later revised as (+)-(2*S*)-2-amino-2-[(2*R*,5*S*)-2,5-dihydro-5-methyl-2-furyl]-acetic acid by X-ray crystallography[4] and a stereodefined synthesis.[5] Although (+)-furanomycin **24** has a seemingly simple structure, its highly enantiospecific synthesis has not been established, in part due to the difficulties in assembling the *trans*-2,5-dihyrofuran and (*S*)-amino carboxylic acid units. Here we describe a highly enantiocontrolled total synthesis of (+)-furanomycin **24** employing mercury cation-promoted cyclizations of γ-hydroxy alkene **4** and homoallylic trichloroacetimidate **11** to construct the aforementioned functionalities.

The known silyl ether **1**, prepared from dimethyl L-tartrate in 83% overall yield,[6] was desilylated using TBAF, and the resulting alcohol **2**, $[\alpha]_D^{23}$ −3.1 (*c* 1.01, $CHCl_3$), was treated with I_2, PPh_3 and imidazole in THF[7] to yield the corresponding iodide **3**, $[\alpha]_D^{22}$ −10.1 (*c* 1.01, $CHCl_3$), quantitatively from **1** (Scheme 1). The substitution reaction of **3** was conducted with vinylmagnesium bromide, which should be generated freshly, in the presence of $CuBr{\cdot}SMe_2$ and HMPA in THF at −50 °C.[8] The somewhat volatile diene acetonide, without purification, was hydrolyzed with methanolic HCl to give diene diol **4**, $[\alpha]_D^{23}$ −11.6 (*c* 1.01, $CHCl_3$), in 75% overall yield. For the stereoselective formation of *trans*-2,5-disubstituted tetrahydrofuran, the cyclization[9] of **4** was attempted using I_2, IBr or *N*-iodosuccinimide (NIS) under various reaction conditions to provide a 1–3 : 1 mixture of *trans*- and *cis*-isomers. However, when $Hg(OCOCF_3)_2$ was employed as an electrophile, the stereoselectivity was improved significantly. Accordingly, **4** was treated with $Hg(OCOCF_3)_2$ in the presence of K_2CO_3 in THF at −78 °C to afford a mixture of *trans*- and *cis*-2,5-disubstituted tetrahydrofurans **5** and **6**, which was found to revert to the starting material **4** during work-up with brine or aq. KBr and chromatographic purification. In order to elude the reversion, the *in situ* demercuration of the crude organomercurials **5** and **6** was attempted with various reducing reagents[10] in the absence or presence of phase transfer catalyst, NaOAc, NaOH or AcOH to furnish the expected *trans*- and *cis*-tetrahydrofurans **7** and **8**, accompanied by variable amounts of the starting diol **4** and alcohols **9** and **10**. After intensive experimentation, reproducible demercuration conditions were established, involving treating the cyclization reaction mixture *in situ* with BEt_3 and $LiBH_4$ at −78 °C to produce an inseparable 8.5–9 : 1 mixture of **7**, $[\alpha]_D^{22}$ +57.0 (*c* 1.00, $CHCl_3$), and **8** in 83% overall yield from **4** without appreciable formation of side products.

The mixture of **7** and **8** was converted into the readily separable trichloroacetimidates **11** and **12**, which provided after chromatographic purification the requisite imidate **11**, $[\alpha]_D^{22}$ +47.0 (*c* 1.00, $CHCl_3$), in 83% yield. While the proposed cyclization[11] of **11** hardly proceeded with I_2 or NIS, the use of IBr resulted in poor stereoselectivity,[12] yielding a 2.5 : 1 mixture of iodides **13** and **14**, of which the relative stereochemistries were determined by NOE difference experiments, *i.e.* irradiation at H–C(6) showed enhancements at H–C(4) for the former and at H_2–C(10) for the latter (Scheme 2). On the other hand, when the intramolecular amination of **11** was performed with $Hg(OCOCF_3)_2$ in the presence of K_2CO_3 in THF at 0 °C, only the desired organomercury bromide **15** could be isolated in higher than 95% yield after work-up with aq. KBr. Its stereochemistry was corroborated by converting it into iodide **13** with I_2 in THF. For the oxidation of **15** to alcohol **16**, oxygen was bubbled vigorously through a solution of **15** and $NaBH_4$ in DMF,[13] but only the reductive demercuration product **17** was generated. Alternatively exposure of **15** to TEMPO and $LiBH_4$ in the presence of BEt_3 in THF provided the oxidized product **18**, mp 134.5–135.5 °C, $[\alpha]_D^{23}$ −32.0 (*c* 0.99, $CHCl_3$), in 76% yield. It is noted that without BEt_3 the chemical yield decreased to 50–55%. The dihydro-1,3-oxazine heterocycle of **18** was hydrolyzed with HCl and then the unmasked amino alcohol was



Scheme 1 *Reagents and conditions*: i, Bu_4NF, H_2O, THF, 20 °C; ii, I_2, PPh_3, imidazole, THF, 20 °C; iii, CH_2=CHMgBr, $CuBr{\cdot}SMe_2$, HMPA, THF, −50 °C; iv, 6 M HCl, MeOH, 20 °C; v, $Hg(OCOCF_3)_2$, K_2CO_3, THF, −78 °C, then Et_3B, $LiBH_4$, −78 °C; vi, Cl_3CCN, DBU, MeCN, −30 °C



Scheme 2 *Reagents and conditions*: i, $Hg(OCOCF_3)_2$, K_2CO_3, THF, 0 °C, then aq. KBr; ii, TEMPO, Et_3B, $LiBH_4$, THF, 20 °C; iii, 6 M HCl, MeOH, THF, reflux; iv, BnOCOCl, K_2CO_3, MeOH, 20 °C; v, I_2, PPh_3, DMAP, PhH, CH_2Cl_2, 0 °C, then 60 °C; vi, DBU, DMF, 80 °C; vii, Zn, NH_4Cl, H_2O, MeOH, 80 °C; viii, $(COCl)_2$, DMSO; ix, $NaClO_2$, NaH_2PO_4, 2-methylbut-2-ene, Bu^{t}OH, H_2O, 20 °C; x, PhSMe, TFA, 50 °C

protected with benzyl chloroformate to afford carbamate **19**, $[\alpha]_D^{25}$ −12.0 (*c* 1.00, $CHCl_3$), in 95% overall yield.

The dihydrofuryl ring could not be formed by the basic or pyrolytic elimination reaction of the mesylate, triflate or xanthate derivatives of **19**. In addition their substitution reaction with iodide or phenylselenide anion did not yield the expected product. Various experimental attempts revealed that iodide **20**, $[\alpha]_D^{25}$ −65.2 (*c* 0.99, $CHCl_3$) could be prepared in 76% yield by treating **19** with I_2 and PPh_3 in the presence of DMAP in a mixture of benzene and CH_2Cl_2, while the reaction using imidazole[7] instead of DMAP resulted in a poor chemical yield of 35%. The ensuing elimination reaction was effected by heating **20** with DBU in DMF to provide dihydrofuran **21**, $[\alpha]_D^{27}$ +105.3 (*c* 1.02, $CHCl_3$), regioselectively in 89% yield. The TEMP group of **21** was reductively removed with zinc dust in methanolic NH_4Cl to afford the primary alcohol **22**, $[\alpha]_D^{28}$ +195.8 (*c* 0.99, $CHCl_3$), in 92% yield. Since Jones oxidation of **22** proceeded inefficiently, it was oxidized using Swern conditions[14] followed by sodium chlorite[15] to give carboxylic acid **23**, $[\alpha]_D^{27}$ +175.4 (*c* 0.57, MeOH), in 89% yield. Finally removal of the BnOCO group of **23** with thioanisole in TFA produced (+)-furanomycin **24**, mp 222–224 °C, $[\alpha]_D^{26}$ +136.0 (*c* 0.4, H_2O), in 97% yield, the physical and spectroscopic data of which were identical with those previously reported.

ESIPT-Induced photocyclization of *N,N′*-diphenyl-1,5-dihydroxy-9,10-anthraquinone diimine

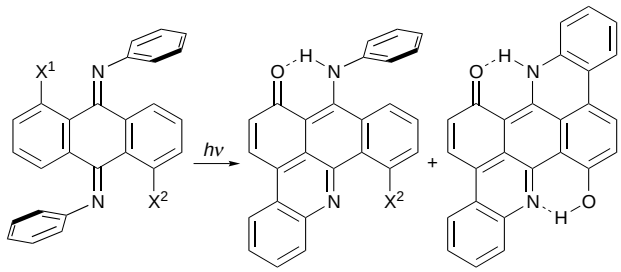
Photolysis of *N,N′*-diphenyl-1,5-dihydroxy-9,10-anthraquinone diimine affords acridine-condensed aromatic compounds *via* excited-state intramolecular proton-transfer, as revealed by time-resolved IR spectroscopy.

Excited-state intramolecular proton-transfer (ESIPT) has been extensively investigated in relation with photochromic materials and UV stabilizers.[1] In ESIPT phenomena, mostly observed in salicylates[2] and salicylideneanilines,[3] the photoexcited keto form is produced by rapid proton transfer from the photoexcited enol form and undergoes deactivation nonradiatively and/or radiatively to the ground-state keto form, which regenerates thermally the original enol. In such a reversible phototautomeric cycle, the ESIPT-induced excited enol is fated to follow the tautomeric pathway and other relaxation processes have rarely been encountered. We report herein a novel photochemical reaction which is, to the best of our knowledge, the first irreversible transformation *via* ESIPT in a phototautomeric system.

N,N′-diphenyl-1,5-dihydroxy-9,10-anthraquinone diimine **1a** in benzene was irradiated at room temperature, using a 100 W high pressure Hg lamp through a Pyrex filter, under argon for 48 h (Scheme 1). The photoproducts were chromatographed on silica gel and acridine-condensed compounds **2a** and **3** were obtained in 64 and 14% yields, respectively. Irradiation of **2a** under the same conditions as used for **1a** gave rise to **3**, indicating that **3** is a secondary photoproduct of **1a**. The photocyclization was also accomplished in monohydroxy derivative **1b**; irradiation of **1b** in benzene for 54 h led to the formation of **2b** (18%). The structure of **2a** was deduced from an X-ray crystallographic analysis‡ and that of **2b** was proved on the basis of its spectral properties. The formation of **2a** and **2b** is ascribed to aromatic cyclization at C(4) accompanied by enol-to-keto tautomerization of the hydroxy group at C(1). These common characteristics of the photoproducts indicate that the same type of the photoreaction occurred in **1a** and **1b**.



1a $X^1 = X^2 = OH$ **2a** $X^2 = OH$ **3**
b $X^1 = OH$, $X^2 = H$ **b** $X^2 = H$
c $X^1 = X^2 = H$
d $X^1 = X^2 = OMe$

Scheme 1

The irradiation of **1c** and **1d**, which have no hydroxy groups at the peri positions, caused no photoreactions even after irradiation for 60 h. The absence of photoreactivity in **1c** and **1d** clearly shows that the hydroxy group at the peri position plays an essential role in promoting the photocyclization. Furthermore, the role of the hydroxy group cannot be ascribed to its electron-donating nature, since the methoxy derivative was not photoreactive. The above results provide chemical evidence for the involvement of ESIPT in the photocyclization. It should also be noted here that compound **1a** exists almost completely in the enol form (96%) under the fast equilibrium with the keto form in the ground state, as monitored by temperature dependent ^1H and ^{13}C NMR spectroscopy.

The intervention of the ESIPT in the photocyclization was probed by means of sub-microsecond time-resolved IR spectroscopy,[4] which can detect the increase in the ground-state keto form upon irradiation. Fig. 1 shows the transient IR spectra of **1a** in CCl_4 following excitation at 262 nm with 5 ns pulses.§ Several new positive absorption bands appear following excitation, in addition to negative peaks due to the ground-state depletion. Those are ascribed to two transient species; one (**A**: ~1550 cm^{-1}) decays rapidly and almost disappears after 200–300 μs, while the other (**B**: 1630 and 1240 cm^{-1}) decays very slowly and still remains after 800 μs. The lifetimes of transient species **A** and **B** were estimated to be 80–90 μs and 1.3 ms, respectively, by the curve fitting of Fig. 2, assuming a simple exponential decay.

Transient species **B** could be assigned to the keto imine tautomer in the ground-state, since its absorptions 1630 and 1240 cm^{-1} are attributed to vibration of the hydrogen bonded C=O group and the C–N stretching, respectively. With respect to transient species **A**, we postulate an intramolecular cycloadduct as the most plausible candidate based on its IR absorption at *ca*. 1550 cm^{-1}, corresponding to the absorption

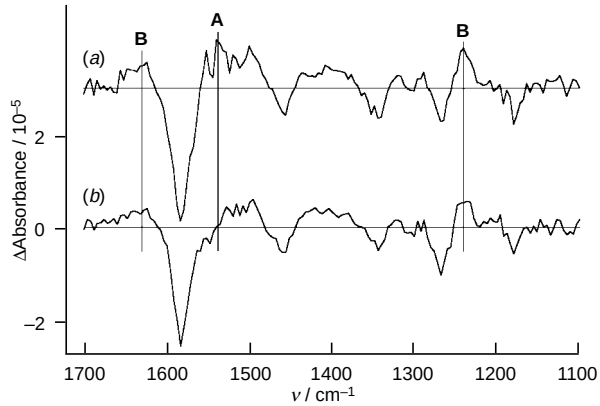


Fig. 1 Time-resolved IR spectra of **1a** after (*a*) 0–20 and (*b*) 200–800 μs of excitation. The figure is represented as a difference spectrum. Negative peaks represent a decrease in the infrared absorption due to the depletion of the ground state and positive peaks correspond to an increase in the absorption by the photogenerated transient species.

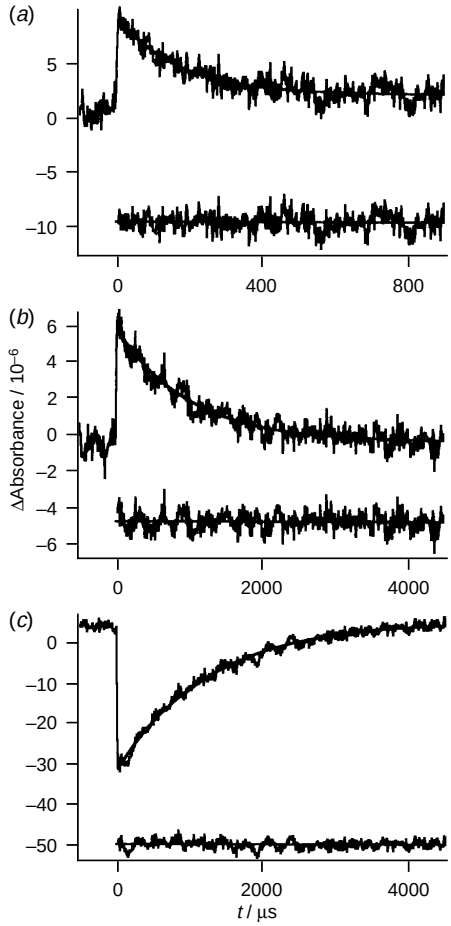

Fig. 2 Decay curves of the absorption bands at (*a*) 1550 (**A**) and (*b*) 1630 cm^{-1} (**B**), and (*c*) recovery curve of the absorption band at 1584 cm^{-1} (**1a**)

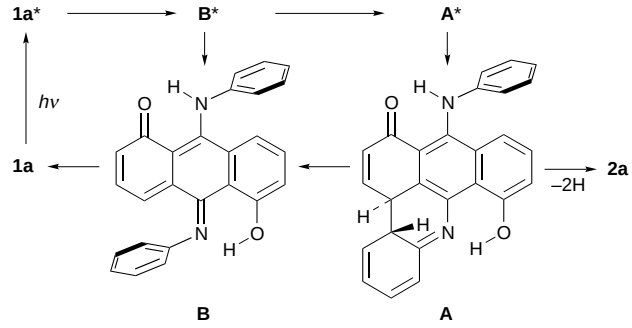
band of a C=N bond incorporated in the cyclic framework. Thus we can depict the fate of the ESIPT as shown in Scheme 2.

No photoproduct **2a** could be detected after the time-resolved measurements. The bubbling of argon through the reaction is considered to work effectively to prevent oxidation of transient species **A** to give **2a**. Thus, all the spectral changes were reversible. However, when argon was not bubbled through the reaction, the formation of **2a** was confirmed by its UV absorption at 530 and 460 nm; the formation of **2a** upon photolysis of **1a** on a preparative scale is ascribed to inefficient argon bubbling. Irradiation of a cautiously degassed sample of **1a** in an NMR sample tube suppressed the formation of **2a** down to a few percent.

The formation of polycyclic systems by intramolecular photocyclization is a common process for several types of aromatic compound. However, benzilideneanilines and azo-



Scheme 2

benzenes fail to undergo aromatic photocyclization under the usual conditions; it has been reported that addition of sulfuric acid or Lewis acids promotes the heteroaromatic cyclization.[5] Thus this work demonstrates a novel photocyclization promoted by ESIPT and hence provides an example of deactivation other than phototautomerization that is possible for the ESIPT of a tautomeric system.

Relative M–X bond dissociation energies in 16-, 17- and 18-electron organotransition-metal complexes (X = halide, H)

Mats Tilset,*[a]† Jean-René Hamon*[b] and Paul Hamon[b]

[a] *Department of Chemistry, University of Oslo, PO Box 1033 Blindern, N-0315 Oslo, Norway*
[b] *UMR CNRS 6509, 'Organométalliques et Catalyse: Chimie et Electrochimie Moléculaires', Université de Rennes 1, Campus de Rennes-Beaulieu, F-35042 Rennes Cedex, France*

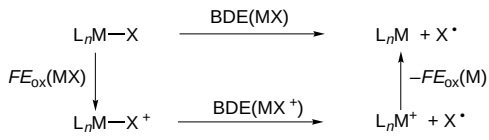
The Fe–halide bonds in Cp*Fe(dppe)X (X = F, Cl, Br, I) complexes are weakened as a consequence of one and two-electron oxidations; the bond weakening decreases in the order F << Cl < Br < I and is much less pronounced for F than the other halides, indicating a pronounced effect of apparent fluoride-to-metal backbonding as a consequence of the removal of electrons.

Knowledge of the nature and energetics of metal–ligand bonding in organotransition-metal complexes is crucial to the understanding of organometallic reactions and catalysis.[1] Recently, the nature of the bonding between organotransition-metal centers and electronegative σ-bonded ligands such as halide, alkoxide, and amido groups has received considerable attention.[2] In addition to forming covalent M–X bonds, these ligands are capable of acting as π donors towards the metal. A ligand p_π to metal d_π electron-pair donation generally serves to destabilize electronically saturated complexes *via* filled–filled repulsive interactions, whereas coordinatively unsaturated species may achieve considerable stabilization through partial π bond formation.[3–9] A substantial line of evidence,[2] including IR ν_{CO} spectroscopy data,[4,5] electrode potentials,[6,10] chemical reactivity,[4,7] and theoretical calculations,[3,4,8] suggests that among the halides, it is the fluoride ligand that is the most efficient electron-pair donor towards the metal.‡

The presence of significant π bonding from halide to metal should be reflected in bond dissociation energy (BDE) changes when this bonding is 'switched on'[3a] by the generation of coordinative unsaturation. To the best of our knowledge, there exist no quantitative data on the homolytic M–X BDEs of metal–halide bonds in closely related pairs of coordinatively saturated (18 electron) and unsaturated (16 electron) species. Here we present the first data concerning the relative M–X bond strengths in 18-, 17- and 16-electron complexes which differ only in their number of valence electrons and thence charge of the central atom. The data establish a pronounced 'fluorine effect', and suggest that a specific electronic or ionic effect of the fluorine is evident already in the 17-electron systems.

Thermochemical cycles that incorporate electrode potential data, introduced by Breslow and Chu,[11] have been frequently used in organic[12] and organometallic[13–15] chemistry to obtain bond-energy data that are not available by direct methods. We have employed this technique to establish a bond-weakening effect of *ca.* 25–33 kJ mol^{-1} when 18-electron metal hydrides were oxidized to their 17-electron cation radicals.[13c,d] Eqn. (1) derived from the thermochemical cycle in Scheme 1, was used to quantify this effect for X = H.

$$\mathrm{BDE(MX)} - \mathrm{BDE(MX^+)} = F[E_{ox}(\mathrm{MX}) - E_{ox}(\mathrm{M})] \quad (1)$$



Scheme 1

Scheme 1 is quite general and eqn. (1) can therefore be applied for any other X, and also to evaluate relative BDEs between multiply oxidized species.§ The pertinent 16- and 17-electron species M^+ amd MX^+ are usually so short-lived that electrode potential data, and thereby BDE data, are inaccessible. However, it has been recently demonstrated that the sterically crowded and electron-rich Cp*Fe(dppe) moiety¶ supports metal complexes in a great number of oxidation states, and compounds have been isolated with electron counts ranging from 16 to 19.[16] The persistent 15-electron $Cp^*Fe(dppe)^{2+}$ has even been generated in solution.[16d] The Cp*Fe(dppe) derivatives therefore are particularly well suited for the application of thermochemical cycles.

Table 1 summarizes electrochemical data obtained by cyclic voltammetry for the Cp*Fe(dppe)X–$Cp^*Fe(dppe)X^+$ and $Cp^*Fe(dppe)X^+$–$Cp^*Fe(dppe)X^{2+}$ couples for X = H, F, Cl, Br, I. All neutral–monocation redox couples in Table 1 were chemically reversible, near-Nernstian processes (ΔE_p = 67–75 mV). Remarkably, except for X = H, the cation–dication couples were also reversible.

The electrochemical data for these halides constitute the first example of reversible electrode potentials for a complete organometallic L_nMX series (X = F, Cl, Br, I). Interestingly, the reversible oxidation to monocation occurs most readily for the most electronegative halide and becomes progressively more difficult in the series F < Cl < Br < I.[17,18] The trend is the opposite of that predicted on the basis of halide electronegativities alone, and most likely is a manifestation of the importance of apparent π donation from halide to metal. The particularly large jump, > 0.2 V, in the $E°$ value for F relative to Cl and the other halides support the idea that F acts as an exceptionally good donor.‡

The electrochemical data are used in conjunction with eqn. (1) to give the differences in M–X BDEs between $Cp^*Fe(dppe)X^{n+}$ complexes when *n* changes from 0 to 1 to 2. The results are summarized in Table 2. It is important to keep in mind that the data show only the net change in the bond energies caused by oxidation state changes. The data carry no information about

Table 1 Cyclic voltammetry data for the oxidation of Cp*Fe(dppe) derivatives[a]

Compound M	E_1 (M/M^+)[b]	E_2 (M^+/M^{2+})[b]
$Cp^*Fe(dppe)$[c]	−1.272	−0.290
Cp*Fe(dppe)H	−0.747	0.75[d]
Cp*Fe(dppe)F[e]	−0.824	0.688
Cp*Fe(dppe)Cl	−0.618	0.823
Cp*Fe(dppe)Br	−0.582	0.811
Cp*Fe(dppe)I	−0.540	0.780

[a] THF–0.2 M $NBu_4^+PF_6^-$, T = 20 °C, Pt disk electrode (d = 0.4 mm), voltage sweep rate v = 1.0 s^{-1}. [b] Oxidation potential, V *vs.* Cp_2Fe–Cp_2Fe^+. The voltammograms were reversible unless otherwise stated. [c] Measurements were done on $Cp^*Fe(dppe)^+PF_6^-$ which, contrary to Cp*Fe(dppe)•, is stable in THF at room temperature. [d] Peak potential for irreversible process. [e] Measurements were performed on $Cp^*Fe(dppe)F^{\bullet+}PF_6$ (ref. 19).

Table 2 Relative bond dissociation energies for $Cp^*Fe(dppe)X^{n+}$ complexes (kJ mol^{-1})[a]

Compound M–X	ΔBDE ($MX–MX^+$)	ΔBDE ($MX^+–MX^{2+}$)	ΔBDE ($MX–MX^{2+}$)
$Cp^*Fe(dppe)H$	51	100[b]	151[b]
$Cp^*Fe(dppe)F$	43	94	138
$Cp^*Fe(dppe)Cl$	63	107	171
$Cp^*Fe(dppe)Br$	67	106	173
$Cp^*Fe(dppe)I$	71	103	174

[a] Obtained using the data in Table 1 and eqn. (1). [b] Minimum value. The corresponding value for $E_{ox}(MX^+–MX^{2+})$ is a minimum value due to the unknown kinetic potential shift that is imposed by the irreversible nature of this electrode process for X = H.

absolute BDEs. The observed bond energy changes result from the combined σ and π effects.‡ For all X, overall bond weakening occurs as a consequence of oxidation of the neutral $Cp^*Fe(dppe)X$ to their monocations. A further bond weakening, almost twice as large, results when the monocations are oxidized to dications. Thus, the data unambiguously demonstrate that for all X studied, Fe–X bond energies decrease in the order $Fe–X > Fe–X^{\bullet+} > Fe–X^{2+}$.

For both oxidation processes, there is a very interesting and obvious trend in the bond activation for the halides. The oxidatively induced bond weakening decreases in the order I > Br > Cl > F and is particularly less pronounced for F than for the other halides. In particular, for the overall two-electron oxidation (which in principle corresponds to the generation of a vacant coordination site) the difference between F and the other halides is > 30 kJ mol^{-1}. It is tempting to attribute this phenomenon to a more efficient donation from F to the metal. This quantity may be viewed as an extra stabilization of the unsaturated 16-electron complex $Cp^*Fe(dppe)X^{2+}$ that is provided by F, relative to the other halides.

Interestingly, whereas the bond weakening is less pronounced for X = F than for H, a pure σ donor, the opposite is true when Cl, Br and I are compared to H. For a pure σ donor, $E_{ox}(MX)$ should be more positive than for $E_{ox}(M)$ when X is more electronegative than M, and eqn. (1) shows that an oxidation in this case should lead to a weakening of the σ bond. In particular, this situation applies to X = H. For X = F, π donation to the metal is enhanced by the oxidation, and this in part compensates for the σ bond weakening. On the other hand, for X = Cl, Br, and I, a combination of a greater σ bond weakening and a poorer π donation to the metal leads to an overall bond weakening that exceeds even that found for X = H. As noted in the introduction, metal–halide bonding can be rather complex, and we plan to further develop these issues in an extended study that includes theoretical aspects of the Fe–X bonding.**

Costuas for their assistance and helpful discussions.

Notes and References

† E-mail: mats.tilset@kjemi.uio.no

‡ The theoretical results[3b,4,8] imply that π-effects, σ-effects and the ionicity of the M–X bond must all be taken into account when trends in ν_{CO} and other observable parameters are to be explained.

§ The ΔBDE data obtained from eqn. (1) are in reality free energy based. However, the enthalpic ΔBDE values will be identical to the free-energy ones if ΔS for the top and bottom homolytic processes in Scheme 1 cancel. This will be the case here since M and MX have the same charges and the different X groups are small in comparison to the M fragment. Thus, one might anticipate MX and M to have nearly identical solvation properties. The same applies to MX^+ *vs.* M^+.

¶ Abbreviations: Cp^* = η^5-C_5Me_5; dppe = η^2-$Ph_2PCH_2CH_2PPh_2$.

‖ The X-ray crystal structures of $Cp^*Fe(dppe)^{n+}$ (n = 0, 1) have been reported. The cation does not bind THF or counter anion. There was no indication of stabilization by agostic interactions with ligand C–H bonds.[16d]

** Preliminary DFT calculations on the halide series indicate that the MX and MX^+ BDEs defined in Scheme 1 include, in addition to the energy necessary to break the M–X bond, a significant component associated with electronic reorganization of the L_nM fragment. However, the reorganization energy barely varies in the halogen series, so that the big jump observed in the ΔBDE values from F to the other halogens is essentially associated with variations on the M–X bond.

1-Benzostannepines: first synthesis and novel conversion into 1-benzo-borepines, -stibepines and -tellurepines[1]

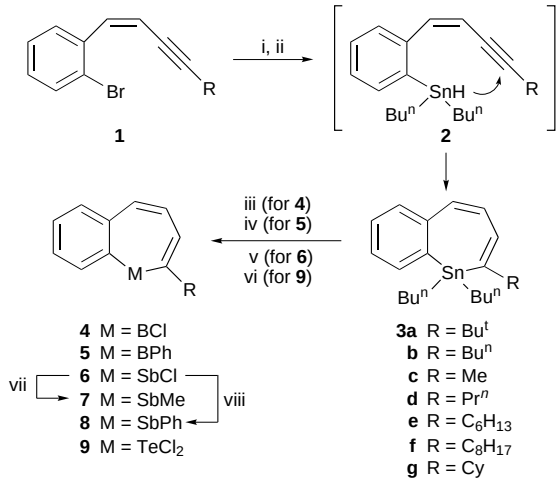
Haruki Sashida,*† Atsuhiro Kuroda and Takashi Tsuchiya

Faculty of Pharmaceutical Sciences, Hokuriku University, Kanagawa-machi, Kanazawa 920-11, Japan

2-Alkyl-1-benzostannepines 3 were prepared in one pot from (*Z*)-1-(*o*-bromophenyl)but-1-en-3-ynes 1 *via* tin hydride intermediates 2 and easily converted into 1-benzo-borepines 4 and 5, -stibepines 6, 7 and 8, and -tellurepines 9 by tin–metal exchange reaction in moderate to good yields.

3-Benzostannepines,[2] fully unsaturated seven-membered tin-containing heterocycles, were synthesized by hydrostannation of *o*-diethynylbenzenes more than 30 years ago. Monocyclic,[3] thiophene ring-,[4] pyrrole ring-[5] and cyclopentane ring-fused[6] stannepines have also been prepared by extension of this reaction. It is well-known that these parent stannepines can be converted into the corresponding derivatives of borepine[2b,3b,4–7] and stibepine.[8] However, no 1-benzostannepines **3**, a theoretically possible structural isomer, have been prepared until now, in spite of much synthetic effort. Recently, we reported the synthesis of 1-benzotellurepines **9**,[9] novel tellurium-containing seven-membered heterocycles, *via* the successive intramolecular addition of telluroles to a triple bond. In our continuing studies[10] on the synthesis of new heterocyclic ring systems using efficient intramolecular cyclization reactions with a participating acetylenic group, we herein describe the preparation of novel stable 1-benzostannepines **3** and the transformation of **3** into 1-benzoborepines **4** and **5**, 1-benzostibepines **6**, **7** and **8**, and also 1-benzotellurepines **9**; the former compounds are new heterocyclic ring systems.

(*Z*)-1-(*o*-Bromophenyl)but-1-en-3-ynes **1**[11] were lithiated with Bu^tLi in the presence of tetramethylethylenediamine in *n*-hexane, followed by hydrostannation with Bu^n_2ClSnH[12] to give the desired 2-alkyl-1-benzostannepines **3**‡ as a sole product in 30–40% yield. The intermolecular hydrostannation of acetylene compounds induced by radical initiators,[13] transition metal catalysts,[14] base catalysts[2] or Lewis acid catalysts[15] to form vinylstannanes has been given extensive attention, and this hydrostannation frequently proceeds in the absence of a catalyst.[16] Therefore, the stannepines **3** may probably be obtained by the intramolecular *endo*-mode ring closure of stannyl hydride intermediates **2** at the sp carbon of the ethynyl moiety, as shown in Scheme 1. These compounds are quite stable and are not sensitive to air, light or even moisture.



Scheme 1 *Reagents and conditions*: i, Bu^tLi (2.2 equiv.), $Me_2NC_2H_4NMe_2$, hexane, −80 °C, then room temp., 3 h; ii, Bu^n_2SnHCl, room temp., 1 h; iii, BCl_3 (1 equiv.), hexane, room temp., 1 h; iv, $PhBCl_2$ (1 equiv.), hexane, room temp., 1 h; v, $SbCl_3$ (1 equiv.), $CHCl_3$, room temp., 30 min; vi, $TeCl_4$ (1 equiv.), PhH, room temp., 1 h; vii, MeLi (1.2 equiv.), Et_2O, −20 °C, 30 min; PhLi (1.2 equiv.), Et_2O, −20 °C, 30 min

The reaction of the 1-stannepine **3a** with 1.0 equiv. of BCl_3 in *n*-hexane at room temperature afforded 2-*tert*-butyl-1-chloro-1-benzoborepine **4a**,§ which could be purified by distillation under reduced pressure in spite of being air- and moisture-sensitive. A 1-phenyl derivative **5a** was similarly obtained.

The stannepines **3a**,**b** also reacted readily with 1.0 equiv. of $SbCl_3$ in $CHCl_3$ at 0 °C to give the corresponding 1-chlorostibepines **6a**,**b**¶ almost quantitatively, but these compounds were too unstable to be isolated. Thus, we have examined the conversion of **6** to the Sb-alkyl or -phenyl substituted derivatives. Treatment of the 1-chlorostibepines **6**, which were freshly prepared without purification after removal of the solvent and $Bu^n_2SnCl_2$ under reduced pressure, with a small excess of MeLi in Et_2O at −20 °C gave the 1-methylstibepines **7**. The phenyl derivative **8** was prepared in a similar manner. Compounds **7** and **8**‖ were more stable than the 1-chloro derivatives **6**, and could be chromatographed on silica gel, contrary to our expectation. However, the 3-alkyl-3-benzostibepines are thermally labile. The structure of **6** was determined by comparison of its NMR spectra with those of **7** and **8**.

1,1-Dichlorotellurepines **9a**,**b** were formed from the parent stannepines **3** by tin–tellurium replacement reaction in 77–82% yield and were identical with authentic samples.[11] To the best of our knowledge, this tin–tellurium exchange reaction, accompanied by fission of a tin–carbon single bond and the simultaneous formation of a tellurium–carbon bond, is a new discovery.

Monocyclic fully unsaturated borepines, 3-benzoborepines and other ring-fused derivatives have now been recognized and established as aromatic compounds[4–7,17] by ^1H and ^{13}C NMR spectropic studies, molecular orbital calculations and X-ray crystal analyses. The ^1H NMR chemical shift values of the borepine ring protons in **4** and **5** appear rather lower than those of the other seven-membered heterocycles obtained in this work; in particular, the proton signals of 4-H of **4** and **5** are shifted 0.34–0.64 ppm downfield. These results suggest that the 1-borepines **4** and **5** are aromatic.

Further detailed studies on the ring transformation and reactivities of these novel 1-benzostannepines and its analogues, and on the aromaticity of the 1-benzoborepines, are in progress.

Tetraphenyldihydrocyclobutaarenes—what causes the extremely long 1.72 Å C–C single bond?

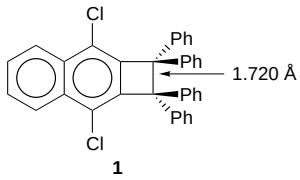
Holger F. Bettinger,[a,b] Paul v. R. Schleyer*[a]† and Henry F. Schaefer III[b]

[a] *Computer Chemie Center, Institut für Organische Chemie, Universität Erlangen-Nürnberg, Henkestr. 42, D-91054 Erlangen, Germany*

[b] *Center for Computational Quantum Chemistry, The University of Georgia, Athens, GA, 30602, USA*

The exceptional 0.19 Å lengthening (to 1.720 *vs.* 1.53 Å in ethane) of the C_{sp^3}–C_{sp^3} bond in tetraphenyldihydrocyclobutaarenes is attributed to a combination of cyclobutene ring strain (0.04 Å), through-bond coupling (0.08 Å) and steric repulsion (0.07 Å) by comparison with model systems.

The 1.720(4) Å C_{sp^3}–C_{sp^3} distance in 3,8-dichloro-1,1,2,2-tetraphenylcyclobuta[*b*]naphthalene **1** is currently the longest



1

known single bond length in hydrocarbons.[1–3] Since semiempirical methods (PM3 and MNDO) underestimate the C_{sp^3}–C_{sp^3} bond length in **1** by as much as 0.05 Å,[3] it was suggested that 'special bonding effects exist'[2] in **1**. Moreover, recent studies concluded that through-bond coupling 'never has more than a 2–3 pm effect'[4] on the length of the mediating single bond.[4,5] Hence, we agree that the extremely long C–C single bonds in 1,1,2,2-tetraphenyldihydrocyclobutaarenes[3] 'are of utmost importance for our understanding of chemical bonding.'[2] Choi and Kertesz recently showed that electron correlation effects have to be included in order to give agreement between quantum mechanical calculations and experiment.[6]

We computed the geometry of C_2 symmetric **1** at various levels of theory.‡ Since B3LYP/6-31G** gives the best agreement with the X-ray data of **1** (Fig. 1), all subsequent

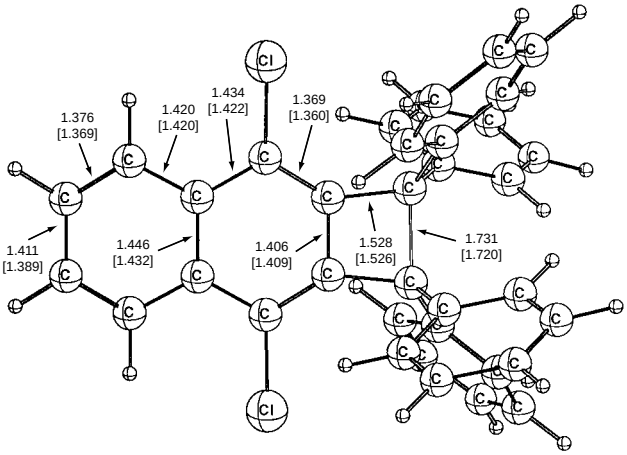


Fig. 1 The structure of 3,8-dichloro-1,1,2,2-tetraphenylcyclobuta[*b*]-naphthalene **1** optimized at the B3LYP/6-31G** level of theory. Bond lengths are in Å, experimental bond lengths are given in brackets.

calculations on model systems **2**–**6** were carried out with this hybrid functional.[9,12] Note that at HF/6-31G** the C_{sp^3}–C_{sp^3} bond length of **1** is underestimated by 0.06 Å. The C_{2v} symmetric form of **1** is a transition state at HF/STO-3G (81*i* cm^{-1}) and 9.4 kcal mol^{-1} higher in energy at B3LYP/6-31G** than the C_2 ground state.

Which effects cause the extremely long bond in **1**? A very similar C_{sp^3}–C_{sp^3} distance (1.718 Å) as for **1** (1.731 Å) is computed for 1,1,2,2-tetraphenylbenzocyclobutene **2** (Fig. 2). Obviously, the two chlorine atoms and the presence of the annelated naphthalene (instead of benzene) ring have only a small influence on the C_{sp^3}–C_{sp^3} bond length. Ring strain in the cyclobutane moiety engenders elongated C_{sp^3}–C_{sp^3} bonds in cyclobutane **3** (1.555 Å),[13] in cyclobutene **4** (1.566 Å, *via* microwave analysis)[14] and in benzocyclobutene **5** (1.580 Å, *via* X-ray analysis)[15] with respect to ethane (1.535 Å; 1.530 Å at B3LYP/6-31G**).[16] the C_{sp^3}–C_{sp^3} bonds in **1** and **2** are 0.14–0.15 Å longer than in the parent compound **5**. However, abnormally long C–C single bonds in the 1.64–1.66 Å range have been observed previously for cyclobutane derivatives with vicinal phenyl groups.[1,2]

The lengthening of a mediating C–C single bond by vicinal phenyl groups has been attributed to through-bond interactions[17] of the favorably aligned π-oribtals of the benzene rings.[1] The benzene rings in **1**, *trans*-1,2-diphenylbenzocyclobutene **6** and **2** are orientated ideally, and due to the low lying σ*(C_{sp^3}–C_{sp^3}) orbital of the cyclobutane ring, the through-bond interaction is expected to be enhanced.[1]

A distance of 1.622 Å between the C_{sp^3} centers is obtained for **6**. Inspection of the MOs reveals an orbital ordering similar to the one reported for *anti*-1,2-diphenylethane.[4] Through-bond coupling is indicated by the reversal of the conventional out-of-phase above in-phase MO ordering,[5] and through-space coupling is not observed due to the 3.72 Å separation of the benzene rings. Thus, the bond elongation of 0.042 Å in **6** with respect to **5** can only be ascribed to through-bond interaction, and is significantly larger than the 0.02–0.03 Å limit of Baldridge *et al.*[4]

Assuming that the elongation effect is additive, a C_{sp^3}–C_{sp^3} bond length of 1.58 + 2 × 0.04 = 1.66 Å, based on through-

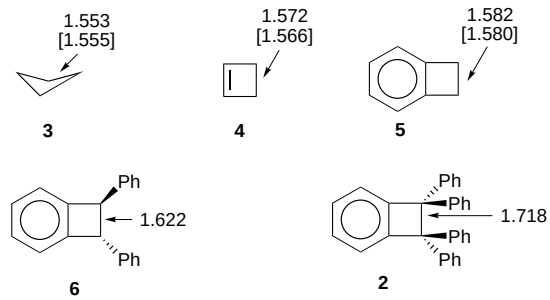

Fig. 2 Calculated (B3LYP/6-31G**) and experimental [in brackets, where available] bond lengths (Å) in molecules **2** to **6**

bond interaction, is expected for **2**. The difference of 0.07 Å with the calculated 1.73 Å length can be ascribed to repulsive steric interactions (and perhaps to through-space interactions) among the phenyl groups.

Indeed, the MM2[18] value for the C_{sp^3}–C_{sp^3} bond length in **2** is 1.651 Å, 0.08 Å shorter than the B3LYP/6-31G** result. As MM2 includes ring strain effects and steric congestion, but not through-bond interactions, our estimate of 0.08 Å as the contribution of the latter effect seems to be reasonable. The C_{sp^3}–C_{sp^3} bond in **1** is 0.18 Å longer than in cyclobutane **3**. Of this, the benzoannelation strain (*i.e.* in **5**) contributes 0.03 Å. Through-bond interaction elongates the bond by an additional 0.08 Å, and repulsion and possible through-space interaction of the phenyl groups contributes another 0.07 Å.

The elongation of a bond is in general associated with the decrease of the corresponding force constant. Thus, a perturbation's effect on the bond length is larger for an already elongated bond than for a 'normal' bond. We conclude that bonds which are weakened (elongated) by other influences are more prone to further bond lengthening by through-bond coupling than concluded recently.[4]

Versatile pentadentate 1,5-bis(salicylideneamino)pentan-3-ol type ligands yield novel tri- and tetra-manganese(II) complexes: structure and properties

Lutz Stelzig,[a] Alexander Steiner,[b] Benoît Chansou[a] and Jean-Pierre Tuchagues*[a]†

[a] *Laboratoire de Chimie de Coordination du CNRS, UP 8241, 205 route de Narbonne, 31077 Toulouse Cedex, France*
[b] *Department of Chemistry, University of Liverpool, Crown Street, Liverpool, UK L69 7ZD*

Novel manganese–oxygen cores observed in trinuclear $[Mn^{I}I_3(L^3)_2(\mu_2\text{-OAc})]Na$ and tetranuclear $[Mn^{II}_2L^3(\mu_3\text{-OMe})(MeOH)]_2$ complexes [H_3L^3 = 1,5-bis(3-Cl,5-NO_2-salicylideneamino)pentan-3-ol] illustrate the coordination versatility of the 1,5-bis(salicylideneamino)pentan-3-ol type of trianionic pentadentate Schiff bases.

The coordination versatility of 1,3-bis(salicylideneamino)propan-2-ol type ligands towards transition metal ions, particularly manganese,[1] has prompted us to further explore the possible coordination modes of the related 1,5-bis(salicylideneamino)pentan-3-ol Schiff bases. The ligands in both series are potentially dinucleating pentadentate with two imine nitrogen, two phenolate and one alcoholate oxygen donors. Owing to the difference in aliphatic chain-length between their imine nitrogens, their dinucleating coordination mode results in five- and six-membered central chelate rings in the first and second series, respectively. As illustrated by work of Mikuryia *et al.*[2] with 1,5-bis(salicylideneamino)pentan-3-ol, H_3L^1, and manganese(III), the resulting increased flexibility allows formation of approximately planar dinuclear M_2L species which may be stabilized either with two additional bridges (one in-plane monoatomic and one out-of-plane triatomic), or through dimerization when two monoatomic μ_3-oxo and two triatomic bridges are provided. From the 3,5-NO_2-salicylidene substituted ligand H_3L^2, we have recently obtained a bis-dinuclear manganese(II) structure where two approximately planar dinuclear M_2L units are bridged by two μ_3-hydroxy anions.[3] Our efforts are directed towards exploration of the different types of manganese polynuclear structures obtainable from these flexible dinucleating pentadentate ligands, depending upon the electronic influence of the salicylaldimine-ring substituents, manganese oxidation state, and nature of the ancillary ligands.

As part of this project, we report here the first data concerning the novel bis-dinuclear $[Mn^{II}_2L^3(\mu_3\text{-OMe})(MeOH)]_2$ **1** and trinuclear Na $[Mn^{II}_3(L^3)_2(\mu_2\text{-OAc})]\cdot H_2O\cdot 0.25$thf **2** complexes based on the same 1,5-bis(3-Cl,5-NO_2-salicylideneamino)pentan-3-ol pentadentate ligand, H_3L^3. Reaction of $Mn(OAc)_2\cdot 2H_2O$ with H_3L^3 and NaOH (2 : 1 : 3 molar ratio) in methanol yields a very air-sensitive orange precipitate within hours. Isolation and subsequent crystallisation from dmf–MeOH yields **1** as well shaped orange–red crystals. Treatment of the initial mother-liquor with water induces precipitation of a second compound. Crystallisation of this complex from thf–pentane gives red crystals of **2**.

The X-ray crystallographic study of **1**‡ revealed a bis-dinuclear structure related to that of $[Mn^{II}_2L^2(\mu_3\text{-OH})(thf)]_2\cdot 2$thf **3**:[3] two layered M_2L^3 dinuclear units bridged by two μ_3-methoxo anions and two L^3-phenolato oxygen atoms are related by a crystallographic inversion centre (Fig. 1). The significant differences between **1** and **3** are the presence of μ_3-methoxo (**1**) instead of μ_3-hydroxo (**3**) bridges, and of a Mn(2)-bonded methanol molecule (**1**) instead of thf (**3**). The two manganese atoms within the M_2L^3 unit have different coordination spheres: Mn(1) is in a square pyramidal NO_4 ligand environment while the NO_5 environment of Mn(2) is distorted octahedral. The Mn–L bond lengths and angles, and the intra- and inter-dinuclear Mn···Mn separations (Fig. 1) differ significantly from those in related Mn^{III}_4 and $Mn^{II}_2Mn^{III}_2$ species,[2,4] but are similar to those reported for **3** and characteristic of the +2 oxidation state of the Mn ions.[3] Two strong hydrogen bonds (Fig. 1) involving the coordinated Me*OH* molecules and N*O*$_2$ substituents of L^3 link each dinuclear unit to its nearest neighbour, thus generating infinite 1D chains of bis-dinuclear molecules.

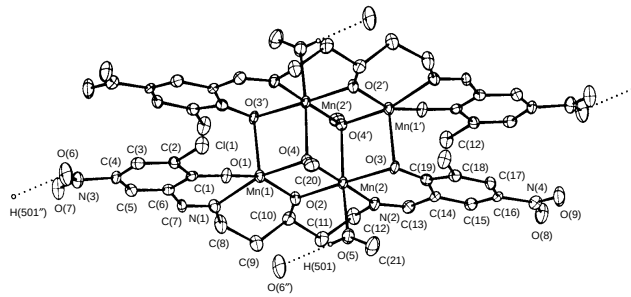

Fig. 1 Molecular structure of $[Mn^{II}_2(L^3)(\mu_3\text{-OMe})(MeOH)]_2$ **1**. Selected distances (Å): Mn(1)–O(1) 2.080(3), Mn(1)–O(2) 2.032(3), Mn(1)–O(3′) 2.200(3), Mn(1)–O(4) 2.131(3), Mn(1)–N(1) 2.206(3), Mn(2)–O(2) 2.077(3), Mn(2)–O(3) 2.157(3), Mn(2)–O(4) 2.162(3), Mn(2)–O(4′) 2.237(3), Mn(2)–O(5) 2.271(3), Mn(2)–N(2) 2.216(4), Mn(1)···Mn(2) 3.154(1), Mn(1)···Mn(2′) 3.240(1), Mn(2)···Mn(2′) 3.372(1), Mn(1)···Mn(1′) 5.432(1) (′ = $-x$, $-y$, $-z$).

The X-ray crystallographic study of **2**‡ reveals an unprecedented surpamolecular array of trinuclear $[Mn^{II}_3(L^3)_2(\mu_2\text{-OAc})]^-$ anions bonded to Na^+ cations (Fig. 2 and 3). The core of the complex anion, a triangle of Mn^{II} cations bridged by the alkoxo μ_3-O atoms of both L^3 ligands, is reminiscent of a [1.1.1]-

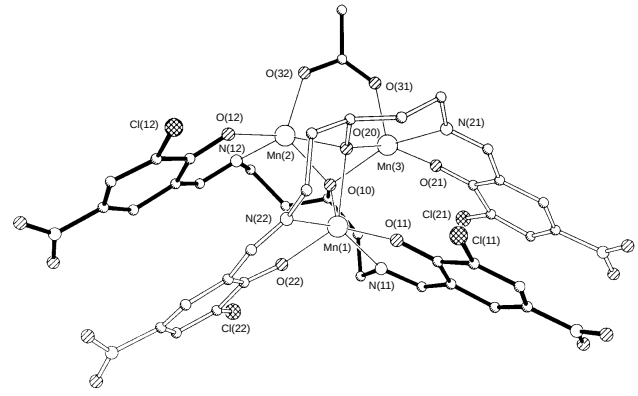

Fig. 2 Molecular structure of the trinuclear $[Mn^{II}_3(L^3)_2(\mu_2\text{-OAc})]^-$ complex anion of **2**. Selected distances (Å): Mn(1)–O(10) 2.285(8), Mn(1)–O(11) 2.064(10), Mn(1)–O(20) 2.254(9), Mn(1)–O(22) 2.166(19), Mn(1)–N(11) 2.287(11), Mn(1)–N(22) 2.17(2), Mn(2)–O(10) 2.164(8), Mn(2)–O(12) 2.030(8), Mn(2)–O(20) 2.181(8), Mn(2)–O(32) 2.094(10), Mn(2)–N(12) 2.181(11), Mn(3)–O(10) 2.112(8), Mn(3)–O(20) 2.129(7), Mn(3)–O(21) 2.083(8), Mn(3)–O(31) 2.084(9), Mn(3)–N(21) 2.172(11), Mn(1)···Mn(2) 3.174(3), Mn(1)···Mn(3) 3.121(2), Mn(2)···Mn(3) 3.067(3).

propellane. The +2 oxidation state of the Mn ions is deduced from stoichiometric and structural considerations, further confirmed by the EPR and magnetic studies. In addition to the two alkoxo μ_3-oxygens, the trigonal prismatic Mn(1) coordination sphere includes one imine-N and one phenolate-O from each L^3 ligand. The basal plane of the square pyramidal ligand environment of Mn(2) and Mn(3) includes one imine-N, one phenolate-O and the alkoxo μ_3-O atoms from one L^3 ligand, in addition to the alkoxo μ_3-O atom from the second L^3 ligand. The apical position of each square pyramid is occupied by one oxygen atom of the bridging acetate. As a result, Mn(1) is doubly bridged to Mn(2) and Mn(3) while Mn(2) and Mn(3) are triply bridged, which is reflected in the 3.067(3) Å Mn(2)···Mn(3) distance compared to the 3.174(3) [Mn(1)···Mn(2)] and 3.121(2) Å [Mn(1)···Mn(3)] separations. Both L^3 ligands are helically arranged around the trinuclear metal core, and show π-stacking interactions between their aromatic rings (Fig. 2). Interestingly, additional aromatic-ring interactions operate between adjacent trinuclear units throughout the crystal lattice, resulting in a 1D supramolecular array of alternating pairs of $[Mn^{II}_3(L^3)_2(\mu_2\text{-OAc})]^-$ anions and Na^+ cations (Fig. 3). Sodium cations interact with terminal 5-nitro and central alkoxo functions of L^3 and bridging acetate anions of the anionic trinuclear units. In addition each Na cation also interacts with one water molecule.

The structure of **2** is unique among the trinuclear manganese complexes reported: those including three Mn^{II} ions are linear[5] or triangular,[6] $Mn^{II}Mn^{III}_2$ complexes include the extensively studied oxo-centred carboxylato compounds,[7] and linear species;[8] Mn^{III}_3 complexes include oxo-centred carboxylato compounds,[9] and a triangular species including a double methoxo μ-oxygen bridge and two single alkoxo μ-oxygen bridges;[10] Mn^{IV}_3 complexes include the $[Mn_3O_4]^{4+}$ core with a double μ-oxo and two single μ-oxo bridges.[11]

The 300–80 K X-band powder spectra of complex **1** exhibit an extremely broad (*ca.* 3500 G) and featureless $g \approx 2$ centred resonance. At variance with the reasonably broad absorption typical of tetranuclear Mn^{II} complexes,[3] the broadness of this EPR absorption indicates the presence of weak extended interactions in the solid state.[12] This agrees with the crystallographic observation of 1D chains of tetramanganese(II) units. The 100 K dmf–toluene X-band glass spectrum of **1** exhibits a reasonably broad (*ca.* 700 G) $g \approx 2$ centred isotropic resonance devoid of any fine or hyperfine structure. This indicates that, (*i*) the tetranuclear structure is retained in solution, and (*ii*) the weak extended interactions are not operating in solution, *i.e.* the 1D chains of hydrogen-bonded tetranuclear molecules are broken. The 300–80 K X-band powder spectra of **2** are similar to those reported for **3**,[3] and typical of magnetically interacting Mn^{II} ions. On the other hand, the 100 K dmf–toluene glass X-band EPR spectrum of **2** indicates dissociation, not only of its supramolecular architecture, but also of the trinuclear Mn^{II} complex anions. Two resulting Mn^{II} species are clearly identified: (*i*) a mononuclear one showing the usual ^{55}Mn six-line hyperfine pattern at $g \approx 2$, and (*ii*) a dinuclear one showing the typical 11-line hyperfine pattern superimposed on several fine structure absorptions (0–5000 G).[13] The magnetic susceptibilities of complexes **1** and **2** have been measured in the 300–2 K temperature range. For both complexes, μ_{eff} mol^{-1} at 300 K is lower than the spin-only value for non-interacting spin systems (11.83 μ_B for four $S = 5/2$ spins and 10.25 μ_B for three $S = 5/2$ spins) and decreases from 10.50 to 4.89 μ_B (**1**) and 9.00 to 4.91 μ_B (**2**) at 2 K, indicating overall antiferromagnetic coupling of the $S = 5/2$ spins of the Mn^{II} ions in both complexes.

Owing to the possible role of the vacant coordination sites at the Mn^{II} centres of both novel complexes, their redox behaviour and reactivity are currently under study.

This work was supported by a postdoctoral grant from the European community to L. S. (Human Capital and Mobility Programme, Contract No ERBCHBGCT 93-0417).

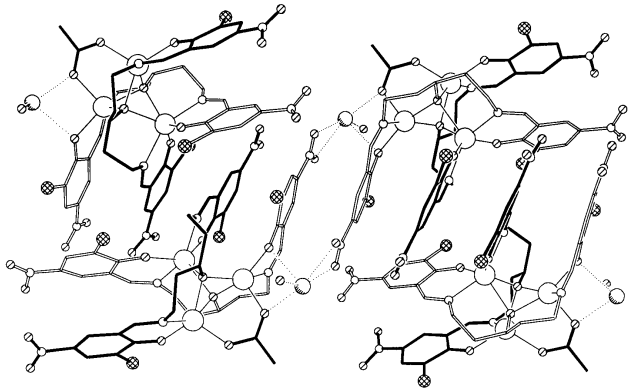

Fig. 3 View of four $[Mn^{II}_3(L^3)_2(\mu_2\text{-OAc})]^-$, $Na^+\cdot H_2O$ ion pairs **2** emphasizing the infinite π-stackings perpendicular to [001]. The intramolecular π-stacking distances are 3.4 and 3.5 Å. The two crystallographically independent intermolecular π-stacking distances are 3.3 and 3.4 Å.

Effects of the arrangement of a distal histidine on regioselectivity of the coupled oxidation of sperm whale myoglobin mutants

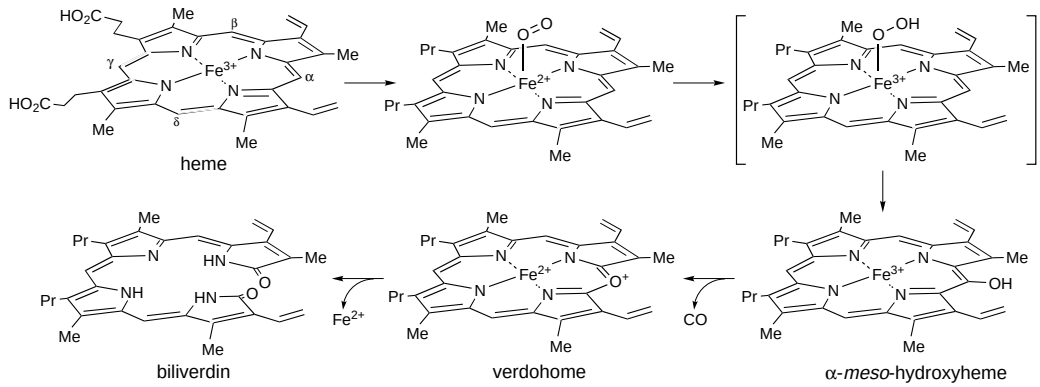
The arrangement of a distal histidine of sperm whale myoglobin alters the regioselectivity of the heme degradation by coupled oxidation.

Heme oxygenase (HO), a monooxygenase of the heme catabolism,[1] utilizes electrons from NADPH and molecular oxygen to transform heme into biliverdin (Scheme 1). The formation of an oxy complex[2] is followed by the hydroxylation of the α-*meso*-carbon presumably *via* a ferric hydroperoxide intermediate.[3] The release of carbon monoxide from hydroxyheme and subsequent ring opening affords biliverdin.[1] Therefore, α-*meso*-hydroxyheme formation from the oxy complex is a key step for the regiospecific opening of the tetrapyrrole macrocycle. Recently, Torpey and co-workers reported that the regiochemistry of the reaction is primarily controlled by the electronic effect of the heme.[4] However, resonance Raman studies suggested that an oxygen molecule of the O_2-bound heme–HO complex had a bent structure and that the terminal oxygen atom was in van der Waals contact with the α-*meso*-carbon of the porphyrin ring.[5] These results might imply that orientation of the bound oxygen also affects the regioselective heme degradation by HO.

Myoglobin (Mb), normally an oxygen storage protein, is also known to transform its prosthetic heme into mainly biliverdin IXα in the presence of ascorbate under aerobic conditions, the so-called coupled oxidation of Mb.[6] Although the coupled oxidation of Mb is much slower than the heme degradation catalyzed by HO, Mb and heme–HO complex both have a histidine residue as a ligand of the heme iron.[7] Furthermore, the crystal structure of oxyMb indicates that the molecular oxygen bound to the heme is restricted by the distal histidine (His-64) toward the α-*meso*-position, and the oxy complex is stabilized by a hydrogen bond with His-64 (Fig. 1). In order to examine whether or not the reorientation of the bound oxygen caused by removal or relocation of the distal histidine affects the regiospecific degradation of heme in Mb, we have constructed H64L, L29H/H64L, F43H/H64L and I107H/H64L Mb and analyzed the biliverdin regioisomers generated by the coupled oxidation of the MBs.§

The high-pressure liquid chromatograph (HPLC) trace of the biliverdin regioisomers prepared from protoheme IX [Fig. 2(*a*)] exhibits four separate peaks. Comparison of the elution profiles of authentic biliverdins allows us to identify the peaks at 8.4, 9.8, 10.4, and 13.6 min as the α-, β-, δ- and γ-isomers, respectively. Wild type Mb affords mainly biliverdin IXα with a trace amount of the β-isomer, as reported previously [Fig. 2(*b*)].[8] Elimination of the distal histidine does not alter the major product [Fig. 2(*c*)]; however, a small amount of the γ-isomer, which is absent in the case of wild type Mb, is observed presumably because the replacement of His-64 with a smaller residue such as Leu allows the bound oxygen to be directed toward the γ-*meso* position (Fig. 1). Interestingly, the His-64 → Leu/Phe-43 → His double mutation significantly alters the product distribution [Fig. 2(*d*)]. Although one of the major degradation products for F43H/H64L Mb is still biliverdin IXα (40%) as observed for the wild type and H64L mutant, a significant amount of the β- (16%) and γ-isomers (44%) are accumulated (Table 1). More importantly, the L29H/H64L mutant is almost regiospecifically oxidized to biliverdin IXγ [Fig. 2(*e*)]. Finally, the substitution of Ile-107 of the H64L mutant with a histidine residue does not change the regioselectivity with respect to H64L Mb [Fig. 2(*f*) and (*d*)].

We have for the first time observed changes in the regioselectivity of the coupled oxidation process of Mb by relocating the distal His.¶ In particular, L29H/H64L Mb is almost regiospecifically oxidized to biliverdin IXγ, although the distal His at position 29 is located too far from the heme iron (6.6 Å)[9] to directly interact with the bound oxygen. The increased amount of the γ-isomer for H64L Mb can be explained by elimination of His-64, which sterically blocked the γ-*meso*-position.[10] Introduction of the His at various positions in H64L Mb tends to further enhance γ-isomer formation. Although the mechanism is not clear at this moment, these observations could imply that the distal His, except for His-64



Scheme 1

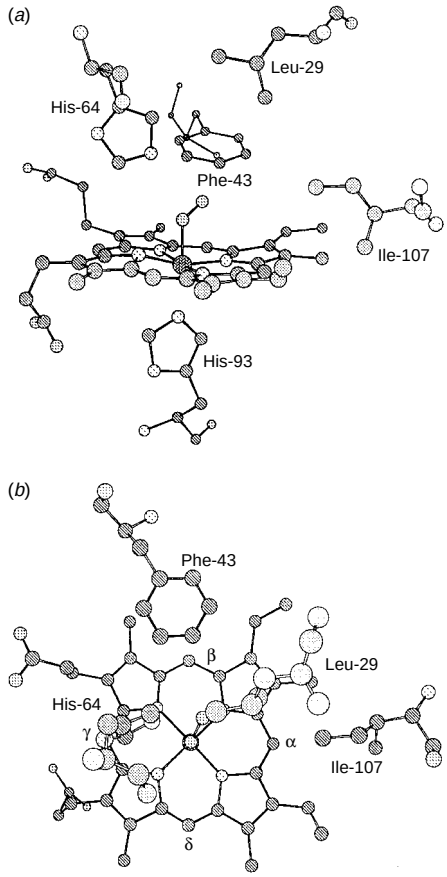


Fig. 1 Heme environmental structure of myoglobin. Heme and some selected residues are shown. (*a*) Side view. (*b*) Top view.

in the wild type, enhances orientation of the bound oxygen toward the γ-*meso*-position by an indirect effect, *e.g.* a biased polarity in the distal site. As discussed before, His-64 in wild type Mb forces the oxygen toward the α-position, thus preventing γ-isomer formation.

Very recently, we have shown that F43H/H64L Mb reacts with H_2O_2 much faster than wild type Mb to form compound I as an observable species.[11] Detailed kinetic studies support the participation of His-43 in F43H/H64L Mb as a general acid/base catalyst, *i.e.* the hydrogen peroxide bound to heme interacts with His-43 *via* a hydrogen bond. In fact, the distance between the terminal oxygen atom and the N_ε atom of His-43 is estimated to be approximately 3 Å, within the range of normal hydrogen bond distances, based on calculations using DISCOVER.[12] Thus, the increase in the ratio of the β-isomer for the oxidation of F43H/H64L Mb would be due to a hydrogen bond between the terminal oxygen atom and the His-43 near the β-*meso*-position in the oxy complex.

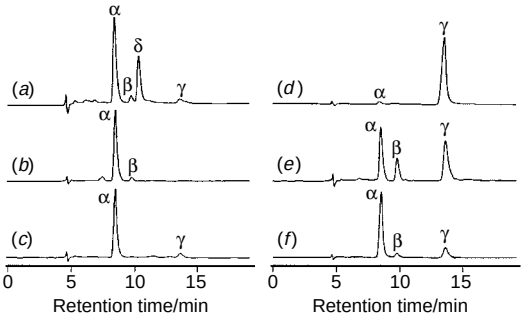

Fig. 2 HPLC analysis of the biliverdin regioisomers isolated from the coupled oxidation of Mbs with ascorbate at 37 °C for 3 h: (*a*) hemin, (*b*) wild type Mb, (*c*) H64L Mb, (*d*) L29H/H64L Mb, (*e*) F43H/H64L Mb and (*f*) I107H/H64L Mb

Table 1 Ratio of four biliverdin isomers produced by the coupled oxidation of Mbs[a]

	Ratio (%)			
Mb	α :	β :	γ :	δ
Wild-type	95 :	5 :	0 :	0
H64L	94 :	0 :	6 :	0
L29H/H64L	3 :	0 :	97 :	0
F43H/H64L	40 :	16 :	44 :	0
I107H/H64L	72 :	6 :	22 :	0

[a] Ratio of the peak area.

In summary, the arrangement of a distal histidine of Mb alters the regioselectivity of the heme degradation even without direct interaction of histidine with the peroxide bound to heme. This type of effect on the regioselectivity in HO reaction has never been considered. Introduction of a more polar or even charged residue in the active site to study the basis for regioselectivity of the coupled oxidation of Mb is now under way.

§ To a 250 μl solution of ferric Mb or its mutants (40 μm) was added sodium ascorbate (2 mg) and the resulting solution was incubated at 37 °C for 3 h. Extraction of the biliverdin regioisomers was previously reported by Brown and Docherty.[13] The products dissolved in MeOH were loaded onto a HPLC (Waters 600) apparatus equipped with Waters 741 data module and a TOSOH CO-8020 column oven. A reversed-phase HPLC column (Whatmann Partisil 5 ODS-3) was employed at 40 °C at a flow rate of 0.7 ml min^{-1} with 75 : 25 (v/v) MeOH–25 mM ammonium phosphate buffer (pH 3.5) and monitored at 380 nm. A mixture of four biliverdin regioisomers was prepared from protoheme IX according to the method previously reported [ref. 4(*a*)].

¶ We assumed that the structural framework of the mutant proteins remained unchanged.

Structure–activity relationship for quantifying aromatic interactions†

Fiona J. Carver,[a] Christopher A. Hunter*[a]‡ and Eileen M. Seward[b]

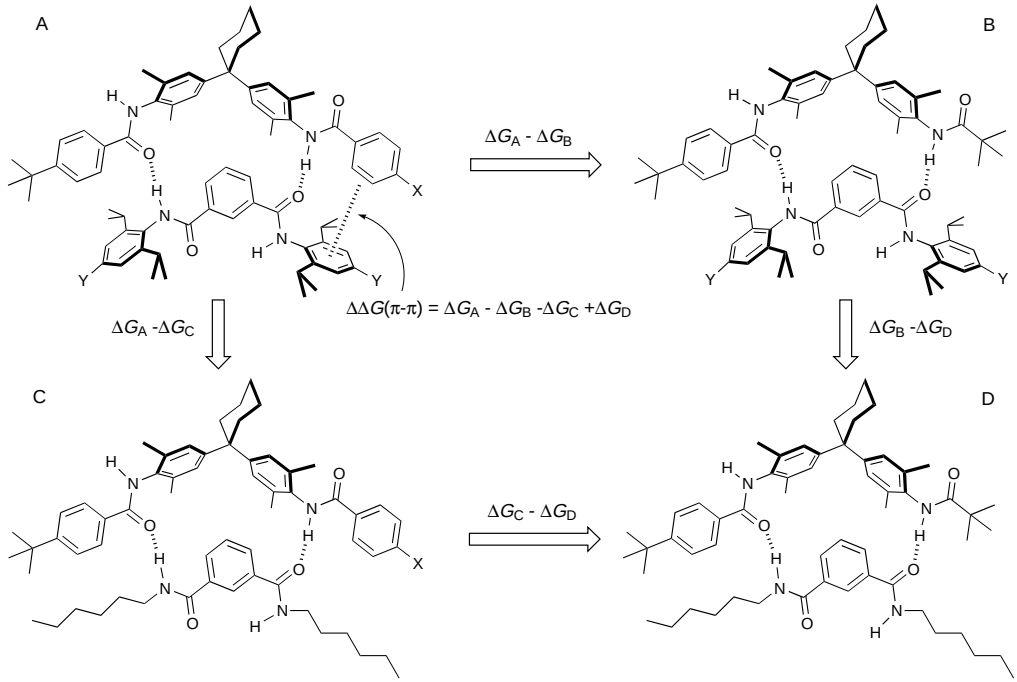
[a] *Krebs Institute for Biomolecular Science, Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*
[b] *Merck Sharp and Dohme, Terlings Park, Harlow, UK*

The magnitudes of a range of intermolecular edge-to-face aromatic interactions are measured using chemical double mutant cycles in synthetic H-bonded molecular zipper complexes, and good correlations are obtained with the Hammett substituent constants, suggesting that the results can be extrapolated to other functional group combinations.

Molecular recognition events are complex processes which are influenced by a large number of different factors that make it difficult to quantify the thermodynamic properties of the basic functional group interactions involved.[1–10] We have adapted the double mutant cycle approach developed to quantify side chain–side chain interactions in proteins[5] to quantify functional group interactions in a synthetic supramolecular system. Here we apply this method to derive a quantitative structure–activity relationship for aromatic interactions.[2,8,11,12] The results not only yield a molecular explanation for the properties of these interactions, they also allow us to make quantitative predictions about the influence of chemical structure on the magnitudes of aromatic interactions.

The chemical version of the double mutant cycle which enables us to dissect out and isolate the contribution of the terminal aromatic interaction to the overall free energy of binding for zipper complex **A** is shown in Scheme 1.[13,14] Chemical mutation of one aromatic ring to a Bu^t group (**A** → **B**) removes the aromatic interaction of interest, but this change also removes secondary interactions between the aromatic ring and the core of the complex. In addition, the mutation alters the strength of the neighbouring H-bond. However, the magnitude of the secondary interactions and the change in H-bond strength can be measured directly by carrying out the same chemical mutation in complex **C** (**C** → **D**). Thus by determining association constants for all four complexes and constructing the cycle in Scheme 1, we can quantify the aromatic interaction of interest. The advantages offered by this synthetic system are that the two interacting groups are attached to a relatively rigid framework which determines the geometry of the interaction, and that a wide range of different functional groups can be studied. The geometry of interaction is probably not the optimum orientation for all combinations of functional group, but it will be essentially identical in each case. This means that electronic structure–activity relationships are not buried by differences in conformation. A limitation of the approach is that we assume that the magnitudes of the core interactions in all four complexes in a cycle are insensitive to changes in the overall binding energy.[1,6] The magnitude of entropy–enthalpy compensation effects in such systems has not yet been established, but even if they are large enough to affect our measurements, they will not alter the trends in the magnitudes of the functional group interaction energies.

Using the system in Scheme 1, we have carried out a quantitative study of substituent effects on the magnitudes of edge-to-face aromatic interactions. The required compounds were synthesised using standard protocols and characterised by a range of spectroscopic and analytical techniques. The complexes were characterised using ^{1}H NMR spectroscopy in $CDCl_3$. ^{1}H NMR titrations were used to determine the association constants and hence free energies of complexation for use in the thermodynamic cycles. The final results are



Scheme 1 Chemical double mutant cycles used to measure the magnitude of edge-to-face aromatic interactions, $\Delta\Delta G(\pi–\pi)$. X, Y = NO_2, H, NMe_2

Table 1 Magnitudes of edge-to-face aromatic interactions [$\Delta\Delta G(\pi–\pi)$ in kJ mol^{-1}] measured in $CDCl_3$ at 295 K using the chemical double mutant cycles shown in Fig. 1. Errors are ± 0.5–0.8 kJ mol^{-1}

Y	X = NO_2	X = H	X = NMe_2
NO_2	+1.2	−0.2	−1.4
H	−3.4	−1.4	−1.1
NMe_2	−4.6	−1.8	−0.9

summarised in Table 1. Intermolecular NOEs from ROESY experiments and the magnitudes of the complexation-induced changes in chemical shift from the titrations show that all four complexes in each of the nine double mutant cycles adopt essentially the same conformation in solution, *i.e.* the chemical mutations do not grossly alter the three-dimensional structure of the core of the complex. More detailed information about the geometry of the edge-to-face aromatic interactions under investigation was obtained from X-ray structures of model compounds such as **1** which corresponds to half of the zipper complex and crystallises with the same H-bonds and edge-to-face aromatic interactions inferred from our solution studies.[13,14]

The magnitude of the aromatic interaction, $\Delta\Delta G(\pi–\pi)$, is clearly sensitive to the nature of the substituents and varies from +1.0 kJ mol^{-1} repulsive to −4.9 kJ mol^{-1} attractive (more than an order of magnitude in binding strength). The ability to measure both repulsive and attractive interactions allows us to properly characterise the potential energy surface in this system. The trends in Table 1 are difficult to interpret, and so we have analysed the results using the Hammett substituent parameters (σ) which quantify the electronic effects of the substituents on the aromatic ring.[15] The correlation is remarkable and allows us to describe the experimental results using eqn. (1) (Fig. 1).

$$\Delta\Delta G(\pi–\pi) = 5.2\ \sigma_X\ \sigma_Y - 1.9\ \sigma_X + 1.4\ \sigma_Y - 1.5 \qquad (1)$$

This equation gives some insight into the molecular basis for the variations in interaction energy in Table 1. The last three terms in eqn. (1) are interpreted as an electrostatic interaction between the positively-charged CH groups on the edge ring and the negatively charged π-electron density on the face ring [Fig. 2(*a*)].[16] This part of the interaction is sensitive to changes in the local charge distributions on the two rings. The first term in eqn. (1) is attractive when the two groups X and Y exert opposite effects which reflects an interaction between the global charge distributions across the two aromatic rings, *i.e.* an electrostatic interaction between the overall dipoles caused by the polarising effects of the substitutents [Fig. 2(*b*)].

Eqn. (1) implies that although we have only studied nine interactions, the results can be extrapolated to a wide range of functional group combinations provided the Hammett parameters are available from the literature. It is unlikely that eqn. (1) will accurately predict ΔG values for aromatic interactions in other systems, but we expect it to provide a reasonable estimate of the magnitudes of substituent effects, *e.g.* if an edge-to-face aromatic interaction is implicated in a drug-receptor complex,[17] there is no point looking at lots of different Y groups if X is electron donating (NMe_2), because the magnitude of the interaction is relatively insensitive to Y. However if X is electron withdrawing (NO_2), the nature of Y is likely to have a dramatic effect on the interaction energy.

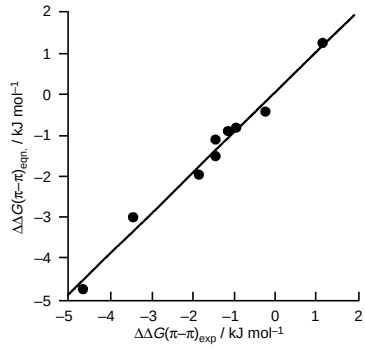


Fig. 1 Correlation of the experimental measurements of the aromatic interaction energies from Table 1 with the interaction energies calculated using eqn. (1) and the Hammett substituent parameters

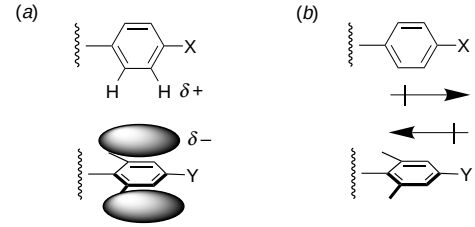

Fig. 2 Molecular interpretation of eqn. (1). (*a*) Electrostatic interactions between the CH groups of the edge ring and the π-electron density of the face ring are sensitive to changes in the local charge distributions on the two aromatic rings. (*b*) Electrostatic interactions between the overall dipoles of the π-systems are sensitive to changes in the global charge distributions on the two aromatic rings.

The generality of these results remains to be tested in different contexts, using alternative molecular frameworks and solvents, but the approach is clearly a promising method for dissecting out individual contributions to the overall thermodynamic stability of a particular molecular recognition event. By studying different interaction geometries and types, we hope to develop a database of thermodynamic measurements that can be used alongside the structural data from crystallography for understanding the chemical basis of complex molecular recognition phenomena and ultimately for rational design.

We thank the Lister Institute (C. A. H.), the EPSRC and Merck Sharp & Dohme (F. J. C.) for funding.

Synthesis, luminescence and electrochemistry of novel pentanuclear rhenium(I)–copper(I) mixed-metal acetylide complexes. X-Ray crystal structure of $[Cu_3(\mu\text{-dppm})_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}CC_6H_4C{\equiv}C\text{-}p\text{–}Re(bpy)(CO)_3\}_2]^+$

Vivian Wing-Wah Yam,*† Wendy Kit-Mai Fung, Keith Man-Chung Wong, Victor Chor-Yue Lau and Kung-Kai Cheung

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China

A series of luminescent mixed-metal acetylide complexes $[Cu_3(\mu\text{-LL})_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{–}C_6H_2R_2\text{-}2,5\text{–}C{\equiv}C\text{-}p\text{–}Re(NN)(CO)_3\}_2]^+$, (LL = dppm, Pr^nPNP; NN = bpy, Bu^t_2bpy; R = H, Me) have been synthesized and their electrochemical properties studied; the X-ray crystal structure of $[Cu_3(\mu\text{-dppm})_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{–}C_6H_4C{\equiv}C\text{-}p\text{–}Re(bpy)(CO)_3\}_2]^+$ has also been determined.

The highly conjugated polyynes and their transition metal complexes have attracted enormous attention in recent years owing to their potential technological applications as precursors for non-linear optical materials and rigid-rod molecular wires.[1] With our recent interest in the design and synthesis of luminescent Re^I[2] and Cu^I acetylide complexes,[3] it would be interesting to extend our studies to mixed-metal acetylide complexes using the 'metal complex as ligand' or metalloligand approach.[1c,4] Here, we report the synthesis of a series of Re^ICu^I mixed-metal acetylide complexes (**1**–**5**), $[Cu_3(\mu\text{-LL})_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{–}C_6H_2R_2\text{-}2,5\text{–}C{\equiv}C\text{-}p\text{–}Re(NN)(CO)_3\}_2]^+$, {LL = bis(diphenylphosphino)methane (dppm), bis(diphenylphosphino)-*n*-propylamine (Pr^nPNP); NN = 2,2′-bipyridine (bpy), 4,4′-di-*tert*-butyl-2,2′-bipyridine (Bu^t_2bpy); R = H, Me} with a rigid-rod acetylide backbone employing Re^I acetylide as the metalloligand. We believe that these mixed-metal acetylide complexes would be ideal building blocks for the design of luminescent rigid-rod oligomers.

$[Cu_3(\mu\text{-LL})_3\{\mu_3\text{-}\eta^1\text{-}C{\equiv}C\text{–}C_6H_2R_2\text{-}2,5\text{–}C{\equiv}C\text{-}p\text{-}Re(NN)(CO)_3\}_2]^+$ {LL = dppm, NN = bpy, R = H (**1**); LL = dppm, NN = bpy, R = Me (**2**); LL = dppm, NN = Bu^t_2bpy, R = H (**3**); LL = Pr^nPNP, NN = bpy, R = H (**4**); LL = Pr^nPNP, NN = bpy, R = Me (**5**)} were prepared by reaction of the corresponding $[Cu_2(\mu\text{-LL})_2(MeCN)_2]X_2$ (X = BF_4, PF_6)[3c,5] with $[Re(NN)(CO)_3(C{\equiv}C\text{–}C_6H_2R_2\text{-}2,5\text{–}C{\equiv}CH\text{-}p)$[6] in a 3 : 4 molar ratio in the presence of an excess of KOH in CH_2Cl_2–MeOH at room temp. Recrystallization from CH_2Cl_2–Et_2O gave orange crystals of **1**–**5**. Complexes **1**–**5** have been characterized by elemental analyses, ^1H NMR, IR and Raman spectroscopy. The X-ray crystal structure of **1** has been determined.‡

Fig. 1 shows a perspective drawing of the complex cation of **1**. It consists of an isosceles triangular array of Cu atoms with a dppm ligand bridging each edge to form a roughly planar Cu_3P_6 core, with two Re acetylide metalloligands capping the triangular Cu^I in a μ_3-η^1 fashion. The bridging mode of the alkynyl group is asymmetric with Cu–C bond distances in the range 2.10(1)–2.34(2) Å. The C≡C bond distances are 1.17(2)–1.23(2) Å, typical of metal–acetylide σ bond.[7] The Cu···Cu separations in the range 2.556(2)–2.674(3) Å, which are shorter than the sum of van der Waals radii for Cu are suggestive of the presence of weak Cu···Cu interactions.

The electronic absorption spectra of **1**–**5** in CH_2Cl_2 show high-energy absorption bands at *ca*. 250–300 nm, tentatively assigned as ligand-localized transitions. Absorptions at *ca*. 348–378 nm appear as vibronically structured bands with vibrational progressional spacings of *ca*. 1350–1500 cm^{-1}, typical of ν(C··C) stretching modes of the aromatic ring in the excited state. In addition, a low-energy absorption is observed at *ca*. 440 nm, which is likely to arise from a $[d_\pi(Re) \rightarrow \pi^*(NN)]$ MLCT transition,[8] since the mononuclear Re^I diimine acetylide complexes $HC{\equiv}C\text{–}C_6H_2R_2\text{-}2,5\text{–}C{\equiv}C\text{-}p\text{-}Re(NN)(CO)_3$ (NN = bpy, Bu^t_2bpy; R = H, Me) absorb in a similar region.[2,6]

Excitation of **1**–**5** in the solid state and in fluid solutions resulted in strong orange luminescence. The photophysical data are summarized in Table 1. All spectra showed a low-energy emission band at *ca*. 600–660 nm. With reference to previous spectroscopic studies on Re^I diimine acetylide systems,[2,6] the low-lying emission band in **1**–**5**, which resembles that of the corresponding mononuclear Re^I diimine acetylide, is assigned as derived from an emissive state of $[d_\pi(Re) \rightarrow \pi^*(NN)]$ MLCT character. The shift in emission energy upon changing the bipyridine and the acetylide ligands lends further support to the MLCT assignment. A blue shift in energy of the lowest lying emission band of 0.09 eV from **1** to **3** in CH_2Cl_2 is in accord with the higher π^* orbital energy of Bu^t_2bpy than bpy. A similar blue shift in emission energy (0.11 eV) has also been observed

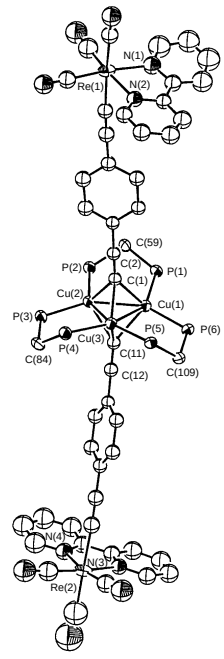

Fig. 1 Perspective drawing of the complex cation of **1** with the atomic numbering scheme. Hydrogen atoms and phenyl rings have been omitted for clarity. Thermal ellipsoids are shown at the 40% probability level. Selected bond lengths (Å) and angles (°): C(1)–C(2) 1.20(2), C(11)–C(12) 1.21(2), Cu(1)···Cu(2) 2.556(2), Cu(2)···Cu(3) 2.674(3), Cu(1)···Cu(3) 2.674(3); Cu(1)–Cu(2)–Cu(3) 61.44(7), Cu(2)–Cu(1)–Cu(3) 61.47(7), Cu(1)–Cu(3)–Cu(2) 57.09(6).

[a] Excitation at 400 nm. [b] Excitation at 510 nm. [c] In MeCN (0.1 M $NBu^n_4PF_6$), glassy carbon electrode, scan rate 100 mV s^{-1}, 298 K. $E_{1/2}$ (V *vs.* Fc–Fc$^+$) is taken to be the average of E_{pa} and E_{pc}.

on going from $[Re(bpy)(CO)_3Cl]$[8b] to $[Re(Bu^t_2bpy)(CO)_3Cl]$.[2a] A comparison of the emission energies for the complexes with the same Re acetylide but different bidentate phosphine ligands, that is, between **1** and **4** and **2** and **5**, showed that a slight red shift in energy occurred on going from **1** to **4** and **2** to **5**. Such a trend may be rationalized by the fact that the Pr^nPNP ligand is more electron rich than dppm, which upon coordination to Cu^I would render the Cu^I-coordinated acetylide more electron rich, which in turn raises the energy of the Re d orbitals, causing a lower energy ^{3}MLCT emission. Similar findings have been reported in Re^I-acetylide and Re^I-alkyl systems.[2,9] On the contrary, an acetylide-to-Cu LMCT origin would predict an opposite trend since a more electron rich diphosphine on Cu^I would lower the electron-accepting ability of Cu, raising its acceptor orbital energy, leading to a higher emission energy. Furthermore, the lifetime in the range of submicroseconds is typical of ^{3}MLCT emission.

The electrochemistry of complexes **1**–**5** has been studied by cyclic voltammetry and the electrochemical data are listed in Table 1. Complexes **1**–**5** in MeCN (0.1 M $NBu^n_4PF_6$) show both a quasi-reversible oxidation couple and a quasi-reversible reduction couple. In general, complexes with electron rich ligand are found to be more easily oxidized, with the potential values decreasing for the series with dppm as bridging ligand: **1** > **3** > **2** and the series with Pr^nPNP as bridging ligand: **4** > **5**. These trends are consistent with the greater electron richness of the 2,5-dimethyl-1,4-diethynylbenzene than the unsubstituted 1,4-diethynylbenzene and Bu^t_2bpy than bpy. The oxidation couples are tentatively assigned as the one-electron oxidation of the Cu^I center, with the more electron rich ligands preferentially stabilizing the Cu^{II} center to a larger extent. Oxidation couples at similar potential values have also been observed in the trinuclear Cu^I acetylide systems.[3a–c]

The quasi-reversible reduction couple for **1**–**5** has been assigned as the one-electron reduction couple of bpy ligands[10] on the basis of the similarity of their reduction potential. The greater ease of reduction in **1** and **2** than **3** is in line with the greater π-acceptor ability of bpy than Bu^t_2bpy.

Synthesis of silica-pillared layered titanium niobium oxide

Wenfeng Shangguan, Kozo Inoue and Akira Yoshida*†

Inorganic Materials Department, National Industrial Research Institute, Shuku-machi, Tosu-shi, Saga-ken, 841, Japan

A silica-pillared layered titanium niobium oxide with high thermal stability has been synthesized and characterized for the first time.

The successful methods for preparation of pillared materials that were first developed from pillaring clays and clay minerals,[1–3] led to many attempts to prepare new classes of porous materials, which can be used as shape-selective catalysts and molecular sieves.[4,5] There are also a wide variety of layered metal oxides that have the potential to undergo ion-exchange reactions similarly to clays, but the pillaring procedures developed for smectite clays are not generally applicable to these laminar metal oxides that do not spontaneously delaminate in aqueous media owing to their high charge densities on the frameworks. Recently, the preparation of alumina-pillared layered sodium trititanate, $Na_2Ti_3O_7$[6] and silica-pillared layered tetratitanate $K_2Ti_4O_9$[7] have been reproted. Silica is one of the most commonly used pillars. Silica-pillared layered lanthanum–niobium oxides were also prepared and investigated as catalysts.[8,9] As for titanium–niobium oxides, Wadsley[10] first prepared potassium titanoniobate $KTiNbO_5$ and found that it had a layered structure. Raveau and coworkers[11–13] studied the ion-exchange properties of potassium titanoniobate $KTiNbO_5$ and the intercalation of organic materials into titanoniobic acid. Nakato *et al.*[14] reported the preparation of a methyl viologen–$HTiNbO_5$ intercalation compound. We report here the preparation of silica-pillared layered titanoniobate with high porosity and good thermal stability by a novel pillaring method, in which *n*-hexylamine and tetraethylorthosilicate [$Si(OEt)_4$] are employed as an interlayer exchange guest and a pillar precursor, respectively.

The starting material, layered potassium titanoniobate $KTiNbO_5$ was prepared by heating a mixture of K_2CO_3 (Katayama), TiO_2 (Katayama) and Nb_2O_5 (Wako) (molar ratio = 1 : 2 : 1) at 1060 °C in air. Ion exchange of $KTiNbO_5$ was carried out with 6 M HNO_3 at room temperature for 72 h to afford $HTiNbO_5$. Since $HTiNbO_5$ cannot react directly with tetraethylorthosilicate to form an intercalate, the *n*-hexylamine–$HTiNbO_5$ intercalation compound was prepared first in order to increase the interlayer distance and lower the charge density.

n-Hexylamine-intercalated titanoniobate was obtained by adding $HTiNbO_5$ to a 50% *n*-hexylamine (Wako)–ethanol (Wako) solution and stirring at room temperature for one week, followed by filtering off the product and washing successively with ethanol–water (1 : 1) and distilled water. The obtained *n*-hexylamine-intercalated titanoniobate (3.0 g) was then added to 120 ml of tetraethylorthosilicate (Wako). Having failed to obtain a silica-pillared titanoniobate by reaction between *n*-hexylamine-intercalated titanoniobate and tetraethylorthosilicate at room temperature, the present operation was performed by stirring for one week at *ca.* 65 °C with two additions of tetraethylorthosilicate (40 ml) during this period. After the reaction, the product was separated and washed as above and finally dried at room temperature. Obtained products were studied by X-ray diffraction (Gigaku Geigerflex, Cu-Kα radiation). In $KTiNbO_5$, units consisting of two MO_6 (M = Ti, Nb) octahedra are linked in the *b*-direction to form layers with the potassium ions in the interlayer spaces. XRD analysis shows [Fig. 1(*a*), 2(*b*)] that obtained $KTiNbO_5$ has an interlayer distance of 9.01 Å by measuring the first diffraction peak (2θ = 9.82°) which decreases to 8.28 Å (2θ = 10.69°) upon exchanging K^+ with H^+ in HNO_3 solution, which is comparable to the value of 8.35 Å[11] but is smaller than 8.5 Å[4] published previously. These differences may be due to the differential preparation conditions. As shown in Fig. 1(*c*), *n*-hexylamine readily intercalates layered titanoniobate and leads to an extremely strong peak at 2θ = 4.08 Å. This interlayer distance is 21.7 Å, which is more than twice that of $HTiNbO_5$. The *n*-hexylamine intercalated titanoniobate had rather low thermal stability, and collapses after calcination at 400 °C [Fig. 1(*d*)]. However, the opened layers can facilitate the reaction of layered-hexylamine intercalated titanoniobate with tetraethylorthosilicate, which gives rise to a lower 2θ (3.68°) and a larger layer distance [24.01 Å, Fig. 1(*e*)]. Fig. 1(*f*) shows that the interlayer distance of the product calcined at 400 °C decreases remarkably to 15.61 Å (2θ = 5.66°) as a result of decomposition of organic matter. The peak is still retained upon heat treatment at 600 °C with only slightly increased 2θ and lower intensity [Fig. 1(*h*)]. TG–DTA analysis at a heating rate of 5 °C min^{-1} for the product intercalated with tetraethylorthosilicate indicated that the interlayer organic matter was decomposed between 300 and 440 °C, and no mass loss was observed at higher temperatures. From these results, it is concluded that silica-like clusters are formed in the interlayer, which act as pilalrs to prop up the titanoniobate layers after interlayer

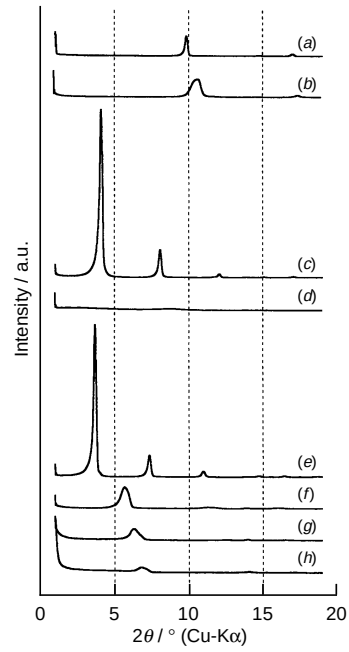

Fig. 1 Cu-Kα X-ray diffraction patterns of (*a*) $KTiNbO_5$ synthesized at 1060 °C; (*b*) as (*a*), proton-exchanged by 6 M HNO_3 at room temperature for 72 h; (*c*) reaction product of $HTiNbO_5$ with *n*-hexylamine solution; (*d*) as (*c*), calcined in air at 400 °C for 2 h; (*e*) reaction product of *n*-hexylamine-intercalated titanoniobate with tetraethylorthosilicate; (*f*) as (*e*), calcined in air at 400 °C for 2 h; (*g*) as (*f*), calcined in air at 500 °C for 2 h; (*h*) as (*g*), calcined in air at 600 °C for 2 h.

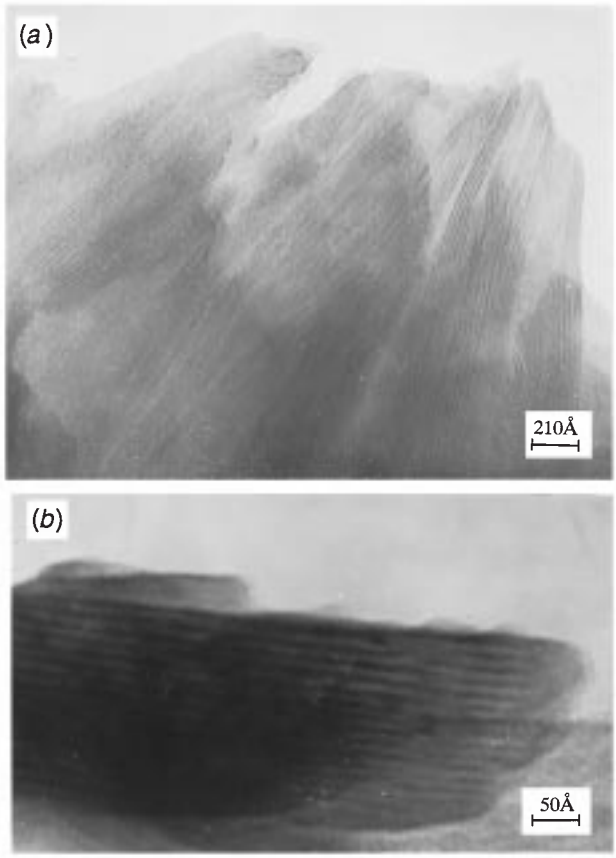

Fig. 2 TEM image of layered silica-pillared titanium niobium oxide with no calcination (*a*) and calcined at 500 °C for 2 h (*b*)

organic matter is removed. The interlayer spacing of the product calcined at 500 °C is found to be 14.05 Å [2θ = 6.29°, Fig. 1(*g*)], which is nearly twice that of $HTiNbO_5$. Fig. 2 shows transmission electron microscopy (TEM, recorded with a JEOL JEM-200CX microscope) images of untreated silica-pillared layered titanoniobate [Fig. 2(*a*)] and a sample calcined at 500 °C [Fig. 2(*b*)]. The layer structures are clearly visible, and the interlayer separations observed by TEM are consistent with those obtained from XRD. While the interlayer spacing of the material increases, the BET surface area of the titanoniobates increases from 1.8 $m^2\ g^{-1}$ for the original $KTiNbO_5$ to 20.0 $m^2\ g^{-1}$ for pillared SiO_2–$TiNbO_5$ calcined at 500 °C, and decreases to 11.3 $m^2\ g^{-1}$ at 600 °C. Elemental analysis results showed that the SiO_2 content in this silica-pillared material is *ca*. 56 mass%. The BET surface area is perhaps lower than expected due to a large amount of SiO_2 incorporated into the interlayers and the weak Bronsted acidity of $HTiNbO_5$ as compared to some layered compounds.[15]

The UV–VIS spectra of SiO_2–$TiNbO_5$ shifted into the visible region as compared to those of $KTiNbO_5$ and $HTiNbO_5$. Hydrogen evolution from the photocatalytic decomposition of water on the pillared layered titanoniobate was observed under a mercury lamp and sunlight. Thus, the new material is expected to show photocatalytic activity. Future investigation on its systematic characterization and catalytic properties is being undertaken.

Non-planar structures of Et_3N and Pr^i_3N: a contradiction between the X-ray, and NMR and electron diffraction data for Pr^i_3N

The crystal structures of Et_3N and Pr^i_3N were determined by X-ray analysis using the *in situ* crystallization technique for single crystal growth on the diffractometer; both have a pyramidal configuration of the nitrogen atom, even Pr^i_3N, which was considered to be planar in accord with electron diffraction and NMR data.

Aliphatic amines represent an important class of compounds widely used in organic chemistry. One of the dominant characteristics of saturated amines is that in the absence of steric congestion their ground state is pyramidal, whereas the exited state is planar. Sterically hindered tertiary amines are particularly interesting in this respect because strong steric effects of substituents can be used to change the geometry around the nitrogen atom. The stereodynamics of simple tertiary amines has been the subject of a few reviews[1] and original publications.[2–9] Most of these studies dealt with investigations into the dynamics of the inversion-rotation processes in amines and/or energetic molecular mechanics and quantum calculations.[9b]

The molecular structures of $MeNH_2$, Me_2NH, Me_3N and Me_2EtN were studied by the gas electron diffraction (GED) and microwave techniques,[10] Me_3N was also studied in the solid state.[11] All compounds have pyramidal configuration around the nitrogen, with C–N–C angles of 110.4–111.8° and C–N lengths of 1.451–1.471 Å $(CF_3)_3N$.[12] has a larger C–N–C angle [117.9(4)°] and a shorter C–N length [1.426(6) Å]. The GED and theoretical studies of Et_3N showed[13] that it exists as a mixture of three conformers with C_3, C_s and C_1 symmetry having very similar energies [angle around N = 112.6(26)°, N–C = 1.466(1) Å]. The structure of the partially fluorinated analogue, $(CH_2CF_3)_3N$, was studied *via* GED and X-ray analysis.[14] The GED investigation[15] of $(CF_2CF_3)_3N$ detected only one conformer having C_3 symmetry with almost planar configuration around the nitrogen atom (C–N–C = 119.3°) and rather a long C–N bond length [1.482(7) Å].

Amongst all known structures of noncyclic trialkylamines there is only one other example where a planar configuration around nitrogen was assumed. This is a GED study of Pr^i_3N by Bock *et al.*[16] [C–N–C = 119.2(3)°, C–N = 1.460(5) Å, C_3 symmetry with C–N–C′–H′ = 5.0(18)°.] Although these data are mostly in line with NMR studies of this compound in solution and in the solid state,[2,7] there are some contradictions with the results of quantum chemical calculations of its molecular structure.[9] Thus, AM1 and PM3 methods predict a nonplanar structure (C–N–C = *ca.* 116.3°) with rather small inversion barriers. In contrast, STO-3G, 3-21G and 6-31G calculations predict a planar structure, while a 6-31G** calculation yields a nearly planar structure (bond angle at N = 119.01°).

Here we compare the X-ray crystal structure of Me_3N **1**[11] with those of Et_3N **2** and Pr^i_3N **3**, the latter two being reported here for the first time; for **1** we present a redetermination based on data which covers a wider 2θ range and twice as many unique reflections.§

In the crystal structure of **1**, the pyramidal molecules have effective C_{3v} symmetry.[11] Those C–H bonds which have an *anti* orientation with respect to the N atom lone pair have a slightly longer bond length [0.997(10) Å] in comparison with the two others [0.959(18) and 0.957(11) Å], which may be attributed to the hyperconjugation effect. Geometrical parameters around the N atom in the crystal [C–N–C = 110.7(1)°, height of N pyramid = 0.450 Å and C–N = 1.448(1) Å] almost coincide with those in the gas phase (110.6° and 1.451 Å)[9] and the previous X-ray determination (110.4° and 1.454 Å). The charge density distribution (Fig. 1), using a quasi-high-order refinement with the Seiler and Dunitz weight scheme,[17] contains the DED maximum at the nitrogen lone pair position at a distance about 0.58 Å from its nuclei, as well as DED peaks at the N–C and C–H bonds. The DED maximum at the N–C bond is slightly shifted from the N–C line inside the NC_3 tetrahedron, which may reflect bending of this bond due to repulsion between the electron density of the lone pair and the covalent N–C bond. Very similar bond bending was found in crystals of NH_3.[18]

The crystal structure of Et_3N **2** is characterized by a rather complicated disorder phenomenon related with the crystallographic m-plane passing through the nitrogen and Me C(1) atoms, such that each CH_2 group has two distinguishable orientations in the crystal, while the carbon atoms of the Me groups have only one position with differing orientations of their hydrogens. The nitrogen has the usual pyramidal configuration [C–N–C = 107.9–112.1(1)°, height of N pyramid = 0.467 Å, and C–N = 1.422–1.497(2) Å; their relatively large scatter is related to the disordering]. As expected, the orientation of all Me groups with respect to the N atom lone pair was found to be *gauche*. We cannot exclude, however, the possibility that the complicated crystal disordering in **2** may be a result of some crystal twinning that was not resolved.

X-Ray diffraction data for Pr^i_3N **3** were collected at 203, 168, 118 and 84 K in order to reveal the nature of the structural disordering. The crystals are hexagonal, space group $P6_3/m$, $Z = 3$, and no indication of a phase transition was found in the temperature interval studied. The structure was solved and refined first at 203 K in this space group with the strictly planar

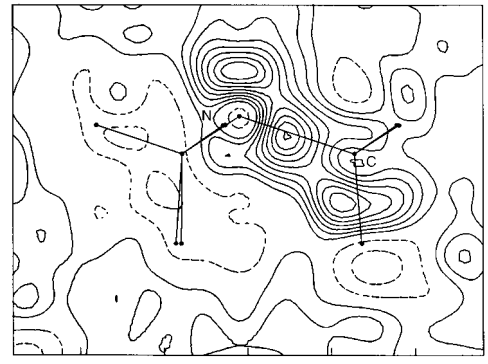

Fig. 1 Deformation electron density in the plane of the three-fold axis and N–C bond. Positive and negative contours are given through 0.025 and −0.05 e Å^{-3}, negative contours dashed.

configuration around the N atom in the special position $\bar{6}$ (2/3, 1/3, 1/4). In accord with this symmetry, the central C and methine H atoms of the Pr^i groups must be in the crystallographic m-plane together with nitrogen, while two Me groups of each Pr^i substituent are above and below this plane and perpendicular to it. The refinement of this model, however, resulted in an unreasonably large U_{33} component of the nitrogen thermal ellipsoid, indicating some kind of disordering, therefore its position was split into two 'halves' below and above the m-plane with a distance of 0.529(8) Å between them. This model was found to be more significant than the previous one and resulted in 'normal' thermal ellipsoids of all atoms and a nonplanar geometry around nitrogen (Table 1). Because these data alone could not give an answer about the nature of the crystal disordering (whether it is dynamic and related to the inversion of the N atom in the crystal, or it is static and the crystal structure represents a superposition of two pyramidal molecules having so-called 'crystal-imposed' symmetry), additional diffraction data at 168, 118 and 84 K were analyzed. We expected that in the case of a dynamic disorder a lowering of the temperature would result in a proportional decrease of the nitrogen thermal ellipsoid (mostly of its U_{33} component), but even at 84 K this ellipsoid still was very large (Fig. 2) and the split model with two 'halves' of the nitrogen atom was found to be significant. These additional data therefore give a definite proof of the pyramidal structure of Pr$^i_3$N in the crystal and the static nature of the disordering.

Our X-ray data for Pr$^i_3$N to a certain extent contradict earlier GED and NMR measurements[2,7,16] but they agree well with AM1, PM3 and *ab initio* calculations[9] giving a nonplanar structure for this molecule. However, we cannot totally exclude the possibility that the nonplanar structure of **3** may be enhanced by the crystal field effect. On the other hand, for tricyclopropylamine[19] which has the same spatial requirements as Pr$^i_3$N, effective C_s symmetry was found, it was not planar (height of N pyramid = 0.467 Å with C–N–C = 110°) and it is not disordered,[20] thus being very similar to Me_3N. In all three structures the intermolecular contacts are significantly larger than the sum of van der Waals radii (H···H > 2.75 Å). In comparison with the structures of **1** and **2**, the height of the N atom pyramid in **3** is the smallest (0.27–0.29 Å) and the inversion barrier is probably not very high.

Table 1 Geometry of Pr$^i_3$N in the crystal at different temperatures

Parameter	203 K	168 K	118 K	84 K
Bond length/Å				
N–C(1)	1.461(2)	1.468(1)	1.469(1)	1.469(1)
C(1)–C(2)	1.511(2)	1.519(1)	1.520(1)	1.522(1)
N–N′	0.529(8)	0.543(4)	0.564(3)	0.583(3)
Bond angle (°)				
C(1)–N–C(1′)	116.8(1)	116.7(1)	116.4(1)	116.2(1)
N–C(1)–C(2)	122.3(2)	122.5(1)	122.8(1)	123.0(1)
N–C(1)–C(2A)	103.8(2)	103.6(1)	103.2(1)	102.7(1)

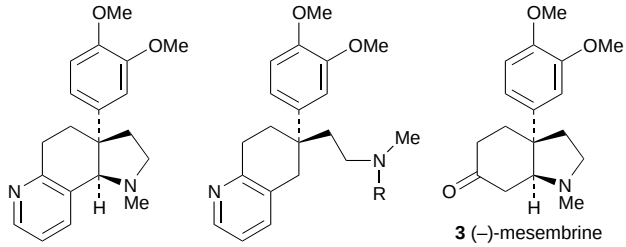
First enantiocontrolled synthesis of sceletium alkaloid A-4: determination of the absolute configuration

Takashi Kamikubo and Kunio Ogasawara*†

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578, Japan

Sceletium A-4, a pyridine alkaloid isolated from the *Sceletium* species, has been synthesized for the first time in an enantiocontrolled manner along with (−)-mesembrine, an alkaloid isolated from the same plant, starting from a chiral cyclohexadienone synthon to determine the absolute configuration.

The alkaloid (+)-sceletium A-4[1,2] **1** is a minor constituent of various *Sceletium* species of the family *Aizonaceae* and was



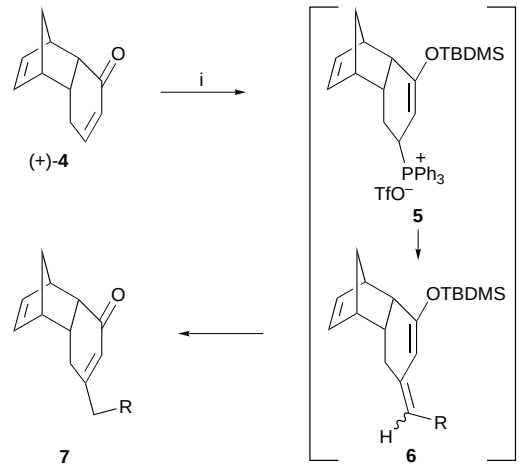
isolated with congeners such as (−)-tortuosamine[2b,d] **2a**, (−)-*N*-formyltortuosamine[2d] **2b** and (−)-mesembrine[1] **3**. (+)-Sceletium A-4 **1** afforded (−)-tortuosamine **2a** on hydrogenolysis[2b,d] while the latter afforded (−)-*N*-formyltortuosamine **2b** on formylation, indicating that they possess the same absolute configuration at the benzylic quaternary centers. The structure determination, both by a single-crystal X-ray analysis[2c] and by racemic syntheses,[3] revealed that (+)-sceletium A-4 **1** possesses the same relative stereochemistry as (−)-mesembrine **3** with respect to two stereogenic centers. However, the absolute configuration of the former alkaloid has not been correlated to the latter, whose absolute configuration has been determined both by X-ray analysis[4] and by enantioselective syntheses.[5]

In order to determine the absolute configuration of (+)-sceletium A-4 **1** as well as of the two congeners **2** by correlation to the stereochemistry of (−)-mesembrine **3**, we examined enantiocontrolled synthesis of Sceletium A-4 **1** along with (−)-mesembrine **3** using the common tricyclic chiral building block (+)-**4**, serving as a chiral cyclohexadienone.[6,7] We report here the first enantiocontrolled synthesis of (+)-sceletium A-4 **1** and a new synthesis of (−)-mesembrine **3** leading to the unambiguous determination of the absolute configuration of (+)-sceletium A-4 **1** and its two congeners, (−)-tortuosamine **2a** and (−)-*N*-formyltortuosamine **2b**.

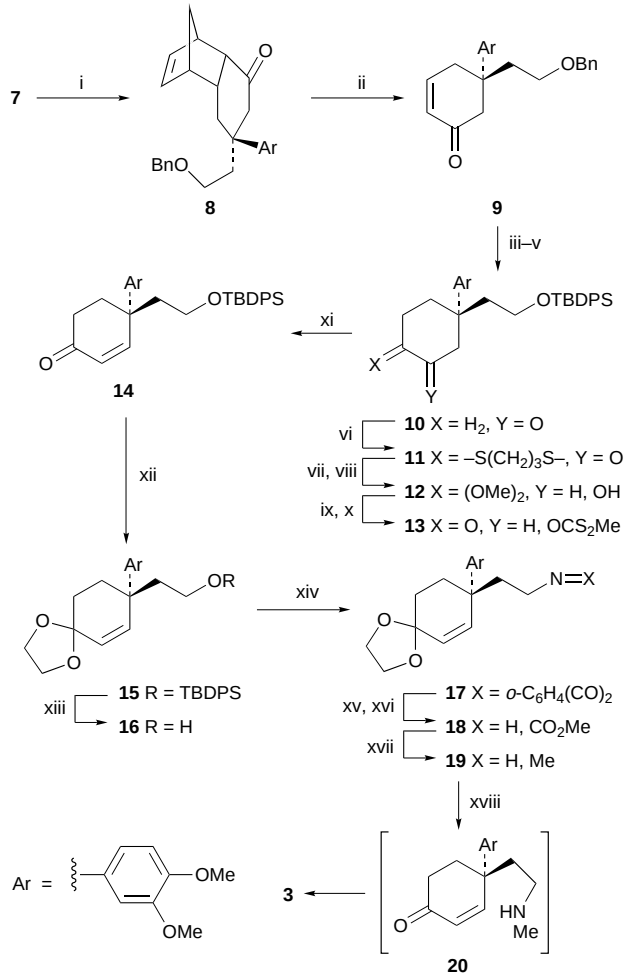
We have recently demonstrated[8] that the tricyclic enone **4** may be β-alkylated to furnish the β-substituted enone **7** by a single-flask sequential Michael–Wittig process[9] *via* the phosphonium trifrate **5** and the 1,3-diene **6** (Scheme 1). Employing this procedure, we prepared the β-substituted enone‡ **7** (R = CH_2OBn), $[\alpha]_D^{28}$ +164.3 (*c* 1.13, $CHCl_3$), in 71% yield from (+)-**4** and 2-benzyloxyacetaldehyde. Reaction of **7** with 3,4-dimethoxyphenylmagnesium bromide in the presence of copper(I) bromide–dimethyl sulfide complex[10] proceeded from the convex face to give the β,β-disubstituted ketone **8** after acid workup, which on thermolysis afforded the cyclohexenone **9**, $[\alpha]_D^{28}$ +64.2 (*c* 1.38, $CHCl_3$). To transpose its 5,5-disubstituted cyclohex-2-enone structure to the 4,4-disubstituted cyclohex-2-enone structure **14**, **9** was first transformed into the α-diketone monothioketal **11** *via* the cyclohexanone **10**, by sequential 1,4-reduction,[11] debenzylation, silylation and α,α-thioketalization.[12] On reduction of the ketone functionality, followed by the thioketal–methyl ketal exchange reaction,[13] **11** furnished the secondary alcohol **12** which was then transformed to the methyl xanthate **13** after acid hydrolysis. Finally, **13** was heated to give the 4,4-disubstituted cyclohex-2-enone **14**, $[\alpha]_D^{29}$ −21.7 (*c* 0.62, $CHCl_3$).

To produce (−)-mesembrine **3**, **14** was first transformed into the ketal alcohol **16** *via* **15**. Employing the Mitsunobu reaction,[14] **16** was next converted to the secondary amine **19**, *via* the imide **17**, and the carbamate **18**. Finally, **18** was treated with perchloric acid in THF to give (−)-mesembrine **3**, $[\alpha]_D^{29}$ −55.4 (*c* 1.16, MeOH) [lit.,[5b] $[\alpha]_D^{30}$ −57.5 (*c* 0.146, MeOH) (Scheme 2).

Having obtained (−)-mesembrine **3**, we investigated the transformation of the same enone **14** into (+)-sceletium A-4 **1** to correlate the stereochemistry (Scheme 3). The enenone **14** was exposed to I_2 in CH_2Cl_2 containing pyridine[15] to furnish the α-iodo ketone **21**. Palladium-mediated cross-coupling reaction[16] between the iodo ketone **21** and *N*-*tert*-butylcarbamoylprop-1-yne yielded the enyne **22** which was converted into the ketal **24** *via* **23** by sequential ketalization and desilylation. Employing a five-step sequence including the Mitsunobu reaction,[14] **24** was transformed into the bis-carbamate **27** *via* the imide enyne **25** and the imide diene **26**. On standing in diluted hydrochloric acid in THF at room temperature, **27** collapsed gradually to the pyridine **30** through a concurrent deketalization, chemoselective decarbamoylation, double cyclization and dehydrogenation, presumably through the allyl amine **28** and the dihydropyridine **29**. The pyridine **30** was exposed to TFA to give the secondary amine **31**, which was immediately subjected



Scheme 1 *Reagents and conditions*: i, PPh_3, TBDMSOTf, THF, −78 °C, then Bu^nLi, −78 °C, then RCHO, 10% HCl



Scheme 2 *Reagents and conditions*: i, 3,4-$(MeO)_2C_6H_3MgBr$, $CuBr{\cdot}SMe_2$, Me_3SiCl, HMPA, THF; ii, Ph_2O, *ca.* 260 °C (77% from **7**); iii, DIBAL-H, CuI, HMPA, THF; iv, H_2, 10% Pd–C; v, Bu^tPh_2SiCl, imidazole, DMF (72% from **9**); vi, $TsS(CH_2)_3STs$, Bu^tOK, THF–Bu^tOH (70%); vii, $NaBH_4$, $CeCl_3{\cdot}7H_2O$; viii, $(CF_3CO_2)IPh$, MeOH (87% from **11**); ix, NaH, CS_2, MeI, THF; x, 70% $HClO_4$–THF (1 : 20); xi, *o*-$C_6H_4Cl_2$, *ca.* 180 °C (77% from **12**); xii, $(CH_2OH)_2$, TsOH, C_6H_6, (100%); xiii, Bu_4NF, THF (94%); xiv, phthalimide, PPh_3, $Pr^iO_2CN{=}NCO_2Pr^i$ (DIPAD), THF (94%); xv, hydrazine·H_2O, EtOH, reflux; xvi, $ClCO_2Me$, Et_3N, CH_2Cl_2 (79% from **17**); xvii, $LiAlH_4$, THF, reflux; xviii, aq. $HClO_4$, THF (66% from **18**)

to the Eschweiler–Clarke reaction[17] to afford (+)-Sceletium A-4 **1**, mp 153.5–154.5 °C, $[\alpha]_D^{27}$ + 120.5 (*c* 1.10, MeOH) (lit.,[2a] mp 153.5–154.5; lit.,[2b] 132–134 °C, lit.,[2c] $[\alpha]_D$ +131 (MeOH); lit.,[2d] $[\alpha]_D$ +131 (EtOH)). The synthetic material had a circular dichroism (CD) spectrum (in 95% EtOH) showing the first cotton effect (positive) at 278 nm, the second (positive) at 274 nm and the third (negative) at 247 nm which was identical to that reported[2d] for (+)-sceletium A-4 **1** (positive at 278 nm, positive at 274 nm and negative at 247 nm in 95% EtOH). Since (+)-**1** thus obtained has the same CD spectrum as the natural product, the absolute configuration of natural (+)-Sceletium A-4 **1** as well as its two natural congeners, (+)-tortuosamine **2a** and (−)-*N*-formyltortuosamine **2b**, has now been established as that shown by correlation to (−)-mesembrine **3**.

Solution-phase combinatorial synthesis of 4-hydroxyquinolin-2(1*H*)-ones

Bheemashankar A. Kulkarni and A. Ganesan*†

Institute of Molecular and Cell Biology, National University of Singapore, 30 Medical Drive, Singapore 117609

Ion-exchange resins catalyse an intramolecular Claisen-type condensation leading to the title compounds, and also serve to purify the products.

In recent years, much effort has been devoted to the synthesis of chemical libraries, particularly for the generation and optimisation of biologically active compounds.[1] High-throughput synthesis by traditional solution-phase chemistry (as opposed to solid-phase techniques) is gaining in popularity with the advent of efficient methods for compound purification. One approach employs polymer-supported reagents[2] that can be readily removed by filtration. Recent examples include immobilized Sc^{III},[3] hydroxybenzotriazole,[4] carbodiimides[5] and guanidines.[6] Another application[5,7] of polymer-supported functional groups is to scavenge unreacted or excess starting materials in solution. Conventional ion exchange resins have been used both as a reagent[8] as well as a purification aid,[9] and we have recently reported[10] a synthesis of tetramic acids in which the resin performs both functions. Here, we demonstrate the application of this technique to the preparation of a pharmacologically important heterocyclic ring system.

4-Hydroxyquinolin-2(1*H*)-ones have attracted considerable attention for various therapeutic areas including antimicrobial and antitumour activity,[11] local anaesthetics[12] and antiinflammatory agents,[13] as well as being antagonists of thyroid hormone,[14] *N*-methyl-D-aspartate[15] and serotonin.[16] A common route to these compounds is the intramolecular Claisen-type condensation of *N*-acylated anthranilate esters. Various bases were used[17] for the cyclization (*e.g.* NaOH, alkoxides, lithium amides, TBAF), but removing these and other impurities is relatively tedious in the context of parallel synthesis. We envisioned that an insoluble quaternary ammonium resin would be more suitable, as in our tetramic acid synthesis.

We prepared a set of Claisen-type condensation precursors from methyl anthranilate by Schotten–Baumann two-phase acylation to give primary amides **1a**–**d** (Scheme 1). For increased diversity, additional examples were first reductively alkylated[18] before acylation to afford secondary amides **1e**–**j**. Treatment of compounds **1** with Amberlyst A-26 resin (OH^- form) uniformly resulted in cyclization. As expected, the 4-hydroxyquinolin-2(1*H*)-ones **2** remain tightly bound to the quaternary ammonium resin, enabling impurities to be removed by simple filtration. Subsequent acidification then releases the product in high yield and purity (Table 1). These cyclizations proceed more readily than with the tetramic acids, as shown by the ability of R^2 = Ph and SPh to be sufficiently activating.

We have further extended this procedure to substituted anthranilic acids (for examples, see Table 2, entries **1k**–**p**). Finally, the selectivity of product sequestration by the resin after the Claisen-type condensation enables the use of crude precursors **1** (Table 2, entries **1q**–**t**). These were obtained without purification after the reductive alkylation or acylation steps, the workup consisting of only aqueous washing. The ability to carry forward intermediates without full purification facilitates the overall sequence for high-throughput synthesis.

In summary, this protocol is suitable for the preparation of diverse 4-hydroxyquinolin-2(1*H*)-ones from commercially available building blocks, while permitting wide variations in the substitution pattern.

Polymer induced multiphase generation in water/organic solvent mixtures. Strategies towards the design of triphasic and tetraphasic liquid systems

Luis H. M. da Silva† and Watson Loh*‡

Instituto de Química, Universidade Estadual de Campinas, Campinas, SP 13083-970, Brazil

The addition of polyethylene oxide to mixtures of CH_2Cl_2 and heptane caused the formation of a biphase liquid system, allowing the attainment of triphase and tetraphase liquid systems upon addition of aqueous salt solutions.

It has been known since the beginning of this century,[1] that ternary mixtures of water and certain pairs of polymers, such as polyethylene oxide (PEO) and Dextran, may form aqueous two-phase systems, each phase being rich in one of the polymers. The same phenomenon has been observed when some inorganic salts, like alkaline sulfates, carbonates or phosphates, are added to aqueous solutions of polymers like PEO.[2] Again, one of the phases is rich in the polymer and the other in the salt. Many theoretical models have been proposed to account for such phenomena,[3] but a comprehensive explanation is not yet available. In general, the current view assumes mutual segregation between the two polymers or the polymer and the inorganic anion, associated with their competition for the water molecules, leading to the exclusion of one of the components to another aqueous phase. Owing to the biocompatibility of their components and to the predominance of water as solvent, these systems have been extensively studied in bioseparation processes involving proteins, nucleic acids and even whole cells.[4]

CH_2Cl_2 and heptane are miscible over their whole composition range. However, upon addition of small amounts of polyethylene oxide (PEO 3350, Sigma) to a mixture of these solvents (CH_2Cl_2: Merck, p.a., previously distilled over CaH_2 and stored over molecular sieves; *n*-heptane: Merck, extra pure), we observed the formation of a stable two-phase liquid system. PEO is almost insoluble in alkanes,[5] but it is very soluble in polar organic solvents like CH_2Cl_2. Therefore, adding heptane to a CH_2Cl_2 solution of PEO should lead to polymer precipitation, as commonly performed in polymer fractionation. The occurrence of liquid–liquid demixing might be explained by the exclusion of PEO from the alkane solution associated with the carrying of CH_2Cl_2 molecules due to their strong interaction with the polymer, similar to what is observed for the aqueous two-phase systems. This view is in accordance with literature reports on solvent preferential adsorption onto polymers in ternary mixture.[6–9] The phase diagram for PEO, CH_2Cl_2 and heptane at 298 K is shown in Fig. 1.

Fig. 1 reveals that the biphase system forms even at low polymer fractions and is favoured by the addition of heptane, whereas an excess of CH_2Cl_2 (more than 60 mol%) leads to a homogeneous system. As PEO is strongly solvated by CH_2Cl_2, the bottom phase is expected to contain solvent molecules which are somewhat bound to the polymer, as they would otherwise mix with heptane. In fact, analysis of the phases' composition,§ performed for the systems represented in Fig. 1 as A and B, supported this view and the segregation between PEO and heptane. The upper phases of systems A and B were composed of 59.7 and 56.3% heptane, 40.3 and 43.7% CH_2Cl_2 and negligible amounts of PEO, respectively. The bottom phases contained 38.2 and 36.1% CH_2Cl_2, 61.8 and 63.9% PEO and no detectable heptane. As more polymer was added, more CH_2Cl_2 was extracted into the bottom phase. In addition, the volume of the bottom phase was observed to increase with the polymer content, agreeing with the proposed polymer solvation role of CH_2Cl_2.

Other polymers were investigated in order to verify the generality of this phenomenon. This behaviour was not observed with polypropylene oxide (1000, Aldrich), poly(tetrahydrofuran) (Terathane 1000, Aldrich) or poly(vinyl alcohol) PVA (13 000–23 000, 98% hydrolysed, Aldrich). For the first two only homogeneous systems were observed, probably because the polymers are less polar than PEO and do not interact so strongly with CH_2Cl_2, or are not so strongly segregated by heptane. For PVA, the addition of heptane led to polymer precipitation, probably due to its higher polarity. For poly(*N*-vinyl-2-pyrrolidone) (PVP, 10000, Aldrich), however, liquid–liquid demixing was observed, but the volume of the bottom phase (which contained PVP and CH_2Cl_2) was much smaller than the one formed with PEO. This suggests that, although PVP interacts sufficiently strongly with CH_2Cl_2 to carry some solvent molecules to another phase, these solvation molecules are fewer in number than those of PEO. Preliminary studies with PEO 10000 produced a phase diagram very similar to that of PEO 3350.

In addition to the water/organic solvent systems widely used for liquid extraction, these organic biphase systems provide two phases without the use of water, which might be harmful to some chemical compounds, and which do not have such extreme polarity differences and thus might overcome solubility problems for some extracts. Furthermore, the strong interaction between the polymer and CH_2Cl_2 could be used to extract this chlorinated solvent from mixtures with other less polar organic solvents, without the need for distillation.

This phenomenon also allows the generation of other multiphase systems. Addition of small amounts of water to this biphase system causes the appearance of a third phase, containing water and PEO. For this system, 77.0% of the

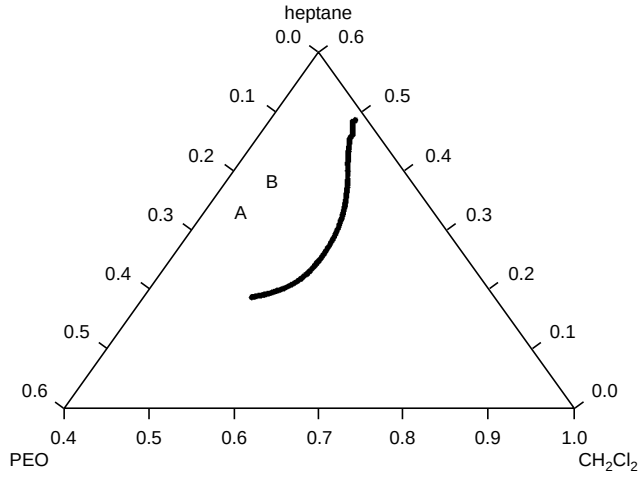

Fig. 1 Phase diagram for mixtures of PEO, CH_2Cl_2 and heptane; the polymer fraction is expressed in terms of monomer units. The two-phase region is the area containing points A and B (see text for the phase compositions).

polymer is in the aqueous phase. As more water is added, more PEO is transferred from the CH_2Cl_2 phase to the aqueous phase. At higher water contents (more than 74.0%), the system becomes biphasic again.

To avoid the destruction of the three-phase system due to polymer extraction, a salt solution may be used, taking advantage of its incompatibility with PEO. This has been observed for a three-phase system with an overall composition of 9.5% PEO, 21.7% CH_2Cl_2, 16.3% heptane, 0.1% sodium sulfate and 51.5% water. The upper phase contained heptane (58.5%) and CH_2Cl_2. The middle phase contained PEO (43%) and CH_2Cl_2. The bottom phase is constituted by the aqueous salt solution containing small amounts of CH_2Cl_2. No polymer was detected in this phase, confirming its segregation from the salt solution.

Other three-phase systems can be obtained by adding an organic solvent such as heptane to an aqueous biphase system, and might be useful in extracting apolar components in bioseparation processes designed for aqueous biphasic systems.

With the addition of larger amounts of salt, it is possible to obtain a four-phase liquid system, with an overall composition of 7.1% PEO, 15.5% CH_2Cl_2, 10.9% heptane and 66.5% sodium sulfate and water. In general, this system may be rationalised as a mixture of aqueous and organic biphasic systems. In fact, the upper phase of the above system contains only heptane (50.2%) and CH_2Cl_2. The second upper phase is composed predominantly of an aqueous solution of PEO (containing 66.3% of the total polymer). The third phase occurs as a sphere and contains PEO and CH_2Cl_2, with a little water. Addition of more salt turns this phase turbid and, by optical microscopy and addition of Methylene Blue, it was verified to consist of a water-in-oil emulsion, probably stabilised by PEO molecules. The spherical shape of this phase is determined by the attainment of the smallest area to volume ratio, in order to minimise the unfavourable interfacial energy due to the contact with the aqueous phase. Finally, the bottom phase of this four-phase system contains an aqueous salt solution, with no polymer due to its mutual incompatibility with sulfate.

These multiphasic liquid systems allow much higher selectivities than the usual water/oil or aqueous biphasic systems, providing phases with a wide range of polarities and chemical properties to suit different purposes. Furthermore, the presented general procedure may be extended to include other polymers or organic solvents and opens a variety of possibilities for improvement of liquid extraction processes.

§ These compositions were determined by weighing the carefully separated phases and assaying heptane by gas chromatography (HP 5890 chromatograph, using N_2 as carrier, a FID detector and cyclooctane as internal standard) and PEO by dry weight. All compositions are expressed on the basis of mol% and, for PEO, mol refers to moles of monomer units.

NMR evidence for the nucleation of a β-hairpin peptide conformation in water by an Asn-Gly type I′ β-turn sequence

Samuel R. Griffiths-Jones, Allister J. Maynard, Gary J. Sharman and Mark S. Searle*†

Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD

The contribution of the β-turn sequence to the folding and stability of a peptide β-hairpin in water has been analysed from studies of a truncated peptide lacking one β-strand and hence the majority of the interstrand hydrophobic interactions; NMR analysis shows that the Asn-Gly type I′ β-turn conformation is significantly populated, suggesting that the intrinsic conformation preference of the turn sequence may play an important role in nucleating hairpin folding.

Hydrogen bonding,[1] hydrophobic interactions[2,3] and conformational preferences[4,5] (largely associated with the β-turn sequence) have been variously proposed to play key roles in the folding of peptide and protein fragments into β-hairpin structures. Given the prominent position of anti-parallel β-sheets in the architecture of globular proteins, autonomously folding β-hairpin peptides provide useful model systems for probing β-sheet stabilisation in solution, for assessing their possible role in nucleating protein folding and as novel motifs in molecular recognition.[6–8]

We have recently described a 16-residue model peptide that folds into a β-hairpin in water (50% populated at 303 K) without the need for cross-links or incorporation of non-natural amino acids [Fig. 1(*a*)].[8] Our sequence was designed, and subsequently shown, to adopt a β-hairpin with a type I′ two-residue β-turn forming at the Asn-Gly sequence. This choice of β-turn sequence was based upon statistical analyses of two-residue turns in the Protein Data Bank which are predominantly of the type I′ variety (and to a lesser extent type II′ variety) with the Asn-Gly sequence having a high abundance.[3,9,10] To understand further the origin of the stability of the hairpin in water we have investigated the conformational properties of several shorter peptide fragments to assess the role of the turn sequence in nucleating the folding and in stabilising the β-hairpin conformation. Thermodynamic analysis of the intact β-hairpin has shown that the folded conformation in water is stabilised by cross-strand hydrophobic interactions between the residue side chains of the two β-strands.[8] Such interactions give rise to an entropy-driven folding process which is associated with a large negative change in the heat capacity (ΔC_p^o) between the folded and unfolded states. Both of these features are hallmarks of the hydrophobic effect playing a key role in the self-assembly process.[11] Here we assess whether these hydrophobic contacts are pivotal to the formation of the adopted conformation or whether they act to stabilise an intrinsic conformational preference nucleated by the residues in the turn sequence.

In the peptide shown in Fig. 1(*b*), residues 1–5 of the N-terminal β-stand have been deleted leaving only residues immediately adjacent to the turn sequence on the N-terminal strand and all residues of the C-terminal strand. The majority of interstrand hydrophobic contacts previously identified[8] (involving Y^3, T^4 and V^5) have now been removed such that any tendency for the β-turn to form must now reflect, in large part, the intrinsic conformational preference of the turn sequence and the immediately flanking residues. The residues flanking the Asn-Gly turn sequence on the N-terminal strand (namely S^6 and I^7) were retained in the sequence of the truncated peptide (**1b**) to provide convenient NMR 'handles' for detecting turn formation. In the hairpin (**1a**), cross-strand Hα–Hα (S^6–K^{11}) and NH–NH (I^7–K^{10}) medium range NOEs are detected that are consistent with this conformation.[8]

Analysis of the 200 ms ROESY spectrum of **1b** at 278 K reveals the presence of both of these cross-strand interactions [S^6 Hα–K^{11} Hα, Fig. 2(*a*); I^7 NH–K^{10} NH, Fig. 2(*b*)], providing convincing evidence that the two-residue turn conformation is populated in water in the absence of the interstrand hydrophobic interactions that appear to stabilise the intact hairpin. While these medium range ROEs provide evidence for secondary structure formation, the intensity of the ROEs between protons

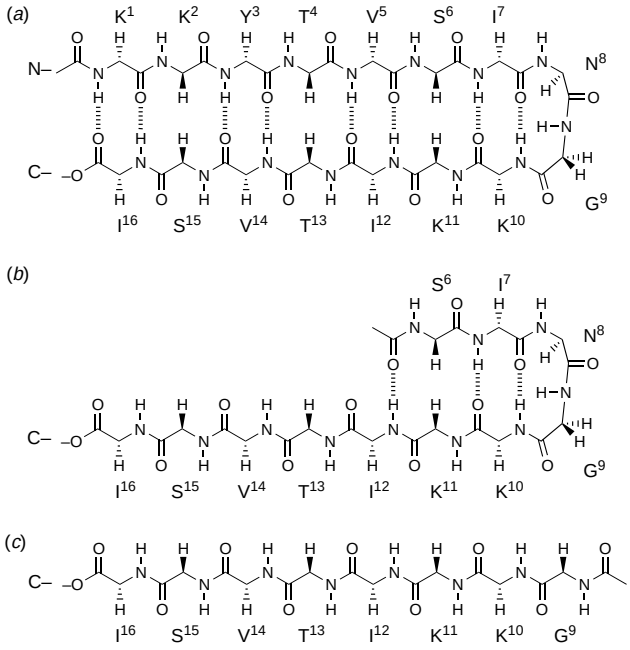

Fig. 1 Amino acid sequences (one letter code, numbering from the N-terminus) and the proposed folded conformations. Side chains are excluded for clarity.

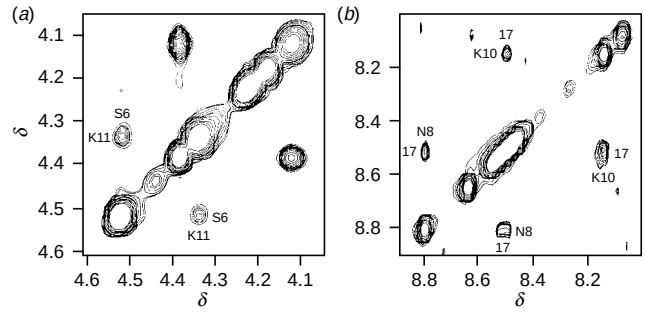

Fig. 2 Portions of the 200 ms ROESY spectrum of peptide **1b** at 278 K recorded at 500 MHz on a Bruker DRX500 spectrometer: (*a*) Hα–Hα and (*b*) NH–NH cross-strand interactions are highlighted that are consistent with the folded conformation shown in Fig. 1(*b*)

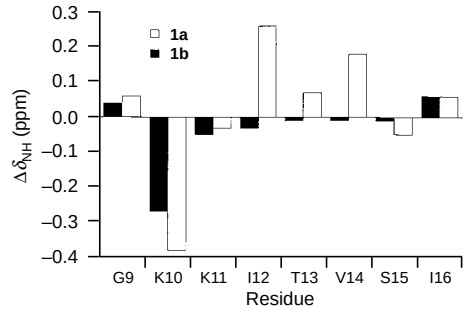

Fig. 3 Plot of difference in NH chemical shift ($\Delta\delta_{NH}$) for residues 9–16 of the folded hairpin peptide **1a** and the truncated analogue **1b** with respect to reference peptide **1c**

of neighbouring residues provide additional support for local order in the peptide backbone, consistent with the population of a type I′ turn conformation. For example, a significant NH–NH interaction is detected for I^7–N^8, while all other sequential NH–NH ROEs are too weak to observe [Fig. 2(*b*)]. In general, sequential Hα–NH ROEs are stronger than the equivalent intraresidue Hα–NH interaction (ratio of intensities > 4),[12] but for N^8 and G^9 the ratio of intensities is very close to 1, again characteristic of the reverse turn conformation found for the hairpin (**1a**).[8]

To what extent is the turn formed under these conditions? Perturbations to the Hα and NH chemical shifts are characteristic of secondary structure formation and can provide a method of estimating the population of folded structures.[8] To this end we have examined perturbations to the chemical shifts of residues on the C-terminal strand of the hairpin and peptide **1b** to estimate relative populations. As a reference state we have used the corresponding Hα and NH chemical shifts of the isolated C-terminal strand (**1c**) to fully account for any sequence-dependent effects on chemical shifts. Thus, differences in chemical shifts between **1a** and **1c**, and between **1b** and **1c**, are expected, in large part, to reflect perturbations due to secondary structure formation. The data in Fig. 3 show the difference in NH chemical shifts ($\Delta\delta_{NH}$) at 278 K for residues 9–16 of the hairpin (**1a**) and truncated peptide (**1b**) with respect to the reference state **1c**, and illustrate convincingly the folding pattern of the two peptides. The NH of K^{10} shifts upfield for both peptides reflecting the anisotropic effect from the carbonyl group of G^9 in the folded structure. T^{12}, V^{14} and I^{16} of the hairpin are proposed to form hydrogen bonds to the opposite strand and significant downfield shifts are observed for the NHs of these residues that are consistent with this model. In contrast, only the NH of I^{12} of the truncated peptide (**1b**) has the opportunity to form a hydrogen bond, but no significant perturbation is observed suggesting a very weak interaction that probably reflects the more dynamic nature of its hydrogen bonding partner, the *N*-acetyl carbonyl of S^6 at the N-terminus.

Since both peptides are able to form the same β-turn conformation, as is evident from the ROE data described above, we interpret the larger change in shift for K^{10} NH of the hairpin (**1a**) as reflecting a greater population of the folded conformation than is present for the truncated peptide (**1b**). We estimate the population of turn conformation of **1b** to be *ca*. 70% of that of the hairpin under the same conditions (278 K). We have previously estimated the folded population of the hairpin at this temperature to be *ca*. 32% *versus* 68% 'random coil';[8] on this basis the population of the folded conformation of **1b** is *ca*. 22%. Quantitative estimates of the intensity of the cross-strand ROEs shown in Fig. 2 similarly suggest a folded population in the range 20–30%, indicating some agreement between the different methods of estimation.

The data show convincingly that the sequence INGK at the core of the β-hairpin peptide used in these studies has a natural propensity to form a two-residue β-turn conformation in water *alone*, in the absence of significant structure stabilising hydrophobic interactions or a conformationally restricted proline residue. The INGK turn sequence is likely to play an important role in nucleating hairpin formation through association of the two β-strands.

We thank the EPSRC, BBSRC, Roche Ltd, the Nuffield Foundation and the Department of Chemistry for financial support. We are grateful to John Keyte in the Department of Biochemistry for peptide synthesis.

A new feature in the chemistry of nitrobenzofuroxans: ambident reactivity in Diels–Alder condensations

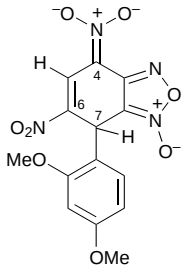
Dominique Vichard,[a]† Jean-Claude Hallé,*[a]‡ Boris Huguet,[a] Marie-José Pouet,[a] Didier Riou[b] and François Terrier*[a]§

[a] *Laboratoire SIRCOB, CNRS EP 102, Université de Versailles-Saint Quentin, Bâtiment Lavoisier, 45 Avenue des Etats-Unis, 78035 Versailles Cedex, France*

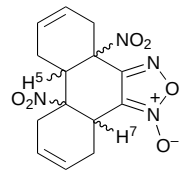
[b] *Laboratorie IREM, CNRS CO173, Université de Versailles-Saint Quentin, Bâtiment Lavoisier, 45 Avenue des Etats-Unis, 78035 Versailles Cedex, France*

The 4,6-dinitrobenzofuroxan (DNBF) structure is shown to act both as a dienophile and a heterodiene upon treatment with 1-trimethylsilyloxybuta-1,3-diene and vinyl ethyl ether, providing in two steps a highly functionalised stereoselective compound.

In recent years, a large body of evidence has been accumulated showing that 4,6-dinitro-2,1,3-benzoxadiazole 1-oxide, commonly known as 4,6-dinitrobenzofuroxan (DNBF), is a neutral 10π-electron heteroaromatic substrate which, in many processes, exhibits extremely high electrophilic character.[1–5] In fact, recent studies have shown that DNBF is a stronger electrophile than the 4-nitrobenzenediazonium cation.[2] This makes DNBF a remarkable probe to assess the reactivity of such weak carbon nucleophiles as benzenoid aromatics or π-excessive heteroaromatics with large negative pK_a^{CH} values, *e.g.* 1,3-dimethoxybenzene (pK_a^{CH} = −9) or 3-methoxythiophene (pK_a^{CH} = −6.5).[6,7] In all of the above processes, covalent addition of the carbon nucleophile takes place at C(7) of the carbocyclic ring of DNBF to give stable anionic σ-complexes, *e.g.* **1**.[6] The same principle applies in all reported interactions of DNBF with oxygen, nitrogen or sulfur nucleophiles.[1,3,4,8–10]



1

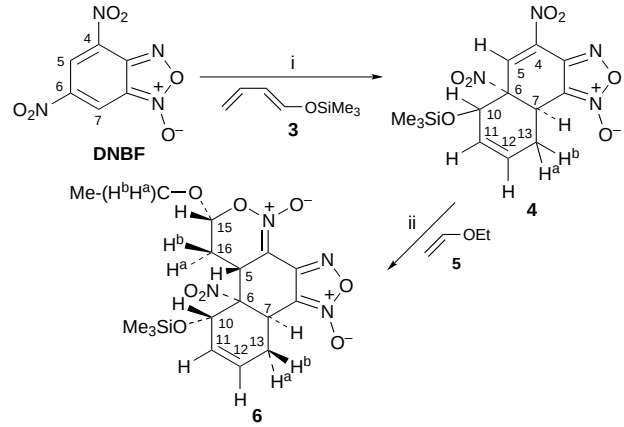


2

Interestingly it has been argued that the low aromatic character of the benzofuroxan system should be one of the major factors responsible for the exceptional electrophilic reactivity of DNBF and nitrobenzofuroxans in general.[1,2,9] Should this be true, the idea that these compounds might be involved in Diels–Alder type reactions under some experimental conditions could not be excluded. In 1973, Kresze and Bathelt reported the very slow formation of the diadduct **2** upon reaction of DNBF with butadiene.[11] Although the most reasonable explanation for the formation of this adduct was in terms of a Normal Electron Demand Diels–Alder (NEDDA) mechanism, this finding did not lead to further investigation and the stereochemistry was not investigated. Here we present the first evidence that the DNBF structure can in fact exhibit an ambident Diels–Alder reactivity, acting as a dienophile in NEDDA reactions or as a heterodiene in Inverse Electron Demand Diels–Alder (IEDDA) reactions, depending upon the experimental conditions and the reaction partners employed.

Treatment of DNBF with 1-trimethylsilyloxybuta-1,3-diene **3** (used as the solvent at room temperature) (Scheme 1) results in the rapid and nearly quantitative formation of a product which we readily isolated as a pale yellow solid. Based on ^{1}H NMR and electrospray mass spectroscopy data,¶ this product can be formulated as the cycloadduct **4** in racemic form, resulting from a regioselective NEDDA process involving the C(6)=C(7) double bond of DNBF as the dienophile contributor. Strong support for the regioselectivity of the condensation comes from ^{15}N labelling of the 4- and 6-NO_2 groups in **4**. In this instance, only the H(5) proton appears to be coupled with both ^{15}N atoms [$J_{N(4)H(5)}$ = 3.1 and $J_{N(6)H(5)}$ = 0.7 Hz]. Interestingly, the ^{1}H NMR spectra of **4**, recorded in $CDCl_3$, consisted of only one set of signals, indicating that the reaction is also diastereoselective and affords only the cycloadduct resulting from an *endo* condensation, as will be confirmed in the second step. In contrast with Kresze and Bathelt's finding that the addition of butadiene to DNBF eventually afforded the diadduct **2** within a few weeks at low temperature,[11] further reaction of **3** with **4** to give the related bis-NEDDA adduct did not occur in our case.

Most interestingly, we found that a second cycloaddition process takes place readily on treatment of **4** with vinyl ethyl ether **5** (Scheme 1). In this cycloaddition process, the DNBF moiety does not act as a dienophile but clearly as a heterodiene, according to an IEDDA process, to give the dihydrooxazine *N*-oxide **6**‖ in 92% yield. As found for the formation of **4**, the reaction is highly stereoselective, affording only the diastereomer **6**, shown in Scheme 1, whose stereochemistry could be safely attributed *via* ^{1}H NMR and NOE experiments in solution. A determination of the crystallographic structure of **6** by X-ray analysis** confirmed the consecutive NEDDA and the IEDDA



Scheme 1 *Reagents and conditions*: i, 1-trimethylsilyloxybuta-1,3-diene **3** (50 equiv., no solvent), 84%; ii, vinyl ethyl ether **5** (50 equiv., no solvent), 92%

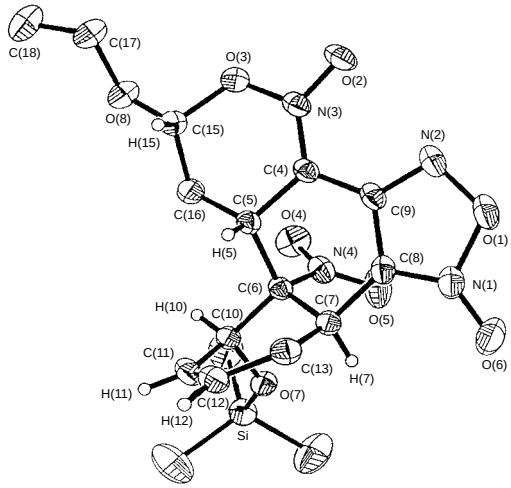


Fig. 1 ORTEP view of **6** (only one enantiomer is represented). Bond lengths (Å): C(4)–N(3) 1.321(3), C(6)–N(4) 1.544(3), C(15)–O(3) 1.476(3), C(15)–O(8) 1.360(3), N(3)–O(2) 1.245(2), N(3)–O(3) 1.404(3), N(4)–O(4) 1.215(3), N(4)–O(5) 1.208(3).

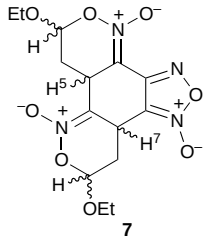
additions as well as the stereochemistry assignment in the solid state (Fig. 1). This ORTEP view shows that H(7), the 6-NO_2 group and the $OSiMe_3$ substituent are located on the same side of the molecule, *trans* to both H(5) and H(15). This clearly indicates that both Diels–Alder condensations proceed through *endo* processes which take place *via* consecutive *trans* addition.

Such nitro group participation has previously been observed in the reaction of DNBF with indene.[12] Recently, we found that direct treatment of DNBF with **5** affords the bis(dihydrooxazine *N*-oxide) adduct **7**.[13] In this instance, both experimental and



7

theoretical studies indicated that **7** was the result of two consecutive IEDDA processes involving the 4-NO_2 and 6-NO_2 heterodienyl moieties of DNBF, respectively.[13,14] In the present work we extend considerably the scope of the reactivity of DNBF by showing that this compound may also be consecutively involved in NEDDA and IEDDA cycloadditions to give a functionalised diadduct which is formed with high stereoselectivity. Interestingly, this ambident reactivity of DNBF in Diels–Alder condensations is a feature of general significance, being a promising new approach to synthesis in heterocyclic chemistry. Also such behaviour is in itself evidence that DNBF has a low resonance energy, a feature which has been commonly accepted but has not yet been specifically addressed.[1]

Further experimental and theoretical work towards a better understanding of how one can modulate the dienophile or heterodiene behaviour of DNBF with respect to the structure of the opposed electron-rich substrate is currently underway.

¶ *Synthetic procedure* for **4**: 2 ml of 1-trimethylsilyloxybuta-1,3-diene (11.4 mmol) were added to 48 mg of DNBF (0.212 mmol) charged in a tube. The mixture was maintained under stirring at room temperature for 30 mn. A pale yellow precipitate rapidly appeared. The precipitation was complete after addition of a large excess of pentane. The precipitate was isolated by centrifugation, washed with pentane and dried *in vacuo* (84%). For **6**: A similar procedure was applied, under 4 h stirring in the presence of vinyl ether ether (92%). A single crystal was obtained by slow diffusion of pentane into a THF solution of **6**.

Palladium-catalyzed allylic substitution on solid support

Lutz F. Tietze,*† Thomas Hippe and Adrian Steinmetz

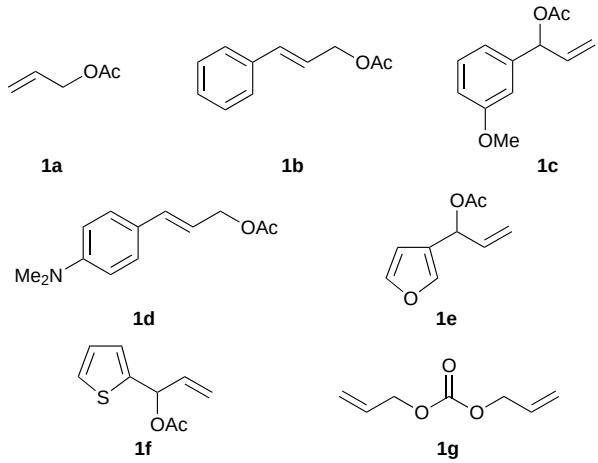
Institut für Organische Chemie, Georg-August-Universität, Tammannstr. 2, D-37077 Göttingen, Germany

Different polymer-bound 1,3-dicarbonyl compounds react as nucleophiles in Pd-catalyzed allylic substitutions on solid support with a variety of allylic acetates, chlorides and carbonates.

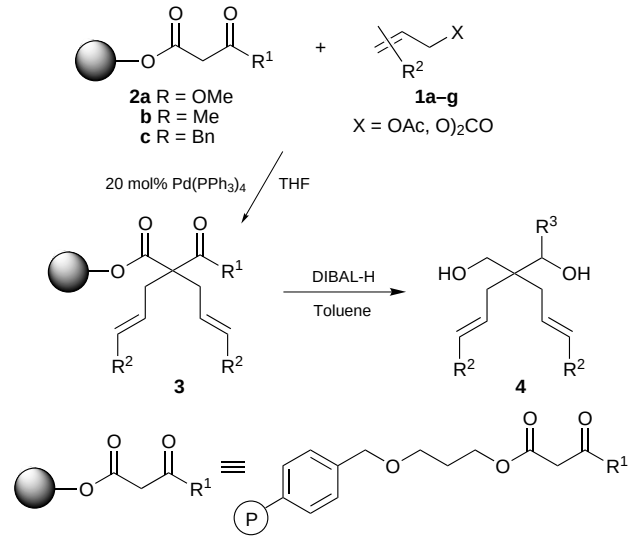
Combinatorial chemistry is regarded as a powerful tool to improve the search for new pharmacologically interesting compounds.[1] In most of the cases solid phase synthesis is used to generate combinatorial libraries, which are subsequently tested for their biological activity. Therefore, the development of basic carbon–carbon bound-forming reactions on the solid phase is an important task, especially in combinatorial synthesis of organic compounds of low molecular weight.

In the course of our studies on the use of resin-linked 1,3-dicarbonyl compounds to build up combinatorial libraries, we have previously reported on a two-component domino–Knoevenagel–ene reaction[2] and a three-component domino–Knoevenagel-hetero-Diels–Alder reaction[3] to afford structurally diverse cycloalkanes and 3,4-dihydro-2*H*-pyrans, respectively. Furthermore, we established an efficient method to synthesise highly diverse pyrazolones by treatment of a variety of polymer-bound β-keto esters with hydrazine derivatives, resulting in concomitant release of the final products from the support.[4]

Herein, we report on the use of polymer-bound 1,3-dicarbonyl compounds in Pd^0-catalyzed allylic substitution reactions with a variety of allylic substrates **1a**–**g**, **5** and **8a**,**b**. The Pd-catalyzed allylation[5] is well known for its high control of stereoselectivity and functional group tolerance, as well as good yields, and is therefore of great interest for combinatorial chemistry.[6]



Polymer-bound malonate **2a** and acetoacetates[2,3] **2b** and **2c** reacted with a variety of aliphatic and aromatic allylic acetates **1a**–**f** (5 equiv., Scheme 1) in the presence of 20 mol% of tetrakis(triphenylphosphine)palladium as a catalyst and bis-(trimethylsilyl)acetamide (BSA)[7] as a base (5 equiv.) in THF at reflux temperature for 6–15 h. The resin-bound products **3** were cleaved under reductive conditions with DIBAL-H (10 equiv., toluene, 0 °C, 12 h) to afford the desired diols **4a**–**h** in 20–57% overall yield based on the concentration of free hydroxy groups



Scheme 1

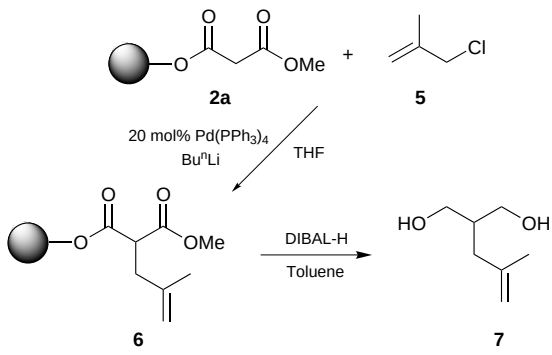
in the spacer-modified polystyrene-resin (0.75 mmol per gram resin)[2] (Table 1). Using the sterically less hindered allylic acetates **1a**–**f** dialkylation was observed in all cases, showing the expected high reactivity of the polymer-bound β-keto esters **2a**,**b** towards allylic substitution.

In addition to the allylic acetates, allylic chlorides and carbonates were also used. Employing allylic carbonates, no addition of base is required since the carbonate moiety reacts as a leaving group and simultaneously forms an alkoxide as a base after loss of carbon dioxide.[5] Thus, reaction of diallyl carbonate **1g** (3 equiv.) with the polymer-bound benzyl-substituted acetoacetate[4] **2c** was performed at room temperature in THF for 1 h using 10 mol% Pd catalyst. After cleavage from the resin the dialkylated product **4i** was obtained in 76% yield, showing the very high reactivity of allylic carbonates (Table 1). In the case of β-methallyl chloride **5**, Bu^nLi (1 equiv.) was used as base and the reaction was performed at room temperature for 21 h. In this

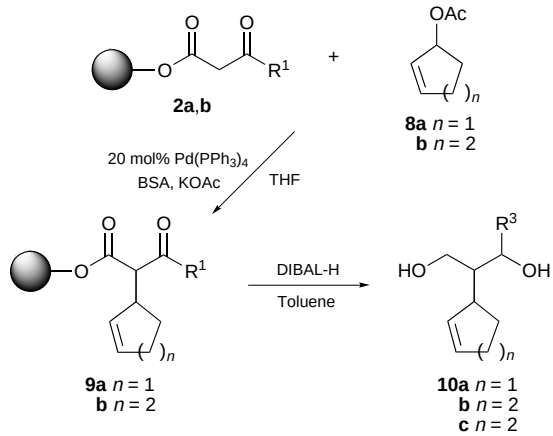
Table 1 Synthesised 1,3-diols **4**

Substrates		Products				
1	**2**	**4**	R^1	R^2	R^3	Overall yield (%)[a]
a	**a**	**a**	OMe	H	H	30
b	**a**	**b**	OMe	Ph	H	57
b	**b**	**c**	Me	Ph	Me	40
c	**b**	**d**	Me	3-$MeOC_6H_4$	Me	23
d	**b**	**e**	OMe	4-$Me_2NC_6H_4$	Me	34
e	**a**	**f**	OMe	3-Furyl	H	20
e	**b**	**g**	Me	3-Furyl	Me	23
f	**b**	**h**	Me	2-Thienyl	Me	20
g	**c**	**i**	Bn	H	Bn	76[b]

[a] The products were purified by flash chromatography. The yields are based on the concentration of free hydroxy groups in the spacer-modified polystyrene-resin (0.75 mmol per gram resin) (ref. 2). [b] No base was used. The reaction was performed at room temperature.



Scheme 2



Scheme 3

reaction only monoalkylation was observed. Thus, after reductive cleavage product **7** was obtained in 28% yield (Scheme 2).

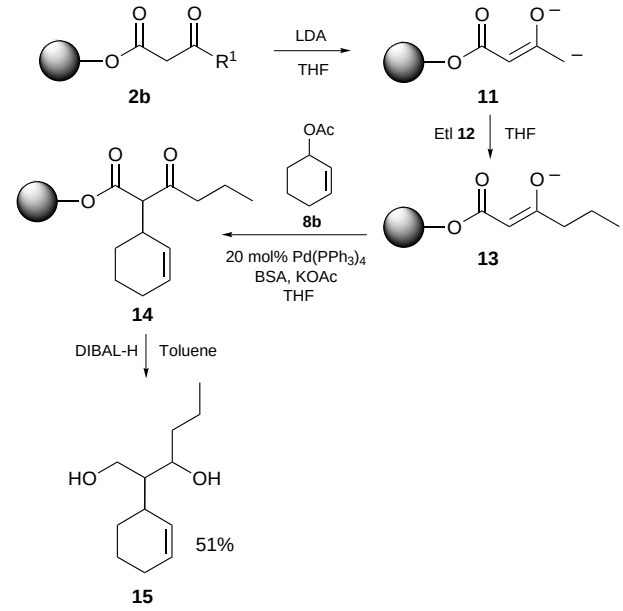
Selective monoalkylation could also be achieved using sterically more hindered cyclic allylic acetates (Scheme 3). Under the conditions described for **1a**–**f** [20 mol% $Pd(PPh_3)_4$, BSA, KOAc, THF, reflux, 10 h] the reaction of the cyclic acetates **8a**,**b** and **2a**,**b** gave after reductive cleavage the desired diols **10a**–**c**, respectively, in 40–59% yield (Table 2). The formation of the dialkylated products was not observed.

Table 2 Synthesis of the 1,3-diols **10**

Substrates		Products				
2	**8**	**10**	*n*	R^1	R^3	Overall yield (%)[a]
a	**a**	**a**	1	OMe	H	53
a	**b**	**b**	2	OMe	H	40
b	**b**	**c**	2	Me	Me	59

[a] The products were purified by flash chromatography. The yields are based on the concentration of free hydroxy groups in the spacer-modified polystyrene-resin (0.75 mmol per gram) (ref. 2).

A further possibility to increase diversity in a one-pot procedure is shown in Scheme 4. As previously described by our group,[4] γ-alkylation of polymer-bound acetoacetate **2b** can be achieved by generating the dianion **11** with LDA at 0 °C and subsequent treatment with an alkylating reagent in THF at 0 °C, *e.g.* iodoethane **12**. The resulting monoanion **13** can now react as a nucleophile in an allylic substitution with **8b** to give the



Scheme 4

resin-bound product **14**, which was reductively cleaved as described above to afford the diol **15** in 51% overall yield.

In conclusion, we have shown that the Pd-catalyzed allylic substitution of allylic substrates such as acetates, chlorides and carbonates with different polymer-bound 1,3-dicarbonyl compounds is a very efficient C–C bond-forming reaction. Since allylic substrates are readily available building blocks, the solid phase reaction presented above should be amenable for combinatorial synthesis. Furthermore, the development of a one-pot protocol consisting of γ-alkylation and α-allylation of solid supported acetoacetate provides an even greater diversity of the desired products. We are currently investigating the possibility of using vinylic epoxides and bisallylic templates as substrates and resin-bound allylated 1,3-dicarbonyl compounds for further transformations.

This work was supported by BASF AG, the Fonds der Chemischen Industrie and the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie (Grants No. 03 D0056 2).

Linked arene clusters: the interaction of tetracobalt nonacarbonyl with [2.2.2]paracyclophane

Paul Schooler,[a] Brian F. G. Johnson,*[a]† Caroline M. Martin,[a] Paul J. Dyson[b] and Simon Parsons[c]

[a] *University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*
[c] *Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

The thermolysis of [2.2.2]paracyclophane in the presence of an excess of $[Co_4(CO)_{12}]$ yields three new arene clusters $[\{Co_4(CO)_9\}_n(C_{24}H_{24})]$ (n = 1, 2 and 3): the molecular structures of the mono- and bis-cluster complexes have been established by single crystal X-ray diffraction while the tris-complex has been characterised by spectroscopy.

The interaction of the $[2_n]$cyclophanes with transition and main group metals has received much attention since their conception by Cram several decades ago.[1] These complexes were initially used to probe the unusual electronic properties of the $[2_n]$cyclophane ligands, which stem from the interpenetration of arene π molecular orbitals, giving rise to unusual and unique effects.[2] More recently, interest has been stimulated by the potential for the $[2_n]$cyclophane ligands to serve as bridging units between metal centres in organometallic polymers and networks which should have interesting electrical and non-linear optical properties.[3]

Metal atoms and ions may bond to [2.2.2]paracyclophane by either endo- or exo-coordination. In the former the metal atom resides in or near the ligand cavity such as in the π cryptates formed with gallium(I) and silver(I) salts[4] while in the latter the metal atom interacts with the external face of the aromatic rings as in the piano-stool complexes formed with $[M(CO)_3]$ (M = Cr, Mo or W) fragments.[5] There are few reports concerning the coordination of more than one metal atom to [2.2.2]paracyclophane; only recently has diffraction data become available for the mono- and bis-$[Cr(CO)_3]$ complexes,[6] and structural data for the tris-chromium tricarbonyl has not yet been obtained. Here, we report the molecular structure of the complexes $[Co_4(CO)_9(\eta\text{-}C_{24}H_{24})]$ **1** and $[\{Co_4(CO)_9\}_2(\eta:\eta\text{-}C_{24}H_{24})]$ **2** in which one and two of the C_6-rings of [2.2.2]paracyclophane are coordinated to $[Co_4(CO)_9]$ cluster units respectively. Spectroscopic characterisation of the tris-$[Co_4(CO)_9]$ complex, $[\{Co_4(CO)_9\}_3(\eta:\eta:\eta\text{-}C_{24}H_{24})]$ **3**, is also reported. These latter two compounds represent the first examples of clusters linked *via* a cyclophane ligand.

The thermolysis of [2.2.2]paracyclophane with 10 molar equiv. of $[Co_4(CO)_{12}]$ in hexane under reflux over 5 h affords three new complexes $[Co_4(CO)_9(\eta\text{-}C_{24}H_{24})]$ **1** (20%), $[\{Co_4(CO)_9\}_2(\eta:\eta\text{-}C_{24}H_{24})]$ **2** (2%) and $[\{Co_4(CO)_9\}_3(\eta:\eta:\eta\text{-}C_{24}H_{24})]$ **3** (*ca.* 0.1%) which were separated by thin layer chromatography on silica using dichloromethane–hexane (1 : 3 v/v) as the eluent. These complexes can be conveniently interconverted (Scheme 1) by either adding cluster units to compounds **1** and **2** by thermolysis with $[Co_4(CO)_{12}]$ in hexane or by the thermolysis of compounds **2** and **3** in toluene whereby cluster units are removed from the cyclophane ligand *via* arene exchange. The molecular structures of compounds **1** and **2** are shown in Figs. 1 and 2, respectively. In both molecules the coordinated rings of the cyclophane ligands lie parallel to, and staggered with respect to, the metal triangle defined by Co(2)Co(3)Co(4). The cobalt–ring carbon distances indicate that the coordinated rings are not planar as the average distances involving the bridgehead carbon atoms are slightly longer than the remaining four carbon atoms [*cf.* 2.174(6) and 2.107(8) Å in **1** and 2.174(5) and 2.120(12) Å in **2**]. Although the coordinated rings of the cyclophane in both compounds are expanded owing

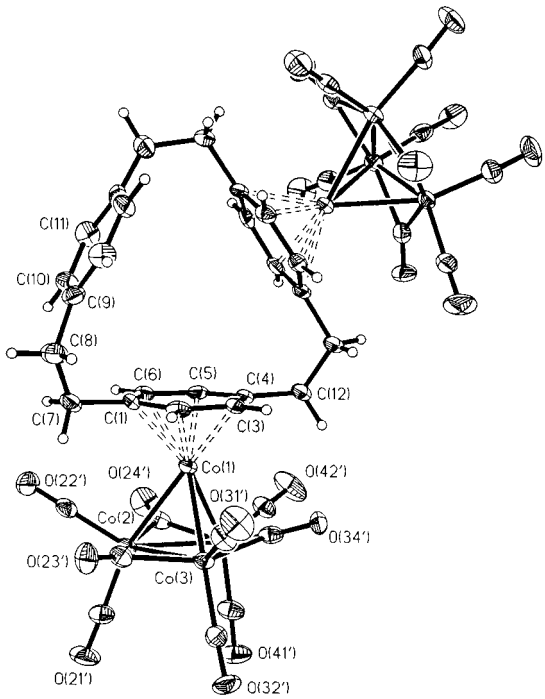

Fig. 2 The molecular structure of [{$Co_4(CO)_9$}$_2$(η-$C_{24}H_{24}$)] **2**. Important bond lengths (/Å): Co(1)–Co(2) 2.5078(12), Co(1)–Co(3) 2.4646(12), Co(1)–Co(4) 2.4758(12), Co(2)–Co(3) 2.4628(13), Co(2)–Co(4) 2.4413(14), Co(3)–Co(4) 2.4513(13), Co(1)–C(1) 2.166(7), Co(1)–C(2) 2.104(6), Co(1)–C(3) 2.141(6), Co(1)–C(4) 2.179(6), Co(1)–C(5) 2.111(6), Co(1)–C(6) 2.122(6), C(1)–C(2) 1.396(10), C(1)–C(6) 1.398(10), C(2)–C(3) 1.409(10), C(3)–C(4) 1.408(11), C(4)–C(5) 1.429(11), C(5)–C(6) 1.387(10), C(9)–C(10) 1.346(11), C(10)–C(11) 1.389(11), average C–O (terminal) 1.13(2) and average C–O (bridging) 1.173(16).

to the electron-withdrawing nature of the cluster [*cf.* average C–C distances of 1.401(13) and 1.37(2) Å in **1** and 1.40(2) and 1.36(3) Å in **2**], little significance can be placed upon this observation owing to the magnitude of the electron shift densities. It should be noted that the cyclophane ligand in compound **1** is much less symmetrically coordinated than in **2**; this is reflected in the dihedral angles made between the bow and stern of the C_6 rings of 5.9° (coordinated), 2.8 and 0.9° while the ethano bridge C(15)–C(16) lies some 2.17 Å out of the plane defined by Co(1)C(1)C(4)C(7)C(24).

The average Co–Co bond distances in the base of the clusters are short compared to the sides owing to the contracting action of the bridging CO groups [2.459(2), 2.469(2) Å in **1** and 2.452(2), 2.483(2) Å in **2**, respectively]. Both bridging and equatorial terminal carbonyl ligands point upwards toward the cyclophane.

Compounds **2** and **3** are of particular interest as precursors to organometallic one and two-dimensional networks and polymers since the [2.2.2]paracyclophane ligands in these complexes bridge cluster units. However, it should be noted that we have been unable to introduce a second cyclophane ligand to a Co_4 cluster in order to sustain chain growth: the weakness of the metal–arene interaction (as demonstrated by arene exchange reactions with toluene) permits multiple complexation of clusters by a single ligand but is too weak to allow the substitution of further carbonyl ligands with poorer π-acceptors upon the arene cluster. We have also found that, for example in compound **1**, the cobalt cluster is unwilling to share the cyclophane ligand with more electronically demanding subunits such as [$Ru_6C(CO)_{14}$], Ga^I or Ag^I. Although the linkage of cobalt clusters through arene systems in itself is not novel (this has been previously achieved using diphenylmethane),[7] the combination of the unique electronic properties of clusters and cyclophanes may allow novel types of electronic communication. Our preliminary electrochemical analyses, although complex, indicate this and our investigation is ongoing.

We wish to thank the EPSRC, Cambridge University, and the Newton Trust (P. S.) for financial support. P. J. D. would like to thank the Royal Society for a University fellowship.

The first stable scandocene: synthesis and characterisation of bis(η-2,4,5-tri-*tert*-butyl-1,3-diphosphacyclopentadienyl)scandium(II)

Polly L. Arnold, F. Geoffrey N. Cloke*† and John F. Nixon*

School of Chemistry, Physics and Environmental Sciences, University of Sussex, Brighton, UK BN1 9QJ

The first isolable example of a molecular scandium(II) complex, the dark purple scandocene [Sc(η^5-P$_2$C$_3$Bu$^t_3$)] 1, has been isolated from the cocondensation of scandium vapour with *tert*-butylphosphaalkyne, Bu^{t}CP at 77 K.

To date the only stable divalent lanthanoid metallocenes are those of the elements Sm, Eu and Yb for reasons which have been well documented.[1] These metallocenes are all highly reactive, showing strong reducing properties and consequent unusual reaction chemistry.[2] Very recently, two lanthanum species that are intermediates in the potassium reduction of [La(Cp″)$_3$] {Cp″ = η-C$_5$H$_3$(SiMe$_3$)$_2$} have been observed and characterised, by EPR spectroscopy, as containing a La^{II} centre; one of the latter has been shown to be a dme solvated metallocene, La(Cp″)$_2$(dme).[3]

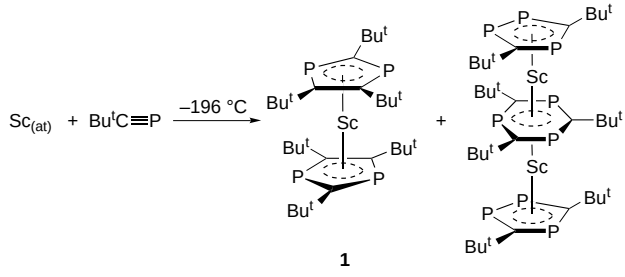
In recent years metal vapour synthetic techniques have afforded a variety of novel and reactive low valent organometallic complexes of group 3 and the lanthanides directly from the elements; the technique remains the only route to zero-valent molecular lanthanide complexes.[4] Cyclisation reactions undergone by 2,2-dimethylpropylidynephosphine (*tert*-butylphosphaalkyne, Bu^{t}CP) at metal atoms during cocondensation reactions are of considerable current interest since the choice of metal clearly dictates the nature of ring or rings formed.[5] The most common cyclisation observed to date is the combination of five phosphaalkyne units resulting in the isolation of sandwich complexes such as [(V(η^5-P$_3$C$_2$Bu$^t_2$)(η^5-P$_2$C$_3$Bu$^t_3$)].[6] Here, we report the synthesis of [Sc(η^5-P$_2$C$_3$Bu$^t_3$)$_2$] **1**, which represents only the second reported scandium(II) complex. The first example, also described by our laboratory, resulted from ligand metallation during the cocondensation of scandium vapour with tri-*tert*-butylbenzene; this product was unfortunately not separable from the admixture with [Sc(η-C$_6$H$_3$Bu$^t_3$-1,3,5)$_2$].[7] The present work is thus the first instance in which we have been able to isolate, and thus fully characterise, a complex of scandium in this oxidation state.

Cocondensation of electron beam vaporised scandium with an excess of Bu^{t}CP at 77 K affords a dark brown matrix which is soluble in hexanes. Two products are separable from the dark solution by flash sublimation (220 °C, 10^{-5} mbar), Scheme 1.‡ The dark purple microcrystalline [Sc(η^5-P$_2$C$_3$Bu$^t_3$)$_2$] **1** may be obtained from the sublimate by repeated sublimation and removal of by-product volatile oils. The forest-green triple-decker complex [(η^5-P$_3$C$_2$Bu$^t_2$)Sc(μ-η^6:η^6-P$_3$C$_3$Bu$^t_3$)Sc(η^5-P$_3$C$_2$Bu$^t_2$)], can be extracted from the sublimant and has been the subject of a recent communication.[8]

The 1,2,4-triphospha-3,5-di-*tert*-butylcyclopentadienyl ring is regularly formed in conjunction with the 1,3-diphospha-2,4,5-di-*tert*-butylcyclopentadienyl ring in cyclisation reactions at a number of both transition elements and main group metal centres.[5b] Since the yield of **1** is approximately the same as that of the scandium(I) triple-decker complex [(η^5-P$_3$C$_2$Bu$^t_2$)Sc(μ-η^6:η^6-P$_3$C$_3$Bu$^t_3$)Sc(η^5-P$_3$C$_2$Bu$^t_2$)], which contains a greater proportion of ligated phosphorus, the number of phosphaalkyne monomers is preserved between the two complexes. This leads us to believe, at least in this case, that the fusion of a number of Bu^{t}CP molecules around the metal does not simply involve one metal centre.

Complex **1** is extremely air- and moisture-sensitive and is soluble in pentane and other non-polar solvents; a solution in thf decomposes immediately giving no tractable products, precluding electrochemical studies. Unfortunately, single crystals of **1** suitable for X-ray structural determination could not be obtained owing to its extreme solubility in solvents with which it does not react. The intense purple colour of **1**, due to an absorption maximum observed at 571 nm in the UV–VIS spectrum, is characteristic of a charge transfer band and appears to be a common feature in low- and zero-valent group 3 and lanthanide complexes.[4a]

Magnetic and EPR studies have been employed to study the d^1 electronic configuration of **1**. The EPR spectrum of **1** in toluene at 295 K is broad and shows coupling only to the ^{45}Sc nucleus, presumably due to rapid relaxation at this temperature, characterised by g_{iso} 1.9823 and A_{iso}(^{45}Sc) 3.757 mT (I = 7/2, 100%). Upon cooling the sample to a glass at 120 K, well resolved coupling to scandium is observed, accompanied by further hyperfine coupling to the four phosphorus nuclei (I = ½, 100%) which are equivalent on the EPR timescale at this temperature, Fig. 1. The resonance is characterised by $g_\perp$ 2.0098 with a calculated value of $g_\parallel$ 1.9273 and is well simulated using values of $A_\perp$(^{45}Sc) 2.99 mT, $A_\parallel$(^{45}Sc) 5.29 mT and A(^{31}P) 0.72 mT. The solution magnetic moment is found to be 1.70 μ_B at room temperature,[9] showing no evidence for any orbital contribution to the spin only value (μ_{eff} = 1.73 μ_B).



Scheme 1 Synthesis of **1**

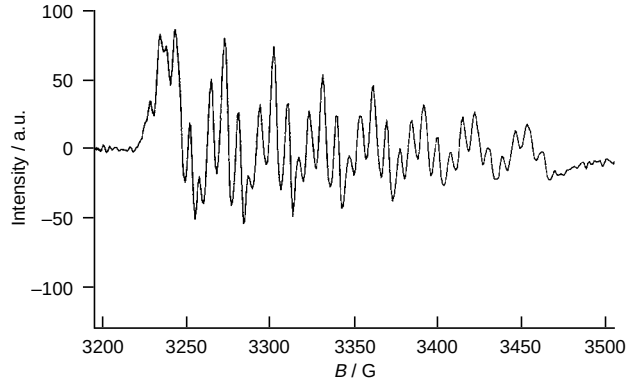


Fig. 1 EPR spectrum of **1** (toluene glass, 120 K)

Warren has suggested,[10] in a review of the ligand field theory for pseudo-axially symmetric metallocenes that a distortion and subsequent lowering to C_{2v} symmetry occurs since the degenerate ground state is necessarily Jahn–Teller unstable. The majority of d^1 metallocene systems extant in the literature are bent from pseudo-axial symmetry and the resulting quenching of any orbital contribution results in isotropic *g* values close to 2.00 and near spin-only values of the magnetic moment.[11] A similar argument is appropriate here since **1** is not modelled well as axial, owing to the unsymmetric substitution of the cyclopentadienyl rings.[12] The phosphorus atom in the diphosphatri-*tert*-butylcyclopentadienyl ligands provides a second magnetic nucleus, thus the resolution of coupling to the ligand nuclei by the electron, particularly at lower temperatures when the relaxation processes are slowed, strongly suggests that the single electron resides in the degenerate d_{xy} or $d_{x^2-y^2}$ orbitals (rather than the d_{z^2} orbital), as predicted.

The existence and stability of **1**, which thus completes the series of divalent metallocenes for the 3d elements, presumably result from a combination of steric shielding of the diphosphatri-*tert*-butylcyclopentadienyl rings and the increased π-electron accepting properties of the rings induced by phosphorus incorporation.

The authors are grateful to Dr A. Abdul-Sada for determination of the mass spectrum of **1**, to Mr C. Dadswell for recording of the EPR spectrum of **1** and to the EPSRC (ROPA) for funding.

‡ Scandium (0.30 g, 0.66 mol) was vaporised (power input 200 W) and cocondensed with Bu^tCP (10 g, 0.1 mol, M : L ratio 1 : 10) at 77 K.[1] The dark brown matrix formed over a period of 2.5 h persisted on warming to room temperature under an inert atmosphere. The product was washed from the reactor with hexanes (2 l), filtered through a bed of Teflon powder (20 μm), and evaporated to dryness. Flash sublimation (by introduction of the sublimer into a tube furnace pre-heated to 220 °C) at 10^{-5} mbar of the resultant solid yielded a purple oil. From this, **1** is obtained pure in 5–10% yield, *ca*. 30 mg (based on scandium) after resublimation. UV–VIS for **1**: λ_{max}/nm (pentane) 571 (ε/dm^3 mol^{-1} cm^{-1} 15 000). MS (EI): *m/z* 583 (90%, M^+), 269 (43, $P_2C_3Bu^t{}_3^+$); HRMS: *m/z* found 583.273922. $C_{30}P_4H_{54}Sc$ requires 583.273519. Solution state magnetism (Evans method, [$^2H_8$]toluene): μ_{eff} = 1.70 μ_B.

Catalytic deoxygenation of epoxides with $(Cp^*ReO)_2(\mu\text{-}O)_2$ and catalyst deactivation

Kevin P. Gable,*† Fedor A. Zhuravlev and Alexandre F. T. Yokochi

Department of Chemistry, Orgeon State University, Corvallis, OR 97331-4003, USA

***In situ* reduction of Cp^*ReO_3 by PPh_3 to form $(Cp^*ReO)_2(\mu\text{-}O)_2$ allows catalytic deoxygenation of epoxides, however, conproportionation between the Re^{V} and Re^{VII} species to form clusters of $\{(Cp^*Re)_3(\mu\text{-}O)_6\}^{2+}(ReO_4^-)_2$ and new compound $\{(Cp^*Re)_3(\mu^2\text{-}O)_3(\mu^3\text{-}O)_3ReO_3\}^+(ReO_4^-)$ leads to removal of rhenium from the catalytic cycle and loss of activity.**

A primary focus of recent work with metal oxo systems has been formation of new C–O bonds.[1] However, cleavage of C–O bonds with concomitant formation of one or more new M=O bonds is also a useful transformation. One example of this is deoxygenation of epoxides, wherein removal of an oxygen atom generates a new C=C π bond. Given that most methodology for making epoxides begins with the alkene, the combination epoxidation/deoxygenation would provide a useful protection/deprotection sequence for the multiple bond. Few such sequences now exist,[2] and many of these risk loss of stereochemical integrity or remain incompatible with other functional groups in the organic substrate.

We recently observed that $(Cp^*ReO)_2(\mu\text{-}O)_2$ reacted stereospecifically with epoxides to form alkene plus Cp^*ReO_3, presumably *via* the monomeric form Cp^*ReO_2.[3] Cook and Andrews recently reported catalytic deoxygenation of vicinal diols with this rhenium system,[4] so we decided to explore the catalytic deoxygenation of epoxides.

Conditions similar to stoichiometric deoxygenation reactions were used: toluene solvent, sealed under vacuum, heated to 90–120 °C. An initial study of deoxygenation of 1,2-epoxydodecane using 5 mol% Re gave only traces of alkene after extensive reaction times. As seen in Table 1, increasing the porportion of rhenium led to improved yields, but very little turnover. However, catalytic turnover could be achieved if the electronic properties of the epoxide were properly tuned.‡ The optimum turnover was seen in the case of electron-withdrawing substituents (Table 1).

It was evident from these experiments that catalyst turnover was being impeded by an interfering reaction. Further, in cases where poor turnover was observed (Table 1, entries 1, 2, 7), a green solid was seen to precipitate. The rapid reduction of Cp^*ReO_3 to $(Cp^*ReO)_2(\mu\text{-}O)_2$ at room temperature[5a] implied the two compounds did not react with each other, but this might not be true under the fairly severe reaction conditions of the deoxygenation (> 100 °C). Indeed, heating equimolar amounts of the two at 110 °C for 14 h formed a precipitate (sealed tube; isolated yield 5% from $CHCl_3$). This green solid was isolated by filtration and washing with benzene, and was identified as $\{(Cp^*Re)_3(\mu\text{-}O)_6\}^{2+}(ReO_4^-)_2$ **1**, first characterized by Herrmann *et al.*[5] The IR spectrum (908s cm^{-1}, 609, 650w cm^{-1}) and ^1H NMR spectrum (δ 2.22, s; CD_3CN) were identical to reported values. As expected, this salt was unreactive toward epoxides at elevated temperatures. Anion exchange with NaI in water gave the iodide salt; the perrhenate band disappeared from the IR spectrum, though the weak μ-O bands remained. Oxidation of the iodide salt with aqueous H_2CrO_4 (Jones' reagent) gave a 37% yield of Cp^*ReO_3 [based on formulating the salt as $\{(Cp^*Re)_3(\mu\text{-}O)_6\}I_2$].

In epoxide reductions and in conproportionation of Cp^*ReO_3 with $(Cp^*ReO)_2(\mu\text{-}O)_2$, this compound was accompanied by formation of an air-stable purple compound **2** that was insoluble in benzene. This second compound became predominant at relatively high rhenium concentrations (Table 1, entries 4, 5); and it was isolated from the conproportionation reaction by precipitation from benzene in 28% yield. Aside from the dramatically different visible spectrum, the only other significant spectroscopic difference from **1** was a new IR peak at 736 cm^{-1} and weak shoulder on the very strong perrhenate Re–O stretch at 908 cm^{-1}. A single sharp peak appeared in the ^1H NMR (δ 2.23 in CD_2Cl_2). We obtained high quality crystals of this compound for X-ray diffraction analysis;[6]§ the structure of the cation is shown in Fig. 1.

This compound is formulated as $\{(Cp^*Re)_3(\mu^2\text{-}O)_3(\mu^3\text{-}O)_3ReO_3\}^+(ReO_4^-)$, a monoperrhenate salt of a cluster. Formally, it can be represented by the coordination of ReO_3^- to **1**, although a more useful interpretation is to view it as the neutral $(Cp^*Re)_3(\mu\text{-}O)_6$ coordinated to ReO_3^+. (The latter is consistent with the theoretical prediction that compound **1** should be a ground-state triplet,[7] and similar to other reported structures.[8]) The ReO_3 unit is a slightly distorted octahedral rhenium in a typical $LReO_3$ environment: the terminal oxo bond lengths are normal [1.668(10), 1.685(13), 1.707(12) Å] as are the O–Re–O angles [103.2(6)°, 105.9(6), 104.1(6)°]. The $Re_3(\mu\text{-}O)_6$ core is similar to the trinuclear dication; the Re–Re distances are 2.750(1) and 2.759(1) Å. There is significant distortion of the

two sets of bridging oxo ligands compared to compound **1**, with bond lengths averaging to 1.94 Å (μ_2) and 2.02 Å (μ_3). The O–(ReO_3) distances are long at an average of 2.18 Å.

Compound **2** is a precursor to the trinuclear cluster **1**. Heating a Me_2SO solution of **2** in air to 100 °C for 2 h results in quantitative conversion. (Under conditions of the conproportionation or epoxide deoxygenation, Cp^*ReO_3 can play the same chemical role as Me_2SO in converting the ReO_3 unit to perrhenate.)[9] It is still not clear what the origin of the trinuclear core is, nor the fate of the Cp* ligands lost in formation of **1** and **2**. We have seen NMR evidence for monomeric Cp^*ReO_2,[3] but do not see evidence for a trimeric species. It is possible that Cp^*ReO_2 can condense with Cp^*ReO_3, and that this dimeric species initiates a cascade resulting in **2**. Alternatively, if indeed the trinuclear Re^V cluster forms as an equilibrium aggregate of Cp^*ReO_2 units, it may attack Cp^*ReO_3 irreversibly.

Clearly, the success of the catalytic cycle for epoxide deoxygenation (or any other system involving this chemistry) depends on a careful balance of reaction rates (Scheme 1). Cp^*ReO_2 must react with the epoxide substrate rapidly, or else conproportionation will lead to inactivation. The rate of O-atom transfer from epoxide is controlled by the reactivity of the substrate, as seen by the impact of substituent on turnover number. Likewise, Cp^*ReO_3 must be rapidly reduced to Cp^*ReO_2; there is again a competition between reduction and cluster formation. We tested this by increasing the concentration of PPh_3; a 2.4-fold excess led to an increase in conversion from < 5% to 50% (Table 1, Entry 6)! It must be noted that this required an almost saturated solution of PPh_3. Although this modification interferes with the practicality of this catalytic cycle, it shows that the key to an improved system is to design a kinetically more reactive stoichiometric reductant that does not interact with the epoxide.

§ *Crystal data* for $\{Cp^*Re)_3(\mu^2\text{-}O)_3(\mu^3\text{-}O)_3ReO_3\}ReO_4\cdot NCMe$ (**2**·NCMe). Data were collected on a block shaped (0.5 × 0.3 × 0.2 mm) dark brown crystal of $C_{32}H_{48}NO_{13}Re_5$ (M = 1585.71) on a Siemens P4 equipped with graphite monochromated Cu radiation (μ = 30.002 mm^{-1}) at room temperature. Automated search and indexing routines revealed that the crystals belong to the monoclinic space group $P2_1/c$ (no. 14) with a = 11.180(1), b = 15.631(1), c = 22.612(3) Å, β = 98.614(8)°, U = 3906.8(7) $Å^3$, Z = 4, D_c = 2.696 Mg m^{-3}. Of 10 677 data collected, 5191 were unique (R_{int} = 9.10%), and of these 4997 had $I > 2\sigma(I)$. Data were corrected for the effects of absorption anisotropy by analytical methods (face indexing). The structure was solved using a Patterson map search using SHELXS-90, and expanded by Fourier techniques and refined (full-matrix least-squares refinement on F^2) using SHELXL-93. Refinement of 492 parameters using all data yielded final residuals of R_1 = 0.661, wR_2 = 0.1768. The largest residual electron density peaks (3.28 e^- $Å^{-3}$) were all very close to the Re atoms and are not of chemical significance. CCDC 182/789.

Triamidoamine complexes of scandium, yttrium and the lanthanides

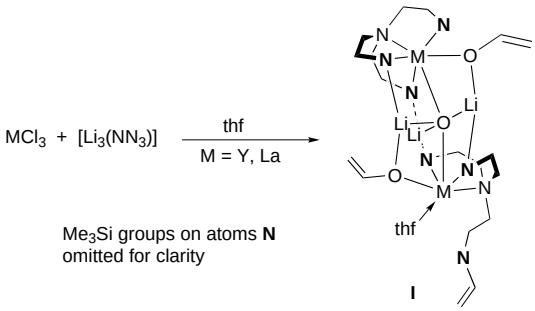
Paul Roussel, Nathaniel W. Alcock and Peter Scott*†

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL

Synthesis of the simple triamidoamine complexes of the group 3 and lanthanide elements is achieved for the first time by reaction of $[Li_3(NN'_3)(thf)_3]$ [NN'_3 = $N(CH_2CH_2NSiMe_3)_3$] with the metal trichlorides; the 'ate' complexes $[M(NN'_3)ClLi(thf)_3]$ (M = Sc, Y, La) thus produced are converted smoothly to $[M(NN'_3)]$ on sublimation *in vacuo*.

The quadridentate triamidoamines $[N(CH_2CH_2NR)_3]^{3-}$ are established as an important class of ligand for the main group, transition and actinide elements. The complexes formed have unique properties as a result, for example, of the formation of a single, sterically protected fifth coordination site.[1] Most recently we have reported the complexation of dinitrogen to a (triamidoamine)uranium centre; an unprecedented feat for an actinide element.[2]

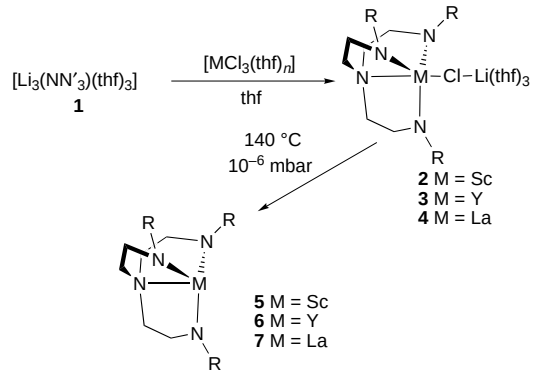
Reported attempts to synthesise the group 3 and lanthanide triamidoamines have thus far led to isolation of a novel trigonal monopyramidal lithium compound,[3] or the formation of the unusual product **I** below.[4]



The triamidoamine ligand $[N(CH_2CH_2NR)_3]$ (R = $SiMe_3$) would be expected to have a lower steric demand than the closely related fragment $\{N(SiMe_3)_2\}_3$ because of the constraints of the tripodal chelate structure. The actinide complexes $[U\{N(CH_2CH_2NSiMe_3)_3\}X]$ for example tend to have dimeric or distorted structures unless strong π-donor ligands X are used[5] while the compounds $[U\{N(SiMe_3)_2\}_3X]$ are monomeric.[6] The more sterically demanding triamidoamines R = $SiPr^i_3$ and $SiMePh_2$ form complexes which, in our experience, are difficult to isolate and unreactive. The ligand R = $SiMe_2Bu^t$[7] (henceforth NN'_3) however represents a suitable compromise between steric demand and synthetic utility. In its complexes with the actinides, three *tert*-butyl groups are oriented such that they encircle the equatorial plane in three-fold symmetric (trigonal pyramidal) structures and thus stabilise this geometry while allowing reactivity at the remaining axial site.[8] The complexes are crystalline, soluble and volatile. Using this type of ligand we have synthesised for the first time the simple group 3 and lanthanide triamidoamines.

Reaction of pure $[Li_3(NN'_3)(thf)_3]$ **1** with anhydrous $[MCl_3(thf)_n]$ (M = Sc, Y, La) in thf leads to rapid dissolution of the metal halide and formation of the analytically pure, colourless 'ate' complexes $[M(NN'_3)ClLi(thf)_3]$ (M = Sc **2**, Y **3**, La **4**) in near quantitative yields (Scheme 1).‡

Single crystals of the yttrium compound **3** were grown by slow cooling of a concentrated solution in pentane. The



Scheme 1 Synthesis of complexes **2**–**7**

molecular structure shown in Fig. 1 was determined by X-ray diffraction.§ The crystallographically threefold symmetric (triamidoamine)yttrium fragment is distorted from trigonal monopyramidal geometry by the displacement of the yttrium atom 0.67 Å out of the plane defined by the three amido nitrogen atoms. In the related triamides $[M\{N(SiMe_3)_2\}_3]$ (M = Sc, Eu[9] Y,[10] Nd,[11] Yb[12]) the metal atoms all lie 0.4 Å above the plane regardless of the ionic radius of the metal.[13] The apical amino N(1)–Y bond length in **3** is 2.588(4) Å. The amido N(1)–Y bond length of 2.231(2) Å is comparable to 2.226(6) Å found in $[Y\{N(SiMe_3)_2\}_3]$. The Y–Cl bond of 2.6526(16) Å is slightly longer than 2.55 and 2.598(2) Å observed in the 'ate' complexes $[Y\{N(SiMe_3)_2\}_3Cl][Li(thf)_4]$ and $[YR_3ClLi(Et_2O)_3]$ [R = $CH(SiMe_3)_2$], respectively,[10] presumably as a result of the *trans* effect of the amino N(1).

Heating compounds **2**–**4** to 140 °C and 10^{-6} mbar led to the distillation of pure colourless $[M(NN'_3)]$ (M = Sc **5**, Y **6**, La **7**) which solidified on cooling.‡ Trigonal monopyramidal triamidoamine complexes of the first row transition metals have been

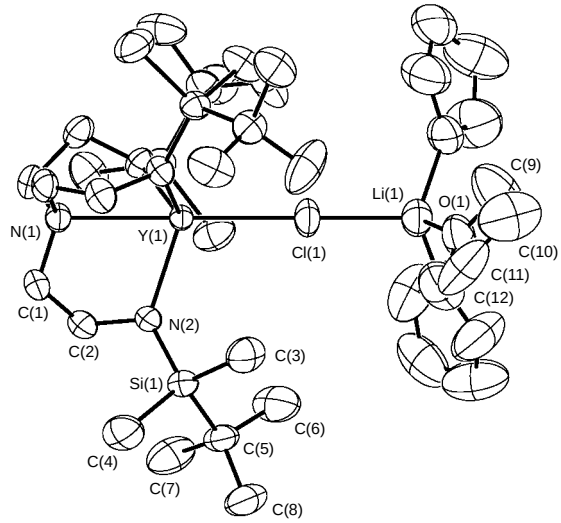


Fig. 1 Thermal ellipsoid plot of the molecular structure of **3**; hydrogen atoms omitted

synthesised,[7,14] but similar complexes of the second and third row have not been detected despite their implication in dinitrogen activation processes.[15] We cannot at present exclude the possibility of an agostic C–H–Y interaction in the apical coordination site, although no unusual NMR or IR shifts were observed.

Variable temperature NMR spectra of **2** in [$^2H_8$]toluene solution show that an equilibrium is established between the 'ate' complex [Sc(NN′$_3$)ClLi(thf)$_3$] **2** and [Sc(NN′$_3$)] **5** with the ratio [**5**] : [**2**] = 1 : 2.0 at 293 K. For the yttrium compounds, the ratio [**6**] : [**3**] is 1 : 22 while for lanthanum the base-free compound [La(NN′$_3$)] is not observed up to *ca*. 373 K. Thus the increase in atomic radius from Sc^{III} (0.89 Å) to Ln^{III} (1.17 Å) is accompanied by increased stability of the 'ate' complex; a good example of the prevalence of steric over electronic effects in lanthanide chemistry.

Complexes analogous to **2**–**7** are readily prepared for all of the stable lanthanides; we will report the trends in magnetic and spectroscopic properties of these compounds in due course. They have potential applications as regioselective Lewis acid catalysts by virtue of their single, sterically protected coordination site; related chiral titanatranes are effective enantioselective catalysts.[16] For the moment, we have shown that with suitable choice of ligand substituent, the elusive triamidoamine complexes of scandium and the rare earth elements can be synthesised.

P. S. wishes to thank the EPSRC for a Project Studentship, BNFL for a CASE award (to P. R.), and Pfizer Ltd. and SmithKline Beecham for support.

Resonant magnetization tunnelling in the half-integer-spin single-molecule magnet $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$

Steps are observed on the magnetization hysteresis loop for an oriented crystal sample of $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ and these are taken as evidence for field-tuned resonant magnetization tunnelling between quantum levels of the $S = 19/2$ ground state.

The interest in single-molecule magnets (SMM) is growing.[1,2] A SMM has a large spin ground state with such a large magnetic anisotropy that an individual molecule exhibits hysteresis in its magnetization *vs.* external field response. The first SMM reported[3–5] is neutral $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]\cdot 2(HO_2CMe)\cdot 4H_2O$ **1** (denoted Mn_{12}-acetate), which has an $S = 10$ ground state. Molecules possessing Mn_{12},[6] Mn_4,[7] Fe_8,[8] and V_4[9] metal contents have been found to function as SMM. Recently, Friedman *et al.*[10] reported the initial observation of resonant magnetization tunnelling for Mn_{12}-acetate; steps were observed at regular intervals of magnetic field in the magnetization hysteresis loop for oriented crystals. Here, we report the observation of steps in the hysteresis loop for oriented crystals of the salt $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ **2**. In previous work we have shown[11] the $[Mn_{12}]^-$ anions in **2** have an $S = 19/2$ ground state. The observation of resonant quantum tunnelling in this salt is of considerable interest since a half-integer-spin system should not tunnel coherently in the absence of a magnetic field.[12,13]

In solution, it is possible to add a single electron to a Mn_{12} molecule, and the X-ray crystal structure[11] for complex **2** shows that the added electron is localized on an outer (originally Mn^{3+}) ion rather than an inner (cubane) Mn^{4+} ion, producing a trapped-valence Mn^{2+}, $Mn^{3+}{}_7$, $Mn^{4+}{}_4$ anion in the crystal. The $[Mn_{12}]^-$ anion has an $S = 19/2$ ground state with the double-well potential energy diagram shown in Fig. 1. There are 20 different states with $m_s = \pm 19/2, \pm 17/2 \ldots, \pm 1/2$. The double well represents the change in potential energy of one $[Mn_{12}]^-$ anion in zero field as the anion changes the direction of its magnetic moment from 'spin up' (parallel to *z*-axis) where $m_s = +19/2$ to 'spin down' (antiparallel to *z*-axis) where $m_s = -19/2$. The barrier height U is $90|D|$, where D is the parameter characterizing the axial zero-field splitting (DS_z^2) in the $S = 19/2$ ground state.

The rate of relaxation of the magnetization was measured for a polycrystalline sample of **2** equilibrated at one of five temperatures in the range 1.8–2.5 K in an external magnetic field of 3.5 T; the latter was then quenched to zero. The decrease in the magnetization measured at each temperature was fitted to a distribution of single exponentials to give the relaxation rate. Relaxation rates were also determined in the range 3.2–7.2 K by means of ac magnetic susceptibility measurements in zero dc field. At a fixed temperature, the in-phase (χ_M') and out-of-phase (χ_M'') components of magnetic susceptibility were measured as the frequency of the ac field (0.05 Oe) was varied from 0.01 to 1500 Hz. The relaxation time (τ) at a given temperature was determined by fitting the data to eqn. (1),[14] where ω is the angular frequency ($2\pi\nu$), χ_S is the adiabatic susceptibility (*i.e.* $\omega \rightarrow \infty$) and χ_T is the isothermal

$$\chi_M' = \chi_S + (\chi_T - \chi_S)/(1 + \omega^2\tau^2) \quad (1)$$

susceptibility (*i.e.* $\omega \rightarrow 0$). The relaxation rates vary from 3.94×10^4 s^{-1} at 7.2 K to 6.19×10^{-6} s^{-1} at 1.8 K. Fig. 2 shows an Arrhenius plot of $\ln(1/\tau)$ *vs.* $1/T$. These data were fit to the Arrhenius law to give a barrier height, U, of 60.2 K with a pre-exponential ($1/\tau_0$) of 1.31×10^8 s^{-1}. This compares with $U = 61$–67 K and $1/\tau_0 \simeq 10^7$ s^{-1} found[4,5] for the $S = 10$ molecule, Mn_{12}-acetate.

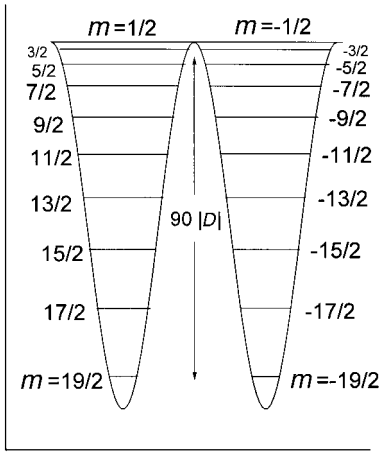

Fig. 1 Plot of potential energy *vs.* the magnetization direction for a single molecule with an $S = 19/2$ ground state in zero magnetic field. Axial zero-field interactions split the $S = 19/2$ state into $m = \pm 19/2, \pm 17/2, \ldots, \pm 1/2$ levels.

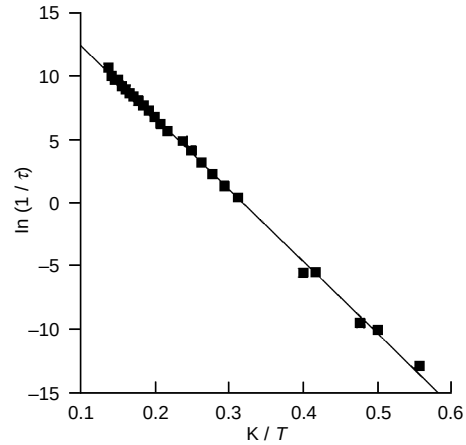

Fig. 2 Plot of the logarithm of the rate of relaxation *vs.* the inverse absolute temperature for $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ **2**

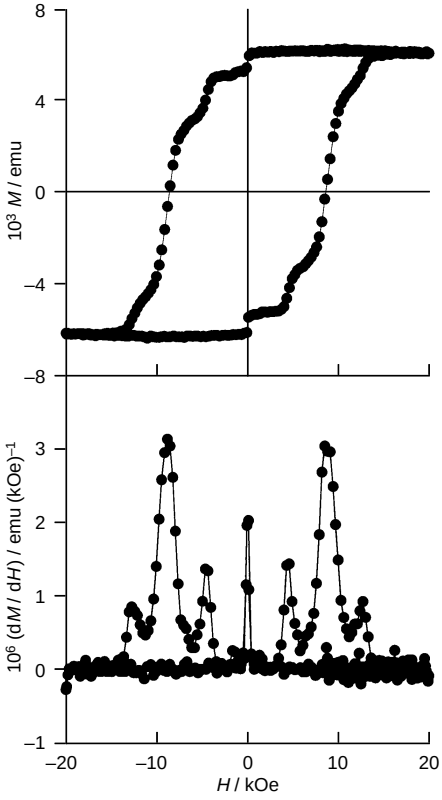

Fig. 3 The top plot shows the magnetization hysteresis loop measured at 1.85 K for five crystals of $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ **2** oriented in an eicosane wax matrix. In the lower plot is shown a plot of the first derivative of the magnetization hysteresis loop.

Five small crystals (3 × 0.1 × 0.1 mm) of **2**, grown from CH_2Cl_2–hexanes, were suspended in eicosane held at 40 °C and the suspension introduced into a 5.5 T field, whereupon the five crystals were oriented each with its easy axis parallel to the field. The eicosane was then cooled to room temperature, to give a solid wax cube with the five crystals oriented with parallel easy axes. Fig. 3 shows the hysteresis loop taken at 1.85 K with the magnetic field applied along the easy axes of the crystals. The sample was first saturated in a field of +2.0 T, and the field then swept down to −2.0 T, and cycled back to +2.0 T. The rate of change of the field was 25 Oe s^{-1} and each data point was measured within a few milliseconds. The whole hysteresis loop was collected in 1 h. Steps can clearly be seen on the hysteresis loop, as was reported[10] for the neutral molecule, Mn_{12}-acetate. In the lower part of Fig. 3 is shown the first derivative of the hysteresis plot. As the field is decreased from +2.0 T, the first step is seen at zero field, followed by steps at −0.4686, −0.9022 and −1.262 T. The steps correspond to increases in the rate of change of the magnetization, and are attributable to resonant tunnelling between quantum spin states. With reference to Fig. 1, a +2.0 T field leads to a stabilization in energy of the m_s = −19/2 and a destabilization of the m_s = +19/2 state. When there is saturation, all of the molecules are in the m_s = −19/2 state. As the field is decreased, the first step in the hysteresis loop is seen at zero field. Resonant tunneling occurs because the m_s levels on the right-hand side of the double well have the same energies as the m_s levels on the left.

The simplest Hamiltonian for $[PPh_4][Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ **2** is given by eqn. (2).

$$\hat{H} = -D\hat{S}_z^2 - g\mu_B\hat{S}\cdot\hat{H} \quad (2)$$

If the field is applied along the easy axis, then the eigenstates are $|S, m_s>$. The first term in the Hamiltonian gauges the axial zero-field splitting of the S = 19/2 ground state. Physically, this zero-field splitting of the ground state is largely due to the single-ion zero-field splitting at the Mn^{3+} ions in the $[Mn_{12}]^-$ anion. With the above Hamiltonian, it can be shown that the spacings between the steps in the hysteresis loop are given as $\Delta H = -Dn/g\mu_B$, where n = 0, 1, 2, 3, ... From Fig. 3, we calculate the average step size to be ΔH = 0.42 T, which gives a value of D/g of 0.20 cm^{-1}, identical to the value obtained for **2** by fitting variable-field magnetization data,[11] and high-field EPR data more recently.

Friedman *et al.*[10] observed six steps for the neutral Mn_{12}-acetate, including the step at zero field, as the field was swept from zero to −3 T after saturation in a +3 T field. We have observed only four steps for the salt **2**, presumably due to the faster relaxation rate of the latter complex. At lower temperatures, more steps should be seen since the relaxation rate will decrease. For both molecular systems, each successive step is seen. This is interesting because the Mn_{12}-acetate molecule has an integer spin ground state with S = 10, whereas the $[Mn_{12}]^-$ anion has a half-integer-spin ground state with S = 19/2. There have been several papers[12,13] addressing the fact that a molecule with an odd number of unpaired electrons (such as S = 19/2) should not exhibit resonant tunnelling in the absence of a magnetic field. For such a molecule, each pair of $\pm m_s$ levels in zero-field exhibits Kramers degeneracy. An S = 19/2 molecule should not be able to tunnel coherently between the m_s = −19/2 and m_s = +19/2 levels, or for that matter, between any m_s and $-m_s$ pair in the absence of a magnetic field. However, clearly the salt of $[Mn_{12}]^-$ shows steps on the hysteresis loop. A possible mechanism for resonant tunneling in this S = 19/2 molecule centers around the nuclear spins in the molecule. The ^{55}Mn and ^1H nuclei have spins of I = 5/2 and I = 1/2, respectively, and this will give rise to a small internal magnetic field (10–200 G) in the molecule. A transverse component of this internal magnetic field may lead to resonant tunnelling for an oriented collection of $[Mn_{12}]^-$ molecules in zero external field.

This work was supported by the National Science Foundation. The W. M. Keck Foundation provided funds for the SQUID magnetometer used in the ac susceptibility experiments.

Solar light induced carbon–carbon bond formation *via* TiO_2 photocatalysis

Laura Cermenati,[a] Christoph Richter[b] and Angelo Albini[a]†

[a] *Department of Organic Chemistry, University of Pavia, via. Taramelli 10, 27100 Pavia, Italy*
[b] *Plataforma Solar de Almeria, PO Box, 22, 04200 Tabernas, Almeria, Spain*

Solar light irradiation of a TiO_2 suspension in MeCN containing maleic anhydride and 4-methoxybenzyl(trimethyl)silane gives benzylated succinic acid (or anhydride) on a gram scale.

Irradiation of a semiconductor ($\lambda \geqslant \Delta E_{bg} = E_{cb} - E_{vb}$, see Scheme 1) causes charge separation. If a significant part of the solar emission is absorbed, methods for solar energy conversion based on this principle can be devised. Most of the research in this field makes use of titanium dioxide, an inexpensive, chemically stable and atoxic semiconductor which absorbs all of the UV component of the solar spectrum.[1–4] Photoelectrochemical solar cells have been devised and their efficiencies have been considerably improved over the years. However, solar light is diffuse, and electrical power produced in this way remains expensive.[5] The same holds for the production of fuels, *e.g.* hydrogen, which is also feasible using this principle.[5] On the other hand, the production of fine chemicals may be rewarding. We report here an example of the use of solar light for the most typical reaction of organic synthesis, carbon–carbon bond formation, *via* TiO_2 photocatalysis. The reaction considered is the radical alkylation of electron-withdrawing substituted olefins.

When planning a synthesis based on TiO_2 photocatalysis, the problem is to translate a *transient* charge separation (electron-hole recombination on the semiconductor surface takes place in *ca*. 30 ps)[6] into an irreversible and selective reaction. The system we used is outlined in eqns. (1)–(4). The solution

$$TiO_2(h^+, e^-) + R^1X + R^2Z \rightarrow TiO_2 + R^1X^{+\cdot} + R^2Z^{-\cdot} \quad (1)$$

$$R^1X^{+\cdot} + TiO_2(e^-) \rightarrow TiO_2 + R^1X \quad (2)$$

$$R^1X^{+\cdot} + R^2Z^{-\cdot} \rightarrow R^1X + R^2Z \quad (3)$$

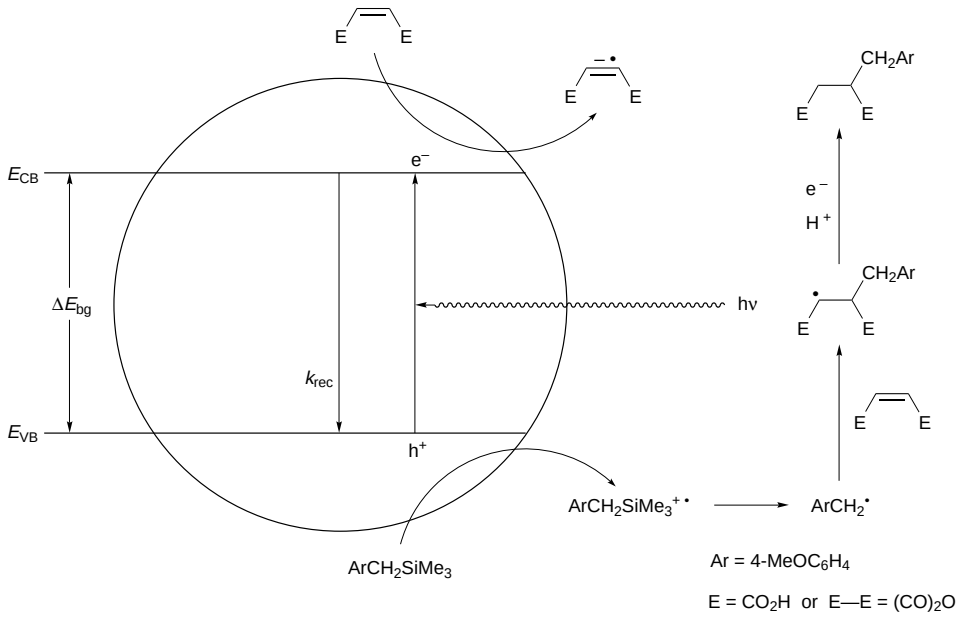
$$R^1X^{+\cdot} \rightarrow R^{\cdot} \rightarrow \text{Products} \quad (4)$$

must contain *both* a donor and an acceptor with the suitable redox potential [see eqn. (1)] since return electron transfer to the surface [*e.g.* eqn. (2)] would otherwise immediately quench the key intermediate. One of the radical ions should react rapidly in order to prevent back electron transfer after diffusion [eqn. (3)] from quenching the reaction. In our case, the reaction is cleavage of the radical cation leading to a radical, which is then trapped in the desired chemical reaction [eqn. (4)]. This implies that the radical anion should not fragment, because otherwise statistical radical coupling ($R^{1\cdot} + R^{2\cdot}$) would result, and that efficient trapping prevents dimerisation of $R^{1\cdot}$.

In the present case, 4-methoxybenzyl(trimethyl)silane (see Scheme 1, E_{ox} 1.31 V *vs*. SCE in MeCN, *cf.* E_{vb} 2.2 V for TiO_2) functions as the fragmentable donor and either maleic acid or maleic anhydride (E_{red} −0.84 V, *cf.* E_{cb} −0.8 V) has the double role of electron acceptor and radical trap.

Thus, an MeCN solution (1 l) of the silane (3.88 g, 0.02 M) and maleic anhydride (2.16 g, 0.022 M) containing TiO_2 (1.4 g) (untreated Degussa P25 pigment) was pumped by means of a peristaltic pump through a refrigerated tube sitting in the focus of a parabolic mirror (surface exposed to the sun 0.2 m^2), while maintaining a slow flux of nitrogen and keeping the temperature at 15 °C. This arrangement was sufficient for maintaining a uniform suspension of TiO_2 in the tube. After 10 h (July, Almeria, sunny day) of exposure to solar light, the suspension was filtered, the solvent evaporated and the residue recrystallized to give 2.86 g (65%) of 2-(4-methoxybenzyl)succinic anhydride. Minor products were 4,4′-bis(4-methoxy)bibenzyl and 2,3-bis(4-methoxybenzyl)succinic anhydride.

Monitoring the reaction by GC showed that it followed the expected zero-order kinetics, and reagent consumption and



Scheme 1

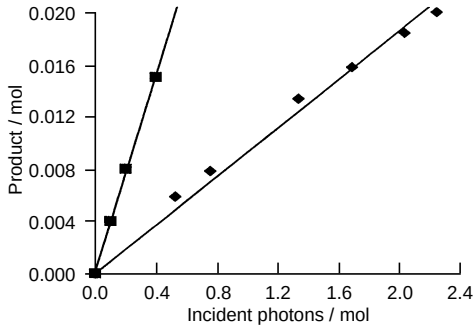


Fig. 1 Formation of (■) 4-Methoxybenzylsuccinic anhydride or (◆) acid *vs.* incident UV photons

product formation were proportional to the integrated incident flux‡ (Fig. 1). A similar reaction course and a similar yield of the benzylated succinic acid was obtained when maleic acid was used in the place of the anhydride, although this required 22 h exposure overall. Furthermore, the alkylation could be effected with other donors, *e.g.* 4-methoxyphenylacetic acid.

These reactions are initiated by hole/electron transfer to produce a pair of radical ions (see Scheme 1). The alkene radical anion is stable, while the silane radical cation fragments and gives the 4-methoxybenzyl radical. Under the present conditions this is mainly trapped by maleic anhydride (or acid), rather than coupling. The adduct radical is reduced by the persistent radical anion of the acceptor or by electron transfer at the semiconductor surface, and protonated by water present in MeCN to give the final products. Operation of a similar mechanism for photoinduced electron transfer initiated alkylation of unsatured acid derivatives had been previously demonstrated to occur when a soluble sensitizer was used (although in that case no benzylation was observed),[7] but has no precedent in photocatalysis.§ The change to a heterogeneous sensitiser simplifies the method, since introduction of other species into the solution is avoided, work-up is simpler and the semiconductor can be recovered.

Exploitation of solar light in this way is not efficient (at the present stage 'apparent'¶ quantum yields are *ca*. 3% for the anhydride and 1% for the acid, see Fig. 1, and the literature shows that in general this quantity does not exceed 10% with TiO_2 sensitised reactions,[9] in part due to reflection). However, a good yield of alkylated products is obtained on a reasonable scale by this simple method, both solvent and semiconductor are easily recovered and reused, and little excess reagents or by-products remain. This may induce further exploration of heterogeneous photocatalysis for organic synthesis beyond the few cases that are known to date,[8,10] and lead to its use, along with homogeneous photoreactions,[11] for the exploitation of solar light.

Support of this work by the EC under the TMR program is gratefully acknowledged.

New type formation of 1,3-enynes (or internal alkynes) *via* coupling of organoboranes with alkynylcopper compounds mediated by copper(II)

Yuzuru Masuda,*† Miki Murata, Kaname Sato and Shinji Watanabe

Department of Materials Science, Kitami Institute of Technology, Kitami 090-8507, Japan

The copper(II)—mediated coupling reaction of alkenyldialkyl- or trialkyl-boranes with alkynylcopper compounds (generated *in situ*), in the presence of appropriate solvents and a small amount of water, gives (*E*)-1,3-enynes (or disubstituted alkynes) with various functional groups in reasonable yields.

Conjugated enynes are attractive organic compounds,[1,2] and in recent years[3] have been mainly constructed *via* coupling reactions[4] of organometallic compounds (alkynyl[5] or alkenyl[6,7]) with organic halides (alkenyl[5] or alkynyl[6,7]) respectively. They can also be synthesized *via* the internal coupling of lithium (dialkyl) (alkenyl)(alkynyl)borates by I_2[8a] or of (alkyl)-(alkenyl) (alkynyl)boranes by I_2 and MeOK.[8b] Internal alkynes can also be formed in a similar manner.[4,8c]

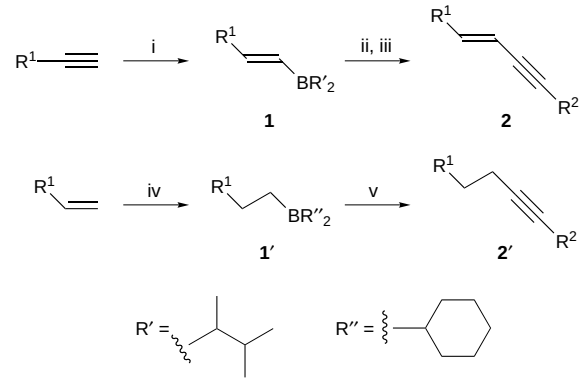
Previously we found a synthesis of alkenyl[9a] or alkyl[9b] cyanides *via* copper(II) acetate—mediated reactions of alkenyl- or alkyl-boranes[10] with copper(I) cyanide. This observation led us to investigate a synthetic approach to 1,3-enynes (or substituted alkynes) *via* a similar reaction employing copper(I) acetylides, regarding them simply as copper(I) cyanide analogues.

Thus, although the reaction of (*E*)-hex-1-enylbis(1,2-dimethylpropyl)borane[11] **1a** with neat hexynylcopper (prepared and isolated *via* the generally known method), in the presence of copper(II) acetate, HMPT and a small amount of water, generated (*E*)-dodec-5-en-7-yne **2a** in unsatisfactory yield (35%), accompanied with dodeca-5,7-diyne (10%), the introduction of copper(II) nitrate trihydrate to the reaction mixture provided the enyne **2a** in 77% yield (GC) and the diyne in 3% yield. In a similar reaction employing hexyldicyclohexylborane[11] **1a′**, the introduction of $Cu(acac)_2$[9b] along with $Cu(OAc)\cdot H_2O$ afforded dodec-5-yne **2a′** in 70% yield [in the absence of $Cu(acac)_2$, the yield was 25%].

In order to obtain more practical synthesis, further improvements of the reaction procedures were attempted. Consequently, the sequence shown in Scheme 1, which probably proceeds *via in situ* generation[12] of the alkynylcopper species [from alk-1-ynes with copper(I) iodide], was used instead of that previously described which utilised neat reactants prepared separately. DMA–pyridine was the solvent system of choice for enynes **2** (or DMA alone for internal alkynes **2′**).

For the synthesis of internal alkynes **2′**, the participation of CuI was not always essential (suggesting that copper acetate might take the place of the copper iodide).[13] However, for the syntheses of enynes **2**, its absence always led to poor results. In this manner, conjugated (*E*)-alkenynes **2** or disubstituted alkynes **2′** were produced easily‡ and isolated§ with high selectivities [*E*-isomers > 99%; the diynes (by-product) were present in trace amounts] and in reasonable yields as shown in Table 1 (entries 1–3 and 13–14).

The present reaction tolerates various functional groups on the alkyne moiety (R^2) to afford **2d** (entry 4), **2e** (entry 5), **2f** (entry 6), **2g**¶ (entry 7), **2h**‖ (entry 8), **2l** (entry 12), **2d′** (entry 15) and **2m′** (entry 16), in a similar manner to that for the reaction using alkynylcopper.[5a] In contrast, the reaction using lithium alkynylborate[8a] would have some problems in this aspect. Also, the toleration of functional groups on the boron



Scheme 1 *Reagents and conditions*: i, R'_2BH (1 equiv.), THF, −15 °C, then 0 °C, 3 h; ii, $R^2C{\equiv}CH$ (1 equiv.), CuI (1.1 equiv.), pyridine (2 equiv.), DMA, 0 °C, then 20 °C, 3 h; iii, $Cu(OAc)_2$ (2 equiv.), $Cu(NO_3)_2\cdot 3H_2O$ (2 equiv.), THF, 0 °C, then 20 °C, 18 h; iv, R''_2BH (1 equiv.), THF, 0 °C, 2 h; v, $R^2C{\equiv}CH$ (1 equiv.), $Cu(OAc)_2\cdot H_2O$ (2 equiv.), $Cu(acac)_2$ (0.25 equiv.), DMA–THF, 0 °C, then 20 °C, 18 h

reagent (R^1)[15] was confirmed by the reactions which gave **2i** (entry 9), **2j** (entry 10), **2k** (entry 11), **2l** (entry 12) and **2n′** (entry 17).

We feel that the organocopper species (*i.e.* alkenyl- or alkylcopper) is probably generated *via* a transmetalation of the organoborane. However, the detailed mechanism of the present reaction is unclear due to the absence of direct or obvious evidence, like many organocopper reactions to date.

In summary, the present reaction is not only interesting as a new method for formation of (*E*)-1,3-enynes (or disubstituted alkynes), but is also remarkably useful for the synthesis of such

‡ It was observed that galvinoxyl (a radical scavenger) depressed the formation of the disubstituted alkyne **2′** but not that of the enyne **2**.

§ After filtration the reaction mixture was washed and extracted, followed by oxidation with $NaBO_3 \cdot 4H_2O$ in H_2O and THF (ref. 14). The mixture was then worked up as usual. The pure product, isolated from the mixture (consisting of **2** or **2′** and an almost quantitative amount of R′OH or R″OH derived from the residual dialkylboryl groups) by column chromatography or Kugelrohr distillation, gave satisfactory spectral data (IR, ^{1}H NMR, ^{13}C NMR, mass).

¶ This would be applicable to the synthesis of the pheromone of the tent caterpillar *Malacosoma disstria* [(5*Z*,7*E*)-dodeca-5,7-dien-1-ol] [ref. 8(*b*)].

‖ Such enynes are known to be converted into terminal enynes (RCH=CHC≡CH) *via* the elimination of acetone using alkali (ref. 16).

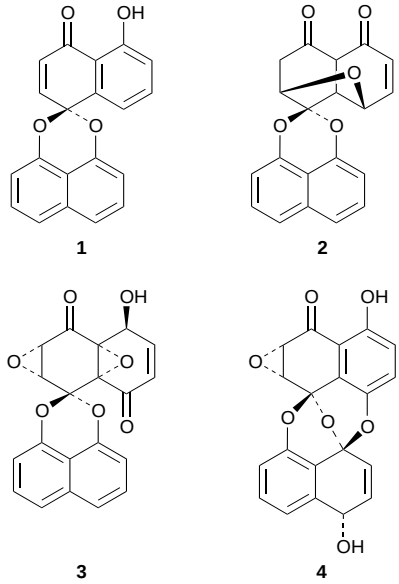
Total syntheses of palmarumycins CP_1 and CP_2 and CJ-12,371: novel spiro-ketal fungal metabolites

Anthony G. M. Barrett,*† Dieter Hamprecht and Thorsten Meyer

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY

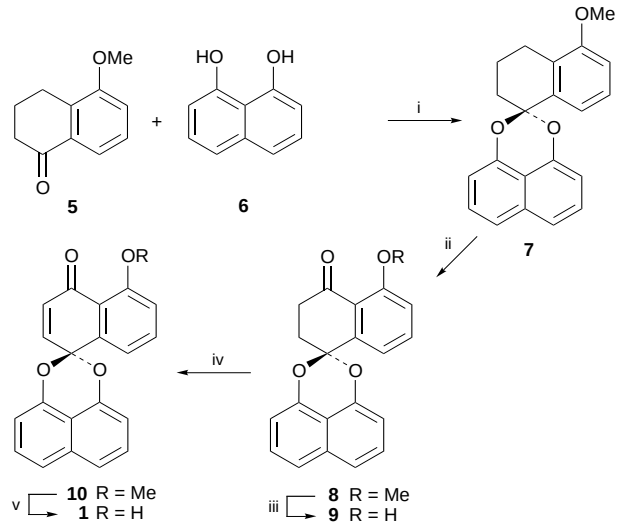
Total syntheses of palmarumycins CP_1 1 and CP_2 9 and the structurally related CJ-12,371 11 are reported, thereby establishing a strategy for the synthesis of further natural products in the palmarumycins, diepoxines and preussomerines family.

The palmarumycins,[1] diepoxines[2] and preussomerines[3] are a structurally remarkable class of natural products isolated from various fungi cultures. They all are graced with a spiro-ketal entity formally derived from naphthalene-1,8-diol **6** and 1,4-naphthoquinone, yet at rich and varied oxidation levels. All three classes of fungal metabolites are undoubtedly closely interrelated biosynthetically and may well be derived from a naphthalene-1,8-diol spiro-ketal with late introduction of the unusual oxygenation patterns. These secondary metabolites are



exemplified by palmarumycin CP_1 **1**, palmarumycin CP_3 **2**, diepoxine σ **3** and preussomerine E **4**, which show diverse biological effects including selective antifungal and antibacterial activities.[4] Although Wipf and Jung have reported studies towards the synthesis of diepoxine σ **3**[5] and Krohn *et al.* have reported an elegant biomimetic cyclisation approach to a model spiro-ketal array,[6] there have been no reports on the total synthesis of any natural product in this intriguing series. Herein we now report the total syntheses of three natural products palmarumycins CP_1 **1** and CP_2 **9** and CJ-12,371 **11**.

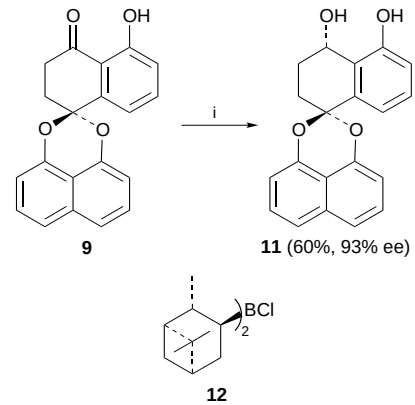
Condensation of 5-methoxytetralone **5** and diol **6**[7] under acid catalysis gave spiro-ketal **7**‡ in an 86% yield (Scheme 1). Subsequent benzylic oxidation using bipyridinium chlorochromate[8] and a 30-fold excess of *tert*-butyl hydroperoxide gave the corresponding ketone **8** in 61% yield. Alternative oxidants including Jones' Reagent or potassium permanganate were much less efficient for the preparation of ketone **8**. Reaction of



Scheme 1 *Reagents and conditions*: i, TsOH (cat), PhH, Dean–Stark, 48 h, reflux, 86%; ii, CrO_3·HCl·bipy, BtOOH, Celite, PhH, 10 h, room temp., 61%; iii, MgI_2, PhH, 1.5 h, reflux, 84%; iv, DDQ, PhH, 10 h, reflux, 65%; v, *B*-bromocatecholborane, DBU, CH_2Cl_2, 10 min, 5 °C, 50%

the methyl ether **8** with a freshly prepared solution of magnesium iodide[9] in benzene gave palmarumycin CP_2 **9** (84%). Deprotection using magnesium iodide was found to be far superior to trimethylsilyl iodide (32%) or sodium ethanethiolate (63%).[10] Oxidation of ketone **8** with DDQ[11] followed by deprotection of the methyl ether with *B*-bromocatecholborane[12] gave palmarumycin CP_1 **1**, the dehydro analogue of **9**, in 33% yield over two steps.

Finally, palmarumycin CP_2 **9** was converted into its corresponding dihydro derivative **11** (60% yield, 93% ee)§ by asymmetric reduction using (+)-*B*-chlorodiisopinocampheylborane **12**[13] (Scheme 2). It is germane to mention that reduction presumably takes place *via* intramolecular hydride delivery thereby reversing the absolute stereochemistry of reaction seen



Scheme 2 *Reagents and conditions*: i, (+)-**12**, THF, room temp., 18 h, then H_2O_2, KOH

with simple alkyl aryl ketones.[13] The product of reduction, alcohol **11**, is a natural product in its own right named CJ-12,371 **11**,[14] a DNA-gyrase inhibitor isolated from an unidentified fungus (N983-46). The authenticity of both palmarumycins CP_1 **1** and CP_2 **9** were established by comparison of the synthetic compounds with authentic samples (^1H and ^{13}C NMR spectroscopy). Unfortunately, we have been unable to obtain an authentic sample of CJ-12,371 **11** and the characterisation of our synthetic material rests on comparison of our data with those published for the natural product.[14]

It is clear that the spiro-ketal **7** is a useful intermediate for further redox manipulations and the synthesis of simple palmarumycins. Further studies towards the total synthesis of the more challenging and higher oxidation level diepoxines and preussomerines are currently under investigation and will be reported in due course.

We thank SmithKline Beecham for support of our research, Glaxo Wellcome Research Ltd. for an endowment (to A. G. M. B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College and Professor Karsten Krohn for authentic samples of palmarumycins CP_1 **1** and CP_2 **9**.

Laser-induced molecular mixing of electron donor and acceptor in poly(ethyl methacrylate)

Guillaume Gery, Hiroshi Fukumura*† and Hiroshi Masuhara

Department of Applied Physics, Osaka University, Suita, Osaka 565, Japan

Dicyanoanthracene molecules are ejected from a polymer film by pulsed UV laser irradiation and are transferred into another polymer film containing hexamethylbenzene, resulting in the formation of the charge-transfer complex in a polymer solid.

Intense irradiation with UV laser pulses has been considered to decompose organic molecules in polymer solids by multiphotonic chemical reactions.[1] However, we have recently shown that aromatic molecules dispersed in polymers hardly decompose by nanosecond laser irradiation and can be ejected from the polymer surfaces without decomposition.[2–4] The evidence that a large thermal jump dominates in laser ablation of doped polymers has been provided by transient thermal expansion of the polymer surfaces.[5] Based on these mechanistic studies of dopant-sensitized laser ablation, we have developed laser molecular implantation (LMI) as an innovative method to generate patterns of intact molecules on polymer surfaces.[6–8] The process involves the overlay of two polymer films: the source film, which contains dopant molecules absorbing the laser light, and the target film, which may be a neat polymer film. Molecules embedded in the source film are excited by a pulsed excimer laser and implanted into the target film in contact. From fluorescence measurements under total internal reflection conditions, the thickness of the implanted layer is estimated to be of a few tens of nanometers.[7] Our attention is now focused on space-selective chemical reactions in a controlled volume beneath a polymer surface by transferring reactants by LMI. This method can be applied for the fabrication of devices using a variety of organic functional molecules. The successful attempt described in this report is opening new prospects for nano-scale chemistry in solid macromolecular structures.

Poly(ethyl methacrylate) (PEMA, $\overline{M}_w = 3.4 \times 10^5$, Aldrich) films were prepared by spin coating on glass plates from chloroform (Nacalai Tesque Inc. HPLC grade) solutions. The typical thickness of the films was 3 μm when the concentration of PEMA in chloroform was 6 wt% and the spin speed was 1000 rpm. Source films were prepared from a saturated solution of 9,10-dicyanoanthracene (DCNA, Kodak) in PEMA–chloroform. Micro-crystals were removed by syringe filters (PTFE 0.2 μm, DISMIC-25 JP, Advantec Toyo). The concentration of hexamethylbenzene (HMB, Nacalai Tesque Inc.) in target films was 0.4 M. For each measurement a neat PEMA target film was irradiated under the same conditions and used as a reference. Only DCNA exhibited an absorption band in the spectral region above 320 nm and a XeF excimer laser pulse (351 nm, fwhm ≈ 30 ns) allowed the selective excitation of DCNA molecules. After irradiation, the fluorescence spectrum of the target film was recorded on a conventional spectrofluorometer (Hitachi F-4500) and the surface was observed by both a fluorescence microscope (Olympus BX 50) with a U-MWU filter unit (λ_{ex} < 400 nm; observation: 400–700 nm) and a scanning electron microscope (SEM) (JEOL JXA-8600X). In the case of repetitive irradiation, it was carried out at 1 Hz or less in order to avoid any cumulative heating effect.

DCNA and HMB are known to form exciplexes in solution and in the gas phase.[9–12] Fluorescence spectra of polymer films doped with DCNA and of films doped with both DCNA and HMB were recorded and used as standards. DCNA films emitted blue fluorescence with a maximum at 430 nm when excited at 380 nm. When HMB was introduced, the monomer fluorescence was quenched, and a broad and structureless band appeared at *ca*. 500 nm (green emission). The excitation spectrum of this compound corresponded to the superposition of the vibrational structure of DCNA monomer fluorescence and a broad charge-transfer band indicating complex formation in ground state between DCNA and HMB.

Laser-implanted area was first examined by fluorescence microscopy. With the first laser shot, the surface was implanted with a gold–yellow emissive compound. This compound was

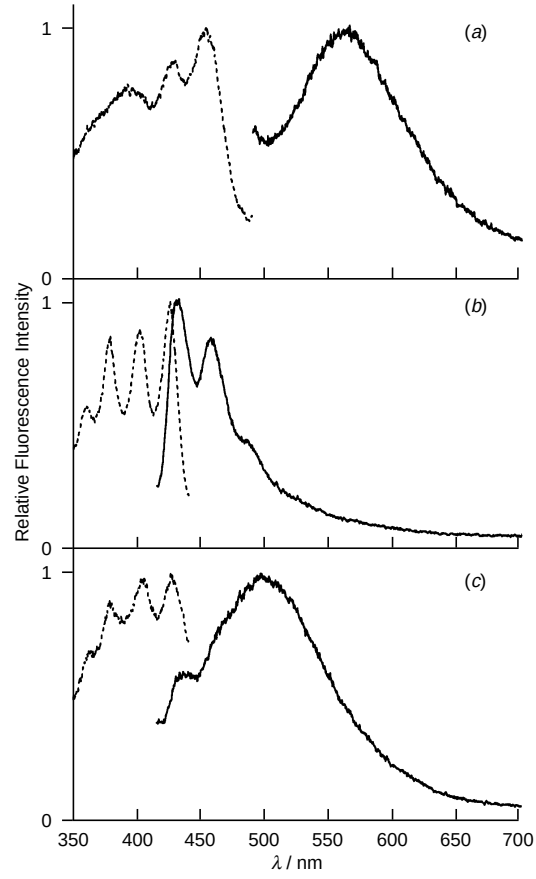

Fig. 1 Fluorescence (——, excited at 380 nm) and their excitation (- - -, observed at 550 nm) spectra of the target films after laser irradiation (laser fluence, 200 mJ cm^{-2}; source film ablation threshold, 400 mJ cm^{-2}). (*a*) The emission band of the yellow compound formed by the first laser shot appeared at *ca*. 560 nm. The excitation spectrum was shifted to longer wavelengths compared to monomeric DCNA. (*b*) After 10 shots irradiation, the emission spectrum of the implanted area almost corresponded to the monomer emission and the excitation spectrum was identical to the DCNA monomer absorption spectrum. (*c*) When HMB was involved in the target film a clear charge transfer band of the DCNA–HMB complex appeared at *ca*. 500 nm.

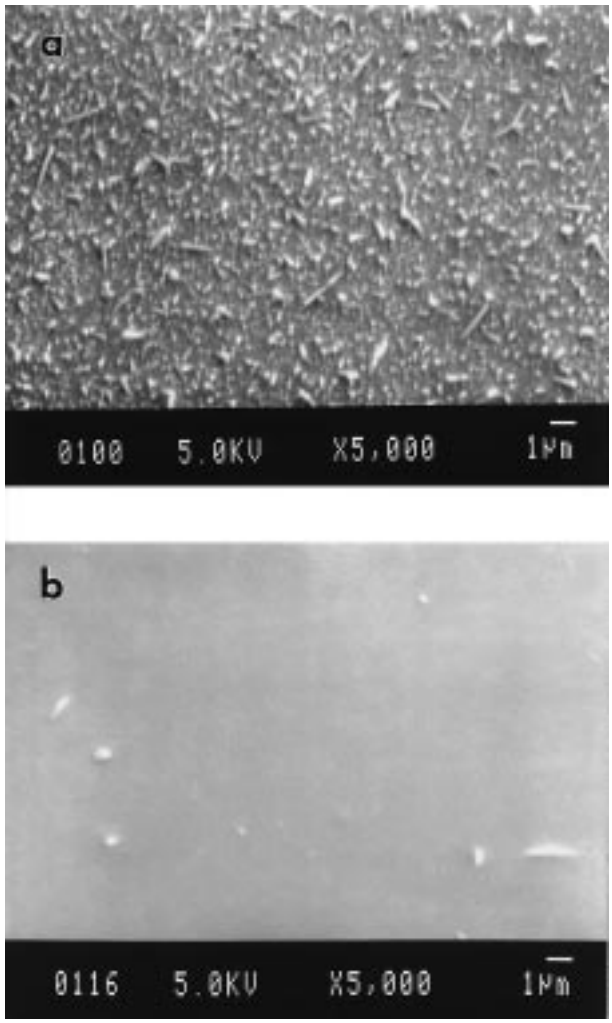

Fig. 2 SEM micrographs of the target film surfaces. (a) With the first laser pulse nano-crystals were formed on the surface of the target film. (b) By repetitive irradiation (10 shots), the nano-crystals almost disappeared and the surface recovered the original flatness.

always formed with the first laser shots irrespective of the existence of HMB in the target film. By increasing the number of laser shots, the yellow fluorescence disappeared and instead blue monomer fluorescence was observed for the target film not including HMB. When the target film contained HMB, the color of the implanted pattern turned to green fluorescence suggesting the formation of the charge transfer complex.

In order to confirm the complex formation in the polymer matrix, we also measured fluorescence spectra of those implanted polymer films (Fig. 1). After the first laser shot, the emission spectrum of the target film exhibited a broad band centered at *ca*. 560 nm and the excitation spectrum was shifted to a longer wavelength region compared to the DCNA monomer absorption band [Fig. 1(*a*)]. The emission changed to that of the DCNA monomer after 10 laser shots and then its excitation spectrum was almost coincident with the DCNA absorption spectrum [Fig. 1(*b*)]. When the target film was doped with HMB, an emission band centered around 500 nm clearly ascribed to the charge transfer emission emerged [Fig. 1(*c*)].

The origin of the yellow emissive compound should be solely ascribed to DCNA as it was found to be independent of HMB. Scanning electron microscope images of the surface revealed the presence of aggregates of a few hundreds of nanometers after the first laser shot [Fig. 2(a)]. The amount of those aggregates decreased with increasing the laser shot number [Fig. 2(b)]. This suggests that upon repetitive irradiation the nano-aggregates absorbed light, reached a high temperature, melted a thin layer of the polymer surface and were dispersed into deeper layers of the surface, which resulted in the recovery of a smooth surface of the polymer. Changes in the fluorescence spectra of the target film also supports the aggregate dispersion by repetitive irradiation.

The yellow emissive aggregates formed by the first laser shot may be attributed to a specific crystal form of DCNA. Meso-substituted anthracene derivatives generally have two crystal forms, α and β, depending on the overlapping of aromatic rings[13,14] and some spectral changes have been reported in the case of thermal treatment of DCNA[15] The α-form is produced by recrystallization from solution while the β-form is obtained either by sublimation or by heating the α-form at temperatures above 453 K for 24 h. A similarity in the fluorescence spectra of the aggregates and the β-form crystal suggests that DCNA in the source film was sublimated by a high transient temperature rise and condensed on the surface of the target film to crystallize as the yellow emissive β-form.

Since the two films in contact were irradiated from the backside of the target film, the crystals formed on the surface of the target film absorb light efficiently, transform it into thermal energy by non-radiative processes and diffuse into a deeper layer of the film. The curve of the fluorescence intensity of the target films as a function of the shots number reached a constant value after a few laser shots indicating that most of the molecules are transferred by the first laser shots. The following shots provide the energy required to dissociate molecular aggregates and release the monomer into deeper layers of the target film where complex formation occur.

In this paper, light has been used for the first time to transfer molecules from one film to another and to mix two components in a polymer matrix without the transfer of the source film polymer matrix itself. LMI appears as a promising tool to induce a chemical reaction in a limited volume of macro-molecular solids leading to a wide range of applications, from the manufacturing of biochemical sensors to that of optical and electronic circuits by using organic functional molecules.

Poly(alkylbenzyls), a promising new polymeric material

D. Baudry-Barbier, A. Dormond,*† F. Dumont and F. Duriau-Montagne

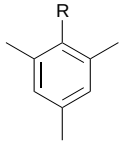
Laboratoire de Synthèse et d'Electrosynthèse Organométalliques (L.S.E.O.), U.M.R. 5632-C.N.R.S., Université de Bourgogne, 6 bd Gabriel, 21000 Dijon, France

The reaction of mesitylene substituted by alkyl or alkoxy chains of various lengths and α,α′-dichloro-*p*-xylene with K10 Montmorillonite as catalyst affords a new class of poly(alkylbenzyls) soluble in common organic solvents.

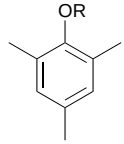
The synthesis of thermostable and water resistant polymers has been widely investigated, but remains even today an important economical challenge. For this purpose, polybenzyls, first reported in 1885,[1] were reinvestigated in the 1970s by several groups.[2–5] These polymers obtained in Friedel–Crafts type polyalkylation reactions[6–8] were found to be thermally stable up to 400 °C,[5,9] but the molecular weights were often very low[5] and little information about their nature and their properties was available. All these materials were described as insoluble in organic solvents, this insolubility preventing any possibility of industrial use. Moreover, it was noted that although *para* substitution in the main chain was predominant,[5,9] the possibility of lateral substitution on the polybenzyl skeleton leading to branched polymers is not excluded.[10] Then, it was interesting to synthesize non-crosslinked, linear polybenzyls, with a high solubility in usual organic solvents.

To obtain a linear and defined material, the polycondensation of α,α′-dichloro-*p*-xylene on 1,2,4,5-tetramethylbenzene has been performed using K10 Montmorillonite as catalyst. This acidic clay is widely used as a Friedel–Crafts alkylation and acylation supported catalyst.[11–13] The alkylation is then expected to occur preferentially at the two *para* positions of durene[14] rather than on the disubstituted ring. A linear polymer (**P1**) was effectively obtained: the ^{1}H NMR spectrum showed only one singlet due to the four protons of the methylene groups and only one sharp signal due to the four protons of the equivalent aromatic protons. But the solubility was low in usual solvents ($CHCl_3$ THF, toluene, CH_2Cl_2, *etc.*). The molecular weight of the THF soluble fraction ranged from 7000 to 10 000.

The solubility may be increased by replacing one of the methyl groups by a long aliphatic chain to obtain a polymer containing flexible segments after condensation. Moreover both the interactions between side-chains and the free volume created by the side-chains in the material influence the physical properties. Two alkyl and three alkoxy side-chains were chosen and the starting materials were synthesized from mesitylene by a Friedel–Crafts reaction (**2** and **2′**) or from sodium 2,4,6,trimethylphenolate and the appropriate alkyl bromide by a Williamson (**3**,**3′** and **3″**) reaction. These substrates were characterized by elemental analysis, mass, IR, ^{1}H and ^{13}C NMR spectroscopy.

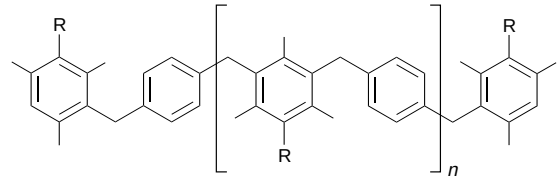


2 R = $C_{16}H_{31}$
2′ R = C_8H_{17}



3 R = $C_{16}H_{31}$
3′ R = C_8H_{17}
3″ R = Bu

The stoichiometric (1 : 1) reaction between the substrate (**2**, **2′**, **3**, **3′** or **3″**) and α,α′-dichloro-*p*-xylene was performed in refluxing decane (174 °C) during 24 h in the presence of K10 Montmorillonite. After usual work up, removal of the catalyst and of the solvent, dissolution in the appropriate solvent and precipitation by MeOH, the polymers **P2**, **P2′**, **P3**, **P3′** and **P3″**



P2 R = $C_{16}H_{31}$
P2′ R = C_8H_{17}
P3 R = $OC_{16}H_{31}$
P3′ R = OC_8H_{17}
P3″ R = OBu

were obtained respectively as white powders in *ca*. 60% yield. The solubility of these compounds increases with the length of the chain:

P3″ (THF, moderately) < **P2′** (Et_2O, moderately) < **P3′**, **P2** (Et_2O) < **P3** (heptane)

Elemental analyses and the IR, ^{1}H and ^{13}C NMR spectra of the crude materials are in agreement with the proposed formulae.‡ Note that these compounds contain a small amount of chlorine (*ca*. 0.1%), which could be due to terminal $-CH_2Cl$ groups of the macromolecular chains which were not quenched. The signal at 4.5 ppm due to a terminal $-CH_2Cl$ group is either extremely weak or not depicted. Consequently, the small amount of chlorine implies that most of the terminal groups are substituted phenyl groups.

The apparent volume of these polymers is strongly dependent on the length and the spatial position of the side-chains. It was thus very difficult to establish their molecular weight (M_w) by steric exclusion chromatography (SEC) using polystyrene samples as calibration standards. The polydispersity index (I_p) of the soluble fraction ranged from 1.3 to 2. Therefore, M_w values were estimated from the NMR data: to each signal of the substituted phenyl group are joined signals of *ca*. 10 times lower intensity whereas the signal of the C_6H_4 protons is virtually unique: only a shoulder and two extremely weak signals (nearly 1% of the total integral value) were observed. The molecule is therefore linear, with a level of branching which does not exceed a few percent. The weak signals of the substituted phenyl group are due to the terminal groups (traces of residual polyalkylbenzene might also give such signals) and the minimal chain length and indeed the minimal averaged molecular weight can be deduced from the signals rate: *ca*. 20 units and 7000, respectively, for **P3′**. These results are also in good accordance with the molecular weight of **P1** (7000–10 000) determinated by SEC.

In conclusion, soluble polybenzyls can be synthesized by Friedel–Crafts polycondensation, using a non-toxic, mineral and removable catalyst. Their solubility should permit easy

casting of thin films or coatings. Further experiments are in progress to enhance the macromolecular chain length of these polymers.

‡ Melting points were determined on a Kofler hot-stage apparatus. The weight-average molecular weight (M_w) of **P1** was obtained on a gel permeation chromatograph (Spectra Physics P200) connected to a Spectra Series UV 100 detector (λ = 254 nm) after calibration of the column using polystyrene standards (Polymer Laboratories). The column was a mixed PL-Gel column (particle size: 5 μm, pore type: 10 000 Å, length: 300 mm, internal diameter: 7.5 mm) with THF as solvent. The GPC Plus program was used to calculate the polydispersity index (I_p). ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ as internal reference (δ 7.25) on Bruker AC 200 (200 MHz) or DRX 500 (500 MHz) spectrometers. Mass spectra of the substrates were obtained on a GC–MS coupled spectrometer (Hewlett Packard G1800A) and elemental analyses on a EA 1108 CHNS-O (Fisons Instruments). The FTIR absorbance spectra were performed on a IFS 66v apparatus. The reactions were performed in a two necked-flask connected to a condenser. This flask was heated by a sand-bath and the mixture stirred by a magnetic stirrer. The condenser was connected to a drying tube for the substrates synthesis and to a HCl-trap for the polycondensations.

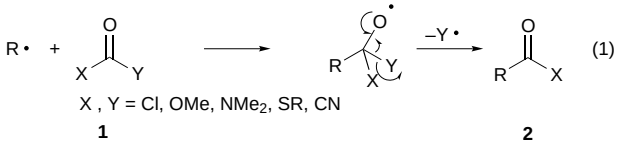
Radical reaction of *S*-phenyl chlorothioformate with alkyl iodides: free radical-mediated carboxylation approach

Sunggak Kim*† and Sang Yong Jon

Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea

Free radical-mediated carboxylation is achieved by treatment of alkyl iodides with *S*-phenyl chlorothioformate and bis(tributyltin) with irradiation at 300 nm.

Since a free radical-mediated carboxylation reaction was reported by Kharasch and co-workers in the 1940s,[1] no further developments in this area have been noted during the last 50 years, although a free radical carboxylation approach involving carbonylation and iodine atom transfer has recently been reported.[2] This could be due to the fact that alkyl radical additions to C=O bonds are inefficient due to the reversibility of the addition step and the high π-bond strengths of C=O bonds.[3] Thus, intermolecular addition of alkyl radicals to C=O and C=N bonds[4,5] is relatively rare, as compared to C=C bonds. Recently, we have shown that alkyl radical additions to phenylsulfonyl oxime ethers are highly efficient, suggesting the importance of the substituent at the C=N bond.[6] We conceived that the success of alkyl radical additions to C=O bonds would depend very much on the nature of the substituent, which would be closely related to the LUMO energy of carbonyl derivative **1**. We have studied the possibility of developing a free radical carboxylation reaction utilizing carbonyl derivative **1** as a carboxyl equivalent radical acceptor [eqn. (1)].



Before we began our studies with carbonyl derivatives, AM1 calculations for several carbonyl derivatives were performed, as nucleophilic alkyl radicals would react more rapidly with radical acceptors having lower LUMO energy.[7] According to the computational studies, *S*-phenyl chlorothioformate exhibited the lowest LUMO energy among carbonyl derivatives tested in this study. To see whether the computational results are in accordance with experimental results, free radical carboxylation reactions were carried out with 4-phenoxybutyl iodide, carbonyl derivative **1** and bis(tributyltin) using irradiation at 300 nm.[8] As shown in Table 1, dimethylcarbamoyl chloride, methyl chlorofomate and phosgene were totally ineffective.

Table 1 LUMO energy of **1** and chemical yields of **2**

	Carbonyl derivative **1**	LUMO energy[a]/eV	Product **2**	Yield (%)
1a	$ClC(O)NMe_2$	0.1377	$RCONMe_2$	0
1b	$ClCO_2Me$	0.0039	RCOOMe	0
1c	$C(O)Cl_2$	−0.7740	RCOCl	0
1d	$C(O)(SPh)_2$	−1.0911	RCOSPh	31
1e	ClC(O)SMe	−1.1810	RCOSMe	32
1f	ClC(O)SPh	−1.3863	RCOSPh	60
1g	NCC(O)SPh	−1.2635	RCOCN	0[b]

[a] The LUMO energy was calculated using MOPAC. [b] 4-Phenoxybutyl cyanide (75%) was obtained.

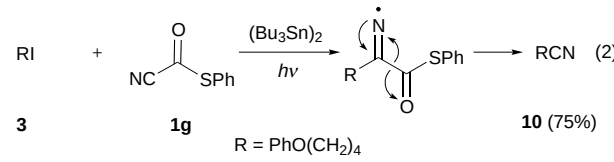


Table 2 Preparation of *S*-phenyl thioates from alkyl iodides with *S*-phenyl chlorothioformate

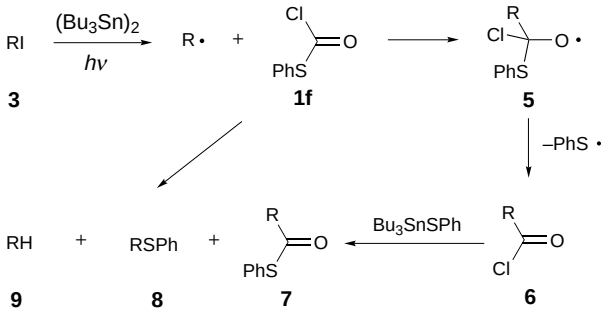
Substrate	Product	Yield (%)
		53 (5)[a] (20)[b]
		55 (5)[a]
		44 (11)[a]
		52 (12)[a] (27)[b]
		48 (9)[a]
		56
		51 (8)[a]
		53
		49
		56 (4)[a]

[a] Sulfide product. [b] Direct reduction product.

S-Phenyl chlorothioformate **1f** gave the best result, although bis(thiophenyl) carbonate **1d** and *S*-methyl chlorothioformate **1e** were effective to some extent. Furthermore, it is noteworthy



Scheme 1

that the radical reaction with *S*-phenyl cyanothioformate **1g** afforded 4-phenoxybutyl cyanide **10** [eqn. (2)]. Apparently, the 4-phenoxybutyl radical attacked the cyano group rather than the carbonyl group. The present result clearly indicates that the LUMO energy is a very important factor in predicting and designing the radical reactions. Treatment of 4-phenoxybutyl iodide with **1f** and bis(tributyltin) in benzene with irradiation at 300 nm for 10 h afforded *S*-phenyl thioate **7** in 60% yield. In addition, 4-phenoxybutane **9** was obtained in 15% yield along with 4-phenoxybutyl phenyl sulfide **8** (8%) due to homolytic substitution by the alkyl radical at the sulfur atom.[9] When the same reaction was carried out in the presence of an equimolar amount of isobutyryl chloride, a mixture of **7** (26%) and *S*-phenyl thioisobutyrate (52%) was obtained.

According to our experimental results, the present approach involves an alkyl radical addition to the C=O bond to generate alkoxy radical **5**, which undergoes β-fragmentation to afford acid chloride **6** (Scheme 1). Reaction of acid chloride **6** with tri-*n*-butyltin phenylthiolate would provide *S*-phenyl thioate **7**.[10]

Table 2 summarizes the experimental results and illustrates the efficiency of the present method. For most of the cases observed, the reaction required 10 h for completion of the reaction and afforded the *S*-phenyl thioates in reasonably good yield. Sterically hindered tertiary alkyl iodides gave similar results. We also studied sequential radical reactions involving cyclization and carboxylation. Radical reaction of olefinic iodide **11** under similar conditions afforded the desired product **12** in 53% yield along with **13** (9%) and **14** (30%) [eqn. (3)]. When a similar reaction was carried out with **15**, cyclopentanone **16** was obtained in 40% yield along with *S*-phenyl thioate **17** (27%) [eqn. (4)]. Further studies on free radical carboxylation related reactions are underway.[11]

We thank The Korea Research Foundation for financial support.

11 A typical procedure for the radical reaction of *S*-phenyl chlorothioformate with an alkyl iodide is as follows. A benzene solution (0.5 ml, 0.4 M in the iodide) of cyclohexyl iodide (42 mg, 0.2 mmol), *S*-phenyl chlorothioformate (70 mg, 0.4 mmol) and bis(tributyltin) (140 mg, 0.24 mmol) in a quartz tube was degassed for 10 min and then irradiated at 300 nm in a photochemical reactor for 9 h. The reaction mixture was concentrated under reduced pressure. EtOAc (3 ml), water (2–3 drops) and KF (116 mg, 2 mmol) were then added and the mixture was stirred at room temperature for 30 min. After the mixture was filtered through a short column of silica gel, the filtrate was concentrated under reduced pressure. The crude product was purified by flash silica gel column chromatography to give *S*-phenyl cyclohexanecarbothioate (25 mg, 56%) as a colorless oil: δ_H (200 MHz, $CDCl_3$) 1.23–1.54 (m, 4 H), 1.56–1.87 (m, 4 H), 1.88–2.13 (m, 2 H), 2.53–2.68 (m, 1 H), 7.38 (s, 5 H); δ_C (50 MHz, $CDCl_3$) 25.4, 25.5, 29.5, 52.4, 127.8, 129.1, 129.2, 134.4, 200.6; ν_{max}(NaCl)/cm^{-1} 2928, 1708, 1066, 950.

Synthesis of a novel pseudodisaccharide glycoside as a potential glycosidase inhibitor

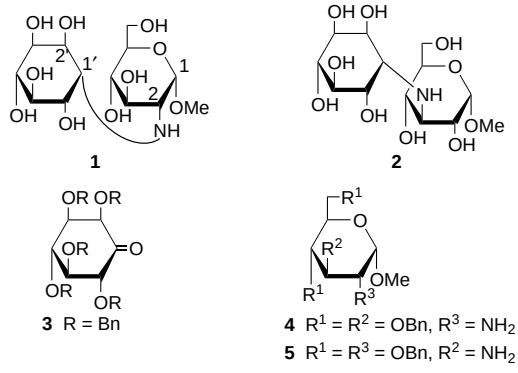
Alan H. Haines*† and Ivone Carvalho‡

School of Chemical Sciences, University of East Anglia, Norwich, UK NR4 7TJ

An *N*-linked pseudodisaccharide 2 containing an inositol moiety in place of a glycopyranosyl residue has been synthesised to mimic the disaccharide unit, 3-*O*-(α-D-glucopyranosyl)-D-glucopyranose, cleaved by Glucosidase II during glycoprotein processing; an attempt to prepare the analogous 2-*N*-linked compound 1 as an inhibitor of Glucosidase I led to the novel *N*-phenyl derivative 10 of 2-amino-2-deoxy-D-glucopyranose.

Glycoprotein processing, a key step in the formation of cell surface oligosaccharides, initially involves the action of Glucosidase I and II on the *N*-linked oligosaccharide $Glc_3Man_9GlcNAc_2$ for sequential removal of the α(1 → 2)- and α(1 → 3)-linked glucose residues.[1] Inhibition of either of these two key enzymes leads to incorrect modification of nascent oligosaccharides.[2] Malformation of gp 120 on the surface of the AIDS virus is the likely reason why glycosidase inhibitors such as 1-deoxynojirimycin (DNJ) or castanospermine exhibit anti-HIV activity.[3]

We wished to design potential glycosidase inhibitors which mimic the *disaccharide units* which form the substrates for Glucosidase I and II, 2-*O*-(α-D-glucopyranosyl)-D-glucopyranose and 3-*O*-(α-D-glucopyranosyl)-D-glucopyranose, respectively. There are clear advantages in introducing nitrogen into such structures at strategic points[4] but in view of the likely hydrolytic instability of simple *N*-linked mimics, which are glycosylamines, and the efficacy of *N*-linked monocarba-oligosaccharide inhibitors such as acarbose[5] and oligostatin,[6] we decided to prepare the corresponding *N*-linked pseudodisaccharides **1** and **2** in which the non-reducing glycosyl moiety is imitated by an inositol unit, which only fails in its ability to mimic the α-D-glucopyranose unit in having an OH in place of the usual 5-CH_2OH group and a –CH(OH)– group in place of the ring oxygen atom. We report an unexpected result in our attempt to synthesise **1**,§ the synthesis of **2**, and a



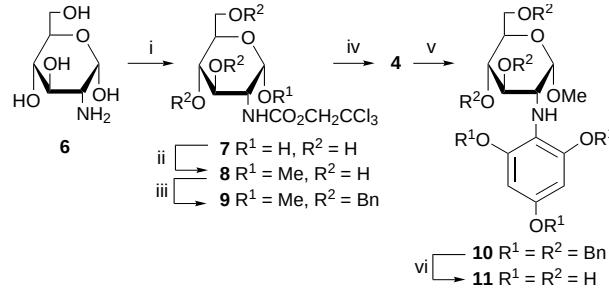
preliminary result on inhibition studies with **2** on yeast α-glucosidase.

Our proposed syntheses were based on the reaction between the chiral penta-*O*-benzylinosose **3**[7] and either methyl 2-amino-3,4,6-tri-*O*-benzyl-2-deoxy-α-D-glucopyranoside **4** or methyl 3-amino-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranoside **5** to afford corresponding imines, which we aimed to reduce stereoselectively, creating a chiral centre which, in the final product **1** and **2**, mimics the α-anomeric link in the oligosaccharide.

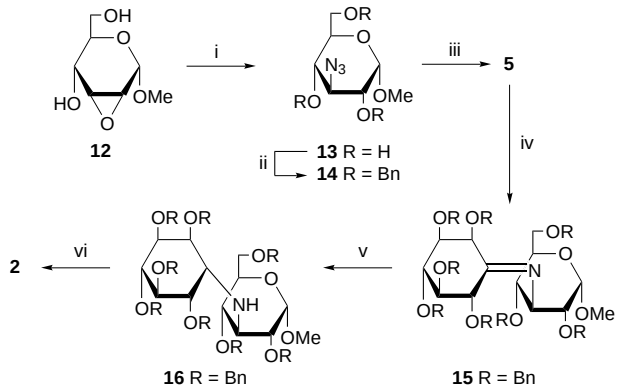
To prepare amine **4**, 2-amino-2-deoxy-D-glucopyranose **6** was *N*-protected by reaction with 2,2,2-trichloroethoxycarbonyl chloride, and the resultant amide **7** was converted by reflux in MeOH containing HCl into the corresponding methyl α-D-glycoside **8** (Scheme 1). Attempted *O*-benzylation of the latter compound using NaH–BnBr led to extensive decomposition, but treatment with benzyl trichloroacetimidate[8] under acidic catalysis gave the required protected benzyl ether **9** which was de-*N*-protected by treatment[9] with Zn/Cu couple in KH_2PO_4–THF–H_2O to give **4**.

Storage of **4** with an equimolar quantity of inosose **3** in benzene over molecular sieves at 20 °C for several days gave no reaction, but repeated evaporation of benzene from the mixture at 60 °C under reduced pressure afforded a new product with a characteristic single at δ 6.25 in its ^{1}H NMR spectrum. NMR spectral data and elemental analysis indicated the compound to be methyl 3,4,6-tri-*O*-benzyl-2-(2,4,6-tribenzyloxyphenylamino)-2-deoxy-α-D-glucopyranoside **10** which can arise from an initially formed imine by elimination of two molecules of benzyl alcohol followed by aromatisation of the imino quinone so formed.¶ Subjecting **10** to catalytic transfer hydrogenation conditions without careful exclusion of air led to the initial formation of a purple solution followed by extensive decomposition as evidence by TLC, presumably because of oxidation of the initially formed aminophloroglucinol derivative. Hydrogenation with subsequent manipulations under an atmosphere of argon gave material with the expected ^{1}H and ^{13}C NMR spectra of methyl 2-deoxy-2-(2,4,6-trihydroxyphenylamino)-α-D-glucopyranoside **11**.

In contrast, our related strategy for the preparation of **2** was successful. Amine **5** was prepared in three steps from methyl 2,3-anhydro-α-D-allopyranoside **12** by reaction with azide ion, followed by conventional benzylation (NaH–BnBr in DME) of the 3-azido-*gluco* product **13**, chromatographically isolated from the simultaneously formed 2-azido-*altro* isomer, and then



Scheme 1 *Reagents and conditions*: i, CCl_3CH_2OCOCl, aq. $NaHCO_3$, 10 °C for 2 h, then 20 °C for 19 h, 72%; ii, 2.5% w/v HCl in MeOH, reflux 8.5 h, 96%; iii, $CCl_3C(NH)OBn$, CH_2Cl_2–cyclohexane (1 : 2), TFA, 20 °C, 2.5 h, 78%; iv, Zn/Cu, THF–1 M aq. KH_2PO_4 (5 : 1), 20 °C, 8.5 h, 51%; v, **3**, C_6H_6 (addition and evaporation, ×5), 60 °C, 79%; vi, EtOH–cyclohexene (2 : 1), Pd black, reflux under Ar, 38 h, yield not determined (air-unstable product)



Scheme 2 *Reagents and conditions*: i, NaN_3, $(NH_4)_2SO_4$, DMF, 110 °C, 3 h, 47%; ii, NaH, BnBr, DMF, 20 °C, 1 h, 91%; iii, Ph_3P, THF–H_2O (10 : 1), 80 °C, 7 h, 70%; iv, **3**, C_6H_6, 4 Å molecular sieves under N_2, 20 °C, 70 h; v, $NaBH_3CN$, DMF, 20 °C, 70 h and 100 °C, 1 h, 61%; vi, EtOH–cyclohexene (2 : 1), Pd black, reflux 24 h, 67%

reduction (Ph_3P–THF–H_2O) of the so-produced azido benzyl ether **14** (Scheme 2). Condensation of **5** with the protected chiral inosose **3** to give imine **15** occurred on storage of a mixture of the two reactants in a 1.2 : 1 molar ratio in benzene solution over molecular sieves at 20 °C for 70 h. Surprisingly, attempted formation of the imine **15** by an aza-Wittig reaction of **3** with the iminophosphorane obtained by treatment of azide **13** with PPh_3 under anhydrous conditions proved unsuccessful.

Reduction of imine **15** with sodium cyanoborohydride in DMF occurred with the required stereoselectivity, the major product being shown by ^{1}H NMR spectroscopy at 600 MHz to be the amine **16**. Thus, on the reasonable assumption that the inositol ring in **16** adopts a chair conformation with four equatorial substituents, an assumption supported by the vicinal coupling constants, the signal for the proton (1′-H) on the inositol carbon carrying the nitrogen substituent would be expected to be an overlapping doublet of doublets, each with $J \sim 3$ Hz, resulting in an apparent triplet with ~ 3 Hz splitting. The alternative stereoisomer would be expected to show for the same proton a true doublet of doublets with component splittings of ~ 9 and 3 Hz. The observed apparent triplet with a J value of 4.4 Hz confirmed structure **16**. Signal allocation for 1′-H on the inositol ring was confirmed by measurement of the ^{1}H NMR spectrum of the analogous deuterated compound obtained by reduction of imine **15** with sodium borodeuteride.

De-*O*-benzylation was achieved by catalytic transfer hydrogenation (cyclohexene–Pd black–EtOH) at reflux temperature for 24 h. Purification of the product by chromatography on silica gel with 1 : 1 EtOAc–MeOH gave the required pseudodisaccharide **2** as a foam. Inspection of the ^{1}H NMR spectrum of the crude hydrogenolysis product indicated a 'satellite' doublet at δ 4.64 to that of the anomeric proton at δ 4.67, with an integrated intensity $\leqslant$5% of the major signal, but no other difference from the spectrum of **2** could be observed. That the benzyl ether **16** appeared 'anomerically pure' results from the very small amount of the diastereoisomer present and extensive overlap of the absorption region for anomeric protons with that of the benzylic CH_2 resonances.

Preliminary inhibition studies on yeast α-glucosidase indicate that **2** is a much poorer inhibitor of the enzyme than DNJ. Thus, under identical conditions (30 °C, pH 6.5, PIPES buffer), an approximately 100-fold greater molar concentration of **2** was required compared to that for DNJ to bring about a 20% reduction in the rate of enzyme-catalysed release of 4-nitrophenol from 4-nitrophenyl α-D-glucopyranoside. This result reflects, most likely, a different inhibitory mechanism for **2** compared to that of DNJ;[5] the latter carries an endocyclic N-atom in contrast to **2**, in which the N-atom replaces the usual glycosidic O-atom.

We thank C. MacDonald for expert help in obtaining ^{1}H NMR spectra at 600 MHz, A. W. R. Saunders for microanalysis, and the Mass Spectrometry Service Centre at Swansea for high resolution mass spectra.

§ All new compounds, except for the unstable imine **15**, gave satisfactory elemental analyses or high resolution mass spectral data and gave NMR spectra in accord with expected structures.

¶ Although the isomeric 3,4,5-tribenzyloxy isomer cannot be ruled out, the structural allocation is based on the combined considerations of: (i) a comparison of the observed ^{13}C NMR chemical shifts for Ar-C in the tetrasubstituted aromatic ring of **10** with those estimated for the two isomers; (ii) a comparison of the observed ^{1}H NMR chemical shift for Ar-H at δ 6.25 with those for 3,4,5-trimethoxyaniline (δ 5.91) and 2,4,6-trimethoxyaniline (δ 6.05), all measured in $CDCl_3$; (iii) the likely mechanism of elimination from the supposed intermediate imine.

The synthesis, solution redox behaviour and intramolecular charge transfer properties of novel D(=CH–CH)$_n$=A compounds (n = 0, 1, 3; D and A are 1,3-dithiole and nitrofluorene moieties, respectively) are reported.

Organic compounds with asymmetric π-electron delocalization exhibit properties such as non-linear optical effects (NLO), photoconductivity and electron transport properties.[1] Electron acceptors of the fluorene series are widely used for optical information recording.[2] It has been shown that fluorene acceptors substituted with a donor moiety can efficiently sensitise the photoconductivity of carbazole-containing polymers in the spectral region of intramolecular charge transfer (ICT) of the acceptors.[3] Although 1,3-dithiole electron donor are well-known building blocks in conductive charge transfer salts,[4] there are few reports of 1,3-dithioles as components of π-conjugated push-pull compounds.[5] Herein we report a new series of D(=CH–CH)$_n$=A compounds containing 1,3-dithioles and nitrosubstituted fluorenes as D and A moieties, respectively.

Compounds **2**–**9** were synthesised (Scheme 1) by condensation of the substituted fluorenes **1** with the appropriate dithiolium salts (for **2**–**5**) or aldehydes (for **6**–**9**) in DMF, (20–70 °C, 0.5–50 h; 30–90%). The intramolecular charge transfer (ICT) in these compounds is manifested in the appearance of long-wavelength absorbance bands in their electronic spectra (Fig. 1, Table 1). Increasing the acceptor character of the fluorene fragment with electron withdrawing substituents results in a bathochromic shift of the ICT band that can be described quantitatively by eqn. (1), where $h\nu_{ICT}$ is the

$$h\nu_{ICT} = h\nu^0_{ICT} + \rho^-_{ICT}\,\Sigma\sigma^-_p \qquad (1)$$

ICT energy defined by the maxima of the ICT band (λ_{ICT}), $h\nu^0_{ICT}$ is $h\nu_{ICT}$ for the reference compound (unsubstituted benzene rings in fluorenes, $\Sigma\sigma^-_p = 0$), ρ^- is a parameter showing ICT energy sensitivity to substituents, and $\Sigma\sigma^-_p$ is a sum of σ^-_p (nucleophilic constants of the substituents in the fluorene nucleus).

The sensitivity parameter ρ^-_{ICT} shows only minor changes with changing the substituents in the 1,3-dithiole ring (**2** → **3** → **4**) or with lengthening the C=C chain between the D and A moieties (**2** → **6** → **7**) (Table 1). The values of ρ^-_{ICT} ≈ 0.14–0.17 eV are higher than that reported for 9-(4-phenyl-1,2-dithiol-3-ylidene)fluorenes (0.12 ± 0.01 eV).[6]

The structure of **3g** was determined by X-ray analysis (Fig. 2).§ As a result of ICT, the exocyclic C(9)=C(14) double bond is lengthened [1.395(5) Å] and is close to that observed in another ICT compound of the fluorene series, *i.e.* 9-(α-cyano-α-dimethylaminomethylene)-2,4,5,7-tetranitrofluorene [1.388(4) Å].[3b] The distortions of the substituents in the fluorene ring are a result of the close contact between the nitro groups in positions 4 and 5. The dihedral angle between the planes of the fluorene five-membered ring and the 1,3-dithiole ring is 21.3°. Fig. 2 shows that the acceptor moieties in the molecules related by symmetry centres form stacks (interplanar distance 3.58 Å). Interstack interactions occur through weak contacts of the donor fragments; S(2b)···S(3a) and S(2a)···S(3b) distances are slightly shortened (3.543 Å) compared to double

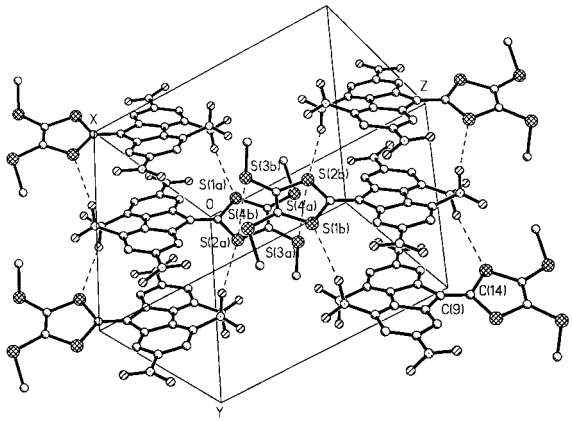

Fig. 2 Crystal packing of compound **3g**; short intermolecular S···S and S···O contacts are shown by dashed lines

the van der Waals radius of sulfur (3.6–3.7 Å).[7] There are also weak intermolecular S···O contacts (3.25–3.42 Å).

The electrochemical redox properties of the compounds **2**–**4** and **6** have been studied by cyclic voltammetry (Table 1).¶ Compounds **2**–**4** display two reversible single-electron reduction waves ($E^{\frac{1}{2}}_{1red}$ = −1.44 → −0.81 V, $E^{\frac{1}{2}}_{2red}$ = −1.60 → −1.02 V in the sequence **a** → **g**). Third quasi-reversible or irreversible single-electron reduction [$E^{\frac{1}{2}}_{3red}$ = −(1.88–2.15) V] and oxidation ($E^{\frac{1}{2}}_{ox}$ = +0.63–0.70 V) processes were observed in some, but not all, cases. Insertion of an additional double bond between the A and D moieties (**6**) leads to a shift of both $E^{\frac{1}{2}}_{1red}$ and $E^{\frac{1}{2}}_{2red}$ by *ca* . 0.3 V to more cathodic potentials. Correlation analyses of $E^{\frac{1}{2}}_{1red}$ and $E^{\frac{1}{2}}_{2red}$ for compounds **2**–**4** by eqn. (2), where $E^{\frac{1}{2}}$ is the half-wave potential of reduction or

$$E^{\frac{1}{2}} = E^{\frac{1}{2}}_0 + \rho^-_{CV}\,\Sigma\sigma^-_p \qquad (2)$$

oxidation of a compound, $E^{\frac{1}{2}}_0$ is $E^{\frac{1}{2}}$ for the reference compound (unsubstituted benzene rings in fluorenes, $\Sigma\sigma^-_p = 0$), and ρ^- is a parameter showing electrochemical potential sensitivity to substituents, gave good linear relationships (r = 0.98–0.999); sensitivity parameters ρ^-_{CV} for the first and second reduction steps of compounds **2**–**4** were close and lay in the region of 0.20–0.24 V, which is slightly higher compared to ρ^-_{CV} for nitrosubstituted 9-aminomethylenefluorenes.[3b] The electron affinities obtained for compounds **2**–**4** from their $E^{\frac{1}{2}}_{1red}$ potentials[8] are *ca.* 0.2 eV lower than for the corresponding 4,5-X,Y-2,7-dinitrofluoren-9-ones, and for tetranitro substituted derivatives **2g**–**4g** are *ca.* 2 eV. This characterises compounds **2**–**4** as moderate acceptors.

Due to the low solubility of compound **3g** we tested the more soluble long-chain homologue **5g** as a sensitiser in photothermoplastic storage media (PTSM) based on poly[*N*-(2,3-epoxypropyl)carbazole] (PEPC).‖ Fig. 1 shows the spectral distribution of the electrophotographic sensitivity ($S_{\Delta V}$) of PTSM on the basis of PEPC films sensitized by **5g** and by 2,4,7-trinitrofluoren-9-one (TNF) which is widely used for these purposes.[2b] In contrast to TNF, for which $S_{\Delta V}$ decreases with increasing wavelength in the visible region, **5g** displays increased sensitivity in its ICT region. Excellent rheological properties of PTSM sensitised with **5g** (diffraction efficiency for plane lightwave holograms η_{max} = 25%) allowed the attainment of extremely high values of holographic sensitivity, S_η = 250–300 m^2 J^{-1} at the level of η = 1% (He-Ne laser, λ = 632.9 nm),** suggesting that this type of acceptor is extremely promising as sensitisers for hologram recording.

We thank the EPSRC the Royal Society for funding (I. F. P., L. M. G. and L. G. K.), and the Royal Society for a Leverhulme Senior Research Fellowship (to J. A. K. H.).

On the mechanism of the synergistic oxidation of saturated hydrocarbons and hydrogen sulfide under Gif conditions

Derek H. R. Barton*† and Tingsheng Li*

Department of Chemistry, Texas A & M University, PO Box 300012, College Station, TX 77842, USA

It is demonstrated by a study of cyclohexane phenylselenation that the synergistic oxidation of cyclohexane with H_2S and O_2 does not involve carbon or oxygen radicals.

Recently we reported a new reaction in which saturated hydrocarbons were oxidized synergistically with H_2S and O_2.[1] This unusual reaction is an extension of Gif chemistry that should be of industrial importance. We now present further evidence on the mechanism of this reaction.

The bond strength[2] in the H–SH bond is 90.5 (±1.1) kcal mol^{-1}. Thus any secondary or primary carbon radical would be immediately reduced by H-atom transfer. When we photolyzed the Barton ester of adamantane-1-carboxylic acid in the presence of H_2S it was converted quantitatively into adamantane. Similarly, oxidation of adamantane in the presence of H_2S gave a *normalized* secondary/tertiary ratio of about 1. This is three times as great as normal and corresponds to the reduction of tertiary radicals back to hydrocarbon.[3] Since there are no secondary radicals, secondary position oxidation proceeded normally.

Cyclohexane gave a mixture of cyclohexanone and cyclohexanol. The latter was produced by reduction of the intermediary hydroperoxide[4] by H_2S.

The formation of alcohol and ketone at the same time enabled us to determine the kinetic isotope effect (KIE) for alcohol formation. It was of the order 1.1–1.2.

Recently[5] we showed that phenylselenation of saturated hydrocarbons[6a] involves PhSeH, an excellent trap for radicals.[6b] In fact the earlier work[6a] involved reduction with Zn^0–Fe^{II} catalyst. Methylation showed that all the PhSeSePh had been reduced to PhSeH.[7] This was, in fact, a proof of the non-involvement of carbon radicals. Our recent work[5] has shown that selenide anion is not involved.[8] Another factor to consider is the relative rates of reaction (3×10^9 and 2.3×10^7 M^{-1} s^{-1}) for radicals with PhSeH and PhSeSePh, respectively.[6b]

In the present study, PhSeSePh was added to a system where H_2S and O_2 were being passed through a mixture of cyclohexane and picolinic acid (Table 1). This afforded ketone, alcohol and a very high yield of phenylselenocyclohexane with respect to the amount of PhSeSePh added (entries 1 and 2). Unlike in the earlier study[5] using H_2O_2, when H_2S was used the picolinic acid was no longer needed. The phenylselenocyclohexane was then produced in quantitative yield (entries 3, 4 and 5).

We consider that phenyselenocyclohexane must be produced by the same type of mechanism that we proposed before[5] (Scheme 1).

In our first publication on the H_2S–O_2 reaction[1] we did not comment on the mechanism except to classify it as 'Gif chemistry'. We suggested that the oxidant was superoxide and that this reacted with Fe^{II} to furnish the species Fe^{III}–OOH. The species can also be produced by displacement on Fe^{III} with H_2O_2. Without hydrocarbon this has $t_{\frac{1}{2}}$ *ca*. 45 min. Upon addition of hydrocarbon it is rapidly inserted into the Fe–C bond, which slowly ($t_{\frac{1}{2}}$ *ca*. 45 min) affords ketone or, with iodide, rapidly gives the iodide of the hydrocarbon.[9] In order to explain why the selective functionalization of saturated hydrocarbons takes place in the presence of H_2S, Ph_2S, Ph_3P, $(MeO)_3P$, PhSH and even PhSeH, we proposed in 1992 that it was the contact of a relatively inert iron species with the hydrocarbon which created the active iron species, which then reacted immediately with the hydrocarbon. We cited the agostic effect[10] as an explanation. It is the reactivity of PhSeH, produced by[5] PhSeSePh and Bu_3P, that gives real substance to our proposal. We now suggest that Fe^{IV} and Fe^{V} are only produced at the moment of contact with the hydrocarbon and that these species react instantly with their hydrocarbon activator. We offer the same explanation for the KIE of close to 1 (see above).

Thus the Fe^{III}–Fe^{V} manifold can be modified according to Scheme 2. The H_2S–O_2 chemistry then takes place by H_2S reduction of Fe^{V} to Fe^{IV}.

The alternative route for phenylselenation is from Fe^{II} and H_2O_2, which we have used in our work with PhSeSePh and Bu_3P already cited. We modify our concept of the Fe^{II}–Fe^{IV} manifold as shown in Scheme 3. Normally, the Fe^{IV}–CHR_2 species can fragment into Fe^{III} and a carbon radical. This, however, does not happen when $PhSe^-$ is one of the ligands.

In our recent work on the phenylselenation reaction we showed by ^{77}Se NMR spectroscopy that the reaction of PhSeSePh and Bu_3P (50% excess) with a drop of water was an excellent method for quantitative synthesis of PhSeH *in situ*. The presence of the excess Bu_3P guaranteed that there was no

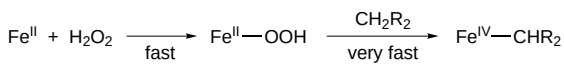

Scheme 3

adventitious oxidation of PhSeH back to PhSeSePh. We studied this reaction by ^{31}P NMR spectroscopy and showed that the reduction was complete in 2 min (experiment by Dr J. A. Smith). Before adding H_2O_2 we waited for 10–20 min to make sure that the reduction was complete.

Table 2 shows further experiments in which Bu_3P is used in the presence of PhSeSePh. Entries 1 and 2 used the H_2S–O_2 system as studied in Table 1. For entry 1 the yield of phenylselenocyclohexane was 92%, whilst the total activation including ketone and alcohol was 4.56 mmol. This is a good conversion as judged by past experiments.[1] All the selenium was present as PhSeH prior to reaction with the hydrocarbon yet the ketone and alcohol were formed in significant amounts. So not only are no radicals present but also the Bu_3P does not react with the iron species prior to activation by the hydrocarbon.

Using H_2O_2 as a minor component in the presence of an excess of PhSeH, the yield of the phenylselenocyclohexane (the only product) was 74 and 85% for entries 3 and 5, respectively (for 1 mmol of H_2O_2), and 65 and 77% for entries 4 and 6, respectively (for 2 mmol of H_2O_2). The increased yields in entries 5 and 6 were due to an increase in the available PhSeH. A further increase in the amount of H_2O_2 (entries 7 and 8) reduced the yield with respect to H_2O_2 to 64%.

The formation of cyclohexyl chloride in the Fe^{II}–Fe^{IV} manifold is usually accepted[11] to imply the reaction of a carbon radical with an Fe^{III}–Cl bond. The reaction can also be considered as a ligand-coupling reaction with an Fe^{IV}–C bond as in formation of the selenide (Scheme 1). The formation of cyclohexyl chloride using H_2O_2, like the phenylselenation reaction, requires the presence of the right carboxylic acid (here picolinic acid) and the correct amount of a suitable pyridine base (here 4-*tert*-butylpyridine). If the formation of the chloride can only take place *via* radical formation then the presence of PhSeH would remove the radical and no chloride would be formed. In fact entries 9 and 10 show that chloride formation is in competition with the phenylselenation reaction.

Finally we examined an oxidant, *tert*-butyl hydroperoxide (TBHP), that always reacts with Fe^{II} to make *tert*-butoxy radicals.[12–14] When TBHP (3 mmol) was added to cyclohexane (20 mmol) in MeCN (31 ml) and 4-*tert*-butylpyridine (2 ml) containing $FeCl_2{\cdot}4H_2O$ (1 mmol) and picolinic acid (3 mmol) with passage of H_2S, only traces of oxidation (0.05 mmol) were seen. From workup, 3 mmol of *tert*-butyl alcohol were recovered. This result is in keeping with the reduction of *tert*-butoxy radicals by H_2S. We conclude that carbon and oxygen radicals do not play a role in the synergistic oxidation of saturated hydrocarbons.

We thank Unilever, for support of this work. We thank Dr J. A. Smith for the ^{31}P NMR experiment.

Porous copper(I) coordination polymers containing both the cyclic ion ligating agent methylcycloarsoxane $(MeAsO)_4$ and rigid aromatic heterocycles as spacers

Iris M. Müller, Thomas Röttgers and William S. Sheldrick*†

Lehrstuhl für Analytische Chemie, Ruhr-Universität Bochum, D-44780 Bochum, Germany

Porous lamellar networks with flexible $[Cu_xI_y\{cyclo\text{-}(MeAsO)_4\}]$ ribbons bridged by either π–π stacked terminal benzonitrile ligands ($x = y = 2$), rigid *p*-diaminobenzene spacers ($x = y = 2$) or ionic $[Cs\{cyclo\text{-}(MeAsO)_4\}_2]^+$ sandwiches ($x = 3$, $y = 4$) may be constructed by self-assembly from CuI and $(MeAsO)_n$ in the presence of the respective structure-directing agents.

The rational design of porous solid-state coordination networks with potential ion exchange or molecular sieving properties has aroused considerable current interest.[1] Although the majority of known examples involve Ag^I or Cu^I centres separated by rigid organic spacers (*e.g.* piperazine, pyrazine, 4,4′-bipyridine and 4,4′-biphenyldicarbonitrile), a few encouraging reports of the employment of more flexible connecting ligands such as methylene bridged dichalcogeno ethers,[2] thioether macrocycles[3] or alkylcycloarsoxanes $(RAsO)_n$ (R = Me, Et; n = 4, 5)[4] have recently appeared. In analogy both to zeolites[5] and porous group 14 or 15 chalcogenidometalates,[6] such layers or frameworks might be expected to be capable of undergoing elastic deformations in response to different structure-directing agents or imbibed molecular guests. Our current extension of this line of coordination polymer design to networks containing both ion ligating alkylcycloarsoxanes and aromatic heterocycles has been motivated by the desire to construct multifunctional materials. To our knowledge, only one previous report of the self-assembly of an extended solid-state structure with both flexible and rigid spacers has appeared, namely that of $^2_\infty[\{Cu_2(C_3H_2O_4)_2(4,4'\text{-bipy})(H_2O)_2\}\cdot H_2O]$, in which small cyclic $[Cu(C_3H_2O_4)]_4$ tetramers ($C_3H_2O_4^{2-}$ = malonate) are linked through 4,4′-bpy ligands into a 4^4 net.[7]

We have recently demonstrated that ribbons of the type $^1_\infty[Cu_2X_2\{cyclo\text{-}(MeAsO)_4\}]$ (X = Cl, Br, I) can be joined into comparable square networks by employment of additional bridging $(MeAsO)_4$ ligands.[4c] When the self-assembly reaction‡ between CuI and $(MeAsO)_n$ is performed in PhCN instead of MeCN, the connectivity role of these linking cyclic tetramers is taken over by terminally coordinated solvent molecules, whose aromatic π-systems stack to generate the large channels depicted in Fig. 1.§ The pore size increases significantly from 0.41 × 0.72 nm (shortest transannular H···H contacts) in $^2_\infty[Cu_2I_2\{cyclo\text{-}(MeAsO)_4\}_2]$[4c] to 0.82 × 0.82 nm in $^1_\infty[\{Cu_2I_2(PhCN)_2[cyclo\text{-}(MeAsO)_4]\}\cdot PhCN]$ **1**, with the result that relatively large guest PhCN molecules can now be accommodated in the extended structure. In a second 4^4 net shown in Fig. 2, this design principle has been extended to bridging 1,4-diaminobenzene spacers. Deep-red crystals of the layered structure $^2_\infty[Cu_2I_2(p\text{-}H_2NC_6H_4NH_2)\{cyclo\text{-}(MeAsO)_4\}]$ **2** may be grown by carefully underlayering a $p\text{-}H_2NC_6H_4NH_2$–$(MeAsO)_n$ solution in MeCN with a CuI solution in the same solvent at 0 °C. Optical properties of zeolites with analogous imbibed parallel chromophore molecules such as *p*-nitroaniline are of considerable current interest.[8] The identical building principles of the triclinic lattices of **1** and **2** suggest that the construction of larger pores should be possible by employing longer rigid bidentate aromatic spacer molecules.

Alkylcycloarsoxanes $(RAsO)_n$ coordinate alkali metal ions M in sandwich complexes of the type $[M\{cyclo\text{-}(RAsO)_n\}_2]$, that are reminiscent of those formed by macrocyclic polyethers. The ring size of the crown-shaped $(RAsO)_n$ ligands is controlled by the volume of the central cation (M = Na, n = 4; M = NH_4, K, Cs, n = 5).[4b,9] Attachment of crown polyethers to solid supports such as silica gel has successfully been employed in commer-

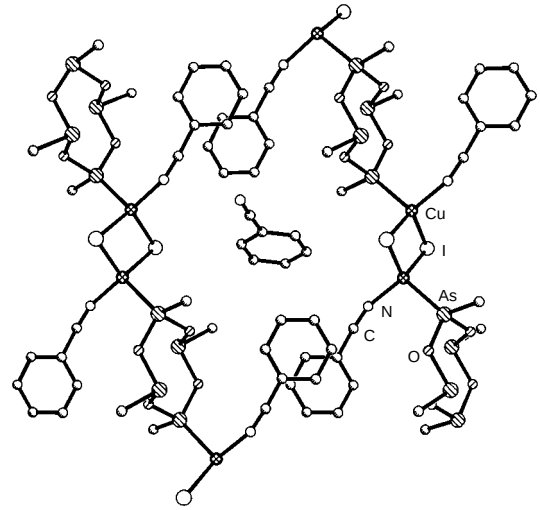

Fig. 1 Packing diagram for the π–π stacked $^1_\infty[Cu_2I_2(PhCN)_2\{cyclo\text{-}(MeAsO)_4\}]$ chains of **1**. Methyl groups have been omitted for clarity.

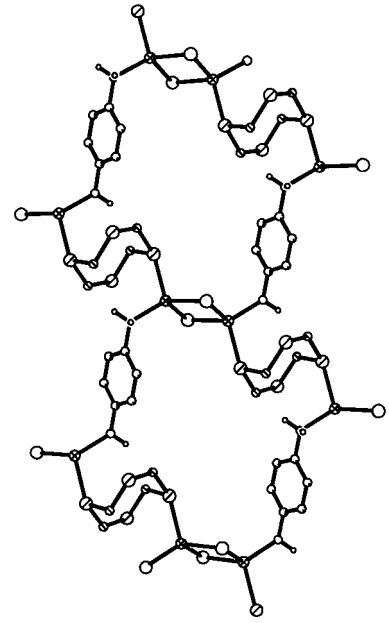

Fig. 2 Packing diagram for the lamellar $^2_\infty[Cu_2I_2(p\text{-}H_2NC_6H_4NH_2)\{cyclo\text{-}(MeAsO)_4\}]$ 4^4 net of **2**. Methyl groups have been omitted for clarity.

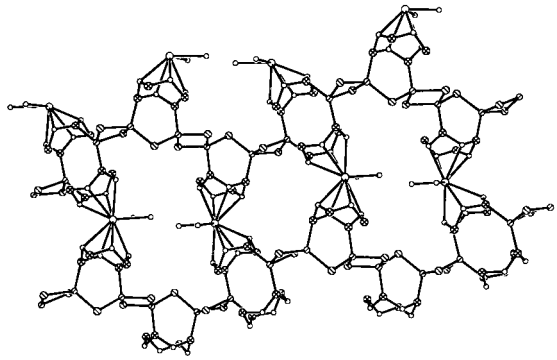

Fig. 3 Packing diagram for anionic $^1_\infty[Cu_3I_4\{cyclo\text{-}(MeAsO)_4\}_2]$ chains that are linked together through $[Cs\{cyclo\text{-}(MeAsO)_4\}_2]^+$ sandwiches into the porous sheet of **3**. Methyl groups have been omitted for clarity.

cially available solid-phase extraction systems (SPE).[10] Designed incorporation of such ion ligating agents into ordered solid-state networks offers, therefore, an attractive assignment for crystal engineering, that has been realized in the anionic $^1_\infty[Cu_3I_4\{cyclo\text{-}(MeAsO)_4\}_2]$ chains depicted in Fig. 3. Two water ligands were found to be necessary to complete the tenfold κ^1O coordination spheres of the Cs^+ cations, which were used to direct the self-assembly of this structure, $[Cs(H_2O)_2][Cu_3I_4\{cyclo\text{-}(MeAsO)_4\}_2]$ **3**, from CuI and $(MeAsO)_n$ in MeCN–MeOH–H_2O. The presence of these H_2O molecules lends the larger cavities a degree of polar character and these contain disordered methanol molecules.

A DTA trace for **3** reveals initial endothermic loss of methanol and water (35–120 °C) followed by exothermic collapse of the solid-state network in the temperature range 122–149 °C. This indicates that the flexible sheet structure of **3**, whose individual $(MeAsO)_4$ and $[Cu_6I_8]^{2-}$ building blocks are illustrated in a schematic manner in Fig. 4, could be capable of imbibing a range of small polar molecules whilst retaining its integrity. We are currently studying whether this and similar anionic networks could be suitable for selective cation exchange.

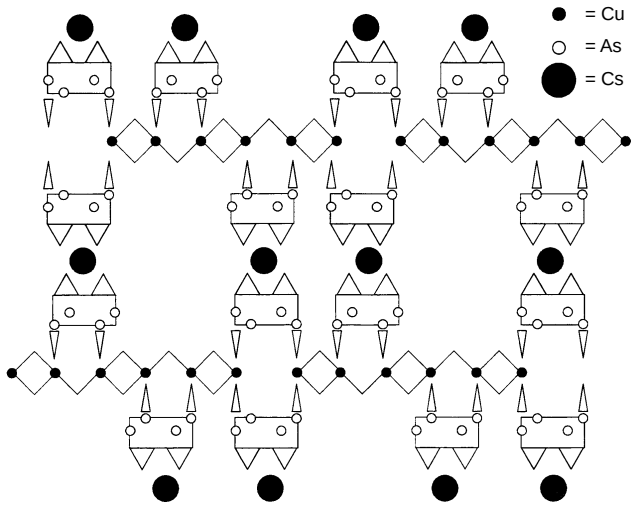

Fig. 4 A schematic diagram of the building principle of **3**, showing the μ-1 $\kappa As^1:2\kappa As^2$ and μ-1$\kappa As^1:2\kappa As^3$ bridging of $[Cu_6I_8]^{2-}$ units by different crown-shaped $(MeAsO)_4$ ligands which also simultaneously coordinate Cs^+ cations in a κ^4O fashion. Two water ligands complete the tenfold coordination sphere to the Cs^+ cations in the actual structure (Fig. 3).

Potassium cation induced switch in anion selectivity exhibited by heteroditopic ruthenium(II) and rhenium(I) bipyridyl bis(benzo-15-crown-5) ion pair receptors

Paul D. Beer*† and Simon W. Dent

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR

Cl^- and $H_2PO_4^-$ anion selectivity properties of new heteroditopic Ru^{II} and Re^{I} bipyridyl bis(benzo-15-crown-5) receptors are remarkably dependent upon the presence of co-bound intramolecular sandwich crown ether complexed K^+.

The design of new multisite ion pair receptors that contain covalently linked binding sites for both cations and anions is a new topical area of coordination chemistry.[1–6] In addition to being potential selective extraction/membrane transportation reagents for metal salts these ditopic ligand systems can be tailored to exhibit novel cooperative and allosteric behaviour whereby the complexation of one charged guest can influence, through electrostatic and conformational effects, the subsequent coordination of the pairing ion. We report here the synthesis of new heteroditopic Ru^{II} and Re^{I} bipyridyl bis(benzo-15-crown-5) receptors whose selectivity towards Cl^- and $H_2PO_4^-$ anionic guest species is remarkably dependent upon allosteric conformational and electrostatic effects of co-bound intramolecular sandwich crown ether complexed K^+ cations.

The synthetic routes to preparing the bipyridyl amide functionalised mono- and bis(benzo-15-crown-5) ligands and 3,4′-dimethoxyphenyl appended analogues are shown in Scheme 1. Reaction with $[RuCl_2(bipy)_2]$ followed by NH_4PF_6 and with $[Re(CO)_5Br]$, respectively, afforded the new receptors L^1–L^4 in good yields (Scheme 2). The K^+ cation and both Cl^- and $H_2PO_4^-$ anion coordination properties of the receptors were investigated by ^1H and in some instances by ^{13}C NMR titration experiments in $(CD_3)_2SO$ solution. The addition of KPF_6 to solutions of L^1 and L^3 caused the crown ether methylene carbons of the ^{13}C NMR spectra to significantly shift upfield by up to 0.6 ppm. Analysis of the resulting titration curves using the computer program EQNMR[7] suggested both receptors were forming 1 : 1 stoichiometric intramolecular sandwich bis crown ether complexes with K^+ with respective stability constant values of 350 and 540 M^{-1} for L^1 and L^3. The relatively smaller value of stability constant for L^1 may reflect the positively charged Ru^{II} centre electrostatically destabilising the crown ether bound K^+. Negligible shifts were observed with L^2 and L^4 suggesting K^+ complexation only takes place at the crown ether binding sites. Significant downfield perturbations of the respective receptor's amide and H^3-bipyridyl protons were observed on the addition of NBu_4Cl and $H_2PO_4^-$ salts to $(CD_3)_2SO$ solutions of L^1–L^4 indicating the amide-bipyridyl vicinity of the receptor is the site of anion binding. In all cases with Cl^- the titration curves suggested 1 : 1 complex stoichiometry which was also observed with $H_2PO_4^-$ and L^1, L^3. Precipitation problems unfortunately prevented complete $H_2PO_4^-$ titration curves from being obtained with receptors L^2 and L^4. Where possible titrations with both anions were repeated in the presence of 2 equiv. of KPF_6 and EQNMR determined stability constant values for all these titration experiments are presented in Tables 1 and 2. As found previously with related simple acyclic transition metal bipyridyl amide derivatives[8] a comparison of Tables 1 and 2 reveals L^1 and L^3 exhibit a pronounced selectivity preference for $H_2PO_4^-$ over Cl^-. It is noteworthy that Table 1 explicitly shows that the bis crown ether containing receptors L^1 and L^3 exhibit substantial increases in the magnitudes of stability constant for Cl^- binding on addition of KPF_6 by nearly sixfold for L^3. Interestingly no such increase in stability constant value is displayed by receptors L^2 and L^4 which do not contain crown ether binding sites. In contrast Table 2 displays a dramatic decrease in the stability constant values for $H_2PO_4^-$ binding for L^1 and L^3 on addition of KPF_6. The important consequence of which is the presence of K^+ can in principle induce a novel switch in the anion selectivity properties of both receptors. Tables 1 and 2 clearly illustrate the free receptors L^1, L^3 are $H_2PO_4^-$ selective whereas initial coordination of K^+ changes their anion selectivity preference to Cl^-. Repeating the titrations in the presence of tenfold excess of NBu_4PF_6 resulted in virtually no change in the determined stability constant values which negates simple ion pairing as a possible explanation for these positive and negative cooperative binding effects.

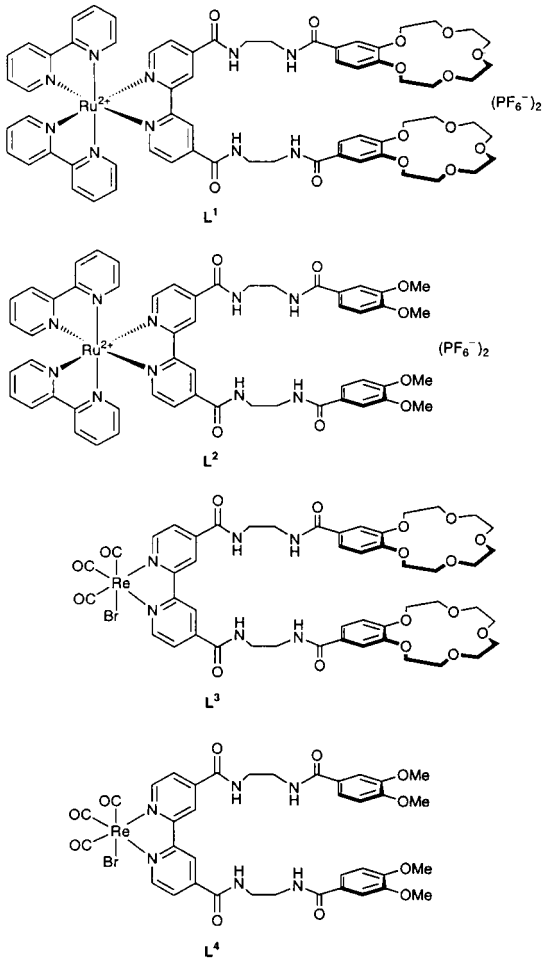

Scheme 2

Table 1 Stability constants for Cl^- binding in the presence and absence of K^+ in $(CD_3)_2SO$

Receptor	K^a/M^{-1}
L^1	190
L^1 + 2 equiv. KPF_6	660
L^2	195
L^2 + 2 equiv. KPF_6	165
L^3	55
L^3 + 2 equiv. KPF_6	300
L^4	46
L^4 + 2 equiv. KPF_6	55

[a] Errors estimated to be ≤10%.

The K^+ induced positive cooperativity of Cl^- binding may be a consequence of favourable electrostatic attraction between the crown ether bound K^+ and bipyridyl amide complexed anion, and, in addition be due to a favourable allosteric K^+ induced conformational effect. Solution formation of the 1 : 1 bis-benzo-15-crown-5 potassium cation intramolecular sandwich complex results in L^1 and L^3 forming a pseudo-macrocyclic preorganised structure which enhances Cl^- recognition but disfavours the binding of $H_2PO_4^-$ (Fig. 1). Of particular note is the structurally related macrocyclic receptor L^5 which exhibits remarkable thermodynamic stability and selectivity for Cl^- and does not bind $H_2PO_4^-$ phosphate at all in $(CD_3)_2SO$ solutions.[9]

Preliminary fluorescence emission spectroscopic measurements corroborate the NMR binding studies. The addition of Cl^- and $H_2PO_4^-$ to MeCN solutions of L^1 caused significant increases of up to 140% in luminescence intensity of the MLCT emission band (λ_{max} = 640 nm) with a concomitant hypsochromic shift of 7 nm. However in the presence of 1 equiv. of KPF_6 the subsequent addition of $H_2PO_4^-$ had very little effect on either the emission intensity or λ_{max}. In contrast with Cl^- a significant enhancement of intensity was observed.

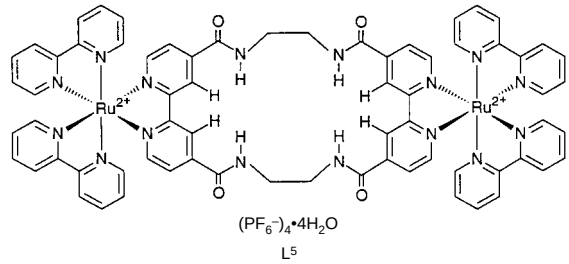

Table 2 Stability constants for $H_2PO_4^-$ binding in the presence and absence of K^+ in $(CD_3)_2SO$

Receptor[a]	K^b/M^{-1}
L^1	900
L^1 + 2 equiv. KPF_6	60
L^3	205
L^3 + 2 equiv. KPF_6	35

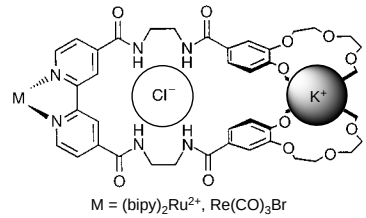

Fig. 1 Proposed solution structure of K^+Cl^- ion pair complex of L^1 and L^3. M = $Ru(bipy)_2^{2+}$ or $Re(CO)_3Br$

In summary the anion selectivity properties of new Ru^{II} and Re^{I} bipyridyl bis(benzo-15-crown-5) receptors can be dramatically switched *via* the binding of K^+ cations. In the absence of K^+ the receptors are selective for $H_2PO_4^-$ over Cl^-, whereas following the formation of the intramolecular K^+ bis crown sandwich complex the reverse selectivity Cl^- over $H_2PO_4^-$ is exhibited.

We thank Kodak Ltd for a studentship (S. W. D.), the EPSRC for use of the mass spectrometry service at University College Swansea and Johnson Matthey for a generous loan of ruthenium salts.

Formation of 1,11-bis(pendant donor)-cyclam derivatives *via* the formamidinium salt (cyclam = 1,4,8,11-tetraazacyclotetradecane)

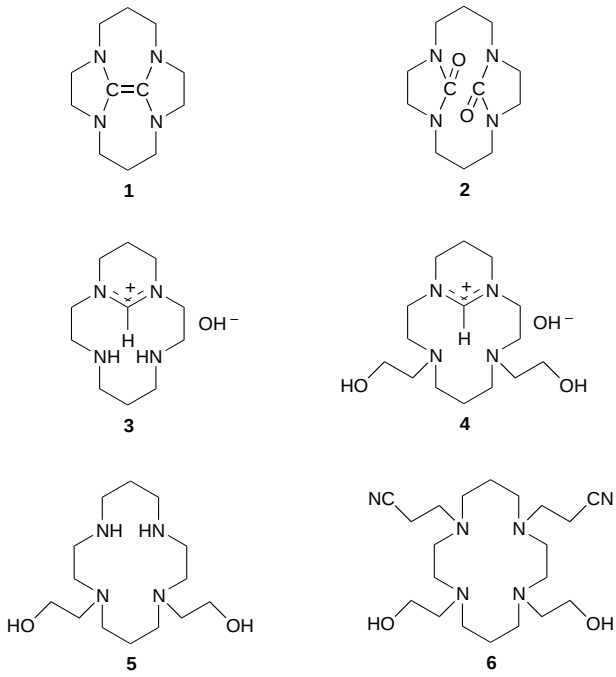
Philip J. Davies, Max R. Taylor and Kevin P. Wainwright*†

Department of Chemistry, The Flinders University of South Australia, GPO Box 2100, Adelaide, South Australia 5001, Australia

When reacted in chloroform, the dimethyl acetal of dmf and cyclam (1,4,8,11-tetraazacyclotetradecane) forms a stable formamidinium salt which can be used as an intermediate for very simple formation of 1,11-bis(pendant donor)-cyclam derivatives.

Some years ago we reported that reaction of the dimethyl acetal of dmf, dmfdma, with 1,4,8,11-tetraazacyclotetradecane (cyclam) in ethanol generates the electron rich alkene **1** which can subsequently undergo atmospheric oxidation to the bis(urea) derivative of cyclam **2**.[1] In a recent adaptation of that work we had cause to change the solvent from ethanol to chloroform and found that the outcome of the reaction is totally changed. The serendipitous result of this is that we have now found a simple means for producing 1,11-dialkylated derivatives of cyclam which upon deprotection can be used to afford mixed pendant donor ligands.

Reaction of cyclam with an equimolar amount of dmfdma in refluxing chloroform (instead of ethanol) for a period of 18 h gives a 75% yield, after crystallisation from aqueous acetonitrile, of the previously unreported formamidinium salt, **3**.‡ The formation of stable formamidinium salts from triaza macrocycles having secondary amines separated by trimethylene units (1,5,8-triazacyclododecane and some derivatives) has been reported,[2] but those derived from tetraaza macrocycles have only been invoked as reactive intermediates formed along the hydrolysis pathways between the orthoamide and formyl structures.[3] In the case of the triaza ligands the formamidinium salt forms upon treatment of the similarly stable orthoamide with HCl, but in the case of cyclam we did not observe the orthoamide, despite vigorous attempts to dehydrate **3**.



Formation of **3** affords protection of one pair of 1,11-related amine sites on the cyclam moiety whilst allowing alkylation at the other two. Thus, in reaction with ethylene oxide the substituted salt **4** was generated quantitatively and then converted to the free base, **5**, in 79% yield, by reaction with 10 M sodium hydroxide for 6 h.

As an illustration of the utility of this sequence, **5** was quantitatively derivatised by reaction with acrylonitrile giving the bis(cyanoethyl) ligand, **6**. The zinc(II) complex of **6** was formed through the reaction of **6** with $Zn(ClO_4)_2 \cdot 6H_2O$ in ethanol. Recrystallisation of the crude complex from hot water gave crystals of sufficiently high quality for structure determination by X-ray diffraction.§ This revealed that the complex is a rare example of a macrocyclic complex in which a pendant hydroxyethyl group coordinated to a divalent metal ion has undergone deprotonation at neutral pH.[4] The complex has the trigonal bipyramidal structure, shown in Fig. 1, in which the four nitrogen atoms of the macrocycle and one deprotonated pendant hydroxyl group coordinate. The macrocycle is in the *trans*-I configuration (the four pendant arms project in the same direction). The axial sites are occupied by a nitrogen atom [N(4)] carrying a pendant 2-cyanoethyl group and by the nitrogen atom [N(11)] carrying the pendant alkoxide. The N(4)–Zn–N(11) angle is 169.8(2)° and the equatorial angle, N(1)–Zn–N(8), internal to the macrocycle, is 138.7(2)°. The Zn–O^- bond length is 1.923(4) Å which is significantly shorter than the 1.994 Å separation seen for a Zn–neutral pendant alcohol bond in the zinc(II) complex of

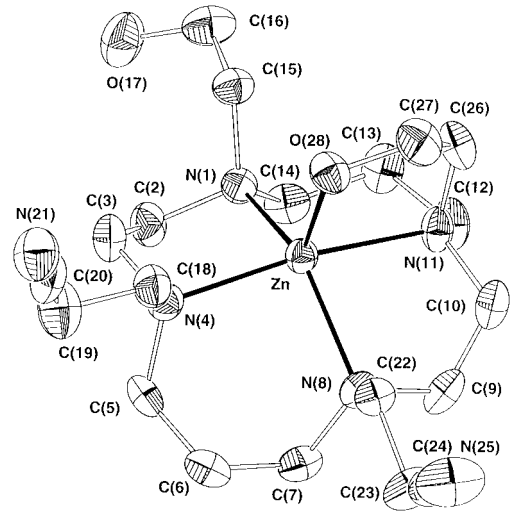


Fig. 1 Molecular structure of the cation in [Zn(**6** − H)]$ClO_4 \cdot H_2O$. Displacement ellipsoids are drawn at the 50% probability level. Important bond distances (Å) and angles (°): Zn–N(1) 2.155(5), Zn–N(4) 2.200(4), Zn–N(8) 2.204(5), Zn–N(11) 2.187(4), Zn–O(28) 1.923(4); N(1)–Zn–N(4) 85.0(2), N(1)–Zn–N(8) 138.7(2), N(1)–Zn–N(11) 93.4(2), N(1)–Zn–O(28) 110.0(2), N(4)–Zn–N(8) 91.6(2), N(4)–Zn–N(11) 169.8(2), N(4)–Zn–O(28) 104.3(2), N(8)–Zn–N(11) 83.0(2), N(8)–Zn–O(28) 110.7(2), N(11)–Zn–O(28) 85.7(2).

N-(2-hydroxyethyl)cyclen (cyclen = 1,4,7,10-tetraazacyclododecane).[5]

X-Ray reflection studies on the monolayer-mediated growth of mesostructured MCM-41 silica at the air/water interface

Stephen J. Roser, Harish M. Patel, Michael R. Lovell, Jane E. Muir and Stephen Mann*†

Department of Chemistry, University of Bath, Bath, UK BA2 7AY

X-Ray reflection has been used to study the nucleation and growth of thin films of a silica–surfactant mesophase (MCM-41) at the air/water interface in the presence and absence of an insoluble lipid monolayer of phosphatidylcholine; the rate of self-assembly and structural order of films comprising up to four micellar layers were enhanced under the lipid monolayer.

One of the most promising routes to new silica-based mesostructured materials with pore diameters greater than those of conventional materials such as zeolites involves the co-operative assembly of inorganic precursors with supramolecular organic templates.[1–7] The resulting silica–surfactant liquid crystalline mesophases can have a range of symmetries, including hexagonal (MCM-41) or cubic (MCM-48), and can be processed to produce mesoporous replicas consisting of an ordered array of channels with 1 nm thick silica walls. Several studies have recently shown that thin films of MCM-41 materials can be formed under acidic conditions at the air/water,[8] mica/water,[9] or graphite/water interface,[10] as well as on Au substrates that had been chemically patterned.[11] In a recent study,[12] X-ray reflection (XRR) was used to investigate the time-dependent growth of MCM-41 under acidic conditions at the air/water interface. In this report we use X-ray reflectivity to probe the nucleation and growth of thin films of MCM-41 under alkaline conditions at the air/water interface in the presence of an insoluble lipid monolayer that acts as a secondary template in the self-assembly process.

MCM-41 silica was synthesised at room temperature from a dilute basic solution *via* condensation of tetraethoxysilane (TEOS) in the presence of hexadecyltrimethylammonium bromide (C_{16}TMABr).‡ The films were grown slowly at the air/water interface from a quiescent solution contained within a Teflon trough which was sealed in a Perspex box with thin Mylar windows for X-ray transmission. In experiments involving phosphatidylcholine (PC) monolayers, a known volume of PC in chloroform was spread onto the air/water interface prior to recording of the XRR data.§ Analysis of X-ray reflection data was performed according to established procedures.¶

Fig. 1 shows the fitted reflectivity profile and calculated scattering density (inset) for the initial measurements for MCM-41 films grown from alkaline solutions under a PC monolayer. The zero-time fit has a fringe periodicity which corresponds to a thickness of 4 nm and demonstrates that the electron density profile perpendicular to the surface has two maxima, both of which have similar electron density values. The presence of the fringes indicates that a single micellar layer of a silicate–surfactant film is nucleated under the lipid monolayer. Similar data were obtained for the zero-time measurements for MCM-41 grown at an unmodified air/water interface, except that the peak values of the scattering length density profiles were slightly lower, suggesting that the presence of the PC monolayer induced the nucleation of a more densely packed arrangement of silicated rod-like micelles. In both cases, the model used to fit the data was based on a layer of amorphous silica-coated cylindrical micelles with an overall diameter of 4 nm. Interestingly, the data could not be fitted with a model corresponding to a primary surface layer of hemispherical micelles, as has been recently proposed as the initial stage in the nucleation of MCM-41 films from acidic solutions.[8] Thus, under alkaline conditions, mineralized micellar cylinders are considered to constitute the first layer of MCM-41 nuclei formed at the air/water or monolayer/solution interfaces.

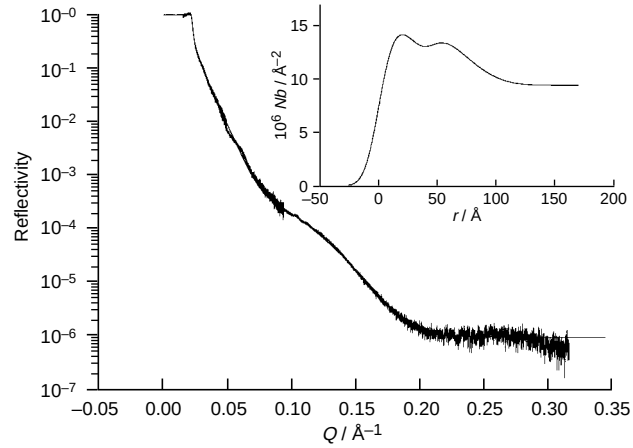

Fig. 1 Fitted reflectivity profile and calculated scattering length density (*Nb*, inset) for MCM-41 films grown for 1 h under a PC monolayer

Significant differences were observed in the XRR scattering length density profiles for thin films grown for 3 days under a PC monolayer (Fig. 2). The complex profile shows five distinct peaks with a repeat spacing of 3.9 nm in the density plot, leading to a broad Bragg peak centred at $\boldsymbol{Q}$ *ca.* 0.16 Å^{-1}. If the cylinders are hexagonally close packed, this corresponds to a film consisting of four silica–surfactant micellar layers, but with the scattering length density less than that expected from a perfectly ordered structure. The Bragg peak was consistent with small angle powder XRD and electron diffraction data of the retrieved thin films which confirmed the formation of the hexagonal mesophase.‖ In contrast, the MCM-41 silica prepared at the unmodified air/water interface showed a less well developed

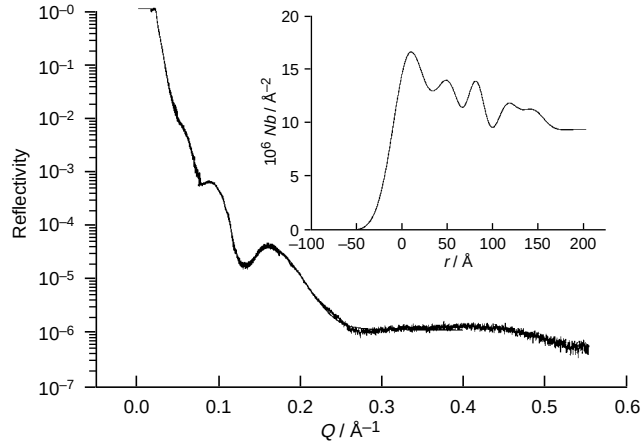

Fig. 2 Fitted reflectivity profile and calculated scattering density (inset) for MCM-41 films grown for 3 days under a PC monolayer

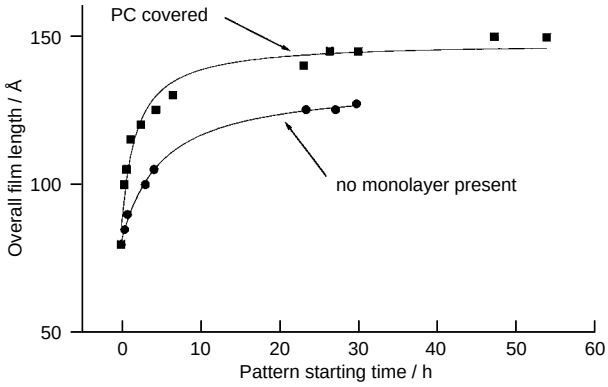

Fig. 3 Plot of film thickness *vs*. time for MCM-41 deposition from monolayer-covered and uncovered reaction solutions

fringe structure, and no Bragg peak after 48 h (data not shown). This indicates that under these conditions the silica–surfactant mesophase was significantly less ordered perpendicular to the air/water interface than the thin film nucleated under the lipid monolayer.

We also undertook preliminary studies on the time-dependence of the Bragg peak and scattering length profiles. In the presence of the PC monolayer, a Bragg peak at 0.16 $Å^{-1}$ was discernible after 4 h and clearly visible after 1 day. After this time, the peak did not change in position, width or intensity, indicating that the ordered internal structure was stable at the monolayer/solution interface. The scattering length profiles were used to determine the rate of growth in thickness of the MCM-41 films and clearly indicated that the presence of the PC monolayer results in faster growth and a more ordered mesophase (Fig. 3).

In conclusion, we have demonstrated that it is possible to obtain detailed information on the growth and structure of mesostructured MCM-41 silica films at the air/water interface using X-ray reflection. Spreading of a PC monolayer at the air/water interface enhances the rate of formation and quality of the thin films, suggesting that interactions between the lipid headgroups and molecular or supramolecular silica/surfactant species facilitate the assembly of the first layer of the nucleus. Further work using a range of lipids and their associated phase behaviour is underway to elucidate these interfacial processes.

‡ In a typical experiment, 0.16 g of C_{16}TMABr was dissolved in 318.0 g of H_2O and stirred continuously. 2.0 g of 1 M NaOH were added, followed by 0.828 cm^3 of TEOS, (molar composition = 0.001 C_{16}TMABr : 0.11 NaOH : 0.009 TEOS : 40.2 H_2O). The solution was left to stir for 3 min before being placed in the Teflon trough of the X-ray reflectometer. Growth of the MCM-41 film was extremely slow because of the constant vapour pressure of ethanol in the sealed environment which arose from the initial condensation reactions. In contrast, the results of ref. 12 were obtained from an evaporative environment. Measurements were made using an in-house energy-dispersive X-ray reflectometer, and typically consisted of three separate runs at different angles, lasting in total for 1 h. Measurements of MCM-41 growth were taken over a period of several days.

§ 124 μl of a chloroform solution of PC (100 mg cm^{-3}) were spread at the air/water interface using a micro-syringe. The volume added was calculated to produce a solid phase monolayer after solvent evaporation.

¶ In general, each discontinuity in scattering length density ($Nb/Å^{-2}$) between thin layers lying parallel to the interface under investigation contributes to the X-ray reflectivity, given by the well known Fresnel coefficient. This is modified by a factor, which allows for the roughness of the interface. The contributions from each layer are then combined using a matrix method. The usual procedure in fitting a reflectivity profile is to assume a model profile, and allow variation of numerous parameters, until the best fit between the model and the real $R(\boldsymbol{Q})$ is found. The layer electron density in $Å^{-3}$ can be determined by dividing Nb by the scattering length of a single electron (2.8×10^{-5} Å). Thus, the experiment measures the change in electron density perpendicular to the air/water interface, but averages information in the plane of the surface. Further details can be found in ref. 13.

‖ Samples for SAXRD, electron diffraction, ^{13}C and ^{29}Si solid state NMR, FTIR and TGA were collected from the air/water or monolayer/water interfaces after growth for 3 days in an unsealed environment. Data for monolayer-mediated synthesis; SAXRD *d* spacings, 4.0, 2.31, 1.99, 1.51 nm (as-synthesized), 3.16, 1.97, 1.75 nm (calcined); ^{29}Si NMR, δ −89.7 (Q^2), −99.6 (Q^3), −109.4 (Q^4) (as-synthesized); ^{13}C NMR, δ 14.46, 23.25, 26.99, 30.68, 32.62, 54.04, 66.91 (as-synthesized); FTIR, ν(Si–O–Si) 1000–1200 cm^{-1}, $\nu(CH_2)$ 1460–1490, 2850–2950 cm^{-1}; CHN analysis, 32 mass% C (as-synthesized). Hexagonal arrays of 4 nm spaced lattice fringes were observed by TEM.

In situ synthesis and the catalytic properties of platinum colloids on polystyrene microspheres with surface-grafted poly(*N*-isopropylacrylamide)‡

Chun-Wei Chen, Ming-Qing Chen, Takeshi Serizawa and Mitsuru Akashi*†

Department of Applied Chemistry and Chemical Engineering, Faculty of Engineering, Kagoshima University, 1-21-40 Korimoto, Kagoshima 890-0065, Japan

Well dispersed platinum colloids were synthesized *in situ* on polystyrene microspheres with surface-grafted poly(*N*-isopropylacrylamide) *via* the reduction of $PtCl_6^{2-}$ by ethanol, and found to be active and stable heterogeneous catalysts for the hydrogenation of allyl alcohol in water.

There is currently much interest in the preparation of colloidal noble-metal particles with a diameter of a few nanometers or less, not only owing to their unique physical and chemical properties, but for widespread applications such as in catalysis.[1,2] The synthesis of catalytically active metal colloids by aqueous alcohol reduction of metal salts in the presence of a protective polymer was firstly reported by Hirai and coworkers.[3,4] In a proportion of cases the polymer-protected metal colloids have been immobilized on a support,[5–7] thus giving the advantages of a truly heterogeneous catalytic system. These synthesis routes are based on a two-step process involving synthesis of colloidal nanoparticles and immobilization *via* covalent interaction or ligand coordination between the protective polymers and supports. These methods obviously suffer from special design of the protective copolymer and/or complex steps for the immobilization. Here, we report an alternative approach involving the synthesis *in situ* of the platinum colloids on polystyrene microspheres with surface-grafted poly(*N*-isopropylacrylamide) (PS-PNIPAAm). The catalyst, separated from the reaction mixture by centrifugation, retains high activity on recycling in the aqueous hydrogenation of allyl alcohol.

A range of monodispersed microspheres have been prepared by emulsifier-free dispersion copolymerization of styrene with a PNIPAAm macromonomer of molecular mass 3600. The average diameter and polydispersity index of the microspheres showed here, as determined from TEM image, are 500 nm and 1.01, respectively. The PNIPAAm branches covalently attached on the surface of microspheres provide a steric stabilization for the long-term water dispersibility of microspheres. The details concerning the synthesis and characterization of such microspheres have been given elsewhere.[8] We have already reported the formation of platinum colloids with an average diameter of 20.9 Å by ethanol reduction of $PtCl_6^{2-}$ in the presence of PNIPAAm with a mean molecular mass of 4000.[9] By using the PNIPAAm branch on the surface of the microspheres as the capping polymer, we have firstly synthesized *in situ* the well dispersed platinum colloids on the surfaces of polystyrene microspheres.

The synthesis *in situ* of platinum colloids on polystyrene microspheres by alcohol reduction of $PtCl_6^{2-}$ is similar to that of PNIPAAm-protected colloidal Pt sol.[9] For example, $H_2PtCl_6{\cdot}6H_2O$ (0.01 mmol Pt) and PS-PNIPAAm (45.2 mg, 0.4 mmol as PNIPAAm monomeric unit) were added in an ethanol–water mixed solvent (6/4, v/v, 38 ml), and the solution was then refluxed at 90 °C for 1.5 h. After separating the dark brown microspheres from the reaction mixture by centrifugation (7000 rpm, 10 min) and redispersing them in water, we studied the activity and stability of the Pt colloids on the microspheres for the aqueous hydrogenation of allyl alcohol.

The ESCA data for the Pt colloids on PS-PNIPAAm showed that the platinum appears to be in a zero-valent state after the recycling processes and a coordination interaction exists between the platinum colloid and the nitrogen atoms in PNIPAAm. Therefore, PNIPAAm branches of a polystyrene microsphere are adsorbed on the surface of the Pt colloids by both the hydrophobic interaction of the main chain and the coordination interaction of the amide group in the side chain. As a consequence, the strong interaction of PNIPAAm branches with Pt particles prevents or slows the migration and agglomeration of the metal particles by steric stabilization.

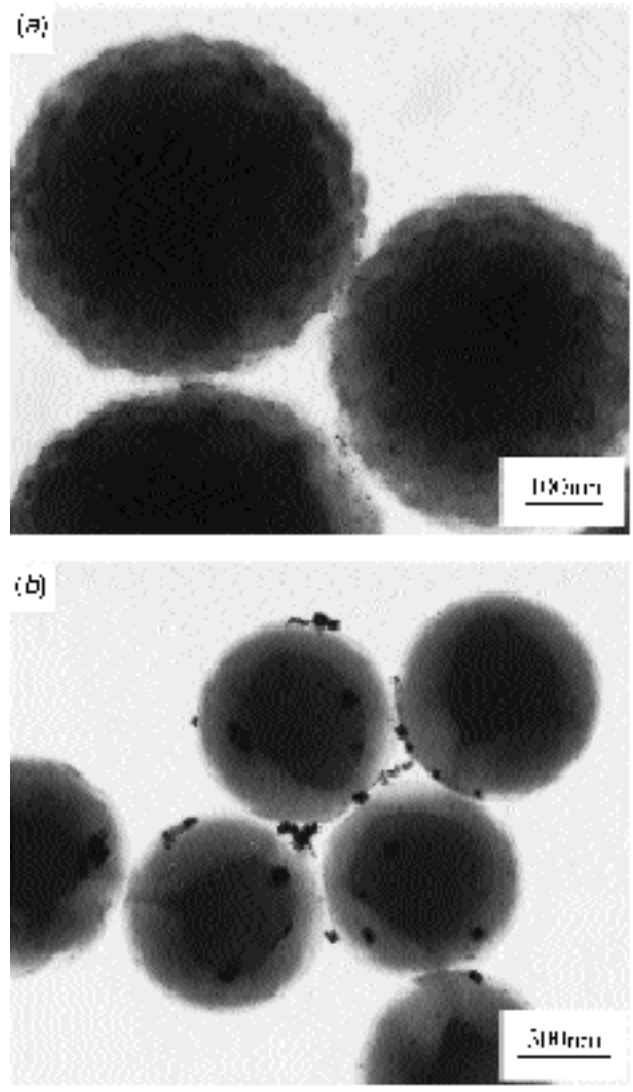

Fig. 1 TEM images of the platinum colloids on (*a*) PS-PNIPAAm after seven recycles and (*b*) commercial polystyrene beads

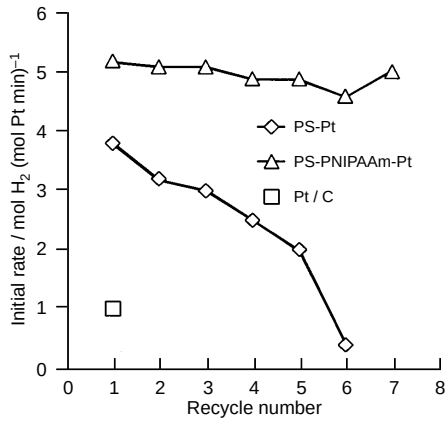

Fig. 2 Recycling of platinum colloids on PS-PNIPAAm and commercial PS beads in the hydrogenation of allyl alcohol (recovered by centrifugation). Conditions: Pt, 0.004 mmol (PS-Pt, 0.005 mmol); allyl alcohol, 2 mmol; solvent, water, 20 ml; 25 °C; H_2, 1 atm.

The PNIPAAm branches not only stabilize the platinum colloids by steric repulsion, but also immobilize them on polystyrene microspheres. TEM images of the platinum colloids on polystyrene microspheres showed that the particles have been immobilized in a well dispersed manner on the polymeric supports. The average particle size (diameter) and size distribution (standard deviation) of the fresh catalyst were 15.0 and 5.6 Å, respectively, which are smaller than those of the platinum colloids protected by free PNIPAAm (20.9 and 6.3 Å, respectively).[9] This may suggest that the migration and agglomeration of the metal colloids can be further prevented by covalently bonding the protective polymer to the surface of the polystyrene microspheres. The immobilized Pt colloids on the surfaces of the microspheres were in a very stable state and little change in the measured size distributions after seven recycling times was observed. Fig. 1(*a*) shows that the immobilized colloids are located at the surface of microspheres, and the vast majority of particles are isolated from each other after seven catalytic runs. Here, the average diameter and standard deviation of the Pt colloids are 15.2 and 5.7 Å, respectively. However, the TEM image of platinum colloids on the commercial PS beads shows that most of the Pt particles agglomerated together owing to the total lack of steric stabilization of the polymer [Fig. 1(*b*)].

The platinum colloid on the commercial PS beads or synthesized PS-PNIPAAm was employed as a heterogeneous catalyst for the hydrogenation of allyl alcohol in water. The data in Fig. 2 show the initial hydrogenation rate, with the same sample of catalyst recycled seven times. It can be seen that a PS-PNIPAAm-Pt catalyst showed higher activity than the catalysts of commercial platinum-activated carbon and Pt colloids on PS beads, and retained high activity in the hydrogenation on recycling seven times. We have previously seen the unusual temperature dependence of activity of the PNIPAAm-protected Pt sol for the same reaction.[9] The reported catalytic properties of the platinum colloids on PS-PNIPAAm in the hydrogenation are therefore most encouraging. We have evaluated thermosensitive properties of the microspheres,[8] and suggest that the activity of the catalyst must be moderated through a temperature change.

This work was financially supported in part by a Grant-in-Aid for Scientific Research in Priority Areas of New Polymers and Their Nano-Organized Systems (277/09232249) and a Grant-in-Aid for Scientific Research (08651055) from the Ministry of Education Science, Sports and Culture, Japan. Deposition of thin films of CdSe or ZnSe by MOCVD using simple air stable precursors

M. Chunggaze, J. McAleese, P. O'Brien*† and D. J. Otway

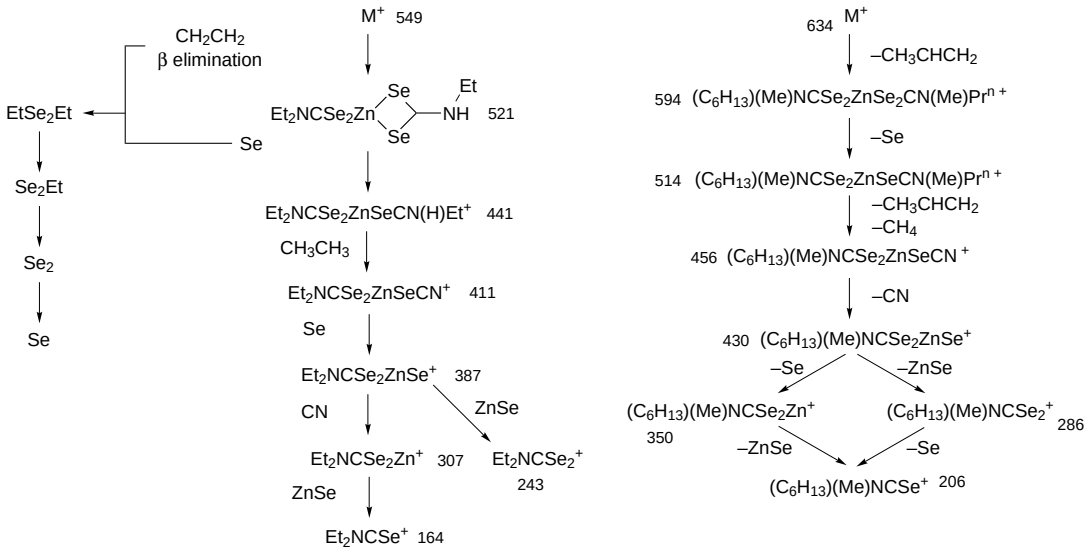
Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY

The air-stable bis-complexes of methyl (*n*-hexyl)diselenocarbamate with cadmium or zinc have been shown to be effective precursors for the deposition of the metal chalcogenides by MOCVD; studies of their thermal decomposition mechanism provide possible explanations as to why these complexes are effective whilst simpler ones are not.

Cadmium and zinc selenide are compound semiconductors with optoelectronic and/or photovoltaic applications.[1] There are many reports in the literature of attempts to develop effective single-source precursors for the deposition of such materials by MOCVD (metal organic chemical vapour deposition).[1,2] We have developed one such approach using dithio-[3,4] monothio-[5] and diseleno-carbamates.[6,7] One striking observation has concerned differences between the behavior of the simple bis-diethyldithio- and bis-diethyldiseleno-carbamates of zinc and cadmium. The bis-diethyldithiocarbamates are effective precursors for materials such as CdS and films of good quality can be deposited.[4,8] However, attempts to use the related selenium compounds lead to films of elemental selenium or metal selenide films heavily contaminated with elemental selenium.[9] In efforts to increase the volatility of this family of precursors we have used bulkier substituents on the amine parent of the carbamate.[4] Here, we report that we have now discovered that some of these air stable compounds are effective precursors for the deposition of the metal selenides. This unexpected result can be understood in terms of quite subtle changes in the mechanism of thermal decomposition of the complexes.

Fig. 1 Typical thin film of CdSe on glass from $[Cd\{Se_2CNMe(C_6H_{13})\}_2]$, T_{source} = 250 °C, T_{growth} = 450 °C, 2 h growth run; bar is 10 μm

The complexes used as precursors, bis[methyl(*n*-hexyl)-diselenocarbamato]-zinc **1** or -cadmium **2**, are air stable solids melting at 151–152 and 130–132 °C respectively.‡ Thin films of CdSe and ZnSe were deposited by low pressure (LP)–MOCVD as described previously.[10] Films were deposited on glass microscope slides and growth runs were typically for times between 30 min and 2 h. After 2 h, thick, *ca.* 3 μm films were deposited (T_{source} = 200–250 °C, T_{growth} = 400–450 °C). Growth rates were *ca.* 1 μh^{-1} for ZnSe and 1.5 μh^{-1} for CdSe. The films formed were all of substantial thickness, adherent and fully dense; Fig. 1 shows a typical electron micrograph. The surface of all these films tended to be featureless. Cross-sectional microscopy of thicker samples revealed a columnar structure.§ EDAX analysis results of the selenide films gave a metal : chalcogenide ratio approximating 1 : 1; in the case of zinc there appeared to be a significant, but small, oxygen content (*ca.* 3% of total). The optical band gaps of the as-



Scheme 1 Plausible decomposition mechanism for $[Zn(Se_2CNEt_2)_2]$ and $[Zn\{Se_2CNMe(C_6H_{13})\}_2]$ combining the steps observed from GC–MS and EI^+ studies of the precursors

deposited films were estimated by using the direct band gap method (from plots of absorbance^2 *vs.* energy) as 1.70 eV for CdSe and 2.58 eV for ZnSe (literature 1.74 and 2.58 eV). The films were further characterized by X-ray diffraction.¶

Compounds **1**, **2** and the analogous bis-diethyldiselenocarbamate were studied by pyrolysis GC–MS (pyrolysis temperature of 370 °C) and EIMS to develop plausible decomposition pathways/mechanisms for both sets of precursors.‖ These methods give valuable information concerning probable stable decomposition products and the results of these studies are summarized in Scheme 1. The gas chromatogram of the bis-diethyldiselenocarbamates for both cadmium and zinc shows the formation of a number of organoselenide products of which the most abundant is diethyl diselenide, $EtSe_2Et$. At the higher GC-column temperature (*ca.* 240 °C) elemental selenium fragments Se_n (n = 1–7) are observed which indicates that clusters of selenium are being formed on the pyrolysis of the precursor. These species may be responsible for the formation of selenium films during MOCVD. The selenium clusters were probably formed *via* an intermediate organoselenium complex on the column, $EtSe_2Et$ is a likely candidate as the mass spectrum of $EtSe_2Et$ shows it to dissociate to elemental selenium. In contrast to the diethyl derivative, the GC–MS traces of **1** and **2** show no evidence for the formation of selenium clusters, or the volatile organoselenium compound $EtSe_2Et$.[11]

We believe that by changing the alkyl groups on the parent amine of the diselenocarbamates from the symmetric diethyl to the asymmetric methyl(*n*-hexyl) derivative, the formation of diethyl diselenide is hindered and thus the deposition of selenium during film growth is inhibited. This subtle change results in the successful deposition of the ZnSe and CdSe from **1** and **2**.

Paul O'Brien is the Royal Society Amersham International Research Fellow and the Sumitomo/STS Professor of Materials Chemistry. We thank the EPSRC and the Leverhulme foundation for grants supporting work on single molecule precursors. M. C. thanks the EPSRC for a studentship. We thank the ULIRS mass spectrometry service at Kings College for pyrolysis GC–MS studies and J. Barton for other mass spectra. We would also like to thank Dr J. R. Walsh for earlier studies on the precursors.

‡ The compounds were prepared by adaptations of the literature methods[3,4] for metal bis-dithiocarbamates and have been fully characterized by: NMR, mass spectrometry, microanalysis and IR spectroscopy.

§ For the purposes of analysis, samples were carbon coated and electron microscopy/EDAX was performed on a JEOL Superprobe 733 microscope.

¶ X-Ray diffraction of the films gave intense peaks with *d* values (% relative intensity, *hkl*) of 3.26 Å (100, 111), 2.00 Å (20, 220) and 1.71 Å (12, 311) for ZnSe (corresponding to cubic zinc selenide with a preferred orientation of 111; 3.27 (100), 2.00 (70), 1.71 Å (44) {ASTMS}) and 3.72 Å (21, 100), 3.51 Å (100, 002), 3.28 Å (18, 101), 2.54 Å (14, 102) 2.15 Å (15, 110), 1.98 Å (36, 103), 1.83 Å (11, 112), 1.45 (4, 203) Å for CdSe (corresponding to hexagonal CdSe with a preferred orientation of 001; 3.72 (100), 3.51 (70), 3.29 (75), 2.55 (36), 2.15 (85), 1.98 (70), 1.83 (51), 1.45 Å (20) {ASTMS}).

‖ EI-MS: a micromass AutoSpec-Q, using Micromass OPUS software was used. An electron impact energy of 70 eV at 10^{-7} Torr was used to initiate mass fragmentation. GC-MS: analysis of the samples was carried out using a Hewlett Packard Series II Gas/Liquid chromatograph linked to a JEOL JMS AX505W mass spectrometer. The chromatography conditions were as follows: column BP1 (supplied by SGE). Bonded phase methyl siloxane, length of 25 m, inner diameter of 0.22 mm, Phase thickness 0.25 μm. The temperature program employed for analysis was, initial temperature 30 °C, initial time 2 min, 8 °C min^{-1} to 100 °C (first ramp rate), 12 °C min^{-1} (second ramp rate), final temperature 280 °C. The pyrolysis injector temperature was 370 °C. Carrier gas helium pressure of 12 psi, flow 1 cm^3 min^{-1}. MS settings were a 3 kV accelerating voltage, 100 μA beam current and a detector voltage of 2 kV. Mass spectra were recorded between 10 and 600 u with a scan speed of 0.9 s. The precursor was dissolved in chloroform and 1 μl aliquots were injected onto the heated injector with a 30 : 1 split where pyrolysis occurred. Mass spectra of the volatile pyrolyzates were recorded as described above.

Magnetic communication in acyclic mixed-valence trimolybdenum complexes mediated by redox switching

Eleftheria Psillakis, John P. Maher, Jon A. McCleverty* and Michael D. Ward*

School of Chemistry, University of Bristol, Cantocks Close, Bristol, UK BS8 1TS

Reversible one-electron reduction converts the 'V-shaped' [Mo(NO)[HB(dmpz)$_3$]{OC$_6$H$_4$XpyMo(NO)[HB(dmpz)$_3$]-Cl}$_2$] (dmpz = 3,5-dimethylpyrazolyl; X = nothing, CH=CH or CH$_2$CH$_2$; py = pyridyl) with two unpaired electrons on the peripheral metals, whose magnetic exchange properties depend on X, into a monoanion having three unpaired paired spins on each metal centre which engage in magnetic exchange in solution irrespective of X.

Molecular magnets are materials which may be derived either from organic radicals or from oligonuclear metal complexes containing at least one paramagnetic transition metal centre.[1] The construction of stable multicentre high-spin organic molecules remains a difficult synthetic challenge and the confirmation of interesting magnetic behaviour has been elusive.[2] However, the assembly of two or more transition metal components of differing spin, whose 'magnetic' orbitals are orthogonal and which are embedded in chain-like structures incorporating relatively short rigid organic bridges, has been more successful leading, for example, to solids exhibiting bulk ferromagnetic behaviour.[3]

The identification of paramagnetic transition metal components which can be easily linked within a rigid carbon-based architectural framework and which may couple magnetically is an important objective in the design and assembly of 'molecular magnets'. Central to this type of work is the control of the sign and magnitude of the magnetic exchange interaction J which depends critically on the nature of the pathway linking the interacting spins. We have recently shown that in paramagnetic isovalent dinuclear molybdenum nitrosyl complexes containing bipyridyl ligands (metal configuration 17 valence electrons), the sign of J can be predicted using a spin-polarisation mechanism,[4] and ferromagnetic behaviour has been detected in [{Mo(NO)-[HB(dmpz)$_3$]Cl}$_2$(3,4′-bpe)] (bpe = bipyridylethene; J = +2.4 cm^{-1}).[5] Furthermore, we have demonstrated that antiferromagnetic coupling can occur over surprisingly long distances, as in the isovalent [{Mo(NO)[HB(dmpz)$_3$]Cl}$_2${py(CH=CH)$_4$py}] (*ca.* 20 Å; J *ca.* −6.6 cm^{-1}).[6]‡ We have also shown that spin correlation, a manifestation in solution of magnetic coupling detected by EPR spectroscopy, occurs in the trinuclear species [1,3,5-{Mo(NO)[HB(dmpz)$_3$]Cl(pyCH=CH)}$_3$C$_6$H$_3$] and [1,3,5-{Mo(NO)[HB(dmpz)$_3$]Cl(pyC≡C)}$_3$C$_6$H$_3$] although we have not yet determined the relative signs of J.[7]

The mixed-valence/mixed donor atom species [{Mo(NO)-[HB(dmpz)$_3$]Cl}$_2$(OC$_6$H$_4$CH=CHpy)] which we prepared earlier contains a diamagnetic 16e$^-$ and a paramagnetic 17e$^-$ metal centre. The solution EPR spectrum shows A_{Mo} = 5.0 mT, consistent with valence-trapped behaviour, but on reduction to the isovalent monoanion, the EPR spectrum revealed that the two unpaired spins correlate strongly (A_{Mo} = 2.5 mT). The reduced species is isoelectronic and probably 'isomagnetic' with [{Mo(NO)[HB(dmpz)$_3$]Cl}$_2$(4,4′-bpe)] (A_{Mo} = 2.5 mT, J = −18 cm^{-1}),[5] the magnetic interaction between the two molybdenum centres being 'switched on' by reversible reduction of the molybdenum phenolate terminus from a 16e$^-$ to a 17e$^-$ configuration.

By substitution of both chlorides in [Mo(NO){HB(dmpz)$_3$}Cl$_2$] by the appropriate pyridine–phenol the diamagnetic bis-phenoxides [Mo(NO){HB(dmpz)$_3$}(4-OC$_6$H$_4$py)$_2$] **1**, [Mo(NO){HB(dmpz)$_3$}(4-OC$_6$H$_4$CH=CHpy)$_2$] **2** and [Mo(NO){HB(dmpz)$_3$}(4-OC$_6$H$_4$CH$_2$CH$_2$py)$_2$] **3**, have been obtained. Further reaction of these with [Mo(NO){HB(dmpz)$_3$}Cl$_2$] in the presence of NEt$_3$ afforded a mixture of di- and tri-metallic species which were separated by chromatography. The trimetallic species, [Mo(NO){HB-(dmpz)$_3$}{4-OC$_6$H$_4$pyMo(NO)[HB(dmpz)$_3$]Cl}$_2$] **4**, [Mo(NO)-[HB(dmpz)$_3$]{4-OC$_6$H$_4$CH=CHpyMo(NO)[HB(dmpz)$_3$]Cl}$_2$] **5** and [Mo(NO)[HB(dmpz)$_3$]{4-OC$_6$H$_4$CH$_2$CH$_2$pyMo(NO)-[HB(dmpz)$_3$]Cl}$_2$] **6**, contain a mixed-valence 17 : 16 : 17e$^-$ trimetal core in a 'V-shaped' array because of the *cis*-disposition of the phenoxide groups at the central molybdenum atom.§ Cyclic voltammetry¶ of **4**, **5** and **6** in dichloromethane revealed two synchronous one-electron oxidations of the molybdenum–pyridyl terminal groups and two reduction processes, one one-electron process associated with the central bis-phenolato molybdenum group and two synchronous one-electron reductions of the molybdenum–pyridyl termini. The formation potentials for the generation of the monoanion fall in the range −1.05 to −1.29 V *vs*. ferrocene–ferrocenium couple, entirely consistent with the reduction of {Mo(OC$_6$H$_4$–)$_2$} cores and with the cyclic voltammetric behaviour of **1**, **2** and **3**,[8] and are well-separated from the reduction processes of the terminal molybdenum–pyridyl groups.

The EPR spectrum (room temp., CH_2Cl_2 solution) of **5** is typical of significant spin exchange coupling in dinuclear molybdenum nitrosyl systems (g_{iso} = 1.977, A_{Mo} = 2.4 mT), *i.e.* strong spin correlation with $|J| \gg A_{Mo}$.[5] The spectrum of **4** is different from that of **5** (Fig. 1), being probably second order and characteristic of significant reduction in the exchange interaction, $|J| \approx A_{Mo}$, perhaps brought about by twisting of the rings within the bipyridyl fragments.‖ We have observed similar effects in related molecules.[9] However, the EPR spectrum of **6** reveals no spin correlation and therefore negligible magnetic interaction between the paramagnetic termini, *i.e.* $|J| \ll A_{Mo}$; A_{Mo} = 4.9 mT. This is probably a consequence of the insertion of saturated hydrocarbon links in the bridging ligands, of the number of bonds between the peripheral Mo centres (in ligands with extensive delocalisation,

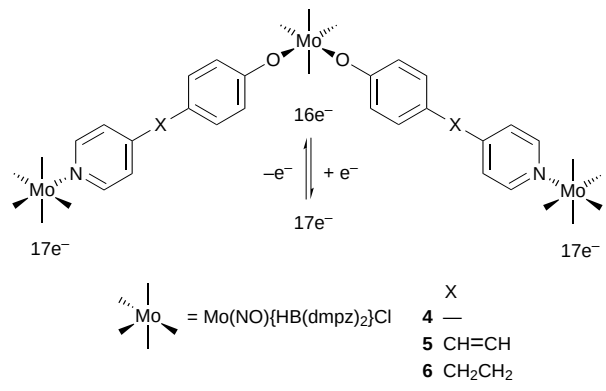

Fig. 1

strong correlation seems to persist up to about 20 atoms), and of possible twisting which degrades π-delocalisation.[10]

Reduction of the monometallic precursors **1**, **2** and **3** gave EPR spectra entirely similar to that of **6**, namely characteristic of one unpaired electron on an isolated 17-valence electron molybdenum nitrosyl group. However, the EPR spectra of $\mathbf{4}^-$ and $\mathbf{5}^-$, produced by chemical or electrochemical reduction of **4** and **5**, provided EPR spectra revealing strong correlation between all three 17-electron metal centres, g_{iso} = 1.976, A_{Mo} = 1.7 mT, very similar to the data obtained from the symmetrical [1,3,5-{Mo(NO)[HB(dmpz)$_3$]Cl(pyCH=CH)}$_3$-C_6H_3]. Even more remarkably, the EPR spectrum of $\mathbf{6}^-$ also revealed strong spin correlation (large $|J|$) between all three metal centres (g_{iso} = 1.973, A_{Mo} = 1.7 mT).

It appears, therefore, that reduction of the central molybdenum bis(phenoxy) moiety from a 16- to a 17-valence electron unit is essential to facilitate strong spin-correlation and so strong magnetic interaction between all three 17-electron metal centres. The EPR spectral consequences of the correlation in these 'V-shaped' molecules appear to be broadly similar to those in the more symmetrical [1,3,5-{Mo(NO)-[HB(dmpz)$_3$]Cl(pyCH=CH)}$_3$C$_6$H$_3$] and its analogues. Thus the reversible conversion of **6** to $\mathbf{6}^-$ can be interpreted as an example of a simple molecular magnetic or '*J* switch' in that changing the redox level of the central atom increases spin correlation (*i.e.* magnetic exchange) between the terminal groups.

While the molecular components and the effects described here are of themselves small by molecular electronic standards, by elaboration of the design of these mixed phenoxy–pyridine complexes into oligomeric and polymeric species, it should be possible to build up an extended array of mixed-oxidation state metal systems which may be switched to isovalent species whose magnetic properties may be sufficiently strong to constitute useful devices.

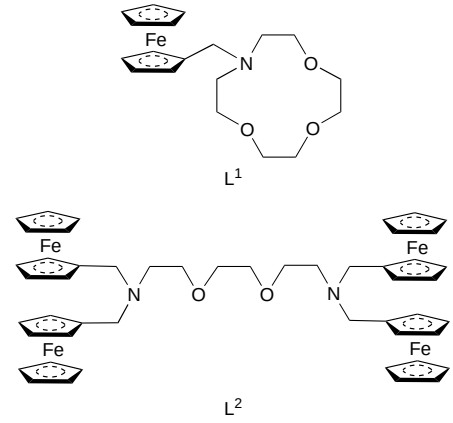
Selective electrochemical recognition of mercury in water by a redox-functionalised aza-oxa crown derivative

José M. Lloris, Ramón Martínez-Máñez,*† Teresa Pardo, Juan Soto and Miguel E. Padilla-Tosta

Departamento de Química, Universidad Politécnica de Valencia, Camino de Vera s/n, 46071 Valencia, Spain

The ability of the new cyclic aza-oxa redox-active receptor *N*-ferrocenylmethyl-1,4,7-trioxa-10-azacyclododecane to selectively and electrochemically recognize Hg^{2+} in water over other commonly water-present metal ions is reported.

The design and synthesis of promising new materials from supramolecular chemistry for the development of novel chemical sensors is a field of current interest. Of special interest are novel functionalised molecules which are able to change an easily measurable physical property by coordination with a target substrate. Among these new molecules are redox-functionalised receptors able to display a shift of the redox potential upon addition of particular substrates.[1] We have recently been involved in the synthesis of electroactive water soluble receptors for the electrochemical recognition of toxic heavy metal cations. A combination of well known molecular properties and suitable redox groups could prove to be a good method to strategically design new molecules for the selective electrochemical recognition of target substrates. The design strategy was inspired by two well known properties; (*i*) macrocyclic receptors compared to acyclic structures generally provide more selective complexation, and (*ii*) the presence of central oxygen donors in macrocycles has been used to control the selectivity for large metal ions over small ones.[2,3] Taking these two principles into account the aza-oxa crown derivative 1,4,7-trioxa-10-azacyclododecane ([12]-aneNO$_3$),[4] which has been reported to display higher stability constants with mercury than with other common metal ions, was chosen and functionalised with ferrocenyl groups. Synthesis of L^1 was carried out by reaction of [12]-aneNO$_3$ with (ferrocenylmethyl)-trimethylammonium iodide in acetonitrile (Scheme 1).



Scheme 1

L^1 is an oil but can be obtained as a solid by adding [NH$_4$][PF$_6$] to a solution of L^1 in ethanol and further addition of water to give [HL^1][PF$_6$]. Crystals‡ were obtained by slow diffusion of hexane into dichloromethane solutions of [HL^1][PF$_6$]. Fig. 1 shows the molecular structure of the $[HL^1]^+$ cation. The protonation constants of the free ligand and the stability constants for the formation of the Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Hg^{2+} complexes of L^1 have been determined using potentiometric methods (25 °C, 0.1 mol dm^{-3} KClO$_4$; titration was carried out with KOH from previously acidified solutions with HClO$_4$ of L^1 and the corresponding metal ion).[6] Stability constants are gathered in Table 1. The formation of the $[ML^1(OH)]^+$ and $[ML^1(OH)_2]$ complexes has been observed for all the metal ions. Additionally, for Pb^{2+} and Hg^{2+}, $[ML^1]^{2+}$ species have also been found to exist. Functionalisation with the ferrocenyl group does not basically appear to modify the coordination behaviour of the cyclic oxa-aza cavity. Fig. 2 displays the distribution diagrams of the L^1–H^+–Cu^{2+} and L^1–H^+–Hg^{2+} systems. Hg^{2+} shows a quite different diagram and, when the $[HgL^1]^{2+}$ complex is predominant (near pH 5), there is not interaction between the receptor and Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} ions. This can be explained taking into account

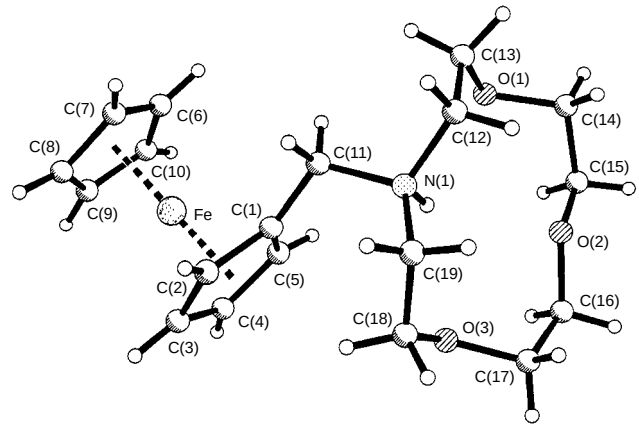


Fig. 1 Molecular structure of the $[HL^1]^+$ cation

Table 1 Stability constants (log *K*) for the formation of Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Hg^{2+} complexes of L^1 in H_2O at 25 °C in 0.1 mol dm^{-3} KClO$_4$[a]

	M				
Reaction	Cu^{2+}	Zn^{2+}	Cd^{2+}	Pb^{2+}	Hg^{2+}
$M^{2+} + L^1 \rightleftharpoons [ML^1]^{2+}$	—	—	—	5.29(5)[b]	10.03(4)
$M^{2+} + L^1 + H_2O \rightleftharpoons [ML^1(OH)]^+ + H^+$	−0.72(2)	−3.49(3)	−6.19(2)	−3.47(7)	3.0(1)
$M^{2+} + L^1 + 2H_2O \rightleftharpoons [ML^1(OH)_2] + 2H^+$	−10.10(4)	−13.10(4)	−16.52(2)	−13.23(6)	−4.08(7)

[a] The titration curves were merged and treated simultaneously to give the stability constants: L^1–H^+–Hg^{2+}, three titration curves, pH 3–8; L^1–H^+–M^{2+} (M = Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}), three titration cures, pH 3–9. [b] Values in parentheses are standard deviations on the last significant figure.

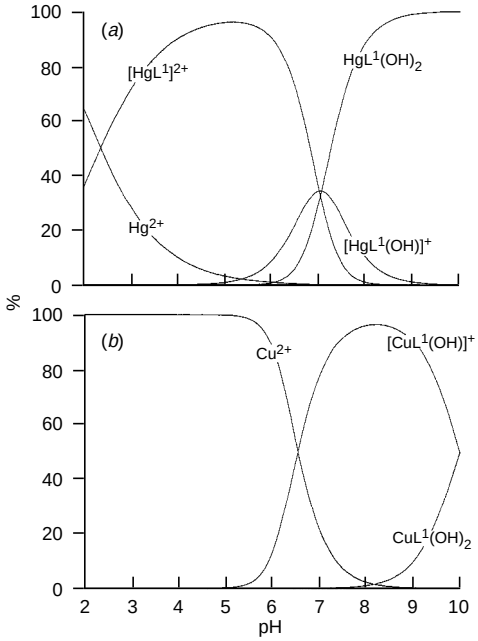

Fig. 2 Distribution diagram for the systems (*a*) L^1–H^+–Hg^{2+} and (*b*) L^1–H^+–Cu^{2+}

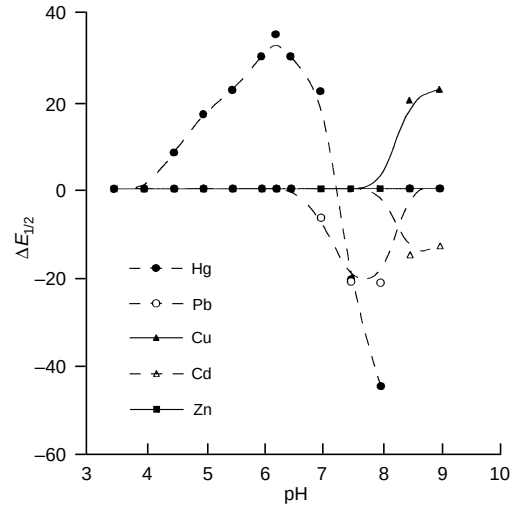

Fig. 3 Plot of $\Delta E_{1/2}$ *vs.* pH as a function of the pH for L^1–H^+–M^{2+} (M^{2+} = Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Hg^{2+})

the larger affinity of Hg^{2+} for L^1, which is able to produce the reaction $Hg^{2+} + HL^{1+} \rightleftharpoons [HgL^1]^{2+} + H^+$ at a lower pH value than the remaining metal ions. To determine if the ferrocenyl group is able to amplify the selective mercury-binding behaviour found at molecular level into a macroscopic signal using electrochemical methods, the oxidation potential of the free receptor and the oxidation potential of L^1–M^{2+} systems (M = Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}) has been monitored as a function of the pH in water. $E_{1/2}$ of the free receptor is pH-dependent. $E_{1/2}$ is *ca.* 175 mV at pH = 10. When the pH decreases there is an anodic shift until pH = 8 ($E_{1/2}$ = 375). In the pH range 8–3 the potential remains constant with a total shift between basic and acid pH of near 200 mV. Fig. 3 shows $\Delta E_{1/2}$ found in the presence of metal ions [M = Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}; $\Delta E_{1/2}$ is defined for a particular pH as $E_{1/2}$(L^1–H^+–M^{2+}) − $E_{1/2}$(L^1–H^+), studies have been carried out using 1 : 1 metal-to-ligand molar ratios; typical metal concentrations were 3–4 × 10^{-4} mol dm^{-3}]. It can be observed that there is a selective electrochemical recognition of Hg^{2+} over other common typically water-present metal ions as was predicted from the potentiometric results. At pH 6 there is no interaction between L^1 and Cu^{2+}, Zn^{2+}, Cd^{2+} or Pb^{2+}, and the addition of these metal ions (*ca.* 3 × 10^{-4} mol dm^{-3}) to solutions of L^1 and Hg^{2+} ([Hg^{2+}] *ca.* 3 × 10^{-4} mol dm^{-3}) does not shift $E_{1/2}$. Additionaly L^1–M^{2+}–H^+ curves in Fig. 3 are transformed into the L^1–Hg^{2+}–H^+ curve by adding equimolecular amounts of mercury to L^1–M^{2+} solutions (M^{2+} = Cu^{2+}, Zn^{2+}, Cd^{2+} or Pb^{2+}), indicating that Hg^{2+} is able to displace other metal ions in pre-formed $[ML^1]^{2+}$ complexes. L^1 behaves as a selective sensing molecule for Hg^{2+}.

To study the role played by the cyclic nature of L^1 similar experiments have been carried out using L^2 as receptor, which has been isolated after condensation of 2,2′-(ethylenedioxy)-bis(ethylamine) and (ferrocenylmethyl)trimethylammonium iodide. Electrochemical data showed, in contrast with L^1, that the values of $E_{1/2}$ *vs.* pH found for the free receptor and $E_{1/2}$ *vs.* pH obtained in the presence of metal ions (M^{2+} = Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Hg^{2+}; 1 : 1 metal-to-ligand molar ratios) were the same within the experimental error, pointing out the importance of the molecular architecture in L^1.

We should like to thank the DGICYT (proyecto PB95-1121-C02-02) for support.

Amplified microgravimetric quartz-crystal-microbalance analyses of oligonucleotide complexes: a route to a Tay–Sachs biosensor device

Amos Bardea,[a] Arie Dagan,[a] Iddo Ben-Dov,[a] Boaz Amit[b] and Itamar Willner*[a]†

[a] *Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem, 91904, Israel*
[b] *General Biotechnology, Kiryat Weizmann, Rehovot, Israel*

An oligonucleotide monolayer acts as an active interface for the microgravimetric, quartz-crystal-microbalance analysis of the complementary oligonucleotide.

The formation of specific double-stranded (ds)-oligonucleotide complexes on solid supports has evoked substantial recent research activities directed to the nanoscale architecture of metal-colloid arrays by means of oligonucleotide bridges[1] and to the tailoring of functionalized surfaces for gene detection.[2,3] Electrochemical DNA-sensors based on the intercalation or interaction of redox-active transition metal complexes,[4,5] *e.g.* $Co(bpy)_3^{3+}$, or dyes[6] such as acridine or Hoechst 33258, were reported. Microgravimetric quartz-crystal-microbalance (QCM) analyses, that use oligonucleotide sensing interfaces, were recently initiated to identify oligonucleotide–protein[7] or oligonucleotide–DNA complexes.[8] Although oligonucleotide–protein interactions were reported to reveal specificity,[7] the sensitivity of the oligonucleotide–oligonucleotide or DNA sensors is low and the specificity of these devices needs to be established. Recently, we applied antigen or antibody monolayer-functionalized Au–quartz crystals for the microgravimetric analyses of the complementary antibodies[9] or antigens.[10]

The assembly of biologically active monolayers on Au-supports *via* thiol bridging units has been extensively developed by our laboratory.[11] Enzyme-electrodes,[12] photoactive enzyme-electrodes,[13] immunosensors[9,10] and reversible immunosensors[14] were developed by this method. Here we wish to report on the development of an active oligonucleotide interface for the microgravimetric, piezoelectrical analysis of the complementary oligonucleotide. The method is exemplified for the analysis of the oligonucleotide residue characterizing the Tay–Sachs genetic disorder.[15] We demonstrate means to confirm and amplify the formation of the oligonucleotide–oligonucleotide complex at the crystal interface.

The 41-mer oligodeoxynucleotide **1** includes ten successive thiophosphate thymine residues linked to the 5′-terminus and acts as thiol-tag for attachment to the Au surface.[16] The remaining 31-mer oligonucleotide includes the complementary characteristic base-order of the normal Tay–Sachs gene. The 31-mer oligodeoxynucleotide **2** includes the base sequence of TS 4I-N in the gene in which mutations lead to the Tay–Sachs genetic disorder.[15] The thiol-tagged oligonucleotide **1** was assembled on a Au–quartz crystal (AT-cut, 9 MHz, EG&G) by interaction of the crystal with a phosphate buffer (0.01 M, pH 7.3) solution of **1**, 50 μg ml for 12 h at 4 °C.

Fig. 1(*b*)–(*e*) show the frequency changes of different crystals exposed to different concentrations of the complementary oligonucleotide **2**. Interaction of the monolayer-functionalized crystal with **2** yields a frequency decrease, implying a mass increase on the crystal surface as a result of the formation of the ds-oligonucleotide between **1** and **2**, Scheme 1. The extent of the crystal frequency decrease is enhanced as the bulk concentration of **2** increases, consistent with the increased surface coverage of the sensing interface by **2**. At a bulk concentration of **2** corresponding to 11.5 μg ml^{-1} [Fig. 1(*e*)], the crystal frequency decreases by 11 Hz and it levels-off to a constant value after *ca.* 200 s. Exposure of the monolayer-functionalized crystal to higher concentrations of **2** does not enhance the crystal frequency change, and the value of $\Delta f = -(11 \pm 1)$ Hz is preserved. This implies that the **1**–monolayer interface is saturated by **2** as a result of the formation of the ds-oligonucleotide. Using the observed frequency change, we estimate the surface coverage of the ds-oligonucleotide or the surface density of the base monolayer of **1** to be *ca.* 4.4×10^{-12}

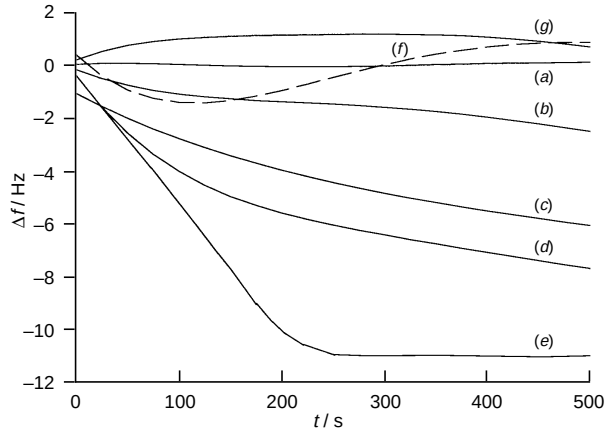

Fig. 1 Time-dependent frequency changes of a **1**-functionalized Au–quartz crystal upon addition of: (*a*) SSC buffer solution, pH = 7.0; (*b*) **2**, 0.6 μg ml^{-1}; (*c*) **2**, 2.4 μg ml^{-1}; (*d*) **2**, 3.5 μg ml^{-1}; (*e*) **2**, 11.5 μg ml^{-1}; (*f*) **3**, 11.5 μg ml^{-1}, (*g*) **2a** 2.4 μg ml^{-1}. Oligonucleotides are dissolved in SSC buffer, pH = 7.0, SSC = 30 mM Na–citrate and 300 mM NaCl.

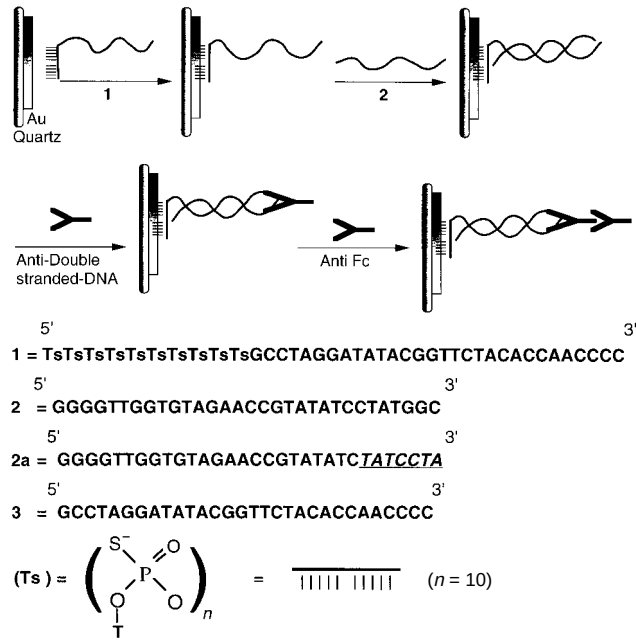

Scheme 1 Schematic amplified microgravimetric analysis of an oligonucleotide

mol cm^{-2}. This corresponds to *ca*. 50% of a densely packed monolayer of the ds-oligonucleotide. Control experiments reveal that the frequency of a bare Au–quartz crystal is unaffected upon interaction with **2**, (0.6 μg ml^{-1}), $\Delta f = -(1 \pm 1)$ Hz. Also, treatment of the **1**-functionalized crystal with a pure buffer solution [Fig. 1(*a*)] or with the 31-mer oligonucleotide solution **3**, (11.5 μg ml^{-1}), [Fig. 1(*f*)], does not yield any significant change in the crystal frequency. Note that the oligonucleotide **3** is essentially complementary to **2**. Thus, the lack of frequency changes upon interaction of the **1**-functionalized crystal with **3** indicates that non-specific oligonucleotide binding interactions are not operative on the interface. The frequency change observed upon interactions of the **1**-modified crystal with **2** originates from specific complementary interactions that generate the ds-assembly. A major concern in the development of the microgravimetric DNA-sensor relates to the specificity of interactions of the sensing interface with oligonucleotide mutants. Accordingly the quartz-crystal functionalized with the oligonucleotide **1** was interacted with the 31-mer oligonucleotide **2a**. The latter oligonucleotide includes the characteristic mutation differentiating the normal gene and 75% of the Tay–Sachs genetic disorder carriers. Note, that a seven-base mutation occurs in **2** as compared to **2a**. Fig. 1(*g*) shows the crystal frequency response upon interaction of the sensing interface with **2a** (2.4 μg ml^{-1}). No detectable crystal frequency decrease is observed, indicating that the removal of the seven-base pair recognition between the sensing interface and **2a** is sufficient to eliminate significant binding interactions. Thus, the sensing interface reveals sufficient specificity to distinguish between the normal and mutated DNA-sequences involved with Tay–Sachs genetic disorder.

At a bulk concentration of **2** corresponding to 0.6 μg ml^{-1}, a frequency change of only 2 Hz is observed after 500 s. This seems to be the sensitivity limit. In order to confirm that the frequency change observed in Fig. 1(*b*) originates from specific complementary interactions, and to amplify the transduced sensing signal, the resulting ds-assembly was interacted with a mouse anti-ds-DNA antibody (Ab). Fig. 2(*a*) shows the crystal frequency changes upon the interaction of **1**-functionalized crystal with **2** (0.6 μg ml^{-1}). A frequency change of $\Delta f = -(2 \pm 1)$ Hz is observed. Fig. 2(*b*) shows the crystal frequency changes upon interaction of the ds-assembly with the anti-ds-DNA antibody. Note that although the coupling of **2** results in a frequency change of only $\Delta f = -(2 \pm 1)$ Hz, the association of the Ab results in a frequency change of $\Delta f = -(14 \pm 1)$Hz. This is consistent with the fact that the mass ratio of **2** : Ab is 1 : 15. Challenging of the supramolecular ds-oligonucleotide/anti-ds-DNA antibody with the goat anti-mouse Fc-antibody results in a further decrease in the crystal frequency of $\Delta f = -(8 \pm 1)$ Hz, Fig. 2(*c*). This originates from the association of the secondary antibody to the Fc-part of the anti-ds-DNA antibody, Scheme 1. The frequency decrease in the presence of the secondary antibody is only half of the frequency decrease observed with the primary anti-ds-DNA antibody. This originates from the fact that the secondary antibody includes two binding sites for the primary antibody. Control experiments reveal that the anti-ds-DNA antibody or the anti-mouse-Fc-antibody do not bind to the **1**-functionalized interface [$\Delta f = -(2 \pm 1)$ Hz]. Thus, the ds-assembly formed by the interaction between the functionalized crystal and **2** specifically associates the anti-ds-DNA antibody. The latter complex with the mouse antibody binds the secondary goat anti-mouse antibody.

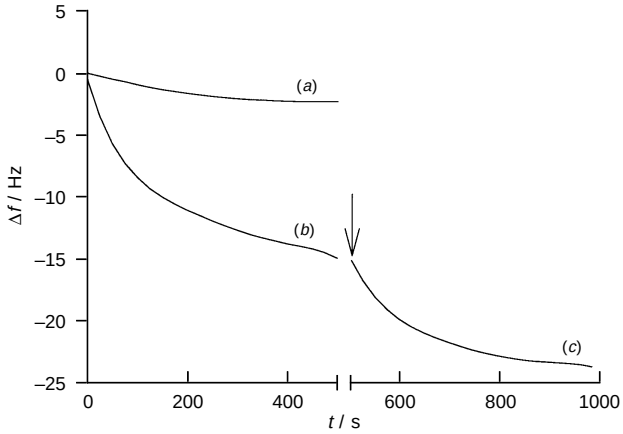

Fig. 2 Time-dependent frequency changes of the **1**-functionalized Au–quartz crystal upon addition of: (*a*) **2**, 0.6 μg ml^{-1}; (*b*) addition of anti-ds-DNA-Ab, 1.2 μg ml^{-1}, to the **1** and **2** double stranded complex on the surface; (*c*) addition of anti-Fc-Ab, 21 ng ml^{-1} to the **1** and **2** ds-complex with linked anti-ds-DNA-Ab. Arrow indicates the time of anti-Fc-Ab addition. Prior to addition of the anti-Fc-Ab, the cell was rinsed with PBS buffer.

Thus, we have developed a novel means to assemble an interface for the specific microgravimetric analysis of complementary oligonucleotides. The interaction of the resulting surface-bound ds-oligonucleotide assembly with the anti-ds-DNA antibody and with the respective anti-antibody provides means to confirm and amplify the primary formation of the complementary oligonucleotide complexes. Further attempts to regenerate the sensing interface by unfolding of the ds-oligonucleotide complex by thermal or chemical treatments are underway in our laboratory.

Practical route to high activity enzyme preparations for synthesis in organic media

Johann Partridge,*† Peter J. Halling and Barry D. Moore*

Department of Pure and Applied Chemistry, University of Strathclyde, Thomas Graham Building, 295 Cathedral Street, Glasgow, Scotland, UK G1 1XL

A single pot method to rapidly prepare immobilised subtilisin Carlsberg and α-chymotrypsin gives 1000-fold greater catalytic activities in polar organic solvents than freeze-dried powders.

The application and utility of enzymes such as serine proteases and esterases in organic synthesis is well established. This has led to increased demand for enzyme preparations which exhibit high activity and reproducible selectivity, particularly in organic solvents.[1–4] The commonly used freeze-dried powders are known to exhibit low activity,[5,6] but are often used because they can be obtained in one step from commercially supplied enzymes. Enzymes immobilised onto a support often show higher activity in organic media but the types of support material reported may not always be readily available and well controlled immoblisation procedures are often required.[7–11] Recently, commercial cross-linked enzyme crystals (CLECs) have been introduced and these exhibit high activity, good stability and excellent reproducibility but are only currently available for certain enzymes.[12]‡ Here we demonstrate how enzyme preparations of very high activity can be rapidly and economically produced in a normal chemistry laboratory utilising a novel dehydration process.

The procedure employed is summarised in Fig. 1. The enzyme is first immobilised onto a support and for convenience we have used adsorption onto a standard silica chromatography gel.[13,14]§ For the enzymes tested the adsorption takes place quantitatively on stirring the protein with the silica in aqueous buffer solution at pH 7.8.¶ The immobilisation process disperses the biocatalyst over a large surface area and ensures good active site accessibility is obtained when the preparation is transferred to an organic solvent.‖ Following adsorption most of the aqueous solution is decanted from the silica–enzyme preparation ensuring the solid remains wetted. The key dehydration step is then achieved simply by rinsing the silica–enzyme preparation with successive aliquots of dry *n*-propanol, again keeping the solid wetted with solvent at all times. Where required, a final rinse with the reaction solvent of choice can be used to remove the propanol before the reactants are added. The propanol rinse rapidly removes water associated with the protein by a mechanism which minimises denaturation and appears to leave the majority of enzyme molecules in an active conformation. Ethanol and longer chain alcohols can also be used for the rinse, but methanol produces a much less active preparation.

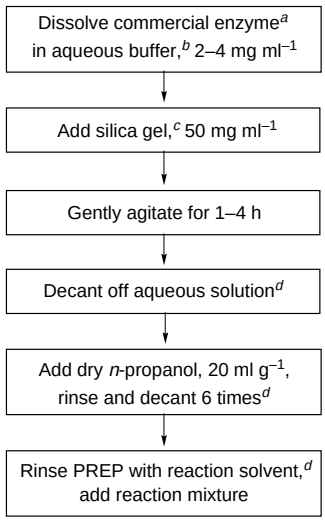

Fig. 1 Typical preparation of enzyme for use in organic solvent. [a] Highest purity available. [b] pH of maximum activity. [c] No special treatment required. [d] Ensure silica remains immersed.

The propanol rinsed enzyme preparations (PREPs) of subtilisin Carlsberg and α-chymotrypsin are found to exhibit very high activities in synthetically useful polar organic solvents such as acetonitrile (ACN) and THF.** Table 1 shows a comparison of the initial reaction rates obtained for a standard transesterification reaction in ACN using subtilisin Carlsberg prepared in different forms. At water levels of 1% (v/v) and above, the rates for the PREP are found to be comparable to the CLEC, and over 1000 times greater than the commonly used freeze-dried powders. Cross-linked enzyme crystals of chymotrypsin are not commercially available but under the same reaction conditions described in Table 1 the PREP of this enzyme exhibited transesterification activities of 21 and 131 nmol mg^{-1} min^{-1} in ACN, containing 1 and 4.5% v/v water, respectively. Again this is two orders of magnitude better than the freeze-dried powder.

If the PREP is removed from propanol and dried in air prior to assaying in the organic solvent most of the activity is lost and the residual level approaches that obtained for the lyophilised powder (see Table 1). However, aqueous suspensions of the silica adsorbed enzymes can be stored in the fridge for at least

Table 1 Effect of preparation type on subtilisin Carlsberg activity. Reaction conditions: 10 mM *N*-acetyl-L-tyrosine ethyl ester, 1 M propan-1-ol, in ACN containing water added as shown (% v/v). The mixture was incubated at 24 °C with constant reciprocal shaking (150 min^{-1}). Samples were analysed by HPLC on a Gilson 715 equipped with an ODS2 reversed phase column (Hichrom)

	Rate[a]/nmol mg^{-1} min^{-1}		
Enzyme form	0% H_2O v/v in ACN[b] (a_w < 0.01)	1% H_2O v/v in ACN (a_w = 0.22)	4.5% H_2O v/v in ACN (a_w = 0.55)
Freeze-dried powder	< 0.01	0.13	0.28
Cross-linked crystal (CLEC)	226	172	105
Propanol rinsed (PREP)	0.82	142	124
Propanol rinsed, air dried[c]	—	0.60	—

[a] mg refers to weight of enzyme in preparation. [b] Water content of dry ACN was < 0.007% v/v. [c] Sample prepared as in Fig. 1, placed in sealed jar over molecular sieves for 3 days, then equilibrated for a further 3 days over H_2O-saturated potassium acetate (a_w = 0.22).

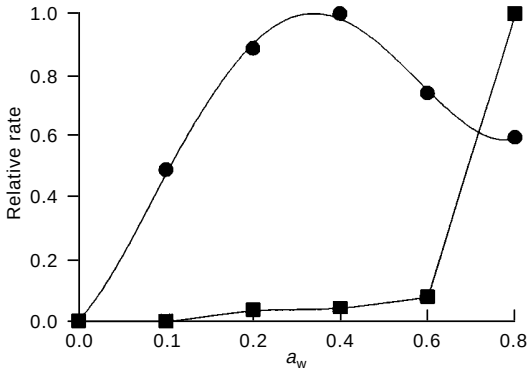

Fig. 2 Relative rate as a function of a_w for the transesterification reaction catalysed by subtilisin PREP (●) and freeze dried subtilisin Carlsberg (■). Rates for each preparation were normalised relative to the maximum value. These were 159.7 nmol mg^{-1} min^{-1} at a_w of 0.44 for the PREP and 3.3 nmol mg^{-1} min^{-1} at a_w of 0.76 for the freeze-dried powder. Reaction conditions as for Table 1.

3 weeks with negligible loss of activity and converted to the PREP as required.

It is perhaps surprising the method described here for preparing biocatalysts for reactions in low water media has not been reported previously. However, until recently the large hydration hysteresis effects obtainable with enzymes had not been fully recognised.[15,16] This work and that previously with CLECs[15] has shown that different methods of water removal can dramatically affect the enzyme activity obtained. Two possible explanations are (*i*) different dehydration protocols effect the amount of water left bound to the enzyme, or (*ii*) the conformation of the dried enzyme is very sensitive to the method of water removal. Most probably these two effects are intimately related.

According to previous studies the amount of water bound to a protein in solvent would be expected to be controlled by the thermodynamic water activity, a_w.[17,18] We therefore compared the catalytic activities of a freeze-dried powder and a PREP of subtilisin as a function of this parameter. Under these conditions differences in the amount of residual bound water should be eliminated and hence similar rate *vs*. a_w profiles might be expected for the PREP and powder. As can be seen in Fig. 2 this is not the case. The activity of the lyophilised powder continues to increase even up to a_w 0.76 while a maximal but much higher rate is obtained with the subtilisin PREP at a_w 0.44.†† Note that since the activity per unit weight of enzyme is much lower in the lyophilised powder (see Table 1), the rate profiles for the two preparations compared in Fig. 2 are relative rates normalised to the maximum value.

The different rate profiles could arise because the two forms of the enzyme differ in either water binding or the water required for catalytic activity. A large difference in water binding isotherms is unlikely, but kinetic factors may be significant. The water content of the lyophilised powder will be determined by its adsorption isotherm. In contrast, the treatment of the PREP imposes a water desorption process, for which the isotherm will be different due to hysteresis, and even the apparent equilibrium value may not be reached in the time allowed. An alternative hypothesis is that the PREP requires less water because the propanol dehydration process leaves a large proportion of the enzyme molecules in a conformation close to the active form. Only low levels of water may then be needed to promote catalysis and further increases in water availability provide no beneficial effect. With the dry freeze-dried powder the very low rates suggest most of the enzyme is initially inactive. In this case a water catalysed reorganisation process is probably required to convert the enzyme back to an active state since much greater water levels are needed to obtain high activity. The difference in profiles in Fig. 2 therefore reflects the fact that water plays different roles in promoting enzyme catalysis depending on the hydration history of the system.

We have shown here that very high activity propanol rinsed enzyme preparations (PREPs) can be obtained with both subtilisin Carlsberg and α-chymotrypsin, enzymes with very different secondary and tertiary protein structures. This suggests the procedure may find widespread application as a simple and economical way of preparing biocatalysts for reactions in organic media.

We would like to thank the BBSRC for funding this work.

‡ Other enzyme forms recently reported to exhibit high activity in organic media include enzymes entrapped in sol-gels[19] and dissolved enzymes.[20]

§ Silica gel was Sigma S-0507, 230–400 mesh, 60 Å pores.

¶ The adsorption pH used corresponds to the optimum activity of the enzymes in aqueous solution. Typical adsorption conditions used; 20 ml of subtilisin Carlsberg (2 mg ml^{-1}) in 20 mM sodium phosphate buffer, pH 7.8, was mixed with 1 g of silica gel and the mixture shaken for 1 h at 25 °C. 20 ml of α-chymotrypsin (4 mg ml^{-1}) in 25 mM tris buffer, pH 7.8, containing 10 mM calcium chloride (to minimise autolysis) was shaken for 4 h at 25 °C. After mixing the adsorbed enzymes were stored in aqueous buffer at 4 °C.

‖ Since enzymes are generally insoluble in most organic solvents a heterogeneous reaction mixture is obtained and diffusion limitations can become important.

** It is often useful to carry out reactions at known thermodynamic water activity, a_w.[18] In polar solvents, in order to achieve a fixed a_w, a known concentration of water can be conveniently added to the system.[21] For ACN, a_w values of 0.11, 0.22, 0.44, 0.55 and 0.76 can be achieved by adding 0.5, 1.0, 2.7, 4.5 and 13% water (v/v) to the solvent.

†† Similarly, for freeze-dried chymotrypsin the rate increases with a_w, whereas an optimum rate is achieved at a_w of 0.55 for the PREP of this enzyme. The shift in rate *vs*. a_w for the chymotrypsin PREP in comparison to subtilisin PREP is interesting. This is also apparent when comparing profiles for the lyophilised powders of the two enzymes.

Solid state polymerization of the unsymmetrical [1]ferrocenophane Fe(η-C_5H_4)$_2$SiMePh; synthesis of the first stereoregular organometallic polymer

John Rasburn, Daniel A. Foucher, William F. Reynolds, Ian Manners*† and G. Julius Vancso*‡

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ontario M5S 3H6, Canada

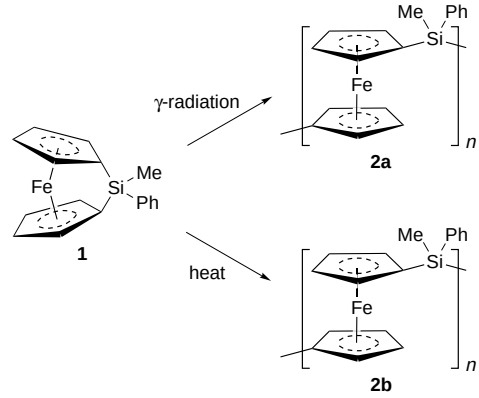
Solid state polymerization of the [1]ferrocenophane Fe(η-C_5H_4)$_2$SiMePh yields a stereoregular poly(ferrocenylmethylphenylsilane), the first example of a stereoregular organometallic polymer.

Although stereoregular organic polymers (*e.g.* isotactic or syndiotactic polypropylene) are well studied materials of considerable industrial importance, stereoregular inorganic polymers are virtually unknown.[1] A rare recent report describes the preparation of poly(methylphenylsilane) [SiMePh]$_n$ using a chiral dehydrocoupling catalyst.[2] In this case the tacticity was not deduced unequivocally, but a syndiotactic microstructure was tentatively proposed on the basis of NMR data. Here, we report the first synthesis of a stereoregular organometallic polymer using the technique of solid-state polymerisation.

Owing to the possibility of accessing processable materials with novel electronic and optical properties, the synthesis and study of inorganic and organometallic polymers has attracted increasing recent interest.[3] Significant among these are the poly(ferrocenylsilanes), unusual polymers with a main-chain comprising alternating ferrocene and organosilane units.[4] A common method of polymerisation involves thermal ring-opening polymerization (ROP) of strained, silicon-bridged [1]ferrocenophanes to give high molecular mass materials (M_w = 10^5–10^6 Da).[5–10] More recently, anionic and transition metal catalyzed ROP has also been reported.[11] However, by analogy with the well known case of the topotactic polymerisation of trioxane and tetroxane to produce polyoxymethylene,[12–14] strained [1]ferrocenophanes would also seem to be excellent candidates for topotactic or solid-state polymerisation. Indeed, recently we showed that the symmetrically substituted [1]ferrocenophane Fe(η-C_5H_4)$_2$SiMe$_2$ yielded a high-molecular-weight poly(ferrocenyldimethylsilane) [Fe(η-C_5H_4)$_2$SiMe$_2$]$_n$ with properties similar to the thermally ring-opened materials on ^{60}Co γ-irradiation of symmetrically-substituted monomer crystals.[15] Nevertheless, important issues such as whether the reaction was topotactic remained open.

To gain further insight, we have investigated the use of an unsymmetrically-substituted [1]ferrocenophane monomer, Fe(η-C_5H_4)$_2$SiMePh **1**.[16] The resulting microstructure can be examined by solution NMR and hence represents an alternative approach to reliance on X-ray scattering methods, although not as detailed. In the reaction scheme (Scheme 1) **2a** refers to the solid-state polymerised polymer, to be compared with **2b**, the thermally ring-opened material.

For our study, large maroon single-crystals of **1** were synthesised as described previously,[10] purified by repeated high-vacuum sublimations, and then sealed (0.65 g) in a Pyrex tube. The crystal structure of this monomer is well established.[16] The tube was then irradiated *via* placement close to a ^{60}C γ-ray source at 25 °C at 0.71 MRad for 24 h (for a total dosage of 17 MRad). On removal from the source, the temperature was measured to be 38 °C, well below the melting temperature of the crystals.[10,16] Any post-irradiation heat-treatment was avoided. The tube was then returned to the N_2 atmosphere and the contents extracted with an excess of



Scheme 1

hexanes to remove unreacted monomer and oligomeric species. The product **2a** was obtained as 0.30 g (46%) of yellow–orange platelets on which the original superstructure of the monomer crystals could be vaguely discerned. The platelets could be teased apart into fibrils. For solution NMR analysis, the product was purified by reprecipitation from THF into chilled *n*-propanol to give a pale yellow powder (M_w was determined to be 90 000 Da with a polydispersity of 1.4 by gel permeation chromatography *vs.* polystyrene standards). The thermally ring-opened polymer **2b** was synthesised as described previously.[10]

Wide-angle X-ray analysis of **2a** revealed three main scattering peaks at d = 7.81, 5.69 and 4.26 Å, all rather broad and suggestive of small and imperfect crystallites. By contrast, samples of **2b** give broad and featureless amorphous halos characteristic for this amorphous polymer. This suggested a different and more regular stereochemistry for **2a** compared to **2b**. Moreover, conspicuous differences in the ^{1}H and ^{13}C NMR spectra were evident when the solid state polymerized material **2a** was compared with the thermally generated product **2b**. In both the ^{1}H and the ^{13}C NMR spectra the methyl resonance of **2a** was a singlet. This implies stereoregularity when compared to the three observed resonances for **2b** where the approximate 1 : 2 : 1 intensity ratio can be assigned to mm (or rr), mr/rm, and rr (or mm) triads for an atactic polymer [see Fig. 1(*b*) *cf.* 1(*d*) and 2(*c*) *cf.* 2(*f*), respectively].[17] Similarly, the observed ^{1}H NMR resonances for the cyclopentadienyl group for **2a** [shown in Fig. 1(*a*)] constitute a subspectrum of that of **2b** [Fig. 1(*c*)]. Interestingly, the *ipso*-carbon atoms in the cyclopentadienyl groups show tetrad resolution with six ^{13}C NMR resonances in Fig. 2(*e*). In striking contrast, only one of the tetrad sequences is present in **2a** [Fig. 2(*b*)].[17,18]

The actual tacticity of **2a** (syndiotactic or isotactic) has not yet been definitively elucidated. The assignment is not straightforward, particularly as there is negligible *J*-coupling across the iron centres, and therefore some interpretation of the chemical shifts or dipolar couplings in terms of likely rotational isomeric states is required.[17,18] However, we tentatively assign

a syndiotactic architecture. Thus, for the melt polymerized polymer **2b** although atactic triads (mr/rm) clearly predominate, syndiotactic triads (mm§) would be expected to be slightly more favoured than isotactic triads (rr§) based on steric arguments. This suggests the assignment of the ^{1}H NMR resonances at δ 0.772 in Fig. 1(*d*) and the ^{13}C NMR resonance at δ −3.17 in Fig. 2(*f*) to syndiotactic (mm) triads. Consideration of Fig. 1(*b*) *cf.* 1(*d*) and 2(*c*) *cf.* 2(*f*) shows that the ^{1}H and ^{13}C NMR resonances assigned to the methyl groups of **2a** correspond to these resonances of **2b** which we tentatively assign to syndiotactic triads.

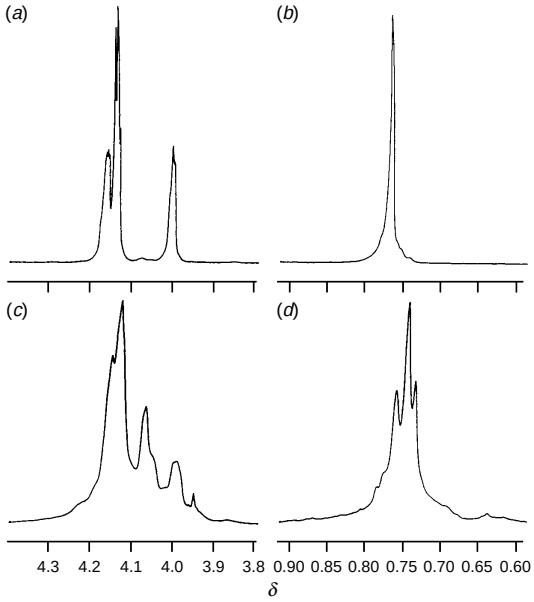


Fig. 1 ^{1}H NMR spectra (300 MHz, C_6D_6, 20 °C) of **2a** [(*a*), (*b*)] and **2b** [(*c*), (*d*)]. Spectra (*a*) and (*c*) compare cyclopentadienyl resonances, and (*b*) and (*d*) methyl resonances.

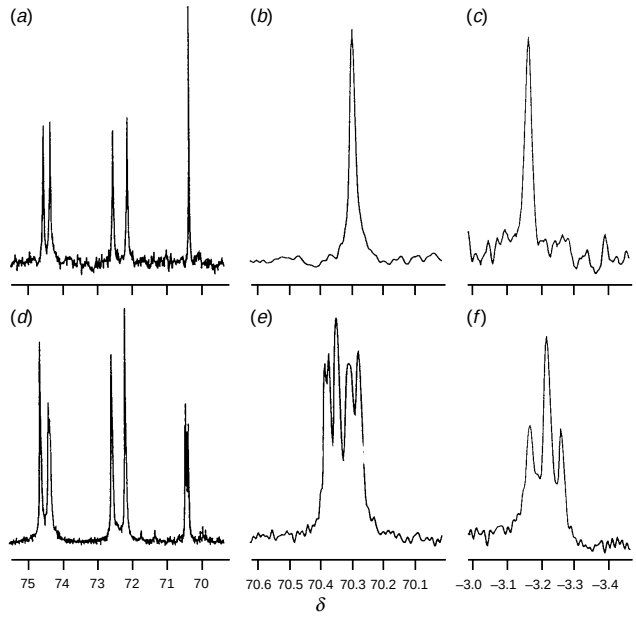

Fig. 2 Quantitative ^{13}C NMR spectra (75 MHz, C_6D_6, 20 °C) of **2a** [(*a*)–(*c*)] and **2b** [(*d*)–(*f*)]. Spectra (*a*) and (*d*) show resonances for cyclopentadienyl carbons, (*b*) and (*e*) show resonances for *ipso* cyclopentadienyl carbons, and (*c*) and (*f*) show resonances for methyl carbons.

Further work is aimed at definitively determining the stereochemistry of **2a** (isotactic or syndiotactic) as well as obtaining further insight into the kinetics and topotaxis of this novel solid-state reaction.

The authors would like to thank Dr J. K. Pudelski for provision of the thermally polymerised polymer sample. G. J. V. and I. M. are grateful to the Natural Science and Engineering Research Council (NSERC) and Institute for Chemical Sciences and Technology (ICST) for funding this research. I. M. also thanks NSERC for an E. W. R. Steacie Fellowship (1997–99), the Alfred P. Sloan Foundation for a Fellowship (1994–98), and the University of Toronto for a McLean Fellowship (1997–2003).

§ For an isotactic poly(ferrocenylsilane) (*i.e.* a chain comprising repeat units of identical stereochemistry) inspection of the asymmetic center by Newman projections from within a given dyad indicates that both have the same handedness and hence isotactic dyads are r and syndiotactic dyads are m, in contrast to the situation with vinyl and silane polymers.

$[NBu^n_4]_4[(Re_6S_5OCl_7)_2O]$, an oxo-bridged siamese twin cluster of two hexanuclear oxochalcohalide rhenium clusters

Falk Simon, Kamal Boubekeur, Jean-Christophe P. Gabriel and Patrick Batail*†

Institut des Matériaux de Nantes, UMR 6502 CNRS-Université de Nantes, 2, rue de la Houssinière, 44322 Nantes, France

A report of the solid state synthesis and X-ray crystal structure analysis of $[NBu^n_4]_4[(Re_6S_5OCl_7)_2O]$, the first oxo-bridged, tetravalent hexanuclear oxochalcohalide rhenium cluster.

The potassium and rubidium salts of hexanuclear chalcohalide rhenium clusters, $M[Re_6(Q_5Cl_3)Cl_6]$ (M = Rb, Q = S; M = K, Q = Se), obtained from high temperature solid state reactions, are soluble in a variety of organic solvents,[1] and have been shown to be splendid starting materials for a variety of heterosubstituted or functionalized rhenium clusters.[2–5] These reactions, performed at room temperature and in organic solvents, always lead to the cluster dianions, $[NBu^n_4]_2[Re_6(Q^i_5E^iCl^i_2)Cl^a_6]^{2-}$ (E = O, S, Se, Te, NH, NMe, NBz), and involve the substitution of one of the μ_3-face-capping chloride ligand of the Re_6L_8 cluster core in $[NBu^n_4][Re_6(Q_5Cl_3)Cl_6]$ (Q = S, Se), with a divalent anion or its synthetic equivalent, for example the silylated main group reagents $E(SiMe_3)_2$.[4,5] We now report a novel high temperature solid state reaction, in the presence of minute amounts of water which (*i*) achieves the concomitant solid state synthesis and former transformation of the cluster monoanion form into the corresponding dianion upon a single core ligand substitution, and (*ii*) involves a single apical-chloride displacement and a subsequent linkage of two clusters across an oxo-bridge, both unprecedented in this chemistry.

The compound $[NBu^n_4]_4[(Re_6S_5OCl_7)_2O]$ was synthesized by mixing Re (206 mg, 1.11 mmol), $ReCl_5$ (200 mg, 0.55 mmol), KCl (30 mg, 0.40 mmol) and S (35 mg, 1.09 mmol) in an inert gas atmosphere. The powder was then pressed into a pellet and placed in a silica tube (inner diameter 10 mm, external diameter 12 mm; *ca*. 105 mm long), into which H_2O (0.014 ml, 0.78 mmol) was carefully condensed (the hydrolysis of $ReCl_5$ leads to the formation of $HReO_4$, ReO_2 and HCl).[6] After 10 min the system was evacuated to 10^{-2} Torr, sealed and heated for 4 days at 850 °C in a furnace, using a 30 °C h^{-1} rate for heating and cooling ramps. The crude material was washed with water and dissolved in ethanol. An ethanolic solution of NBu^n_4Cl was then added, forming rapidly an orange precipitate, which was recrystallized from acetone to give 470 mg of dark red crystals [Yield = 42% (based on Re). Anal. for $C_{64}H_{144}Cl_{14}N_4O_3S_{10}Re_{12}$. Calc. C, 18.89; H, 3.57; N, 1.38; Cl, 12.20; S, 7.88. Found: C, 16.95; H, 3.10; N, 1.33; Cl, 12.21; S, 8.13%].

The structure was solved by single crystal X-ray diffraction.‡ The asymmetric unit contains one cluster tetra-anion and four tetrabutylammonium cations. The cluster anion (Fig. 1) consists of two identical $[Re_6(S_5OCl_2)]^{4+}$ cores linked by an apical oxygen ligand [O(2)], the ten other apical positions being occupied by chlorine atoms. Thus, the charge of each cluster moiety is 2−. The average rhenium to apical chloride bond length (Re–Cl^a, where Cl^a denotes such a chlorine atom in Schäfer's notation)[7] is 2.380(4) Å [range 2.367(4)–2.389(3) Å], as expected for a cluster dianion.[3,4] The Re–Q distances observed for the μ_3-bridging, disordered Cl and S inner atoms (Q = S^i, Cl^i) are in the range of 2.385(3)–2.450(3) Å, whereas the μ_3-bridging oxo ligands are much closer to the Re atoms [2.090(7)–2.105(8) Å]. This distance is similar to that found in the oxygen substituted cluster, $[NBu^n_4]_2[Re_6S_5OCl_8]$ [average Re–(S^i, Cl^i) 2.415(11) Å, Re–O 2.087(6) Å].[4] It is important to note that there is no evidence for disorder in the position of the oxo ligands, a rare event in this type of chemistry.[4,5] Finally, the rhenium octahedra are slightly distorted, a manifestation of the closer approach of the face capping oxo ligand, consistent with the shortening of the Re–Re bond lengths observed for rhenium octahedra when one goes from the Re–Se–Cl to Re–S–Cl system.[3,8,9] In the structure of $[NBu^n_4]_4[(Re_6S_5OCl_7)_2O]$, the three rhenium atoms capped by the μ_3-oxo ligands have regular Re–Re distances [$< d_{Re-Re} >$ = 2.530(6) Å], whereas the opposing triangular Re_3 face is also regular, $< d_{Re-Re} >$ = 2.595(8) Å, but with Re–Re distances similar to those observed in all hexanuclear clusters in the Re–S–Cl system.[3,9] The remaining Re–Re bond lengths, that connect these two Re_3 triangles, are intermediate to the two former, $< d[Re_3(O)–Re_3(S)] >$ = 2.585(8) Å, very close to the barycentre calculated as [(2.530 × 1 + 2.595 × 7)/8] = 2.587 Å.

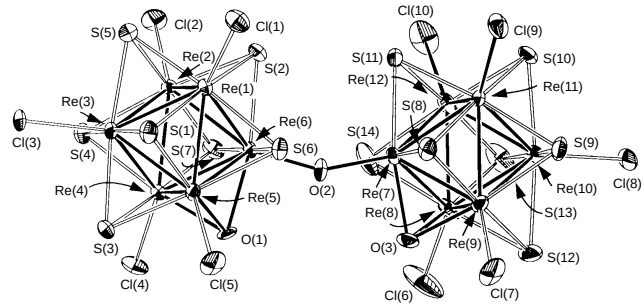

Fig. 1 ORTEP drawing and numbering scheme for the cluster $[(Re_6S_5OCl_7)_2O]^{4-}$ in $[NBu^n_4]_4[(Re_6S_5OCl_7)_2O]$. The thermal ellipsoids are drawn at the 50% probability level. Face-capping ligands S are composite S/Cl atoms (ratio: 5/2), the two face-capping O ligands are located. The cluster molecule is totally asymmetric. The relevant bond lengths are described in the text.

The present oxo-bridged siamese twin cluster compound differs from $[Re_{12}Se_{16}(PEt_3)_{10}][SbF_6]_4$, which was recently reported by Zheng *et al.*,[10] since, in the latter case, the two rhenium clusters are connected *via* two bonds, one Re–Se^{a-i} and the other Re–Se^{i-a}, in a similar fashion to the Chevrel phases.[11] The novel class of solid state reaction disclosed in this work opens the way for an infinite oxo-bridged cluster polymer.

A unique and highly facile method for synthesising disulfide linked neoglycoconjugates: a new approach for remodelling of peptides and proteins

Wallace M. Macindoe, Anita H. van Oijen and Geert-Jan Boons*

School of Chemistry, The University of Birmingham, Edgbaston, Birmingham, UK B15 2TT

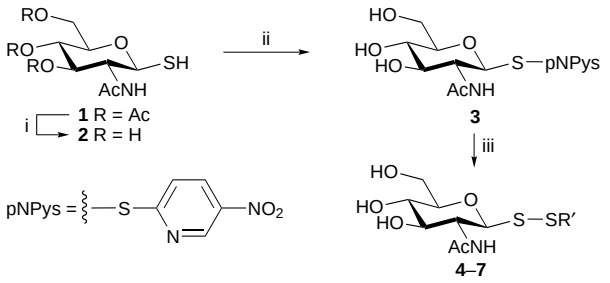
An asymmetric disulfide linkage, formed by conjugation of a 5-nitropyridine-2-sulfenyl activated thioglycoside and a protein or pre-assembled peptide sequence, represents a good structural mimic of natural asparagine glycosylation.

Most eukaryotic cellular proteins with the exception of some hormones and enzymes are reliant on the sugar units bound to them to confer a broad range of important biological functions, including immunogenicity, solubility, recognition, protection from proteolytic attack, and induction and maintenance of the protein conformation in a biologically active form.[1] The biosynthesis of *N*-linked glycoproteins is complex and results in micro-heterogeneity in the carbohydrate structure (formation of glycoforms).[2] Several studies have highlighted that each glycoform should be seen as a unique population of molecular species with particular biological properties.[3]

Much effort has been directed to alter the constitution of the carbohydrate protion of particular glycoproteins.[4] Saccharide glycoprotein remodelling (GPR) originally relied on cumbersome and inefficient means of adding carbohydrate structures, either by chemical or enzymatic methods, to proteins.[5] This approach has been supplanted by a technique using recombinant proteins to alter the intrinsic glycosylation pattern of cells.[6] However, the drawback of this technology is that it has the propensity to produce either inactive, undesired or missing glycoforms as part of the protein product.[7]

We report here an approach to the GPR problem which is based on asymmetric disulfide conjugation (an S–S glycosidic linkage) between a 5-nitropyridine-2-sulfenyl activated thioglycoside (*e.g.* **3**, Scheme 1) and a protein or pre-assembled peptide sequence having its natural asparagine glycosylation site replaced with a cysteine residue (R′SH). The merit of such an asymmetric disulfide linkage is that it represents a good structural mimic for natural *N*-linked glycoproteins[9] since the disulfide linkage is flexible enough to adopt conformations imposed by natural amide linkages at glycosylation sites.[10]

The synthesis of compound **3** was executed in five steps (25% yield overall) from commercially available *N*-acetylglucosamine *via* a modified procedure precedent for preparing 2-acetamido-2-deoxy-1-thio-β-D-glucose **2**.[11] Compound **1** decomposed during both Zemplén and KOBu^t mediated deacetylation conditions, but quantitatively gave thiol sugar **2** by a mild saponification procedure (Et_3N–MeOH–H_2O). The 5-nitropyridine-2-sulfenyl (pNpys) function was easily introduced onto mercapto-sugar **2** by treating the latter with 2,2′-dithiobis(5-nitropyridine) (DTNP) in AcOH–water[12] to yield compound **3** in a satisfactory yield of 58%. We anticipate the synthesis to be amenable for preparing oligosaccharide analogues thereof as judged by the mildness of the procedure.



Scheme 1 *Reagents and conditions*: i, Et_3N–MeOH–H_2O (2 : 5 : 5), 0.5 h, quant.; ii, DTNP, AcOH–water (12 : 1), 6 h, 58%; iii, R′SH, NH_4OAc (1 M) pH 5, 2–15 min

The activated thio-*N*-acetylglucosamine **3** under mild buffered conditions (1 M NH_4OAc, pH 5) is able to form asymmetric disulfide conjugates with a variety of free thiol-containing substrates. Reaction times are in the range of 2–15 min and yields are quantitative with excesses of **3** (*e.g.* product **7**). The generality thus far encompasses peptide, protein and polymer substrates, as shown in Table 1. Certainly, model conjugate **6** is of high immunological importance, in that the pentapeptide moiety represents that of a human IgG2 sequence[13] with Cys in place of Asn-297. Unfortunately, the ^{1}H NOESY spectra of both conjugate **6** and the natural glycopentapeptide equivalent (in this case Cys is replaced by Asn and thus becomes a structural motif for the natural *N*-glucoasparagine linkage found in wild-type human IgG2) did not reveal any cross peaks between sugar-peptide protons. Therefore the structural similarities between the disulfide and natural amide glycopeptide linkages of the neoglycotripeptide AcPhe(1-thio-β-GlcNAc-1→*S*)CysSerNHCH$_3$ **8** were examined by molecular modelling. Thus, a starting structure of compound **8** was built based on the tripeptide moiety of the same IgG2 sequence[13] (*vide supra*) with Cys in place of Asn-297 [AcPhe(β-GlcNAc-1→*N*)AsnSerNHCH$_3$ **9**] and subjected to Monte Carlo multi-

Table 1 Generality of synthesis of disulfide linked neoglycoconjugates

1 : 1	 **4a** X = Ac **b** X = palmitoyl	53–65[a]
5 : 1	 **5**	63[b]
2 : 1	 **6**	77
50 : 1	 BSA = Bovine serum albumin **7**	quant.[c]

[a] Yields are representative for two different *N*-acylated cysteine derivatives prepared, X = Ac (65%) and X = Palmitoyl (53%). [b] Determined by the amount of **1** cleaved from the support (1,2-dithioerythritol–CH_2Cl_2) after treatment with Ac_2O–pyridine. [c] Absolute yield determined by HPAEC-PAD analysis of thio-*N*-acetylglucosamine **2** deconjugated from **7** using 1,2-dithioerythritol–water.

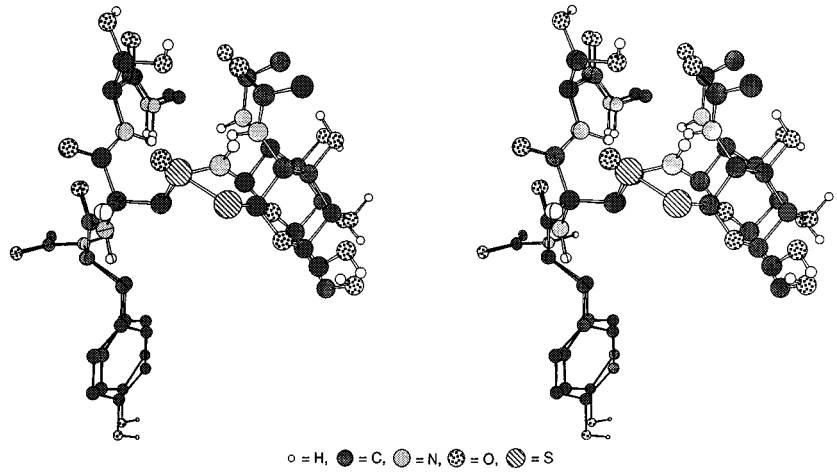

Fig. 1 Stereoviews showing superimposition of neoglycotripeptide **8** and neoglycotripeptide **9** as present in human IgG2

conformer analysis in combination with molecular mechanics calculations.[14] The global minimum of neoglycotripeptide **8** as well as all conformations lying within a 50 kJ mol^{-1} energy window were investigated using both filtering and clustering analysis resulting in families of conformers. Overlays of the resulting families of these conformations with glycopeptide **9** demonstrate that a similar spatial orientation as present at the glycosylation site of human IgG2[15] can be adopted by disulfide analogue **8** (see Fig. 1).

Bovine serum albumin (BSA) was chosen as a model protein on the merit of its availability and the convenience of having a single cysteinyl function at Cys-58 of its protein sequence. After 15 min of reacting **3** with BSA, the BSA-containing fractions were quickly isolated free from the excess amount of **3** and other low molecular weight thiol by-products (Sephadex G-15; eluent, water). Ellman analysis[16] of the isolated conjugate **7** against a blank sample of non-reacted BSA gave a zero absorbance reading at 412 nm, showing the conjugation to be complete. Further spectroscopic corroboration of conjugate **7** came from electrospray mass spectrometry. The mass increase for conjugate **7** over the BSA sample was 160 ± 100 while the theoretical difference is 235.[17]

The conjugate **7** was treated with a 50-fold excess of glutathione. After 7 days, the MALDI-TOF spectra of test sample aliquots showed only molecular ion peaks of the conjugate and no exchange products, which supports the idea that the disulfide bond contained in the conjugates are of considerable stability.

Currently, we are involved in the construction of an aglycosylated IgG recombinant antibody by site-directed mutagenesis which bears a cysteine residue in lieu of Asn-297. Covalent introduction of defined and activated oligosaccharide thiol derivatives will provide neoglycoconjugates that will enable us to study in detail the relationship between carbohydrate microstructure and biological properties of IgG molecules.

Financial support for this project was provided by the Engineering and Physical Sciences Research Council.

9 In a similar approach, other workers have favored the attachment of iodoacetate-sugar derivatives to the cysteine residues of proteins: N. J. Davis and S. L. Flitsch, *Tetrahedron Lett.*, 1991, **32**, 6793. This approach however suffers the drawback that the resulting *N*-thioacetamide linkage is longer by a CH_2S group than the natural glycopeptide linkage; thus it can be anticipated that many of the protein–oligosaccharide interactions that would normally be in place will be annihilated.

14 Molecular modelling was carried out using MACROMODEL version 5.0 (G. Chang, W. C. Guida and W. C. Still, *J. Am. Chem. Soc.*, 1988, **9**, 343) on a Silicon Graphics Indigo 2 Powerx2 computer. The energy minimisation method was PRCG (relative permittivity = 10) with the United Atom Amber Force field (S. J. Weiner, P. A. Kollman, D. A. Case, U. C. Sigh, C. Ghio, G. Alagona, S. Profeta and P. Weiner, *J. Am. Chem. Soc.*, 1984, **106**, 765; S. J. Weiner, P. A. Kollman, D. T. Nguyen and D. A. Case, *J. Comput. Chem.*, 1986, **7**, 230) in BATCHMIN version 5.0. The torsion angles of the pyranose-ring and the peptide-backbone were maintained during energy minimisation and conformational searches. Using the filter option all conformations with a distance between C-1 and Cys-C^2 of 4.7–5.1 Å were selected. Conformational families were obtained for these conformations using XCLUSTER version 1.2 (P. S. Shenkin and D. Q. McDonald, *J. Comput. Chem.*, 1994, **15**, 899). The distance between corresponding atoms (C-1, C-2, O-5, Cys-C^1, Cys-C^2 and Cys-N) in pairs of structures was used as the criterion. Superimposition of conformations was achieved by selecting pairs of atoms (Cys-C^1, Cys-C^2 and Cys-N).

A new family of olefin polymerization catalysts, derived from iron and cobalt complexes bearing 2,6-bis(imino)pyridyl ligands, is described.

Metallocene catalyst technology has made a dramatic impact on the polyolefins industry, providing access to polyolefinic materials with new or improved performance parameters.[1–7] There is thus great interest in the discovery and development of new families of catalysts for α-olefin polymerisation with a view to obtaining ever greater control over the properties of the resultant polymers and to extending the family of products to new monomer combinations. Late transition metal catalysts are particularly attractive because of their potential for tolerating heteroatom functionalities, which may open up the possibility for copolymerizations of polar comonomers. A significant development in late transition metal polymerization technology was reported by Brookhart and co-workers who showed that catalysts based on nickel and palladium could be used to access a range of linear and branched polyethylenes.[8–11]

Here we describe a new, strikingly active family of ethylene polymerization catalysts based on iron and cobalt bearing 2,6-bis(imino)pyridyl ligands. To the best of our knowledge these are the first iron based catalysts to show significant activities for the polymerization of ethylene. The precursor complexes are prepared by treatment of $FeCl_2$ or $CoCl_2$ with the 2,6-bis(imino)pyridines in excellent yields according to Scheme 1.‡ Derivatives containing a variety of bulky aryl substituents are accessible, the iron compounds **1a**–**d** being blue, while the aldimine complex **1e** and the cobalt compound **2** are green; all are paramagnetic. The magnetic moment of 5.34 μ_B (Evans balance) of complex **1a** indicates a high spin electronic configuration with four unpaired electrons for the d^6 iron(II) centres in these complexes.

Crystals of **1a** suitable for an X-ray structure determination§ were grown from a layered CH_2Cl_2–pentane (1 : 1) solution; the molecular structure is shown in Fig. 1. The complex has molecular C_S symmetry about a plane containing the iron, the two chlorides and the pyridyl nitrogen atom. The geometry at the Fe^{II} centre can probably be best described as distorted square pyramidal, with Cl(1) occupying the apical position. The four basal atoms are co-planar to within 0.02 Å, the iron atom lying 0.59 Å out of this plane. The Fe–Cl bonds are noticeably asymmetric, with that to the apical chloride being significantly longer [at 2.311(2) Å] than that to its basal counterpart [2.266(2) Å]. The Fe–N(imino) distances [av. 2.244(4) Å] are noticeably longer than the Fe–N(pyridyl) bond length [2.088(4) Å], probably as a consequence of satisfying the tridentate chelating constraints of the ligand. The bis(imino)pyridine unit is co-planar to within 0.19 Å, the plane extending to include the basal chloride Cl(2) with the 2,6-diisopropylphenyl rings each being inclined by 79° to this plane. There is no apparent delocalisation of the imino double bonds into the pyridyl ring system, the C(7)–N(7) and C(9)–N(9) bond lengths being 1.285(6) and 1.280(6) Å, respectively.

[a] General conditions: 1 atm Schlenk tests carried out in toluene over 30 min, reaction quenched with dil. HCl and the solid PE washed with MeOH (50 cm^3) and dried in a vacuum oven at 50 °C. 10 atm tests performed in 1 l autoclave, procatalyst dissolved in toluene, isobutane solvent, triisobutylaluminium scavenger, runs carried out over 60 min.

The results of ethylene polymerization tests are collected in Table 1. Several features are noteworthy. In general, the activities of the iron catalysts are exceptionally high, in many cases comparable or even higher than those seen by metallocenes under analogous conditions. All of the catalysts produce essentially linear polyethylene with molecular weights that are dependent upon the aryl substitution pattern. Most notable is a dramatic fall-off in molecular weight to α-olefin oligomers for derivatives with one *o*-methyl substituent (runs 7,8) compared with derivatives that contain methyl substituents in both *ortho* positions. Clearly steric protection of the active site is a crucial factor in controlling molecular weight.

There is also a marked dependence of the polymer molecular weight on ethylene pressure for the iron catalyst system, an effect that is not seen for the cobalt catalyst **2** (runs 10, 11); the cobalt catalyst also displays a considerably lower activity than its iron analogue. ^{13}C NMR end-group analysis of the polymers generated by **1a**–**c** (runs 2, 4, 6) reveals isopropyl end-groups in addition to low levels of vinyl unsaturation. This is consistent with a termination mechanism involving alkyl group transfer from the $AlBu^i_3$ scavenger in addition to β-H transfer. The polymers formed from **1d** and the aldimine catalyst **1e** contain a larger proportion of vinyl end-groups (> 4 per 1000 carbons) indicating that β-H transfer plays a more dominant role in chain termination for these catalysts.

The new catalyst family described herein represents a significant addition to the growing armoury of technologically important olefin polymerization catalysts.

BP Chemicals Ltd is thanked for financial support. Dr J. Boyle and Dr G. Audley are thanked for NMR and GPC measurements, respectively.

FEATURE ARTICLE

Catalysis of liquid phase organic reactions using chemically modified mesoporous inorganic solids

James H. Clark* and Duncan J. Macquarrie

Department of Chemistry, University of York, Heslington, York, UK YO1 5DD

The modification of silicas and related materials by attachment of organic functionalities to their surface is an important area of research in heterogeneous catalysis and green chemistry. The methods available for the preparation of these hybrid organic–inorganic materials are reviewed, as are their applications as catalysts in a range of reactions.

Catalysts played a major role in establishing the economic strength of the chemical industry in the first half of the 20th century. As we approach the first half of the 21st century increasingly demanding environmental legislation, public and corporate pressure and the resulting drive towards clean technology in the industry will provide new opportunities for catalysis and catalytic processes. Some of the major goals of 'Green Chemistry' are to increase process selectivity, to maximise the use of starting materials (aiming for 100% atom efficiency), to replace stoichiometric reagents with catalysts and to facilitate easy separation of the final reaction mixture including the efficient recovery of the catalyst.[1] The use of efficient solid catalysts can go a long way towards achieving these goals.[2] Polymer-supported catalysts have been widely used.[3] Their popularity comes mainly from the fact that product isolation is simplified and that milder conditions and higher selectivity can be attained although they can suffer from limited thermo-oxidative stability. Catalysts based on high surface area inorganic support materials should have better thermal stability and have also attracted a lot of interest as solid catalysts and reagents in liquid phase organic reactions. They form the basis of some new industrial catalysts which are used as replacements for toxic and corrosive traditional reagents.[4] The mesoporous nature of silicas and acid-treated clays for example, allows reasonably good molecular diffusion rates and can lead to activity enhancement through the concentration of active centres.[5] These first generation supported reagent catalysts are, however, based on physisorbed reagents, are frequently unstable in polar media and, consequently, often cannot be reused. An emerging area of research which seeks to retain the 'green benefits' of heterogenisation and enhanced activity and/or product selectivity while avoiding the drawbacks of catalyst instability and limited reusability is the development and use as catalysts of mesoporous inorganic support materials with chemically bound active centres.

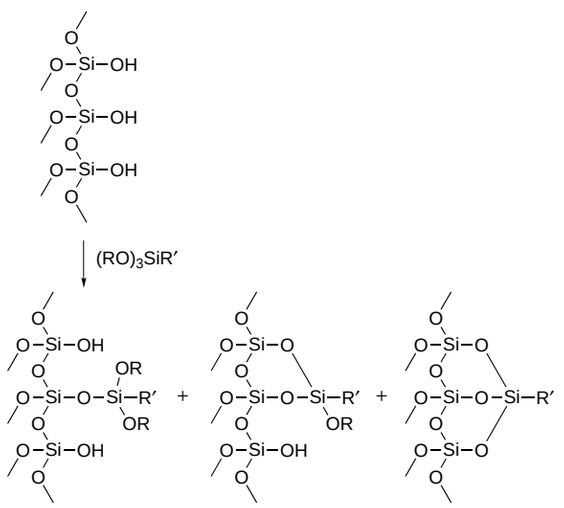
Preparative methodology

A range of possible methodologies exists for attaching organic functionality to the surface of a support. We will concern ourselves primarily with those methods which result in covalent attachment to a silica surface. Thus, purely electrostatic methods, such as those used to attach porphyrins to supports (*via e.g.* sulfonate-supported pyridinium ion pairs) will not be described. Nor will concepts such as the supported aqueous phase catalysts pioneered by Davis amongst others.

Several routes exist for the covalent attachment of organic functionality to the surface of a silica. These include grafting of functional organosilanes, surface chlorination and subsequent displacement, direct sol–gel preparation of organomodified silicas (especially micelle templated versions) and post-functionalisation of existing organic groups at the surface.

Grafting

This remains the most popular method, mostly due to its simplicity, at least in terms of experimental procedures. The silica is reacted with an appropriate organosilane in a suitable solvent, typically toluene at reflux, although ethanol at room temperature is also effective in some cases. The resulting solid is collected and washed (Scheme 1).



Scheme 1 Simplified grafting reaction at a silica surface

This method is versatile and relatively rapid, with many silanes being commercially available. Loadings of organic groups on the surface vary from *ca.* 0.3 mmol g^{-1} for cyanoethyl groups to *ca.* 1 mmol g^{-1} for amine-containing silanes. Loadings for the more recent controlled porosity MCM-based materials† can be significantly higher (1–1.7 mmol g^{-1}). Pore size distributions vary little from the original silica used, although surface areas can drop by a significant amount.[6] While this is a good method for initial studies, drawbacks can include the formation of several surface species resulting from binding *via* one, two or three Si–O–Si groups, attachment of oligomeric silanes, and the presence of physisorbed material, which must be thoroughly washed off before the catalyst can be used in reactions. Loading can often be low, resulting in the need for relatively large amounts of catalyst. Nonetheless, many catalysts have been successfully prepared by this method, and it remains the most commonly used route to new catalysts. The catalytically active group can be present in the silane which is attached to the surface, or can be introduced by subsequent post-modification reactions.

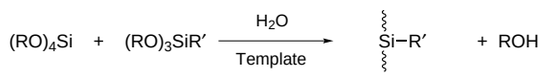
Surface chlorination and subsequent displacement

This is a much less frequently used method, although it has advantages of forming a direct Si–C bond at the surface and precludes the formation of surface bound oligomers and

variable modes of attachment. Groups are robustly bound, and are typically less prone to leaching than those attached *via* grafting. The technique is less easy to use, requiring the reaction of silica with the chlorinating agent, converting surface hydroxyls to Si–Cl bonds, and is typically achieved using thionyl chloride at reflux,[7] or with CCl_4 in a fluidised bed reactor[8] at 400–450 °C. The Si–Cl material thus produced is reacted with a solution of a Grignard reagent or an organolithium species, leading to displacement of the Cl and the formation of a Si–C surface bond. The main drawback in this method is that the requirement for strongly nucleophilic reagents limits the functionality which can be successfully attached. This approach has been used for silicas[8,9] and clays.[7,10] One article describes the exchange of Si–Cl for Si–Li,[10] rather than the normal Si–R, although no reason for this inverted reactivity was given.

Templated sol–gel techniques

This methodology is essentially the co-polymerisation of a silica precursor (typically a tetraalkylorthosilicate) with an organosilicate precursor [typically a trialkoxy(organo)silane] (Scheme 2).



Scheme 2 Templated sol–gel synthesis of organofunctionalised silicas

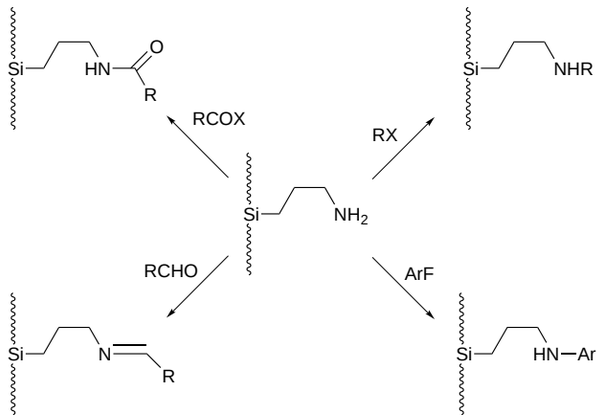
The most important impetus for this approach has come from the discovery of the MCMs, which has allowed the predictable formation of very regular mesoporous materials, which show a great deal of promise as highly selective catalysts. This technique, which was initially used for the preparation of purely inorganic materials, has been successfully extended to include organomodified materials.[11–13]

Reaction conditions are very mild and the procedure is remarkably simple. The materials produced are very thermally stable; organic groups do not detach from the surface at temperatures lower than *ca.* 450 °C, and, as the groups are intimately bound into the surface, they are also solvolytically stable. Loadings can be very high, and are essentially independent of the silane used. We have recently prepared a material with a loading of 3.0 mmol g^{-1}, much higher than those obtainable by grafting. Loading is controlled by the ratio of silanes in the preparation. The surface areas reported are very high, ranging from 700 to *ca.* 1600 m^2 g^{-1}. Typical silica supported reagents have surface areas of *ca.* 75–300 m^2 g^{-1}.

Post modification

This is often a necessary step in the synthesis of chemically modified surfaces, since the range of silanes available is limited (they are also moisture sensitive and can be difficult to work with) and the use of Grignard or organolithium reagents means that the chlorination methodology can only be used with a few functional groups. One of the commonest grafted functions is the primary amine, usually *via* the cheap 3-aminopropyl-(trimethoxy)silane. This group behaves like a typical amine function, and can thus be derivatised by formation of amides or imines, and by alkylation. Nucleophilic aromatic substitution of suitable activated rings is also possible (Scheme 3).

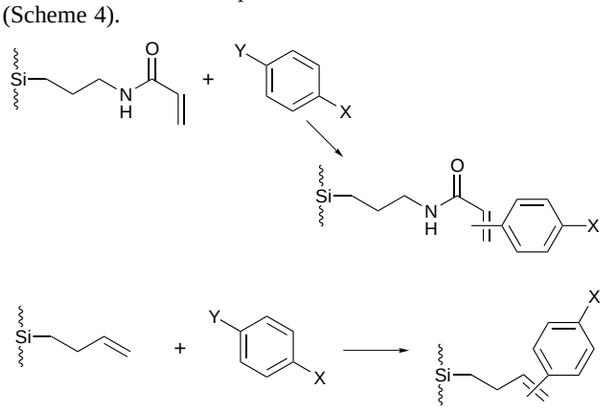
The formation of amides can be carried out with anhydrides, acids or acid chlorides. Esters will also form amides, although slowly.[14] A particularly attractive option is to use acids without solvent in a vapour phase reaction at 150–170 °C. For example, 4-aminobenzoic acid can be reacted to form the silica-bound amide by mixing with the amine-functionalised silica in the absence of solvent and heating to 170 °C under vacuum.[15] This allows the vapour to enter the pores of the catalyst and react. Water and excess acid are removed under the reaction conditions, leaving the surface bound amide. The supported aniline thus formed can be further functionalised *via* diazonium



Scheme 3 Reactions of aminopropyl-functionalised silica

chemistry, and forms the basis for an effective base catalyst.[16] The attachment of a silane to a surface often allows the selective monofunctionalisation of a doubly functional molecule. This approach has been used in the synthesis of the supported metal salt depicted in Scheme 6, a very versatile and active oxidation catalyst (see following section).[17]

Newer methods for the functionalisation of surface bound alkenes (from chlorination/displacement routes) include the Heck reaction.[18] This methodology allows the attachment of a variety of aryl groups to the surface under solvent free conditions at temperatures between 130 and 150 °C (Scheme 4).



Scheme 4 The functionalisation of surface alkenes *via* the Heck reaction: X = H, CHO, CO_2H, CN; Y = Br, I

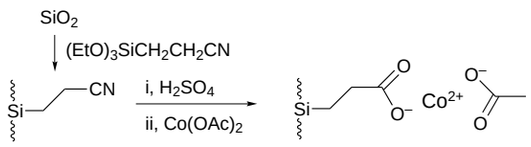
The use of the resulting materials in catalysis is currently under study.

Catalysis of oxidation reactions

Oxidation is the area where chemically modified surfaces have found most use. A wide variety of materials have been prepared, using several methods for attaching the organics to the surface, with many areas of oxidation chemistry benefiting from the materials thus derived.

We recently reported a simple immobilised form of $Co(OAc)_2$ which is capable of the epoxidation of alkenes.[19] This material was prepared according to Scheme 5.

This is a remarkable result, since the organo-functionalised silica is shown to survive the harsh conditions required to



Scheme 5 Preparation of supported $Co(OAc)_2$

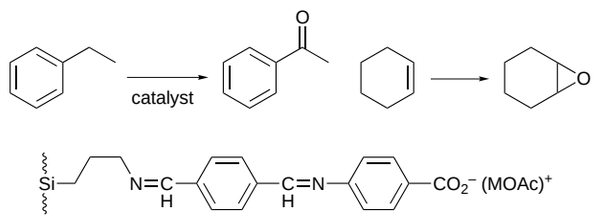
hydrolyse the nitrile group (50% H_2SO_4 at reflux, 24 h). The materials was found to efficiently catalyse the epoxidation of alkenes using sacrificial aldehydes and oxygen (Table 1).

Table 1 Epoxidation of alkenes using supported cobalt acetate

Alkene	*t*/h	Yield of epoxide[a]
Cyclohexene	5	85
Oct-1-ene	5	45
Octa-1,7-diene	24	48[b]
2,4,4-Trimethylpentene	5	95
Hex-1-ene	24	30
Styrene	3	32[c]

All reactions were carried out at 19 °C in dichloromethane with isobutyraldehyde as sacrificial aldehyde. [a] GC yield with internal standard. [b] Monoepoxide; 7% of diepoxide was also formed. [c] 5% PhCHO and 21% polymer also formed.

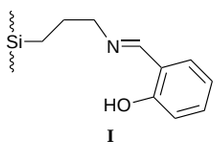
A related catalyst type has been recently reported,[17] where the metal centre is supported by a longer spacer chain (Scheme 6). This material was prepared from aminopropyl-silica by reaction with terephthalaldehyde to form the monoimine (attachment of the amine to the surface precludes reaction at both ends of the dialdehyde), followed by formation of a second imine with *p*-aminobenzoic acid. The supported acid was then treated with metal acetates to generate the active catalyst.



Scheme 6 Reactions catalysed by supported metal acetates

The catalyst is active in the same epoxidation reaction as the supported Co acetate above. Interestingly, the Ni version is most active, followed closely by Cr and Cu, with Mn and Co being distinctly poorer. Of particular interest is the ability of this catalyst to carry out the oxidation of alkyl aromatics. In this case the Cr version is the best, and allows a conversion rate of 370 turnovers h^{-1} to be achieved.

Kurusu and Neckers have also prepared simple complexed metal species on silica, based on the salicylimine species **I**:



I

The metals complexes show some activity in the oxidation of cyclohexane[20,21] and in alkylaromatics.[21]

Jacobs and coworkers have prepared an active epoxidation catalyst based on supported metal complexes with the triazacyclononane ligand system.[22] Both silicas and MCMs were used as supports. The catalysts were prepared by the reaction of the cyclic ligand with a supported glycidyl material, in the case of the MCM, and with both glycidyl and chloropropyl in the case of the silica. The ligand system was then modified by reacting the two free amines with propylene oxide, and subsequent metal complexation. The epoxidation of styrene was used as a test reaction. Selectivities and turnover numbers (mol h^{-1}) were higher in the case of the MCM-derived materials than the silicas, regardless of the nature of the supported ligand.

Metalloporphyrins have also been the subject of much work, and several routes have been developed to attach them to heterogeneous supports. Porphyrins are expensive, and thus recovery becomes economically important. It is also possible that attachment to a surface may hinder destructive oxidation of the electron rich ring system, a factor which traditionally limits their useful lifetime. The use of charged groups, typically ammonium or sulfonate attached to the periphery has been used to enhance adsorption to polar supports such as silica and magnesium oxide.[23,24] Direct covalent binding to silica surfaces has been achieved by coordinative binding of the metal centre to supported imidazoles, pyridines, *etc*.[25,26] The second mode of attachment is *via* aryl groups attached to the periphery of the ring system. Thus, Mansuy and coworkers have used aminopropyl silica to tether a perfluorophenyl-substituted porphyrin.[27] These approaches are summarised in Fig. 1.

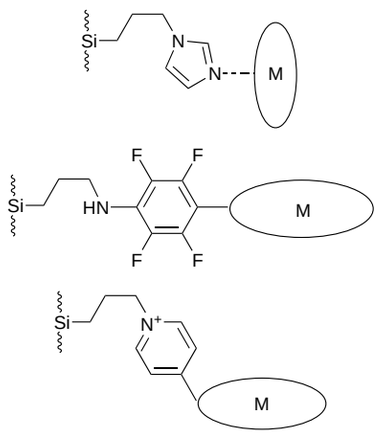


Fig. 1 Examples of covalently bound porphyrins

A second approach is the nucleophilic displacement of chloride from chloropropylsilica with a pyridine-substituted porphyrin.[28] These materials are active in the epoxidation of alkenes, where iodosylbenzene is the preferred oxidant, and in the oxidation of alkanes to alchols and ketones.

A further example of this approach is the copolymerisation of a porphyrin containing four attached trimethoxysilane groups with tetraethoxysilane, leading to an active hybrid silica–porphyrin.[29]

Finally, one problem relating to the oxidation of hydrocarbons with hydrogen peroxide is the difficulty of having appreciable concentrations of the non-polar substrate and the polar oxidant together at the catalytic centre. One elegant solution has recently been published by Neumann and Wange.[30] They have shown that attachment of a mixture of poly(ethylene oxide) and poly(propylene oxide) to a silica, followed by the physisorption of methylrhenium trioxide allows the efficient mixing of both reaction partners (Fig. 2). The catalyst allows the efficient epoxidation of alkenes with hydrogen peroxide.

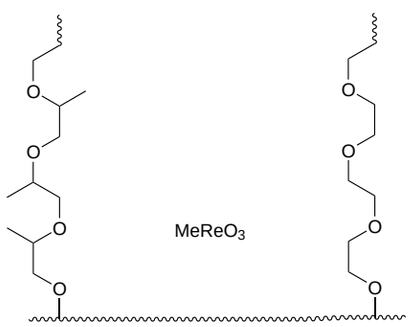

Fig. 2 Polyether modified supported methylrhenium oxide

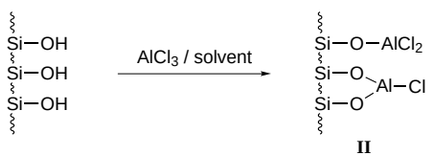
A mix of the two polymeric chains was shown to be better than a single type of chain. This is attributed to a combination

of the relatively hydrophilic poly(ethylene oxide) and the more hydrophobic poly(propylene oxide) giving the right balance of properties, and allowing optimum mixing of the two reagents.

Solid acid catalysts

Solid acids are the most widely studied and commonly used heterogeneous catalysts. Their use however, is heavily biased towards large-scale continuous vapour phase processes such as catalytic cracking and alkane isomerisations. There is also a great need for solid acid catalysts which are effective in liquid phase organic reactions such as those employed in many batch-type reactors by fine, speciality and pharmaceutical intermediate chemical manufacturers. These include Friedel–Crafts alkylations, acylations and sulfonylations, isomerisations, dehydrations, oligomerisations and aromatic halogenations and nitrations. At present these reactions are commonly catalysed by mineral acids such as H_2SO_4 and HF and by Lewis acids such as $AlCl_3$ and BF_3. These traditional reagents suffer from many drawbacks including hazards in handling, corrosiveness, and difficulty in separation along with the inevitable production of often large volumes of toxic and/or corrosive waste. Solid acids based on organic polymers such as ion-exchange resins and Nafion are available but suffer from poor stability or high cost whereas supported reagents such as 'clayzic' (acid-treated clay supported zinc chloride)[31] have a limited range of applications and their weak support–reagent interaction may result in leaching of metal ions into polar media. The development of active and truly catalytic, heterogeneous alternatives to traditional soluble or liquid acids is a very important goal in green chemistry and while solid acids based on organically modified supports are relatively uncommon, significant progress using supports which have been chemically modified by reaction with Lewis acids has recently been made in our laboratory and elsewhere.

Aluminium chloride is one of the most widely used inorganic reagents in organic chemistry, being highly soluble and very active. However, its many drawbacks, such as its corrosive nature, difficulties in separation and recovery, and the large volumes of environmentally hazardous waste associated with its use, make it a prime target for heterogenisation.[4,32] We have reported an active heterogeneous form of aluminium chloride which is highly effective at least in Friedel–Crafts alkylation reactions.[33] The material **II**, which is believed to contain a mixture of $OAlCl_2$ and O_2AlCl sites, is prepared by reaction of a surface-hydroxylated high surface area mesoporous inorganic solid such as silica gel or acid-treated montmorillonite with aluminium chloride in a low-polarity aprotic organic solvent (Scheme 7).



II

Scheme 7 Preparation of supported aluminium chloride

The optimum loading is support dependent with the higher surface area mesoporous silica gel having an optimum loading (1.5 mmol g^{-1}) twice as high as that of K10 montmorillonite. The former catalyst is also a little more active and selective towards monoalkylation although K10 is a less expensive support material.

Previous attempts at preparing immobilised aluminium chloride have met with limited success. Catalysts prepared in the vapour phase or from a CCl_4 solution have proved to be active in the gas phase (*e.g.* in cracking reactions) but their activity in liquid phase reactions has generally been poor.[34] Catalysts of this type should be differentiated from those which undergo a final high temperature calcination stage after treatment with a soluble aluminium salt. Thus various mesoporous materials such as MCM-41, MCM-48, SBA-1 and KIT-1 have been treated with reagents including ethanolic solutions of $AlCl_3$ and $Al(NO_3)_3$ and slurries of $Al(OPr^i)_3$ in non-polar solvent (*e.g.* hexane) followed by calcination of the resulting solid at temperatures of > 800 K to give solid acids.[35,36] This typically results in the formation of tetrahedral (framework) and octahedral (non-framework) Al. Such materials are more commonly associated with vapour phase reactions such as cracking.[36]

The catalyst represented by **II** shows excellent activity in the room temperature alkylation of benzene with alkenes.[33] Its activity is comparable to that of aluminium chloride but it shows improved selectivity towards monoalkylation compared to $AlCl_3$ itself and is readily recoverable and reusable (unlike $AlCl_3$ which need to be removed from the reaction after one use, typically by a water quench). The reaction can be extended to alkylbenzenes but halobenzenes are considerably less reactive presumably because of complexation of the polarisable halogen centre to active catalyst centres (Table 2).

Table 2 Activity of (optimised) supported aluminium chloride solid acids in the alkylation of aromatic substrates [2 : 1 mol ratio of ArH to alkene; 10 g catalyst (mol ArH)$^{-1}$]

Substrates	Catalyst	Reaction conditions *t*/h (*T*/°C)	Monoalkyl-aromatic yield (GC%)
PhH + oct-1-ene	$AlCl_3$	2(20)	61.6
PhH + oct-1-ene	SiO_2(70 Å)-$AlCl_3$	1.25(20)	78.3
PhH + oct-1-ene	K10-$AlCl_3$	2(20)	76.3
PhH + hex-1-ene	K10-$AlCl_3$	2(20)	69.2
PhH + dodec-1-ene	K10-$AlCl_3$	2(20)	77.3
PhH + hexadec-1-ene	K10-$AlCl_3$	2(20)	71.0
PhMe + oct-1-ene	K10-$AlCl_3$	1.5(20)	80.9
PhEt + oct-1-ene	K10-$AlCl_3$	3.5(20)	74.3
PhF + oct-1-ene	K10-$AlCl_3$	4(20)	29.6
PhCl + oct-1-ene	K10-$AlCl_3$	4.5(20)	14.2

It is interesting that reaction of mesoporous silica gel with $MeAlCl_2$ under similar conditions gives a catalyst with comparable activity to that prepared using $AlCl_3$. In contrast, reaction of $MeAlCl_2$ with K10 gives an appreciably less active catalyst, an observation that is consistent with the theory that the HCl released during the reaction of $AlCl_3$ with the clay helps to convert the more microporous clay structure into a more mesoporous silica structure[37] ($MeAlCl_2$ reacts with the surface hydroxyls by elimination of CH_4). Remarkably, $MeAlCl_2$ itself is less active again[33] suggesting that the methyl group is more deactivating than the support surface although the presence of isolated Lewis acid sites on the surface, rather than dimers in solution, may be a more important factor.

We have shown that it is possible to extend the methodology for supported aluminium chloride for liquid phase applications to the relatively new hexagonal mesporous silicas as supports (HMSs).[38,39]† Activity in the alkene alkylation of alkylaromatics is again comparable to that of $AlCl_3$ itself, and the solid acids are also easily recovered and can be reused. Most significantly, the increase in selectivity towards monoalkylation through the use of the heterogenised Lewis acid is further enhanced (Fig. 3). By using external site poisons such as Ph_3N (to block external acid sites through complexation) or Ph_3SiCl (to destroy external hydroxyl groups), there is a still greater increase in selectivity with close to 100% monoalkylation being achievable with hexadec-1-ene. This may be the first significant illustration of zeolitic like effects (in-pore selectivity) in catalysts based on these structured mesoporous materials operating in the liquid phase. The extension of this phenomenon from the small molecules transformed by zeolites to large molecules is clearly very important. It promises significant improvements in product selectivity, while maintaining the

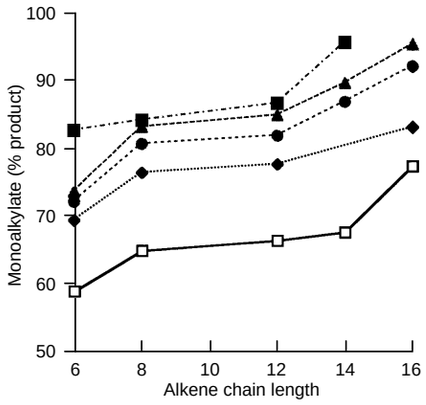


Fig. 3 Selectivity *vs*. chain length for a series of alkenes with HMS catalysts. (□) $AlCl_3$, (◆) $AlCl_3$/K10, (●) $AlCl_3$/HMS24, (▲) $AlCl_3$/HMS24-TPS, (■) $AlCl_3$/HMS24-Ph_3N; TPS = triphenylsilyl. HMS24 refers to a parent HMS with av. pore diameter 24 Å.

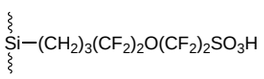
relatively fast reaction rates that mesoporous catalysts can give in liquid phase organic reactions.

It seems likely that heterogeneous versions of other very active Lewis acids can be prepared by similar methods although there are few other references to this in the existing literature. Iron(III) chloride should be reactive enough to form surface $OFeCl_2$ bonds for example and a stable form of supported $FeCl_3$ has been recently reported.[40] The material has been used to catalyse liquid phase Friedel–Crafts benzoylations[40] reminiscent of a commercial catalyst[41] although the surface structure and activity on reuse of the catalyst have not been described.

Brønsted acids can also be fixed to the hydroxylated surfaces of support materials. Most spectacularly surface attached perfluorosulfonic acids have been reported[42] which supercede the perfluorinated sulfonic acid resin (Nafion)-silica composites reported a year earlier.[43] The route to these requires the preparation of the new reagent $(OH)_3Si(CH_2)_3(CF_2)_2O(CF_2)_2SO_3^-M^+$ which is then bonded to an existing support or incorporated in an *in situ* sol–gel technique to give the novel silica based solid acid **III**.



III

The materials are catalytically active for a number of typically acid-catalysed liquid phase organic reactions such as alkene alkylations of aromatics (although they are considerably less active than the supported aluminium chloride described above) and the benzoylation of activated aromatics such as *m*-xylene. They are orders of magnitute more active than conventional acidic ion exchange resins.

On a somewhat more mundane level, there are various reports of solid Brønsted acids derived from reaction of support materials with conventional liquid acids although the nature of the support–acid interaction and catalyst stability are generally not well understood. Thus simple treatment of silica gel with sulfuric acid followed by mild drying gives a solid acid that is active in various aromatic nitrations (nitric acid or isopropyl nitrate as nitrating agent).[44] Activity of the solid acid is comparable to the more expensive Nafion-H.

Heterogeneous versions of heteropoly acids have also been prepared. Apart from direct deposition into support materials, they can be more firmly bonded to the surface through chemical surface modification. Acids such as 12-tungstophosphate (PW_{12}) will react with silica gels which have been treated with aminoalkylsilanes.[45] The acidic site of PW_{12} reacts with the surface-bound amino group. The activities of such catalysts are generally higher than those of supported reagents prepared by direct deposition[45] and it is likely that further improvements are achievable by using the structured hexagonal mesoporous materials.[46]

Base catalysis

The use of supported basic groups as heterogeneous catalysts has been researched by a few groups over the last decade. The majority of work has been carried out on the simple 3-aminopropyl-derivatised silica. A variety of papers has been published describing the use of this material as an efficient catalyst for the Knoevenagel reaction.[47–49] Most of the papers deal with the relatively facile reaction of benzaldehyde with nucleophiles such as ethyl cyanoacetate and malononitrile. We have carried out an indepth study of this reaction system with a variety of aldehydes and ketones, and have shown that this simple material is indeed a versatile and active catalyst.[14] Several important features have emerged. One of the most important parameters is the solvent, a recurrent theme in heterogeneous liquid phase catalysis. In this case the solvent must play two roles. Firstly it must remove water from the system. The reaction is reversible, and the rates of all but the simplest reactions are significantly reduced by the presence of water. Secondly, the partitioning of reactants between the solvent phase and the catalyst surface is important. Since the catalyst surface is probably the most polar phase in the system, the use of non-polar solvents will allow the reagent to preferentially adsorb onto the catalyst surface (polar solvents will compete for the surface). Both these criteria are met by hydrocarbon solvents such as alkanes. Indeed it was found that the rates of reaction varied with solvent according to the following order: cyclohexane > toluene > 1,2-dichloroethane > chlorobenzene when the reaction was performed at the boiling point of each solvent. Even the higher temperature used with toluene and chlorobenzene did not bring about a rate close to that of cyclohexane (Fig. 4).

Interestingly, the much more polar[50] catalysts based on aminopropyl groups incorporated into hexagonal mesoporous silicates (HMS)[51,†] show essentially the same trend, although

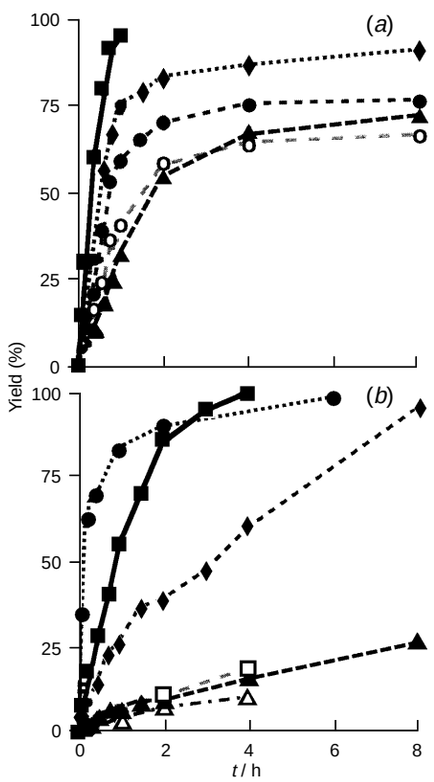


Fig. 4 Solvent effects in the Knoevenagel reaction using aminopropyl silica (*a*) and aminopropyl HMS catalysts (*b*); (■) cyclohexane, (●) toluene, (◆) hexane, (▲) 1,2-dichloroethane, (□) chloroform, (○) chlorobenzene, (△) ethyl acetate

the more polar surfaces of the HMS materials mean that toluene is the optimum solvent, with partition onto the catalyst surface still being favourable even with the more polar solvent. Increasing the solvent polarity further again reduces the rate dramatically.

Reaction studies on both sets of catalysts showed that both materials were active for a variety of reactions (Table 3).

[a] GC yields with *n*-dodecane as internal standard. Isolated yields are 5–10% lower. [b] Number of mol product per mol of NH_2 groups. Catalyst **1** is aminopropyl-silica; catalyst **2** is aminopropyl-HMS.

Aldehydes and ketones (aliphatic and aromatic) both react readily, as had been shown by previous authors and turnover numbers are generally good (200–600). The poisoning mechanism was also shown to be due to amide formation by reaction of the amine with the ester group of ethyl cyanoacetate. The HMS catalysts are generally slightly less active when compared directly, but their ability to function well in toluene, and the much higher loadings achievable (2.5 *cf.* 1.0 mmol g^{-1}) means that under optimum conditions they can match the silica catalysts in terms of rate. Their turnover numbers are typically higher by a factor of 4–5, and the poisoning mechanism is different. These materials thus display a great deal of promise as novel catalysts. Rates, selectivity and conversion were found to be much higher than for typical homogeneous conditions (piperidine as base).

Brunel and coworkers[52] have studied aminopropyl-grafted MCMs as catalysts for this reaction. They used Me_2SO as solvent, and achieved complete conversion of reactants (benzaldehyde and ethyl cyanoacetate) after 100 min. They also found that a supported piperidine catalyst (prepared by reaction of piperidine with chloropropyl-MCM) was significantly less active as a catalyst. Unfortunately, the different conditions used preclude meaningful comparison with the materials mentioned above at this time.

We have recently described the preparation and use of two novel base catalysts (Fig. 5) which have phenolates as the basic centre.[16] One was prepared using the amidation/diazonium chemistry described above, the other using alkylation of surface bound amine groups with a polyether tosylate. The catalysts are active in the Michael addition, and extension of the methodology to enantioselective catalysis is currently underway.

Solid catalysts for other applications

The concept of triphase catalysis, whereby a phase transfer catalyst (PTC) is immobilised onto a support material and the

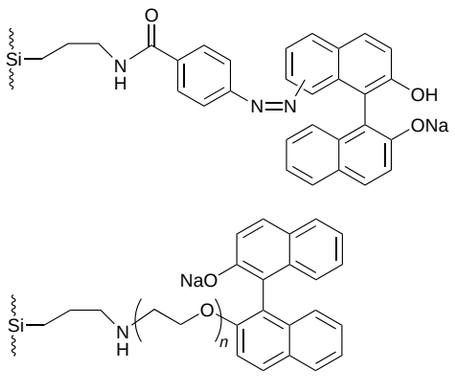

Fig. 5 Supported phenolates derived from diazotisation of surface bound aniline and from alkylation of surface bound amine

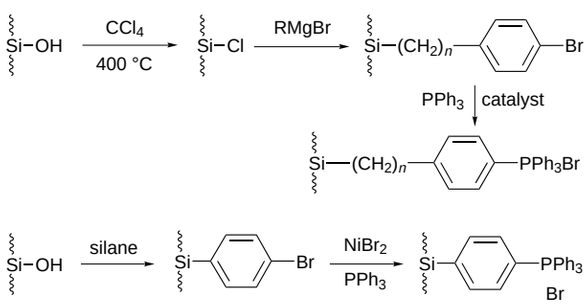
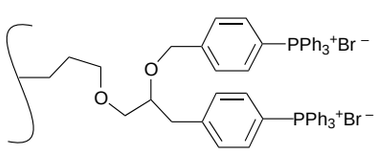
resulting supported PTC is then used in a biphasic aqueous–organic solvent reaction mixture is well established. We have recently reported a series of supported tetraarylphosphonium PTCs which show particularly high thermal stabilities and useful activities in nucleophilic substitution reactions and aromatic oxidative brominations.[9,53,54] The catalysts are often reusable and are effective in non-polar solvents such as hydrocarbons even when the unsupported phosphonium salt is inactive (owing to poor solubility, the supported catalysts are believed to operate at the aqueous–organic interface). The catalysts can be prepared by a variety of methods as shown in Scheme 8.



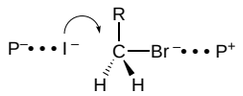
Scheme 8 Preparation of heterogeneous phase transfer catalysts

The most remarkable of these catalysts is the mesoporous silica based material which contains two adjacent phosphonium centres referred to as a 'bicipital supported phosphonium phase transfer catalyst' IV.[9]



IV

This catalyst is considerably more active than other supported phosphonium salts in the model nucleophilic substitution reaction of 1-bromooctane with potassium iodide. It is also very dependent on the pore size of the silica with an average pore diameter of *ca.* 100 Å giving the highest activity; this is consistent with more simple physisorbed silica-based supported reagents and seems to support the view that for liquid phase reactions catalysed by porous solids, a reasonably large pore is required to give a good molecular diffusion rate.[2,5] Most significantly, the analogous material with only one of the aromatic rings substituted with a phosphonium group is significantly less active per phosphonium centre than the bicipital material. It is likely that the neighbouring centres can

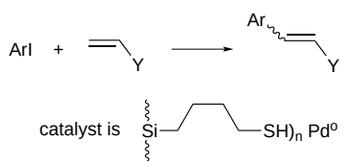


Scheme 9

produce a synergistic effect through simultaneous polarisation of the C–Br bond by one phosphonium centre and attack by the I^- delivered by the other cation (Scheme 9).

This is supported by the unusually low activation enthalpy and entropy found for reactions catalysed by the bicipital material, which are consistent with a lower energy pathway and a more ordered transition state.[9]

Chemically modified solid supports can also make very effective ligands for metal ions enabling heterogenisation of many valuable catalyst structures. These are to be distinguished from the very many examples of supported metals and metal oxides which are often prepared *via* metal complexes which are then decomposed in a final, typically high temperature stage.[55] The immobilisation of palladium and applications of the resulting solid catalysts in important reactions such as carbonylation, amidation and carbon–carbon forming coupling reactions are good examples of this.[56–58] Apart from organic polymer based materials, catalytically active clay and silica supported palladium complexes are known. These include a silica-supported sulfur palladium complex which can be used to catalyse the arylation of styrene and acrylic acid at 100 °C[57] (Scheme 10).



Scheme 10 Arylation reactions catalysed by supported Pd centres

Other metals can be similarly immobilised. Remarkably, the heterogenisation process can confer dramatically enhanced activity on the metal complex. Thus, the dimolybdenum complex $[Mo_2(MeCN)_8]BF_4$-SiO_2 prepared by direct reaction of the silica with the metal complex is unusual in its ability to catalyse the polymerisation of norbornene in the absence of an aluminium co-catalyst and at moderate temperatures.[59] Catalysts can be made directly by sol–gel methods. Thus sol–gel processing of the ruthenium complex *cis*-$[RuCl(H)(CO)(P)_3]$ (where P is a coordinated ether–phosphine) with tetraethoxysilane and $[Al(OPr^i)_3]$ gives a stable material with moderate surface area which is active in the hydrogenation of *trans*-crotylaldehyde with reasonable chemoselectivity to the carbonyl reduced products, *cis*- and *trans*-crotyl alcohol.[60]

Non-metallic chemically modified solids have also been developed for liquid phase catalytic applications. Silica-supported guanidinium chloride for example, has been shown to have high efficiency in the decomposition of methyl chloroformate (into MeCl + CO_2) and electrophilic reactions of carboxylic acids and epoxides.[61]

Recent advances in solid state synthesis offer some interesting possibilities for the future. Thus the preparation of a biomolecular tether device based on a silica support chemically modified with 4,4′-azodianiline units and its successful use in binding a peptide residue[62] suggests potential for biocatalysis. Covalently bound calixarenes[63] help demonstrate complex surface structures which could be used to bind catalytically active metal ions. Our recently reported highly fluorinated materials derived from the reaction of perfluorocarboxylic acids with aminopropyltrimethoxysilated silica may also point the way forwards.[64] These materials are capable of reversibly binding perfluorocarboxylates to the exclusion of other salts. Clearly the improved selectivity that could result from adding molecular recognition to the already impressive list of attributes of chemically modified mesoporous solids will further enhance their growing popularity.

† MCMs are silicas or aluminosilicates, prepared by polymerisation of silicon (and aluminium) containing monomers around micelles of quaternary ammonium surfactants. HMS refers to analogous materials prepared using micelles of long chain amines. We originally called the organomodified materials MCMs. According to the above scheme of nomenclature, these materials should be referred to as derivatives of hexagonal mesoporous silicas (HMS).

Highly stereoselective indium trichloride-catalysed asymmetric aldol reaction of formaldehyde and a glucose-derived silyl enol ether in water

Teck-Peng Loh,*† Guan-Leong Chua, Jagadese J. Vittal and Meng-Wah Wong

Department of Chemistry, National University of Singapore, 10 Kent Ridge Crescent, Singapore 119260

The yield and stereochemical outcome of the reaction between D-glucose-derived silyl enol ether 1 (*Z* and *E* isomers) and commercial formaldehyde in water catalysed by indium(III) choride was studied.

The many possible advantages of performing carbon–carbon bond formation in aqueous media has resulted in studies by several groups. This relatively unfamiliar territory, especially reactions that are done without organic solvents, lends itself to exploration in terms of reaction characteristics and stereochemical behaviour.[1]

Here we report an efficient and highly stereoselective aldol reaction between commercially available aqueous formaldehyde (37% in water) and silyl enol ether **1**, which can be easily obtained using glucose as starting material (Scheme 1). The reaction conditions chosen have allowed for formaldehyde to be used without prior dissolution or *in situ* generation in highly basic or acidic conditions from paraformaldehyde, as compared to reactions in organic solvents.

The use of **1** has allowed for the study of asymmetric induction *via* the chiral centers and steric bulk of the various groups. In addition, we aim to provide a stereoselective one-carbon extension of glucose under mild conditions employing readily available starting materials, in contrast to existing methodologies.[2] Previously reported use of commercial formaldehyde solution for Mukaiyama aldol reactions using lanthanide triflates was unable to be carried out efficiently in the absence of organic solvents.[3] Our aim in completely excluding organic solvents had led us to our choice of $InCl_3$ as a water-stable Lewis acid from our earlier work.[4] We had also studied the characteristics of the unexplored $In(OTf)_3$ and did a comparative study with the lanthanide triflate $Yb(OTf)_3$. Our study demonstrated the superiority of $InCl_3$ in terms of yield and selectivity.

Ketone **5**, precursor of silyl enol ether **1**, was derived from diacetone D-glucose in two steps (Scheme 2). Deprotonation of C-6 using LDA and subsequent trapping of the enolate with trimethylsilyl chloride gave (*Z*)-**1** and (*E*)-**1** in an approximate ratio of 80 : 20 [Scheme 3, reaction conditions (i)]. The ratio of the isomers was determined *via* ^{1}H NMR spectroscopy, through integration of the α-vinylic proton resonances, with the *Z*-isomer at a lower field than the *E*-isomer.[5]‡

The aqueous Mukaiyama aldol-type reaction was performed by first activating the formaldehyde (commercial solution, 37% in water, 2 equiv.) using Lewis acid (0.4 equiv. $InCl_3$, 0.02 equiv. $In(OTf)_3$ or 0.4 equiv. $Yb(OTf)_3$) and then adding this solution to the silyl enol ether. The reaction mixture was then stirred vigorously§ at room temperature and monitored by TLC for complete consumption of **1**. Aqueous workup followed by flash chromatography gave the desired products. The results are shown in Table 1 (entries 1 to 3). The low yield observed for the reaction catalysed by triflates was due to the significant conversion of **1** to the ketone, particularly with 0.4 equiv. of $In(OTf)_3$, and deprotection of C-6 hydroxy group from the product **2**. Diastereoselectivities obtained were good, with catalysis by $InCl_3$ proceeding with excellent selectivity.¶ The stereochemistry about C-6 of product (*R*)-**2** was determined by X-ray crystallographic analysis of (*R*)-6 obtained from deprotection of the C-6 hydroxy group (Scheme 4).‖

The lack of correlation between the isomer ratio of **1** and the diastereoselectivities of the products suggests that both isomers gave the same major product *via* conformational preference

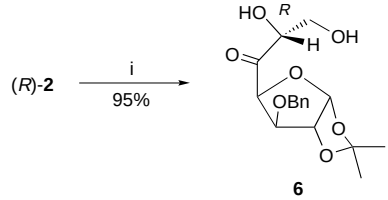

Scheme 4 *Reagents and conditions*: i, TBAF, THF, 0 °C, 1 h

governed by thermodynamic factors. To further investigate this, we managed to obtain exclusively (Z)-**1** by use of Et_3N as base instead of LDA [Scheme 3, reaction conditions (ii)].[6] Reaction of (Z)-**1** with formaldehyde using $InCl_3$ as catalyst results in a (*R*)-**2** : (S)-**2** ratio of 82 : 18 (Table 1, entry 5), a lower diastereoselection from that previously obtained. Similar trends were also observed with the triflates as Lewis acids (Table 1, entries 6 and 7).

To rationalise our results, we propose the existence of a preferred path of approach of the formaldehyde nucleophile owing to the steric requirements imposed by the rigid silyl enol ether. Hence, diastereofacial selection would depend on the favoured conformation of the silyl enol ether. Standard *ab initio*[7,8] studies carried out for the four possible conformers of silyl enol ether **4** are in good accord with the experimental finding that the *R*-isomer is the preferred observed product (Fig. 1).

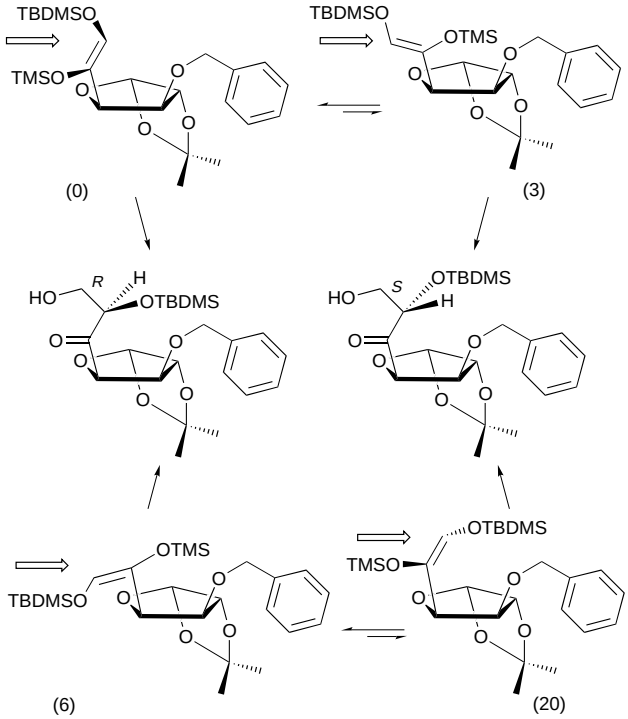

Fig. 1 Numbers in parentheses denote the calculated relative energies in kJ mol^{-1}

In effect, this methodology exploits the structure provided by the glucose derivative to achieve a highly stereoselective means of one carbon extension under mild and readily accessible reaction conditions. This, together with the well-established chemistry of the carbohydrates, would provide for its adaptation to natural product syntheses.

A likely pathway to the sex pheromones of *Bactrocera oleae* (olive fruit-fly) is presented, based mainly on feeding experiments with deuterium labelled precursors.

There is little knowledge of the chemistry, enzymology or molecular biology of the biosynthesis of fruit-fly pheromones which could be linked with the known chemistry[1,2] of these species to facilitate species-specific monitoring and control. We now describe experiments with the pestilent species, *Bactrocera oleae* (olive fruit-fly),[1,3] that permit a proposal for the biogenesis of the (female) pheromone, which is essentially one component.[4] This suggests the operation of a single, major biosynthetic pathway for study, and possible disruption.

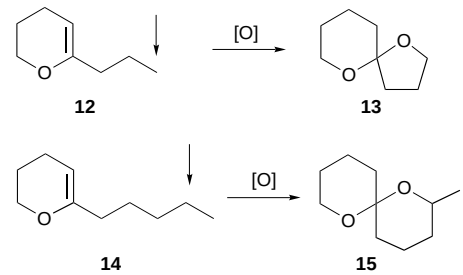
The major component of the pheromone is racemic 1,7-dioxaspiro[5.5]undecane **1**[5] which is accompanied by low levels (*ca.* 3%) of hydroxy derivatives **2**–**4**.[6] We selected 6-*n*-butyl-3,4-dihydro-2*H*-pyran **5**[7] for investigation as an advanced precursor of **1**[8] for the following reasons. Although **5** has not been identified in the olive fruit-fly, it co-occurs with **1** in *B. cacuminata*,[9] in which keto alcohol **6a** also occurs; dehydration of the corresponding hemiketal **6b** would afford **5**. Secondly, 2-methyl-6-*n*-pentyl-3,4-dihydro-2*H*-pyran **8**[10] and keto alcohol **9** accompany isomers of 2,8-dimethy-1,7-dioxaspiro[5.5]undecane **10** in *B. halfordiae* and *B. kraussii*,[2] so that the nexus that applies to **5** and **1** also applies to **8** and **10**. Appropriate side-chain hydroxylation of these dihydropyrans (**5** and **8**) followed by cyclisation would yield the corresponding spiroacetals **1** and **10**.

A [$^2H_3$]-labelled analogue of **5**, *viz* **11**, was prepared from [$^2H_6$]-propanone,[11] and essentially complete deuteration at the indicated positions in **11** was confirmed by ^{1}H and ^{13}C NMR and mass spectral analyses.‡ Examination by GC–MS of the rectal glandular contents of female olive flies, subsequent to the receipt of diet-administered **11**, established that **1** was now significantly ^{2}H-enriched, as were the accompanying hydroxyspiroacetals **2**–**4**, and the fragmentation patterns confirmed that deuterium was located at the anticipated positions α to the spiro centre. In this and in other cases described here, variation is isotopic composition for **1** was observed by progressive mass spectral examination from the foreside to the centre of the GC peak. More highly deuterated species elute earlier.[11] These examinations showed at least 40% of **1** incorporated deuterium. It is possible that *in vivo* hydration of **5** to form the hydroxy ketone **6a** (or the corresponding cyclic hemiketal **6b**) provided the real substrate for methyl oxidation. Thus, **7** (a deuterium analogue of **6**) was synthesised and administered and resulted in efficient formation of labelled **1**, indicating that **6** is also a possible penultimate precursor of **1**.

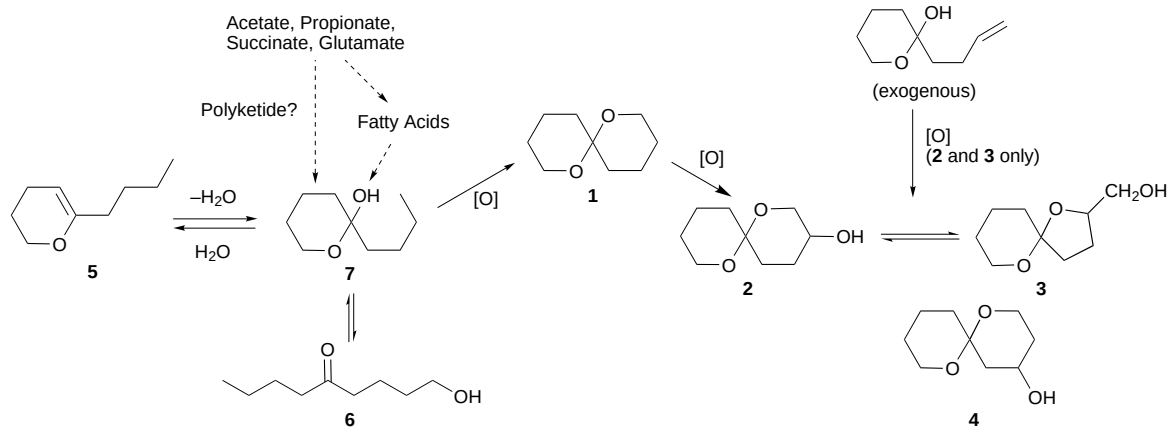
To explore the nature and specificity of the presumed side-chain oxidation, dihydropyrans **12** and **14** were also administered to female olive flies and inefficient oxidation (compared with **11**) occurred, to provide low levels of the known spiroacetals **13** and **15**,[2] respectively (Scheme 1). To the best of our knowledge these have never been detected in olive fruit-flies under natural conditions. Labelled alkenes **16** and **17**, which correspond to possible precursors of the hydroxyspiroacetals **2** and **3**, were also administered to whole female *B. oleae*. Analyses confirmed that deuterium from **16** or, more effectively, **17** was specifically incorporated into **2** and **3**, but not **4** or the parent spiroacetal **1**. This outcome is shown in Scheme 2.

The proportion of labelled **2** and **3** relative to **1** and **4** increased to a level twenty times higher when **17**, but not **16**, was administered. This supports the view that the penultimate step in the biosynthesis of **1** in *B. oleae* is ω-oxidation of **6**, followed by cyclisation. Significantly, the results for **12**, **14**, **16** and **17** demonstrate that exogenous compounds can access the enzymes of the biosynthetic sequence, a crucial feature if enzyme inhibitors[12] are to be devised for pest control.

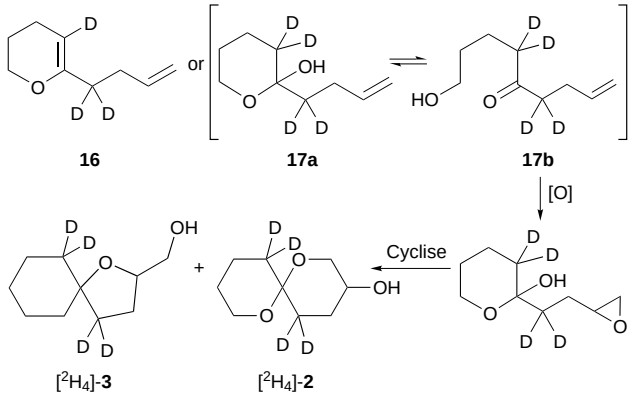
With respect to the origin of the minor co-occurring hydroxyspiroacetals **2**–**4**, we considered these might arise from hydroxylation of intact, initially formed spiroacetal **1**. To test this proposal, [5,5,11,11-$^2H_4$]-**1** was synthesised[13] and administered, and GC–MS analysis confirmed the efficient formation



Scheme 1



Scheme 3



Scheme 2

of labelled **2**–**4**. The enantiomeric compositions of the hydroxy spiroacetals from this trial group closely matched those from the control group.[13,14] In contrast to this, the enantiomeric profile of the hydroxy derivatives resulting from administration of **16** or **17** was quite different. For example, **3** from the control group was predominantly (2*R*,5*R*) and (2*R*,5*S*) (20% ee), but was predominantly (2*S*,5*S*) and (2*S*,5*R*) (60% ee) for those derived from **17**.[13] This indicates that epoxidation of an unsaturated precursor is an unlikely natural route to **2** and **3**. We believe that **2**–**4** are hydroxylation products of intact **1** (or a chemically equivalent species).[15]

In summary, the above results are consistent with ω-hydroxylation of **6** (or possibly **5**) followed by dehydrative spirocyclisation to yield **1**. The remarkable, highly regioselective oxidation (compare results from **5**, **12** and **14**) of a remote Me or CH_2 group is reminiscent of similar oxidations mediated by cytochrome P450s in other eucaryotic systems.[16] This class of enzymes is known to occur in insects, mediating important transformations such as pesticide detoxification.[17]

With this framework established (Scheme 3), we are now directing attention to the origin of **6**, the likely precursor of **1**, and to establishing the generality of the biosynthetic relationship between keto alcohols and the corresponding spiro acetals, *e.g.* **9** and **10**. Keto alcohols **6** and **9** could conceivably arise by either a fatty acid or polyketide pathway and experiments to differentiate these are being conducted. In this context, it is of interest that labelled nonanoic acid and 5-oxononanoic acid were not incorporated into **1** in *B. oleae*. The isolation and characterisation of the likely P450 enzyme in *B. oleae* and *B. cacuminata* are also being pursued.

We are grateful to the Australian Research Council for financial support.

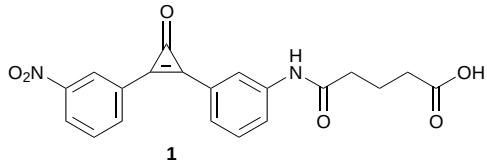
Antibodies elicited against the planar cyclopropenone hapten 1 efficiently catalyze ester hydrolysis, highlighting the importance of charge rather than shape complementarity as a design element of hydrolytic antibodies.

In the most common approach to the design of antibody catalysts the experimenter simultaneously incorporates a series of parameters that will operate in concert to achieve a catalytic event. A less frequently discussed but equally important approach is to apply special hapten design to induce only selected parameters and thereby assess their role in catalysis. Here we take the less common approach in order to examine the relative importance of two key parameters—charge *vs.* shape complementarity in the antibody active site. The relative importance of these parameters is of central significance not only in hapten design but also in immunochemistry in general.

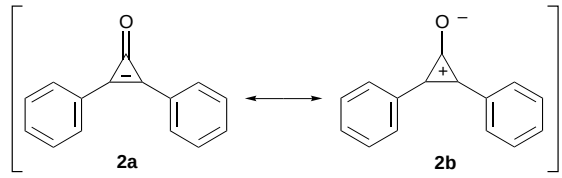
Mechanistic and X-ray crystallographic studies of both esterolytic enzymes[1] and catalytic antibodies highlight the importance of three design elements when planning inhibitors and haptens. I. *Tetrahedral geometry*, needed to mimic the rehybridization of the carbonyl carbon in the transition state. II. *Negative charge*, needed to create a stabilizing environment for the developing oxyanion. III. *Positive charge*, needed to generate a general base residue in the active site. Haptens with design elements I and II, *e.g.* phosphonates, amidophosphonates, phosphates, have been extensively used to elicit antibodies that catalyze various interconversion reactions of carboxylic acid derivatives.[2] Design elements I and III were also used to generate hydrolytic antibodies.[3] Few attempts to simultaneously employ all design elements, I, II and III, in order to achieve polyfunctional catalytic antibodies have been reported.[4,5]

A common assumption that lies at the basis of all of the above mentioned studies is that the shape complementarity element I is an indispensable feature to be considered in the design of hydrolytic antibodies. Here we report on esterolytic antibodies that were raised against the cyclopropenone functionality. Hapten **1** reflects the electrostatic design elements II and III but lacks the geometrical design element I, thereby allowing us to examine the importance of charge complementarity alone.



1

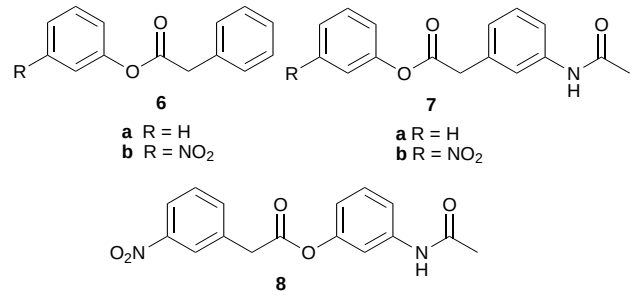
Hapten **1** presents a cyclopropenone ring as well as two aromatic recognition elements. Diphenylcyclopropenone, **2**,[6] may be described by two canonical resonance forms **2a** and **2b**. The solid state structure of **2** indicates that its carbonyl bond is highly polarized, suggesting a significant contribution of the aromatic (2π electrons) zwitterionic structure **2b**. This polarization may be enhanced by the formation of hydrogen bonds.[7] The physical properties of **2** (^{17}O NMR, IR and dipole moment) provide supporting evidence for the existence of a negative charge on the oxygen atom.[5] The remarkable chemical stability of **2** under acidic conditions is also attributed to the aromatic nature of the cyclopropenium moiety.



2a **2b**

The synthesis of **1** was achieved in four steps starting with mono-nitration of **2** (Aldrich) to give 2-(3-nitrophenyl)-3-phenylcyclopropenone **3**.[8] The nitro group was reduced with Ti^{III} to the corresponding amine, **4**. Reaction with glutaric anhydride to produce the monoamide **5** (**3**–**5** not shown),[9] followed by nitration of the unsubstituted phenyl ring, afforded hapten **1**.[10]

The five substrate esters **6**–**8** were prepared by acid catalyzed esterification of the substituted phenylacetic acid with the appropriate phenol.



6 **7** **8**

a R = H
b R = NO_2

a R = H
b R = NO_2

Following immunization of 129^{IX+} mice with the Keyhole Limpet Hemocyanin (KLH) conjugate of **1**, 15 hybridoma cells producing anti-**1** antibodies were selected for further studies. Antibodies from each cell-line were purified by ammonium sulfate precipitation, anion exchange, and protein-G affinity chromatography. The antibodies were screened for catalytic activity by monitoring the release of *m*-nitrophenol (λ_{max} = 330 nm) in the hydrolysis of **6b** and **7b** using a microplate reader. Antibodies 10E8, 11G4, 12G2, 13B6 and 15D3 were found to be catalytic and antibody 12G2 was selected for this study.

The antibody catalyzed reactions were carried out by mixing a phosphate-buffered saline (PBS) solution (50 mM phosphate, 100 mM NaCl, at different pHs) of antibody 12G2 (12 μM, 0.045 ml) with MeCN solutions (0.005 ml) of the substrate **6b** at different concentrations (0.04–0.6 mM) and monitoring them

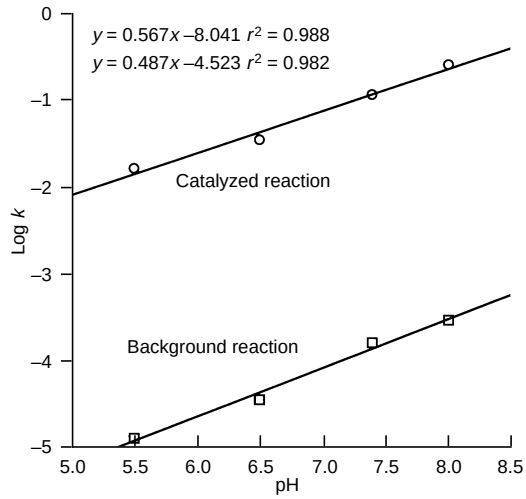


Fig. 1 pH–rate profile of 12G2-catalyzed hydrolysis of **6b**

Table 1 Kinetic parameters 10^{-5} for the 12G2 catalyzed hydrolysis of the studied substrates

Substrate	$k_{un}/10^{-5}$ min^{-1}	K_m/μM	$k_{cat}/10^{-2}$ min^{-1}	k_{cat}/k_{un}
6b	3.6	100	3.5	970
7b	7.0	480	1.4	200
8	2.7	90	0.3	110

by HPLC. The background (uncatalyzed) reaction rate constants (k_{un}) were determined in the presence of 12G2 and **1** (0.001 ml, EtOH solution, equimolar to the substrate).[11] The catalyzed reaction rate constants (k_{cat}) were obtained from Lineweaver–Burk plots of the kinetic data.

The pH rate profiles (log *k vs.* pH) of the catalyzed and uncatalyzed hydrolysis of **6b** between pH 5.5 and 8 (Fig. 1) show that both reactions have the same linear dependence on pH. The fact that both lines in Fig. 1 exhibit the same slope suggests that catalysis does not involve any strain/rehybridization effect and both reactions proceed along the same mechanism, namely, general base catalysis.

A comparative study of the substrate range was carried out at pH 6.5. The kinetic parameters for three different substrates, derived from the corresponding Lineweaver–Burk plots are given in Table 1. While rate enhancement of 2–3 orders of magnitude is achieved with substrates **6b**, **7b** and **8**, no catalysis is observed with **6a** and **7a**, a fact that highlights the importance of the nitro group as a substrate recognition element. Comparison of the kinetic data of **6b** and **7b** indicates that the presence of an acetamido group in the substrate decreases both substrate binding and catalytic efficiency. This observation supports the above-mentioned conclusion that the antibody cannot distort the substrate to fit the binding pocket of 12G2. Ester **8** binds to 12G2 as well as **6b** does but its catalyzed hydrolysis is one order of magnitude slower.

Interestingly, very little is known about natural products containing a cyclopropenone fragment.[12] A papain inhibitor possessing a cyclopropenone moiety exhibits a K_i in the submicromolar level. The mechanism for the action of this unique protease inhibitor still remains unclear.[13]

Catalytic antibodies offer unique opportunities to examine mechanistic hypotheses and the relative importance of individual design elements in catalysis. We have shown here that antibodies elicited against hapten **1** catalyze ester hydrolysis with a 1000-fold rate enhancement. As hapten **1** does not mimic the shape of the transition state, yet elicits efficient catalysts, it is likely to generate the necessary charge complementarity in the active site. Thus, haptenic tetrahedral geometry is a desirable feature but not a prerequisite to generating hydrolytic antibodies. This study, together with the information reported about a cyclopropenone-containing protease inhibitor, highlights the potential applications of the rarely used cyclopropenone functionality in the future design of both haptens and enzyme inhibitors.

We are grateful to Dr S. C. Sinha for early contributions to this work and to D. M. Kubitz for antibody preparation. We thank Pharmore Therapeutics and The Skaggs Institute for Chemical Biology for financial support. F. G. thanks the Lady Davis foundation for a postdoctoral fellowship.

9 Preparation of **5**: **4** (0.55 g, 2.5 mmol) was dissolved in dry THF (25 ml). Glutaric anhydride (1.42 g, 12.5 mmol) was added and the mixture was stirred at room temp. for 12 h. Work-up and purification by column chromatography (silica gel, EtOAc–hexane 4 : 1) afforded **5** (0.21 g, 25%) in the form of a colorless solid. δ_H($CDCl_3$ with 2 drops CD_3OD) 8.05 (s 1 H), 7.90 (s br, 2 H), 7.84 (s br, 1 H), 7.59 (d, *J* 9.72, 1 H), 7.50 (s, 3 H), 7.41 (t, *J* 7.48, 1 H), 2.35 (t, *J* 7.68, 2 H), 2.31 (t, *J* 6.76, 2 H), 1.91 (t, *J* 7.80, 2 H); *m/z* (ESI) 334 ($M - H^+$).
10 Preparation of **1**: sodium nitrate (0.025 g, 0.298 mmol) was added to a stirred solution of 2-[3-(4-carboxybutanamido)phenyl]-3-phenylcyclopropenone (0.1 g, 0.298 mmol) in conc. sulfuric acid (1 ml). The mixture was stirred for 1 h at room temp., then heated to 100 °C for 1 h and poured into ice–water. The precipitate was washed with water, dissolved in EtOAc and passed through a silica gel bed using EtOAc to give **1** (0.053 g, 31%) in the form of a colorless solid. δ_H(CD_3OD) 8.87 (s, 1 H), 8.52 (d br, 1 H, *J* 8.28), 8.50 (s, 1 H), 8.44 (d br, 1 H, *J* 7.04), 7.95 (t, 1 H, *J* 7.72), 7.82 (d, 1 H, *J* 8.04), 7.76 (d, 1 H, *J* 7.44), 7.66 (s, 1 H), 7.61 (t, 1 H, *J* 7.80); *m/z* (LSI) 381 (MH^+).
11 No change in the rate of the 12G2-catalyzed hydrolysis of **6b** could be detected in the presence of ethanol (0.001 ml). Partial inhibition of the reaction was observed in the presence of compounds **2**, **3** and **5** (1 equiv. with respect to the substrate).

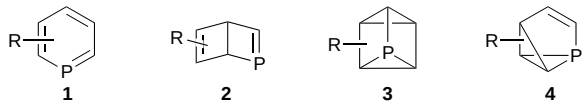
Synthesis and crystal structure of a bis(phosphiren-1-yl)–iron complex[1]

J. Simon, U. Bergsträßer and M. Regitz*†

Fachbereich Chemie der Universität Kaiserslautern, Erwin-Schrödinger-Straße, D-67663 Kaiserslautern, Germany

1-Chloro-1*H*-phosphirenes 5 react with disodium tetracarbonylferrate to furnish the novel mono-complexed bis(phosphirenyl)s 7 which, in turn, are converted to the doubly-complexed species 8 by treatment with nonacarbonyldiiron.

Investigations on the synthesis and reactivity of λ³-phosphinines **1** in the 1960s played a major role in the development of

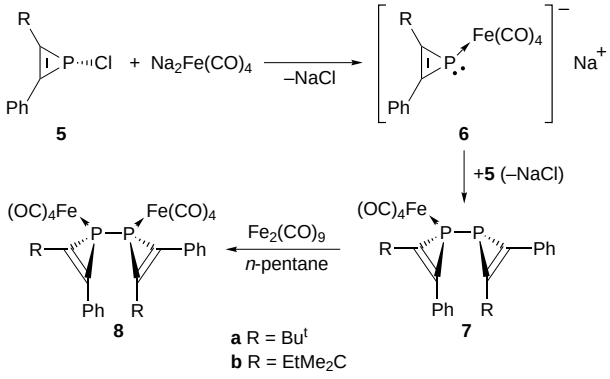


the chemistry of low-coordinated phosphorus.[2,3] Somewhat later, their classical valence isomers such as, for example, λ³,σ²-Dewar-benzenes **2**,[4] phosphaprismanes **3**[5] and λ³,σ³-benzvalenes **4**[5] were also prepared.

The Dewar-benzene derived from 2,4,6-tri-*tert*-butyl-1,3,5-triphosphinine was recently added to this list.[6] In contrast, very little information about the diphosphinines is available,[7] and the valence isomers derived from them are still unknown. We now report the first synthesis of a complexed bis(phosphirenyl), representing a new type of phosphinine valence isomer.

The starting materials for the syntheses of the bis(phosphirenyl)s **7a**,**b** were the 1-chloro-1*H*-phosphirenes **5a**,**b** (Scheme 1).[8] Reactions of the latter with disodium tetracarbonylferrate (0.5 equiv.) furnished the mono-complexed bis(phosphirenyl)s **7a**,**b** in good yields (60%). The composition and constitution of the products were elucidated with the help of NMR and mass spectroscopy.‡ Because of the presence of centres of chirality at the two phosphorus atoms and their configurational stability, these reactions give rise to two diastereomers which, however, cannot be separated by column chromatography. One of the diastereomers in each case can be enriched up to a ratio of 8:1 (**7a**) or 4:1 (**7b**) (as determined from their ^{1}H NMR spectra) by crystallization.

The formation of **7** is reflected in the ^{31}P NMR spectra by a significant $^1J_{P,P}$ coupling constant of 427 Hz. The complexed ring phosphorus atom gives rise to a signal at considerably lower field than that of the uncomplexed ring (δ −88, as compared to −132). Complexation with the tetracarbonyliron fragment is also apparent in the ^{13}C NMR spectra from a drastic reduction in the intracyclic $^1J_{C,P}$ coupling constant of the complexed phosphirene to 22–27 Hz, in comparison to 50–57 Hz for the uncomplexed ring. A similar phenonemon has also been reported for complexation reactions of other 1*H*-phosphirenes.[9c] The signals for the ring carbon atoms of **7a**,**b** occur in the typical region for 1*H*- phosphirenes.[9]



Scheme 1

The initial reductive substitution of the chlorine atom of **5** by the tetracarbonyliron fragment results in the anionic phosphirene complex **6** which participates in an immediate nucleophilic substitution with a second molecule of **5** to afford **7**.

Treatment of the compounds **7a**,**b** with nonacarbonyldiiron results in the formation of the symmetrical, doubly-complexed bis(phosphirenyl)s **8a**,**b** in yields of 63% (**8a**) and 54% (**8b**).§ As a consequence of the high symmetry of compounds **8** their ^{31}P NMR spectra each contain only one singlet signal. Complexation of the additional tetracarbonyliron fragments effects further shifts to lower field [δ −69.3 (**8a**) and −70.5 (**8b**)].

The ^{13}C NMR spectra of **8** do not show any significant changes in chemical shifts due to the additional complex fragments in comparison to those of **7**.

An X-ray crystallographic analysis of the complex **8a** confirmed the proposed structure (Fig. 1).¶ In the crystal the two tetracarbonyliron fragments and, respectively, the two phosphirene rings have *syn* orientations to each other. Because of the extreme steric situation, the two phosphirene rings are somewhat twisted, as reflected in torsional angles of 39.4° [Fe(1)–

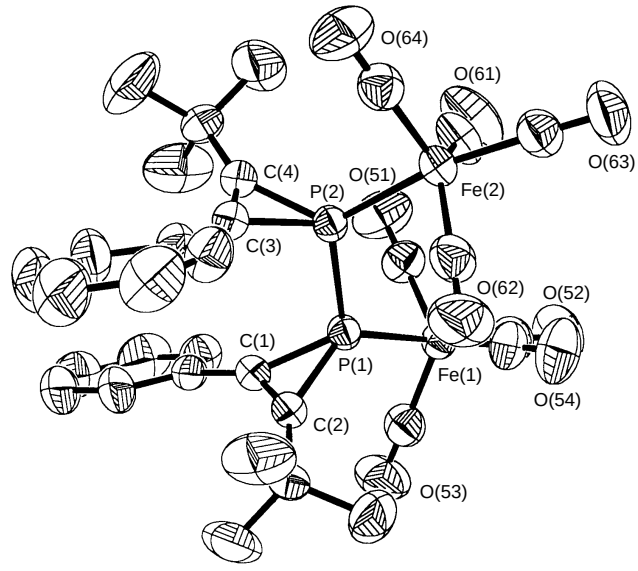


Fig. 1 Crystal structure of **8a**. Selected bond lengths (Å) and angles (°): Fe(1)–P(1) 2.2311(7), Fe(2)–P(2) 2.2185(7), P(1)–P(2) 2.2516(10), P(1)–C(1) 1.793(2), P(1)–C(2) 1.796(2), P(2)–C(3) 1.793(2), P(2)–C(4) 1.797(2), C(1)–C(2) 1.317(3), C(3)–C(4) 1.319(3); C(1)–P(1)–C(2) 43.05(11), C(1)–P(1)–P(2) 108.23(8), C(2)–P(1)–P(2) 108.97(8), C(3)–P(2)–C(4) 43.11(11), C(3)–P(2)–P(1) 108.55(8), C(4)–P(2)–P(1) 109.05(8), C(2)–C(1)–P(1) 68.60(14), C(1)–C(2)–P(1) 68.3(2), C(3)–C(4)–P(2) 68.3(2), C(4)–C(3)–P(2) 68.58(14).

P(1)–P(2)–Fe(2)] and 33.9° [C(1)–P(1)–P(2)–C(4)]. The P(1)–P(2) bond length amounts to 2.2516(10) Å and is thus somewhat lengthened as a result of the spatially demanding substitution pattern. The intracyclic P–C bond lengths of 1.793 to 1.797 Å, as well as the carbon–carbon double bond length of 1.317 Å, are of the expected sizes for a complexed 1*H*-phosphirene.[9c] Similary, the C–P–C bond angles of 43.05(11) and 43.11(11)° are comparable with those of other 1*H*-phosphirenes.[9]

We thank the Landesregierung von Rheinland-Pfalz for a graduate grant (to J. S.) and the Fonds der Chemischen Industrie for generous financial support.

Synthesis, crystal and molecular structure of the first indium trihydride complex, $[InH_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]$

David E. Hibbs,[a] Michael B. Hursthouse,[a] Cameron Jones*[b] and Neil A. Smithies[b]

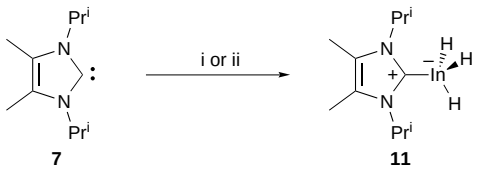
[a] *EPSRC X-ray Crystallography Service, Department of Chemistry, University of Wales, Cardiff, PO Box 912, Park Place, Cardiff, UK CF1 3TB*

[b] *Department of Chemistry, University of Wales, Swansea, Singleton Park, Swansea, UK SA2 8PP*

The reaction of either $[InH_3(NMe_3)]$ or $LiInH_4$ with an excess of the imidazol-2-ylidene carbene, $:\overline{CN(Pr^i)C_2Me_2N(Pr^i)}$, affords the first example of an indium trihydride complex, $[InH_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]$, the X-ray crystal structure of which is described.

The chemistry of the binary hydrides of aluminium and gallium, $[(MH_3)_n]$ (M = Al, Ga), and their Lewis base adducts is now a well established field that derives its current importance from the application such compounds have in areas ranging from organic synthesis to chemical vapour deposition.[1] Despite early claims,[2] it seems unlikely that the corresponding indium trihydride $[(InH_3)_n]$ has yet been synthesised although monomeric InH_3 has been isolated and studied in a solid argon matrix.[3] In fact, the weakness of the In–H bond has meant that to date only five indium hydride compounds have been structurally characterised (*viz.* $[Li(thf)_2][\{(Me_3Si)_3C\}_2In_2H_5]$ **1**,[4] $K[H\{In(CH_2CMe_3)_3\}_2]$ **2**,[5] $K_3[K(Me_2SiO)_7]$ $[InH(CH_2CMe_3)_3]_4$ **3**,[6] $[InH\{2\text{-}Me_2NCH_2(C_6H_4)\}_2]$ **4**[7] and $[Me_2InB_3H_8]$ **5**[8]). In our laboratory we have become interested in extending this field to the stabilisation of indium trihydride complexes, which are as yet unknown. With this goal in mind we saw imidazol-2-ylidene carbenes as potentially useful ligands, primarily because their AlH_3 complexes (*e.g.* $[AlH_3\{\overline{CN(Mes)C_2H_2N(Mes)}\}]$ **6**, Mes = $C_6H_2Me_3$-2,4,6, mp 246 °C[9]) are known to be considerably more stable than normal AlH_3 adducts (*e.g.* $[AlH_3(NMe_3)]$ decomp. at 100 °C[10]). This stability stems from the high nucleophilicity of such carbenes which we have previously exploited in the preparation of a series of complexes between $:\overline{CN(Pr^i)C_2Me_2N(Pr^i)}$ **7** and indium trihalides, *viz.* $[InX_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}_n]$ (n = 1, **8**; 2, **9**) and $[HCN(Pr^i)C_2Me_2N(Pr^i)]^+[InX_4\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]^-$ **10** (X = Cl, Br).[11] We now wish to report the use of **7** in the synthesis of the first structurally authenticated indium trihydride complex.

Treatment of an ethereal solution of $[InH_3(NMe_3)]$[12] (generated *in situ* from $LiInH_4$[2] and $NMe_3{\cdot}HCl$ at −30 °C) with 2 equiv. of **7** at −40 °C led to a moderate yield (42%) of $[InH_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]$ **11** after recrystallisation from diethyl ether (Scheme 1). Complex **11** is an extremely air sensitive, colourless material that decomposes, depositing indium metal and generating hydrogen gas, at temperatures greater than −20 °C in solution and −5 °C in the solid state. Interestingly, treatment of $LiInH_4$ with 2 equiv. of **7** also gave **11** in a moderate yield (38%). This is not surprising and has a precedent in aluminium chemistry with the reaction of $LiAlH_4$ with tertiary amines which can yield alane adducts, $[AlH_3(NR_3)]$, and Li_3AlH_6.[13] It seems likely that in the present reaction a related complex indium hydride is being generated as a by-product in the formation of **11**. Unfortunately attempts to characterise this by-product have so far proved fruitless owing to its thermal instability. It is noteworthy that the aluminium analogue of **11**, *viz.* $[AlH_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]$ **12**, can also be prepared in high yield by the reaction of **7** with either $[AlH_3(NMe_3)]$ or $LiAlH_4$.[12]



7 **11**

Scheme 1 *Reagents and conditions*: i, $[InH_3(NMe_3)]$, Et_2O, −30 °C, 2 h; ii, $LiInH_4$, Et_2O, −30 °C, 5 h

It is interesting that only a 1 : 1 complex is formed in the reaction of an excess of **7** with $[InH_3(NMe_3)]$ despite the fact that 2 : 1 complexes of the same carbene with indium halides, *e.g.* **9**, are readily formed.[11] This is presumably because the InH_3 unit is less Lewis acidic than InX_3 (X = Cl, Br), and therefore more easily electronically satisfied. Indeed, treatment of **11** with tertiary amines did not lead to the formation of five-coordinate complexes and no other reaction occurred.

The molecular structure of **11** is depicted in Fig. 1. During the course of refinement it was found that the methyl groups attached to C(6) were disordered over two sites, each having a 50% occupancy (only one disordered set is depicted in Fig. 1). The molecule is monomeric, sits on a mirror plane and does not display any intermolecular interactions. Unfortunately the hydride ligands attached to In could not be located from difference maps but their presence can be assumed from spectroscopic evidence (*vide infra*). By contrast the hydride ligands were located in the crystal structure of the isostructural

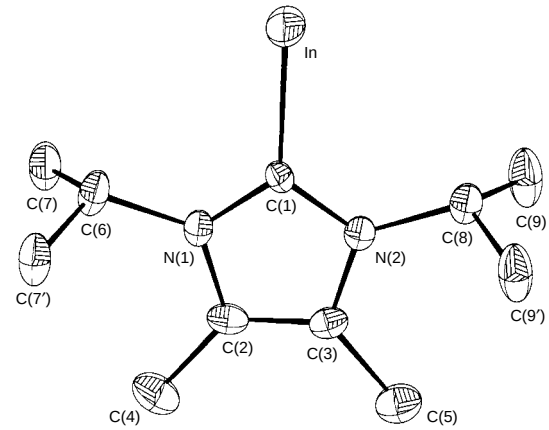


Fig. 1 Molecular structure of $[InH_3\{\overline{CN(Pr^i)C_2Me_2N(Pr^i)}\}]$ **11**. Selected bond lengths (Å) and angles (°): In–C(1) 2.260(6), N(1)–C(1) 1.354(9), N(1)–C(2) 1.402(8), N(2)–C(1) 1.331(9), N(2)–C(3) 1.413(9), C(2)–C(3) 1.340(11); N(2)–C(1)–N(1) 105.8(6), N(2)–C(1)–In 125.6(5), N(1)–C(1)–In 128.6(5), C(1)–N(1)–C(2) 110.2(6), C(1)–N(2)–C(3) 110.9(6), C(3)–C(2)–N(1) 106.9(7), C(2)–C(3)–N(2) 106.2(6).

compound **12**, the aluminium centre of which was found to have a distorted tetrahedral environment.[12] The In–C(1) distance in **11** is longer than is normally seen for In–C bonds [*e.g.* 2.174 Å av. in trimethyl(quinuclidine)indium].[14] Similar trends in M–C (carbene) bond lengths have been observed in other group 13–carbene complexes.[9,11] In addition, the bond lengths and angles within the carbene heterocycle are close to those in **8** and suggest a degree of delocalisation within the ring. Of particular note is the N–C(carbene)–N angle of 105.8(6)° which lies between the normal value for free imadazolylidene carbenes (*ca.* 102°) and imadazolium cations (*ca.* 108°).[9]

The solution NMR data for **11** support its proposed structure. Its ^{1}H NMR spectrum is similar to that of **8** but also displays a very broad resonance at δ 5.58 which integrates for three hydrogens and has been assigned as the hydride resonance. The broadness of this peak is due to the high quadrupole moment of the indium centre (^{115}In 95%, I = 9/2, ^{113}In 5%, I = 9/2) to which the hydrides are attached. This also accounts for the fact that no resonance was observed for the indium coordinated carbene centre, C(1), in the ^{13}C NMR spectrum of **11**, as was the case in the ^{13}C NMR spectrum of **8**.[11] Additionally, no signal was seen in its ^{115}In NMR spectrum which is not surprising considering the lack of spherical symmetry about In. The IR spectrum of **11** (Nujol mull) displays a strong, broad absorbance centred at 1640 cm^{-1} which has been attributed to its In–H stretching modes. This is at a significantly lower frequency than in free InH_3 (1754.5 cm^{-1}),[3] presumably because the nucleophilic carbene donor is weakening the In–H bonds in **11** relative to those in InH_3. Moreover, the In–H stretching absorbance for **11** is at a lower wavenumber than the corresponding Al–H stretching regions for its aluminium counterparts **6** (1743 cm^{-1})[9] and **11** (1730 cm^{-1}).[12] A similar trend is seen for the uncoordinated, monomeric hydrides, InH_3 (1754.5 cm^{-1}) and AlH_3 (1882.9 cm^{-1}).[3]

The indium trihydride complex **11** represents the first example of a new class of compound, the chemistry of which should prove fruitful. To establish this we are currently examining its further reactivity and the preparation of a series of related indium trihydride complexes. The results of these studies will be presented in a later publication.

We gratefully acknowledge financial support from the EPSRC (studentship for N. A. S.).

Stereoselective synthesis of *O,O*-dimethylkorupensamine A *via* palladium(0)-mediated cross-coupling of a planar chiral (arene)$Cr(CO)_3$ complex with naphthylboronic acid

Takashi Watanabe and Motokazu Uemura*†

Department of Chemistry, Faculty of Integrated Arts and Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan

***O,O*-Dimethylkorupensamine A was stereoselectively synthesized by using the palladium(0)-mediated cross-coupling of the enantiomerically pure tricarbonylchromium complex of 3,5-dimethoxy-2-bromobenzene having a functional group at C-1 position with naphthylboronic acid as a key step.**

Korupensamines and michellamines have been isolated from the tropical liana *Ancistrocladus korupensis* in Cameroon and some of these alkaloids possess significant pharmacological activities such as antimalarial properties,[1] and remarkable antiviral activity against human immunodeficiency virus strains HIV-1 and HIV-2.[2] Structurally, the korupensamines have a naphthyltetrahydroisoquinoline skeleton with an axial chirality between the naphthalene and tetrahydroisoquinoline rings, and the michellamines are atropisomerically dimeric alkaloids of the korupensamines. These alkaloids have been previously synthesized *via* construction of the axial bond between the naphthalene and tetrahydroisoquinoline rings as a key step.[3,4] However, the palladium(0)-catalyzed cross-coupling[3] of two arene rings or nucleophilic addition[4] of aryl Grignards to the *o*-methoxyaryl oxazoline compounds for the central bond formation of the naphthalene and tetrahydroisoquinoline rings gave unfortunately various ratios of the atropisomeric mixture in the previous reports. In continuation of our studies on development of the planar chiral (arene)chromium complexes in the asymmetric reactions, we have recently reported[5,6] that both enantiomers of the axial biaryls could be stereoselectively prepared from a single planar chiral (arene) chromium complex by the palladium(0)-mediated cross-coupling of (2,6-disubstituted 1-bromobenzene)chromium complexes with arylboronic acids and following axial isomerization of the cross-coupling products under thermal conditions. This paper describes the asymmetric synthesis of (−)-*O,O*-dimethylkorupensamine A (**1**, R = Me) utilizing the stereoselective palladium(0)-catalyzed cross-coupling of the planar chiral (arylhalide)$Cr(CO)_3$ with napthylboronic acid as the key step.

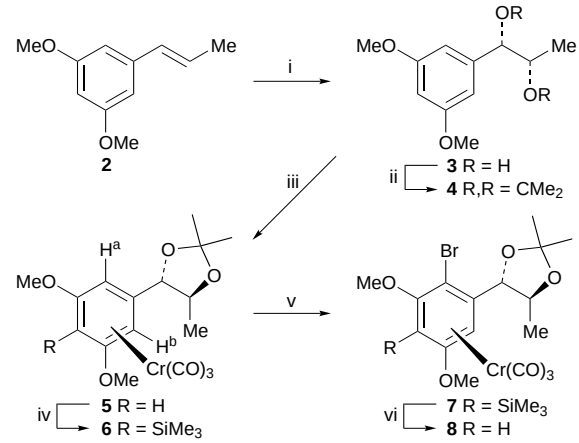
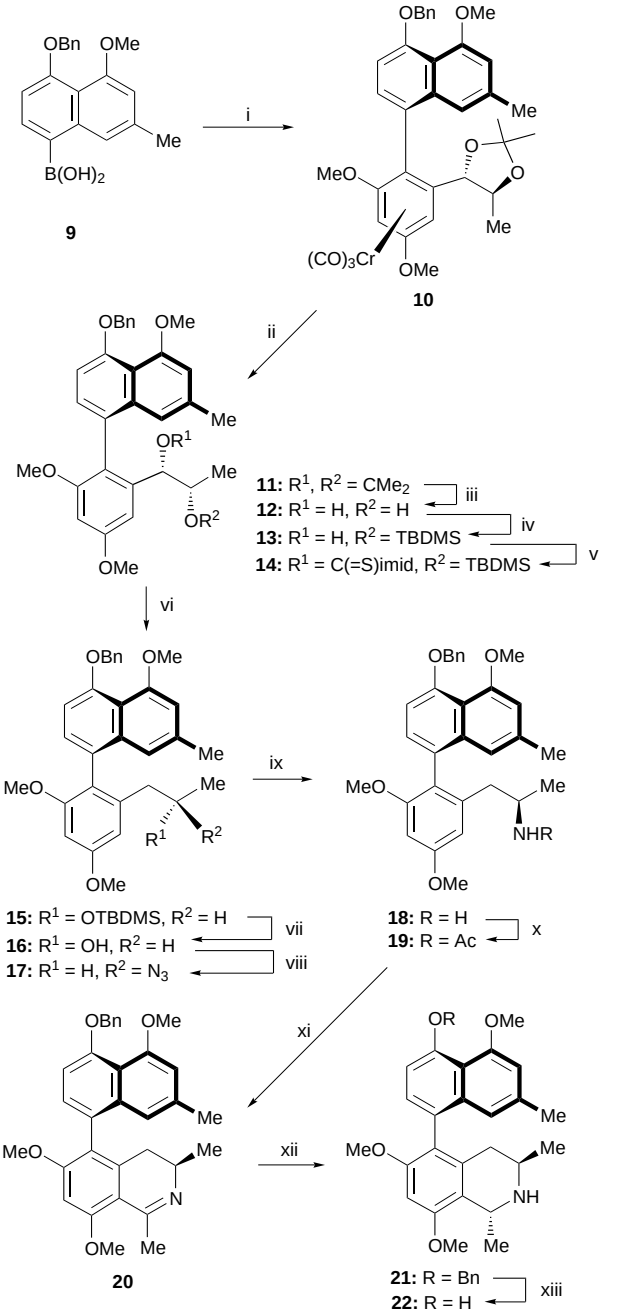
R = H; Korupensamine A
R = Me; *O,O*-Dimethylkorupensamine A

The planar chiral tricarbonylchromium complex of 3,5-dimethoxyphenylbromide having a functional group at C-1 position as a coupling partner was initially prepared as follows (Scheme 1). An asymmetric catalytic dihydroxylation of (*E*)-(3,5-dimethoxyphenyl)propene **2** was treated with AD-mix-α,[7] and the resulting diol was subsequently protected with acetone dimethylacetal to give the acetonide **4** ($[\alpha]_D^{27}$ +23.8)‡ in 96% yield with > 98% ee. Tricarbonylchromium complexation of **4** with $Cr(CO)_6$ in dibutyl ether and THF (10 : 1) at reflux gave the corresponding (arene)chromium complex **5** ($[\alpha]_D^{26}$ −4.0) in 89% yield. In order to introduce the bromine atom at either *ortho*-position of the C-1 side-chain group regioselectively, the C-4 position was initially protected by the introduction of the easily removable Me_3Si group. Thus, the lithiation of **5** with Bu^nLi followed by treatment with trimethylsilylchloride afforded the trimethylsilylated complex **6** ($[\alpha]_D^{27}$ −36.0) in 97% yield. Subsequent lithiation§ of **6** followed by quenching with 1,2-dibromo-1,1,2,2-tetrafluoroethane gave the bromination complex **8** ($[\alpha]_D^{26}$ −93.0) at the H^a-position without the regioisomeric complex after detrimethylsilylation in 95% overall yield. The planar chirality of **8** was determined by X-ray crystallography.¶



Scheme 1 *Reagents and conditions*: i, AD-mix-α, $CH_3SO_2NH_2$, Bu^tOH, H_2O, 99%, > 98% ee; ii, $Me_2C(OMe)_2$, TsOH, 97%; iii, $Cr(CO)_6$, dibutyl ether, THF, reflux, 20 h, 89%, > 99% ee; iv, Bu^nLi, THF, TMEDA, −78 °C, then Me_3SiCl, THF, −78 °C, 97%; v, Bu^nLi, THF, TMEDA, −78 °C, then $BrCF_2CF_2Br$, THF, −78 °C, 98%; vi, $Bu^n{}_4NF$, THF, AcOH, 97%

The palladium(0)-catalyzed cross-coupling of the planar chiral (arene)$Cr(CO)_3$ complex **8** with 4-benzyloxy-5-methoxy-6-methylnaphthylboronic acid **9**[8] in the presence of sodium carbonate in aqueous MeOH at reflux for 30 min produced a single atropisomeric coupling product **10** ($[\alpha]_D^{28}$ −142.9) in 90% yield without any formation of the atropisomers (Scheme 2). The axial stereochemistry of the coupling product **10** was assigned to be the (*S*)-configuration by ^1H NMR spectra, in which the *peri*-proton of the naphthalene ring appeared at lower field (δ 8.62) due to the anisotropic effect of the *syn*-$Cr(CO)_3$ fragment.[5] An oxidative demetallation of **10** and subsequent treatment with dilute HCl afforded the dihydroxyl compound **12** ($[\alpha]_D^{27}$ +3.5). Selective protection of the hydroxyl at the homobenzylic position of **12** with *tert*-butyltrimethylsilyl chloride gave the monosilylated compound **13** ($[\alpha]_D^{25}$ +35.8) in



Scheme 2 *Reagents and conditions*: i, **8**, $Pd(PPh_3)_4$ (0.05 mol equiv.), aq. Na_2CO_3, MeOH, 75 °C, 30 min, 90%; ii, *hν*, O_2, diethyl ether, 92%; iii, 1 M aq. HCl, THF, 50 °C, 96%; iv, Bu^tMe_2SiCl, imidazole, DMF, 84%; v, $(imid)_2C{=}S$, THF; vi, Bu^n_3SnH, AIBN, toluene, 62% from **13**; vii, Bu^n_4NF, THF, 96%; viii, $(PhO)_2PON_3$, DEAD, PPh_3, THF; ix, $SnCl_2$, MeOH; x, Ac_2O, py, 66%, from **16**; xi, $POCl_3$, MeCN; xii, $LiAlH_4$, Me_3Al, THF, −78 to 0 °C, 70% from **19**; xiii, Pd-black, HCO_2H, MeOH, 45 °C, 91%

84% yield. The benzylic hydroxyl of **13** was removed by the Barton method[9] to give the deoxygenation compound **15** ($[\alpha]_D^{26}$ +11.9) in 62% yield. The substitution of the hydroxyl to nitrogen atom with stereochemical inversion was achieved under Mitsunobu conditions.[10] Thus, deprotection of the silyl ether **15** and subsequent treatment with $(PhO)_2PON_3$ in the presence of DEAD and PPh_3 produced the azide compound **17** which was reduced with $SnCl_2$ followed by acetylation to give the amide compound **19** ($[\alpha]_D^{26}$ +8.1) in 66% overall yield. Bischler–Napieralski cyclization of **19** with $POCl_3$ in acetonitrile gave the naphthyldihydroisoquinoline compound **20**. Reduction[11] of the imine double bond of **20** with $LiAlH_4$ in the presence of Me_3Al afforded *trans*-dimethyl compound **21** ($[\alpha]_D^{23}$ −20.6) along with a small amount of the corresponding *cis*-isomer (ratio, 93 : 7) in 70% overall yield. Finally, debenzylation with Pd-black in a solution of 8.8% formic acid in MeOH gave *O*,*O*-dimethylkorupensamine A **22** (R = H) ($[\alpha]_D^{22}$ −29.1) in 91% yield.

In conclusion, we have demonstrated the asymmetric synthesis of *O*,*O*-dimethylkorupensamine A *via* a stereoselective Pd^0-mediated cross-coupling method for the construction of the highly hindered biaryl bond as the key bond forming reaction. This procedure should have broad utility for the stereoselective synthesis of structural analogs of the atropisomeric naphthyltetrahydroisoquinoline alkaloids.

Synthesis of poly(anthra-9,10-quinone-2,6-diyl)

Gerald Power, Philip Hodge,*† Ian D. Clarke, Michael A. Rabjohns and Ian Goodbody

Chemistry Department, University of Manchester, Oxford Road, Manchester, UK M13 9PL

The synthesis, *via* a precursor polymer, of poly(anthra-9,10-quinone-2,6-diyl) 1 is described and some of its properties are reported.

Poly(anthra-9,10-quinone-2,6-diyl) **1** is of interest for several reasons. For example, it is expected to have novel redox properties and these might lead to applications of the polymer in electrochromic displays and/or as charge injection layers in electroluminescent displays. A previous attempt[1,2] to synthesise polymer **1** directly from 2,6-dichloroanthraquinone **2**, by nickel(0)-mediated couplings, led only to very small oligomers because of the extremely low solubilities of compounds of this general type in all common organic solvents. Even the dimer **3** has very low solubilities.[3] We now report a synthesis of polymer **1**, *via* the soluble precursor polymer **4**, which produces a product with a number average molecular weight corresponding to an average degree of polymerisation, $\overline{DP}$, of 13.

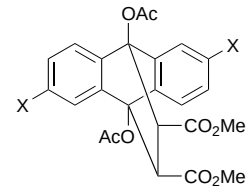
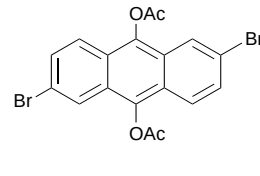
4

Quinone-containing polymers have been described before,[1,2,4] but most are electron-transfer polymers.[4] The latter are usually crosslinked polymers with quinone-containing pendant groups.[5] Very few quinone-containing polymers that have been described actually have the quinone moiety in the main chain and conjugated with the π-electron systems of the neighbouring units. The work most relevant to the present is the synthesis of poly(2-methylanthra-9,10-quinone-1,4-diyl) **5** and several very closely related polymers by nickel(0)-mediated couplings of dichloroquinones.[1,2] For steric reasons, the neighbouring anthraquinone moieties in these polymers are essentially orthogonal to each other.

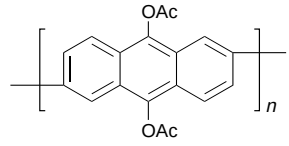
The basic strategy of the present synthesis was to prepare Diels–Alder adduct **6**, carry out a nickel(0)-mediated coupling to give the soluble precursor polymer **4**, then, after characterisation of the latter, convert it into polymer **1**. Thus, commercial 2,6-diaminoanthraquinone **7** was converted into 2,6-dibromoanthraquinone **8**, mp 282–283 °C (lit.,[6] 289–290 °C) (60% yield) using a Sandmeyer reaction.[7,8] Reductive acetylation of quinone **8** by treatment with zinc dust, Ac_2O and NaOAc at reflux temperature gave the anthracene **9**, mp 310 °C (decomp.)‡ (81% yield), and treatment of this with an excess of maleic anhydride in xylene at reflux temperature for 18 h gave the Diels–Alder adduct. The latter was treated with MeOH at reflux temperature to give the half esters. These reacted smoothly with ethereal CH_2N_2 to give compound **6**, mp 195–200 °C (decomp.)‡, (35% overall yield of recrystallised product from compound **9**).



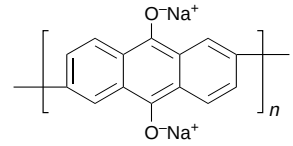
6 X = Br
11 X = H



9



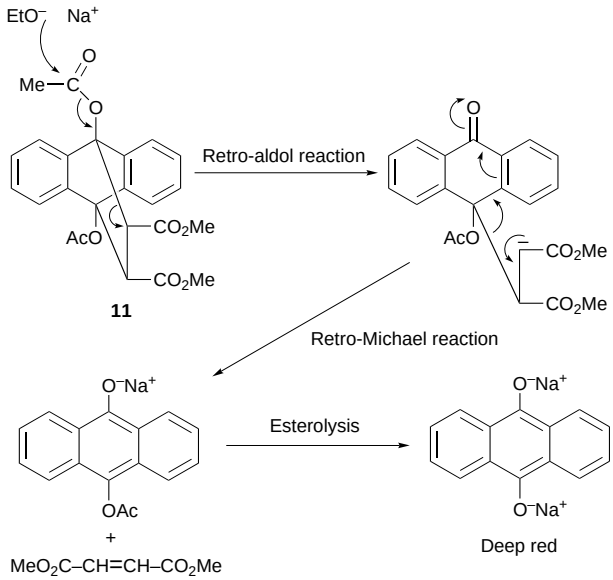
10



12 Very dark green

Treatment of compound **6** in DMA at 80 °C with 1.2 equiv. of $Ni^0[cod]_2$ in the presence of cod (1.0 equiv.) and 2,2′-bipyridyl (1.2 equiv.)[2,8–11]gave precursor polymer **4**‡ in 82% yield. The polymer was highly soluble in many organic solvents including $CHCl_3$ and THF. The infrared and ^1H NMR spectra of the product were consistent with structure **4**. By gel permeation chromatography polymer **4** had, relative to polystyrene standards, a number average molecular weight M_n, of 5690, a weight average molecular weight M_w, of 8980 and a peak molecular weight M_p, of 6830. The $\overline{M}_n$ value corresponds to a DP of 13.

Heating polymer **4** to 240 °C did not bring about a clean retro-Diels–Alder reaction to give polymer **10** even though analogous reactions in syntheses of related polymers proceed cleanly.[8,12] However, model studies showed that the dimethyl maleate-9,10-diacetoxyanthracene Diels–Alder adduct **11**‡ reacts readily with 5 equiv. of NaOEt and EtOH in NMP at 20 °C under nitrogen to give a deep red solution of the disodium salt of 9,10-dihydroxyanthracene, and that exposure of this to air rapidly gives anthra-9,10-quinone in essentially 100% yield. We suggest that the key steps in this overall conversion are, successively, (i) a retro-aldol reaction, (ii) a retro-Michael reaction and (iii) an esterolysis (see Scheme 1). Treatment of polymer **4** with NaOEt under similar conditions to those used above gave a very dark green *solution* which we attribute to the formation of polymer **12**. Passage of air through the green solution precipitated polymer **1**, as a pale brown solid, in 95% overall yield from the precursor polymer **4**.



Scheme 1

Polymer **1**, like most anthraquinones, is soluble in concentrated sulfuric acid and trifluoromethanesulfonic acid but it is insoluble in all common organic solvents. The product had an elemental analysis consistent with structure **1**. The FT-IR spectrum of polymer **1** displayed the expected bands at 1679 and at 1592 cm^{-1}: there were no bands which could be attributed to the presence of either maleate or aryl acetate groups. Thermogravimetric analysis of the polymer in air showed no significant weight loss up to 175 °C, then a steady weight loss up to 480 °C by which temperature 35% of the weight had been lost. There was no further significant loss up to 600 °C, the temperature limit of the instrument. A very similar pattern of weight loss was observed when the polymer was heated under nitrogen.

These results demonstrate a practical synthesis of polymer **1**. They also indicate how closely related polymers with these or other anthraquinone moieties might be prepared. Optimisation of the synthesis to obtain a higher $\overline{DP}$ and a more detailed study of the properties of polymer **1**, including its redox properties, are currently under investigation.

We thank the EPSRC for financial support.

Cp_2TiPh-coordinated cyano and ester groups as efficient ketyl radical acceptors in the reductive radical cyclization of γ- and δ-cyano ketones and δ-keto esters

Yoshihiko Yamamoto, Daisuke Matsumi and Kenji Itoh*†

Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan

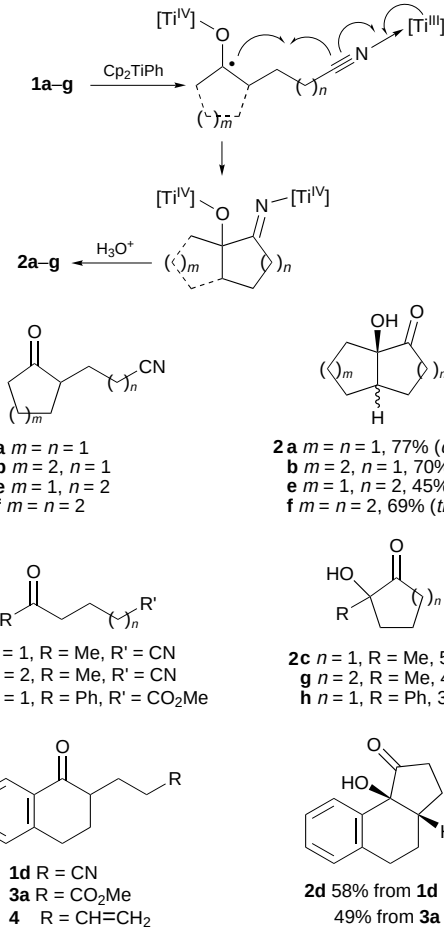
Cp_2TiPh promotes the reductive radical cyclization of γ- and δ-cyano ketones and δ-keto esters to give α-hydroxycycloalkanones in moderate to good yields; the titanium reagent coordinates to both the ketone and the cyano or ester terminus, the LUMO of the cyano or ester group is thus lowered, and cyclization proceeds irreversibly without formation of the unstable iminyl or alkoxy radical intermediates.

Radical cyclizations have been extensively utilized as powerful tools for the construction of carbocyclic skeletons, especially five-membered ring systems.[1] In these processes, C–C bonds are generally formed by the addition of a carbon-centered radical to a non-polar carbon–carbon multiple bond. On the other hand, radical additions to a carbonyl or cyano group are generally not efficient because they generate highly unstable alkoxy or iminyl radicals.[1] However, radical addition to these polar multiple bonds might be successful if the resulting unstable radical intermediates are effectively scavenged and converted into the desired products. With this in mind, we have developed a Ti^{III}-mediated reductive coupling of γ- and δ-cyano ketones leading to α-hydroxycycloalkanones, in which the Ti^{III} complex Cp_2TiPh coordinates to the cyano group so that the ketyl radical efficiently cyclizes to the coordinated cyano group without formation of the undesired iminyl radical intermediate (Scheme 1).[2] In addition, coordination of the Ti^{III} species lowers the LUMO of the cyano group and increases its ketyl trapping ability.[3]

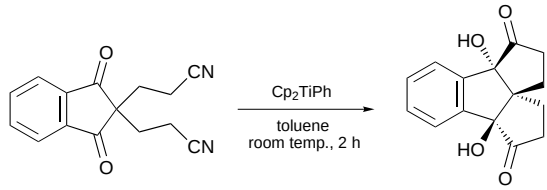
Cp_2TiPh was prepared according to the reported procedures[4] and used for further reactions without isolation. Typically, commercial Cp_2TiCl_2 (3 mmol) was treated sequentially with dry, degassed Et_2O solutions of Pr^iMgCl (3.3 mmol) and PhMgBr (3.3 mmol) in dry, degassed toluene (10 ml) under Ar at ambient temperature.[5] To the resultant dark green solution of Cp_2TiPh was added dropwise a 0.1 M toluene solution of 2-cyanoethylcyclopentanone **1a** (1 mmol) and the reaction mixture was stirred for 1 h at ambient temperature. Acid hydrolysis followed by silica gel chromatography afforded the 5-*exo* cyclization product **2a**[6] in 77% yield. The phenyl–titanium bond is essential, since analogous Ti^{III} species generated by the reduction of Cp_2TiCl_2 by Pr^iMgCl did not promote the cyclization under the same conditions. Similarly, intramolecular coupling product **2b**[6] was obtained from cycloalkanones **1b** in 70% yield. Acyclic ketone **1c** also gave **2c**,[6] but the yield was lower than those of the above cyclic precursors due to conformational flexibility around the carbonyl group. High dilution (0.04 M) and prolonged reaction time (2 h) was required to increase the yield to 50%. In contrast, the inverse addition of the Ti^{III} reagent to **1c** decreased the yield (17%). Thus the concentration of the Ti^{III} reagent is critical for the present cyclization. It is noteworthy that the present method is applicable to aryl-substituted ketone **1d** to afford tricyclic α-hydroxy ketone **2d**[6] in 58% yield, whereas the reported electrochemical reduction gave cyano alcohol due to simple reduction of the carbonyl group.[7,8] In the same manner, 6-*exo* cyclization of δ-cyano ketones **1e**,**f** and acyclic δ-cyano ketones **1g** gave the desired α-hydoroxycyclohexanones **2e**–**g**[6] in 45, 69 and 42% yields, respectively. It is interesting that the *trans*-fused product was selectively obtained from **1f**, whereas the *cis*-fused isomer was obtained for **2a**,**b**,**d** and **e**.

In addition to the cyano group, the ester group is an effective ketyl radical accepting group when coordinated by Cp_2TiPh.[2] Aromatic keto esters **3a** and **3b** were treated with the Ti^{III} reagent under high dilution conditions to afford 5-*exo* cyclization products **2d** and **2h** in 49 and 38% yields, respectively.

Recently, Molander and Kenny reported the SmI_2-promoted reductive cyclization of δ,ε-unsaturated keto esters, demonstrating that the ketyl-trapping ability of nitriles is lower than those of alkenes, alkynes, ketones and aldehydes.[9] In our hands, the double coordination to both carbonyl and cyano or ester groups by the Ti^{III} complex resulted in efficient reductive cyclization of a variety of keto nitriles and keto esters under mild conditions. In this context, alkenyl groups are no longer superior to the cyano group as a ketyl radical acceptor. In fact,



Scheme 1



5 **6** 75%

Scheme 2

α-butenyl ketone **4** did not give the expected cyclization product after treatment for 24 h with the Ti^{III} reagent, and the starting material was recovered with the carbonyl group intact (75% recovery).[10] This result shows that ketyl radical formation is reversible and this reversibility combined with the steric hindrance of the Cp_2TiPh-coordinated ketyl moiety makes the 5-*exo*-*trig* cyclization of **4** ineffective.

In conclusion, the Cp_2TiPh-mediated reductive radical cyclization of cyano ketones in both 5- and 6-*exo* modes was successful to provide an easy entry to 5- and 6-membered α-hydroxycycloalkanones. The coordination to the cyano group plays a key role in the present cyclization, *i.e.* the titanium reagent coordinates to both carbonyl and cyano moieties, and therefore, a low concentration of the Ti^{III} reagent is unfavorable. As a result, the LUMO of the cyano group is lowered and cyclization proceeds irreversibly without formation of the unstable iminyl radical intermediates. To the best of our knowledge, the intramolecular reductive coupling of keto nitriles is quite rare, and thus far only a few examples using one-electron reducing agents such as Zn[11] and SmI_2[9] have been reported in addition to the electroreductive method.[7] In our hands, intramolecular reductive radical cyclization of aromatic keto esters also gave the corresponding α- hydroxycycloalkanones, in which the Cp_2TiPh-coordinated ester group functions as a ketyl radical acceptor. Such an effect did not operate for the α-butenyl ketone, producing no reductive cyclization product. The synthetic utility of the cyano ketone cyclization was also demonstrated in the double cyclization of dicyano diketone **5**, giving rise to an interesting angular triquinane derivative **6**[6] in 75% yield (Scheme 2).

Efficient aerobic epoxidation of alkenes in perfluorinated solvents catalysed by chiral (salen) Mn complexes

Gianluca Pozzi,*† Flavio Cinato, Fernando Montanari and Silvio Quici

Centro CNR and Dipartimento di Chimica Organica e Industriale dell'Università, Via Golgi 19, I-20133 Milano, Italy

Chiral complexes selectively soluble in perfluorocarbons have been synthesized for the first time and tested as catalysts for the epoxidation of alkenes under fluorous biphasic conditions.

The use of perfluorocarbons as reaction media in preparative organic chemistry and homogeneous catalysis is a topic of growing interest.[1] In particular, the value of a new phase-separation and immobilization technique known as FBS (Fluorous Biphase Systems), developed by Horváth and Rábai,[2] is now becoming evident to both academic and industrial researchers. Principles and current achievements of this technique have been recently reviewed.[3] The introduction of FBS raises a number of questions, among them the possible application to enantioselective reactions. Besides helping recovery and reuse of precious chiral reagents or catalysts, it has been repeatedly proposed that the unique solvation environment provided by perfluorocarbons might have unforeseen beneficial effects on the selectivity of the reactions.[4] However, neither examples of enantioselective FBS reactions nor feasibility studies have been reported so far. Metal complexes of salen ligands are able to catalyse the epoxidation of unfunctionalized alkenes.[5] The synthetic route to salen ligands is straightforward and can be adapted to the preparation of many different compounds, including chiral ones.[6] This offers the opportunity to increase the very limited number of known catalysts for FBS oxidations,[7,8] and also to begin assessing the true potential of FBS in enantioselective catalysis. For these reasons we have synthesized two optically active (salen)Mn^{III} complexes (Jacobsen–Katsuki catalysts) selectively soluble in fluorocarbons (Scheme 1). They were tested as catalysts in the epoxidation of alkenes under FBS conditions, in the presence of various oxygen donors.

Both C_2 symmetric salen ligands **1** and **2** were obtained in good yields (75 and 82%, respectively) by the condensation of 2 equiv. of the perfluoroalkylated salicylaldehyde **3** with the proper chiral 1,2-diamine (Scheme 1).‡ The synthesis of the key compound **3** was easily achieved following the pathway reported in the same scheme. The free OH groups of 3,5-diiodosalicyclic acid were protected by methylation with Me_2SO_4 (quantitative yield) before the coupling reaction with 2 equiv. of $C_8F_{17}I$ mediated by Cu powder (65% yield).[9] The ester **4** was converted into **3** by reduction to benzylic alcohol (70% yield) followed by oxidation (85% yield) and demethylation (88% yield). The use of trifluoromethylbenzene as solvent greatly improved the yield of the oxidative step,[10] which was conveniently carried out under aqueous-organic two-phase conditions according to a procedure already reported by us.[11] The free salen ligands were soluble in cold perfluorocarbons,§ CCl_2FCF_2Cl and Et_2O, soluble in hot EtOH and only sparingly soluble in cold halogenated solvents. The corresponding manganese complexes (Mn–**1** and Mn–**2**), obtained in quantitative yield by refluxing an ethanolic solution of ligand with an excess of $Mn(OAc)_2{\cdot}4H_2O$, were soluble in cold perfluorocarbons and CCl_2FCF_2Cl, but completely insoluble in common organic solvents.

Mukaiyama and co-workers have shown that optically active (salen)Mn complexes catalyse the enantioselective epoxidation of alkenes in the presence of molecular oxygen and a sacrificial aldehyde.[12] Fluorocarbons dissolve large quantities of molecular oxygen and this property has been exploited in oxidation reactions, including the epoxidation of alkenes under FBS conditions in the presence of aliphatic aldehydes.[7a,8b] Complexes Mn–**1** and Mn–**2** were thus first tested adapting Mukaiyama conditions to a typical FBS procedure (see Table 1 for results and conditions). Reactions were carried out in the dark at 20 °C under atmospheric pressure of O_2, with Mn–**1** and Mn–**2** immobilized in the fluorinated phase. In the absence of the catalyst, conversions were negligible. As already reported in

MCPBA–NMO[e]	CH_2Cl_2	6	−20	98	86	5
MCPBA–NMO[e,f]	CH_2Cl_2	4	−50	90	85	71

[a] Conditions: [catalyst] = 0.005 M in D-100; [substrate] = 0.1 M in CH_2Cl_2; volume of D-100 = 1 ml; volume of CH_2Cl_2 = 1 ml; oxidant: 0.2 mmol. Stirring rate = 1300 rpm. [b] Determined by capillary GC integration against an internal standard (dichlorobenzene). [c] Determined by capillary GC using a Cyclodex-B chiral column. [d] The catalyst bleached in 30 min. [e] NMO = *N*-methylmorpholine *N*-oxide (0.5 mmol). Addition of the oxidant was carried out according to the procedure described in ref. 13. [f] Substrate = indene.

the case of the cobalt complex of a perfluoroalkylated tetraarylporphyrin, the presence of two distinct phases did not preclude the oxidation of the substrate dissolved in the organic solvent.[7a] Both complexes were found to be active catalysts, affording epoxides in isolated yields up to 85%. Moreover we were able to use the catalysts in substantially lower amounts than those required under homogenous conditions (catalyst = 1.5% with respect to the alkene, instead of 12%).[12] The brown perfluorocarbon layer recovered by simple decantation could be generally recycled in a second run without appreciable decrease of activity. Rather surprisingly, only indene was epoxidized with high enantioselectivity (> 90%). All the other alkenes that we tested gave low (15%) or even 0% ee. The same trend was observed when reactions were carried out in the presence of other oxygen donors more commonly used in combination with chiral (salen)Mn. Results are exemplified in Table 2 for the epoxidation of 1,2-dihydronaphthalene and indene catalysed by Mn–**1**. Epoxidations with the couple *m*-chloroperbenzoic acid–*N*-methylmorpholine *N*-oxide (MCPBA–NMO) were very slow at −78 °C, probably because of hindered mass-transfer between the two liquid phases. Although still lower than in the case of homogeneous systems,[13] reaction rates in the FBS became reasonable at −50 °C. Catalyst Mn–**2** gave lower ee (58%) and conversion (50%) with respect to Mn–**1** in the MCPBA–NMO epoxidation of indene. In the case of 1,2-dihydronaphthalene ee was improved (15 *vs*. 7%), but conversion of the substrate was not satisfactory (45% after 5 h).

Despite the low enantioselectivities generally observed with our prototype catalysts, the FBS approach described here offers distinct advantages over other reported methods of immobilization of salen complexes. Note that in just one case the reported activities, chemoselectivities and ees of heterogenized Jacobsen–Katsuki catalysts were as high as those obtained with one of the best homogeneous chiral (salen)Mn complexes.[14] Stability of the catalyst immobilized in the fluorocarbon layer toward bleaching is increased and its activity remains high. The easy separation of the products from the catalyst which can be readily reused is another considerable benefit that was not given, for instance, by embedding salen complexes into the pores of zeolites.[15] The present results show that an improvement in enantioselectivity does not necessarily follow from the use of FBS versions of chiral catalysts. In this context, the behaviour of Mn–**1** and Mn–**2** is coherent with a strong electron-withdrawing effect exerted by the four perfluoroalkyl chains on the Mn–oxo intermediate responsible for the oxygen transfer.[16,17] Further synthetic efforts are required in order to improve enantiofacial discrimination, still maintaining the peculiar solubility of the catalysts in fluorocarbons.

We thank Ausimont S.p.A. (Milano) for a kind gift of Galden®-D100 and the Progetto Strategico per la Difesa dai Rischi Chimico-Industriali ed Ecologici, CNR (Rome) for financial support.

Recognition-induced control of a Diels–Alder reaction

Douglas Philp*† and Andrew Robertson

School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT

The rational design of a system which is capable of controlling the stereochemical outcome of a Diels–Alder reaction between a maleimide and a furan is presented.

The acceleration of chemical reactions and the control of their regio- and/or stereo-chemical outcome by the intervention of recognition processes in solution—achieved so elegantly by enzymes—has prompted synthetic chemists to design a variety[1] of unnatural systems which are capable of performing similar tasks. We are interested in achieving acceleration and control in solution phase reaction processes *via* the use of molecular recognition. In particular, we wished to investigate the acceleration and control of the Diels–Alder reaction[2] between a maleimide and a furan. In principle, this reaction can give rise to two products—the *endo* and the *exo* adducts—depending on the orientation of the approach of the diene to the dienophile. Normally, the *endo* adduct is the kinetic product and the *exo* adduct is the thermodynamic product of this reaction. In principle, rate acceleration[3]‡ can be achieved by transforming the bimolecular reaction between the diene and dienophile in solution into a unimolecular reaction within a non-covalently bound complex.

The objective can be accomplished most readily by locating complementary recognition sites on the diene and dienophile. Accordingly, we designed (Fig. 1) the maleimide **1**, which bears an amidopicoline moiety, and the furan **2**, which bears a carboxylic acid. These two species would be expected to bind to each other through the mutual recognition between the amidopicoline and the carboxylic acid. Molecular mechanics calculations§ suggested that we could expect the furan and maleimide rings to be positioned (Fig. 1) in an orientation which should accelerate the rate of the Diels–Alder cycloaddition and/or control its stereochemical outcome. The benzene ring used as a rigid spacer between the recognition site and the maleimide ring in **1** might be expected to function in a manner which would permit discrimination between the *endo* and *exo* transition states, hence generating stereoselectivity. Here, we report the observation of the control of the Diels–Alder reaction between **1** and **2** and the rationalisation and analysis of this control by kinetic simulation.

Maleimide **1** was synthesised¶ by standard methods in five steps from 4-(aminomethyl)benzoic acid in an overall yield of 32%. Furan **2** was synthesised in 88% yield by catalytic hydrogenation of commercially-available 3-furylacrylic acid.

In order to assess the efficiency of the rate acceleration and control induced by the formation of a complex betwen **1** and **2**, we followed the course of the reaction between these components in $CDCl_3$ at 30 °C. The initial concentrations of the reactants were 5 mM and the emergence of the resonances arising from **3** and **4** were monitored by 400 MHz ^{1}H NMR spectroscopy over a period of 60 h. The reaction between **2** and benzyl maleimide was chosen as the control reaction and was performed and monitored under identical conditions. The data obtained (Fig. 2) indicates that the recognition-mediated (RM) reaction proceeds significantly faster than the control reaction at this concentration and with high stereoselectivity.

Kinetic simulation and optimisation[4] of the model parameters (Fig. 1) afforded best fit values for the rate constants (Table 1) for the control reaction which, in turn, were used in the kinetic model for the RM reaction. The ratio k_7/k_3 for the *endo* product gives an estimate of 64 mM for the effective molarity (EM) achieved within the [**1**·**2**] complex. The corresponding value for the *exo* isomer (k_5/k_1) is only 6 mM. The *endo* reverse reaction is significantly slower (k_4/k_8 = 170) in the RM system. This observation is consistent with stabilisation of the *endo* product by a strong intramolecular hydrogen bond. The value of k_5/k_6 suggests that there is little or no net product of the *exo* product *via* the recognition mediated pathway.

The kinetic data shown in Table 1 can be converted into an energy profile for the recognition mediated reaction (Fig. 3) by application of standard thermodynamic relationships. In the absence of any stabilising or destabilising effect on the transition states induced by complexation, the activation barrier for the reaction within the complex [**1**·**2**] should simply be the sum of the bimolecular activation barrier and the free energy of binding. For the *exo* isomer, this relationship holds suggesting that the formation of the [**1**·**2**] complex has no net effect on the reaction leading to the *exo* isomer. By contrast, the transition state leading to the *endo* isomer is stabilised by 6.1 kJ mol^{-1}. This stabilisation is not enough to offset the increase (13.1

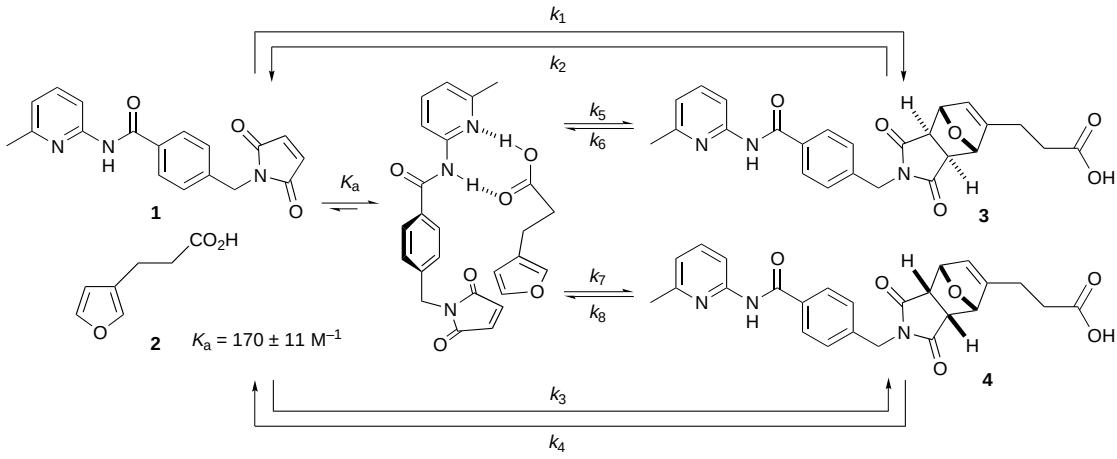

Fig. 1 The design and kinetic scheme for the recognition-mediated Diels–Alder cycloaddition between **1** and **2**. Rate constants are given in Table 1.

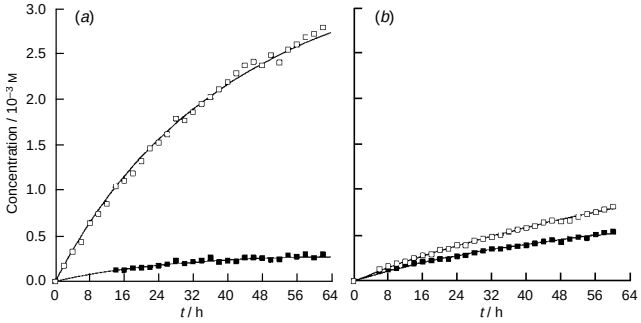

Fig. 2 Concentration–time profiles for (*a*) the reaction between **1** and **2** in $CDCl_3$ at 30 °C and (*b*) the reaction between benzyl maleimide and **2** in $CDCl_3$ at 30 °C. In both cases, the starting concentrations of the reactants were 5 mM. In both plots, the open squares represent the concentration of the *endo* product and the filled squares represent the concentration of the *exo* product. The solid lines represent the best fit of the appropriate kinetic model to the experimental data. For clarity, error bars are omitted from the graphs (errors in concentration are ±3%).

Table 1 Kinetic parameters for the recognition-mediated reaction obtained from the simulation and fitting of the experimental data to the kinetic scheme shown in Fig. 1

$k_1/10^{-5}$ M^{-1} s^{-1}	160 ± 3
$k_2/10^{-5}$ s^{-1}	1.68 ± 0.13
$k_3/10^{-5}$ M^{-1} s^{-1}	209 ± 4
$k_4/10^{-5}$ s^{-1}	0.34 ± 0.03
$k_5/10^{-5}$ s^{-1}	0.99 ± 0.06
$k_6/10^{-5}$ s^{-1}	0.89 ± 0.04
$k_7/10^{-5}$ s^{-1}	13.3 ± 0.11
$k_8/10^{-5}$ s^{-1}	0.002

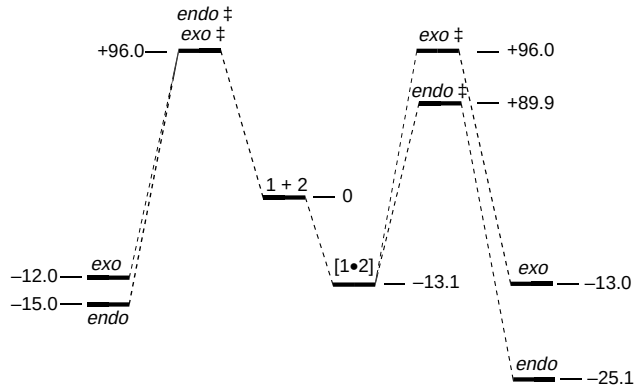

Fig. 3 Thermodynamic profile for the recognition-mediated reaction obtained by the simulation and fitting of the experimental data. The zero point for energy comparisons is set at the energy of the uncomplexed reactants **1** and **2**. All energy values are in kJ mol^{-1}. Data shown to the left of the zero energy point refer to the bimolecular reaction (k_1 to k_4). Data shown to the right of the zero energy point refer to the recognition-mediated reaction (k_5 to k_8).

kJ mol^{-1}) in activation barrier brought about by complexation (thus reflecting the fact that EM < 1 M), however, it does ensure that the *endo* product is produced at a faster rate than the *exo* product within the [**1**·**2**] complex. A more profound effect is observed on the stabilities of the products themselves. Molecular mechanics calculations indicate that the most stable conformation of the *endo* isomer contains an intramolecular hydrogen bond. The *exo* product is incapable of forming an intramolecular hydrogen bond—mechanics calculations indicate that the closest approach of the acid to the amidopyridine is 6.9 Å. This intramolecular interaction is the source of the large discrimination (12.1 kJ mol^{-1}) between the product ground states and, hence, in conjunction with the difference in activation barriers, the selectivity expressed by the reaction for the *endo* isomer.

In conclusion, we have demonstrated that by attaching appropriate recognition sites to a diene and a dienophile, it is possible to exert a high degree of stereocontrol on a Diels–Alder cycloaddition reaction between maleimide and a furan. This control is achieved through the intermediacy of the mutual recognition between reactive partners and by ensuring that only one product—in this case, the *endo* product—is capable of forming stabilising intramolecular hydrogen bonds. The reaction reported here is accelerated only modestly (EM = 64 mM for the *endo* isomer). We are currently addressing this matter and exploring the use of the methodology reported here in the regio- and stereo-control of other [4 + 2] and [3 + 2] cycloaddition reactions.

This research was supported by the University of Birmingham and the EPSRC (Quota Award to A. R.). We thank Professor G. von Kiedrowski for providing us with a copy of his SimFit program. We thank Mr P. Ashton for performing mass spectrometric analyses and Dr Neil Spencer and Mr Malcolm Tolley for the acquisition of the NMR data.

‡ In the present context, we are not concerned with catalysis in the sense of turnover, but rather ensuring that, by encoding the appropriate recognition features within the reagents, the Diels–Alder reaction is accelerated and its stereochemical outcome controlled.

§ Molecular mechanics calculations on the [**1**·**2**] complex were carried out using the AMBER* forcefield as implemented in Macromodel (Version 5.0, F. Mohamadi, N. G. J. Richards, W. C. Guida, R. Liskamp, M. Lipton, C. Caufield, G. Chang, T. Hendrickson and W. C. Still, *J. Comput. Chem*., 1990, **11**, 440) together with the GB/SA solvation model (W. C. Still, A. Tempczyk, R. C. Hawley and T. Hendrickson; *J. Am. Chem. Soc*., 1990, **112**, 6127) for $CHCl_3$. Conformational searching was carried out using 10 000 step Monte Carlo simulations and all conformations generated within 10 kcal mol^{-1} of the global minimum were minimised. The sets of low energy conformations generated were then filtered to locate those conformations where the maleimide and furan were in close proximity (centroid–centroid distance < 5 Å). This produced a significant number (> 10% of total set size) of conformations corresponding to the pro-*endo* complex.

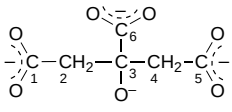
New approach to the solution chemistry of bismuth citrate antiulcer complexes

John A. Parkinson,* Hongzhe Sun and Peter J. Sadler*†

Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ

The use of ^{13}C-labelled citrate together with diffusion-ordered 2D [^{1}H,^{13}C] HSQC NMR spectroscopy has allowed the detection of cluster complexes formed by a bismuth(III) antiulcer complex in aqueous solution at pH 7.4.

Citrate is an important biological ligand for metal ions. It is present at high concentration (*ca.* 200 μM) in blood plasma and forms strong complexes not only with natural metal ions such as Ca^{II}, Mg^{II} and Fe^{III}, but also with ions of toxic (*e.g.* Al^{III}),[1] therapeutic (*e.g.* Bi^{III}) and diagnostic (*e.g.* $^{67}Ga^{III}$)[2] importance. Notable features of the chemistry of citrate are the low pK_a values of its three carboxyl groups (3.13, 4.76 and 5.40 at 25 °C, I = 0.1 M),[3] and, consequently, its existence as a trianion at biological pH (7.4), and the ability of the more highly charged metal ions to deprotonate the hydroxyl group (pK_a *ca.* 11.0)[4] giving rise to very strong metal–alkoxide bonds. Since citrate is a dendritic ligand with seven potential oxygen donors, it is perhaps not surprising that both solution equilibria and solid-state structures of metal citrate complexes are complicated, and often dominated by oligomer formation.



citrate

For example, X-ray crystallography has demonstrated the existence of an iron(III) citrate dimer,[5] an aluminium(III) citrate trimer[6] and a wide variety of structures (dimers, cubes, chains, sheets) for bismuth(III) citrate containing additional hydroxide and oxide ligands.[7] These form the basis of antiulcer drugs such as Colloidal Bismuth Subcitrate (CBS) and Ranitidine Bismuth Citrate (RBC).[8] Equilibria between different types of bismuth citrate complexes in aqueous solution are poorly understood and difficult to study. We show here that the combined use of ^{13}C-labelled citrate and a novel 2D diffusion-ordered [^{1}H,^{13}C] HSQC NMR method provides new insights into the structures and dynamics of bismuth(III) citrate complexes in aqueous solution and can readily be applied to studies of a wide range of other metal citrate complexes.

The normal 1D ^{1}H NMR spectrum of ranitidine bismuth citrate in the region δ 2.0–3.4 is characterized by a combination of sharp intense resonances from ranitidine (which is not bound directly to Bi^{III}),[9] some relatively intense AB quartets and some very broad peaks close to the baseline assignable to citrate. In order to investigate the types of Bi-bound citrate present in ranitidine bismuth citrate solutions at pH* 7 (pH meter reading for D_2O solution), we prepared the complex using citrate labelled at C2 and C4 with >95% ^{13}C.‡ As can be seen in Fig. 1, the peaks in the 2D [^{1}H,^{13}C] HSQC NMR spectrum cover a remarkably large chemical shift range in both the ^{1}H (δ 2.3–3.4) and ^{13}C (δ 47–57) dimensions. The appearance of the spectrum was the same at ranitidine bismuth citrate concentrations of 2 and 5 mM. At a given ^{13}C shift, the ^{1}H peaks appear as doublets of doublets due to the presence of $^{13}C_XH_AH_B$ spin systems, and the two CH_2 groups within one citrate ligand can be non-equivalent, as has been observed for $Na_2[Bi_2(cit)_2]$ by solid-state ^{13}C CP MAS NMR spectroscopy.[7e] The peaks in region 1 of the 2D [^{1}H,^{13}C] HSQC NMR spectrum (Fig. 1) have shifts close to those of free (unbound) citrate, whereas the marked high frequency ^{13}C shifts and pronounced separation of H_A and H_B peaks in region 3 suggest that these cross-peaks arise from rigidly-bound citrate ligands which place H_A and H_B in markedly different environments (*e.g.* bridging ligands in clusters). To investigate the dynamic properties of these bismuth(III) citrate species we measured their self-diffusion coefficients using 2D diffusion-edited heteronuclear single quantum coherence NMR spectroscopy (DOSY-HSQC).

Although DOSY-HSQC has been alluded to in the literature,[10] the present use appears to be the first direct application. One-dimensional homonuclear and heteronuclear diffusion-ordered NMR methods have been used recently to correlate chemical shifts and molecular self-diffusion coefficients. In view of the limitation of peak overlap in 1D ^{1}H NMR spectra, techniques have been developed which combine diffusion methods with standard 2D homonuclear techniques *e.g.* DOSY-COSY,[11] DOSY-NOESY[12] and diffusion-ordered TOCSY.[13] These depend on the existence of either scalar or dipolar coupling between spins and are useful only if cross-peaks from different species are not degenerate. The heteronuclear DOSY-HSQC method in combination with specific ^{13}C labelling can overcome the problem of overlap of ^{1}H resonances, and also provides greatly increased sensitivity in the ^{13}C dimension compared to direct heteronuclear observation.

Self-diffusion coefficients (D) were evaluated from measurements of volume integrals [$A(g_d)$] of peaks in 2D [^{1}H,^{13}C] DOSY-HSQC NMR spectra acquired using the pulse sequence

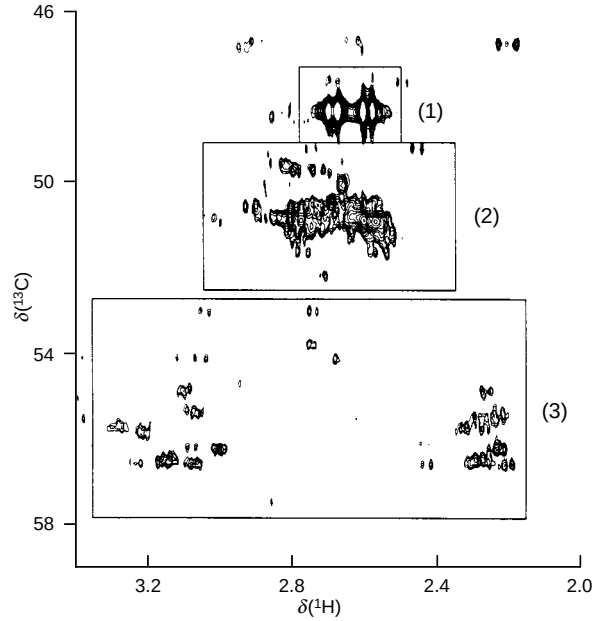


Fig. 1 2D [^{1}H,^{13}C] HSQC NMR spectrum of 5 mM ranitidine bismuth citrate (pH* 7.4) with diffusion weighting at a bipolar gradient strength of 25.05 mT m^{-1} acquired using the scheme in Fig. 2. The volume integrals of peaks in areas labelled 1–3 were used to measure self-diffusion coefficients. The total areas of each region were determined but the behaviour of the individual peaks in each region appear to be similar.

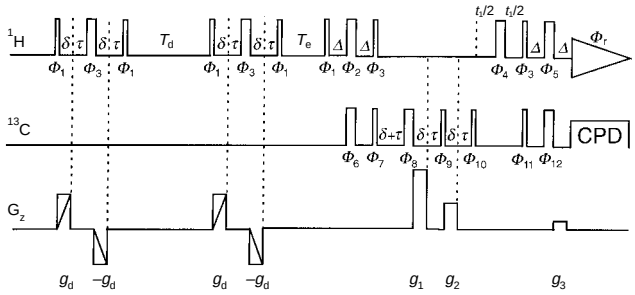

Fig. 2 Pulse sequence used for 2D [^{1}H,^{13}C] DOSY-HSQC experiments. Along the ^{1}H and ^{13}C schemes, narrow and wide vertical bars represent 90° and 180° pulses, respectively. Phase cycling: $\phi_1 = \phi_2 = \phi_5 = \phi_6 = \phi_8 = \phi_{10} = x$; $\phi_3 = y$; $\phi_4 = x, x, -x, -x$; $\phi_7 = 4(y), -4(y)$; $\phi_{11} = x, -x$; $\phi_r = x, -x, x, -x, -x, x, -x, x$. An XY32 composite pulse (CPD) decoupling scheme was applied during acquisition. Diffusion period T_d = 120 ms; settling period prior to the start of the HSQC section of the experiment T_e = 30 ms; gradient duration δ = 2 ms; gradient recovery period t = 100 μs; $\Delta = 1/4J_{HC}$ = 1.84 ms; gradients g_1, g_2 and g_3 were set in the ratio 80 : 30 : 20 with gradient strengths of 60.7, 24.1 and 15.17 mT m^{-1}, respectively. Rectangular gradients were used throughout.

shown in Fig. 2. This uses gradients to select for the correct quantum transitions. The peak volumes vary with the applied gradient strength (g_d) according to eqn. (1):[13c]

$$A(g_d) = \exp[-D(2\gamma g_d \delta)^2(T_d + \tau/2 + 4\delta/3)] \quad (1)$$

where γ is the gyromagnetic ratio of the observed nucleus, T_d the diffusion time, τ the time interval between bipolar gradients, and δ the gradient duration.

As can be seen from Fig. 3, the diffusion coefficients associated with peaks in regions 2 and 3 are less than half that associated with region 1, which in turn is less than half of the value measured for citrate itself. If we make the assumption that the molecules concerned are approximately spherical (with radius, r) then, according to the Stokes–Einstein equation, the diffusion coefficient is proportional to r^{-1}. If free citrate is assumed to have a diameter of *ca*. 4 Å then the bismuth(III) citrate complexes giving rise to the peaks in regions 2 and 3 have diameters of *ca*. 20 Å. This is close to the size of the dodecanuclear cluster $[Bi_{12}O_8(cit)_8]^{12-}$ in the crystalline state.[7d] In this structure some of the citrate ligands form bridges between three Bi^{III} ions and such a coordination mode might

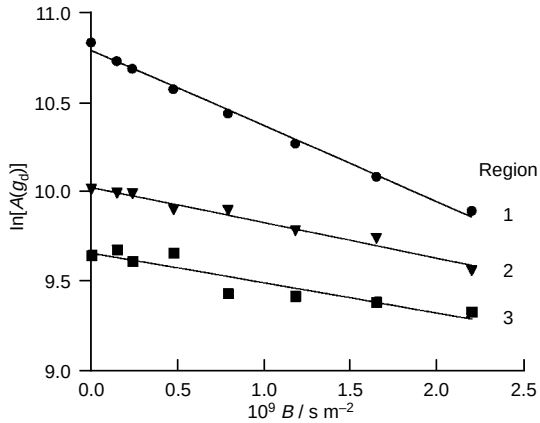

Fig. 3 Plots of ln[$A(g_d)$] *vs.* $B = q^2(T_d + \tau/2 + 4\delta/3)$ where $A(g_d)$ is the (arbitrary) volume integral at a diffusion gradient strength g_d, and $q = (2\gamma g_d \delta)$, and g_d varies from 8.35 to 125.25 mT m^{-1} in increments of 16.7 mT m^{-1}, for peaks in region 1 (●), region 2 (▼) and region 3 (■) of Fig. 1. The slope is proportional to D, the self-diffusion coefficient, giving the values: 4.3, 1.9, 1.7 and 10.2 × 10^{-10} m^2 s^{-1} for regions 1, 2, 3 and free citrate, respectively.

give rise to the unusual shifts we observe, although several types of cluster species appear to be present in solution.

In conclusion we have shown that the use of diffusion-ordered 2D [^{1}H,^{13}C] HSQC NMR spectroscopy, together with ^{13}C-enriched citrate, allows the sensitive detection of a wide range of types of bound citrate in aqueous solutions of the antiulcer drug ranitidine bismuth citrate at pH* 7.4. The unusual ^{1}H,^{13}C shifts and slow diffusional behaviour of some of these species provide a new method of characterising citrate cluster complexes. The identification of cluster species in solution is particularly important since they may be taken up by cells by a different mechanism compared to low molecular mass complexes. We are applying similar methods to the study of a range of biologically important citrate complexes.

We thank GlaxoWellcome for their support of this work, the EPSRC for access to the 600 MHz NMR Service Instrument in Edinburgh and Professor John Lindon (Birkbeck College) for helpful discussions.

Production and isolation of the C_{80}-based group 2 *incar*-fullerenes: *i*CaC_{80}, *i*SrC_{80} and *i*BaC_{80}

T. John S. Dennis and Hisanori Shinohara*†

Department of Chemistry, Nagoya University, Nagoya 464-8602, Japan

We report the first production and isolation of mono-*incar*-fullerenes based on the missing fullerene C_{80}, and their characterisation by UV–VIS–NIR absorption spectroscopy.

Mass spectroscopic measurements of solvent-extracted fullerenes obtained from arc-processed carbon reveal good signals from C_{76}, C_{78}, C_{82}, C_{84}, C_{86} *etc*., but the signal from C_{80} is meagre. Small quantities of C_{80} were isolated only recently by Hennrich *et al.*[1] Thus at first sight, it seems surprising that C_{80}-based *incar*-fullerenes are isolated in yields similar to other *incar*-fullerenes. The dilanthanum *incar*-fullerene, *i*La_2C_{80}, was first produced and solvent extracted by Whetten and coworkers.[2] Isolation of *i*La_2C_{80}[3,4] and *i*Ce_2C_{80}[5] has recently been achieved, and their UV–VIS–NIR absorption spectra,[3,5] and their ^{139}La and ^{13}C NMR[4] spectra were reported.

In our continuing efforts to elucidate structures and electronic properties of group 2 element-based *incar*-fullerenes,[6–13] we have fortuitously found C_{80}-based *incar*-fullerenes in arc-processed soot. Here we present the first successful production, isolation, and characterisation of mono *incar*-fullerenes based on C_{80}: namely *i*MC_{80} (M = Ca, Sr, Ba). The yields of these materials are relatively high; comparable to those of *i*MC_{82} and *i*MC_{84}.[6–9]

Fullerene-soot containing group 2 element-based *incar*-fullerenes is produced by the direct-current contact-arc method using graphite–metal carbide composite rods.[9,12] The fullerenes are extracted using ultrasonication and CS_2 solvent. Although the extracted *incar*-fullerenes are air stable, they are air sensitive prior to extraction, and are collected and extracted under totally anaerobic conditions.[12]

Isolation schemes for all three *incar*-fullerenes are very similar, being achieved by our three stage HPLC treatment. Stage 1 is a rough separation step used primarily to remove C_{60} and C_{70}. A Cosmosil Buckyprep column (28 mm × 250 mm) is used with a high injection volume (100 ml; 30 ml min^{-1} flow rate, toluene eluent). LD-TOF mass spectroscopy reveals that for each case *i*MC_{80} elutes from the column with the C_{86}-containing fraction. Following concentration, the *i*MC_{80}-containing fraction is subjected to further HPLC treatment. In stage 2, recycling HPLC, a Cosmosil 5PYE column (20 × 250 mm; 10 ml injections, 18 ml min^{-1} flow rate, toluene eluent) is used as retention times on this column are approximately half those on the buckyprep, yet its resolution is similar. After typically four cycles separation into several subfractions is complete. The final eluting sub-fraction contains C_{86}, *i*MC_{84},[7–9] and *i*MC_{80}; all other sub-fractions contain minor isomers of C_{84}. In stage 3, again recycling HPLC, a Regis Buckyclutcher column (20 × 300 mm) is used to separate the materials that cannot be resolved on either Buckyprep or 5PYE columns (5 ml injections; 9.3 ml min^{-1} flow rate, toluene eluent). After 9 recycles three fractions are observed to be completely separated. These contain, in order of increasing retention time, empty C_{86}, *i*MC_{84},[7–9] and *i*MC_{80}. To ensure the purity of the sample, stage 3 HPLC was repeated on the *i*MC_{80} fractions. The result was fine black powders of mass 0.60, 0.30 and 0.10 mg for *i*CaC_{80}, *i*SrC_{80} and *i*BaC_{80}, respectively. Complete isolation is confirmed by HPLC analysis and laser-desorption time-of-flight mass spectrometry. Fig. 1 shows a stage 3 recycling-HPLC chromatogram for *i*BaC_{80}.

Fig. 2 shows the UV–VIS–NIR absorption spectra of *i*CaC_{80}, *i*SrC_{80} and *i*BaC_{80}, recorded between 400 and 2000 nm in CS_2 solution. All three spectra are remarkably similar, being characterised by onsets near 1400 nm, three characteristic and sharp absorption bands at *ca*. 500, 600 and 700 nm, and a broad feature around 1050 nm. These particularly sharp absorption bands may arise from electron transfers from the encased metals to the C_{80} cages. They have not been observed in any absorption spectrum of any previous *incar*-fullerene,[12] suggesting unique electronic and structural properties for these C_{80}-based mono *incar*-fullerenes. These spectra differ considerably from the UV–VIS–NIR spectrum of empty C_{80}.[1] That spectrum has an onset near 900 nm, and contains weak broad absorption bands near 600, 800 and 880 nm. The present spectra can also be contrasted with those of other C_{80}-based *incar*-fullerenes. For *i*Ce_2C_{80}[5] and *i*La_2C_{80},[3] both spectra have onsets near 600 nm, but are otherwise practically featureless.

There are seven structural isomers (D_2, D_{5d}, C_{2v}, C_{2v}', D_3, D_{5h} and I_h) for the empty C_{80} fullerene that satisfy the isolated pentagon rule (IPR).[14] A ^{13}C NMR study on C_{80} indicates the most abundant isomer has D_2 symmetry.[1] However, *ab initio* calculations[15] predict encapsulation of two La atoms in the I_h isomer is much more stable than the D_2 or other isomers. Confirmation of I_h symmetry for *i*La_2C_{80} has come from recent ^{13}C NMR measurements.[4] [80-I_h]Fullerene has two electrons in a fourfold degenerate HOMO. Accommodation of six further electrons forms a closed shell electronic state, *i*$La_2^{6+}C_{80}^{6-}\{I_h\}$.[15,16] The late onsets and featureless nature of the UV–VIS–NIR absorption spectra of *i*La_2C_{80} and *i*Ce_2C_{80} have been attributed to the closed-shell nature of the icosahedral *incar*-fullerene cage.[3,5]

Our studies suggest two electrons are transferred to the cage of group 2 element-based *incar*-fullerenes.[6–11] If *i*Ca/Sr/BaC_{80}

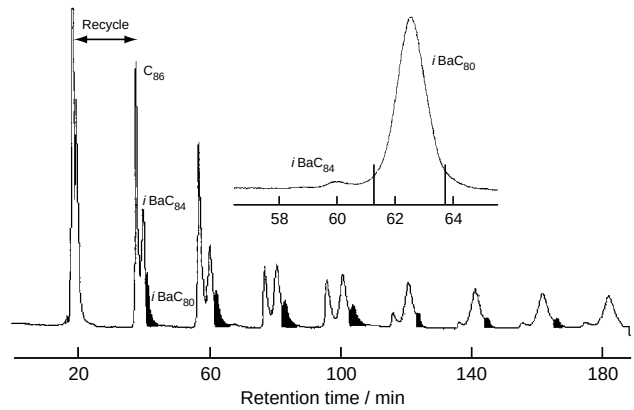

Fig. 1 Stage 3 recycling HPLC chromatogram for the purification of *i*BaC_{80}. The three peaks, in order of increasing retention time, are C_{86}, *i*BaC_{84} and *i*BaC_{80} (highlighted) (the changing relative intensities after the third cycle is due to peak cutting by the experimenter). Inset, the third-cycle chromatogram for *i*BaC_{80} from the repeat stage 3 separation, indicates the high sample purity.

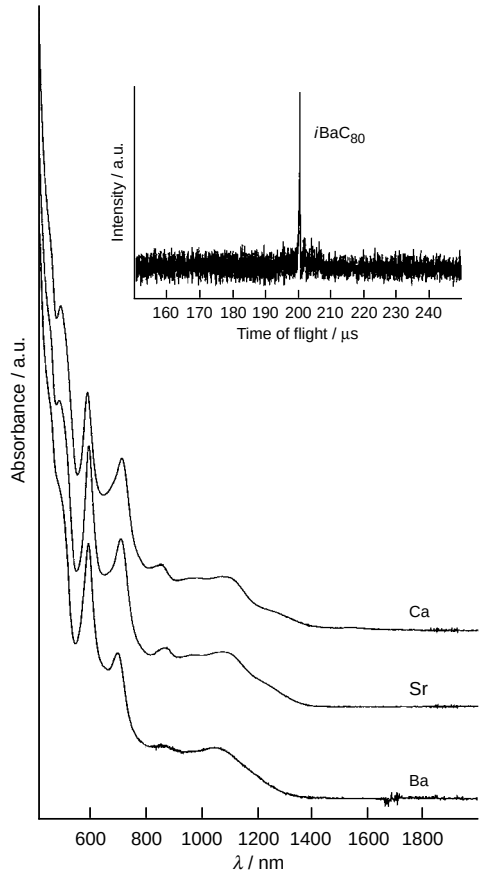

Fig. 2 The UV–VIS–NIR absorption spectra of *i*Ca/Sr/BaC_{80}. The absorption dips at *ca*. 500 and 700 nm account for three CS_2 solutions being greenish brown. The three sharp peaks appearing between 500 and 700 nm are particularly salient (see text). The LD-TOF mass spectrum (inset) of isolated *i*BaC_{80} confirms sample purity.

also has I_h symmetry, these materials may possess novel solid state properties, high-T_c superconductors, for example, because the transfer of two electrons to the fullerene cage would result in forming a half-filled degenerate HOMO: a situation strikingly similar to the half-filled threefold degenerate HOMO of superconducting A_3C_{60} (A = K, Rb).

The great similarity between the UV–VIS–NIR absorption spectra of the present samples (Fig. 2), coupled with their near identical HPLC retention times, strongly suggests that all three *incar*-fullerenes share the same C_{80} isomer.

Bi- and tri-nuclear ruthenium(II) complexes containing tetrapyridophenazine as a rigid bridging ligand

Pierre Bonhôte,*[a]† Ariane Lecas[b] and Edmond Amouyal*[b]‡

[a] *Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139, USA and Laboratoire de Photonique et Interfaces, Ecole Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland*

The rigid, aromatic bis-tridentate bridging ligand tetrapyrido[2,3-a:3′,2′-c:2″,3″-h:3‴,2‴-j]phenazine (tpp) allowed the preparation of linear, stable bi- and tri-nuclear complexes of ruthenium(II) exhibiting low energy Ru → tpp MLCT absorptions and a strong electronic coupling in the mixed-valence state.

Following the pioneering work of Creutz and Taube,[1] much interest has been devoted to the bridged bi- and poly-nuclear ruthenium complexes, particularly in their mixed valence state.[2,3] The short bridging ligands such as pyrazine,[1] *tert*-butylmalonitrile, dinitrogen, cyanogen[2] or 4,4-dithiodipyridine[4] provide often a strong enough coupling between ruthenium–amine centers to allow complete electronic delocalization in the mixed-valence (MV) state (class III MV complexes). On the other hand, polynuclear ruthenium–polypyridine complexes usually show weaker electronic coupling and are valence-trapped (class II).[5] Tetrakis(2-pyridyl)pyrazine (tppz) was up to now the only polyazine bridging ligand allowing a Ru–Ru coupling of a similar intensity as in the Creutz–Taube ion.[5–8] Polynuclear complexes of ruthenium(II) are valuable sensitizers for the conversion of light into chemical or electrical energy[9] as they are efficient MLCT chromophores in which the absorption maximum can be tuned to almost any wavelength of the visible spectrum.[10] In order to ensure a potentially good charge separation from an excited state in a donor–chromophore–acceptor triad, it is suitable to aim at linear, rigid assembly.[11] It is thus obvious that the most promising bridging ligands are the bis-tridentate ones, like tppz. In that class of polyazines, tetrapyrido[2,3-a:3′,2′-c:2″,3″-h:3‴,2‴-j]phenazine (tpp), is the representative which is at the same time the most rigid and the shortest intermetallic spacer. We have developed a straightforward synthesis of this compound[12] and report here on its outstanding properties as a bridging ligand between ruthenium–terpyridine units.

Attempts to react directly a blue solution of ruthenium(II) chloro complexes with tpp in various ratios in refluxing ethylene glycol led only to the mononuclear complex $[Ru(tpp)_2]Cl_2$ **1**. For the elaboration of polynuclear Ru–tpp complexes, we used $RuCl_3$(ttp) (ttp = 4′-*p*-tolyl-2,2′-6′,2″-terpyridine) as a starting ruthenium containing unit.[5,7,8,11,13] The advantage of ttp[14] over terpyridine is the availability of a methyl group for further linkage with electron donors or acceptors[11] and as a useful internal standard for NMR integration. Reaction of $RuCl_3$(ttp) with an excess of tpp in refluxing ethanol–water–triethylamine, followed by precipitation by NH_4PF_6 afforded the orange $[Ru(tpp)(ttp)][PF_6]_2$ **2** in 52% yield (Scheme 1). This complex reacted under the same conditions with $RuCl_3$(ttp) to give, after chromatography over SiO_2, the green binuclear complex $[(ttp)Ru(ttp)Ru(ttp)][PF_6]_4$ **3** in 39% yield. The same product was obtained by reacting tpp with $RuCl_3$(ttp) (28% yield). In the reductive solvents mentioned above, the main product obtained by reaction of **1** with 3 equiv. of $RuCl_3$(ttp) was surprisingly the binuclear complex **3**, and not the expected trinuclear species $[(ttp)Ru(tpp)Ru(tpp)Ru(ttp)][PF_6]_6$ **4**. Similarly, the reaction of $RuCl_3$(ttp) with a slight excess of **1** afforded **2** only instead of the expected $[(ttp)Ru(tpp)Ru(tpp)][PF_6]_4$. The use of a less reducing mixture [water–methanol (3:1)] allowed finally the synthesis of **4** in 16% yield by reaction of **1** with $RuCl_3$(ttp). Even in this case, a small amount of the binuclear complex was formed. It appears thus that $RuCl_3$(ttp) is able to abstract a tpp ligand from $[Ru(tpp)_2]^{2+}$ under reducing conditions.§

For all the investigated compounds, the first one-electron cathodic wave observed by cyclic voltammetry¶ was attributed to the tpp-centered reduction. It shifts from −1.23 V *vs.* SCE in the free ligand to −0.80 V in **2** and further to −0.38 V in **3**. The oxidation waves corresponding to the $Ru^{2+/3+}$ couple appeared at 1.52 V in **2** but at 1.32 and 1.71 V in **3**. This splitting ΔE of 0.39 V between the $(Ru–Ru)^{4+/5+}$ and the $(Ru–Ru)^{5+/6+}$ redox potentials, symmetrically above and below the potential of **2**, indicates a strong degree of interaction between the two metallic centers. It corresponds to a comproportionation constant $K_c = [(Ru–Ru)^{5+}]^2/\{[(Ru–Ru)^{6+}][(Ru–Ru)^{4+}]\} = \exp(\Delta EF/RT) = 4 \times 10^6$ which is identical to the value reported for the Creutz–Taube ion[1] and higher than the value obtained for $[(ttp)Ru(tppz)Ru(ttp)]^{5+}$ ($K_c = 10^5$).[5] The insolubility of **1** and **4** in the presence of supporting electrolytes prevented any determination of their electrochemical properties.

[a] As hexafluorophosphate.

The visible absorption spectra of **1**, **2**, **3** and **4** as well as the emission spectrum of **2** are shown in Fig. 1 and the corresponding parameters are given in Table 1. The monometallic complexes show a sharp Ru→tpp MLCT band around 520 nm. In **2**, an additional Ru→ttp MLCT band appears at 450 nm and the complex emits at room temperature at 738 nm, with a yield of $1.2 \pm 0.2 \times 10^{-4}$ and a lifetime $\tau = 60$ ns. No emission was detected from **1**. In **3** and **4**, the low-energy absorption band is attributed to the Ru→tpp MLCT. It is strongly red-shifted compared to those of the monometallic species, while the Ru→ttp band is only slightly affected. This shift is attributed both to the strong stabilization of the π* orbital of the tpp ligand by the chelation of the second Ru^{II}, as shown by the associated low reduction potential, and to the splitting of the t_{2g} orbitals, the d_{xy} set engaged in the bonds with the π* orbital on the pyrazine ring of tpp being destabilized by the metal–metal interaction, while the other sets linked to ttp are less (d_{yz}) or not at all (d_{xz}) affected. From **3** to **4**, the Ru→tpp MLCT band only red-shifts by 14 nm but grows by 70%, which means that the set of t_{2g} orbitals does not undergo a significant additional splitting by addition of a third Ru^{II} center, certainly because the environment is different for the central and for the two terminal metals. While solutions of **3** in acetonitrile could be stored for weeks at room temperature without degradation, **4** was observed to break down quite rapidly, its solution showing after 7 days essentially the spectrum of **2**. No emission was detected below 900 nm for **3** and **4** which could emit further in the IR. The photophysical study of these complexes will be published elsewhere. Oxidation of **3** by Ce^{4+} in acetonitrile acidified by 0.5 M CF_3CO_2H led to the disappearance of the Ru→tpp MLCT band accompanied by the rise of a new absorption at 592 nm, attributed to a tpp→Ru ligand-to-metal charge transfer. Concomitantly, an 'intervalence' absorption band appeared at 1388 nm (7206 cm^{-1}). Its width at half-intensity $\Delta\nu_{1/2}$ is only 2000 cm^{-1}, half the value calculated by the Hush model for a class II complex (4080 cm^{-1}).[2,15] This discrepancy indicates that **3** is a class III complex. In such a case, the electron coupling matrix element V_{ab} is half the energy of the band maximum, *i.e.* 0.447 eV.

In conclusion, tpp appears to form stable mono- and binuclear ruthenium complexes and to mediate a strong interaction between the metallic centers. The intense low-energy Ru→tpp MLCT absorption could prove useful for the development of supramolecular systems and for the photochemical conversion of solar energy.

Hydrogen evolution and oxygen reduction at a titanium sonotrode

H. N. McMurray, D. A. Worsley*† and B. P. Wilson

The Department of Materials Engineering, University of Wales Swansea, Singleton Park, Swansea, UK SA2 8PP

A titanium sonotrode is used to demonstrate that ultrasonic irradiation significantly enhances the rate of electrochemical oxygen reduction and hydrogen evolution reactions in neutral aqueous electrolyte.

The effect of ultrasound in the 15–40 kHz frequency range on the kinetics and mechanism of electrochemical reactions is a topic of rapidly growing interest. Power ultrasound produces cavitation in solution which may influence electrode processes through four distinct modes of interaction: (*i*) mass transport enhancement owing to turbulence and microstreaming,[1–4] (*ii*) continuous activation of the electrode surface,[5] (*iii*) the formation of ions, radicals and other high energy intermediates,[1] (*iv*) the mediation of chemical processes associated with heterogeneous electron transfer steps[6] and (*v*) product desorption.[7] Ultrasound baths or probes may be used to irradiate electrodes indirectly.[8] However, recent studies have demonstrated greater rate enhancement using directly stimulated 'sonotrodes' in which the solution contacting end of a ultrasonic transducer horn acts as the electrode surface.[9,10] In the work described here a titanium sonotrode was used to investigate the effect of ultrasound on electrochemical hydrogen evolution [reaction (1)] and oxygen reduction [reaction (2)] in aqueous electrolyte.

$$2H^+_{(aq)} + 2e^- \rightarrow H_{2(g)} \quad (1)$$

$$O_{2(aq)} + 2H_2O + 4e^- \rightarrow 4OH^-_{(aq)} \quad (2)$$

Reactions (1) and (2) are the cathodic reactions most commonly associated with metallic corrosion in aqueous systems and acceleration of corrosion rates in the presence of cavitation is a significant technological problem.[11] Both reactions have complex multistep mechanisms involving chemisorbed intermediates,[12,13] and reaction rates could potentially be influenced through any one of modes (*i*)–(*v*) above. In the current study we aim to determine the extent to which the cathodic processes associated with metallic corrosion are influenced by the presence of intense cavitation.

The titanium (Ti) tip sonotrode and sono-electrochemical cell arrangement, used in this work is illustrated in Fig. 1. A 20 kHz ultrasound generator (Branson Ultrasonics Sonifier 250) was used with a standard flat 10 mm titanium tip. The ultrasonic power level used throughout was 26 W cm^{-2}, as determined using calorimetry.[4] The circulation of water from a thermostated bath through a stainless steel cooling coil,[9] allowed the electrolyte temperature to be kept constant to within 1 °C during all experiments. All voltammetric measurements were carried out at 30 °C using a Solartron 1280 potentiostat under computer control. The electrolyte used was a 0.7 mol dm^{-3} aqueous Na_2SO_4 adjusted to pH 7 using 0.1 M NaOH. All chemicals were obtained from BDH at Analar grade purity and doubly distilled water was used throughout. Prior to measurement under deaerated conditions the electrolyte was purged with prepurified argon (BOC) for 30 min. Linear sweep voltammograms were recorded by sweeping the sonotrode potential from −2.5 to 0 V *vs.* SCE at 0.014 V s^{-1}. Prior to recording voltammetric data the sonotrode potential was cycled between −2.5 and 0 V at ±0.014 V s^{-1} in the absence of ultrasound until the voltammogram became reproducible (< three cycles).

The voltammetric response of the Ti sonotrode in deaerated and aerated electrolyte is shown as a series of Tafel plots in Fig. 2(*a*) and (*b*) respectively; H_2 evolution occurred visibly at potentials < −1.6 V. It may be seen from Fig. 2 that the characteristic shapes of the Tafel plots remained similar under silent and sonicated conditions but that current density values were higher at all potentials in the presence of ultrasound. The magnitude of the sono-electrochemical effect, its reproducibility and reversible nature are highlighted in Fig. 3(*a*) and (*b*) for the deaerated and aerated solutions, respectively which illustrates the transient (time dependent) current responses of the sonotrode when subject to short (1–5 s) pulses of sonication at constant potential. Fig. 3(*a*) shows the response at −1.3 V in deaerated electrolyte and Fig. 3(*b*) shows the response at −1.25 V in aerated electrolyte. In both cases it can be seen that the

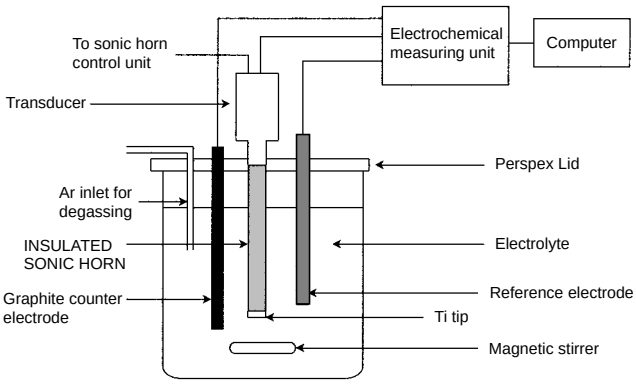

Fig. 1 Schematic diagram of sonotrode and electrochemical cell arrangement

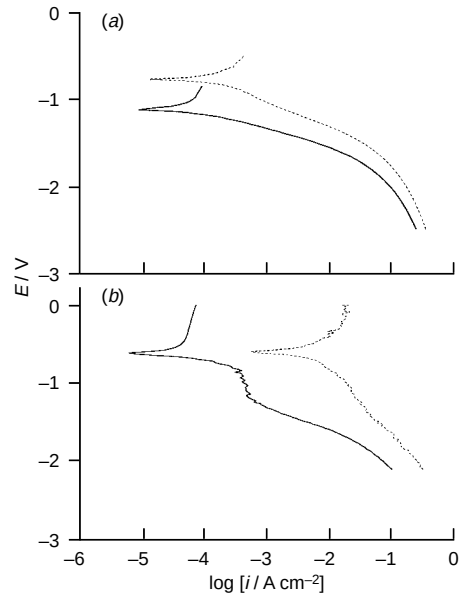

Fig. 2 Tafel plots of titanium sonotrode voltammetric response under silent (—) and sonicated (---) conditions in (*a*) deaerated and (*b*) aerated neutral 0.7 M aqueous Na_2SO_4 at 30 °C. Potential sweep rate = 0.014 V s^{-1}.

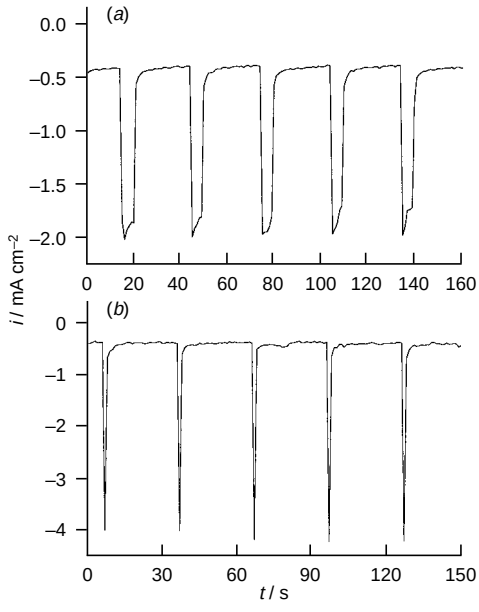

Fig. 3 Transient (time dependent) current response of titanium sonotrode in neutral 0.7 M aqueous Na_2SO_4 at 30 °C. (*a*) Deaerated, 5 s ultrasound pulses at −1.3 V *vs.* SCE. (*b*) Aerated, 1 s ultrasound pulses at −1.25 V *vs.* SCE.

changes in current density resulting from sonication are instantaneous and reversible. This finding rules out the possibility that bulk heating by ultrasound contributes significantly to the observed current density increases. The n-type semiconducting TiO_2/Ti_2O_3 layer, which rapidly forms on Ti exposed to air, can limit the rate of electrochemical reactions (especially anodic reactions) at Ti sonotrodes.[9] However, Figs. 2 and 3 suggest that the Ti sonotrode is an adequate cathode for reactions (1) and (2) at the potentials indicated and that reaction rates are significantly enhanced by sonication.

Considering the deaerated case first, it is assumed that the cathodic currents in Fig. 2(*a*) are entirely due to reaction (1). Under silent conditions the Tafel plot is approximately linear over the range −1.25 to −1.6 V which is consistent with reaction (1) being activation controlled; the Tafel slope is 190 mV decade^{-1}. At potentials cathodic of −1.7 V the Tafel plots curve in a manner suggestive of current limiting. Under sonicated conditions the Tafel plot is shifted anodically by approximately 500 mV and the Tafel slope in the linear region increases to 280 mV decade^{-1}. The change in Tafel slope is consistent with ultrasound producing a change in mechanism or rate determining step for reaction (1). Ultrasonic current density enhancement at constant potential is greatest in the linear, activation controlled region (a factor of *ca*. five) and smaller in the current limiting region (a factor of *ca*. two). Since the effect of ultrasound is greatest when reaction (1) is activation controlled it is probable that interaction with the electrochemical process occurs primarily through modes (*ii*)–(*v*) above.

Considering the aerated case, under silent conditions the Tafel plot in Fig. 2(*b*) shows a well developed current plateau between −0.9 and −1.4 V due to reaction (2) becoming limited by mass transport of O_2 to the sonotrode surface.[15] It is therefore assumed that the cathodic currents in Fig. 2(*b*) result predominantly from reaction (2) at potentials cathodic of −1.4 V, and from a combination of reactions (1) and (2) at potentials anodic of −1.4 V. Ultrasonic current density enhancement at constant potential is greatest (more than one order of magnitude) at potentials anodic of −1.4 V and the diffusion limited current plateau becomes indistinct in the sonicated Tafel plot. The current density increase between −0.9 and −1.4 V must arise primarily through mode (*i*) above and implies a decrease of at least tenfold in the effective thickness of the Nernst diffusion layer under sonicated conditions. Modes (*ii*)–(*v*) may be significant at potentials anodic of −0.9 V where reaction (2) is not mass transport limited, but mode (*i*) probably remains an important contribution to the current increase observed on sonication.

These preliminary results show that the rates of electrochemical O_2 reduction and H_2 evolution at a titanium surface are significantly increased by power ultrasound. Ultrasonically enhanced mass transport appears to be the principle cause of rate increase in the case of O_2 reduction but significant rate increase also occurs in the case of activation controlled H_2 evolution. The acceleration of both these cathodic processes may contribute to the increased rates of metallic corrosion observed in the presence of intense cavitation. Furthermore, the finding that activation overpotentials for H_2 evolution may be reduced by ultrasound suggests that electrocatalytic sonotrodes might usefully be investigated as a means of increasing the efficiency of technologically important gas evolving electrolyses.

Evidence for the presence of dual emission in a ruthenium(II) polypyridyl mixed ligand complex

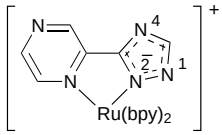
Tia E. Keyes, Christine O'Connor and Johannes G. Vos*†

Inorganic Chemistry Research Centre, School of Chemical Sciences, Dublin City University, Dublin 9, Ireland

The complex $[Ru(bpy)_2(pztr)]^+$ 1 [bpy = 2,2′-bipyridyl, Hpztr = 3-(pyrazin-2-yl)-1,2,4-triazole] exhibits two emission maxima in fluid solution [ethanol–methanol (4 : 1)] over the temperature range 120–260 K; from fluorometric studies two well resolved emission maxima are observed at 590 and 700 nm, accompanied by two different lifetimes; the observations suggest the presence of two emitting states in this compound, one bpy and one pyrazine based.

The photophysical properties of ruthenium(II) polypyridyl complexes make them attractive building blocks for supramolecular assemblies and as a result several thousands of homo- and hetero-leptic compounds have been reported in the literature.[1] It is generally accepted that emission in ruthenium polypyridyl complexes originates from a triplet metal-to-ligand charge-transfer (^{3}MLCT) state.[1] In the case of a mixed ligand complex this excited state can in principle be located on any of the ligands. Many detailed studies have therefore been carried out to determine the location of the emitting state in such compounds. From theoretical considerations one would predict that emission will occur from the lowest triplet state only[2] and indeed this is observed in almost all cases. In rigid media a number of dual emissions have been documented.[3] However, in solution such reports are rare,[4] and to our knowledge no clear-cut cases have been reported in solution for ruthenium polypyridyl type compounds.

In this contribution, we wish to present direct evidence for dual emission in solution over a wide temperature range for the mononuclear mixed ligand ruthenium(II) polypyridyl complex $[Ru(bpy)_2(pztr)]PF_6$, **1** [bpy = 2,2′-bipyridyl, Hpztr = 3-(pyrazin-2-yl)-1,2,4-triazole].



The compound under investigation was synthesised as described previously.[5] The N^2 and N^4 isomers were separated by semi-preparative HPLC and characterized by ^{1}H NMR spectroscopy, analytical diode array HPLC, and elemental analysis. These techniques confirm that the purity of **1** is > 99%. In this study only the N^2 isomer, shown above, was investigated.

Earlier work on these compounds has shown that isomerisation, photoinduced or otherwise, of the deprotonated N^2 and N^4 isomers does not occur,[5c,d] while pK_a values obtained for the ground state and excited state for the N^2 isomer are between 3.5 and 4 and as a result, protonation of **1** under the experimental conditions discussed here is unlikely.[5a]

One can therefore be confident that in the experiments carried out in this contribution only one species will be present. It is furthermore important to note that pK_a values, electrochemical experiments and resonance Raman data have shown that bpy and pyrazine based excited states are similar in energy. In **1** the bpy state is lower in energy, while in the complex containing a protonated triazole the emitting state is pyrazine based.[5b,d] Finally, emission and absorption maxima of **1** in its protonated and deprotonated states are very similar.[5a]

Selected temperature dependent luminescence spectra for **1** [ethanol–methanol (4 : 1), containing 1% diethylamine or ammonia to assure deprotonation of the triazole ring] are shown in Fig. 1. At 90 K, the spectrum obtained [Fig. 1(*a*)] is typical for compounds of this type with a single emission being observed at 617 nm. After laser excitation at 355 nm the luminescence decays according to a single exponential with a lifetime of 3200 ns (all lifetimes ±10%). On increasing the temperature to 145 K, [Fig. 1(*b*)] the emission spectrum of **1** is resolved into two distinct bands; one, as expected, at 710 nm and an additional feature at 590 nm. The luminescent signal obtained at this temperature monitored at 650 nm cannot be fitted as a single exponential. Normal curve fitting procedures yield lifetimes of 2400 and 800 ns with ratios of 60 and 40%, respectively. Measurements monitored out at 700 and 590 nm yield single exponential decays and identify the long lifetime as belonging to the 700 nm signal. At higher temperatures the contribution from the higher energy component decreases. The temperature dependence of the emission decay for the two signals is therefore different. Excitation spectra obtained at both emission maxima are sufficiently similar to suggest that both emissions are based on MLCT emissions. The excitation spectrum of the 590 nm emission shows an absorption maximum at 440 nm, while for the 700 nm band a maximum is observed at 465 nm.

In cases where a dual emission is observed, the contribution from impurities is always a concern. However, we do not believe that the data above can be attributed to the presence of an impurity. First of all, the lifetimes and intensities observed for the two emission components (see above) suggest that the concentration of an impurity would have to be high and this is not observed. Also, the same results were obtained for various samples of **1**. Finally, when the triazole is protonated a normal single exponential behavior is obtained over the entire temperature range [77 K (2200 ns), 175 K (800 ns) and room temperature (230 ns)].

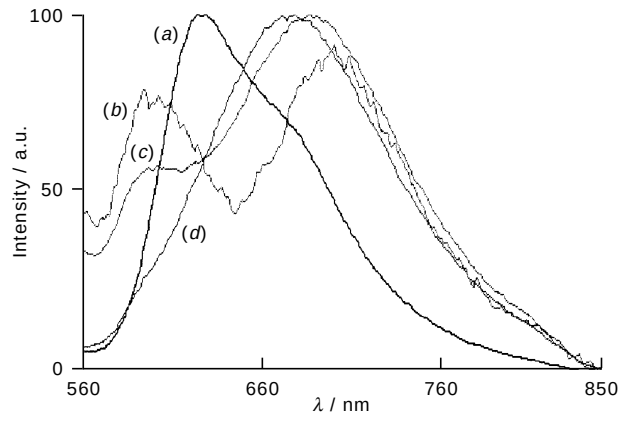


Fig. 1 Temperature dependent luminescent spectra of **1** in ethanol–methanol (4 : 1) and 1% diethylamine, at (*a*) 90, (*b*) 145, (*c*) 220 and (*d*) 298 K

On the basis of these considerations we are confident that the results obtained are best explained by the presence in the title compound of two weakly coupled emitting states. As pointed out above, earlier work has shown that bpy and pyrazine based MLCT states are similar in energy. For example, the energy separation between these two emitting states of 2400 cm^{-1} which at 145 K is consistent with the electrochemistry of this complex which shows a potential difference of 0.33 eV between the first two bpy and pyrazine based reductive steps of **1**. We therefore propose, based on our earlier results,[5] that the highest energy emitting state observed between 120 and 260 K, is pyrazine based. After excitation to the ^{1}MLCT level, efficient intersystem crossing to the lowest, strongly coupled bpy based triplet state is observed. Up to 260 K it is the lowest energy manifold of the bpy triplet that is populated. Population of the pyrazine based triplet state can in this model only occur by thermal means. The lower energy components of this manifold are weakly coupled to a pyrazine state, and population of the pyrazine state occurs thermally between *ca*. 120 and 260 K. Above this temperature the upper, fourth ^{3}MLCT of the bpy triplet manifold is thermally populated,[6] such population is observed in the temperature dependent luminescent lifetimes of related[5c] complexes, where population of this state was observed to occur from around 240 K. This upper state, which contains more singlet character, is not coupled to the pyrazine, and therefore a single emission primarily based on the fourth ^{3}MLCT is observed. Further investigations are at present in progress to further develop this picture.

The authors thank the EC Training and Mobility Programme (Contract CT96-0076), the EC Joule programme, Forbairt and the Electricity Supply Board for financial assistance. Johnson Matthey are thanked for a generous loan of $RuCl_3 \cdot xH_2O$.

Distinction between the weak hydrogen bond and the van der Waals interaction

Thomas Steiner*[a] and Gautam R. Desiraju*[b]†

[a] *Institut für Kristallographie, Freie Universität Berlin, Takustraße 6, D-14195 Berlin, Germany*
[b] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*

The angular distributions of C–H···O interactions for different types of C–H groups show that the directionality decreases with decreasing C–H polarisation, but that it is still clearly recognisable for methyl groups; for C–H···H–C van der Waals contacts, in contrast, isotropic angular characteristics are observed.

It is by now well-recognised that C–H groups can act as weak hydrogen bond donors.[1,2] While vibrational spectroscopy shows that the C–H donor strength depends on the carbon hybridisation as C(sp)–H > C(sp^2)–H > C(sp^3)–H,[3] early crystallographic data suggests some donor potential even for the weakly polarised methyl groups.[4] Statistical database surveys demonstrate that mean C···O distances in C–H···O contacts correlate convincingly with conventional C–H acidities,[5] and even for methyl groups R–CH_3, mean H···O distances have been found to depend on the nature of the R group.[6] All these experimental studies indicate that most kinds of C–H groups can donate weak hydrogen bonds. While the bonds formed by acidic C–H groups (alkynes, haloforms) are moderately strong, those that involve weakly polarised C–H groups are much weaker. Many studies have concentrated on the stronger of the C–H···O hydrogen bonds, possibly because they are associated with more dramatic structural and spectroscopic effects, and this has meant that experimental information on weakly polarised C–H donors is relatively scarce. Still, theoretical calculations have been published for weakly polarised C–H groups,[7] estimating C–H···O hydrogen bond energies to be around 0.5 to 1 kcal mol^{-1}.

Despite this wealth of experimental and theoretical work, the concept of the C–H···O hydrogen bond, and that of the weak hydrogen bond in general, has been persistently questioned. The strong disapproval that was published[8] in the 1960s has, over the years,been steadily diluted into oral objections that may best be described as stationary. It is therefore of some interest that a recent paper in this journal states that the typical C–H···O/N hydrogen bond represents 'nothing more than a classical van der Waals interaction.[9] Here this claim will be directly falsified.

A fundamental difference between hydrogen bonds and the van der Waals interaction lies in their different directionality characteristics. Hydrogen bonds are inherently *directional*, with linear or close to linear geometries favoured energetically over bent ones. In contrast, van der Waals contacts are *isotropic*, with interaction energies independent of the contact angle θ. This difference allows one, in principle, to distinguish between hydrogen bonds and the van der Waals interaction. However, hydrogen bond directionality is soft,[10] and even for moderately strong bonds it cannot be characterised from single examples or small data samples. A proper description of angular preferences, or lack thereof, requires statistical analysis of large quantities of structural data, such as may be retrieved from the Cambridge Structural Database (CSD).[11] Database analysis is complicated by factors such as steric hindrance and chemical inhomogeneity, which in adverse situations can completely smear structural trends.‡ However, one can plan and perform CSD analyses so as to minimise these complicating factors.

The angular characteristics of the weakest kinds of C–H···O hydrogen bonds have not yet been described. Therefore, we report here a CSD study of these characteristics in conjunction with those for van der Waals contacts of the type C–H···H–C. Structural data were retrieved§ for C–H···O contacts involving the prototypes of the C(sp)–H, C(sp^2)–H and C(sp^3)–H groups, that is ethynyl, vinyl and ethyl groups. For comparison, data for conventional hydrogen bonds from hydroxy donors is also presented. To reduce chemical inhomogeneity, only organic carbonyl acceptors were considered. For the H···O distance cutoff, a long value of 3.0 Å was selected; this is greater than the van der Waals sum by 0.3 Å.[12] Initial tests showed that this cutoff value is not critical for the subsequent analysis. Data for C–H···H–C van der Waals contacts were also retrieved to the distance limit of the van der Waals sum plus 0.3 Å (= 2.7 Å). Numerical data giving mean hydrogen bond distances and angles are listed in Table 1. To examine the degree to which linear contact geometries are preferred, histograms of angular C–H···O distributions were generated (Fig. 1). Since the solid angle covered by an angular interval $\Delta\theta$ is smaller for nearly linear angles θ than for bent ones (Fig. 2), the angular distribution must be weighted by a correction factor of $1/\sin\theta$ to properly reflect angular preferences. This is termed the 'cone correction'.[13]

The histogram for hydroxy donors shows the well-known directional behaviour of conventional hydrogen bonds [mean θ = 154.0(4)°].[10,13] For the acidic ethynyl donors C≡C–H, the mean C–H···O angle θ is only slightly smaller, 152(2)°, and the angular distribution is only slightly broader. For vinyl donors, the mean angle θ falls to 143(1)° and the angular distribution widens considerably. For the very weakly polarised methyl donor of the ethyl group, the mean angle θ falls further to 137.1(7)° and the angular distribution is correspondingly softened, *but it still shows directional behaviour with linear contact geometries being favoured*. Finally, the mean C–H···H angle for C–H···H–C contacts of methyl groups is 128.6(3)°. Here, however, the angular distribution is almost ideally isotropic in the range 120 to 180°, while for θ < 120°, the frequencies fall because side-on contacts are sterically disfavoured [Fig. 1(*e*)]. This is exactly the picture that is expected for the non-directional van der Waals interaction.

The sequence of histograms in Fig. 1 clearly shows a gradual decrease of directionality for C–H···O interactions with decreasing C–H polarisation. For alkyne donors, the directionality

Table 1 Numerical data for X–H···Y contacts with H···Y< 3.0 Å (2.7 Å for H···H contacts). Data for normalised H-atom positions

Contact type	Number	Mean H···Y (Å)	Mean X···Y (Å)	Mean X–H···Y (°)
C(*sp*^{3})–O–H···O=C	3330	1.974(6)	2.837(4)	154.0(4)
C≡C–H···O=C	44	2.36(4)	3.31(2)	152(2)
C=CH_2···O=C	124	2.67(1)	3.56(2)	143(1)
CH_2–CH_3···O=C	767	2.761(6)	3.590(7)	137.1(7)
CH_2–CH_3···H–C	3975	2.500(2)	3.246(4)	128.6(3)

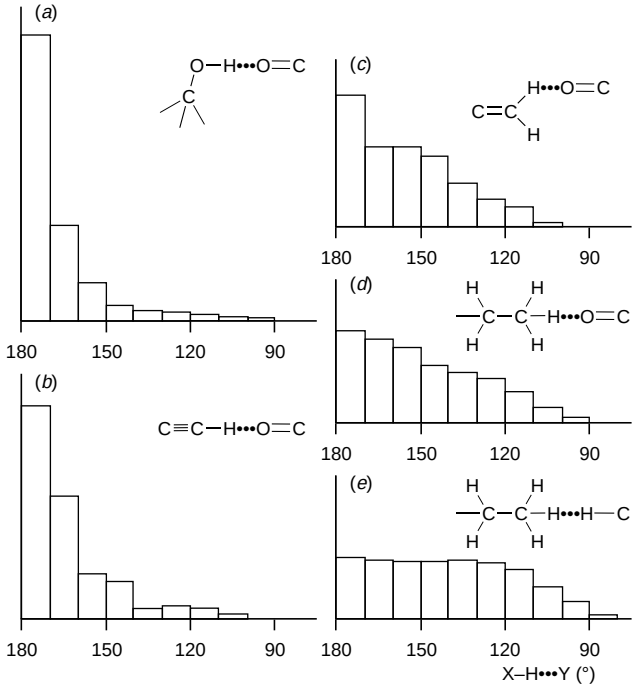

Fig. 1 CSD results. Histograms with angular frequencies of X–H···O=C contacts for different donor types, and of C–H···H–C van der Waals contacts: (*a*) hydroxy, (*b*) ethynyl, (*c*) vinyl and (*d*) ethyl donors and (*e*) van der Waals contacts. The distributions are 'cone-corrected' (ref. 13) (*i.e.* weighted by 1/sinθ) and scaled in such a way that they cover the same area.

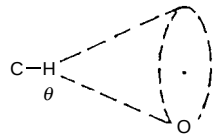

Fig. 2

behaviour is that of conventional hydrogen bonds such as those formed by hydroxy groups. For vinyl donors, the directionality is weaker, but is still clearly pronounced. For methyl groups, the directionality is the weakest, but is still clearly different from the perfectly isotropic behaviour for C–H···H–C contacts. Since C–H···O interactions of alkyl groups are *not* isotropic (even at the long distance cutoff of 3.0 Å), they should definitely not be classified as mere van der Waals contacts. The observed differences in directionality behaviour between any kind of C–H···O hydrogen bond and the van der Waals interaction is a consequence of the fundamentally different distance and angle fall-off characteristics of these interactions.

It is important to note that weak hydrogen bonds encompass a wide scale of strengths just as do carbon acidities. It is therefore misleading to consider all kinds of C–H···O hydrogen bonds as being exactly alike, even as it is misleading to assign hydrogen bond character only to a certain class of C–H···O contacts and consider the rest as nothing more than classical van der Waals interactions. *A C–H···O hydrogen bond does not become a van der Waals contact just because the H···O distance crosses an arbitrary threshold.* It is pointed out, however, that this does not mean that every C–H···O contact of a methyl group is 'automatically' a hydrogen bond: it has been shown theoretically and also experimentally that some C–H···O geometries formed by methyl groups have zero or possibly even positive interaction energies.[7,14]

In this light, the more interesting question is the nature of the interface between the weak hydrogen bond and the van der Waals interaction. Recent experiments indicate that this grey area is shrinking.[15] Investigating such matters will undoubtedly be difficult, but given the continuous spectrum of these structural phenomena, it is not hard to conceive of a domain wherein the distance falloff characteristics of an interaction X–H···A varies between those expected for a hydrogen bond and for a van der Waals interaction. Exploration of this region will surely yield new insights.

T. S. thanks Professor Wolfram Saenger for giving him the opportunity to carry out a part of this work in his laboratory. G. R. D. acknowledges financial support from the Department of Science and Technology, Government of India (SP/S1/G-19/94) and discussions with Dr Ashwini Nangia.

‡ When studying the correlation of carbon acidity with mean C···O distances in C–C–H···O interactions, it was observed that this correlation is clearcut for sterically unhindered donor types, but completely smeared for sterically hindered groups (ref. 5). The finer effect of acceptor basicity on mean distances could subsequently be shown *only* in chemically homogeneous sets of sterically unhindered C–H···O hydrogen bonds (ref. 6).

§ Database analysis: Cambridge Structural Database, June 1997 update with 167 797 entries, ordered and error-free organic crystal structures with R values < 0.05 (for alkynes: R < 0.07), H-atom positions normalised. Distance cutoff values: H···O < 3.0 Å for hydrogen bonds, H···H < 2.7 Å for van der Waals contacts. No angle restriction.

Triple fluorescence of 4-(1,4,8,11-tetraazacyclotetradecyl)benzonitrile

Ling-Siu Choi and Greg E. Collins*†

Naval Research Laboratory, Chemistry Division, Washington, DC 20375-5000, USA

Triple fluorescence is observed for DMABN-cyclam in EtOH, corresponding to a locally excited (LE) singlet state, a twisted intramolecular charge transfer (TICT) state, and an intramolecular exciplex (E).

More than 30 years ago, Lippert investigated the dual fluorescence of 4-(dimethylamino)benzonitrile (DMABN) in polar solvent.[1] Several models have been proposed to address the cause of the anomalous long-wavelength fluorescence, including bending of the cyano group,[2] solute–solvent exciplex formation,[3] and twisted intramolecular charge transfer (TICT).[4] The concept put forward by Grabowski of a TICT state, or charge transfer reaction which is accompanied by a twisting motion and orbital decoupling of the phenyl acceptor ring from the dimethylamino donor group, is generally favored.[4] In addition to TICT state formation, benzonitriles bearing flexible, alkylamino chains, *e.g.* 3-(4-cyanophenyl)-1-dimethylaminopropane (CNP3NM), can form intramolecular exciplexes which arise due to the conformational flexibility of the alkylamino chain, and its ability to form a sandwich configuration promoting excited state, charge transfer.[5] Van der Auweraer *et al.*[6] observed a correlation between intramolecular exciplex formation and Hirayama's rule,[7] which states that the most stable sandwich conformation will arise when $n = 3$ for a $Ph(CH_2)_nNMe_2$ system. We report here the triple fluorescence of 4-(1,4,8,11-tetraazacyclotetradecyl)benzonitrile (DMABN-cyclam), corresponding to the LE state, a TICT state, and an intramolecular exciplex (E) (Fig. 1).

The UV spectrum for DMABN-cyclam in EtOH shows a single absorption peak at 295 nm. Excitation at this wavelength leads to three emission peaks: 352 (LE state), 421 and 473 nm (Fig. 2). Intensity contributions from the three individual excited states were estimated using the Voigt Amplitude function of Jandel's PEAKFIT 4.0. Recently, Létard *et al.* reported the dual fluorescence of two compounds structurally similar to DMABN-cyclam, 4-(1-aza-4,7,10-trioxacyclododecyl)benzonitrile (DMABN-crown4) and 4-(1-aza-4,7,10,13-tetraoxacyclopentadecyl)benzonitrile (DMABN-crown5).[8] DMABN-crown5 exhibited a TICT emission that red-shifted and increased in intensity as the solvent polarity increased from hexane (where the emission band was too weak to be measured accurately) to toluene (λ_{max} = 406 nm), to acetonitrile (λ_{max} = 466 nm). Similarly, DMABN-cyclam, which differs from DMABN-crown4 primarily in the replacement of nitrogen binding sites for the oxygen atoms of the crown ether, reports a similar trend in the emission spectra (Fig. 2): hexane (λ_{max} = 390 nm), toluene (λ_{max} = 413 nm) and EtOH (λ_{max} = 473 nm). We, therefore, attribute the third emission band in EtOH at 473 nm to a TICT state. Unlike DMABN-crown4, however, DMABN-cyclam has two pendant amine groups linked by a short chain (n = 3 and 4) to the benzonitrile acceptor. Despite the cyclic nature of cyclam, this molecule exhibits sufficient flexibility to form a sandwich complex in the excited state that gives rise to an intramolecular exciplex peak (E) (Fig. 1). The peak position identified for the exciplex peak of DMABN-cyclam in hexane (λ_{max} = 392 nm) compares favorably with that found for CNP3NM in isopentane (λ_{max} = 390 nm).[9]

Several trends are evident from Fig. 2 with regards to the effect of solvent polarity on the triple fluorescence of DMABN-cyclam. The TICT emission band red-shifts by more than 80 nm and increases in intensity relative to the LE emission as solvent polarity is increased. The relative intensity of the TICT band increases with solvent polarity due to a stabilization of the charge separation. The exciplex emission does not red-shift quite as severely (34 nm), due to a smaller dipole moment compared with the TICT configuration, and reflects a maxima in the solvent, toluene. Apparently, a ground state sandwich configuration is promoted for DMABN-cyclam in toluene, fostering enhanced intramolecular exciplex formation despite

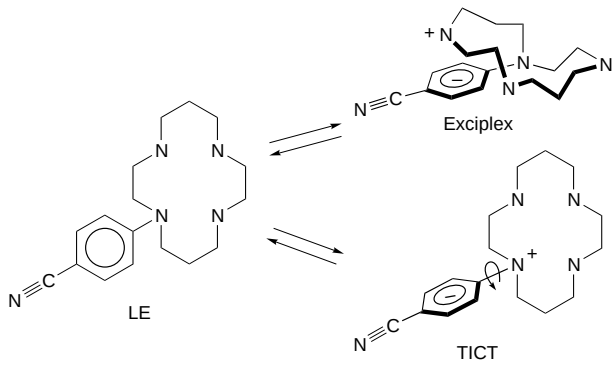

Fig. 1 Proposed structures and equilibria existing between the three excited state species, LE, TICT and E, generating the observed triple fluorescence

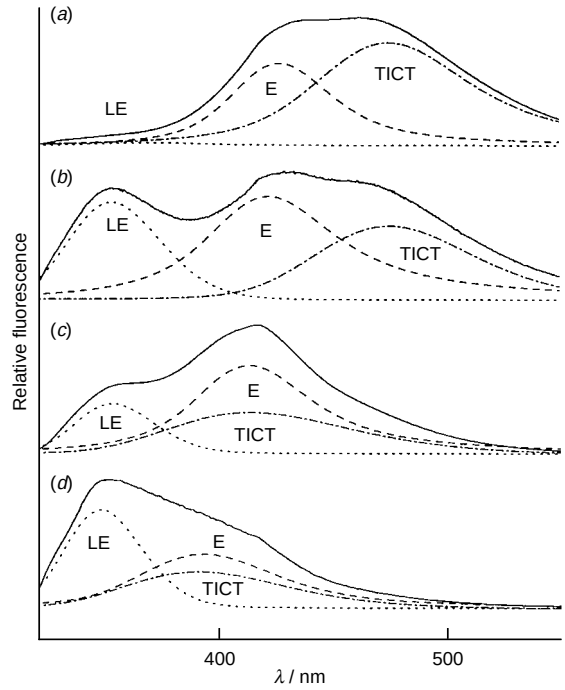

Fig. 2 Solvent effect on the triple fluorescence of DMABN-cyclam: (*a*) water, (*b*) EtOH, (*c*) toluene and (*d*) hexane

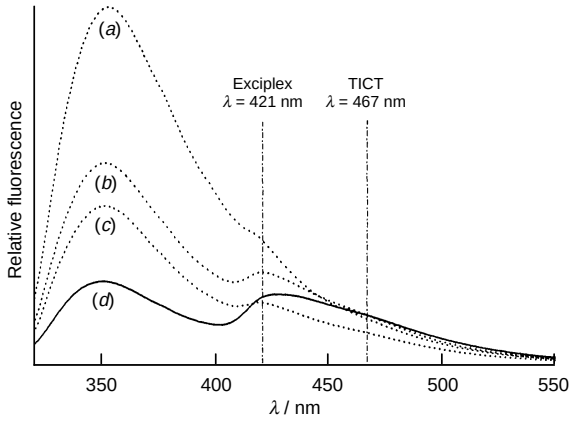

Fig. 3 Emission spectra of DMABN-cyclam in poly(vinyl alcohol) at (*a*) 20, (*b*) 40, (*c*) 60 and (*d*) 80 °C

the lower polarity of this solvent. The LE band exhibits an intensity minimum in water because of the high polarity of this solvent, and its capability for stabilizing the two charge transfer complexes.

Temperature studies of the fluorescence arising from thin films of DMABN-cyclam in poly(vinyl alcohol) (PVA) indicate the dependence of the two excited-state charge-transfer emission peaks (E and TICT) on the conformational mobility of the molecule.[9] PVA was chosen as a support material for DMABN-cyclam because it provides a solid matrix with similar polarity to EtOH. PVA is hydrophilic and absorbs moisture from the air, decreasing the glass transition temperature (T_g) and facilitating the conformational transitions in the excited state at higher temperatures. At room temperature, DMABN-cyclam in PVA shows only a single peak at 357 nm, with a slight shoulder evident at 421 nm (Fig. 3). As the temperature increases, the overall fluorescence intensity correspondingly decreases. However, as the temperature approaches 80 °C (above the T_g for PVA), the exciplex shoulder at 421 nm becomes a more prominent peak, and there is evidence for the formation of the TICT state at 467 nm. This result verifies the dependence of these excited-state charge transfer bands on the conformational mobility of DMABN-cyclam in PVA as it transitions from a glass to a rubbery state.

In conclusion, DMABN-cyclam is a unique molecule which exhibits triple fluorescence arising from the LE state and two excited state complexes, a TICT state and an intramolecular exciplex (E). All three emission bands are strongly perturbed by solvent polarity and conformational mobility.

The authors gratefully acknowledge J. H. Callahan and M. Shahgholi for the mass spectroscopic identification of DMABN-cyclam, and the Office of Naval Research for funding this study.

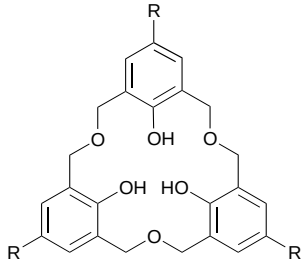
Complexation of C_{60} with hexahomooxacalix[3]arenes and supramolecular structures of complexes in the solid state

Kazunori Tsubaki,[a] Kiyoshi Tanaka,[a] Takayoshi Kinoshita[b] and Kaoru Fuji*[a]†

[a] *Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan*
[b] *Basic Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Kashima, Yodogawa, Osaka 532-8514, Japan*

Hexahomooxacalix[3]arenes 1–5, which possess a variety of substituents on their upper rim, have captured fullerene C_{60} in toluene with association constants of K_a = 9.1–35.6 dm^3 mol^{-1}; X-ray analysis of the complex of C_{60} and 4 indicated that a van der Waals attractive interaction is the dominant driving force which brings the hexagonal faces of the C_{60} close to both the aromatic rings and the dibenzyl ether oxygen of 4.

Supramolecular complexes with C_{60} as the guest molecule have provoked a great deal of interest in the field of host–guest chemistry.[1–8] Recent studies on this complexation have focused on the inclusion phenomena of C_{60} with so-called 'dish-shaped' hosts in solution.[9–15] Among these studies, X-ray analyses of the complexes of C_{60} with calix[5]arenes[14,16,17] and with cyclotriveratrylene (CTV)[12,15] have been reported. Quite recently, Shinkai reported the inclusion complex of C_{60} and *tert*-butylhexahomooxacalix[3]arene **2** in organic solution.[11] However, the precise details of the structural features of the inclusion complex are still ambiguous. Here we report the first X-ray analyses of the complexes of C_{60} with hexahomooxacalix[3]arenes **2** and **4**, and the formation of supramolecular complexes of C_{60} with hexahomooxacalix[3]arenes possessing different substituents on their upper rims.



1 R = H
2 R = Bu^t
3 R = OMe
4 R = Br
5 R = $CMe_2C_6H_4$-*p*-OMOM

We have developed a stepwise synthesis for a variety of hexahomooxacalix[3]arenes having different substituents on their upper rim portion, revealing that some hexahomooxacalix[3]arenes adopt a cone conformation owing to an intramolecular hydrogen-bonding network in the solid state.[18] The interaction between hexahomooxacalix[3]arenes **1**–**5**‡ and C_{60} was examined using UV–VIS spectroscopy. Thus, upon addition of hexahomooxacalix[3]arenes to a solution of C_{60} in toluene, a slight change in color (from purple to pale brown), based on an increase in the absorption band at *ca*. 430 nm, was observed. The UV–VIS titration method allowed us to determine the association constants, which were determined by the Rose–Drago method[19] to be those of a 1 : 1 complex (λ = 425 or 430 nm, 298 K, toluene solution, $[C_{60}]_0 = 5.1 \times 10^{-4}$ M). The composition ratio of C_{60} and **2** has been reported,[11] and that of C_{60} and **5** was determined by Job plot, but this was not effective for the determination of the composition ratios of C_{60} and **1**, **3** and **4** due to both the very small K_a and the change in absorption. These results are shown in Table 1. Generally, neither the magnitude of nor the difference between association constants for the five hosts **1**–**5** is particularly large. Consequently, it might be concluded that the strength of complexation is not affected by the electron density of the aromatic rings of the host compounds.

Table 1 Association constants for hexahomooxacalixarene–C_{60} complexation in toluene at 298 K[a]

Compound	K_a/dm^3 mol^{-1}
1	9.1 ± 1.0
2	35.6 ± 0.3
3	20.7 ± 0.9
4	14.9 ± 2.0
5	13.3 ± 0.4

[a] Association constants were determined by the Rose–Drago method (ref. 19) for a 1 : 1 complex at 425 or 430 nm.

The inclusion complexes were obtained as dark brown crystals by allowing a toluene solution of C_{60} and the corresponding hexahomooxacalix[3]arenes **2**–**5** in a molar ratio of 1 : 10–20 to stand for a couple of weeks. The crystal structure of the complex of C_{60} and **4** was clarified by X-ray analysis and is shown in Fig. 1.§ As a result of the suppression of the rotational disorder of C_{60} in the solid state, all the atoms of the inclusion complex can be identified. The inclusion complex has a C_{3d} symmetric structure in the solid state, in which a six-membered ring of C_{60} is disposed parallel to the mean plane composed of the three phenolic oxygens of **4**. In addition, three six-membered rings around the above-mentioned six-membered ring at the bottom position of C_{60} are approximately parallel to three six-membered rings of **4**, where the closest distance [3.615 (6) Å] between two sp^2 carbons is very close to those reported for related complexes (3.51 Å[15] and 3.60–3.62 Å[16]). The inclination angle (θ) of the three phenol rings from the mean plane composed of three phenol oxygens in **4** is 147°, which is consistent with the dihedral angle between the six-membered ring at the bottom and the neighboring five- and six-membered rings of C_{60} (average angle of 145°). The additional striking feature of this complex is that the closest distance from the dibenzyl ether oxygens of **4** to the six-membered ring at the bottom of C_{60} is only 3.290 (5) Å. Taking into account these close contacts, as well as the weak electrostatic effect mentioned above, it can be suggested that van der Waals forces are the predominant attractive forces for complexation. The packing arrangement of C_{60} and **4** is shown in Fig. 2. The closest intermolecular distance of 3.51 (3) Å between carbons of C_{60} suggests some attractive interactions between C_{60} molecules, which is comparable to that observed in graphite (3.35 Å).

Similarly, X-ray analysis of the crystals of the complex of C_{60} with **2** indicated a complexation pattern with a 1 : 1 ratio, in which **2** is ordered, whereas the packing of the guest C_{60} molecules is rotationally disordered in the solid state. This packing arrangement is shown in Fig. 3.¶

The authors are grateful to Professor Y. Tobe and Dr K. Hirose (Osaka University) and Dr T. Hayashi (Kyoto University) for their useful suggestions.

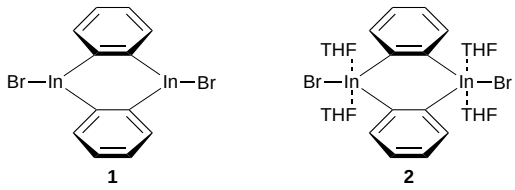
Recognition of 1,2-diazines by a bidentate Lewis acid

François P. Gabbaï,*[a]† Annette Schier,[a] Jürgen Riede[a] and Michael J. Hynes[b]

[a] *Anorganisch-chemisches Institut der Technischen Universität München, Lichtenbergstrasse 4, D-85747 Garching, Germany*
[b] *Department of Chemistry, National University of Ireland, Galway, Ireland*

Dimeric *ortho*-phenyleneindium bromide 1 shows a higher affinity for 1,2-diazines than for 1,3- and 1,4-diazines; as shown by the X-ray crystal structure analysis of the host–guest complex 3 the observed selectivity results from subtle structural variation which can bring the indium p orbitals to converge.

The chemistry of group 13-based bidentate Lewis acids, while still in its infancy, appears to have a promising future. Research activity in this area has mainly focussed on the use of these compounds as anion receptors.[1,2] More scarcely, those compounds have been used as catalysts[3,4] or as selective receptors for neutral nucleophiles.[5,6] We have recently reported the synthesis of dimeric *ortho*-phenyleneindium bromide **1**.[7] The specific arrangement of the two indium centers of this derivative indicates that selectivity in the binding of bifunctional bases might be attainable. In order to verify this assumption, we have investigated the ligative behavior of **1** toward the different diazine structural isomers and report that **1** is a selective 1,2-diazine receptor.



1 **2**

Compound **1** was isolated as a tetrakis(tetrahydrofuran) adduct **2**, which dissolves only in polar solvents. Addition of 1 or 2 equiv. of pyrazine (1,4-diazine) or pyrimidine (1,3-diazine) to a [$^2H_8$]THF solution of **2** at 25 °C did not result in any detectable changes of the ^{1}H NMR features of **2** thus indicating weak association between **1** and pyrazine or pyrimidine under those conditions.‡ In contrast, incremental addition of pyridazine (1,2-diazine) or phthalazine (2,3-benzodiazine) to a [$^2H_8$]THF solution of **2** at 25 °C resulted in an up-field shift of the H^{2,3,6,7} NMR resonances of the diindacycle **1** (Fig. 1).‡

These observations reflect the formation of complexes between **1** and the 1,2-diazines (pyridazine or phthalazine). Moreover, the inflection observed in the titration curve of **1** by phthalazine occurs at an added amount of base of one equivalent, thus suggesting the formation of a 1 : 1 host–guest complex, possibly **1**·phthalazine·2THF. Based on this hypothesis, the stability constants of the 1 : 1 complexes **1**·pyridazine·2THF and **1**·phthalazine·2THF can be derived and are respectively equal to 80 ± 10 and 1000 ± 150 M^{-1} (Scheme 1).[8] These data as a whole indicate that **1** is a selective receptor for 1,2-diazines.[9,10]

While the 1 : 1 complex **1**·phthalazine·2THF seems to be the preferred species in solution, colorless pale yellow crystals of the less soluble 1 : 2 complex **1**·2(phthalazine)·THF **3** spontaneously formed in a saturated THF solution containing equimolar amounts of **2** and phthalazine.‡§ Compound **3** crystallizes in the monoclinic space group $P2_1/n$ with one solvate THF.¶ As shown in Fig. 2, the diindacycle acts as a ditopic receptor for one phthalazine molecule. Each indium atom adopts a trigonal bipyramidal coordination geometry. As in the parent compound,[7] the equatorial sites are occupied by the two phenylene rings and the bromine atoms. The two nitrogen atoms of the chelated phthalazine molecule [N(21) and N(22)] occupy one of the axial sites of each indium center [In(2) and In(1), respectively]. The coordination sphere of each indium atom is completed by axial ligation of one THF molecule [In(2)] and one phthalazine [In(1)]. The chelation of one phthalazine molecule by the diindacycle has some noteworthy structural consequences. The two indium atoms are displaced towards their respective coordinated nitrogen atoms N(21) and N(22), respectively. As a result, the six-membered ring containing the two indium atoms has a boat-like conformation rather than being planar as in **2**.[7] The two phenylene rings of **3** are not coplanar (dihedral angle of 16.5°) and the dimeric *ortho*-phenylene indium moiety adopts a saddle shape. There is one metrical parameter, which merits comment. The N(22)–In(1) distance [2.824(5) Å] is significantly longer than the other In–N bond lengths observed in **3** [2.398(5) and 2.446(5) Å]. While one could question the existence of a N(22)–In(1) interaction, examination of the bond angles at In(1) and N(22) indicates

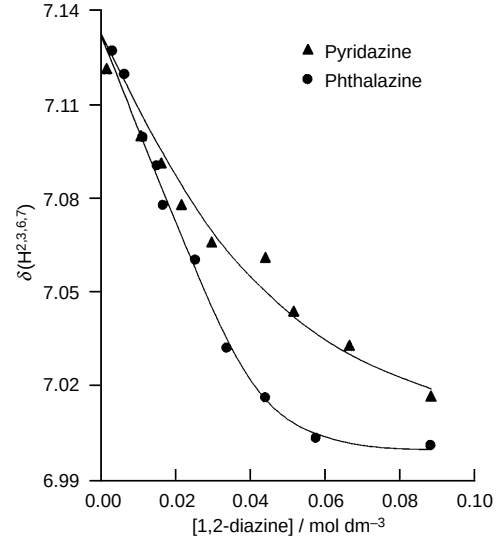


Fig. 1 ^{1}H chemical shift of H^{2,3,6,7} of **1** *vs*. the concentration of 1,2-diazines; [**1**] = 0.044 mol dm^{-3}

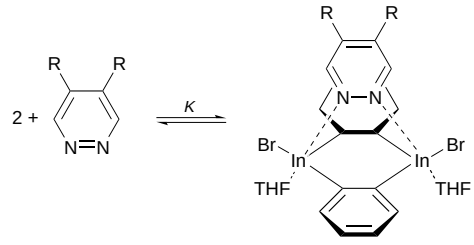

R = H, K = 80 M^{-1}
RR = *o*-C_6H_4, K = 1000 M^{-1}

Scheme 1

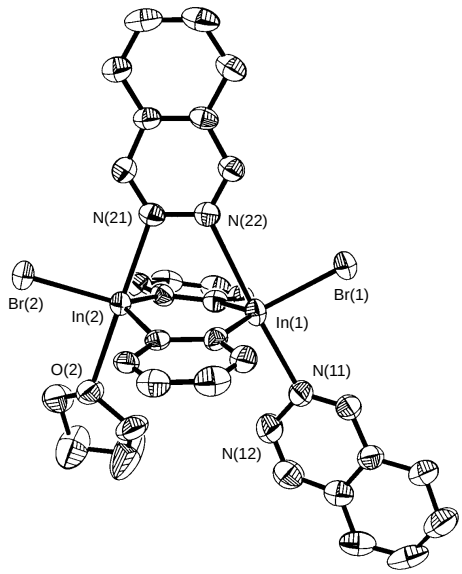

Fig. 2 Structure of **3**. ORTEP drawing with 50% probability ellipsoids; H atoms omitted for clarity. Selected bond lengths (Å) and angles (°): In(2)–O(2) 2.480(4), In(2)–N(21) 2.446(5), In(1)–N(11) 2.398(5), In(1)–N(22) 2.824(5); N(21)–In(2)–O(2) 179.5(2), N(11)–In(1)–N(22) 173.3(2).

clearly that N(22) is positioned at an axial site of the indium coordination sphere. Moreover, the N(22)–In(1) distance is much shorter than the sum of the van der Waals radii [r_{vdw}(N) = 1.5 Å,[11] r_{vdw}(In) = 1.9 Å][12] and just slightly longer than the previously reported longest In–N bond of 2.776 Å.[13] Altogether, these observations suggest the presence of a weak N(22)–In(1) dative bond.

In conclusion, as a result of subtle structural variations, the indium p orbitals of **1** can be brought to converge thus allowing chelation of bifunctional bases with adjacent electrophilic centers. The observed selectivity (phthalazine > pyridazine > pyrimidine ≅ pyrazine) follows the basicity order phthalazine (pK_a 3.5) > pyridazine (pK_a 2.3) > pyrimidine (pK_a 1.23) > pyrazine (pK_a 0.6).[14] It has however been noted previously that pK_a values are poor indicator of the donor ability of nitrogen ligands.[15] Hence, the ability of **1** to chelate 1,2-diazines can be taken as an alternative explanation for the observed selectivity.

We thank Professor H. Schmidbaur who made this work possible. Financial support from the European Commission (Training and Mobility of Researcher Program), the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is thankfully acknowledged.

‡ *^{1}H NMR titration experiment*: incremental addition of pyrazine or pyrimidine (2 × 4 mg, 2 × 50 μmol) to a [$^2H_8$]THF solution (0.5 ml) of **1** (34 mg of **1**·2THF,[7] 50 μmol) did not result in any change of the chemical shift of the aromatic proton signals of either **2** and pyrazine or pyrimidine. The titration curves of **1** by pyridazine and phthalazine were obtained by adding incremental amounts of the 1,2-diazines to a [$^2H_8$]THF (0.45 ml) solution of **1** (14 mg, 20 μmol). After each addition, all solids were brought into solution by gentle heating. Following cooling and before formation of any precipitate, the ^{1}H NMR spectrum of the resulting solution was measured. The stability constant K is defined by K = [Host–Guest]/{[**2**][1,2-diazine]}. The THF concentration is considered as constant and it is therefore not taken into account in the expression of K. *^{1}H NMR data* for **3**: ^{1}H NMR (400 MHz, [$^2H_8$]THF): δ 1.77 (br, 8 H, OCH_2CH_2), 3.61 (br, 8 H, OCH_2), 7.00 (m, 4 H, $H^{2,3,6,7}$), 7.49 (m, 4 H, $H^{1,4,5,8}$), 7.97 (m, 4 H, $H^{5,6}$, phtha), 8.08 (m, 4 H, $H^{8,5}$, phtha), 9.64 (m, 4 H, $H^{1,4}$, phtha).

§ *Synthesis of* **3**: compound **1**·2THF[7] (34 mg, 50 μmol) was dissolved in THF (1 ml) and added to a THF (0.5 ml) solution of phthalazine (6.5 mg, 50 μmol). Crystals of **3** spontaneously precipitated in a 63% yield (15 mg) based on phthalazine [mp 215–255, (decomp)]. Elemental analysis. Calc. for $C_{36}H_{36}Br_2In_2N_4O_2$: C, 45.66; H, 3.80; N, 5.91. Found: C, 45.71; H, 3.83; N, 6.04%.

¶ *Crystal and structure determination data* for **3**: $C_{36}H_{36}Br_2In_2N_4O_2$, M = 946.15, monoclinic, space group $P2_1/n$, a = 10.252(1), b = 18.535(1), c = 19.140(2) Å, β = 99.76(1)°, U = 3584.4(5) Å^3, Z = 4, D_c = 1.753 g cm^{-3}, F(000) = 1856, Enraf-Nonius CAD4 diffractometer, Mo-Kα radiation (λ = 0.710 69 Å), T = 21 °C. Data were corrected for Lorentz, polarization, and absorption effects (ψ-scans, $T_{min/max}$ = 83/99%). The structure was solved by direct methods and refined by full-matrix least squares against F^2 (SHELXTL-PLUS, SHELXL-93). Of 6980 measured reflections [$(\sin\theta/\lambda)_{max}$ = 0.62 Å^{-1}], 6902 were used for refinement. The thermal motion of all non-hydrogen atoms was treated anisotropically. All H atoms were calculated in idealized geometry and allowed to ride on their corresponding C atom with U_{iso} = 1.5U_{eq} of the attached C-atom. The structure converged for 415 refined parameters to R_1 = 0.0498 and wR_2 = 0.0930. Residual electron densities: +1.607 and −0.463 e Å^{-3}. CCDC 182/800.

On the origin of 1,5-induction in tin(IV) halide-promoted reactions of 4-alkoxyalk-2-enylstannanes with aldehydes

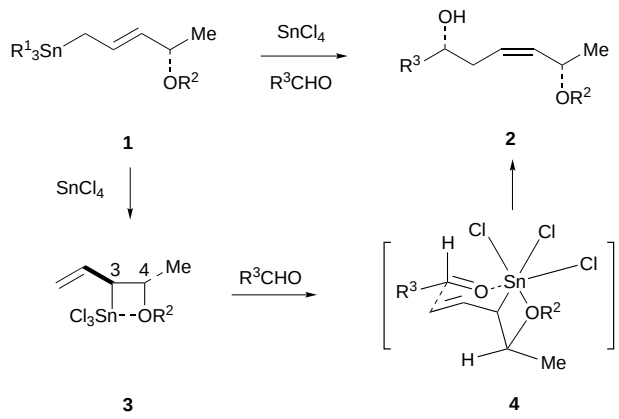
Lindsay A. Hobson, Mark A. Vincent, Eric J. Thomas*† and Ian H. Hillier*

The Department of Chemistry, The University of Manchester, Manchester, UK M13 9PL

A combination of experiment and theory has identified both the allyltin trichlorides 3 (R^2 = Bn, H) as key intermediates in tin(IV) chloride-promoted reactions of allylstannanes 1 (R^2 = Bn, H) and the transition structures that are involved in their reactions with aldehydes.

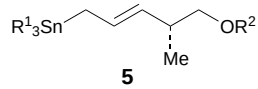
Useful levels of 1,5-, 1,6- and 1,7-asymmetric induction are obtained in tin(IV) halide-promoted reactions of 4-, 5- and 6-alkoxyalk-2-enylstannanes and aldehydes.[1] For example, tin(IV) chloride-promoted reactions betweeen aldehydes and the (4-benzyloxypent-2-enyl)stannane **1** (R^2 = Bn) (Scheme 1) give the 1,5-*syn*(*Z*)-alkenols **2** with excellent stereoselectivity (*syn*:*anti* ⩾ 97:3).[2] Similar results are obtained using the 4-hydroxypent-2-enylstannane **1** (R^2 = H).[3]

This stereoselectivity is consistent with generation of the allyltin trichlorides **3**, which react with the aldehydes *via* the chair-like transition structures **4**.[2] However, alternative explanations are possible, notwithstanding the results from trapping the allyltin trichlorides generated from the 5-alkoxypent-2-enylstannanes **5**.[4,5] For example, participation of the C(3)-epimers of the allyltin trichlorides **3** and boat-like transition structures for the reactions with aldehydes, would account for the overall 1,5-*syn* (*Z*)-stereoselectivity. We now report confirmation of the involvement of the allyltin trichlorides **3** in these reactions, together with high level modelling of the transition structure **4**.



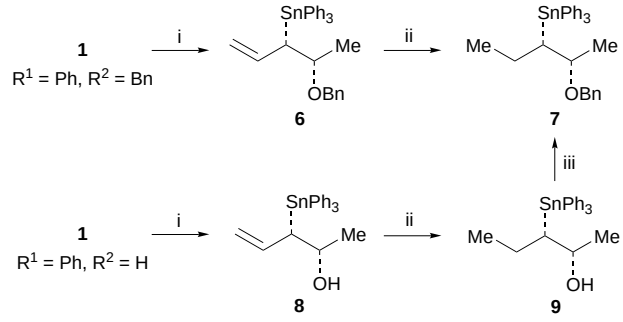
Scheme 1

Tin(IV) chloride was added to a solution of the 4-benzyloxypent-2-enylstannane **1** (R^2 = Bn) at −78 °C followed by an excess of PhLi. From this mixture the *syn*-4-benzyloxypent-1-en-3-yl(triphenyl)stannane **6**, containing less than 5% of its *anti* diastereoisomer, was isolated (see Scheme 2.) To avoid 1,3-migration of the triphenyltin moiety,[6] the alkenylstannane **6** was reduced using diimide to give (2*S*,3*S*)-2-benzyloxypent-3-yl(triphenyl)stannane **7**. The same sequence of reactions starting with the 4-hydroxypent-2-enylstannane **1** (R^2 = H) gave the 3-triphenylstannylpentan-2-ol **9** which was benzylated to give the *syn*-benzyl ether **7**.

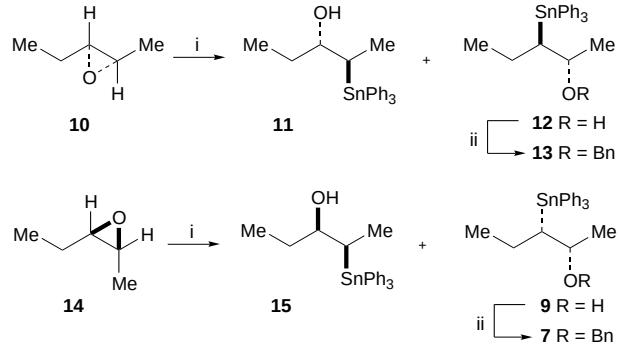


5

The hydroxyalkylstannane **9** could not be converted into a crystalline material suitable for X-ray diffraction and so its structure was confirmed by comparison with an authentic sample (see Scheme 3.) The racemic (*E*)- and (*Z*)-epoxides **10** and **14** were obtained from the corresponding alkenes using NBS and KOH.[7] Ring-opening using triphenylstannyllithium then gave the regioisomeric hydroxystannanes **11**/**12** and **15**/**9** which were separated and characterised spectroscopically. The configurations of these products were assigned on the basis that analogous epoxide ring-openings are known to proceed with inversion of configuration.[8] The *syn*-hydroxyalkylstannane **9** obtained from the *cis*-epoxide **14** was spectroscopically and chromatographically identical to that obtained from the trapping reaction of the hydroxystannane **1** (R^2 = H). Moreover, *O*-benzylation gave a benzyl ether which was identical to that prepared by reduction of the alkenylstannane **6**. The *anti*-hydroxyalkylstannane **12** obtained from the *trans*-epoxide **10** was distinctly different from that obtained from the trapping reaction of the hydroxystannane **1** (R^2 = H), and benzylation gave the *anti*-benzyloxystannane **13** which was clearly distinguishable from its *syn*-diastereoisomer **7** by ^{1}H and ^{13}C NMR spectroscopy.



Scheme 2 *Reagents and conditions*: i, $SnCl_4$, −78 °C, 5 min, then PhLi (**6**, 54%; **8**, 35%); ii, diimide (**7**, 68%; **9**, 69%); iii, NaH, BnBr (68%)

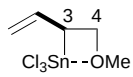


Scheme 3 *Reagents and conditions*: i, Ph_3SnLi (**11**, 30%; **12**, 20%; **15**, 20%; **9**, 20%); ii, NaH, BnBr (**13**, 61%; **7**, 72%)

It would appear that transmetallation of the 4-benzyloxy- and 4-hydroxy-pent-2-enylstannanes **1** (R^2 = Bn, H) with tin(IV) chloride gives the (3*S*,4*S*)-4-benzyloxy- and (3*S*,4*S*)-4-hydroxy-pent-1-en-3-yl)tin trichlorides **3** (R^2 = Bn, H) as originally postulated. By analogy with the transmetallation of the 5-alkoxypent-2-enylstannanes **5**,[5] it is likely that this transmetallation is due to kinetic control. However only low yields of products were obtained on attempted transmetallation of the pent-1-en-3-ylstannane **6** using either tin(IV) chloride or bromide, and so the interconversion of regioisomeric allyltin trihalides could not be investigated in this case.

The formation of the 1,5-*syn* (*Z*)-products from the reactions between the tin trichlorides **3** and aldehydes is consistent with participation of chair-like transition structures akin to **4**. However, why does the C(3)–C(4) bond prefer to be axial rather than equatorial, *i.e.* why are (*Z*)-alkenes obtained as the dominant products from these reactions rather than their (*E*)-isomers? To probe the factors involved in this stereoselectivity, high level electronic structure calculations have been carried out on the allyltin trichloride **16** and the transition structures for its reactions with formaldehyde which would lead to (*E*)- and (*Z*)-alkenols. A split valence basis was employed,[9] with electron correlation included at the density functional theory level (B3LYP), using GAUSSIAN94.[10] Stationary structures were identified as minima or saddle points by the calculation of harmonic frequencies.

We find two conformations of the allyltin trichloride **16**, corresponding to rotamers about the C(2)–C(3) bond, to be energy minima with Sn–O bond lengths of 2.457 and 2.531 A. Transition states for reactions of **16** with formaldehyde leading



16

to both *cis*- and *trans*-double-bonded products have been located and identified as saddle points on the potential energy surfaces. These are summarised in Fig. 1.

There are considerable differences in the transition state structures and energy barriers leading to the two different stereoisomers. The transition structure leading to the *cis*-double-bonded product [Fig. 1(*a*)] has a considerably lower barrier (1.9 kcal mol^{-1}) and different structure, particularly about the tin atom, than the transition structure leading to the *trans*-isomer [Fig. 1(*b*)], which has a barrier of 12.0 kcal mol^{-1}. The favoured structure has a six-coordinated tin atom, with Sn–C and Sn–O bond lengths in the range 2.2–2.4 Å. The transition structure leading to the unfavoured *trans*-isomer has one of its Sn–O bond lengths considerably longer than normal (3.3 Å), so that the tin is effectively five-coordinated.

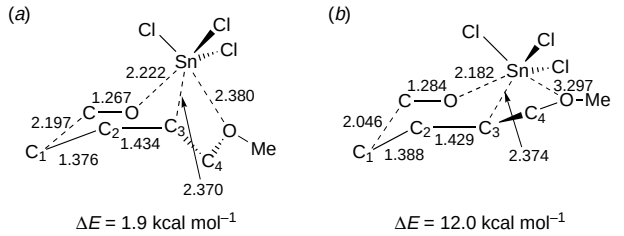


Fig. 1 Transition structures leading to (*a*) *cis* and (*b*) *trans* products. Bond lengths are in Å.

Two factors favour the transition structure shown in Fig. 1(*a*). Firstly, there is greater steric repulsion between the C(3)–C(4)–OMe entity and the chlorine atoms in the transition structure for formation of the unfavoured *trans*-isomer. Secondly, the different orientations of the C(3)–C(4) bond in the two transition structures leads to the long Sn–O bond in the disfavoured transition structure.

This work confirms the participation of the allyltin trichlorides **3** in tin(IV) chloride-promoted reactions of the allylstannanes **1**. The theoretical studies provide an insight into the factors which favour the formation of *cis*-alkenes in reactions of these allyltin trichlorides with aldehydes and complement recently reported computational studies into reactions between allylsilanes and aldehydes.[11,12]

We thank the University of Manchester and SmithKline Beecham for support (to L. A. H.) under the CASE Scheme, Dr M. Fedouloff of SmithKline Beecham for helpful discussions, and the EPSRC for support.

Synthesis and X-ray crystal structure of the first tetrathiafulvalene-based acceptor–donor–acceptor sandwich

Klaus B. Simonsen,[a] Niels Thorup,[b] Michael P. Cava[c] and Jan Becher*[a]†

[a] *Department of Chemistry, Odense University, Campusvej 55, DK-5230 Odense M. Denmark*

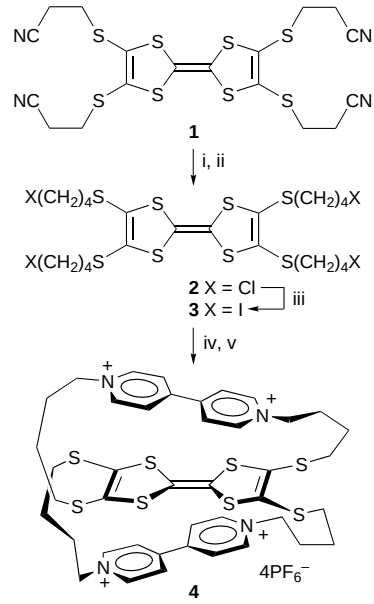
The synthesis and characterization of the bis-macrocyclic A–D–A sandwich 4·4PF_6 produced in a simple one-pot reaction is reported; only one acceptor unit participates in charge-transfer interactions with the TTF unit in the solid state of 4·4PF_6.

Since Stoddart reported the self-assembly of cyclobis(paraquat-*p*-phenylene) in the presence of electron-donating systems[1] and demonstrated the strong effect of noncovalent interactions, a remarkable number of related catenanes and rotaxanes have been prepared and studied.[2] These assemblies rely upon molecular recognition based on hydrogen bonding, donor–acceptor and π–π stacking interactions.[3] It is known that TTF forms a 1:1 electron-transfer complex with the π-electron deficient, tetracationic cyclobis(paraquat-*p*- phenylene).[4]

We were therefore interested in exploring the possibility of synthesizing a related acceptor–donor–acceptor (A–D–A) system in which the electroactive moieties were covalently fixed within the same molecule. Although, Staab and co-workers have reported a large series of elegant donor–acceptor cyclophanes, and modelled the orientation and distance dependence of charge-transfer (CT) interactions,[5] the alternative bis-macrocyclic A–D–A systems with TTF have not been reported. We have recently demonstrated the facile preparation of macrocyclic donor–acceptor systems based on TTF and the bipyridinium acceptor.[6] The relatively simple synthesis of this macrocycle may rely upon a templating effect due to the formation of a CT complex, which appears to be optimal when butane-1,4-diyl linkers were employed. Here we describe the efficient preparation of the first TTF-containing bis-macrocyclic A–D–A complex **4**·4PF_6, in which the π-electron donor TTF is sandwiched between two moderate π-electron acceptors. This unique structure was characterized *via* X-ray structure analysis.

The TTF thiolate protection protocol[7] developed in our group has made it possible to construct a variety of TTF-containing macrocycles[7b,8] and TTF-based catenanes.[9] Compound **4**·4PF_6 was prepared by treatment of **3** [prepared in two steps from tetrakis(2-cyanoethylthio)-TTF[7a] as outlined in Scheme 1] with 2 equiv. of 4,4′-bipyridine in refluxing MeCN. The macrocycle **4**·4PF_6 was isolated in 32% yield as the *trans* isomer, as a crystalline green solid, after chromatography[10] and anion exchange (NH_4PF_6).‡ This yield is quite acceptable, considering the formation of two macrocyclic rings in a one-pot reaction. The formation of a donor–acceptor complex during the reaction probably assists the ring-forming processes.[6]

The crystal structure of **4**·4PF_6MeCN was determined by X-ray diffraction,§ and the structure of the tetracation with atomic numbering is shown in Fig. 1 (anions and solvent molecules have been omitted for clarity). The unit cell contains two formula units, *i.e.*, two complex cations, eight PF_6 anions and six molecules of MeCN. The TTF part of the complex has a boat-like conformation. The dihedral angles between the least-squares planes A [S(1), S(2), C(3), C(42)] and B [S(1), S(2), S(3), S(4), C(1), C(2)] and between B and C [S(3), S(4), C(22), C(23)] are 6.5(1) and 21.3(1)°, respectively. Somewhat similar



Scheme 1 *Reagents and conditions*: i, N_2, $CsOH·H_2O$ (6 equiv.), MeOH, DMF, room temp., N_2, 1 h, 79%; ii, 1-bromo-4-chlorobutane (6 equiv.), DMF, room temp., N_2 2 h, 89%; iii, NaI (40 equiv.), acetone, reflux, N_2, 48 h; iv, 4,4′-bipyridine (2 equiv.), MeCN, reflux, N_2, 4 d; v, NH_4PF_6, 32%

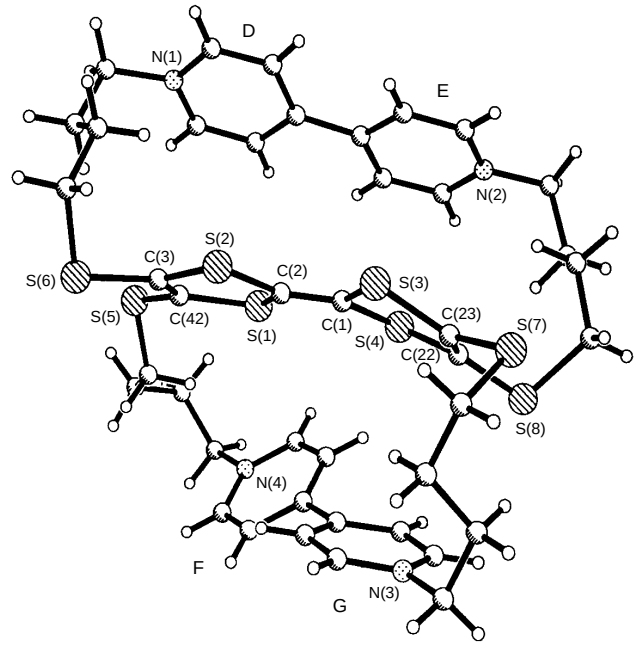


Fig. 1 Structure of **4**·4PF_6·3MeCN

Table 1 Cyclic voltammetry data: oxidation peak potentials

Compound	$E_{1/2}^1$/V	$E_{1/2}^2$/V
2	0.58	0.86
3	0.57	0.85
4	0.64	0.94

distortions have been observed in other TTF systems.[11] The bipyridinium units differ in conformation. The dihedral angle between the pyridine rings D(N1) and E(N2) is 7.3(2)°, whereas the angle between F(N4) and G(N3) is 39.3(2)°. The four pyridine rings D, E, F and G make angles of 25.1(1), 17.8(1), 24.1(2) and 55.0(2)° with the central part of TTF (plane B). Thus, the corresponding interplanar distances are not well defined. However, inspection of **4**·4PF_6 in Fig. 1 suggests a stronger interaction between the TTF part and the bipyridine part involving N(1) and N(2) than between TTF and the other bipyridine part, although no short S···N contacts are observed. The displacement parameters for the F atoms of the anions are rather high, indicating orientational disorder. Likewise, the solvent molecules appear to be somewhat disordered. Compound **4**·4PF_6 is prevented from stacking in homologous columnar stacks.[12] The shortest intermolecular S···S distance is 3.744(3) Å [between S(5) and S(7) (x − 1, y, z)], likewise indicating a weak interaction. Several C–H···F hydrogen bonds appears to be present, but the disorder of the F positions prevents a detailed description.

The simple ^{1}H NMR spectrum of **4**·4PF_6 indicates that the system must be flexible in solution as, due to high symmetry, all the butane-1,4-diyl linkers are equivalent in solution. Furthermore the ^{1}H NMR spectrum of **4**·4PF_6 is independent of temperature in the range 238–303 K.

The redox behavior of the precursors **2** and **3** and the donor acceptor complex **4**·4PF_6 were investigated by cyclic voltammetry (CV) (Table 1). The positive changes in the redox pattern are significant when going from the isolated TTF systems (**2** and **3**) to **4**·4PF_6. The change for the first potential (ΔE^1 = 70 mV) are a consequence of two factors. First, the charge transfer interactions are comparable with systems containing only one acceptor unit,[6] as evidenced by the UV–VIS (MeCN) spectrum, where **4**·4PF_6 showed a broad charge-transfer absorption band centered at 645 nm (470 M^{-1} cm^{-1}), similar to the one reported for the simpler systems.[6] Because of conformational restrictions the TTF unit is unable to interact with both of the acceptor units at the same time and therefore only a part of the change (*ca*. 30–40 mV) can be attributed to the charge transfer interactions. The rest is due to electrostatic repulsion, because the proximity of four positive charges on nitrogen makes it less favorable for the TTF moiety to generate the radical cation. The significant positive change for the second potential (ΔE^2 = 90 mV) can only be explained by electrostatic repulsion from the four pyridinium cations and the TTF radical cation, making the second oxidation less favorable, as no effect was observed in the parent system.[6]

The template-directed synthesis of the bismacrocyclic A–D–A sandwich **4**·4PF_6 shows the effect of charge-transfer interaction upon macrocyclization. The crystal structure of **4**·4PF_6 revealed two different bipyridinium units in the solid state, while NMR, UV–VIS and CV analyses illustrate that the system is very flexible in solution.

2-Chloro-2-cyclopropylideneacetate 1 and spiropentane analog 2 cycloadd pyrroline *N*-oxide 3 to give spiro[cyclopropane-1,5′-isoxazolidine]s 4 and 5 in good yields; due to the presence of a chlorine substituent on the carbon α to the spirocyclopropane ring, which facilitates a cyclopropyl to cyclobutyl ring enlargement, these compounds undergo a cascade rearrangement to yield indolizinone derivatives 8 and 9 cleanly (70–73% yield), offering a new method for the synthesis of the indolizine skeleton.

The strain energy incorporated in a cyclopropane ring is an extremely useful handle for molecular transformations in organic synthesis.[1] The selectivity of such a transformation and the operational conditions strongly depend on the molecular surroundings of the cyclopropane ring in a given skeleton.

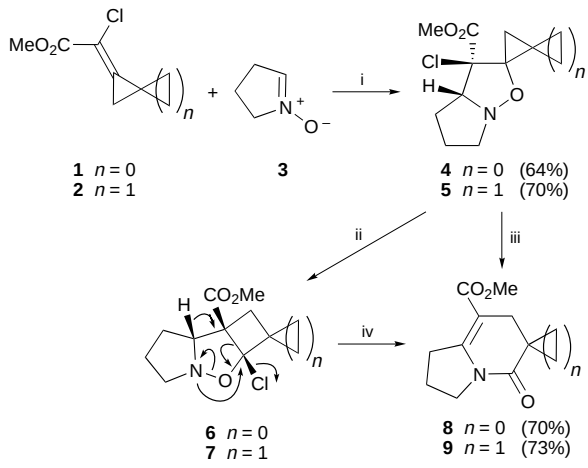
It has already been demonstrated that isoxazolidines or isoxazolines with a spirocyclopropane ring at the 5-position are capable of undergoing a selective rearrangement affording 2-substituted tetrahydro- or dihydro-4-pyridones, respectively.[2] This process has been applied to the synthesis of natural and non-natural heterocyclic compounds and it has proved particularly useful for the synthesis of heterocycles with nitrogen at the bridgehead.[3] We now report a new selective thermal cascade ring enlargement process of 4-chloro substituted spiro[cyclopropane-1,5′-isoxazolidine]s, obtained by nitrone cycloaddition to methyl 2-chloro-2-cyclopropylideneacetate **1**[4,5] and to methyl (*Z*)-2-chloro-2-spiropentanylideneacetate **2**[6] which further expands the synthetic utility of this class of compounds.

Compounds **1** and **2** smoothly react with pyrroline *N*-oxide **3** at room temperature to give cycloadducts **4** and **5**, respectively, as single regioisomers (Scheme 1).

The regioselectivity of these cycloadditions is in accord with the one previously observed for electron-acceptor substituted methylenecyclopropanes.[3b,7] Compounds **4** and **5** are obtained as single diastereoisomers, the configuration of which has tentatively been assigned on the basis of the known preference of the methoxycarbonyl group to be placed *endo* with respect to the nitrone in the cycloaddition process.[7,8]

When the isoxazolidines **4** and **5** were submitted to the usual conditions for thermal rearrangement (toluene, 110 °C),[2] a complex mixture of products was obtained. However, by replacing toluene with the more polar DMSO a clean reaction occurred at 100 °C to give the hexahydroindolizin-5-ones **8**[9] and **9** in 70 and 73% yield, respectively (Scheme 1). These compounds were present only in minute amounts in the heated toluene solution. Spectroscopic data were consistent with the proposed structures **8** and **9**. The regioselective formation of compound **9**, the structure of which was assigned on the basis of the long-range coupling (^5J = 1.8 Hz) between the two groups of allylic protons observed in the ^{1}H NMR spectrum, is quite remarkable. This unexpected result was finally confirmed by an X-ray crystal structure analysis of compound **8** (Fig. 1).§

The fact that a polar solvent is essential for the success of this rearrangement suggests that it occurs *via* a highly polar transition structure. The polar solvent would certainly favour the cyclopropyl to cyclobutyl ring enlargement leading from **4**/**5** to **6**/**7**.[10] This might occur as an intramolecular S_N2 displacement or *via* tight ion-pair intermediates. The further ring-enlargement could be initiated by abstraction of the bridgehead proton in **6**/**7**, followed by N–O bond cleavage and reclosure to the indolizidin-5-ones **8**/**9**.



Scheme 1 *Reagents and conditions*: i, CH_2Cl_2, room temp., 5 d; ii, Al_2O_3, CH_2Cl_2, room temp.; iii, DMSO, 100 °C, 3 h; iv, DMSO, 100 °C

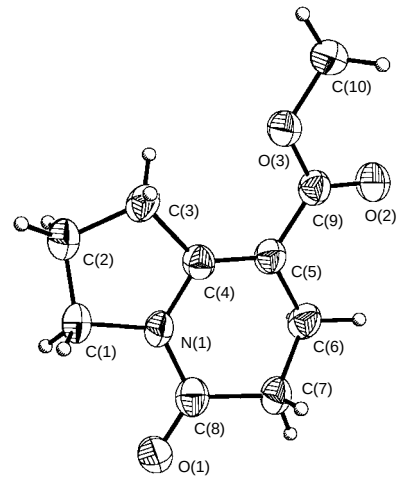


Fig. 1 Structure of 8-methoxycarbonyl-5-oxo-2,3,6,7-tetrahydro-1*H*-indolizine **8** in the crystal.

The intermediacy of the cyclobutyl derivatives **6**/**7** is probable, since these compounds could actually be isolated after stirring the isoxazolidines **4** and **5** in CH_2Cl_2 in the presence of Al_2O_3 at room temperature. Isoxazolidine **5** rearranged completely to **7** in 4 h, whereas **4** under the same conditions remained as a 6 : 1 mixture of **6** and **4** after 3 days.

The structural assignment of **6** and **7** was based on the presence of chlorine as proved by the mass spectrum, and the observation of diagnostic signals for the cyclobutane ring in the ^{13}C NMR spectrum (δ_C 102.1, 72.9, 27.7 and 25.8 in **6**; 107.5, 70.5, 28.5 and 25.5 in **7**). The *cis* relationship of the methoxycarbonyl group and the chlorine in **6**/**7** was tentatively assigned on the assumption that the displacement of chloride in **4** and **5** occurs *via* an S_N2 process, which fixes the relative configuration of the bridgehead proton and the CO_2Me group in any potential intermediate *en route* to **6**/**7**. The chloride then can enter only from the convex face of the molecule. When heated to 100 °C in DMSO, compounds **6** and **7** gave the same indolizidinones **8** and **9** as obtained directly from **4** and **5**.

In conclusion, a new domino rearrangement of spiro[cyclopropane-1,5′-isoxazolidine]s has been discovered. This process is made possible by the presence of a chlorine substituent on the carbon α to the spirocyclopropane ring, which facilitates a cyclopropyl to cyclobutyl ring enlargement mediated by a polar solvent. At higher temperature a further ring enlargement ensues with elimination of hydrogen chloride to produce hexahydroindolizidin-5-ones.

The generalization of this new process and its synthetic application are now being studied in our laboratories.

This work was supported on the Italian side by research funds from the University of Florence and, in part, CSCEA (CNR). On the German side this work was supported by the Deutsche Forschungsgemeinschaft (SFB 416, Project A) and the Fonds der Chemischen Industrie; generous gifts of chemicals by the BASF, Bayer, Hoechst, Degussa AG, and Hüls companies are gratefully acknowledged. C. Z. is grateful for financial support for the period in Göttingen by the ERASMUS Exchange Program.

Ylide-like addition complexes in insertion reactions of CH with PH_3 and H_2S

Z.-X. Wang and M.-B. Huang*†

Graduate School at Beijing, University of Science and Technology of China, Academia Sinica, PO Box 3908, Beijing 100039, China

The intermediate addition complexes HC–PH_3 and HC–SH_2 formed in the CH insertion reactions with PH_3 and H_2S have large binding energies and short central bond lengths, exhibiting 'ylidic' features in their molecular and electronic structures.

We previously studied the CH insertion reactions with NH_3, H_2O and HF by means of *ab initio* calculations[1] and found intermediate addition complexes existing prior to the transition states in the reaction paths. The reaction paths for these reactions are illustrated by eqns. (4)–(6) where the reactants,

$$\underset{\textbf{ma}}{CH + XH_n} \rightarrow \underset{\textbf{mb}}{HC{-}XH_n} \rightarrow \underset{\textbf{mc}}{TS} \rightarrow \underset{\textbf{md}}{H_2CXH_{n-1}}$$

(1) X = P, n = 3; (2) X = S, n = 2; (3) X = Cl, n = 1

(4) X = N, n = 3; (5) X = O, n = 2; (6) X = F, n = 1

intermediate complexes (HC–XH_n), transition states (TS), and insertion products (H_2CXH_{n-1}) are denoted as **ma**, **mb**, **mc** and **md** (m = 4, 5 or 6), respectively, and the energy profiles have the following skeletons: E (**ma**) > E (**mb**) < E (**mc**) ⩾ E (**md**).

Recently we performed *ab initio* calculations for the CH insertion reactions with PH_3, H_2S and HCl. These reactions have similar reaction paths [illustrated by eqns. (1)–(3), respectively] and similar skeletons of the energy profiles to those for reactions (4)–(6). However, we have found that the intermediate addition complexes HC–PH_3 **1b** and HC–SH_2 **2b** initially formed in reactions (1) and (2) are not the simple complexes,[1] but are similar in nature to the phosphonium and sulfonium ylides (P- and S-ylides).

Standard *ab initio* molecular calculations were performed by using the Gaussian 94 W suite of programs.[2] The structures of reactants, intermediate complexes, transition states, and products were optimized at the (U)MP2(FC)/6-31G(d) and (U)MP2(FC)/6-311++G(d,p) levels. Frequency calculations were carried out at the (U)MP2(FC)/6-31G(d) level to characterize stationary points and to evaluate zero-point energies (ZPEs). Finally single-point (U)MP4SDTQ(FC)/6-311++G(2d,p)//(U)MP2(FC)/6-311++G(d,p) calculations were performed. For open-shell systems the $< S^2 >$ values are all < 0.8. We recalculated the insertion paths for reactions (4)–(6) at these levels and obtained similar results to those reported in ref. 1. The MP4SDTQ/6-311++G(2d,p)//MP2/6-311++G(d,p) energetic results (the spin-projected ones for the open-shell systems) corrected with the (MP2/6-31G(d)) ZPEs and the MP2/6-311++G(d,p) geometrical results are used unless otherwise noted.

The potential energy curves in Fig. 1 represent the calculated insertion reaction paths for reactions (1)–(3). The relative energies of **mb**, **mc** and **md** and the structures of **mb** (m = 1–3) are shown in Fig. 1. The term 'relative energy' (of a species) in the present article means the energy of a species relative to the reactants in the same reaction.

The binding energies of the intermediate addition complexes **1b**, **2b** and **3b** in reactions (1)–(3) are 43.4, 22.1 and 3.8 kcal mol^{-1} (1 cal = 4.184 J) respectively. The negative relative

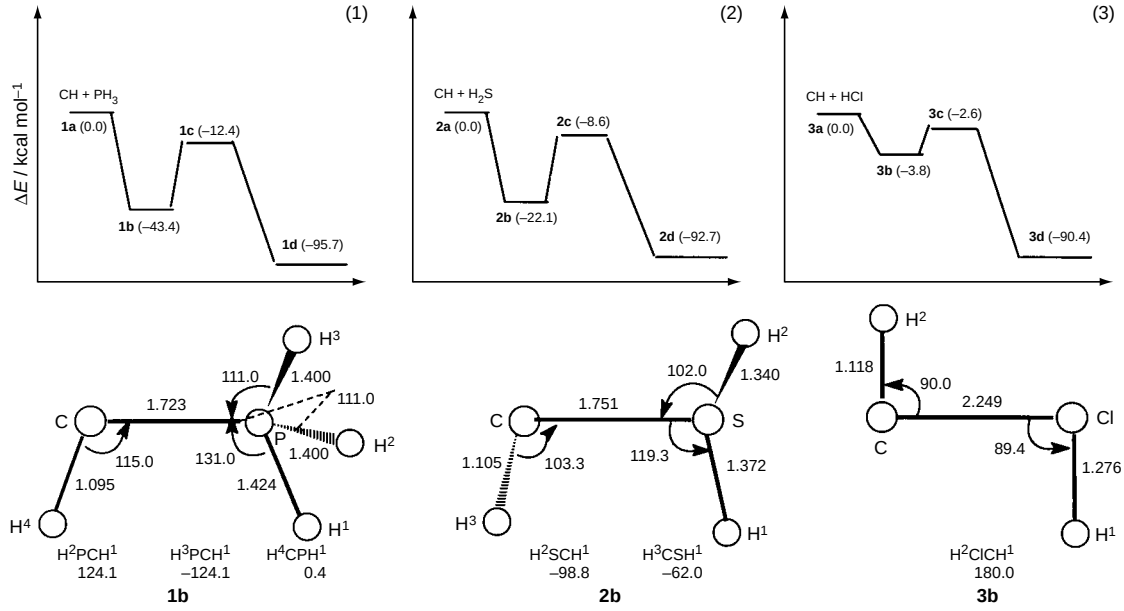

Fig. 1 A schematic diagram of the potential energy curves of the CH insertion reactions with PH_3 (1), H_2S (2) and HCl (3) with the MP4SDTQ/6-311++G(2d,p)//MP2/6-311++G(d,p) relative energies in kcal mol^{-1} [corrected with the MP2/6-31G(d) ZPEs] in parentheses. In the lower part of the figure are the MP2/6-311++G(d,p) structures of the intermediate addition complexes **mb** (m = 1–3) formed in the three insertion reactions (bond lengths in Å and angles in °).

Table 1 Binding energies (E_b) and the C–X bond distances (R) of the addition complexes HC–XH_n

	HC–PH_3 **1b**	HC–SH_2 **2b**	HC–ClH **3b**	HC–NH_3 **4b**	HC–OH_2 **5b**	HC–FH **6b**
E_b[a]/kcal mol^{-1}	43.4[b]	22.1[b]	3.8	24.9	7.9	1.5
R(C–X)[c]/Å	1.723	1.751	2.249	1.588	1.801	2.173
	(1.787)[d]	(1.724)	(1.700)	(1.398)	(1.368)	(1.344)

[a] The MP4SDTQ/6-311++G(2d,p)//MP2/6-311++G(d,p) + ZPE energetic results. [b] After the (MP4) BSSE corrections, these two values (the E_b values for **1b** and **2b**) are reduced by 3.4 and 3.4 kcal mol^{-1}, respectively. [c] Optimized at the MP2/6-311++G(d,p) level. [d] Values in parentheses are the C–X bond lengths in the respective insertion products.

Table 2 Calculated properties of HC–PH_3 and HC–SH_2

	E_{pt}[a]/ kcal mol^{-1}	ΔE[a]/ kcal mol^{-1}	H–C–X[b]/°	Q(C)[b]/e	Q(X)[b]/e
HC–PH_3 **1b**	52.3	0.2	115.0	−0.620	0.691
HC–SH_2 **2b**	70.6	7.1	103.3	−0.660	0.513

[a] E_{pt} and ΔE denote the proton-transfer energy and internal rotation barrier, respectively, calculated at the MP4SDTQ/6-311++G(2d,p)//MP2/6-311++G(d,p) + ZPE level. [b] H–C–X and Q (the charge on atomic centers) are predicted at the MP2/6-311++G(d,p) level.

energy values of the transition states **1c**, **2c** and **3c** (−12.4, −8.6 and −2.6 kcal mol^{-1}, respectively) and the large negative relative energy values of the insertion products **1d**, **2d** and **3d** (−95.7, −92.7 and −90.4 kcal mol^{-1}, respectively) indicate that the CH insertion reactions with PH_3, H_2S and HCl are all feasible and strongly exothermic.

In the following we focus on the addition complexes. Table 1 lists the binding energies and the C–X bond distances of the intermediate addition complexes **mb** (m = 1–6), together with the C–X bond lengths of the insertion products (**md**). As shown in Table 1, **1b** (HC–PH_3) and **2b** (HC–SH_2) have very large binding energies and very short C–X bond distances (1.723 and 1.751 Å, respectively) which are shorter than or comparable with the C–X bond lengths (1.787 and 1.724 Å) in **1d** and **2d**, respectively. The binding energies for **3b**, **5b** and **6b** are all very small (< 10 kcal mol^{-1}), and they all have very long C–X bond distances compared with those in their respective insertion products. Although the binding energy for **4b** is quite large (about half the value for its analogue **1b**), the C–N bond distance (1.588 Å) in **4b** is significantly longer than that (1.398 Å) in **4d**. It is also noted that the HCX angles in **1b** and **2b** (115.0 and 103.3°, respectively) are significantly larger than 90° while the HCX angles in the other complexes (also see ref. 1) are close to 90°. It is concluded that **1b** and **2b** are different from the other complexes which are the loosely bound lone-pair (of the X-atom) donor–acceptor complexes.[1]

The P- and S-ylides (H_2CPH_3 and H_2CSH_2) are important reactants in synthetic organic chemistry. In our previous studies,[1,3] we already noticed that the $^1CH_2$ insertion reactions into hydrides have similar reaction paths and similar energy profile skeletons to those for the CH insertion reactions. The P- and S-ylides could be considered as the intermediate addition complexes in the $^1CH_2$ insertion reactions with PH_3 and H_2S, respectively (see ref. 7), and it is natural to infer that the CH addition complexes **1b** and **2b** are similar to the P- and S-ylides (although **1b** and **2b** are radicals). As a prototype of ylides the P-ylide has been extensively investigated by quantum chemists[4–8] (its bonding nature is still being explored[4]), and the following features are known. The P-ylide has a short C–P bond length[4–6] (shorter than the length in H_3C–PH_2) and very large binding energy towards $^1CH_2$ + PH_3. There is a large charge separation at its C^-P^+ bond[4,6,8] and the rotational barrier about this bond is extremely low.[4,5,8] These features are considered as general features in the molecular and electronic structures of ylides.

Table 2 lists the calculated properties of **1b** and **2b**. The proton-transfer energy[8] (E_{pt}) is defined as a criterion of 'hypervalency' in ylides, and we have defined the E_{pt} values for **mb** as the energy differences between **mb** and **md**. The binding energies and E_{pt} values for the P- and S-ylides can be evaluated based on the energetic results reported in ref. 7 which were calculated at the MP levels comparable to those in the present study. The large binding energies for **1b** and **2b** (43.4 and 22.1 kcal mol^{-1}, respectively) are somewhat smaller than those for the P- and S-ylides (54–74 and 27–48 kcal mol^{-1}, respectively). The E_{pt} values for **1b** and **2b** are 52.3 and 70.6 kcal mol^{-1}, respectively, which are comparable with those for the P- and S-ylides (53–59 and 73–81 kcal mol^{-1}, respectively). The C–P bond length in **1b** is only 0.046 Å longer than the length of 1.677 Å[4,5] [at the MP2/6-311+G(d,p) level] in the P-ylide, and the C–S bond length in **2b** is about 0.1 Å longer than the length [1.635 Å[7] at the MP2/6-31G(d) level] in the S-ylide. The MP2 Mulliken charges on the C and P atoms in **1b** are −0.620 and +0.691, respectively (the MP2 charges of −0.76 and +0.55 for the P-ylide were reported in ref. 4) and the charges on the C and S atoms in **2b** are −0.660 and +0.513, respectively, which implies considerable charge separations in **1b** and **2b**. The rotational barrier in **1b** is extremely low (0.2 kcal mol^{-1}) as in the P-ylide (*ca*. 1 kcal mol^{-1} or less[4,5]), and the barrier in **2b** is 7.1 kcal mol^{-1} (no reported post-SCF results for the barrier in the S-ylide are available).

1b and **2b** are not loosely bound complexes and they have ylidic features in their molecular and electronic structures. Since **1b** and **2b** exist in deep minima in the potential energy surfaces (Fig. 1), they might be observed in some experiments (spectroscopy, EPR, *etc*). We would expect the ylide-like radicals **1b** and **2b** to be useful in synthetic chemistry as are the P- and S-ylides.

We thank the NNSFC for the financial support.

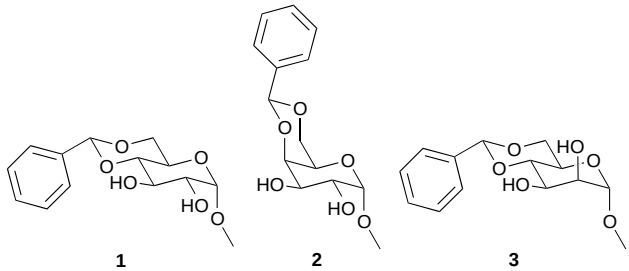
Three 1-*O*-methyl-4, 6-*O*-benzylidene derivatives of monosaccharides (D-glucose, D-galactose and D-mannose) were synthesised: they acted as versatile gelators of various organic fluids, indicating that saccharides are useful as potential building-blocks for molecular design of chiral gelators.

The development of new gelators of organic fluids has recently received much attention. They not only gelatinise various organic fluids but also create novel networks with fibrous superstructures which can be characterised by SEM pictures of the xerogels.[1–11] The gelators can be classified into two categories according to the difference in the driving force for the molecular aggregation, *viz*. hydrogen-bond-based gelators and nonhydrogen-bond-based gelators. Typical examples of the former group are the aliphatic amide derivatives,[1–4] whereas those of the latter group are cholesterol derivatives.[6–9] The superstructures of the organic gels of aliphatic amide derivatives show that they satisfy the complementarity of the intermolecular hydrogen-bonding interactions.[5–9] This observation stimulated us to use saccharides as a hydrogen-bond-forming segment in the gelators, because one can easily introduce a variety of hydrogen-bond-forming, chiral segments into gelators by selection from a saccharide library. In the literature examples of saccharide-containing gelators are very limited in spite of their high potential.[8,12] We synthesised glucose-based **1**, galactose-based **2** and mannose-based **3** and studied their gelation abilities. We found that the gelation properties, such as gel stability, superstructure and solvent-dependence, were profoundly related to the saccharide structure.



The synthesis of **1** has already been reported.[13] Gelators **2** and **3** were synthesised in a similar manner by treatment of the saccharide with benzaldehyde and $ZnCl_2$. The products were identified by ^{1}H NMR and IR spectroscopy and elemental analyses.

The gelation test was carried out as follows: the gelator (**1**–**3**: 3.0 mg) was mixed with solvent (0.10 ml) in a septum-capped test tube and the mixture was heated until the solid dissolved. The solution was cooled to room temperature and left for 1 h (G in Table 1 denotes that a gel was formed at this stage). Some solutions gelatinised at a gelator concentration below 1.0 wt% (SG or super-gelator; Table 1). Solvents in Table 1 are those which were gelatinised by either **1**, **2** or **3**.[14] Table 1 reveals that, in general, **2** acts as an excellent gelator of many organic fluids. In contrast, comparison of the gelation ability for *n*-heptane and cyclohexane reveals that **1** is more cohesive and tends to form a precipitate, whereas **3** is more soluble than the other two gelators and is frequently unable to coagulate in solution.

What is the origin of the difference in their gelation ability? The sole structural difference among **1**, **2** and **3** is the absolute configuration of C-2 and C-4. It is reasonable to assume that **1**, **2** and **3** show a different ability to form a gel network because of the different intermolecular hydrogen-bonding interactions. In the FT-IR spectra, the gel solutions gave two peaks (3473–3240 and 3576–3659 cm^{-1}) in the ν_{OH} region which could be assigned to hydrogen-bonded OH and free OH groups, respectively. As shown in Fig. 1, the peak intensity ratio (R) of hydrogen-bonded OH *vs*. free OH abruptly increased at the sol-gel phase-transition concentration. Furthermore, the largest R value was observed for **2**, which also features the greatest gelation ability. In contrast, the peak arising from hydrogen-bonded OH groups was hardly observed for **3** up to 0.5 wt%, indicating that **3** is too soluble to use as a good gelator. These FT-IR spectral data consistently indicate that the gel network in the present system is primarily constructed by intermolecular hydrogen-bonding interactions. A computational study (MOPAC 93 included in CS CHEM3D) indicated that the

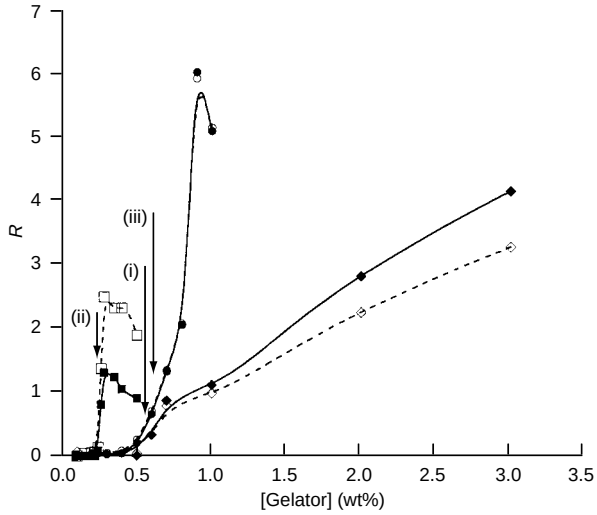

Fig. 1 Plot of the peak intensity ratio (R) of hydrogen-bonded OH groups *vs.* free OH groups as a function of [gelator] in toluene at 20 °C. There are two major peaks for hydrogen-bonded OH groups: the filled points were obtained from the intensities at ν_{OH} 3312–3240 cm^{-1}, whereas the open points are obtained from those at ν_{OH} 3473–3350 cm^{-1}; (○,●) **1**, (□,■) **2** and (◇,◆) **3**. The arrows indicate the sol-gel transition temperatures of (i) **1**, (ii), **2** and (iii) **3**.

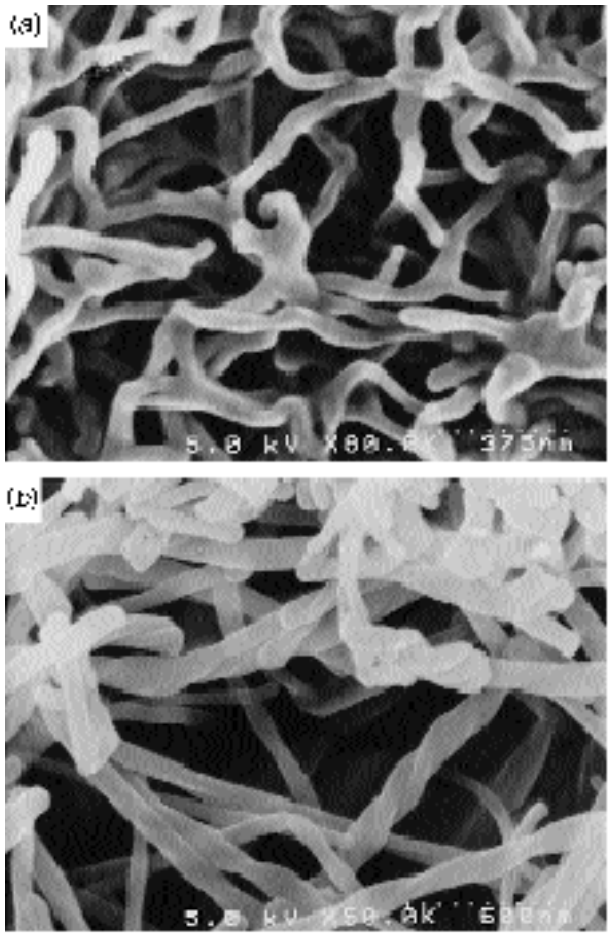

Fig. 2 SEM pictures of (*a*) the **1**/CCl_4 system and (*b*) the **3**/water system

intramolecular hydrogen-bonding distance (H···O) between 3-OH and 4-OR of the saccharides is not significantly different (*e.g.* 2.5 Å for **1** and 2.38 Å for **2**). This suggests that the differences in gelation ability are not due to the presence of a special OH group useful for intermolecular hydrogen-bonding, but rather is due to a structural preference in the molecular aggregation. We now consider that **2**, which has the benzylidene group and the pyranose ring arranged at almost a right angle, is able to enjoy both a benzene–benzene π–π stacking interaction and an OH–OH intermolecular hydrogen bonding interaction, whereas **1** and **3**, which are flatter than **2**, cannot enjoy both interactions simultaneously.

To obtain visual insights into the aggregation mode, we prepared a dry sample for SEM studies.[15] Fig. 2(*a*) shows a typical picture obtained from the xerogels of **1** or **2**. It is clear that the gelator forms a three-dimensional network with 50–200 nm frizzled fibrils. On the other hand, the fibrils obtained from the toluene gel of **3** are more linear (the picture is not shown here). Very interestingly, the fibrils obtained from the aqueous gel of **3** show a regular left-handed helical structure [Fig. 2(*b*)]. Presumably, in an aqueous system the balance between the hydrogen-bonding interaction and the hydrophobic interaction is different from that in other, organic media.

In conclusion, the present study has demonstrated for the first time that saccharides are promising building-blocks for new gelators with different gelation abilities and different three-dimensional network structures. We believe that such versatility of synthesis and diversity of products (including the creation of the helical structure) cannot be attained in a more simple fashion than with saccharides as building-blocks.

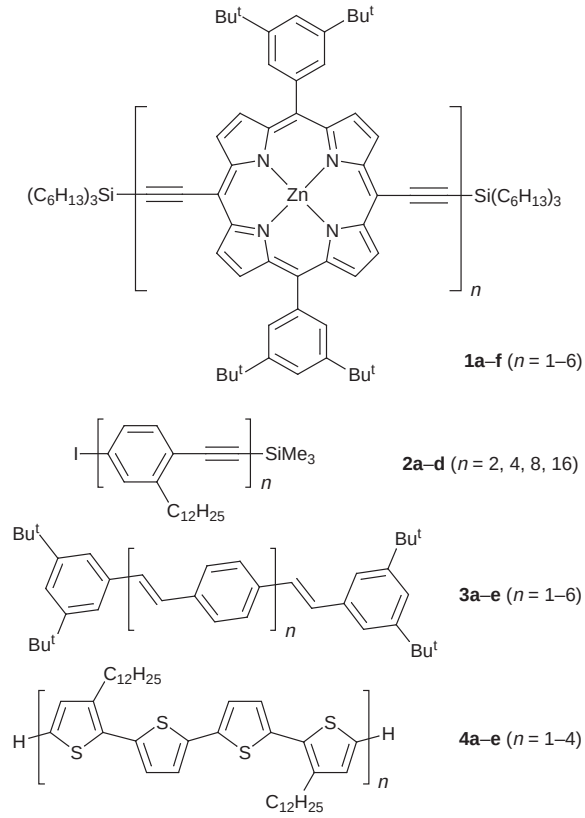
A series of conjugated porphyrin oligomers have been prepared and the evolution in their electronic properties is discussed; the crystal structure of the dimer is presented, as well as the MALDI TOF mass spectrum of the hexamer.

Conjugated organic polymers are interesting because of their versatile opto-electronic properties and processability.[1] Recently many groups have focused on the synthesis of homologous series of precisely defined conjugated oligomers because the evolution in electronic properties with chain-length reveals the extent of π-conjugation.[2] Pure monodisperse oligomers also have the advantage that they can be characterised more fully, *e.g.* by single crystal X-ray diffraction, than polydisperse materials. Here we present the synthesis and electronic spectra of a series of conjugated porphyrin oligomers from monomer to hexamer, as well as the crystal structure of the dimer.

Many types of aromatic units have been used to synthesise conjugated polymers. The polarisability, optical oscillator strength and extensive coordination chemistry of the porphyrin macrocycle make it an ideal unit from which to build low band-gap materials. Most porphyrin oligomers are not conjugated because non-planarity leads to poor π-overlap, for example in *meso*-aryl porphyrins there is generally a twist of about 70° between the plane of the aryl ring and that of the porphyrin. Two strategies have been devised to overcome this problem: conjugated porphyrin oligomers have been synthesised by linking porphyrins with edge-fused aromatic units[3] or by linking them with acetylenes[4–7] (as the acetylene is linear it cannot twist out of conjugation with the porphyrin). The first soluble conjugated porphyrin polymer to be prepared had *iso*decylpropanoate sidechains[5b] which provide excellent solubility, but make short oligomers difficult to purify and have undesirable reactivity towards nucleophiles. In this work we chose to study oligomers derived from 5,15-bis(3,5-di-*tert*-butylphenyl)-10,20-bis(trihexylsilylethynyl)porphyrin **1a** because of their greater accessibility, stability and crystallinity.[8]

A stepwise approach was used to synthesise oligomers **1b**–**f** from the monomer **1a**, using just two reactions: (i) protodesilylation with TBAF and (ii) Glaser–Hay coupling with CuCl·TMEDA in CH_2Cl_2 under air.[5] The trihexylsilyl end-group was chosen because it facilitates chromatographic separation of unprotected, mono-protected and bis-protected oligomers generated by partial protodesilylation. Like all other types of conjugated oligomers, the solubility of these compounds decreases with increasing chain length; all the oligomers were characterised by ^{1}H NMR spectroscopy, but only the monomer, dimer, trimer and tetramer are soluble enough for ^{13}C NMR analysis. Attempts to prepare the octamer of this series, by coupling mono-protected tetramers, gave a totally insoluble material. FAB mass spectrometry does not work well with these compounds; a weak molecular ion peak was observed for the monomer, but no signals could be obtained for any of the oligomers. Fortunately, reflectron MALDI TOF MS using a anthracene-1,8,9-triol matrix, gave excellent spectra for all five oligomers, with the expected $M^{+\cdot}$ signals as the dominant species in each spectrum. Isotope resolved spectra were



obtained for **1b**–**f** by tuning the time-lag focusing pulse voltage for each sample.[9] The observed and calculated isotopomer patterns for the hexamer **1f** are shown in Fig. 1. The crystal structure of the dimer **1b**,‡ illustrated in Fig. 2, shows that the entire 56-atom π-system is remarkably planar (to ±0.391 Å). The torsional angle between the porphyrins is zero in the solid

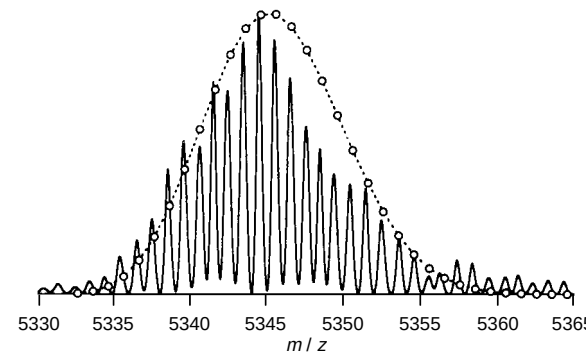


Fig. 1 Reflectron MALDI TOF mass spectrum of **1f**, using an anthracane-1,8,9-triol matrix. The calculated isotopomer pattern for $C_{348}H_{378}N_{24}Si_2Zn_6$ is marked by circles.

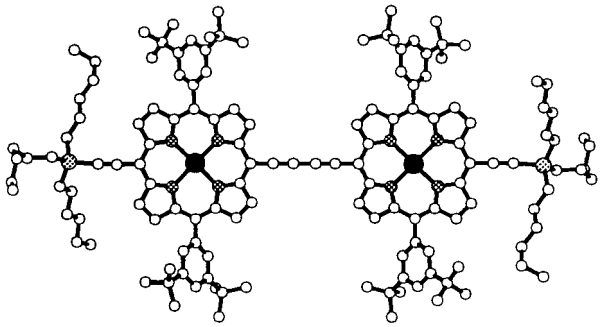

Fig. 2 Molecular structure of the dimer **1b** (pyridine ligands omitted for clarity). The bond lengths in the central butadiyne unit are 1.429(4) (*meso*-C–C), 1.210(4) (C≡C) and 1.368(5) Å (central C–C).

state, due to a crystallographic inversion centre at the centre of the molecule, although rotation about the butadiyne link may occur freely in solution. The crystal structures of several *meso*-ethynyl porphyrins have been reported,[4b,10] but this is the first structure of a *meso*-butadiyne-linked porphyrin dimer.

The electronic absorption spectra of **1a**–**f** in 1% pyridine–CH_2Cl_2 are shown in Fig. 3. As expected, the Q-band is red-shifted and intensified with increasing chain-length. A similar trend is seen in the fluorescence spectra; compounds **1a**–**f** each give a single emission peak at 650, 749, 810, 830, 850 and 858 nm respectively.§ Estimates for the optical HOMO–LUMO energy gap E_g were obtained from these fluorescence maxima, and also from the centres of gravity of the Q absorption bands. The values of E_g are plotted against reciprocal chain-length ($1/L$, where L is the length of the π-system in Å) in Fig. 4. The curves are linear, particularly for the longer oligomers, with no sign of saturation. The intercept at $L = \infty$ gives a predicted band gap for the polymer of 1.55 eV from absorption and 1.34 eV from emission; the absorption maximum of the *iso*decylpropanoate-substituted polymer in the same solvent is at 1.42 eV.[5b] We chose to plot reciprocal chain length, $1/L$, rather than $1/N$, where N is the degree of polymerisation, to facilitate comparison with other conjugated polymers. Fig. 4 includes data for oligomers of poly(*p*-phenyleneethynylene) **2a**–**d**,[2b] poly(*p*-phenylenevinylene) **3a**–**e**[2c] and poly(α-thiophene) **4a**–**d**.[2d] The gradient of these curves is a measure of the π-conjugation efficiency between neighbouring units. We conclude that the poly(porphyrinbutadiynylene) system (**1a**–**f**) has a similar conjugation efficiency to other, more conventional, conjugated polymers and yet it reaches a lower limiting π–π* gap because the porphyrin monomer unit starts at a lower HOMO–LUMO separation.

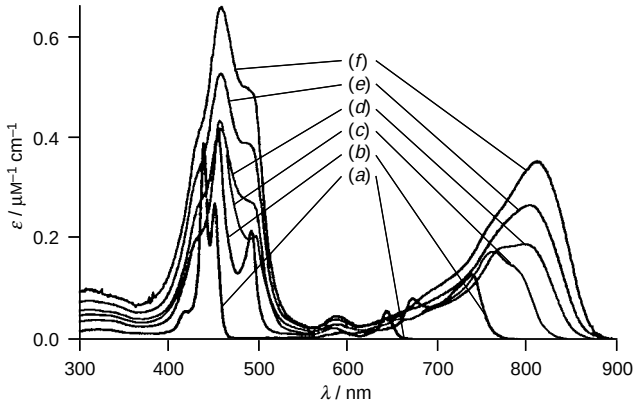

Fig. 3 Electronic absorption spectra of **1a**–**f** in 1% C_5H_5N–CH_2Cl_2: (*a*) **1a**, (*b*) **1b**, (*c*) **1c**, (*d*) **1d**, (*e*) **1e** and (*f*) **1f**

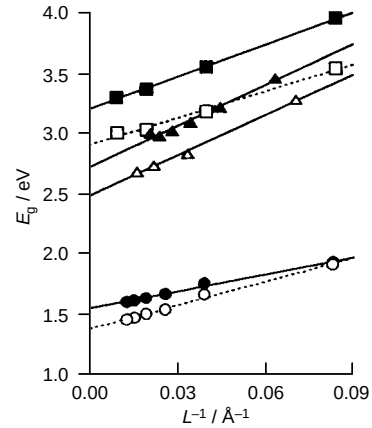

Fig. 4 Plot of optical band gap energy E_g against reciprocal chain length $1/L$ for (●) **1a**–**f** (absorption), (○) **1a**–**f** (emission), (■) **2a**–**d** (absorption), (□) **2a**–**d** (emission), (△) **3a**–**e** (absorption) and (▲) **4a**–**e** (absorption)

We thank the EPSRC (Polymer Synthesis Initiative), the Finnish Academy and the Emil Aaltonen Foundation for financial support, and the EPSRC mass spectrometry service (Swansea) for FAB mass spectra. Crystallographic work was done at Chemical Crystallography, University of Oxford, with generous assistance from Dr D. J. Watkin. We are grateful to Julia A. Elliott and Philip D. Siverns (Imperial College, London) for recording emission spectra.

Driving crystal construction *via* stoichiometry: π–π stacks in squaric acid organometallic salts

Dario Braga*† and Fabrizia Grepioni*‡

Dipartimento di Chimica G. Ciamician, Università di Bologna, Via Selmi 2, 40126 Bologna, Italy

Depending on the stoichiometric ratio, squaric acid (H_2SQA) reacts with $[Co(\eta^5\text{-}C_5H_5)_2][OH]$ to form crystalline materials based on anion–cation π–π stacks and/or squarate ion ribbons held together by O–H···O hydrogen bonds between squarate anions and by charge-assisted $C–H^{\delta+}\cdots O^{\delta-}$ hydrogen bonds between organometallic and organic components.

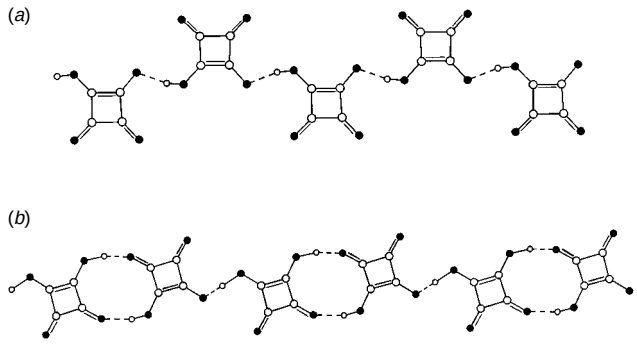
Organometallic crystal engineering is an almost uncharted territory. Work in this field promises a great deal of new discoveries because of the possibility of combining physical and chemical features of organic and organometallic molecules and ions in the solid state.[1] This may lead to the isolation of materials with novel conducting, magnetic or optoelectronic properties.

We have demonstrated that a great variety of new architectures can be obtained by combining organic moieties held together by strong O–H···O hydrogen bonds with non coordinating organometallic cations, such as $[Co(\eta^5\text{-}C_5H_5)_2]^+$ and $[Cr(\eta^6\text{-}C_6H_6)_2]^+$.[2] Chiral organic frameworks have also been obtained when enantiomerically pure chiral acids, such as L-tartaric and L-bisbenzoyltartaric acids have been used.[3]

We are now able to report that the reaction of the hydroxide $[Co(\eta^5\text{-}C_5H_5)_2][OH]$ with squaric acid (3,4-dihydroxy cyclobut-3-ene-1,2-dione, H_2SQA) in water (or THF) yields two different crystalline materials, namely $[Co(\eta^5\text{-}C_5H_5)_2]^+$-$[(HSQA)]^-$ **1** and $[Co(\eta^5\text{-}C_5H_5)_2]^+[(HSQA)(H_2SQA)]^-$ **2**, depending on the stoichiometric ratio between cobaltocenium hydroxide and squaric acid.§ The different stoichiometry is associated with a dramatic change in crystal structure, which is also reflected in a different colour of the crystalline materials. Squaric acid has been widely investigated for its electronic and physical properties.[4]

When the stoichiometric ratio between cobaltocenium hydroxide and squaric acid is 1 : 1, crystalline **1** is obtained. Contrary to what is usually observed with cobaltocenium salts, which are yellow, crystals of **1** are orange. Indeed, the structure of **1** presents some unique features that may account for this physical difference. The crystal is constituted of ribbons of $[(HSQA)]^-$ monoanions (Scheme 1) bonded *via* negatively charged O–H···O hydrogen bonds [O···O 2.446 Å] and of ribbons of cobaltocenium cations, Fig. 1. The 1 : 1 stoichiometry, combined with a good matching in size and shape between the cyclopentadienyl ligands and the $[(HSQA)]^-$ ions, leads to a superstructure in which the hydrogen bonded squarate ribbons intercalate between cobaltocenium cations (Fig. 1). The π–π distance is *ca*. 3.35 Å. The oxygen atoms form the outer rims of the $\{[(HSQA)]^-\}_n$ ribbons and interact with the $[Co(\eta^5\text{-}C_5H_5)_2]^+$ cations on both sides *via* charge assisted $C–H^{\delta+}\cdots O^{\delta-}$ hydrogen bonds (five H···O distances in the range 2.272–2.500 Å). What is more, the packing arrangement is chiral in space group $P2_1$. The unusual orange colour suggests formation of a charge transfer complex and prompts for further investigations in due course.[5]

On changing the stoichiometry to 1 : 2, the yellow crystalline **2** is obtained. It is constituted of supramolecular monoanions $[(HSQA)(H_2SQA)]^-$ resulting from the loss of one proton every two squaric acid molecules and arranged in ribbons bonded *via* negatively charged O–H···O hydrogen bonds (O···O 2.440, 2.436 Å).[6] The bonding within the superanions is provided by



Scheme 1 (*a*) The $\{[(HSQA)]^-\}_n$ ribbon in crystalline **1** and (*b*) the $\{[(HSQA)(H_2SQA)]^-\}_n$ ribbon in crystalline **2**

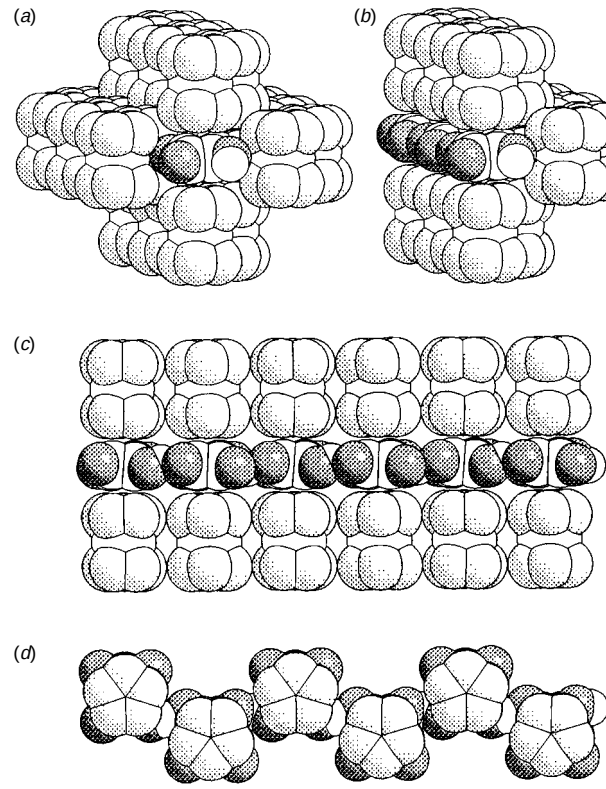


Fig. 1 'Dissection' of the packing arrangement in crystalline **1**: space filling representation of the $\{[(HSQA)]^-\}_n$ ribbon encapsulated within four (*a*), three (*b*) and two (*c*) rows of $[Co(\eta^5\text{-}C_5H_5)_2]^+$ cations. Note the good match in size and shape of the squaric acid moieties and of the cyclopentadienyl ligands (*d*). H atoms of the cations omitted for clarity. Relevant hydrogen bonding parameters (in Å, C–H···O < 2.5 Å): $O^-\cdots Q_{OH}$ 2.446; $C–H_{Cp}\cdots O$ 2.272, 2.339, 2.455, 2.455, 2.467.¶

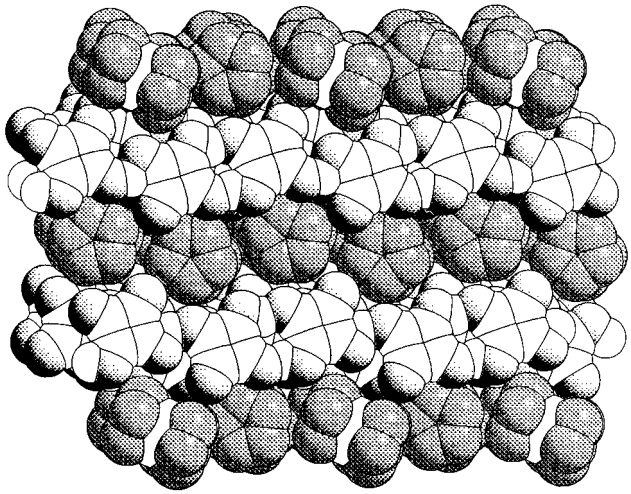

Fig. 2 Space filling representation of the stacking sequence of $\{[Co(\eta^5\text{-}C_5H_5)_2]^+\}_n/\{[(HSQA)(H_2SQA)]^-\}_n$ in crystalline **2**. H atoms of the cations omitted for clarity. Relevant hydrogen bonding parameters (in Å, C–H···O < 2.5 Å): $O_{OH}\cdots O_{CO}$ 2.550, 2.550, 2.574, 2.539; $O^-\cdots O_{OH}$ 2.436, 2.440; $C\text{–}H_{Cp}\cdots O$ 2.192, 2.213, 2.314, 2.328, 2.343, 2.401, 2.407, 2.408, 2.414, 2.437, 2.453, 2.465, 2.499, 2.500.¶

O–H···O hydrogen bonds, with formation of ten-membered ring systems (O···O distances in the range 2.539–2.574 Å) reminiscent of the carboxylic rings (Scheme 1). The ribbons are stacked in such a way that squarate moieties overlap hydrogen bonded rings, resulting in layers with oxygen atoms protruding above and below the layer surface. The cobaltocenium cations lie side-on the layer and interact *via* charge-assisted $C\text{–}H^{\delta+}\cdots O^{\delta-}$ hydrogen bonds (14 distances in the range 2.191–2.500 Å). Hence crystalline **2** can be described as a stacking sequence $\{[Co(\eta^5\text{-}C_5H_5)_2]^+\}_n/\{[(HSQA)(H_2SQA)]^-\}_n$ along the *c*-axis in the $P\bar{1}$ crystal (Fig. 2).

$C\text{–}H^{\delta+}\cdots O^{\delta}$ distances in both **1** and **2** fall towards the lower limit for interactions of this type, clearly indicating that the electrostatic interaction is reinforced by the difference in charge between organic anionic ribbons and organometallic cations.[7]

We have previously shown that self-aggregation of organic molecules into robust supramolecular frameworks can be controlled by reacting common organic acids with metallocene or metalloarene hydroxides. Since the organometallic cations possess only C–H donors they do not compete in the formation of strong hydrogen bonds. We have now shown that the same strategy can be used to obtain different structures starting from the same acid by changing the stoichiometry ratio. Though simple it may appear, this allows us to control the number of strong hydrogen bonding donor and acceptor sites, therefore the resulting crystal architectures. Analogous reactions involving the bis-benzene chromium cation are under investigation.

§ Brown powder of $[Co(C_5H_5)_2]$ (4.73 mg, 0.025 mmol) was added to 10 ml of bidistilled water at room temperature. Oxygen was bubbled to completely oxidize cobaltocene to bright yellow $[Co(C_5H_5)_2]^+$. The resulting solution of $[Co(C_5H_5)_2][OH]$ is strongly basic (pH > 10). White powder of squaric acid (2.8 mg, 0.025 mmol for **1**, 5.6 mg, 0.050 mmol for **2**) was then added. **1** and **2** were crystallized by evaporation at room temperature in the air. The same materials can be obtained by oxidizing cobaltocene in THF at room temperature in the presence of the appropriate stoichiometric amount of solid squaric acid. The reaction in THF very likely proceeds *via* formation of the peroxide anion ($CoCp_2 + O_2 \rightarrow CoCp_2^+ + O_2^{\cdot-}$) which deprotonates the acid as in the case of the reaction between $[Cr(C_6H_6)_2]$ and cyclohexane-1,3-dione.[2] Compounds **1** and **2** separate out as orange and yellow solids, respectively, which are filtered and dissolved in a minimum quantity of water for recrystallization.

¶ *Crystal data*: $[Co(\eta^5\text{-}C_5H_5)_2]^+[HSQA]^-$ **1**: $C_{14}H_{11}CoO_4$, T = 150(2) K, M = 302.16, monoclinic, space group $P2_1$, a = 7.368(3), b = 11.017(6), c = 7.368(2) Å, β = 94.66(2), U = 596.1(4) Å^3, Z = 2, D_c = 1.683 g cm^{-3}, $F(000)$ = 308, μ = 1.445 mm^{-1}, θ-range 3.0–28°, 1626 reflections measured, 1512 of which independent, refinement on F^2 for 154 parameters, wR (F^2, all reflections) = 0.1624, R_1 [1196 reflections with $I > 2\sigma(I)$] = 0.0402. $[Co(\eta^5\text{-}C_5H_5)_2]^+[(HSQA)(H_2SQA)]^-$ **2**: $C_{18}H_{13}CoO_8$, T = 223(2) K, M = 416.21, triclinic, space group $P\bar{1}$, a = 6.732(3), b = 11.582(11), c = 21.033(7) Å, α = 92.99(6), β = 92.43(3), γ = 96.34(6)°, U = 1626(2) Å^3, Z = 4, D_c = 1.700 g cm^{-3}, $F(000)$ = 848, μ = 1.103 mm^{-1}, θ-range 3.0–25°, 6315 reflections measured, 4984 of which independent, refinement on F^2 for 454 parameters, wR (F^2, all reflections) = 0.2092, R_1 [3229 reflections with $I > 2\sigma(I)$] = 0.0662. Three cobaltocenium cations were found, one in general position and two lying on two independent inversion centres, while two squaric acid and two squarate moieties were found in general positions. Common to both compounds: Mo-Kα radiation, λ = 0.710 69 Å, monochromator graphite, ψ-scan absorption correction. All non-H atoms were refined anisotropically. (O)H atoms directly located from Fourier maps and not refined. H atoms bound to C atoms were added in calculated positions. The computer programs SHELX86[8a] and SHELXL92[8b] were used for structure solution and refinement. The computer program SCHAKAL92 was used for all graphical representations.[8c] In order to evaluate the C–H···O bonds the C–H distances were normalized to the neutron derived value of 1.08 Å and the program PLATON was used.[8d] CCDC 182/808.

New cluster condensation modes in early transition metal thiophosphates: synthesis, structure and properties of $CsTa_4P_3S_{19}$, a novel layered material

Volkmar Derstroff and Wolfgang Tremel*†

Institut für Anorganische Chemie und Analytische Chemie, Universität Mainz, Becherweg 24, D-55099 Mainz, Germany

The new layer compound $CsTa_4S_5(S_2)(PS_4)_3$ was synthesized by the reaction of Ta metal in polythiophosphate melts. Its structure is based on $Ta_4S_5(S_2)$ clusters which are condensed by PS_4^{3-} groups.

In the past 20 years, lamellar transition metal chalcogenophosphates have been studied extensively because of their potential as cathodic materials and their intriguing structural, chemical and physical properties.[1–3] Among the group 5 derivatives, the structural dimensionality can vary from one- to three-dimensional as exemplified by V_2PS_{10},[4] Nb_2PS_{10}[5] and $Ta_4P_4S_{29}$.[6] This can be attributed to the variability in the metal coordination for the group 5 metals as well as the fascinating flexibility in the coordination of the chalcogen ligands.[7] The structures of typical group 5 thiophosphates are based on bicapped M_2S_{12} biprismatic units with a metal–metal bond inside. These biprisms are bonded together to form infinite M_2S_9 chains. In contrast to the 3d transition metal thiophosphates of the MPS_3 series, no intercalation behavior has been reported for group 5 thiophosphates.[8] This is surprising in view of their low-dimensional structures, but may be due to the fact that the complex host structures are not stable during the intercalation process.

In the quest for new intercalated early transition metal thiophosphates we have investigated reactions in $M–P_2Q_5–A_2Q–Q$ melts (M = Nb, Ta; Q = S, Se; A = alkali metal). The most significant results of these studies are that (*i*) a 'quasi-topotactic' cation insertion in porous host structures may be achieved[9] and (*ii*) that low-dimensional compounds with structures that exhibit novel unexpected cluster condensation modes can be obtained from reactions in thiophosphate melts as demonstrated by the first quaternary tantalum thiophosphate $CsTa_4(S_2)S_5(PS_4)_3$ whose synthesis, structure, and properties are reported here.

Single phase samples of the title compound were prepared by reacting the starting materials Ta, P_2S_5, Cs_2S and S in a 8 : 3 : 1 : 11 ratio at 600 °C.‡ The product was isolated in yields > 85% based on Ta. The crystal structure§ of this compound was determined by single-crystal X-ray diffraction. A view of a single anionic layer and the unit cell of $CsTa_4P_3S_{19}$ is given in Fig. 1(*a*). The Cs^+ cations are situated between the layers. The characteristic structural feature is a $(S_4P)_2TaS_2(S_4P)$-$TaS(S_2)Ta(PS_4)_2S_2Ta(PS_4)_2$ fragment with a $Ta_4S_5(S_2)$ core, which is shown in Fig. 1(*b*). The central Ta_2S_{11} unit is located on a crystallographic mirror plane; it is derived from the distorted bicapped biprismatic M_2Q_{12} units encountered in the structures of group 5 thiophosphates by replacing a bridging S_2^{2-} disulfide group by a S^{2-} anion. This leads to a seven-fold coordination for the central Ta atoms. The S–S distance of the S_2^{2-} pair is 2.046(10) Å, whereas the remaining S···S separations span the range from *ca.* 3.2 to 3.8 Å and must be considered non-bonding. Similarly, the Ta···Ta distance of 3.386(1) Å within the Ta_2S_{11} units is outside the metal–metal bonding range. The Ta_2S_{11} groups are not tied to each other through their own edges as is observed for Nb_2PS_{10},[5] but are interconnected by two each of their surrounding sulfur atoms through phosphorus atoms which are located at the center of adjacent tetrahedral PS_4 units and octahedrally coordinated tantalum atoms which share the remaining four S atoms of their coordination sphere with two adjacent PS_4 groups. Thus, each Ta_2S_{11} unit is fused in a *cis*-orientation with two PS_4 and two TaS_6 groups and may be viewed as a four-fold connecting element of the Ta–P–S network. The PS_4 groups act as chelating ligands for two adjacent tantalum atoms and serve as linear spacer units. The TaS_6 groups in turn are linked with two PS_4 groups and one Ta_2S_{11} unit. Thus, they act as centers with threefold connectivity. Combining these three structure elements in a 1 : 3 : 2 ratio {as indicated by the formulation $Cs[Ta_2S_5(S_2)Ta_2(PS_4)_3]$} leads to a network with two different hollows; the larger one (smallest diameter *ca.* 7 Å) takes up the

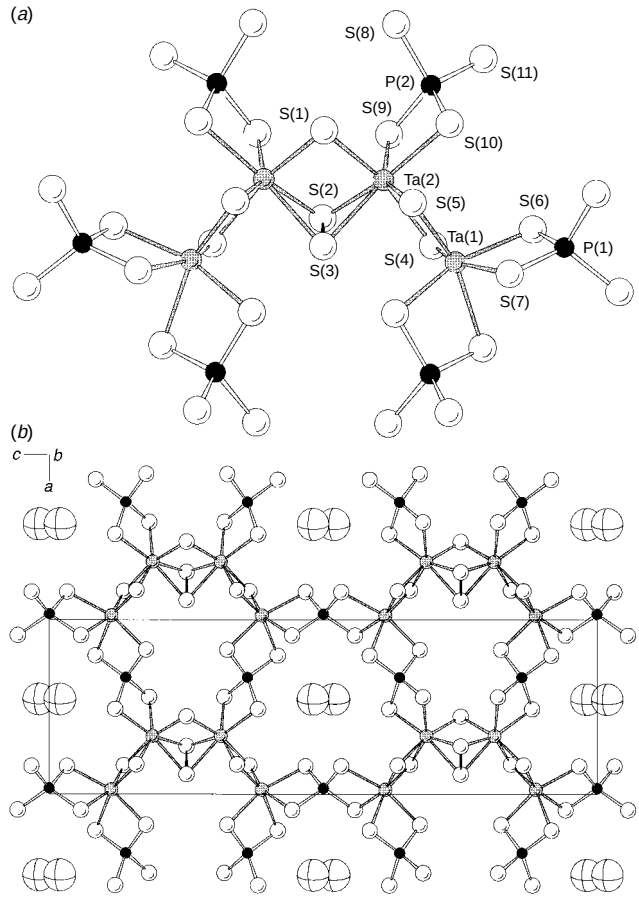

Fig. 1(*a*) Structure of the unit cell and a single $Ta_4P_4S_{19}$ layer (P, small black circles; Ta, large gray circles; S, large open circles) with Cs^+ cations above and below. (*b*) View of the central $(S_4P)_2TaS_2(S_4P)$-$TaS(S_2)Ta(PS_4)_2S_2Ta(PS_4)_2$ unit with atomic labeling scheme. Selected distances (Å): Ta(1)–Ta(2) 3.371(1), Ta(2)–Ta(2) 3.386(1), S(2)–S(3) 2.045(10), Ta(1)–S(4) 2.317(5), Ta(1)–S(5) 2.274(5), Ta(1)–S(6) 2.497(4), Ta(1)–S(7) 2.548(5), Ta(1)–S(8) 2.460(4), Ta(1)–S(11) 2.626(5), Ta(2)–S(1) 2.373(5), Ta(2)–S(3) 2.556(5), Ta(2)–S(4) 2.459(4), Ta(2)–S(5) 2.534(5), Ta(2)–S(9) 2.474(5), Ta(2)–S(10) 2.495(4), P(1)–S(7) 2.020(6), P(1)–S(6) 2.034(6), P(2)–S(11) 2.014(6), P(2)–S(10) 2.053(7), P(2)–S(8) 2.044(7), P(2)–S(9) 2.023(7).

Cs^+ cations whereas the smaller one (smallest diameter *ca.* 3 Å) remains empty.

The most significant structural feature of $CsTa_4P_3S_{19}$ that makes it unique compared to the known ternary group 5 thiophosphates is that the familiar bonding mode of a M_2Q_{11} or M_2Q_{12} cluster which is linked through its four outer coordination sites to four neighboring PS_4 groups is not observed and an additional structural motif, the TaS_6 group, is found instead. This may be caused by the size requirements of the counter cations which are located between layers or in channels of the anion framework. Since the TaS_6 fragment has a connectivity of three in these network structures, a more versatile structural chemistry may be envisaged.

The electronic structure of $CsTa_4P_3S_{19}$ may be approached in a zeroth order approximation by assigning formal charges according to $[Cs^+][(Ta^{5+})_4(S^{2-})_5(S_2^{2-})(PS_4^{3-})_3]$; the oxidation state of 5+ has been observed in other thiophosphates such as $Ta_4P_4S_{29}$;[6] this is in harmony with the observed non-bonding Ta···Ta distances; thus diamagnetic and semiconducting behavior are expected. Consequently, the optical spectrum of $CsTa_4P_3S_{19}$ (diffuse reflectance measurement) exhibits a sharp optical gap which is consistent with semiconducting behavior. The experimentally determined value is E_g = 1.65 eV.

From a synthetic point of view, $CsTa_4P_3S_{19}$ is the first group 5 compound that has been synthesized from a reactive chalcogenophosphate flux system.[11] Finally, the alkali ion-filled tunnels in the two-dimensional structure of $CsTa_4P_3S_{19}$, the three-dimensional structure of $CsNb_2P_2S_{12}$,[9] in which Cs^+ cations replace an isolated S_{10} ring from the $Ta_4P_4S_{29}$ structure,[6] as well as the observed ion conductivity in $LiTi_2(PS_4)_3$[12] suggest the possibility of ion exchange reactions.

A novel test system for *in situ* catalytic and electrochemical measurements on fuel processing anodes in working solid oxide fuel cells

Caine M. Finnerty, Robert H. Cunningham, Kevin Kendall and R. Mark Ormerod*†

Birchall Centre for Inorganic Chemistry and Materials Science, Department of Chemistry, Keele University, Keele, Staffordshire, UK ST5 5BG

A novel test system based around an extruded solid electrolyte tube enables the study of both the catalytic chemistry of fuel processing anodes in working solid oxide fuel cells and the electrochemical performance of the cell under the same conditions, allowing a direct correlation to be made between the fuel cell performance and the reforming characteristics of the anode.

Fuel cells are currently attracting a great deal of interest because they offer the possibility of more efficient and cleaner power generation. Solid oxide fuel cells (SOFCs) offer potential advantages over other fuel cell types because the high operating temperatures allow the possibility of running the cell directly on natural gas and other hydrocarbon fuels, internally reforming the fuel.[1–3] When a natural gas/steam mixture is passed over an SOFC anode at operating temperature, steam reforming (2) occurs, in addition to the methane decomposition (1) which results in carbon deposition. The CO produced by steam reforming may then undergo further reaction *via* the Water Gas shift reaction (3) and the Boudouard reaction (4).

$$CH_4 \rightarrow C_{(ads)} + 2H_2 \quad (1)$$

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad (2)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (3)$$

$$2CO \rightarrow C_{(ads)} + CO_2 \quad (4)$$

The CO and H_2 produced at the anode *via* internal reforming can then react with the oxygen ions [reactions (5) and (6)] that are formed at the cathode [reaction (7)] and pass through the solid electrolyte to the anode.

Anode cell reactions

$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \quad (5)$$

$$CO + O^{2-} \rightarrow CO_2 + 2e^- \quad (6)$$

Cathode cell reactions

$$O_2 + 4e^- \rightarrow 2O^{2-} \quad (7)$$

However, several major problems of internal reforming remain to be solved, including the problem of carbon deposition on the anode and its subsequent deactivation which leads to poor durability,[3] obtaining the optimum anode formulation and the design of a suitable test system. Consequently, many SOFC studies use hydrogen as a fuel, and there is a lack of studies using hydrocarbons, whilst other studies have focused on important aspects of materials development.

In terms of obtaining the optimum anode formulation and cell operating conditions, one of the key problems is the design of a suitable test system to study the catalytic chemistry occurring at the anode and to evaluate the cell performance. The design and construction of such a system is not straightforward. In particular the problems of rapid heating of the cell to operating temperature, thermal cycling, sealing, obtaining gas tight connections and being able to make both electrochemical and gas analysis measurements all have to be overcome; a particular difficulty with planar-type devices.

Nickel/zirconia cermet anodes can be considered to be somewhat analogous to supported nickel steam reforming catalysts, which have been studied extensively.[4–6] It is therefore possible to study the catalytic behaviour of nickel-based anodes in powder form inside a conventional catalytic reactor; this approach has been demonstrated by several research groups.[2,7] In many other studies the primary focus is the electrochemical performance of the cell, and the influence of electrode composition or structure and other experimental parameters are monitored by measuring current or power densities.[8–10] There are a lack of studies in which the catalytic chemistry of the fuel reforming anode is studied when the anode is part of an actual SOFC.

Here, we report the development of a test system based on a small diameter, thin-walled extruded yttria-stabilised zirconia tubular reactor which can be used to study the catalytic activity of the fuel reforming anode, the chemistry occurring at the anode surface and the electrochemical performance of the fuel cell. This allows a direct correlation between the cell performance and the reforming characteristics of the anode. In addition the test cell can be readily used to study the problems of carbon deposition and poor durability in operation. The particular benefits of this test cell are that it can be rapidly assembled, heated and cooled, and it has no sealing or leakage problems, which many test devices suffer from. The zirconia reactor is housed in a furnace operated by a temperature controller which allows linear control up to 1373 K. As yttria-stabilised zirconia is a good thermal insulator, the ends of the electrolyte tube which project beyond the outer walls of the furnace remain sufficiently cool for a gas tight seal to be made, even when the furnace is at 1373 K. The test cell inlet is linked to a stainless-steel gas manifold which allows complete flexibility in the choice of fuel and fuel/steam ratio. The gas feed can be instantly switched between H_2, O_2, inert gas and fuel and gas mixtures of any combination can be achieved, enabling evaluation over a wide range of operating conditions and fuel compositions. The reactor outlet is linked to an on-line mass spectrometer which permits the fuel processing reactions at the anode to be directly studied in the actual SOFC under operating conditions, and allows the chemistry occurring at the anode surface to be investigated using temperature programmed measurements.

The anodes were prepared from a slurry of nickel oxide and 8 mol% yttria-stabilised zirconia which was milled for 3 h, with a small quantity of binding agent added at the end of the milling period. The anode can then be studied as a powder in a conventional reactor following firing. However, in this case the anode slurry is applied to the inside of the electrolyte tube prior to firing as in an actual SOFC. Following drying, the coated zirconia tubes were fired to 1573 K. Strontium-doped lanthanum manganite was used as the cathode. Nickel wire was used for current collection from the anode and silver wire from the cathode. A specially designed potentiostat was used for the electrochemical measurements. Following firing the anodes were reduced in the reactor at 1173 K for 30 min in H_2. Reforming reactions were carried out by passing the fuel mixture over the reduced anode at reaction temperature.

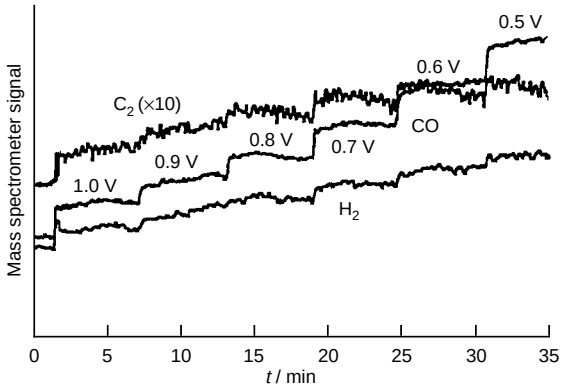

Fig. 1 The effect of drawing current on the reforming activity of a tubular SOFC with a nickel/zirconia anode running on a 19 : 1 methane–steam mixture at 1123 K

Thus the system allows the catalytic performance of the fuel reforming anode of an SOFC to be continuously monitored and can be used to study the reforming characteristics of different anode formulations over the full range of fuel cell operating conditions of temperature, gas flow rate and fuel composition. Importantly the anode is tested in an identical form and under the same conditions as in a working SOFC. The continuous real-time sampling of the on-line mass spectrometer enables any transient phenomena to be observed; such phenomena cannot be detected using a gas chromatograph. In combination with the linear temperature controller this also permits temperature programmed measurements to be carried out on the cells; temperature programmed reduction (TPR), oxidation (TPO) and reaction spectroscopy (TPRS). These have been used to study the firing and reduction characteristics (TPR, TPO), methane activation, methane steam reforming and the reaction pathways occurring at the anode surface (TPRS) and the nature and extent of carbon deposition following reforming (TPO). The detailed interpretation of these results will be reported elsewhere.[11] The same system and identical experimental arrangement can be used to carry out electrochemical measurements on the same cell, allowing a direct correlation to be made between the reforming characteristics of the anode and the fuel cell performance.

Furthermore, the system allows the chemistry occurring at the fuel reforming anode and the electrochemical performance of the SOFC to be simultaneously monitored under actual operating conditions. Fig. 1 shows the effect of drawing current from an SOFC with a nickel/zirconia anode, operating at 1123 K in a 19 : 1 methane–steam mixture, on the reforming reaction. It can clearly be seen that as the current drawn increases, *i.e.* as the cell potential decreases, there is increased methane conversion, stepwise increased production of hydrogen, and significantly increased formation of CO and C_2 species which parallel the increase in H_2 formation. Table 1 shows the corresponding cell performance. This demonstrates that we can directly correlate changes in the catalytic behaviour of the anode with the fuel cell performance.

Table 1 Electrochemical performance of a tubular SOFC running on a 19 : 1 methane/steam mixture at 1123 K

Cell potential/V	Current density/ mA cm^{-2}
1.0	93
0.9	117
0.8	146
0.7	160
0.6	197
0.5	232

In summary, we have developed an SOFC test system, based on an extruded zirconia tubular reactor, which can be used to investigate the catalytic behaviour of the fuel reforming anode, the anode surface chemistry and the electrochemical performance of the fuel cell, under genuine operating conditions. Catalytic measurements can be made on a working SOFC. Temperature programmed measurements can be carried out on anodes in an actual SOFC, and have been used to characterise different anode formulations, to study methane activation and reforming, and to evaluate the nature and level of carbon deposition on the anode during operation.

We thank the EPSRC for support under grant GR/K58647 and the award of a studentship to C. M. F.

Cleavage of an aryl–CF_3 C–C bond with a transition metal in solution

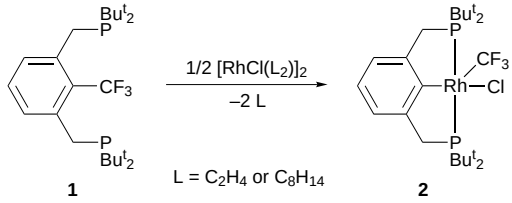
Milko E. van der Boom, Yehoshoa Ben-David and David Milstein*†

The Weizmann Institute of Science, Department of Organic Chemistry, Rehovot 76100, Israel

Unprecedented oxidative addition of a strong, unstrained Ar–CF_3 bond to a metal complex in solution yields the new aryl–Rh^{III}–CF_3 complex 2.

Activation of strong C–C and C–F bonds by soluble metal complexes are topics of much current interest.[1–5] Recently, we reported homogeneous cleavage of a strong C–C bond and catalytic C–F activation by transition metal complexes.[2,5] Here we report the first metal insertion into an unstrained C–C single bond of a fluorocarbon in solution. The Ar–CF_3 bond cleaved is among the strongest known C–C bonds.

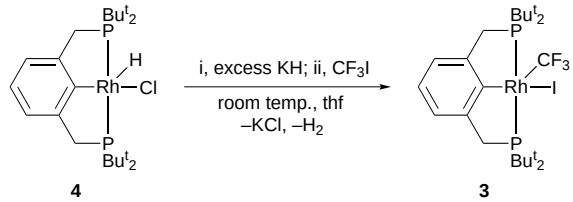
The new phosphine $C_6H_3CF_3$-1-$(CH_2PBu^t)_2$-2,6 **1** was prepared from 2-bromo-*m*-xylene by trifluoromethylation,[6] bromination and phosphination with $HPBu^t_2$.[7a] Compound **1** was obtained as a white powder and fully characterized by various NMR techniques and MS.‡ Reaction of $[RhCl(L)_2]_2$ (L = C_2H_4 or C_8H_{14}) with 2 equiv. of **1** (0.040 mmol) in a dioxane or toluene solution (10 ml) at 180 °C for 9 h in a sealed vessel affords exclusively the new rhodium complex $[Rh(CF_3)Cl\{C_6H_3(CH_2PBu^t)_2$-2,6$\}]$ **2**,§ which was characterized by ^1H, $^{31}P\{^1H\}$, $^{19}F\{^1H\}$ NMR and FDMS (Scheme 1).‡ The reaction can be run at lower temperatures when an excess of **1** is used, leading to quantitative formation of **2** after heating at 120 °C overnight. No other complexes were found. It is noteworthy that the cleaved bond is among the strongest C–C bonds known (compare BDE: Ph–CF_3 = 108.9 kcal mol^{-1}).[8a,b]



Scheme 1

In order to confirm the identity of complex **2**, we prepared the iodide analog $[Rh(CF_3)I\{C_6H_3(CH_2PBu^t)_2$-2,6$\}]$ **3** by dehydrochlorination of the known rhodium complex $[Rh(H)Cl\{C_6H_3(CH_2PBu^t)$-2,6$\}]$[7] (**4**; 0.080 mmol) with excess KH (40 equiv.) in THF (5 ml) followed by oxidative addition of CF_3I (5 psi) in a pressure vessel at room temperature (Scheme 2).¶

Complexes **2** and **3** exhibit similar spectroscopic properties.‡ The $^{31}P\{^1H\}$ NMR spectrum of **2** displayed a doublet of quartets at δ 62.6 ($^1J_{RhP}$ 116.7 Hz, $^3J_{PF}$ 16.3 Hz) for the two magnetically equivalent phosphorus nuclei which are coupled to rhodium and to three fluoride nuclei. The Rh–CF_3 moiety is clearly observed by $^{19}F\{^1H\}$ NMR as a doublet of triplets at δ 9.0 ($^2J_{RhF}$ 21.3 Hz, $^3J_{PF}$ 16.5 Hz). The ^1H NMR shows two 1 : 2 :1 triplets for the inequivalent Bu^t groups at δ 1.42 and 1.05 ($^3J_{PH}$ 7.0, 6.0 Hz), respectively, which collapse to singlets upon phosphorus decoupling. The four benzylic protons (CH_2P) appear as a typical AB pattern at δ 3.10 (ΔABq = 138 Hz, $^2J_{HH}$ 17.0, $^2J_{PH}$ 4.4 Hz), confirming the C_1 symmetry. The FDMS spectrum shows the M^+ (600) and a correct isotope pattern. Recently, two isostructural pentacoordinated rhodium-methyl complexes have been fully characterized by X-ray analysis.[2f,g]

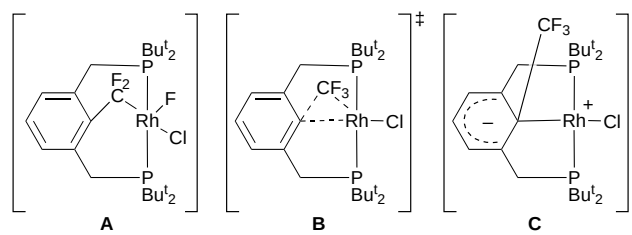


Scheme 2

Mechanistically, coordination of **1** to the metal centre is likely to precede the C–C bond activation step (Scheme 1). Coordination of both phosphine arms to the metal centre was postulated for the Me (instead of CF_3) analog of **1** with rhodium and iridium and was observed for similar substrates with platinum and ruthenium.[2,9] Performing the reaction at room temperature results in the formation of oligomers as indicated by NMR spectroscopy, which probably collapse to monomeric species upon heating. Formation of the oligomeric species is retarded when excess of **1** is used, enabling the C–C activation reaction at lower temperatures.

Interestingly, the expected product of $ArCF_2$–F bond cleavage **A** was not observed during the reactions, indicating a significantly lower activation barrier of the C–C *vs.* C–F oxidative addition. While the C–F bond is slightly stronger than C–CF_3 (BDE: $PhCF_2$–F = 112 kcal mol^{-1}),[8c] three C–F bonds are accessible for activation *vs.* one C–C bond. The formation of two strong aryl– and fluoroalkyl–M σ bonds and two five-membered rings at the expense of an unstrained sp^2–sp^3 C–C bond provides a substantial thermodynamic driving force for the oxidative addition process. There is an increased thermodynamic stability of M–C σ bonds with increasing fluorination of the alkyl group.[10]

This unique bond activation process may proceed *via* a concerted three-centered transition state **B** as recently elucidated for oxidative addition of rhodium and iridium to an Ar–CH_3 bond,[2f] which can be thermodynamically and even kinetically more favorable than the competing C–H activation process. However, the strongly electron withdrawing nature of the CF_3 group may make a nucleophilic attack on the arene by the electron-rich metal centre possible. Formation of an intermediate hexadienyl anion **C** followed by a 1,2-migration of the trifluoroalkyl group would give complex **2**. Further studies are required in order to clarify the mechanism of this unique oxidative addition process.



In conclusion, an unprecedented activation of a strong C–C single bond of a fluorinated organic substrate was achieved using a soluble transition metal complex. No $ArCF_2$–F bond cleavage was observed in parallel to the Ar–CF_3 oxidative addition process, although low-valent metal complexes are capable of activating C–F bonds,[3–5] indicating that nucleophilic rhodium complexes might be designed to selectively activate C–C bonds of fluorocarbons.

^{1}H NMR study of the hydrolysis of *N*-acylhydroxy[^{2}H]methylpyrroles

Andrew D. Abell,*† J. Christopher Litten‡ and Brent K. Nabbs

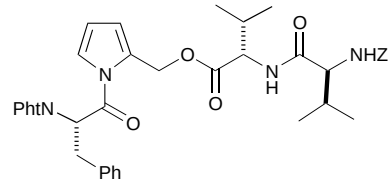
Department of Chemistry, University of Canterbury, Christchurch, New Zealand

KOH catalysed hydrolysis of the (*S*)- and (*R*)-*N*-(*N*-phthalylleucinyl)hydroxy[^{2}H]methylpyrroles 6b and 6c, in CD_3CN containing 1 equiv. of (+)-*sec*-butylamine, proceeds by an initial *N*- to *O*-acyl transfer with retention of configuration at the labelled centre, followed by trapping of an azafulvene to give (*S*)- and (*R*)-*sec*-butylamino[^{2}H]methylpyrroles 9b.

An electron-withdrawing group (EWG) on the nitrogen of a pyrrole of the type **5** is thought to suppress the formation of a highly electrophilic azafulvenium species **4** in nucleophilic substitution reactions (Scheme 1). In the absence of such deactivation, the analogous pyrroles **1** readily react with a nucleophile, *via* the postulated azafulvene intermediate **2**, to give products of the type **3a**.[1,2] Such a sequence is thought to be involved in the biosynthesis of uroporphyrinogen III, an important intermediate in the biosynthesis of vitamin B_{12} and related pigments.[3]

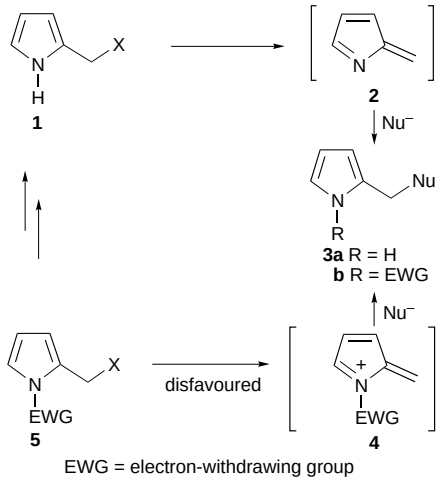
Pyrroles substituted with an EWG are found in natural products,[4] and they are also useful intermediates in organic synthesis[2,5] (*e.g.* in the synthesis deuterium-labelled porphobilinogen[2,6]—an important probe for studying the biosynthesis of vitamin B_{12}). The idea of suppressing azafulvene formation, with the introduction of an EWG on nitrogen, has also been used to develop latent reactive inhibitors of serine proteases.[7] Here, a hydroxymethylpyrrole derivative such as **6a** (a peptidic example of the general compound **5**) is stabilised by *N*-acylation with an amino acid—chosen to be recognised by the target enzyme. Enzyme catalysed deacylation yields a reactive azafulvene **2** which is then thought to lead to covalent inactivation of the enzyme by alkylation (see Scheme 1 where Nu^- is an amino acid in the enzyme's active site).

Removal of an EWG from a pyrrole nitrogen, by chemical or enzymatic hydrolysis, represents a key step in all the above applications of compounds of the type **5**. Here we report the stereochemical fate of the deuterium label of (*S*)- and (*R*)-*N*-(*N*-phthalylleucinyl)hydroxy[^{2}H]methylpyrroles **6b** and **6c** upon KOH catalysed hydrolysis in the presence of an external nucleophile [(+)-*sec*-butylamine]. This study provides evidence for (i) an intramolecular acyl transfer to give an *O*-acylpyrrole **8** [pathway (*a*), Scheme 2] as an intermediate in the deacylation sequence, and (ii) the facile formation of an azafulvene **2** on deacylation as evidenced by its trapping with an external nucleophile to give equal amounts of the (*S*)- and (*R*)-amino[^{2}H]methylpyrroles **9**. This sequence also serves to model the proposed mechanism of action of **6a** as a latent reactive inhibitor of serine proteases—the KOH mimics the protease catalysed deacylation and the external nucleophile mimics the final inactivation step. It should also be noted that the *O*-acyl intermediate **8** bears a strong resemblence to **10** which is also an inhibitor of serine proteases.[7]

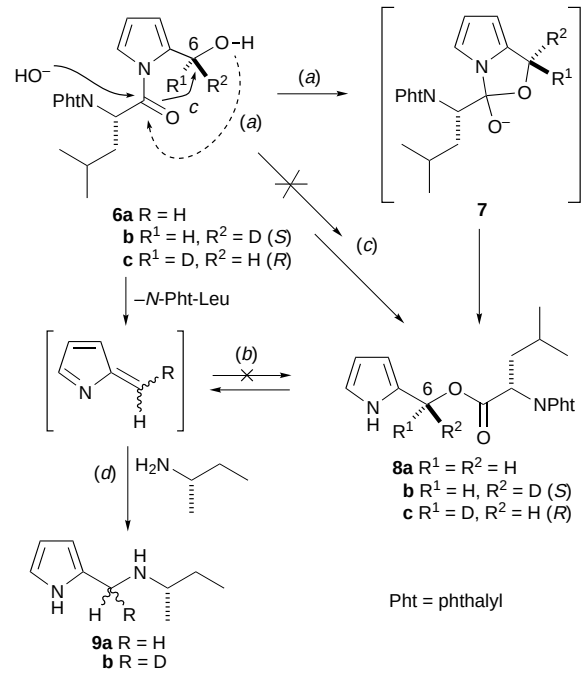


10

The key deuterium labelled hydroxymethylpyroles **6b** and **6c** were prepared from pyrrole-2-[^{2}H]carbaldehyde[2] by acylation with *N*-phthalylleucine acid fluoride according to the literature method,[8] followed by reduction with *R*- and *S*- Alpine-borane®, respectively.[2] The unlabelled analogue **6a** was similarly prepared by acylation of pyrrole-2-carbaldehyde followed by $Zn(BH_4)_2$ reduction of the formyl group. The epimeric purity at the deuterated centres of **6b** and **6c** was determined to be $> 9:1$ (see first column, Table 1) by integration of the pyrrole–CHD



Scheme 1



Scheme 2

Table 1 ^{1}H NMR resonances§ [CD_3CN, $CHCl_3$ internal standard (δ 7.25)] for the pyrrolemethylene group of **6** and the hydrolysis products **8** and **9** [KOH and (*S*)-(+)-*sec*-butylamine added]. In the spectra of **6a**–**c**, coupling of the signals with the OH proton were removed by homonuclear decoupling

	6a	**8a**	**9a**
	6c : **6b**	**8b** : **8c**	**9b**

singlet resonances at δ 4.21 and 4.24 respectively. The assigned configurations were consistent with related examples in which the absolute configuration has been determined by chemical conversion to the *O*-camphanate of [2-^{2}H] glycolic acid, a known literature reference compound.[2]

The mechanism of hydrolysis of compounds **6** was then studied.[7] In a typical experiment, an equivalent of KOH in D_2O (approx 10 μl) was added to a solution of either **6a**,**b** or **c** (3 mg) in CD_3CN (150 μl) containing $CHCl_3$ as an internal standard, and 1 equiv. of (+)-*sec*-butylamine (external nucleophile). The ratio of **6**, **8** and **9** was then monitored by ^{1}H NMR spectroscopy (the *exo*-methylene proton resonances of these compounds are shown in Table 1). The spectum taken immediately after mixing contained starting material **6**, *O*-acyl intermediate **8** and pyrrole amine **9** in a typical ratio of 1 : 1 : 1. ^{1}H NMR spectra of the mixtures after 18 h revealed that **6** and **8** had been completely converted to the pyrrole amine **9**.

The key points to note from the results shown in Table 1 are that the configurational purity (> 9 : 1) and absolute configurations§ of the starting materials **6b** and **c** are retained in the corresponding *O*- acyl intermediates **8b** and **c** (rows 2 and 3, Table 1). In theory, the formation of the *O*-acylpyrrole **8** could occur by either an intramolecular acyl transfer *via* the tetrahedral intermediate **7** [Scheme 2, pathway (*a*), retention of configuration], trapping of the azafulvene **2** with released *N*-phthalylleucine [Scheme 2, pathway (*b*), epimerisation at the methylene] or by an S_N2 like displacement [Scheme 2, pathway (*c*), inversion of configuration). The fact that the configurational purity at the [^{2}H]methylene centre of **8b** and **c** is intact, and also did not change with time, implies that these species are not in equlibrium with the azafulvene **2b**, hence pathway (*b*) is not operating. In addition, an S_N2 displacement at the methylene position of a hydroxymethylpyrrole has only been reported in extreme examples using a combination of Mitsunobu reaction conditions and an *N*-triflyl substituent to strongly deactivate the pyrrole ring and hence suppress azafulvene formation.[2] An *N*-acyl group is not sufficiently deactivating to promote S_N2 like displacement,[2] and hence a reaction of the type shown in pathway (*c*) is chemically unlikely under the conditions of the hydrolysis experiment. Pathway (*a*) is, however, consistent with both the literature and the observed results, *i.e*. the formation of **8** occurs with retention of configuration at the deuterated methylene centre. A second point to note is that equal mixtures of the (*S*) and (*R*) deuterium-labelled amines **9b** were produced as the end product in the reactions of **6b** and **c**, a result clearly consistent with the intermediacy of the azafulvene **2** [Scheme 2, pathway (*d*)]. Finally, as expected, the two oppositely labelled series **6b** and **c** gave complimentary results (rows 2 and 3, Table 1).

In summary, the above observations suggest that the *O*-acylpyrrole **8** is most likely formed *via* an intramolecular acyl transfer on hydrolysis of the *N*-(*N*-phthalylleucinyl)hydroxymethylpyrroles **6**. Evidence for the subsequent release of an azafulvene **2** is gained from the observed scrambling of the deuterium label at the [^{2}H]methylene position of **9** on trapping with (+)-*sec*-butylamine. Ongoing work is centred on the further development of these compounds as useful synthetic intermediates and inhibitors of serine proteases.

§ In the case of *N*-acylhydroxy[^{2}H]methylpyrroles, the methylene resonance is upfield for the (*S*)-isomer (*e.g.* **6b**) relative to the (*R*)-isomer (*e.g.* **6c**). This observation is reversed for *O*-acylpyrroles (*e.g.* **8b** and **8c**) (see ref. 2).

Structural dependence of the reagent Ph_3PCl_2 on the nature of the solvent, both in the solid state and in solution; X-ray crystal structure of trigonal bipyramidal Ph_3PCl_2, the first structurally characterised five-coordinate R_3PCl_2 compound

Stephen M. Godfrey,† Charles A. McAuliffe, Robin G. Pritchard and Joanne M. Sheffield

Department of Chemistry, University of Manchester Institute of Science and Technology, Manchester, UK M60 1QD

The very delicate structural balance of Ph_3PCl_2 when prepared in diethyl ether solution is illustrated by its X-ray crystallographic study; unlike the ionic species, $[Ph_3PCl^+\cdots Cl^-\cdots{}^+ClPPh_3]Cl$, which prevails in dichloromethane solution, the non-solvated molecular species Ph_3PCl_2 is formed in diethyl ether which is the first example of a trigonal bipyramidal R_3PCl_2 compound to be structurally characterised, and this may have an effect on the chlorinating ability of the reagent.

Although there are a number of previous reports concerning compounds of stoichiometry R_3PCl_2, which are mainly focused on Ph_3PCl_2, they are predominantly concerned with the nature of such species in solution, using ^{31}P NMR spectroscopy.[1–9] All such studies, performed in acetonitrile or dichloromethane solution, concluded that the compounds are ionic, $[R_3PCl]Cl$. Similarly, conductivity studies of Ph_3PCl_2 in acetonitrile solution led Harris and coworkers[10,11] to conclude that the compound is ionic, $[Ph_3PCl]Cl$, since values close to those expected for a 1:1 electrolyte were recorded. However, Arzoumandis[13] investigated the structural nature of Ph_3PCl_2 in haloform solvents and concluded, from cryostatic and vibrational spectroscopic studies, that 1:1 $Ph_3PCl_2{\cdot}YCX_3$ (Y = H, D; X = Cl, Br) adducts were formed. It was reasoned that these species were molecular dimeric entities which contain six-coordinate phosphorus atoms.

Studies concerning the solid-state structure of R_3PCl_2 compounds are rare, and studies concerning R_3PCl_2 (R = Me, Ph) again concluded an ionic structure, $[R_3PCl]Cl$.[13–15]

There is renewed interest in the structural nature of compounds of stoichiometry, R_3EX_2 (E = P, As, Sb). We have established the solid-state molecular charge transfer 'spoke' structure for Ph_3PX_2, *viz*. $Ph_3P–X–X$, (X_2 = Br_2,[16] I_2,[17–19] IBr[20]), whereas other workers have shown that Ph_3PF_2 is trigonal bipyramidal[21,22] A Raman spectroscopic study[23] of Ph_3PCl_2 prepared in toluene solution suggested that two structural modifications could exist, an ionic form, $[Ph_3PCl]Cl$, prepared by bubbling dichlorine gas through a toluene solution of PPh_3 and, possibly, a trigonal bipyramidal form, prepared by passing a stream of dichlorine over the surface of a toluene solution of PPh_3.

Until very recently, no single crystal X-ray crystallographic data was available for any compound of stoichiometry R_3PCl_2. However, a crystallographic study[24] of the compound prepared from the reaction of PPh_3 and dichlorine in dichloromethane solution revealed an unusual dinuclear ionic compound, $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl{\cdot}CH_2Cl_2$. The long Cl···Cl contacts are 3.279(6) Å (van der Waals radius for dichlorine is 3.6 Å). The solution $^{31}P\{H\}$ NMR of this species, recorded in $CDCl_3$ and CD_3CN gave single resonances at δ 65.5 and 66.5, respectively, these values being very similar to the values quoted by previous workers and indicating that the simple ionic species $[Ph_3PCl]Cl$ prevails in solution for these solvents, and the long range Cl···Cl contacts are broken, as expected.

It therefore occurred to us that a different structural modification of Ph_3PCl_2 could be exhibited in solvents of low relative permittivity (low polarity). One reason for this was the fact that $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl{\cdot}2CH_2Cl_2$ contains a dichloromethane solvent molecule in the structure,[24] suggesting non-innocent behaviour, and although no bonding interactions between the solvent and the compound are observed, there nevertheless remains the fact that δ^+ hydrogens on the dichloromethane point towards the Cl^- ions giving a suspicion of long range electrostatic interaction, and, therefore, an implied influence on the structure adopted. Considering the widespread use of Ph_3PCl_2 as a chlorinating agent, the structural nature of the reagent is of great importance since the structure may influence its efficacy as a chlorinating agent and, possibly, the mechanism of chlorination. Consequently, the choice of solvent employed for a given chlorination reaction utilising Ph_3PCl_2 may be of fundamental importance.

Triphenylphosphine dichloride was prepared by us from the direct reaction of triphenylphosphine with dichlorine in diethyl ether in a 1:1 stoichiometric ratio [eqn. (1)].

$$PPh_3 + Cl_2 \xrightarrow[N_2, Et_2O]{\text{room temp.}} Ph_3PCl_2 \qquad (1)$$

The resultant white powder, which formed almost immediately upon addition of the dichlorine, was recrystallised from diethyl ether solution to produce a large quantity of colourless crystals on standing at room temperature for *ca*. 1 week. The melting point of the crystals was determined to be 118–119 °C {*cf*. 160–161 °C for $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl{\cdot}2CH_2Cl_2$}. A crystal was chosen for analysis by single crystal X-ray diffraction. Interestingly, the structure‡ of Ph_3PCl_2 is shown to be the sole example of a molecular trigonal bipyramidal R_3PCl_2 compound, Fig. 1, and not the ionic structure, $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl{\cdot}2CH_2Cl_2$ which prevails in dichloromethane solution. This result is important for two reasons: firstly, the very delicate balance between ionic and covalent forms for Ph_3PCl_2 is clearly illustrated, in the more polar CH_2Cl_2 an ionic structure is adopted whereas in diethyl ether a molecular form is revealed. Secondly, the acute solvent dependency of the structure of this reagent is clearly shown, and other workers utilising the reagent for chlorination reactions may find different rates and/or products which are dependent solely on the polarity of the solvent chosen. The structure of Ph_3PCl_2 contains two crystallographically independent molecules in the asymmetric unit which exhibit quite different P–Cl bond lengths. In one molecule, *d*(P–Cl) are quite similar, being 2.252(2) and 2.262(2) Å, however differences are observed in the other, 2.280(2) and 2.225(1) Å. Both molecules also exhibit slight distortions from regular trigonal bipyramidal geometry. These distortions and the asymmetry of the *d*(P–Cl) may arise from the ease of ionisation of the molecule. However, asymmetric bonds in multiple halide systems are not un-

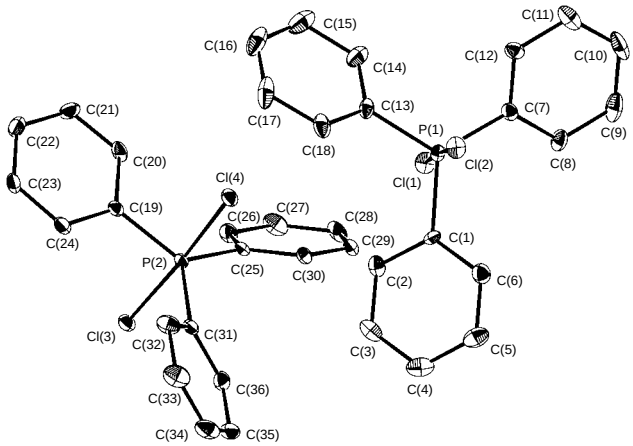

Fig. 1 X-Ray crystal structure of trigonal bipyramidal Ph_3PCl_2 (two crystallographically independent molecules are present in the asymmetric unit). Selected bond lengths (Å) and angles (°): P(1)–Cl(1) 2.280(2), P(1)–Cl(2) 2.225(1), P(2)–Cl(3) 2.262(2), P(2)–Cl(4) 2.252(2), C(7)–P(1)–C(1) 123.5(2), C(7)–P(1)–C(13) 118.2(2), C(1)–P(1)–C(13) 118.2(2) Cl(2)1–P(1)–Cl(1) 176.09(6), C(19)–C(25) 120.0(2), C(19)–P(1)–C(31) 123.6(2), C(25)–P(2)–C(31) 116.42, CI(4)–P(2)–Cl(3) 176.20(6).

common. The classic example is I_3^-, where asymmetric I–I bonds are ascribed to the influence of surrounding molecules or ions. Our recent work has shown even more dramatic examples of autosolvation in R_3PCl_2 systems.[25] In the case of Ph_3PCl_2 described here, comparison of the four Cl environments shows that the closest approaches between Cl and H in adjacent molecules are 2.92, 3.05, 2.83 and 2.82 for Cl(1), Cl(2), Cl(3) and Cl(4), respectively. As P–Cl(4) is the shortest P–Cl bond, it would appear that phenyl rings are exerting their influence on *d*(P–Cl). We have previously observed this phenomenon with interaction of Cl with δ^+ hydrogens on propyl chains.[25] Caution must be exercised when discussing E–X (E = P, As, Sb, Bi; X = Br, Cl) bond lengths however, since considerable asymmetry has already been illustrated from crystallographic studies *e.g.* Ph_3BiCl_2[26] [*d*(Bi–Cl) 2.529–2.615 Å], $[Me_3CH\text{-}CH_2]_3AsBr_2$,[27] [*d*(As–Br) 2.530–2.596 Å], Ph_3SbCl_2 [*d*(Sb–Cl) 2.382–2.490 Å].[28]

The solution structure of Ph_3PCl_2 in low-polarity solvents is also of importance since the trigonal bipyramidal structure of Ph_3PCl_2 could simply be a solid-state phenomenon, *i.e.* the molecule could auto-ionise in any given solvent, which has already been illustrated[25] when Ph_3PCl_2 is dissolved in CH_2Cl_2. Deuterated ether, C_2D_6O is not really available; however, we dissolved a sample of crystalline Ph_3PCl_2 prepared in Et_2O in deuterated benzene, C_6D_6, *i.e.* a non-polar solvent. A single resonance was observed in the NMR spectrum at δ −47, very different to that observed for the ionic $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl\cdot CH_2Cl_2$ which exhibited resonances at δ 65.5 or 66.5 (recorded in CH_2Cl_2 and CH_3CN, respectively). This value of δ −47 is also completely different to any previously reported value for a sample of Ph_3PCl_2 which, prior to this work, has only been studied by $^{31}P\{H\}$ NMR spectroscopy in solvents of quite high polarity. This value of δ −47 is however comparable to analogous difluorophosphoranes, R_3PF_2, which are known to retain a molecular five-coordinate geometry in solution, *e.g.* $MePh_2PF_2$ (δ −43.2) and Ph_3PF_2 (δ −58.1).

The only $^{31}P\{H\}$ NMR study of a compound of stoichiometry R_3PCl_2,[27] which was claimed to be trigonal bipyramidal is $(C_6F_5)_3PCl_2$, which gave a single resonance at δ −110.[29]

Clearly, therefore, Ph_3PCl_2 retains a molecular trigonal bipyramidal structure in solvents of low polarity. Addition of CH_2Cl_2 to the C_6D_6 solution of Ph_3PCl_2 ionises the molecule to produce $[Ph_3PCl\cdots Cl\cdots ClPPh_3]Cl\cdot 2CH_2Cl_2$, since a resonance at δ 65.5 is observed and the former resonance at δ −47.0 disappears.

In conclusion, the solvent of preparation is critical in determining the structure of Ph_3PCl_2. A molecular form persists in solvents of low polarity which is converted into an ionic form in solvents of higher polarity. Which structure is adopted will almost certainly have an effect on the chlorinating ability of the reagent, and, possibly, the nature of any products formed.

We are grateful to the EPSRC for a research studentship (to J. M. S.).

Parahydrogen enhanced NMR studies on thermally and photochemically generated products from $[IrH_3(CO)(PPh_3)_2]$

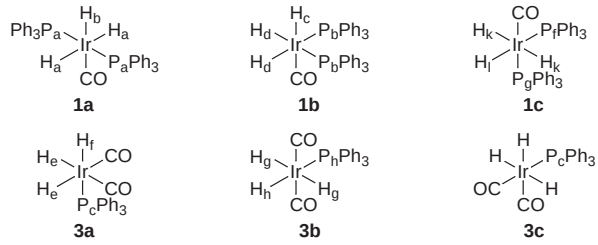
Sarah Hasnip,[a] Simon B. Duckett,*[a]† Diana R. Taylor[b] and Mike J. Taylor[b]

[a] *Department of Chemistry, University of York, Heslington, York, YO1 5DD*
[b] *BP Chemicals, BP Chemicals Limited, Saltend, Hull, UK HU12 8DS*

Parahydrogen induced polarisation is used to enable the rapid NMR characterisation of thermally and photochemically generated complexes of general formula $[IrH_3(CO)_{3-x}(PPh_3)_x]$ (x = 1–3).

It has been shown that parahydrogen (p-H_2) increases the size of detectable signals in NMR spectroscopy by enabling access to non-Boltzmann spin populations.[1,2] This phenomenon has facilitated the observation of materials found in low concentrations, such as intermediates in catalytic hydrogenation reactions, species in minor reaction pathways such as $[RhH_2(PPh_3)_2Cl_2Rh(PPh_3)(CO)]$ and minor constituents in equilibria, for example *all-cis*-$[Ru(PMe_3)_2(CO)_2(H)_2]$.[3]

The reaction chemistry presented here relates primarily to hydrogen exchange reactions of $[IrH_3(CO)(PPh_3)_2]$. This complex has been shown by Harrod and Yorke[4] to exist in solution in two isomeric forms, **1a** with *trans* phosphines and *mer*-hydrides and **1b** with *cis* phosphines and *fac*-hydrides (Scheme 1). We describe how the sensitivity gain provided by p-H_2 allows the rapid characterisation of these, and related trihydride complexes of iridium, and enables the examination of their thermal and photochemical reactivity. We use pulsed field gradient-assisted 2D homo- and hetero-nuclear NMR methods to monitor these reactions.



Scheme 1 Structural isomers of the trihydrides $[IrH_3(CO)(PPh_3)_2]$ and $[IrH_3(CO)_2(PPh_3)]$

When a 0.1 mM solution containing equal amounts of **1a** and **1b**, in [$^2H_6$]benzene under 3 atm of p-H_2, is monitored between 303 K and 343 K by ^1H NMR spectroscopy, enhanced resonances are detected in the hydride region of the spectrum. The $^1H\{^{31}P\}$ NMR spectrum shown in Fig. 1(*a*) was recorded at 343 K and shows two pairs of anti-phase multiplets that can be assigned to the hydride ligands of **1a** and **1b**.‡ These results confirm that the hydride ligands in **1a** and **1b** undergo exchange with free H_2. We note that under these conditions, even with the p-H_2 derived signal amplification, no resonances are detected that can be attributed to isomer **1c** (Scheme 1). The spectral features of the p-H_2 enhanced trihydrides, illustrated in Fig. 1, are surprising.[5] The two polarised hydride resonances at δ −9.29 and −10.02 are assigned to the hydride ligands H_a and H_b of **1a**, respectively.[4] In a regular $^1H\{^{31}P\}$ spectrum these signals would appear as doublets and triplets respectively with peak separation J_{HH}. The observed signals have relative intensities of 2 : 1 and their anti-phase line separation (4.4 and 8.8 Hz) indicates that the central feature of the triplet is no longer visible. This can be understood by examining the p-H_2 controlled populations of the eight spin wavefunctions of the trihydride (AX_2). While four wavefunctions are simple products of the form ααα, **αββ**, **βαα** and βββ, four belong to combinations of the form **α(αβ − βα)**, **α(αβ + βα)**, **β(αβ − βα)** and **β(αβ + βα)**. Exchange with p-H_2 (αβ − βα spin state) at **1a** involves the A and one X nucleus, with the result that the six product states indicated, **in bold**, become equally populated while the ααα and βββ states are unpopulated. Consequently, the only visible transitions for nucleus A, spin flips ααα↔**βαα** and **αββ**↔βββ, correspond to the outer lines of the triplet and are seen in emission and absorption. The emission–absorption phase profile reveals that J_{HH} is negative.[2] The central line, corresponding to spin flips **α(αβ − βα)**↔**β(αβ − βα)** and **α(αβ + βα)**↔**β(αβ + βα)**, vanishes because the associated levels have identical populations. In a similar way, examination of the symmetry allowed transitions for H_a (X_2) reveals that observable spin flips connect ααα↔α(αβ + βα), and β(αβ + βα)↔βββ. These transitions are separated by J_{AX} (J_{HH}) and are

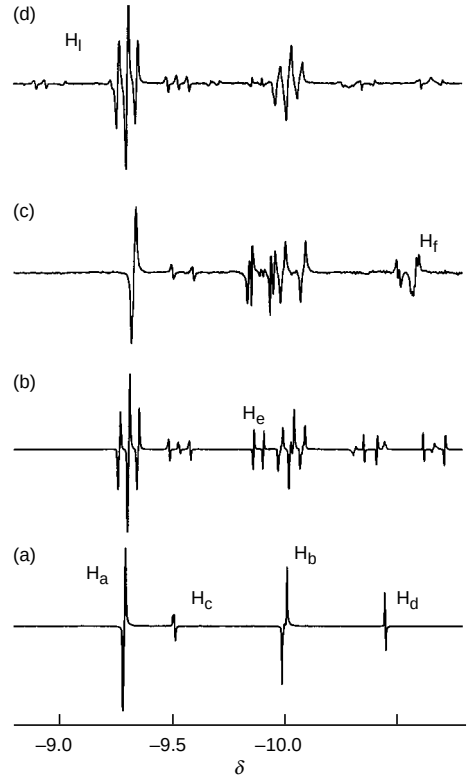


Fig. 1 NMR spectra (400 MHz) of $[IrH_3(CO)_{3-x}(PPh_3)_x]$ (x = 1–3) obtained with p-H_2 in C_6D_6 showing the hydride region only. The anti-phase components arise in transitions involving protons that originate from p-H_2. (*a*) $^1H\{^{31}P\}$ spectrum of **1a** and **1b** at 343 K; (*b*) ^1H spectrum of **1a** **1b** and **3a** generated *in situ* from $[IrH(CO)_2(PPh_3)_2]$; (*c*) $^1H\{^{31}P\}$ spectrum of a ^{13}CO labeled sample of **1a**, **1b** and **3a**; (*d*) $^1H\{^{31}P\}$ spectrum recorded at 313 K immediately after UV photolysis of a sample of **1a** and **1b**.

visible as emission and absorption signals, with twice the overall intensity seen for signal A (H_b).

Interestingly, isomer **1b** reveals a different pattern; the two hydride resonances at $\delta -9.53$ and -10.48, assigned to H_c and H_d respectively, appear as absorption and emission signals because J_{HH} is now positive. Because both hydride resonances are enhanced we can confirm that the dominant dihydrogen exchange pathway involves reductive elimination of H_cH_d rather than H_dH_d in **1b**. At 333 K the hydride resonance enhancements, 30-fold for **1a** and 5-fold for **1b**, are consistent with faster dihydrogen exchange at **1a**.

A modified heteronuclear multiple quantum correlation experiment (HMQC) using gradients and ^{31}P decoupling was used to measure the chemical shifts of the phosphorus nuclei of **1a** and **1b**.[6] In the two-dimensional map cross-peaks connect the hydrides to the corresponding phosphorus nuclei; P_a [$\delta(^{31}P)$ 18.0] connects to H_a and H_b whilst P_b [$\delta(^{31}P)$ 8.8] connects to H_c and H_d. Spectra recorded on this sample at 333 K using a ^{31}P decoupled gradient-assisted EXSY sequence (mixing time of 300 ms) contain cross-peaks that connect the two hydride resonances of **1a**. This indicates that the hydride ligands of **1a** are able to interchange identities *via* a process which is intramolecular with respect to the hydrides. This spectrum also contains nOe-derived cross-peaks that connect the hydrides to the *ortho*-phenyl protons of the phosphine ligand.[7] Under these conditions no cross-peaks connect the hydride resonances of **1a** to those of **1b**. However, with a mixing time of 500 ms cross-peaks connect the hydrides resonances of **1a** to free H_2.

When a frozen C_6D_6 solution of $[IrH(CO)_2(PPh_3)_2]$ **2**, under an atmosphere of *p*-H_2, is thawed and rapidly introduced into the NMR spectrometer for monitoring by ^1H spectroscopy at between 313 and 333 K, three hydride containing species are detectable [Fig. 1(*b*)]. Two of these species can be assigned to the previously described **1a** and **1b**, produced by CO loss from **2** and subsequent H_2 addition. The two new sets of anti-phase multiplets at $\delta -9.86$ and -10.54, are assigned to the hydride ligands H_e and H_f of the new product **3a** (Scheme 1) with $J_{HH} = -1.8$ Hz.‡ The H_e resonance of **3a** shows one additional *cis* phosphorus splitting [$J(P_cH)$ 17.24 Hz] while the resonance due to H_f shows a larger *trans* phosphorus splitting [$J(P_cH)$ 121.6 Hz]. Interestingly, if the sample is monitored after degassing and refilling with fresh *p*-H_2 then the observed resonances for **3a** are weaker than those seen initially. Repeating this process reduces their signal intensity still further, until eventually they are no longer visible.[8] The ^1H NMR spectrum of this sample, collected 48 h after filling the NMR tube with 50 Torr of ^{13}CO, revealed that $[IrH(^{13}CO)_2(PPh_3)_2]$ was formed, as evidence by the ^{13}C coupled hydride resonance at $\delta -10.3$ (J_{CH} 6.4 Hz). This sample was then refilled with *p*-H_2 and monitored by NMR spectroscopy as before. The fully carbon decoupled ^1H–^{13}C HMQC spectrum of this sample located a single carbonyl resonance for **3a**, while the corresponding ^1H–^{31}P spectrum reveals that the hydride resonance for H_e possesses additional ^{13}C couplings which are indicative of a planar $(H)_2Ir(^{13}CO)_2$ core [Fig. 1(*c*)]. These additional data indicate that **3a** has *fac*-hydrogen atoms (Scheme 1).[9] When a sample of the related complex $[IrH(CO)(PPh_3)_3]$ was examined with *p*-H_2 only **1a** and **1b** were detectable as *p*-H_2 enhanced products. These reactions are illustrated in Scheme 2.

$^1H\{^{31}P\}$ NMR spectra were obtained for C_6D_6 solutions under 3 atm of *p*-H_2 containing < 1 mg of $[IrH_3(CO)(PPh_3)_2]$, with normal and enriched levels of ^{13}CO, after 5 min UV irradiation.[10] These spectra contain enhanced hydride resonances for several new species in addition to those already described for **1a**, **1b** and **3a**. In order to characterise these new species gradient-assisted COSY{^{31}P} and HMQC experiments were recorded. Signals due to the remaining isomer of the bis-phosphine trihydride **1c** were assigned. Additional resonances assigned to the mono-triphenylphosphine complex **3b** are also present. For example, the hydride H_h at $\delta -9.08$ [J(HH) −4.6, J(PH) 136.4, J(PH) 17.6 Hz] seen in Fig. 1(*d*) connects with a hydride resonance at $\delta -10.10$ in the COSY spectrum and to two phosphorus nuclei [$\delta(^{31}P)$ 5.1 and 20.5] in the HMQC. These new isomers have short lifetimes with the result that after several minutes at 313 K the only species seen are **1a** and **1b**. They can be regenerated by repeating the photolysis step, however, when the sample is irradiated in the presence of benzaldehyde, a good CO source, resonances for **3a** are visible for much longer.

Here, we have shown that *p*-H_2 derived spectral amplification can be used to examine trihydride systems, and view species that are normally only readily visible under high pressures of H_2.[11] *In situ* ^{13}CO labelling of 1 mg samples proved to be a viable and cost-effective way of fully characterising the ligand sphere of these species. In addition, we have demonstrated that UV irradiation may be employed to generate normally unstable structural isomers for characterisation with *p*-H_2.[12]

Financial support from the EPSRC (Spectrometer and S. H.), BP Chemicals (CASE award S. H.), the Royal Society, NATO and Bruker Spectrospin, and discussions with Mr C. Sleigh, Professor R. Eisenberg, Professor R. N. Perutz and Dr R. J. Mawby are gratefully acknowledged.

Carbohydrates to carbocycles: an expedient synthesis of pseudo-sugars

A. V. R. L. Sudha and M. Nagarajan*†

[a] *School of Chemistry, University of Hyderabad, Hyderabad-500 046, India*

A short and versatile synthesis of pseudo-sugars from sugars utilizing the Claisen rearrangement as the key step is described.

Conversion of sugars into carbocycles is an area which has attracted considerable attention in recent times.[1] Some important methodologies for achieving this are (i) Ferrier's mercuric ion mediated conversion of 6-deoxyhex-5-enopyranosyl compounds to deoxyinososе derivatives,[2] (ii) the radical cyclization approach of RajanBabu[3] and (iii) the zirconium mediated ring contraction of carbohydrate derivates to carbocycles by Taguchi.[4]

Pseudo-sugars are 2,3,4,5-tetrahydroxy-1-(hydroxymethyl)cyclohexanes, in which the ring oxygen atom of a sugar has been replaced by a methylene group. Pseudo-D-glucose, pseudo-D-galactose and pseudo-D-fructose have been suggested as replacements for their sugar counterparts as non-nutritive sweeteners.[5] Amino pseudo-sugars, which form the aglycon part of many aminoglycoside antibiotics, have chemotherapeutic potential as glycosidase inhibitors.[6] Pseudo-sugars and some related carbocyclic compounds are components of some antibiotics (validamycins) and enzyme inhibitors (adiposins).[7]

The biological significance of pseudo-sugars has led to the development of several approaches for their synthesis in optically pure form from various chiral sources. A comprehensive review on pseudo-sugars has been published.[8] Pseudo-β-D-altro-, pseudo-α-L-manno- and pseudo-β-D-gluco-pyranoses have been synthesized by Hudlicky[9] from homochiral microbial metabolites. Vandewalle[10] prepared eight pseudo-sugars belonging to the allo, gulo, manno and talo series which possess 2,3-*cis*-diol units from (1*R*,2*S*,3*R*,4*S*)-4-butyryloxy-2,3-(propane-2,2-diyldioxy)cyclohex-5-en-1-ol. The synthetic versatility of quinic acid was demonstrated by Shing in his synthesis of pseudo-β-D-manno-,[11] pseudo-β-D-fructo-,[11] pseudo-α-D-gluco-[12] and pseudo-α-D-manno-pyranoses.[12] Ferrier prepared crystalline pseudo-α-D-glucopyranose[13] from 2-deoxyinososе.

It occurred to us (as shown in the retrosynthesis in Scheme 1), that controlled hydroxylation of cyclohexene **1** should lead to the four pseudo-sugars, pseudo-α-D-glucopyranose, pseudo-α-D-mannopyranose, pseudo-β-D-glucopyranose and pseudo-β-D-mannopyranose. The conversion of **2** to **1** involves transformation of a glycal derivative into a cyclohexene, prototypes of which have been reported earlier by Büchi.[14] Compound **1** in turn can be readily derived from D-glucose *via* **2** and **3**. We describe here the successful realization of this strategy.

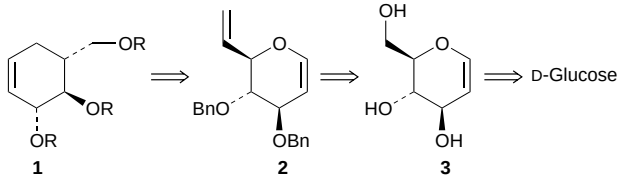
The primary hydroxy group in **4** was oxidized using pyridinium dichromate (PDC) to the aldehyde **5**, which was used without purification.[15] In order to introduce the C6–C7 double bond in **2**, methylenation of **5** was investigated under various conditions. Treatment of **5** with methyltriphenylphosphonium iodide and Bu^{n}Li led to a complex mixture. Wittig olefination of **5** with formylmethylene(triphenyl)-phosphorane and decarbonylation of the resultant unsaturated aldehyde with Wilkinson's catalyst gave **2** in very low yield. Finally, a combination of methyltriphenylphosphonium iodide and sodamide gave **2** in 40% overall yield from **4**.

Heating **2** in a sealed tube in *o*-dichlorobenzene at 240 °C afforded the rearranged chiral carbocycle **6** in 84% yield, based on recovered starting material (4%). The product **6**, being unstable, was subjected to $NaBH_4$ reduction without purification to give **1**.‡ The IR spectrum of **1** showed an olefin band at 1643 cm^{-1} and the presence of a hydroxy absorption at 3445 cm^{-1}. Unlike **2**,§ which showed the presence of five olefinic protons in its ^{1}H NMR spectrum, the rearranged carbocycle **1** exhibited only two olefinic protons as a multiplet at δ 5.74–5.78. The presence of the double bond in **1** was further confirmed from its ^{13}C NMR spectrum, which displayed resonances at δ 125.95 and 138.42 (Scheme 2).

Having synthesized the highly functionalized chiral synthon **1**, attempts were made to prepare the four pseudo-sugars, namely, pseudo-α-D-glucopyranose, pseudo-α-D-mannopyranose, pseudo-β-D-glucopyranose and pseudo-β-D-mannopyranose.

Catalytic OsO_4 dihydroxylation[16] of the double bond in **1** from the less hindered β-face gave the triol **7** in quantitative yield, which on debenzylation with 20% $Pd(OH)_2/C/H_2$ yielded pseudo-α-D-glucopyranose **8**, $[\alpha]_D$ +57.0 (*c* 0.65, H_2O) [lit.,[12] + 63.0 (*c* 0.6, H_2O)].

The primary hydroxy group in **1** was protected as the benzyl ether to yield **9**.¶ A mixture of partially benzylated pseudo-α-D-mannopyranose **10** and pseudo-β-D-glucopyranose **11** was obtained in one step from **9** involving a sequence of epoxidation and ring opening using MCPBA, water and 10% H_2SO_4.[17] Purification and separation by preparative TLC of the partially benzylated mixture gave **10** and **11** in 34 and 26% yields, respectively. Deprotection under similar conditions as those for



Scheme 1

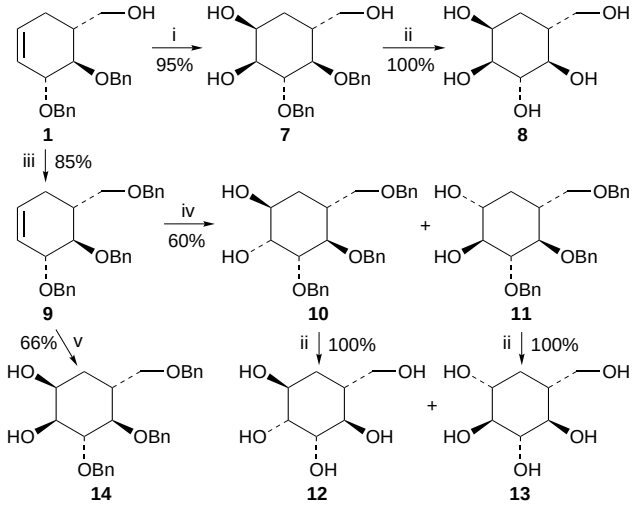

Scheme 3 *Reagents and conditions*: i, OsO_4, $K_3Fe(CN)_6$, K_2CO_3, Bu^{t}OH, H_2O, 24 h; ii, 20% $Pd(OH)_2/C/H_2$, 55 psi, 2 h; iii, NaH, DMF, BnBr, room temp., 10 h; iv, MCPBA, H_2O, 10% H_2SO_4, 48 h; v, aq. AcOH, AgOAc, I_2, Na (cat.), MeOH, 15 h

7 gave pseudo-α-mannopyranose **12**, $[\alpha]_D$ +1.5 (*c* 0.4, MeOH) [lit.,[12] $[\alpha]_D$ +1.9 (*c* 1.0, MeOH)], and pseudo-β-D-glucopyranose **13**, $[\alpha]_D$ +10.0 (*c* 0.3, H_2O) [lit.,[18] $[\alpha]_D$ +10.9 (*c* 0.83, H_2O)], from **10** and **11**, respectively, in quantitative yields (Scheme 3).

cis-Hydroxylation[19] of the alkene **9** under Woodward's conditions gave in 66% yield the tribenzyl diol **14** which on debenzylation afforded only pseudo-α-D-glucopyranose instead of the anticipated pseudo-β-D-mannopyranose, in quantitative yield. This is surprising as Woodward's hydroxylation is expected to give overall *syn*-hydroxylation from the more hindered face, in contrast to the osmium tetroxide hydroxylation.

The ^{1}H NMR spectra of all the pseudo-sugars were in consonance with the data reported in the literature. The structures of all new compounds were unambiguously established from their spectral and analytical data wherever appropriate.

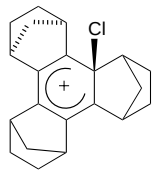
X-Ray structure of bridged 2,2′-bi(adamant-2-ylidene) chloronium cation and comparison of its reactivity with a singly-bonded chloroarenium cation

T. Mori, R. Rathore, S. V. Lindeman and J. K. Kochi†

Department of Chemistry, University of Houston, Houston, Texas 77204-5641, USA

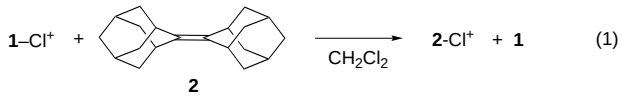
The unsymmetrically bridged 2,2′-bi(adamant-2-ylidene) chloronium hexachloroantimonate shows distinctive electrophilic (transfer) chlorination reactivity in comparison with the singly-bonded chloroarenium cation.

We recently reported[1] the isolation and structural characterization of a novel cationic chlorine–aromatic complex in which the chlorine atom is directly bonded to a single aromatic carbon atom in a manner similar to that qualitatively described for Wheland intermediates in electrophilic aromatic chlorinations.[2] The lability of the C–Cl bond in the highly colored (red) chloroarenium cation (**1**–Cl^+) is demonstrated by its ready



1–Cl^+

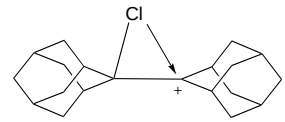
ability to transfer the positive chlorine (Cl^+) to a variety of aromatic and olefinic donors.[1] For example, an ice-cold solution of 2,2′-bi(adamant-2-ylidene)[3] (**2**) reacts with an equimolar amount of **1**–Cl^+ $SbCl_6^-$ in CH_2Cl_2 and immediately leads to the bleaching of the red color. The addition of cold hexane affords a colorless microcrystalline precipitate of **2**–Cl^+ $SbCl_6^-$ in quantitative yield [eqn. (1)]. The identity of **2**–Cl^+ $SbCl_6^-$ is



(1)

confirmed by spectral (IR and NMR) comparison with an authentic sample prepared from olefin **2** and $SbCl_5$ according to the procedure of Nugent.[4] Note that the chloronium salt **2**–Cl^+ $SbCl_6^-$ is extremely robust (if protected from moisture), and it may be stored at room temperature for several days without any decomposition. However despite its remarkable stability,[4] the structural proof for the nature of bonding in the olefin–chloronium complex **2**–Cl^+ has not been forthcoming. Accordingly, we now report (a) the single-crystal structure analysis of **2**–Cl^+ $SbCl_6^-$ and (b) its reactivity with various aromatic and olefinic donors in comparison with that of the chloroarenium cation **1**–Cl^+ $SbCl_6^-$.

A colorless crystal suitable for X-ray crystallography was grown by slow diffusion of hexane into a CH_2Cl_2 solution of **2**–Cl^+ $SbCl_6^-$ at −23 °C. Single crystal analysis‡ by X-ray crystallography established its molecular structure, and the ORTEP diagram in Fig. 1 shows that the chlorine atom is bonded to both olefinic carbon atoms, resulting in a bridged structure akin to that of the corresponding bromonium cation reported previously by Brown and co-workers.[5] The attachment of a positive chlorine (Cl^+) to the olefinic bond [C(1)–C(11)] in **2** generates an unsymmetrical cyclopropane ring system in which the C(1)–C(11) bond (2.08 Å) is significantly longer than the C(1)–C(17) bond (1.92 Å); the C(1)–C(11) bond (1.49 Å) is close to a normal single C–C bond. [Note that the hexachloroantimonate anion is only weakly coordinated to C(l7).][6]



We ascribe the unique features of **2**–Cl^+ to an unsymmetrical structure in which chlorine is σ bonded to a single carbon center [C(11)], and the cationic charge on the adjacent center (C1) is stabilized (solvated) by the chlorine lone pair (acting as an n-donor). The bridged structure of **2**–Cl^+ is reminiscent of that described for the stabilization of carbocations by neighboring group participation.[7] Such a 'non-classical' structure of **2**–Cl^+ leads to a highly stabilized chloronium cation in comparison to the singly-bonded chloroarenium cation **1**–Cl^+ that readily transfers its positive chlorine to a variety of aromatic and olefinic donors [eqn. (1) and Table 1].

The electrophilic (transfer) chlorination of various aromatic donors with **2**–Cl^+ $SbCl_6^-$ was carried out as follows. A solution of **2**–Cl^+ $SbCl_6^-$ (0.02 M) in CH_2Cl_2 was treated with pentamethylbenzene (3 equiv.) at room temperature under an argon atmosphere. The colorless reaction mixture was stirred for 3 h, during which the solution took on a pale brown coloration. Aqueous workup of the reaction mixture and GC and GC–MS analysis indicated that only a trace amount of chloropentamethylbenzene (< 1%) was formed. The decom-

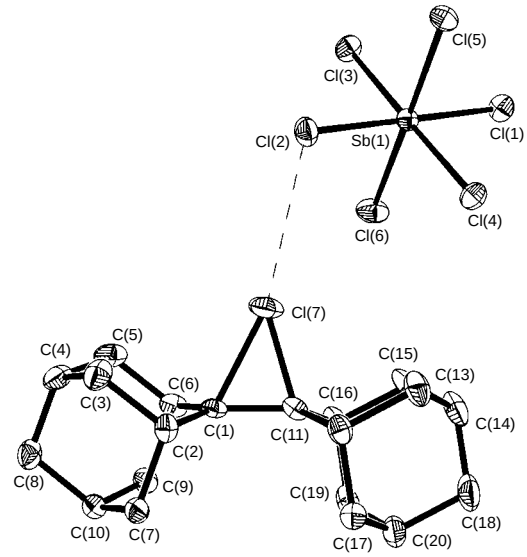


Fig. 1 ORTEP diagram of chloronium cation **2**–Cl^+ $SbCl_6^-$

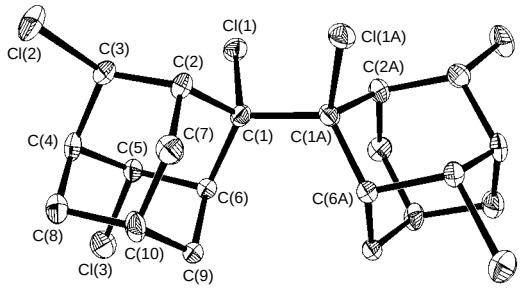

Fig. 2 ORTEP diagram of 2,2′,4,4′,9,9′-hexachloro-2,2′-biadamantane

position products of **2**–Cl^+ $SbCl_6^-$ were identified as the recovered olefin **2** (27%), the rearranged spiroketone (58%) and several unidentified products.[8] Similarly, the reaction of **2**–Cl^+ $SbCl_6^-$ with various other aromatic donors listed in Table 1 yielded mainly the decomposition products of **2**–Cl^+.[8] Furthermore, the treatment of excess cyclohexene (3 equiv.) with **2**–Cl^+ $SbCl_6^-$ in CH_2Cl_2 afforded only the decomposition products of **2**–Cl^+, and no chlorinated product derived form cyclohexene was detected. This remarkable absence of transfer chlorination toward various aromatic and olefinic donors by **2**–Cl^+ is in sharp contrast to the corresponding bromonium (or iodonium) cation which readily transfers its positive halogen (Br^+ or I^+) to a variety of olefinic donors.[9] The insufficient reactivity of **2**–Cl^+ towards various electron donors is consistent with our proposal of rather tight σ-bonded character to the bridged chloronium cation (*vide supra*). On the other hand, the enhanced reactivity of the corresponding **2**–Br^+ (or **2**–I^+) may be attributed to a more loose bromonium–olefin complex with predominant π-character.[10]

Although **2**–Cl^+ is an ineffective Cl^+-transfer agent, it readily oxidizes electron-rich aromatic donors to the corresponding cation radicals in its capacity as a one-electron oxidant. For example, treatment of a hexasubstituted aromatic donor (CRET)[11] with a solution of **2**–Cl^+ in CH_2Cl_2 at 25 °C yields the orange cation radical [$CRET^{\cdot+}$, λ_{max} = 518, 486 (sh) nm][11] in close to quantitative yield during the course of a 3 h period.

To further examine the differences in reactivities of **2**–Cl^+ and **2**–Br^+, we carried out the reaction of olefin **2** with dichlorine in CH_2Cl_2.[12] Thus, the addition of a cooled (−30 °C) solution of **2** to a yellow solution of chlorine in CH_2Cl_2 rapidly led to bleaching; and the careful subsequent addition of hexane led to colorless crystals during the course of a three day period. The crystalline material was filtered, and X-ray structure determination§ of a colorless single crystal revealed the molecular structure of the chlorinated product to be 2,2′,4,4′,9,9′-hexachloro-2,2′-biadamantane **3** as illustrated in Fig. 2. Removal of solvent from the filtrate revealed the presence of several other unidentified (chlorinated) products. The irreversible reaction of gaseous chlorine with **2** is to be constrasted with the corresponding reaction with bromine, in which **2** reacts reversibly with Br_2 resulting in a variety of intermediates together with **2**–Br^+. However, removal of the solvent and gaseous bromine *in vacuo* led to the quantitative recovery of olefin **2**.[13]

Further experiments are underway to determine the electron-density distribution in various aromatic and olefinic halonium complexes,[10] in order to more precisely characterize the nature of the bonding in these complexes.

‡ *Crystal data* for 2,2′-bi(adamant-2-ylidene) chloronium hexachloroantimonate [$(C_{20}H_{28}Cl)^+$ $SbCl_6^-\cdot CH_2Cl_2$]. X-Ray quality crystal (0.40 × 0.15 × 0.04 mm) was obtained from a CH_2Cl_2–C_6H_{14} mixture at −23 °C. M = 723.25, orthorhombic, space group $P2_12_12_1$, a = 10.3394(1), b = 16.0104(1) and c = 16.0930(1) Å, D_c = 1.803 mg m^{-3}, V = 2664 $Å^3$, Z = 4. Data collection was carried out on a Siemens SMART diffractometer equipped with a CCD detector, using Mo-Kα radiation (λ = 0.71073 Å), at −150 °C. The total number of reflections measured was 34 182, of which 12 224 reflections were symmetrically non-equivalent. The structure was solved by direct methods and refined by full-matrix least-squares procedure. Final residuals were $R1$ = 0.054 and $wR2$ = 0.103 for 8640 reflections with $I > 2\sigma(I)$.

§ *Crystal data* for 2,2′,4,4′,9,9′-hexachloro-2,2′-biadamantane [$(C_{20}H_{24}Cl_6)$]. Bi(adamantylidene) was added to a solution of chlorine in CH_2Cl_2 at −30 °C and the resulting pale yellow solution was layered with prechilled (−30 °C) hexane. A well-formed crop of crystals was obtained after a three day period at −23 °C. A colorless crystal with dimensions (0.1 × 0.1 × 0.15 mm) was used for X-ray structural study. M = 477.09, monoclinic, space group $C2/c$, a = 14.116(2), b = 6.8734(8) and c = 19.537(3) Å, D_c = 1.686 mg m^{-3}, V = 1879.4 $Å^3$, Z = 4. Data collection was carried out as described above and the total number of reflections measured was 4085, of which 2679 reflections were symmetrically non-equivalent. The structure was solved by direct methods and refined by full-matrix least-squares procedure. Final residuals were $R1$ = 0.074 and $wR2$ = 0.136 for 1727 reflections with $I > 2\sigma(I)$. (Note that this crystal also contained ~8% of 2,2′,9,9′,10,10′-hexachloro-2,2′-biadamantane as an isomeric impurity.)

6 In various **2**–X^+ cations, the disposition of counteranion with respect to X^+ may be viewed as an indicator of the degree of the positive charge on the halogen atom. Thus the hexachloroantimonate anion in **2**–Cl^+ is only weakly coordinated (Cl^+–$ClSbCl_5^-$ = 3.51 Å) whereas the tribromide in **2**–Br^+ (Br^+–Br_3^- = 3.10 Å) and a water molecule in **2**–I^+ (I^+–OH_2 = 2.63 Å) are strongly coordinated to the halonium cation.

N^1-(Acridin-9-ylcarbonyl)spermine binds at 5′-pu-p-pu..5′-py-p-py sites of DNA with the acridine moiety asymmetrically intercalated, stacked between the two purine bases; the spermine moiety interacts with the homopyrimidine phosphodiester backbone of the intercalation site and protects against DNase I cleavage of this backbone, but does not protect against cleavage of the homopurine backbone at the same intercalation site.

Acridine, a common DNA intercalator, has been used extensively to modulate the DNA binding properties of many ligands through covalent attachment of the acridine moiety. Examples include acridine conjugates with peptides,[1] oligodeoxynucleotides,[2] minor-groove DNA binders such as netropsin and distamycin[3] and the DNA alkylating agent cisplatin.[4,5] The binding selectivity of these conjugates generally reflects that of the non-acridine part of the molecule, although acridine conjugation seems to redirect the alkylation selectivity of some aniline mustards.[6] The site-specific photocleavage of DNA by acridine- 9-carboxamide–imidazole conjugates, in association with Co^{III}, may be a result of an acridine preference for intercalation at a 5′-GpG..5′-CpC site.[7]

Polyamines, such as spermine and spermidine, are polycationic molecules that have limited DNA-sequence selectivity, but may preferentially bind to GC-rich major grooves,[8] and AT-rich minor grooves.[9] Amongst many examples of polyamine conjugates[10] are those having polyamines covalently bound to long-chain lipids,[11] anthracene[12] and mustard alkylating agents such as chlorambucil.[13] There is no apparent evidence of the polyamine introducing a sequence-selective binding effect into any of these molecules, but in each it is believed that the polyamine enhances the binding affinity through electrostatic interactions with DNA.

To combine the intercalating effects of acridine and the high affinity polyamine binding to DNA, we have synthesized N^1-(acridin-9-ylcarbonyl)spermine **1**.‡ To investigate any possible sequence selectivity of **1**, we then used a DNase I protection assay with the Hind III/Nhe I restriction fragment of pBR322 plasmid duplex DNA.§ The protection from DNase I cleavage by **1** was pronounced at eight sites within the readable window of the gel (approximately from base-pair 81 to 150, Fig. 1). Of these, seven are homopyrimidine tracts of two or more bases. The remaining site corresponds to a 5′-CpG..5′-CpG sequence (site 5) and was only weakly protected. Of the pyrimidine tract sites, five span only two pyrimidine bases, with both 5′-CpC (sites 1 and 3, with weak protection at site 4) and 5′-TpT (sites 6 and 7) equally protected. Sites 2 and 8 contain longer 5′-CpCpT and 5′-CpTpTpT tracts, respectively, both of which are fully protected. Hence, the nature of the pyrimidine (C or T) seems to be unimportant in establishing protection against DNase I by polyamine amide **1**. In addition to the pyrimidine protection sites, some enhancement of cleavage is observed adjacent to several protection sites (for example, to the 3′ side of site 7). Such enhancement has been observed previously in this assay,[3] and could be the result of a DNA conformational change brought about by the binding of **1**.

1

In the DNase I assay we found no protection of purine tracts on the bottom strand (italicised in Fig. 1). This is an interesting result, given that such tracts have corresponding complementary pyrimidine tracts in the top strand. One might anticipate that the ligand binding causing the protection described above would also occur in these regions of the DNA, and would offer similar protection to the homopurine regions of the bottom strand. We conclude from this that there is an asymmetric binding of polyamine amide **1** to the homopurine..homopyrimidine DNA, such that only the pyrimidine backbone is protected from DNase I.

To investigate further this unusual experimental result, computer simulations were performed using 18-mer duplexes containing intercalation sites[12] corresponding to two protection sites. These were site 3 (intercalation site between base pairs

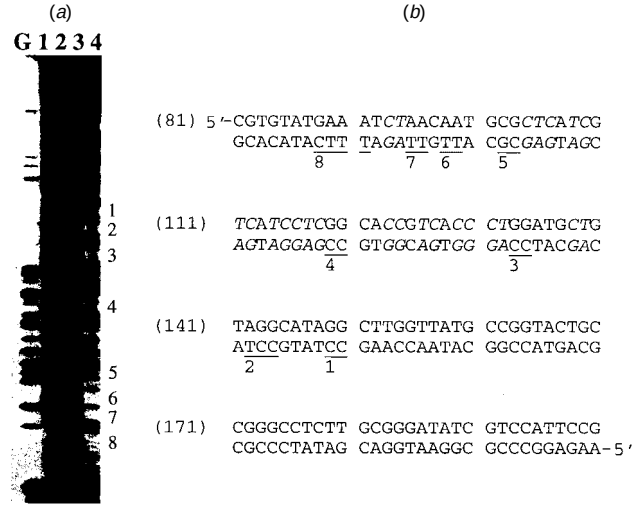

Fig. 1 Sites of DNase I protection by N^1-(acridin-9-ylcarbonyl) spermine **1** in a 3′-end [^{32}P]-bottom strand labelled Hind III/Nhe I restriction fragment of pBR322. (*a*) Autoradiogram showing Maxam–Gilbert dimethyl sulfate–piperidine mediated guanine specific cleavage (lane G), and DNase I cleavage in the presence of no polyamine amide **1** (lane 1), 0.2 μM **1** (lane 2), 1.0 μM **1** (lane 3) and 5.0 μM **1** (lane 4). Protection sites are numbered 1 to 8 in the 5′ to 3′ direction of the bottom strand. (*b*) Sequence of restriction fragment corresponding to the autoradiogram. Numbered and underlined sequences show protection sites; note that no protection was observed at italicised sequences.

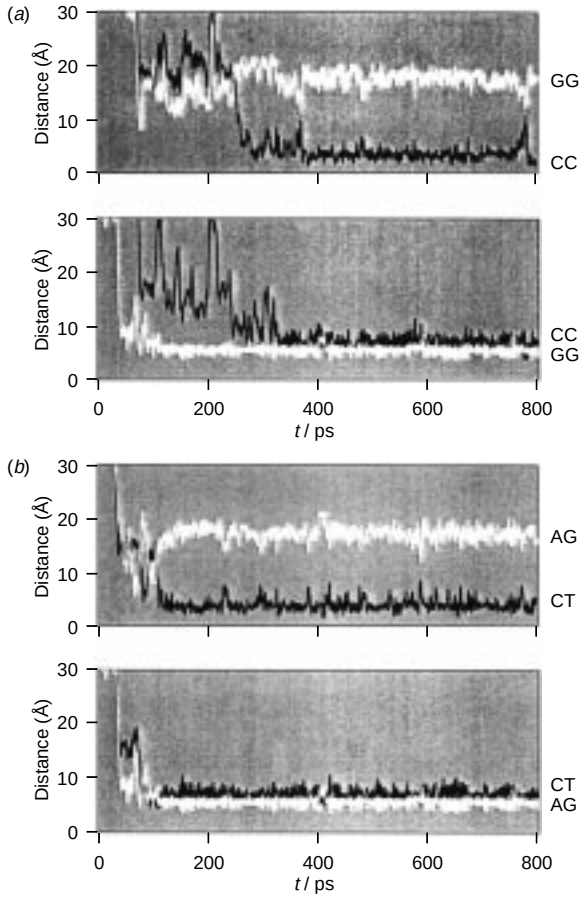

Fig. 2 Simulations of polyamine amide **1** with 18-mer DNA molecules having (a) a central 5′-GpG..5′-CpC intercalation site (site 3) and (*b*) a central 5′-ApG..5′-CpT intercalation site (site 2), showing in the upper panels of (*a*) and (*b*) the polyamine contact distances to the phosphates of the respective homopyrimidine and homopurine backbones, and in the lower panels the acridine contact distances to the C1′ atoms of the same backbones

133 and 134, 5′-GpG..5′-CpC in a sequence corresponding to base pairs 125 to 142) and site 2 (intercalation site between base pairs 142 and 143, 5′-ApG..5′-CpT, in a sequence corresponding to base pairs 134 to 151). Molecular dynamics simulations of the interactions of **1** with each site were performed in the AMBER4.1 forcefield using similar conditions to those described elsewhere.[12] Simulations were performed for 800 ps and the DNA motion was frozen throughout the calculations.[12] The ligand was initially positioned about 20 Å from the DNA, allowing it to move to the DNA, bind and then intercalate from either groove with a random orientation of the polyamine moiety.[12]

In Fig. 2 we show the results of these simulations. The data shown in the upper panels of Fig. 2(*a*) and (*b*) are the distances of the polyamine moiety to the phosphodiesters of each intercalation site, using, at each time point, the phosphate in each strand closest to the 'centre' of the polyamine (defined as the midpoint of the two secondary amines). In the lower panels, the distance from the centre of the acridine (pyridine) ring to the C1′ atoms of the deoxyriboses of each intercalation site, using, at each time point, the C1′ atom of each strand closest to the acridine centre. Following intercalation (after 300 ps for site 3 and 100 ps for site 2, from the major groove for each site), the acridine moiety remains closer to the homopurine strand for both sites. Conversely, whilst the acridine moiety is intercalated, the polyamine interacts only with the homopyrimidine strand for both sites.

This asymmetric intercalation binding geometry of the acridine moiety, stacked between two purine bases, and the concurrent polyamine location on the homopyrimidine phosphodiester backbone, provides a clear explanation of our DNase I protection data. Acridine and spermine show but small DNA sequence selective binding (see above), and neither molecule alone apparently exhibits the kind of sequence specificity shown by polyamine amide **1**. Based on computer simulation, this specificity seems to arise from acridine binding, and the polyamine plays the role of 'reporting' the specificity by binding to the homopyrimidine backbone and blocking DNase I cleavage. However, it is possible that the polyamine moiety plays a more direct role in determining the sequence selectivity of **1**, and we are currently synthesizing analogues of **1** to investigate this possibility further.

‡ Polyamine amide **1** was synthesized using N^1-mono-Boc-spermine[14] starting with spermine (free base) and Boc_2O (THF, 0–25 °C, 14 h, 54% after flash silica gel chromatography). Acylation with acridine-9-carboxylic acid [DCC (1.5 equiv.), cat. HOBt (0.05 equiv.), 48 h, DMF, 25 °C] afforded the desired mono-Boc protected conjugate as a viscous yellow oil (48% after flash silica gel chromatography). Deportection (TFA, 0 °C, 1 h) of the primary amine gave **1** as its poly-TFA salt, a yellow solid (100%) after lyophilisation.

§ The 197 base pair Hind III / Nhe I restriction fragment of pBR322 was labelled on the 3′-end of the bottom strand at the Hind III site (making base 34 the 3′-end of the bottom strand) with α-[^{32}P]dATP and reverse transcriptase (ref. 15). The labelled fragment was isolated, purified (PAGE, 6% non-denaturing gel), eluted from the gel with Tris–EDTA (TE) buffer (10 mM Tris, 0.1 mM EDTA, pH 8.0), precipitated with EtOH and redissolved in TE buffer. DNA footprinting with polyamine amide **1** (0.2–25.0 μM) was performed using DNase I (0.01 units ml^{-1}) at 25 °C (4 min, 2 mM $MgCl_2$, 2 mM $MnCl_2$, 20 mM NaCl, pH 7.5). The reaction was stopped using 80% formamide (5 μl) and cleavage products identified by co-electrophoresis with Maxam–Gilbert G-specific cleavage products on a denaturing gel (6% acrylamide, 8 M urea, 1500 V, 2 h).

Routine determination of molecular crystal structures from powder diffraction data

William I. F. David,*[a]† Kenneth Shankland[a] and Norman Shankland[b]

[a] *ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, UK OX11 0QX*
[b] *Department of Pharmaceutical Sciences, University of Strathclyde, Glasgow, UK G1 1XW*

The state of the art in determining molecular crystal structures from powder diffraction data using a global optimisation method is illustrated with a fast, automated simulated annealing approach to solving the previously unknown crystal structures of capsaicin, thiothixene and promazine hydrochloride.

The routine structure determination of molecular materials from single-crystal diffraction data is one of the principal triumphs of crystallography. In contrast, structure determination from powder diffraction data is problematic, hampered as it is by the severe loss of information arising from Bragg peak overlap. Here, we present a fast, automated, simulated annealing approach to the problem that provides a significant alternative to direct methods usually employed in attempts to solve structures from powder diffraction data.[1]

X-Ray diffraction data were collected for the compounds illustrated in Fig. 1 at 100 K on BM16 of the European Synchrotron Radiation Facility[2] (λ = 0.6528 Å), and the structures solved as follows. The position, orientation and conformation of an entire molecule in the refined unit cell were postulated and the level of agreement between the trial structure and the experimental diffraction data quantified by:[3]

$$\chi^2 = \sum_h \sum_k [(I_h - c\,|F_h|^2)(V^{-1})_{hk}(I_k - c\,|F_k|^2)]$$

where I_h and I_k are Lorentz-polarisation corrected, extracted integrated intensities from a Pawley refinement[4] of the diffraction pattern, V_{hk} is the covariance matrix from the Pawley refinement, c is a scale factor, and $|F_h|$ and $|F_k|$ are the structure factor magnitudes calculated from the trial structure.

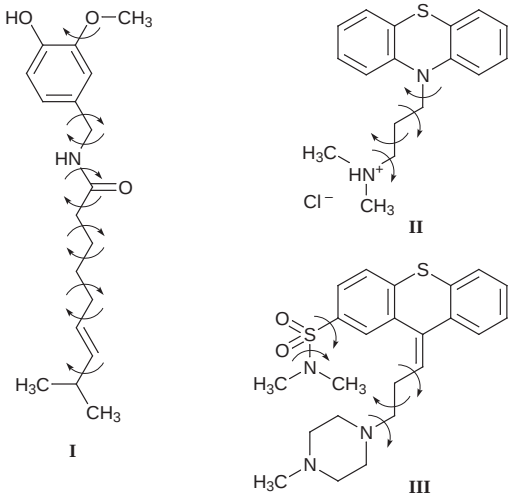

Fig. 1 Capsaicin **I** is the 'hot' component of chilli peppers. Promazine hydrochloride **II** and thiothixene **III** are tranquillisers. Internal degrees of freedom (indicated by the arrows) are 0–360° in every case, except for H–N–C=O in capsaicin, where the range 160–200° was sampled. The configurations around the C=C bonds in capsaicin and thiothixene were fixed as shown, in accordance with prior chemical knowledge, and the piperazine ring fixed in a chair conformation. The molecules have six, nine and five external degrees of freedom respectively.

The trial structure was subjected to a global optimisation in which torsion angles were the only internal degrees of freedom (Fig. 1) and bounds on the external degrees of freedom (three fractional coordinates for position and four quaternions for orientation[5]) were derived from the Euclidean normalisers of the relevant space groups.[6] Finally, the structure solutions obtained at the end of the simulated annealing runs were verified by Rietveld refinements[7] in which only scale and overall temperature factors were refined.

The method presented here has two distinctive elements. Firstly, the correlated integrated intensities figure-of-merit is formally equivalent to, but calculated typically two orders of magnitude faster than, the agreement factors used by others[8–10] that operate *via* a point-by-point comparison with the measured diffraction pattern. Secondly, the simulated annealing protocol contains a novel combination of elements that facilitate global searching of the complex multi-dimensional parameter space. These include a temperature reduction that cools more slowly if the χ^2 fluctuations (*cf.* heat capacity) are large, the capacity to generate random mutations (*cf.* a genetic algorithm approach[3]) and an algorithm to generate new parameter sets that samples the neighbouring parameter space efficiently whilst allowing large perturbations with an exponentially decreasing probability.

High quality solutions were obtained with ease for all three structures (Table 1), with remarkably good agreement between the observed and calculated diffraction patterns (Fig. 2). This close agreement arises from the ability of the simulated annealing algorithm to 'fine tune' both the internal and external

Table 1 Refined unit cells, extracted intensity information and final χ^2 for the compounds shown in Fig. 1[a]

	Compound		
	Capsaicin **I**	Promazine HCl **II**	Thiothixene **III**
Space group	$P2_1/c$	$P2_1/c$	$P2_1$
a/Å	12.2234(1)	11.8081(2)	10.1471(4)
b/Å	14.7900(1)	11.4895(3)	8.6883(1)
c/Å	9.4691(1)	13.4270(2)	13.6806(3)
β/°	93.9754(3)	111.722(1)	110.650(1)
2θ Data/°	2.7–22.5	3.0–20.0	2.5–20.4
Res./Å	1.67	1.88	1.84
N_{ref}	379	271	216
t_d/min	40	8	9
χ^2_{Paw}	13.05	3.70	9.43
χ^2_{Riet}	51.19	5.03	63.74
t_s/min	1860	112	205

[a] N_{ref} = Number of reflections in the data range shown. χ^2_{Paw} = Chi-squared for the Pawley type fit to the data range shown. χ^2_{Riet} = Chi-squared for the Rietveld fit of the output simulated annealing model to the data range shown, with only scale and overall temperature factor refined. Res = Maximum spatial resolution of data. t_d = Data collection time over the specified range. t_s = Time to simulated annealing solution (DEC Alphastation 500/500).

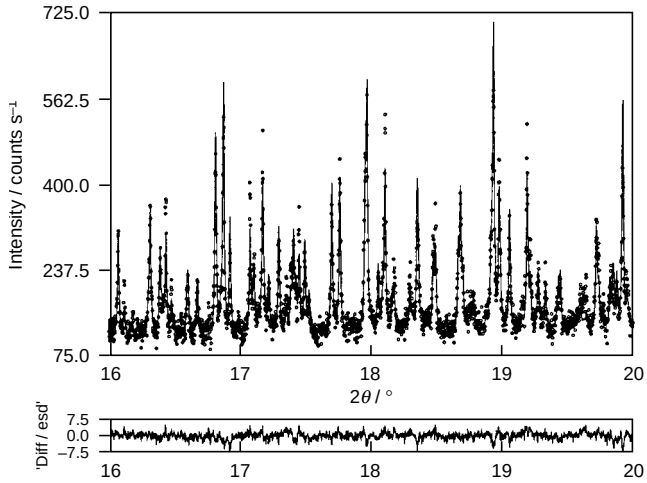

Fig. 2 Calculated (—) and observed (·) diffraction data for promazine hydrochloride **II**, with the crucial higher angle (*i.e.* higher spatial resolution) region shown. The calculated pattern is the result of a Rietveld refinement of the simulated annealing solution in which only the scale factor and overall temperature factor were refined. The atomic coordinates obtained from the simulated annealing algorithm were not refined.

degrees of freedom. Equally remarkable, given the limited spatial resolution of the data, is the agreement between the simulated annealing solution for capsaicin and a 0.7 Å resolution single-crystal structure determined subsequently in order to validate the simulated annealing approach (Fig. 3).

A combination of factors make the simulated annealing approach attractive as a method for structure determination: (*a*) the method works well on relatively low spatial resolution data, opening the way to rapid data collections (Table 1), (*b*) input models are easily constructed in internal coordinates using standard bond lengths and angles, (*c*) the process is entirely structure factor driven and thus no intra- or inter-molecular distance or energy checks are needed, and (*d*) the agreement factor is quick to calculate, leading to the rapid evaluation of the correct solution. In the case of capsaicin, structures were evaluated at a rate of *ca*. 150 per second. On smaller molecules, rates in excess of 1000 structure evaluations per second have been achieved. Ongoing optimisation of the goodness-of-fit χ^2 evaluation code promises to increase this rate still further.

In conclusion, we have demonstrated a very powerful method for solving molecular crystal structures from powder diffraction data. Although the experimental data were collected at a synchrotron source, the ability to solve structures reliably with data extending to resolutions of only $\approx$1.8 Å means that the approach will also be applicable to data collected on laboratory-based X-ray diffractometers. Approximately 77% of organic structures reported in the Cambridge Structural Database[11] have fewer atoms than thiothixene. It follows that the approach should have broad applicability in molecular crystal structure analysis.

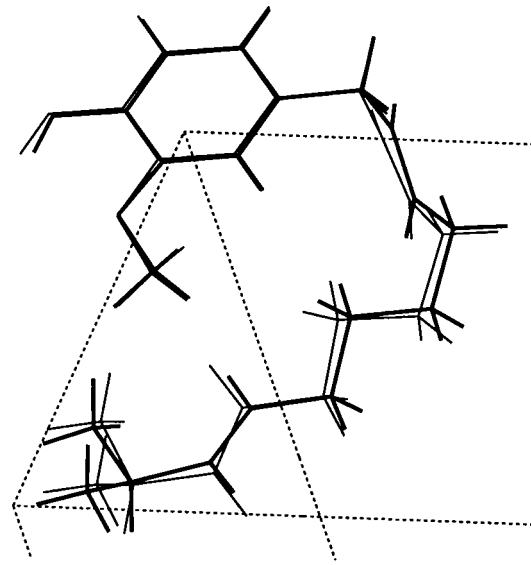

Fig. 3 The solved crystal structure of capsaicin **I** output directly from the simulated annealing algorithm, with the single-crystal solution shown overlaid in bold. The minimum, maximum and mean distances between pairs of corresponding capsaicin atoms are 0.045, 0.418 and 0.150 Å, respectively.

We thank Dr Andy Fitch of the ESRF for setting up BM16, Dr Chris Frampton of Roche Drug Discovery for determining the single-crystal structure of capsaicin, and Dr Joel Oliver of Procter and Gamble for helpful discussions regarding the structure of capsaicin.

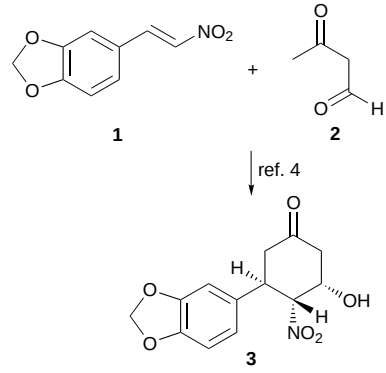
Diastereoselective intramolecular nitroaldol entry to lycoricidine alkaloids

James McNulty*† and Ruowei Mo

Department of Chemistry, Brock University, St. Catharines, Ontario, Canada L2S 3A1

The alumina promoted 6-*exo*-*trig* intramolecular nitroaldol cyclization described proceeds in a highly diastereoselective manner *via* a proposed chelation controlled chair-like transition state, the major diastereomer having the correct relative configuration at three stereocentres as observed in the pancratistatin series of antitumor agents, in contrast to prior literature cyclization methods.

Nitroalkenes are valuable synthetic intermediates by virtue of their high reactivity and *umpolung* nature compared to carbonyl and amino substrates, to which they may be subsequently converted. They are highly reactive as Michael acceptors in conjugate addition processes[1] and dienophiles in Diels–Alder cycloadditions,[2] in addition to undergoing other valuable transformations.[3] Nitroalkenes are therefore valuable intermediates for the preparation of compounds of biological interest. Seebach has made extensive use of their high reactivity as Michael acceptors[1] and described applications towards the synthesis of alkaloids.[4] One attractive annulation strategy (Scheme 1) involves a combination Michael addition of a dianion onto the nitroalkene followed by subsequent intramolecular nitroaldol cyclization onto an appropriately functionalized carbonyl-containing side chain. This methodology has been applied towards the preparation of deoxylycorinone derivatives.[4] Other routes to lycoricidine-type alkaloids utilizing nitroalkenes have also been reported.[5]



Scheme 1

In consideration of the structure of the valuable anticancer alkaloids pancratistatin **4** and *trans*-dihydrolycoricidine **5**,[6] the development of an intramolecular nitroaldol cyclization exhibiting alternative diastereoselectivity to that of the base promoted example described above would be of great value. We are currently addressing the issue of the nature of the C-ring hydroxy substituents of compounds **4** and **5** with respect to the anticancer pharmacophore and require a means of access to deoxy derivatives of **5**. The observation that the three substituents on the cyclohexane C-ring at positions 4, 4a and 10b‡ in the desired natural diastereomeric series lie in *equatorial* positions led us to consider the possibility of a chelation controlled intramolecular nitroaldol cyclization as a means of controlling the relative stereochemistry. We now report a neutral alumina promoted nitroaldol cyclization that provides the desired diastereoselectivity.

Michael addition of the copper–zinc reagent[7] derived from ethyl 4-bromobutyrate **6** (Scheme 2) to the piperonal derived nitroalkene **1** proceeded cleanly to give the ester **7**. Selective reduction of the ester with DIBAL-H gave aldehyde **8**, the key substrate for the intramolecular nitroaldol. Our analysis of the possibility of a chelation controlled chair-like transition state

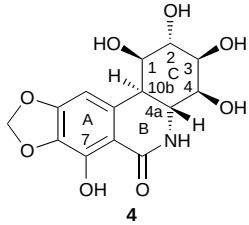

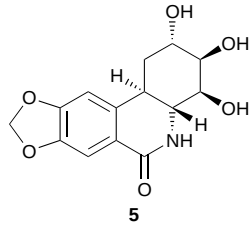

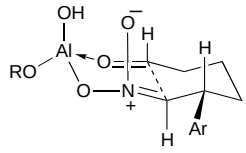

Fig. 1

(Fig. 1) for the intramolecular cyclization in conjunction with earlier reports[8a,b] on basic alumina promoted *inter*molecular nitroaldol reactions led to the following procedure. Aldehyde **8** was dissolved in CH_2Cl_2 and treated with *neutral* alumina at ambient temperature while solvent was removed under a nitrogen flow. Clean cyclization slowly occurred giving two diastereomers, **9** and **10**, in the ratio of 95 : 5. Importantly, no dehydration is observed when neutral alumina is employed at room temperature; however simply warming to 40 °C can result in the formation of nitroalkenes.[8a] Separation of the compounds was readily achieved (neutral alumina, CH_2Cl_2–MeOH, 95 : 5) and to our delight the *major* isomer proved to be **9**, as evidenced by ^{1}H NMR analysis (H-4a δ 4.45, dd, J = 11.2, 9.8 Hz). The high diastereoselectivity observed is consistent with the transition state model we propose in which an alumina–nitronate bischelated intermediate undergoes intramolecular cyclization *via* a late, chair-like transition state in which all developing substituents occupy equatorial-like positions. This model should prove useful in the prediction of diastereoselectivity in related 6-*exo*-*trig* nitroaldol reactions.

The utility of this diastereoselective cyclization was demonstrated by elaboration of the nitroaldol product **9** (Scheme 2) to lycoricidine analogue **15** retaining the desired natural stereochemistry. The alcohol of **9** was first protected§ to give the silyl ether **11**, which was quantitatively reduced over Raney Ni and protected to give the carbamate **12**. Attempts to cyclize this silyl protected carbamate by the method of Banwell[9] failed due to the instability of the TBDMS group under the cyclization conditions. The protecting group was therefore changed using the one-pot procedure of Ganem[10] providing the acetate **13**, which was cyclized[9] to give the tetracycle **14**. The yield on the Bischler–Napieralski cyclization was optimized by extending the hydrolysis time to 14 h, and employing an aqueous HCl–THF mixture instead of the reported aqueous AcOH. This also resulted in a small amount of acetate hydrolysis, as was observed under Banwell's conditions.[9] An overall yield of 85% of **14** could be realized from **13** when a final re-acetylation step was employed. Banwell's cyclization protocol is clearly more efficient than earlier methods in effecting this key transformation.[9] Finally, clean removal of the acetate protecting group provided us with the desired analogue 2,3-dideoxy-*trans*-dihydrolycoricidine **15**.

The diastereoselective nitroaldol cyclization described above provides a valuable access to deoxy derivatives of alkaloids **4** and **5**, both of which exhibit a high degree of anticancer activity,[6] having the correct relative stereochemistry at key positions C-4, C-4a and C-10b. Alkaloid **5** is currently the simplest known derivative that exhibits the full spectrum of anticancer activity.[6] The chemistry reported allows access to the simplified C-ring analogue **15**, lacking two hydroxy groups from **5**, which will provide valuable information concerning the pharmacophore of these alkaloids.

Further modifications of the C-ring based on the proposed transition state model and anticancer evaluation is currently in progress and will be reported shortly.

Chiral diiminophosphoranes: a new class of ligands for enantioselective transition metal catalysis

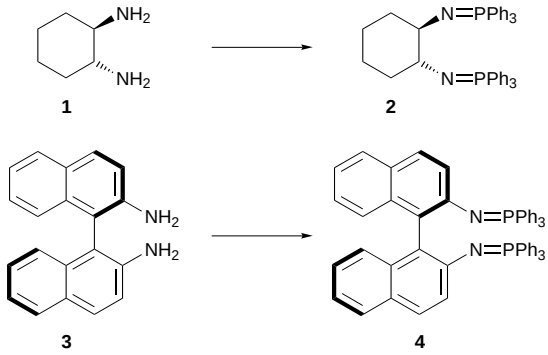
Manfred T. Reetz,*† Edward Bohres and Richard Goddard

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim/Ruhr, Germany

Chiral diamines such as (1*R*,2*R*)-1,2-diaminocyclohexane or *R*-2,2′-diamino-1,1′-binaphthalene can be converted into the corresponding diimino(triphenyl)phosphoranes, which serve as C_2-symmetric ligands for enantioselective transition metal catalyzed reactions such as copper-mediated cyclopropanations.

Chiral nitrogen-containing compounds are gaining increasing importance as ligands in enantioselective transition metal catalyzed reactions.[1] Although iminophosphoranes[2] of the general structure $R_3P{=}NR'$ possess a donor position at the nitrogen function capable of metal complexation,[3] chiral versions have not been prepared to date. Since iminophosphoranes are readily available from the corresponding primary amines $R'NH_2$, we envisioned a simple route to chiral chelating diiminophosphoranes and their possible use as ligands in enantioselective transition metal catalyzed reactions. Here we report the first examples of this concept.

Upon reacting the commercially available diamines **1** and **3** with Ph_3PBr_2 followed by base treatment according to a literature procedure (modified by working in the presence of molecular sieves),[4] compounds **2** and **4** were obtained in yields of 82 and 75%, respectively.



Scheme 1

Ligands **2** and **4** are crystalline compounds, which were characterized by standard methods, including ^{31}P NMR spectroscopy (δ −0.5 and −4.6, respectively, in CD_2Cl_2) and X-ray crystallography‡ (Fig. 1). The effect of the crystal environment appears to have a more significant effect on **2** than **4**, since whereas **4** exhibits exact C_2 symmetry in the crystal [N···N* 3.617(8) Å], even in spite of the presence of solvent of crystallization, in **2** the local C_2 symmetry is restricted to the cyclohexane ring and the two nitrogen atoms [N(1)···N(2) 3.770(2) Å].

These two chiral ligands are suitable for preparing a wide variety of new types of transition metal complexes. Indeed, the complexes **2**·Rh(cod)BF_4, **2**·$CoCl_2$ and **4**·CuOTf were readily synthesized in yields of *ca*. 80% by reacting the corresponding ligands with $[RhCl_2(cod)]_2$ (followed by $NaBF_4$), $CoCl_2(thf)_x$ or CuOTf, as appropriate. The crystal structures of **2**·Rh(cod)BF_4 and **2**·$CoCl_2$ confirm the flexibility of the diimino(triphenyl)-phosphorane ligand (Fig. 2). Thus, whereas the iminophosphor-

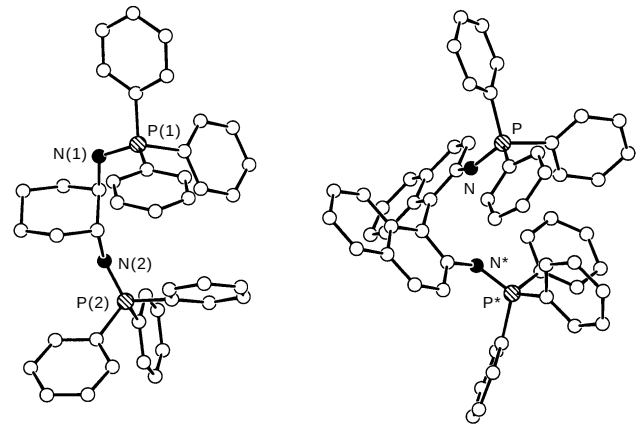


Fig. 1 Molecular structures of **2** (left) and **4** (in **4** the CD_2Cl_2 solvent of crystallization has been removed for clarity)

ane groups in the free ligand (**2**) occupy diaxial positions, in the complexed ligand both groups are equatorial, presumably enabling the N atoms to accommodate the metals [**2**·Rh(cod)BF_4 N···N 2.665(6) Å, N–Rh–N 77.3(3)°; **2**·$CoCl_2$ N···N 2.75(2) Å, N–Co–N 85.6(6)°]. In addition, the extent of the C_2 symmetry induced by the ligand strongly depends on the coordination sphere of the metal. In **2**·Rh(cod)BF_4 the approximately square-planar coordinated Rh atom deviates strongly (2.818 Å) from the local C_2 symmetry of the iminocyclohexane ring (dashed line, Fig. 2, left). In **2**·$CoCl_2$, on the other hand, the loss of symmetry is much smaller and distorted tetrahedral Co lies approximately (±0.2 Å) on the local C_2 axis of symmetry (dashed line, Fig. 2, right).

Preliminary studies using these chiral metal complexes for enantioselective catalysis have also been undertaken. Particularly worthy of note is the copper catalyzed cyclopropanation[5] of styrene **5** by ethyl diazoacetate **6** using the complex **4**·CuOTf (1.5 mol%) as the catalyst (Scheme 2). Adducts **7** and **8** were

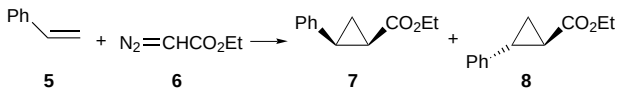

Scheme 2

formed in equal amounts, each having an enantiomeric excess (ee) of 90 and 74% in favour of the absolute configurations (*S*,*R*) and (*R*,*R*), respectively.§

In summary, we have developed a new and readily accessible class of chiral nitrogen containing ligands for asymmetric transition metal catalysis. The possibility of varying the substituents of phosphorus and/or utilizing other chiral diamines or functionalized amines is currently being explored.

Synthesis of characteristic lipopeptides of lipid modified proteins employing the allyl ester as protecting group

Thierry Schmittberger, Alain Cotté and Herbert Waldmann*†

Universität Karlsruhe, Institut für Organische Chemie, Richard-Willstätter-Allee 2, D-76128 Karlsruhe, Germany

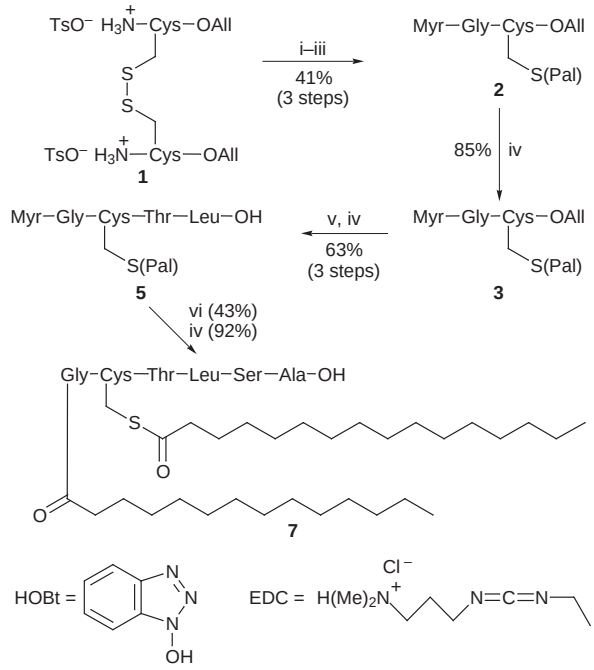
Lipidated peptides which represent characteristic lipid modified substructures of lipidated human $G_{\alpha O}$ protein and the human N- and R-*Ras* proteins were built up efficiently by employing the selective Pd^0-mediated removal of allyl esters under very mild conditions as the key step.

Lipid modified proteins are critically involved in biological signal transduction.[1] Thus, the transmembrane G protein coupled receptors are *S*-palmitoylated, their downstream effectors, the heterotrimeric G proteins are *N*-myristoylated, *S*-palmitoylated and *S*-farnesylated, the H- and the N-*Ras* proteins carry palmitoyl and farnesyl groups and the R-*Ras* protein is palmitoylated and geranylgeranylated. For the proper execution of their biological functions the correct lipidation of these classes of proteins is paramount.[2–4]

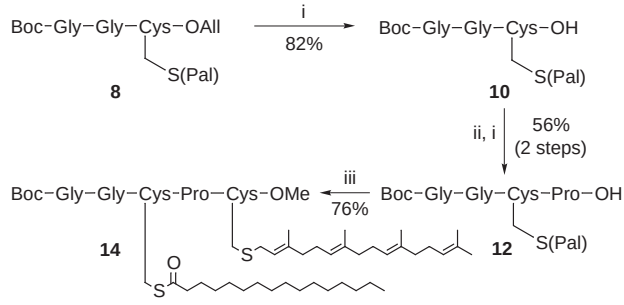
For the study of the biological significance of lipidated proteins, in particular their possible roles in signal transduction processes, lipidated peptides that contain the characteristic structural elements of their parent proteins are very useful reagents.[5,6] Therefore, the development of efficient methods for the construction of lipidated peptides is of particular interest. However, the thioesters present in these peptide conjugates are readily hydrolyzed at pH > 7 and may be lost *via* base-mediated β-elimination; also the double bonds present in farnesyl and geranylgeranyl groups are attacked under acidic conditions.[7,8] Consequently, protecting groups have to be employed that can be removed under neutral conditions.[5,8] We now report that characteristic lipidated peptides which represent lipid modified substructures of lipidated proteins can efficiently be built up by employing the allyl ester[9] as a protecting group.

In order to construct the *N*-myristoylated and *S*-palmitoylated *N*-terminus **7** of a human $G_{\alpha O}$ protein which embodies the characteristic Myr-Gly-Cys(Pal)-AA-AA-Ser/Thr-AA motif found in many G proteins,[10] cystine bisallyl ester **1** was coupled with *N*-myristoylglycine and after reductive cleavage of the disulfide bond the liberated mercapto groups were *S*-palmitoylated to give the protected thioester **2** (Scheme 1). From **2** the allyl ester was removed with complete selectivity in high yield by Pd^0-mediated transfer of the allyl group to morpholine as the accepting nucleophile. Subsequent elongation of the peptide chain by the dipeptide **4** yielded a lipidated tetrapeptide allyl ester from which the allyl group was also cleaved to give the selectively unmasked lipotetrapeptide **5** in high yield.‡ Further extension of the peptide chain by the dipeptide allyl ester **6** and final Pd^0-mediated removal of the allyl group delivered the desired myristoylated and palmitoylated *N*-terminal G protein fragment **7**. The three allyl ester cleavages performed in this sequence proceeded with complete selectivity and without any undesired side reactions. The conditions of the noble-metal complex mediated allyl transfer are so mild that neither an attack on the base-sensitive thioester nor a base-induced β-elimination of the palmitoyl group occurred.

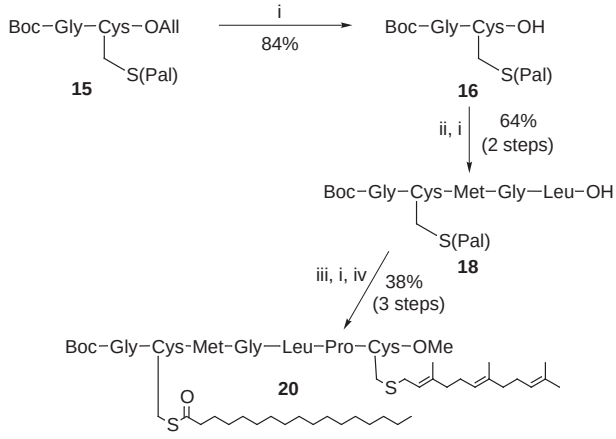
By means of this advantageous technique also the *S*-palmitoylated and *S*-geranylgeranylated *C*-terminus **14** of the human R-*Ras* protein[11] was efficiently built up (Scheme 2). To this end, the *S*-palmitoylated cysteinyl tripeptide allyl ester **8** was synthesized from $(BocGlyGlyCysOAll\text{-}S)_2$ by reductive cleavage of the disulfide and *S*-acylation, as described for **2** in Scheme 1 [the cystinyl precursor was built up from BocGly-GlyOH and cystine bis(allyl ester) by peptide coupling]. In this case 1,3-dimethylpyrimidine-2,4,6-trione (*N*,*N*′-dimethylbarbituric acid) **9**[12] was employed as accepting C-nucleophile in the Pd^0-mediated reaction. The C-terminal deprotection proceeded smoothly to give the desired carboxylic acid **10** in high yield. Elongation of the peptide chain by proline allyl ester **11** and a further Pd^0-mediated allyl ester cleavage in the presence of **9** delivered the *S*-palmitoylated tetrapeptide carboxylic acid **12** in high yield.‡ Finally, the synthesis was completed by coupling of **12** with *S*-geranylgeranylated cysteine methyl ester **13** to give the desired R-*Ras* peptide **14**.



Scheme 1 *Reagents and conditions*: i, Myr-Gly-OH, EEDQ, NEt_3, CH_2Cl_2, Pr^iOH; ii, DTT, NEt_3, CH_2Cl_2; iii, palmitoyl chloride, DMAP, NEt_3, CH_2Cl_2; iv, $Pd(PPh_3)_4$, morpholine, THF; v, H-Thr-Leu-OAll **4**, EDC, HOBt, CH_2Cl_2; vi, H-Ser-Ala-OAll **6**, EDC, HOBt, CH_2Cl_2



Scheme 2 *Reagents and conditions*: i, $Pd(PPh_3)_4$, **9**, THF; ii, ProOAll **11**, EDC, HOBt, CH_2Cl_2; iii, Cys(GerGer)OMe **13**, EDC, HOBt, CH_2Cl_2



Scheme 3 *Reagents and conditions*: i, $[Pd(PPh_3)_4]$, **9**, THF; ii, MetGly-LeuOAll **17**, EDC, HOBt, CH_2Cl_2; iii, **11**, EDC, HOBt, CH_2Cl_2; iv, Cys(Far)OMe **19**, EDC, HOBt, CH_2Cl_2

In a third application the *S*-palmitoylated and *S*-farnesylated C-terminus **20** of the human N-*Ras* protein[11] was built up by employing the Pd^0 mediated cleavage of allyl esters as the key step (Scheme 3). In order to construct this molecule, the *S*-palmitoylated allyl ester **15** was deprotected in high yield to give the selectively unmasked *S*-palmitoylated dipeptide **16**. Coupling with the tripeptide **17** and subsequent allyl transfer to **9** yielded the pentapeptide carboxylic acid **18** in an efficient manner.‡ A chain elongation with proline allyl ester **11**, a further allyl removal and subsequent coupling with *S*-farnesylated cysteine methyl ester **19** delivered the N-*Ras* peptide **20**.

All Pd^0-catalyzed allyl ester cleavage reactions proceeded without any undesired side reaction. In no case could a β-elimination or a nucleophilic attack on the activated thioesters be observed.

The use of the allyl ester blocking function thus makes sensitive lipidated peptides available in an efficient manner which up to now has only been matched by enzymatic protecting techniques proceeding under extremely mild conditions.[8] This useful strategy readily gives access to further functionalized lipidated peptides.

‡ *General procedure*. To a solution of the peptide allyl ester (1 mmol) in THF or CH_2Cl_2 (30 ml) under Ar was added $Pd(PPh_3)_4$ (0.01 equiv.) and morpholine or **9** (1.2 equiv.). The solution was stirred at room temperature for 30–60 min. If morpholine was used as the nucleophile the solution was extracted with 10 ml of 1 M HCl and 10 ml of brine. The organic layer was dried with $MgSO_4$, the solvent was evaporated *in vacuo* and the product was isolated from the residue by flash chromatography on silica gel.

According to this procedure **5**, **12** and **18** were obtained.

Selected data for **5**: 84%; mp 127–131 °C; R_f 0.56 [CH_2Cl_2–MeOH–AcOH 90 : 10 : 1 (v/v/v)]; $[\alpha]_D^{25}$ −6 (*c* 0.5, DMF); δ_H(400 MHz, CD_3OD) 0.86 (t, *J* 7, 6 H, Me Pal, Me Myr), 0.90 (d, *J* 5.5, 3 H, Me Leu), 0.94 (d, *J* 5.5, 3 H, Me Leu), 1.17 (d, *J* 6.3, 3 H, Me Thr), 1.23 (s, 44 H, 12 CH_2 Pal, 10 CH_2 Myr), 1.40–1.51 (m, 7 H, β-CH_2 Pal, β-CH_2 Myr, β-CH_2 Leu, γ-CH Leu), 2.27 (t, *J* 8, 2 H, α-CH_2 Myr), 2.55 (t, *J* 8, 2 H, α-CH_2 Pal), 3.13 (dd, *J* 14, *J* 8, 1 H, α-CH Cys), 3.23 (dd, *J* 14, 4, 1 H, β-CH Cys), 3.75 (d, *J* 17, 1 H, α-CH Gly), 3.95 (d, *J* 17, 1 H, β-CH Gly), 4.21 (t, *J* 5.8, 1 H, α-CH Leu), 4.33 (d, *J* 3.5, α-CH Thr), 4.40 (dd, *J* 8, 4, 1 H, α-CH Cys), 4.40–4.47 (m, 1 H, β-CH Thr); δ_C(100.6 MHz, CD_3OD) 14.15 (Me Pal, Me Myr), 18.79 (Me Thr), 21.65 (Me Leu), 22.79 (CH_2 Pal, CH_2 Myr), 23.00 (Me Leu), 24.97 (γ-CH Leu), 25.61 (CH_2 Cys), 29.00–30.00 (12 CH_2 Pal, 10 CH_2 Myr), 32.04 (α-CH_2 Pal), 36.22 (α-CH_2 Myr), 40.71 (CH_2 Leu), 44.10 (CH_2 Cly), 51.67 (α-CH Leu), 54.45 (α-CH Cys), 58.53 (α-CH Thr), 67.25 (β-CH Thr), 170.53 (C=O), 170.79 (C=O), 175.41 (3 C=O), 201.22 (C=O, thioester); *m/z* [FABMS (glycerol)] 842.1 $[M + H]^+$. Synthesis and crystal structures of low-valent binuclear vanadium complexes using the tethering ligand *m*-xylylenebis(acetylacetonate) (*m*-xba^{2-})

Peter J. Bonitatebus, Jr., Sanjay K. Mandal and William H. Armstrong*†

Department of Chemistry, Eugene F. Merkert Chemistry Center, Boston College, Chestnut Hill, MA 02167-3860, USA

An intriguing structural type new to low-valent vanadium chemistry and the binucleating ligand *m*-H_2xba is exhibited by the reported V^{III} dimers and the first structurally characterized bis(acetylacetonate) ligated complex of V^{II}.

Our interest in small molecule and organic functional group reduction using low-valent vanadium species featured in an anionic oxygen donor environment, as in the cases of carboxylate[1a] and aryloxide,[1b,c] has prompted us to investigate bis(acetylacetonates) as ligands in an attempt to synthesize binuclear complexes capable of intramolecular substrate binding and activation. Di- and tri-valent vanadium acetylacetonates are involved as undefined *in situ* intermediates in reactions ranging from epoxide deoxygenations[2] to dinitrogen uptake,[3] yet curiously very few structurally defined examples of bis(acetylacetonate) ligated V^{III} species have been reported.[4] Structurally characterized complexes with acetylacetonate bonded exclusively to V^{II} remain unknown,[4e] although they have been studied spectroscopically in solution.[5] The flexible *m*-xba^{2-} limits intermetallic distances acting as a tether, and should allow for a face-to-face approach of vanadia as observed in the chemistry of Cu^{II} where a discrete cofacial binuclear complex has been synthesized providing a cavity of well defined size and shape [Cu···Cu, 4.908(2) Å] appropriate for diatomic guest molecule incorporation (Fig. 1). Complexes of this type potentially will serve to promote and catalyze multielectron redox reactions, a strategy conceptually reminiscent of Collman's cofacial dimetalloporphyrin approach.[7]

We sought to prepare binuclear vanadium assemblies envisioning a target structure analogous to the Cu^{II} example, whereby reducible small molecules could be intramolecularly bound and activated. One obstacle in discrete dimer synthesis expected was oligomerization for these six-coordinate metal centers, yet here we report on the self-assembly and structures of novel discrete binuclear paramagnetic V^{II} and V^{III} complexes exhibiting an intriguing 'cage-like' structural type new to low-valent vanadium chemistry and the *m*-xba^{2-} ligand system. These compounds represent an important advance toward our target structure.

The reaction of $[VX_3(thf)_3]$[8] (X = Cl, Br) with 1 equiv. of the disodium salt of *m*-H_2xba,[9] generated in thf using 2 equiv. of NaH, proceeds at room temperature to produce complexes of the general formula $[V_2X_2(thf)_2(m\text{-xba})_2]$ (X = Cl, **1**, Br **2**) in 65% yield for both cases.‡ These compounds do not oligomerize upon standing in dichloromethane or thf solution over time, yet in the preparation of **1** and **2** insoluble precipitates thought to be oligomeric in nature along with NaX are removed by filtration. Complexes **1** and **2** were isolated as golden yellow–brown crystalline materials from concentrated thf solutions stored at 0 °C and were characterized by X-ray crystallography. The IR spectra§ of **1** and **2** show a strong band at 1559 cm^{-1} indicative of β-diketonate moieties chelated to the vanadia, along with two sets of doublets positioned at 867, 1020 and 918, 1065 cm^{-1}, assignable to ν_{C-O-C} stretching modes of coordinated and free thf molecules respectively.[10] The structure of **1** is shown in Fig. 2.¶

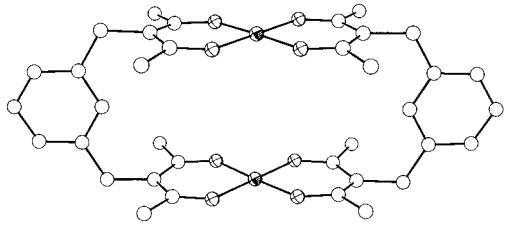

Fig. 1. Structure of $[Cu_2(m\text{-xba})_2]$[6]

The crystal structures of **1** and **2** revealed binuclear molecules with crystallographically imposed inversion symmetry. Compounds **1** and **2** are structurally analogous. The average V–O(acac) bond length of **1** [1.961(3) Å] is in good agreement with corresponding lengths of other rare acetylacetonates of V^{III} [av. 1.964(3) Å[4a] and 1.989(4) Å[4e]]. Considering the conformation of *m*-xba^{2-} in this structure, spanning the two vanadium atoms with a V···V distance of just over 11.66 Å and an aromatic ring-plane (centroids) separation of 5.366 Å, a structural rearrangement will be required to obtain the optimal distance for dual binding and activation of a small molecule. It is anticipated that dimers **1** and **2** will serve as useful precursors in establishing the desired *strati* conformation (see Fig. 1). Upon reduction of **1** or **2** in solution to reactive (II,II) species a structural change will be permitted to occur owing to rotational freedom about the C_{phenyl}–C_{benzyl} bond of the xylylene unit.

Our success with the synthesis of a discrete $V^{II,II}_2$ dimer compound $[V_2(tmeda)_2(m\text{-xba})_2]$ **3** is very encouraging considering the intention of generating a lower-valent species from a tethered $V^{III,III}_2$ assembly (**1** or **2**). Compound **3** was prepared in a similar manner (53% yield) to **1** and **2** using instead $[VCl_2(tmeda)_2]$[11] as a starting material.‡ Intensely colored midnight-blue X-ray quality crystals were isolated from concentrated thf solutions after removal of insoluble precipitates and NaCl by filtration, and cooling to 0 °C. The molecular structure and selected dimensions for **3** are shown in Fig. 3.¶ A structure similar to **1** and **2** was revealed with a V···V distance of 11.444(1) Å and an aromatic ring-plane (centroids) separation of 5.426 Å, as dictated by the *m*-xba^{2-} ligand orientation which again is in an extended conformation. The remaining sites are occupied by tmeda molecules. In comparing the changes in the vanadium coordination sphere, a subtle lengthen-

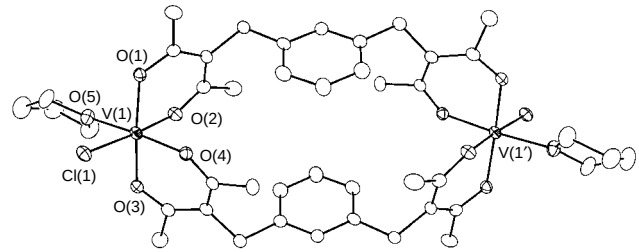

Fig. 2. Structure of **1** showing 30% probability thermal ellipsoids and atom-labeling scheme (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°): V(1)–O(1) 1.941(2), V(1)–O(2) 1.962(2), V(1)–O(3) 1.985(2), V(1)–O(4) 1.955(2), V(1)–O(5) 2.097(2), V(1)–Cl(1) 2.366(1); O(1)–V(1)–O(2) 87.1(1), O(3)–V(1)–O(4) 85.4(1).

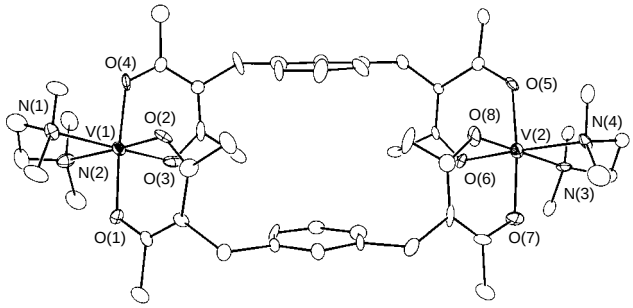

Fig. 3. Structure of **3** showing 30% probability thermal ellipsoids and atom-labeling scheme (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°): V(1)–O(2) 2.035(9), V(1)–N(1) 2.23(1), V(1)–O(4) 2.04(1), V(1)–N(2) 2.26(1), V(1)–O(1) 2.03(1), V(1)–O(3) 2.00(1), V(2)–O(6) 2.020(9), V(2)–N(3) 2.20(2), V(2)–O(5) 2.06(1), V(2)–N(4) 2.22(1), V(2)–O(7) 2.02(1), V(2)–O(8) 2.05(1); O(5)–V(2)–O(6) 85.9(4), O(7)–V(2)–O(8) 86.8(5), O(1)–V(1)–O(2) 87.0(4), O(3)–V(1)–O(4) 86.8(5).

ing of the V–O(acac) bonds is observed [V–$O_{av.}$: **1** 1.961(3) Å, **3** 2.033(9) Å] consistent with a decrease in oxidation state. Compound **3** is, to our knowledge, the first example of a structurally characterized bis(acetylacetonate) ligated complex of V^{II}. An X-band EPR spectrum§ in frozen (77 K) thf solution displays an intense broad signal at $g = 4$ with no higher-field absorbances detected under these conditions. The successful preparation of a (II,II) dimer is of great interest considering the application of precursors **1** and **2** toward *strati* target structure synthesis *via* reduction and terminal halide removal.

Ongoing studies focus on testing the rearrangement proposition described above in working toward a cofacial conformation. We are also interested in extending our investigations to include bis(β-diketonates) with bridging groups other than the *m*-xylylene framework.

‡ Complexes **1**–**3** analyzed satisfactorily. The scale of a typical reaction was on the order of 0.54 mmol in *m*-H_2xba ligand and vanadium-containing starting materials.

§ *Selected spectroscopic data*: **1**; UV–VIS (CH_2Cl_2): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) = 304 (31 900), 359 (16 600); IR (Nujol, cm^{-1}) 1559vs, 1288s, 1207m, 1173m, 1065w, 1020s, 948s, 918w, 867s, 742m. **3**; EPR (thf 77 K, X-band) $g = 4$ (br); UV–VIS (thf): λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) = 288 (49 800), 343 (9110), 484 (2040), 592 (3380), 684 (2580); IR (Nujol, cm^{-1}) 1558vs, 1286s, 1201m, 1165w, 1127w, 1029s, 949s, 796s, 743m, 693w.

¶ *Crystal data*: **1**·thf; $C_{44}H_{56}Cl_2O_{11}V_2$, M = 989.763, monoclinic, space group $C2/c$, a = 20.2285(4), b = 13.0235(2), c = 20.2383(4) Å, β = 94.395(1)°, U = 5316.0(2) Å^3, Z = 4, D_c = 1.347 g cm^{-3}, F(000) = 2240, μ = 0.515 mm^{-1}, T = 183 K, λ = 0.710 73 Å, $2\theta_{max}$ = 56.58°, 15 553 measured reflections on a Siemens SMART CCD area-detector diffractometer, 6099 unique (R_{int} = 0.0376, no absorption correction). The structure was solved by direct methods and refined by FMLS methods on F^2 with statistical weighting, anisotropic displacement parameters for all non-hydrogen atoms (except those of the disordered thf solvent molecule), constrained isotropic H atoms to give $R' = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ = 0.0771 on all data, conventional R_1 = 0.0604 on F values of 4997 reflections having $F_o^2 > 4\sigma F_o^2$, goodness of fit S = 1.087 for all F^2 values and 300 refined parameters. Final difference map features were within ±0.920 e Å^{-3}. Programs: Siemens SMART and SAINT control and integration software, Siemens SHELXTL Version 5.

2·thf; $C_{44}H_{56}Br_2O_{11}V_2$, M = 1078.675, monoclinic, space group $C2/c$, a = 20.081(6), b = 13.264(6), c = 20.670(4) Å, β = 95.75(2)°, U = 5478.0(3) Å^3, Z = 4, D_c = 1.395 g cm^{-3}, F(000) = 2384, μ = 1.857 mm^{-1}, λ = 0.71073 Å, T = 183 K. 6944 reflections measured, 3894 unique data ($2\theta_{max}$ = 56.44°, R_{int} = 0.0917, no absorption correction). Structure solution and refinement were as for **1** including a disordered thf molecule to give 2698 reflections having $F_o^2 > 4\sigma F_o^2$ with conventional R_1 = 0.0968 (wR_2 = 0.1709) and goodness of fit S = 1.260 (307 parameters). Final difference map features were within 0.680 and −0.780 e Å^{-3}.

3·2thf; $C_{52}H_{80}N_4O_{10}V_2$, M = 934.943, monoclinic, space group Pn, a = 13.7459(8), b = 11.1388(6), c = 18.6718(5) Å, β = 90.816(2)°, U = 2858.6(2) Å^3, Z = 2, D_c = 1.249 g cm^{-3}, F(000) = 1148, μ = 0.385 mm^{-1}, λ = 0.710 73 Å, T = 183 K. 7530 reflections measured, 6244 unique data ($2\theta_{max}$ = 56.42°, R_{int} = 0.0658, semi-empirical absorption corrections). Structure solution and refinement performed as above including a partially disordered thf molecule to give 4173 reflections having $F_o^2 > 4\sigma F_o^2$ with conventional R_1 = 0.0655 (wR_2 = 0.1223) and goodness of fit S = 1.092 (644 parameters). Final difference map features were within 0.309 and −0.283 e Å^{-3}. CCDC 182/763.

Synthesis and characterization of poly(butyl acrylate-co-styrene)–silver nanocomposites by γ radiation in W/O microemulsions

Yadong Yin, Xiangling Xu,*† Chuanjun Xia, Xuewu Ge and Zhicheng Zhang

Department of Applied Chemistry, University of Science and Technology of China, Hefei 230026, PR China

Poly(butyl acrylate-co-styrene)–silver nanocomposites were prepared by γ-irradiation of microemulsions and metallic silver nanoparticles of near uniform size were found to be well dispersed in the polymer matrix.

Much attention has been paid to the synthesis and characterization of nanometer metal particle–organic polymer composites, owing to their intriguing optical, electrical and mechanical properties.[1–3] These composites are considered to be highly functional materials, with wide potential application in electromagnetic inference shielding films, non-linear optical materials and the like.

Several methods have been developed to synthesis the composites.[4–6] In general, two steps were needed: firstly, monomer was polymerized in the solutions, with metal ions introduced before or after the polymerization. Secondly, metal ions in the polymer matrix were reduced by a reducing agent or by calcining. Since polymerization and reduction were performed separately metal nanoparticles were not well dispersed in the polymer matrix.

Recently, Zhu *et al.*[7] developed a γ radiation method to prepare polyacrylamide–silver nanocomposites at room temperature. In this method, aqueous soluble monomer and metal salt were mixed homogeneously in aqueous solution. When the system was γ-irradiated, polymerization and reduction took place simultaneously, leading to a homogeneous dispersion of nanocrystalline metal particles in a polymer matrix.

However, in the above method, the compatibility of monomer and metal salt or metal salt aqueous solution was of importance. The application of the method was restricted when the metal salt was insoluble in the monomer or monomer solutions. In addition, the dimension of the metallic nanoparticles was not uniform, and size control was difficult. Furthermore, the polymer–metal nanocomposites were water absorptive, limiting their practical applications.

Here we report a novel method for preparing polymer–metal nanocomposites in microemulsions using γ radiation at room temperature. It was found that products formed by this method contained not only well dispersed but also monodisperse metal nanoparticles.

A W/O microemulsion was produced with Span 80 (sorbitanol monooleate) and SDS (sodium dodecyl sulfate) as emulsifier. The metal salt was dissolved in water before producing the microemulsion, and monomers (styrene or butyl acrylate) were dissolved in toluene. In order to reduce the emulsifier content in the microemulsion, 2-hydroxy-α-methacrylate (HEMA) was used as coemulsifier and comonomer simultaneously.

An aqueous solution containing 8.5 mass% $AgNO_3$ was prepared in advance. 10 g of the solution was then added to a mixture of 48 g toluene, 19 g butylacrylate (BA), 10 g styrene (St), 3 g SDS and 5 g HEMA. Span 80 was titrated into the mixture under stirring until a transparent microemulsion suddenly formed. After bubbling with N_2, the microemulsion was irradiated in the field of a ^{60}Co γ-ray source for 6 h with a radiation dosage of 1.8×10^4 Gy. After irradiation, the brown, semi-transparent microemulsion was de-emulsified by acetone and distilled water. The products were washed with distilled water, dried and ground into powder for further analysis.

The size and morphology of the P(BA-co-St)–silver nanocomposites were investigated by transmission electron microscopy (TEM) (Fig. 1) and X-ray diffraction (XRD) analysis. TEM images were conducted using a Hitachi Model H-800 transmission electron microscope and XRD patterns were recorded by a D_{max} γ_A X-ray diffractometer with graphite-monochromated Cu-Kα radiation (λ = 0.154 178 nm), using an accelerating voltage of 200 kV.

Fig. 2 shows the XRD pattern of the same sample as Fig. 1. The broad peak at $2\theta \approx 19.8°$ is attributed to the diffraction of non-crystalline co-polymer. The other three peaks with 2θ values of 38, 44.5 and 64° correspond to three crystal faces of 111, 200 and 220 of metallic crystalline silver, respectively (cubic system, a = 4.101 Å). The broadening in diffraction peaks shows that the product consisted of small metallic particles. The average size of silver particles estimated by Scherrer's equation[8] is 8.5 nm, which is in good agreement with the TEM result.

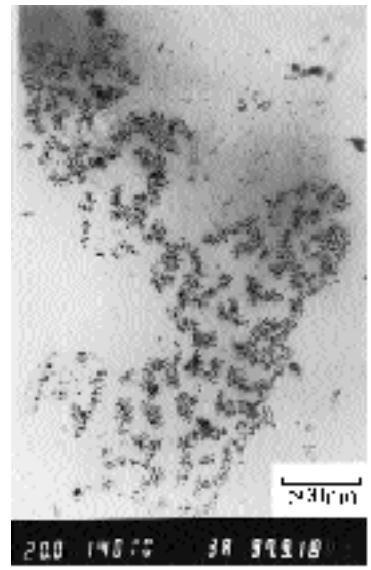

Fig. 1 TEM image of a poly(BA-co-St)–silver nanocomposite prepared by γ-irradiation of a microemulsion. Details in text.

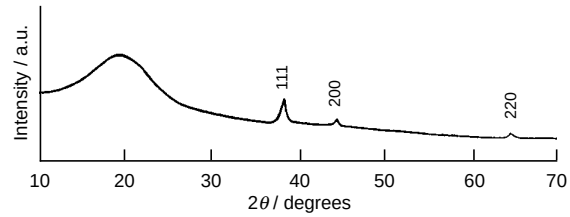

Fig. 2 XRD pattern of the same sample as in Fig. 1

In the conventional microemulsion method,[9,10] the metal salt was dissolved in one microemulsion system, and the reducing agent dissolved in another, in advance. When these two microemulsions were mixed together, only through interaction of two types of droplets could the metal ions be reduced to form metal clusters. However, control of particle size and distribution was difficult.

Another advantage of the new method is that polymerization of monomer and reduction of metal ions are both achieved by γ-irradiation. Radiolysis of the microemulsion system may produce radicals in the oil and aqueous phase. These radicals may effectively initiate the monomer in oil polymerization. Since the polymerization is a chain process it will be faster than the reduction process. With polymerization, the microemulsion system changes from liquid to viscous liquid, rubber or solid material, depending on the monomer type and the monomer content in the oil phase. The increase of the system's viscosity will certainly restrict water droplet aggregation and favour the synthesis of well-dispersed polymer–metal nanocomposites.

In summary, this novel method not only has all the advantages of the microemulsion and irradiation methods to produce metal nanoparticles, but also makes the process easier to control and gives near monodispersed nanoparticles. Furthermore, it makes it possible to synthesize versatile metal particles–polymer nanocomposites. It has advantages over the method developed in ref. 7, in which the monomer has to be soluble in water, because many more monomers are oil soluble than are water soluble. Moreover the composites prepared using oil soluble monomers have wider application.

STM observation of *N*-octadecylacrylamide and *N*-octadecylcinnamoylamide monolayers self-assembled on a graphite surface

Pu Qian,*[a]† § Hiroshi Nanjo,[a] Toshiro Yokoyama,[a] Tokuji Miyashita[b] and Toshishige M. Suzuki*[a]‡

[a] *Tohoku National Industrial Research Institute, 4-2-1 Nigatake, Miyagino-ku, Sendai, 983-8551 Japan*
[b] *Institute for Chemical Reaction Science, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai, 980-8577 Japan*

The STM observation of self-assembled *N*-octadecylacrylamide (ODA) and *N*-octadecylcinnamoylamide (ODC) on a graphite substrate clarified the head to tail alignment of the molecules and *s-trans* geometry of the alkene double bond and carbonyl group.

We have attempted to fabricate uniform Langmuir–Blodgett (LB) films having a well defined molecular orientation. In our previous study, we found that *N*-octadecylacrylamide (ODA) can form stable Langmuir monolayer and LB films on a solid substrate.[1–4] The X-ray diffraction study revealed that ODA forms two dimensional crystals in LB films.[5,6] Recently, we have observed the molecular arrangement of an ODA based LB film on a mica surface by atomic force microscopy (AFM) and obtained a molecular resolution image in which *N*-octyl chains are highly ordered to form two dimensional crystals.[7] The analysis of the AFM image and linear dichroism in polarized FTIR of the LB film[5,6] suggested that *N*-alkyl chains are tilted by *ca.* 28° against the film plane. Hydrogen bonding between ODA molecules was considered to be very important to stabilize the monolayer and the LB film. However direct evidence of intermolecular interaction between ODA molecules has not been clarified.

The scanning tunneling microscope (STM) is a powerful tool to image molecules at atomic resolution. Monolayers of physisorbed *n*-alkane and substituted alkanes on a flat substrate have been observed and the topological features of self-assembled two dimensional crystals discussed.[8–11] Different from LB films on mica, the molecules are aligned parallel to the graphite surface. This allows one to directly observe the molecular orientation and geometrical arrangement of monolayer. In the present study we applied the STM method to observe the molecular alignment of ODA molecules on the basal plane surface of highly oriented pyrolytic graphite (HOPG) to study their ordered structure and intermolecular interaction *in situ*. In addition, the molecular alignment of an ODA analogue *N*-octadecylcinnamoylamide (ODC) was also imaged.

ODA or ODC was dissolved in phenyloctane to near saturation and a drop of the solution was applied on the surface of freshly cleaved HOPG. The STM images were obtained in both constant current mode and constant height mode using Nano-Scope IIIa STM (Digital Instruments). The tunneling tip was a Pt–Ir tip purchased from Digital Instruments or a tungsten wire which was sharpened by electrolytical etching prior to use.

Fig. 1 shows the STM image of monolayer of ODA physisorbed on the HOPG surface (constant height mode). The two dimensional array of ODA molecules is clearly visible as stripes. The size of two dimensional crystals varies from a few 100 nm^2 to > 10 000 nm^2. Domain boundaries of adjacent crystals are observed with a rotation angle of 60°. This result suggests that ODA molecules are aligned by the influence of the graphite surface where the C–C–C atomic angle is 60°. Well ordered ODA molecules form stripe shaped lamella bands of *ca.* 2.7 nm width. A high resolution image of the monolayer is shown in Fig. 2 over a scan area of 8 × 8 nm (constant height mode). Increased brightness of the image corresponds to areas of higher electric conductance. Therefore the brighter parts can be attributed to the head groups containing conjugated π-electron systems and darker moieties to the alkyl chains. The molecular alignment is obviously in the head to tail structure. The alkene double bond appears to be downward to the molecular axis of ODA. The length of ODA observed along the molecular axis is roughly 2.7 nm which is consistent with that estimated by a CPK model. The separation of alkyl chains is *ca.* 0.47 nm. This value is slightly longer than that of two dimensional crystals of *n*-alkanes[8,9] presumably due to the presence of the bulky head group. The molecular axis of ODA

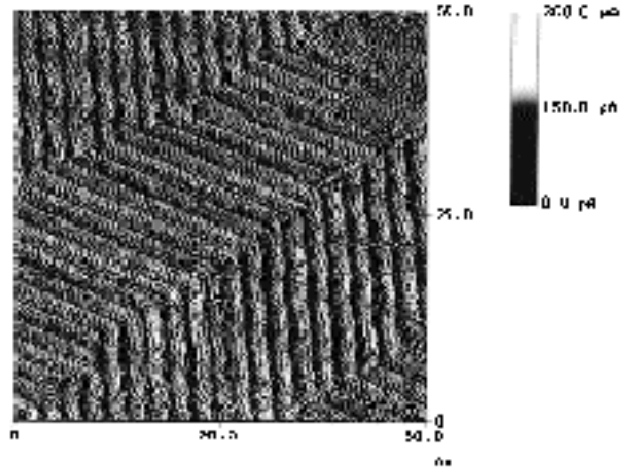

Fig. 1 STM image of a monolayer of ODA molecules self-assembled on a graphite surface. Image was taken in constant height mode. The area is 50 × 50 nm. Bias voltage is 1.1 V (tip positive) and current is 72 pA.

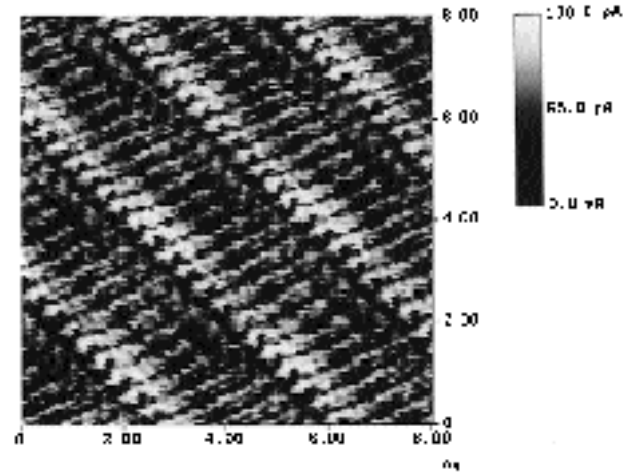

Fig. 2 STM image of a monolayer of ODA molecules self-assembled on a graphite surface. Image was taken in constant height mode. The scan area is 8 × 8 nm. Bias voltage is 1.0 V (tip positive) and current is 292 pA.

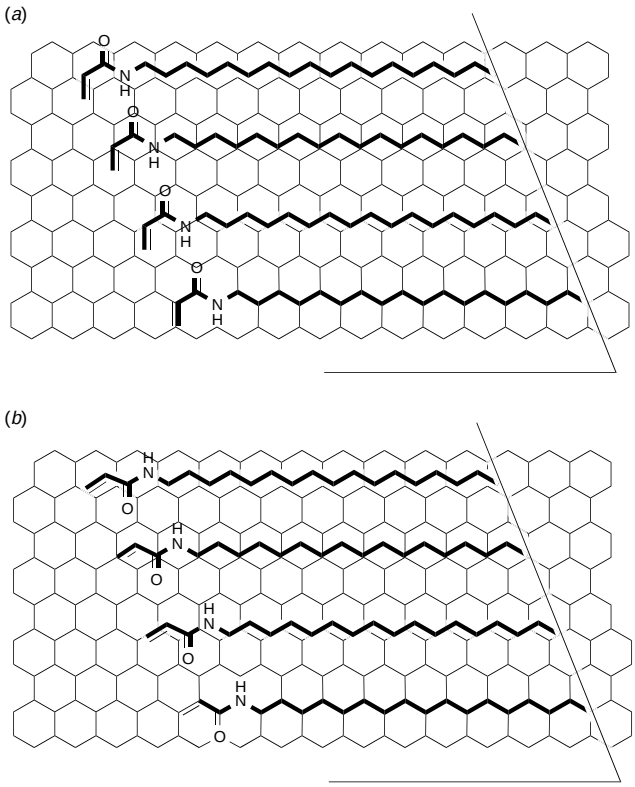

Fig. 3 Possible molecular arrangements of ODA with (*a*) an *s-trans* geometry and (*b*) an *s-cis* geometry, on a graphite surface. There are 18 carbon atoms in the alkyl chain of an ODA molecule.

appears to be inclined with an angle of *ca.* 70° *vs*. the orientation of the lamella band.

Possible molecular alignments of ODA on the graphite surface are schematically represented in Fig. 3(*a*) and 3(*b*) by which the observed inclination between the molecular axis of ODA and lamella band can be reproduced. Those two models are rotational isomers of ODA with respect to the amide group. The *s-trans* geometry [Fig. 3(*a*)] can consistently explain the observed alignment of ODA molecules where the intermolecular hydrogen bonds effectively link ODA molecules to form a molecular network. Such hydrogen bonds are unlikely to take place in *s-cis* geometry because the amide proton is then spatially remote from the carbonyl oxygen of an adjacent ODA molecule. The imaged morphology of the monolayer provides structural information of the constituent molecule and the observed inclination is very similar to that of the LB film deduced by FTIR and X-ray diffraction studies.[5,6]

Fig. 4 shows the high resolution STM image of ODC (scan area 8 × 8 nm, constant current mode) where a phenyl group is attached to an alkenic terminal of ODA. We can clearly distinguish the benzene rings and alkyl chains. The molecular ordering is again of head to tail structure as found in ODA. The head to tail distance is *ca.* 3.1 nm which agrees with the

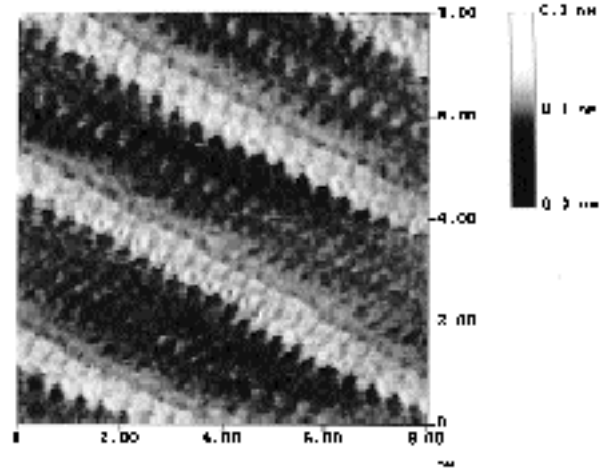

Fig. 4 STM image of a monolayer of ODC molecules self-assembled on a graphite surface. Image was taken in constant current mode. The scan area is 8 × 8 nm. Bias voltage is 0.85 V (tip positive) and current is 340 pA.

molecular length of ODC. Here also an inclination of ODA is observed against the lamella bands and the *s-trans* geometry around the amide group can explain the observed molecular arrangement.

The present STM observations have clarified the geometrical configuration of self-assembled ODA and ODC molecules where the intermolecular hydrogen bond in the amide group plays an important role in controlling the morphology of the molecular alignment.

Macromolecular tetrathiafulvalene chemistry

Martin R. Bryce,*† Wayne Devonport, Leonid M. Goldenberg and Changsheng Wang

Department of Chemistry, University of Durham, Durham, UK DH1 3LE

Recent developments in the functionalisation of tetrathiafulvalene (TTF) have enabled TTF units to be covalently linked into macromolecular systems. Convergent syntheses of dendrimers containing TTF units are presented, including a $(TTF)_{13}$ system in which TTF units are emplaced at all layers of the structural hierarchy. Thin layer cyclic voltammetry has established that the redox activity of TTF is retained in these macromolecules: sequential oxidation to the radical cation and dication occurs for all the TTF units, yielding highly-charged species in solution. Macromolecules comprising four and eight TTF units built around a phthalocyanine core are also described. These materials present novel architectures with the key property of multi-electron redox activity.

Tetrathiafulvalene—its molecular properties and functionalisation

Tetrathiafulvalene (TTF)[1,2] is famous as a π-electron donor in the field of organic molecular metals,[3] *e.g.* the complex TTF–TCNQ (TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane),[4] where the delocalised electrons responsible for conduction are derived from intermolecular charge transfer from TTF to the acceptor species. A few derivatives of TTF, notably bis(ethylenedithio)TTF (BEDT-TTF) form superconducting radical cation salts with closed shell anions,[5] *e.g.* the salt κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Br which superconducts at temperatures below a T_c value of 11.5 K.[6] BEDT-TTF is also a component of interesting magnetic materials.[7]

In view of the unabated interest during the past 25 years in the molecular chemistry of TTF derivatives,[2,5] it is striking that TTF has rarely been incorporated into polymeric systems.[8] In this context, the key properties of TTF which make it an interesting building block are these: (i) oxidation of the TTF ring system to the radical cation and dication species occurs sequentially and reversibly at a very accessible potential window in a range of organic solvents (for unsubstituted TTF, $E_1^{\frac{1}{2}}$ = +0.34 and $E_2^{\frac{1}{2}}$ = +0.78 V *vs*. Ag/AgCl in MeCN); (ii) the oxidation potentials can be finely tuned by the attachment of appropriate substituents; (iii) the TTF radical cation is thermodynamically very stable (due to 6π-electron heteroaromaticity of the 1,3-dithiolium cation); (iv) TTF derivatives and their derived cation radicals readily form dimers, highly-ordered stacks, or two-dimensional sheets, which are stabilised by intermolecular π–π interactions and non-bonded sulfur ···sulfur interactions; and (v) TTF is stable to many synthetic transformations, although it is important to avoid strongly acidic conditions and oxidising agents.

Macromolecular aspects of TTF chemistry have been neglected primarily because of the synthetic challenge of obtaining suitably functionalised TTF derivatives in reasonable quantities. This barrier has recently been overcome with major progress in three important branches of synthetic TTF chemistry: (i) TTF can now be readily synthesised in 20 g batches;[9] (ii) methodology involving electrophilic substitution of lithiated TTF has been optimised to afford facile entry into a wide range of mono-substituted derivatives in high yield;[10] and (iii) selective protection/deprotection chemistry of the thiolate groups of the 1,3-dithiole-2-thione-4,5-dithiolate (dmit) system (and derived TTFs) has been developed, primarily by Becher and co-workers,[11] to provide multi-gram quantities of versatile building blocks for highly-functionalised TTF systems, including supramolecular architectures.[12]

Our work breaks new ground in the synthesis and redox properties of monodisperse macromolecules containing multi-TTF functionality, and this short review article will highlight progress in this area. At the outset our aim was to synthesise structurally well-defined multi-electron redox systems, exploiting the known solubility enhancement in highly-branched macromolecules (compared to their linear counterparts). A longer term aim is to combine the properties of TTF, which have been stated above, with the beneficial properties of polymers, such as film formation and processability. It should be noted that from a similar viewpoint other polymeric TTFs have been synthesised.[8] In earlier work, disubstituted TTFs were condensed to form polyamides,[8*a*] polyesters[8*b*] and polyurethanes,[8*c*] some of which were oxidised to radical cation systems. More recently, some well-defined main chain and side chain polymeric TTFs have been obtained,[8*d–g*] including some electrochemically polymerised systems.[8*g*]

Constructing TTF dendrimers

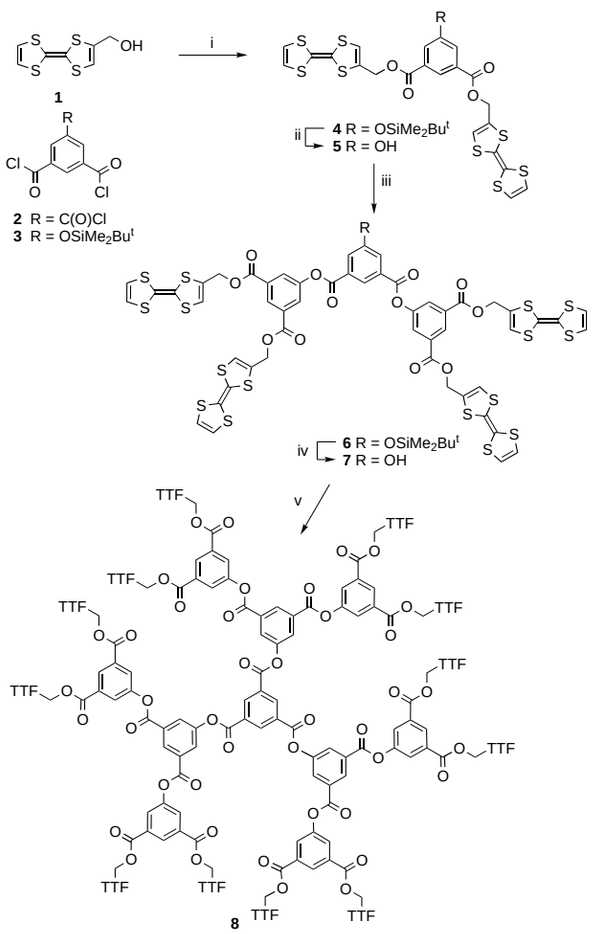
The study of dendrimers, cascade molecules and related hyperbranched systems is a rapidly-expanding topic in macromolecular science.[13] These materials comprise a multifunctionalised core, from which radiate repeating layers of monomers with a branch occurring at each monomer unit. They possess well-defined, three-dimensional structural order, and their size and architecture is precisely regulated in their synthesis, providing unique molecular frameworks for the disposition of functional groups in predetermined spatial arrangements. Initial research into dendrimers focused on obtaining higher generation systems with large molecular weights, whereas nowadays the emphasis is mainly on systems which incorporate functional groups at the exterior surface of, or embedded within, the dendrimer framework.[14] In the context of functional dendrimers, a variety of redox-active substituents have been built into the structures.[15,16] These materials are relevant to the development of: (i) new electron-transfer catalysts; (ii) studies on the dynamics of electron transport at surfaces and within restricted reaction spaces; (iii) new materials for energy conversion (iv) electronic and photo-optical materials; (v) organic magnets; and (vi) mimics of biological redox processes. The redox groups may behave independently in multi-electron processes (*n* identical non-interacting electroactive centres giving rise to a single *n*-electron wave) or they may interact intra- or inter-molecularly, in which case overlapping or closely-spaced redox waves are observed at different potentials.

Synthesis of arylester TTF dendrimers

In the first phase of our work on multi-TTF macromolecules, we synthesised aryl ester dendrimers functionalised with peripheral TTF groups.[17] 4-(Hydroxymethyl)-TTF **1**, which is readily available in multi-gram quantities,[10*a*] served as a convenient

starting material. A convergent strategy, based on a repetitive coupling/deprotection sequence, furnished dendrimer **8** comprising a 1,3,5-benzene triester core (derived from reagent **2**) and surface-functionalised with 12 TTF units. (In a convergent synthesis,[18] dendrimer construction begins at what will become the surface of the molecule, and progresses inwards *via* a series of dendron wedges of increasing size, several of which are attached to the core unit in the final step.) We used 5-(*tert*-butyldimethylsiloxy)isophthaloyl chloride **3**[19] as the functionalised reagent for the esterification reactions to build up successive generations.

The synthesis of the $(TTF)_{12}$ dendrimer **8** is shown in Scheme 1. The reaction of **1** with reagent **3** gave compound **4** (83% yield), deprotection of which (TBAF in THF at room temperature) afforded the bis(TTF) derivative **5** (85% yield) as a dendron wedge carrying the phenolic group as a reactive handle for further reactions. Following the same procedures that gave compounds **4** and **5**, reaction of 2 equiv. of alcohol **5** with reagent **3** yielded **6** (76% yield) and then $(TTF)_4$ dendron wedge **7** in 95% yield. Compound **7** reacted with the core reagent **2** to give the target dendrimer **8** in 48% yield.



Scheme 1 *Reagents and conditions*: i, NEt_3, **3**, CH_2Cl_2, 20 °C; ii, TBAF, THF, 20 °C; iii, DMAP, **3**, CH_2Cl_2, 20 °C; iv, TBAF, THF, 20 °C; v, DMAP–$PhNMe_2$, **2**, CH_2Cl_2, 35 °C

Within this series of macromolecules, stability decreased with increasing generation, so no attempts were made to assemble molecules of higher molecular weight than **8**. Macromolecule **8** is an oil which is readily soluble in polar organic solvents. It is reasonably stable to storage at < 0 °C; however, when stored at room temperature, even in the dark and under an argon atmosphere, it decomposed after a few days. ^{1}H NMR spectroscopy and plasma desorption mass spectra (PDMS) were entirely consistent with structure **8**. The energy-minimised conformation of compound **8** is shown in Fig. 1: it is notable that all the TTF groups are exposed and, therefore, are available to participate in redox processes. (The proviso must be made that the conformation may be very solvent dependent.) The instability of **8** is possibly due to the high density of ester groups in the interior of the molecule.

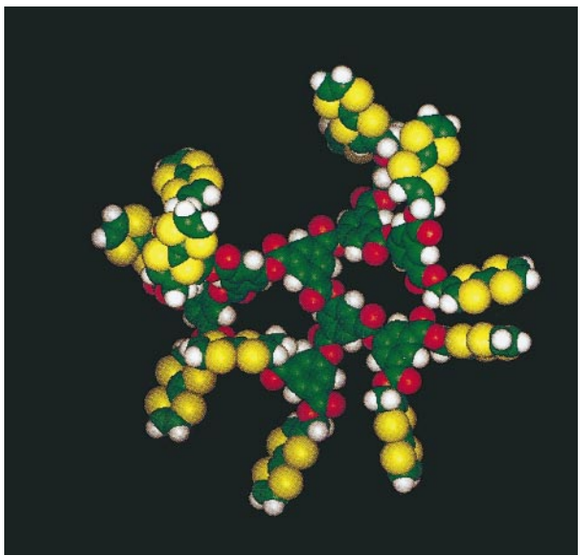


Fig. 1 Energy minimised conformation of **8**. Green = carbon; white = hydrogen; red = oxygen; yellow = sulfur.

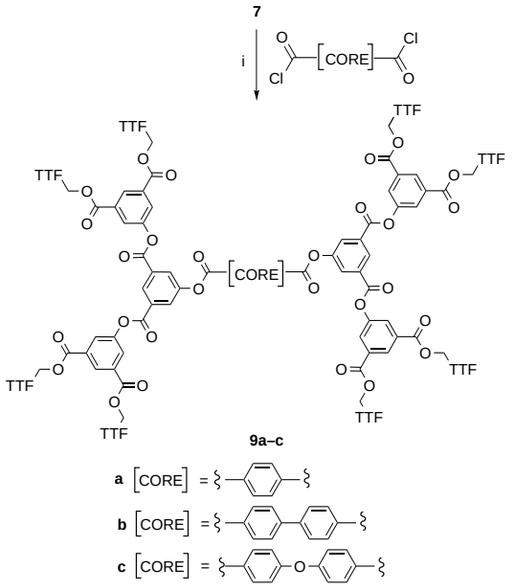
With a view to improving the stability of the $(TTF)_x$ aryl ester dendrimers, we changed from trifunctional to bifunctional core units, to obtain more 'open' structures. Thus, using terephthaloyl chloride, biphenyl-4,4′-dicarbonyl dichloride and 4,4′-oxydibenzoyl dichloride as core reagents, the series of $(TTF)_8$ systems **9a–c** was constructed.[17b,20] These three compounds were all stable upon storage at room temperature in air and daylight for at least one year. However, the compounds containing the benzene and biphenyl cores, *viz*. **9a** and **9b**, were only sparingly soluble in organic solvents, whereas analogue **9c**, with the more flexible biphenyl ether core unit, showed good solubility in polar organic solvents (*e.g*. acetone and CH_2Cl_2).

Synthesis of *p*-xylyl TTF dendrimers

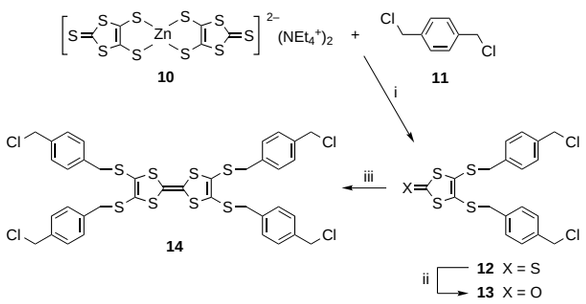
The use of entirely different building blocks afforded a second genre of TTF dendrimers, culminating in the synthesis of the macromolecule **21** comprising thirteen TTF units.[21] The special features of this work are that: (i) TTF units are emplaced at all layers of the structural hierarchy (unlike compounds **8** and **9**); and (ii) compound **14** was introduced as a new, readily-accessible (in multi-gram quantities) building block for TTF chemistry. The synthesis of **14** is shown in Scheme 3.

Zincate salt **10**,[22] which is a well-known precursor to the 1,3-dithiole-4,5-dithiolate dianion,[11b] reacted with α,α′-dichloro-*p*-xylene **11** to yield 4,5-disubstituted 1,3-dithiole-2-thione derivative **12** (60% yield) which was converted into the ketone **13** (84% yield) using mercuric acetate. Compound **14** was then synthesised in 78% yield by self-coupling of **13** in the presence of $P(OEt)_3$ under standard conditions,[23] and isolated as orange crystals. Compound **14** is our four-directional core reagent, and displacement of the benzylic chlorines of **14** by thiolate anions proved to be a facile process. For this purpose, we identified **20** as a suitable wedge from which a reactive thiolate anion could be generated, following the protocol developed by Becher *et al*. for related cyanoethyl-protected TTF-thiolate systems.[11]

Compound **16** was prepared in high yield by the literature route from **15**,[11a] and converted into ketone **17** (98% yield) using $Hg(OAc)_2$ (Scheme 4). Cross-coupling of equimolar



Scheme 2 *Reagents and conditions*: i, DMAP–PhNMe$_2$, **3**, CH_2Cl_2, 35 °C

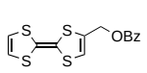


Scheme 3 *Reagents and conditions*: i, acetone reflux; ii, $Hg(OAc)_2$, $CHCl_3$–AcOH, 20 °C; iii, $P(OEt)_3$, 120 °C

amounts of thione **12** and ketone **17**, in the presence of $P(OEt)_3$, gave compound **18** in an optimised yield of 45%. The benzylic chlorides of compound **18** were then displaced by the thiolate derived from compound **19** (prepared by direct analogy with **18**) to afford **20** in 74% yield. The caesium thiolate salt of **20** (4 equiv.) reacted cleanly with compound **14** to furnish the $(TTF)_{13}$ macromolecule **21** in 66% yield, as an air-stable yellow–brown solid, which was soluble in polar organic solvents. Compound **21** was characterised unambiguously by a combination of elemental analysis, MALDI TOF mass spectrometry [which showed the parent ion peak at *m/z* 7377 (M^+: calc. for $C_{314}H_{276}S_{104}$ = 7372)] and ^{1}H NMR spectroscopy.

Redox properties of $(TTF)_x$ dendrimers

An important aspect of this work was to evaluate the solution redox properties of these macromolecules, for which we have used a variety of electrochemical techniques, *viz.* cyclic voltammetry (CV) using conventional disc platinum electrodes, CV using platinum ultra-microelectrodes (UME CV), chronoamperometry (CA) and thin layer cyclic voltammetry (TLCV). CV data are collated in Table 1 for a selection of the new compounds, together with TTF and the model TTF phenyl ester derivative **22** for comparison.



22

Table 1 Solution electrochemical data obtained by CV[a]

Compound	Solvent	$E_1^{\frac{1}{2}}$/V	$E_2^{\frac{1}{2}}$/V
TTF	MeCN–CH_2Cl_2 (1 : 1)	0.34	0.71
TTF	PhCN	0.34	0.78
5	MeCN–CH_2Cl_2 (1 : 1)	0.42	0.81
7	MeCN–CH_2Cl_2 (1 : 1)	0.42	0.81

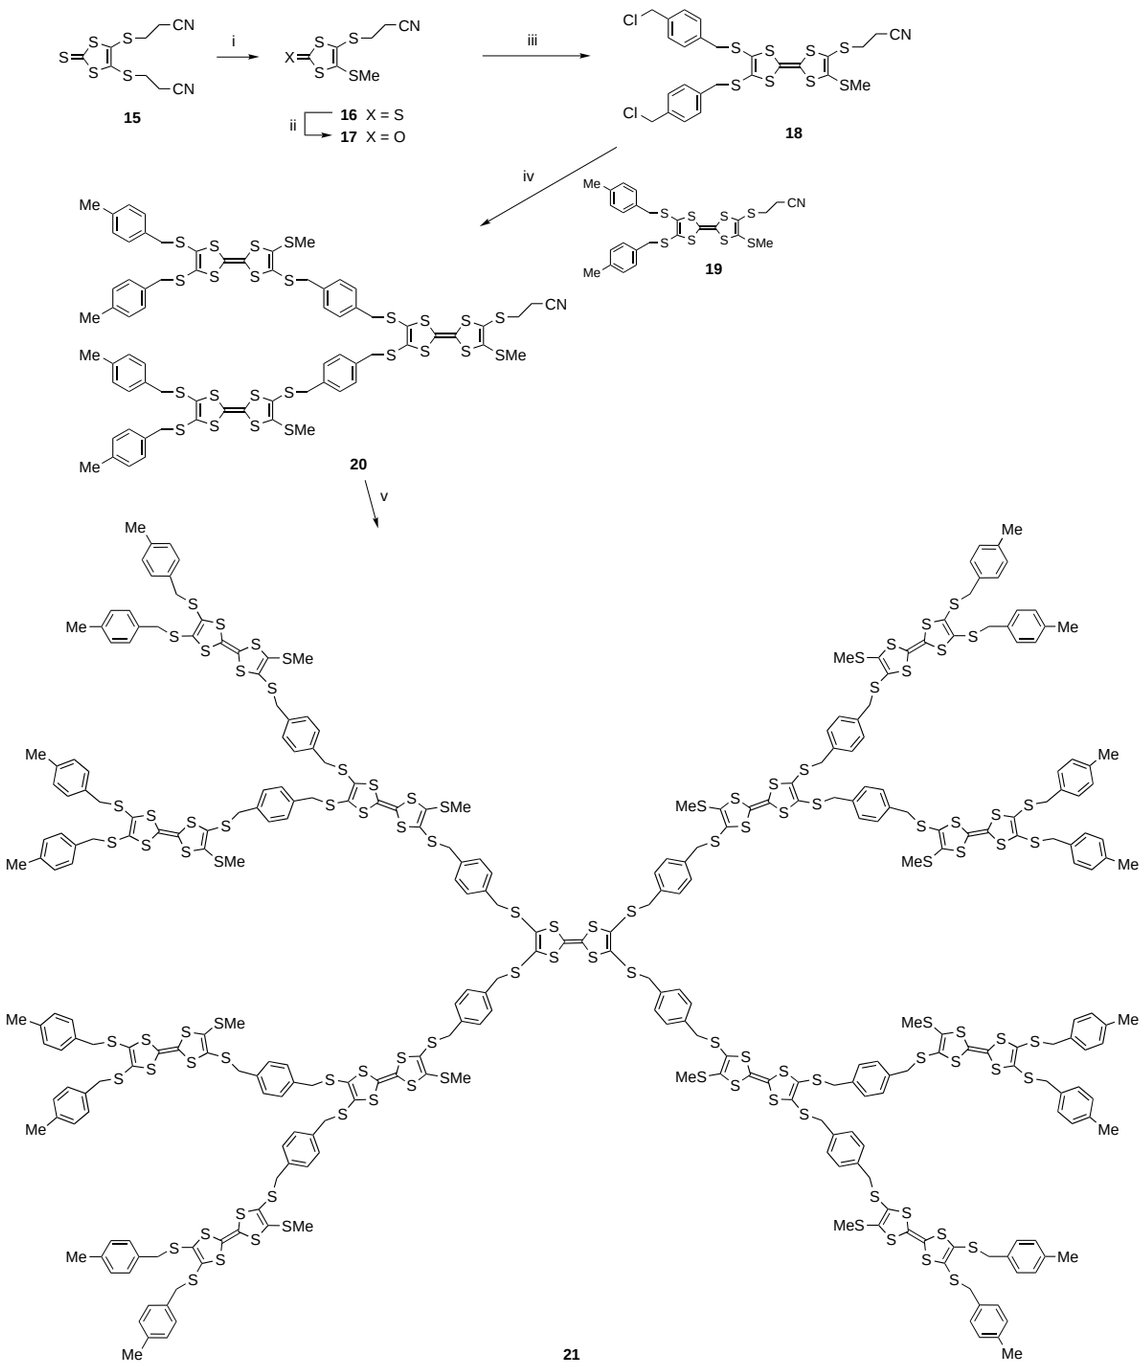
[a] Data were obtained at 20 °C under argon using a platinum working electrode (1.6 mm diameter) and a platinum wire counter electrode, compound (*ca.* 5×10^{-4} M), electrolyte = Bu_4N^+ PF_6^- (0.1 M); scan rate = 100 mV s^{-1} *vs.* Ag/AgCl.

These experiments established that all the compounds exhibited two redox couples typical of the TTF system (*i.e.* the sequential formation of the TTF radical cation and the dication).[24] The direct attachment of an ester substituent to TTF (*i.e.* TTF-CO_2R) is known to raise both the first and second oxidation potentials:[10c,25] surprisingly, a quantitatively similar effect is observed for compound **22**. This substituent effect accounts for the increased oxidation potentials of multi-TTF systems **5**, **7**, **8** and **9c**, compared to TTF. The attachment of alkylsulfanyl substituents to TTF also raises the oxidation potential[24] (an additive effect has been noted for one, two and four alkylsulfanyl substituents)[26] and this gives rise to the consistent anodic shift in the values of E_1 and E_2 for compounds **14**, **20**, **21**, in which each TTF unit contains four alkylsulfanyl groups, relative to TTF under the same conditions. For the *p*-xylyl TTF systems **14**, **20** and **21**, the redox waves were reversible. Within the aryl ester series, reversibility was observed only with the mono- and bis-(TTF) derivatives **22** and **5**, respectively: for the higher oligomers **7**, **8** and **9c**, slightly increased peak separations at higher scan rates were observed, consistent with quasi-reversible behaviour.

A general trend with our aryl ester TTF macromolecules is that as the number of TTF units increases, the first redox wave broadens slightly and the second wave sharpens.[17b] Similar behaviour has been reported previously for TTF amides immobilised on RuO_2 or PtO_2 surfaces,[27] and the data can be explained by adsorption or precipitation on the electrode surface. The CV and UME CV of $(TTF)_{12}$ system **8**, which are representative, are shown in Figs. 2(*a*) and (*b*), respectively.

The electrochemistry of the stable macromolecules **9c** and **21** has been studied using TLCV techniques.[28] In contrast to conventional CV, in TLCV the current is not limited by the mass transport to the electrode. Integrating the voltammetric waves against the one-electron reduction peak of the internal standard 2,3-dichloronaphthoquinone (DCNQ) provides convincing evidence that complete oxidation occurs for all the TTF units in these compounds. We note that the second TTF oxidation wave is slightly narrower than the first wave, which could be due to adsorption phenomena. Fig. 2(*c*) shows the TLCV of compound **9c** in the presence of DCNQ. We have established that TLCV is the most reliable method for assessing the extent of oxidation of multi-TTF derivatives in solution.[17b,21] These macromolecules provide some of the first all-organic dendritic poly(radical cations) and poly(dications). Almost all other workers in the field decided to include metal centres as redox active species,[15] although naphthalene diimides have been attached to PAMAM dendrimers to form poly(radical anions),[29] and interior anthraquinone units have been studied.[30]

We have also studied the chemical oxidation of the stable $(TTF)_8$ macromolecule **9c**.[17b] UV–VIS Spectroscopy is a convenient method for monitoring the formation of TTF radical



Scheme 4 *Reagents and conditions*: i, $CsOH.H_2O$ (1 equiv.), DMF–MeOH, 20 °C, followed by MeI; ii, $Hg(OAc)_2$, $CHCl_3$–AcOH, 20 °C; iii, **12**, $P(OEt)_3$, 125 °C; iv, **19**, $CsOH·H_2O$ (1 equiv.), DMF–MeOH, then **18**, 20 °C; v, $CsOH·H_2O$, DMF–MeOH, then **14**, 20–80 °C

cations, which have a characteristic absorption band at λ_{max} 580 nm for unsubstituted TTF.[31] As mentioned earlier, oxidised TTF units can form dimers or stacks, and they display lower energy absorptions, *e.g.* 830 nm for $(TTF^{+\cdot})_2$ dimers.[31b] The UV–VIS spectrum for **9c** in CH_2Cl_2 showed significant changes upon addition of I_2 to the solution: new broad absorption bands appeared at λ_{max} 525 and 830 nm. The higher energy band is consistent with the formation of isolated (non-interacting) TTF radical cations, while the lower energy band suggests the existence of interacting dimers. Dilution studies established that the absorption coefficient of the latter band decreased with increasing dilution; it is, therefore, assigned to an intermolecular dimer band. These data provide evidence that the oxidised macromolecules self-associate in solution, by virtue of intermolecular interactions of their peripheral TTF radical cations. The relatively rigid and short aryl ester branching units in **9c** presumably disfavour intramolecular dimerisation.[32] Intermolecular self-association of dendrimers by hydrogen-bonding[33] or coordinative bonds[34] has also been reported recently.

A phthalocyanine core with pendant multi-TTF functionality

Prompted by our increasing knowledge of the synthesis and redox properties of TTF dendrimers possessing aryl ester and TTF cores, reported above, we have investigated closely related macromolecules with core units of increased complexity, *e.g.*

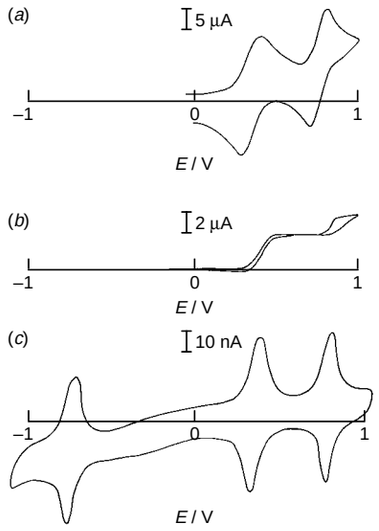


Fig. 2 Solution electrochemistry: (*a*) CV of **8** (solvent = MeCN, electrolyte = $Bu_4N^+PF_6^-$, Pt electrode, *vs*. Ag/AgCl, scan rate = 100 mV s^{-1}); (*b*) UME CV of **8** [solvent = MeCN–CH_2Cl_2 (1 : 1 v/v) electrolyte = $Bu_4N^+PF_6^-$, Pt electrode, *vs*. Ag/AgCl, scan rate = 20 mV s^{-1}]; (*c*) TLCV of **9c** (0.5×10^{-4} M) and 2,3-dichloronaphthoquinone (4.0×10^{-4} M) as internal reference (which gives rise to the wave at negative potential) in 1 M $Bu_4N^+PF_6^-$, solvent = CH_2Cl_2, *vs*. Ag/Ag^+, scan rate = 10 mV s^{-1}

phthalocyanines. It is envisaged that combining the versatile electrochemical, optical and coordination properties of phthalocyanines,[35] with the redox properties of pendant multi-TTF functionality should provide novel optoelectronic materials. In the longer term, the tendency of both phthalocyanines and TTFs to self-assemble by face-to-face π–π stacking, and the potential for coordinatively linking metallophthalocyanines to form stable polymers, might be harnessed to afford nanometer-sized molecular wires and cables, which could be electronically and/or ionically conducting.[36]

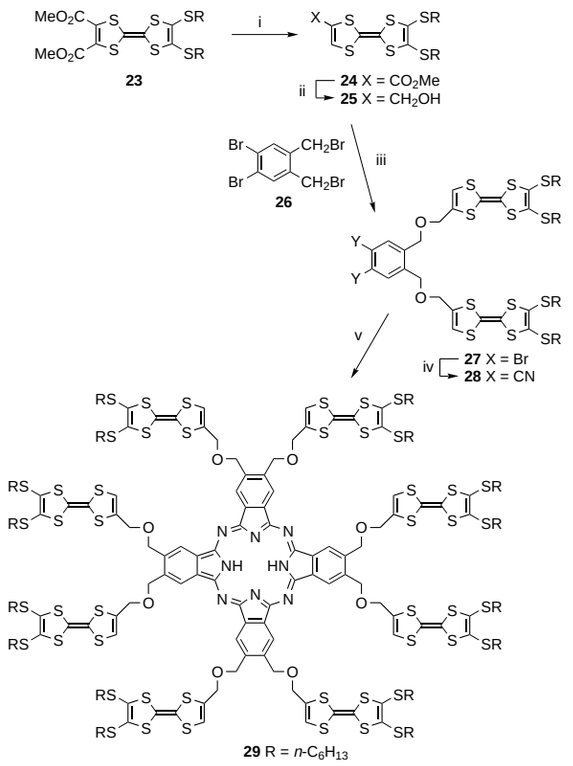
Synthesis of prototype Pc-$(TTF)_8$ and Pc-$(TTF)_4$ systems

The simplest methodology to symmetrically substituted phthalocyanines involves tetramerisation of a phthalonitrile precursor.[37] We, therefore, targeted compound **28**, with peripheral hexylsulfanyl substituents to impart solubility.[38] The synthesis is shown in Scheme 5.[39] TTF derivative **23** was obtained in 63% yield from readily available 1,3-dithiole half-units by cross-coupling methodology. One of the ester substituents on **23** was removed by treatment with LiBr in HMPA at 80 °C,[40] to afford monoester derivative **24** (88% yield) which was reduced with DIBAL-H to yield the alcohol derivative **25** (86% yield). The alkoxide ion of **25** (2 equiv.) reacted with 2,3-dibromo-4,5-di(bromomethyl)benzene **26** to yield the bis(TTF) system **27** (64% yield) which upon reaction with CuCN in DMF at 140 °C produced phthalonitrile derivative **28** (28% yield), this being the most problematical step in the whole Scheme. Tetramerisation of **28** to furnish the Pc-$(TTF)_8$ derivative **29** (56% yield) was achieved upon reaction with lithium pentanolate in pentanol at 125 °C. Analogous chemistry gave the Pc-$(TTF)_4$ system **30**.[39]

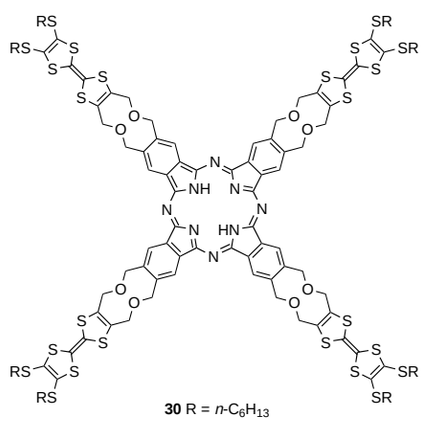
Compounds **29** and **30** were both isolated as dark green solids, which were soluble in a range of organic solvents (*e.g.* $CHCl_3$, CS_2, CH_2Cl_2 and toluene) but insoluble in alcohols, MeCN and DMF. Spectroscopic data, elemental analysis and MALDI TOF mass spectra were entirely consistent with the proposed structures.

Spectroscopic and electrochemical studies

Evidence for supramolecular aggregation of **29** and **30** was obtained from ^{1}H NMR and UV–VIS spectroscopic studies.[39] The ^{1}H NMR spectra of **29** and **30** at 20 °C in $CDCl_3$ gave broad



Scheme 5 *Reagents and conditions*: i, LiBr, HMPA, 80 °C; ii, DIBAL-H, THF, −78 to 20 °C; iii, NaH, THF, 40 °C, then **26**, 20 °C; iv, CuCN, DMF, 140 °C; v, lithium pentanolate, pentanol, 125 °C



signals with no fine structure: ^{13}C NMR spectra were obtained at 50 °C in $CDCl_3$ and the signals for compound **29** were much sharper than those for compound **30**, suggesting that the latter compound is more aggregated in this solvent at the relatively high concentration of the NMR sample. No ESR signals were observed for either compound, suggesting that the broad NMR spectra were not due to radical impurities.

UV–VIS spectra of compounds **29** and **30** dissolved in a mixture of toluene and pyridine (99 : 1 v/v) at 20 °C are shown in Fig. 3. The split Q-band, which is characteristic of a metal-free phthalocyanine, is observed at λ_{max} 665 and 700 nm (for compound **29**) and at λ_{max} 674 and 709 nm (for compound **30**). The additional broader hypsochromically-shifted band at λ_{max} 636 (for **29**) and 648 (for **30**) is indicative of aggregated species.[36*a*]

The luminescence emission from compounds **29** and **30** was found to be of very low intensity and fell in the same spectral region as that of unsubstituted metal-free phthalocyanines.

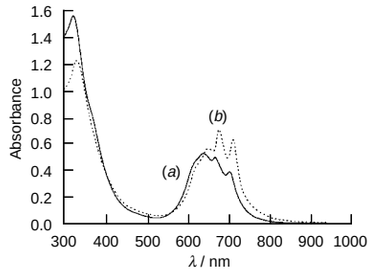


Fig. 3 UV–VIS spectra of (*a*) **29** (1.18×10^{-5} M) and (*b*) **30** (1.44×10^{-5} M) in toluene–pyridine (99 : 1 v/v)

Fluorescence quantum yields were $< 10^{-4}$ and $1.7 \pm 0.3 \times 10^{-4}$ for **29** and **30**, respectively. These values are very much lower than that obtained for a metal-free Pc lacking the TTF moieties, *cf.* Bu_4PcH_2 ($\Phi = 0.50$). We demonstrated that the fluorescence from Bu_4PcH_2 is efficiently quenched by the addition of TTF to the solution: in toluene the rate constant for this process was found to be diffusion controlled, $k_Q(1.1 \pm 0.1) \times 10^{10}$ $dm^3\ mol^{-1}\ s^{-1}$. Quenching in the tethered compounds **29** and **30** is, therefore, ascribed to rapid intramolecular electron transfer between the excited singlet state of the Pc core and a peripheral (neutral) TTF acting as an electron donor group. It will be interesting to explore if the fluorescence can be switched on when the TTF units are oxidised.

Solvent-dependent CV data were obtained for systems **29** and **30**. In PhCN, compound **29** exhibits the expected two TTF redox waves at $E_1^{\frac{1}{2}}$ +0.50 and $E_2^{\frac{1}{2}}$ +0.87 V (*vs.* Ag/AgCl) together with a third irreversible oxidation peak at +1.18 V (the corresponding reduction is not seen on the reverse sweep), and on the cathodic sweep a reduction peak is observed at $E^{\frac{1}{2}}$ −0.51 V. Based on literature precedents,[41] we assign these additional redox waves to a single-electron oxidation and reduction, respectively, of the phthalocyanine core unit. The electrochemistry of **30** was qualitatively similar to **29**, although the redox waves of the Pc unit were more discernable in CH_2Cl_2 than in PhCN, and they are clearly seen in the differential pulse voltammogram (DPV). The CV and DPV for **30** in CH_2Cl_2 are shown in Figs. 4(*a*) and (*b*), respectively.

Based on the CV peak current for compounds **29** and **30**, we suggest that all the TTF units are oxidised, although for compound **29** especially, the second TTF wave was less intense than the first wave. The solvent dependency of the electrochemistry and the UV–VIS spectra of these compounds suggests that the conformation and/or extent of aggregation vary considerably with the solvent. We have obtained qualitatively similar data for a pyrazinoporphyrazine system with eight appended TTF groups.[42]

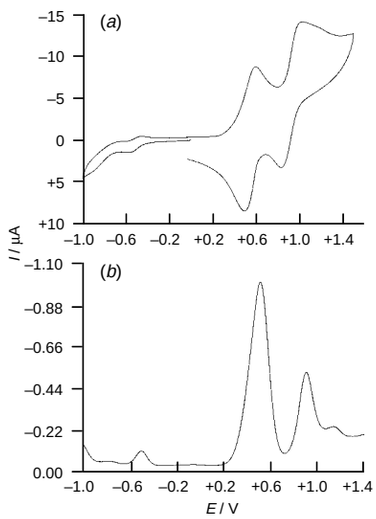

Fig. 4 (*a*) Cyclic voltammogram of **30** in CH_2Cl_2. Pt disc working electrode, 1.6 mm diameter; Pt wire counter electrode, *vs.* Ag/AgCl. Supporting electrolyte = 0.1 M $Bu_4N^+PF_6^-$; scan rate = 100 mV s^{-1}. (*b*) Differential pulse voltammogram of **30** in CH_2Cl_2: sample width = 8 ms; pulse amplitude = 50 mV; pulse width = 10 ms; pulse period = 200 ms; electrodes as Fig. 4(*a*).

Conclusions and future prospects

It is intended that this article will reinforce the fact that TTF is an interesting building block for covalent attachment into a variety of macromolecular assemblies. The synthesis of these multi-TTF systems would have been virtually impossible prior to the recent developments in synthetic methodology which have made available the functionalised TTF starting materials in multi-gram quantities. The materials described herein are tractable and amenable to unambiguous characterisation by standard spectroscopic, mass spectrometric and analytical techniques: they also possess aesthetically pleasing structures. If insolubility of the TTF system is a problem, this can be readily overcome by attachment of alkylsulfanyl chains (*e.g.* compound **29**). This substitution slightly raises the oxidation potential, which for our compounds generally has the added benefit of increased stability to acids and oxidising agents.

These materials present novel macromolecular architectures, with controlled emplacement of TTF groups, and our attention has focused on establishing their multi-electron redox activity. This work paves the way for combining the unique properties of the TTF molecule, which have fascinated scientists in the field of molecular solid state chemistry for over 25 years, with the beneficial properties of polymers, such as film formation and processability, to provide new optoelectronic materials.

Our results suggest interesting targets for future synthetic studies. Unsymmetrical systems, *i.e.* macromolecules constructed by the attachment of different wedges to the core units, are unexplored: in particular, combinations of different substituted TTF units with a strong gradient of redox properties, or π-donor and π-acceptor wedges within the same dendrimer structure, could lead to vectoral electron transport. The study of intra- and inter-dendrimer π–π stacking interactions of oxidised TTF units also promises to be a fruitful line of research.

We thank the EPSRC for funding (W. D. and C. W.) and the Royal Society for financial support (L. M. G.).

Martin Bryce was born in Sutton Coldfield, UK in 1953. He obtained a BSc from Wolverhampton Polytechnic and a DPhil from York University, under the supervision of Drs P. Hansen and J. M. Vernon. He was a postdoctoral fellow with Professor L. Weiler (University of British Columbia) and Professor R. W. Alder (University of Bristol). He was appointed as a Senior Demonstrator at Durham University in 1981, and subsequently as a Lecturer, Senior Lecturer, Reader and Professor of Chemistry (in 1995). In 1988 he was a Visiting Scientist at the Univesity of California, Santa Barbara, working in Professor Wudl's group. He has received the Bader Award and the Interdisciplinary Award from the Royal Society of Chemistry, and a Nuffield Foundation Research Fellowship. His research interests embrace the synthesis of new organic materials with unconventional electrical, optical and magnetic properties, supramolecular chemistry and new synthetic methodology.

Wayne Devonport was born in Barnsley, UK in 1970. He obtained his BSc from Bradford University, and a PhD from Durham University for work on the synthesis of TTF dendrimers. He then held a postdoctoral post at IBM, San Jose, and is currently employed as a research chemist at the Cabot Corporation, near Boston, USA. His research interests focus on well-defined surface modifications by organic and polymeric substrates.

Leonid Goldenberg was born in Zaporozh'e, Ukraine in 1957. He obtained his PhD for work on TTF salts at the Institute of

Chemical Physics of the USSR Academy of Sciences in Chernogolovka, where he is currently a Senior Research Fellow. He has recently been a visiting scientist at Durham University, working on organic thin films and the electrochemistry of charge-transfer materials.

Changsheng Wang was born in Hebei, China in 1963. He obtained his PhD for work on heterocyclic synthesis at Nankai University, China. He joined the faculty of Tsinghua University in 1988 and is currently working at Durham University with Professor Bryce on dendrimer and polymer synthesis.

Slow diffusion of aqueous solutions containing $K_4[Mo^{III}(CN)_7]\cdot 2H_2O$ and a Mn^{II} salt, respectively, affords well shaped single crystals of two cyano-bridged bimetallic phases ordering ferromagnetically with a pronounced magnetic anisotropy in the magnetically-ordered phase.

Bimetallic hexacyanometallate compounds involving 3d metal ions, of the Prussian Blue type, are interesting materials at the frontier between solid state and molecular chemistry.[1–6] As a matter of fact, all their magnetic characteristics (nature of the interaction between nearest neighbors, saturation magnetization, coercivity) are nicely in line with the theoretical models developed in molecular magnetism,[7,8] in particular as far as the symmetry rules involving the magnetic orbitals are concerned.[9] However, these compounds have some drawbacks. First, nobody, as yet, has succeeded in growing single crystals suitable for thorough physical measurements; secondly, their crystal structure as deduced from X-ray powder patterns is cubic, so that they exhibit no magnetic anisotropy. Here, we report on two new cyano-bridged bimetallic species obtained as well shaped single crystals, exhibiting long-range ferromagnetic ordering along with pronounced magnetic anisotropy.

Slow diffusion in a H-shaped tube under nitrogen of two deoxygenated aqueous solutions containing $K_4[Mo(CN)_7]\cdot 2H_2O$[10] and $Mn(NO_3)_2\cdot 6H_2O$, respectively, afforded two kinds of single crystals, with elongated plate (α phase) and prism (β phase) shapes, respectively. Both phases are air sensitive, and all the magnetic investigations were carried out with either single crystals protected by a grease envelop or powder samples placed in quartz tubes sealed under vacuum.

The crystal structures of both phases were solved.‡ The local environments of the metal sites are similar, but the three-dimensional organizations are different. There is one molybdenum and two manganese sites. The molybdenum atom is surrounded by seven C–N–Mn linkages. All the cyano groups are bridging. The coordination polyhedron may be viewed as a distorted pentagonal bipyramid.[11,12] The two manganese sites are in distorted octahedral surroundings. The manganese atom Mn1 is surrounded by four N–C–Mn linkages and two water

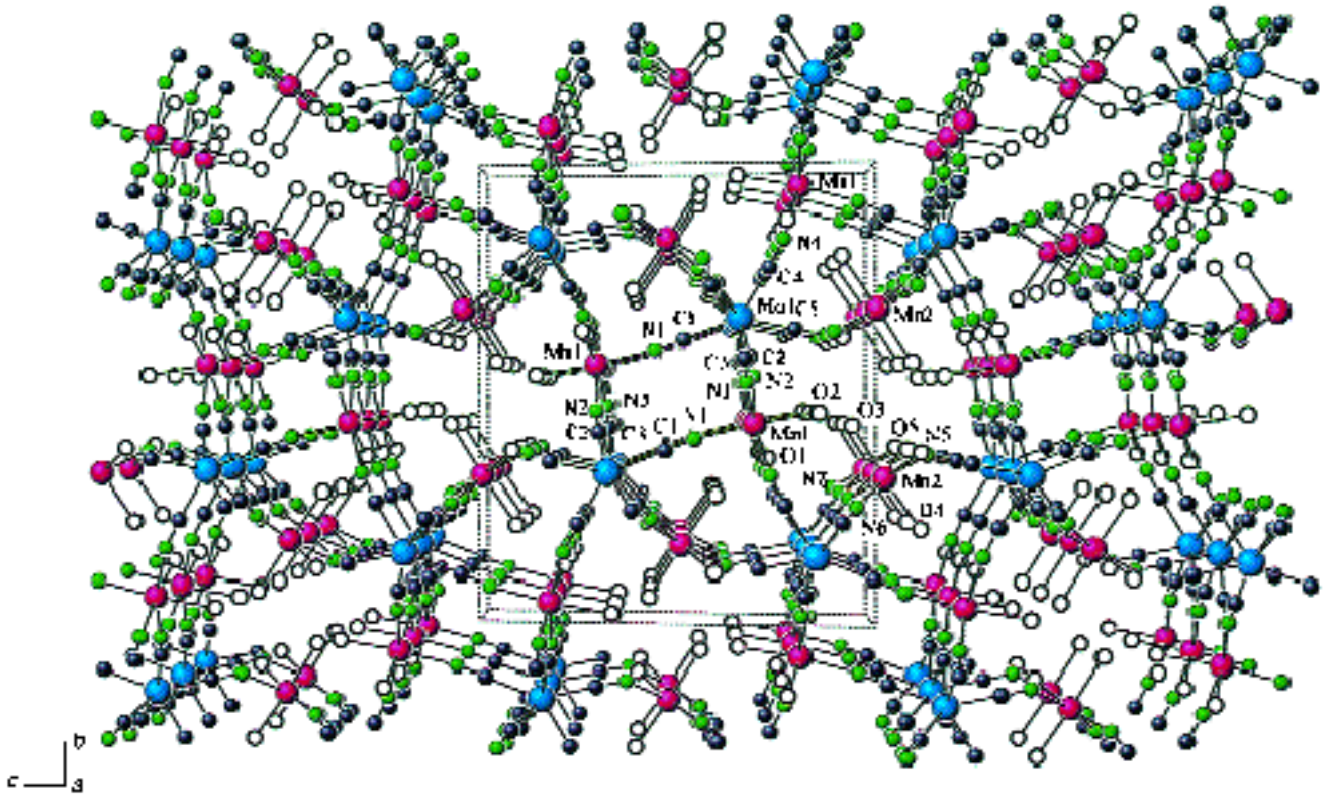

Fig. 1 Crystal structure of $Mn(H_2O)_5Mo(CN)_7\cdot 4H_2O$ (α phase). The manganese atoms are in red, the molybdenum atoms in blue, the oxygen atoms in white, the nitrogen atoms in green, and the carbon atoms in black. The non-coordinated water molecules are omitted for clarity. The Mo–C bond lengths range from 2.127(4) to 2.174(4) Å, the Mn–N bond lengths from 2.181(4) to 2.242(3) Å and the Mn–O bond lengths from 2.195(4) to 2.308(4) Å.

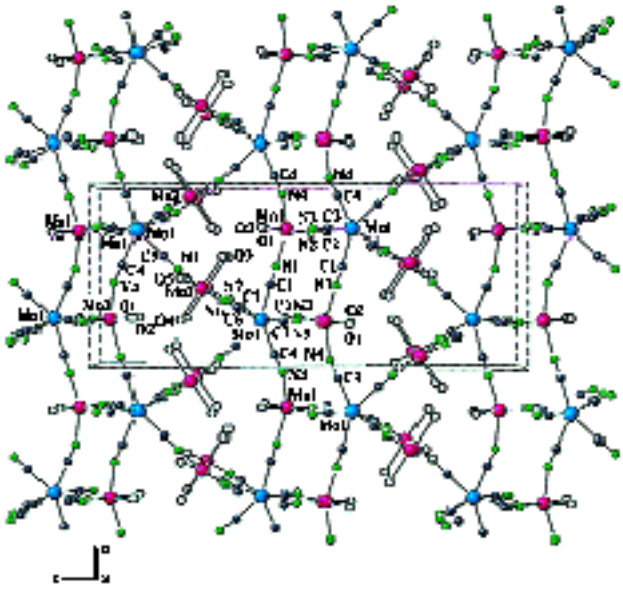

Fig. 2 Crystal structure of $Mn(H_2O)_5Mo(CN)_7{\cdot}4.75H_2O$ (β phase). The color codes are the same as in Fig. 1. The non-coordinated water molecules are omitted for clarity. The Mo–C bond lengths range from 2.110(7) to 2.191(7) Å, the Mn–N bond lengths from 2.158(5) to 2.190(6) Å and the Mn–O bond lengths from 2.223(6) to 2.350(5) Å.

molecules, and the manganese atom Mn2 is surrounded by three N–C–Mo linkages and three water molecules. The structural arrangements may be described as cyano-bridged $Mo1_2Mn1_2$ lozenge motifs linked to each other through two cyano bridges along the *a* axis direction to form a sort of accordion. The Mn2 atoms, located between the accordions, are linked to two molybdenum atoms of one of the accordions and one molybdenum atom of an adjacent accordion. In the α phase each lozenge is linked to four other lozenges through a cyano bridge in the *bc* plane along the [011] and [01$\bar{1}$] directions (Fig. 1). In the β phase each lozenge is linked to only two other lozenges through two cyano bridges in the *bc* plane along the [011] direction (Fig. 2).

Both phases exhibit a long-range magnetic ordering at T_c = 51 K. The field-cooled magnetization curves obtained in cooling a single crystal of the α phase within a magnetic field of 100 Oe aligned along the *a*, *b* and *c** axis directions, successively, are shown in Fig. 3. These curves display a characteristic break at T_c, then the magnetization remains constant as the temperature is lowered further. The strong magnetic anisotropy which is observed is probably of dipolar origin,[13] and reflects the low crystal symmetry which contrasts with the perovskite-like structure of the Prussian Blue phases. The field dependences of the magnetization below T_c reveal a saturation magnetization very close to 11 μ_B. This value corresponds to what is expected for a ferromagnetic state in which the S_{Mo} = 1/2 and S_{Mn} = 5/2 local spins are aligned along the field direction. The overall ferromagnetic nature of the interactions between the spin carriers is supported further by the profile of the $\chi_M T$ *vs.* *T* curves of polycrystalline samples, χ_M being the magnetic susceptibility per repeat unit and *T* the temperature. At room temperature, $\chi_M T$ is equal to 9.1(1) emu K mol^{-1} for both phases, which corresponds to what is expected for non-interacting Mo^{3+} and Mn^{2+} ions, and increases continuously and more and more rapidly as *T* is lowered.

Several factors confer a great interest on the compounds described in this paper, namely: (*i*) the beauty of the crystal

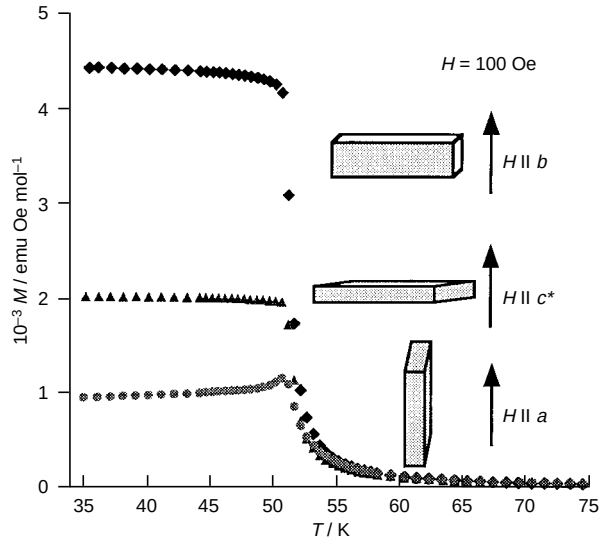

Fig 3 Field-cooled magnetization curves along the *a*, *b* and *c** axis directions of a single crystal of the α phase. The applied magnetic field is 100 Oe.

structures; (*ii*) the possibility of growing rather large single crystals suitable for anisotropy measurements; (*iii*) the presence of high-spin 3d and low-spin 4d spin carriers;[14] (*iv*) finally, the originality of the physical properties in the magnetically ordered state. These properties will be detailed in a subsequent paper.

A hydrolytically stable analogue of the Tn antigen has been efficiently synthesized for the first time employing a SmI_2-promoted coupling of the pyridyl sulfone of *N*-acetylgalactosamine with an aldehydoamino acid derivative.

The Tn (GalNAcα1→*O*-Ser/Thr) and sialyl Tn (NeuAcα-2→6GalNAcα1→*O*-Ser/Thr) epitopes are major tumor-associated *O*-linked glycopeptide motifs of cell surface glycoproteins which are expressed in over 70% of human epithelial cancers such as lung, colon, stomach and breast carcinomas.[1] In normal cells, however, the Tn antigen is cryptic, where it is further glycosylated giving rise to complex carbohydrates of the mucin-type glycoproteins.[2] This antigen has also been identified as a partial structure of the HIV envelope glycoprotein gp120.[3] We are particularly interested in preparing analogues of these epitopes as molecular components of potential small molecular weight synthetic vaccines,[4] with high immunogenicity and *in vivo* stability against various carcinoma. A *C*-glycoside analogue in which the interglycosidic oxygen is replaced with a methylene group[5] may well conform to such desired properties. Here we present for the first time the synthesis of one such mimic of these tumor-associated antigens, namely that of *O*-(2-acetamido-2-deoxy-α-D-galactopyranosyl)-L-serine (Scheme 1).

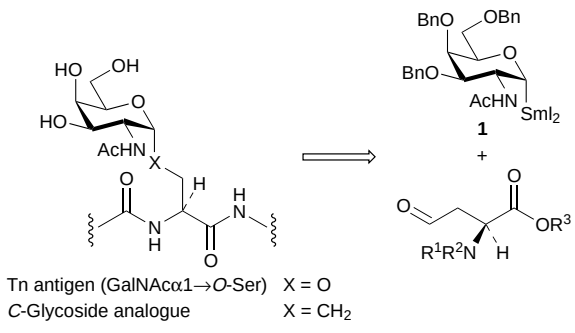
Several recent syntheses of *C*-glycosidic amino acids have now appeared in the literature, although only one has been directly applied to 2-hexosamine derivatives. In this approach, Kessler reported the stereoselective synthesis of a *C*-glycoside mimic of N^4-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-L-asparagine, an important constituent of *N*-glycopeptides, *via* the coupling of a glycosyl dianion with a modified asparatic acid derivative as the key step.[6,7]

We have recently shown that reductive samariation of glycosyl pyridyl sulfones in the presence of carbonyl substrates leads to a viable and rapid route to *C*-glycosides.[8] In particular, we have demonstrated that the anomeric organosamarium of *N*-acetylgalactosamine affords predominantly α-*C*-glycosides upon condensation with simple aldehydes and ketones.[8c,f] We hypothesized that with a suitable aldehyde precursor of an amino acid derivative, its coupling with **1** could lead to the required *C*-glycosidic amino acid after a subsequent deoxygenation step (Scheme 1). Preliminary results in this direction showed that the carbon chain of the aldehyde precursor was of ideal length for the coupled product to undergo *in situ* lactonization upon addition of the C^1-glycosyl anion to the aldehyde C=O bond, thus complicating the following deoxygenation.[8f] To prevent this event, we decided to employ the cyclic carbamate derivates of the type **2**, the synthesis of which is outlined in Scheme 2.

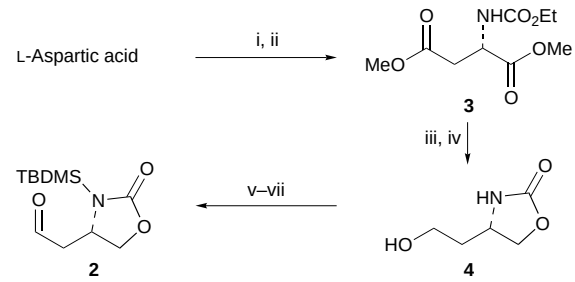
L-Aspartic acid was easily converted to alcohol **4** in four steps adopting the protocol described by McKillop for the conversion of amino acids to their corresponding cyclic carbamates.[9] Hence, esterification in acidic MeOH and treatment with $ClCO_2Et$ led to the dimethyl ester **3**. Subsequent reduction to the diol and cyclisation upon treatment with 2 equiv. of NaH afforded the cyclic carbamate **4** in an overall yield of 81%. Bis(silylation) was accomplished upon treatment of **4** with TBDMSOTf in collidine, after which the primary alcohol could be selectively liberated with HF in MeCN.[10] Oxidation employing the Swern conditions then gave crystalline aldehyde **2** in high yield.

The key coupling step, outlined in Scheme 3, was performed by adding a THF solution of SmI_2 (2 equiv.) to the previously described glycosyl pyridyl sulfone **5**[8c,f] and aldehyde (1.2 equiv.) at room temperature. An immediate reaction ensued, as monitored by the instantaneous consumption of the one-electron reducing agent, leading after work up to the isolation of the desired *C*-glycosides in high yield (82%) in favor of the α-anomers **6**‡ (α : β, 3.3 : 1). We note again the success of this anionic *C*-glycosylation reaction even though pyridyl sulfone **5** possesses an acidic NH proton. It was necessary to install a protecting group at the carbamate nitrogen in **2** for the coupling reaction to succeed. In its absence (*e.g.* replacing the TBDMS group by H), protonation at C1 of the sugar unit was the sole product observed.§

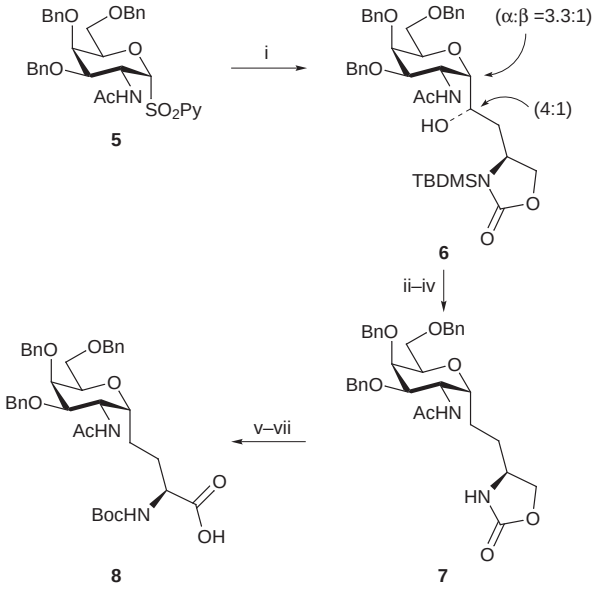
Whereas treatment of **6** (major isomer) with thiocarbonyl diimidazole¶ surprisingly led to the formation of a cyclic oxazoline involving the C2 acetamido group, use of the traditional Barton deoxygenation method proved effective for the removal of the newly created C7 hydroxy group. Thus



Scheme 1



Scheme 2 *Reagents and conditions*: i, AcCl, MeOH; ii, $ClCO_2Et$, $NaHCO_3$, 93% (2 steps); iii, $NaBH_4$, $CaCl_2$, EtOH–THF (2 : 1); iv, NaH, THF, 87% (2 steps); v, TBDMSOTf, collidine; vi, HF, MeCN, 71% (2 steps); vii, $(COCl)_2$, Et_3N, DMSO, 99%



Scheme 3 *Reagents and conditions*: i, **2** (1.2 equiv.), SmI_2 (2.2 equiv.) THF, 20 °C, 82%; ii, NaH, CS_2, MeI, THF, 83%; iii, $HSnBu_3$ (1.5 equiv.), AIBN (0.05 equiv.), toluene, 110 °C; iv, TBAF (3.5 equiv.), THF, 95% (2 steps); v, $(Boc)_2O$ (1.5 equiv.), Et_3N (2.0 equiv.), DMAP (cat.), THF; vi, Cs_2CO_3 (cat.), MeOH, 83% (2 steps); vii, Jones oxidation, 70%

formation of the methyl xanthate from alcohol **6**, followed by tin hydride promoted radical deoxygenation, afforded **7** after desilylation in 79% (three steps). A three-step procedure involving introduction of a Boc group, selective hydrolysis of the cyclic carbamate[11] and oxidation of the primary alcohol to its corresponding carboxylic acid **8** then completed the synthesis of the desired *C*-glycosyl amino acid.‖

In conclusion, we have successfully prepared a hydrolytically stable Tn antigen mimic *via* a SmI_2-promoted *C*-glycosylation protocol. This important amino acid building block is now ready to be incorporated into small peptide chains in order to test them as potentially viable synthetic peptide vaccines against various human epithelial cancers, the results of which will be reported in due course.

‡ *Selected data*: for **6** δ_H(250 MHz, $CDCl_3$) (major isomer) 6.18 (d, 1 H, *J* 8.4, NH), 4.37 (ddd, 1 H, *J* 9.4, 6.5, 2.9, H_5), 4.18 (dd, 1 H, *J* 11.2, 9.4, H_{6a}), 4.16 (ddd, 1 H, *J* 8.4, 3.1, 2.2, H_2), 3.88 (dd, 1 H, *J* 3.1, 3.1, H_3), 3.76 (dd, 1 H, *J* 6.5, 3.1, H_4), 3.74 (dd, 1 H, *J* 3.5, 2.2, H_1), 3.69 (dd, 1 H, *J* 11.2, 2.9, H_{6b}).

§ The protecting group on the carbamate nitrogen also plays a pivotal role for obtaining high coupling yields of the *C*-glycoside as exemplified by the use of the Boc group, where the *C*-glycosylation yield was reduced by one half. Another advantage is that it provides easily separable isomers.

¶ We have recently applied this reagent successfully for the deoxygenation of a *C*-disaccharide prepared *via* the SmI_2 route [see ref. 8(*b*)].

‖ It is interesting to note that *C*-glycoside **8** does not occupy the normally expected $^4C_1$ chair conformation, as is seen from the coupling constants ($J_{2,3}$ = 4.0, $J_{3,4}$ = 2.9, $J_{4,5}$ = 5.6 Hz). This has also been observed for other *N*-acetyl-α-*C*-galactosamines (ref. 12) and monosaccharides (ref. 13) derivatives possessing benzyl protecting groups at the C3, C4 and C6 hydroxy groups. However, the corresponding deprotected or peracetylated *C*-glycosides were found to possess the normal chair conformation.

Induced separation of a binate vesicle into two independent entities

Fredric M. Menger,*† Stephen J. Lee and Jason S. Keiper

Department of Chemistry, Emory University, Atlanta, Georgia 30322, USA

Two lipid vesicles, one residing in the aqueous interior of the other, separate into independent vesicles upon increasing the temperature or osmotic pressure; phase-contrast microscopy provides the details of the process.

Giant vesicles are spherical lamellar structures having diameters greater than one micrometer. Single giant vesicles can be isolated, manipulated and observed in real time by light microscopy. By contrast, small vesicles (so-called 'SUVs'), used conventionally in most vesicle research, are sub-microscopic and thus evaluatable in solution only by indirect spectroscopic means. Capitalizing upon this size advantage of giant vesicles, researchers have recently reported diverse membrane events ranging from cytomimetic phenomena[1] to surface reactions.[2]

Giant vesicles undergo a variety of morphological changes brought about by mechanical,[1] thermal,[3–5] chemical,[6–8] electrical[9] and pressure[10] alterations in the environment. Thermally-induced shape changes have, perhaps, garnered the most attention from the scientific community. For example, it was shown[5] that temperature affects the vesicle area-to-volume ratio, leading to budding and other shape transitions. Mathematical models explaining the various membrane phenomena are also available.[11,12]

Both natural phospholipids and synthetic lipids can self-asemble into giant vesicles. Didodecyldimethylammonium bromide (DDAB) is a good example of the latter. Use of 'unnatural' lipids is important because it provides a large array of compounds with which to relate membrane properties to molecular structure. We ourselves have employed DDAB, among various synthetic lipids, to observe vesicle aggregation, fusion, endocytosis and birthing.[1]

On occasion, a population of DDAB giant vesicles will contain a 'binate' vesicle that consists of one sphere within another of slighly larger size. Usually the components of the binate vesicle have a common area of contact as portrayed in Fig. 1.

When the system is subjected to heat or osmotic pressure, the binate vesicle separates into two independent vesicles. Since the initial and final surface areas and volumes of the vesicles can be quantified, one has a prime opportunity to monitor the translocation of lipid and vesicular water during the morphological change. Tracking the fate of components in model membrane systems is relevant to cell biology where membrane reorganization occurs in a controlled but poorly understood manner.

A few experimental details will clarify the procedure. DDAB and cholesterol were mixed by dissolving the solids in $CHCl_3$–MeOH and removing the solvent under reduced pressure. The resulting film was sonicated in deionized water and lyophilized to yield a white powder of intimately mixed lipids. Less than 0.1 mg of lipid mixture was smeared onto a glass microscope slide within the confines of a cemented 14 mm i.d. O-ring. Approximately 0.5 ml of deionized water was added to the sample, a glass coverslip applied, and the excess water drained. About 3 h of incubation at 20 °C produced a colony of giant vesicles.

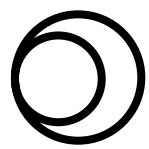

Fig. 1 Schematic representation of a binate vesicle

For heating experiments, the microscope slide was mounted on a hollow brass plate through which flowed water from a constant temperature bath. Temperatures were read from a thermocouple residing directly in the vesicle medium. Dilution experiments, in which the osmotic pressure was altered, were performed by taking up to 25–75 μl of vesicle suspension into a micropipet and gently releasing it into 0.5 ml of deionized water.

Vesicle transformations were observed with phase-contrast optics using a Nikon Diaphot-TMD inverted microscope. Images were recorded with the aid of a Dage-MTI CCD-72 solid-state camera connected in series to a Panasonic AG-1960 SVHS, a Hamamatsu Argus-10 image procesor, and a Sony black and white monitor. Image processing and radii determination from calibrated distances were accomplished using Image-Pro Plus software on a Micron Millenia workstation, while images were printed using a Tektronix Phaser 440 dye sublimation printer.

Fig. 2 shows the effect of heating a 95% DDAB–5% cholesterol vesicle from 20 to 29 °C. In Fig. 2(A), one sees a binate vesicle (adhered to a smaller single vesicle) with considerable apparent contact between the inner and outer bilayers (arrows). The outer vesicle seemingly 'peels' away from the inner vesicle [Fig. 2(B)–(E)] while assuming various non-spherical shapes in the process. In less than 1 min, two unattached spherical vesicles are formed [Fig. 2(F)].

Table 1 records the volumes and surface areas for vesicles in Figs. 2(A) and 2(F). Since the total volume of the two vesicles in Fig. 2(F) is 15.3 pl [compared to only 13.9 pl for the outer vesicle in Fig. 2(A)], 1.4 pl of water were incorporated into the system during the separation process. External water must have

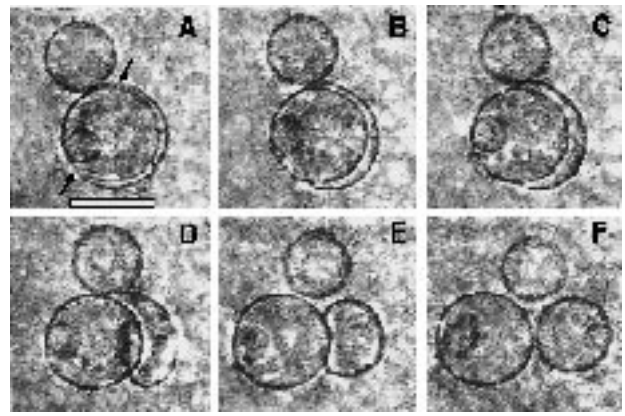

Fig. 2 Progressive separation of the outer shell of a binate vesicle induced by a temperature increase. Arrows in micrograph (A) define the region of membrane contact between the inner and outer vesicle before separation became evident. T = 29 °C raised from 20 °C; time from (A) to (F) = 1 min; bar = 25 μm.

Table 1 Vesicle radii, internal volumes and surface areas in Figs. 2 and 3[a]

	Before separation		After separation	
	Vesicle-1	Vesicle-2	Vesicle-1	Vesicle-2
Fig. 2				
Radius/μm	13.7	14.9	13.7	10.3
Volume/pl	10.7	13.9	10.7	4.6
Surface area/μm²	2360	2790	2360	1330
Fig. 3				
Radius/μm	24.4	27.8	23.5	24.1
Volume/pl	60.8	90.0	54.3	58.6
Surface Area/μm²	7450	9680	6940	7300

[a] Vesicle-1 represents the inner 'static' vesicle and vesicle-2 represents the outer 'active' vesicle.

entered the 'active' vesicle-2 exclusively because the volume of the 'static' vesicle-1 remained constant at 10.7 pl. Since the permeation rate of water through bilayers is generally much too slow to explain the observed influx,[13] it is likely that water enters vesicle-2 *via* an intervesicular gap as was observed previously in a laser-induced vesicle expulsion.[14]

Vesicle separation in Fig. 2 also led to a sizable decrease in the total surface area (from 5150 to 3690 μm² based on the assumption that the 'active' vesicle was originally an intact sphere). Even if the 'active' vesicle is taken to be an incomplete sphere [terminating at the arrows in Fig. 2(A)], there is a net decrease in lipid surface area of about 570 μm² as the new vesicle in Fig. 2(F) (of area 1330 μm²) is formed. One possible explanation is that lipid is deposited upon the 'static' inner vesicle by the 'active' outer vesicle. If this is true, then the deposited lipid must exist as a 'patch' on the surface of the 'static' vesicle because insufficient lipid was made available to coat the receptor vesicle entirely. Formation of bilayer patches residing on intact vesicles has been observed previously.[15]

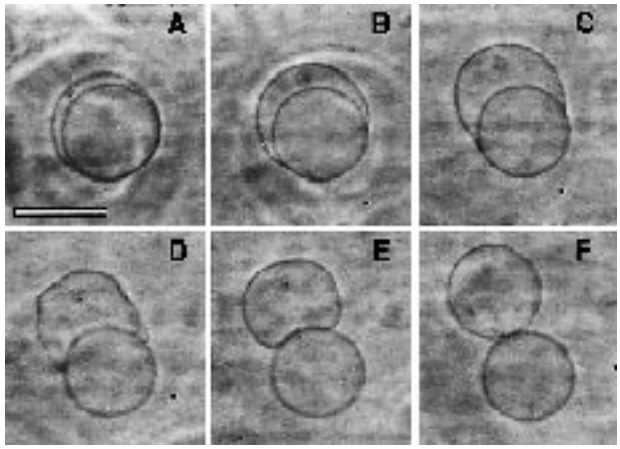

Fig. 3 Separation of a binate vesicle caused by dilution. Note the extreme undulation depicted in micrograph (D). T = 20 °C; time from (A) to (F) = 3 min; bar = 50 μm.

Lipid material could also have been lost to the bulk medium as sub-microscopic vesicles.[14]

An osmotic pressure change at constant temperature, created by dilution with deionized water, also induces vesicle separation (Fig. 3). Once again Table 1 reveals a volume increase requiring the input of external water. Thus, the total volume in Fig. 3(F) (112.9 pl) exceeds that of the outer periphery in Fig. 3(A) (90.0 pl). The need to supply external water is evident in Fig. 3(D) showing a flaccid and strongly undulating intermediate. Entry of water at narrow juncture gaps must be osmotically driven by monomeric DDAB and impurities that invariably exist in the inner vesicular regions.

Within the limits of uncertainty in the measurements, it appears that the surface area data are adequately explained by the two vesicles in Fig. 3 sharing a common membrane (*i.e.* the 'active' vesicle consisting of an incomplete sphere attached to an intact inner vesicle). Two-thirds of 9680 μm² plus a small osmotic swelling gives a value close of 7300 μm², the surface area found for the newly formed vesicle. The 7% volume decrease seen with the 'static' vesicle may reflect a compaction of bilayer lipid upon departure of the attached membrane.

Control experiments showed that vesicles composed of DDAB without cholesterol also manifested the separation phenomenon upon exposure to elevated temperatures and osmotic pressures. Thus, cholesterol-rich domains, if they exist at all, do not seem to play a role here in the observed membrane reorganization.

We thank the National Institutes of Health for supporting this work.

Synthesis and characterization of $Co_3(O_2CCH_2CH_2PO_3)_2 \cdot 6H_2O$, a metal carboxylate–phosphonate with a framework structure

Anne Distler and Slavi C. Sevov*†

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556, USA

The title compound is the first carboxylate–phosphonate with an extended three-dimensional structure, a framework of trimers of edge-sharing CoO_6-octahedra and organic species with two different functional groups, carboxylic and phosphonic, both coordinated to the metal atoms.

The use of multifunctional ligands for building infinite frameworks by coordination to metal centers has become an area gaining much interest in recent years.[1] Many such crystalline coordination polymers with two- and three-dimensional structures are already known for polynitrilies and polyamines coordinated to noble metals.[2] Similarly, polycarboxylic acids,[3] polyalcohols and polyethers,[4] and polyphosphonic acids,[5] have been used for the construction of such solid-state architectures through coordination to a variety of transition metals. Compounds utilizing organic species with two different functional groups, both coordinated to metal atoms, are very rare. Known are an aminophosphonate with an open-framework type structure,[6] and two layered compounds based on carboxylate–phosphonates.[7] Owing to the directionality of the coordination bond, most of these structures have relatively large voids, and are of potential interest for a variety of guest–host interactions and molecular recognition. A common problem for many of them, especially those with long bridging ligands, is the interpenetration of the frameworks which essentially results in blocking the otherwise available large openings. As far as thermal stability is concerned the phosphonates tend to be the more stable group. We are interested in combining two or more different functionalities in a single compound with a three-dimensional open-framework structure. Here we report on a carboxylate–phosphonate compound with such an extended framework built of transition metals coordinated by a bridging ligand with two different functional groups.

The title compound was initially made in an autoclave at 110 °C from $CoCO_3$ and 2-carboxyethylphosphonic acid, $HO_2CCH_2CH_2P(O)(OH)_2$, mixed in a molar ratio of 2 : 1. The synthesis can be also carried out in an open system as low as 80 °C. The compound crystallizes as spherical aggregates of red-purple crystals. A single crystal structure determination‡ revealed a three-dimensional network of linear trimers of edge-sharing CoO_6-octahedra with the organic molecules coordinated to the cobalt atoms by both functional ends (Fig. 1). The cobalt atoms are of two types, Co2 at an inversion center at the center of the trimer, and Co1 inside the other two octahedra (Fig. 2). The Co2-octahedron shares the two opposite parallel edges, O1 and O6, with the Co1-octahedra. The latter are rotated in opposite directions around the common edges keeping the three cobalt atoms in a straight line. This leads to shorter distances between some of the apical oxygen atoms, O2 and O3. These and one of the shared oxygens, O1 from an adjacent trimer, are bonded to a single phosphorus atom.

The acidic oxygens of both functional groups are fully deprotonated. The carboxy group is coordinated to Co1 as a monodentate ligand through its deprotonated oxygen atom leaving the 'double'-bonded oxygen, O5, as non-bonding (Fig. 2). Thus an extended structure of covalently bonded network –Co–O–P–C–C–C–O–Co– is formed. This network has one-dimensional, S-shaped voids filled with the water molecules, O6, 7 and 8 (Figs. 1 and 3). The latter complete the octahedral coordination sphere around the cobalt atoms by

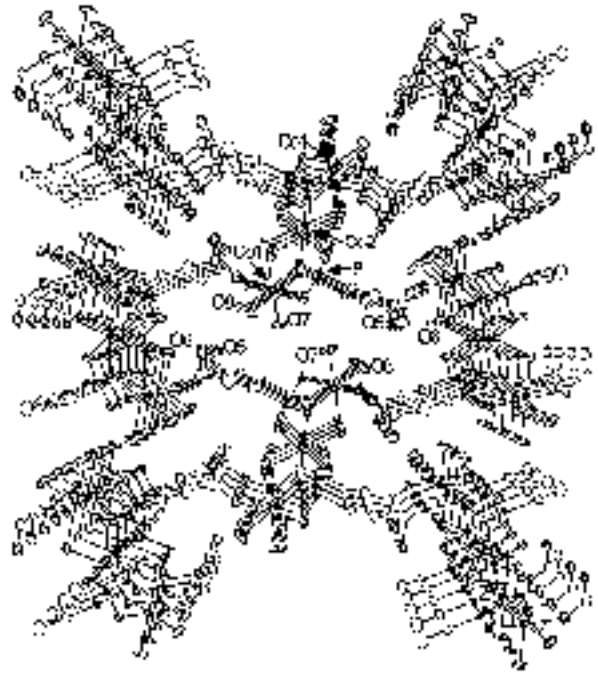

Fig. 1 A general view of $Co_3(O_2CCH_2CH_2PO_3)_2 \cdot 6H_2O$ along the *a* axis (*c* is horizontal) drawn with thermal ellipsoids with 50% probability. The atoms are shown with ellipsoids that are: open for C, cross- hatched for O, and shaded for Co and P. The water oxygens (O6, 7 and 8), the double bonded oxygen (O5), and cobalt and phosphorus of one trimer are labeled.

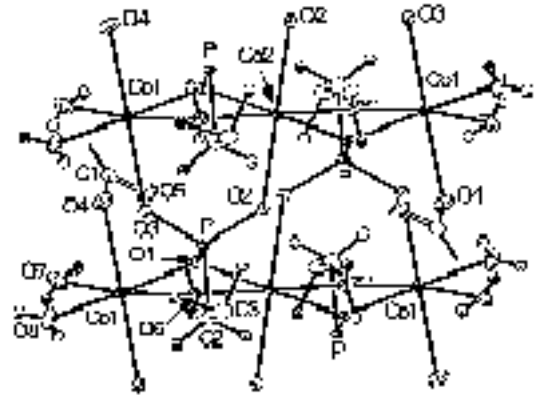

Fig. 2 A closer view of the bonding within and between the trimers of edge-sharing octahedra. Selected distances (Å): Co1–O1 2.066(4), Co1–O3 2.057(3), Co1–O4 2.105(4), Co1–O6 2.215(4), Co1–O7 2.098(4), Co1–O8 2.052(5), Co2–O1 2.098(3), Co2–O2 2.059(3), Co2–O6 2.168(4), P–O1 1.545(4), P–O2 1.517(4), P–O3 1.525(4), P–C2 1.807(6), C1–C2 1.509(8), C2–C3 1.516(9), C1–O5 1.260(7), C1–O4 1.267(7).

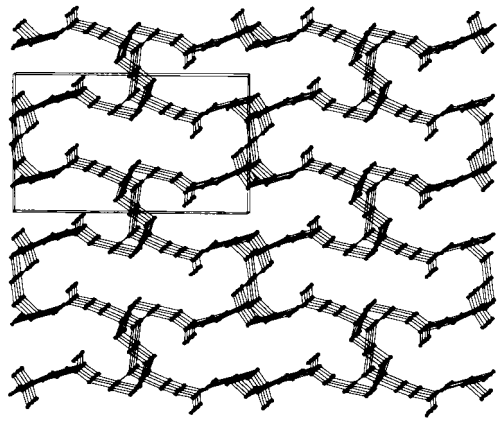

Fig. 3 A view along *a* (as in Fig. 1) of the compound with the water molecules omitted for clarity. The S-shaped one-dimensional openings are easier to see. This is what the dehydrated compound may look like.

coordinating to either one (O7 and O8 to Co1) or two (O6 to both Co1 and Co2) of them.

The IR spectrum of the compound shows the asymmetric and symmetric vibrations of the carboxy group at 1541 and 1419 cm^{-1}, respectively, the vibrations of the phosphonic group in the region 900–1100 cm^{-1}, and the typical bands of the coordinated water (broad at 3369 and sharp at 1646 cm^{-1}). The absence of a band in the region 1690–1730 cm^{-1} (the O–H vibration of a CO_2H group) is in agreement with a deprotonated carboxy group. Magnetic susceptibility measurements in the range 10–300 K show a Curie-type paramagnetism consistent with the structure of 'isolated' islands of cobalt trimers (μ = 9 μ_B). A mass loss of 17.5% was measured by TG at *ca.* 150 °C, and this is consistent with six molecules of water (also confirmed by IR after the dehydration). At that temperature the sample changes color from purple to an intense blue, and this confirms the lowering of the cobalt coordination number. Fig. 3 depicts the structure of the compound without the water molecules. Based on the van der Waals radii, the calculated free volume per unit cell of the treated compound is *ca.* 190 $Å^3$, or 23% of the total volume.§

This new compound provides potential for further explorations. For example, it may be possible to replace the water molecules with different amines. Also, the fact that the C=O part of the carboxylic acid is 'intact' can eventually be used for reactions with different organic molecules with catalytic, photoelectric, or other useful properties in order to 'anchor' them to the solid.

‡ *Crystal data* for $Co_3(O_2CCH_2CH_2PO_3)_2 \cdot 6H_2O$: M_w = 586.95, monoclinic, space group $P2_1/c$, Z = 2, a = 4.6086(9), b = 10.278(3), c = 17.504(3) Å, β = 95.74(1)°, U = 825.0(3) $Å^3$, μ = 32.61 cm^{-1}. A hemisphere of data was collected on a CAD4 single crystal diffractometer with graphite-monochromated Mo-Kα radiation at room temperature (crystal size 0.04 × 0.08 × 0.10 mm, ω–2θ scans, 2998 and 1455 collected and independent reflections (R_{int} = 7.87%), respectively). The structure was solved by direct methods and refined with the aid of the SHELXTL-V5.0 package. All lighter atoms, including hydrogen, were located from difference Fourier maps, and refined without constraints. XABS empirical absorption correction was applied to the data after the structure was refined with isotropic thermal parameters. Final residual values: R_1/wR_2 = 0.0498/0.1036 for 1185 observed reflections ($I \geqslant 2\sigma_I$) and 163 refined parameters (R_1/wR_2 = 0.0634/0.1114 for all data). CCDC 182/825.

§ While the manuscript was being reviewed we made and characterized two more metal carboxylate–phosphonates, an isostructural magnesium analog [a = 4.598(2), b = 10.278(4), c = 17.628(7) Å, β = 96.28(3)°, U = 828.1(4) $Å^3$] and a calcium carboxylate–phosphonate with a different structure. According to the structure determined from single crystal X-ray diffraction and IR spectra of the latter, the calcium is seven-coordinate, and the carboxylic group is not deprotonated but rather coordinated to the calcium *via* the carbonyl oxygen.

Remarkable helix stabilization *via* edge-to-face tryptophan–porphyrin interactions in a peptide-sandwiched mesoheme

David A. Williamson and David R. Benson*†

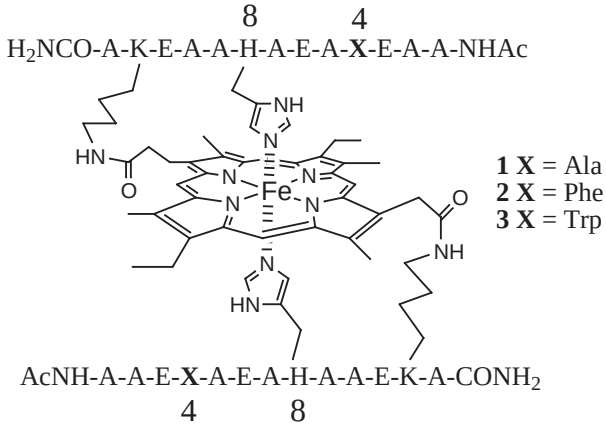
Department of Chemistry, University of Kansas, Lawrence, KS 66045-0046, USA

Tryptophan residues in a peptide-sandwiched mesoheme provide helix stabilization *via* edge-to-face interactions between the Trp indole side-chains and the porphyrin ring.

Binding of heme by apomyoglobin and cytochrome b_5 is driven to a large extent by interactions between apolar amino acid side-chains and the porphyrin ring. This was convincingly demonstrated by an experiment in which the proximal histidine (His) ligand of myoglobin (Mb) was mutated to glycine without greatly diminishing the apoprotein's affinity for heme.[1] Furthermore, removal of heme from Mb[2] and from cytochrome b_5[3] leads to reduced protein helix content and decreased protein stability as interactions between the heme and amino acid side-chains in the heme binding pocket are lost.

The F-helix of *Aplysia limacina* Mb provides the proximal ligand (His-95) to the heme iron (Fig. 1).[4] A phenylalanine residue (Phe-91), which is also within the F-helix, is located at position $i - 4$ relative to His-95 (in mammalian Mbs, this position is usually occupied by leucine). The phenyl ring of Phe-91 is nearly perpendicular to the heme plane, and the hydrogen atoms in the 3- and 4-positions of the phenyl side-chain make van der Waals contact with the heme.[4] Similar interactions between heme and Phe residues are observed in cytochrome b_5.[5] An edge-to-face orientation between two aromatic groups is energetically favorable.[6] Stabilization arises from electrostatic interactions between hydrogen atoms on one ring, which bear a partial positive charge, and the π-electrons of the second ring.[7]

We have developed a class of hemoprotein models that we call peptide-sandwiched mesohemes (*e.g.* **1**).[8–11] His-to-iron



coordination in **1** induces the covalently attached peptides to adopt conformations with *ca.* 50% helix content, in aqueous solution at 8 °C.[10] Helix content can be increased to > 90% by addition of propan-1-ol (PrOH). From molecular modelling studies we have predicted that in **1** the angle between the peptide helix axis and the porphyrin plane will be about 30°.[12] When His ligands to heme iron in natural hemoproteins reside within helices, this angle is usually closer to 0°. The different

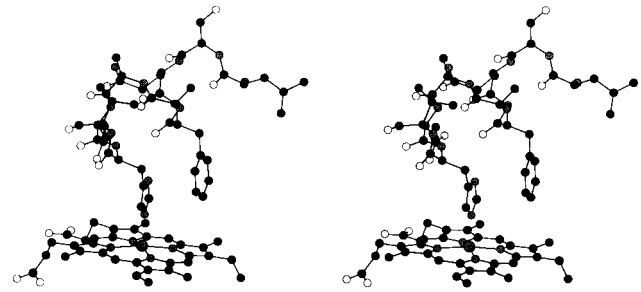


Fig. 1 Heme and F-helix of *Aplysia Limocina* Mb.[4] Atom colors: carbon (black); nitrogen (grey); oxygen (white).

orientations result from alternate combinations of His side-chain torsional angles χ_1 and χ_2. In **1** we predict that $\chi_1/\chi_2 \approx 180°/-90°$,[9,12] whereas in most hemoproteins utilizing His residues that reside in α-helices (including *Aplysia limacina* Mb), these values are closer to $-60°/90°$.[8]

In **1**, Ala-4 is at position $i - 4$ relative to the His ligand (His-8). Using the structure of **1** predicted from molecular modeling studies,[12] we replaced Ala-4 by Phe and by tryptophan (Trp) to investigate whether edge-to-face interactions between either aromatic amino acid side-chain and the heme was possible. From these studies we found that the indole side-chain of Trp can make such interactions if its side-chain torsional angles χ_1 and χ_2 are limited to *ca.* 180 and 90°, respectively. An energy minimized structure predicted for **3** is shown in Fig. 2. In contrast, the side-chain of Phe appears to be too small to permit contact with the heme in **2**.

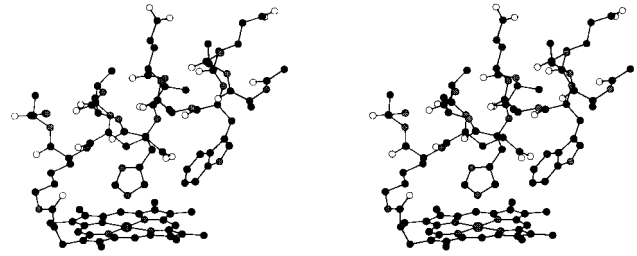

Fig. 2 Structure of **3** predicted by molecular modelling. Only one peptide is shown. Atom colors as in Fig. 1.

We have prepared **2** and **3** using our previously reported synthetic method.[8,9] CD spectra of **1** and **3** in neutral aqueous solution at 8 °C are shown in Fig. 3. The spectrum of **2** (not shown) is nearly identical to that of **1**. Using the mean residue ellipticity at 220 nm (θ_{220}) as a measure of peptide helix content,[8] we estimate that changing Ala-4 to Trp increases peptide helix content from *ca.* 50 to *ca.* 90% (maximum θ_{220} for **1**–**3** is calculated to be $-27\,700$ deg cm^2 dmol^{-1}). In contrast, changing Ala-4 to Phe leaves the peptide conformation unaltered. Both results are consistent with predictions from molecular modelling.

Aromatic amino acid side-chains,[13] as well as heme itself,[8,14] can contribute to CD spectra in the wavelength range normally

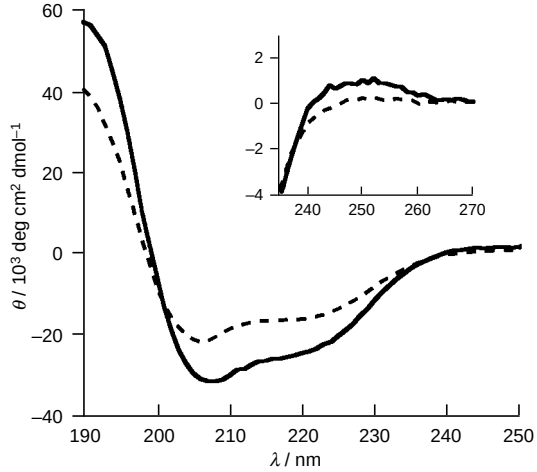

Fig. 3 CD spectra of **1** (- - -) and **3** (——) in 2 mM pH 7 potassium phosphate buffer at 8 °C

employed to determine peptide helix content. In fact, we observe a positive contribution in the CD spectrum of **3** near 250 nm that is absent in the spectra of **1** and **2** (Fig. 3, inset). This positive ellipticity probably arises *via* exciton coupling of the Trp side-chain with the peptide backbone amides and/or with the heme. Such contributions can lead to errors in peptide helix content determined by CD.[13] The amount of organic solvent required to achieve the maximum value of θ_{220} provides additional information about relative helix content in pure aqueous solution when comparing similar systems such as **1**–**3**. Fig. 4 shows θ_{220} plotted *vs.* volume percent of PrOH for **1** and **3** (the plot for **2** is identical to that for **1**, and thus is not shown). Whereas **1** and **2** require more than 30% (v/v) PrOH to reach maximal helix content, **3** reaches maximal helix content with only about 5% PrOH. This is consistent with **3** having much higher helix content than **1** and **2** in aqueous solution.

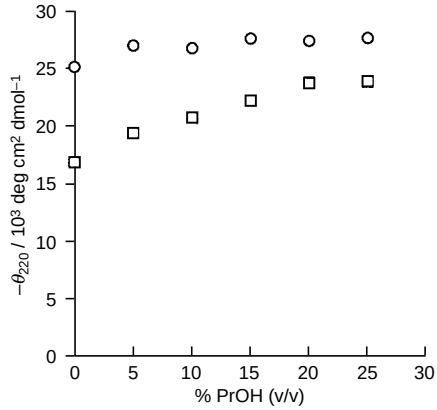

Fig. 4 θ_{220} as a function of PrOH concentration for **1** (□) and **3** (○). The plot for **2** is identical to that for **1**.

Aromatic amino acids are considered to be helix breakers[15] because their side-chain torsional angle χ_1 is restricted to the g^+ (300°) and t (180°) regions when they are forced to reside within a helix.[16] However, when the amino acid is within the first (*N*-terminal) turn of a helix, $\chi_1 = g^-$ (60°) is also accessible.[16] Because Phe-4 is within the first helical turn of **2**, it is not surprising that **1** and **2** exhibit similar conformational properties. In order for Trp to make edge-to-face contact with the heme in **3**, however, we predict that its side-chain must be restricted to $\chi_1 \approx 180°$ and $\chi_2 \approx 90°$. Our CD data indicate that the indole–heme interactions are sufficiently stabilizing to overcome the large entropy loss associated with such conformational restrictions. This is in keeping with the importance of such interactions in maintaining the structural integrity of natural hemoproteins.[2,3]

Unsaturated polymers containing boron and thiophene units in the backbone

Robert J.-P. Corriu,*[a] Thomas Deforth,[a] William E. Douglas,*[a]† Gilles Guerrero[a] and Walter S. Siebert*[b]

[a] *CNRS UMR 5637, Université Montpellier II, 34095 Montpellier cedex 5, France*
[b] *Anorganisch-Chemisches Institut der Universität, 69120 Heidelberg, Germany*

2,5-Dialkynylthiophenes $(RC{\equiv}C)_2C_4H_2S$ (R = Ph, Me_3Si or Bu^t) treated successively with $HBCl_2$ and Et_3SiH in CH_2Cl_2 undergo hydroboration polymerization to give intensely-coloured polymers of general structure $–[CH{=}CR–BCl–CR{=}CH–C_4H_2S]_n–$ for which the ^{11}B NMR resonances occur *ca*. 50 ppm upfield of those for analogous monomers.

Polythiophenes are important conjugated electroactive polymers. They possess interesting optical and electrical properties, and have many potential applications, for example in energy storage, electrochromic devices and electrochemical sensors.[1] Several of these effects depend on the nature and extent of doping of the polythiophene, usually with electron acceptors. We report here the synthesis by hydroboration polymerization of unsaturated polymers containing both thiophene and boron units. It was expected that such polymers possessing both electron-donor (sulfur) and electron-acceptor (boron) sites would show interesting properties, the boron with a vacant 2p orbital being available to act as an *in situ* electron-acceptor dopant.

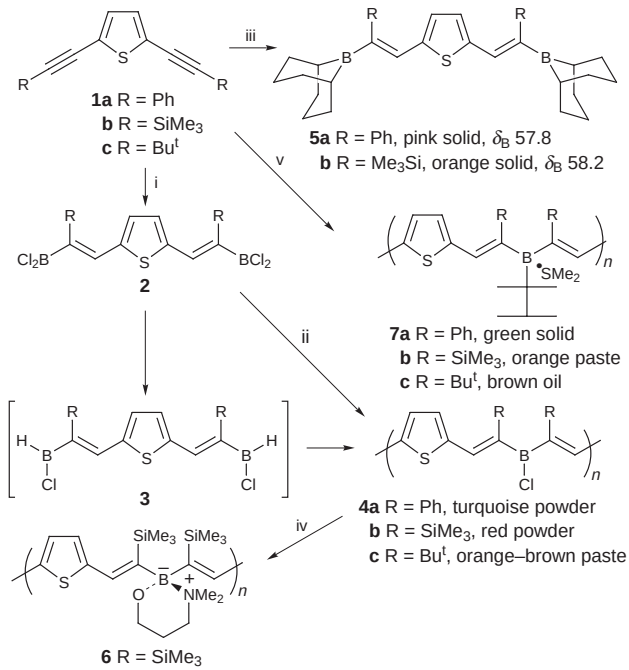
Hydroboration polymerization has been previously described for polyaddition betwen thexylborane–dimethyl sulfide complex and either dienes[2] (affording saturated organoboron polymers) or diynes[3] (giving unconjugated unsaturated organoboron polymers). The hydroboration polymerization of dienes has also been performed with monobromoborane–dimethyl sulfide complex to give functional organoboron polymers.[4] However, for all these polymers the boron 2p orbitals are occupied because of the presence of the dimethyl sulfide donor ligand. We describe here the preparation of analogous polymers containing thiophene and alkene units in which the boron 2p orbital remains vacant.

The starting diynes **1a**,[5] **1b**[6][ν (C≡C) 2146 cm^{-1} (CCl_4)] and **1c** [ν (C≡C) 2220 cm^{-1} (CCl_4)], which were synthesized from 2,5-dibromothiophene and the corresponding alkynylzinc reagent RC≡CZnCl, undergo hydroboration with $HBCl_2$ (formed *in situ* from BCl_3 and Et_3SiH[7]) at −80 °C to give the bis(dichloroborane) derivatives **2** in 60–70% yield (Scheme 1). Subsequent reduction of **2** with Et_3SiH in the presence of additional diyne **1** gives the corresponding polymers **4**, most probably by hydroboration polymerization of intermediate bis(monochloroborane) derivatives **3** (Scheme 1).‡ The polymers are highly sensitive to oxygen and water and so far it has not been possible to obtain either satisfactory UV–VIS spectra or consistent molecular weight data by size exclusion chromatography (SEC) because of the very dilute nature of the solutions required in both cases. However, the SEC chromatograms show a component of molecular weight in excess of 100 000, which is possibly an overestimate since it was determined using polystyrene calibrants. The polymer colour is strongly dependent on the substituent R groups, being turquoise in the case of phenyl substituents (**4a**), red for trimethylsilyl groups (**4b**), and green for the homologue containing both phenyl and trimethylsilyl substituents.

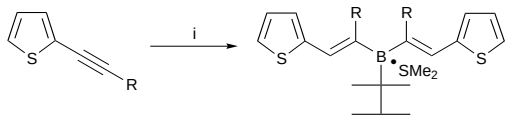
The ^{11}B NMR resonance for the polymers in $CDCl_3$ solution occurs at δ_B 6–7 (*e.g.* **4a**: δ_B 6.5), about 50 ppm upfield of the resonance for **2** (δ_B 53) or chlorodivinylborane (δ_B 56).[8] These remarkable properties suggest the existence of electronic interactions between the boron and thiophene groups along the polymer chain. Further support for this interpretation is provided by the contrasting properties of model monomers **5a** and **5b** prepared by hydroboration of **1a** and **1b**, respectively, with 9-borabicyclo[3.3.1]nonane (9-BBN) in THF solution (Scheme 1). The model monomers are pale-coloured solids exhibiting ^{11}B NMR resonances around δ_B 58 as expected.[8] The formation of all three structural isomers for each model monomer **5** is to be expected since the reaction of 9-BBN with alkynes is known to be of low regioselectivity.[9]

The polymers **4** can be stabilized by transformation of the boron chloro functional group. Thus, treatment of **4b** with 3-dimethylaminopropan-1-ol in toluene under reflux afforded **6** as a red paste in 80% yield. SEC indicates that **6** is an oligomer of about 8 units and therefore polymer degradation has occurred during the synthesis. The ^{11}B NMR resonance at δ_B 2.8 lies in the region expected for amine adducts,[8] the boron 2p orbital being occupied.

Treatment of **1a**–**c** with thexylborane–dimethyl sulfide complex in CH_2Cl_2 in the presence of $(PPh_3)_2PdCl_2$ affords, respectively, polymers **7a**–**c** (Scheme 1), this borane reagent being known to give linear polymers with internal diynes.[3] The ^{11}B NMR resonances (δ_B 18–19) lie in the region expected for dimethyl sulfide adducts.[8] The boron 2p orbital is occupied and the colours are less intense than those of **4**. SEC showed that **7b** is an oligomer of 25 units with a polydispersity index of 3.7 (polystyrene calibrants). For comparison, the analogous model



Scheme 1 *Reagents and conditions:* i, BCl_3, Et_3SiH, CH_2Cl_2, −78 to −40 °C; ii, **1**, Et_3SiH, −50 °C to room temp.; iii, 9-BBN, $Pt(PPh_3)_4$, THF, −78 to 65 °C; iv, $Me_2N(CH_2)_3OH$, PhMe, 110 °C; v, thexylborane–Me_2S, $(PPh_3)_2PdCl_2$, CH_2Cl_2, −78 °C to room temp. Only one of the various possible structural isomers is shown in each case.



8a R = Ph, pink paste
b R = Me_3Si, red–orange oil
c R = Bu^t, brown oil

Scheme 2 *Reagents and conditions:* i, thexylborane–Me_2S, CH_2Cl_2, −78 °C to room temp. Only one of the three possible structural isomers is shown.

monomers **8a–c** were made starting from the corresponding monoalkynylthiophene (Scheme 2). The change in colour, corresponding to an absorption red-shift, on going from the model monomers **8a** and **8b** to the polymers **7a** and **7b** indicates the presence of some additional electron delocalization in the polymers. However, the extent must be slight since the ^{11}B NMR chemical shifts for the model monomers are essentially the same as those for the polymers. This is in contrast to the case of the intensely-coloured polymers **4** with an empty boron 2p orbital, for which an ^{11}B NMR upfield shift of *ca*. 50 ppm is observed (*vide supra*). Work is in progress on the synthesis by hydroboration polymerization of more stable analogues of **4**.

The European Commission is thanked for a fellowship awarded to T. D. under contract no. ERBCHBGCT940539 of the Human Capital and Mobility (Institutional Fellowships) Programme. Financial support from the Deutsche Forschungsgemeinschaft (SFB 247) and the Alexander von Humboldt Stiftung (to R. J.-P. C.) is gratefully acknowledged.

‡ Polymers **4a–c** were prepared using the following one-pot procedure. A solution of BCl_3 in CH_2Cl_2 at −78 °C was treated dropwise with a CH_2Cl_2 solution containing Et_3SiH (2 equiv.) and the starting diyne **1** (0.5 equiv.). Addition of 50% of the latter Et_3SiH/diyne solution resulted in formation of the bis(dichloroborane) intermediate **2**. At this stage excess BCl_3 was removed from the reaction mixture *in vacuo* (5 min at −78 °C followed by 5 min at −40 °C) and addition of the Et_3SiH/diyne solution was then resumed at −50 °C. After addition was complete the reaction mixture was allowed to warm to room temperature overnight, becoming intensely coloured, and the polymers were isolated by removal of the solvent.

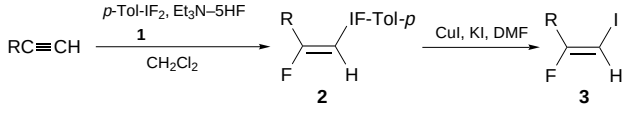
Stereo- and regio-selective addition of iodotoluene difluoride to alk-1-ynes. Selective synthesis of 2-fluoro-1-iodoalk-1-enes

Shoji Hara,*† Masaki Yoshida, Tsuyoshi Fukuhara and Norihiko Yoneda*

Division of Molecular Chemistry, Graduate School of Engineering, Hokkaido University, Sapporo 060, Japan

***p*-Iodotoluene difluoride reacted with 1-alkynes to give *trans* adducts which could be converted to 2-fluoro-1-iodoalk-1-enes without isolation.**

The introduction of a fluorine atom into the double bond of natural products, such as terpenes,[1] nucleosides,[2] retinal,[3] fatty acids,[4] prostaglandins[5] and peptides[6] has been of great interest because the fluorinated analogues of natural compounds are expected to have different pharmacological properties from the original ones. The fluoroalkenyl parts of such compounds have been synthesized by the condensation of α-fluorocarbanions with carbonyl compounds[3,5,6*a*,*b*,7] or the β-elimination reaction from fluorohaloalkanes[2,4*b*,6*c*] but the stereoselectivities are generally low. A cross-coupling reaction using fluoroalkenyl halides or fluoroalkenylmetals would be a versatile method for the stereoselective synthesis of fluoroalkenes.[8] However, the cross-coupling method has not been adequately developed for fluoroalkene synthesis because stereoselective synthesis of the fluoroalkenyl halides is difficult. Recently, we reported that *p*-iodotoluene difluoride (**1**) can be directly prepared from *p*-iodotoluene by an electrochemical method and used for the fluorination of β-dicarbonyl compounds.[9] During our continuing study of the organic synthesis using **1**, we found that **1** adds to alk-1-ynes to give (*E*)-(2-fluoroalk-1-enyl)(4-methylphenyl)iodonium fluorides (**2**)[10,11] which could be converted to (*E*)-2-fluoro-1-iodoalk-1-enes stereo- and regio-selectively (Scheme 1).



Scheme 1

p-Iodotoluene difluoride **1** was electrochemically prepared from *p*-iodototoluene in Et_3N–5HF[9] and used for further reaction without isolation. (*E*)-(2-Fluoroalk-1-enyl)(4-methylphenyl)iodonium fluoride (**2**), which was stable and could be isolated and characterized, was used for the further transformation without isolation. The iodonation of **2** by modification of the reported procedure[12] provided (*E*)-2-fluoro-1-iodoalk-1-enes (**3**) in good yields (Table 1).‡ The reaction can be carried out without the protection of functionalities such as ketones, esters, and even hydroxy groups in alkynes. Further application of this method to the stereoselective synthesis of fluoroalkenes is under investigation.

Table 1 Synthesis of (*E*)-1-iodo-2-fluoroalk-1-enes[a]

	Alkyne R	Yield of **3** (%)[b]
a	$Me(CH_2)_9$–	80[c]
b	$HO(CH_2)_9$–	65[d]
c	$Cl(CH_2)_9$–	77[d]
d	$MeO_2C(CH_2)_8$–	80
e		65
f		55
g		72

[a] If not mentioned elsewhere, the reaction was carried out as described in the notes. [b] Isolated yields based on alkynes used. [c] After the reaction of alkyne with **1**, 1 equiv. of CuI and KI in DMF (2 ml) was added. [d] After the reaction of alkynes with **1**, the reaction mixture was added to 10 equiv. of CuI and KI in CH_2Cl_2 (30 ml).

‡ *Typical experimental procedure*: *p*-iodotoluene difluoride was electrochemically prepared in a divided cell made of Teflon™ PFA with a Nafion™ 117 film using two smooth Pt Sheets (20 × 20 mm) for the anode and cathode. *p*-Iodotoluene (3 mmol) and Et_3N–5HF (22 ml) were introduced into the anodic cell and Et_3N–5HF (22 ml) was introduced into the cathodic cell. The electrolysis was carried out under constant electricity (50 mA h^{-1}) until 2 F mol^{-1} of electricity was passed. The resulting Et_3N–5HF solution of *p*-iodotoluene difluoride in the anodic cell was used for further reaction. Methyl undec-10-ynoate (293 mg, 2 mmol) and CH_2Cl_2 (6 ml) were introduced into a reaction vessel made of Teflon™ PFA and *p*-iodotoluene difluoride (3 mmol) in Et_3N–5HF (22 ml) was added at 0 °C. After stirring for 1 h, the mixture was extracted with CH_2Cl_2, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was dissolved in CH_2Cl_2 (5 ml) and added to CuI (3.8 g, 20 mmol) and KI (3.32 g, 20 mmol) in CH_2Cl_2 (25 ml). The reaction mixture was stirred at room temperature for 3 h and extracted with CH_2Cl_2. The product was isolated by column chromatography (silica gel/hexane–diethyl ether) in 80% yield. C=C Stereochemistry of **3a**–**g** was determined from $^3J_{H-F}$ data. Stereospecificities of >98% are indicated by GC, and ^1H and ^{19}F NMR spectroscopy. *Spectral data* for **2a**: δ_H(400 MHz, $CDCl_3$) 7.866 (d, *J* 8.3, 2 H), 7.2015 (d, *J* 8.3, 2 H), 6.725 (d, *J* 15.125, 1 H), 2.662–2.754 (m, 2 H), 2.361 (s, 3 H). 1.167–1.576 (m, 14 H), 0.881 (t, 7.1, 3 H); δ_F(84.67 MHz, $CDCl_3$)(C_6F_6 as an internal standard) −69.131 to −69.834 (m, 1 F). For **3d**: δ_H(400 MHz, $CDCl_3$) 5.67 (d, *J* 17.81, 1 H), 3.67 (s, 3 H), 2.50 (dt, *J* 7.32, 22.4 Hz, 2 H), 2.31 (t, *J* 7.56, 2 H), 1.64–1.51 (m, 4 H), 1.35–1.31 (m, 8 H); δ_F(84.67 MHz, $CDCl_3$)(C_6F_6 as an internal standard) −81.969 to −82.721 (m, 1 F); ν(neat)/cm^{-1} 1735 and 1650.

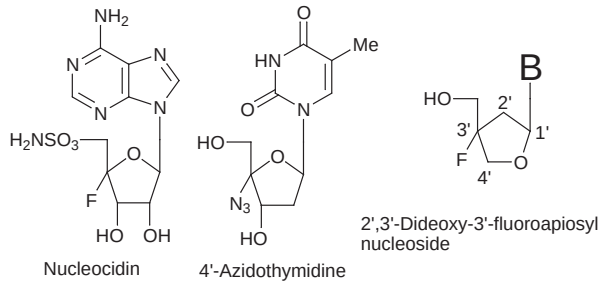
Synthesis of (±)-2′,3′-dideoxy-3′-fluoroapiosylpyrimidine nucleosides

Soon Kil Ahn,*[a,b]† Deukjoon Kim,[a] Hoe Joo Son,[b] Byeong Seon Jeong,[b] Ryung Kee Hong,[b] Bok Young Kim,[b] Eung Nam Kim,[b] Ku Hun Chung[b] and Jung Woo Kim[b]

[a] *College of Pharmacy, Seoul National University, San 56-1, Shinrim-dong, Kwanak-gu, Seoul, South Korea*
[a] *Chong Kun Dang Research Institute, 410 Shindorim-dong, Guro-gu, Seoul, South Korea*

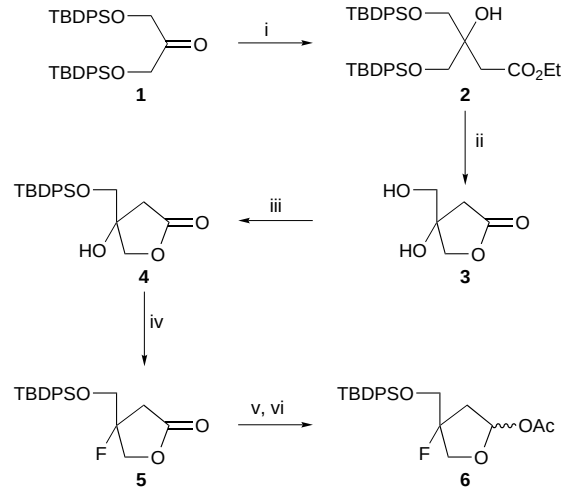
Various (±)-2′,3′-dideoxy-3′-fluoroapiosylpyrimidine nucleoside analogs have been prepared.

Since the discovery and synthesis of nucleocidin,[1] which has a unique 4′-fluorosugar, a number of 4′-substituted nucleosides[2] and 4′-substituted carbocyclic nucleosides[3] have been synthesized and their biological activities evaluated. Among them, 4′-azidothymidine exhibited potent anti-HIV activity.

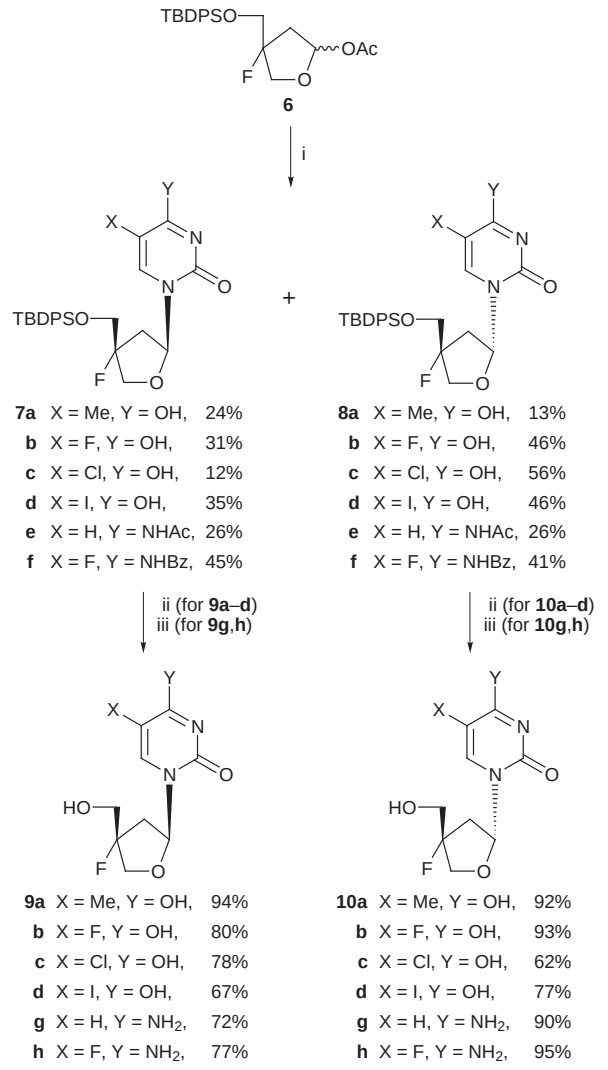


In our effort to synthesize novel 4′-substituted nucleoside derivatives with biological activity, we envisioned 2′,3′-dideoxy-3′-substituted apiosyl nucleosides to be one of these 4′-substituted nucleosides. While the synthesis and biological activities of a great many structurally modified nucleoside analogs have been reported, relatively little work has been done on the synthesis and biological activities of nucleoside analogs which contain apiose as the sugar moiety.[4] Here we report on the synthesis of (±)-2′,3′-dideoxy-3′-fluoroapiosylpyrimidine nucleosides.

The synthesis of the key intermediate, 2,3-dideoxy-3-fluoroapiofuranosyl acetate **6**, is shown in Scheme 1. Reformatsky reaction[5] of bis-silyl protected dihydroxyacetone **1**[6] with ethyl bromoacetate in the presence of activated zinc gave a β-hydroxy ester **2**. This was then treated with a 12% methanolic HCl solution at room temperature to afford hydroxy lactone **3** in 77% yield over two steps. The primary hydroxy group of **3** was selectively protected with a *tert*-butyldiphenylsilyl group to give **4** in 93% yield.[7] Fluorination of the tertiary alcohol of **4** with DAST in CH_2Cl_2 at room temperature gave fluoro lactone **5** in 32% yield. In this reaction the α,β-unsaturated lactone was obtained by elimination reaction in 27% yield. Reduction of fluoro lactone **5** to lactol with DIBAL-H at −78 °C followed by acetylation with Ac_2O gave the key intermediate, 2,3-dideoxy-3-fluoroapiofuranosyl acetate **6**, in 70% yield over two steps.



Scheme 1 *Reagents and conditions*: i, $BrCH_2CO_2Et$, activated Zn, benzene–toluene (2 : 1), reflux, 4 h; ii, 12% HCl in MeOH, room temp., 20 h, 77% (2 steps); iii, TBDPSCl, DMAP, Et_3N, CH_2Cl_2, room temp. overnight, 93%; iv, DAST, CH_2Cl_2, room temp. 1 h, 32%; v, DIBAL-H, CH_2Cl_2, −78 °C, 0.5 h; vi, Ac_2O, Et_3N, DMAP, CH_2Cl_2, room temp. 0.5 h, 70% (2 steps)



Scheme 2 *Reagents and conditions*: i, bis-silylated base, TMSOTf, $ClCH_2CH_2Cl$, 0 °C, 0.5 h; ii, TBAF, THF, room temp.; iii, methanolic NH_3, room temp. then TBAF, THF, room temp.

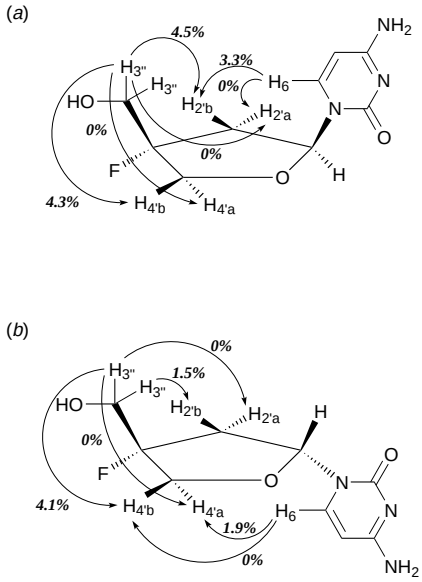


Fig. 1 NOE experiments of compounds (*a*) **9g** and (*b*) **10g**

The coupling of acetate **6** with bis-silylated pyrimidine derivatives under Vorbrüggen conditions is depicted in Scheme 2.[8] Bis-silylated pyrimidine derivatives were condensed with fluorosugar **6** in the presence of TMSOTf in 1,2-dichloroethane to give an α:β mixture of **7** and **8** in moderate yield. The mixtures were separated by silica gel column chromatography to give the individual isomers **7** and **8**. Deprotection of **7** and **8** afforded the pyrimidine nucleosides **9** and **10**, respectively.‡

The structural assignment of the uracil and cytosine analogs was made on the basis of ^{1}H NMR studies. For example, upon irradiation of the H-3″ protons in compound **9g**, nuclear Overhauser effects (NOEs) were observed for the H-2′$_b$ (4.5%) and H-4′$_b$ (4.3%) protons, while no NOEs were detected for the H-2′$_a$ and H-4′$_a$ protons. Irradiation of the H-6 proton resulted in an NOE for the H-2′$_b$ (3.3%) proton, while no NOE was observed for the H-2′$_a$ proton. In compound **10g**, upon irradiation of the H-3″ proton, NOEs were detected for the H-2′$_b$ (1.5%) and H-4′$_b$ (4.1%) protons, while no NOEs were observed for the H-2′$_a$ and H-4′$_a$ protons. Irradiation of the H-6 proton resulted in an NOE for the H-4′$_a$ (1.9%) proton, while no NOE was detected for the H-4′$_b$ proton (Fig. 1). The above results showed **9g** was the β-isomer and **10g** was the α-isomer. The relative configuration of the rest of the compounds in this report was assigned using the results of the same NOE experiments. The β-configuration of cytosine analog **9g** was determined conclusively on the basis of X-ray crystallography (Fig. 2).§ Compound **9g** assumes the 4′-*endo* conformation, in which the fluorine at C-4′ is approximately in a *gauche* disposition relative to the furan oxygen.

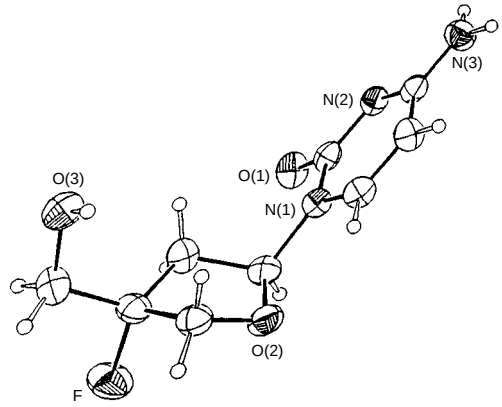

Fig. 2 ORTEP drawing of (±)-1-(2,3-dideoxy-3-fluoroapio-β-furanosyl)cytosine **9g**

Evaluation of antiviral activities and asymmetric synthesis of 2′,3′-dideoxy-3′-fluoroapiosyl nucleosides are in progress.

We are grateful to Drs C. I. Hong and S. J. Lee for helpful discussions. Special thanks are due to Mr W. K. Choi for ^{1}H NMR studies and Dr S. H. Kim for X-ray crystallography. One of us (D. Kim) acknowledges financial support from the KOSEF and Ministry of Health and Welfare (HMP-96-D-1017).

Phthalocyanines substituted with dendritic wedges: glass-forming columnar mesogens

Matthew Brewis, Guy J. Clarkson, Andrea M. Holder and Neil B. McKeown*†

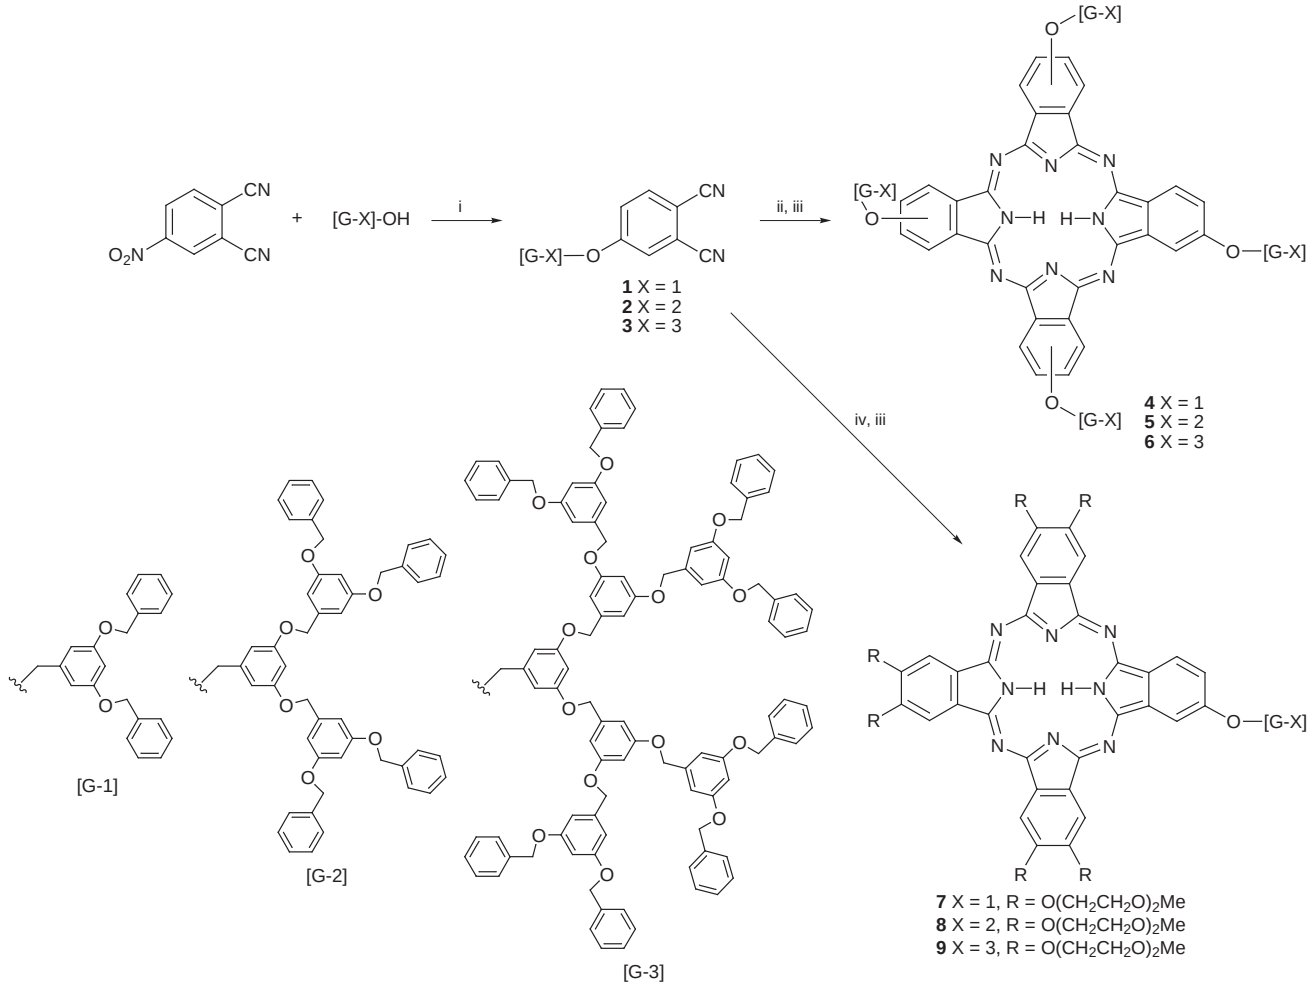
Department of Chemistry, University of Manchester, Manchester, UK M13 9PL

Peripheral substitution of the phthalocyanine macrocycle with poly(aryl ether) dendritic wedges produces materials whose properties are dominated both by the columnar self-association of the phthalocyanine core and by the glass-forming character of the dendritic substituents.

Dendrimers are currently the focus of much attention due to their compact hierarchical structures. Although research into the synthesis of novel dendrimers continues at a rapid pace,[1] there is also considerable interest in the functionalisation of existing systems. For example, the versatile, convergent synthetic route to the poly(aryl ether) dendrimers of Fréchet[2] has allowed the incorporation of functional groups based on fullerene,[3] prophyrin[4] and ferrocene[5] moieties.

Our interests lie in the preparation of novel phthalocyanine (Pc) derivatives in which control over the structure of the bulk material is achieved by the attachment of suitable substituents to the Pc core.[6] This will help exploit the exciting electro-optical properties displayed by Pcs, *e.g.* photoconductivity and third-order harmonic generation. We describe here the synthesis of some phthalocyanine (Pc) derivatives which are substituted by poly(aryl ether) wedges and reveal the interesting properties of these novel materials which are dominated both by the self-association of the Pc subunit and by the glass forming character of the dendritic substituents. The preparation of these phthalocyanine-centred dendrimers involves a novel modification of the convergent route to dendrimer synthesis in which the formation of the core is used for dendrimer assembly, rather than the attachment of the dendritic wedges to a pre-existing core.

Phthalocyanine derivatives are best prepared from substituted phthalonitrile precursors. The aromatic nucleophilic substitution reaction between 4-nitrophthalonitrile and the benzylic alcohol group of the first, second and third generation



Scheme 1 *Reagents and conditions*: i, anhydrous K_2CO_3, DMF, 50 °C; ii, $C_5H_{11}OLi$, $C_5H_{11}OH$, 135 °C; iii, AcOH; iv, 4,5-bis(1,4,7-trioxaoctyl)-phthalonitrile, $C_5H_{11}OLi$, $C_5H_{11}OH$, 135 °C

Table 1 Transition temperatures of dendrimer-substituted Pcs[a]

Compound	Transition/°C			*D*/Å
	Glass → I	Glass → φ_h	φ_h → I	
4	—	115[b]	270[b]	31.2
5	112	—	—	—
6	71	—	—	
7	—	< −20[b]	> 320[b]	28.9
8	—	115	250–255	30.0
9	—	94	108–112	35.0

[a] I = isotropic liquid, φ_h = hexagonal columnar mesophase, *D* = intercolumnar distance calculated from 1,0 diffraction ring. [b] Transition not observed by DSC.

poly(aryl ether) wedges ([G-1]-OH, [G-2]-OH, [G-3]-OH)[2] gives the required phthalonitriles **1**–**3**, respectively, in 75–90% yield (Scheme 1). Cyclotetramerisation of **1**–**3** using lithium pentanolate in refluxing pentanol gives **4**–**6** in 10–20% yield, respectively, as a mixture of four inseparable isomers. Alternatively, a mixed cyclotetramerisation between each of the phthalonitriles **1**–**3** and a ten-fold excess of 4,5-bis(1,4,7-trioxaoctyl)phthalonitrile[7] produces unsymmetrical Pcs **7**–**9**, respectively. Each of these compounds is readily separated from octakis(1,4,7-trioxaoctyl)phthalocyanine and other Pc by-products by column chromatography. The structures of **1**–**9** were confirmed by ^{1}H NMR, UV–VIS absorption and IR spectroscopy.‡ All compounds gave satisfactory elemental analyses and all, except Pc **6**, exhibited a parent mass ion using fast atom bombardment (FAB) mass spectrometry.

Despite the steric bulk of the dendritic substituents, there is evidence of self-association of the Pc cores of **4**, **5** and **6** in dilute solution. For example, the ^{1}H NMR resonances corresponding to the twelve protons attached to the Pc core of **4**–**6** are broadened considerably even at a concentration of 1×10^{-4} mol dm^{-3} in $CDCl_3$. Aggregation is also apparent in the UV–VIS spectra of **4**–**6** in chloroform solution (1×10^{-5} mol dm^{-3}) by the presence of a broad peak centred at 630 nm. Aggregation is more evident in toluene at similar concentrations. The solution behaviour of these materials is analogous to that of 1,3,4-oxadiazole-based dendrimers which were specifically designed to produce columnar supramolecular structures.[8] There is much less evidence of broadening due to aggregation in the ^{1}H NMR spectra of **7**–**9**.

The thermal behaviour of **4**–**9**, as measured by optical polarising microscopy and differential scanning calorimetry (DSC), is reported in Table 1. On cooling from the isotropic melt, **4**, **7**, **8** and **9** display optical textures characteristic of a hexagonal columnar mesophase, although the initially observed 'sandy texture' exhibited by **9** requires annealing at 105 °C for several hours in order to obtain a recognisable texture. The hexagonal columnar mesophase is commonly encountered in Pc derivatives.[9] It is remarkable that the presence of the large dendritic wedge on Pc **9** does not prohibit columnar mesophase formation but merely limits the thermal range over which the mesophase is stable. A small angle X-ray diffraction analysis (powder) of the mesophase of **4** and **7**–**9** reveals in each case a single strong, sharp band which we believe originates from the (1, 0) plane of the hexagonal lattice. Based on this assumption, the calculated intercolumnar spacings are given in Table 1.

A potentially useful aspect of the thermal behaviour of these materials is their tendency to form a glassy rather than a crystalline solid phase, as indicated by DSC studies which show distinct second-order glass transitions both on heating and cooling. Thus, the non-mesogenic **5** and **6** produce clear, crack-free solid films by cooling from the melt or by spin-coating onto a glass substrate. UV–VIS absorption spectra of these non-birefringent films (λ_{max} = 620 nm) indicates strong cofacial interactions of the Pc cores. The absence of light scattering from domain boundaries is an attractive feature for optical studies.[10]

DSC analysis of **8** and **9** also shows a distinct reversible glass transition. No change in the optical texture is observed on cooling the mesophase below the glass transition temperature and it is concluded that an anisotropic glassy state is obtained in which the columnar structure is 'frozen'.[11] Small angle X-ray diffraction studies of the resulting brittle solids are also consistent with the retention of the columnar structure. Materials such as **8** and **9** which display both an anisotropic glassy phase and a readily aligned mesophase could be used to fabricate monodomainal films suitable for optical or electronic studies.

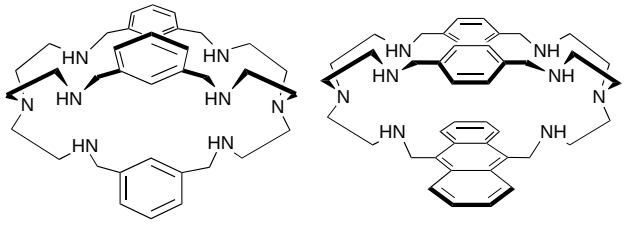
A fluorescent cage for anion sensing in aqueous solution

Luigi Fabbrizzi,*† Ilaria Faravelli, Giancarlo Francese, Maurizio Licchelli, Angelo Perotti and Angelo Taglietti

Dipartimento di Chimica Generale, Università di Pavia, I-27100 Pavia, Italy

The dizinc(II) complex of the bistren cage 2 selectively includes the isostructural N_3^- and NCO^- ions in aqueous solution, but only N_3^- inclusion is signalled through the quenching of the fluorescent emission of the anthracene spacer.

Molecular recognition of anions is in most cases based on electrostatic interactions (which include hydrogen bonding). Typically, the receptor offers a concave array of sites suitable for anion binding: ammonium or guanidium groups, amide hydrogen atoms.[1] In general, the intrinsically low energy of the electrostatic interaction does not compete successfully with the anion hydration energy and recognition studies have to be carried out in non-aqueous and poorly polar solvents. Efficient binding of anions in water would require the use of stronger host–guest interactions. This may be the case of the metal–ligand interactions. In fact, metal containing receptors perform efficient anion recognition in aqueous solution. As an example, the dicopper(II) complex of the bistren cage **1** selectively includes polyatomic anions, *e.g.* N_3^-, NCO^-, HCO_3^-. While anion inclusion is demonstrated by X-ray diffraction studies on the solid complexes,[2] recognition in aqueous solution can be monitored spectrophotometrically and is characterised by values of the association constant, K_{assn}, as high as 10^5 dm^3 mol^{-1}.[3] Each of the two donor atoms of the included ambidentate anion occupies a vacant coordination site of each Cu^{II} centre (the axial position of a trigonal bipyramid) and selectivity derives from the matching between the anion 'bite' (*i.e.* the distance between the two donor atoms) and the distance between the two vacant axial positions.



1 **2**

The function of recognition can be implemented to sensing if the receptor system contains a reporter subunit capable of signalling substrate binding through the variation of a chosen well detectable property. Fluorescence seems a particularly convenient property since it can be monitored in real time, even at very low concentration levels, by using a rather simple instrumentation. Fluorosensors for a large number of biotic and abiotic analytes have been designed during the past decade by appending a fluorescent fragment to the envisaged receptor framework:[4] in all cases, an efficient mechanism has to be provided for either quenching or reviving fluorescence, following substrate recognition. In contrast to the many efficient fluorosensors reported for cations to date, fluorescent sensors for anions are still rare.[4]

We have now synthesised the cage **2**, in which one of the spacers connecting the two tren compartments is the strongly fluorescent 9,10-anthracenyl fragment. The synthetic procedure, first involved the appending of two tren subunits to a 9,10-anthracenyl fragment; then, the terminal amine groups of each subunit were connected by 1,4-xylyl spacers.‡ Cage **2** incorporates pairs of metal ions, *e.g.* two Cu^{II}, and, following a cascade mechanism, can include ambidentate anions like N_3^- and NCO^-. However, we could not use the dicopper(II) complex as a fluorosensor, since Cu^{II} itself quenches the fluorescence of any proximate fluorophore through either an electron transfer (eT) or an energy transfer (ET) mechanism.[5] Therefore, we switched to Zn^{II}, which still forms stable complexes with amine ligands and, being redox inactive and having a filled 3d level, cannot be involved in either an eT or an ET process. Polyamine systems containing two Zn^{II} ions have been used to sense the imidazolate anion.[6]

The emitting behaviour of **2** (= L) in the pH range 2–12 was investigated by titrating with standard base a solution containing its octahydrochloride, $[H_8L]Cl_8$, plus excess acid, in the spectrofluorimetric cuvette. The corresponding fluorescence intensity, I_F, *vs.* pH profile, is shown in Fig. 1 (circles). At low pH values full anthracene fluorescence is observed. Then, I_F decreases in the pH range 4–6 following a sigmoidal pattern. Noticeably, the plot of I_F *vs.* the equiv. of added OH^- shows that fluorescence quenching takes place during the addition of the third equivalent of base (after that the excess acid had been neutralised). Amine groups display reducing properties and can transfer an electron to the proximate excited anthracenyl fragment, *An, quenching its fluorescence. It is possible that, after the neutralisation of the two protons released from the apical ammonium groups, the third proton leaves one of the ammonium groups adjacent to the An fragment allowing an eT process to take place. Then, a similar titration experiment was carried out on a solution containing also 2 equiv. of Zn^{II}. The corresponding I_F *vs.* pH profile (triangles) superimposes well on that observed for the titration of the cage alone until pH = 7. Here, I_F stops decreasing and increases again to reach a maximum at pH = 8.5. We ascribe this behaviour to the fact that from pH = 7 Zn^{II} ions enter the two tren compartments engaging all the amine nitrogen atoms in the coordinative bonds and preventing the electron transfer to *An. The maximum

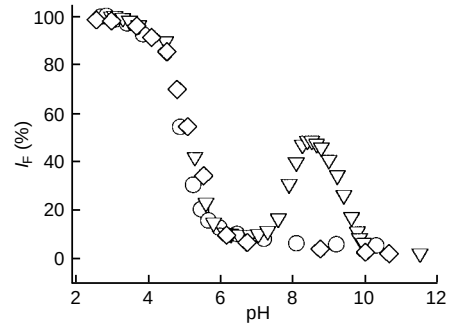


Fig. 1 pH dependence of the fluorescence intensity (I_F) for aqueous solutions containing: (○) **2** (10^{-4} M) plus excess acid; (▽) **2**, 2 equiv. of Zn^{II}, plus excess acid; (◇) **2**, 2 equiv. of Zn^{II}, 1 equiv. of N_3^-, plus excess acid.

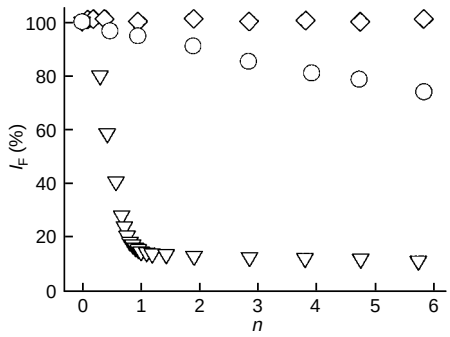

Fig. 2 Spectrofluorimetric titrations of aqueous solutions containing $[Zn^{II}(\mathbf{2})]^{2+}$ (10^{-4} M) and buffered to pH = 8.5: (▽) addition of N_3^-; (◇) addition of NO_3^- (no modification of I_F was observed also on addition of HCO_3^-, SO_4^{2-}, Cl^-, Br^-, NCO^-); (○) addition of N_3^- to a solution containing also 5 equiv. of NCO^-. *n* = Number of added equivalents of anion.

fluorescence should correspond to the maximum concentration of the $[Zn^{II}_2L_2]^{4+}$ complex. A further pH increase makes I_F decrease again. This may be due to the formation of a species in which an OH^- ion is coordinated to each metal centre. In particular, in the $[Zn^{II}_2L_2]^{4+}$ complex a water molecule is expected to occupy the axial position of each metal centre, completing five-coordination. Therefore, hydroxide containing species result from the deprotonation of the Zn^{II} bound water molecules.§ The OH^- anion can undergo an eT process and quench the proximate *An fragment. Intramolecular fluorescence quenching by coordinated OH^- ions is typically observed in Zn^{II} anthrylpolyamine complexes. Finally, in order to test the sensing behaviour of the dizinc(II) cage towards polyatomic anions, a titration with standard NaOH was carried out on a solution containing **2**, 2 equiv. of Zn^{II}, 1 equiv. of N_3^-, plus excess acid. In the corresponding profile (diamonds in Fig. 1) no fluorescence revival is observed above pH = 7, but I_F keeps decreasing until complete quenching. We ascribe this behaviour to the formation of a $[Zn^{II}_2L(N_3)]^{3+}$ inclusion complex.¶ Quenching may be due to an eT process from the electron rich N_3^- ion to the close *An fragment.

From molecular modelling, distances as short as 3 Å can be calculated between the closest nitrogen atoms of N_3^- and carbon atoms of the anthracene fragment, which may allow a fast through-space eT process to occur. Intermolecular quenching of anthracene by the N_3^- ion has been previously observed in aqueous ethanol and has been ascribed to an eT mechanism.[7] Comparison of the I_F *vs*. pH profiles of Figs. 1 and 2 indicates that at pH ≈ 8 the dizinc(II) cage could behave as a fluorescent sensor for the N_3^- ion: in particular, azide inclusion should be signalled through a substantial quenching of the anthracene fluorescence. Indeed, by titrating with a standard N_3^- solution an aqueous solution 10^{-4} M in **2**, containing 2 equiv. of Zn^{II} and buffered to pH = 8.0, a linear decrease of fluorescence was observed until the addition of 1 equiv. of azide (Fig. 2).

Least-squares analysis of the titration profile gave a value of $\log K_{assn}$ of 5.8 ± 0.1. Then, the receptor solution (1 equiv. of **2**, 2 equiv. of Zn^{II}, adjusted to pH = 8) was titrated with a series of anions: NO_3^-, HCO_3^-, SO_4^{2-}, Cl^-, Br^-. In all cases, no I_F decrease was observed even after the addition of 10 equiv. Moreover, the N_3^- titration profile as shown in Fig. 2 was not altered when the receptor solution contained also 10 equiv. of each one of the above anions. This indicates that these anions do not compete with N_3^- for inclusion: in particular, the corresponding K_{assn} values should be lower than $10^{3.6}$. The case of NCO^- is unique. On addition of NCO^- to the receptor solution, no I_F decrease was observed. However, the titration profile of N_3^- was remarkably affected by the presence of NCO^-: the greater the NCO^- concentration, the less steep the I_F decrease, indicating severe competition for inclusion within the cage. The profile reported in Fig. 2 refers to a solution containing 5 equiv. of NCO^-. From this a $\log K_{assn}$ of 6.5 can be calculated for NCO^-. Thus, NCO^- has a slightly greater affinity for **2** than N_3^-, but, due to its less pronounced reducing tendencies, when included in the cage, it is unable transfer an electron to the nearby *An fragment. N_3^- and NCO^- anions have a similar bite length (2.34 and 2.42 Å, respectively) and the rather high values of K_{assn} should reflect the favourable matching with the distance between the two vacant axial positions of the two Zn^{II} centres. The other linear triatomic anion, NCS^-, quenches fluorescence, but according to a much less steep profile, to which a much lower value of $\log K_{assn}$ corresponds: 2.45 ± 0.05. NCS^- is a one-electron reducing agent of strength comparable to that of N_3^- ($NCS^{\cdot}/NCS^-$ potential: 1.62 V *vs*. NHE; $N_3^{\cdot}/N_3^-$: 1.33),[8] which accounts for the occurrence of an intracomplex photoinduced eT process and fluorescence quenching. However, the much greater bite length (2.75 Å) should induce an endothermic rearrangement of the cage framework, making inclusion 2200 times much less favourable than for N_3^-.

This study demonstrates that the zinc(II) containing cage **2** is an efficient and selective receptor for ambidentate anions. First, it discriminates polyatomic anions from monoatomic anions, which have a less pronounced tendency to bridge two metal centres and whose inclusion is then disfavoured. Then, it recognises polyatomic anions on the basis of their bite length. Finally, the presence of the 9,10-anthracenyl spacer permits the inclusion of anions prone to a photo-induced eT process being signalled through fluorescence quenching.

‡ A solution of terephthalaldehyde (4.0 mmol in 250 ml of MeOH) was added dropwise over 2 h under magnetic stirring to a solution of the bistren derivative of the 9,10-anthracenyl fragment[6] (2.0 mmol in 750 ml of MeOH). The stirred solution was then heated to 50 °C and 2.5 g of $NaBH_4$ were added in small portions over 3 h. The solution was then stirred overnight at room temperature. MeOH was distilled off under reduced pressure, and the residue was dissolved in 100 ml of water. The aqueous solution was extracted with CH_2Cl_2 (3 × 50 ml). The organic phase was dried over Na_2SO_4 and the solvent was removed under reduced pressure to give a gold–yellow solid (yield: 55%). FAB MS *m/z* (%): 699 (100) M − H^+. **2** was used in solution studies as its hydrochloride, **2**·8HCl, which was satisfactorily analysed.

§ The following species were found to be present at equilibrium, in the 2–12 pH range, in a dioxane–water mixture (4 : 1, v/v), as ascertained through non-linear least-squares analysis of potentiometric titration data: $[Zn^{II}(H_3L)]^{5+}$, $[Zn^{II}_2L]^{4+}$, $[Zn^{II}_2L(OH)]^{3+}$, $[Zn^{II}_2L(OH)_2]^{2+}$. The dioxane–water medium was used to ensure a concentration of **2** ⩾ 10^{-3} M, as required, for potentiometric studies. A potentiometric titration study in pure water could not be carried out owing to the poor solubility of **2** (≈ 10^{-4} M).

¶ Potentiometric titration experiments in dioxane–water (4 : 1 v/v) indicated that the $[Zn^{II}_2L(N_3)]^{3+}$ complex is present as a major species in the pH range 6.5–9.0.

14e η^1-Hydrocarbyliron complexes supported by hydrotris(3,5-diisopropylpyrazolyl)borate: the allyl complex prefers a highly coordinatively unsaturated 14e η^1-structure to a 16e η^3-structure‡

Munetaka Akita,*† Nobuhiko Shirasawa, Shiro Hikichi and Yoshihiko Moro-oka*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan

Coordinatively unsaturated allyl and benzyl complexes with the hydrotris(3,5-diisopropylpyrazolyl)borate ligand (Tp^{iPr}), $Tp^{iPr}M$–allyl (M = Ni, Co, Fe) and $Tp^{iPr}Fe$–*p*-methylbenzyl, are prepared and characterized by X-ray crystallography, and the allyl ligand is coordinated to the Fe center in a η^1-fashion to form a 14e species in contrast to the η^3-coordination found for the Ni and Co complexes.

Coordinatively unsaturated organo-transition metal species have attracted much attention, in particular, in connection with catalytic transformations, which require open coordination sites for substrates (*e.g.* 14e species as polymerization catalysts),[1] and electron transfer processes.[2] Although many coordinatively unsaturated early transition metal complexes have been studied, few isolated examples of late transition metal complexes are known.[3] During the course of our study on organometallic complexes supported by the hydrotris(3,5-diisopropylpyrazolyl)borate ligand (Tp^{iPr}),[4]‡ we have found that coordinatively unsaturated hydrocarbyl complexes of the first row, late transition metals are obtained by using the Tp^{iPr} auxiliary. Herein we wish to report synthesis and structural characterization of coordinatively unsaturated hydrocarbyl complexes including a series of allyl complexes, $Tp^{iPr}M(allyl)$ (M = Ni, Co, Fe), and a η^1-*p*-methylbenzyliron complex, $Tp^{iPr}Fe$–$CH_2C_6H_4Me$-*p*.[5]

As the first attempts, we examined syntheses of complexes with the allyl ligand, which might stabilize a coordinatively unsaturated species through η^3-coordination. Treatment of the chloride precursors, $Tp^{iPr}MCl$ (M = Ni, Co, Fe), with allylmagnesium chloride in THF afforded the allyl complexes, $Tp^{iPr}M(allyl)$ (M = Ni **1**, Co **2**, Fe **3**), after extraction with pentane followed by crystallization (Scheme 1). The diamagnetic Ni complex **1** was stable in the air, whereas the other paramagnetic complexes **2** and **3** should be kept under an inert atmosphere.

The deep red Ni complex **1** was readily assigned to the structure with a η^3-allyl ligand on the basis of its ^1H NMR data similar to that of the structurally characterized analogue with the non-substituted Tp ligand,[6]‡ which also indicated occurrence of a dynamic process averaging the three pyrazolyl rings. X-Ray crystallography of **1**§¶ revealed the apparently C_s-symmetrical, square-pyramidal structure with the apical N(31) atom. The structure is similar to those of the Tp derivative[6] and the Co complex (Fig. 1), and distortion toward a square-planar structure is evident from the dissimilar Ni–N distances [Ni–N(11) 1.962(6), Ni–N(21) 1.962(5), Ni–N(31) 2.220(6) Å (difference: 0.26 Å)]. The allyl ligand is coordinated to the Ni center in a η^3-fashion as indicated by the very similar Ni–C distances [Ni–C(1) 1.991(9), Ni–C(2) 2.032(6), Ni(1)–C(3) 2.00(1) Å (difference: 0.04 Å)]. The deep green Co complex **2**§ with similar Co–η^3-allyl-carbon distances [Co–C(1) 2.066(6), Co–C(2) 2.056(4), Co–C(3) 2.077(8) Å] is isostructural with **1** (Fig. 1), though the square-pyramidal character is more evident compared to **1** judging from the smaller difference in the Co–N distances [Co–N(11) 1.983(4), Co–N(21) 1.995(4), Co–N(31) 2.153(4) Å (difference: 0.17 Å)]. Thus the Ni and Co allyl complexes are characterized as square-pyramidal η^3-allyl complexes with 18e- and 17e-configuration, respectively.

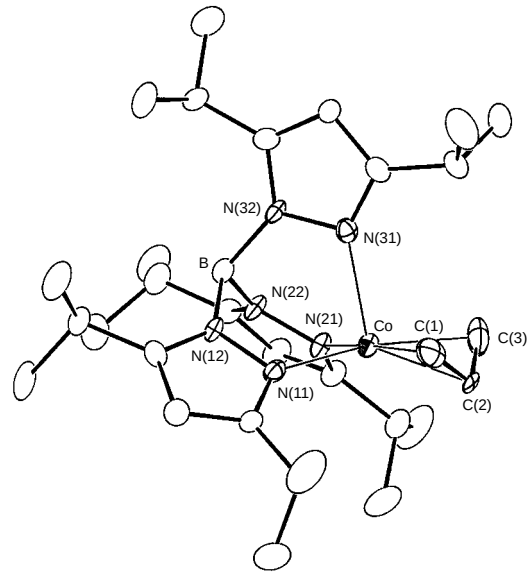

Fig. 1 Molecular structure of **2** drawn at the 30% probability level

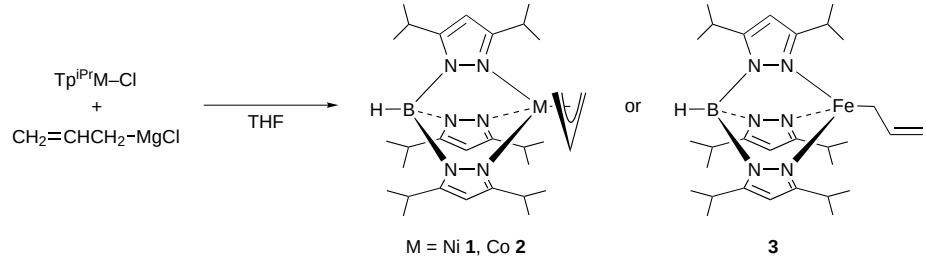

Scheme 1

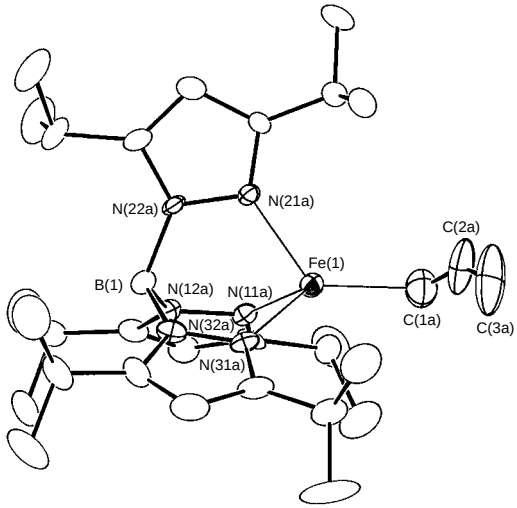

Fig. 2 Molecular structure of **3** drawn at the 30% probability level

The structure of the yellow Fe complex **3** (Fig. 2: two independent molecules)§ is in sharp contrast to those of the Ni and Co complexes. The Fe(1)–C(2a) [2.87(1) Å] and Fe(1)–C(3a) distances [3.75(2) Å] are non-bonding [*cf.* Fe–C(1a) 2.04(1) Å] and, therefore, the allyl ligand is coordinated to the iron center in a η^1-fashion. The iron center adopts a tetrahedral coordination geometry [Fe(1)–N(11a) 2.069(7), Fe(1)–N(21a) 2.071(8), Fe(1)–N(31a) 2.099(9) Å (difference: 0.03 Å)], although a slight deviation from an ideal C_3-symmetrical structure is indicated by the N–Fe(1)–C(1) angles [C(1a)–Fe(1)–N(11a) 119.2(4), C(1a)–Fe(1)–N(21a) 126.5(5); C(1a)–Fe(1)–N(31a) 130.8(6)°]. These structural features lead to the characterization of **3** as a 14e tetrahedral η^1-allyliron complex. Let us point out the curious electronic structure of **3**. If the allyl ligand is coordinated to the iron center in a η^3-fashion (4e-donor), the iron center can receive two more electrons to attain a 16e-configuration closer to coordinative saturation. Such structures are observed for the Ni (**1**) and Co complexes (**2**) with more metal d electrons as mentioned above. Despite this advantage of a η^3-structure, the iron complex with a lower number of d electrons does not adopt the η^3-structure (16e) but the η^1-structure (14e). According to our previous results, the monomeric Tp^RM–X type complexes‡ favor a tetrahedral structure,[7] although X is coordinated through a heteroatom (*e.g.* O, S) with lone-pair electrons, which may stabilize the coordinatively unsaturated metal center through π donation. For **3**, however, such stabilization is not available, and some intrinsic property of the Tp^RM-system may contribute to stabilization of the tetrahedral structures.

The successful isolation of the coordinatively unsaturated hydrocarbyl complex **3** prompted us to examine syntheses of other η^1-hydrocarbyl complexes.[5] As a typical example, the *p*-methylbenzyliron complex, $Tp^{iPr}Fe$–$CH_2C_6H_4Me$-*p* **4**, was prepared by the Grignard method analogous to Scheme 1, and X-ray crystallography§ revealed a tetrahedral coordination geometry of iron. The structural parameters around the iron center are essentially the same as those of the allyl complex **3** {Fe–C(1) 2.05(1) Å [C(1) is the α-carbon atom of the *p*-methylbenzyl group]; N–Fe–C(1) 116.9(4), 122.7(4), 136.5(4)°}, and slight distortion from a C_3-symmetrical structure is also noted.

In conclusion, coordinatively unsaturated 14e-organoiron complexes including allyl- (**3**) and benzyl-type complexes (**4**) have been synthesized and characterized. Further studies on molecular orbital analysis of the allyl complexes **1**–**3**, synthesis of other hydrocarbyl complexes and reactivity of the obtained hydrocarbyl complexes are now in progress. Preliminary experiments revealed that the η^1-hydrocarbyl complex **4** was readily carbonylated under a CO atmosphere (1 atm) to give the coordinatively saturated dicarbonyl–acyl complex, Tp^{iPr}-$Fe(CO)_2C(=O)CH_2C_6H_4Me$-*p* **5**. It is also found that **4** shows reactivity toward unsaturated hydrocarbons, and the results will be reported in due course.

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government for financial support of this research (Grant-in-Aid for Specially Promoted Research: 08102006).

Face selectivity in electrophilic additions to methylenenorsnoutanes: relative importance of through-space, through-bond and electrostatic interactions

Goverdhan Mehta,*[a]† Chebolu Ravikrishna,[a] Shridhar R. Gadre,*[b] C. H. Suresh,[b] P. Kalyanaraman[c] and Jayaraman Chandrasekhar*[c]

[a] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*
[b] *Department of Chemistry, University of Pune, Pune 411 007, India*
[c] *Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India*

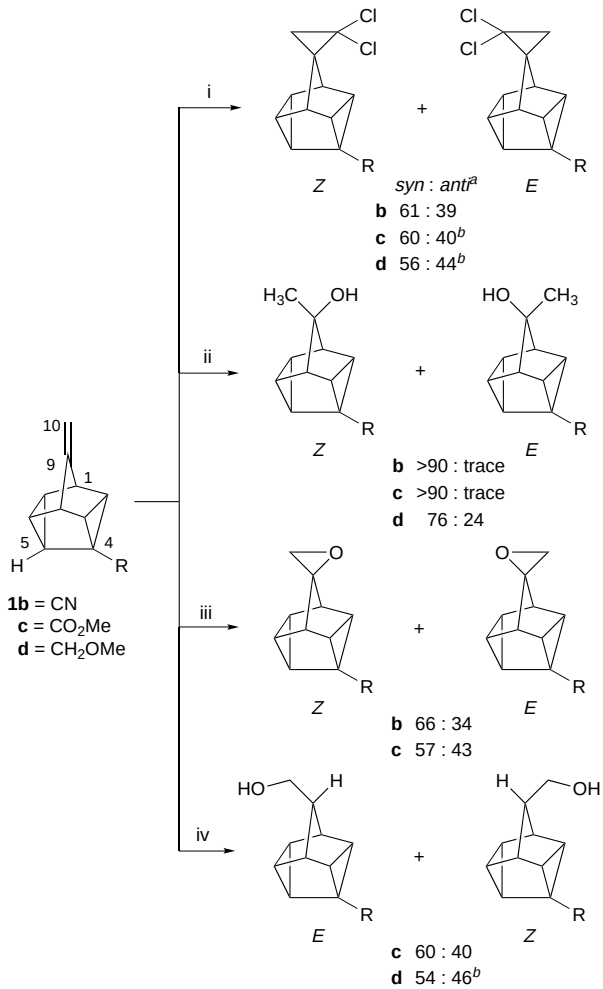
4-Substituted 9-methylenenorsnoutanes undergo a variety of electrophilic additions with a small but consistent *syn* preference; *ab initio* MESP maps indicate that electrostatic factors and through-space interaction between the double bond and cyclopropane Walsh orbitals are unimportant in determining the face selectivity, while AM1 transition state energetics suggest that the observed preferences are determined primarily by through-bond interactions.

The origin of π-face selectivity in sterically unbiased substrates continues to be a challenging problem in spite of many innovative experimental[1a–d] and theoretical investigations.[1c–e] While the importance of hyperconjugative interactions has been clearly demonstrated in electrophilic additions in several olefinic substrates,[2a–c] the competing role of electrostatic effects has been equally well established in nucleophilic additions to related carbonyl derivatives.[1d–e,2d] However, the mode by which some substituents, like the vinyl and aryl groups, induce face selectivity is often complex.[1a,2d] Recently, the cyclopropyl ring has also been shown to exhibit unusual trends in selectivity. Three-membered ring fusion causes *anti* selectivity in electrophilic additions to 7-methylenenorbornanes, but a *syn* preference in isomeric bicyclo[2.2.2]octenes.[3] This reversal is especially surprising because through-space interaction between the olefinic bond and a cyclopropane Walsh orbital is strong in both substrates on the basis of photoelectron spectral studies.[4] In order to critically evaluate the relevance of such orbital interactions in the context of alternative models, we now report the results of a combined experimental and computational examination of face selectivity in electrophilic additions to 4-substituted 9-methylenenorsnoutanes **1**. These substrates enable a comparison of the effect of two subtly different cyclopropyl units in a truly sterically unbiased environment. This study complements our earlier investigation of nucleophilic additions to the corresponding ketones,[5] in which significant face selectivity was observed and attributed to effective transmittal of orbital and electrostatic effects through three-membered rings.

The 9-methylenenorsnoutanes **1b**–**d**, readily synthesized from the corresponding ketones[5] *via* Wittig olefination ($Ph_3P^+MeBr^-$, Bu^tOK, 80%), were subjected to dichlorocarbene addition, oxymercuration, epoxidation and hydroboration reactions (Scheme 1). The structures of the *E,Z*-diastereomers were deduced on the basis of ^1H and ^{13}C NMR data, but more specifically from (i) the greater deshielding of H-5 in the *E*-series compared to *Z*-series, (ii) the relative deshielding of H-2 and H-3 in the *Z*-series compared to the *E*- series and (iii) the deshielding of the quaternary C-4 carbon resonances in the *Z*-series compared to *E*-series. These observations could be further confirmed through selected lanthanide-induced shift (LIS) studies.

All the derivatives **1b**–**d** show a consistent preference for *syn* face addition. As noted in earlier studies[1,2] on remotely substituted 7-methylenenorbornanes and 2-methyleneadamantanes, oxymercuration shows the highest facial preference. Neutral electrophiles exhibit modest selectivity.

In order to interpret the above results, the topographical features of the molecular electrostatic potentials (MESP) of methylenenorsnoutane **1a** and its cyano analog **1b** were examined at the *ab initio* HF/6-31G(d,p)//HF/3-21G level using the program INDMOL.[6] Typically, a $R_2C{=}CH_2$ unit has MESP minima above and below the π cloud, shifted towards the methylene group, while a cyclopropyl ring has three minima in the CCC plane about 1.4 Å away from each C–C bond.[7] In **1a**,



Scheme 1 *Reagents and conditions*: i, $CHCl_3$, 50% *aq.* NaOH, Et_3BnNCl, room temp., 75–80%; ii, $Hg(OAc)_2$, aq. THF, $NaBH_4$–NaOH, 80%; iii, MCPBA, CH_2Cl_2, Na_2CO_3, 5–10 °C, 75%; iv, B_2H_6–THF, H_2O_2–aq. NaOH, 80%. [a] Ratios based on ^1H NMR integration of crude reaction mixture (±5%). [b] *E* : *Z* mixture could not be separated. However, ^1H NMR data enabled identification of each isomer.

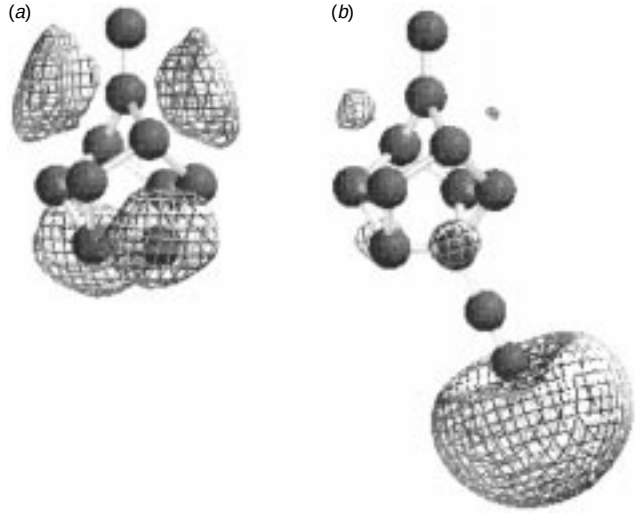


Fig. 1 MESP isopotential surfaces (contour level = −0.024 au) of (*a*) **1a** and (*b*) the cyano analogue **1b**

all the (3, +3) critical points (CPs at which the gradient of the potential vanishes and all the three eigen values of the Hessian are positive)[8] expected for the double bond and cyclopropyl rings are found. The pairs of CPs which share large negative regions [and are linked through (3, +1) saddle points] offer graphic proof of strong interactions between each of the cyclopropyl units and the olefinic π-bond as well as between the two cyclopropyl rings (see Fig. 1). These interactions were quantified earlier using photoelectron (PE) spectroscopy. In particular, σ–π interactions raise the π MO energy to 9.0 eV, compared to the value of 9.4 eV found in 7-methylenenorbornane.[4a]

The above interactions are substantially reduced by the introduction of a cyano group. The MESP minima due to the π-bond become shallow (−0.029 au compared to −0.047 au in the parent), while the CPs due to the cyclopropyl bonds are all virtually eliminated. There are no common negative regions indicative of σ–π interactions (see Fig. 1). These results are consistent with the PE spectrum of **1b**.[9] The first ionization potential, assigned to the π-bond, corresponds to 9.53 eV, fairly close to that of 7-methylenenorbornane.[4a] In the absence of electrostatic bias as well as through-space σ–π interactions in the substrate, the observed face-selectivities must have a different origin.

The activation energies for singlet : CCl_2 addition to substrates **1b**–**d** computed at the AM1 level with a modified version of MOPAC[10] provide further insights. As pointed out earlier,[2a,b] transition state geometries for carbene addition to olefins are unsymmetrical, with one C–C bond being formed to a greater extent. Hence, four sets of transition states were computed for each substrate, with facial approach being *syn* or *anti*, and the initial site of attack being C-9 or C-10.

As expected, no facial preference is computed for the transition states corresponding to initial approach towards the distal carbon (Table 1). However, in the higher energy structures in which the carbene attacks at the C-9 center, the substituents are computed to exert a small face selectivity. Consistent with the experimental data, both cyano and ester groups lead to a *syn* preference. The prediction for the methoxymethyl derivative is ambiguous since the relative activation energies are sensitive to the conformation of the

substituent. These results, especially the absence of selectivity for initial approach at C-10 and *syn* selectivity for approach at C-9 for strongly electron-withdrawing groups, suggest the operation of a relay of hyperconjugative interactions, which makes the *syn* face C–C bonds relatively electron deficient. Stabilization due to interactions between electron-rich C–C bonds and the σ*-orbital of the newly formed bond with the electrophile is greater for *syn* face approach.[11]

In summary, 4-substituted 9-methylenenorsnoutanes show *syn* selectivity in a variety of electrophilic additions. Electrostatic effects and through-space σ-π mixing are both unimportant in these substrates, as confirmed through MESP topographical analyses. The observed selectivities are primarily due to Cieplak-type hyperconjugative interactions[11] in the transition states, whose energetics are fairly correctly reproduced using AM1 calculations.

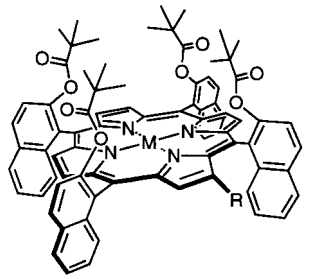
Synthesis and dioxygenation of [5,10,15,20-tetrakis(α,α,α,α-*o*-pivaloyloxynaphthyl)porphinato]iron(II) with a covalently bound imidazolylalkyl group

Teruyuki Komatsu, Kaoru Sano and Eishun Tsuchida*†‡

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan

Intramolecular *N*-imidazole coordinated [5,10,15,20-tetrakis(α,α,α,α-*o*-pivaloyloxynaphthyl)porphinato]iron(II) forms a stable dioxygen adduct in toluene at 25 °C; the sterically regulated coordination of the axial base leads to the low electron donation from the central iron to the bound O_2.

Synthetic tetraphenylporphinatoiron (FeTPP) derivatives have been extensively used for the study of hemoprotein analogs, because of their stability and advantage of covalent modification.[1] In particular, the design of both-faces encumbered models has been a topic of great interest for the preparation of stable O_2 carrying hemes.[2–5] The double-sided hindered porphyrins have actually prevented the undesired μ-oxo dimer formation. Symmetric 2,6-disubstituted TPPs are useful precursors, but the total synthetic yields to construct different structures on each side of the porphyrin plane are rather low.[6,7] In order to simply provide a second cavity under the porphyrin macrocycle, we have introduced *o*-substituted α-naphthyl groups to the four *meso*-positions. Non-substituted (tetranaphthylporphinato)iron(II) or (tetraanthracenylporphinato)iron(II) itself, however, cannot form a stable O_2 adduct at ambient temperature.[8,9] Basolo and coworkers only reported the dioxygenation of the single-face capped (naphthylporphinato)iron(II) at 0 °C.[10] Herein, we report for the first time, the synthesis, characterization and reversible O_2 coordination of [tetrakis(α,α,α,α-*o*-substituted-naphthyl)porphinato]iron(II) with covalently bound imidazolylalkyl chains at 25 °C.



The precursor porphyrin, tetrakis(β-naphthol)porphine, was prepared by Lindsey's procedure from pyrrole and 2-methoxy-1-naphthaldehyde followed by removal of the methyl groups with BBr_3.[11,12] The α,α,α,α-isomer separated by column chromatography was condensed with pivaloyl chloride in THF at 65 °C, giving 5,10,15,20-tetrakis(α,α,α,α-*o*-pivaloyloxynaphthyl)porphine **1a** (71%). Introduction of imidazolylalkyl chains to the β-pyrrolic position of the porphyrin was performed according to our previously reported procedure with 8-imidazolyl-1-yl-octanoic acid.[13] For initial formylation, the copper(II) complex **1b** gave a high yield in the Vilsmeir reaction (97%). The obtained 2-formyl–**1b** was, however, rapidly decomposed in H_2SO_4/CH_2Cl_2, which is a typical copper removal condition. All attempts for demetallation of the 2-formyl-**1b** failed. These are in sharp contrast to the 2-formyl–[tetrakis(pivalamidophenyl)porphinato]copper(II) result.[13] Fortunately, we found that the direct Vilsmeir reaction with free base **1a** yielded 2-formyl–**1a** in 21% yield. Iron insertion was carried out using $FeBr_2$ in dry THF affording **2c′**, which is now available in gram quantities. The analytical data of all compounds described above were satisfactory obtained.

2c′ was converted to the iron(II) complex **2c** by reduction in a heterogeneous two-phase system (toluene/aqueous $Na_2S_2O_4$) under an N_2 atmosphere.[7] The UV–VIS absorption spectrum of the orange solution showed five-N-coordinated iron(II) species (λ_{max} = 439, 541, 562 nm, Fig. 1), which was constant in the range of 10 μmol dm^{-3}–3 mmol dm^{-3} at 10–70 °C. The paramagnetic S = 2 state of **2c** was evidenced by the β-pyrrolic proton signals at δ 46.8–59.4 downfield to TMS (25 °C).[14] No peaks were seen between δ −5 and −15, showing that a square planar iron(II) porphyrin (S = 1) did not exist. Consequently, we can conclude that **2c** is a five-coordinated complex *via* intramolecular imidazole binding under an N_2 atmosphere.

When O_2 or CO binds to **2c**, the resulting complexes are diamagnetic and the ^{1}H NMR spectra represented characteristics of S = 0. Its UV–VIS absorption also changed to those of the O_2 or CO adduct immediately upon exposure to O_2 or CO (Fig. 1). The dioxygenation was kinetically sufficiently stable and reversible at 25 °C depending on the O_2 partial pressure. Oxidation to iron(III) porphyrin, however, took place slowly (half-life ≈ 22 h at 25 °C). The final product was the Fe^{III}(OH)

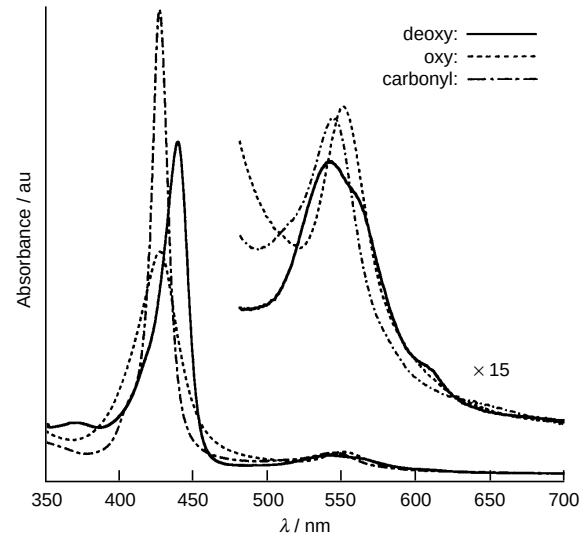


Fig. 1 Visible absorption spectral changes of **2c** in toluene at 25 °C

complex with λ_{max} at 420 and 567 nm.[15] The α-naphthalene rings obviously prevent μ-oxo porphyrin dimer formation. The rates of oxidation are strongly sensitive to water content, which is present in organic solvents when the two-phase preparation is used. From the results of the molecular simulation, the total energy of the **2c** μ-oxo-dimer was also extremely high and unlikely to be produced.

The O_2 and CO binding affinities [$P_{1/2}(O_2)$, $P_{1/2}$(CO)] were determined based on the UV–VIS absorption spectral changes (Table 1). The $P_{1/2}(O_2)$ value was 18 Torr at 25 °C, which is 60 times larger than that of [2-imidazolyloctanoyloxymethyl-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamidophenyl)porphinato]-iron(II) [Fe^{II}(TpivPPIm), $P_{1/2}(O_2)$ = 0.29 Torr].[13] The thermodynamic parameters of the dioxygenation of **2c** were also measured; $\Delta H°$ = −68 kJ mol^{-1} and $\Delta S°$ = −136 J K^{-1} mol^{-1}. Laser flash photolysis gave the association and dissociation rate constants (k_{on}, k_{off}) of these gaseous molecules.[13,16c,17] We considered that the low O_2 and CO binding affinities are mainly caused by two reasons, (*i*) the sterically regulated imidazole coordination by α-naphthyl groups and (*ii*) the relatively crowded pivaloyloxy cavity around the O_2 binding site. The following results clearly support these assumptions. (*i*) The equilibrium constant for 1,2-dimethylimidazole binding to **1c** (3×10^3 dm^3 mol^{-1}) was sterically hindered and one order of magnitude lower than those of the non-substituted Fe^{II}(TPP) or Fe^{II}(TpivPP).[10,16a] (*ii*) In the IR spectra, the coordinated CO or O_2 to **2c** showed a ν_{CO} at 1976 cm^{-1} ($\Delta\nu_{1/2}$ = 12 cm^{-1}) and a $\nu_{16_{O_2}}$ at 1169 cm^{-1} ($\Delta\nu_{1/2}$ = 11 cm^{-1}); the shifts in the stretching frequencies of $^{16}O_2$ and $^{18}O_2$ adducts (70 cm^{-1}) were in good agreement with Hooke's law. These values are significantly higher than other model hemes.[16b] The differences are probably due to the low π-back donation from the central iron, indicating weak coordination of the *trans* imidazole in **2c**. (*iii*) Kinetically, the low $k_{on}(O_2)$ leads to the low binding affinities of O_2. Based on the earlier important studies,[16c,17] the distal steric hindrance only reduces the association constant for O_2. The pivaloyloxy groups of **2c** are therefore more tilted in comparison to the pivalamide residues of Fe^{II}(TpivPPIm).

The structure of the dioxygenated **2c** complex was then simulated.[18] The dihedral angles of the four α-naphthyl groups with respect to the porphyrin plane are 75–83°, indicating the presence of an apolar space with a depth of *ca*. 4.5 Å under the porphyrin macrocycle. The imidazole coordination to the central iron is definitely oriented to avoid the four bulky naphthalene walls. It is also remarkable that the imidazole plane is unusually tilted from the Fe–N(Im) vector (ψ) with an angle of *ca*. 150°, which can not be seen in the same calculation of any other dioxygenated Fe^{II}(TPP) compounds [*e.g.* Fe^{II}(TpivPPIm)]. We considered that the unique tilting geometry of the imidazole ring may be related to the low electron donation from the central iron to the bound O_2 or CO.

Shish kebab-like chirality

Hans Engelkamp,[a] Cornelis F. van Nostrum,[a] Stephen J. Picken[b] and Roeland J. M. Nolte*[a]†

[b] *Akzo-Nobel Central Research Laboratories, Velperweg 76, 6800 SB Arnhem, The Netherlands*

The phthalocyanine units in a new optically active phthalocyaninatopolysiloxane are arranged in a rigid helical structure, providing a new kind of main-chain chirality in polymers.

In an earlier paper, we reported on the structure and properties of a chiral phthalocyanine with branched aliphatic tails derived from (*S*)-citronellol **1a**. This compound was shown to form a novel chiral columnar mesophase at room temperature, and an achiral D_r mesophase at elevated temperatures.[1] The helical structure that was proposed for the chiral mesophase is shown in Fig. 1(*c*). It represents one of the three possible arrangements of the phthalocyanine rings. In the first, these rings are arranged in a 'spiral staircase-like' manner [Fig. 1(*a*)]. In the second [Fig. 1(*b*)], the rings are positioned on top of each other, but the staggering angle between neighbouring phthalocyanines is nearly constant and always in the same direction. In the third, the normal of the plane of each phthalocyanine ring is tilted and gradually rotating along the stacking axis. The latter case was more fully in agreement with our X-ray diffraction and circular dichroism results. We denoted this new mesophase by D_h*. The second arrangement, however, could not be completely ruled out. To resolve this problem we recently synthesised a phthalocyaninatopolysiloxane **2a** with the same chiral side chains as **1a**. We present evidence here that in this polymer the phthalocyanine rings are arranged as depicted in Fig. 1(*b*), which confirms that in the mesophase of **1a** the rings have the previously proposed arrangement [Fig. 1(*c*)]. To the best of our knowledge, polymer **2a** is the first example of an optically active phthalocyaninatopolysiloxane. It displays what we would like to call 'Shish kebab-like chirality'[2] which is a new type of main chain chirality in polymers.

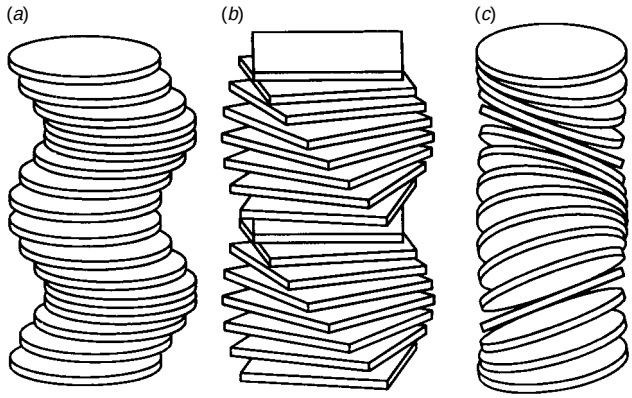

Fig. 1 Schematic representation of three possible helical arrangements of phthalocyanine molecules. The phthalocyanine rings are represented as discs in (*a*) and (*c*) and as squares in (*b*) to show more clearly the helical packing arrangement of the building blocks.

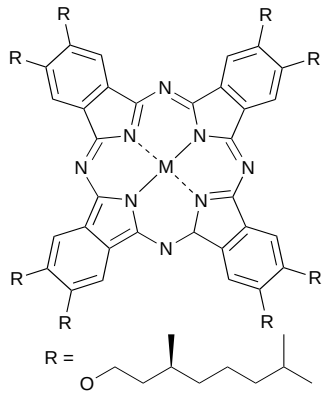
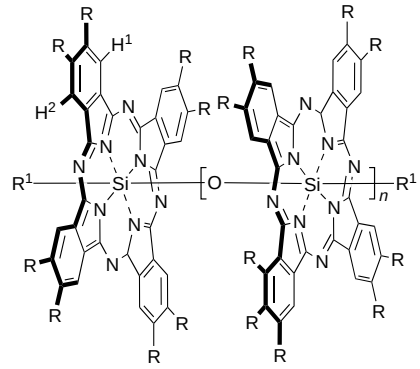
Dihydroxy(phthalocyaninato)silicon **1b** was synthesised following procedures previously developed for other octaalkoxyphthalocyanines.[3] This monomer was polymerised by heating *in vacuo* at 200 °C to give polymer **2a** as a dark blue solid, which was soluble in organic solvents.‡ From the exciton shift of the Q-band, from 680 nm in monomer **1b** to 550 nm in the polymer, the degree of polymerisation (DP) was roughly estimated to be 27.[4] In order to increase the molecular weight of polymer **2a**, we tried to polymerise dimers of the type HO(SiPC)O(SiPC)OH which were synthesised and purified separately. This method has been successfully used by Wegner to prepare high molecular weight phthalocyaninatopolysiloxanes.[3b] We were not able, however, to increase the molecular weight of **2a** by this procedure. We believe that the bulkiness of the aliphatic tails is the reason for this behaviour. In order to be able to compare the optical properties of **2a** with those of a reference compound we synthesised dimer **2b** from hydroxy(methyl)phthalocyaninatosilicon **1c**, which was prepared in an analogous manner to **1b**.‡

The circular dichroism and electronic absorption spectra of **1a**, **1b**, **2a** and **2b** in $CHCl_3$ are presented in Fig. 2. As can be seen, monomer **1b** [Fig. 2(*d*)] does not display any CD effect,



1a M = 2H
b M = $Si(OH)_2$
c M = Si(Me)OH



2a R^1 = OH, $n \approx 26$
b R^1 = Me, n = 1

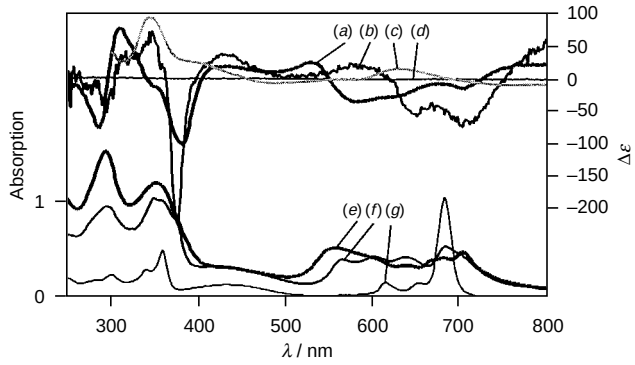


Fig. 2 Circular dichroism spectra of (*a*) **2a**, (*b*) **2b**, (*c*) **1a** and (*d*) **1b**, and electronic absorption spectra of (*e*) **2a**, (*f*) **2b** and (*g*) **1b**. All spectra are in $CHCl_3$ (10 μM) except for the mesophase of **1a**. In the latter case, the spectrum is of a film of 20 bilayers on a quartz plate; the scale is arbitrary.

indicating that its tails do not have a chiral influence on the electronic transitions of the aromatic core of this compound. The polymer **2a** [Fig. 2(*a*)] however, is strongly CD active. The negative couplet at 550 nm corresponds to the Q-band of the polymerised species, suggesting that its phthalocyanine rings are arranged in a left-handed helix.[5] This helicity is caused by the chiral side chains. Again, one could propose for the helical structure the three arrangements that are shown in Fig. 1. However, the silicon–silicon distance in phthalocyaninato-polysiloxanes is 3.3 Å (*vide infra*),[3] which is too short for the structures in Fig. 1(*a*) and 1(*c*) to be formed. This leaves only the structure of Fig. 1(*b*) as the possible helical arrangement for polymer **2a**. In the spectrum of **2a** recorded in dodecane at 120 °C (not shown), the intensity of the CD effect was only slightly decreased (by about 25%) suggesting that even at high temperatures the helical structure of **2a** is retained. The CD spectrum of dimer **2b** [Fig. 2(*b*)] shows the same features as that of polymer **2a**, but the couplet corresponding to the Q-band in the dimer is red-shifted with respect to the polymer. In the ^{1}H NMR spectrum of dimer **2b**, two resonances were present for the phthalocyanine protons (shown as H^1 and H^2 in the structure of **2**, confirming the asymmetry of the molecule. Increasing the temperature caused broadening of these resonances, but no coalescence could be observed below 120 °C. This result shows that the structure is very rigid. The CD spectrum of the mesophase of **1a** is also presented in Fig. 2(*c*). This spectrum is completely different from that of the polymer, eliminating the structure in Fig. 1(*b*) and therefore confirming the previous structural model for this mesophase [Fig. 1(*c*)]. If the polymer and the columnar mesophase had the same helical arrangement of molecular units, the CD spectra should be similar. The spectrum of an LB multilayer of **2a** (not shown) was very similar to the solution spectrum, which implies that effects due to orientational order or intercolumnar effects cannot explain the differences between the spectra of **1a** and **2a**.

X-Ray diffraction experiments were carried out, but did not provide any information about the periodicity or the pitch of the helix in **2a**. This negative result may be due to the rather low degree of polymerisation of **2a**. For such a pitch to be visible by X-ray, it should persist over extended length, *i.e.* several helical turns. This is easily accomplished in a liquid crystalline phase, *e.g.* in that of **1a**,[1] but probably not in a polymer with a degree of polymerisation of 25–30. In the X-ray diffraction pattern, the reflection corresponding to the intracolumnar Pc–Pc spacing was rather broad, probably as a result of the limited degree of polymerisation. A value of 3.3 Å could be calculated, which is in line with literature values.[3]

In summary, we have provided evidence that the stacked phthalocyanine molecules in the mesophase of **1a** and in polymer **2a** have a different helical arrangement. Current studies are aimed at the use of polymers of type **2a** as nonlinear optical materials and as optical switches.

‡ Polymer **2a** was synthesised starting from (*S*,*S*)-1,2-dicyano-4,5-bis(3,7-dimethyloctoxy)benzene (ref. 1). The latter compound was converted quantitatively into the diiminoisoindoline derivative with NH_3 and NaOMe in MeOH [ref. 3(*a*)]. After subsequent reaction with $SiCl_4$ in quinoline at 190 °C, followed by hydrolysis with water, a dark green crude product was formed. After repeated precipitation in MeOH and acetone, the dihydroxy-(phthalocyaninato)silicon **1b** was obtained (40%), which was polymerised *in vacuo* at 200 °C to give the violet–blue polymer **2a**. *Selected data* for **1b**: δ_H($CDCl_3$, 300 MHz) 0.7–2.8 (br, 152 H, aliph. H), 3.8–5.0 (m, 16 H, OCH_2), 6.5–9.0 (br, 8 H, ArH) ($C_{112}H_{176}N_8O_9Si$): Found (%) (Calc.): C, 74.45 (74.46). H, 9.86 (9.82); N, 6.16 (6.20).

Dimer **2b** was synthesised from hydroxy(methyl)phthalocyaninatosilicon **1c**, which was synthesised in a similar manner to **1b** using $MeSiCl_3$ instead of $SiCl_4$ as the silylating agent (yield 60%). Dimerisation with TlOTf in pyridine gave **2b** in 75% yield. *Selected data* for **1c**: δ_H($CDCl_3$, 300 MHz) −6.3 (s, 3 H, $SiCH_3$), 0.7–2.5 (m, 152 H, aliph. H), 4.0–4.8 (br, 16 H, OCH_2), 9.0 (s, 8 H, ArH). For **2b**: δ_H($CDCl_3$, 300 MHz) −8.35 (s, 6 H, $SiCH_3$) 0.8–2.5 (m, 304 H, aliph. H), 4.1–4.9 (br, 32 H, OCH_2), 8.26 (s, 8 H, ArH), 8.64 (s, 8 H, ArH).

Scandium triflate-catalyzed Strecker-type reactions of aldehydes, amines and tributyltin cyanide in both organic and aqueous solutions. Achievement of complete recovery of the tin compounds toward environmentally-friendly chemical processes

Shū Kobayashi,* Tsuyoshi Busujima and Satoshi Nagayama

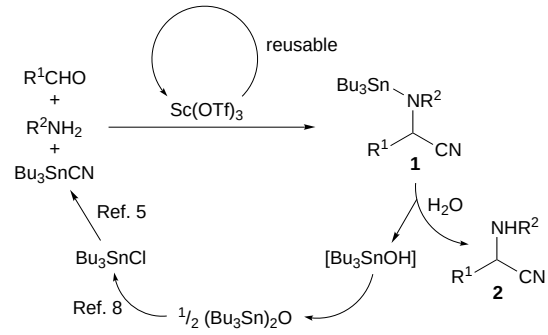
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo (SUT), and CREST, Japan Science and Technology Corporation (JST), Kagurazaka, Shinjuku-ku, Tokyo 162-0825, Japan

Scandium triflate ($CF_3SO_3^-$)-catalyzed Strecker-type reactions were successfully carried out by simply mixing aldehydes, amines and tributyltin cyanide at room temperature, to afford α-amino nitriles in high yields. The reactions proceeded smoothly in both organic and aqueous solutions, and complete recovery of the tin materials has been achieved.

The Strecker reaction provides one of the most efficient methods for the synthesis of α-amino nitriles, which are useful intermediates in the synthesis of amino acids[1] and nitrogen-containing heterocycles such as thiadiazoles, imidazoles, *etc*.[2] Although classical Strecker reactions have some limitations, use of trimethylsilylcyanide (TMSCN) as a cyano anion source provides promising and safer routes to these compounds.[1b,3] However, TMSCN is easily hydrolyzed in the presence of water, and it is necessary to perform the reactions under strict anhydrous conditions. In the course of our program to develop new synthetic reactions in aqueous media,[4] we have focused on tributyltin cyanide (Bu_3SnCN).[5] Bu_3SnCN is stable in water and a potential cyanate source, albeit there have been no reports of Strecker-type reactons using Bu_3SnCN to the best of our knowledge. Here we report scandium triflate ($CF_3SO_3^-$)-catalyzed Strecker-type reactions of aldehydes, amines and Bu_3SnCN in both organic and aqueous solutions. Complete recovery of the toxic tin compounds is also described.

We chose valeraldehyde, diphenylmethylamine and Bu_3SnCN as models, and the Strecker-type reaction was first performed in the presence of 10 mol% of $Sc(OTf)_3$ in organic solvents. The reactions proceeded smoothly at room temperature in acetonitrile, benzene, dichloromethane and toluene to afford the corresponding α-amino nitrile in high yields. Among these solvents tested, acetonitrile–toluene (1 : 1) gave the best yield (84%). It was found that no dehydration reagents such as molecular sieves, $MgSO_4$, drierite, *etc.* were needed in these reactions. We then performed the reaction in water. It was found that the model Strecker-type reaction also proceeded smoothly in the presence of a catalytic amount of $Sc(OTf)_3$‡ to give the corresponding α-amino nitrile in a 94% yield. No surfactant was needed in this reaction.[4a–c] The reaction is assumed to proceed *via* imine formation and successive cyanation,§ and it is noted that the dehydration process (imine formation) proceeded smoothly in water. Moreover, it was found that the reaction rate in water was almost the same as those in organic solvents.

While the desired reaction proceeded smoothly, it was thought that use of the toxic tin reagent might restrict the application of the reaction.[6] We then tried to recover the tin materials after the reaction (Scheme 1). The Strecker-type reaction was performed using an equimolar amount of an aldehyde and an amine, and a slight excess of Bu_3SnCN. After the reaction was completed, excess Bu_3SnCN was treated with a weak acid to form bis(tributyltin) oxide.[7] On the other hand, the adduct, α-(tributylstannylamino) amino nitrile (**1**), was hydrolyzed by adding water to produce α-amino nitrile **2** and tributyltin hydroxide, which was readily converted to bis(tributyltin) oxide.[7] Thus, all tin sources were converted to bis(tributyltin) oxide, which could be recovered quantitatively (*vide infra*). It has already been reported that bis(tributyltin) oxide can be converted to tributyltin chloride[8] and then to Bu_3SnCN.[5] Since the catalyst, $Sc(OTf)_3$, is also recoverable and reusable,[9] the present Strecker-type reactions represent a completely recyclable system.

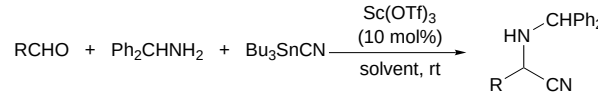


Scheme 1 Recycle system of the novel Strecker-type reactions

Several examples of the Strecker-type reaction are shown in Table 1. In all cases, including aromatic, aliphatic, heterocyclic, as well as α,β-unsaturated aldehydes, the reactions proceeded smoothly to afford the corresponding α-amino nitriles in high yields. While the adducts, α-(*N*-benzhydryl)amino nitriles, were readily converted to α-amino acids,[10] the present Strecker-type reactions using other amines such as aniline and benzylamine also proceeded smoothly to afford the corresponding adducts in high yields.

A typical experimental procedure is as follows. To a solution (3 ml) of aq. $Sc(OTf)_3$ (0.05 mmol, 10 mol%) were added an amine (0.5 mmol), Bu_3SnCN (0.75 mmol) and an aldehyde (0.5

Table 1 $Sc(OTf)_3$-catalyzed Strecker-type reactions



R	Yield (%) [in MeCN–toluene (1 : 1)]	Yield (%) (in H_2O)
Ph	88	88
PhCH=CH	83	84
2-Furyl	88	89
$Ph(CH_2)_2$	94	79
Bu	84	94
c-C_6H_{11}	86	94

mmol) successively, and the mixture was stirred at room temperature. After 20 h, the mixture was diluted with water, and the aqueous layer was extracted with ethyl acetate. $Sc(OTf)_3$ was recovered from the aqueous layer quantitatively and reused.[9] The combined organic layers were dried, filtered, and concentrated. The crude materials were treated with THF–1 M HCl (4 : 1, 3 ml) at room temperature for 1 h. Hexane and aq. saturated $NaHCO_3$ were added and the aqueous layers were extracted with ethyl acetate. The combined organic layers were dried, filtered and concentrated. The adduct was purified by column chromatography on alumina to afford the pure desired α-amino nitrile. Bis(tributyltin) oxide was recovered quantitatively (> 98%) by eluting with MeOH.

In summary, we have developed Strecker-type reactions of aldehydes, amines and Bu_3SnCN using $Sc(OTf)_3$ as a catalyst. The reactions proceeded smoothly in both organic and aqueous solutions to afford α-amino nitriles in high yields. Note that the experimental procedure is very simple; just mixing the three components and $Sc(OTf)_3$ in an appropriate solvent at room temperature. Moreover, complete recovery of the tin materials in these reactions has been achieved. While many useful tin reagents have been developed, their toxicity has sometimes limited their use in organic synthesis. This report provides a solution to this problem, and moves us further toward environmentally-friendly chemical processes.

‡ We found that rare earth triflates are stable Lewis acids in water.[9] Other rare earth triflates are also available in the present Strecker-type reactions.

§ It was confirmed that imine formation was much faster than cyanohydrin ether formation under these reaction conditions.

An unusual by-product from a non-synchronous reaction between ethyl 1,2,4-triazine-3-carboxylate and an enamine

John E. Macor,*[a]† William Kuipers[a] and Rene J. Lachicotte[b]

[a] *Department of Medicinal Chemistry, Astra Arcus USA, PO Box 20890, Rochester, NY 14602, USA*
[b] *Department of Chemistry, University of Rochester, Rochester NA 14627, USA*

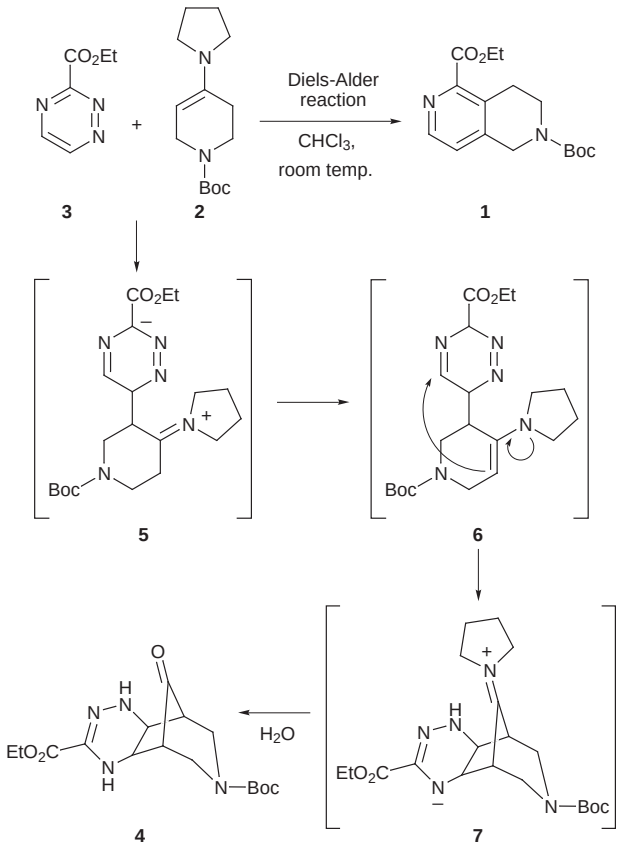
The main product from the reaction of ethyl 1,2,4-triazine-3-carboxylate 3 and the pyrrolidine enamine of *N-tert*-butoxycarbonylpiperidone 2 was an azabicyclo[3.2.1]octane 4 which resulted not from a Diels–Alder reaction, but from a series of non-synchronous steps, demonstrating a heretofore unknown reaction pathway for the electron-deficient diene 3 and electron-rich dienophile 2.

Utilization of 1,2,4-triazines as electron-deficient dienes in inverse electron demand Diels–Alder reactions with enamines has found extensive use for the synthesis of substituted pyridine derivatives. The work of Boger,[1] Taylor,[2] Snyder[3] and others have demonstrated the generality and utility of this approach to functionalized pyridines.

In a series of studies,[4] Boger and Panek examined the reaction of ethyl 1,2,4-triazine-3-carboxylate **3**[5] with a variety of enamines, and found those reactions to be relatively low yielding and complicated by uncharacterized side products. However, we desired the tetrahydronaphthyridine **1** (Scheme 1) for a medicinal chemistry study and believed that the inverse electron demand Diels–Alder reaction between **3**[5] and the enamine derived from *N-tert*-butoxycarbonyl-4-piperidone **2** would provide rapid access to the desired heterocycle **1** (Scheme 1). The necessary enamine **2** was directly available from the reaction of pyrrolidine and *N-tert*-butoxycarbonyl-4-piperidone in anhydrous Et_2O in the presence of anhydrous $MgSO_4$, and the 1,2,4-triazine **3** was available from previous studies.[5] Reaction of **2** and **3** in $CHCl_3$ at room temperature provided only a trace (8%) of the desired tetrahydronaphthyridine **1** (Scheme 1).[6] The major component of the reaction mixture (26%) was an unidentified product whose preliminary spectral data suggested the incorporation of both components **2** and **3** from the reaction without the elimination of nitrogen as would be seen in a Diels–Alder adduct. Extensive NMR studies and mass spectral data suggested that the compound was a tetrahydro-1,2,4-triazine fused to an azabicyclo[3.2.1]octane core (**4**, Scheme 1).[7] Crystals were prepared of this compound (ethyl acetate–benzene) of sufficient quality that X-ray diffraction studies could be performed, and this experiment confirmed the structure of the by-product as that depicted by **4** (Fig. 1).[8]

The azabicyclo[3.2.1]octane clearly was not the result of a Diels–Alder reaction. A likely mechanism for its formation is shown in Scheme 1. The electron-rich β-position on enamine **2** attacked the electron-deficient C6 position of 1,2,4-triazine **3** in a vinylogous Michael reaction fashion. The negative charge introduced into the 1,2,4-triazine ring was stabilized by the electron-delocalizing carboxylate located at C3 of the heterocycle. Probably because of this stabilized zwitterionic species **5**, the ammonium moiety that resulted from the vinylogous Michael attack of the enamine underwent a proton transfer reaction which protonated the enolate and reformed the enamine, leading to **6**. The enamine **6** then attacked the proximate imine (Scheme 1) forming intermediate ammonium species **7** which yielded **4** upon hydrolysis.

These results, coupled with evidence from the literature,[4,9,10] suggest that the presence of an electron-delocalizing substituent at C3 of the 1,2,4-triazine can shift the balance of reactivity from a concerted Diels–Alder reaction to a stepwise, non-synchronous reaction which gives rise to the observed by-



Scheme 1

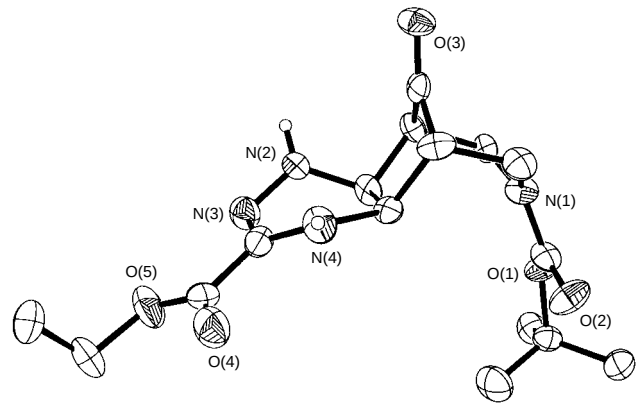


Fig. 1 Crystal structure of **4**

product **4**, especially if the C6 position is unsubstituted. The presence of the ethoxycarbonyl group provided resonance stabilization of the negative charge introduced into the 1,2,4-triazine ring from the attack of the enamine. This and possibly the steric hindrance of the ethoxycarbonyl group discouraged further reaction of C3 of the 1,2,4-triazine with the electrophilic iminium species in **5**, leading to the creation of the second enamine moiety. This newly formed enamine could then react in a relatively unhindered fashion, leading to the 7-azabicyclo[3.2.1]octane moiety found in **4**.

The result of this reaction might have general implications for the reactions of enamines (and other electron-rich dienophiles) with 1,2,4-triazines (or other electron-poor dienes) in attempted inverse electron demand Diels–Alder reactions. Previous examples of enamines reacting with azadienes with electron-delocalizing substituents on *both* carbon atoms involved with the Diels–Alder reaction (*i.e*. diethyl 1,2,4,5-tetrazine-3,6-dicarboxylate[9] and triethyl 1,2,4-triazine-3,5,6-tricarboxylate[4b]) are generally high yielding, suggesting that non-synchronous side reactions are either minimal or nonexistent. For example, triethyl 1,2,4-triazine- 3,5,6-tricarboxylate reacted with the pyrrolidine enamine derived from phenyl *n*-propyl ketone to afford the expected pyridine in 73% yield, whereas ethyl 1,2,4-triazine-3-carboxylate afforded only 10% of its expected pyridine when reacted with the same enamine.[4b] Also, when 3-(dimethoxymethyl)-1,2,4-triazine was used in place of ethyl 1,2,4-triazine-3-carboxylate, the Diels–Alder reactions of the acetal with enamines proceeded in higher yield.[4a] Therefore, it would appear that only in those cases where a resonance delocalizing group exists on one of the carbon atoms involved with the Diels–Alder reaction and the other, *para* carbon atom on the azadiene is unsubstituted, the balance of reactivity may be sufficiently altered to allow for, or favor, non-synchronous reactions such as vinylogous Michael reactions which would limit the amount of Diels–Alder product seen from these reactions. The result of these reactions would be products analogous to **4**. We are presently attempting to examine the generality of this hypothesis, and the implications for inverse electron demand Diels–Alder reactions.

The authors wish to thank Dr Paul Rosenberg for his efforts in establishing the collaboration for X-ray diffraction experiments between Astra Arcus and the University of Rochester.

8 Crystals of **4** were grown in a concentrated EtOAc–benzene solution, and benzene was incorporated into the crystalline lattice in a ratio of 1 : 1 with **4**. A small single crystal was mounted on glass fiber under Paratone-8277 and placed on the X-ray diffractometer in a cold N_2ogen stream supplied by a Siemens LT-2A low temperature device. The X-ray intensity data were collected on a standard Siemens SMART CCD Area Detector System equipped with a normal focus molybdenum target X-ray tube operated at 2.0 kW (50 kV, 40 mA). A quadrant of data were collected using a narrow frame method with scan widths of 0.3° in *w*, and an exposure time of 30 s per frame. Frames were integrated to 40° with the Siemens SAINT program yielding a total of 3416 reflections, of which 1832 were independent reflections [*R*(int) = 0.0700]. The unit cell parameters were based upon the least-squares refinement of three dimensional centroids of 857 reflections at −80 °C, giving a monoclinic cell with *a* = 15.038(1), *b* = 13.967(1), *c* = 10.777(1) Å, β = 99.594(4)°, *V* = 2232.0(2) Å^3. The space group was assigned as $P2_1/c$ (*Z* = 4 and D_c = 1.281 g cm^{-3}) on the basis of systematic absences using the XPREP program (Siemens, SHELXTL 5.04). The absorption coefficient was 0.092 mm^{-1}. The structure was solved by direct methods and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined with anisotropic thermal parameters, with H atoms included in idealized positions. The empirical formula is $C_{16}H_{24}N_4O_5{\cdot}C_6H_6$ giving a formula weight of 430.50 g mol^{-1}. Final *R* indices [1143 data having $I > 2\sigma(I)$]; R_1 (%) = 7.90 [R_1 = 0.0790; wR_2 = 0.1481]. CCDC 182/810.

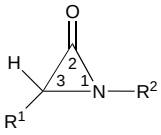
Regioselectivity in nucleophilic ring-opening of aziridinones

Erach R. Talaty*† and Mashitah M. Yusoff

Department of Chemistry, Wichita State University, Wichita, Kansas 67260-0051, USA

The proportions of products derived from competing modes of ring-opening of 1,3-di-*tert*-butylaziridinone and similar aziridinones by a variety of nitrogen, oxygen, sulfur and halogen nucleophiles do not agree with simple guidelines postulated in the literature for these types of aziridinones.

An important aspect of the chemistry of aziridinones is their mode of ring-opening by nucleophiles and the factors that



1 $R^1 = R^2 = Bu^t$
2 $R^1 = R^2$ = 1-adamantyl
3 R^1 = 1-adamantyl, $R^2 = Bu^t$
4 $R^1 = Bu^t$, R^2 = 1-adamantyl

govern the outcome. It has been reported[1,2] that ionic, aprotic nucleophiles (Z^-) cause rupture exclusively of the acyl–nitrogen bond (1,2-bond), whereas non-ionic protic nucleophiles (HZ) afford products derived solely or mainly from scission of the alkyl–nitrogen bond (1,3-bond). Our previous publications[3,4] clearly contradict this sample rule, albeit with a limited set of nucleophiles. We have embarked on a broader study of nucleophilic ring-opening of aziridinones.

An examination of the nitrogen nucleophiles (aprotic) in Table 1 reveals immediately that all of them do not cleave solely the alkyl–nitrogen bond of **1** as alleged in the literature.[1,2] In fact, the only ones that exhibit this pattern are all of the aromatic amines (entries 10–17), none of which was used previously in conjunction with aziridinones **1**–**4**. On the other hand, the simple aliphatic primary amines rupture exclusively the acyl–nitrogen bond of **1**. The secondary amines exhibit varying degrees of ring-opening (entries 3 and 5 giving exactly opposite results) that also seem to depend on the nature of the aziridinone (*e.g.* compare entries 2 and 32), indicating a subtle dependence on steric factors. Roughly speaking, stronger, unhindered nitrogen nucleophiles tend to cleave the acyl–nitrogen bond, whereas sterically hindered, weaker ones favor scission of the alkyl–nitrogen bond. However, there are exceptions to even this rough rule (entries 5, 18 and 19). The aprotic oxygen and sulfur nucleophiles also exhibit considerable variation in their selectivity, the alcohols being most consistent in favoring cleavage of the alkyl–nitrogen bond. The protic ionic nucleophiles also do not all afford products derived from acyl–nitrogen cleavage, as suggested in the literature.[1,2] In fact, the sharp difference between bromides and iodides on one hand and alkoxides on the other hand suggests the intervention of yet another factor, namely, hardness or softness of the nucleophile. Iodide, a soft nucleophile, attacks the soft alkyl carbon of **1**, whereas alkoxide, a hard nucleophile, prefers to attack the harder acyl carbon.

A priori, one can envisage the following two schemes that may determine the selectivity in ring-opening of the aziridinones. Scheme 1 resembles the S_N1/S_N2 type dichotomy encountered in nucleophilic aliphatic substitution [path (*a*) being unimolecular and path (*b*) being bimolecular], whereas Scheme 2 (competing bimolecular pathways) was apparently the basis of the guidelines given in the literature.[1,2] If Scheme 1 were to be the exclusive one prevailing, then the selectivity could be altered proportionately by changing the concentration of a nucleophile that tends to give both types of products. In our case, no such alteration or, at best, minor alterations could be effected in some cases that we examined. Scheme 1 would also indicate a strong dependence on nucleophilicity, path (*b*) being favored by powerful nucleophiles. However, as observed above, an excellent nucleophile such as iodide affords just the opposite type of product. It thus appears that, at least in the case of aziridinones **1**–**4**, no one scheme can satisfactorily explain the competing modes of ring-opening by nucleophiles, a conclusion that does not follow from a study of other types of aziridinones.[9]

We have extended the study of nitrogen nucleophiles to include those that might be synthetically useful as a route to larger heterocycles, as illustrated by the three new examples shown in Scheme 3.[10]

Note that (i) these are the only heterocyclic products isolated in each case; (ii) PhNHCN and $PhNH_2$ (mentioned in Table 1) give products derived from opposite modes of cleavage; (iii) specificity in the substitution pattern of these five-membered heterocyclic compounds can be controlled by the method of synthesis; and (iv) the structures of these three heterocyclic compounds could not have been predicted by previous guidelines.

Magnetoresistance is observed in non-ferromagnetic oxides containing Fe^{IV} which have magnetic behaviour characteristic of small magnetic clusters.

Much attention has recently been focused on the observation of colossal magnetoresistance (CMR, *i.e.* almost 100% suppression of the zero-field resistance upon application of a magnetic field) near the coincident Curie and metal–insulator transition temperatures of ferromagnetic manganese oxides.[1] Investigation of oxides of metals other than manganese has shown CMR $\{\Delta\rho/\rho = [\rho(0) - \rho(B)]/\rho(0) < 72\%$ in 10 T$\}$ in ferromagnetic $La_{1-x}Sr_xCoO_3$[2] with a similar mechanism to that of the manganites being invoked, and $\Delta\rho/\rho = 4\%$ in a 7 T field at 150 K in the metallic ferromagnet $SrRuO_3$.[3] $\Delta\rho/\rho = 20\%$ at 6 T in Cr-based chalcogenide spinels has recently been reported.[4] We have been engaged in a search for magnetoresistance in first-row transition metal oxides,[5,6] and report here the first observation of significant magnetoresistance ($\Delta\rho/\rho \leqslant 19\%$ in 12 T at 4.2 K) in iron-based oxides with significant cooperative magnetic interactions but no long-range ferromagnetic order. The systems were chosen as dilute solid solutions between the itinerant helical antiferromagnet $SrFeO_3$, the ferromagnetic metal $SrCoO_3$ and the valence-unstable $CaFeO_3$, which undergoes disproportionation into Fe^{III} and Fe^{V}.[7]

Perovskite oxides of composition $SrFe_{0.9}Co_{0.1}O_3$ and $Sr_{0.9}Ca_{0.1}FeO_3$ were prepared by solid state reaction of the starting oxides plus strontium carbonate in air at 1100 °C followed by annealing under 800 bar O_2 at 400 °C for three days to maximise the metal oxidation states.‡ Rietveld refinement of powder neutron and X-ray (from both laboratory and high resolution synchrotron sources) diffraction data showed that both products were undistorted pure cubic perovskites, with an oxygen content corresponding to a mean cation oxidation state of +IV. This was confirmed by TGA reduction under hydrogen. Magnetic measurements over a range of fields and temperatures indicate the presence of strong and competing exchange interactions, consistent with the strong covalency produced by the high metal oxidation states. The Curie–Weiss law is obeyed above 260 K with moments of 7.9 (Ca) and 9(Co) μ_B, significantly enhanced over the high-spin Fe^{IV} spin-only value of 4.9 μ_B in both cases, in agreement with previous work on $SrFeO_{3.00}$[8] and $SrFe_{0.9}Co_{0.1}O_3$.[9] The Weiss constant was significantly more positive for the Co doped phase (210 K *cf.* 10 K).

History-dependent measurements on $SrFe_{0.9}Co_{0.1}O_3$ at 100 G show a maximum in both field-cooled (FC) and zero-field cooled (ZFC) magnetisations at 85 K (Fig. 1). $M(H)$ is linear at 300 K but becomes sigmoidal in shape (without hysteresis) below 170 K and shows no sign of saturation in a 50 kG measuring field (Fig. 1 inset). These observations are consistent with the existence of cooperative magnetic interactions without long-range magnetic order, resulting in the formation of small magnetic domains often characterised as cluster glass behaviour.[10] Mössbauer spectroscopy has previously suggested that the distribution of Co at low (< 0.2) doping levels in $SrFe_{1-x}Co_xO_3$ is inhomogeneous, with Co-rich regions being ferromagnetic in a non-ferromagnetic matrix.[11,12]

The magnetic behaviour of $Sr_{0.9}Ca_{0.1}FeO_3$ differs. The magnetisation is smaller than that of the Co-doped sample and decreases after a sharp maximum at 120 K. Neutron powder diffraction measurements (Fig. 2 inset) show that this coincides with the onset of antiferromagnetic long-range order with the

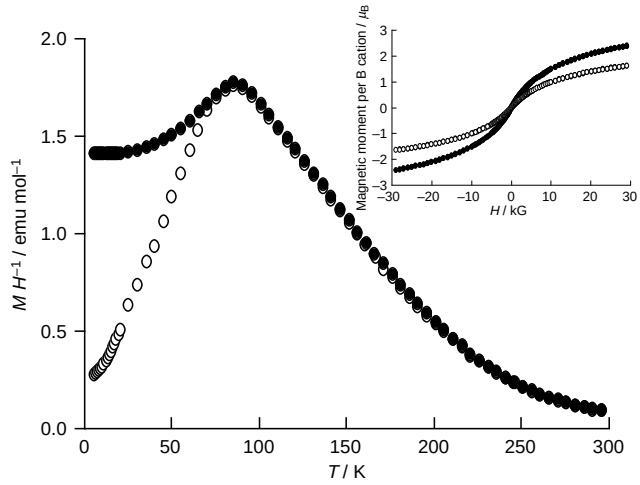

Fig. 1 Temperature dependence of M/H for $SrFe_{0.9}Co_{0.1}O_{3.00}$ in a measuring field of 100 G. Field-cooled (FC) data are shown as filled circles, zero-field-cooled (ZFC) as empty circles. Inset: ZFC $M(H)$ isotherm of $SrFe_{0.9}Co_{0.1}O_{3.00}$ at 45 K (filled circles) and 170 K. The sigmoidal shape indicates the existent of magnetic domains within the sample. $M(H)$ isotherms at different temperatures do not fall on a universal curve when plotted as a function of H/T, indicating the compound is not a classical superparamagnet.

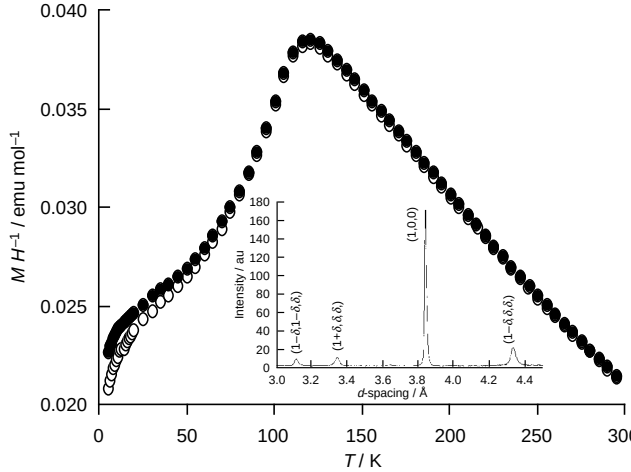

Fig. 2 Temperature dependence of M/H for $Sr_{0.9}Ca_{0.1}FeO_{3.00}$ in a 100 G measuring field. Field-cooled (FC) data are shown as filled circles, zero-field-cooled (ZFC) as empty circles. Inset: incommensurate magnetic Bragg peaks for the helical magnetic structure observed at 5 K (the nuclear (1 0 0) reflection is also shown.)

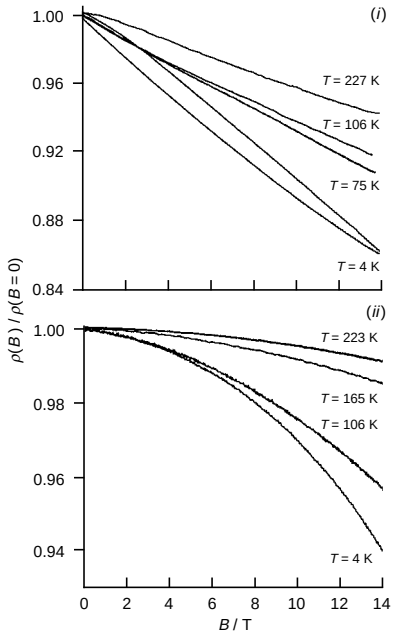

Fig. 3 Magnetoresistance isotherms of (*i*) $SrFe_{0.9}Co_{0.1}O_3$ and (*ii*) $Sr_{0.9}Ca_{0.1}FeO_3$

helical antiferromagnetic structure found for $SrFeO_3$.[13] There is, however, significant divergence between FC and ZFC data below 100 K (Fig. 2) suggesting the development of magnetic disorder at low temperatures. The adoption of a helical magnetic structure by $SrFeO_3$ in preference to one of the collinear structures common amongst perovskites,[14] demonstrates that the competing interactions necessary to cause spin-glass behaviour are present in this system. Furthermore, the presence of a disordered Ca/Sr distribution will introduce an element of randomness into the superexchange interactions; this effect is likely to be relatively large, given the sharp contrast in the properties of $SrFeO_3$ and $CaFeO_3$.

Despite the clear absence of a transition to a three-dimensionally ordered ferromagnetic state in the magnetisation measurements on either compound, significant magnetoresistance is observed for temperatures below 250K (Fig. 3), with values of the conservative figure-of-merit $[\rho(B = 12\ T) - \rho(B = 0)]/\rho(B = 0)$ of 9% at 50 K for $Sr_{0.9}Ca_{0.1}FeO_3$ and 18% at 4 K for $SrFe_{0.9}Co_{0.1}O_3$ (11% at 100 K).

Powder neutron diffraction indicates a smooth structural evolution with temperature. The absence of a localised to itinerant electron transition signalled by ferromagnetism produced by double exchange and of structural features associated with strong Jahn–Teller electron–phonon coupling provides a clear distinction from the behaviour of mixed-valence manganates. The observation of both magnetic behaviour suggestive of ferromagnetically correlated inhomogeneities and magnetoresistance appears to be analogous to the behaviour of the heterogeneous, ferromagnetic Cu–Co and Ag–Co alloys which are some of the best 'giant' magnetoresistance (GMR) materials.[15] In the alloys, the scattering of electrons at the grain boundaries between the ferromagnetic regions embedded in a conducting matrix is strongly reduced by the application of a magnetic field, which reduces the angle between the moments of the magnetic regions and suppresses spin-dependent scattering. The presence of ferromagnetic regions in the Co-doped system, seen by magnetisation isotherms to be present at temperatures where significant magnetoresistance is observed, may indicate that a similar mechanism operates in the present materials.

The magnetisation of both phases reported here suggests the presence of competing interactions and non-equilibrium behaviour due to cluster formation and blocking. The presence of competing ferro- and antiferro-magnetic interactions is a common feature of the two ternary iron oxides presented here, and suggests that this recipe for significant, albeit not colossal, magnetoresistance in oxides deserves further exploration, a suitable starting point being the optimisation of the effect in the current system.

We thank the EPSRC for support including a studentship for L. E. S. and access to station 2.3 at Daresbury Laboratory, where C. C. Tang assisted us, and to the HRPD and IRIS instruments at ISIS. We are particularly indebted to R. M. Ibberson for his assistance at the ISIS facility. J. L. thanks the Basque Government ('Gobierno Vasco-Eusko Jaurlarita') for a studentship and M. J. R. thanks the Royal Society for a grant towards the cost of developing the high pressure oxygen apparatus.

‡ The high oxygen pressure was generated by diaphragm compression of 200 bar oxygen using a Fluitron compressor. The reaction mixture was contained in gold foil within an externally heated Rene 41 cold-seal vessel. X-Ray powder diffraction data were recorded using a Siemens D5000 diffractometer (Cu-Kα_1 radiation) in Bragg–Brentano geometry and also on station 2.3 of the Synchrotron Radiation Source, Daresbury Laboratory. Neutron powder diffraction data were recorded for $4 \leqslant T/K \leqslant 300$ on the high resolution diffractometer HRPD and on the long-wavelength IRIS instrument at the ISIS pulsed neutron source, Rutherford Appleton Laboratory. Rietveld refinement was carried out with the GSAS suite of programs. The refined compositions from the neutron data were $SrFe_{0.9}Co_{0.1}O_{3.00(1)}$ [a = 3.846 25(6) Å] and $Sr_{0.9}Ca_{0.1}FeO_{2.99(1)}$ (a = 3.846 21(5) Å], consistent with the observation that the cubic perovskite is only stable for oxygen content $2.97 \leqslant y \leqslant 3.00$[16] and TG estimates of $y = 3.00 \pm 0.05$. Our synthetic method for $SrFeO_3$ gives a = 3.85097(3) Å. Magnetic measurements were made with a Quantum Design MPMS5 SQUID magnetometer. Magnetoresistance measurements were made using standard, low-frequency (31 Hz), four-wire ac techniques in fields of up to 14 T with the current (0.2 mA) perpendicular to the magnetic field.

A new manganese(IV) oxamato complex possessing a bis(μ-oxo)dimanganese core has been synthesized, magnetically and structurally characterized, and found to catalyze the aerobic oxidation of secondary alcohols to ketones with co-oxidation of pivalaldehyde to pivalic acid with good yields and high selectivities.

Interest in high valent manganese coordination chemistry stems largely from the fundamental role that manganese ion in relatively high oxidation states plays in biological dioxygen activation.[1] Manganese interacts with dioxygen and its reduced derivatives in a variety of enzymes from mononuclear (manganese superoxide dismutase) and dinuclear (manganese catalase or manganese ribonucleotide reductase) to tetranuclear (water-oxidizing complex in photosystem II), making use of the Mn^{II}, Mn^{III}, Mn^{IV} and, probably, Mn^{V} oxidation states. Once it was recognized that the active site in catalase and the water-oxidizing complex contains oxo-bridged dimanganese cores, considerable effort was devoted to obtaining dimeric manganese complexes which could be structural as well as functional models for this class of metalloproteins.[2] During the last two decades several bis(μ-oxo)dimanganese complexes with different ligand types have been reported, but comparatively scarce are the studies concerning their reactivities and, particularly, their use as oxidation catalysts.[3,4] In fact, the manganese complex in the water-oxidizing center also exhibits oxidation chemistry in its lower oxidation states.[5] Here we report the synthesis and physical characterization,‡ and the crystal and molecular structure§ of the manganese complex $[PPh_4]_4[Mn(opba)(O)]_2\cdot 4H_2O$ **1**, where opba = *o*-phenylenebis(oxamato) ligand, as well as a preliminary investigation of its catalytic oxidation properties with dioxygen.

The structure of **1** consists of centrosymmetric bis(μ-oxo)dimanganese(IV) complex anions, $[Mn_2(opba)_2(O)_2]^{4-}$ (Fig. 1), tetraphenylphosphonium cations and crystallization water molecules. The two crystallographically equivalent manganese atoms adopt a distorted octahedral geometry formed by two amide nitrogen and two carboxylate oxygen atoms from two symmetric related opba ligands (I = $-x$, $-y$, $-z$), each donating one of its NO donor set from oxamato to each of the manganese atom at *cis* sites; the coordination sphere of the manganese atoms being completed by two oxygen atoms from the two *cis*-bridging oxo groups. The short Mn–O(1) and Mn–O(1^{I}) bonds of 1.799(4) and 1.797(4) Å, respectively, and the acute O(1)–Mn–O(1^{I}) angle of 85.9(2)°, are entirely consistent with a di(μ-oxo)-bridged manganese(IV) complex.[2b] Within the planar Mn_2O_2 rhomb, the Mn···Mn^{I} and O···O distances are equal to 2.631(2) and 2.453(3) Å, respectively. The most interesting structural feature of **1** is, however, the bis-bidentate dinucleating coordination mode of the opba ligand. In fact, the oxamato groups of each opba ligand clamp the two manganese atoms, which are in turn tethered by the phenylene backbone between the amide nitrogen donor set. The phenylene linker forces a twist of the N(1)–C(5) and N(2)–C(10) bonds by 125.1(5) and 127.0(5)°, respectively, resulting in a dihedral angle between the mean planes of the oxamato groups of the opba ligand of 71.7(2)°. This distortion is also reflected in the Mn–N(amide) bond distances [1.986(5) and 2.006(5) Å] which are slightly longer than the Mn–O(carboxylate) ones [1.970(4) and 1.965(4) Å]. This unprecedent situation contrasts with that found for the related mononuclear manganese(III) complex with the 4,5-dichloro-opba derivative where the Mn–N(amide) and Mn–O(carboxylate) bond distances average 1.95 and 1.98 Å, respectively.[6] Within this complex the oxamato ligand adopts an almost planar configuration, and the coordination scheme is the familiar tetradentate N_2O_2 one with the ligand occupying the equatorial plane about the manganese atom (*trans* isomer).

We have investigated the capability of this novel dinuclear manganese(IV) complex towards oxidative catalytic transformations of various organic substrates by the combined use of dioxygen and an aldehyde as oxidant.[7] The results obtained for some representative primary and secondary alcohols, both aromatic and aliphatics, are detailed in Table 1. Complex **1** selectively catalyzes the oxidation of 1-phenylethanol to the corresponding ketone, acetophenone, by dioxygen plus pivalaldehyde in dichloromethane solution with good yields, *i.e.*

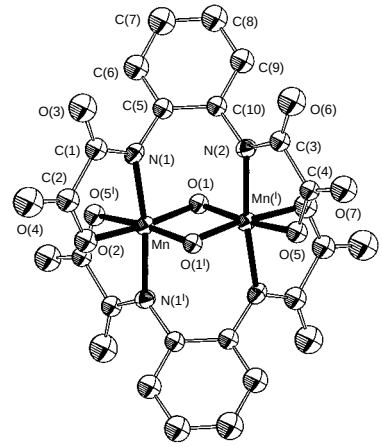

Fig. 1 Perspective view of the anionic dinuclear unit of **1** with the atom-numbering scheme (thermal ellipsoids are at the 30% probability level and hydrogen atoms have been omitted for clarity). Selected bond distances (Å) and angles (°) with standard deviations in parentheses: Mn–O(1) 1.799(4), Mn–O(1^{I}) 1.797(4), Mn–O(2) 1.970(4), Mn–O(5^{I}) 1.965(4), Mn–N(1) 1.986(5), Mn–N(2^{I}) 2.006(5), Mn–Mn^{I} 2.631(2); O(1)–Mn–O(1^{I}) 85.9(2), O(1)–Mn–O(2) 173.0(2), O(1)–Mn–O(5^{I}) 93.6(2), O(1)–Mn–N(1) 91.1(2), O(1)–Mn–N(2^{I}) 94.9(2), O(1^{I})–Mn–O(2) 93.8(2), O(1^{I})–Mn–O(5^{I}) 172.8(2), O(1^{I})–Mn–N(1) 94.5(2), O(1^{I})–Mn–N(2^{I}) 91.1(2), O(2)–Mn–O(5^{I}) 87.6(2), O(2)–Mn–N(1) 81.9(2), O(2)–Mn–N(2^{I}) 92.2(2), O(5^{I})–Mn–N(1) 92.7(2), O(5^{I})–Mn–N(2^{I}) 81.8(2), N(1)–Mn–N(2^{I}) 172.1(2), Mn–O(1)–Mn^{I} 94.1(2) (symmetry code: I = $-x$, $-y$, $-z$).

Table 1 Results for the oxidation of alcohols by dioxygen and pivalaldehyde catalyzed by **1**[a]

Entry	Alcohol	*t*/h	Yield (%)[b,c]
1	1-Phenylethanol	24	70
2	1-(*p*-Methoxyphenyl)ethanol	24	75
3	1-(*p*-Bromophenyl)ethanol	24	68
4	1-(*p*-Trifluoromethylphenyl)ethanol	24	65
5	1-(*p*-Nitrophenyl)ethanol	24	60
6	4-(*tert*-Butyl)cyclohexanol	48	50
7	*p*-Methoxybenzyl alcohol	12	95[d]

[a] Reactions were carried out at room temp. by adding a CH_2Cl_2 solution (0.2 cm^3) of alcohol (0.11 mmol) to a stirred mixture of metal catalyst (6.5×10^{-3} mmol) and pivalaldehyde (0.33 mmol) in CH_2Cl_2 (0.2 cm^3) under O_2 atmosphere. Consumption of alcohol and formation of ketone during the reaction were monitored by TLC. Obtained ketone and unreacted alcohol were separated by flash column chromatography on silica gel. [b] Yields refer to isolated and pure compounds (column chromatography on silica gel). All compounds exhibited spectral data consistent with their structures. [c] In the absence of metal catalyst some extension of oxidation was observed. [d] Reaction product was exclusively *p*-methoxybenzoic acid.

70% after 24 h (entry 1), with formation of pivalic acid as a coproduct. Moreover, for the series of *para*-substituted phenyl derivatives a small but non-negligible electronic effect is observed, as the substrate with the electron-donating methoxy substituent gives a somewhat higher yield of ketone than that with electron-withdrawing substituents such as trifluoromethyl or nitro groups, *e.g.* 75 *vs.* 60% after 24 h (entries 2 and 5, respectively). For all secondary benzyl alcohols, however, ketones were the only oxidation products as confirmed by ^1H NMR spectroscopy. Notably, for the oxidation of 4-(*tert*-butyl)cyclohexanol only 4-(*tert*-butyl)cyclohexanone was obtained, and no traces were detected of the corresponding Baeyer–Villiger oxidation product, 4-(*tert*-butyl)caprolactone (entry 6).[8] This observation suggests that the acylperoxy radicals generated *in situ* from the auto-oxidation of the aldehyde are not directly involved as potential oxidizing agents. As expected, under the same reaction conditions used for the oxidation of secondary alcohols to ketones, the primary alcohols give mixtures of both the aldehyde and the acid oxidation products in variable amounts depending on the reaction time, as exemplified by *p*-methoxybenzyl alcohol which leads to almost quantitative formation of *p*-methoxybenzoic acid, *i.e.* 95% after 12 h (entry 7).

Although it is premature to discuss the precise role of the metal complex in the catalytic mechanism at the present stage, it is noteworthy that **1** alone does not lead to alcohol oxidation under stoichiometric conditions and, consequently, involvement of a bis(μ-oxo)dimanganese(IV) species as the active oxidizing agent can also be ruled out. In a typical experiment, complex **1** (0.11 mmol) in dichloromethane (20 cm^3) does not react with the more reactive substrate 1-(*p*-methoxyphenyl)ethanol (0.11 mmol) even after a period of three days under stirring at room temperature with or without oxygen atmosphere conditions. That being so, manganese(IV)–acylperoxo or higher valent metal intermediate species, such as manganese(V)–oxo, derived from the oxidation of the bis(μ-oxo)manganese(IV) dimer by the combination of dioxygen and pivalaldehyde, are considered more likely to be responsible for the oxidation in our system. More interestingly, stable manganese(V)–oxo monomeric complexes with amido-containing ligands analogous to that used herein have been isolated and structurally characterized.[9] Attempts to isolate these reactive intermediate species using transition metal ions with more accessible high-valent oxidation states such as chromium are in progress.

This work was supported by the DGICYT, Ministerio de Educación y Ciencia (Spain) through projects PB94-0985 and PB94-1002. R. R. and B. C. thank the Ministerio de Educación y Ciencia (Spain) and the Conselleria de Educació i Ciència de la Generalitat Valenciana (Spain) for grants. We would also like to express our gratitude to Professor J. J. Girerd and Dr G. Blondin for fruitful discussions and continuous interest in this work.

‡ *Synthesis and selected data for* **1**: the diethyl ester derivative of the opba ligand (1.54 g, 5 mmol) was dissolved in deoxygenated MeOH (100 cm^3), NMe_4OH at 25% in MeOH (8 cm^3, 20 mmol) was added to the solution and the resulting mixture was stirred at 60 °C for 15 min under N_2. A deoxygenated MeOH solution (50 cm^3) of $Mn(ClO_4)_2 \cdot 6H_2O$ (1.79 g, 5 mmol) was then added dropwise *via* a dropping funnel under N_2, and a gelatinous light yellow precipitate [presumably a Mn^{II} complex] rapidly formed, together with the crystalline white precipitate of NMe_4ClO_4. Addition of 33% aq. H_2O_2 (1 cm^3, 10 mmol) caused immediate darkening of the solution with concomitant disappearance of the yellow precipitate. The reaction mixture was further stirred at 60 °C for 30 min under N_2. The dark-brown solution was filtered to eliminate the solid NMe_4ClO_4, and reduced to a final volume of 10 cm^3 on a rotatory evaporator. The concentrated solution was treated successively with diethyl ether and acetone to give a black solid which was recuperated in warm water (50 cm^3). The resulting mixture was filtered to eliminate solid particles (mainly MnO_2), and an excess of PPh_4Cl (3.75 g, 10 mmol) dissolved in the minimum amount of water was then added dropwise to the dark-brown solution under gentle warming. Slow evaporation of the filtered solution in air afforded, after a few days, well shaped large prismatic dark-brown crystals of **1** suitable for X-ray analysis which were filtered on paper and air-dried (60%). Satisfactory chemical analyses obtained (C, H, N, P, Mn). ν_{max}/cm^{-1} (KBr) 3477vs (O–H) from H_2O, 1672 (sh), 1647vs, 1617vs (C=O) and 1403s, 1306s (C–O) from opba ligand, and 643m (Mn–O) from Mn_2O_2 ring. λ_{max}/nm 390 ($\varepsilon/dm^3\ mol^{-1}\ cm^{-1}$ 10800), 440 (sh) (7080) and 605 (1170) (MeCN). Variable-temperature magnetic susceptibility (Faraday balance, 80–300 K): $J = -158.0\ cm^{-1}$ ($H = -J\ S_1 \cdot S_2$, $S_1 = S_2 = 3/2$).

§ *X-Ray crystal structure analysis*: Enraf-Nonius CAD-4 diffractometer, Mo-Kα, $\lambda = 0.710\,73$ Å, graphite monochromator, 293 K. Lorentz and polarization effects but not absorption correction ($\mu = 3.78\ cm^{-1}$). *Data collection, solution and refinement*: *ω–θ*, standard Patterson methods with subsequent full-matrix least-squares refinement. SHELX86, SHELX93.[10] $C_{116}H_{96}Mn_2N_4O_{18}P_4$, triclinic, space group $P\bar{1}$, $a = 13.245(3)$, $b = 13.964(3)$, $c = 14.835(3)$ Å, $\alpha = 73.59(2)$, $\beta = 77.98(2)$, $\gamma = 84.60(2)°$, $U = 2572.6(10)$ Å^3, $Z = 2$, $D_c = 1.33\ g\ cm^{-3}$, $1 \leqslant \theta \leqslant 25°$, crystal $0.15 \times 0.15 \times 0.10$ mm. 6681 reflections measured, 4485 assumed as observed with $I \geqslant 2\sigma(I)$. Refinement on F^2 of 651 variables with anisotropic thermal parameters for all non-H atoms gave $R = 0.060$ and $R_w = 0.150$ with $S = 0.936$ (obs. data). CCDC 182/809.

Arylsulfurdiimides: a new class of sulfur–nitrogen anion

Andrey V. Zibarev,[a] Enno Lork[b] and Rüdiger Mews*[b]†

[a] *Institute of Organic Chemistry, Russian Academy of Sciences, Siberian Division, 630090 Novosibirsk, Russia*

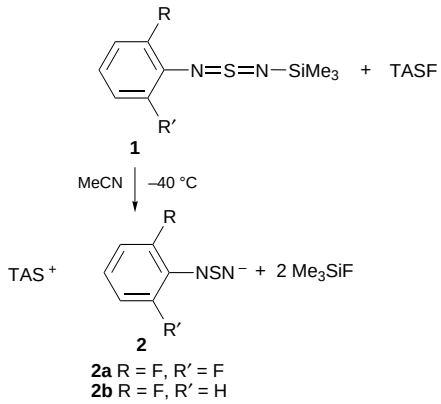
***N*-Aryl-*N′*-trimethylsulfurdiimides (aryl = 2,6-$F_2C_6H_3$, 2-FC_6H_4) react with TASF to give quantitatively the corresponding TAS salts with the $ArNSN^-$ anions (2a, 2b), isoelectronic with arylthionylimides 3; because of the short terminal SN bond the anions should be regarded as thiazylamide rather than sulfurdiimide anions.**

Sulfurdiimide salts K^+RNSN^- [R = Me_3C,[1] Me_3Si,[1] $(Me_3C)_2P$,[2] $(Me_3C)_2As$,[2] $PhSO_2$[3]] have been prepared from the appropriate silyl derivatives $RNSNSiMe_3$ and KNH_2 or $KOCMe_3$ while $Li^+Me_3NSN^-$ was obtained from $Me_3SnNSNSnMe_3$ and LiMe.[4] The reaction of $Me_3SiNSNSiMe_3$ and $KOCMe_3$ under more drastic conditions leads to the cleavage of the second Si–N bond with formation of K_2N_2S,[5] which has been used, particularly by the research groups of Herberhold and Chivers as reagents in the chemistries of groups 14 and 15.[6] Protonation with CF_3CO_2H leads to unstable RNSNH (R = Me_3C, Me_3Si) and HNSNH, respectively.[7] Titanosulfurdiimides are obtained from $K^+Me_3CNSN^-$ and Cp_2TiCl_2.[8] Strong covalent metal–nitrogen interaction is expected for these complexes as Woollins and coworkers have shown for *cis*-$[Pt(NSNSiMe_3)_2(PPh_3)_2]$[9] and $[Pt(NSNSC_6H_4NO_2\text{-}4)_2(Ph_2PCH_2CH_2PPh_2)]$.[10]

Arylsulfurdiimide anions are unknown, fluoroarylsulfur diimide anions are likely intermediates in the CsF promoted cyclisation of *N*-fluoroaryl-*N′*-silylsulfurdiimides $Ar_FNSNSiMe_3$ under elimination of Me_3SiF to give benzothiadiazoles.[11,12] Even spectroscopic evidence for these intermediates is lacking.

Upon cleavage of the SiN bond in $Ar_FNSNSiMe_3$ with TASF $\{[(Me_2N)_3S]^+[Me_3SiF_2]^-\}$[13] the sulfurdiimide salts **2** are readily available (Scheme 1).



Scheme 1

After removal of all volatiles at −30 to −20 °C, salts **2** are isolated in quantitative yield as orange–yellow solids.‡ On warming to room temperature these highly reactive salts decompose immediately to give brown tars. With MeI they react even at −35 °C to give Ar_FNSNMe.

Single crystals of salts **2** were obtained from MeCN–diethyl ether solutions at −40 °C and X-ray data were collected at −110 °C. Figs. 1 and 2 show the anions of salts **2a** and **2b**; for comparison the structure of 2,6-difluorophenylthionylimide $C_6H_3F_2NSO$ **3a** (Fig. 3), isoelectronic with **2a**, was also determined.§ All three compounds adopt the *Z*-conformation and the torsion angle between the aryl plane and the NSA group

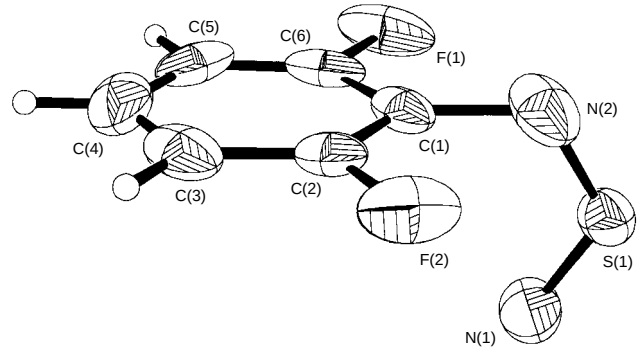


Fig. 1 Structure of the anion of **2a** with selected bond distances (pm) and angles (°) (average of three independent anions): S(1)–N(1) 144.2, S(1)–N(2) 158.9, N(2)–C(1) 140.7; N(1)–S(1)–N(2) 122.3, S(1)–N(2)–C(1) 119.0; τ = 77.7

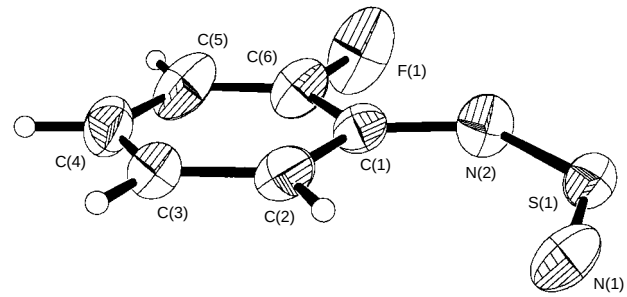

Fig. 2 Structure of the anion of **2b** with selected bond distances (pm) and angles (°): S(1)–N(1) 145.8(4), S(1)–N(2) 159.9(4), N(2)–C(1) 139.0(6), N(1)–S(1)–N(2) 124.8(2), C(1)–N(2)–S(1) 126.5(3); τ = 6.8(5)

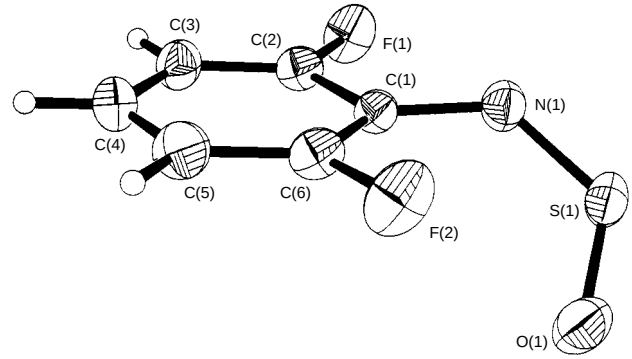

Fig. 3 Structure of **3a** with selected bond distances (pm) and angles (°): S–O 144.8(1), S–N 151.5(1), N–C 140.4(2), N–S–O 120.7(1), C–N–S 130.1(1); τ = 43.6(1)

(A = O,N) seems to be determined by the electronic repulsion between the *ortho* substituents and these groups. In the thionylimide **3a** this angle is 43.6°, in the corresponding negatively charged sulfurdiimide anions these angles are between 75.6 and 79.0° (three independent molecules). In **2b** this repulsion forces the NSN group almost into the aryl plane (τ = 6.8°).

According to the bond lengths in the –NSN– fragment the anions of salts **2** should be regarded as thiazylamides **A** rather than sulfurdiimides **B** (Scheme 2).

A **B**

Scheme 2

The terminal SN bond distances in **2a** (144.2 pm) and **2b** (145.8 pm) correspond to the $S^{IV}{\equiv}N$ triple bond in thiazylhalides (NSF 144.6 pm,[14] NSCl 145.0 pm[15]) and $(CF_3)_2NO(SN)$ (142.3 pm)[16] and also agree well with the SO bond in the isoelectronic thionylimide 2,6-$C_6H_3F_2NSO$ **3a** (144.8 pm). In thiazyl derivatives the XSN angle is 117–119°, in **3a** 120.7° and in the anions of **2** 122–125°. For the bridging SN bonds of **2** the distances 158.9 pm for **2a** and 159.9 pm for **2b** are between double and single bond lengths.

‡ *Preparation of* ***2***: TASF[13] (1.37 g, 5 mmol) was placed into one side of a two-armed lambda-shaped glass vessel fitted with a Teflon valve, 5 mmol of the corresponding $ArNSNSiMe_3$ **1**[17] was placed into the other side. In a vacuum line 20 ml of MeCN was distilled onto TASF, this solution was mixed with **1** at −40 °C and stirred at this temperature for 2 h. Then 30 ml of Et_2O was condensed onto the reaction mixture at −196 °C, the λ-tube was placed into a cryostat at −40 °C for crystal growth and **2a** and **2b** were obtained as orange–yellow crystalline solids after removal of the solvents. Because of their thermal instability the compounds were characterised only by low temperature X-ray crystallography.

§ *Crystal data*: $C_{12}H_{21}F_2N_5S_2$ **2a**, monoclinic, space group $P2_1/c$, a = 1666.7(6), b = 1159.4(4), c = 2549.0(11) pm; β = 92.42(3)°, U = 4.921(3) nm³, Z = 12, D_c = 1.366 g cm^{-3}, μ = 0.345 mm^{-1}, F(000) 2136, crystal dimensions 1.1 × 0.4 × 0.2 mm, 12 180 reflections collected with 2.64 < θ < 27.52°, 9824 used in structural analysis. The data for **2a**, **2b** and **3a** were collected on a Siemens P4 diffractometer using Mo-Kα radiation (λ = 71.073 pm) at 173 K. The structures were solved by direct methods.[18] All non-hydrogen atoms were refined anisotropically. The refinement (597 parameters) converged with wR_2 = 0.2521 (R_1 = 0.0867) and final difference electron density maxima and minima of 1510 and −840 e nm^{-3}.

$C_{12}H_{22}FN_5S_2$ **2b**: monoclinic, space group $C2/c$, a = 2685.2(6), b = 898.8(2), c = 1505.1(5) pm, β = 115.54(2)°, U = 3.278(2) nm³, Z = 8, D_c = 1.295 g cm^{-3}, μ = 0.333 mm^{-1}, F(000) 1360, crystal dimensions 0.5 × 0.4 × 0.1 mm. 4477 reflections collected with 2.65 < θ < 22.50°, 2147 used in structural analysis. The refinement (189 parameters) converged with wR_2 = 0.1381 (R_1 = 0.0555) and final difference electron maxima and minima of 493 and −383 e nm^{-3}.

$C_6H_3F_2NOS$ **3a**: monoclinic, space group $C2_1/c$, a = 374.37(4), b = 2106.4(3), c = 873.7(2) pm, β = 100.95(1)°, U = 0.6765(2) nm³, Z = 4, D_c = 1.720 g cm^{-3}, μ = 0.448 mm^{-1}, F(000) 352, crystal dimensions 0.8×0.6×0.5 mm. 2041 reflections collected with 2.56 < θ < 27.49°, 1402 used in structural analysis. The refinement (102 parameters) converged with wR_2 = 0.0809 (R_1 = 0.0297) and final difference electron maxima and minima of 337 and −229 e nm^{-3}. CCDC 182/817.

Stereoselective synthesis of linear bipyridyl–phenylene based ruthenium rods from enantiopure building blocks

Kenneth Wärnmark,[a] Paul N. W. Baxter[b] and Jean-Marie Lehn*[b]†

[a] *Organic Chemistry 1, Department of Chemistry, Lund University, PO Box 124, SE-221 00 Lund, Sweden*
[b] *Laboratoire de Chimie Supramoléculaire, ISIS, Institut Le Bel, Université Louis Pasteur, 4 rue Blaise Pascal, F-67000 Strasbourg, France*

Extended stereochemically pure C_2-symmetric diruthenium rods, Λ,Λ-1, Δ,Δ-1, Λ,Λ-2 and Δ,Δ-2, have been synthesized from enantiomerically pure building blocks.

The synthesis of nanosize-components for potential applications in electronic or optical systems is a central theme in current material science.[1] The design of molecular counterparts to macroscopic electronic components has largely focussed on molecular wires.[2]

In a molecular approach to microscopic semiconductor technology, we are interested in finding molecular counterparts to doped material. Conjugated π-systems such as rods consisting of linear phenylene chains could function as molecular wires. In principle, electronic conductivity along the axis of the rods in the form of photo- or electro-chemically generated positive hole doping may be achieved by incorporation of photo- and redox-active metal centres, such as Ru^{II}, into the periphery of the rods. The ruthenium doping would be expected to change the conductivity and optical properties of the phenylene chain and add signal reading abilities to it.

Directly connected or phenylene bridged 2,2′-bipyridyl (bpy) units may be regarded as phenylene chains that contain sites for metal coordination. The 4′,4″-linkage between two 2,2′-bipyridyl (bpy) units in $[\{(bpy)_2Ru\}_2(LL)][PF_6]_4$ (LL = 2,2′:4,′4″:2″,2‴-quaterpyridine) gives the complex a transoid overall conformation and mediates a weak metal-to-metal interaction.[3] However, to construct a linear molecular wire containing ruthenium centres, the bpy units must be linked in the 5-position either directly or by a linker such as phenylene. In addition, the electronic transitions that are the most intense in the bpy and phen (phen = 1,10-phenanthroline) rings take place along the longer axis of these ligands making linkages of bpy or phen units in the 5,5′- and 3,8-positions, respectively, attractive.[4]

We herein present the synthesis of the shortest constituents of a series of linear π-conjugated phenylene type ruthenium rods **1** and **2** (Fig. 1) in which bpy units are linked directly, dmqtby‡ (**3**), or *via* a *para*-phenylene bridge, bmbpyb‡ (**4**), to each other in the 5-position.§

The incorporation of more than one $[(phen)_2Ru]^{2+}$ unit into the molecular wire of bpy-type will give rise to diastereoisomers since each unit may have Λ- or Δ-configuration at the ruthenium centre. Enantiomerically pure (ep) and diastereomerically pure (dp) syntheses of various polypyridine ruthenium complexes using the appealing concept of ep building blocks have been successfully pursued by several groups.[5]

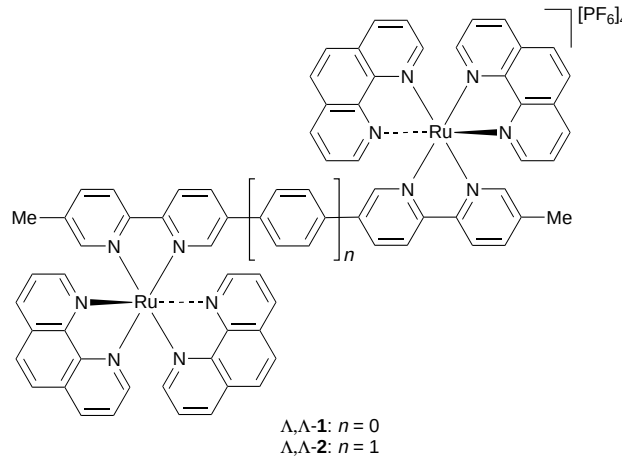
Ligands **3** and **4**, respectively, were reacted with 2.2 equiv. of ep Λ-**5** and Δ-**5**,¶ respectively, giving Λ,Λ-**1**, Δ,Δ-**1**, Λ,Λ-**2** and Δ,Δ-**2**, respectively [58% yield of **1** and 49% yield of **2** after purification on a Bio-Beads S-X1 (Bio-Rad laboratories) size-exclusion column, MeCN–toluene (1:1)].‖ Ligands **3** and **4**, respectively, were also reacted with 2.2 equiv. of racemic **5**, giving the mixture of all stereoisomers Λ,Λ-**1**, Δ,Δ-**1**, Δ,Λ-**1** (mix-**1**) and Λ,Λ-**2**, Δ,Δ-**2**, Δ,Λ-**2** (mix-**2**), respectively.

The ligand **3** and the phenylene-bridged homologue **4** were synthesized by a $Pd(PPh_3)_4$ catalysed Stille cross-coupling protocol[6] between respectively, the dibrominated bridging units 6,6′-dibromo-3,3′-bipyridyl and 1,4-bis[5-(2-bromopyridyl)]benzene and two equiv. each of 2-trimethylstannyl-5-methylpyridine.

The ^{1}H NMR spectrum of Λ,Λ-**1** (and Δ,Δ-**1**) is much less complicated than the ^{1}H NMR spectrum of mix-**1**. Obviously, the short distance between the asymmetric ruthenium centres in **1** leads to large enough differences in ^{1}H NMR shifts for the diastereoisomers Λ,Λ-**1** (Δ,Δ-**1**) and Δ,Λ-**1** to be observable. For **2** in contrast, where the asymmetric ruthenium centres are further apart (by a *para*-phenylene unit), the ^{1}H NMR spectrum of Λ,Λ-**2** (and Δ,Δ-**2**) is identical to the ^{1}H NMR spectrum of mix-**2**.

That Λ,Λ-**1**, Δ,Δ-**1**, Λ,Λ-**2** and Δ,Δ-**2** are essentially ep and dp as demonstrated by the fact that in the circular dichroism spectra, Λ,Λ-**1** and Δ,Δ-**1** as well as Λ,Λ-**2** and Δ,Δ-**2**, respectively, are almost perfect mirror images (Fig. 2). For Λ,Λ-**1** and Δ,Δ-**1** the diastereomeric excess could be determined to > 98.5% by ^{1}H NMR spectroscopy because of the differences in ^{1}H NMR chemical shifts between Λ,Λ-**1** (Δ,Δ-**1**) and mix-**1**.

One measure of the degree of electronic communication between metal centres in symmetrical dimers is the separation of the oxidation potential between the two centres. The results from cyclic voltammetry (CV) of the linear complexes **1** show only one reversible oxidative wave at 1.31 V *vs.* SCE in MeCN, indicating no communication between the ruthenium centres.** Furthermore, one reversible reductive wave at −1.11 V *vs.* SCE in DMF and two reductive cathodic waves at −1.32 and −1.49 V appeared (the corresponding anodic waves could not be detected because of extensive adsorption). The first reductive wave is assigned to ligand **3** and the two others most likely to the phenanthroline ligand in analogy with the assignments of the



Λ,Λ-**1**: $n = 0$
Λ,Λ-**2**: $n = 1$

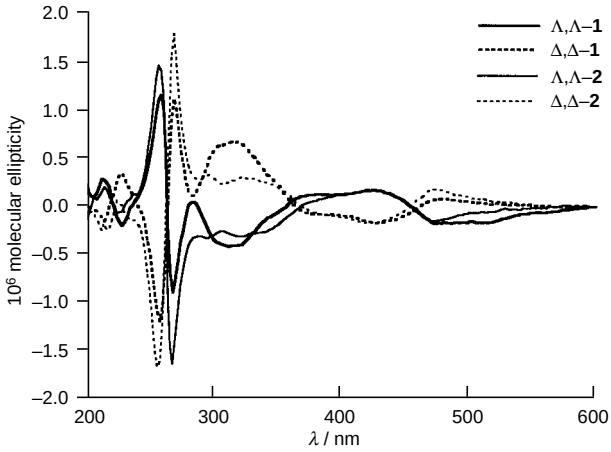

Fig. 2 Circular dichroism spectra of Λ,Λ-**1**, Δ,Δ-**1**, Λ,Λ-**2** and Δ,Δ-**2** in MeCN

CV of the analogue $[\{(bpy)_2Ru\}_2(LL)][PF_6]_4$, bridged in the 4′,4″-position (reversible reductive waves at −1.10, −1.44, −1.57 V *vs*. SCE in MeCN).[3] The CV of the phenylene-bridged linear complexes **2** shows also only one reversible 2e oxidative wave at 1.29 V *vs*. SCE in MeCN, one reversible reductive wave at −1.19 and one reductive cathodic wave at −1.36 V *vs*. SCE in DMF (a third reductive wave could not be observed). The reductive waves in complex **2** are assigned in analogy with complex **1** to ligands **4** and phen, respectively.

The complexes **1** and **2** have almost identical electronic spectra in MeCN. Only one flat MLCT band could be detected [λ = 450 (ε = 2.54 × 10^4), 448 nm (2.98 × 10^4 dm^3 mol^{-1} cm^{-1}), respectively] demonstrating that the Ru–dmqtpy and Ru–bmbpyb transitions are of similar energy as for Ru–phen and being almost identical to the monoruthenium complex $[Ru(bpy)_3]^{2+}$ [λ = 452 nm (ε = 1.45 × 10^4 dm^3 mol^{-1} cm^{-1})].[7] Thus the red-shift for the Ru–(bridging ligand) MLCT band, observed in the analogue $[\{(bpy)_2Ru\}_2(LL)][PF_6]_4$ and indicating a weak metal–metal interaction,[3] seems to be absent in complexes **1** and **2**. The π–π* transitions for compounds **1** [λ = 265 (ε = 1.52 × 10^5), 224 nm, (1.13 × 10^5 dm^3 mol^{-1} cm^{-1})] and **2** [λ = 263 (ε = 1.69 × 10^5), 223 nm, (1.22 × 10^5 dm^3 mol^{-1} cm^{-1})] are located almost at the same wavelength as for $[Ru(phen)_3]^{2+}$ [λ = 263 (ε = 1.13 × 10^5), 224 nm (8.03 × 10^4 dm^3 mol^{-1} cm^{-1})].[8] The values of the absorption coefficients indicate that these π–π* transitions in complexes **1** and **2** are phenanthroline based. More difficult is the assignment of Ru–(bridging ligand) π–π* transitions.

The excitations of compounds **1** and **2** in the MLCT band resulted in intense emission at 639 and 613 nm, respectively, being somewhat red-shifted compared to $[\{(bpy)_2Ru\}_2(LL)][PF_6]_4$. Excitation in the phenanthroline π–π* bands leads to an intense emission at 735 and 417 nm for each of the two complexes **1** and **2**.

In conclusion stereoisomerically pure linear bipyridyl–phenylene based ruthenium rods, **1** and **2**, have been synthesized from ep building blocks. By the methods used in this work no electronic communication between the two halves of the rods could be detected. Oxidation or reduction at a given centre may however be expected to delocalize over the whole system and provides means for p and n doping of such types of inorganic molecular rods.

Ruthenium-catalysed synthesis of indoles from anilines and trialkanolamines in the presence of tin(II) chloride dihydrate

Chan Sik Cho, Hyo Kyun Lim, Sang Chul Shim,*† Tae Jeong Kim and Heung-Jin Choi

Department of Industrial Chemistry, College of Engineering, Kyungpook National University, Taegu 702-701, Korea

Anilines react with trialkanolamines in dioxane in the presence of a catalytic amount of a ruthenium catalyst together with tin(II) chloride dihydrate to give the corresponding indoles in moderate to good yields.

Transition metal-catalysed cyclisation reactions have been a useful and convenient method for the formation of a wide variety of heterocycles. Thus, the formation of the structural core of indoles has also been attempted using transition metal catalysts[1] since several naturally occurring indoles exert a broad spectrum of physiological activities.[2] As part of our continuing studies on transition metal-catalysed synthesis of *N*-heterocyclic compounds,[3] we have recently developed and reported a novel ruthenium-catalysed synthesis of *N*-alkylindoles from *N*-alkylated anilines and triethanolamine as the C_2-fragment.[4] However, aniline did not act as a cyclisation counterpart in the formation of indole itself under the ruthenium-catalysed system. After numerous attempts were made to achieve the formation of indoles from the primary aromatic amines under the reaction system used, eventually, it was found that the addition of tin(II) chloride dihydrate allows the formation of indoles. We now report a facile synthesis of indoles from readily available primary aromatic amines and triethanolamine in the presence of a ruthenium catalyst together with $SnCl_2{\cdot}2H_2O$.

We examined the cyclisation between aniline (**1**) and triethanolamine (**2**) in the presence of $SnCl_2{\cdot}2H_2O$ to optimise the reaction conditions using similar catalytic systems which we employed for the synthesis of *N*-alkylindoles. The yield of indole (**3**) was considerably affected by the molar ratio of **1** to **2** as has been observed in our recent report (Scheme 1).[4] Table 1 shows that the highest yield of **3** was obtained at the molar ratio of 10. The reaction was also affected by the amount of $SnCl_2{\cdot}2H_2O$. The use of equimolar amounts of **2** and $SnCl_2{\cdot}2H_2O$ resulted in the best yield of **3**. A decrease in the amount of $SnCl_2{\cdot}2H_2O$ afforded **3** in a lower yield, but the yield of **3** did not change with an increase in the amount of $SnCl_2{\cdot}2H_2O$ employed. However, the reaction did not proceed at all without $SnCl_2{\cdot}2H_2O$. The effect of several metallic halides other than $SnCl_2{\cdot}2H_2O$ upon this cyclisation was examined. As shown in Table 1, all the salts except for iron(III) chloride examined were moderately effective in the formation of **3**, but $FeCl_3$ exhibited nearly the same activity as $SnCl_2{\cdot}H_2O$ under the reaction conditions employed.

The present cyclisation could also be applied to many primary aromatic amines, several representative results being summarised in Table 2.‡ The product yield was dependent on the electronic nature of the substituent on anilines. With anilines such as toluidine and anisidine, having electron-donating

10	$LaCl_3$ (1)	7
10	$FeCl_3$ (1)	52
10	$ZnCl_2$ (1)	15

[a] All reactions were carried out with **2** (1 mmol), $RuCl_3{\cdot}nH_2O$ (7 mol% based on **2**), and PPh_3 (2 mol% based on **2**) in dioxane (10 ml) at 180 °C for 20 h. [b] Based on **2**.

character, the product yield was generally higher than that when chloroanilines having electron-withdrawing Cl substituent were used (runs 2–8). In the cases of *meta*-substituted anilines such as *m*-toluidine and *m*-anisidine, the corresponding indoles were obtained as a regioisomeric mixture in good yields (runs 3 and 5). The enhancement of reactivity of the two-methyl substituted anilines is interesting when compared to the reactivity of the mono-substituted anilines (runs 10–12). However, in the case of 2,5-dimethoxyaniline, the corresponding indole was obtained only in 15% yield (run 13).

Similar treatment of anilines **4** with tri(propan-2-ol)amine (**5**) under the above reaction system afforded two regioisomeric

Table 2 Ruthenium-catalysed synthesis of various indoles[a]

Scheme 2

indoles, **6** and **7**, in quantitative isolated yields, favoring the formation of 2-methylindoles **6** (Scheme 2). In a separate experiment, we observed that a similar reaction of *p*-toluidine with **5** gave two isomeric indoles in 118% GLC yield based on **5**. This result indicates that at least two propan-2-ol groups out of three in **5** are available for the C_2-fragment counterpart.

Although the exact role of $SnCl_2{\cdot}2H_2O$ in the present reaction is still obscure, the reaction pathway seems to be the initial formation of 2-anilinoethanols§ by amine exchange reactions[4b,5] between anilines and trialkanolamines followed by a similar catalytic cycle to that which has already been proposed in ruthenium-catalysed synthesis of indoles from anilines and ethylene glycols.[6]

‡ General experimental procedure: a mixture of aniline (10 mmol), alkanolamine (1 mmol), $RuCl_3{\cdot}nH_2O$ (0.07 mmol), $SnCl_2{\cdot}2H_2O$ (1 mmol) and PPh_3 (0.21 mmol) in dioxane (10 ml) was placed in a stainless steel autoclave. After the system was flushed with nitrogen gas, the mixture was stirred at 180 °C for 20 h. The reaction mixture was filtered through a short column (silica gel, CH_2Cl_2) and evaporated under reduced pressure. To the residual oily material was added 30 ml of CH_2Cl_2 and the mixture was washed twice with 50 ml of aq. 5% HCl solution to remove excess aniline. The organic layer was dried over anhydrous NA_2SO_4. Removal of the solvent left an oil which was separated by column chromatography (ethyl acetate–hexane) to give indoles.

§ In a separate experiment, we observed that a similar ruthenium-catalysed reaction between *N*-benzyl-*p*-toluidine and triethanolamine resulted in the formation of a small amount of 2-(*N*-benzyl-*p*-tolylamino)ethanol by GC–MS analysis.

Unexpected enhancement of the photonuclease activity of $Ru(bpz)_3^{2+}$ by Cu/Zn superoxide dismutase

Etienne Gicquel, Nicole Paillous*† and Patricia Vicendo

Laboratoire IMRCP, UMR 5623, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse Cedex 4, France

Cu/Zn SOD led to an unexpected enhancement of the photonuclease activity of $Ru(bpz)_3^{2+}$ *via* an increase in the production of singlet oxygen.

The ruthenium complexes possess versatile photoredox properties, which are exploited in a wide variety of applications including the photolysis of water,[1–3] development of novel photonucleases[4–8] and more recently for modelling chemical photolyases.[9] The photonuclease[4] activity of these complexes stems in part from their redox potential in the excited state. If this is above that of guanine,[10] the nucleobase with the lowest oxidation potential, under irradiation the polypyridyl ruthenium complexes may induce an electron transfer from DNA to the dye in the excited state, giving rise to single strand breaks in the double helix of DNA.[11,12] The efficiency of this type I mechanism for producing single strand breaks is higher than that of the type II mechanism.[13] Furthermore, it has been shown that electron transfer leads to formation of covalent photoadducts between ruthenium complexes such as tris(1,4,5,8-tetraazaphenanthrene)ruthenium(II) [$Ru(tap)_3^{2+}$][14] and tris(2,2′-bipyrazyl)ruthenium(II) [$Ru(bpz)_3^{2+}$][15] and DNA.

In the case of $Ru(bpz)_3^{2+}$, the mechanism of single strand breaking is complex, involving electron transfer, formation of singlet oxygen and radical species.[15] In order to identify the various oxygenated species involved in the photonuclease activity of $Ru(bpz)_3^{2+}$, and the superoxide anion in particular, we used the Cu/Zn superoxide dismutase (Cu/Zn SOD). While this enzyme should give rise to a reduction in efficiency of the DNA cleavage by $Ru(bpz)_3^{2+}$, *via* a dismutation of $O_2^{\cdot -}$, an unexpected increase in photonuclease activity of this complex was observed. Here, we report the main characteristics of this unexpected effect.

As shown in a previous study,[15] $Ru(bpz)_3^{2+}$ (1.8 μM) in solution [5 mM phosphate buffer (pH 7.4), 10 mM NaCl] and irradiated at 436 nm in the presence of supercoiled phage φX174 DNA (18 μM) induced single strand breaks with a quantum yield of 10^{-5} (Fig. 1). In the presence of Cu/Zn SOD (Cu/Zn SOD from human erythrocytes, 22 U ml^{-1}, 0.299 μM), the number of single strand breaks was 2.4-fold higher at 60 s. This enzyme is not able to induce alone DNA breakage upon irradiation at 436 nm. The same finding was obtained, under similar experimental conditions, with Cu/Zn from bovine erythrocytes. Furthermore, the plot of the number of photoinduced DNA single strand breaks against time in the presence of SOD was not linear. There was an increase in rate with duration of irradiation. After 90 s irradiation, nearly all the supercoiled form of the plasmid had been transformed into the relaxed circular form. This was not observed in the absence of SOD even after 30 min of irradiation.

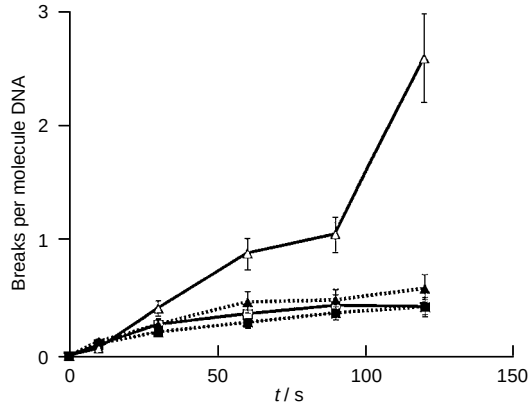

Fig. 1 Plot of number of DNA single strand breaks per molecule of φX174 plasmid DNA photoinduced by $Ru(bpz)_3^{2+}$ at 436 nm against irradiation time: (□) $Ru(bpz)_3^{2+}$, (■) $Ru(bpz)_3^{2+}$ in the absence of oxygen, (△) $Ru(bpz)_3^{2+}$ with Cu/Zn SOD and (▲) $Ru(bpz)_3^{2+}$ with Cu/Zn SOD in the absence of oxygen

In the absence of oxygen, SOD had no significant effect on the DNA single strand breaks induced by $Ru(bpz)_3^{2+}$ (Fig. 1). This indicated that the action of SOD depended on the presence of oxygen, and was mediated by the production of oxygenated species. Catalase (22 U ml^{-1}) and desferioxamine (17 mM) were not found to modify the number of DNA single strand breaks induced by $Ru(bpz)_3^{2+}$ in the presence of Cu/Zn SOD. This observation indicates that the effect of Cu/Zn SOD did not result from the formation of $OH^{\cdot}$ *via* a Fenton reaction. Furthermore, the photonuclease activity of $Ru(bpz)_3^{2+}$ was not augmented in the presence of iron SOD (from *Escherichia coli*). It thus appeared that the action of Cu/Zn SOD was specific to this particular enzyme.

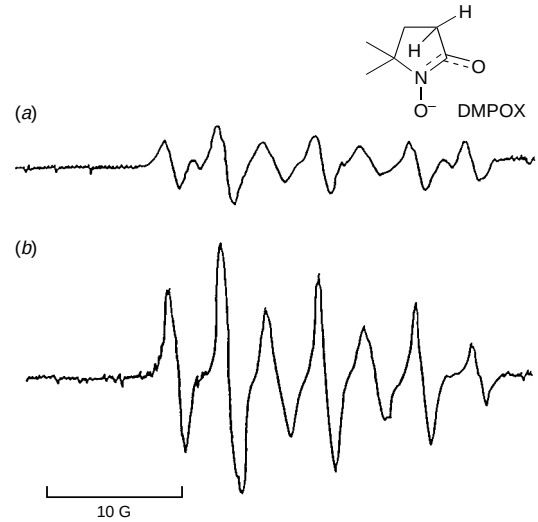

Fig. 2 EPR spectra of UV irradiated (λ > 400 nm) solutions containing DMPO and ruthenium complexes: (*a*) $Ru(bpz)_3^{2+}$ and (*b*) $Ru(bpz)_3^{2+}$ with Cu/Zn SOD

In order to better understand the function of oxygenated radical species in the photoactivation of $Ru(bpz)_3^{2+}$ by Cu/Zn SOD, EPR studies have been performed. EPR studies on $Ru(bpz)_3^{2+}$ (10^{-3} M) irradiated (λ > 400 nm) in the presence of 5,5-dimethyl-2-pyrolidine 1-oxide (DMPO) (150 mM) failed to detect $OH^{\cdot}$ radicals, and indicated the presence of 5,5-dimethyl-2-pyrolidone 1-oxyl radicals (DMPOX) (a_N = 4.1, a_H = 7.2) derived from the oxidation of DMPO by singlet oxygen[16]

(Fig. 2). The formation of this radical was increased almost three-fold by addition of Cu/Zn SOD (22 U ml^{-1}) (Fig. 2). EPR studies of irradiated Cu/Zn SOD in the presence of DMPO did not show the formation of radicals. It thus appeared that the action of Cu/Zn SOD on $Ru(bpz)_3^{2+}$ was mediated by an increase in the production of singlet oxygen, which is responsible for the enhanced photonuclease activity of this complex. This hypothesis was supported by the results obtained on addition of *N*-acetylhistidine (50 mM) and DABCO (20 mM), singlet oxygen scavengers. They led to a 100% inhibition in production of DMPOX radicals in the presence or absence of Cu/Zn SOD. Moreover, *N*-acetylhistidine abolished totally the increase in DNA single strand breaks obtained after photosensitization of DNA by $Ru(bpz)_3^{2+}$ in the presence of this enzyme (Fig. 3).

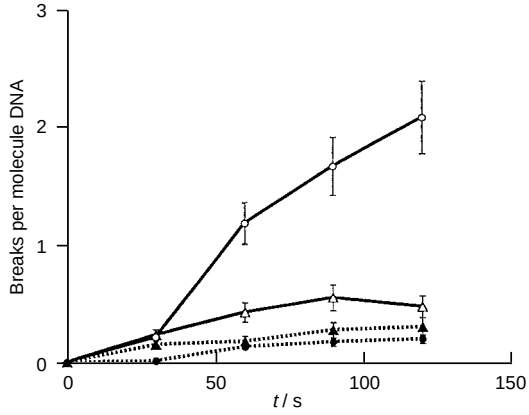

Fig. 3 Plot of number of DNA single strand breaks per molecule of ϕX174 plasmid DNA photoinduced by $Ru(bpz)_3^{2+}$ at 436 nm against irradiation time: (△) $Ru(bpz)_3^{2+}$, (▲) $Ru(bpz)_3^{2+}$ with *N*-acetylhistidine, (○) $Ru(bpz)_3^{2+}$ with Cu/Zn SOD and (●) $Ru(bpz)_3^{2+}$ with Cu/Zn SOD and *N*-acetylhistidine

The action of Cu/Zn SOD (22 U ml^{-1}) on the electron transfer process was investigated by determining the efficiency of $Ru(bpz)_3^{2+}$ (1.5×10^{-4} M) covalent addition to calf thymus DNA (1.5×10^{-3} M in nucleotides) upon irradiation at 436 nm in the presence or absence of this enzyme. Quantification of ruthenium bound to DNA by ICP[15] analysis failed to identify any difference in the kinetics or equilibrium of the addition of $Ru(bpz)_3^{2+}$ to DNA. After 2 h of irradiation at 436 nm in the presence or absence of SOD, the photoadditions reached a plateau corresponding to 1.4×10^{-7} mol of $Ru(bpz)_3^{2+}$ per mg of calf thymus DNA or one molecule of complex for 11 ± 1 nucleotides. SOD thus did not appear to alter the photoreactivity of $Ru(bpz)_3^{2+}$ mediated by electron transfer.

Analysis by UV–VIS spectroscopy of the photochemical behavior of $Ru(bpz)_3^{2+}$ (10^{-5} M) in 5 mM phosphate buffer (pH 7.4) and 10 mM NaCl irradiated at 436 nm showed that SOD did not affect the rate of photodecomposition of $Ru(bpz)_3^{2+}$ (Fig. 4). This observation suggested that the increase in production of singlet oxygen by $Ru(bpz)_3^{2+}$ in the presence of SOD was not due to enhanced photostability of the complex. EPR studies on solutions of complexes of ruthenium of various redox potentials such as tris(2,2′-bipyridyl)ruthenium(II) [$Ru(bipy)_3^{2+}$] [$E(Ru^{2+*}/Ru^{+})$ = 0.77 V *vs*. SCE in MeCN][17] (10^{-3} M) and tris(2,2′-bipyrazyl)(dipyrido[3,2-*a*:2′3′-*c*]phenazine-N^4,N^5)ruthenium(II) [$Ru(bpz)_2dppz^{2+}$] [$E(Ru^{2+*}/Ru^{+})$ = 1.21 V *vs*. SCE in MeCN[13] (10^{-3} M) revealed that, in the absence of SOD, these two compounds generated under irradiation the same radical DMPOX as $Ru(bpz)_3^{2+}$ [$E(Ru^{2+*}/Ru^{+})$ = 1.45 V *vs*. SCE in MeCN].[17] In the presence of Cu/ZnSOD, the increase in production of this radical was, with $Ru(bipy)_3^{2+}$ and $Ru(bpz)_2dppz^{2+}$, 1.4- and 2.6-fold higher, respectively, than in the absence of Cu/Zn SOD. These results show that the increase in production of the DMPOX radical generated by these

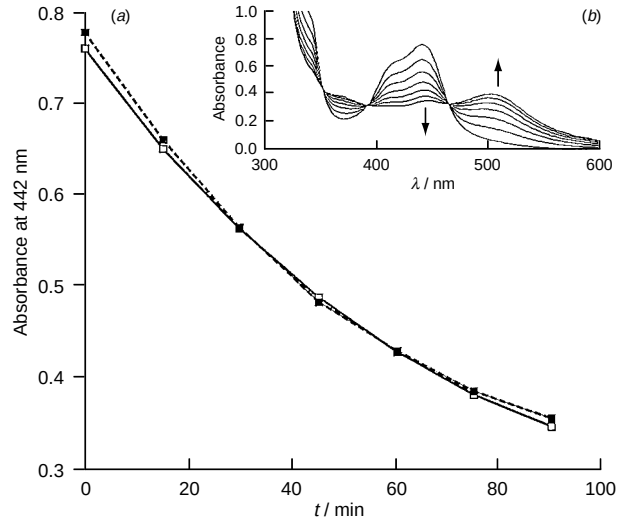

Fig. 4 (*a*) Absorbance at 442 nm of UV irradiated (λ = 436 nm) solutions of $Ru(bpz)_3^{2+}$ (□) without additive and (■) with SOD. (*b*) Variation in absorption spectra of $Ru(bpz)_3^{2+}$ in 5 mM phosphate buffer (pH 7.4) and 10 mM NaCl upon irradiation at 436 nm.

ruthenium complexes in the presence of Cu/Zn SOD partly depends on the redox potential of their excited state.

In conclusion, Cu/Zn SOD led to an unexpected enhancement of the photonuclease activity of $Ru(bpz)_3^{2+}$, which may result from an increase in singlet oxygen production. This unusual phenomenon may be correlated to the strongly oxidizing nature of this dye.

We thank Mr Alain Mari for his technical assistance with the EPR studies.

Novel mechanistic proposal for the Dötz reaction derived from a density functional study: the chromahexatriene route

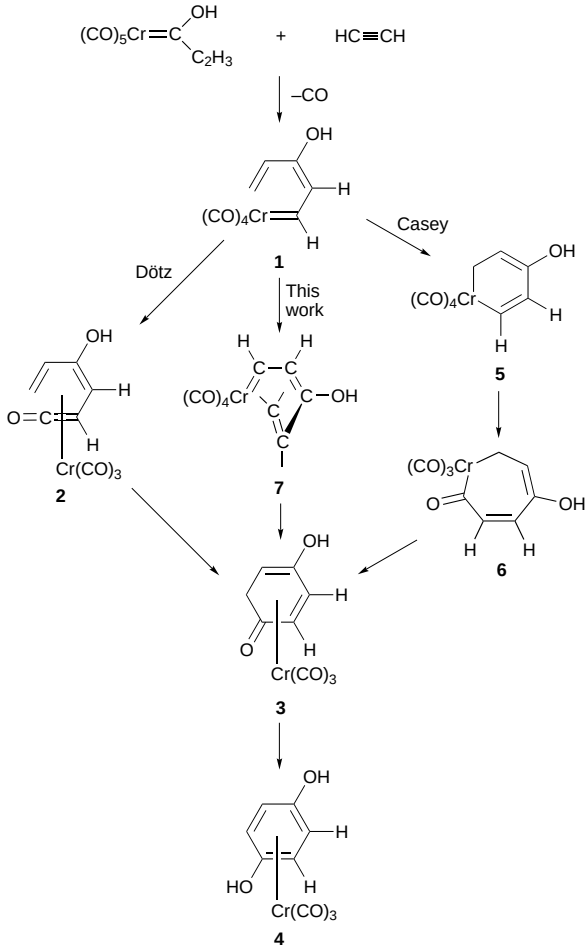
Maricel Torrent, Miquel Duran and Miquel Solà*

Department of Chemistry and Institute of Computational Chemistry, University of Girona, E-17071 Girona, Spain

A new mechanism for the Dötz reaction of vinylcarbene complexes with ethyne proceeds through a chromahexatriene intermediate instead of a vinylketene with smooth energy changes and low energy barriers.

One of the most important synthetic transformations leading to C–C bond formation involves the reaction of chromium carbenes with alkynes. This process, a formal [3 + 2 + 1] cycloaddition known as the benzannulation or Dötz reaction,[1] generates substituted phenols by sequential coupling of the alkyne, the carbene and one carbonyl ligand at a $[Cr(CO)_3]$ template. The major interest in this reaction is its utility in organic and organometallic synthesis.

The most widely accepted mechanism[2] assumes that the reaction starts with a reversible decarbonylation followed by alkyne coordination, yielding η^3-vinylallylidene complexes **1** (Scheme 1). Two diverging routes have been postulated from this point. According to Dötz,[2] complexes **1** form η^4-vinylketenes **2** by CO insertion into the chromium–carbene bond, followed by electrocyclic ring closure to yield η^4-cyclohexadienones **3**, which can finally turn into the direct precursor of the phenol derivative **4** after enolization and aromatization. As suggested by Casey,[3] an alternative possibility is that metallation of the arene ring occurs in complex **1** to form **5**, which subsequently undergoes carbonylation to yield **6**. Reductive elimination from **6** gives intermediate **3**, where both scenarios merge again.



Scheme 1 Postulated routes for the benzannulation reaction

It has proven difficult to validate these mechanistic suggestions since the rate-limiting step typically involves CO ligand loss to open a coordination site for the alkyne to bind. Once bound, rapid ring closure occurs to give the observed products. No single reaction has been followed completely through the individual steps illustrated in Scheme 1, although there are now several examples of isolation and structural characterization of presumed intermediates relevant to η^3-allylidene complexes[4] and η^4-vinylketene complexes.[5] Additional support for the Dötz route has also been provided by extended Hückel molecular orbital[6] and recent quantum chemical calculations.[7] However, most steps are still only postulated. Thus, although kinetic investigations[8] strongly support the assumption for the CO loss as one of the first reaction steps, most of the subsequent intermediates have so far escaped experimental observation.

According to our calculations,[9–14]‡ vinylallylidene complex **1** is a branching point from which the reaction may go on through a third energy path, different from the ones mentioned above. The new proposed pathway also leads to η^4-cyclohexadienone **3**, but, instead of inserting a CO ligand into the Cr–carbene bond, complex **1** can better create first a π-interaction with the terminal C–C double bond yielding a chromahexatriene complex, which undergoes CO insertion in the next step.

The advantage of such a structural arrangement taking place before CO insertion can be seen from Fig. 1. Complex **1** (usually described as an η^3-vinylallylidene[2]) is found to be more favorable in an η^1-coordination (as depicted in Fig. 1) by 11.8 kcal mol^{-1}. The most outstanding feature of η^1-vinylallylidene complex **1** is the agostic interaction between chromium and one of the C_5–H bonds of the terminal alkenyl ligand. The length of the C_5–H bond is *ca.* 0.05 Å larger than the usual distance for a C(sp^2)–H bond, and clearly corresponds to the ones observed for this kind of interactions.[15] The vacant coordination site in complex **1** created after release of a CO ligand *cis* to the carbene fragment remains temporarily blocked by the C_5–H group, and the reaction is prevented from going backwards to the reactants. Once **1** is formed, the ring chain evolves to a more stable conformation through a dπ interaction between chromium and the C_4–C_5 olefinic bond, the release of energy being 11.2 kcal mol^{-1} (Fig. 1). An early, small energy barrier in the path from **1** to **7** (1.8 kcal mol^{-1}) arises from the loss of the agostic interaction while C_4 has not approached the metal center enough (Cr–C_4 = 3.248 Å in **1**, 3.055 Å in TS1, and 2.272 Å in **7**). A crucial feature of complex **7** as compared to complex **1** is the shortening of the distance between C_5 and the CO ligand to be transferred to the Cr–C_5 bond (C_5–CO = 3.517 Å in **1**, and 2.559 Å in **7**), which facilitates CO insertion in the subsequent step (C_5–CO = 2.262 Å in TS2, and 1.533 Å in **3**). Intermediate **7** is directly comparable to η^2-alkenylamino(aryl)carbene complexes of W[16] and Mn,[17] as well as to the more recently

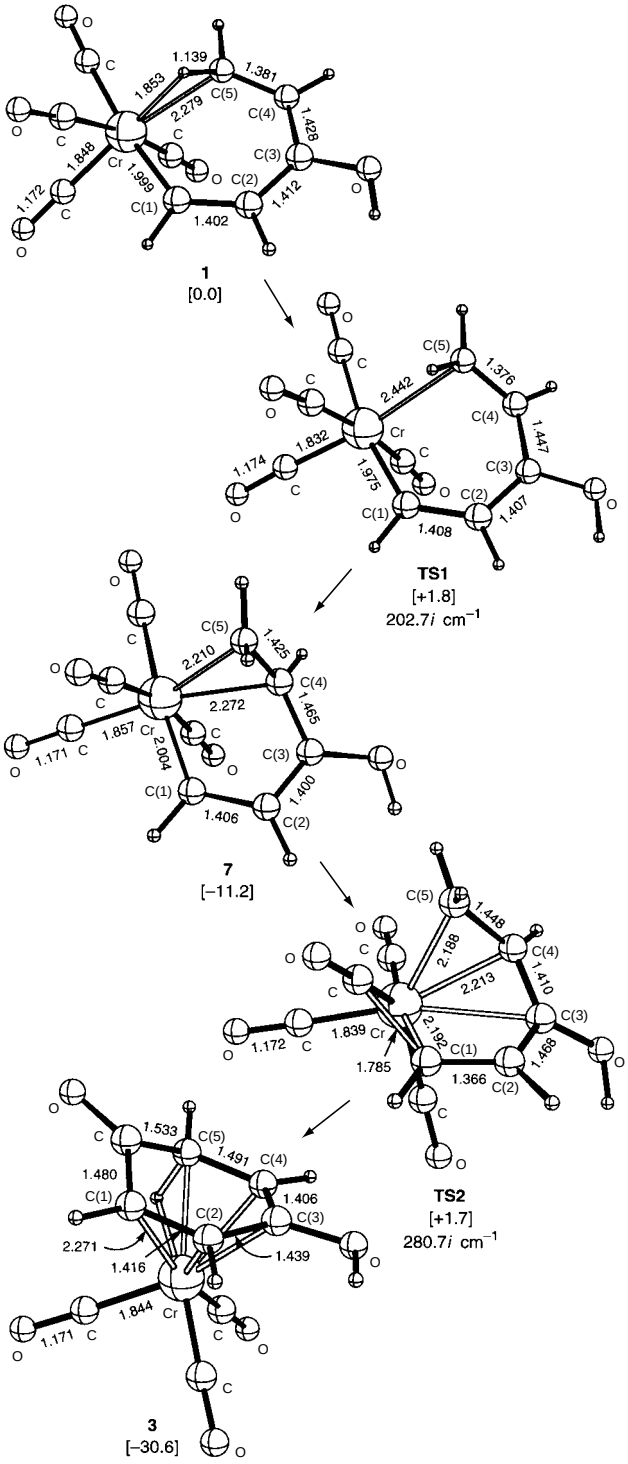


Fig. 1 Geometries of all stationary points and energies relative to complex **1**. Selected bond distances are given in Å, and energies (in square brackets) in kcal mol^{-1}. Compounds **1**, **7** and **3** correspond to minimum energy structures; their absolute energies are −1767.313742, −1767.331596 and −1767.362571 au, respectively. **TS1** (−1767.310883 au) and **TS2** (−1767.310945 au) are first-order saddle points.

reported structure of an alkynylarylcarbene complex of tungsten.[18] In the field of organochromium chemistry, a similar olefin coordination has been also observed for an alkene-[19] and some alkyne-carbenechromium[20] complexes. The strongest support for the existence of **7**, however, probably comes from a recent investigation by Barluenga *et al*.,[4] where a chromahexatriene similar to **7** has been isolated and characterised by ^{1}H and ^{13}C NMR spectroscopy. Experimental data from this study demonstrate that the alkenyl ligand is attached to the metal center through the C_4–C_5 double bond.

Interestingly, chromahexatriene **7** is not an endpoint of the reaction because it connects to a more stable intermediate, as shown in Fig. 1. Distortion of the $Cr(CO)_4$ umbrella mainly accounts for the energy required to reach **TS2** (12.9 kcal mol^{-1}). This is largely compensated by the formation of an agostic interaction in **3**, together with the new Cr–C coordinated bonds in the formed ring. Species **3** with such an agostic interaction has a known precedent in related cationic manganese cyclohexenyl complexes.[21] The fact that the reaction does not end at **7** is consistent again with the experimental results reported by Barluenga *et al*.[4] These authors found that the synthesised chromahexatriene was not stable in solution at room temperature, and decomposed to yield the most common final product in the Dötz reaction with aminocarbenes.[4]

Additional theoretical work on the routes proposed by Dötz and Casey is presently in progress in our laboratory. Preliminary results indicate that the chromahexatriene mechanism presented here seems to be the most favorable of the three proposed routes. Whether this conclusion can be generalised to substrates other than vinyl carbene complexes is the subject of further research.§

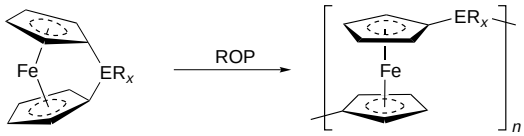
Synthesis, structure and cationic ring-opening polymerization (ROP) of a strained [2]carbathioferrocenophane

Rui Resendes, Paul Nguyen, Alan J. Lough and Ian Manners*†

Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, Ontario, Canada M5S 3H6

The synthesis and cationic ring-opening polymerization of a novel [2]carbothiaferrocenophane is reported; the polymerization represents the first cationic ring-opening polymerization of a metal-containing ring.

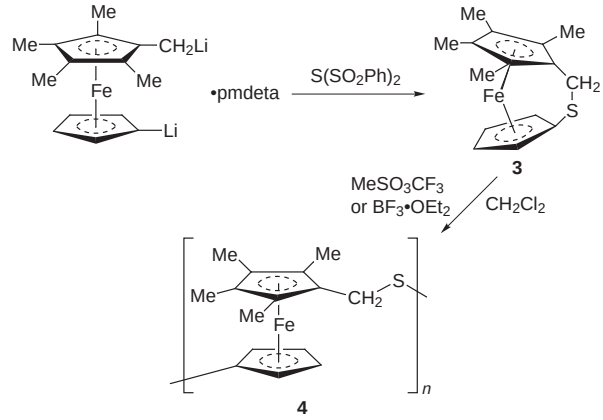
Macromolecules containing transition metal atoms in the main chain are attracting growing attention as a result of their combination of processability and interesting physical properties.[1–3] Until recently, the development of this area has been hindered by the lack of viable synthetic routes to these materials.[2] The recent discovery of a thermal ring-opening polymerization (ROP) route to poly(ferrocenes) from strained [1]- and [2]-metallocenophanes **1** provided facile access to high molecular mass metallocene-based polymers **2** with interacting metal atoms.[4–6] Subsequently, examples of anionic and transition metal-catalyzed ROP of [1]ferrocenophanes have also been reported which afford routes to polymers with controlled architectures including block and graft copolymers.[7–10] Recent attention has focused on detailed studies of the interesting properties of the resulting poly(metallocenes) including their electrochemical, charge transport, electrochromic and morphological (*e.g.* liquid crystalline) properties and their potential function as precursors to spin-aligned magnetic materials *via* oxidation or pyrolysis.[5,11–15]



1 **2**

Cationic polymerization provides an important, well established methodology for the preparation of organic polymers which complements other synthetic routes.[16,17] However, to date, cationic ROP of a metal-containing ring has not been reported. In this paper we report the synthesis of a novel [2]ferrocenophane which undergoes the first example of such a cationic ROP process.

Few examples of unsymmetrically bridged [2]ferrocenophanes have been reported.[18] We found that the reaction of the pmdeta (pmdeta = 1,1,4,7,7-pentamethyldiethylenetriamine) adduct of ($C_5Me_4CH_2Li$)(C_5H_4Li)Fe in Et_2O at −78 °C with 1 equiv. of $S(SO_2Ph)_2$ afforded **3** in 30% yield as deep red crystals after purification by vacuum sublimation. The identity of **3** was confirmed by ^{1}H and ^{13}C NMR and GC–MS.[19] The ^{1}H NMR spectrum revealed the α and β protons of the Cp ring at δ 4.69 and 3.64, respectively. The large separation of the Cp proton resonances is indicative of the ring strain present in **3**. Of note, is the bridging CH_2 resonance which occurs quite downfield at δ 4.17, indicating a deshielded environment. The ^{13}C NMR shows the C_{ipso} resonances of the Cp′ (tetramethyl-Cp) and Cp rings occurring at δ 83.8 and 93.7, respectively. This is, again, consistent with the proposed structure of **3**. An X-ray diffraction analysis of a suitable single crystal was also performed.[20] The molecular structure of **3** is shown in Fig. 1; of note is the 18.5(1)° angle between the planes of the Cp′ and Cp rings. This



3

4

Scheme 1

suggests that **3** possesses significant ring strain and may be a suitable candidate for ROP.

DSC analysis of **3** revealed an endotherm associated with the melting point at 68 °C and an exotherm due to ROP at 210 °C. When a sample of **3** was heated at 215 °C in a sealed, evacuated Pyrex tube, a yellow fibrous material which was insoluble in common organic solvents was obtained. A small fraction, which was soluble in C_6D_6, was shown to be the ring-opened poly(carbothiaferrocene) **4** by ^{1}H NMR (see below). GPC analysis of this soluble fraction (in THF) revealed a M_w of *ca.* 6000 with a PDI value of 1.1.

Samples of **3** in C_6D_6 did not undergo ROP under the influence of anionic initiators such as Bu^{n}Li. However, treatment of both CH_2Cl_2 and C_6D_6 solutions of **3** with methyl triflate, $MeSO_3CF_3$, resulted in a color change from bright red to light orange, followed by the precipitation of a fine yellow powder. ^{1}H NMR analysis of the soluble fraction demonstrated

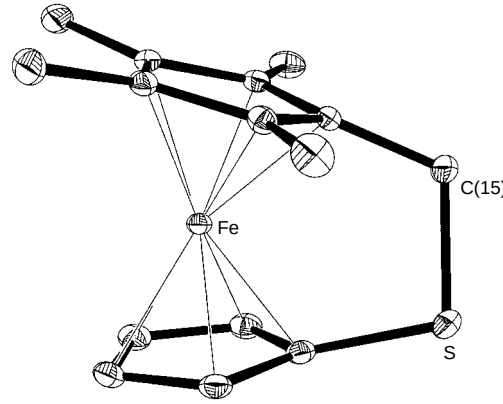


Fig. 1 X-Ray crystal structure of **3**, showing 30% thermal ellipsoids. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Fe–Cp$_{centroid}$ 1.82(2), C(15)–S 1.844(2), Cp$_{ipso}$–S 1.783(2), Cp′$_{ipso}$–C(15) 1.513(3); α (angle between Cp planes) 18.51(14), β_1 [angle between Cp plane and Cp$_{ipso}$–S bond) 10.9(2), β_2 [angle between Cp′ plane and Cp′$_{ipso}$–C(15) bond] 9.5(2).

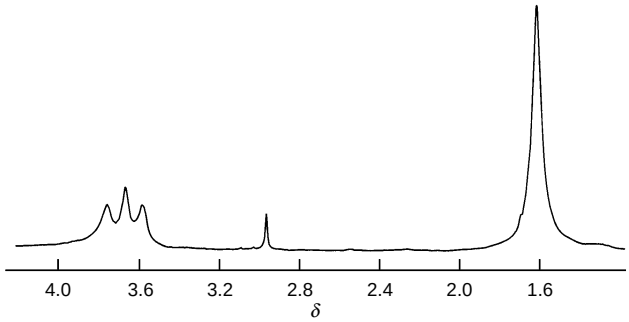

Fig. 2 400 MHz ^{1}H NMR (C_6D_6) of **4** (soluble fraction)

that ROP to yield **4** had indeed occurred (Fig. 2).[21] Of note in the ^{1}H NMR spectrum of **4** is the broad multiplet centered at δ 3.65 which arises from both the Cp and bridging methylene protons as well as the broad resonance centered at δ 1.61 corresponding to the Cp′ methyl protons.

A side reaction of the MeOTf initiated polymerization involved oxidation of the resulting material. In an attempt to circumvent this, initiation of ROP was attempted with the alternative Lewis acid, $BF_3{\cdot}OEt_2$. Indeed, when a toluene solution of **3** was treated with 0.02 equiv. of $BF_3{\cdot}OEt_2$, ROP did occur, as evidenced by ^{1}H NMR, the immediate color change of the solution, and the precipitation of **4**. However, unlike the MeOTf initiated polymerization, no oxidation of the polymer was apparent. ^{1}H NMR analysis of the soluble fraction and CP MAS ^{13}C NMR[22] analysis of the bulk material confirmed the presence of **4** and is consistent with the proposed structure. In addition, analysis by mass spectrometry revealed peaks which could be assigned to species possessing oligomeric $[(\eta\text{-}C_5Me_4)Fe(\eta\text{-}C_5H_4)CH_2S]_x$ units where x = 1–3. This again is consistent with the proposed polymeric structure of **4**.

In summary, we have shown that the novel [2]ferrocenophane **3** successfully undergoes both thermal and cationic initiated ROP to afford the polymer **4**, the high molecular mass fraction of which is insoluble in common organic solvents. Future work in this area will involve studies of the ROP mechanism and copolymerization of **4** with other heterocycles in an effort to obtain soluble, high molecular mass materials.

We would like to thank the Petroleum Research Fund (PRF) administered by the American Chemical Society for funding of this research. R. R. thanks the University of Toronto for an Open Scholarship (1997–98) and P. N. thanks the Natural Science and Engineering Research Council of Canada (NSERC) for a postdoctoral fellowship. I. M. is grateful to the Alfred P. Sloan Foundation for a Research Fellowship (1994–98), NSERC for an E. W. R. Steacie Fellowship (1997–1998), and the University of Toronto for a McLean Fellowship (1997).

Sulfur dioxide gas detection by reversible η^1-SO_2–Pt bond formation as a novel application for periphery functionalised metallo-dendrimers‡

Martin Albrecht,[a] Robert A. Gossage,[a] Anthony L. Spek[b] and Gerard van Koten*[a]†

[a] *Debye Institute, Department of Metal-Mediated Synthesis, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands*

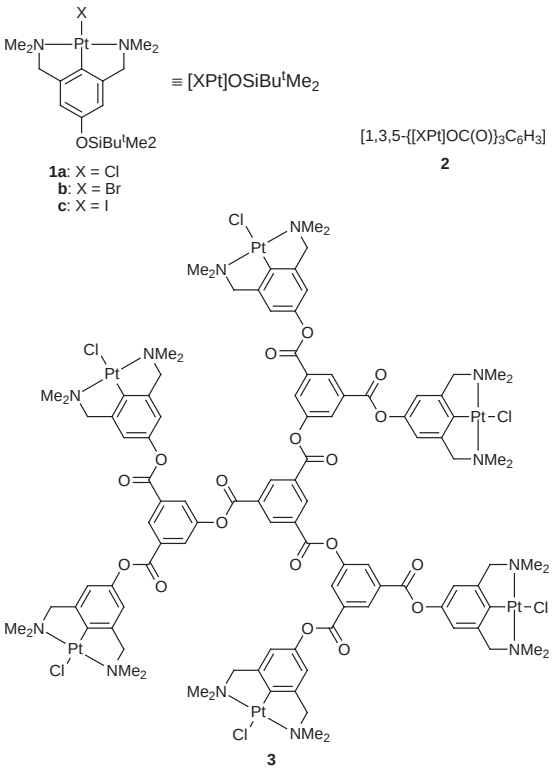
Multimetallics such as dendrimer 3 which are functionalised at their periphery with platinum(II) metal centres reversibly absorb SO_2 to yield macromolecules with significantly enhanced solubility characteristics and drastic colour changes; properties which make these compounds highly active sensors for milligram quantities of toxic SO_2 gas.

Since the first reports of synthetic dendrimers in the late 1970s, these compounds have been of widespread interest.[1] Several applications for this type of macromolecule have been realised owing to their unique properties, *e.g.* homogeneous catalysis,[2] as receptors for bioactive molecules[3] or in photophysical applications.[4] Herein we report the first example of transition-metal modified dendrimers which reversibly bind SO_2 and therefore have potential for use as molecular sensors for this toxic gas.

Platinum(II) complexes of type **1** (Scheme 1) have been shown to be suitable precursors for the synthesis of multimetallic systems. Using the methodology developed by Miller *et al.*[5] trimetallic compound **2** and dendrimer **3** containing platinum(II) functional units have been prepared from **1** (Scheme 1).[6,7] The characterisation of these materials, however, is hampered by their low solubility properties. In contrast to their carbosilane analogues,[2] dendrimers which contain aryl-ester core units have been calculated to be planar molecules.[6] This molecular geometry may be the reason for the low solubility of **2** and **3** in common organic solvents. From earlier experiments however, it has been shown that mononuclear platinum and nickel complexes containing the terdentate monoanionic diaminoaryl ligand [NCN$^-$ = {C_6H_2-(CH_2NMe_2)$_2$-2,6-R-4}$^-$] reversibly bind SO_2[8–10] and coordination of this ligand is known to greatly increase the solubility of the resulting five-coordinate platinum(II) compounds.[11] All these SO_2 adducts possess a generalised square pyramidal geometry around the metal centre.[12] A crystal structure determination of the SO_2 adduct of **1c** (**4**; Fig. 1) confirms that SO_2 is bound to Pt in a η^1-binding mode through sulfur and is positioned at the apex of a distorted square-pyramid, which best describes the geometry around the metal centre.§ No disorder arising from interactions with iodide have been found. It is noteworthy that in earlier studies,[13] SO_2 has been found to be bound to iodide, which is competitive to platinum in size and electronegativity.

Thus, we have studied the effect of the presence of SO_2 on dendrimers which are functionalised with square planar platinum(II) metal centres. Compounds **2** and **3** react instantaneously when exposed to SO_2 (g) to form the corresponding SO_2 adducts **5** and **6**,¶ respectively (Scheme 2), both in the solid state and in solution (*e.g.* $CHCl_3$, toluene; max. solubility of **6** in $CHCl_3$: 2.5 mass%). Adduct formation is suggested by ^{1}H NMR spectroscopy, since the resonance signals of protons in close proximity to Pt undergo a characteristic down field shift [0.23 ppm for the CH_2N methylene protons and 0.16 ppm for the $N(CH_3)_2$ groups].[8] Owing to the change of the coordination number around the metal centre, the electronic spectrum shows two new absorption bands at *ca.* 350 and 400 nm (CH_2Cl_2 solution). The exact wavelengths of these bands depend on the metal-bound halogen atom, but are not significantly changed by different substituents on the aryl ring of the NCN ligand.[14] The band at higher frequency is quite strong with absorption coefficients > 20 000 dm^3 mol^{-1} cm^{-1}. In an atmosphere of SO_2, adduct formation of these new materials occurs quantita-



Scheme 1 Mono- and multi-metallic platinum(II) complexes containing aryldiamine ligands

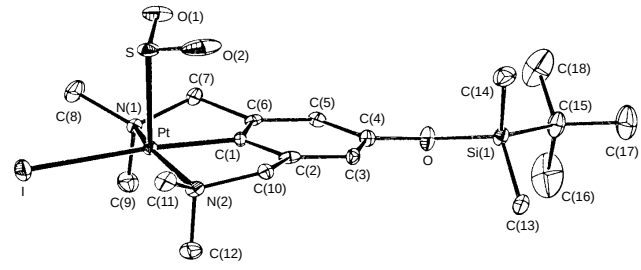


Fig. 1 ORTEP plot (50% probability level) of **4**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°), Pt–I 2.7175(7), Pt–N(1) 2.112(4), Pt–N(2) 2.113(5), Pt–C(1) 1.946(6), Pt–S 2.4792(15), S–O(1) 1.443(4), S–O(2) 1.433(6); I–Pt–S 94.14(4), C(1)–Pt–S 91.44(18).

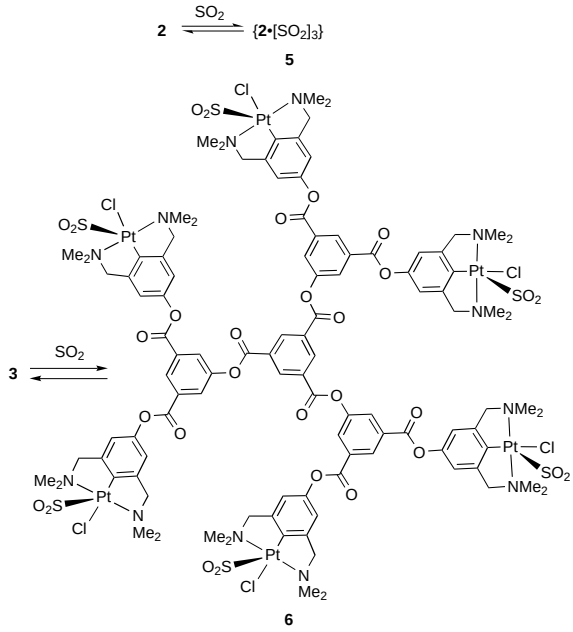

Scheme 2 Formation of the SO_2 adducts **5** and **6** from the corresponding multimetallic precursors upon addition of sulfur dioxide

tively both when the compounds are in the solid state or in solution. The reaction process can be followed visually and/or by UV–VIS spectroscopy, as a characteristic change from colourless to bright orange is noted. Traces of SO_2 are sufficient to observe this change. For example, with a CH_2Cl_2 solution of **2** which is exposed to SO_2, concentrations as low as 10 mg dm^{-3} (at a platinum/SO_2 molar ratio of 0.2) can be detected using UV–VIS spectroscopy. Similarly, when the atmosphere contains SO_2 (3 ± 0.5%), coating of a filter paper with **2** by 10 nmol mm^{-2} is already sufficient to detect a significant colour change. Obviously, higher sensitivity towards SO_2 can be achieved by increasing the concentration of the adsorbed dendrimer.‖

Desorption of SO_2 from adducts **5** and **6** can be achieved by a number of mild procedures, such as heating to 40 °C for several minutes or reducing the pressure to *ca.* 2.7 kPa (20 mm Hg). Both methods quantitatively regenerate **2** or **3**, respectively. Repetitive adsorption/desorption cycles have been performed without significant loss of material or activity.

In contrast to monomeric analogues or dendrimers containing flexible cores (*e.g.* carbosilanes or aminoalkanes), the organometallic trimer and dendrimer presented here possess a rigid disc-like molecular structure and therefore are probably better candidates for recovery *via* ultrafiltration technology.[15,**] Owing to the electronic characteristics of the NCN–metal unit,[16] the Pt–C bond in monomeric and dendritic compounds is resistant to insertion reactions of SO_2. In addition, this stability allows the construction of macromolecules starting from simple organometallic building blocks rather than from metal-free ligand precursors.[1,2] Such a methodology reduces the difficulties associated with quantitative end-group substitution.[6]

The organometallic compounds presented here are characterised by their high reactivity towards sulfur dioxide and even submillimolar quantities of this gas are indicated by a drastic colour change. Moreover, mild and selective methods are available to recycle the adducts to the SO_2 free compounds in order to regenerate the 'detector'. In addition, these materials can be used in the solid state (pure or adsorbed onto an inert surface) or in dilute solution, a property which greatly broadens their potential application. An increase in sensitivity and/or efficiency may be possible with dendrimers of higher generation or by adjustment of the ligand array around the Pt metal centre, *e.g.* by changing the metal-bound halogen atom. Optimization of the properties of these dendrimers is a subject of current investigation in our laboratories.

We thank Huub Kooijman for crystal data collection and Utrecht University for financial assistance. This work was supported in part (A. L. S.) by the Netherlands Foundation for Chemical Research (S. O. N.) with financial aid from the Netherlands Organisation for Scientific Research (N. W. O.).

Systematic synthesis of a series of hydroperoxo-, alkylperoxo- and μ-peroxo-palladium complexes supported by the hydrotris(3,5-diisopropylpyrazolyl)borate ligand (Tp^{iPr}), $Tp^{iPr}Pd(py)–OOX$ [X = $PdTp^{iPr}(py)$, H, Bu^t], *via* dehydrative condensation of a hydroxo complex, $Tp^{iPr}Pd(py)–OH$

Munetaka Akita,*† Taichi Miyaji, Shiro Hikichi and Yoshihiko Moro-oka*

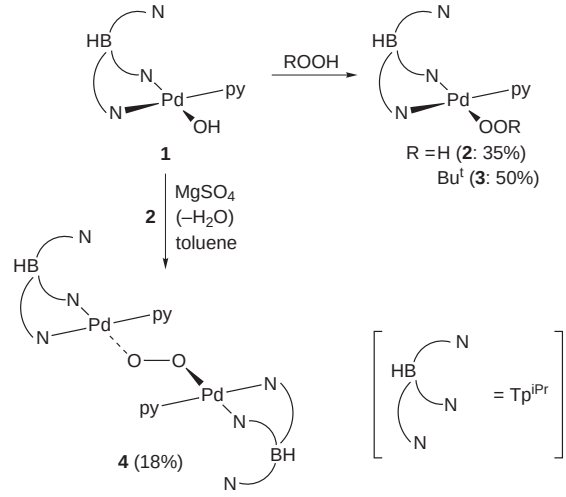
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan

A series of hydroperoxo, *tert*-butylperoxo and μ-peroxo complexes of palladium, $Tp^{iPr}Pd(py)(OOX)$ [X = H, Bu^t, $PdTp^{iPr}(py)$; Tp^{iPr}: hydrotris(3,5-diisopropylpyrazolyl)borate] is prepared by dehydrative condensation of a hydroxo complex, $Tp^{iPr}Pd(py)(OH)$, with HOOX.

Transition metal peroxo, hydroperoxo and alkylperoxo species are postulated as key intermediates of catalytic oxygenations such as transition metal catalyzed oxidation of organic compounds and physiological metabolic reactions.[1] For investigation of the reaction mechanisms it is essential to characterize the structure and chemical properties of possible intermediates but well-characterized examples of peroxo complexes‡ are still rare. In our laboratory first row transition metal peroxo complexes supported by hydrotris(pyrazolyl)borate ligands (Tp^R) have been studied from the bioinorganic viewpoint.[2] As for their synthetic methods, we have established that transition metal hydroxo complexes are versatile precursors for peroxo complexes *via* dehydrative condensation with ROOH. Recently our research target is extended to peroxo complexes not related to metalloproteins (Co, Ni, and the second row metals)[3] for comprehensive understanding of chemistry of transition metal dioxygen complexes based on the Tp^R ligand system. Herein we report synthesis and characterization of a series of peroxo palladium complexes, $Tp^{iPr}Pd(py)–OO–X$ [X = H, Bu^t, $PdTp^{iPr}(py)$; Tp^{iPr}: hydrotris(3,5-diisopropylpyrazolyl)borate].§

The starting hydroxo complex, (κ^2-Tp^{iPr})Pd(py)–OH **1**,¶ was prepared by hydrolysis of the corresponding chloro complex, (κ^2-Tp^{iPr})Pd(py)–Cl,‖ with aqueous NaOH solution. Complex **1** turned out to be basic enough to be condensed with various protic substrates including acetic acid, phenol, methanol and hydroperoxides (Scheme 1). Reaction with a slight excess amount of H_2O_2 (30% aqueous solution) in THF gave the hydroperoxo complex **2** as yellow solids, and the yellow *tert*-butylperoxo complex **3** was obtained *via* condensation with *tert*-butylhydroperoxide (70%; the remaining part was Bu^t–OO–Bu^t) in benzene. The condensation products **2** and **3** were characterized as square-planar 16e Pd^{II}-complexes on the basis of their spectroscopic features [(*i*) the three non-equivalent pyrazolyl rings; (*ii*) the incorporation of py; (*iii*) the B–H stretching vibration appearing below 2500 cm^{-1} indicating κ^2-coordination of the Tp^{iPr} ligand[3b]]. Characterization of the hydroperoxo complex **2** was based on the OOH signal (^{1}H NMR) observed at δ 6.86 (*cf.* the OH signal of **1**: δ −1.79), which disappeared upon addition of a drop of D_2O, but neither ν(O–O) nor ν(O–H) stretching vibration was detected. The molecular structure of *tert*-butylperoxo complex **3** was confirmed by X-ray crystallography** (Fig. 1.)

The successful condensation reactions of **1** prompted us to examine synthesis of a dinuclear μ-peroxo complex *via* reaction



Scheme 1

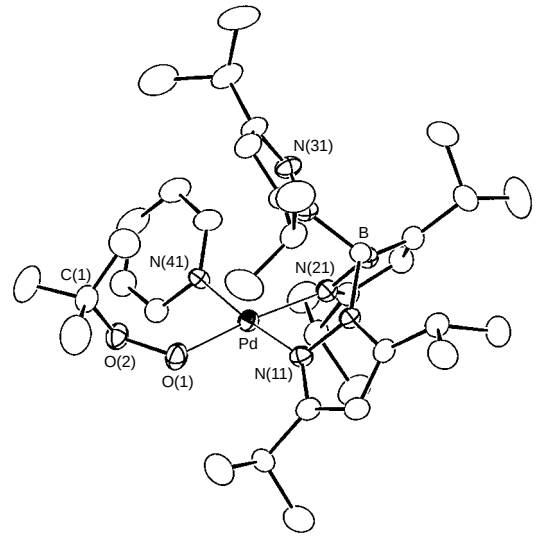


Fig. 1 Molecular structure of the *tert*-butylperoxo complex **3**. Selected interatomic distances (Å) and angles (°): O(1)–O(2) 1.440(5), O(2)–C(1) 1.439(6), Pd(1)–O(1) 1.981(4), Pd–N(11) 1.983(4), Pd–N(21) 2.021(4), Pd(1)···N(31) 3.582(5), Pd–N(41) 2.010(4); Pd–O(1)–O(2) 114.2(3), O(1)–O(2)–C(1) 109.5(4), N(21)–Pd–O(1) 174.4(1).

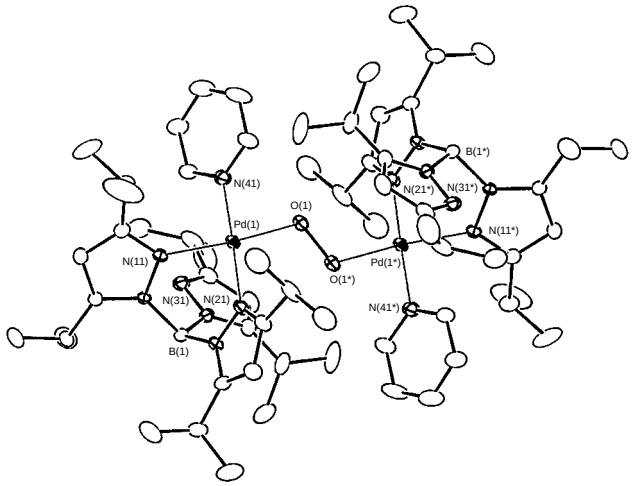

Fig. 2 Molecular structure of the μ-peroxo complex **4** drawn at the 30% probability level. Selected interatomic distances (Å) and bond angles (°). O(1)–O(1*) 1.445(5), Pd(1)–O(1) 1.971(3), Pd(1)–N(11) 2.056(3), Pd(1)–N(21) 2.020(3), Pd(1)···N(31) 3.486(3), Pd(1)–N(41) 2.035(3); Pd(1)–O(1)–O(1*) 111.8(2), N(11)–Pd(1)–O(1) 174.2(1).

with the hydroperoxo complex **2**. As was expected, stirring a mixture of **1** and **2** in toluene in the presence of $MgSO_4$ (a dehydrating reagent) gave the μ-peroxodipalladium complex **4** after crystallization from pentane–ether (Scheme 1). Because **4** was sensitive to moisture, addition of $MgSO_4$ was essential to remove water formed by the condensation. Otherwise the condensation was reversed and an equilibrated mixture of **1**, **2** and **4** was obtained. The μ-peroxo complex **4** could be also formed by condensation of **1** with 0.5 equiv. of H_2O_2, but a mixture of products containing **4** was obtained. The spectroscopic features of **4** were similar to those of **1**–**3** mentioned above, and its molecular structure was determined by X-ray crystallography** (Fig. 2).

According to the CSD database, **3** and **4** are the first examples of structurally characterized η^1-alkylperoxo and μ-peroxo complexes of palladium, respectively.[5] The four-coordinated square-planar geometry around the palladium centers is evident from the interligand N–Pd–N (or O) angles close to right angles [87.2–96.0(2)° **3**, 85.0–96.9(1)° **4**] as well as the Pd(1)···N(31) separations [3.582(5) Å **3**, 3.486(3) Å **4**] non-bonding interaction. The lone pair electrons of the N(31) atoms do not project toward the vacant axial site of the palladium centers. The O–O distances of **3** [1.440(5) Å] and **4** [1.445(5) Å] fall in the typical range of the O–O distances of organic and inorganic peroxo compounds.[1,4] Because no interaction is observed between Pd(1) and O(1*) [2.845(3) Å] in **4**, the bridging O_2 part is described as a μ-η^1 : η^1-peroxo ligand. It is notable that the Pd–O distances of the peroxo complexes **3** [1.981(4) Å] and **4** [1.971(3) Å] are slightly shorter than that of the hydroxo complex **1′** [2.021(7) Å]. Although two diastereomeric structures are possible for the dinuclear complex **4** due to the (κ^2-Tp^{iPr})Pd(py) fragment being chiral, only one isomerically pure species (X-ray structure: *meso* form lying on a crystallographic inversion center) is present as indicated by the observation of only one set of the three CH signals for the three pyrazolyl rings in Tp^{iPr}.‖

The stability and reactivity of the square-planar peroxo complexes were considerably different from those of the first row metal complexes with tetrahedral or trigonal-bipyramidal geometry.[2–4] The peroxopalladium complexes **2**–**4** were thermally stable. The *tert*-butylperoxo complex **3** decomposed when heated at 85 °C for 3 h (in C_6D_6) in the absence of an external substrate, and the hydroperoxo (**2**) and μ-peroxo complexes (**4**) slowly (1–3 days) decomposed at ambient temperature. Addition of PPh_3, however, caused their decomposition giving the phosphine oxide (O=PPh_3) in 43% (from **2**), 71% (from **3**) and 45% yields (from **4**), although the fate of the Tp^{iPr}Pd-moieties was not clear. A complicated mixture of coordination products was merely obtained as observed by ^{1}H NMR monitoring of reaction mixtures. Preliminary experiments on reactivity of the peroxo complexes **2**–**4** toward hydrocarbons revealed that vinyl ethyl ether was converted to ethyl acetate by the action of **2**–**4** but no reaction was observed with simple alkene such as hex-1-ene.

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government for financial support of this research (Grant-in-Aid for Specially Promoted Research: 08102006).

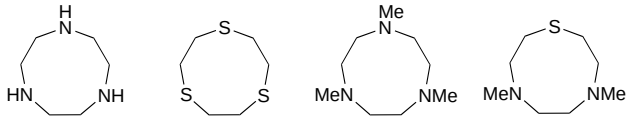
Syntheses and structures of a new class of aza- and thio-ether macrocyclic d^0 imido complexes

Paul J. Wilson, Alexander J. Blake, Philip Mountford*† and Martin Schröder*†

Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD

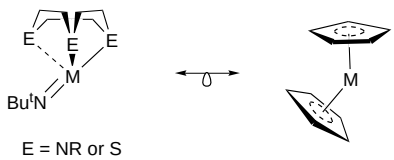
The synthesis and structures of a family of macrocyclic, d^0 titanium imido complexes $[Ti(NBu^t)(L)Cl_2]$ (L = $[9]aneN_3$, $Me_3[9]aneN_3$, $[9]aneS_3$ or $Me_2[9]aneN_2S$) are reported; the new compounds are isolobal analogues of group 4 metallocene dichlorides.

The triaza macrocycle $R_3[9]aneN_3$ (R = H or alkyl) and its thioether analogue, $[9]aneS_3$, are effective six-electron capping ligands for a range of transition metal centres.[1] As part of a study of early transition metal imido chemistry,[2] we were interested to determine whether these ligands might support imido chemistry at d^0 centres. No $R_3[9]aneN_3$- or $[9]aneS_3$-supported imido complexes have been reported previously,[3] and none of $[9]aneS_3$ with any group 4 element. Indeed, previous



$[9]aneN_3$ $[9]aneS_3$ $Me_3[9]aneN_3$ $Me_2[9]aneN_2S$

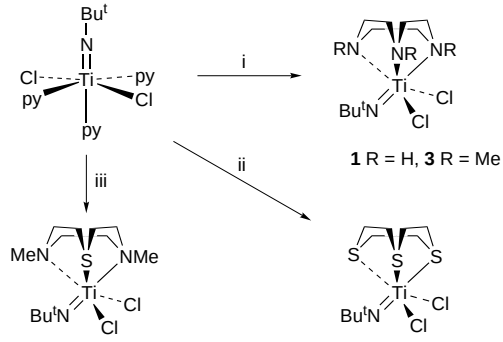
examples of $[9]aneS_3$ transition metal complexes have been almost entirely restricted to later, low to mid-oxidation state transition metals,[1b] presumably due to hard–soft acid–base considerations;[4] the two exceptions are the d^1 V^{IV} vanadyl complex $[V(O)([9]aneS_3)Cl_2]$[5a] and the trioxorhenium species $[R(O)_3([9]aneS_3)]^+$.[5b] The $[9]aneN_3$ or $[9]aneS_3$ macrocycle–metal–imide fragment (Scheme 1) is isolobal and valence isoelectronic[6] with the ubiquitous bis(η^5-cyclopentadienyl)metal moiety. Consequently complexes containing this ligand set would clearly promise an interesting and extensive reaction chemistry that may have applications in alkene polymerisation and related catalysis.[7] Additionally, both the ring and/or the imido ligand N-substituents in such complexes may be readily varied so as to control solubility and electronic and steric properties. We report herein a new class of macrocyclic, d^0 imido complexes containing $[9]aneN_3$, $[9]aneS_3$, $Me_3[9]aneN_3$, and $Me_2[9]aneN_2S$.



E = NR or S

Scheme 1

The syntheses and structures of the new compounds are shown in Scheme 2.‡ Addition of $[9]aneN_3$ or $[9]aneS_3$ to a dichloromethane solution of $[Ti(NBu^t)Cl_2(py)_3]$[2d] results in displacement of the pyridine ligands and formation of $[Ti(NBu^t)([9]aneN_3)Cl_2]$ **1** and $[Ti(NBu^t)([9]aneS_3)Cl_2]$ **2**, respectively. For comparative purposes and to establish the scope of the reactions, we also prepared the related complex $[Ti(NBu^t)(Me_3[9]aneN_3)Cl_2]$ **3** and its mixed N_2S-donor homologue $[Ti(NBu^t)(Me_2[9]aneN_2S)Cl_2]$ **4** in an analogous fashion.



Scheme 2 *Reagents and conditions*: i, $R_3[9]aneN_3$, CH_2Cl_2, room temp., 2 h, 71% (for **1**) or 92% (for **3**); ii, $[9]aneS_3$, CH_2Cl_2, room temp., 2 h, 21%; iii, $Me_2[9]aneN_2S$, CH_2Cl_2, room temp., 24 h, 68%

Compound **4** crystallises exclusively as the isomer shown in Scheme 2 (*i.e.* with S *cis* to the *tert*-butylimido group). The yellow–orange compounds **1**–**4** are all mildly air- and moisture-sensitive.

Recrystallisation from cold dichloromethane solutions yielded crystals suitable for X-ray diffraction analysis.§ The molecular structures of **1** and **2** are shown in Figs. 1 and 2 respectively, and selected bond lengths and angles for all four compounds **1**–**4** are summarised in Table 1 for ease of comparison. The solid state structures are fully consistent with solution ^1H and ^{13}C NMR data in $CDCl_3$.

All four monomeric complexes feature an approximately octahedral titanium(IV) coordination sphere that is comprised of a *fac*-coordinated macrocycle, a multiply-bonded *tert*-butylimido ligand and two mutually *cis* chloride ligands. The Ti–$N_{macrocycle}$ or Ti–S bonds *trans* to NBu^t are significantly lengthened relative to their *cis* Ti–$N_{macrocycle}$ or Ti–S counterparts, reflecting the well known *trans* influence of the imido ligand.[3b] The angles subtended at the imido nitrogen lie in the

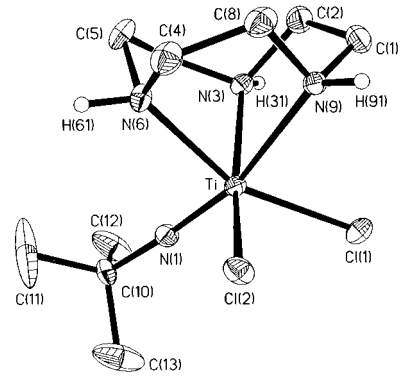


Fig. 1 Displacement ellipsoid (40% probability) plot for $[Ti(NBu^t)([9]aneN_3)Cl_2]$ **1**. Hydrogen atoms are excluded except for those bonded to N; these are drawn as spheres of arbitrary radius. The CH_2Cl_2 solvent molecule is also excluded.

Table 1 Comparison of selected distances (Å) and angles (°) for **1**–**4**; *cis* and *trans* refer to coordination sites with respect to NBu^t

Compound	Ti–N_{cis}	Ti–N_{trans}	Ti–S_{cis}	Ti–S_{trans}	Ti–Cl	Ti–N_{imide}	Cl–Ti–Cl	C–N_{imide}–Ti
1	2.213(3) 2.227(3)	2.359(3)	—	—	2.407(1) 2.403(1)	1.703(3)	97.23(4)	174.3(2)
2	—	—	2.575(1) 2.591(1)	2.750(1)	2.370(1) 2.379(1)	1.694(3)	103.02(4)	178.3(3)
3	2.265(3) 2.270(3)	2.437(3)	—	—	2.394(1) 2.392(1)	1.694(2)	95.75(4)	171.0(2)
4	2.285(9)	2.498(8)	2.561(4)	—	2.379(4)[a] 2.397(4)[b]	1.708(8)	98.0(2)	166.4(6)

[a] *Trans* to S_{cis}. [b] *Trans* to N_{cis}.

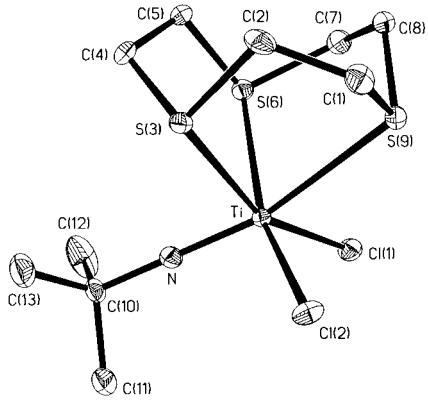

Fig. 2 Displacement ellipsoid (40% probability) plot for [Ti(NBu^t)([9]aneS$_3$)Cl$_2$] **2**. Hydrogen atoms and the CH_2Cl_2 solvent molecule are excluded.

range 166.4(6)–178.3(3)°, consistent with the NBu^t ligand acting as four-electron donor to Ti^{IV} and forming a Ti≡N_{imide} triple bond (pseudo-$\sigma^2\pi^4$ configuration).[3a] Table 1 shows that the Ti–Cl bond lengths in **1** and **3** (*i.e.* both *trans* to N) are significantly longer than those in **2** (*i.e. trans* to S). Consistent with these observations, compound **4** has a Ti–Cl bond *trans* to N [2.397(4) Å] that is significantly longer than that *trans* to S [2.379(4) Å]. In addition, the ligand R_3[9]aneN$_3$ in **1** and **3** produces Cl–Ti–Cl angles of 97.23(4) and 95.75(4)°, respectively, while [9]aneS$_3$ gives a substantially increased angle of 103.02(4)° in **2**. These data demonstrate clearly the importance of the different macrocycles in tuning and varying structural parameters of **1**–**4**, which, in other systems, have been shown[7] to be important features in catalyst design.

The complexes [Ti(NBu^t)([9]aneS$_3$)Cl$_2$] **2** and [Ti(NBu^t)(Me$_2$[9]aneN$_2$S)Cl$_2$] **4** are the first group 4 derivatives of [9]aneS$_3$ or R_2[9]aneN$_2$S.[8] Furthermore, the four complexes **1**–**4** represent the first such macrocycle–imido derivatives, and are related to oxo complexes of Me$_3$[9]aneN$_3$.[9] Preliminary studies have demonstrated that the chloride ligands in **3** may be substituted to give [Ti(NBu^t)(Me$_3$[9]aneN$_3$)(R)$_2$] (R = CH_2SiMe_3 or CH_2Ph), and we have also prepared the cationic group 5 complexes [Nb(NBu^t)(Me$_3$[9]aneN$_3$)Cl$_2$]X (X = Cl or PF_6) which are valence isoelectronic with **1**–**4**. Reactivity studies of all the new complexes are underway.

Electrochemical–hydrothermal synthesis and structure determination of a novel layered mixed-valence oxide: $BaV_7O_{16}{\cdot}nH_2O$

Xiqu Wang, Lumei Liu, Ranko Bontchev and Allan J. Jacobson*†

Department of Chemistry, University of Houston, Houston, Texas 77204, USA

The electrochemical–hydrothermal synthesis of a new mixed-valence oxide $BaV_7O_{16}{\cdot}nH_2O$ ($n \approx 4.4$) with $[V_7O_{16}]$ layers containing both vanadium oxygen tetrahedra and distorted octahedra is reported.

Vanadium oxide bronzes have been the focus of many studies because of their complex structural, physical and chemical properties. Compounds formed by high temperature synthesis and by intercalation reactions of V_2O_5 have been reported.[1–3] Most recently, hydrothermal methods have been shown to be an effective approach for the synthesis of new layered vanadium oxide bronzes containing either inorganic or organic interlayer cations.[3–12] Such materials have been of interest because of their potential application as cathode materials in secondary lithium batteries.[12] The structures of the vanadium bronzes are based on distorted vanadium–oxygen octahedra or square pyramids and VO_4 tetrahedra. The layered structures contain either single layers of corner and edge-shared polyhedra[3–8] or double layers that also contain face-shared units.[9–12] Examples of single layer structures recently reported are $(C_3N_2H_{12})_{0.5}V_2O_5$[3] and $(C_6H_{14}N_2)V_6O_{14}{\cdot}H_2O$[5,6] while the compounds δ-$M_{0.25}V_2O_5{\cdot}H_2O$ (M = Ni, Ca)[10] and $NMe_4V_8O_{20}$[12] have double layers.

Hydrothermal reactions can lead to high yields of well developed single crystal products but are known to be very sensitive to the specific reaction conditions used. For example, the pH has been shown to play a critical role in determining the final products of hydrothermal synthesis of vanadium oxides in reactions containing tetramethylammonium cations.[13] At present, we are investigating whether a modification of conventional hydrothermal synthesis in which one of the metal ion reactants is electrochemically introduced can provide better control over product formation. Previous studies of the hydrothermal electrosynthesis of thin films of $BaTiO_3$ and $SrTiO_3$ have been reported but the technique has not been used specifically for the synthesis of new compounds.[14] Here, we report the synthesis and structure of the new layered vanadium oxide bronze $BaV_7O_{16}{\cdot}nH_2O$ using the electrochemical–hydrothermal method. Other barium vanadium oxide bronzes have been synthesized hydrothermally.[15–17]

The synthesis experiments were performed using a Teflon-lined autoclave fitted with feedthroughs for electrical connections between the electrodes inside the reaction chamber and the external circuit. In a typical experiment, 40 ml of 0.01 M $Ba(NO_3)_2$ solution (pH = 1.2) was sealed in the autoclave. The anode (working electrode) was a vanadium metal plate (20 × 10 × 0.254 mm). A gold foil was used as cathode (counter electrode) and a Pt wire as a pseudo-reference electrode. The experiment was conducted with current densities in the range 0.1–1 mA generated by a commercial power source (MacPile, Biologic Scientific Instruments) at 170 ± 2 °C for 100 h. Black shiny plates of $BaV_7O_{16}{\cdot}nH_2O$ coprecipitated together with black needles of the known compound BaV_3O_8[15] and an unidentified minor phase.

The tetragonal structure of $BaV_7O_{16}{\cdot}nH_2O$ is a new structure type in which $[V_7O_{16}]$ double layers are stacked along the [001] unit cell direction with Ba^{2+} ions and H_2O molecules located between the layers (Figs. 1 and 2).‡ There are three different vanadium atom positions in the layers. V(1) and V(2) atoms are coordinated by oxygen atoms to form distorted octahedra while V(3) has tetrahedral coordination. The $V(2)O_6$ distorted octahedra share *trans* edges with two $V(1)O_6$ units to form trimers which in turn are connected by edge sharing $V(1)O_6$ octahedra to form zigzag chains. The chains are interconnected into single layers by sharing one oxygen atom. The layers are stacked along [001] with all of the short V=O oxygen atoms on the same side of the layer. The two octahedral layers are directly connected by sharing common edges to form a double layer of composition $[V_7O_{16}]$. The tetrahedra are located between the distinctive 1 × 2 windows of both octahedral layers.

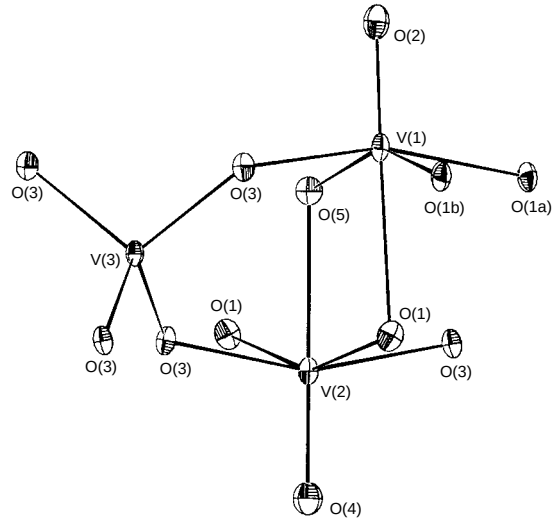

Fig. 1 Coordination environments of the vanadium atoms. Thermal ellipsoids are drawn with 50% probability. Bond lengths (Å): V(1)–O(2) 1.600(5); V(1)–O(5) 1.843(2), V(1)–O(1a) 1.941(4), V(1)–O(1b) 2.006(4), V(1)–O(3) 2.020(4), V(1)–O(1) 2.390(4), V(2)–O(4) 1.611(7), V(2)–O(1) (×2) 1.976(4), V(2)–O(3) (×2) 1.995(4), V(2)–O(5) 2.273(6), V(3)–O(3) (×4), 1.790(4).

The $V(1)O_6$ and $V(2)O_6$ octahedra show distortions typical of V_2O_5 related oxides. The vanadium atoms are displaced from the center of each octahedron along a local [001] direction to give short 'vanadyl' distances of 1.600 and 1.611 Å for V(1) and V(2), respectively. The corresponding distances *trans* to the vanadyl oxygen atoms are 2.390 and 2.273 Å. The $V(1)O_6$ $V(2)O_6$ octahedra are comparably distorted with O···O distances in the range 2.57–2.95 Å [V(1)] and 2.58–2.91 Å [V(2)]. The $V(2)O_6$ octahedron is noticeably elongated in the basal plane along the axis of the trimeric edge-shared unit (2.91 *cf.* 2.58 Å). Bond valence sums were calculated using the parameters for V^{IV}–O.[18] The values calculated are 4.42, 4.18 and 3.94 v.u. for V(1), V(2) and V(3) respectively and are consistent with mixed valence vanadium ions with an average oxidation state of 4.29. The bond valence sums suggest that V(3) which is tetrahedrally coordinated by oxygen atoms [d(V–O) = 1.790 Å] is tetravalent. This unusual V^{IV}–O coordination is found only in rare cases such as in the structure of Ba_2VO_4 [average d(V–O) = 1.76 Å].[19] The V(1) and V(2) positions are occupied both

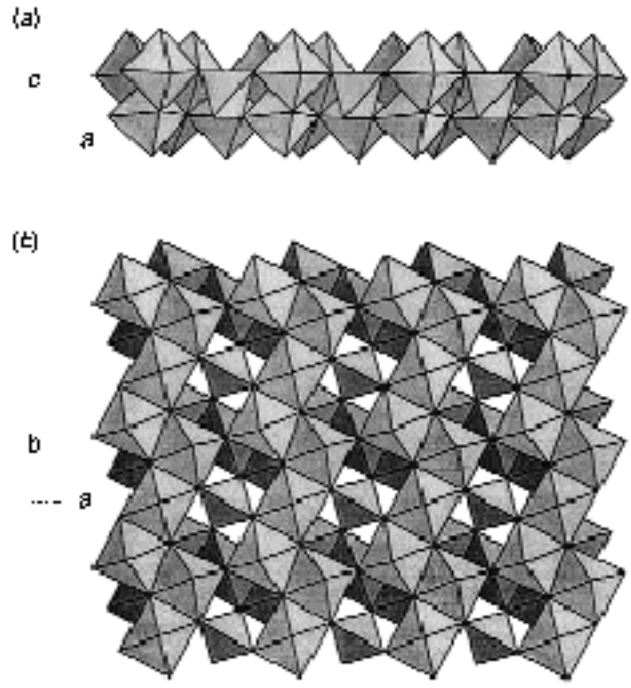

Fig. 2 Projections of the $[V_7O_{16}]$ layer along (*a*) [010] and (*b*) along [001]

by V^{IV} and V^{V}, with some preference for V^{V} at the V(1) position where symmetry is lower.

The barium cations occupy two different interlayer positions both with an occupancy of about one third. The two Ba positions are only 2.61 Å apart and cannot be occupied simultaneously. Both barium atoms are coordinated by vanadyl oxygen atoms from the layers above and below and by interlayer H_2O molecules. One water molecule is located between the Ba cation layer and the vanadate layer and is well ordered. The water molecules located in the same layer as the barium cations are highly disordered. Four distinct partially occupied sites were located and refined to give a total water content $n \approx 4.4$ in $BaV_7O_{16}{\cdot}nH_2O$. Refinement of the barium occupancies gave a Ba : V atomic ratio of 1.04(1) : 7, in good agreement with a ratio of 0.98 : 7 determined by electron microprobe analysis.§

The structure of the $BaV_7O_{16}{\cdot}nH_2O$ layers is an example of a new layer topology but is related to other double layer vanadate structures, for example, δ-$Ca_{0.25}V_2O_5{\cdot}H_2O$[10] and σ-$Zn_{0.25}V_2O_5{\cdot}H_2O$.[11] In the δ phase, all of the vanadium atoms have distorted octahedral environments. In the layer structure of the σ phase the vanadium atoms are found in distorted octahedral, square pyramidal and tetrahedral coordinations. One of the oxygen atoms in the tetrahedron is not coordinated to other vanadium atoms in the layer, an arrangement observed in several single layer structures.[3–6] In contrast, in the title compound all oxygen atoms in the $V(3)O_4$ tetrahedra are shared with V(1) and V(2) atoms.

In summary, a new layered mixed-valence barium vanadium oxide $BaV_7O_{16}{\cdot}nH_2O$ with vanadium ions present in both distorted octahedral and tetrahedral coordination environments was synthesized by electrochemical–hydrothermal synthesis. This result together with preliminary data on other vanadium systems suggest that the combination of electrocrystallization under hydrothermal conditions is a generally useful synthetic method.

‡ *Crystal data* for $BaV_7O_{16}{\cdot}nH_2O$, M = 829.1, space group $P4_2/m$, a = 6.1598(4), c = 21.522(2) Å, Z = 4, D_c = 3.38 g cm^{-3}, black thin plate, crystal size 0.15 × 0.15 × 0.01 mm, Mo-Kα radiation (λ = 0.710 73 Å), μ = 6.30 mm^{-1}, $2\theta_{max}$ = 57°, $R(F)$ = 0.0517, $wR(F^2)$ = 0.112, GOF = 1.245 for 89 parameters and 819 unique reflections with $I > 2\sigma(I)$.

Intensities were measured on a SMART platform diffractometer equipped with a 1 K CCD area detector using graphite-monochromatized Mo-Kα radiation at −50 °C. A hemisphere of data (1271 frames at 5 cm detector distance) was collected using a narrow-frame method with scan widths of 0.30° in ω and an exposure time of 30 s per frame. The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability, and the maximum correction applied on the intensities was *ca.* 1%. The data were integrated using the Siemens SAINT program, with the intensities corrected for Lorentz factor, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. Final cell constants were refined using 2547 reflections having $I > 10\sigma(I)$. An absorption correction was first made using the program SADABS based on equivalent reflections. The structure was solved with direct methods and refined using SHELXTL. All atom positions except the disordered water oxygen atoms were derived by direct methods and refined anisotropically in the final refinements. The disordered water oxygen atoms were located from difference maps and refined isotropically with the same thermal parameter and free occupancies. CCDC 182/816.

§ Electron microprobe analysis was carried out with a JEOL JXA-8600 instrument operating at 15 keV with a 10 μm beam diameter and a beam current of 30 nA. Counting times in the range of 40–100 s were used for both peaks and background.

First structurally characterised lithium hexafluorophosphate complexes with acyclic Lewis bases: ion-separated $[Li_2(hmpa)_5]^{2+}\cdot 2(PF_6^-)$ and ion-contacted $[(pmdeta)LiPF_6]_2$ [hmpa = $(Me_2N)_3PO$; pmdeta = $MeN(CH_2CH_2NMe_2)_2$]

Reactions of NH_4PF_6 with Bu^nLi in toluene containing hmpa or pmdeta afford the complexes $[Li_2(hmpa)_5]^{2+}\cdot 2(PF_6)^-$ 1, an ion-separated species containing an unusual dinuclear dication, and $[(pmdeta)LiPF_6]_2$ 2 in which PF_6^- anions bridge (pmdeta)Li^+ units *via* Li···F interactions, this being the first observation of a bridging mode for this anion; *ab initio* MO calculations help explain the very different structures of 1 and 2.

Lithium salts are favoured electrolytes in medium-sized rechargeable batteries[1] which have military use as well as use in laptops/personal computers and mobile phones. Anions stable at the voltages generated (typically, 4.2 V) are required for these applications. Hence, $LiPF_6$ dissolved in organic carbonates such as ethylene or dimethyl carbonate has attracted much interest. However, there are practical problems: commercially supplied $LiPF_6$ is expensive and often impure, it is difficult to handle owing to its sensitivity to air, moisture and light, and it releases toxic hydrogen fluoride upon hydrolysis. Further, and surprisingly, there are no published structural data on complexes of $LiPF_6$ with other than macrocyclic ligands (which lead to ion-separated species).[2] Given these deficiencies, we have investigated and now report a synthetic method for assembling $LiPF_6$ complexes *in situ* and the solid-state structures of two of them: $[Li_2(hmpa)_5]^{2+}\cdot 2(PF_6^-)$ **1** an ion-separated species containing a previously unknown dinuclear dication, and $[(pmdeta)LiPF_6]_2$ **2** an ion-contacted species in which PF_6^- anions bond in an unprecedented way, bridging metal centres *via* Li···F contacts. We report also the results of *ab initio* MO calculations on $LiPF_6$ and its complexes with selected acyclic Lewis bases.

Complexes **1** and **2** were synthesised by the 'ammonium salt' route whereby ammonium salts are reacted with metal sources in toluene containing stoichiometric amounts of a Lewis base.[3] Here, NH_4PF_6 suspended in toluene containing hmpa or pmdeta was treated with Bu^nLi solution, cooling of the resulting solutions affording high yields of crystalline materials, identified as **1** and **2**. The advantages of this *in situ* route are clear: $LiPF_6$ units are assembled from very pure precursors prior to being captured by Lewis bases present, and these steps occur quickly and under mild and anhydrous conditions. In contrast, the direct route to these complexes is ineffective: solid $(LiPF_6)_\infty$ dissolves in hmpa or pmdeta (neat or with non-polar solvents present also) to give oils, from which crystalline materials are unobtainable.

The solid-state structures of **1** and **2** have been determined by X-ray crystallography.‡ Complex **1** crystallises in the trigonal space group $P6_3/m$ and consists of dications $[Li_2(hmpa)_5]^{2+}$ and separate PF_6^- anions. The former (Fig. 1) are each made up of two terminal (hmpa)Li^+ units [Li(1)–O(1) 1.83(2) Å] linked by three μ-hmpa molecules [Li(1)–O(2) 1.992(12) Å]. Such triple μ-O bridges are extremely rare although they occur in the acetamide complex $(LiClO_4)_2\cdot(\mu\text{-}MeCONH_2)_3\cdot(MeCONHCOMe)_2$[4] and, in the closest analogy, in $[BrLi(\mu\text{-}hmpa)_3LiBr]$.[5]

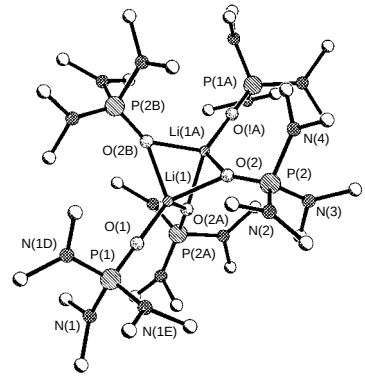

Fig. 1 Molecular structure of the cation of $[Li_2(hmpa)_5]^{2+}\cdot 2(PF_6^-)$ **1**; hydrogen atoms omitted for clarity

Rarity notwithstanding, the dication of **1** appears to represent something of a 'thermodynamic sink'. It forms irrespective of the stoichiometric amounts of hmpa provided during the synthesis of **1**. Further we have observed the same dication in the structures of $[Li_2(hmpa)_5]^{2+}\cdot(GeBr_3^-)_2$ and $[Li_2(hmpa)_5]^{2+}\cdot(SnPh_3^-)_2$.[6]

The solid-state structure of **2** also contains dinuclear units although here the ions are contacted (Fig. 2). Two (pmdeta)Li^+ units [Li–N 2.181(6), 2.189(6), 2.207(6) Å; mean 2.192 Å] are joined *via* two PF_6^- anions each of which provides two bridging fluorine atoms, one to each cation [Li(1)–F(1) 2.140(5), Li(1)–F(3A) 1.914(6) Å]. These bridges, which are almost linear (mean Li–F–P, 175.5°), result in formation of a central $(LiFPF)_2$ eight-membered ring. So far as we can ascertain, **2** is the first ion-contacted $LiPF_6$ complex. More widely, a bridging mode for the PF_6^- anion is seemingly unprecedented. Hitherto, whenever this anion has been found coordinating (in itself, a rare occurrence) it has done so to just one metal centre using one, two or three of its F atoms, *e.g.* η^1 in $(Me_3P)(NO)(CO)_3W(F)PF_5$,[7a] η^2 in $F_4P(F)_2Na\cdot$dibenzo-36-crown-

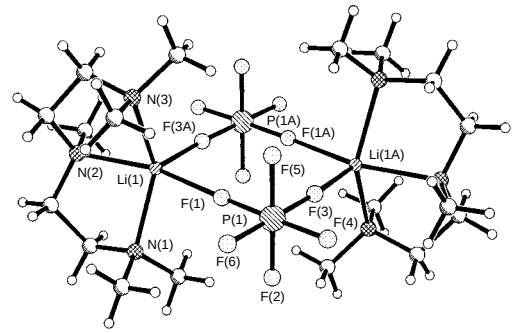

Fig. 2 Molecular structure of $[(pmdeta)LiPF_6]_2$ **2**

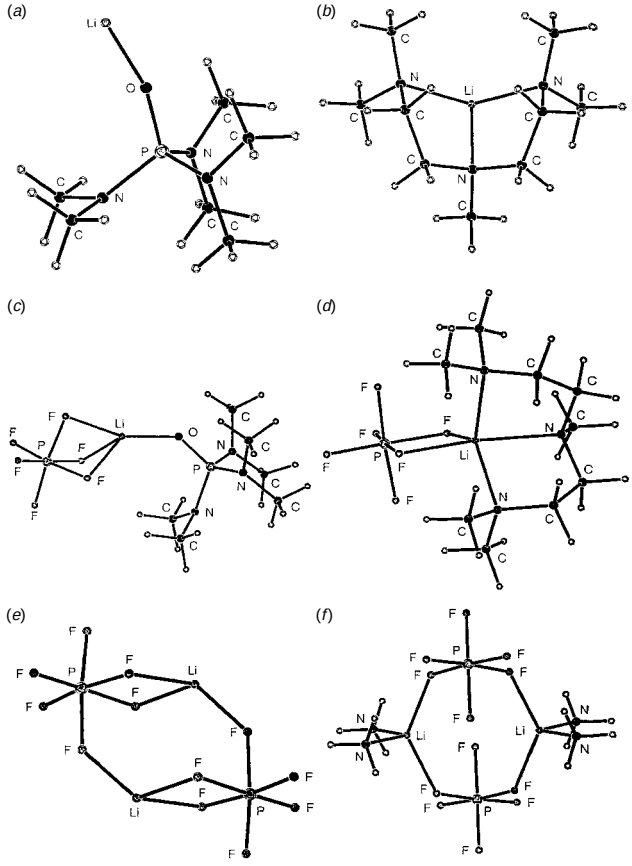

Fig. 3 Optimised structures (6-31G** basis set) of (*a*) Li^+·hmpa, (*b*) Li^+·pmdeta, (*c*) $LiPF_6$·hmpa, (*d*) $LiPF_6$·pmdeta, (*e*) $(LiPF_6)_2$, (*f*) $(LiPF_6·2NH_3)_2$

$12·Na(F)_2PF_4$,[7b] and η^3 in $F_3P(F)_3Na$·ferrocene benzo-15-crown-5.[7c]

Finally, we have employed *ab initio* MO calculations (6-31G** basis set[8] and using the program GAMESS[9]) to probe the reasons behind the very different molecular structures of **1** and **2** and to examine the energetics of $LiPF_6$ complexation. Species were optimised without constraint and confirmed as true minima by positive frequency tests. Monomeric, uncomplexed $LiPF_6$ itself favours an η^3-structure $F_3P(F)_3Li$; an η^2 arrangement is almost as stable (relative energy, +0.7 kcal mol^{-1}) but an η^1 one is of much higher energy (+13.2 kcal mol^{-1}). Calculations on pmdeta and hmpa show that the charges on the N centres of the former are −0.59 (two NMe_2) and −0.62 (NMe), and that the charge on the O centre of the latter is −0.75. In purely electrostatic terms, both of these molecules are more attractive to Li^+ than is anionic PF_6^-, for which the charge on each F centre is −0.49. This is especially so for hmpa, a point borne out by the complexation energy of Li^+ by a single hmpa ligand [Fig. 3(*a*)] being a massive −69.3 kcal mol^{-1}; the enthalpy of formation of Li^+·pmdeta, with all three N atoms coordinated [Fig. 3(*b*)] is −94.5 kcal mol^{-1}. From such data one can see why highly polar hmpa ligands will likely exclude PF_6^- anions from Li^+ coordination spheres, especially so since it is feasible stereochemically to place four hmpa ligands around each Li^+, in a $Li(hmpa)_4^+$ cation or in a dinuclear species $[Li_2(hmpa)_5]^{2+}$, as found in **1**. In contrast, the optimised structure of Li^+·pmdeta shows clearly that it would not be possible to place even two (less polar) pmdeta ligands around a Li^+ cation; hence the appearance of Li–F contacts in **2**.

The monomeric complexes $LiPF_6$·hmpa and $LiPF_6$·pmdeta were also calculated. The lowest energy structure of the former [Fig. 3(*c*)] shows the PF_6^- anion η^3-bonded to Li^+ [Li–F distances, 1.983 Å (twice) and 1.938 Å] and the complexation energy of $LiPF_6$ by hmpa is −39.7 kcal mol^{-1}. For the latter [Fig. 3(*d*)], the asymmetry imposed by the pmdeta ligand (and seen in the structure of **2**) is reflected in two different Li–F bond lengths (1.917, 1.988 Å) and in three different Li–N bond lengths (2.142, 2.194, 2.251 Å); the complexation energy is −49.0 kcal mol^{-1}. Finally, we optimised the structures of some dimeric species. For $(LiPF_6)_2$ itself [Fig. 3(*e*)], each Li^+ has three Li–F contacts, two provided by one PF_6^- anion (Li–F 1.877 Å) and one by the other (1.663 Å). This basic structure is retained when each Li^+ is complexed by a single monodentate Lewis base, as in the structure found for $(LiPF_6·NH_3)_2$. However, bis(complexation), as in $(LiPF_6·2NH_3)_2$ [Fig. 3(*f*)], reproduces the key structural features found in **2**, each Li^+ centre now contacting two F atoms (Li–F, 1.972, 1.973 Å) provided by two PF_6^- anions.

Multinanometer long phenylacetylene-end-capped poly(triacetylene) (PTA) oligomers with dendritic side chains of generation one to three have been prepared; UV–VIS measurements indicate that there is no loss of π-electron conjugation along the PTA backbone in the higher generation compounds despite distortion from planarity due to the bulky dendritic wedges.

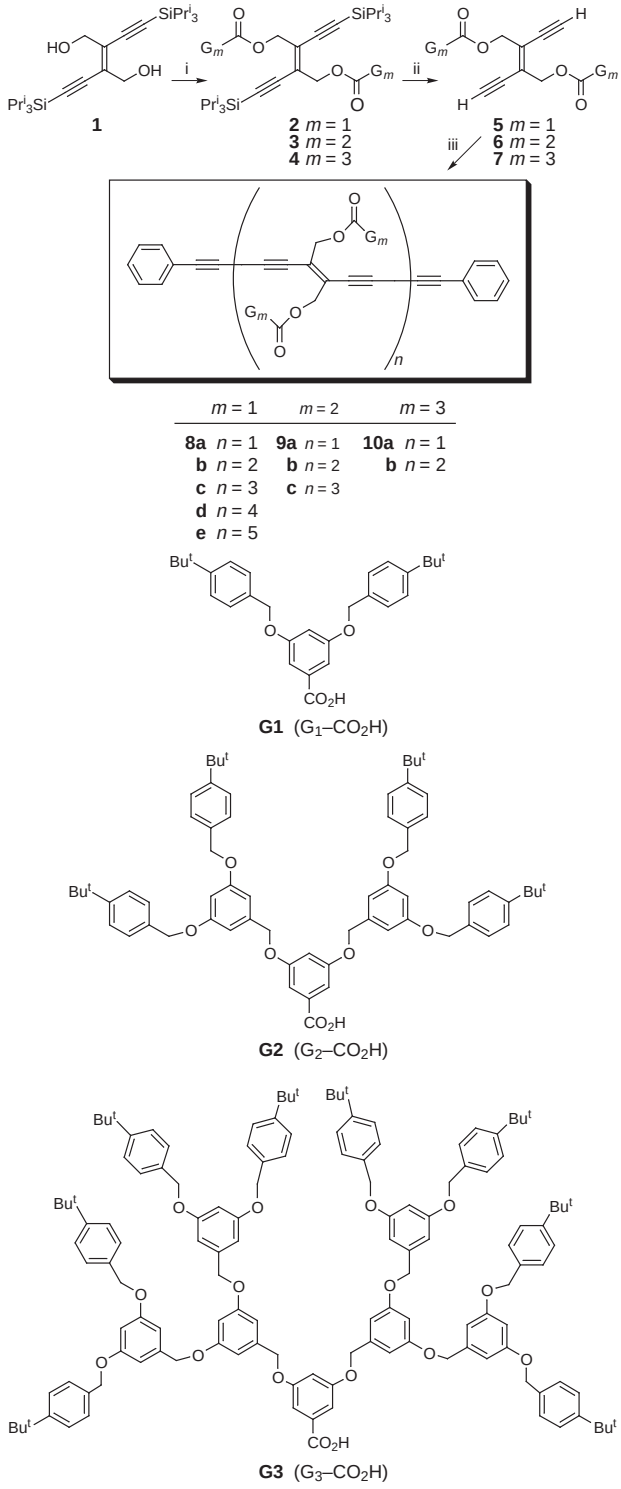
Rigid, linearly-conjugated rod-like oligomers and polymers with the poly(triacetylene) (PTA) backbone feature interesting electronic, nonlinear optical and mesomorphic properties.[1,2] We now describe the merger of dendrimer chemistry[3] with our ongoing development of functionalized PTAs to generate insulated molecular wires. Encapsulation of the linear π-conjugated backbone by laterally attached, sterically shielding dendritic wedges should enhance the processability and stability of PTA oligomers and polymers. At the same time, steric hindrance between adjacent dendritic wedges of higher generation could possibly cause nonplanarity and deconjugation of the backbone. Here, we report the synthesis of monodisperse multinanometer long dendritic PTA rods of first, second and third generation and show that π-electron conjugation in these tubular macromolecules is fully maintained at all generation levels. Previously, Schlüter and co-workers had described the preparation of cylindrical dendrimers with a poly(*p*-phenylene) backbone as the core.[4]

The convergent synthesis of the different dendritic rods is described in Scheme 1. Different generations (**G1**, **G2** and **G3**) of Fréchet-type dendrons[5] were attached to (*E*)-2,3-bis[(triisopropylsilyl)ethynyl]but-2-ene-1,4-diol **1**[1a] using the Mitsunobu reaction[6] to give the dendritic silyl-protected monomers **2**–**4**. The yield of the third generation compound **4** was very low (4%), possibly due to steric shielding of the carboxylic acid reaction centres by the bulky dendritic wedges in the molecule. After deprotection with TBAF in wet THF, the free *trans*-enediynes **5**–**7** were obtained. The dendritic wedges substantially stabilise the usually rather unstable free *trans*-enediynes, and compounds **5**–**7** can be stored in the air at ambient temperature for months without decomposition. Oxidative Hay coupling[7] of **5**–**7** in the presence of phenylacetylene as an end-capping reagent[1a] provided the oligomeric PTAs as solids. The first generation compound **5** afforded separable oligomers up to the pentamer (**8a**–**e**) which were isolated by size-exclusion chromatography (SEC), whereas, for steric reasons, the second generation derivative **6** only yielded isolable oligomers up to the trimer (**9a**–**c**).‡ Finally, due to severe steric overcrowding, conversion of the third generation enediyne **7** only gave end-capped monomer and dimer (**10a**,**b**) in pure form and sufficient yields.§

In the ^{1}H NMR spectra of the different generation oligomers, with averaged C_{2h}-symmetry, the number of *tert*-butyl resonances is equal to the number of monomeric sub-units. The ^{13}C NMR spectra did not display a significant difference in chemical shift between the clearly discernible acetylenic C-atom resonances in oligomers of same length but different dendritic generation. Force-field calculations of the third generation dimer **10b** showed clearly that the conformation of the PTA backbone, including the two end-capping phenyl groups, is not planar due to the steric hindrance of the bulky dendritic wedges. On the other hand, the first generation derivatives **8a**–**e**, similar to previous PTA oligomers,[1] should have a planar conjugated backbone. Such nonplanarity may be achieved by rotating around C(sp)–C(sp^2) and C(sp)–C(sp) single bonds in the backbone. This, in return, suggested that a decrease or even complete loss of the π-electron conjugation along the PTA backbone could occur in the higher generation compounds, which should be observable by means of spectroscopic measurements.[8]

In the electronic absorption spectra of all three oligomeric series ($CHCl_3$, Fig. 1), the longest-wavelength absorption maximum (λ_{max}) is bathochromically shifted with increasing rod length and evidently no saturation in either case was observed, confirming recent findings.[1b,2] A comparison of the spectra of dimers **8b**, **9b** and **10b** revealed that, independent of the dendritic generation number, the longer-wavelength absorptions, which originate from electronic transitions within the conjugated PTA backbone, appear at almost the same positions (around λ = 400 nm) with nearly identical fine structure and molar extinction coefficients [Fig. 1(*a*)]. Similarly, position, fine structure and molar extinction coefficients of the longer wavelength absorption bands in the spectra of trimers **8c** (first generation) and **9c** (second generation) are nearly identical [Fig. 1(*b*)]. A precise determination of λ_{max} required deconvolution of the UV–VIS spectra.¶ The obtained values for the dimers [Fig. 1(*a*)] showed a minimal bathochromic shift in changing from generation one to three: λ_{max} = 428.0 ± 0.2 (**8b**), 430.0 ± 0.3 (**9b**) and 431.1 ± 0.2 nm (**10b**). For all dendritic rods, the λ_{max} values were converted into energies (E_{max}/eV) which were then plotted against the reciprocal number of monomer units (1/*n*). These plots revealed for all three oligomeric series straight lines intersecting the ordinate at nearly identical E_{max} (2.57 ± 0.06 eV).[1b,2] All these data provide impressive support that π-electron delocalisation and effective conjugation length[1b] of the PTA backbone are not affected by distortions out of planarity due to steric compression of the bulky dendritic wedges at higher generations. Apparently, π-electron conjugation involving the acetylenic fragments in the PTA backbone is best described as being cylindrical rather than resulting from orbital overlap within a distinct plane and is therefore fully maintained upon rotation about C(sp)–C(sp^2) and C(sp)–C(sp) single bonds.[8–10]

The electrochemical properties of the dendritic rods **8a**–**e** and **9a**–**c** were studied by steady-state voltammetry and cyclic voltammetry in CH_2Cl_2 (+0.1 M Bu_4NPF_6).‖ All oligomers could not be oxidised in the accessible potential range but were reduced in several irreversible steps, with the electrons being transferred to the conjugated PTA backbone.[1a,b] The irreversibility increases with the dendritic generation due probably to steric hindrance.[11] As the oligomeric length increased, the first reduction step occurred at increasingly less negative potential. Plots of $E_{1/2}$ *vs.* 1/*n* (*n* = oligomeric length) gave a straight line in both series.



Scheme 1 *Reagents and conditions*: i, **G1**, **G2** or **G3**, *N*,*N*,*N*′,*N*′-tetramethylazodicarboxamide (TMAD), PBu_3, THF, 60 °C, 24 h, 81% (**2**), 61% (**3**), 4% (**4**); ii, TBAF, wet THF, 1 h, 99% (**5**), 99% (**6**), 99% (**7**); iii, **5**, **6** or **7**, CuCl, TMEDA, PhC≡CH, CH_2Cl_2, air, 25 °C, 2 h, 17% (**8a**, MW = 1193 D), 6% (**8b**, MW = 2185 D), 3% (**8c**, MW = 3176 D), 1% (**8d**, MW = 4167 D), 0.4% (**8e**, MW = 5159 D), or 9% (**9a**, MW = 2267 D), 6% (**9b**, MW = 4332 D), 2% (**9c**, MW = 6396 D), or 13% (**10a**, MW = 4414 D), 3% (**10b**, MW = 8626 D)

In the dendritic PTA rods described here, the insulating layer created by the dendritic wedges protects and stabilises the central conjugated backbone but does not alter its electronic characteristics. Efforts are now under way to prepare insulated molecular wires with the novel poly(pentaacetylene) backbone

‡ The dendritic rods extend in length from 19.4 (monomer) to 49.4 Å (pentamer).[1a]

§ The separation of the oligomers was achieved by preparative size-exclusion chromatography (SEC) on Bio-Beads S-X1 (Bio-Rad) with CH_2Cl_2 as eluent, and the purity of the fractions was checked by analytical SEC. All new compounds were fully characterised by ^{1}H and ^{13}C NMR, FT-IR, UV–VIS and elemental analyses (except **10b**) and MALDI-TOF-MS (matrix: 9-nitroanthracene), which depicted either the $[M + Na]^+$ or $[M + K]^+$ ions as base peaks.

¶ The UV–VIS spectra were deconvoluted using software programme PRO FIT, ver. 5.0.0 for Power Macintosh, Quantum Soft, Zürich, 1990–1996, with a self-written plug-in module.

Selective epoxidations with transition metal catalysts (V, Ti, Mo) and Bu^{t}OOH proceed with high conversions and high selectivity in dense phase carbon dioxide.

The selective catalytic oxidation of olefins constitutes one of the most fundamentally important classes of synthetically useful reactions and is typically carried out in aromatic or chlorinated hydrocarbon solvents.[1,2] We report here the first demonstration that dense phase carbon dioxide‡ is an effective solvent for the selective oxidation of activated alkenes using Bu^{t}OOH and a number of transition metal catalysts. High valent oxovanadium(V) tri(isopropoxide) [VO(OPr^i)$_3$] with Bu^{t}OOH catalyzes the epoxidation of a wide range of allylic and homoallylic alcohols with high selectivities and catalytic turnovers in CO_2. We have also investigated other known catalysts such as VO(acac)$_2$ and Mo(CO)$_6$ for oxidations in dense phase CO_2. In the presence of chiral ancillary tartrate ligands, titanium isopropoxide catalysts lead to epoxides with high enantioselectivity in this medium in what is believed to be the first example of stereoselective oxidation in a supercritical fluid. We have found that the VO(OPr^i)$_3$-catalyzed epoxidation of allylic and homoallylic alcohols proceeds three times faster in CO_2 than in hexane, a solvent to which CO_2 solubility and reactivity have been compared.[3]

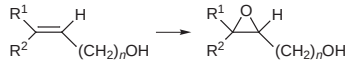
Several recent publications have demonstrated the potential of supercritical CO_2 as an alternative reaction medium for synthetic transformations.[4] Although there are several descriptions of mostly non-selective, low conversion, heterogeneous oxidations,[5] there have been no reports on selective homogeneous metal-catalyzed oxidations in dense phase carbon dioxide despite the fact that CO_2 is oxidatively stable and therefore should be an ideal solvent for this chemistry. Table 1 contains our results from a wide range of allylic and homoallylic alcohols which were oxidized with high conversions and selectivities to the corresponding epoxides using VO(OPr^i)$_3$ and Bu^{t}OOH in liquid CO_2 at 25 °C. We could find no inherent advantage of operating above the critical point of CO_2 since these reactions are often carried out at or below room temperature in conventional solvents. Therefore, the majority of our studies focused on liquid carbon dioxide. Under the anhydrous conditions of our experiments the reactions were visibly homogeneous and the product epoxides were found to be stable and could be isolated in high yields as their acetate derivatives (up to 91%).[6]

We have found that the reactivity of olefins with Bu^{t}OOH and VO(OPr^i)$_3$ as a catalyst parallels that reported in conventional solvents; activated olefins react faster than simple olefins[7] and allylic alcohols react faster than homoallylics.[8] At 25 °C most homoallylic and allylic alcohols reacted completely within 24 h with VO(OPr^i)$_3$, while no detectable reaction was observed for oct-1-ene and cyclohexene under the same reaction conditions. Allylic alcohols were found to react about four times faster than homoallylics.

We studied the kinetics of the VO(OPr^i)$_3$-catalyzed epoxidation of olefins to benchmark the reactivity in CO_2 relative to that in organic solvents since no rate data in any solvent have been reported for epoxidation reactions with this catalyst to date. The rate law was found to be first order in olefin, oxidant and catalyst with an inverse, non-integral dependence on Bu^{t}OH. Table 2 summarizes our kinetic data and shows the overall solvent effect on the epoxidation reaction is not great, as expected for such a non-polar (and non-ionic) reaction. At low constant catalyst concentrations, and during initial conditions (low [Bu^{t}OH]), we can consider the observed rate constant to be pseudo-second order. The rate constant, k', for (*Z*)-non-3-en-1-ol in CO_2 was determined to be 9 M^{-1} s^{-1} at 25 °C. Rates for epoxidations using VO(OPr^i)$_3$ are slower than those observed in CH_2Cl_2 by a third and are roughly equal to those observed in toluene and acetonitrile. The rate constant is about three times larger in CO_2 than in hexane, suggesting that aromatic solvents may be better models than alkanes for solubility in dense phase carbon dioxide.§ The rate of the epoxidation reaction using VO(OPr^i)$_3$ was found to be at least 20-fold slower when run with 90% Bu^{t}OOH in water rather than anhydrous Bu^{t}OOH–decane.¶ VO(OPr^i)$_3$ is a moisture sensitive catalyst and is subject to hydrolysis of the V–OR bonds to form stable, and apparently CO_2-insoluble, complexes in the presence of H_2O thus limiting its activity.

VO(acac)$_2$ is an effective epoxidation catalyst in organic solvents but we have been unable to obtain significant

Table 1 Epoxidation of allylic and homoallylic alcohols with VO(OPr^i)$_3$ in liquid CO_2[a]



R^1	R^2	*n*	Conversion %	Selectivity (%)

H	Me(CH$_2$)$_4$	2	> 99	99	—

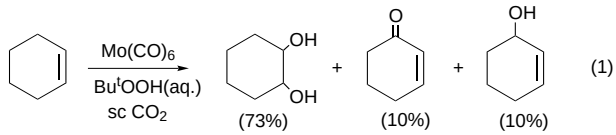
[a] 24 h reaction in liquid CO_2 (10.3 bar), 1.47 mM VO(OPr^i)$_3$ (3.5 mol%), 0.42 mM substrate, 100 mM ROOH, magnetically stirred and analyzed by GC.

Table 2 Rate of epoxidation of (*Z*)-non-3-en-1-ol with $VO(OPr^i)_3$ in serveral solvents[a]

Solvent	k'/M^{-1} s^{-1}	Relative rate
CH_2Cl_2	30	3.3
MeCN	18	2.0
PhMe	17	1.9
CO_2	9	1.0
CCl_4	5	0.6
n-C_6H_{14}	3	0.3

[a] $[VO(OPr^i)_3]$ = 1.47 mM (3.5 mol%), $[Bu^tOOH]$ = 100 mM, [olefin] = 42 mM, T = 24 °C, CO_2 reactions run at 29 bar. $k' = k_{\text{initial,pseudo second order}}$ $[VO(OPr^i)_3]$. Rates reported in this work are accurate to within 10%.

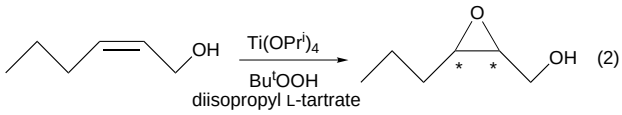
conversions in dense phase CO_2 under similar conditions, presumably due to the limited solubility of $VO(acac)_2$ in CO_2. We are in the process of examining other, more 'CO_2-philic', acetylacetonate-based ligands including highly fluorinated systems. We have also examined the Mo(CO)–Bu^tOOH oxidation system and found that unactivated alkenes such as cyclohexene can be oxidized to their corresponding diols in CO_2 at elevated temperatures [95 °C, eqn. (1)].[9] We were surprised



(1)

to find that oxidations utilizing aqueous Bu^tOOH (*e.g.* 90% Bu^tOOH–H_2O) gave significantly higher conversions than those run with dry Bu^tOOH (*e.g.* Bu^tOOH–decane) for the $Mo(CO)_6$ system suggesting an interesting effect of water.‖ High concentrations of Mo catalysts (200 mg, 12.5 mol%) were necessary for this reaction. The oxidation of cyclohexene resulted in a 73% selectivity to cyclohexene-1,2-diol at 74% conversion (presumably from the hydrolysis of cyclohexene oxide) during a 12 h reaction using aqueous Bu^tOOH with additional products derived from allylic oxidation [eqn. (1)]. Using anhydrous Bu^tOOH resulted in only 15% conversion of cyclohexene to oxidized products.

We have found that $Ti(OPr^i)_4$, in the presence of chiral tartrate ligands, results in enantioselective epoxidation catalysis in CO_2 [eqn. (2)]. Although the limited solubility of diethyl



(2)

tartrate in liquid CO_2 limits the activity of this system, the use of diisopropyl tartrate in its place resulted in high conversions to epoxide. Only 16% enantiomeric excess (ee) was obtained for the epoxidation of(*E*)-hex-2-en-1-ol with the titanium–diisopropyl tartrate (0.322 mmol $Ti(OPr^i)_4$, 0.389 mmol diisopropyl tartrate) catalyst at 25 °C (93% conversion). At 0 °C the enantioselectivity increased to 87% with the same substrate during a 72 h reaction (> 99% conversion). This unoptimized result approaches the 94% ee reported by Katsuki and Sharpless.[10]

It is clear that dense phase CO_2 is an effective solvent for these olefin epoxidation reactions, with rates and selectivities similar to those observed in organic solvents. Given its oxidative stability, CO_2 shows promise as an environmentally benign solvent alternative for chemical oxidation. We are currently exploring a number of other catalytic reactions, including heterogeneous catalytic oxidation, in this important medium.**

This work was supported as part of the Los Alamos Catalysis Initiative by The Department of Energy through a Laboratory Directed Research and Development (LDRD) grant. We would like to acknowledge many helpful discussions with Dr Tom Baker and Dr Steve Buelow.

‡ Dense phase fluids refer to systems that would be considered gases at their temperature of use, but are compressed to the point that they have liquid-like densities (ρ = 0.3 - 1.0 g cm^{-3}) including systems above their critical point (*e.g.* supercritical fluids).

§ The solubility and reactivity of dense phase CO_2 has been compared to hydrocarbons, aromatics and fluorocarbons.

¶ It is important to note that the use of decane to introduce the alkyl hydroperoxide to sc CO_2 reactions constituted less than 1% of the solvent volume (600 μl of 5.6 M Bu^tOOH in decane, or 265 μl decane in 33 ml of solvent).

‖ Preliminary results on the $Mo(CO)_6$-catalyzed oxidation of cyclic olefins with Bu^tOOH (aqueous and anhydrous in decane) yielded $k' = 5 \times 10^{-5}$ s^{-1} for anhydrous ROOH, $k' = 1 \times 10^{-3}$ s^{-1} for aqueous ROOH.

** The overall experimental setup and the general experimental procedures including sampling and product recovery have been described in detail elsewhere.[4,11] All high pressure reactions were carried out in custom-built stainless steel high pressure cells (33 ml volume) with sapphire view windows which enabled the direct visual observation of reactions. Proper safety precautions were taken for these high pressure reactions. An homogeneous solution was observable and complete conversion to the corresponding epoxide was detected, usually within 2 h. Yields were determined by gas chromatography of letdown solutions using authentic standards when available. GC–MS and ^{1}H NMR analysis were also used to confirm product identification.

Novel change in rate-determining step within an E1cB mechanism during aminolysis of a sulfamate ester in acetonitrile

William J. Spillane,*† Paul McGrath, Chris Brack and Keith Barry (in part)

Chemistry Department, National University of Ireland, Galway, Ireland

The observation of biphasic Brønsted plots (β_1 *ca.* 0.7 and β_2 *ca.* 0) in the aminolysis (alicyclic amines, pyridines) of 4-nitrophenyl *N*-benzylsulfamate 1a in MeCN is interpreted as being due to a mechanistic change from $(ElcB)_{irrev}$ to $(ElcB)_{rev}$; the change in rate-determining step occurs at approximately the pK_a of 1a and other more basic substrates give straight line plots; an entropy study supports the change from a bimolecular to a unimolecular mechanism.

Recently in our laboratory we have been studying the elimination-addition reactions of sulfamoyl chlorides with anilines[1] and of sulfamate esters with a series of amines[2] (pyridines, alicyclic amines and quinuclidines) in $CHCl_3$ and MeCN. The mechanism was seen as being E2 with ElcB-like character. UV kinetics fitted the rate law $k_{RR'NH}$[RR′NH][ester], and good straight line Brønsted type plots were obtained in this work. In particular, the aminolysis of the 4-nitrophenyl *N*-benzyl ester **1a** in $CHCl_3$ at 37 °C gave straight line Brønsted plots.[2] However, we have now found that this ester in MeCN at 37 °C gives curved plots with similar series of amines (Fig. 1). These plots are essentially biphasic with slopes β_1 *ca.* 0.7 at lower pK_as and β_2 *ca.* 0 at higher pK_as and are best interpreted in terms of a mechanistic change within the ElcB mechanism from $(ElcB)_{irrev}$ (amines of lower pK_a) to $(ElcB)_{rev}$ (amines of higher pK_a). The change from general to specific base catalysis expected for such a mechanistic change[3] is clearly evident in Fig. 1. The situation may be represented by Scheme 1. At lower amine pK_as the rate-determining step is the bimolecular formation of the conjugate base of the substrate **2** and the second step is relatively rapid departure of the leaving groups and formation of products *p*-nitrophenol and sulfamide ($k_2 >> k_{-1}$[RR′NH_2^+]). The reaction path from **2** to products may involve an *N*-sulfonylamine ($BnN{=}SO_2$)[1,2,4]

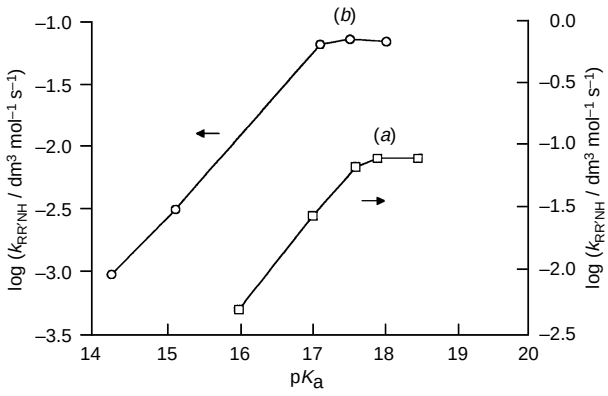

Fig. 1 Biphasic Brønsted plots for the aminolysis of **1a** in MeCN 37 °C: (*a*) alicyclic amines from left to right: morpholine, 1-formylpiperazine, 1-(2-hydroxyethyl)piperazine, 1-(2-aminoethyl)piperazine and piperazine; (*b*) pyridines from left to right: 2-aminopyridine, 2-amino-4-methylpyridine, 4-aminopyridine, DMAP and 4-pyrrolylpyridine

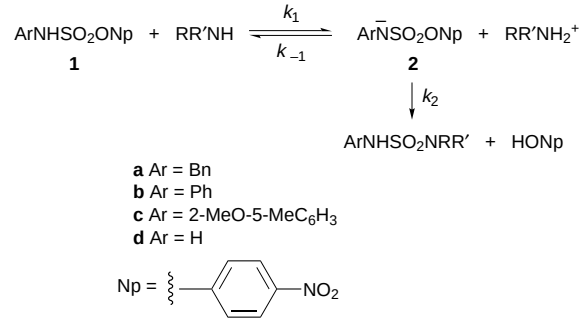
Further support for this mechanistic change comes from an activation study using morpholine, 1-(2-aminoethyl)piperazine and piperazine [Fig. 1(*a*)] and DMAP and 4-pyrrolylpyridine [Fig. 1(*b*)] with the ester **1a** in MeCN. The observed entropy changes ($\Delta S^{\pm}$, J K^{-1} mol^{-1}) are (temperature range in parenthesis): morpholine −262 (17–47 °C), 1-(2-aminoethyl)piperazine −59 (17–47 °C), piperazine −11 (17–47 °C), DMAP −124 (15–43 °C) and 4-pyrrolylpyridine −32 (15–46 °C). These entropy changes support the onset of a unimolecular $(ElcB)_{rev}$ mechanism as the basicity of the catalytic amine is increased, and with piperazine and 4-pyrrolylpyridine the reaction should proceed substantially *via* this mechanism. Typical values of $\Delta S^{\pm}$ for the $(ElcB)_{rev}$ mechanism lie[5] in the range of *ca.* +150 to − 40 J K^{-1} mol^{-1} and these authors also report much more negative entropies (−55 to −170 J K^{-1} mol^{-1}) for studies on related substrates undergoing $B_{AC}2$, S_N2 and E2 mechanisms. $\Delta S^{\pm}$ values of −163 to −130 J K^{-1} mol^{-1} have been reported for the $(ElcB)_{irrev}$ mechanism.[6]

When the substrate was **1b** using the same set of alicyclic amines in MeCN, surprisingly a straight line Brønsted plot was obtained (β = 0.19) [Fig. 2(*b*)]. Again with a slightly less basic ester **1c** no curvature was seen in the Brønsted plot (β = 0.35) using a set of pyridine bases [Fig. 2(*a*)]. The reason for this behaviour became apparent when we measured[7] and calculated[8] pK_as in MeCN for the esters **1**. The values obtained (calculated in parenthesis) were: **1a** 17.68 ± 0.5 (~ 16.5 ± 0.5),[9] **1b** 19.1 ± 0.1 (19.5 ± 0.5) and **1c** 18.56 ± 0.3 (~ 18.87 ± 0.5).[9] The ester **1a** showed curvature because the catalytic bases used are sufficiently strong to remove the substrate proton, the k_1 step becomes unimportant kinetically and k_2 dominates giving the observed $(ElcB)_{rev}$ mechanism. A referee has pointed out that the plots in Fig.1 are analogous to classical Eigen plots, and in keeping with this the changeover in rate-determining step occurs at about the pK_a of **1a**, i.e. ΔpK = 0; in the case of the other two esters studied the available amines are all less basic than the substrate, and the NH proton is not extensively removed and a change in rate determining step is therefore not observed with these esters.



Scheme 1

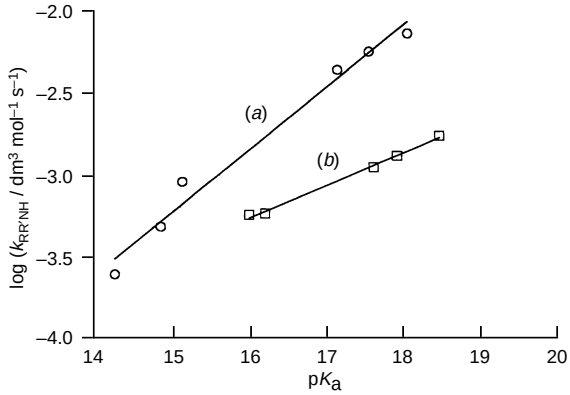


Fig. 2 Brønsted plots for the aminolysis of sulfamate esters in MeCN at 37 °C: (*a*) pyridines from left to right: 2-aminopyridine, 2,4,6-trimethylpyridine, 2-amino-4-methylpyridine, 4-aminopyridine, DMAP and 4-pyrrolylpyridine using **1c**; (*b*) alicyclic amines from left to right: morpholine, thiomorpholine, 1-(2-hydroxyethyl)piperazine, 1-(2-aminoethyl)piperazine and piperazine using **1b**

In $CHCl_3$ we have never observed curvature in Brønsted plots with **1a**, **1b** or with 4-nitrophenylsulfamate **1d** and various series of amines. This may be due to a more substantial difference in basicity between the substrates and the catalytic amines in this medium compared to MeCN. This view can be at least qualitatively supported by considering the Gibbs energy differences ($\Delta\Delta G$) for the ionization of the substrates and the conjugate bases $RR'NH_2^+$ in solvents of differing relative permittivity.[10]

Change in rate-determining step within an ElcB reaction path involving carbanions has been demonstrated by a number of groups.[11–15] However such a change involving nitrogen acids has not been clearly demonstrated previously; Caplow[16] has obtained a very similar plot (β_1 *ca.* 0.77 and β_2 *ca.* 0) to those in Fig.1 for the decomposition of carbamates in water in the presence of various amines, but has interpreted it differently. Hence the present work is the first clear-cut example of this ElcB mechanistic change not involving a carbon acid.

Facial selectivity in the cycloaddition of heterodienes to carbohydrate cyclic ketene acetals. A novel synthesis of disaccharide derivatives

Stephen C. Johnson, Curtis Crasto and Sidney M. Hecht*

Departments of Chemistry and Biology, University of Virginia, Charlottesville, Virginia 22901, USA

Carbohydrate ketene acetals derived from mannopyranose and glucopyranose are shown to serve as electron-rich dienophiles in facially selective, Lewis acid-catalyzed inverse electron demand hetero-Diels–Alder reactions.

The inverse electron demand hetero-Diels–Alder reaction of electron-rich dienophiles with electron-poor enones and enals has been established as a useful method for the stereospecific construction of 3,4-dihydro-2*H*-pyran analogues.[1,2] These intermediates have been transformed easily into synthetically useful carbohydrates, and their structural components have been found to be present in a host of natural products.[2–4]

We recently reported the synthesis of carbohydrate cyclic ketene acetals.[5] Herein, we describe studies that demonstrate the ability of this intrinsically asymmetric class of compounds to serve as electron-rich dienophiles in facially selective, Lewis acid-catalyzed inverse electron demand hetero-Diels–Alder reactions.

To establish the use of carbohydrate cyclic ketene acetals as dienophiles in hetero-Diels–Alder reactions, the mannopyranose (**1**) and glucopyranose (**2**) derivatives[5] were each treated with acrolein (1.2 equiv.) in CH_2Cl_2 at ambient temperature. No reaction occurred in the absence of a Lewis acid, even at 220 °C. However, after 19 h in the presence of Yb(fod)$_3$[6] (0.05 equiv.), the crude product derived from **1** was obtained as a *ca.* 5 : 1 mixture of diastereomers (**3a** and **3b**), as judged by integration of the vinylic proton resonances (Scheme 1). The cycloadduct **3a** was isolated after silica gel chromatography as a single regio- and stereo-isomer in *ca.* 80–85% yield.‡ Analogously, after 72 h the cycloadduct **4** was isolated as a single regio- and stereo-isomer (**4a** or **4b**), albeit in much lower yield (24%), from the glucopyranose derivative **2**. The specific orthoester isomer obtained must reflect both the intrinsic *endo : exo* Diels–Alder selectivity, with the obvious exception of products derived from acrolein, as well as the facial selectivity of addition to the asymmetric dienophile.[7]

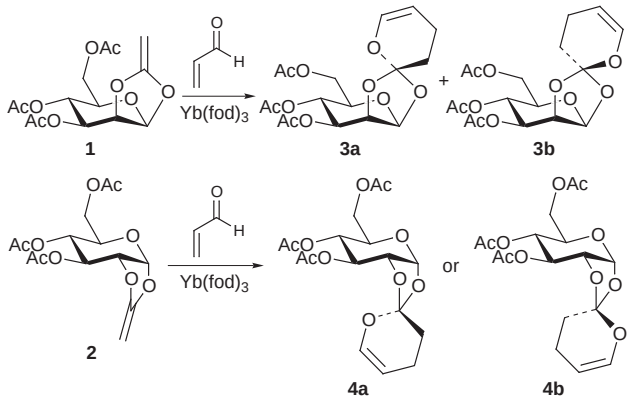
Extensive studies have been conducted to demonstrate the high degree of asymmetric induction in Diels–Alder reactions of 1-oxabuta-1,3-diene analogues with electron-rich dienophiles.[8,9] Boger and Robarge have reported on the pressure-promoted reaction of methyl (*E*)-4-phenyl-2-oxobut-3-enoate (**5a**, Table 1) with a wide range of electron-rich dienophiles to provide cycloadducts that exhibit *endo : exo* Diels–Alder selectivities of 4–9 : 1.[8] Similarly, Tietze has recently utilized several asymmetric 1-oxabuta-1,3-dienes derived from chiral oxazolidinones in which large *endo* Diels–Alder selectivities have been obtained.[9] *exo* Diels–Alder selectivities can be achieved by a judicious choice of Lewis acid catalyst.

In an attempt to provide insight into the stereoselectivity of [4+2] cycloadditions with carbohydrate cyclic ketene acetals, mannopyranose derivative **1** was treated with 1-oxabuta-1,3-diene analogues **5a**–**5d** in the presence of Yb(fod)$_3$ (Table 1).§ Achiral heterodienes **5a** and **5b** exhibited excellent reactivity with **1** in CH_2Cl_2 at ambient temperature, cleanly providing the [4 + 2] cycloadducts **6a**/**7a** and **6b**/**7b** in 97 and 80% yields, respectively.¶ Each analogue was isolated as an *ca.* 1 : 1 mixture of diastereomers; similar results were obtained with Eu(hfc)$_3$. Compounds **6a**/**7a** (as a 1.2 : 1 mixture; *cf.* Table 1) were converted to (*R*)-phenylsuccinic acid *via* a two step procedure to establish the (*S*)-phenyl configuration of the cycloadduct.‖ Therefore, **6a**/**7a**, being a diastereomeric mixture of cyclic *endo*- and *exo*-orthoesters, but having the phenyl substituents with the same absolute configuration, must be derived from a facially controlled orientation of the diene **5a**. Specifically, the cycloaddition of a **5a** with **1** proceeds *via* an *exo* Diels–Alder selective process with attack of the diene onto the back face of the dienophile and an *endo* Diels–Alder selective process with attack onto the front face (*cf.* Table 1).[13]

To further enhance the stereoselectivity of the cycloaddition, **1** was treated with **5c** and **5d** in the presence of Yb(fod)$_3$. The use of asymmetric dienes **5c** and **5d** did provide a more diastereoselective route to [4 + 2] cycloadducts (Table 1). The crude cycloadducts **6c**/**7c** were obtained in 81% yield as a 5.3 : 1 mixture of diastereomers. Likewise, cycloadducts **6d**/**7d** were obtained as a 32 : 1 mixture of diastereomers. Cycloadducts **6c**/**7c** and **6d**/**7d** were determined to be cyclic *endo*-orthoesters by NOESY experiments, thereby establishing the (*R*)-orientation of the spiro-linkage (*i.e.* the same as in **3a**). Presumably this reflects addition of the heterodienes to the ketene acetal from the more hindered face.

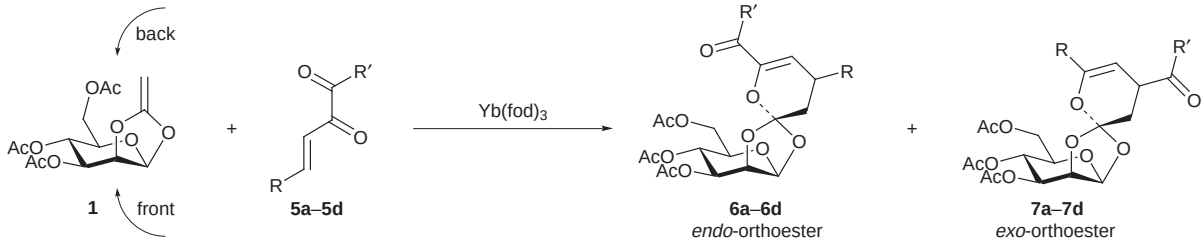
The ability of [4 + 2] cycloadducts derived from carbohydrate cyclic ketene acetals to provide uniquely substituted *O*-glycosides was assessed using cycloadducts **6a**/**7a** and **6d**/**7d**. Treatment with $BF_3{\cdot}OEt_2$ (1.0 equiv.) and Et_3SiH (1.0 equiv.) in dry benzene provided the corresponding β-D-mannopyranosides **9**/**10** and **11**, respectively. Compounds **9**/**10** derived from a 1 : 1 mixture of cyclic *endo*- and *exo*-orthoesters, were also obtained as a diastereomeric mixture of acetals in 54% yield. Compound **11** was obtained as a pure regio- and stereo-isomer in 40% yield; the absolute stereochemistry of the stereocenter produced in the Et_3SiH reduction was defined by the known[14] stereoselective hydride transfer.

The facially and *exo* selective hetero-Diels–Alder reaction described herein constitutes the novel use of a carbohydrate as a scaffold to direct the stereochemistry of formation of a second carbohydrate (precursor).



Scheme 1

Table 1 Results of Diels–Alder reactions



Series	R	R′	Solvent	*T*/°C	Diastereoselectivity[a]	Yield (%)[b]
a	Ph	OMe	CH_2Cl_2	25	1.2:1	97
b	OEt	OEt	CH_2Cl_2	25	1:1	80
c	Ph		Benzene	Reflux	5.3:1[c,d]	81
d	Ph		Benzene	Reflux	32:1[d]	50

[a] Determined by ^{1}H NMR spectroscopy by integration of the vinyl proton resonances. The absolute stereochemistry at the allylic carbon was established explicitly for **6a**/**7a** and **6c**/**7c**. [b] Isolated yields of purified cycloadduct after chromatography on SiO_2. [c] After extensive chromatography on SiO_2, the product was obtained as an almost pure compound, albeit in low yield (13%) from **1**. [d] The *endo*-orthoester is the major product.

‡ Cycloadducts **3a** and **4** were each isolated as oils and characterized by ^{1}H NMR spectroscopy. Each analogue exhibited resonances in the range δ 4.81–4.87 (m) and 6.16–6.19 (d, *J* 6). Additionally, the regioisomers indicated in the scheme were identified by analysis of the allylic resonances (δ 2.25–2.30).

§ The β,γ-unsaturated α-keto esters **5a** (M. Reimer, *J. Am. Chem. Soc.*, 1924, 46, 783) and **5b** (W. Trowitzsch, *Z. Naturforsch., Teil B*, 1977, **32**, 1068) were prepared as described. Heterodiene **5c** was prepared by acylation of lithiated 4-*tert*-butyloxazolidin-2-one[10] with the appropriate α-keto acid chloride by a standard procedure in 43% yield. Analogously, heterodiene **5d** was prepared from lithiated (1*S*)-(−)-camphor-2,10-sultam in 81% yield.[11]

¶ Compounds **6a**/**7a**–**6d**/**7d** were characterized by ^{1}H NMR spectroscopy; especially diagnostic was the resonance in the range δ 5.88–6.24.

‖ Compounds **6a**/**7a** were treated with $BF_3{\cdot}OEt_2$ (2.0 equiv.) and Et_3SiH (1.0 equiv.) in benzene[12] to provide the lactone **8** in 61% yield. Optical rotation for **8**: $[\alpha]_D^{22}$ −47.2 (*c* 1.0, CH_2Cl_2). The enantiopurity of **8** was established by ^{1}H NMR studies conducted with Eu(hfc)$_3$; the enantiopurity exceeded 95%. Ozonolysis of **8**, followed by acid hydrolysis, provided (*R*)-phenylsuccinic acid which was confirmed by comparison with a commercial sample.

Libraries of hydrogen-bonded assemblies formed by mixing the individual components under thermodynamically controlled conditions are characterized by ^{1}H NMR spectroscopy and Ag$^+$ assisted MALDI-TOF mass spectrometry.

The combinatorial strategy to create structural diversity has revolutionized the field of chemistry over the past decade.[1] Instead of synthesizing a single molecule, combinatorial chemistry allows the simultaneous synthesis of large libraries of structurally well-defined molecules.[2] For this purpose combinatorial methodologies have been developed for a variety of synthetic transformations (*e.g.* peptide,[3] oligonucleotide,[4] heterocycle[5] and carbohydrate[6] synthesis) either on solid supports[7,8] or in solution.[9,10] Recently, libraries of synthetic receptor molecules, *e.g.* for sequence-selective peptide binding, were reported using a similar combinatorial strategy.[11,12]

Libraries of organic molecules are prepared by statistical combination of reactive molecular fragments *via* the irreversible formation of covalent bonds. In principle, one could also use non-covalent interactions, like hydrogen bonding, to build in a reversible way libraries of assemblies of small complementary molecules. Non-covalent synthesis is a valuable alternative to the classical covalent synthesis of complex supramolecular systems.[13] Recently, Lehn,[14] Sanders[15] and others[16] reported libraries that were obtained *via* reversible formation of covalent (imines, esters) or coordinative (Zn- or Fe-complexes) bonds under conditions of thermodynamic equilibrium.

Here we describe the first example of a non-covalent synthesis of combinatorial libraries of hydrogen bonded assemblies under thermodynamically controlled conditions. *N* different assemblies [**1x**]$_3$ (**x** = **a,b,c**, . . .,*N*; Fig. 1) were mixed in solution under conditions that allow the reversible exchange of the components **1x** to give *M* heteromeric assemblies in addition to the *N* homomeric assemblies (see Fig. 2). The total number of assemblies *P* (*i.e.* $N + M$) present in such a library rapidly increases with increasing *N* [eqn. (1)].

$$P = N + N(N-1) + [N(N-1)(N-2)]/6 \qquad (1)$$

For the smallest possible library ($N = 2$, $P = 4$) we have studied the combination of calix[4]arene bismelamines **1a**,**b** with 5,5-diethyl barbiturate. The individual homomeric assemblies [**1a**]$_3$ and [**1b**]$_3$ form spontaneously in apolar solvents by mixing 3 equiv. of **1a** (or **1b**) with 6 equiv. of 5,5-diethyl barbiturate and are stable down to submillimolar concentrations.[17] The assembly process is driven by the formation of 36 cooperative hydrogen bonds, resulting in significant downfield shifts for the various NH protons [Fig. 3(*a*) and (*b*)].

Mixing of 5 mM solutions of [**1a**]$_3$ and [**1b**]$_3$ at 0 °C (ratio 2 : 1) in [$^2H_8$]toluene gave only a mixture of the two separate homomeric assemblies [Fig. 3(*c*)]. Exchange of the components **1a** and **1b** between the two assemblies is extremely slow at this temperature and, as a consequence, formation of the heteromeric assemblies [**1a**]$_2$[**1b**] and [**1a**][**1b**]$_2$ is not observed.‡ Only at ⩾15 °C do the heteromeric assemblies start to form slowly. This reflects the relatively high kinetic stability of the separate assemblies in this apolar solvent. After 2.5 h at 25 °C the system has reached the thermodynamic equilibrium [Fig. 3(*d*)]. In the more polar solvent $CDCl_3$ the exchange of components **1a** and **1b** is much faster. The [**1a**]$_3$ and [**1b**]$_3$ mixture equilibrates within seconds at 25 °C. Only below −50 °C are the homomeric assemblies [**1a**]$_3$ and [**1b**]$_3$ kinetically inert.

The low-field region of the ^{1}H NMR spectrum is particularly diagnostic as it exclusively displays the hydrogen bonded NH_{barb} protons (δ 13–15) and NH_{arom} protons (δ 8–9). The [$^2H_8$]toluene ^{1}H NMR spectrum of the four component library shows 12 of the 16 NH_{barb} proton signals as separate peaks and 7 of the 8 NH_{arom} proton signals [Fig. 3(*d*)]. The four different assemblies were identified by means of 2D NOESY, ROESY, COSY and TOCSY analysis.§ The relative concentration of the four different assemblies in the mixture was subsequently determined as 1.0 ([**1a**]$_3$) : 3.0 ([**1a**]$_2$[**1b**]) : 3.0 ([**1a**][**1b**]$_2$) : 1.0 ([**1b**]$_3$) (±10%), in agreement with the statistical distribution of

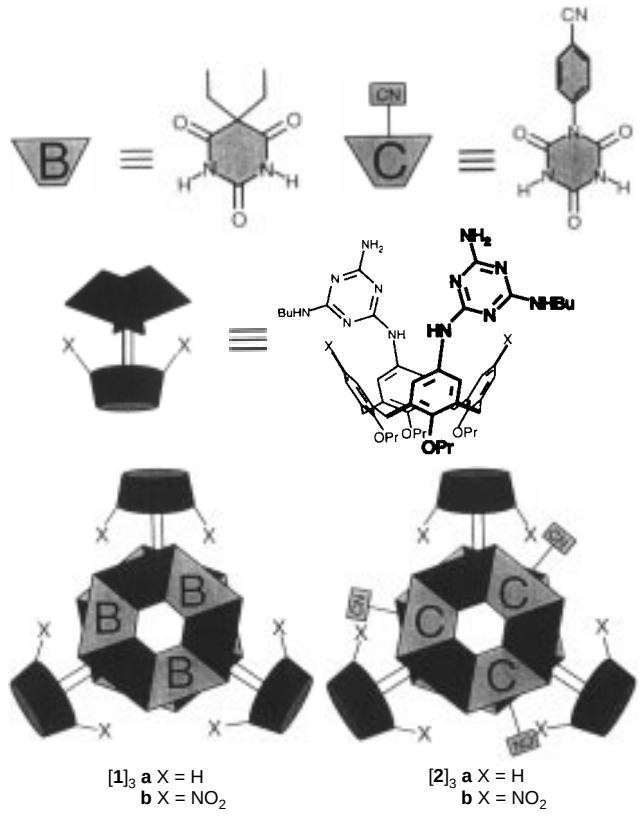

Fig. 1 Schematic representation of hydrogen bonded assemblies [**1**]$_3$ and [**2**]$_3$

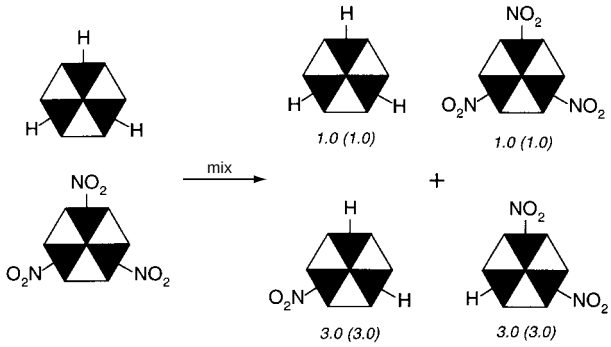

Fig. 2 Non-covalent synthesis of library of assemblies [**1a**]$_3$, [**1a**]$_2$[**1b**], [**1a**][**1b**]$_2$, and [**1b**]$_3$; experimentally determined ratio is given with statistical ratio in parentheses

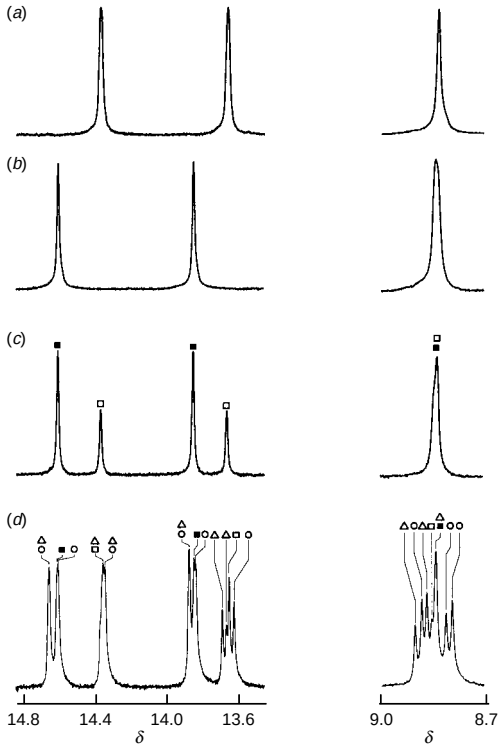

Fig. 3 Low field regions of the ^{1}H NMR spectra of (*a*) homomeric assembly [**1a**]$_3$; (*b*) homomeric assembly [**1b**]$_3$; (*c*) 2 : 1 mixture of homomeric assemblies [**1a**]$_3$ (■) and [**1b**]$_3$ (□) at 0 °C; (*d*) library of assemblies [**1a**]$_3$ (■), [**1a**]$_2$[**1b**] (○), [**1a**][**1b**]$_2$ (△), [**1b**]$_3$ (□) 2.5 h after mixing homomeric assemblies [**1a**]$_3$ and [**1b**]$_3$ at 25 °C (ratio 6 : 4). All spectra were recorded at 400 MHz in [^{2}H$_8$]toluene.

components **1a** and **1b** over the various assemblies. Unfortunately, the $CDCl_3$ spectrum displayed insufficient resolution to determine the relative composition of the mixture.

Characterization of the library was also performed by mass spectrometry using Ag^+ assisted MALDI-TOF MS technique.[18] For this purpose we studied the assemblies [**2a**]$_3$ and [**2b**]$_3$, which contain cyano substituents to coordinate to the Ag^+ labels (Fig. 1). Individual solutions of the assemblies, pretreated with 1.5–2.0 equiv. of CF_3CO_2Ag in $CHCl_3$ for at least 24 h, give intense signals in the MALDI-TOF spectra at *m/z* 4348.1 (calc. for $C_{222}H_{252}N_{60}O_{30}{\cdot}^{107}Ag^+$: 4347.9) and 4620.4 (calc. for $C_{222}H_{246}N_{66}O_{42}{\cdot}^{107}Ag^+$: 4618.8), respectively, for the monovalent Ag^+ complexes. As expected the MALDI-TOF spectrum of a mixture of the CF_3CO_2Ag pretreated $CHCl_3$ solutions (5 mM each) of assemblies [**2a**]$_3$ and [**2b**]$_3$ clearly shows two additional signals for both the monovalent Ag^+ complexes of the heteromeric assemblies [**2a**]$_2$[**2b**] and [**2a**][**2b**]$_2$ at *m/z* 4438.3 (calc. for $C_{222}H_{250}N_{62}O_{34}{\cdot}^{107}Ag^+$: 4437.9) and 4527.7 (calc. for $C_{222}H_{248}N_{64}O_{38}{\cdot}^{107}Ag^+$: 4528.9), respectively.¶ Especially for the characterization of libraries with more components, mass spectrometry will be an important tool.

The reversible library concept presented here can in principle be extended to libraries of any desirable size. For example, by mixing 10 different assemblies [**1x**]$_3$ a library of 220 different hydrogen-bonded assemblies is created. Subsequently, the information in the different assemblies can be stored by a covalent post-modification step, *e.g. via* a metathesis reaction.[19] Covalent post-modification of hydrogen-bonded assemblies is currently under active investigation in our group.

‡ Two different types of kinetic processes characterize the hydrogen bonded assemblies, *i.e.* (*i*) exchange of 5,5-diethyl barbiturate and (*ii*) exchange of components **1**. The rate constant for the former process is in the order of 0.5–3.0 s^{-1} in [^{2}H$_8$]toluene at 303 K as determined by 2D EXSY NMR. The latter process is much slower and can only be measured at the 'laboratory timescale'.

§ The chemical shifts of the NH protons are strongly influenced ($\Delta\delta_{max}$ = 0.15) by the starting concentrations of **1a** and **1b**.

¶ The peak intensity of assembly [**2b**]$_3$ in the MALDI-TOF spectrum of the mixture is significantly lower than that for assembly [**2a**]$_3$ most probably due to the strongly decreased affinity of this assembly for Ag^+ ions as a result of the electron-withdrawing effect of the six NO_2 groups. Evidence comes from the low mass region of the spectrum, which exclusively displays a signal for the [**2a**]$\cdot^{107}Ag^+$ complex and not the [**2b**]$\cdot^{107}Ag^+$ complex even when [**2b**] is present in four-fold excess.

Spectroscopic identification and reactivity of $[Ir(CO)_3I_2Me]$, a key reactive intermediate in iridium catalysed methanol carbonylation

Talit Ghaffar,[a] Harry Adams,[a] Peter M. Maitlis,[a] Glenn J. Sunley,[b] Michael J. Baker[b] and Anthony Haynes*[a]

[a] *Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*
[b] *BP Chemicals Ltd, Hull Research and Technology Centre, Saltend, Hull, UK HU12 8DS*

The dimer $[Ir(CO)_2I(\mu\text{-}I)Me]_2$ 2 reacts with CO to give the tricarbonyl $[Ir(CO)_3I_2Me]$ 3 identified by high pressure IR and NMR spectroscopy and isotopic labelling; kinetic data for the migratory CO insertion reaction of 3 support its role as a key intermediate in iridium catalysed methanol carbonylation.

A new homogeneous catalytic process for the carbonylation of methanol to acetic acid has recently been commercialised by BP Chemicals.[1,2] The *Cativa* process is based on a promoted iridium/iodide catalyst system, and shows enhancements in rate, selectivity and stability compared with the established rhodium-based technology. The catalytic cycles for the two metals are similar, but show some important differences.[3–6] Forster's original kinetic and spectroscopic studies of the iridium system led to the proposal of catalytic cycles involving both anionic and neutral complexes. At moderate iodide concentrations, the resting state of the catalyst is the anionic methyl complex, $[Ir(CO)_2I_3Me]^-$ **1** and the rate determining step is thought to be carbonylation of this species [eqn. (1)]

$$\underset{\mathbf{1}}{[Ir(CO)_2I_3Me]^-} + CO \rightarrow [Ir(CO)_2I_3(COMe)]^- \qquad (1)$$

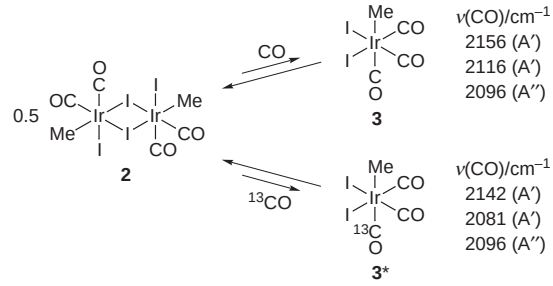
Both the catalytic reaction and the carbonylation of **1** were found to be inhibited at high $[I^-]$, suggesting a mechanism involving neutral intermediates formed by iodide dissociation from **1**.[6] We recently reported that the carbonylation of **1** is promoted substantially by protic solvents which can aid the dissociation of an iodide ligand.[7] Here, we report the synthesis and characterisation of $[Ir(CO)_2I(\mu\text{-}I)Me]_2$ and its reaction with carbon monoxide to give $[Ir(CO)_3I_2Me]$. This tricarbonyl species, a key intermediate in the proposed carbonylation mechanism, was never detected in Forster's original studies. Its observation has now allowed us to compare the rate of migratory CO insertion in neutral and anionic species.

In our initial attempts to synthesise and isolate a neutral iridium methyl complex we used silver salts (*e.g.* $AgBF_4$) to abstract iodide from the anionic precursor, **1**. Although IR spectroscopy indicated the formation of a product with ν(CO) bands (2119 and 2074 cm^{-1}) similar to those reported by Forster for $[Ir(CO)_2I_2Me]_n$, we were not able to isolate a pure product from these reactions. Treatment of **1** with indium triiodide in CH_2Cl_2 gave a species with identical IR absorptions to those found in the reactions with silver salts. In this case the product was isolated in good yield by extraction into hot cyclohexane and characterised as an iodide-bridged dimer, $[Ir(CO)_2I(\mu\text{-}I)Me]_2$ **2** [eqn. (2)], by spectroscopy‡ and X-ray crystallography.§ Addition of 2 equiv. of I^- to **2** quickly regenerates the anion, **1**, indicating that the iodide bridges are broken quite easily.

$$\underset{\mathbf{2}}{NBu_4[Ir(CO)_2I_3Me]} + InI_3 \rightarrow 0.5\,[Ir(CO)_2I_2Me]_2 + NBu_4[InI_4] \qquad (2)$$

Isolation of **2** has allowed us to investigate its reaction with CO. Brief bubbling of CO through a solution of **2** in CH_2Cl_2 resulted in the formation of small amounts of a species, **3**, with ν(CO) bands at 2156 and 2096 cm^{-1}. A third absorption, at 2116 cm^{-1} of similar intensity to the other two, was revealed by computer subtraction of the bands of unreacted **2**. The number and relative intensities of these bands are consistent with a *fac*-tricarbonyl complex [symmetry C_s, ν(CO) modes 2A′ + A″].[9] Under an inert atmosphere, **3** was found to revert to **2** over several minutes.

The reaction stereochemistry was probed by using isotopic labelling. The IR spectrum of the product obtained from the reaction of **2** with ^{13}CO (1 atm) in CH_2Cl_2 displayed three ν(CO) bands, one of which (2096 cm^{-1}) was at identical frequency to a band of unlabelled **3**, whereas the other two absorptions (2142 and 2081 cm^{-1}) were shifted to low frequency. This behaviour is exactly as expected if the incoming ^{13}CO ligand coordinates *trans* to the methyl group to give **3*** (Scheme 1), which retains C_s symmetry. The two A′ ν(CO) modes of **3*** involve vibration of all three carbonyl ligands, explaining the observed shift of two of the ν(CO) bands. The A″ mode involves only the two equivalent carbonyls, and is unaffected by labelling of the CO *trans* to methyl. All the observed ν(CO) frequencies for **3** and **3*** can be modelled accurately by a CO factored force field.¶ When the ^{13}CO atmosphere was removed, **3*** was found to revert cleanly to **2**, with no detectable retention of isotopic label. The reversible reaction of **2** with CO is therefore stereospecific, with the ligand entering and leaving from the site *trans* to methyl. The C–O stretching force constant for the carbonyl ligand *trans* to methyl is calculated to be *ca.* 30 N m^{-1} larger than that for the two carbonyls *trans* to iodides. The unique carbonyl therefore experiences less π back donation from the iridium centre, consistent with the higher lability at this site.



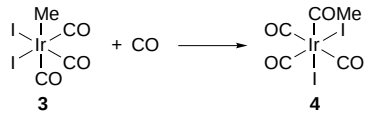
Scheme 1

Less than 10% conversion of **2** into **3** was achieved using CO at atmospheric pressure. Larger quantities of **3** were observed using a high pressure infrared cell to monitor the reaction *in situ*.[5] At 400 psi, essentially complete conversion of **2** into **3** was achieved, using CH_2Cl_2 or chlorobenzene as solvent. By contrast, in acetonitrile formation of **3** was suppressed even at high CO pressures, presumably due to cleavage of the dimer and occupation of the vacant site by a solvent molecule. This was confirmed by the observation of ν(CN) for $[Ir(CO)_2(NC\text{-}Me)I_2Me]$ at 2341 cm^{-1} and osmometry measurements (observed molecular weight 538) for solutions of **2** in MeCN.

Evidence for **3** was also obtained by high pressure NMR spectroscopy using a sample of **2** isotopically enriched with ^{13}C

in both methyl (> 99%) and carbonyl (70–80%) positions. When a solution of this sample in CD_2Cl_2 was placed under 415 psi ^{13}CO (> 99% enriched), new doublets were observed in the ^{13}C NMR spectrum at δ −21.7 and 148.7 ($^2J_{CC}$ 27 Hz) which are assigned to mutually *trans* methyl and carbonyl ligands in **3**. The carbonyls *trans* to iodide gave a singlet at δ 146.1 with no coupling to the *cis* ligands resolved. The methyl group of **3** was also detected by ^1H NMR spectroscopy at δ 2.14 (d, J_{CH} 139 Hz).

It has been proposed previously by Forster[6] and ourselves[7] that **3** is a reactive intermediate in the carbonylation of **1**, and that the tricarbonyl is activated towards migratory CO insertion compared with the anionic precursor. We have therefore studied the reaction of **3** with CO to investigate the validity of this proposal. Below 40 °C, complex **3** was found to be stable indefinitely in chlorobenzene under 400 psi CO. Above this temperature, a reaction was observed in which the ν(CO) bands of **3** were replaced by new absorptions at 2176w, 2115s and 1708m cm^{-1}. These bands correspond well with those assigned by Forster[6] to a neutral acetyl complex, $[Ir(CO)_3I_2(COMe)]$, the relative intensities suggesting a *mer*-tricarbonyl configuration, **4** (Scheme 2). An iridium acetyl species was also observed in the high-pressure NMR experiment after heating to 70 °C [^{13}C, δ 52.4 (CH_3CO), 186.4 (CH_3CO), $^1J_{CC}$ 35 Hz; ^1H, δ 3.04, $^1J_{CH}$ 131, $^2J_{CH}$ 5.5 Hz].



3 **4**

Scheme 2

Pseudo-first order rate constants, k_{obs}, for this reaction were obtained by monitoring the exponential decay of the high frequency ν(CO) band of **3** at 2156 cm^{-1}. Values of k_{obs} measured in chlorobenzene over the temperature range 44–85 °C are shown in Table 1. An Eyring plot of these data yields activation parameters $\Delta H^{\ddagger}$ 89±3 kJ mol^{-1} and $\Delta S^{\ddagger}$ −36 ±8 J mol^{-1} K^{-1}. Carbonylation of complex **3** is more than 800 times faster than for the anion, **1** at 85 °C in chlorobenzene,[7] representing a lowering of the observed $\Delta G^{\ddagger}$ by 20 kJ mol^{-1} on replacing an iodide ligand by CO. Extrapolation to higher temperatures reduces the difference in rates, but even at 180 °C, the neutral complex is predicted to react *ca*. 9 times faster than the anion. These new kinetic data validate the proposal that migratory insertion occurs in a neutral complex after dissociation of iodide from **1**. Addition of small amounts of methanol was found to accelerate the carbonylation of **3** (see Table 1) but not to the dramatic extent found previously for **1**.[7] Activation parameters calculated for the reaction in 1% methanol–chlorobenzene are $\Delta H^{\ddagger}$ 73±2 kJ mol^{-1} and $\Delta S^{\ddagger}$ −79±6 J mol^{-1} K^{-1}.

An explanation for the acceleration of migratory insertion in **3** relative to **1** may reside in the increased competition for π-backbonding in the tricarbonyl complex, **3**. Theoretical calculations on similar systems have suggested that increasing the number of π acceptor ligands lowers the energy of the LUMO (an out of phase combination of π^*_{CO} with d_π) and facilitates methyl migration.[10] Acceleration of migratory CO insertion by coordination of a π acceptor ligand has also been reported for $[Ir(CO)(PPh_3)_2Cl(Me)]^+$.[11]

Table 1 First order rate constants for the carbonylation of **3** in chlorobenzene and in chlorobenzene containing 1% (v/v) methanol (p_{CO} = 400 psi).

T/ °C	10^4 k_{obs}/s^{-1} (PhCl)	*T*/ °C	10^4 k_{obs}/s^{-1} (PhCl–1% MeOH)
44	1.64	44	5.10
		47	6.75
52	3.73	52	10.6
59	9.47	59	17.6
67	19.7	68	39.5
76	41.1		
85	87.6		

To summarise we have confirmed Forster's original suggestion that neutral intermediates play a key role in the migratory insertion step for the iridium catalysed carbonylation of methanol. We have obtained spectroscopic evidence for the previously undetected species, $[Ir(CO)_3I_2Me]$ **3** which undergoes CO insertion at a rate substantially faster than its anionic precursor, **1**.

We thank BP Chemicals, The Royal Society, and the University of Sheffield for supporting this research. We thank Cambridge Isotope Laboratories for an award of ^{13}C labelled carbon monoxide, Dr Mike Taylor (BP, Sunbury, UK) for carrying out high pressure NMR experiments and Dr George Morris for helpful discussions.

Dehydrogenation of ethane over gallium oxide in the presence of carbon dioxide

Kiyoharu Nakagawa,[a,b] Masato Okamura,[a] Naoki Ikenaga,[a] Toshimitsu Suzuki*[a,b]† and Tetsuhiko Kobayashi[c]

Gallium oxide is found to be an effective catalyst for the dehydrogenation of ethane to ethene in the presence of carbon dioxide at 650 °C, giving 18.6% ethene yield with a selectivity of 94.5%.

Ethene is predominantly produced by steam cracking of naphtha, ethane or liquid petroleum gas at high temperatures at short residence time.

In order to reduce energy consumption of ethene production, oxidative dehydrogenation of ethane is proposed [eqn. (1)].

$$C_2H_6 + 1/2O_2 \rightarrow C_2H_4 + H_2O \quad (1)$$

The reaction becomes exothermic and thermodynamically could be possible at relatively low temperatures. However, it is necessary to remove heat from the reaction and to avoid over oxidation to CO_2 to give high selectivity towards ethene. Recently, a great variety of catalysts have been developed and tested for this reaction.[1–3] In the oxidative dehydrogenation of propane, Burch and Crabb[4] pointed out that thermal non-catalytic oxidative cracking of propane proceeded to give propene in the same yield as compared to catalyzed runs which were operated about 50 °C lower than that of non-catalyzed runs. This suggests that catalyzed oxidative dehydrogenation of lower alkanes is not highly superior to thermal oxidative pyrolysis.

Recently, several attempts have been made to use carbon dioxide as an oxidant for coupling of methane,[5] dehydrogenation of ethylbenzene[6] or propane.[7] However, the role of CO_2 in these reactions is still not clear. In addition, the effects of CO_2 on the conversion and yield of the product are not significant.

Here, we study the dehydrogenation of ethane to ethene over several metal oxide catalysts, and we have found that CO_2 markedly promoted dehydrogenation of ethane over Ga_2O_3 catalyst.

The catalysts used were commercially available MgO, Al_2O_3, SiO_2, CaO, TiO_2, V_2O_5, Cr_2O_3, Mn_3O_4, Fe_3O_4, ZnO, Ga_2O_3, Y_2O_3, ZrO_2, Nb_2O_5, MoO_3, In_2O_3, SnO_2, La_2O_3, CeO_2, Ta_2O_5 and Tl_2O_3. The reaction was carried out with a fixed-bed flow type quartz reactor (i.d. 10 × 350 mm) at atmospheric pressure. Using 200 mg of a catalyst, 5 ml min^{-1} of C_2H_6 and 25 ml min^{-1} of CO_2 were introduced. The runs were conducted for 30 min and products were analyzed by gas chromatography.

Fig. 1 shows ethene yields on the various metal oxide catalysts. Thermal dehydrogenation occurred to give only 2.3% of ethene yield. Equilibrium conversion of ethane to ethene is *ca.* 50% at 650 °C at a C_2H_6–Ar (or CO_2) ratio of 1 : 5. MgO, CaO, SiO_2, Ta_2O_5, Al_2O_3, SnO_2, MoO_3, and Tl_2O_3 did not show any catalytic activity while CeO_2, Nb_2O_5, Fe_3O_4, and ZrO_2 exhibited only slight catalytic activity. The order of the activity of oxides at the reaction temperature of 650 °C was as follows: Ga_2O_3 > Cr_2O_3 > V_2O_5 > TiO_2 > Mn_3O_4 > In_2O_3 > ZnO > La_2O_3. The C_2H_4 selectivities in all the metal oxide catalysts were > 85% in the dehydrogenation of ethane in the presence of CO_2. As expected, Cr_2O_3 and V_2O_5 exhibited high activities. These catalysts are known to be active catalysts for dehydrogenation of alkanes. Ga_2O_3 afforded the highest yield of ethene

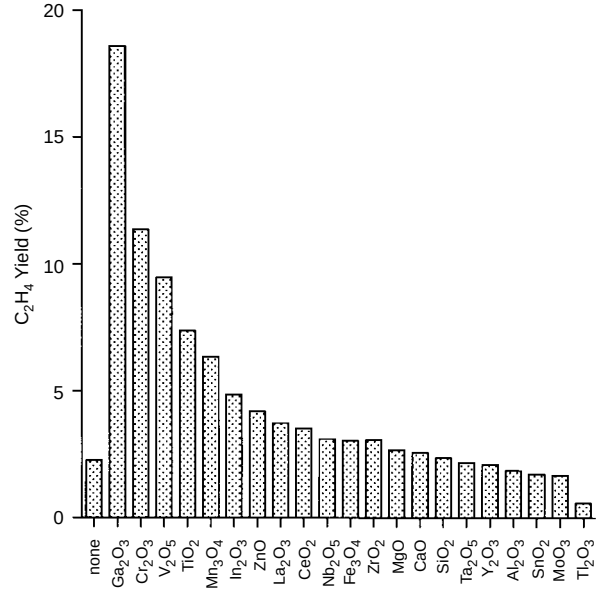

Fig. 1 Dehydrogenation of C_2H_6 in the presence of CO_2. Catalyst 200 mg; temperature: 650 °C; C_2H_6 : CO_2 = 5 : 25 ml min^{-1}; SV = 9000 h^{-1} ml (g cat)$^{-1}$.

(18.6%) amongst the various metal oxide catalysts. However, little work has dealt with Ga_2O_3 catalyst in the dehydrogenation of propane.[8]

Table 1 lists ethene yields on Ga_2O_3, Cr_2O_3, and V_2O_5 catalysts in the presence and absence of CO_2. The activity of the Ga_2O_3 catalyst in the presence of CO_2 was twice that in the absence of CO_2. Dehydrogenation of C_2H_6 in the presence of CO_2 over Ga_2O_3 catalyst produced mainly C_2H_4, CO, H_2 and H_2O. The yield of ethene with the Cr_2O_3 catalyst in the presence of CO_2 was slightly higher as compared to the run in Ar. The promoting effect of CO_2 in the dehydrogenation of C_3H_8 on Cr_2O_3/SiO_2 has been reported,[5] but the increase in the propene yield was only 2.6% at 550 °C. On the other hand, the effect of

Table 1 Dehydrogenation of ethane in the presence of carbon dioxide[a]

Catalyst	Surface area/ m^2 g^{-1}	Conv. (%) C_2H_6	Yield (%) C_2H_4	Selectivity (%) C_2H_4	CH_4	C_3H_8
$Ga_2O_3(CO_2)$	9.8	19.6	18.6	95.0	3.8	1.0
Ga_2O_3(Ar)	9.8	9.6	9.0	94.0	5.0	0.7
$Cr_2O_3(CO_2)$	2.8	12.1	11.4	93.8	5.8	0.4
Cr_2O_3(Ar)	2.8	10.4	10.2	97.6	1.8	0.6
$V_2O_5(CO_2)$	3.5	9.8	9.5	97.1	2.9	—
V_2O_5(Ar)	3.5	12.5	11.5	91.7	7.4	0.9

[a] Reaction conditions: 650 °C, SV = 9000 h^{-1} ml (g cat)$^{-1}$. Composition of the feed gas; C_2H_6 : CO_2(Ar) = 5 : 25 ml min^{-1}.

CO_2 on the yield of ethane with V_2O_5 in the presence of CO_2 was slightly detrimental. CO_2 promoted dehydrogenation of ethane exclusively over Ga_2O_3 catalyst. To our knowledge, such a marked promotion effect of CO_2 in a hydrocarbon conversion process has never been previously observed. The role of CO_2 in dehydrogenation of C_2H_6 over Ga_2O_3 catalyst is, as yet, unclear. With CO_2 considerable amounts of CO and H_2O were formed during the reaction, indicating reaction of CO_2 with H_2. The amount of H_2O was 1.09 mmol and that of CO was 1.07 mmol at 650 °C after 0.5 h. Dehydrogenation of C_2H_6 was strongly inhibited when Ga_2O_3 was impregnated onto a basic oxide such as MgO or La_2O_3. Another characteristic feature in the reaction in CO_2 is the increase in the yield of CH_4. From these findings the role of CO_2 may be as follows: slightly acidic CO_2 may strongly adsorb onto basic sites of gallium oxide, and as a result, the acidity of Ga_2O_3 would be enhanced. This possibility is reinforced by the fact that after dehydrogenation a certain amount of carbon was formed on the catalyst (Ga_2O_3, Cr_2O_3, and V_2O_5). Dehydrogenation of ethane would be catalyzed by acid sites on Ga_2O_3.

Four-electron electrocatalytic reduction of dioxygen to water by an ion-pair cobalt porphyrin dimer adsorbed on a glassy carbon electrode

Francis D'Souza,*† Yi-Ying Hsieh and Gollapalli R. Deviprasad

Department of Chemistry, Wichita State Unviersity, Wichita, KS 6720-0051, USA

An ion-pair porphyrin dimer, formed by reacting the tetrachloro salt of [tetrakis(*N*-methylpyridyl)porphyrinato]-cobalt and the tetrasodium salt of [tetrakis(4-sulfonatophenyl)porphyrinato]cobalt, adsorbed electrochemically on a glassy carbon electrode is shown to catalytically reduce O_2 to water by four electrons.

Mimicking enzymatic catalytic reactions using metalloporphyrin dimers is an area of active research. Towards this, covalently linked porphyrin dimers are most widely used and by employing such dimers, four-electron reduction of O_2 to H_2O has been demonstrated.[1,2] That is, either Co or Fe porphyrin dimers, with closely spaced porphyrin rings (inter-ring distance *ca.* 3.5 Å), adsorbed on a glassy carbon (GC) electrode, catalyze the reduction of O_2 to H_2O at low pH. The postulated mechanism involves formation of a μ-ligated O_2 complex, followed by electrochemical reduction and protonation to produce H_2O. The inter-ring distance and the rigidity of the dimer are believed to be important factors governing the formation of the μ-ligated O_2 complex for the overall catalytic process.[1*a*]

Water soluble monomeric Co porphyrins, bearing either positive charges on the ring periphery, such as the tetrachloro salt of [tetrakis(*N*-methylpyridyl)porphyrinato]cobalt, [Co(TMPyP)]Cl_4 or negative charges on the ring periphery, such as the tetrasodium salt of [tetrakis(4-sulfonatophenyl)-porphyrinato]cobalt, Na_4[Co(TPPS)] (Fig. 1), are known to adsorb irreversibly on a GC electrode and catalytically reduce O_2 by two electrons to produce H_2O_2.[3] It is also known that these oppositely charged porphyrins form stable face-to-face bound porphyrin dimers with 1 : 1 molecular stoichiometry when they are mixed together in solution.[3,4] Spectroscopic investigations have shown[4] that the inter-ring distance between the porphyrin rings of these dimers is *ca.* 3.1 Å. This distance is shorter by 0.4 Å than that of a closely spaced covalently linked porphyrin dimer known to reduce O_2 directly to water.[1*a*] These results suggest that the ion-pair dimers should also be utilized as electrode materials for catalytic reduction of O_2. Sawaguchi *et al.*[1*i*] initially examined the catalytic behaviour for O_2 reduction by using electrodes coated with ion-pair Fe–Fe porphyrin dimer and reported a 12% catalytic efficiency towards four-electron reduction of O_2 to H_2O. In the present study, we have observed a catlaytic efficiency up to 98% when an ion-pair Co–Co porphyrin dimer, adsorbed electrochemically on a glassy carbon electrode, under elevated pH conditions is used.

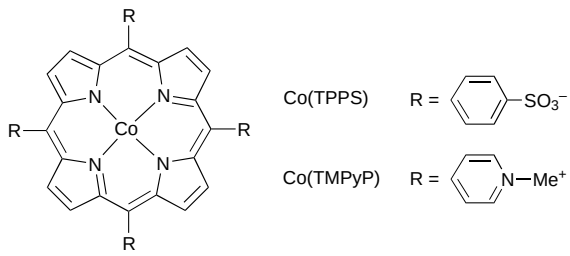

Fig. 1 The structural formulae of the water-soluble Co porphyrins used to form ion-pair dimer

Fig. 2 shows the cyclic voltammograms‡ (CVs) for O_2 reduction on the dimer, [Co(TMPyP)][Co(TPPS)]§ adsorbed GC electrode¶ (curve 1), a monomer, Co(TMPyP)Cl_4 adsorbed GC electrode (curve 2) and a bare GC (curve 3) in O_2 saturated 0.05 M NH_4Cl.‖ Curve 4 shows the CV for the dimer adsorbed electrode in the absence of O_2. Two irreversible peaks located at E_{pc} = −0.49 V and E_{pc} = −0.76 V *vs.* Ag/AgCl, are observed for the dimer adsorbed electrode. There is a positive shift of peak potential by 360 mV for O_2 reduction for the monomer adsorbed GC electrode as compared to that observed for the bare GC electrode (Curves 2 and 3). Similar voltammetric behavior is also seen for the monomer, Co(TPPS) adsorbed electrode and a dimer, [Co(TMPyP)][(H_2TPPS)], in which only one of the porphyrins has a Co metal ion and the other is a free-base porphyrin, adsorbed electrode. These results are similar to that reported for the catalytic two-electron reduction of O_2 to peroxide.[5]

The peak potential for O_2 reduction on the dimer adsorbed electrode is located at E_{pc} = −0.22 V *vs.* Ag/AgCl (curve 1). This peak potential is positively shifted by 120 mV when compared to the peak potential for O_2 reduction on the monomer adsorbed electrode (curve 2). Additionally, larger, peak currents, proportional to (scan rate)$^{1/2}$, are obtained for the dimer adsorbed electrode. The positive shift of the peak potential and the larger catalytic currents for O_2 reduction on the dimer adsorbed electrode suggest the occurrence of four-electron reduction of O_2 to H_2O.[1*a*] In order to quantify these results, voltammetry at a rotating disk-ring electrode has been performed.

Fig. 3(*a*) shows voltammetric curves, recorded with the use of a rotating (Pt ring)–(GC disk) electrode,** for O_2 reduction at various rotation rates. The catalyst was adsorbed on the disk.¶ Disk potential was scanned from 0.1 to −0.5 V while ring

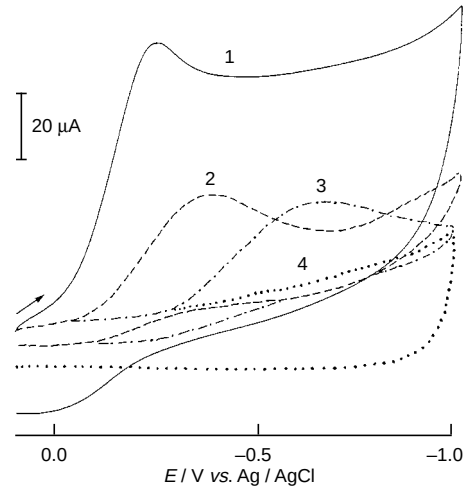

Fig. 2 Cyclic voltammograms for dioxygen reduction at [Co(TPP-S)][Co(TMPyP)]/GC electrode (curve 1), Co(TMPyP)/GC electrode (curve 2) and bare glassy carbon electrode (curve 3) in O_2 saturated 0.05 M NH_4Cl. Curve 4 represents the CV of [Co(TPPS)][Co(TMPyP)] adsorbed electrode in the absence of O_2. Scan rate = 100 mV s^{-1}.

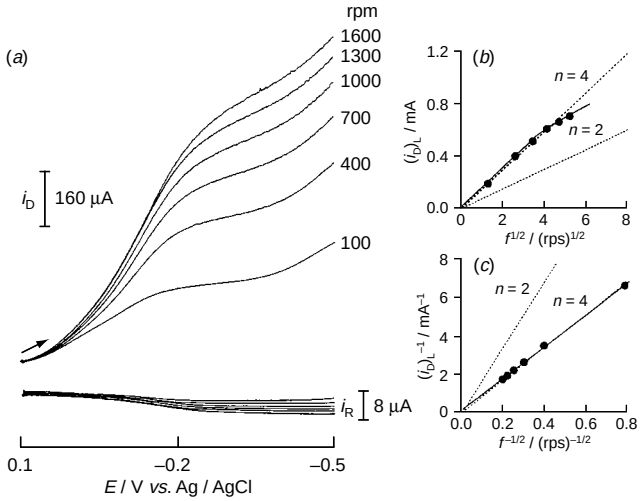

Fig. 3 (*a*) Rotating (platinum ring)–(glassy carbon disk) electrode voltammetry for the [Co(TMPyP)][Co(TPPS)] adsorbed on the disk and the O_2 saturated 0.05 M NH_4Cl aqueous solution. Ring potential, E_R = 1.0 V. Disk potential scan rate, 20 mV s^{-1}. (*b*) and (*c*) are the Levich and Koutecky–Levich plots for the plateau currents from Fig. 3(*a*). Dashed lines are calculated for the O_2 reduction by two and four electrons. Area of the electrode = 0.164 cm^2, concentration of O_2 = 0.5 mM, diffusion coefficient of O_2 = 2.6 × 10^{-5} cm^2 s^{-1}, kinematic viscosity = 0.01 cm s^{-1}.

potential was kept at E_R = 1.0 V in order to detect any H_2O_2 generated by a two-electron reduction process of O_2 at the disk.[1a] Larger disk currents have been obtained for the dimer than for the monomer adsorbed on the graphite electrodes. Levich and Koutecky–Levich plots[6] of the plateau currents from Fig. 3(*a*) are shown in Fig. 3(*b*) and (*c*). The calculated number of electrons involved in the reduction of O_2 from the slope of Fig. 3(*c*) is found to be 3.8 ± 0.2 electrons per O_2 molecule while this value for Co(TMPyP), Co(TPPS) and the Co–H_2 dimer adsorbed electrodes is found to be 2.0 ± 0.2 electrons. It is observed that the occurrence of four-electron reduction for the dimer adsorbed electrode is dependent on the positive switching potential, E_λ during the adsorption of the dimer onto the electrode surface. When E_λ was < 1.2 V, the number of electrons in the process was between 3 and 4.

As expected, negligent amounts of ring currents are observed for the Co–Co dimer adsorbed electrode when the ring potential is held at +1.0 V, *i.e.*, a potential where oxidation of H_2O_2, a two-electron reduction product of O_2 generated at the disk occurs. The ratio of the ring to disk current, i_R/i_D, is 0.01 for the adsorbed dimer which is much smaller than the collection efficiency of 0.36 determined with the use of the $[Fe(CN)_6]^{3-/2-}$ redox couple under the same solution conditions. The i_R/i_D ratio for the adsorbed dimer does not change appreciably with the rotation rate and amounts to 98% of the disk current resulting from four-electron reduction of O_2 to H_2O.[7]

For the electrode coated with the covalently linked Co porphyrin dimer, the catalytic activity towards four-electron reduction of O_2 depends strongly on pH.[1a] For pH > 4.5, only H_2O_2, *i.e.*, a two-electron product is formed.[1a] For the presently investigated ion-pair Co–Co dimer, the calculated 3.8 ± 0.2 number of electrons, at a relatively high pH (5.3) and low ionic strength (0.05 M), indicates its greater ability to catalyze reduction of O_2 by four electrons. This ability of the easy to prepare 'ion-pair' dimer to catalyze, by four-electron reduction of O_2 to H_2O at elevated solution pH is commendable. Further studies to understand the role of E_λ during the process of surface adsorption and the mechanistic details of four-electron reduction of O_2 using different ion-pair porphyrin dimers are in progress.

‡ Cyclic voltammetry was performed on a model 263 A potentiostat/galvanostat of EG & G (Princeton, NJ) by using a typical three-electrode cell arrangement. A glassy carbon electrode (0.3 cm diameter) of BAS was used as the working electrode. A Pt wire served as the counter electrode and an Ag/AgCl electrode was used as the reference one.

§ The dimer, [Co(TMPyP)][Co(TPPS)], was synthesized by a stoichiometric reaction of $[Co(TMPyP)]Cl_4$ (100 mg) (Mid-Century Chemicals Co., Posen, IL) in 20 ml of MeOH–EtOH (1 : 1 v/v) and $Na_4[Co(TPPS)]$ (117 mg) (Mid-Century Chemicals Co.) in 10 ml of MeOH–EtOH (1 : 1 v/v) at room temp. The resulting solid which precipitated was centrifuged, filtered, washed repeatedly with MeOH to yield (71%) pure dimer. UV–VIS in water, λ_{max} (log ε), 322 (4.52), 427 (5.16), 543 (0.16). Elemental analysis of the synthesized dimer revealed the presence of a large number (12 to 16) of water molecules.

¶ The GC working electrode prior to the experiments was initially cleaned with alumina powder and was further treated with 2 M H_2SO_4. The surface of the electrode was roughened by using fine quality sand paper. The porphyrin (dimer or monomer) was adsorbed on the glassy carbon electrode under multicyclic voltammetry conditions. For this, a slurry of porphyrin (*ca.* 1 mM) in 0.025 M NaCl solution was used. The potential was scanned for the range 1.2 to −0.1 V (nearly 30 cycles), until a scan-number-independent voltammogram was obtained. The electrode was then removed from the solution, rinsed thoroughly with distilled water and then immersed in the blank supporting electrolyte solution. The electrochemical measurements were performed at room temperature in 0.05 M NH_4Cl (pH 5.3).

‖ A 0.05 M NH_4Cl solution of low ionic strength (μ = 0.05) was used to avoid possible decomposition of the adsorbed ion-pair porphyrin dimer on the electrode surface.

** The rotating ring-disk electrode (RRDE) voltammetry, was performed by using a Model AFCB1 bipotentiostat, MSRX Speed Control Unit and AFMSRX Modulated Speed Rotator of Pine Instrument Co. (Grove City, PA). A model BD-95 dual channel recorder of Kipp and Zonen (Bohemia, NY) was used to record the voltammograms. Radius of the disk, gap and ring of the platinum-(glassy carbon) ring-disk electrode was 0.23, 0.25 and 0.27 cm, respectively. an Ag/AgCl and Pt wire served as the reference and auxiliary electrodes, respectively.

Lithium fluoride formed *in situ* is trapped by $[TiF_3(C_5Me_5)]_2$: an equilibrium with cleavage of a Ti–F–Ti bond and a model compound for molecular lithium fluoride

Alojz Demsar,*[a]† Andrej Pevec,[a] Ljubo Golič,[a] Saša Petriček,[a] Andrej Petrič[a] and Herbert W. Roesky*[b]

[a] *Faculty of Chemistry and Chemical Technology, University of Ljubljana, Aškerčeva 5, SLO-1000, Ljubljana, Slovenia*
[b] *Institut für Anorganische Chemie der Universität, Tammannstrasse 4, D-37077 Göttingen, Germany*

Synthesis and structure of $[\{(C_5Me_5)TiF_3\}_4(LiF)]$ and its solution equilibrium involving cleavage of a titanium–fluorine–titanium bond is reported.

Fluorine bridging accounts for structural diversity of fluorides of main group elements and transition metals and for formation of reaction intermediates.[1] The reactivity of a Ti–F–Ti unit in fluorotitanium compounds is of particular interest since the cleavage of this unit would leave the titanium centre with high electrophilicity due to polar Ti–F bonds.[2] The catalytic activity of the fluorotitanium binaphthol complex used in the enantioselective addition of allylsilanes to aldehydes[3] was explained by cleavage of two Ti–F–Ti bonds during the catalytic cycle.[2] Here, we report on the equilibrium of cleavage and reformation of two Ti–F–Ti bonds in a solution of $[\{(C_5Me_5)TiF_3\}_4(LiF)]$ **1** observed by ^{19}F NMR spectroscopy.

The high lattice energy of lithium fluoride explains the absence of its solid complexes.[4] Lithium fluoride, prepared *in situ* from lithium chloride and trimethyltin fluoride, has now been successfully trapped by $[TiF_3(C_5Me_5)]_2$ to yield **1**. The reaction of $[TiF_3(C_5Me_5)]_2$, Me_3SnF and LiCl in a molar ratio of 2 : 1 : 1 in THF followed by evaporation of Me_3SnCl and solvent and recrystallization from pentane afforded red crystals of **1**.‡ The molecule of **1** in the solid state§ consists of two $[Ti_2F_6(C_5Me_5)_2]$ units connected by a lithium atom and a bridging fluorine atom (Fig. 1). Each titanium atom is coordinated by five fluorines and a C_5Me_5 ligand. The lithium atom is coordinated by four fluorines arranged in a distorted tetrahedron. The Li–F distances are similar to those in $Li[\{(Me_3Si)_3C\}AlF_3]\cdot THF$[5] with fourfold coordinated lithium, however shorter than those in lithium fluoride (2.009 Å).[6] Bonding to lithium as well as *trans*-positioned C_5Me_5 ligand causes elongation of the Ti–F bonds. The Ti–F–Ti bonds not affected by the *trans*-C_5Me_5 ligand are on average 10% longer than the terminal Ti–F bonds.

A color change from orange to red is observed when cooling toluene or chloroform solutions of **1** from 322 to 272 K. Two temperature dependent sets of resonances are found in variable temperature (VT) ^{19}F NMR spectra of $CDCl_3$ or $[^2H_8]$toluene solutions of **1**. The high temperature set of five resonances reversibly converts to a low temperature set of seven resonances on cooling as shown in Fig. 2 in $[^2H_8]$toluene solution. The changes in spectra are in agreement with the equilibrium shown in Scheme 1. Four sharp resonances in the high temperature set (intensity ratio of 2 : 2 : 1 : 2) are assigned to $[\{(C_5Me_5)_2Ti_2F_7\}Li]$ **1a** by comparison with the ^{19}F NMR spectrum of $[\{(C_5Me_5)_2Ti_2F_7\}_2Ca]$.[7] The assignment is consistent with

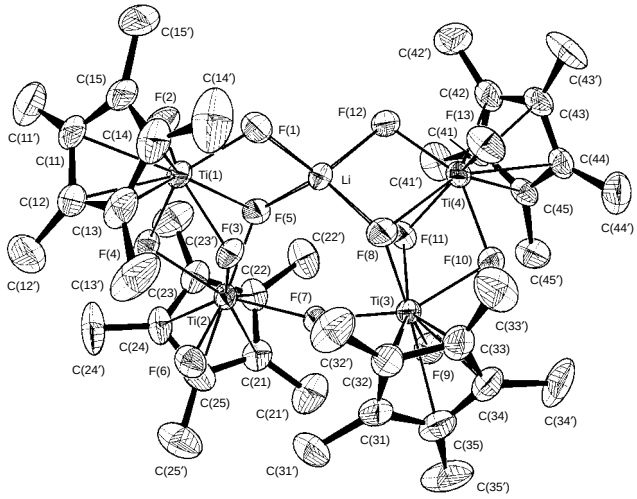

Fig. 1 Crystal structure of **1**. Hydrogen atoms are not shown. Selected bond lengths (Å) and angles (°): Ti(1)–F(1) 1.873(4), Ti(1)–F(2) 1.822(6), Ti(1)–F(3) 1.978(4), Ti(1)–F(4) 1.999(4), Ti(1)–F(5) 2.421(5), Ti(2)–F(6) 1.826(5), Ti(2)–F(5) 1.966(4), Ti(2)–F(7) 2.007(3), Ti(2)–F(4) 2.024(4), Ti(2)–F(3) 2.136(5), Li–F(1) 1.864(13), Li–F(5) 1.926(13), Li–F(8) 1.932(12), Li–F(12) 1.866(12); F(1)–Ti(1)–F(2) 93.0(2), F(1)–Ti(1)–F(5) 75.3(2), F(1)–Ti(1)–F(3) 85.0(2), F(1)–Ti(1)–F(4) 142.9(2), Ti(2)–F(8)–Ti(3) 161.1(2), F(1)–Li–F(12) 110.1(7), F(1)–Li–F(5) 89.1(4), F(5)–Li–F(8) 121.0(7).

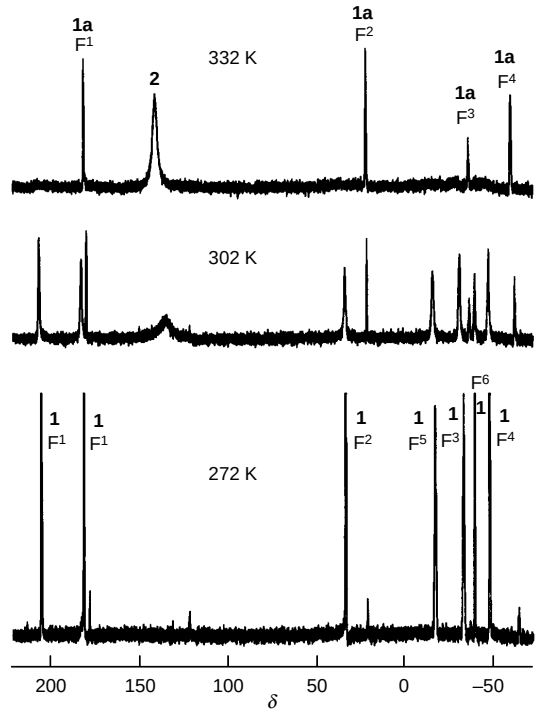

Fig. 2 ^{19}F NMR spectra of **1** ($[^2H_8]$toluene solution) at 332, 302 and 272 K. See Scheme 1 for labels. The area of the signal at δ −38.8 (F^6) in 272 K trace is one half of the respective areas of the other signals.

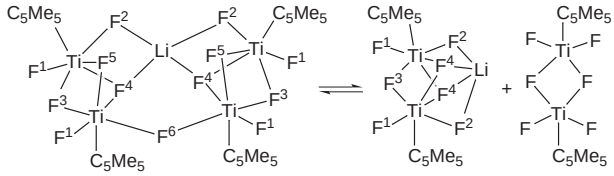

Scheme 1 Equilibrium in solution of **1**

lithium symmetrically bonded to two terminal and to two bridging fluorines from the $[Ti_2F_7(C_5Me_5)_2]^-$ moiety. The bonding of fluorines to quadrupolar lithium causes decoupling of fluorine resonances and a high field shift as already observed in the calcium compound.[7] The resonance of terminal fluorines appears as a quintet due to coupling to four fluorine atoms. The remaining, fifth, broad line of the high temperature set is attributed to the resonance of $[(C_5Me_5)TiF_3]_2$.¶ The low temperature set has six resonances of equal intensities and one with half of the intensity that could be assigned to **1** having six pairs of equivalent fluorine atoms and a single fluorine atom bridging two $[Ti_2F_6(C_5Me_5)_2]$ units. The ^{7}Li NMR signal of **1** appears as a singlet at 302 K, and as a quintet at 272 K, showing coupling to four fluorine atoms.

The equilibrium shown in Scheme 1 was studied by VT ^{19}F NMR of a [$^2H_8$]toluene solution of **1** in the temperature range 272–312 K, and resulted in $\Delta H = 75 \pm 3$ kJ mol^{-1} and $\Delta S = 197 \pm 2$ J mol^{-1} K^{-1}.‖ The large positive ΔS value supports an entropy driven dissociation equilibrium. Moreover, a shift of the equilibrium to dissociation was observed in ^{19}F NMR spectra after diluting the solution of **1**. The dissociation involves cleavage of two titanium–fluorine–titanium bonds and changes in the lithium coordination sphere. The determined enthalpy could be therefore only a crude estimate of the binding energy of the titanium–fluorine bond.

In conclusion, *in situ* prepared lithium fluoride was trapped with $[TiF_3(C_5Me_5)]_2$ giving **1**. Dissociation of **1** to **1a** and $[TiF_3(C_5Me_5)]_2$ is accompanied by a cleavage of Ti–F–Ti bonds. In solution observed **1a** could serve as a model compound for studying the reactivity of 'lithium fluoride' since the lithium atom is in a rather distorted coordination sphere. Its reactivity is already demonstrated by reforming **1** at low temperatures.

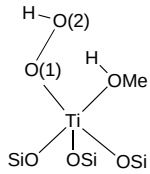
Elucidation of the mechanism of alkene epoxidation by hydrogen peroxide catalysed by titanosilicates: a computational study

Duangkamol Tantanak, Mark A. Vincent and Ian H. Hillier*†

Department of Chemistry, University of Manchester, Manchester, UK M13 9PL

Calculated transition states for alkene epoxidation by hydrogen peroxide, catalysed by titanosilicates, predict that it is the oxygen atom of the titanium(IV)–hydroperoxide intermediate closer to the metal centre which attacks the alkene.

Zeolite-based metal oxide systems are effective catalysts for a variety of oxidation reactions, many of considerable industrial importance.[1] Of particular interest are titanium containing zeolites such as TS-1, TS-2 and Ti-MCM-41, which involve framework Ti^{IV} species, and which catalyse, under mild conditions, many useful oxidations with hydrogen peroxide, such as alkene epoxidation.[2] EXAFS studies[3] suggest that in these catalysts the titanium is 4-coordinate, but may expand its coordination sphere on interaction with adsorbates. The active species for oxidation *via* hydrogen peroxide is generally considered to be a hydroperoxide species accommodated in the titanium coordination sphere, and possibly hydrogen bonded to a water or alcohol molecule, as in structure **I**.[1]



I

The mechanism of the subsequent epoxidation reaction involving structure **I** is far from clear at present, particularly with regards to which oxygen atom [O(1) or O(2)] attacks the carbon–carbon double bond of the alkene. On the basis of stereoselectivity Adam *et al.*[4] propose a mechanism for the epoxidation of chiral allylic alcohols involving attack of O(2), the oxygen atom closer to the hydrogen atom. Using steric arguments, Clerici and Ingallina[5] also suggest that it is this oxygen atom [O(2)] that attacks the alkene. However, there is no real evidence that rules out attack of the oxygen atom [O(1)] directly bonded to the titanium centre. There is thus a need for a more complete understanding of the catalytic mechanism, which will be aided by an investigation of the potential energy surface, particularly of the structure and energetics of the transition states corresponding to attack by either O(1) or O(2). We here describe high level *ab initio* calculations which address this question.

As is common practice,[6] we have used a finite molecular cluster to model the active site of **I**, in which the silicon atoms are terminated by hydrogen atoms. A more complete treatment would naturally take proper account of the effect of the infinite lattice,[7] but finite clusters are taken to be a good initial approximation. Stationary structures on the potential energy surface involving the interaction of the cluster with ethene were located using a 3-21G* basis, electron correlation being included using density functional theory employing a B3LYP functional. The calculations were carried out using GAUSSIAN94.[8]

The minimum energy structures of the cluster with ethene close by are shown in Fig. 1. The structures shown in Fig. 1(*a*) and (*b*), which are close in energy, are on the reaction pathway leading to the two transition states involving attack on ethene by O(1) and O(2), respectively. Of particular note is the sideways coordination of the peroxy group, with both Ti–O distances [1.95 and 2.23 Å in the lowest energy structure, Fig. 1(*a*)] being significantly longer compared to the three Ti–O(Si) distances. Of these two distances, one is considerably shorter, implying preferential interaction of O(1) with the Ti^{IV} centre, and a corresponding weaker interaction of O(2). A previous calculation[9] of the related system, $Ti(OH)_3OOH$, gave one longer (2.59 Å) and one shorter (1.87 Å) Ti–O length, compared to our structure, suggesting a somewhat different coordination mode. Our reactant structures are however similar to that found in the crystal structure of {[(η^2-*tert*-butylperoxo)titanatrane]$_2$·3 dichloromethane},[10] when Ti–O lengths of 1.91 and 2.27 Å were found, although the O–O distance (1.47 Å) is a little shorter than our calculated value (1.54 Å). We have located a third minimum energy structure [Fig. 1(*c*)] with a considerably longer Ti–O(2) length, which is best described as having the O_2H group bonded end-on. We find this structure, which resembles the one calculated by Neurock and Manzer,[11] to be 2.6 kcal mol^{-1} higher in energy than our lower energy structure.

Two transition structures, both leading to the formation of the epoxide, were located (Fig. 2). The lower energy one involves attack on the ethene π-bond by the oxygen atom, O(1) [Fig. 2(*a*)], closest to the titanium centre, with a lengthening of the Ti–O(1) bond compared to the reactant, and an associated shortening of the Ti–O(2) bond. The developing negative charge on the O(2)–H group leads to the formation of a Ti–OH

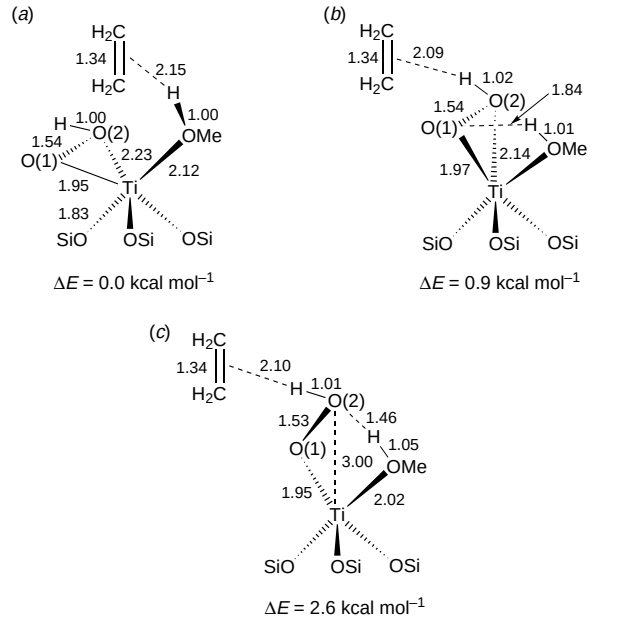


Fig. 1 Structures of ethene-cluster reactants

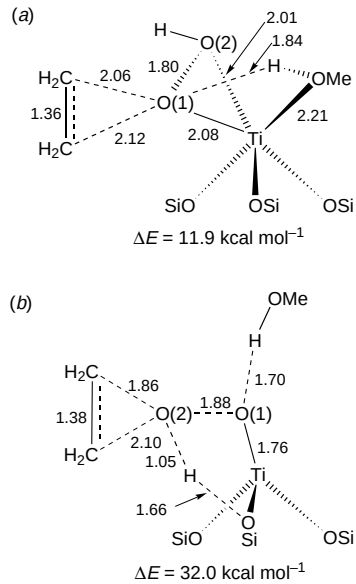

Fig. 2 Transition structures for attack of each hydroperoxide oxygen atom on ethene. ΔE is the calculated barrier.

bond in the product. When compared to this transition state, the second one involving the attack by O(2) [Fig. 2(*b*)] is of higher energy and has both O–C distances shorter and the O–O distance longer, so that the second mechanism, attack by O(2), proceeds *via* a later transition state. This second mechanism is significantly different from the first, involving a developing Ti–O double bond [Fig. 2(*b*)] (of length 1.76 Å in the transition state) and proton transfer to a siloxy group. Such a product involving a Ti–O double bond has been found to be less stable than the corresponding species with Ti–O single bonds.[12]

The two transition states that we have identified correspond to barriers that differ in energy by 20.1 kcal mol^{-1}. The relative ordering of these barriers is unlikely to change if more accurate calculations employing a larger basis and a better treatment of electron correlation were to be carried out. We have also used a continuum treatment[13] to estimate the effect of a polar solvent on the calculated barriers. We find that using a relative permittivity of 78.3 to model solvation by water, the barrier for attack of O(1) is unaltered, whilst the barrier for attack of O(2) is reduced to 25.8 kcal mol^{-1}. We are thus confident that the preferred route for attack involves O(1), and that inclusion of solvent does not affect this conclusion.

We have thus identified the mechanism of the epoxidation reaction, and obtained a transition state structure that may be of value in designing related enantioselective catalysts.[14]

Aldol and Knoevenagel condensations catalysed by modified Mg–Al hydrotalcite: a solid base as catalyst useful in synthetic organic chemistry

M. Lakshmi Kantam,*[a] B. M. Choudary,*[a]† Ch. Venkat Reddy,[a] K. Koteswara Rao[a] and F. Figueras[b]

[a] *Indian Institute of Chemical Technology, Hyderabad 500007 India*

Aldol and Knoevenagel condensations were performed with suitably activated Mg–Al hydrotalcite as catalyst in quantitative yields in the liquid phase under mild reaction conditions at a faster rate for the first time.

In recent years, there has been increasing emphasis on the use and design of environment-friendly solid acid–base catalysts to reduce the amount of toxic waste and by-products arising from the chemical processes prompted by stringent environment protection laws. The challenge is to perform heterogeneous catalysis reactions leading to C–C bond formation which are widely employed in organic synthesis.[1] The versatile Knoevenagel and aldol condensations have numerous applications in the elegant synthesis of fine chemicals[2] and are classically catalysed by bases[3,4] in the liquid phase system. On the laboratory scale, many catalysts have been known to effect the Knoevenagel and aldol condensations and include alumina,[5] sepeolite,[6] zeolites,[7] clays,[8] hydrotalcites[9–11] and anionic resins.[12]

[a] All reactions were performed on 2 mmol substrate in 10.3 ml (140 mmol) acetone using 0.2 g of MHT. [b] ^{1}H NMR yields based on aldehyde. [c] Aldol to dehydrated product (1 : 1). [d] Isolated yield.

Layered double hydroxides (LDHs) or hydrotalcite-like compounds (HTLCs) have recently received much attention[13] in view of their potential usefulness as adsorbents, anion exchangers and most importantly as basic catalysts.[14] LDHs upon thermal decomposition at about 450 °C give a highly active homogeneous mixed oxide which is a potential basic catalyst used for a variety of organic transformations such as aldol condensation,[15] nucleophilic halide exchange,[16] alkylation of diketones,[17] epoxidation of activated olefins with hydrogen peroxide[18] or Claisen–Schmidt condensation.[19]

The previous work[10,15,17,19] on aldolisations using HTLCs was performed generally at higher temperatures. Recently, we reported[20] a modified method for the activation of the hydrotalcite catalyst whose basicity was tuned for base catalysed condensation reactions in the liquid phase under very mild reaction conditions. Herein, we report Knoevenagel and aldol condensations catalysed by this modified hydrotalcite (MHT) with quantitative yields at a faster rate of reaction under very mild liquid phase conditions (Tables 1 and 2) for the first time as part of our investigation into the scope and applicability of MHT for a variety of organic reactions.

In the case of aldol reactions, the aldol was the major product when the reaction was conducted at room temperature but the yields were poor except in the case of benzaldehyde.[20] When the reaction was conducted at 60 °C, yields were improved drastically but the reaction proceeded to give the dehydrated product (entries 2–6) predominantly except in the case of *p*-nitrobenzaldehyde (entry 1) where the ratio of aldol to α,β-unsaturated product was 1 : 1. In the case of *o*-hydroxybenzaldehyde (entry 8) there was no reaction, while the *p*-hydroxybenzaldehyde (entry 7) showed little activity (< 10%) with the formation of both the aldol and the dehydrated product (1 : 1) (Scheme 1). The inactivity of these compounds may be attributed to the fact that the basic sites present on the

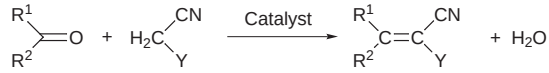
catalyst surface were neutralised by the adsorption of the phenolic moiety which is acidic in nature. All other substrates irrespective of the nature of the substituent present on the phenyl ring shown in Table 1 resulted in good yields in shorter reaction times.

Knoevenagel condensations (Scheme 2) involving various aromatic carbonyl compounds and aliphatic ketone, cyclohexanone with (a) malononitrile and (b) ethyl cyanoacetate as the active methylene compounds were carried out with MHT at room temperature (Table 2). The results are quite impressive, when compared with results reported for solid catalysts requiring vapour phase conditions and longer reaction times, and this present modified hydrotalcite is the first heterogeneous catalyst reported in the literature which perform the reactions at room temperatures in excellent yields. All the reactions proceeded smoothly in toluene with the exception of cinnamaldehyde and cyclohexanone with ethyl cyanoacetate. However, when DMF was used as the solvent, cinnamaldehyde and cyclohexanone condensed affording the corresponding product. The solvent effect established here is in consonance with the results reported by others.[21]



Scheme 2 Knoevenagel condensation of different carbonyl compounds with malononitrile or ethyl cyano acetate

Thus, good yields of aldol and Knoevenagel products can be obtained in heterogeneous catalysis using hydrotalcites provided that the solid is suitably activated. This new solid base catalyst is a practical alternative to soluble bases both in Knoevenagel and aldol reactions in view of the following advantages: (a) high catalytic activity under very mild liquid phase conditions in general for both the reactions described above and specifically at room temperature for the accomplishment of Knoevenagel reactions, (b) easy separation of the catalyst by simple filtration, (c) waste minimisation and (d) possibility of reuse.

This work was realised in the frame of an Indo-French co-operative programme, funded by IFCPAR (project No. IFC/1106-2/96/2460).

Synthesis of double-mesopore silica using aqueous ammonia as catalyst

Xiaozhong Wang,*† Tao Dou and Yongzhuang Xiao

Institute of Special Chemicals, Taiyuan University of Technology, Taiyuan, 030024, China

Double-mesopore silica with a characteristic N_2 adsorption isotherm and narrow bimodal mesopore distribution is synthesized rapidly at room temperature by using aqueous ammonia as the catalyst.

The synthesis of inorganic frameworks with specific and organized pore networks is of potential importance in catalysis,[1,2] separation technology[3] and biomaterials engineering.[4,5] Since the first synthesis of mesoporous MCM-41 materials,[6,7] there has been intense activity in the design and synthesis of a variety of mesoporous solids. Generally, the typical N_2 adsorption isotherm, which plays a significant role in characterization of the new mesoporous materials, of MCM-41 materials shows type IV behavior with a sharp inflection characteristic of capillary condensation within uniform mesopores at P/P_0 *ca.* 0.3–0.4[8] and with an additional hysteresis loop following in the P/P_0 region of 0.8–1.0.[1,7] The hysteresis loop at $P/P_0 > 0.8$ is now acknowledged to arise from interparticle capillary condensation[1,9] or from the structure collapse of portions of the MCM-41 structure during the hydrothermal treatment or calcination.[10,11] However, if this hysteresis loop lifts up sharply, this may imply that a change in the texture has occurred on the mesoporous frameworks of the product. Pang and coworkers[12] recently presented a report on the synthesis of bimodal mesopore distribution silica with a sharp lefting-up hysteresis loop at $P/P_0 > 0.8$ on its N_2 adsorption isotherm by calcining a wet surfactant-containing silicate gel. However, there is no discernable inflection in the vicinity of $P/P_0 = 0.35$ on the N_2 adsorption–desorption isotherms to indicate the existence of smaller mesopores. Kloetstra *et al.*[13] also succeeded in synthesizing a bimodal pore size distribution molecular sieve by overgrowing mesoporous MCM-41 on a faujasite. Unfortunately, they have not provided any information on the detailed analysis of the N_2 adsorption isotherm and the corresponding pore size distribution curve. Double-mesopore molecular sieves of narrow pore distribution may find broad potential applications in electronic, optical or sensing devices.[14,15] Here, we present a synthesis of a double-mesopore silica mesostructure which has a typical mesopore X-ray diffraction pattern but narrow bimodal mesopore distribution. In the synthesis the process was completed in a relatively short time at room temperature by using aqueous ammonia as the catalyst.

The preparation procedure is as follows: stoichiometric surfactant cetyltrimethylammonium bromide (CTAB) was added to deionized water with stirring at room temperature until the solution became clear. The silica source tetraethylorthosilicate (TEOS) was then added to the solution with stirring. Finally, aqueous ammonia was slowly added until the pH of the solution was *ca.* 9.5. The molar composition of final gel mixtures was $2.0TEOS : 0.68–2.0NH_3{\cdot}H_2O : 0.4CTAB : 230H_2O$. The mixtures were stirred continuously for *ca.* 7 min. During this short time the fluid mixture became progressively more viscous, and eventually set into jelly-like monoliths that assumed the shape of the container. Then the jelly-like solid product was washed repeatedly with distilled water in a centrifuge, dried in air at 353 K and finally calcined in air at 2 K min^{-1} to 823 K for 6 h to remove the template.

Powder X-ray diffraction (XRD) patterns (recorded on a D/max-rA diffractometer with Cu-Kα radiation, 40 kV, 20 mA) of the as-synthesized and calcined silica products are shown in Fig. 1. Different from the results of Pang and coworkers[12] that the gel precursor dried at room temperature is amorphous according to XRD, the pattern for the as-synthesized silica product exhibits a broad, yet clear, diffraction peak with a *d*-spacing of 5.2 nm. The appearance of a diffraction peak at this low angle suggests that after a short time of stirring mesostructure has been formed in the jelly-like solid product with a pore system lacking long-range order. Upon removal of the template by calcination, the basal spacing decreases to 4.4 nm and the scattering intensity increases substantially, suggesting that the calcination process may promote siloxane cross-linking and thereby improve the ordering of the oxide framework. The XRD patterns are reminiscent of HMS[11] and MSU[9] mesoporous materials.

Important trends are revealed in Fig. 2 by the N_2 adsorption–desorption isotherms and the corresponding BJH[16] pore size distribution based on the desorption branch (obtained on an ASAP 2000 analyser) for the calcined product. This is a typical irreversible type IV adsorption isotherm with two separate, well expressed H1 hysteresis loops as defined by IUPAC[17] at relative pressures P/P_0 of 0.24–0.45 and 0.8–1.0. Nevertheless, the pore size distribution reveals that there are two mesopore sizes in the material, *i.e.* a bimodal distribution. The first condensation step on the isotherm at $P/P_0 = 0.24–0.45$ is similar to that for usual MCM-41 materials with markedly higher saturation sorption capacity, though not very steep. This was attributed to a slight pore size heterogeneity of the sample with a pore size of *ca.* 2.6–3.0 nm as seen in Fig. 2(*b*), but an exceptionally high mesopore surface area of 1064.6 $m^2\ g^{-1}$, corresponding to a total pore volume of 0.66 $cm^3\ g^{-1}$. This is in agreement with the XRD results, *i.e.* broad lines are observed. However, the second condensation step on the isotherm at $P/P_0 > 0.8$ is much steeper than the first. This indicates the presence of a significant amount of secondary mesopores with a remarkably narrow pore size distribution centred at *ca.* 19 nm. The total pore volume for the larger mesopores is 1.18 $cm^3\ g^{-1}$ with a total surface area of 243.1 $m^2\ g^{-1}$. This inflection at higher relative pressures differs completely from that of previously-synthesized mesoporous materials. In addition, the broad hysteresis loops in the isotherms reflect its long mesopores with no pore-blocking effects, which limit the emptying and filling of the accessible

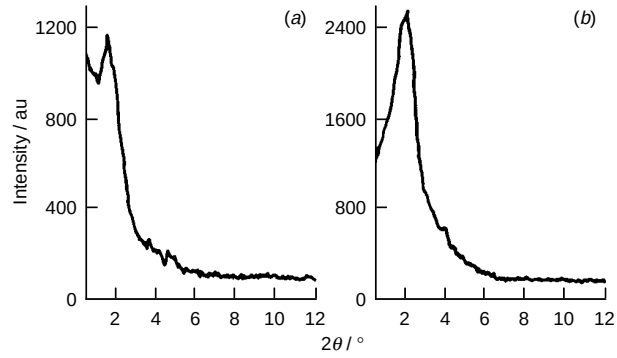

Fig. 1 Powder X-ray diffraction patterns of (*a*) as-synthesized sample and (*b*) calcined sample

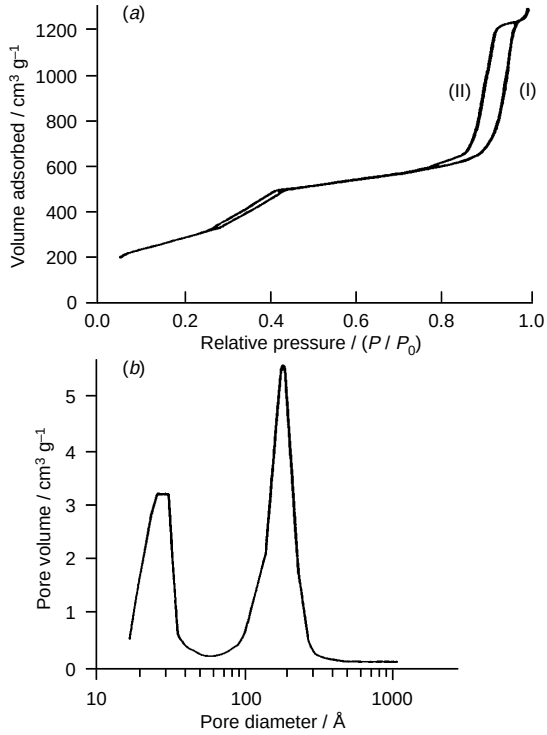

Fig. 2 (*a*) N_2 adsorption (I)–desorption (II) isotherms on the calcined sample and (*b*) the pore size distribution of the material

volume. Fig. 3 is a TEM image of the calcined sample (recorded on a JEOL 200CX microscope). It is evident that, different from most crystalline mesoporous sieves such as MCM-41 which has a well organized hexagonal pore structure, the present material contains a large number of randomly distributed channels with both smaller cylindrical- to hexagonal-shaped channels and larger stripe-like channels lacking long-range packing order. As can be seen from the TEM image, both sets of mesopores are present as a 'homogeneous' mixture throughout the entire sample. The formation of larger stripe-like mesopores may be due to the incomplete condensation of SiO_2 species between adjacent surfactant micelles.

In summary, we have discovered a simple and novel synthesis of a double-mesopore silica with a characteristic N_2 adsorption isotherm and narrow bimodal mesopore distribution. The synthesis process is completed in a relatively short time at room temperature by using aqueous ammonia as the catalyst. This may imply that surfactant micelles in the initial reaction mixtures are of different size or shape, and the hydrolysis of TEOS and the following cooperative condensation of SiO_2 species with surfactant micelles was incomplete over the short time of reaction. Further experimental results show that the similar double-mesopore silicas can also be synthesized by substituting tetraethylammonium hydroxide or NaOH for aqueous ammonia as the catalyst and that pH adjustment of the reaction mixtures plays a critical role in the synthesis. However, if the pH in the reaction mixtures increases beyond a certain degree, the double-mesopore silica will change into considerably ordered single-peaked mesoporous silica. These results provide us with a new angle for a further understanding of the formation mechanism of mesoporous silica materials. More detailed synthetic investigations and studies of the mechanism of formation of double-mesopore silica are in progress.

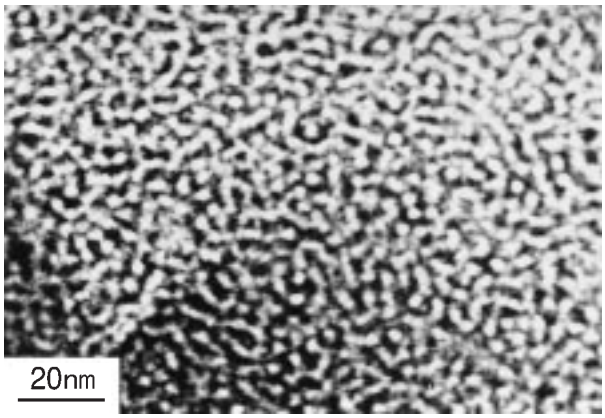

Fig. 3 Transmission electron micrograph of the calcined sample

We would like to thank Dr Guoyi T. and Xihua C. at the Tsinghua University for the TEM data, Dong W. and Yanzheng F. at the Institute of Coal Chemistry, the Chinese Academy of Sciences for the XRD data and N_2 adsorption measurements respectively, and we are also grateful to the National Natural Science Foundation of China, the Oversea-Returned Personnel Foundation of Shanxi Province and the Natural Science Foundation of Shanxi Youth for financial support.

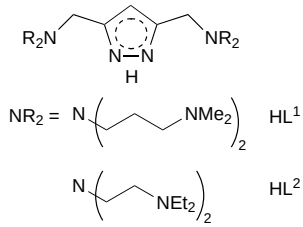
An intramolecular H_3O_2 bridge as the resting form of an active metal-bound hydroxide in a dinuclear zinc(II) complex

Franc Meyer*† and Peter Rutsch

Anorganisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany

An intramolecular Zn–O_2H_3–Zn bridge as a complexed form of metal-bound hydroxide exhibits enhanced reactivity compared to the related Zn–OH–Zn unit, illustrated by the reaction with CO_2.

Various hydrolytic metalloenzymes are known to contain two or more divalent metal ions in close proximity within their active site,[1] and in particular the coordinatively flexible Zn^{II} is found in several native systems like alkaline phosphatase (AP),[2a] P1 nuclease[2b] and phospholipase C (PLC).[2c] Although different and specific mechanisms for the individual catalytic processes are most probably involved, it is believed to be a dominant feature that a metal hydroxide intermediate produced by the deprotonation of zinc-bound water hydrolytically attacks the substrate which itself might be activated by coordination to an adjacent metal ion.[1] Consequently there is considerable interest in the design of polynuclear metal complexes containing Zn–OH_2 or Zn–OH functions to serve as models for these hydrolytic zinc enzymes,[3,4] however hydrolytically active systems with a di- or tri-nuclear zinc core have still remained rare.[5] Recently a combination of both Zn–OH_2 and Zn–OH has been reported in the form of an intermolecular Zn–O_2H_3–Zn bridge and suggested to represent a new structural and possibly functional motif in oligozinc enzyme chemistry.[6] Here we report the synthesis and structural characterisation of a discrete dinuclear zinc(II) complex incorporating an intramolecular $H_3O_2^-$ bridge as well as evidence for its enhanced reactivity compared to the frequently observed Zn–OH–Zn function.[4]



Ligands L^1 and L^2 are employed, which have been shown to predominantly form dinuclear complexes with five-coordinate N_4X ligation for divalent 3d transition metal ions.[7–9] Thereby the range of accessible metal–metal separations can be selectively tuned by altering the chain length of the chelating side arms attached to the pyrazolate heterocycle,[9] *i.e.* the choice of either L^1 or L^2. Deprotonation of HL^1 by means of BuLi and subsequent reaction with 2 equiv. of $Zn(ClO_4)_2·6H_2O$ and $NaBPh_4$ affords the dinuclear zinc(II) complex **1**‡ whose molecular structure has been determined by X-ray diffraction§ (Fig. 1), thereby confirming that a monoatomic oxygen bridge spans two five-coordinate zinc atoms with a metal–metal separation of d(Zn···Zn) = 3.613 Å. Although its proton could not be located in the crystallographic analysis, a sharp IR absorption at 3618 cm^{-1} clearly identifies this secondary bridge as a discrete metal-bound hydroxide.

In contrast, a similar synthetic procedure starting from HL^2 yields a bimetallic complex **2** with an intramolecular $H_3O_2^-$ bridging moiety as revealed by a single crystal X-ray crystallographic analysis (Fig. 2). Obviously the shorter side arms of L^2 pull the two metal centres back and apart [d(Zn···Zn) = 4.374 Å] and thus prevent a bridging position for the small hydroxide ion. Incorporation of an additional water molecule then establishes the $H_3O_2^-$ unit with a very strong intramolecular hydrogen bridge {d[O(1)···O(2)] = 2.462 Å},[10] where the remaining H atoms are involved in weak hydrogen bonding to two acetone solvent molecules incorporated in the crystal lattice {d[O(1)···O(4)] = 2.875 Å; d[O(1)···O(5)] = 3.050 Å}. The $H_3O_2^-$ entity in **2** might be viewed as a hydrated and thereby protected form of a Zn-bound OH^-. For a related FHO(H)-bridged dicobalt complex[9] evidence could be obtained for the reversible extrusion of the incorporated water molecule, which in **2** would generate an active Zn–OH function in close vicinity

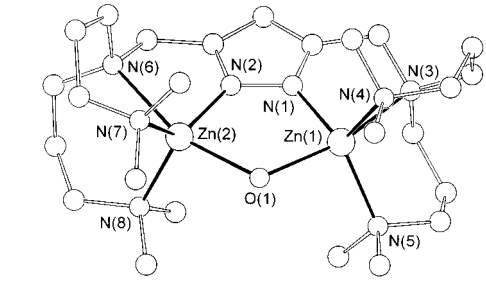


Fig. 1 Molecular structure of the cation of **1**. to a second Lewis-acidic Zn centre. In order to test the expected higher reactivity of **2** compared to **1**, CO_2 was bubbled into solutions of the complexes in acetone. While no reaction was detected for **1**, the appearance of strong IR bands at 1618 and 1401 cm^{-1} for **2** indicates the readily occurring absorption of CO_2 with formation of the bicarbonate complex **3**, whose crystal structure is presented in Fig. 3.

In conclusion the reactivity of these dinuclear complexes is drastically varied by appropriate changes of the ligand matrix, *i.e.* of the chelating side arms attached to the pyrazolate. The intramolecular Zn–O_2H_3–Zn bridge as characterised structurally for **2** can be viewed as a hydrated and thus resting form of an active Zn–OH function in close proximity to a second zinc ion capable of binding potential substrate molecules. It thus resembles the oligonuclear array of zinc ions with intermetallic distances larger than 4 Å found in the active sites of metalloenzymes like PLC and P1 nuclease. As evidenced by the reaction with CO_2, **2** exhibits enhanced reactivity compared to the corresponding OH-bridged complex and should thus be a promising candidate for inducing the hydrolytic cleavage of various substrates, which is presently under investigation.

Acknowledgement is made to Professor Dr G. Huttner for his generous and continuous support of our work as well as to the Deutsche Forschungsgemeinschaft (Habilitandenstipendium for F. M.) and the Fonds der Chemischen Industrie. We thank Dr F. Rominger and Professor Dr P. Hofmann for collecting the X-ray data of complex **3**.

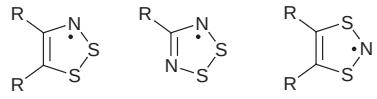
1,1′,2,2′,3,3′-Tetrathiadiazafulvalenes; preparation and characterisation of *trans*-[ClCNS$_2$C=CS$_2$NCCl]

Tosha M. Barclay,[a] A. Wallace Cordes,[a] Richard T. Oakley,*[b]† Kathryn E. Preuss[b] and Robert W. Reed[b]

[a] *Department of Chemistry and Biochemsitry, University of Arkansas, Fayetteville, Arkansas 72071, USA*
[b] *Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario N1G 2W1, Canada*

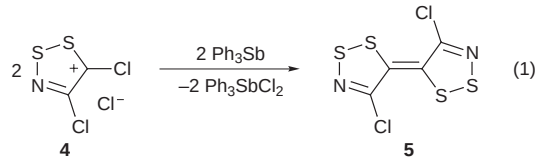
Reduction of 4,5-dichloro-1,2,3-dithiazolylium chloride with two equivalents of triphenylantimony in liquid SO_2 affords the 1,1′,2,2′,3,3′-tetrathiadiazafulvalene *trans*-[ClCNS$_2$C=CS$_2$NCCl]; the structural features and redox chemistry of this novel ring system are described.

A wide range of 1,2,3-dithiazolyl radicals **1** have been characterized in solution by EPR spectroscopy.[1,2] Little, however, is known of the structural fate of such species. Do they associate weakly into S-bonded dimers, as do many 1,2,3,5-dithiadiazolyls **2**[3] and 1,3,2-dithiazolyls **3**,[4–6] or might they bond



1 **2** **3**

through carbon, thereby giving access to fulvalene derivatives? In order to investigate this possibility, we have examined the redox chemistry of 4,5-dichloro-1,2,3-dithiazolylium chloride **4** (Appel's salt[7]), and have discovered that double reduction of this material affords **5** [eqn. (1)], the first example of a 1,1′,2,2′,3,3′-tetrathiadiazafulvalene.



4 **5** (1)

The yield of **5** from **4** is very sensitive to the reaction conditions. We have explored the use of a variety of reducing agents and solvents, and to date the most effective combination utilizes triphenylantimony in liquid sulfur dioxide. Accordingly, when 50 ml of SO_2 was condensed at 77 K onto solid **4** (2.08 g, 10.0 mmol) and triphenylantimony (3.88 g, 11.0 mmol) in an H-cell, and the mixture allowed to warm slowly (2 h) to room temperature, a dark brown precipitate was produced. This solid was filtered off and back-washed twice with liquid SO_2. The solvent was removed from the reactor, and the residual solid washed sequentially with 50 ml MeCN, 50 ml aq. EtOH and 50 ml CH_2Cl_2. The solid was then extracted with 4 × 80 ml hot carbon disulfide, the deep purple extracts combined and the solvent removed to leave crude **5**, which was recrystallized from toluene as dark black–purple needles (0.42 g, 1.5 mmol, 30%), mp 120–121 °C, λ_{max} (CH_2Cl_2) 565 nm ($\varepsilon = 1.3 \times 10^4$ l mol^{-1} cm^{-1}).‡

The crystal stucture§ of **5** consists of discrete molecular units. The molecules, which lie on a crystallographic inversion centre, are planar to within 0.011 Å, and adopt a slipped π-stack structure running along the *x* direction. Fig. 1 illustrates the packing of a coplanar array of molecules, and provides a summary of both inter- and intra-molecular contacts. The pattern of intramolecular distances is consistent with the valence bond representation shown. Taken collectively, the S–S, S–N and S–C distances are all slightly longer than those observed in 1,2,3-dithiazolylium salts,[8] as expected from the lower oxidation state.

Previous investigations of the chemistry of Appel's salt have focussed on its reactions with nucleophiles.[9] Its reduction, as described here, parallels the behavior of 3-chloro-1,2-dithiolylium salts, which can be reduced to 1,1′,2,2′-tetrathiafulvalenes.[10] In the present case we have no evidence for a *cis*-isomer, presumably because of prohibitive steric interactions between the two chlorines. We have been unable to detect (by EPR spectroscopy) any signal attributable to **1** (R = Cl), a presumed intermediate in the reaction; its association (and subsequent reduction) are extremely rapid. Cyclic voltammetry on solutions of **5** in CH_2Cl_2 ($NBu^n_4PF_6$ supporting electrolyte, ref. SCE) reveals a reversible oxidation wave to the radical cation [**5**]$^+$ at $E_{\frac{1}{2}}$ = 0.80 V, with a second reversible oxidation wave at $E_{\frac{1}{2}}$ = 1.25 V, corresponding to formation of the closed shell dication [**5**]$^{2+}$. There is also an irreversible reduction process near −1.10 V. Similar behaviour has been observed for benzo-bis-1,2,3-dithiazoles.[11] Chemical oxidation to the radical cation can be effected by bromine. When dissolved in liquid SO_2 in the presence of $AlCl_3$, the radical cation salt [**5**]Br exhibits a strong and persistent EPR signal (g = 2.015) consisting of a 1:2:3:2:1 quintet arising from hyperfine coupling (a_N = 0.096 mT) to two equivalent nitrogen nuclei. Given the many advances in molecular conductor design that have arisen from the classical tetrathiafulvalene framework,[12] we believe this new system also holds rich potential as a molecular building block. To this end we are currently investigating the charge transfer chemistry of **5** and related compounds.

We thank the NSERC, the NSF/EPSCOR program and the State of Arkansas for financial support. We also acknowledge the NSERC for a post-graduate scholarship to K. E. P. and the US Department of Education for a doctoral fellowship to T. M. B.

Convergent synthesis of the *trans*-fused 6-*n*-6-6 (*n* = 7–10) tetracyclic ether system based on a ring-closing metathesis reaction

Tohru Oishi,[a,b] Yoko Nagumo[a] and Masahiro Hirama*[a,b]†

[a] *Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-8578, Japan*
[b] *CREST, Japan Science and Technology Corporation (JST), Japan*

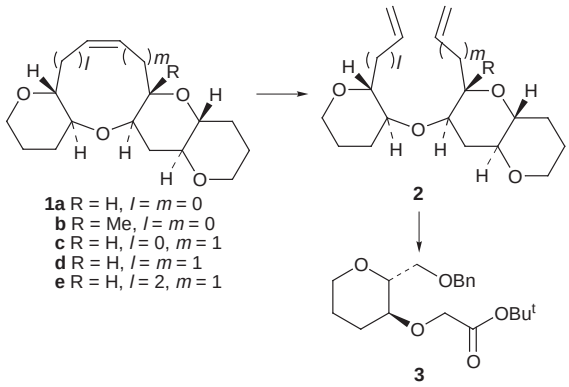
A convergent synthesis of the *trans*-fused 6-*n*-6-6 (*n* = 7–10) tetracyclic ether system was achieved *via* stereoselective alkylation and ring-closing metathesis reaction.

The synthesis of ciguatoxin[1] has received considerable attention because of its striking structure and biological activity. Although numerous techniques have been developed for the synthesis of medium ring ethers,[2] efficient methods for assembling fragments are still needed. In the course of our synthetic study of ciguatoxin,[3] we developed a convergent route to the *trans*-fused 6-7-6 tricyclic ether system *via* formation of the central oxepene ring by alkene metathesis.[4–6] Here we describe a new technique for synthesizing *trans*-fused 6-*n*-6-6 (*n* = 7–10) tetracyclic polyether systems (**1a**–**e**) from glycolate **3** (Scheme 1). The central *n*-6 bicyclic rings of these systems are efficiently constructed by stereoselective alkylation and the subsequent ring-closing metathesis reaction of dienes (**2**).

Syntheses of the dienes **2a** and **2b**, precursors for 6-7-6-6 systems (**1a** and **1b**), are shown in Scheme 2. Coupling of *tert*-butyl ester **3** with iodide **4**‡ using LDA in the presence of HMPA gave **5** and the diastereomer **6** in a 3 : 1 ratio. These compounds were separated using silica gel column chromatography. Removal of the TIPS group of **5** using TBAF followed by treatment with $TsOH{\cdot}H_2O$ in toluene at 90 °C gave lactone **7**. The addition of vinylmagnesium bromide to **7** gave hemiacetal **8**, and reduction of **8** with Et_3SiH in the presence of $BF_3{\cdot}OEt_2$[7] proceeded stereoselectively, giving **10** as a single isomer. Methylation of the hemiacetal **8** using Me_3Al and $BF_3{\cdot}OEt_2$[8] gave **11** only in low yield (~4%); however, the alkylation of the corresponding methyl acetal **9** under the same reaction conditions gave **11** in good yield (72%) as a single isomer. Reductive removal of the benzyl groups of **10** and **11** using lithium naphthalenide[9] followed by Swern oxidation and subsequent Wittig olefination gave dienes **2a** and **2b**, respectively.

Syntheses of dienes **2c**–**e**, precursors for **1c**–**e**, respectively, are also shown in Scheme 2. Treatment of **7** with allylmagnesium bromide followed by reduction of the resulting hemiacetal (Et_3SiH, $BF_3{\cdot}OEt_2$) gave **12** as a single isomer. The olefin **12** was converted to **2c** in the same manner as **2a** and **2b**. Syntheses of **2d** and **2e** were performed using triflate chemistry.[10] Treatment of the triflate derived from alcohol **13** using lithium acetylide in the presence of 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidone (DMPU) followed by partial hydrogenation gave **2d**, whereas treatment of the same triflate using allylmagnesium bromide in the presence of CuBr gave **2e**.

Ring-closing metathesis reactions of dienes **2a**–**e** using Grubbs' catalyst ($(PCy_3)_2Cl_2Ru{=}CHPh$ (**14**) were examined (Table 1). The reactions of **2a** and **2b** in benzene gave 6-**7**-6-6 tetracyclic ethers **1a**, and **1b** having an angular methyl group in



Scheme 1

Table 1 Ring-closing metathesis reaction of **2a**–**e**[a]

Diene	Product	*J*/Hz[b]	Yield (%)
2a	 **1a**	12.9	81[d]
2b	 **1b**	12.8	94[d] 82[e]

81 and 94% yield, respectively. These reactions required five to seven days. However, we found a remarkable solvent effect because the reaction of **2b** in CH_2Cl_2 proceeded smoothly and was completed within two days. This method was also quite effective in the construction of the larger rings. Cyclic polyethers **1c** (6-**8**-6-6), **1d** (6-**9**-6-6) and **1e** (6-**10**-6-6 system) were synthesized from **2c**–**e**, respectively, in good yields. The structures of these products were unambiguously determined by NMR and mass spectroscopy.

The present technique will serve as a versatile synthetic tool for the synthesis of polyether marine toxins. Further synthetic studies of ciguatoxin are presently being conducted in our laboratory.

This work was supported in part by a Grant-in-aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan, the Naito Foundation and the Uehara Memorial Foundation. We also wish to thank Dr M. Ueno and Mr T. Sato, Instrumental Analysis Center for Chemistry, Faculty of Science, Tohoku University for the measurement of NMR and mass spectra.

Probabilities of formation of bimolecular cyclic hydrogen-bonded motifs in organic crystal structures: a systematic database analysis

Frank H. Allen,*[a] Paul R. Raithby,*[b] Gregory P. Shields[a,b] and Robin Taylor[a]

[a] *Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, UK CB2 1EZ*
[b] *Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*

A database methodology has been developed to locate all possible occurrences of bimolecular cyclic hydrogen-bonded motifs in the Cambridge Structural Database and to calculate their probabilities of formation; the top 24 motifs involving D–H···A (D, A = N or O) are identified.

The design process in crystal engineering depends crucially on the high probabilities of formation of a limited number of strong intermolecular interactions.[1,2] These non-covalent motifs, termed bimolecular couplings[3] or supramolecular synthons[2] by analogy with molecular synthesis, often involve strong hydrogen bonds. Despite their successes[1,2] crystal structure prediction and retrosynthesis depend heavily on evidence gleaned from visual surveys of limited subsets of existing crystal structures.[4] To extend the list of potential H–bonded synthons, we must identify and categorise the diversity of motifs that occurs, *e.g.* in the > 170 000 crystal structures recorded in the Cambridge Structural Database (CSD).[5] This data driven approach establishes the topologies, chemical constitutions and probabilities of formation of all H-bonded motifs in an objective manner.

Here we report probabilities of formation for cyclic bimolecular motifs that incorporate D–H···A (D, A = N or O) bonds. Our procedure identifies the important structure-determining H-bonded motifs that link pairs of molecules in crystal structures, *i.e.* we are interested in the immediate non-covalently bonded environment(s) of the molecule(s) that comprise the crystal chemical unit (CCU)‡. Once identified, we envisage that extension of a structure using each of these primary links can be visualised in a manner that mimics crystal growth, and that we can then generate and describe complete networks for structure classification and comparison purposes.[6]

The CSD System program Quest3D,[5] which can locate general non-bonded contacts according to pre-defined geometrical criteria, has been modified to investigate H–bonded motifs. For each target molecule in the CCU, the modifications are (a) identify potential donors (D–H) and acceptors (A), (b) locate bonds D–H···A involving the target molecule according to preset geometrical constraints, (c) establish whether pairs of H-bonds between the target and a neighbouring molecule form a cyclic motif, classify other H-bonds as isolated, (d) establish motif ring sizes (using shortest intramolecular bond paths), their symmetry (both topological and crystallographic), and their chemical constitutions and (e) provide interactive graphical display of each cyclic motif.

Despite the generality of our modifications to Quest3D, the initial analysis specifically addresses cyclic systems: it provides probability statistics for bimolecular cyclic motifs involving N–H or O–H donors and N or O acceptors, *i.e.* motifs that incorporate the strongest H-bonds and, hence, can be regarded as structure determining. In our automated procedure, all D–H bond lengths were normalised to mean values from neutron diffraction,[7] and H···A distance limits were established from histograms generated using the October 1996 release of the CSD: 2.30 Å in N–H···N, 2.25 Å in N–H···O, and 2.20 Å in O–H···N and O–H···O. Additionally, the D–H···A angle was required to be > 90°. CSD entries were accepted for analysis if they were classified as error-free, organic, and had $R < 0.10$.

The size, symmetries and chemical constitution of each cyclic motif were combined into a chemical topology record and these were sorted to yield raw occurrence values (N_{occ}). While these figures are interesting, their interpretation is complicated by the fact that they depend on the number of times that the various donor and acceptor groups occur in the CSD. For example, the carboxylic acid ring motif might have a high N_{occ} value simply because carboxylic acids are common in the CSD. To correct for this effect, we determined a probability of occurrence (expressed as a percentage), Prob = $100\,N_{occ}/N_{poss}$, for each of the 75 most common motifs. Here, N_{poss} is the number of times that the motif could possibly occur, given: (a) the number of structures in the CSD that contain the required functional group(s), and (b) the number of times that the groups(s) occur in the CCU of each structure. The automatic generation of N_{poss} is complicated, *inter alia*, by the need to consider: (a) the presence or absence of topological symmetry, (b) which overlapping fragments can be used simultaneously in forming motifs, (c) the three-dimensional geometry of certain fragments, (d) the effects of bifurcation and other multi-centre bonds and (e) the sharing of H-bonds between two rings. We have generated a set of logical rules§ which take account of these considerations; the effects of (c) are not straightforward to assess, and no account has been taken of competition for donor-

[a] Motif possess crystallographic symmetry; other motifs are topologically (hence crystallographically) asymmetric.

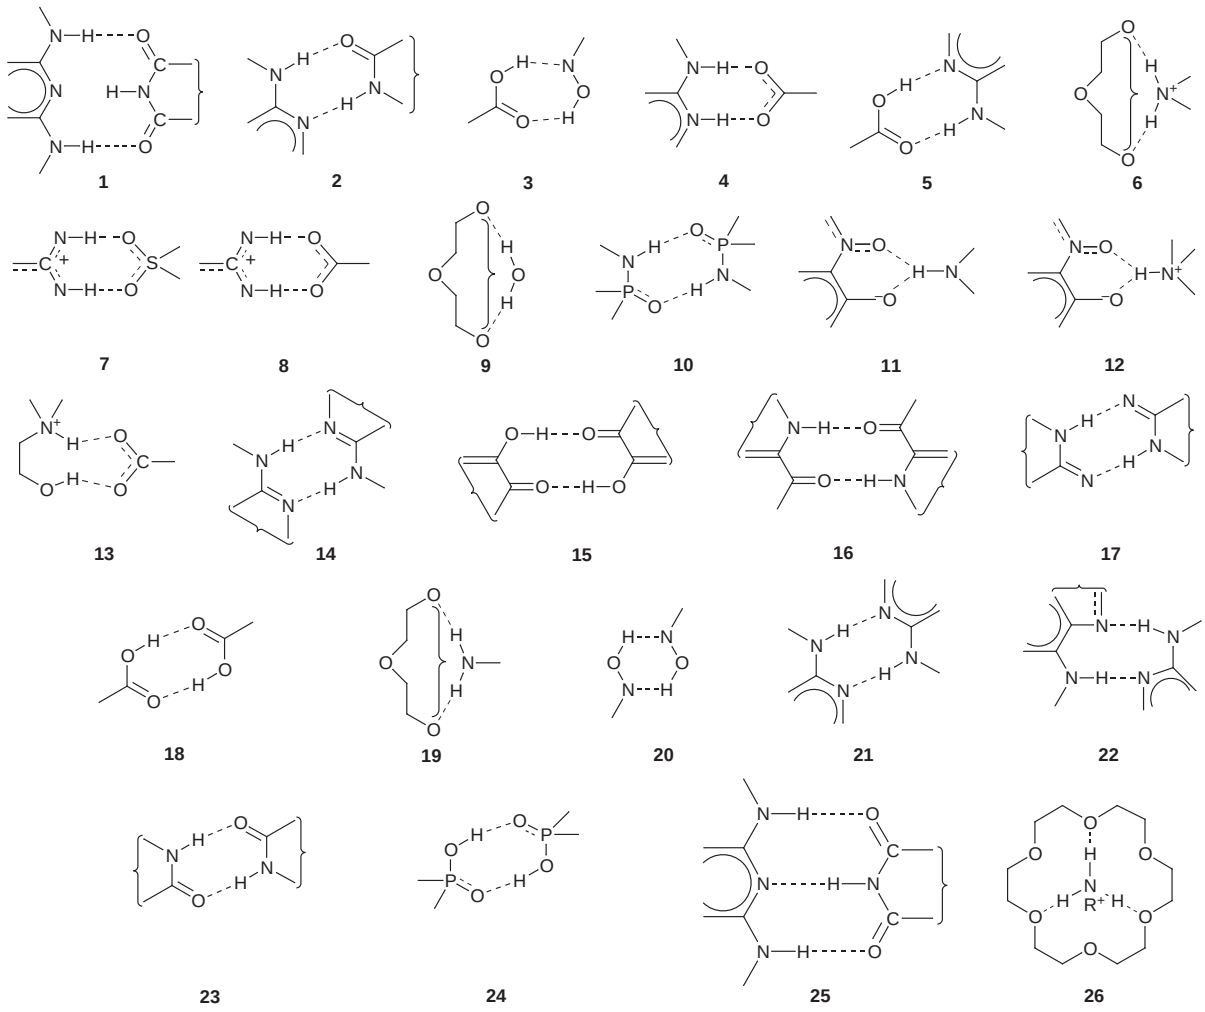

Fig. 1 Probability-ordered H-bonded motifs **1**–**24** and recognition motifs **25** and **26** (see text)

H between different acceptors or *vice versa*. Although the rules are capable of further refinement, principally for rarer situations, we believe that the relative probabilities for the most common motifs presented in Table 1 are reliable.

The probability-ordered Fig. 1 and Table 1 include the 24 motifs that have $N_{occ} > 25$ and Prob > 20%. Motifs **1** and **2** are part of the triply H-bonded motif **25** (**1** is the envelope ring), having some analogies with nucleotide recognition in DNA, and a potent supramolecular synthon.[2,8] The other very high probability motifs, **3**–**5**, all occur in relatively few individual structures (12, 17 and 20 respectively), but **5** is noted by Desiraju.[2] Motif **6** represents a portion of an 18-crown-6 ether–ammonium complex. Here, three N-H donors from $[RNH_3]^+$ normally lie above the ring and the complete pattern, **26**, is best regarded as the recognition motif. Analogous complexes of 18-crown-6 with water (**9**) or RNH_2 (**19**) have lower but still appreciable probabilities.

The low probabilities of formation of the carboxylic acid **18** and cyclic amide **23** motifs might be considered surprising. However, they reflect chemical environments that contain many competing acceptors and donors, together with steric influences, particularly in the amide case. If the analysis is restricted to mono- and di-carboxylic acids without other functional groups, then Prob for motifs **18** and **23** rises to 95.5 and 84.8% respectively. The cyclic amides of motif **23** have their H-donors constrained to be *cis* to the =O acceptor. In flexible acyclic amides, which are usually *anti*, the overall probability of forming a cyclic motif is only 8.4%. However, if the analysis is restricted to structures having only primary or secondary amide functions, then the probability rises to 44.1% for the cyclic case and to 15.7% for the acyclic case. Using these statistics we are now analysing why particular motifs do not occur with greater frequency, and what alternative interactions are possible.

‡ The crystal chemical unit (CCU) contains the complete unique molecule(s) that comprise the crystal structure. Where molecular and crystallographic symmetry coincide the fractional molecules are expanded by symmetry to form the CCU prior to the investigation of H-bonded motifs.

Tropic acid biosynthesis: the incorporation of (*RS*)-phenyl[2-^{18}O,2-^{2}H]lactate into littorine and hyoscyamine in *Datura stramonium*

Chi W. Wong,[a] John T. G. Hamilton,[b] David O'Hagan*[a]† and Richard J. Robins[c]

[a] *Department of Chemistry, University of Durham, Science Laboratories, South Road, Durham, UK DH1 3LE*

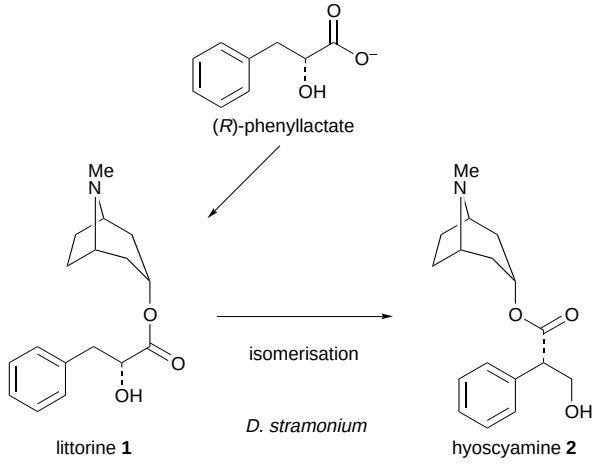
The incorporation of oxygen-18 from (*RS*)-phenyl-[2-^{18}O,2-^{2}H]lactate into the tropane alkaloids littorine 1 and hyoscyamine 2 in *Datura stramonium* reveals that up to 29% of the oxygen-18 is lost during the transformation of 1 to 2.

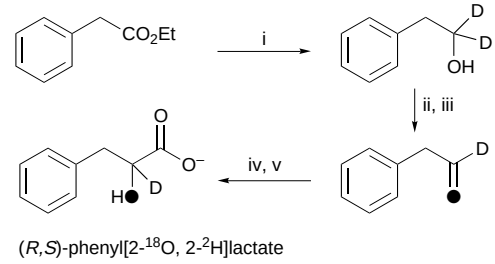
The biosynthetic origin of the tropate ester moiety of the alkaloid hyoscyamine **2** has been the subject of attention for many years.[1,2] It was shown in 1972 that this ester arises as a consequence of a carbon skeleton rearrangement of a phenylpropanoid metabolite derived from L-phenylalanine.[3]

We were able to show in 1995[4] that (*R*)-phenyllactate was the relevant phenylpropanoid metabolite, and in a notable development Robins *et al.* demonstrated[5] that the tropate ester moiety is derived after a *direct isomerisation* of littorine **1**, the (*R*)-phenyllactate ester of tropine, to hyoscyamine **2**, the tropine ester of (*S*)-tropic acid, as represented in Scheme 1. Although the substrate for the isomerisation is now established, the nature of the enzyme and the mechanism of the process remains unknown. There is a superficial similarity of the rearrangement to some coenzyme-B_{12} mediated isomerisations which has led to speculation that this is a coenzyme-B_{12} process,[6,7] however the characteristic vicinal interchange process common to carbon skeleton coenzyme-B_{12} mediated isomerisations[8] *does not occur*[9] in the littorine **1** to hyoscyamine **2** rearrangement.



Scheme 1

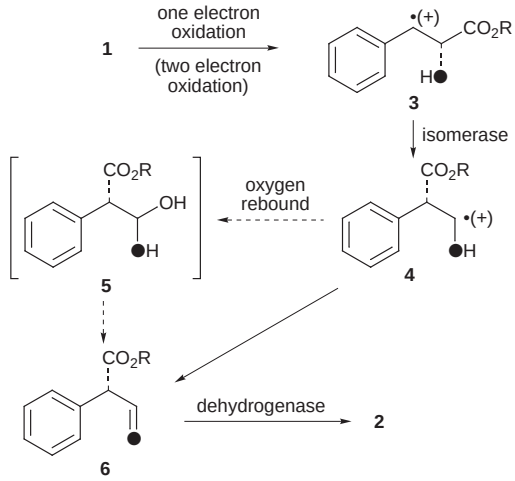
In order to explore this process further we have studied the incorporation of sodium (*RS*)-phenyl[2-^{18}O,2-^{2}H]lactate into both of the alkaloids **1** and **2** in transformed root cultures of *Datura stamonium*.[10] The requisite (*RS*)-phenyl[2-^{18}O,2-^{2}H]lactate was prepared as shown in Scheme 2. In the event only *ca.* 50% of the oxygen-18 isotope from $H_2{}^{18}O$ was introduced by exchange into phenyl[1-^{2}H]acetaldehyde, presumably as the hydrate is stable to dehydration under the reaction conditions. This route provided a sample of (*RS*)-phenyl[2-^{18}O,2-^{2}H]lactate which had an M + 1/M + 3 ratio of 1.10 as determined by GC–MS analysis. The material was pulse fed (days 5, 7 and 9) to transformed root cultures[10] of *D. stramonium* at a final concentration of 0.64 mM, and the alkaloids were extracted from the root tissue on days 11, 13, 15 and 17 as previously described. GC–MS analysis of the alkaloid extracts allowed determination of isotope content from the relative abundances of the M + 1 (^{2}H only) and M + 3 (^{2}H + ^{18}O)



Scheme 2 *Reagents and conditions*: i, $LiAlD_4$, Et_2O, 2 h, 73%; ii, PCC, CH_2Cl_2, 2 h, 83%; iii, $H_2{}^{18}O$ (97 atom%), THF, HCl, 120 °C, 5 h; iv, TMSCN, Et_3N, CH_2Cl_2, 2 h, then aq. HCl, 24 h, 69%; v, aq. NaOH, 46%

Table 1 GC–MS derived data for the alkaloids **1** and **2** on four different days after supplementation of *D. stammonium* root cultures with (*RS*)-phenyl[2-^{18}O,2-^{2}H]lactate. For these studies the mass spectrometer was operated in the selected ion monitoring mode (SIM) measuring ion currents at *m*/*z* 289 (M), 290 (M + 1), 291 (M + 2) and 292 (M + 3). The data are presented after natural abundance levels have been subtracted. The corrections made to each of the ion peak areas for natural isotope abundances were determined experimentally using authentic standard compounds

	Day 11		Day 13		Day 15		Day 17	
	1	**2**	**1**	**2**	**1**	**2**	**1**	**2**
M	83.39	90.58	86.49	90.73	84.39	89.00	87.93	90.01
M + 1	9.19	6.48	7.48	6.53	8.50	7.58	6.74	6.78
M + 3	7.24	3.15	5.88	2.95	6.92	3.61	5.24	3.35
M + 1/M + 3 ratio	**1.27**	**2.06**	**1.27**	**2.21**	**1.23**	**2.10**	**1.29**	**2.02**
^{18}O loss from **1** to **2** (%)	25		29		28		25	

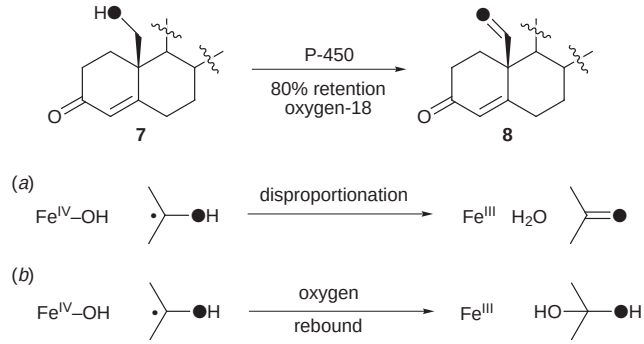


Scheme 3

ions. The levels of incorporation were determined by selective ion monitoring (SIM) and the values in Table 1 are corrected for natural isotope abundances. There was no significant incorporation (M + 2 = 0 ± 0.3) into the M + 2 ions and these are not included in Table 1. Of particular significance for this study is the M + 1/M + 3 ratio in the molecular ions of both **1** and **2**, which is independent of total incorporation (12–17%). The extracted littorine **1** on each of the four days had an M + 1/M + 3 = 1.26 ± 0.02, whereas the hyoscyamine had a value of M + 1/M + 3 = 2.1 ± 0.07. This change of ratio represents a loss of *ca.* 25–29% of the M + 3 abundance in hyoscyamine relative to littorine **1** and a corresponding enrichment of the M + 1 abundance of hyoscyamine **2** relative to littorine in going from **1** to **2**. Thus there is an exchange of *ca.* 25–29% of oxygen-18 for oxygen-16 in going from littorine **1** to hyoscyamine **2**.

Our working hypothesis for the rearrangement of **1** and **2** involves two enzymatic activities, an iron–oxo isomerase and a dehydrogenase, as illustrated in Scheme 3. This hypothesis developed from ideas of Sankawa,[11,12] who rationalised a number of isomerisation reactions in terms of iron–oxo enzyme processes. Three mechanistic scenarios emerge in the light of this result. In general, iron–oxo processes are considered to involve radicals and it can be envisaged that a Fe^{IV}–O· species abstracts hydrogen (the 3′-*pro-R* hydrogen)[9] to generate a substrate radical **3**. After rearrangement, the product radical **4** is quenched in a classical manner by delivery of an hydroxyl radical from Fe^{IV}–OH (oxygen rebound) to generate hydrate **5** followed by collapse of the hydrate to give aldehyde **6**. The high retention of oxygen-18 found experimentally is compatible with this process if (i), a partially stereospecific collapse of the hydrate occurs under enzymatic control, or (ii) a fully stereospecific process removes the unlabelled oxygen, but there is some exchange at the aldehyde prior to reduction by a dehydrogenase. A non-stereospecific process would of course result in 50% loss of oxygen-18 and this is not observed.

A similarly high retention of oxygen (80%) was observed previously[13] in the oxidation of **7** to **8** in a P-450 mediated process operating during oestrogen biosynthesis. It was concluded[13,14] in that case that the observation is most consistent with a disproportionation process [Scheme 4(*a*)] involving $Fe^{IV}OH$ and the product radical, rather than the more common oxygen rebound [Scheme 4(*b*)] process. It is poignant that a similar level of oxygen-18 retention is found in this study and such a disproportionation must remain under consideration. The partial loss of isotope can then be attributed to some exchange of the carbonyl oxygen of aldehyde **6** with the aqueous medium



Scheme 4

prior to reduction by a dehydrogenase. Finally, an additional mechanism would involve a two-electron oxidation of **1** to generate carbocation **3**, as illustrated in the brackets in Scheme 3. Such a process has some precedent with the accepted mechanisms of thromboxane and prostacyclin synthases,[15] where carbocation intermediates are implied, and in some recent mechanistic studies[16] on P-450 systems, where carbocations gave rise to side products during the hydroxylation of cyclopropane substrates. As illustrated in Scheme 3, rearrangement to carbocation **4** followed by a direct collapse to aldehyde **6** prior to reduction would not require any loss of oxygen-18. Some exchange then at the aldehyde level is also consistent with the experimental result. A fuller discussion of the various mechanistic possibilities is given elsewhere.[17]

We thank the CIBA foundation for an ACE award and the EPSRC for a Studentship (C. W. W.).

Chemotransfiguration Project, Japan Science and Technology Corporation (JST), 2432 Aikawa, Kurume, Fukuoka 839, Japan

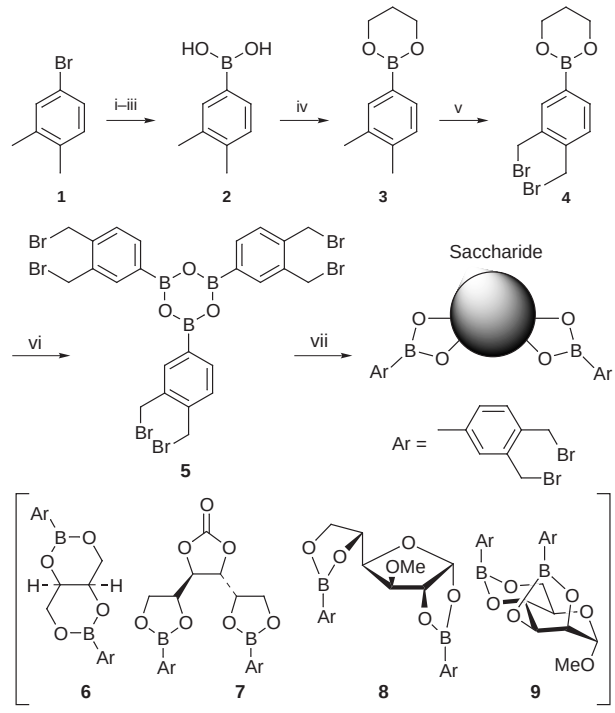
Two boronic acid groups were introduced into [60]fullerene using saccharides as template molecules: it was found that the regioselectivity changes depending on the saccharide structure.

The molecular imprinting technique attracted considerable attention in the 1970s, but recently has been revived as an active research area.[1–3] The principle involves copolymerisation of vinyl monomers with divinyl monomers in the presence of guest metals or molecules to produce three-dimensional network polymers.[1–3] Although this technique has achieved some degree of success, two complex problems have been left unresolved, *i.e.* the evaluation of the imprinting effect is difficult because it can be performed only in a heterogeneous system, and the storage capacity is small because only the particle surface is useful for the re-binding of guests. Is there an alternate method in which both the imprinting process and the estimation process can be carried out in a more reliable homogeneous system? [60]Fullerene and its homologues are moderately soluble in organic solvents and have plenty of reactive C=C double bonds which are useful for the immobilisation of functional groups. It thus occurred to us that they would be useful as a base for the imprinting of functional groups and for use in a homogeneous system. There are a limited number of precedents for regioselective introduction of substituents into [60]fullerene.[4–6] In order to apply [60]fullerene to the memory storage, we here chose saccharides as the template and guest molecules and boronic acids as the functional groups. Saccharides have several specific advantages for the present purpose which other template molecules do not have, *i.e.* (i) they can arrange two boronic acid groups in a variety of spatial positions, (ii) removal and re-binding can occur reversibly, and (iii) because of their inherent chirality, chiroselective introduction of two boronic acid groups is possible.[7] We here report the fact that, using saccharides as template molecules, two boronic acid groups can be regioselectively introduced into [60]fullerene; the regiospectrum is closely related to the structure of saccharides used as template molecules.

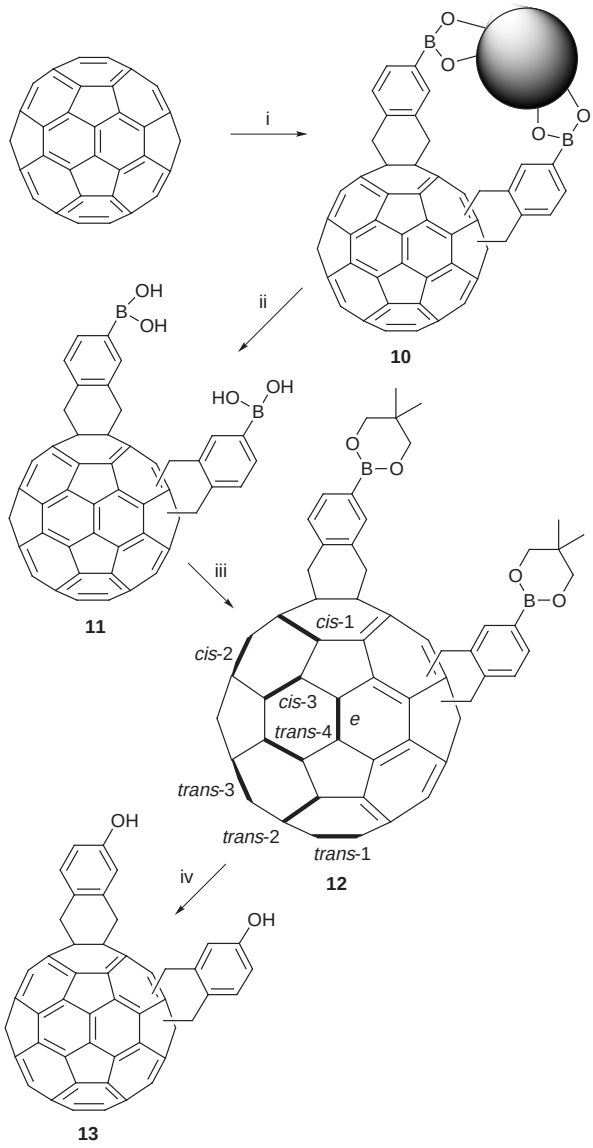
In order to access saccharide–boronic acid 1 : 2 complexes **6**–**9**, we first synthesised **5** from 4-bromo-*o*-xylene **1** (Scheme 1). Compound **5**, which was isolated as a cyclic trimer,[7,8] was identified by ^{1}H NMR, IR (KBr) and mass (negative SIMS) spectral evidence and elemental analysis. Complexes **6**–**9** were synthesised from **5** and the corresponding saccharides in refluxing toluene with azeotropic removal of water under a nitrogen atmosphere. The products were identified by ^{1}H and ^{11}B NMR and IR (KBr) spectral evidence and elemental analyses.[9] The reaction of **6**–**9** with [60]fullerene was carried out in refluxing toluene for 40 h in the presence of 18-crown-6 and KI under a nitrogen atmosphere. To simplify the product analysis, the saccharides were removed by the treatment with aqueous 1.2 mol dm^{-3} HCl solution and then the boronic acid groups in the product **11** were protected using 2,2-dimethylpropane-1,3-diol[10] (Scheme 2). The product was purified by column chromatography. We thus isolated a regioisomeric mixture of **12** in 49–58% yield. This mixture was subjected to HPLC analysis [COSMOSIL 5 PBB, *n*-hexane–toluene (3 : 7 v/v)]. The results are summarised in Table 1.

In the HPLC analysis, 7–8 peaks were always observable and the relative intensity changed depending on the saccharide used as the template molecule. Compounds **6**, **7** and **8** with D-threitol, D-mannito 3,4-carbonate and 3-*O*-methyl-D-glucofuranose as template molecules, respectively, afforded major peaks for Peak 7 (47.3%), Peak 8 (55.7%) and Peak 6 (72.5%), respectively, whereas compound **9** with 1-*O*-methyl-α-D-mannopyranoside as a template molecule featured a rather nonselective product distribution. The results imply that the saccharide changes the distance between two *o*-xylenyl dibromide groups in **6**–**9** and the addition reaction occurs at different C=C double bonds on the [60]fullerene surface.

It is difficult to isolate the eight different isomers of disubstituted **12** and thus identify the structure of each isomer. We decided to attempt the isolation of Peak 6 [with the highest (72.5%) yield] in the mixture obtained from **8** and [60]fullerene. Through trial and error it was found that Peak 6 can be isolated by recrystallisation from *n*-hexane–CH_2Cl_2: the HPLC analysis showed a single peak for Peak 6. In the ^{1}H NMR spectrum (300 MHz, [$^2H_8$]toluene, 90 °C) of this compound (**12a**) one could observe one CH_3 proton peak (δ 0.71, 12 H) and one CH_2 proton peak (δ 3.50, 8 H) for the protective groups and four CH_2 proton peaks (δ 4.04, 4.04, 4.12 and 4.19, 2 H each) and three ArH proton peaks (δ 7.42, 8.13 and 8.17, 2 H each) for the *o*-xylenyl groups. This splitting pattern is commensurate with either C_2 symmetry (*cis*-3, *trans*-2 or *trans*-3) or C_s symmetry (*cis*-1, *cis*-2,



Scheme 1 *Reagent and conditions*: i, Mg, THF; ii, $B(OMe)_3$, −60 °C; iii, H_2SO_4, 69% from **1**; iv, propane-1,3-diol, toluene, reflux, 71%; v, NBS, CCl_4, reflux, 50%; vi, HCl, THF, 90%; vii, saccharide, toluene, reflux, 82% for **6**, 95% for **7**, 76% for **8** and 60% for **9**



Scheme 2 *Reagent and conditions*: i, **6**–**9**, KI, 18-crown-6, toluene, reflux; ii, HCl, THF: iii, 2,2-dimethylpropane-1,3-diol, toluene, reflux, 49% from **6**, 53% from **7**, 58% from **8** and 52% from **9**; iv, 30% H_2O_2, AcOH, THF, 56%

Table 1 Results of HPLC analysis of **12**

Peak number	Retention time/min	Product (%)[a]			
		6	**7**	**8**	**9**
1	39.6	1.5	4.2	0.2	5.6
2	41.5	2.3	4.3	1.5	7.5
3	43.0	5.4	3.4	3.0	11.4
4	46.5	7.8	10.5	3.7	15.2
5	49.7	12.3	7.7	3.6	23.7
6	51.2	11.3	14.2	72.5	15.6
7	52.9	47.3	0	0	0
8	54.1	12.1	55.7	15.5	21.0

[a] Computed from the peak area obtained by the chromatogram followed at 350 nm.

trans-1 or *trans*-4).[4–6,11] Among them, the size of the saccharide used as the template molecule is too small or too large to give *cis*-1, *trans*-1, *trans*-2 and *trans*-3: therefore, these isomers can be excluded. The residual, possible isomers are *cis*-2, *cis*-3 and *trans*-4.

In absorption spectroscopy (CH_2Cl_2, 25 °C) compound **12a** gave two absorption maxima at 643 and 708 nm. Since these absorption maxima are observable only for *cis*-3 and *trans*-4,[11,12] *cis*-2 can be excluded. The solubility of **12a** into deuterated NMR solvents was not high enough to obtain a satisfactory ^{13}C NMR spectrum, so we converted **12a** to **13a** (Nishimura's phenol adduct[6]) *via* treatment with H_2O_2 (56% yield). Compound **13a** did not coincide either with *cis*-2 or with *cis*-3, as reported by Nishimura.[6] Furthermore, the ^{13}C NMR spectrum (75.5 MHz, [$^2H_6$]DMSO, 120 °C) gave 30 sp^2 carbon peaks and 2 sp^3 carbon peaks for the [60]fullerene moiety. This splitting pattern is commensurate with C_s-symmetrical *cis*-2 and *trans*-4.[11,12] Thus **12a** can be identified as *trans*-4.[13]

As a preliminary study to test whether **11a** retains the memory for 3-*O*-methyl-D-glucose, we carried out solid (excess 3-*O*-methyl-D-glucose)–liquid ([$^2H_8$]THF) extraction with **11a**. Judging from the fact that the ratio of the integral intensity between 1-H in the complexed 3-*O*-methyl-D-glucose and ArH in the complexed **11a** is 1 : 6, one can conclude that **11a** can quantitatively bind the templated saccharide.

In conclusion, the present study has demonstrated that saccharides are useful as potential templates to regioselectively introduce two boronic acid groups into [60]fullerene.

9 From extensive ^1H and ^{11}B NMR spectroscopic and X-ray crystallographic studies it was found that in **6** boronic acids react with 1,3-diols to form two six-membered rings, and in **8** the saccharide moiety adopts the furanose form. These results will be discussed in detail elsewhere.

13 In **12a**, three isomers (in–in, out–in and out–out) are available, in principle, owing to the direction of the $B(OCH_2CMe_2CH_2O)$ group in the benzene ring. Judging from the size of the template saccharide and the splitting pattern of the ^1H NMR spectrum, the out–in and out–out isomers can be excluded. Thus, **12a** isolated here is the in–in isomer. For an explanation of the concept of in–in, out–in and out–out isomers, see refs. 4–6.

The conformation of 2,11-diaza[3.3](9,10)anthracenoparacyclophane 1, which underwent photointerconversion with isomer 2, was fixed with the aid of a chiral camphanic auxiliary to have molecular chirality, and the photochemiluminescence from the modified 2a was circularly polarized reflecting the chirality of the emitting state.
